Acetaldehyde

[75-07-0] · C_2H_4O · Acetaldehyde · (MW 44.05)

(reagent used as two-carbon electrophilic component in a wide array of reactions)

Physical Data: mp -123.5 °C; bp 21 °C; *d* 0.788 g cm^{-3}.

Solubility: sol H_2O, alcohol, ether, and most organic solvents.

Form Supplied in: colorless liquid; widely available.

Purification: shaken with powdered $NaHCO_3$ for 30 min; dried over $CaSO_4$, and fractionally distilled at 760 mmHg through a 70 mm Vigreux column.

Handling, Storage, and Precautions: bottles may develop pressure and should be cooled before opening. To help prevent polymerization and autoxidation, store under nitrogen atmosphere and refrigerate. Acetaldehyde is a cancer suspect agent and should be used only in a well-ventilated fume hood. Toxicity (oral) rat LD_{50}: 661 mg kg^{-1}. Incompatible with strong acids, strong bases, oxidizing and reducing agents. Decomposes on prolonged exposure to air.

1,2-Additions.

Acetaldehyde reacts with a myriad of nucleophilic reagents, generally providing excellent yields of the two-carbon extended secondary alcohols. Aryl-,[1] alkynyl-,[2] and alkyllithiums[3] react rapidly with acetaldehyde even at low temperature. A chiral vinyllithium reagent at low temperature reacts stereoselectively to afford a 10:1 mixture of diastereomeric alcohols (eq 1).[4] Aryl[5] or alkyl[6] Grignard reagents behave in an analogous manner with acetaldehyde to give the secondary alcohols or the methyl ketones[7] upon subsequent oxidation. Allyl organometallics react with varying degrees of stereocontrol depending on the metal and conditions to give the corresponding homoallylic alcohols.[8] Chiral allylboronates also react with acetaldehyde at -78 °C to afford the homoallylic alcohols with high enantioselectivity.[9] *trans*-Epoxides are produced selectively through the Darzens reaction of acetaldehyde with halomethyl sulfones under basic phase transfer conditions.[10] Classical Wittig reagents[11] and Horner-Emmons phosphonate[12] ylides react with acetaldehyde to give the alkene.

Aldol Additions.

Acetaldehyde serves as an electrophilic partner in the aldol condensation with a wide array of enolates.[13] Knoevenagel condensation of acetaldehyde with active methylene compounds in the presence of base provides good yields of the ethylidene substituted compounds.[14] Addition of two equivalents of an active methylene compound to acetaldehyde results in a Michael addition of the second equivalent to the initially formed ethylidene.[15] Tollens reaction of acetaldehyde with formaldehyde gives pentaerythritol.[16] The addition of acetaldehyde in a Baylis-Hillman condensation with ***Ethyl Acrylate*** using ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO) as catalyst gives a 90% yield of the allylic alcohol.[17] The stereoselective aldol reaction of acetaldehyde with achiral[18] and chiral[19] imide enolates has received much attention and is a proven method for controlling acyclic relative and absolute stereochemistry.[13] For example, the boron enolate of a norephedrine-derived propionyloxazolidine reacts with acetaldehyde to afford in 90% yield and >98% de the *syn* aldol product (eq 2).[19a] Acetaldehyde also smoothly undergoes nitro-aldol condensation to the corresponding nitro alcohols.[20] The lithium enolates of a variety of heterocycles react with acetaldehyde to give good yields of product alcohols.[21] In addition, the zinc,[22] copper,[23] and boron[24] enolates of esters and ketones provide aldol products with acetaldehyde.

Mannich and Mannich-Type Reactions.

Although not as commonly used as ***Formaldehyde***, acetaldehyde undergoes many synthetically useful Mannich reactions. Intramolecular Mannich reaction of acetaldehyde has been utilized to produce the natural product myrtine (eq 3).[25] The intramolecular Mannich reaction has also been used in the synthesis of proline derivatives.[26] Nucleophiles as diverse as dialkyl phosphites[27] and amines[28] or aryl radicals[29] may also add to the intermediate imine of acetaldehyde in Mannich-type reactions. A historically significant reaction of acetaldehyde in this mode is the Strecker synthesis of alanine, whereby cyanide is added to the adduct of ammonia and acetaldehyde followed by hydrolysis of the intermediate α-aminonitrile.[30] The Pictet-Spengler reaction utilizing acetaldehyde is an important ring-forming reaction.

Acetaldehyde has been extensively used in the synthesis of the biologically active β-carbolines from tryptophan derivatives through this cyclization.[31] Other ring systems such as tetrahydroisoquinolines[32] and dihydrooxazines[33] have also been formed employing Pictet-Spengler cyclization with acetaldehyde.

(3)

Metal and Other Promoted Condensations.

In the mixed Tishchenko reaction using ***Aluminum Isopropoxide*** as promoter, acetaldehyde is predominately the oxidized partner. Thus when condensed with benzaldehyde, benzyl acetate is the major product.[34] Recently an interesting and synthetically useful stereoselective intramolecular Tishchenko reduction of β-hydroxy ketones using acetaldehyde and promoted by ***Samarium(II) Iodide***, affording *anti*-1,3-diol monoacetates, has been reported (eq 4).[35] The stereoselective pinacol cross-coupling of acetaldehyde with other higher-order aldehydes that contain chelating functionalities has been achieved using a vanadium(II) reagent.[36] The photochemical addition of acetaldehyde in the presence of molecular oxygen to α,β-unsaturated esters and ketones provides excellent yields of the 1,4-dicarbonyl compounds (eq 5).[37]

(4)

(5)

Pericyclic Reactions.

The thermal ene reactions of acetaldehyde and other aliphatic aldehydes with alkenes are generally not very productive.[38] However, acetaldehyde can be induced to undergo ene reactions with a variety of alkenes under Lewis acid activation. ***Dimethylaluminum Chloride*** has been used to promote the ene reaction between the relatively reactive 1,1-di-, tri-, and tetrasubstituted alkenes (eq 6).[39] With the more unreactive monosubstituted terminal alkenes, the more

Lewis acidic ***Ethylaluminum Dichloride*** must be employed to obtain reasonable yields of ene products with acetaldehyde.[40] Acetaldehyde is a relatively unreactive dieneophile towards dienes. The hetero-Diels-Alder reaction of acetaldehyde has been reported under high pressure acceleration with 1-alkoxydienes to afford good yields of dihydropyrans with modest *endo* selectivity.[41]

(6)

Paraldehyde and Other Acetaldehyde Derivatives.

Paraldehyde has historically been used as a stabile and less volatile form of acetaldehyde in a wide array of chemical reactions.[42] However, since its classification as a controlled substance, its restricted availability has led to its limited use in modern synthetic organic chemistry. Acetaldehyde can be generated from paraldehyde through acid catalyzed degradation of the trimer and isolated by distillation.[43] The diethyl acetal of acetaldehyde, commonly known as acetal, may be generated from acetaldehyde or paraldehyde, ethanol, and calcium chloride.[44] Acetaldehyde and paraldehyde have also been used for the protection of diols as their ethylidene acetals.[45]

Related Reagents.

Acetaldehyde N-t-Butylimine; ***Acetaldoxime***; ***Crotonaldehyde***; ***Dimethylaluminum Chloride***; ***Ethyl Vinyl Ether***; ***Formaldehyde***; ***Formaldehyde-Dimethylamine***; ***Vinyl Acetate***.

Acetaldehyde 3-Bromopropyl Ethyl Acetal

[34399-67-2] · $C_7H_{15}BrO_2$ · Acetaldehyde 3-Bromopropyl Ethyl Acetal · (MW 211.1)

(electrophilic or nucleophilic hydroxypropylation reagent[1])

Alternate Name: 1-bromo-3-(1-ethoxyethoxy)propane.

Physical Data: colorless liquid, bp 49-51 °C/1 mmHg.[1]

Solubility: sol common organic solvents (i.e. diethyl ether, THF, 1,3-propanediol).

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Method: the reagent has been prepared from 3-bromo-1-propanol and ***Ethyl Vinyl Ether*** using dichloroacetic acid as the catalyst.[1] The choice of the catalyst was reported to be crucial to the success of the procedure. This preparation provided the product in 92% yield.

Purification: purification was performed by vacuum distillation, bp 49-51 °C/1 mmHg.[1]

Handling, Storage, and Precautions: the reagent is acid sensitive and is stored at -30 °C over powdered sodium carbonate.[1] This is an alkylation reagent; proper protective equipment should be worn and use restricted to a fume hood.

Introduction.

Acetaldehyde 3-bromopropyl ethyl acetal (**1**) has been utilized as an electrophilic 3-bromo-1-propanol equivalent and as a source of a nucleophilic three-carbon hydroxypropyl synthon.

Nucleophilic Addition.

1-Lithio-3-(1-ethoxyethoxy)propane, prepared from (**1**) and ***Lithium*** in diethyl ether, has been added to aldehydes,[2] ketones (eq 1),[1,3] lactones (eq 2),[4] lactams,[5] and chlorosilanes.[6] Although the THP ether has also been utilized, the ethoxyethyl ether is hydrolyzed under milder conditions.[7] The corresponding organocopper reagent has been added to α,β-unsaturated ketones and alkyl halides.[8,9]

(1)

(2)

The Grignard reagent prepared from (**1**) has been added to β-alkoxy enones (eq 3) and coupled with allylic bromides.[10-12]

(3)

Alkylation.

Carbanions derived from *N*,*N*-dimethylhydrazones have been alkylated with (**1**) (eq 4).[13,14] The hydrolysis conditions utilized to regenerate the ketone do not allow for the isolation of the protected alcohol product. This can be overcome with the THP ether.[14] Multifunctionalized ethers have also been synthesized using (**1**).[15]

Acetaldehyde *N*-*t*-Butylimine

[7020-80-6] · $C_6H_{13}N$ · Acetaldehyde *N*-*t*-Butylimine · (MW 99.17) (*E*)

[62058-77-9]

(acetaldehyde equivalent; synthesis of α,β-unsaturated aldehydes)

Alternate Names: *N*-ethylidene-1,1-dimethylethylamine; *N*-(ethylidene)-*t*-butylamine; *N*-ethylidene-2-methyl-2-propaneamine.

Physical Data: bp 25-28 °C/95 mmHg; *n*19.2D 1.4005.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: ^{1}H NMR; GC.

Preparative Methods: condensation of freshly distilled ***Acetaldehyde*** with ***t-Butylamine*** without solvent.[1-4] The way the reactants are mixed is crucial. *t*-Butylamine is added dropwise to 1 equiv of the aldehyde at -10 to 0 °C (eq 1). The reaction mixture is further stirred at rt for 10 min after which solid KOH is added (about 10 g per mol). After separation of the water layer, the imine is distilled over KOH using a Vigreux column. It was reported that azeotropic removal of the water, formed during the reaction, with an organic solvent, nonmixable with water, gave good results.[5] However, it was found that this procedure with dichloromethane as solvent gave an end product which was always contaminated with the solvent.[4]

Handling, Storage, and Precautions: very sensitive to hydrolysis; store in closed vessels under an inert atmosphere in the refrigerator. Use of the freshly distilled reagent is recommended. Use in a fume hood.

Introduction.

Imines derived from acetaldehyde and lower alkylamines, e.g. ethylamine, are extremely difficult to handle under basic reaction conditions.[6] More bulky derivatives such as acetaldimines derived from cyclohexylamine and preferably *t*-butylamine are much more stable and can be used as a ready acetaldehyde equivalent.

Reactions of Metalated Acetaldehyde *N*-*t*-Butylimine.

Lithiation of aldimines results in a change from (*E*) to (*Z*) configuration.[7] A facile carbon-carbon bond rotation in 1-azaallyllithium reagents is readily observed by variable temperature ^{1}H NMR spectroscopy.[8] Lithiation is most frequently performed by ***Lithium Diisopropylamide*** or ***Lithium Diethylamide*** in THF or diethyl ether. Lithiated acetaldehyde *t*-butylimine is readily α-monoalkylated by alkyl bromides, but α,α-dialkylation is difficult to avoid.[4] This acetaldimine has been used to prepare the alkaloid stenusine, the spreading agent of the beetle *Stenus comma* (eq 2).[4,9] Attempts to perform the synthesis starting from acetaldehyde *N*-ethylimine failed.[4]

(2)

Similar α-deprotonations and α-alkylations of acetaldehyde cyclohexylimine have been performed with ***Potassium-Graphite*** and alkyl bromides, respectively.[10] o-Halo aldehydes (eq 3),[11] 4-bromo-4-pentenal,[12] and 5-chloro-4-alkenals[12] are accessible from the same aldimine after deprotonation and reaction with α,o-dihaloalkanes, ***2,3-Dibromopropene***, and 3-chloroallyl chloride, respectively.

(3)

Acetaldehyde *t*-butylimine is an extremely versatile building block for the synthesis of α,β-unsaturated aldehydes by lithiation, subsequent reaction with diethyl chlorophosphate, further reaction with aldehydes or ketones, and final hydrolysis (eq 4).[13] Examples include 3-cyclohexylpropenal (**1**),[13] (*E*,*E*)-4-(phenylthiomethyl)-2,4-hexadienal (**2**),[14] polyoxygenated cyclohexanes (**3**)[15] and others.[16,17] An alternative method consists of α-trimethylsilylation of acetaldehyde *t*-butylimine followed by deprotonation and reaction with a carbonyl compound (eq 5).[17,18] α,α-Disilylation is accomplished similarly and leads also via condensation with aldehydes to a wide range of (*E*)-α,β-unsaturated aldehydes (eq 6).[19,20] It should be pointed out also that directed aldol condensations between lithiated acetaldehyde imines and aldehydes or ketones have been frequently reported (eq 7).[6,21] Other electrophiles, e.g. nitriles,[22,23] carboxylic esters,[6] and enones,[6,24] lead to the expected reaction products.

(4)

(1) 76%

(2) 72%

(3) 63% (E:Z = 3:2)

(5)

(6)

Nitration can be accomplished after deprotonation and reaction with ethyl nitrate, but the reaction takes a partially different course with propyl nitrate (eq 8).[25] In a similar way, β-enamino and β-iminosulfoxides are obtained by using menthyl *p*-toluenesulfinate.[26] Lithiated acetaldehyde *t*-butylimine reacts with chlorophosphites to give α-phosphorylated imines, which are in equilibrium with their enamino form.[27,28] Without the initial deprotonation step, *N*-phosphorylation takes place.[29]

α-Functionalization.

Acetaldehyde *t*-butylimine is α,α,α-trichlorinated with ***N-Chlorosuccinimide*** at room temperature (eq 9).[30] The resulting chloral imine is a suitable substrate for conversion into α,α-dichloroacetimidates, α-cyano-β,β-dichloroenamines, α,β,β-trisulfenylated enamines, and β,β,β-trichloroamines.[30] The reaction of acetaldehyde *t*-butylimine with aromatic nitroso compounds affords α-(*N*-hydroxy-*N*-aryl)aminoaldimines or α-diimines.[31,32]

Synthesis of Heterocycles.

Condensation of acetaldehyde *t*-butylimine with enamines at 150-220 °C affords rearranged 1-azabutadienes via cycloreversion of an azacyclobutene intermediate, formed by [2 + 2] cycloaddition of the reactants (eq 10).[33] Further reaction of the 1-azabutadienes with enamines in the presence of *p*-toluenesulfonic acid produces pyridines (eq 10).[33]

A very convenient synthesis of the imidazole nucleus consists of the reaction of acetaldehyde *t*-butylimine with ***p-Tolylsulfonylmethyl Isocyanide*** (TosMIC) in the presence of *t*-butylamine (eq 11).[34] The same aldimine is readily oxygenated by peroxy acids to the corresponding oxaziridine.[35-37] Asymmetric oxidations have been performed with monoperoxycamphoric acid.[35,36]

(11)

Reactions at the Imino Bond.

Nucleophilic addition of dimethyl phosphite across the imino bond of acetaldehyde *t*-butylimine without any solvent delivers the addition product (eq 12).[38] Functionalization at the nitrogen atom is accomplished with ***Phosgene***, which gives the *N*-vinylcarbamoyl chloride (eq 13).[39,40] Upon thermolysis, α,β-unsaturated isocyanates and *t*-butyl chloride are produced (eq 13).[40] Functionalized *N*-nitrosodialkylamines are accessible from acetaldehyde *t*-butylimine via reaction with ***Nitrosyl Chloride*** and, for example, ***Ethanethiol*** (eq 14).[41]

Acetaldoxime

[107-29-9] · C_2H_5NO · Acetaldoxime · (MW 59.07) (*E*)

[5780-37-0] (*Z*)

[5775-72-4]

(acetaldehyde equivalent; acetylation of arenes via diazonium salts;[1] synthesis of aldoximes;[2] rearrangement into acetamide;[3,4] synthesis of heterocycles, e.g. 2-isoxazolines,[5] imidazoles;[6] thiazolidines;[7] precursor for acetonitrile oxide, a useful 1,3-dipole for cycloadditions;[8] 1,3-dipolar cycloaddition[5,9,10])

Alternate Name: acetaldehyde oxime.

Physical Data: (*E*) and (*Z*) mixture bp 114-115 °C; mp 47 °C.

Solubility: sol most organic solvents, e.g. THF, $CHCl_3$, benzene, xylene, diethyl ether, 1,2-dichloroethane.

Form Supplied in: widely available commercially. Commercial samples, which had been refrigerated for several months, showed (*Z*):(*E*) ratios of 10-20:1.[2]

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Method: reaction of freshly distilled ***Acetaldehyde*** with ***Hydroxylamine*** hydrochloride in the presence of a base (eq 1).[3,11]

Handling, Storage, and Precautions: the oxime is preferably freshly prepared. The freshly prepared solid compound decomposes slowly on standing. Use in a fume hood.

Introduction.

Unsymmetrical oximes, like acetaldoxime, occur as a mixture of (*E*) and (*Z*) isomers across the carbon-nitrogen double bond (often referred to as *syn* and *anti* isomers, respectively). The position of the equilibrium changes with the conditions. A frequently reported equilibrium is situated around 40% (*E*) in the pure state and 46% (*E*) in aqueous acid,[12] but the position of the equilibrium is independent of the temperature and the concentration of the acid.[13] (*Z*)-Acetaldoxime can be prepared by slow crystallization of a freshly distilled mixture of (*E*)/(*Z*) isomers.[13] ^{1}H NMR[11,14] and ^{13}C NMR[15] have been used to establish the (*E*)/(*Z*) configurations of oximes.

Acetylation of Arenes via Diazonium Salts.

The reaction of acetaldoxime with aromatic diazonium salts affords oximes of acetophenones, which are hydrolyzed in acid medium to give aryl methyl ketones (eq 2).[1]

α-Alkylation of Acetaldoxime.

Deprotonation of acetaldoxime with 2 equiv of ***n-Butyllithium*** at -78 °C generates the dianion which reacts with ***Benzyl Bromide*** or 1-iodopropane to give excellent yields of α-alkylated (*Z*)-oximes (eqs 3 and 4).[2] α,α-Dialkylation by further alkylation in similar way has been achieved (eq 4).[2] It is generally known that ketone oximes can be deprotonated and alkylated regiospecifically *syn* to the oxime hydroxy group.[16,17] It is essential to perform the deprotonation and alkylation at -78 °C as otherwise no α-alkylated oximes are isolated, the major byproducts being nitriles.[16]

(3)

(4)

Rearrangement into Acetamide.

Heating of acetaldoxime in xylene in the presence of 0.2 mol % ***Nickel(II) Acetate***[3] or silica gel[4] as catalyst caused isomerization into acetamide (eq 5).

(5)

Synthesis of Heterocycles.

Chlorination of acetaldoxime with ***N-Chlorosuccinimide***[5] or ***Chlorine*** gas[8,18] in chloroform affords acetohydroxamic acid chloride, which suffers dehydrochlorination with ***Triethylamine*** to give ***Acetonitrile N-Oxide***. The latter 1,3-dipole undergoes 1,3-dipolar cycloaddition to alkenes giving 2-isoxazolines in a one-pot procedure (eq 6).[5] This reaction is also suitable for the construction of more complex molecules such as the conversion of a 6-ethylideneolivanic acid derivative into the corresponding spiroisoxazoline (eq 7).[8]

(6)

R = *n*-Bu	61%
R = CH=CHMe	72%
R = C≡CH	14%
R = Ph	84%

(7)

The cyclocondensation of acetaldoxime with biacetyl monooxime yields 1-hydroxy-2,4,5-trimethylimidazole 3-oxide,[19] originally believed to be 4-hydroxy-3,4,6-trimethyl-1,2,5-oxadiazine.[20] The reaction is preferably performed in liquid sulfur dioxide in the presence of catalytic amounts of hydrogen chloride (eq 8),[6] and works as well with other α-oximino ketones (eq 9).[21]

(8)

(9)

Upon reaction of acetaldehyde oxime with 2,2-dimethylthiirane, ring expansion to 3-hydroxy-2,5,5-trimethylthiazolidine occurs (eq 10).[7]

(10)

1,3-Dipolar Cycloaddition.

Acetaldoxime cycloadds very slowly to ***Methyl Acrylate*** and ***Acrylonitrile***, giving 2:1 adducts as mixtures of regioisomers and stereoisomers (eq 11).[10] The palladium-catalyzed cycloaddition of the reagent to 1,3-butadiene yields an isoxazolidine via the intermediacy of a nitrone which undergoes 1,3-dipolar cycloaddition (eq 12).[9]

(11)

Addition Reactions Across the Carbon-Nitrogen Double Bond.

Cyanotrimethylsilane adds to acetaldoxime to give the cyanated adduct (eq 13),[22] while allylboronates behave similarly to afford the adduct, which disproportionates and can subsequently be cleaved to the alkenic hydroxylamine (eq 14).[23]

O-Functionalization.

α-Bromo aldoximes are difficult to obtain. Direct α-bromination of aldoximes with a variety of brominating agents was not successful, but smooth bromination of the *O*-silylated derivative was accomplished (eq 15).[24] Functionalization at the oxygen atom has been accomplished with organogermanium[25] and organoarsenium[26] reagents (eq 16), while *O*-alkylation has been performed with the sodium salt of acetaldoxime and an α-bromo ketone.[27] ***Lithium Aluminum Hydride*** readily effected hydrogenolysis of the N-O bond to afford the corresponding 1,2-diol (eq 17).[27]

Miscellaneous.

Thermal decomposition of alkyl peresters or peroxides in H-donor solvents, e.g. cycloalkanes or ethers, in the presence of acetaldoxime afforded C-1 alkylated products.[28] The reaction involves carbon radical addition to the carbon-nitrogen double bond.

Related Reagents.

Acetaldehyde; ***Acetaldehyde N-t-Butylimine***; ***Acetonitrile N-Oxide***; ***Formaldoxime***; ***Hydroxylamine***.

p-Acetamidobenzenesulfonyl Azide

[2158-14-7] · $C_8H_8N_4O_3S$ · *p*-Acetamidobenzenesulfonyl Azide · (MW 240.24)

(reagent for diazo function transfer to activated methylene groups;[1] can functionalize double bonds by cycloaddition reactions[9,10])

Alternate Name: *p*-ABSA.

Physical Data: mp 106-108 °C;[1] 112-114 °C.[2] Decomposition begins at about 120 °C in an open cup system.

Solubility: sol CH_2Cl_2; sparingly sol toluene; insol petroleum ether.

Form Supplied in: colorless or slightly brown crystals.

Analysis of Reagent Purity: ^{1}H NMR, IR, elemental analysis.

Preparative Methods: the title reagent can be prepared by nitrosation of *p*-acetamidobenzenesulfonyl hydrazide,[2,3] by reaction of *p*-acetamidobenzenesulfonyl chloride with ***Sodium Azide*** in acetone solution,[1] or more conveniently under phase transfer conditions with CH_2Cl_2/water in the presence of tetraethylammonium chloride[1] or with benzene/water in the presence of Aliquat 336 (99% yield at rt in 0.5 h).[4]

Purification: recrystallization from toluene.

Handling, Storage, and Precautions: relatively safe reagent and no special instructions for its storage and handling are mentioned in the literature. Proper caution should be used as with all azide reagents. Use in a fume hood.

Diazo Transfer Reagent.

p-Acetamidobenzenesulfonyl azide offers some advantages in safety and ease of product separation and was recommended[1,5] as an alternative and substitute for the standard reagent, ***p-Toluenesulfonyl Azide***,[6] in diazo transfer

chemistry. The reaction times with *p*-ABSA are longer than with other azides.[1a]

Thus far, the reagent has only been employed in the direct transfer of a diazo function to methylene groups flanked by one or two carbonyls.

Well-known diazodicarbonyl compounds, including diazodimedone, diazoisopropylidenemalonic acid, diazomalonic, and diazoacetoacetic acid esters[1] as well as optically active esters of diazoacetoacetic acid (eq 1)[5] are readily available from *p*-ABSA and Et_3N in good yields (72-95%).

In the presence of a stronger base (***Sodium Ethoxide*** in ethanol) the *p*-acetamidobenzenesulfonyl amide of diazomalonic acid ethyl ester was obtained as the major product from diethyl malonate.[3]

p-ABSA also proves to be a versatile and effective reagent for the synthesis of various vinyldiazomethanes with one or two electron withdrawing groups (EWG) (eq 2).[1,7,8] When two EWG are in a parent substrate, ***Triethylamine*** is usually an effective base,[1,7] but with less acidic systems, ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** is required for good yields of vinyldiazomethanes.[8] The presence of a vinyl group apparently enhances the transformation.[1]

$$EWG = CO_2R,\ COR,\ SO_2$$

$$R^1 = CO_2R,\ SO_2R,\ Ph,\ SPh;\ R^2 = H,\ Alk,\ OAlk$$

Activation of a methylene by one carbonyl group as in dihydro-2-indolone, affords a relatively low yield of diazoindolone (39%) with *p*-ABSA and Et_3N as the base.[1a]

Functionalization of Double Bonds.

Nucleophilic double bonds of indole, *N*-methylindole, and tetrahydropyridine readily add to the 1,3-dipole moiety of *p*-ABSA to give, as the final products, indolidylidene-[9] and piperidylidene-2-arylsulfonamides (eq 3)[10] in good

yields.

Nitrenogenic Source.

Catalytic decomposition of *p*-ABSA by platinum(II) complexes,[11] thermolysis at fairly high temperatures (above 130-150 °C) in *o*- and *p*-xylenes, *N*,*N*-dimethylaniline,[2] or pyridine,[2,12] and reaction with triphenylstibine[13] gives rise to the formal insertion or addition products of *p*-acetamidobenzenesulfonylnitrene into the corresponding substrates in good to moderate yields.

Related Reagents.

p-Dodecylbenzenesulfonyl Azide; ***Methanesulfonyl Azide***; ***p-Toluenesulfonyl Azide***.

4-Acetamido-2,2,6,6-tetramethyl-1-piperidinyloxyl[1]

[14691-89-5] · $C_{11}H_{21}N_2O_2$ · 4-Acetamido-2,2,6,6-tetramethyl-1-piperidinyloxyl · (MW 213.30)

(reagent and catalyst for selective oxidation of alcohols[2])

Alternate Names: 4-acetamido-TEMPO; 4-acetylamino-TEMPO.

Physical Data: mp 146-147 °C,[2] 147.5 °C.[3]

Solubility: nearly insol hexane, ether; sol ethanol, acetone, acetonitrile, methylene chloride; slightly sol water, from which it can be recrystallized.

Form Supplied in: red or pink solid, commercially available.

Preparative Method: can be easily prepared in high yield from 4-amino-2,2,6,6-tetramethylpiperidine.[2]

Handling, Storage, and Precautions: completely stable and nonhygroscopic.

Oxidation of Alcohols.

4-Acetamido-TEMPO is a representative of the nitroxide radicals (**1**) which have been used as reagents or catalysts for the oxidation of organic compounds.[1] Several nitroxide radicals have been converted to the corresponding oxoammonium salts (**2**) and used as stoichiometric oxidizing reagents.[1] Nitroxide radicals have also been used as catalysts in the the presence of a secondary, stoichiometric oxidant (see ***2,2,6,6-Tetramethylpiperidin-1-oxyl***).[1]

(1) **(2)**

4-Acetamido-TEMPO (**3**) is not, itself, a reagent for the oxidation of alcohols. Rather, it serves as a convenient precursor for the in situ preparation of an oxoammonium salt (**4**), which is the true oxidant. The oxoammonium salt (**4**) is the product of the acid-catalyzed disproportionation of (**3**) to (**4**) and (**5**) in the presence of ***p-Toluenesulfonic Acid*** (eq 1) and is a highly selective reagent for alcohol oxidation (eq 2).[1] The reactions are carried out in methylene chloride in which TsOH.H_2O is essentially insoluble. The only products of the reaction are the desired carbonyl compound product (**7**) and the hydroxylamine salt (**5**), which is completely insoluble in methylene chloride. Product isolation simply involves the filtration of (**5**) and the evaporation of methylene chloride. Compound (**5**) can be converted back to the nitroxide radical (**3**) in quantitative yield.[2]

(3) **(4)** **(5)**

(6) **(4)** **(7)** **(5)**

The reaction has been used for the oxidation of a variety of alcohols with excellent yields of isolated products.[2] Primary alcohols are converted to the corresponding aldehydes, and no over-oxidation is observed. Secondary alcohols react as well as primary alcohols and provide the corresponding ketones. The mildness of this reaction has been demonstrated by the oxidations of nerol (**8**) and geraniol (**9**) to the corresponding *cis*-citral (**10**) and *trans*-citral (**11**).

(8)

(9)

(10)

(11)

Oxidation with this reagent does not take place when there is an oxygen or nitrogen in the β-position to the alcohol being oxidized and does not take place with 1,2-diols or sugars. Amines,[1,4] thiols,[5] phenols,[6] indoles,[7] benzyl ethers,[1] and ketones (very slow)[1] react with oxoammonium salts and may interfere with alcohol oxidation. However, sulfides, most ethers, amides, esters, and double bonds do not react with oxoammonium salts and should not interfere.[1]

A number of other oxoammonium salts have been described in the literature.[1] In addition, TEMPO-type nitroxide radicals have been used as specific catalysts for the oxidation of alcohols using one or several secondary, stoichiometric oxidants.[1,8] Neither 4-acetamido-TEMPO nor any of its derivatives have been used in this manner, but they should function satisfactorily.

Acetic Acid[1]

[64-19-7] · $C_2H_4O_2$ · Acetic Acid · (MW 60.05)

(common organic reaction solvent; reagent for protonolysis of organometallic compounds,[5,6] synthesis of aromatic methyl ketones,[10] lactones,[15] heterocycles[13])

Alternate Name: ethanoic acid.

Physical Data: weak organic acid, pK_a 4.77; *d*204 1.049 g cm^{-3}; mp 14.7 °C; bp 118 °C (30 °C/31 mmHg). Forms azeotropes with many common solvents, such as benzene, pyridine, DMF, and dioxane.

Solubility: miscible with water, ethanol, acetone, benzene, ether, and carbon tetrachloride; insol CS_2.

Form Supplied in: widely available as glacial acetic acid, >98% purity.

Analysis of Reagent Purity: analyzed by titration with base.[2,18] High purity grades of acetic acid (>99%) are determined by the freeze-point method. Formic acid content can be determined by a redox titration based on oxidation with lead tetraacetate. Methods for analysis of trace impurities such as water, iron, or chlorine are known.

Purification: among many methods, distillation over traces of oxidants in the presence of Ac_2O is effective.[19]

Handling, Storage, and Precautions: acetic acid is flammable with a flash point of 40 °C.[3] This hazard is often overlooked by the practicing chemist and has been the source of laboratory accidents. Acetic acid is a corrosive material. Basic safety equipment including eye protection, gloves, and a chemical apron should be worn during all operations with acetic acid. Vapors will cause intense irritation to mouth, nose, eyes, skin, and upper respiratory tract. Use of an appropriate NIOSH/MSHA respirator is recommended. Use in a fume hood.

Acetic Acid as Reaction Solvent.

The most common use of acetic acid in organic synthesis is as a reaction solvent. Many types of organic compounds

are highly soluble in this reagent, and the stability of acetic acid towards many reagents is good. Examples of reactions often performed in acetic acid include bromination, hydrolysis, solvolysis, reductions, and hydrogenations. A discussion of acetic acid as a reaction solvent with a given reagent will be found in the detailed treatments of individual reagents.

Protonolysis of Organometallic Compounds.

Alkylboranes are readily cleaved by protonolysis with acetic acid.[4] In contrast, organoboranes are stable to water, mineral acids, and aqueous base. This reaction provides a convenient alternative to catalytic hydrogenation in cases where catalyst poisoning or selectivity would be problematic (eq 1).[4] The hydroboration of alkynes followed by protonolysis with acetic acid is a selective sequence producing *cis*-alkenes (eq 2).[5]

Tetraorganoborates containing alkenyl or alkynyl groups react with acetic acid in a completely different manner, leading to the formation of new carbon-carbon bonds. The reader is referred to relevant articles dealing with organoborates for discussions of this reaction.

Acetic acid has been used to cleave organosilicon intermediates produced during the Peterson reaction (eq 3).[6] The acid-catalyzed elimination is *anti*; this complements the base-catalyzed elimination, which is *syn* (eq 4).

Acetic acid promotes the stereospecific conversion of trimethylsilyl epoxides to enol acetates (eq 5).[7] In all cases studied, addition of the acetate nucleophile is α to the silyl group. The stereochemistry of the overall reaction is consistent with nucleophilic addition and inversion, followed by *anti* β-elimination.

Cleavage of a trimethylsilylmethylcyclopropane by an acetic acid-***Boron Trifluoride*** trifluoride complex results in formation of a terminal alkene (eq 6).[8]

Selective cleavage of a 1,2-disilylalkene allows synthesis of the 2-trimethylsilyl-1-alkene, which is not accessible through direct hydrosilation (eq 7).[9]

(7)

Acetylation of Aromatic Compounds.

Acetic acid will acetylate electron-rich aromatic compounds such as phenols or anisoles. Best results are achieved with ***Boron Trifluoride***[10] (eq 8) or ***Trifluoroacetic Anhydride***[11] (eq 9) as an acid catalyst, although other acids such as ***Zinc Chloride***[12] have been used.

(8)

(9)

Synthesis of Heterocycles.

Amino alcohols are cyclized to methyloxazolines by condensation with acetic acid (eq 10).[13]

(10)

A variety of other heterocyclic systems have been formed by dehydration or rearrangement in acetic acid (eqs 11 and 12).[14]

Formation of Lactones.

Treatment of alkenes with ***Manganese(III) Acetate*** in acetic acid leads to formation of lactones.[15] The reaction is general for all alkenes and carboxylic acids, but best yields are obtained with terminal alkenes and acetic acid. Only the lactone of the γ-hydroxy acid is produced. The most convenient laboratory procedure[15a] uses manganese(II) acetate and ***Potassium Permanganate*** to form manganese(III) acetate in situ (eq 13). The mechanism of the reaction involves addition of a carboxymethyl radical to the alkene; the carboxymethyl radicals are generated by thermolysis of the manganese(III) acetate.

Other carboxylic acids can be used in place of acetic acid. Of these, ***Cyanoacetic Acid*** is particularly reactive due to the high stability of the α-cyano radical intermediate (eq 14).[15a,16] Lactones are efficiently formed by the intramolecular reaction of unsaturated acids (eq 15).[17]

Related Reagents.

Acetic Anhydride; ***Formic Acid***; ***Glyoxylic Acid***; ***Oxalic Acid***; ***Propionic Acid***; ***Trifluoroacetic Acid***.

Acetic Anhydride[1]

[108-24-7] · $C_4H_6O_3$ · Acetic Anhydride · (MW 102.09)

(useful for the acetylation of alcohols,[2] amines,[3] and thiols,[4] oxidation of alcohols,[5] dehydration,[6] Pummerer[7] reaction, Perkin[8] reaction, Polonovski[9] reaction, *N*-oxide reaction,[10] Thiele[11] reaction, ether cleavage,[12] enol acetate formation,[13] *gem*-diacetate formation[14])

Physical Data: bp 138-140 °C; mp -73 °C; *d* 1.082 g cm^{-3}.

Solubility: sol most organic solvents. Reacts with water rapidly and alcohol solvents slowly.

Form Supplied in: commercially available in 98% and 99+% purities. Acetic anhydride-d_6 is also commercially available.

Analysis of Reagent Purity: IR, NMR.[15]

Preparative Methods: acetic anhydride is prepared industrially by the acylation of ***Acetic Acid*** with ***Ketene***.[1b] A laboratory preparation of acetic anhydride involves the reaction of sodium acetate and ***Acetyl Chloride*** followed by fractional distillation.[16]

Purification: adequate purification is readily achieved by fractional distillation. Acetic acid, if present, can be removed by refluxing with CaC_2 or with coarse magnesium filings at 80-90 °C for 5 days. Drying and acid removal can be achieved by azeotropic distillation with toluene.[17]

Handling, Storage, and Precautions: acetic anhydride is corrosive and a lachrymator and should be handled in a fume hood.

Acetylation.

The most notable use of acetic anhydride is for the acetylation reaction of alcohols,[2] amines,[3] and thiols.[4] Acids, Lewis acids, and bases have been reported to catalyze the reactions.

Alcohols.

The most common method for acetate introduction is the reaction of an alcohol with acetic anhydride in the presence of pyridine.[2] Often, ***Pyridine*** is used as the solvent and reactions proceed nearly quantitatively (eq 1).

(1)

If the reaction is run at temperatures lower than 20 °C, primary alcohols can be acetylated over secondary alcohols selectively.[18] Under these conditions, tertiary alcohols are not acylated. Most alcohols, including tertiary alcohols, can be acylated by the addition of DMAP (***4-Dimethylaminopyridine***) and ***Acetyl Chloride*** to the reaction containing acetic anhydride and pyridine. In general, the addition of DMAP increases the rate of acylation by 10^4 (eq 2).[19]

(2)

Recently, Vedejs found that a mixture of ***Tri-n-butylphosphine*** and acetic anhydride acylates alcohols faster than acetic anhydride with DMAP.[20] However, the combination of acetic anhydride with DMAP and ***Triethylamine*** proved superior. It is believed that the Et_3N prevents HOAc from destroying the DMAP catalyst.

Tertiary alcohols have been esterified in good yield using acetic anhydride with calcium hydride or calcium carbide.[21] *t*-Butanol can be esterified to *t*-butyl acetate in 80% yield under these conditions. High pressure (15 kbar) has been used to introduce the acetate group using acetic anhydride in methylene chloride.[22] Yields range from 79-98%. Chemoselectivity is achieved using acetic anhydride and ***Boron Trifluoride Etherate*** in THF at 0 °C. Under these conditions, primary or secondary alcohols are acetylated in the presence of phenols.[23]

α-D-Glucose is peracetylated readily using acetic anhydride in the presence of ***Zinc Chloride*** to give α-D-glucopyranose pentaacetate in 63-72% yield (eq 3).[24]

(3)

Under basic conditions, α-D-glucose can be converted into β-D-glucopyranose pentaacetate in 56% yield (eq 4).

(4)

In the food and drug industry, high-purity acetic anhydride is used in the manufacture of aspirin by the acetylation of salicylic acid (eq 5).[25]

(5)

Amines.

The acetylation of amines has been known since 1853 when Gerhardt reported the acetylation of aniline.[3] Acetamides are typically prepared by the reaction of the amine with acetic anhydride (eq 6).

(6)

A unique method for selective acylation of secondary amines in the presence of primary amines involves the use of ***18-Crown-6*** with acetic anhydride and triethylamine.[26] It is believed that the 18-crown-6 complexes primary alkylammonium salts more tightly than the secondary salts, allowing selective acetylation.

In some cases, tertiary amines undergo a displacement reaction with acetic anhydride. A simple example involves the reaction of benzyldimethylamine with acetic anhydride to give dimethylacetamide and benzylacetate (eq 7).[27]

Allylic tertiary amines can be displaced by the reaction of acetic anhydride and sodium acetate.[28] The allylic acetate is the major product, as shown in eq 8.

Cyclic benzylic amines may undergo ring opening upon heating with acetic anhydride (eq 9).[29]

α-Amino acids react with acetic anhydride in the presence of a base to give 2-acetamido ketones.[30] This reaction is known as the Dakin-West reaction (eq 10) and is believed to go through a oxazolone mechanism. The amine base of choice is 4-dimethylaminopyridine. Under these conditions, the reaction can be carried out at room temperature in 30 min.

Cyclic β-amino acids rearrange to α-methylene lactams upon treatment with acetic anhydride, as shown in eq 11.[31]

(11)

Thiols.

S-Acetyl derivatives can be prepared by the reaction of acetic anhydride and a thiol in the presence of potassium bicarbonate.[4] Several disadvantages to the *S*-acetyl group in peptide synthesis include β-elimination upon base-catalyzed hydrolysis. Also, sulfur to nitrogen acyl migration may be problematic.

Oxidation.

The oxidation of primary and secondary alcohols to the corresponding carbonyl compounds can be achieved using ***Dimethyl Sulfoxide-Acetic Anhydride***.[5] The reaction proceeds through an acyloxysulfonium salt as the oxidizing agent (eq 12).

(12)

The oxidations often proceed at room temperature, although long reaction times (18-24 h) are sometimes required. A side product is formation of the thiomethyl ethers obtained from the Pummerer rearrangement.

If the alcohol is unhindered, a mixture of enol acetate (from ketone) and acetate results (eq 13).[32]

(13)

The oxidation of carbohydrates can be achieved by this method, as Hanessian showed (eq 14).[33]

(14)

Aromatic α-diketones can be prepared from the acyloin compounds; however, aliphatic diketones cannot be prepared by this method.[34] The reaction proceeds well in complex systems without epimerization of adjacent stereocenters, as in the yohimbine example (eq 15).[35] This method compares favorably with that of ***Dimethyl Sulfoxide-Dicyclohexylcarbodiimide***.

(15)

Dehydration.

Many functionalities are readily dehydrated upon reaction with acetic anhydride, the most notable of which is the oxime.[6] Also, dibasic acids give cyclic anhydrides or ketones, depending on ring size.[36]

An aldoxime is readily converted to the nitrile as shown in eq 16.[37]

(16)

When oximes of α-tetralones are heated in acetic anhydride in the presence of anhydrous ***Phosphoric Acid***,

aromatization occurs as shown in eq 17.[38]

(17)

Oximes of aliphatic ketones lead to enamides upon treatment with acetic anhydride-pyridine, as shown in the steroid example in eq 18.[39]

(18)

Upon heating with acetic anhydride, dibasic carboxylic acids lead to cyclic anhydrides of ring size 6 or smaller. Diacids longer than glutaric acid lead to cyclic ketones (eq 19).[36]

(19)

N-Acylanthranilic acids also cyclize when heated with acetic anhydride (eq 20). The reaction proceeds in 81% yield with slow distillation of the acetic acid formed.[40]

(20)

Pummerer Reaction.

In 1910, Pummerer[7] reported that sulfoxides react with acetic anhydride to give 2-acetoxy sulfides (eq 21). The sulfoxide must have one α-hydrogen. Alternative reaction conditions include using ***Trifluoroacetic Anhydride*** and acetic anhydride.

(21)

β-Hydroxy sulfoxides undergo the Pummerer reaction upon addition of sodium acetate and acetic anhydride to give α,β-diacetoxy sulfides. These compounds are easily converted to α-hydroxy aldehydes (eq 22).[41]

(22)

2-Phenylsulfonyl ketones rearrange in the presence of acetic anhydride-sodium acetate in toluene at reflux to give *S*-aryl thioesters (eq 23).[42] Upon hydrolysis, an α-hydroxy acid is obtained.

(23)

In the absence of sodium acetate, 2-phenylsulfonyl ketones give the typical Pummerer product. Since β-keto sulfoxides

are available by the reaction of esters with the dimsyl anion, this overall process leads to one-carbon homologated α-hydroxy acids from esters (eq 24).[42]

(24)

Also, 2-phenylsulfonyl ketones can be converted to α-phenylthio-α,β-unsaturated ketones via the Pummerer reaction using acetic anhydride and a catalytic amount of ***Methanesulfonic Acid*** (eq 25).[43]

(25)

The Pummerer reaction has been used many times in heterocyclic synthesis as shown in eq 26.

(26)

The Pummerer rearrangement of 4-phenylsulfinylbutyric acid with acetic anhydride in the presence of ***p-Toluenesulfonic Acid*** leads to butanolide formation (eq 27).[44] Oxidation with ***m-Chloroperbenzoic Acid*** followed by thermolysis then leads to an unsaturated compound.

(27)

An unusual Pummerer reaction takes place with penicillin sulfoxide, leading to a ring expansion product as shown in eq 28.[45]

(28)

This led to discovery of the conversion of penicillin V and G to cephalexin,[46] a broad spectrum orally active antibiotic (eq 29).

(29)

A Pummerer-type reaction was carried out on a dithiane protecting group to liberate the corresponding ketone (eq 30).[47] These were the only reaction conditions which provided any of the desired ketone.

(30)

Perkin Reaction.

The Perkin reaction,[8] developed by Perkin in 1868, involves the condensation of an anhydride and an aldehyde in the presence of a weak base to give an unsaturated acid (eq 31).

(31)

The reaction is often used for the preparation of cinnamic acids in 74-77% yield (eq 32).

(32)

Aliphatic aldehydes give low or no yields of acid. Coumarin can be prepared by a Perkin reaction of salicylaldehyde and acetic anhydride in the presence of triethylamine (eq 33).

(33)

Polonovski Reaction.

In the Polonovski reaction,[9] tertiary amine oxides react with acetic anhydride to give the acetamide of the corresponding secondary amine (eq 34).

(34)

In nonaromatic cases, the Polonovski reaction gives the *N*-acylated secondary amine as the major product and the deaminated ketone as a minor product (eq 35).[48]

(35)

This reaction has been extended to a synthesis of 2-acetoxybenzodiazepine via an *N*-oxide rearrangement (eq 36).

(36)

An application of the Polonovski reaction forms β-carbonylenamines. *N*-Methylpiperidone is reacted with *m*-CPBA followed by acetic anhydride and triethylamine to give the β-carbonyl enamine (eq 37).[49]

(37)

Reaction with *N*-Oxides.

Pyridine 1-oxide reacts with acetic anhydride to produce 2-acetoxypyridine, which can be hydrolyzed to 2-pyridone (eq 38).[10]

(38)

Open chain *N*-oxides, in particular nitrones, rearrange to amides (almost quantitatively) under acetic anhydride conditions (eq 39).[50]

(39)

Heteroaromatic *N*-oxides with a side chain react with acetic anhydride to give side-chain acyloxylation (eq 40).[51]

(40)

This reaction has been used in synthetic chemistry as the method of choice to form heterocyclic carbinols or aldehydes.

Thiele Reaction.

The Thiele reaction converts 1,4-benzoquinone to 1,2,4-triacetoxybenzene using acetic anhydride and a catalytic amount of ***Sulfuric Acid***.[11] Zinc chloride has been used without advantage. In this reaction, 1,4-addition to the quinone is followed by enolization and acetylation to give the substituted benzene (eq 41).

(41)

With unhindered quinones, BF_3 etherate is a more satisfactory catalyst but hindered quinones require the more active sulfuric acid catalyst. 1,2-Naphthoquinones undergo the Thiele reaction with acetic anhydride and sulfuric acid or boron trifluoride etherate (eq 42).

(42)

Ether Cleavage.

Dialkyl ethers can be cleaved with acetic anhydride in the presence of pyridine hydrochloride or anhydrous ***Iron(III) Chloride***. In both cases, acetate products are produced. As shown in eq 43, the tricyclic ether is cleaved by acetic anhydride and pyridine hydrochloride to give the diacetate in 93% yield.[12]

(43)

Simple dialkyl ethers react with iron(III) chloride and acetic anhydride to produce compounds where both R groups are converted to acetates (eq 44).[52]

(44)

Cleavage of allylic ethers can occur using acetic anhydride in the presence of iron(III) chloride (eq 45). The reaction takes place without isomerization of a double bond, but optically active ethers are cleaved with substantial racemization.[53]

(45)

Cleavage of aliphatic ethers occurs with the reaction of acetic anhydride, boron trifluoride etherate, and ***Lithium Bromide*** (eq 46). The ethers are cleaved to the corresponding acetoxy compounds contaminated with a small amount of unsaturated product.[54] In some cases, the lithium halide may not be necessary.

(46)

Cyclic ethers are cleaved to o-bromoacetates using ***Magnesium Bromide*** and acetic anhydride in acetonitrile (eq 47).[55]

(47)

The reaction occurs with inversion of configuration, as shown in eq 48.

(48)

Trimethylsilyl ethers are converted to acetates directly by the action of acetic anhydride-pyridine in the presence of 48% HF or boron trifluoride etherate (eq 49).[56]

(49)

Miscellaneous Reactions.

Primary allylic alcohols can be prepared readily by the action of *p*-toluenesulfonic acid in acetic anhydride-acetic acid on the corresponding tertiary vinyl carbinol, followed by hydrolysis of the resulting acetate.[57] The vinyl carbinol is readily available from the reaction of a ketone with a vinyl Grignard reagent. Overall yields of allylic alcohols are very good (eq 50).

(50)

Enol lactonization occurs readily on an α-keto acid using acetic anhydride at elevated temperatures.[58] The reaction shown in eq 51 proceeds in 89% yield. In general, acetic anhydride is superior to acetyl chloride in this reaction.[59]

(51)

Aliphatic aldehydes are easily converted to the enol acetate using acetic anhydride and potassium acetate (eq 52).[13] This reaction only works for aldehydes and is the principal reason for the failure of aldehydes to succeed in the Perkin reaction. Triethylamine and DMAP may also catalyze the reaction.

(52)

A cyclopropyl ketone is subject to homoconjugate addition using acetic anhydride/boron trifluoride etherate. Upon acetate addition, the enol is trapped as its enol acetate (eq 53).[60]

(53)

When an aldehyde is treated with acetic anhydride/anhydrous iron(III) chloride, geminal diacetates are formed in good to excellent yields.[14] Aliphatic and unsaturated aldehydes can be used in this reaction as shown in eqs 54-56. Interestingly, if an α-hydrogen is present in an unsaturated aldehyde, elimination of the geminal diacetate product gives a 1-acetoxybutadiene.

(54)

(55)

(56)

If an aldehyde is treated with acetic anhydride in the presence of a catalytic amount of ***Cobalt(II) Chloride***, a diketone is formed (eq 57).[61]

(57)

However, if 1.5 equiv of cobalt(II) chloride is added, the geminal diacetate is formed (eq 58).[62]

(58)

Apparently, the reaction in eq 58 occurs only when the starting material is polyaromatic or with compounds whose carbonyl IR frequency is less than 1685 cm^{-1}.

Acetic anhydride participates in several cyclization reactions. For example, enamines undergo a ring closure when

treated with acetic anhydride (eq 59).[63]

(59)

o-Diamine compounds also cyclize when treated with acetic anhydride (eq 60).[64]

(60)

Twistane derivatives were obtained by the reaction of a decalindione with acetic anhydride, acetic acid, and boron trifluoride etherate (eq 61).[65]

(61)

A condensation/cyclization reaction between an alkynyl ketone and a carboxylic acid in the presence of acetic anhydride/triethylamine gives a butenolide (eq 62).[66]

(62)

A few rearrangement reactions take place with acetic anhydride. A Claisen rearrangement is involved in the formation of the aromatic acetate in eq 63.[67] The reaction proceeds in 44% yield even after 21 h at 200 °C.

(63)

Complex rearrangements have occured using acetic anhydride under basic conditions, as shown in eq 64.[68]

(64)

Aromatization occurs readily using acetic anhydride. Aromatization of α-cyclohexanones occurs under acidic conditions to lead to good yields of phenols (eq 65).[69] However, in totally unsubstituted ketones, aldol products are formed.

(65)

Aromatization of 1,4- and 1,2-cyclohexanediones leads to cresol products (eq 66) in over 90% yield.[70]

(66)

Alkynes and allenes are formed by the acylation of nitrimines using acetic anhydride/pyridine with DMAP as catalyst (eqs 67 and 68).[71] Nitrimines are prepared by nitration of ketoximes with nitrous acid.

(67)

(68)

Lastly, acetic anhydride participates in the Friedel-Crafts reaction.[72] ***Polyphosphoric Acid*** is both reagent and solvent in these reactions (eq 69).

(69)

Acetic Formic Anhydride[1]

[2258-42-6] · $C_3H_4O_3$ · Acetic Formic Anhydride · (MW 88.06)

(useful formylating agent for the hydroxyl,[2] phenol,[3] and amine groups[4] as well as other heteroatoms;[5] useful for the synthesis of aldehydes from aromatic Grignard reagents,[6] for the preparation of formyl fluoride,[7] and for the preparation of diazoacetaldehyde[8])

Alternate Name: AFA.

Physical Data: bp 27-28 °C/10 mmHg.

Analysis of Reagent Purity: IR, NMR, MS.[1]

Preparative Methods: acetic formic anhydride is not comercially available. The easiest method of preparation is by the reaction of sodium formate and ***Acetyl Chloride*** in dry ether as reported by Krimen.[9] Alternatively, ***Ketene*** and ***Formic Acid*** form the title compound at room temperature or below.[10] Acetic formic anhydride can be prepared rapidly in situ by stirring formic acid, acetyl chloride, and ***Triethylamine*** in THF at -70 °C for 10 min.[11] AFA is found in a mixture of formic acid (excess) with ***Acetic Anhydride***.[1] The mixture is more accurately described as formic acid-acetic anhydride mixture (FAM) and is also used as a formylating agent.

Purification: by fractional distillation at low pressure.

Handling, Storage, and Precautions: acetic formic anhydride decomposes slowly at room temperature and faster at elevated temperatures, giving acetic acid and carbon monoxide. Due to gas evolution, AFA is best stored at 4 °C in a flask fitted with a polyethylene stopper since sealed samples can explode. The compound is an eye and skin irritant and should be handled in a fume hood.

O-Formylations.

Acetic formic anhydride (AFA) as well as formic acid-acetic anhydride mixture (FAM) can be used to formylate alcohols and phenols.[2,3] While the yields of formates are high, the reaction takes from 50 to 80 days (eq 1).

(1)

An improved method for formation of aryl formates uses pure AFA with the addition of tertiary amine bases or sodium formate.[12] The reaction takes place at 20 °C, is complete in 24-48 h, and gives excellent yields of formate. The procedure is general and is an easy method of preparation of pure aryl formates in high yield with no acetate byproducts. The reaction can be applied to aryl groups with electron donating or electron withdrawing substituents.

Phenolic ketones cyclize to isoflavones with AFA catalyzed by sodium formate or ***Triethylamine*** (eq 2).[13]

(2)

Salicylamide is formylated in 53% yield using AFA with ***Pyridine*** at 0 °C (eq 3).[14] Interestingly, no rearrangement to *N*-formylsalicylamide occurs under these reaction conditions. This protocol is superior to formic acid or ethyl formate which give the *N*-formyl compound exclusively.

(3)

Aliphatic alcohols can be converted to their formates using FAM.[2] Tertiary alcohols yield formate esters exclusively, while secondary and primary alcohols yield mixtures of formate and acetate. Formylation of primary and secondary alcohols can be enhanced by the addition of tertiary nitrogen bases or sodium formate.

Tertiary alcohols that are typically dehydrated upon acetylation yield formates under these reaction conditions. *O*[12a]-

Formyltetracycline (**1**) can be prepared in high yield using AFA.[15]

(1) O^{12a}-Formyltetracycline

Complex hydroxy acids such as gibberellin A3 react with acetic formic anhydride in pyridine to give the 3-*O*-monoformyl derivative (**2**) and the *O*-diformyl derivative in 85% and 13% yields, respectively.[16]

(2) O^{3}-Formylgibberellin A3; R = CHO, R' = H

(3)

Acetic formic anhydride formylates the sugar moiety of some nucleosides such as uridine and others.[17] Polyformylation occurs on all free hydroxyl groups. The 5´-hydroxyl of nucleosides can be formylated efficiently to give a 5´-*O*-formyl derivative (**3**).[18] The selective hydrolysis of formate esters in hot methanol compared with acetates makes formylation an attractive protecting group for some nucleosides.

N-Oxides of tertiary amines are deoxygenated in nearly quantitative yield using AFA (eq 4).[19] The reaction is general for trialkylamine *N*-oxides and *N*,*N*-dialkylarylamine *N*-oxides. Heteroaromatic *N*-oxides and sulfoxides are unchanged under these reaction conditions.[20]

N-Formylations.

Ammonia can be monoformylated using AFA at 0 °C in dry ether as shown in eq 5.[21] No polyformylated products were detected in the reaction.

Many aliphatic and aromatic amines (primary and secondary) have been formylated successfully using AFA or FAM.[4] Primary amines can be monomethylated in a one-pot procedure using excess FAM which gives a monoformylated intermediate (eq 6).[22] Weakly basic and sterically hindered amines are also reactive.

Heterocyclic compounds have been *N*-formylated at the side chain or ring nitrogen using AFA or FAM. Some examples, (**4**),[23] (**5**),[24] (**6**),[25] and (**7**),[26] are shown.

(4)

(5)

(6)

(7)

N-Formylation of amino acids has been achieved using FAM without racemization. An excess of FAM is required; however, AFA can be used in a 2-3 molar excess. Most amino acids have been formylated in 70-94% yields without formation of the acetate.[27]

The formyl group is very useful as a blocking group in peptide synthesis. The formyl group can be introduced without racemization and is selectively removed by mild acid hydrolysis without affecting the peptide linkage. Since the *N*-formyl group is stable toward basic hydrolysis, saponification of esters in amino acids can be achieved. Thus the peptide chain can be extended at the amino or carboxyl ends.

C-Formylations.

A few examples of *C*-formylation reactions have been reported in the literature. The first involves formylation of indole derivatives in the 3-position when this position is free.[28]

Aromatic Grignard reagents react with AFA to give good yields of aldehydes as the only carbonyl product formed without formation of alcohol.[6] However, aliphatic Grignard reagents and AFA lead to substantial amounts of methyl ketone and alcohol formation.

C-Formylation of diazomethane with AFA leads to ***Diazoacetaldehyde*** (eq 7).[8] Diazoacetaldehyde is a precursor of formylcarbene. It has also been used for ethanalation of alkenes.

(7)

Formyl Fluoride.

Anhydrous HF reacts with AFA to yield ***Formyl Fluoride*** in 68% yield. A small amount of acetyl fluoride was also formed.[7] Formyl fluoride is the only known stable halide of formic acid. It has been used in a Friedel-Crafts type reaction to produce aromatic aldehydes (eq 8).

Acetoacetic Acid[1]

[541-50-4] · $C_4H_6O_3$ · Acetoacetic Acid · (MW 102.09)

(acetone enolate equivalent in alkylations,[2] carbonyl additions,[3] conjugate additions,[4] and diazonium ion coupling reactions[5])

Alternate Name: 3-oxobutanoic acid.

Physical Data: mp 36-37 °C; pK_a 3.58; enol content: carbon tetrachloride (35 °C), 49%; DMSO-d_6 (35 °C), 10.8%; D_2O (0 °C), <2%.[6]

Solubility: sol H_2O, alcohol.

Preparative Methods: traditionally prepared by base hydrolysis of ***Ethyl Acetoacetate***.[3,7] A high yield synthesis by acid hydrolysis of ***Diketene*** is also reported.[6]

Handling, Storage, and Precautions: acetoacetic acid is extremely hygroscopic but can be stored under vacuum in a freezer for several weeks with little change. It decomposes rapidly to acetone and carbon dioxide when heated above the melting point. Use in a fume hood.

Functionalization of the active methylene group in acetoacetic acid by reaction with electrophiles and subsequent in situ decarboxylation provides a convenient one-step synthesis of α-substituted acetone derivatives.

Alkylations.

Dilithio acetoacetate can be generated from acetoacetic acid and ***n-Butyllithium*** at 0 °C and then alkylated to give an adduct which decarboxylates at room temperature to give α-alkylated acetone (eq 1).[2]

Addition and Condensation Reactions.

Acetoacetic acid reacts with aliphatic aldehydes in the presence of ***Pyridine*** to give α,β-unsaturated methyl ketones in good yields (eq 2).[3,8] Aromatic aldehydes are generally less reactive under these conditions and give mixtures of β-ketols and enones. Exclusive formation of β-ketol is observed when the phenyl ring bears a strong electron withdrawing substituent (eq 2).[3,8] Although ketones generally do not condense with acetoacetic acid, the corresponding enamine derivatives can be used as ketone equivalents and, in this case, the condensation proceeds without an added base.[9]

The addition of acetoacetic acid to an imine double bond and subsequent decarboxylation can be used in the preparation of α-acetonylated piperidine[10-12] and pyrrolidine derivatives (eq 3).[13] Base catalyzed 1,4-addition of acetoacetic acid to α,β-unsaturated ketones provides β-acetonyl ketones in good yield (eq 4).[14,15]

Diazonium Coupling Reactions.

Coupling of arenediazonium salts with acetoacetic acid provides a useful preparation of pyruvaldehyde monohydrazones (eq 5).[16-18] Symmetrical acetylformazan derivatives are produced via the coupling of two equivalents of diazonium salts.[19] Sequential treatment of acetoacetic acid with two different arenediazonium salts results in unsymmetrical acetylformazan derivatives.[20]

(5)

Related Reagents.

Acetone; ***Acetone Cyclohexylimine***; ***Acetone Hydrazone***; ***Ethyl Acetoacetate***; ***Ethyl 4-Chloroacetoacetate***; ***Ethyl Lithio(trimethylsilyl)acetate***; ***Ethyl 4-(Triphenylphosphoranylidene)acetoacetate***; ***Methyl Dilithioacetoacetate***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

(*S*)-Aceto(carbonyl)(cyclopentadienyl)-(triphenylphosphine)iron

[36548-60-4] · $C_{26}H_{23}FeO_2P$ · (*S*)-Aceto(carbonyl)(cyclopentadienyl)-(triphenylphosphine)iron · (MW 454.29)

(chiral acetate enolate equivalent which can be deprotonated with BuLi or LDA in THF at -78 °C; the enolate reacts stereoselectively with a variety of achiral, prochiral, and chiral electrophiles to generate functionalized organoiron compounds from which the iron can subsequently be removed[1])

Physical Data: mp 142 °C; $[\alpha]^{22}$ +288° (*c* 0.004, C_6H_6), $[\alpha]^{20}$ +160° (*c* 0.04, C_6H_6).

Solubility: insol H_2O; sol THF, $CHCl_3$, CH_2Cl_2, acetone.

Form Supplied in: orange solid.

Handling, Storage, and Precautions: can be stored in air for days with little decomposition. The solid is best stored under nitrogen for long periods of time. More air sensitive when in solution, especially chlorinated hydrocarbons. Like all metal carbonyls, it is best handled in a fume hood.

Preparation and Determination of Absolute Stereochemistry.

The preparation of racemic aceto(carbonyl)(cyclopentadienyl)(triphenylphosphine)iron (**2**) was first reported in 1966.[2] Brunner subsequently recognized that the iron atom in the complex was a chiral center and first reported the preparation of the (+)- and (-)-enantiomers in 1972.[3] Two groups[4,5] recognized in the early 1980s that the enolate of this compound might serve as a chiral acetate enolate equivalent. The absolute configuration of the (+)-enantiomer was reported in 1986[6a] and confirmed in 1988.[7] Alternative preparations of (*S*)-(+)-(**2**) involving kinetic reductions

were published in late 1993.[6b,c] The first reported preparation[3a] of (*S*)-(+)-(**2**) begins with treatment of $[CpFe(CO)_2(PPh_3)]^+PF_6^-$ with sodium mentholate to produce the menthol ester diastereomers which were separated by fractional crystalliza tion.[3b] The (-)-menthol ester (**1**) was then treated with MeLi (1.5 M in Et_2O) (slow addition of the MeLi produces acetyl (**2**) of the highest optical purity)[3c] in THF at -30 °C (eq 1). Aqueous workup and alumina chromatography produced the (*S*)-(+)-acetyl (**2**). A resolution procedure for the separation of the related trimethyl- and triethylphosphine substituted acetyls has also been reported.[8]

Enolate Generation and Subsequent Alkylation or Oxidation.

The (*S*)-(+)-acetyl complex (**2**) is cleanly deprotonated to the configurationally stable enolate anion (**3**) upon treatment with ***n-Butyllithium*** or ***Lithium Diisopropylamide*** in THF at -78 °C.[1] The enolate (**3**) is alkylated in an almost quantitative yield when treated with a variety of alkyl iodides (eq 2). Alkylation of (**3**) with (*R*)-chloromenthyl ether produced (**5**) which was used to establish the absolute stereochemistry of (**2**) (eq 3).[6,1f] Subsequent deprotonation of these alkylated products (**4**) is believed to produce (*E*)-enolates (**6**) which can be alkylated cleanly from the enolate face away from the triphenylphosphine ligand (eq 4).[1]

This sequential alkylation chemistry has been used to synthesize (-)-epicaptopril (**9**) (eq 5)[1b,9] as well as (*S*)-(+)-2-methylhept-4-ynoate (**10**), a key intermediate for the side chain of prostacyclin ZK96480 (eq 6).[10]

Related alkylation chemistry of (**2**) has provided a route to chiral succinic acid derivatives (**11**) (eq 7).[11] In this chemistry, acetyl complex (**2**) was used to produce a succinoyl complex which was subsequently deprotonated α to the ester and alkylated with primary and secondary alkyl halides. This sequence of reactions has been used to produce the succinate fragment of actinonin,[11a] as well as a variety of other succinic acid and amide derivatives.[11b,c]

α-Oxidation of the enolate (**3**) has also been reported. Deprotonation of (**4**) (R = Me) followed by treatment with ***Diphenyl Disulfide*** generated a thioether complex which was oxidized to the sulfoxide and used in an asymmetric synthesis of sulfoxides.[12] Enolate (**3**) has also been trapped with MoOPH (***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)***) and benzylated to produce the α-benzyloxyacetyl complex.[13] Enolate generation from the α-benzyloxyacetyl followed by alkylation with two equivalents of racemic 1-phenylethyl bromide provided almost exclusively the alkylation product derived from reaction with (*S*)-1-phenylethyl bromide. This sequence demonstrated the power of the $CpFe(CO)(PPh_3)R$ fragment as a chiral recognition element. Recently, treatment of (**3**) with ***Chlorodiphenylphosphine*** has been shown to produce chiral phosphine (**12**) which was subsequently used as a ligand in the preparation of several palladium complexes (eq 8).[14]

Aldol and Related Condensations.

The fact that the enolate of the racemic iron acetyl will participate in diastereoselective aldol condensations and that enolate counterions have a large effect on the diastereoselectivity of those reactions has been known for some time.[1] More recently, an alkylation/aldol sequence involving (**2**) was used to prepare complex (**13**) of known absolute configuration. Complex (**13**) was used to assign, by chemical correlation, the absolute configuration to a series of marine cyclic epoxides (eq 9).[15] Similar aldol chemistry followed by iron-carbon bond cleavage using ***Bromine*** has been used to prepare a series of optically active β-lactones (**15**)[16] including tetrahydrolipstatin (eq 10).[17]

Examples of aldol condensations involving chiral aldehydes have also been reported. Condensation of the aluminum enolate derived from (**2**) with Boc-L-prolinal has been shown to proceed in a highly stereoselective manner and the iron chirality overpowered the latent stereoselectivity inherent in Boc-L-prolinal.[18] Subsequent deprotection and demetalation of (**16**) produced (-)-(1*R*,8*S*)-1-hydroxypyrrolizidin-3-one (**17**) (eq 11). Aldol condensation between the tin(II) and aluminum enolates derived from (**2**) and 2,3-isopropylidene-D-glyceraldehyde also proceeded with high stereoselectivity and the iron once again had the overwhelming directing effect on the stereochemical outcome of these condensations (eq 12).[19]

(12)

Synthesis and Reaction Chemistry of α,β-Unsaturated Acyl Complexes Derived from (2).

Two methods for the preparation of optically active (*E*)- and (*Z*)-α,β-unsaturated iron acyls from (**2**) have been reported.[1f] One method involves aldol condensation of (**2**) with aldehydes followed by *O*-methylation to produce diastereomeric acyls (**18**). This mixture (**18**) is then treated with ***Sodium Hydride*** to produce predominantly (*E*)-α,β-unsaturated acyl complexes (**19**) (eq 13).[20] Alternatively, (**2**) can be deprotonated and treated with ***Chlorotrimethylsilane*** to produce the *C*-silylated complex which is subsequently deprotonated and treated with an aldehyde.[1f,21] This Peterson alkenation produced mixtures of the isomers (*E*)-(**19**) and (*Z*)-(**20**) which could be separated via chromatography (eq 14). The (*Z*) isomers (**20**) with γ-protons are deprotonated when treated with strong bases and selectively alkylated α to the carbonyl.[1f] The (*E*) isomers and (*Z*) isomers without γ protons participate in stereoselective Michael additions and Michael addition/alkylation sequences.[1f,20-22] Most often this chemistry has been used to prepare optically active β-lactams and amides (**21**) and (**22**) (eqs 15 and 16).

(13)

(14)

(15)

(16)

The (*E*)- and (*Z*)-α,β-unsaturated acyls (**19**) and (**20**) have also been methylenated as part of an asymmetric route to cyclopropanecarboxylic acid derivatives.[23] The acryloyl complex, which has been used in asymmetric Diels-Alder reactions[24] as well as a verapamil precursor synthesis,[25] has not been prepared in optically active form from (**2**), but can be prepared via an elimination reaction from (**5**).[24,25]

Acetone

[67-64-1] · C_3H_6O · Acetone · (MW 58.08)

(widely used solvent; versatile synthetic reagent)

Alternate Name: 2-propanone.

Physical Data: mp -94 °C; bp 56.5 °C; *d* 0.788 g cm^{-3}; fp -18 °C.

Solubility: sol water, alcohol; miscible with most organic solvents.

Form Supplied in: colorless liquid, widely available.

Handling, Storage, and Precautions: slightly toxic; central nervous system depressant; highly flammable liquid; vapors may form explosive mixtures with air; reacts vigorously with strong oxidizing and reducing agents.

Protection of Diols.

Both 1,2- and 1,3-diols can be protected as acetonides by reaction with acetone (eq 1).[1] Acetonides are resistant to basic and nucleophilic reagents, and can be readily cleaved by aqueous acid.

(1)

Ketene Formation.

Ketene can be prepared by distillation of acetone through a combustion tube packed with pieces of heated porcelain.[2] An improved method of ketene formation from acetone utilized a ketene lamp, which afforded an 80-90% yield of ketene from acetone.[3] Another method, which utilized a pyrolyzing coil, has been reported.[4]

Photochemical Alkylation.

Cyclic ethers undergo an acetone-initiated photochemical addition to terminal alkenes (eq 2).[5] The reaction can be photochemically induced without ketone initiation; however, the ketone-initiated reactions are faster and higher yields are obtained. The photosensitized amidation of aromatic substrates in acetone has been reported.[6]

(2)

Oxidations.

Acetone is widely utilized as a solvent for the oxidation of trimethylsilyl ethers to ketones,[7] alcohols to ketones,[8] alcohols to acids,[9] alkynes to diones,[10] aldehydes to acids,[11] and alkynic carbinols to alkynic ketones.[8]

Solvent for the Formation of Alkyl Iodides.

Alkyl iodides can be prepared from chlorides and bromides by utilizing ***Sodium Iodide*** in acetone. The reaction (sometimes called the Finkelstein reaction) is an equilibrium which is driven by the precipitation of sodium chloride or sodium bromide.[12] This methodology has also been utilized to synthesize alkyl halides from sulfonates,[13] phosphinates,[14] and selenonates.[15]

Regeneration of Ketones.

Acetone undergoes an exchange reaction with tosylhydrazones to regenerate ketones in high yields (eq 3).[16] This mild method has been applied to the regeneration of ketones from oximes,[17] arylhydrazones,[17] and thiazolidines.[18]

(3)

Related Reagents.

2,2-Dimethoxypropane; ***2-Methoxypropene***.

Acetone Cyanohydrin

[75-86-5] · C_4H_7NO · Acetone Cyanohydrin · (MW 85.11)

(hydrogen cyanide source easier to handle and less toxic than HCN; transhydrocyanation; epoxide cleavage; formylation of arenes)

Physical Data: mp -19 °C; bp 82 °C/23 mmHg; bp 95 °C/760 mmHg; *d* 0.932 g cm^{-3}; *n*20D = 1.3992; fp 63 °C.

Solubility: freely sol water, usual organic solvents; insol petroleum ether, carbon disulfide.

Form Supplied in: light yellow liquid; widely available.

Analysis of Reagent Purity: IR: 3480 (s, OH); 2420 (w, CN); ^{1}H NMR: 1.65 (s, 6*H*); 3.68 (br, 1*H*).

Handling, Storage, and Precautions: use in a fume hood. Highly toxic and harmful liquid. May be fatal if inhaled, swallowed, or absorbed through skin (toxicity data: oral (rat) LD_{50} 0.17 g kg^{-1}; skin (rabbit) LD_{50} 17 mg kg^{-1}). Causes severe irritation, while high concentrations are extremely destructive to tissues of mucous membranes and upper respiratory tract, eyes, and skin. Symptoms of exposure may include burning sensation, coughing, wheezing, laryngitis, shortness of breath, headache, or even cyanosis. Keep tightly closed and away from heat and open flame. Store in cool and dry place; combustible. Incompatible with strong acids, strong bases, strong oxidizing agents, and strong reducing agents. Thermal decomposition may produce hydrogen cyanide, carbon monoxide, and carbon dioxide.

Transhydrocyanation (Cyanohydrin Formation).

Acetone cyanohydrin has long been known to interchange HCN with aldehydes or ketones to form their corresponding cyanohydrins.[1] The reaction is catalyzed by bases and the cyanohydrin product is subject to rapid racemization due to the reversible nature of the reaction.[2] However, subsequent acetylation of the cyanohydrin product with ***Isopropenyl Acetate*** acetate using a lipase from *Pseudomonas cepacia* (Amano) as catalyst furnishes preferentially the (*S*)-isomer (eq 1),[3] while the unreacted (*R*)-isomer is continuously racemized through reversible transhydrocyanation.

(1)

(*R*)-Cyanohydrins are obtained in high enantiomeric purity by a one-step biocatalyzed reaction of aromatic or aliphatic aldehydes with acetone cyanohydrin. In this case the use of powered almond meal provides an inexpensive catalyst which eliminates the need to purify and immobilize the enzyme, leading to products with high enantiomeric purity (eq 2).[4] Similar products are obtained using the flavoprotein D-oxynitrilase (EC 4.1.2.10) as catalyst.[5]

(2)

Cyanohydrins of steroid ketones are prepared by HCN exchange with acetone cyanohydrin without the presence of a catalyst, since the product precipitates from solution. Thus the 17-monocyanohydrins of steroidal 3,17-diones are prepared in practically quantitative yield (eq 3).[6] Similarly, α-silyloxynitriles are prepared from *O*-trimethylsilylated acetone cyanohydrin by transcyanosilylation[7] in the presence of ***Potassium Cyanide*** and ***18-Crown-6***.

Hydrogen Cyanide Addition.

Acetone cyanohydrin is used as a ***Hydrogen Cyanide*** source which is easier to handle and less toxic than HCN.[1,8] Thus the Michael addition of HCN to α,β-unsaturated ketones is achieved by an exchange with acetone cyanohydrin in 10% aq Na_2CO_3. This reaction is found to proceed in excellent yield with chalcones[9] or steroid ketones.[10] Similar addition with high stereoselectivity using acetone cyanohydrin in conjunction with naked cyanide ions (KCN in nonpolar aprotic solvent containing 18-crown-6) has also been reported (eq 4).[11] On the other hand, addition of HCN to aldimines using acetone cyanohydrin furnishes α-aminonitriles (eq 5).[12]

(5)

Ring Opening.

Acetone cyanohydrin with stoichiometric ***Triethylamine*** opens 1,2-epoxides regiospecifically to give β-hydroxynitriles. The addition of cyanide occurs at the least substituted carbon (eq 6).[13] The same conditions are applied for the cyclopropane ring opening of methyl 2-oxobicyclo[3.1.0]hexane-1-carboxylate in almost quantitative yields.[14]

(6)

Aromatic Formylation.

Acetone cyanohydrin has been proposed as an easy-to-handle formylation reagent for arenes, thus replacing the hazardous hydrogen cyanide in the Gatterman reaction (eq 7).[15]

(7)

Acetone Cyanohydrin Nitrate.

Caution: moderately explosive, bp 65-66 °C/10 mmHg. Prepared by nitration of acetone cyanohydrin with fuming ***Nitric Acid*** and ***Acetic Anhydride*** (eq 8),[16] this reagent is unique for the conversion of amines to nitramines under alkaline conditions. Thus primary nitramines are obtained in 50-60% yield, while aliphatic and alicyclic secondary nitramines are produced in yields varying from 55-80% (eq 8).[17] The reagent is also useful for the nitration of a variety of active methylene compounds (in the form of their sodio derivatives), providing a general route for the

synthesis of α-nitro esters (eq 9).[18]

Related Reagents.

t-Butyldimethylsilyl Cyanide; ***Cyanotrimethylsilane***; ***Diethylaluminum Cyanide***; ***Hydrogen Cyanide***; ***Potassium Cyanide***; ***Sodium Cyanide***; ***Tetraethylammonium Cyanide***; ***Zinc Cyanide***.

Acetone Cyclohexylimine

[6407-36-9] · $C_9H_{17}N$ · Acetone Cyclohexylimine · (MW 139.24)

(acetonyl equivalent via lithiation and reaction with electrophiles;[1] mild directed aldol condensation;[2] Pd-catalyzed α-arylation of ketones[3])

Alternate Name: N-(2-propylidene)cyclohexylamine.

Physical Data: bp 180.6 °C,[4] 70-72 °C/16 mmHg,[5] 30 °C/1.8 mmHg;[6] *n*20D 1.4671.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: GC; ^{1}H NMR; IR (presence of ketone by hydrolysis).

Preparative Methods: condensation of ***Acetone*** with cyclohexylamine with or without various solvents (eq 1).[4-7] The removal of water is performed afterwards with solid ***Sodium Hydroxide***.[4]

Handling, Storage, and Precautions: very sensitive to hydrolysis; storage in closed vessels under inert atmosphere in the refrigerator. It is recommended to prepare the reagent freshly before each preparation. After some weeks of storage, purification by distillation is recommended. Use in a fume hood.

Introduction.

Acetone cyclohexylimine is the most frequently used acetone imine. Some attention will be given to the *N*-isopropyl analog, while lower alkyl derivatives, e.g. acetone methylimine, are too labile for general use.

Introduction of Acetonyl Group.

In general, most enolates have to be kept and reacted at -78 °C or lower in order to obtain useful results, as otherwise self-condensation reactions and nonselective reactions take place. This disadvantage can be circumvented by working with imines instead of ketones.[2,8] Imines derived from acetone and methylamine or ethylamine are difficult to handle, while the relatively stable *N*-cyclohexylimine derived from acetone offers no problems in handling.[2] One inconvenience is certainly the more complex NMR spectra of the reaction products. Since the desired end-products are usually carbonyl compounds, formed by acidic hydrolysis of these imines, the *N*-cyclohexyl group is only a temporary disadvantage. The most common use of acetone cyclohexylimine is their conversion into their nucleophilic lithiated salts, i.e. 1-azaallylic anions (metalloenamines), which are much more stable than enolates and which do not suffer from proton transfer during further reactions with electrophiles. Acetone cyclohexylimine is readily deprotonated by ***Lithium Diethylamide*** (mostly in benzene-HMPA),[1] ***Lithium Diisopropylamide*** (in ether or THF),[2] or ***n-Butyllithium*** (in THF) (eq 2).[9] Less frequently used deprotonating agents are ***Potassium-Graphite***[10] or ***Potassium on Alumina***.[11]

(2)

The deprotonation is usually followed by the reaction with an electrophile (E^+), affording the α-substituted ketimine (eq 2). Lithiation of imines has *syn* selectivity (eq 3; the formula represents a gross structure, not indicating the definitive position of the Li counterion).[12,13]

(3)

Lithiated acetone cyclohexylimine reacts smoothly with alkyl and allyl halides to form the α-alkylated or α-allylated imines, which are readily hydrolyzed by aqueous acid to afford the corresponding acetonylated compounds (eq 4).[1] Higher analogs, e.g. 2-butanone *N*-cyclohexylimine, after deprotonation, react regiospecifically with electrophiles at the methyl group.[1] Double alkylations of acetone cyclohexylimine at the α- and α´-position and subsequent hydrolysis into α,α´-dialkylated acetones have been reported (eq 5).[1] In a similar way, o-halo ketones (eq 6),[1,14] γ,δ-unsaturated-γ-halo ketones (eq 7),[1a] 1,4-diones (eq 7),[1a] γ,δ-unsaturated-δ-halo ketones,[1b] and 1,5-diones[1b] are accessible.

(4)

R = *n*-C_8H_{17} (X = Cl); R = *n*-C_7H_{15} (X = Br)
R = $Me_2CHCH_2CH_2$ (X = Br); R = CH_2CH_2Ph (X = Br)
R = $CH_2{=}C(Me)CH_2$ (X = Cl); R = $CH_2{=}CHCH_2$ (X = Br)
R = $MeCH{=}CHCH_2$ (X = Br)

(5)

R = Me, *n*-Bu, *n*-C_7H_{15}

1-Azaallylic anions have been utilized for the synthesis of dihydrojasmone (eq 8),[1a,29] geranylacetone,[15] *cis*-jasmone,[29] and other functionalized 2-alkanones.[16] Similar α-alkylations have been performed with aldimines.[17-19]

The use of potassium-graphite (C_8K) in THF[10] or highly dispersed potassium on alumina in THF[11] at room temperature is an alternative method for the lithiation of acetone cyclohexylimine, but the alkylated acetones are obtained in moderate to low yields (eqs 9 and 10). Better yields of acetonylation products are obtained by lithiation of acetone *N*-isopropylamine with ***Lithium*** in THF in the presence of graphite[30] or phenanthrene[31] as hydrogen acceptor, followed by reaction of the lithio salt with electrophiles, e.g. iodobutane, to afford α-monoalkylated acetones after acidic hydrolysis.

(9)

(10)

Directed Aldol Condensation.

Lithiated acetone cyclohexylimine reacts with benzophenone to afford the corresponding isolable β-hydroxy ketimine, which undergoes hydrolysis and dehydration on treatment with aqueous sulfuric acid, while the ketol is obtained under milder hydrolytic conditions using silica gel and water (eq 11).[20] Similar condensations of lithiated acetone cyclohexylimine with benzonitrile or ethyl chloroformate afforded a β-amino-α,β-unsaturated imine[21] or an enamino ester,[2] respectively (eqs 12 and 13).

(11)

(12)

(13)

Palladium-Catalyzed Arylation.

Condensation of acetone cyclohexylimine with bromobenzene in the presence of sodium *t*-butoxide, ***Palladium(II) Acetylacetonate***, and tris(*N*-cyclohexyl-*N*-methylamino)phosphine in THF is reported to afford phenylacetone after hydrolysis (eq 14).[3]

Reactions of 1-Azaallyl Anions with Michael Acceptors.

Lithiated acetone cyclohexylimine reacts with α-methylthiovinyl sulfoxides to give the Michael adducts, which are suitable precursors for γ-keto aldehydes (eq 15).[22]

Lithiation of acetone cyclohexylimine and further treatment with ***Copper(I) Iodide*** produces a copper azaallyl species which undergoes Michael addition to 2-methyl-2-cyclopentenone, the resulting adduct being trapped by ***Chlorotrimethylsilane*** (eq 16).[9] However, it has been reported that lithiated acetone cyclohexylimine condensed with 2,6,6-trimethyl-2-cyclohexenone to give the 1,2-adduct (eq 17).[23] Lithiated acetone cyclohexylamine gives a 9,10-adduct with acridine (eq 18).[21]

(16)

(17)

(18)

Lithiated acetone isopropylimine adds to the double bond of α-(*N*-methyl-*N*-phenylamino)acrylonitrile to give the Michael adduct, which is alkylated and ring closed to afford 2,5-dimethyl-1-isopropylpyrrole (eq 19).[38]

The reaction of acetone cyclohexylamine with ***Methyl Acrylate*** without added base has been investigated in detail. Several reactions take place depending on the concentrations; in particular, *C*-alkylation but no *N*-alkylation products are observed (eq 20).[24] The lack of *N*-alkylation contradicts a previous report which stated that only *N*-alkylation took place.[25,26]

Δ, 14.5 h, conc. 0.8M	49%	14%	20%
neat, rt, 13 d	40%	52%	68%
neat, rt, 2 months (2 equiv acrylate)	4%	86%	8%

Direct condensation of excess acetone *N*-isopropylimine with ***Methyl Vinyl Ketone*** is a suitable method for the synthesis of 3-methyl-2-cyclohexenone via subsequent Michael addition, intramolecular aldol condensation, and hydrolysis (eq 21).[32]

(21)

Miscellaneous.

Oxidation of acetone cyclohexylimine with ***m-Chloroperbenzoic Acid*** gives 2-cyclohexyl-3,3-dimethyloxaziridine (eq 22),[6] while the condensation with pyridinium iodides in DMSO affords indoles.[27] Complete exchange of all six α-hydrogens of acetone cyclohexylimine has been accomplished through photolysis (125 W mercury lamp) in acetone-d_6.[28] Acetone *N*-isopropylimine reacts with nitroso-arenes through an ene reaction to form nitrones via intermediate hydroxylamines and aminyl oxides.[33] Carbonyl diisocyanate condenses with acetone *N*-isopropylimine in ether to give the labile [1,3,5]triazino[2,1-*b*]-1,3,5-oxadiazine-4,8-dione, which is hydrolyzed into hexahydro-*N*,3-diisopropyl-2,2-dimethyl-4,6-dioxo-1,3,5-triazine-1-carboxamide (eq 23).[34]

(22)

Heating acetone *N*-isopropylimine with ***Triethylborane*** at 100 °C for 7 days produced diethyl-substituted vinylaminoboranes (eq 24).[35]

The Ni-ligand catalyzed reaction of acetone *N*-isopropylimine with 1,3-butadiene generated unsaturated amines (eq 25).[36,37]

Lithiated acetone cyclohexylamine condenses with chloro- or ***Bromoacetone*** to afford 1-cyclohexyl-2,4-dimethylpyrrole (eq 26).[39] The same imine is converted into 1-cyclohexyl-3,3-dimethyldiaziridine by reaction with ***Chloramine*** (eq 27).[5]

(26)

(27)

Related Reagents.

Acetaldehyde N-t-Butylimine; ***Acetone Hydrazone***; ***Diketene***; ***N,N-Dimethylhydrazine***; ***Ethyl Acetoacetate***; ***2-Methoxypropene***; ***Methyl Dilithioacetoacetate***; ***Propionaldehyde t-Butylimine***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

Acetone Hydrazone[1]

(**1**; $R^1 = R^2 = H$)

[5281-20-9] · $C_3H_8N_2$ · Acetone Hydrazone · (MW 72.11) (**2**; $R^1 = H$, $R^2 = Ph$)

[103-02-6] · $C_9H_{12}N_2$ · Acetone Phenylhydrazone · (MW 148.21) (**3**; $R^1 = R^2 = Me$)

[13483-31-3] · $C_5H_{12}N_2$ · Acetone Dimethylhydrazone · (MW 100.17)

(metalated dimethylhydrazones as anion equivalents are especially useful for regioselective alkylations[1,2] and as precursors of unsymmetrical ketone hydrazones;[1,3] *gem*-dimethyl synthons in cycloaddition reactions[4])

Physical Data: (**1**) *n*22D 1.4607, colorless liquid, bp 124-125 °C; (**2**) mp 42 °C, rhombic crystals, bp 163 °C/50 mm Hg; (**3**) light yellow liquid, bp 94-95.5 °C (92-94 °C[5]).

Solubility: sol alcohol, ether, THF, CH_2Cl_2.

Analysis of Reagent Purity: (**1**) nitrogen evolution upon treatment with glacial acetic acid; acetone azine is a common impurity; (**2, 3**) IR or NMR spectroscopy.

Preparative Methods: (**1**) is best prepared by either of two methods: from the acetone azine[7] or by an exchange reaction between ***Hydrazine*** and (**3**) in the presence of glacial acetic acid.[6,8] Both methods give nearly quantitative yields of (**1**), but the latter method produces hydrazone without azine contamination. The general method for the preparation of phenylhydrazones can be applied to the synthesis of (**2**).[1a,9] Equimolar amounts of ***Acetone*** and ***Phenylhydrazine*** are refluxed gently in aqueous ethanol with catalytic amounts of glacial acetic acid. The phenylhydrazone separates out upon cooling and can be recrystallized from aqueous ethanol. The synthesis of (**2**) by reaction of acetone, ammonia, and aniline in the presence of water has also been reported.[9b] The dimethylhydrazone can be prepared in very high yield by a general procedure for ketones using anhydrous ***N,N-Dimethylhydrazine***.[6,8] Hydrazines should be handled with care because of their toxicity. *Caution*! Anhydrous hydrazine is also highly reactive with oxidizing agents; the syntheses should be carried out behind a protective screen, in a fume hood.

Handling, Storage, and Precautions: (**1**) usually prepared just before use; unstable in the pure liquid state; disproportionates slowly to hydrazine and acetone azine at rt. Use in a fume hood. It is claimed that simple hydrazones can be stored indefinitely with minimal deterioration in the absence of moisture in the solid state at low temperature.[6] Azine formation is rapid in the presence of moisture. Regeneration of old samples is accomplished by heating the hydrazone at 100 °C for 12-16 h before distillation.[7] Hydrazones (**2**) and (**3**) are relatively stable and can be stored for long periods of time without deterioration.

Hydrazone Oxidations.

The reactions of ketone hydrazones depend largely on the degree and kind of substitution on the *N*-amino group. Hydrazone (**1**) ($R^1 = R^2 = H$) is most prone to oxidation. Oxidation of (**1**) in the presence of ***Mercury(II) Oxide*** or ***Silver(I) Oxide*** and KOH serves as the easiest route to ***2-Diazopropane***.[10] The latter undergoes 1,3-cycloaddition reactions with electrophilic C=C bonds to form substituted pyrazoles,[11] vinylic and epoxy quinones,[12] and pyrazolines.[13] With ***Diphenylacetylene*** a pyrazole is formed that can be subsequently photolyzed to a conjugated alkynylcyclopropane.[14] Thus (**1**), being a precursor of 2-diazopropane, serves as a potential source of *gem*-dimethyl groups in cycloaddition reactions.

Oxidative denitrogenation has also been accomplished by a variety of electrophilic reagents. With HgO/***Mercury(II) Acetate***, (**1**) forms an acetoxy adduct that yields 4-acetoxy-4-methylvaleronitrile upon reaction with ***Acrylonitrile***.[15] In general, simple ketone hydrazones react with excess ***Benzeneselenenyl Bromide*** in the presence of a hindered guanidine base to afford phenyl vinyl selenide[16] or with excess ***Iodine*** in triethylamine-THF to afford vinyl iodides.[17] 1-Alkenyl cobalt complexes are formed in the presence of a Co-dioxygen complex. Subsequent reduction by ***Sodium Borohydride*** produces propene from (**1**) and *cis* alkenes from higher aliphatic ketone hydrazones.[18]

Phenylhydrazone (**2**) couples to form a C-N dimer as the oxidation product when treated with ***Potassium Permanganate*** in acetone. Upon heating, the dimer gives a vicinal bis(azo)alkane (eq 1).[19]

(1)

Oxidation of (**3**) generally leads to C=N bond cleavage and has been utilized most successfully to regenerate acetone and other ketones from their dialkylhydrazones. Oxidizing agents that are commonly used for this purpose include ***Ozone*** at low temperature,[20a] ***Sodium Perborate***, ***Sodium Periodate***, and H_5IO_6.[20] With ***Selenium(IV) Oxide***, however, oxidation leads to α-carbonylation in high yield.[21]

Heterocycles.

1,3-Dipolar cycloaddition reactions involving hydrazones offer a very versatile means of synthesizing five-membered heterocyclic rings. Cycloadditions between (**1**) and nitrile oxides form oxadiazolines in modest yields.[22]

Cyclocondensation of benzoylhydrazinoacrylate from (**1**) affords aminoquinolonecarboxylates.[23] An alternative to the Piloty-Robinson pyrrole synthesis has been used by Baldwin[24] to prepare pyrroles from any enolizable aldehyde or ketone via azines synthesized from the corresponding hydrazones. The reaction is shown for (**1**) (eq 2).

The Fischer indole synthesis provides an efficient route for the synthesis of indoles and related compounds from phenylhydrazones. Heating (**2**) in the presence of ***Zinc Chloride***, ***Formic Acid***/H_2SO_4, formic acid/HCl, or modified alumina catalysts provides 2-methylindole in modest to high yields. Indole formation is favored when anhydrous acid catalysts are used at high temperature to promote formation of the ene-hydrazine intermediate (eq 3).[25,26] In addition, β-lactams[27] and triazolinones[28] have also been synthesized from (**2**). Some cyclic diaza compounds containing other heteroatoms have been prepared from phenylhydrazones. Cycloaddition with thiocyanates or ***Carbon Disulfide*** leads to the formation of substituted thiadiazolidines (eq 4).[29] Treating (**2**) with ***Phosphorus(III) Chloride*** or $AsCl_3$ results in the formation of diazaphosphole and diazaarsole in modest yields (eq 5).[30]

(4)

(5)

With (**3**) and other ketone dimethylhydrazones, formation of heterocycles occurs via annulation reactions of their condensation or alkylation products. The strategy involves either a Michael-type addition or 1,2-addition of the azaallyl anion of (**3**) to carbonyl compounds or esters followed by a ring closure step to afford dihydropyridines[31] and substituted pyridines.[32] 1-Pyrrolines have also been prepared in good yield by alkylation of the anion of (**3**) with o-iodo azide followed by treatment with ***Triphenylphosphine*** (eq 6).[33]

(6)

Metalation and Anion Formation.

Hydrazones react with strong bases to deprotonate the amide NH as well as the α-carbon. Deprotonation usually occurs on the less substituted α-position. The anions thus formed are not isolated, but are used immediately in synthesis. *N*-Deprotonation proceeds smoothly and almost exclusively with equimolar amounts of NaH,[29,34,35] $NaNH_2$ or KNH_2 in liquid ammonia,[36] LDA at 0 °C, KDA, *n*-BuLi, or *t*-BuLi at -78 °C.[37-39] Anions generated by hydride deprotonations of (**2**) have been used in *N*-alkylation reactions with alkyl halides[34] and in a cycloaddition reaction with phenyl isothiocyanate (eq 4).[29] Alternatively, equilibrium deprotonations using 50% aqueous NaOH with a phase-transfer catalyst or NaOH in DMF may be used to generate the azaanion in the presence of alkyl halides.[34,40] The lithium anion of (**2**) can undergo *N*-sulfonation and is also used in the synthesis of siladiazacyclopentenes (eq 7).[41,42]

Carbanions from (**3**) and *N*-deprotonated (**1**) and (**2**) are most commonly generated by reaction with an alkyllithium reagent at -78 °C or LDA at 0 °C using THF or THF/HMPA as solvents. KDA can also be used and has been preferred by some workers due to a more rapid reaction rate and a wider range of hydrazone substrates.[39] The azaallyl lithium and potassium reagents thus generated have limited thermal stability due to side reactions arising from addition to the sp^2 carbon.[43] Transmetalation of the azaallyl lithium anion of (**3**) with either CuI-Me_2S[39,44] or CuI-*i*-Pr_2S[38] provides a route to the formation of the corresponding homocuprate derivative. The mixed cuprate is obtained if Cu^I thiophenoxide is used.[38b]

Alkylations.

Dimethylhydrazone (**3**) serves as a presursor of unsymmetrical ketone hydrazones via α-alkylation reactions involving allyl and alkyl halides, dihalides, tosylates, and epoxides. Compounds (**4**)-(**10**) are examples of compounds prepared from (**3**) and the appropriate alkylating agent. Most of the alkylation products serve as intermediates in the asymmetric synthesis of a wide variety of natural products, e.g. exogonol,[45] rutamycin antibiotics,[46] insect pheromones,[5a,47] lycopodium alkaloids,[48] homotropanes,[49] pyrenophorin,[50] zingeron,[51] and the jasmonoids.[52] The use of (**3**) is preferred over acetone in these reactions because the latter tends to undergo self-aldol condensation in the presence of base rather than *C*-alkylation. Alkylation occurs at the less substituted carbon of unsymmetrical derivatives of (**3**)[36] unless there is an anion stabilizing group present. A study by Rapoport showed a 50:1 preference for the monoalkylation product.[49a] Other functional groups are not usually affected during alkylation or carbonyl regeneration. However, partial debenzylation or hydrolysis of the THP ether upon prolonged heating has been observed in Cu-catalyzed hydrolysis.[49]

(5) 97%

(6) 74%

(7) 63%

(8) 56%

(9) 93%

(10)

Alkylation also provides a method for synthesis of isotopically labeled hydrazones.[53] Use of allyl bromide and 4-bromo-1-butene furnishes unsaturated dimethylhydrazones that can be cleaved by ozonolysis to produce 1,4- and 1,5-keto aldehydes in good yields. These compounds are used in annulation reactions to produce medium-sized rings.[54]

Condensation Reactions.

Anions of (**1**) may undergo condensation reactions with carbonyl compounds and nitriles. Aldol-type condensations using trianions of simple hydrazones have been reported.[19] The monolithium salt of (**1**) adds to acetonitrile and *t*-butyl chloride to yield an amidrazone which can then be cyclized to a triazoline (eq 8).[55]

(8)

Phenylhydrazone (**2**) adds to acetyl isocyanate to give aryl-substituted triazolinones upon elimination of acetone (eq 9).[54] The azaallyl lithium reagent from (**3**) undergoes aldol-like reactions with carbonyl compounds to give high yields of β-hydroxyhydrazones. The strategy described by Corey and Enders[37] entails generation of the anion by BuLi, addition of the aldehyde or ketone to yield the β-hydroxy hydrazone, and oxidative cleavage using $NaIO_4$ in methanol at pH 7 to regenerate the carbonyl compound. This approach has been applied to the synthesis of compounds (**11**)-(**15**) (yields are shown). Periodate does not affect the β-hydroxy groups in these compounds. Ester hydrazone (**18**) was used as an intermediate in the synthesis of α-pyrones (2*H*-pyran-2-ones).[56]

(15) 80%

A stereoselective aldol-type synthesis of (+)-*S*-[6]-gingerol (60% ee) was achieved via a chiral α-sulfinylhydrazone from an unsymmetrical ketone hydrazone derived from (**3**) (eq 10).[57,58] This synthesis complements Ender's synthesis of (-)-*R*-[6]-gingerol (36% ee) via SAMP-hydrazone.[51]

(10)

In the presence of α,β-unsaturated ketones, mixed and homocuprates of (**3**) undergo conjugate addition to form 1,5-ketohydrazones (**16**)-(**18**).[37,38] Heathcock used the homocuprate to prepare a synthesis intermediate of lycopodine. However, Sakurai's method using methallyltrimethylsilane provided higher yields (90%) of the same compound.[47]

(16)

(17)

(18)

An alternative route to β-keto hydrazones involves a Claisen-type condensation of (**3**) with *N*-methoxy-*N*-methylbenzamide (eq 11)[59a] and a variety of acylating agents.[59b] With carbon disulfide, lithium dimethylhydrazonoalkanedithioate is the initial product from which alkyl dithiolates can be prepared in good yields by reaction with various alkyl iodides.[60] The azaallyl potassium from (**3**) undergoes conjugate addition to vinyl sulfones. The adduct serves as an intermediate in annulation reactions for seven-membered rings.[61]

(11)

Removal of the hydrazone group is often one of the steps in these reactions. Bergbreiter[1c] gives a comprehensive list of oxidative and hydrolytic regeneration schemes for ketone and aldehyde hydrazones.

Other Reactions.

Wolf-Kishner reduction of (**1**) to propane occurs in the presence of strong alkali at high temperature. Hydrogenation of (**2**) using Pd/C catalyst affords isopropylamine.[62] Heating (**2**) in base results in its isomerization to methylphenyldiimide.[63] With difluoramine, *N*-fluoroketimine is produced in a vigorous reaction.[64] *N*-Acylation of (**3**) in the presence of various acid chlorides produces ene-hydrazides in high yields.[65]

Related Reagents.

Acetoacetic Acid; ***Acetone***; ***Acetone Cyclohexylimine***; ***2-Diazopropane***; ***N,N-Dimethylhydrazine***; ***Ethyl Acetoacetate***; ***Hydrazine***; ***Phenylhydrazine***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

Acetonitrile[1]

MeCN

[75-05-8] · C_2H_3N · Acetonitrile · (MW 41.05)

(solvent for inorganic and organometallic reagents; undergoes addition reactions to nitrile group; anion is nucleophilic reagent; Ritter reaction reagent; oxidizing agent in combination with H_2O_2)

Alternate Names: methyl cyanide; ethanenitrile; cyanomethane.

Physical Data: mp -45 °C; bp 81.6 °C; *d* 0.787 g cm^{-3} (20 °C).

Solubility: miscible with water and most organic solvents (but not petroleum); forms constant boiling mixture containing 16% water, bp 76 °C.

Form Supplied in: colorless liquid; widely available. *Drying:* fractional distillation from CaH_2 or P_2O_5.

Analysis of Reagent Purity: GLC; HPLC grade (99.9+% purity) commercially available.

Handling, Storage, and Precautions: flammable volatile liquid; keep dry; toxic vapor; mild lachrymator; possible skin irritant; evolves toxic fumes if heated to decomposition; incompatible with fuming HNO_3, N_2O_4/In, 2-cyano-2-propylnitrate, ClF/F_2, Cl_3HSi/diphenyl sulfoxide, metal perchlorates, $HClO_4$, fuming H_2SO_4, heat/conc. H_2SO_4, and *N*-fluoro compounds.[2]

Solvent Properties.

Acetonitrile is neutral, aprotic, polar (3.9 D) with a dielectric constant of 38 at 20 °C; it promotes ionic processes in solution. It is suitable for a wide range of physical organic techniques including HPLC, UV (λ > 190 nm), and electrochemistry.[3] However, its outstanding ability is to facilitate reaction between organic substrates and inorganic materials (eq 1).[4] These reagents include: Group 1 and 2 salts; Ag^{I}, Ce^{IV}, Cu^{I}, Cu^{II}, Fe^{III}, Hg^{II}, Mn^{IV}, Mn^{VII}, Pd^{II}, Rh^{III}, Ru^{IV}, Sn^{II}, Te^{IV}, and Tl^{III} salts; R_4N^+, ArN_2^+, $MeCO^+$, NO_2^+, and Ph_3RP^+ salts. In some cases, such as $CuCl_2.(MeCN)_2$ and $PdCl_2.(MeCN)_2$, the complexes involved are isolable.[5]

Reactions at Methyl.[6]

Deprotonation of acetonitrile using strong base affords the nitrile-stabilized anion,[7a] which can add to other nitrile molecules producing diacetonitrile[7b] or the trimer 4-amino-2,6-dimethylpyrimidine (eq 2).[7c] The dimerization process is the forerunner of the Thorpe-Ziegler synthesis of large ring systems.[8] Mixed β-enaminonitriles[9a] or diacetonitrile itself[9b] undergo condensation with carbonyl compounds, producing pyridine derivatives.

The anion performs conventional substitution reactions with alkyl halides and epoxides,[6] but ***Cyanomethylcopper*** is especially effective for cyanoalkylation of allylic halide reagents (eq 3).[10] Esters react with the monoanion yielding β-ketonitriles, which are readily converted by ***Boron Trifluoride*** or ***Polyphosphoric Acid*** into the corresponding β-ketoamides (eq 4).[11]

(3)

(4)

Aldol-type condensations with aldehydes and ketones produce the cyanomethyl alcohols[12a] or unsaturated nitriles (eq 5),[12b] depending on the chosen conditions. Acetonitrile anion results in exclusively 1,2-addition to conjugated enones in THF at -78 °C, in contrast to the behavior of other nitriles.[12c]

(5)

Addition Reactions.[13]

Acetonitrile yields acetophenone derivatives (eq 6) when reacted with phenols (or phenolic ethers) and Lewis acids (Hoesch reaction).[14] It reacts with alcohols in the presence of dry HCl to yield imidates (Pinner reaction)[15a] which can react with further alcohol to produce orthoacetate esters,[15b] or with amines to yield acetamidines (eq 7).[15c,d]

(6)

(7)

The Blaise reaction[16] of bromo esters with acetonitrile produces β-keto esters (eq 8) in a process analogous to the Reformatsky reaction. Acetonitrile reacts with ammonia and hydrogen sulfide to yield thioacetamide. Higher thioamides can be produced by reacting this with nitriles and distilling the lower boiling MeCN from the resulting equilibrium mixture.[17]

(8)

Acetonitrile also reacts with thiols to yield thioimidates,[15a] with amines to give acetamidines,[18] and with 1,2-amino alcohols to produce 2-oxazolines (eq 9).[19]

(9)

Ritter-Type Reactions.[20]

The acetonitrile nitrogen atom is an extremely weak nucleophile, but attacks carbenium ions to yield a nitrilium ion, which proceeds to an imidate and then undergoes hydrolysis to the amide (eq 10).[21] Since carbenium ions may be generated from a very wide range of functional groups under strongly acidic conditions, the Ritter reaction provides a facile one-flask route to *N*-alkylacetamides. As expected, the carbenium ions may participate in rearrangement or transannular reactions before undergoing substitution (eq 11).[22] Alternatively, the nitrilium ion may be generated via other electrophilic reagents[23] (eq 12),[24] and it can also undergo intramolecular closure to yield heterocyclic products (eq 13).[25]

Reactions with Hydrogen Peroxide and Base.

The Radziszewski reaction[26] describes the formation of amide products and dioxygen when nitriles are treated with ***Hydrogen Peroxide*** solution under basic conditions. Yields of aliphatic amides[27a] are 50-70%, while those of aromatic amides[27b] are typically 80-95%. This reaction proceeds via the intermediacy of the peroxyimidic acid (eq 14).[28] If an alkene functionality is present, then it is epoxidized with concomitant reduction of the peroxyimidic acid to the amide (the Payne oxidation)[29] in a simple one-flask process. A convenient procedure is to react the alkene and nitrile with H_2O_2 in methanol using potassium hydrogen carbonate as the base (pH ca. 8).[30a]

The Payne oxidation has the advantage that the oxidant is generated in situ, while the mildly basic conditions ensure that labile epoxides do not undergo acid-catalyzed degradation (eq 15)[30b] and competing Baeyer-Villiger oxidations may be suppressed (eq 16).[29c] In some cases the peroxycarboxylic acid and Payne processes may give differing outcomes,[31a] stereochemistry,[31b] or regioselectivity.[31c] While both benzonitrile and acetonitrile are commonly employed, the latter reagent has operational advantages. Its oxidation products are water soluble and easily removed during reaction workup, whereas the benzamide coproduct requires a more complex separation.

Acetonitrile *N*-Oxide[1]

[7063-95-8] · C_2H_3NO · Acetonitrile *N*-Oxide · (MW 57.05)

(reactive 1,3-dipolar reagent useful for [3 + 2] cycloadditions,[2] isoxazolines (intermediates useful for natural product synthesis),[3] isoxazoles,[4] heterocycle synthesis[5])

Physical Data: reactive intermediate generated in situ.

Solubility: sol petroleum ether, ether, benzene, dichloromethane, ethanol, chloroform; insol cold (-60 °C) petroleum ether.

Analysis of Reagent Purity: spectroscopic data have been recorded at low temperature:[6,7] NMR (-40 °C) ^1H: CH_3 (δ 2.26); ^{13}C: CH_3 (δ 0.8), CN (δ 35.6); IR (EtOH), 2315 cm^{-1}.

Preparative Methods: the reagent is most commonly generated in situ from ***Nitroethane*** by treatment with ***Phenyl Isocyanate***/***Triethylamine*** at rt (the Mukiayama method).[8] Other reagents (AcCl, Ac_2O, or $POCl_3$[9]) may be used in place of PhNCO. Acetonitrile oxide may be generated by flash vacuum pyrolysis (FVP) of 3,4-dimethylfuroxan,[6,10] by hypochlorite oxidation of acetaldehyde oxime,[4b] or from acetohydroxamoyl chloride.[7] Decomposition (mainly dimerization to 3,4-dimethylfuroxan) is reported[1b] to take place within minutes of generation at 18 °C (however, see Brandi[7]).

1,3-Dipolar Cycloaddition.

Isoxazolines from cycloaddition of acetonitrile oxide to alkenes (eqs 1 and 2)[11,12] are often used intermediates for synthesis of natural products.[3,13] For example, isoxazolines may be elaborated into α,β-unsaturated carbonyl compounds,[14] 1,3-amino alcohols,[15] 3-hydroxycarbonyl compounds[16] (and 2-alkylated or 2-hydroxylated derivatives),[17] and pyrroles.[18]

(1)

major

(2)

minor

The regioselectivity[2] and diastereoselectivity[12,19] of the cycloaddition of nitrile oxides to alkenes has been reviewed. Optically active isoxazolines are formed from acryloyl derivatives bearing bornyl,[8b] cyclitols,[20] or sultams[21] as chiral auxiliaries.

Alkynes produce isoxazoles (eqs 3 and 4),[4] whereas other unsaturated substrates yield a variety of heterocycles (e.g. thioesters -> 1,4,2-oxathiazolines,[5] imines -> 1,2,4-oxadiazolines,[22] and isothiocyanates -> imino-1,4,2-oxathiazoles[23]).

Acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate

[81549-07-7] · $C_{12}H_{17}NO_3S$ · Acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate · (MW 255.20)

(electrophilic aminating reagent for Grignard reagents[1])

Physical Data: mp 95-96.5 °C; *d* 1.12 g cm^{-3}.

Solubility: sol ether, THF; slightly sol benzene; insol hexane.

Preparative Method: ***Acetone*** reacts with ***Hydroxylamine*** hydrochloride in methanol-aq. NaOH solution to yield acetoxime,[2] which is also commercially available. Acetoxime reacts with 2,4,6-trimethylbenzenesulfonyl chloride in triethylamine-DMF to yield acetoxime *O*-(2,4,6-trimethylphenylsulfonyl)sulfonate.[3]

Electrophilic Amination.

The addition of organometallic reagents to oximes[4] has found limited applicability due to the low electrophilicity of oximes and the α-deprotonation requiring the use of a considerable excess of organometallic reagent (eq 1). There are various scattered reports of reactions of Grignard reagents and organolithiums with oximes that furnish amines, amino acids, aziridines, β-amino alcohols, and other products.[5] Ketoximes and their *O*-substituted derivatives can also serve as electrophilic aminating reagents for Grignard reagents and organolithiums (eq 2).[5] So far, acetoxime,[6,7] butanone oxime,[6] cyclohexanone oxime,[8] benzaldoxime,[9] isobutyrophenone oxime,[10] tetraphenylcyclopentadienone oxime *O*-tosylate,[11] and acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate[1] have been used for amination of Grignard reagents and organolithiums.

(1)

(2)

M = Li, MgBr

Acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate aminates aryl and cyclohexyl Grignard reagents in moderate to good yields (eq 3).[1] The use of ***Copper(I) Iodide*** or $MgCl_2$ as a catalyst in the amination of aryl Grignard reagents decreases the reaction time remarkably and/or increases the yield. On addition of 10 mol % of CuI or 20 mol % of $MgCl_2$ in the amination of phenylmagnesium bromide, the yield of aniline is 59% after heating at 75 °C for 22 h compared to 58% in an uncatalyzed reaction of 40 h at the same temperature. On the addition of 7 mol % of $MgCl_2$ in the amination of *p*-tolylmagnesium bromide, the yield of *p*-toluidine is 56% after heating at 75 °C for 23 h compared to 36% in an uncatalyzed reaction of 43 h at the same temperature. The use of phenyllithium, phenylzinc chloride, and bromomagnesium diphenylcuprate results in 6%, 0%, and 22% yields respectively.

(3)

When comparisons are made between the electrophilic aminating abilities of oximes reported so far, acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate is seen to be more effective than acetoxime, but less effective than ***Tetraphenylcyclopentadienone Oxime O-Tosylate***. However, the molar ratio of Grignard reagent to oxime that is needed has been reported to be 7:1 in in the amination with tetraphenylcyclopentadienone oxime *O*-tosylate compared to 1.5:1 in the amination with acetoxime *O*-(2,4,6-trimethylphenyl)sulfonate. The yield of aniline obtained by aminating phenylmagnesium bromide with acetoxime,[6,7] butanone oxime,[6] cyclohexanone oxime,[8] isobutyrophenone oxime,[10] and tetramethylphenylcyclopentadienone oxime *O*-tosylate[11] is 62%, 12%, 25%, 17%, and 95%, respectively.

2-Acetoxyacrylonitrile

[3061-65-2] · $C_5H_5NO_2$ · 2-Acetoxyacrylonitrile · (MW 111.10)

(ketene equivalent for use in the Diels-Alder reaction;[1] undergoes other cycloaddition reactions; reacts with nucleophiles and radicals)

Physical Data: bp 80-82 °C/30 mmHg; *d* 1.040 g cm^{-3}.

Solubility: sol most organic solvents other than pure hydrocarbons.

Form Supplied in: neat light-yellow liquid.

Analysis of Reagent Purity: ^{1}H NMR, ^{13}C NMR.

Preparative Methods: due to the expense of the commercial material it has been suggested[2] that for large scale use, preparation[3] is more reasonable.

Handling, Storage, and Precautions: highly toxic; use only in a fume hood. Reagent can be absorbed through the skin. Always wear gloves when handling this reagent.

[4 + 2] Cycloaddition Reactions.

Historically, 2-acetoxyacrylonitrile was the first ketene equivalent developed for the Diels-Alder reaction.[1] Thus the title compound reacts thermally with cyclopentadiene to yield the cycloadduct (**1**) which upon treatment with base produces norbornenone (**2**) (eq 1).[4] Since this first report, 2-acetoxyacrylonitrile and ***2-Chloroacrylonitrile*** have been the two most popular ketene equivalents used in the Diels-Alder reaction. Dienes which have been shown to react with 2-acetoxyacrylonitrile include substituted cyclopentadienes[5] and cyclohexadienes,[6] fulvenes,[7] cycloalkadienones,[8] polycyclic aromatics,[9] furans,[2,10b] isobenzofurans,[11] dihydropyridines,[12] vinylcycloalkenes,[13] and acyclic dienes.[14] In the case of furans the reaction is usually catalyzed by high pressure[2,10a,c] or Lewis acids.[10b] The reaction shown in eq 1 has been catalyzed with ***Lithium Perchlorate***.[15]

An early comparison between 2-chloro- and 2-acetoxyacrylonitrile indicated that the chloro derivative was slightly more reactive and more regioselective in its reaction with cyclohexadienes.[6a] However, 2-acetoxyacrylonitrile does offer some advantage in that the resulting cycloadduct can, at times, be more easily manipulated. For example, the furan adduct (**3**) was converted to the desired ketone (**5**) by treatment with base followed by exposure to formalin (eq 2).[2,10] The formalin is used to convert residual cyanohydrin (**4**) to the ketone.[10b] The corresponding adduct from 2-chloroacrylonitrile did not yield ketone (**5**) when treated with base. In an another example, adduct (**6**) was converted to ketone (**7**) as shown (eq 3).[13a] This two-step procedure[14b] diminished an unwanted isomerization of the double bond to the more stable α,β-unsaturated enone.[13b,c] Finally, in at least one instance the intermediate α-acetoxynitrile was reduced to a vicinal amino alcohol with ***Lithium Aluminum Hydride***.[6b]

(3)

The preparation of ketone (**5**) in optically pure form[10b,16] has been achieved by use of chiral α-carboxyacrylonitriles derived from camphanic acid[16a] as well as from tartaric acid.[16c] In general the facial selectivity exhibited in the cycloaddition is moderate and the obtention of one stereoisomer is dependent on selective recrystallization. Ketone (**5**) has been used extensively in chiral synthesis.[16c]

Other Reactions.

2-Acetoxyacrylonitrile undergoes both [2 + 3][17] and [2 + 2][18] cycloaddition reactions. Cyclopropanation of 2-acetoxyacrylonitrile with a variety of diazoalkanes represents a facile route to cyclopropanone cyanohydrins (eq 4).[17b] As is expected for an electron deficient alkene, 2-acetoxyacrylonitrile reacts with both nucleophiles[19] and radicals[20] in a conjugate-type addition.

1-Acetoxy-1,3-butadiene

[1515-76-0] · $C_6H_8O_2$ · 1-Acetoxy-1,3-butadiene · (MW 112.13)

(2π or 4π partner in cycloaddition reactions;[1] mono-oxygenation allows high levels of regiocontrol[2])

Alternate Name: 1,3-butadienyl acetate.

Physical Data: bp 60-61 °C/40 mmHg; *d* 0.945 g cm^{-3}.

Form Supplied in: colorless liquid, available as an unspecified mixture of (*E*) and (*Z*) isomers.[3]

Handling, Storage, and Precautions: classified as a flammable liquid and is reputed to be toxic. Compound polymerizes upon extended storage and can be regenerated by distillation. Avoid polymerization initiators. Diene performs best when stored in the cold.

Preparation.

1-Acetoxy-1,3-butadiene (**1**)[4] is commercially available as a mixture of (*E*) and (*Z*) isomers, and can be prepared by reaction of ***Crotonaldehyde*** with acetic anhydride-sodium acetate to provide the diene as an isomeric mixture in ~60% yield.[5a] Pure (*E*)-1-acetoxy-1,3-butadiene can be prepared in high yield by the slow addition of crotonaldehyde to refluxing ***Isopropenyl Acetate*** containing catalytic amounts of *p*-toluenesulfonic acid and copper acetate. After distillation to remove acetone and excess isopropenyl acetate, (*E*)-1-acetoxy-1,3-butadiene can be isolated by vacuum distillation in >80% yield.[5]

Reactivity.

1-Acetoxy-1,3-butadiene (**1**) is primarily used as a 4π partner in $[_{\pi}4_s + _{\pi}2_s]$ cycloaddition reactions of the normal electron demand type, and reacts well with electron-deficient dienophiles.[1] The presence of the weakly electron-donating 1-acetoxy substituent on this open-chain diene imparts a useful degree of regio- and stereoselectivity in cycloaddition reactions;[2] *ortho-endo* adducts predominate and often single isomers are obtained exclusively (eq 1).[6] This high *ortho* selectivity can be rationalized using frontier molecular orbital (FMO) theory.[7] Ab initio STO-3G calculations of energies and coefficients of the frontier molecular orbitals for the *s-cis* conformation of diene (**1**) have been reported.[8] The moderately electron-rich diene (**1**) has been found to be slightly more reactive toward polarized

dienophiles than simple dienes;[5a,9] however, the reported incompatibility of the diene with Lewis acids precludes most low-temperature Lewis acid-catalyzed reaction conditions and limits the general utility of diene (**1**).[8] Reactions employing an excess of a mixture of (*E*,*Z*)-1-acetoxy-1,3-butadiene can potentially yield single cycloadducts due to the increased reactivity of the (*E*) isomer compared to the (*Z*) isomer, thereby obviating the need for purification of individual diastereomers of (**1**).

(1)

Cycloaddition Reactions.

Reactions utilizing diene (**1**) and ***Acrolein*** or crotonaldehyde were reported to afford single cycloadducts in moderate to fair yield with good regioselectivity.[10] However, since that early report, the most frequent use of 1-acetoxy-1,3-butadiene in cycloaddition reactions involves coupling with naphthoquinone derivatives (eq 2). The importance of this reaction is twofold: (1) the cyclohexenyl acetate cycloadduct provides a useful framework upon which further modifications can be made; and (2) either regioisomeric cycloadduct can lead to aromatic products (either spontaneously or promoted) via 1,4-elimination of acetic acid followed by tautomerization to a dihydroquinone system. Employing these tactics, many naphthoquinone,[11] anthracycline,[6e,12] azaanthraquinone,[13] and tetracycline[14] derivatives have been efficiently constructed, and this general use as a butadienyl synthon constitutes a significant portion of the literature on diene (**1**).[6a,e,14,15]

4-Demethoxydaunomycinone (**2**)[12c] and (±)-terramycin (**3**)[14] are representative examples of natural products constructed employing a Diels-Alder strategy with diene (**1**).

Highly regioselective cycloaddition reactions have been realized between diene (**1**) and a wide variety of dienophiles, including substituted acrylonitrile derivatives,[16] haloquinones (eq 3),[17] substituted enones (eq 4),[8,18] naphthoquinone derivatives,[6e,14,19] nitroalkenes,[9] alkenyl sulfones,[19,20] alkenyl metal carbene complexes (eq 5),[21] substituted maleimides,[22] and several others.[23] Useful levels of diastereoselection have been achieved in several of these systems.[6c,18a,21,22,23c]

(3)

(4)

(5)

While these Diels-Alder reactions afford predominately the *ortho-endo* adducts, *ortho-exo* product formation predominates in cycloaddition reactions between diene (**1**) and bridgehead enones (eq 6)[24] or unsymmetrical tropones,[25] presumably due to repulsive secondary FMO interactions.[26]

(6)

Examples of successful Lewis acid-catalyzed cycloaddition reactions of diene (**1**) are limited. ***Boron Trifluoride***

Etherate-mediated cycloaddition between juglone and diene (**1**) afforded a single cycloadduct in 97% isolated yield,[11] whereas uncatalyzed versions of the same reaction afford <50% of the same adduct.[17a] Boron trifluoride etherate[27a] and ***Tin(IV) Chloride***[28] have also been used to enhance[27] or reverse[29] regioselectivity in cycloaddition reactions employing diene (**1**).

An example of an asymmetric Diels-Alder reaction involving diene (**1**) has been reported.[30] Use of a binaphthol-based borane catalyst in the reaction of juglone with diene (**1**) afforded a single adduct in good yield with >98% enantiomeric excess (eq 7).

1-Acetoxy-1,3-butadiene participates in other cycloaddition reactions as well. Assembly of an azetidinone system, a key substructure in the total synthesis of (±)-thienamycin, was accomplished by [2 + 2] cycloaddition of diene (**1**) and ***Chlorosulfonyl Isocyanate*** (eq 8).[31] Diene (**1**) has also been employed as the 2π partner in a 1,3-dipolar cycloaddition reaction.[32]

A highly *endo*-selective cycloaddition for the construction of bicyclo[4.4.1]undecane systems using a photochemical metal-mediated cycloaddition reaction between (η^6-cycloheptatriene)chromium tricarbonyl and diene (**1**) (eq 9) has been reported.[33] In an example of a thermal [6 + 4] cycloaddition reaction, diene (**1**) and unsymmetrical tropone

derivatives afforded predominately *exo* adducts in modest yields.[25b] This type of Diels-Alder strategy was utilized in the synthesis of [4](2,7)troponophane.[25c]

Miscellaneous Reactions.

Diene (**1**), formally a dienol acetate, undergoes anodic oxidation and regioselective γ-methoxylation, which provides a key intermediate in a method for 1,4-carbonyl transposition.[34] A palladium-assisted heteroannulation of diene (**1**) with organomercurials also has been reported (eq 10).[35]

2-Acetoxyisobutyryl Chloride

[40635-66-3] · $C_6H_9ClO_3$ · 2-Acetoxyisobutyryl Chloride · (MW 164.592)

(useful for converting *cis*-diols to *trans*-chloroacetates[1] followed by epoxide formation[2])

Alternate Name: Moffatt reagent.

Physical Data: bp 55-56 °C/6 mmHg; *d* 2.236 g cm^{-3}.

Form Supplied in: liquid of 95% purity commercially available.

Preparative Methods: can be prepared by the acylation of 2-hydroxyisobutyric acid (***Acetyl Chloride***, ***Acetic Acid***) followed by reaction with ***Thionyl Chloride***.[1,3]

Handling, Storage, and Precautions: corrosive and a lachrymator and should be handled accordingly.

2-Acetoxyisobutyryl chloride has been used to convert *cis*-diols to *trans*-chloroacetates (eq 1).[1] *trans*-Diols give many products due to their inability to form the cyclic acetoxonium ion intermediate. Nucleophilic attack occurs primarily at the acetoxy carbonyl group due to the bulky substituents α to the acid chloride carbonyl.

(1)

Ribonucleosides also react smoothly with 2-acetoxyisobutyryl chloride. In this case, a chloroacetate compound was obtained but with retention of configuration due to participation of the C-2 carbonyl group of the uracil ring (eq 2).[1,4]

(2)

Recently, the Moffatt reagent has been used in the total synthesis of complex natural products.[5] The chloroacetate compound is easily converted into an epoxide in excellent yield and on a large scale (eq 3).[2] 2-Acetoxyisobutyryl bromide has been employed similarly in natural product synthesis.[6]

3-Acetoxy-2-trimethylsilylmethyl-1-propene[1]

[72047-94-0] · $C_9H_{18}O_2Si$ · 3-Acetoxy-2-trimethylsilylmethyl-1-propene · (MW 186.33)

(precursor for palladium trimethylenemethane cycloaddition reactions)

Physical Data: bp 68-70 °C/6.5 mmHg;[2] 60-61 °C/2.5 mmHg.[3]

Solubility: sol most organic solvents.

Preparative Methods: commercially available but expensive. Several preparations of (**1**)[2-4] or the precursor alcohol (**2**)[5,6] have been reported. The simplest involves the direct silylation of methallyl alcohol (eq 1).[4,5]

Handling, Storage, and Precautions: volatile, irritant, flammable.

Introduction.

The development by Trost and co-workers of palladium-trimethylenemethane (TMM) cycloadditions employing the title reagent (**1**) and related reagents was a seminal advance in ring-construction methodology. The generality and versatility of these reactions is illustrated below by their use in [3 + 2] cycloadditions to form both cyclopentanes and heterocycles, [3 + 4] and [3 + 6] cycloadditions, and applications in total synthesis.

Methylenecyclopentanes.

Many lines of evidence indicate that in the presence of catalytic Pd^0, (**1**) forms the reactive intermediate palladium-TMM complex (**3**).[7-9] This complex appears to be zwitterionic in character, but its reactivity is governed mainly by its nucleophilicity/basicity. Thus the TMM reactions work best and almost exclusively with electron-deficient alkenes. It appears that in most cases the cycloaddition is stepwise, with the initial Michael-like reaction followed by nucleophilic attack on a cationic π-allylpalladium complex (eq 2). The ion-pair nature of the intermediate (**4**) is thought to be the source of some unusual stereochemical effects which give the reactions some of the characteristics of concerted cycloadditions.[10,11]

The corresponding methylenecyclopentanes are readily formed from a wide variety of activated alkenes, such as unsaturated esters, lactones, and nitriles, enones, vinyl sulfones, and nitroalkenes.[4] The breadth of utility of this reaction is exemplified below by its use as key steps in syntheses of albene (eq 3),[12] brefeldin A (eq 4),[13] hirsutene (eq 5),[14] the core spirocarbocyclic rings of the ginkgolides (eq 6),[15] cephalotaxine (eq 7),[16] and kempanes (eq 8).[17] The use of doubly activated alkenes, as in eq 8, is of particular advantage in the annulation of 2-cycloalkenones.[17b]

(5)

(6)

(7)

(8)

The adducts from vinyl sulfones are readily converted to cyclopentenones.[18] Vinyl sulfoxides are also acceptors for Pd-TMM cycloadditions. The use of optically pure vinyl sulfoxides allows for reasonable asymmetric induction (eq 9).[19] Outstanding asymmetric induction has been observed using chiral alkylideneoxazepadiones (eq 10).[20]

(9)

(10)

Methylenecyclopentenes.

Although Pd-TMM cycloadditions with alkynes are unsuccessful, the formation of methylenecyclopentenes from alkynes can be accomplished via the cyclopentadiene adduct (eq 11).[21]

(11)

Heterocycles.

Aldehydes can be converted to methylenetetrahydrofurans using tributyltin acetate or trimethyltin acetate as a cocatalyst (eq 12).[22] Most ketones are completely unreactive to Pd-TMM chemistry, but some oxacyclohexanones are readily annulated (eq 13), apparently due to activation of the carbonyl by the ring oxygen(s).[23] In reactions of α,β-unsaturated aldehydes and ketones, the competition between conjugate (alkene) and 1,2 (carbonyl) cycloadditions often favors reaction of the alkene. The cocatalyst ***Tris(acetylacetonato)indium*** can be used to favor the 1,2-cycloaddition.[24]

(12)

(13)

Methylenepyrrolidines can be formed in Pd-TMM reactions with imines (eq 14). These reactions have also been accomplished using nickel catalysts.[25]

(14)

[4 + 3], [6 + 3], and [3 + 3] Cycloadditions.

As suggested by the stepwise mechanism of eq 2, appropriately chosen dienes and trienes should undergo [4 + 3] and [6 + 3] cycloadditions in Pd-TMM reactions. Thus pyrones readily undergo [4 + 3] cycloadditions (eq 15),[26] and tropones undergo [6 + 3] cycloadditions (eq 16).[27] The main key to obtaining the higher order cycloadditions appears to be the use of all *s-cis* dienes and trienes.[28]

(15)

(16)

In a reaction that illustrates the nucleophilic character of the Pd-TMM intermediate (**3**), activated aziridines can undergo a [3 + 3] cycloaddition (eq 17),[29] presumably via initial nucleophilic ring opening of the aziridine by the Pd-TMM.

Acetyl Bromide

[506-96-7] · C_2H_3BrO · Acetyl Bromide · (MW 122.95)

(bromoacylation of carbonyl compounds;[1] selective *O*-acetylation;[3,4] addition to carbon-nitrogen double bond of unsubstituted cyclic imidates;[6] coupling with vinylcopper reagents;[7] hydrohalogenation of alkynes[8])

Physical Data: mp -96 °C; bp 75-77 °C; colorless liquid; *d* 1.663 g cm^{-3}.

Solubility: sol organic solvents; reacts violently with water, alcohols, and oxidizing agents.

Handling, Storage, and Precautions: corrosive and lachrymator; keep bottle tightly closed. Reacts violently with water. Store under nitrogen. Store in a cool dry place.

Bromoacylation.

The reaction of aldehydes and ketones with acetyl bromide to prepare α-bromoalkyl esters has been known in the literature since the early 1900s.[2] The low yields are a consequence of the fact that the reaction is an equilibrium and that the reactants can revert to starting materials if heated in the presence of the Lewis acid catalyst.[1] Yields are favorable in the case of aliphatic, α,β-unsaturated, and aromatic aldehydes and aliphatic ketones (eq 1). Highest yields are obtained at low temperatures (-10 °C).[1]

(1)

Addition of acetyl bromide to a solution of 5-methyluridine in acetonitrile heated at reflux gave the bromo ester in 97% yield (eq 2).[3]

Acetylation.

Hydroxy groups can be selectively acetylated in the presence of primary and secondary amino groups with acetyl bromide and ***Trifluoroacetic Acid***. Diacetylapomorphine (**1**) was obtained in 70% yield using this system.[4] Acetylation of apomorphine with ***Acetic Anhydride*** and base or acid afforded the ring-opened product (**2**).[5]

(1)

(2)

Miscellaneous Reactions.

Acetyl bromide reacts with unsubstituted cyclic imidates to yield ring-opened products (eq 3).[6] (*Z*)-Alkenyllithium cuprate reagents are very reactive towards acetyl bromide and give (*Z*)-α,β-enones in moderate yield (eq 4).[7] Terminal alkynes which usually undergo slow addition of HBr in solution afford bromides in good yield on treatment with acetyl bromide over alumina (eq 5).[8]

Related Reagents.

Acetyl Chloride; ***Acetic Anhydride***.

Acetyl Chloride[1]

[75-36-5] · C_2H_3ClO · Acetyl Chloride · (MW 78.50)

(useful for electrophilic acetylation of arenes,[2] alkenes,[2a,3] alkynes,[4] saturated alkanes,[3a,5] organometallics, and enolates (on C or O);[6] for cleavage of ethers;[7] for esterification of sterically unhindered[8] or acid-sensitive[9] alcohols; for generation of solutions of anhydrous hydrogen chloride in methanol;[10] as a dehydrating agent; as a solvent for organometallic reactions;[11] for deoxygenation of sulfoxides;[12] as a scavenger for chlorine[13] and bromine;[14] as a source of ketene; and for nucleophilic acetylation[15])

Physical Data: bp 51.8 °C;[1a] mp -112.9 °C;[1a] *d* 1.1051 g cm^{-3};[1a] refractive index 1.38976.[1b] IR (neat) ν 1806.7 cm^{-1};[16] ^1H NMR ($CDCl_3$) δ 2.66 ppm; ^{13}C NMR ($CDCl_3$) δ 33.69 ppm (q) and 170.26 ppm (s); the bond angles (determined by electron diffraction[17]) are 127.5° (O-C-C), 120.3° (O-C-Cl), and 112.2° (Cl-C-C).

Analysis of Reagent Purity: a GC assay for potency has been described;[18] to check qualitatively for the presence of HCl, a common impurity, add a few drops of a solution of crystal violet in chloroform;[19] a green or yellow color indicates that HCl is present, while a purple color that persists for at least 10 min indicates that HCl is absent.[1b]

Preparative Methods: treatment of ***Acetic Acid*** or sodium acetate with the standard inorganic chlorodehydrating agents (PCl_3,[1b,23] SO_2Cl_2,[1a,24] or $SOCl_2$[1b,25]) generates material that may contain phosphorus- or sulfur-containing impurities.[1b,23a,26] Inorganic-free material can be prepared by treatment of HOAc with $Cl_2CHCOCl$ (Δ; 70%),[27] PhCOCl (Δ; 88%),[28] $PhCCl_3$ (cat. H_2SO_4, 90 °C; 92.5%),[29] or phosgene[30] (optionally catalyzed by DMF,[30e] magnesium or other metal salts,[30a,b,d] or activated carbon[30b,c]), or by addition of hydrogen chloride to acetic anhydride (85-90 °C; practically quantitative).[1a,31]

Purification: HCl-free material can be prepared either by distillation from dimethylaniline[11c,20] or by standard degassing procedures.[20c,21]

Handling, Storage, and Precautions: acetyl chloride should be handled only in a well-ventilated fume hood since it is volatile and toxic via inhalation.[22] It should be stored in a sealed container under an inert atmosphere. Spills should be cleaned up by covering with aq sodium bicarbonate.[1a]

Friedel-Crafts Acetylation.

Arenes undergo acetylation to afford aryl methyl ketones on treatment with acetyl chloride (AcCl) together with a Lewis acid, usually ***Aluminum Chloride***$_3$. This reaction, known as the Friedel-Crafts acetylation, is valuable as a preparative method because a single positional isomer is produced from arenes that possess multiple unsubstituted electron-rich positions in many instances.

For example, Friedel-Crafts acetylation of toluene (AcCl/$AlCl_3$, ethylene dichloride, rt) affords *p*-methylacetophenone predominantly (*p*:*m*:*o* = 97.6:1.3:1.2; eq 1).[32]

(1)

Acetylation of chlorobenzene under the same conditions affords *p*-chloroacetophenone with even higher selectivity (*p*:*m* = 99.5:0.5).[33] Acetylation of bromobenzene[33] and fluorobenzene[33] afford the *para* isomers exclusively. The *para*:*meta*[34] and *para*:*ortho*[32,34] selectivities exhibited by AcCl/$AlCl_3$ are greater than those exhibited by most other Friedel-Crafts electrophiles.

Halogen substituents can be used to control regioselectivity. For example, by introduction of bromine *ortho* to methyl, it is possible to realize *meta* acetylation of toluene (eq 2).[35]

(2)

Regioselectivity is quite sensitive to reaction conditions (e.g. solvent, order of addition of the reactants, concentration, and temperature). For example, acetylation of naphthalene can be directed to produce either a 99:1 mixture of C-1:C-2 acetyl derivatives (by addition of a solution of arene and AcCl in CS_2 to a slurry of $AlCl_3$ in CS_2 at 0 °C) or a 7:93 mixture (by addition of the preformed AcCl/$AlCl_3$ complex in dichloroethane to a dilute solution of the arene in dichloroethane at rt).[36] Similarly, acetylation of 2-methoxynaphthalene can be directed to produce either a 98:2 mixture of C-1:C-6 acetyl derivatives (using the former conditions) or a 4:96 mixture (by addition of the arene to a solution of the preformed AcCl/$AlCl_3$ complex in nitrobenzene).[37] Also, acetylation of 1,2,3-mesitylene can be directed to produce either a 100:0 mixture of C-4:C-5 isomers or a 3:97 mixture.[36c]

Frequently, regioselectivity is compromised by side reactions catalyzed by the HCl byproduct. For example, acetylation of

p-xylene by treatment with $AlCl_3$ followed by Ac_2O (CS_2, Δ, 1 h) produces a 69:31 mixture of 2,5-dimethylacetophenone and 2,4-dimethylacetophenone, formation of the latter being indicative of competitive acid-catalyzed isomerization of *p*-xylene to *m*-xylene.[38] Also, although acetylation of anthracene affords 9-acetylanthracene regioselectively, if the reaction mixture is allowed to stand for a prolonged time prior to work-up (rt, 20 h) isomerization to a mixture of C-1, C-2, and C-9 acetyl derivatives occurs.[39]

These side reactions can be minimized by proper choice of reaction conditions. Isomerization of the arene can be suppressed by adding the arene to the preformed $AcCl/AlCl_3$ complex. This order of mixing is known as the Perrier modification of the Friedel-Crafts reaction.[40] Acetylation of *p*-xylene using this order of mixing affords 2,5-dimethylacetophenone exclusively.[38] Isomerization of the product aryl methyl ketone can be suppressed by crystallizing the product out of the reaction mixture as it is formed. For example, on acetylation of anthracene in benzene at 5-10 °C, 9-acetylanthracene crystallizes out of the reaction mixture (as its 1/1 $AlCl_3$ complex) in pure form.[39] Higher yields of purer products can also be obtained by substituting ***Zirconium(IV) Chloride***[41] or ***Tin(IV) Chloride***[42] for $AlCl_3$.

AcCl is not well suited for industrial scale Friedel-Crafts acetylations because it is not commercially available in bulk (only by the drum) and therefore must be prepared on site.[1] The combination of ***Acetic Anhydride*** and anhydrous ***Hydrogen Fluoride***, both of which are available by the tank car, is claimed to be more practical.[43] On laboratory scale, $AcCl/AlCl_3$ is more attractive than Ac_2O/HF or $Ac_2O/AlCl_3$. Whereas one equivalent of $AlCl_3$ is sufficient to activate AcCl, 1.5-2 equiv $AlCl_3$ (relative to arene) are required to activate Ac_2O.[36a,37b,38,44] Thus, with Ac_2O, greater amounts of solvent are required and temperature control during the quench is more difficult. Also, slightly lower isolated yields have been reported with Ac_2O than with AcCl in two cases.[36a,45] However, it should be noted that the two reagents generally afford similar ratios of regioisomers.[36a,38,46]

Acetylation of Alkenes.

Alkenes, on treatment with $AcCl/AlCl_3$ under standard Friedel-Crafts conditions, are transformed into mixtures of β-chloroalkyl methyl ketones, allyl methyl ketones, and vinyl methyl ketones, but the reaction is not generally preparatively useful because both the products and the starting alkenes are unstable under the hyperacidic reaction conditions. Preparatively useful yields have been reported only with electron poor alkenes such as ethylene (dichloroethane, 5-10 °C; >80% yield of 4-chloro-2-butanone)[47] and ***Allyl Chloride*** (CCl_4, rt; 78% yield of 5-chloro-4-methoxy-2-pentanone after methanolysis),[48] which are relatively immune to the effects of acid.

The acetylated products derived from higher alkenes are susceptible to protonation or solvolysis which produces carbenium ions that undergo Wagner-Meerwein hydride migrations.[49] For example, on subjection of cyclohexene to standard Friedel-Crafts acetylation conditions ($AcCl/AlCl_3$, CS_2 -18 °C), products formed include not only 2-chlorocyclohexyl methyl ketone (in 40% yield)[50] but also 4-chlorocyclohexyl methyl ketone.[2a,51] If benzene is added to the crude acetylation mixture and the temperature is then increased to 40-45 °C for 3 h, 4-phenylcyclohexyl methyl ketone is formed in 45% yield (eq 3).[49a,b]

(3)

Wagner-Meerwein rearrangement also occurs during acetylation of methylcyclohexene, even though the rearrangement is anti-Markovnikov (β-tertiary -> γ-secondary; eq 4).[52] Acetylation of *cis*-decalin[53] (see Acetylation of Saturated Alkanes section below) also produces a β-tertiary carbenium ion that undergoes anti-Markovnikov rearrangement. The rearrangement is terminated by intramolecular *O*-alkylation of the acetyl group by the γ-carbenium ion to form a cyclic enol ether in two cases.[49c,53]

(4)

Higher alkenes themselves are also susceptible to protonation. The resulting carbenium ions decompose by assorted pathways including capture of chloride (with $SnCl_4$ as the catalyst),[51,54] addition to another alkene to form dimer or polymer,[5b,55] proton loss (resulting in *exo/endo* isomerization), or skeletal rearrangement.[56]

Higher alkenes can be acetylated in synthetically useful yield by treatment with AcCl together with various mild Lewis acids. One that deserves prominent mention is ***Ethylaluminum Dichloride*** (CH_2Cl_2, rt), which is useful for acetylation of all classes of alkenes (monosubstituted, 1,2-disubstituted, and trisubstituted).[57] For example, cyclohexene is converted into an 82/18 mixture of 3-acetylcyclohexene and 2-chlorocyclohexyl methyl ketone in 89% combined yield.

The following Lewis acids are also claimed to be superior to $AlCl_3$: Zn(Cu)/CH_2I_2 (AcCl, CH_2Cl_2, Δ), by which cyclohexene is converted into acetylcyclohexene in 68% yield (after treatment with KOH/MeOH);[58] $ZnCl_2$ (AcCl, Et_2O/CH_2Cl_2, -75 °C -> -20 °C), by which 2-methyl-2-butene is converted into a 15:85 mixture of 3,4-dimethyl-4-penten-2-one and 4-chloro-3,4-dimethyl-2-pentanone in quantitative combined yield;[59] and $SnCl_4$, by which cyclohexene (AcCl, CS_2, -5 °C -> rt) is converted into acetylcyclohexene in 50% yield (after dehydrochlorination with $PhNEt_2$ at 180 °C),[60] methylcyclohexene (CS_2, rt) is converted into 1-acetyl-2-methylcyclohexene in 48% yield (after dehydrochlorination),[52] and camphene is converted into an acetylated derivative in ~65% yield.[49c]

Conducting the acetylation in the presence of a nonnucleophilic base or polar solvent is reported to be advantageous. For example, methylenecyclohexane can be converted into 1-cyclohexenylacetone in 73% yield by treatment with $AcSbCl_6$ in the presence of Cy_2NEt (CH_2Cl_2, -50 °C -> -25 °C, 1 h)[61] and cyclohexene can be converted into 3-acetylcyclohexene in 80% yield by treatment with $AcBF_4$ in $MeNO_2$ at -25 °C.[62]

Employment of Ac_2O instead of AcCl is also advantageous in some cases. For example, methylcyclohexene can be converted into 3-acetyl-2-methylcyclohexene in 90% yield by treatment with $ZnCl_2$ (neat Ac_2O, rt, 12 h).[63]

Finally, alkenes can be diacetylated to afford pyrylium salts by treatment with excess AcCl/$AlCl_3$,[55b,56,64] albeit in low yield (eq 5).[64a]

(5)

Acetylation of Alkynes.

Under Friedel-Crafts conditions (AcCl/$AlCl_3$, CCl_4, 0-5 °C), acetylene undergoes acetylation to afford β-chlorovinyl methyl ketone in 62% yield[4] and under similar conditions ($AcSbF_6$, $MeNO_2$, -25 °C) 5-decyne undergoes acetylation to afford 6-acetyl-5-decanone in 73% yield.[65]

Acetylation of Saturated Alkanes.

Saturated alkanes, on treatment with a slight excess of AcCl/$AlCl_3$ at elevated temperature, undergo dehydrogenation (by hydride abstraction followed by deprotonation) to alkenes, which undergo acetylation to afford vinyl methyl ketones. The hydride-abstracting species is believed to be either the acetyl cation[66] or $HAlCl_4$,[67] with most evidence favoring the former. Perhaps because the alkenes are generated slowly and consumed rapidly, and therefore are never present in high enough concentration to dimerize, yields are typically higher than those of acetylation of the corresponding alkenes.[53b,68] A similar hypothesis has been offered to explain the phenomenon that the yield from acetylation of tertiary alkyl chlorides is typically higher than the yield from acetylation of the corresponding alkenes.[55b,64a] For example, methylcyclopentane on treatment with AcCl/$AlCl_3$ (CH_2Cl_2, Δ) undergoes acetylation to afford 1-acetyl-2-methylcyclopentene in an impressive 60% yield (eq 6).[53b,66a]

If the reaction is carried out with excess alkane, a second hydride transfer occurs, resulting in reduction of the enone to the corresponding saturated alkyl methyl ketone.[69,70] For example, stirring AcCl/$AlCl_3$ in excess cyclohexane (30-35 °C, 2.5 h) affords 2-methyl-1-acetylcyclopentane in 50% yield (unpurified; based on AcCl)[55a,69,71] and stirring AcCl/$AlBr_3$ in excess cyclopentane (20 °C, 1 h) affords cyclopentyl methyl ketone in 60% yield (based on AcCl; eq 7).[55c]

If the reaction is carried out with a substoichiometric amount of alkane, the product is either a 2:1 adduct (if cyclic)[53b,66a] or pyrylium salt (if acyclic).[66b,68b]

Unbranched alkanes also undergo acetylation, but at higher temperature, so yields are generally lower. For example, acetylation of cyclohexane by AcCl/$AlCl_3$ requires refluxing in $CHCl_3$ and affords 1-acetyl-2-methylcyclopentene in only 36% yield.[55c,72]

Despite the modest to low yields, acetylation of alkanes provides a practical method for accessing simple methyl ketones because all the input raw materials are cheap.

Coupling with Organometallic Reagents.

Coupling of organometallic reagents with AcCl is a valuable method for preparation of methyl ketones. Generally a catalyst (either a Lewis acid or transition metal salt) is required.

Due to the large number and varied characteristics of the organometallics, comprehensive coverage of the subject would require discussion of each organometallic reagent individually, which is far beyond the scope of this article. Information pertaining to catalyst and condition selection should therefore be accessed from the original literature; some seminal references are given in Table 1.

Table 1 Catalyst Selection Chart[i,ii]

[i] Codes (in headings): L = unspecified ligand and X = halogen; codes (in entries): N = no catalyst required, Fe = Fe^{III} salt, Cu = Cu^{I} salt, Mn = Mn^{I} salt, D = dipolar aprotic additive, I = LiI, Pd = Pd^{0} or Pd^{II} salt, Al = $AlCl_3$, Ti = $TiCl_4$, and Rh = $ClRh(PPh_3)_3$. [ii] Coupling occurs at metal-bearing carbon with retention of configuration to afford RCOMe unless otherwise indicated. [iii] Coupling occurs at g-carbon unless otherwise indicated. [iv] Product is tertiary alcohol. [v] Coupling occurs with inversion of configuration. [vi] Coupling occurs at b-carbon. [vii] Coupling occurs at d-carbon. [viii] Substrate is allenic silane and product is furan. [ix] Substrate is propargylsilane. [x] Coupling occurs at a-carbon.

C-Acetylation of Enolates and Enolate Equivalents.

β-Diketones can be synthesized by treatment of metal enolates with AcCl. *O*-Acetylation is often a significant side

reaction, but the amount can be minimized by choosing a counterion that is bonded covalently to the enolate[6] such as copper[132] or zinc,[133] and by using AcCl rather than Ac_2O.[6a] Proton transfer from the product β-diketone to the starting enolate is another common side reaction.[134] Alternative procedures for effecting *C*-acetylation that avoid or minimize these side reactions include Lewis acid-catalyzed acetylation of the trimethylsilyl enol ether derivative (AcCl/cat. $ZnCl_2$, CH_2Cl_2 or CH_2Cl_2/Et_2O, rt)[135] and addition of ketene to the morpholine enamine (AcCl/Et_3N, $CHCl_3$, rt).[136]

Analogously, esters can be *C*-acetylated by conversion into the corresponding silyl ketene acetal followed by treatment with AcCl. Depending on the coupling conditions (neat AcCl[137] or AcCl/Et_3N[138]), either the *cis*-β-siloxycrotonate ester or the corresponding β,γ-isomer is produced (eqs 8 and 9). The third possible isomer (*trans*-β-siloxycrotonate) is accessible either by silylation of the acetoacetic ester (TMSCl, Et_3N, THF, Δ)[139] or by $HgBr_2/Et_3SiBr$-catalyzed equilibration of the *cis* isomer.[137]

(8)

(9)

The silyl ketene acetal strategy can also be used to effect γ-acetylation of α,β-unsaturated esters (AcCl/cat. $ZnBr_2$, CH_2Cl_2, rt)[140] and β-ketoesters (AcCl, Et_2O, -78 °C).[141]

Enol Acetylation.

Enol acetylation of ketones can be effected by formation of a metal enolate in which the metal is relatively dissociated[6]

(such as potassium[142] or magnesium[143]) followed by quenching with AcCl. Alternatively, enol acetates can be synthesized directly from the ketones. For example, 3-keto-$\Delta^{4,6}$-steroids can be converted into $\Delta^{2,4,6}$-trienol acetates by treatment with AcCl/$PhNMe_2$ or into $\Delta^{3,5,7}$-trienol acetates by treatment with AcCl/Ac_2O.[144]

Acetyl Bromide (AcBr) is apparently superior to AcCl as a catalyst for enol acetylation, based on a report that 17β-benzoyloxyestra-4,9(10)-dien-3-one is converted into estradiol 3-acetate-17-benzoate in higher yield at much lower temperature using AcBr rather than AcCl (87.5% yield with 1:2 AcBr:Ac_2O, CH_2Cl_2, rt, 1 h (eq 10) vs. 81.0% yield with 1:2 AcCl:Ac_2O, Δ, 4.5 h).[145]

β-Keto esters can be converted into either *trans* or *cis* enol acetates. The *trans* isomer is accessible by treatment with AcCl/Et_3N (HMPA, rt)[146] or AcCl/DBU (MeCN, 5 °C -> rt; eq 11),[147] while the *cis* isomer is accessible by treatment with isopropenyl acetate/HOTs.[146] Each isomer couples with dialkylcuprates with retention of configuration to afford stereoisomerically enriched α,β-unsaturated esters.[146,148]

Attempted enol acetylation of β-keto esters by quenching the sodium enolate[146,147] or magnesium chelate[149] with AcCl afforded *C*-acetylated products.

Adducts with Aldehydes and Ketones.

AcCl combines with aldehydes[150] (cat. $ZnCl_2$ or $AlCl_3$[150f]) to afford α-chloroalkyl acetates. The reaction is reversible,[151] but at equilibrium the ratio of adduct to aldehyde is usually quite high, and the reaction is otherwise clean (92% yield for acetaldehyde,[150e] 97% yield for benzaldehyde; eq 12[150f]).

(12)

AcCl also adds to ketones,[150e,151,152] but the adducts are much less thermodynamically stable, so significant amounts of the starting materials are present at equilibrium.[151,152a,b] The equilibrium can be biased in favor of the adduct by employing high concentration, low temperature, a nonpolar solvent, excess AcCl, or AcBr or AcI instead of AcCl.[151,153] For example, the acetone/AcCl adduct can be obtained in good yield (85%) by treatment of acetone with excess (2 equiv) AcCl (cat. $ZnCl_2$, CCl_4, -15 °C).[152c]

Reduction of the aldehyde/AcBr adducts[151,154] with ***Zinc*** or ***Samarium(II) Iodide*** to α-acetoxyalkylzinc[154,155] and -samarium[156] compounds, respectively, completes an umpolung of the reactivity of the aldehyde.

Cleavage of Ethers.

THF can be opened by treatment with AcCl in combination with either ***Sodium Iodide*** (MeCN, rt, 21 h; 91% yield of 4-iodobutyl acetate)[157] or a Lewis acid such as $ZnCl_2$ (Δ, 1.5 h; 76% yield of 4-chlorobutyl acetate),[158] $SnCl_4$,[159] $CoCl_2$ (rt, MeCN; 90%),[160] $ClPdCH_2Ph(PPh_3)_2/Bu_3SnCl$ (63 °C, 48 h; 95%),[161] $Mo(CO)_6$ (hexane, Δ; 78%),[162] $KPtCl_3(H_2CCH_2)$, and $[ClRh(H_2CCH_2)_2]_2$ (rt; 75% and 83%, respectively).[163] Acyclic dialkyl ethers can also be cleaved efficiently and in many cases regioselectively.[159]

Many of these methods are applicable to deprotection of ether-type protecting groups. For example, benzyl and allyl ethers can be deprotected by treatment with AcCl/cat. $CoCl_2$[160] or AcCl/cat. $ClPdCH_2Ph(PPh_3)_2$/cat. Bu_3SnCl.[161] Dimethyl acetals can be cleaved selectively to aldehydes in the presence of ethylene acetals (AcCl/cat. $ZnCl_2$, Me_2S/THF, 0 °C),[164] or to α-chloro ethers (AcCl/cat. $SOCl_2$, 55 °C).[165] Tetrahydropyranyl (THP) ethers[166] and *t*-butyl ethers[167] can be deprotected by stirring in 1:10 AcCl:HOAc (40-50 °C).

Finally, *t*-alkyl esters can be cleaved to anhydrides and *t*-alkyl chlorides by treatment with AcCl ($MeNO_2$, 70 °C).[168]

Esterification.

Although AcCl is intrinsically more reactive than Ac_2O, in combination with various acylation catalysts the reverse reactivity order is exhibited. For example, Ac_2O ***4-Dimethylaminopyridine*** (DMAP) acetylates ethynylcyclohexanol three times faster than AcCl/DMAP ($CDCl_3$, 27 °C).[169] Also, isopropanol does not react with AcCl/Bu_3P (CD_3CN, -8 °C; <5% conversion after 30 min), but after addition of sodium acetate reacts rapidly to form isopropyl acetate (complete in <10 min).[170] As a general rule, therefore, Ac_2O is preferable for acetylation of hindered alcohols while AcCl is preferable for selective monoacetylation of polyols.[171]

Examples of selective acetylations involving AcCl include: acetylation of primary alcohols in the presence of secondary alcohols by AcCl/2,4,6-collidine or *i*-$PrNEt_2$ (CH_2Cl_2, -78 °C);[8,172] acetylation of primary alcohols in the presence of

secondary alcohols,[173] and secondary alcohols in the presence of tertiary alcohols,[174] by AcCl/pyridine (CH_2Cl_2, -78 °C); monoacetylation of a 2,4-dihydroxyglucopyranose by AcCl/pyridine/-15 °C (Ac_2O/pyridine/0 °C is less selective);[175] and acetylation of steroidal 5α-hydroxyls (not 5β) by AcCl/$PhNMe_2$ ($CHCl_3$, Δ).[176]

Although Ac_2O/DMAP[177] and Ac_2O/Bu_3P[170] are the preferred reagents for acetylation of most hindered alcohols, satisfactory results can be obtained with AcCl in combination with $PhNMe_2$ ($CHCl_3$, Δ),[178] $PhNEt_2$ ($CHCl_3$, Δ),[179] AgCN (benzene or HMPA, 80 °C),[180] magnesium powder (Et_2O, Δ; 45-55% yield of *t*-BuOAc),[181] and Na_2CO_3 (cat. $PhCH_2NEt_3Cl$, CH_2Cl_2, Δ; 79% yield of *t*-BuOAc).[182] Use of the combination of AcCl/DMAP is not recommended since unidentified byproducts may be generated.[169]

Although acetylations with AcCl/pyridine produce an acidic byproduct (pyridine hydrochloride), it is possible to acetylate highly acid-sensitive alcohols such as 2-(tributylstannylmethyl)allyl alcohol (eq 13)[9b] and 2-(trimethylsilylmethyl)allyl alcohol[9a] with AcCl/pyridine in >90% yield without competing protiodestannylation or protiodesilylation by selecting a solvent (CH_2Cl_2, 0 °C) in which the pyridine hydrochloride is insoluble.

(13)

Alternatively, acid-sensitive alcohols may be acetylated by deprotonation with ***n-Butyllithium*** (THF, -78 °C)[183] or ***Ethylmagnesium Bromide*** (Et_2O, rt)[184] followed by quenching with AcCl.

Finally, by using a chiral tertiary amine as the base, it is possible to effect enantioselective acetylations. For example, racemic 1-phenethyl alcohol has been partially resolved by treatment with AcCl in combination with (*S*)-(-)-*N*,*N*-dimethyl-1-phenethylamine (CH_2Cl_2, -78 °C -> rt; ee of acetate 52%, ee of alcohol 59.5%).[185]

Generation of Solutions of Anhydrous Hydrogen Chloride in Methanol.

Esterification of alcohols by AcCl proceeds in the absence of HCl scavengers. For example, on addition of AcCl to methanol at rt, a solution of hydrogen chloride and methyl acetate in methanol forms rapidly.[10] This reaction provides a more practical method for access to solutions of HCl in methanol than the apparently simpler method of bubbling anhydrous HCl into methanol because of the difficulty of controlling the amount of anhydrous HCl delivered. Solutions of anhydrous HCl in acetic acid can presumably be prepared analogously by addition of AcCl and an equimolar amount of H_2O to HOAc.

Primary,[186] secondary,[187] and tertiary alcohols[178a,188] also react with AcCl, but the product is the alkyl chloride rather than the ester in most cases. Thus as a preparative esterification method this reaction has limited generality.

AcCl also reacts with anhydrous *p*-toluenesulfonic acid (3-4 equiv AcCl, Δ) to afford acetyl *p*-toluenesulfonate in 97.5%

yield along with anhydrous HCl.[189] AcCl does not react with HOAc to generate HCl and Ac_2O, at least in appreciable amounts.[31]

Dehydrating Agent.

AcCl reacts with H_2O to afford HCl and HOAc rapidly and quantitatively[31b] and thereby qualifies as a strong dehydrating agent. Examples of reactions in which AcCl functions as a dehydrating agent include: cyclization of dicarboxylic acids to cyclic anhydrides (neat AcCl, Δ);[190] cyclization of keto acids to enol lactones (neat AcCl, Δ);[191] dehydration of nitro compounds into nitrile oxides (by treatment with NaOMe followed by AcCl);[192] and conversion of allylic hydroperoxides into unsaturated ketones (AcCl/pyridine, $CHCl_3$, rt).[193] The dehydrating power of AcCl has been invoked as a possible explanation for its effectiveness for activation of zinc dust.[194]

In Situ Generation of High-Valent Metal Chlorides.

Many high-valent metal chlorides are useful as reagents in organic synthesis but are difficult to handle due to their moisture sensitivity. AcCl can be used to generate such reagents in situ from the corresponding metal oxides[11] or acetates.[195] Examples include: α-chlorination of ketones by treatment with AcCl/***Manganese Dioxide*** (HOAc, rt);[196] *cis*-1,2-dichlorination of alkenes by treatment with AcCl/$(Bu_4N)_4Mo_8O_{26}$ (CH_2Cl_2, rt);[197] and dichlorination of alkenes by treatment with AcCl/MnO_2/$MnCl_2$ (DMF, rt).[198] Attempts to dichlorinate alkenes by treatment with AcCl/MnO_2 in THF, however, failed due to cleavage of THF to 4-chlorobutyl acetate.[196,199] A milder reagent that can be used to activate MnO_2 for dichlorination of alkenes in THF is ***Chlorotrimethylsilane***.[199]

Solvent for Organometallic Reactions.

Because of its cheapness, volatility, and ability to form moisture-stable solutions of metal chlorides, AcCl is useful as a solvent for reactions involving hygroscopic metal salts.[11] For example, AcCl has been used as a co-solvent for 1,2-chloroacetoxylation of alkenes by ***Chromyl Chloride*** (1:2 AcCl:CH_2Cl_2, -78 °C -> rt).[200]

Reaction with Heteroatom Oxides.

The key step in a method for α-acetoxylation of aldehydes involves rearrangement of an AcCl-nitrone adduct (eq 14).[201] Analogous methods for α-benzoylation and α-pivaloylation are higher yielding.

(14)

β-Nitrostyrenes cyclize to indolinones on treatment with AcCl ($FeCl_3$, CH_2Cl_2, 0 °C; eq 15).[202]

(15)

A high-yielding method for deoxygenation of sulfoxides to sulfides involves treatment with 1.1 equiv ***Tin(II) Chloride*** in the presence of a catalytic amount (0.4 equiv) of AcCl (MeCN/DMF, 0 °C -> rt).[12] The mildness of this method is demonstrated by its usability for deoxygenation of a cephalosporin sulfoxide (eq 16).

Another method for deoxygenation of sulfoxides involves treatment with two equiv AcCl (CH_2Cl_2, rt);[203] the oxidized byproduct is claimed to be gaseous chlorine.[203]

Chlorine and Bromine Scavenger.

AcCl (cat. H_2SO_4, 40-70 °C) scavenges Cl_2 efficiently (to afford chloroacetyl chloride in 87.1% yield).[13] AcCl also scavenges Br_2 efficiently at 35 °C.[14]

Source of Ketene.

AcCl reacts with ***Triethylamine*** at low temperature (-20 °C) to afford acetyltriethylammonium chloride.[204] This salt functions as a source of ketene (or the functional equivalent). For example, it reacts with silyl ketene acetals (THF, rt) to afford silyl enol ethers of acetoacetic esters (eq 9),[138] with α-alkoxycarbonylalkylidenetriphenylphosphoranes (CH_2Cl_2, rt) to afford allenic esters,[205] with enamines (Et_2O, 0 °C) to afford cyclobutanones,[136a] with certain acyl imines (Et_2O, 0 °C) to form formal [4 + 2] ketene cycloadducts,[206] and with certain nonenolizable imines (Et_2O, rt) to afford formal [4 + 2] diketene cycloadducts in up to 55% yield.[207] Also, on refluxing in Et_2O in the absence of a trapping agent, diketene is formed in 50% yield.[208]

AcCl/$AlCl_3$ decomposes to acetylacetone on heating ($CHCl_3$, 54-61 °C, 6 h; 82.5% yield after aqueous work-up).[209] The mechanism presumably involves ketene as an intermediate. However, an attempt to trap the ketene was unsuccessful.[210]

N-Acetylation.

Primary and secondary amines can be *N*-acetylated to form acetamides by treatment with AcCl under Schotten-Baumann conditions (aq NaOH),[211] but hydrolysis of AcCl is a significant competing side reaction.[212] Use of Ac_2O (2.5 equiv; Δ, 10-15 min) is therefore recommended.[211]

Tertiary amines react with AcCl to afford acetylammonium salts. Ordinarily, these salts fragment to ketene on warming (see above). However, those that possess a labile alkyl group fragment by loss of the alkyl group (von Braun cleavage). For example, bis(dimethylamino)methane reacts with AcCl (Et_2O, rt) to afford chloromethyldimethylamine,[213] a useful Mannich reagent, and 1,3,5-trimethylhexahydro-*s*-triazine reacts with AcCl ($CHCl_3$, Δ, 1 h) to afford chloromethylmethyl acetamide,[214] a useful amidomethylation reagent.[215] Also, aziridines react with AcCl (PhH, 0 °C) to afford chloroethylacetamides.[216] Allylic amines react with in situ-generated AcI (AcCl/CuI, THF, rt) to afford acetamides.[217]

AcCl also activates pyridines toward nucleophilic addition. For example, phenylmagnesium chloride adds to pyridine in the presence of AcCl (cat. CuI, THF, -20 °C -> rt) to afford, after catalytic hydrogenation, *N*-acetyl-4-phenylpiperidine in 65% yield.[218] Also, AcCl catalyzes the reaction between sodium iodide and 2-chloropyridine to afford 2-iodopyridine (MeCN, Δ, 24 h; 55%).[219]

N-Acetylation of enolizable imines to afford enamides can be accomplished by treatment with AcCl/$PhNEt_2$. For example, treatment of crotonaldehyde cyclohexylimine with AcCl followed by $PhNEt_2$ (toluene, rt) affords the enamide in 88% yield.[220]

Primary urethanes can be *N*-acetylated to afford imides by treatment with AcCl (100 °C, 1 h).[221] Alternatively, urethanes can be converted into acetamides by treatment with AcBr (120-130 °C)[221] or in situ-generated AcI[222] (MeCN, 60 °C).[223]

Finally, a convenient method for preparation of ***N-Trimethylsilylacetamide*** (MSA), a useful trimethylsilyl transfer reagent, involves treatment of ***Hexamethyldisilazane*** with AcCl (hexane, Δ; 88%).[224]

S-Acetylation.

Both aliphatic and aromatic thiols can be *S*-acetylated by treatment with AcCl (cat. $CoCl_2$, MeCN, rt).[225]

Nucleophilic Acetylation.

AcCl together with SmI_2 (MeCN, rt) or $SmCp_2$ delivers the acetyl anion synthon to ketones to afford the corresponding acyloins (eq 17).[15]

(17)

Related Reagents.

Acetic Anhydride; ***Acetyl Bromide***; ***Acetyl Fluoride***.

Acetyl Cyanide[1]

(R = Me)

[631-57-2] · C_3H_3NO · Acetyl Cyanide · (MW 69.06) (R = Ph)

[613-90-1] · C_8H_5NO · Benzoyl Cyanide · (MW 131.13)

(versatile electrophile useful for selective acylation, cyanohydrin synthesis, and cycloaddition reactions)

Alternate Names: 2-oxopropanenitrile; pyruvonitrile.

Physical Data: AcCN: bp 92.3 °C; *d* 0.9745 g cm^{-3}; BzCN: mp 30-32 °C; bp 206 °C; *d* 1.106 g cm^{-3}.

Preparative Methods: acyl cyanides are readily prepared from the reaction of acyl halides with ***Copper(I) Cyanide***,[2a] ***Sodium Cyanide***,[2b] or ***Cyanotrimethylsilane***[2c] and via the oxidation of cyanohydrins.[2d]

Handling, Storage, and Precautions: AcCN and its analogs are highly toxic; use in a fume hood.

Acylation.

Acyl cyanides are useful for the selective acylation of alcohols[3] and amines[4] (eq 1). This process is utilized in the reaction of AcCN with orthoesters[5a,b] and amido acetals,[5c] resulting in the substitution of an alkoxy group with a cyano group (eq 2). In addition, aldehydes are cyanoacylated with benzoyl cyanide (BzCN).[1a] Lithium ketone enolates react cleanly with acyl cyanides, producing 1,3-diketones uncontaminated by *O*-acylated or diacylated products (eq 3).[6] Other efficiently acylated carbon nucleophiles include Grignard reagents,[7] primary nitroalkanes,[8] dithianes,[9] nitrosoamines,[10] and active methylene compounds.[11] A one-pot synthesis of pyridines utilizes AcCN as the trapping agent with an intermediate ketone enolate (eq 4).[12]

(1)

(2)

(3)

(4)

Treatment of trimethylsilyl ketene acetals with BzCN in the presence of ***Titanium(IV) Chloride*** affords α-benzoylcarboxylates.[13] In contrast, attack of the nucleophile at the nitrile carbon of BzCN is observed when the same reaction is performed in the absence of catalyst. Nitrile attack is also the preferred mode in the ***Nickel(II) Acetylacetonate*** catalyzed reaction of 1,3-dicarbonyls with BzCN.[14]

A synthesis of 4-chlorooxazoles from aromatic aldehydes and BzCN formally involves the addition of HCl across the nitrile bond (eq 5).[15]

(5)

Cyanohydrin Synthesis.

The addition of silyl enol ethers to AcCN in the presence of $TiCl_4$ affords the corresponding β-hydroxy ketone which retains the cyano functionality (eq 6).[16] Similar results are found with allylsilanes.[16] Retention of the cyano group is also accomplished in the Wittig reaction of dihalomethylenephosphorus ylides with BzCN.[17] Acidic treatment of phenol and AcCN provides a cyano containing bis-adduct (eq 7).[18] Reductive coupling of aldehydes and ketones with BzCN by ***Titanium(III) Chloride*** affords an intermediate cyanohydrin diol, which upon base treatment produces the mixed benzoin.[19]

(6)

(7)

Cycloadditions.

In the presence of ***Zinc Chloride***, AcCN serves as a dienophile in hetero-Diels-Alder reactions (eq 8).[20] Acyl cyanides are also reactive toward photochemically generated *o*-quinodimethanes[21] and act as substrates in the Paterno-Büchi reaction with furan.[22] In addition, AcCN is useful for the preparation of optically pure 1-cyanovinyl esters which serve as dienophilic equivalents of ***Ketene*** in [4 + 2] cycloadditions.[23]

Related Reagents.

Acetic Anhydride; ***Acetyl Bromide***; ***Acetyl Chloride***.

Acetylene

HC≡CH

[74-86-2] · C_2H_2 · Acetylene · (MW 26.04)

(ethynylation reagent,[1] hydrosilylation,[23] carbonylation,[24-26] cycloadditions,[31-33] cyclotrimerization[34])

Alternate Name: ethyne.

Physical Data: bp -83 °C.

Form Supplied in: widely available as compressed gas. *Drying:* can be purified by passing through a trap at -80 °C followed by a column of sulfuric acid and then through a column of sodium hydroxide.[2]

Handling, Storage, and Precautions: flammable, colorless gas which possesses a garlic odor; use only with adequate ventilation; skin irritant. The low electrical conductivity of acetylene requires that care must be taken to eliminate any static charge buildup. Use in a fume hood.

Ethynylation.

Due to the sp hybridization of acetylene's σ-bonds the methine proton has a pK_a of about 25 and can be removed with strong bases to form the acetylide anion.[3] Sodium acetylide is commonly prepared by deprotonation with sodium amide. ***Lithium Acetylide*** can be conveniently prepared using ***n-Butyllithium***, while the corresponding Grignard reagent is commonly generated by treatment with ***Ethylmagnesium Bromide***.[4] Alkyl cuprates undergo nucleophilic addition to acetylene.[5] The dianion of acetylene is available by using higher temperatures during deprotonation.[6] A variety of other counter cations of the acetylide ion have also been formulated, usually starting from the acetylides previously mentioned.[1a] The acetylide anion undergoes nucleophilic addition to a wide range of electrophiles such as halides,[7] alkyl halides,[8] alkyl sulfonates,[9] epoxides,[10] aldehydes,[11] ketones,[12] esters,[13] and imides.[14] In certain cases the yields of addition may be improved by additives such as ethylenediamine[15] or ***Copper(I) Iodide***.[16] When the electrophile is hindered, elimination may become the predominant pathway. This problem may be avoided with trialkylborane electrophiles (eq 1).[17] After treatment with iodine, the intermediate borate yields the substituted alkyne via migration of one of the alkyl groups. This sequence is not as sensitive to steric effects as simple substitutions with halides. Higher yields can be obtained if ***Lithium (Trimethylsilyl)acetylide*** is used instead (see also ***Trimethylsilylacetylene***).

(1)

The nucleophilicity of the acetylide anion is such that discrimination between several electrophilic centers within a substrate is possible (eq 2).[18]

(2)

The regioselectivity of acetylide additions are sensitive to the counter cation. For example, ethynyltriisopropoxytitanium acetylide, prepared from ethynyllithium and ***Chlorotitanium Triisopropoxide***, gives a single addition product with pyrimidin-2(1*H*)-ones while the Grignard and lithium acetylides give mixtures of regioisomers (eq 3).[19] There are also examples of diastereoselective additions of acetylide anions to ketones (eq 4).[20]

(3)

X = Li	20	80
MgBr	50	50
$Ti(O\text{-}i\text{-}Pr)_3$	0	100

(4)

The acetylide anion is useful for the synthesis of enynes which have been used in palladium catalyzed cyclizations (eq 5).[21]

(5)

Ethynylation of aryl halides (Stephens-Castro coupling) with the copper acetylide is synthetically effective when one of the acetylenic methine protons is protected.[22]

Hydrosilylation.

Acetylene can be converted[23] into a vinylsilane under appropriate hydrosilylation conditions using Pt, Rh, Ru, or Al catalysts, but the initial 1:1 product can react further to give a 1,2-disilylethane. Examples of these processes are shown in eq 6.

Reactions with CO and CO_2.

Alkynes react with CO_2 and secondary amines in the presence of ruthenium complexes to afford vinyl carbamates (eq 7).[24] Mononuclear ruthenium complexes and $[RuCl_2(norbornadiene)]_n$ or ***Ruthenium(III) Chloride*** have been shown to be the best catalysts for monosubstituted alkynes and acetylene, respectively.

Acetylene reacts[25] with CO and O_2 in presence of ***Palladium(II) Chloride*** to give dimethyl maleate in 90% yield. Organic acids have been formed by treating acetylene with CO and Ni or Pd catalysts.[25a] Acetylene reacts with CO in presence of $Co_2(CO)_8$ to give an (*E*)-bisbutenolide in aprotic solvents (eq 8), while the (*Z*)-isomer is obtained in the presence of tetramethylurea.[26]

Addition.

Acyl chlorides add across acetylene to give β-chloroenones in CCl_4 in the presence of ***Aluminum Chloride*** (eq 9).[27]

The acid catalyzed hydration of acetylene to acetaldehyde followed by condensation to give crotonaldehyde is a well known reaction first studied by Berthelot in 1862.[28] Although more efficient procedures have been developed since then, the mechanism of hydration of acetylene has not yet been unambiguously resolved.[29] Kinetic data based on NMR experiments suggest that a vinyl cation is probably an intermediate.[30]

Cycloadditions.

Acetylene has low reactivity in Diels-Alder reactions and reacts with electron rich dienes only under severe conditions.[31] The reaction of dienes with vinyl bromide and subsequent elimination of HBr from the adduct leads to the same product as direct addition of acetylene. In addition a number of compounds have been suggested as acetylene surrogates, such as 2-phenyl- and ***2-Thiono-1,3-dioxol-4-ene***,[32] and phenyl vinyl sulfoxide.[33] Vinylene thioxocarbonate and 2-phenyl-1,3-dioxol-4-ene, on reaction[9] with anthracene in benzene at 170 °C for 16 h, gave the corresponding adducts in 60 and 65% yield, respectively. The [4 + 2] adducts yield the corresponding alkene upon treatment with trivalent phosphorus or *n*-butyllithium respectively. Similarly, heating anthracene and phenyl vinyl sulfoxide in chlorobenzene for 120 h afforded dibenzobarrelene in 83% isolated yield (eq 10).[9]

The following example (eq 11) involves in situ reductive extrusion of an oxygen atom. It has been suggested that the liberated PhSOH appears capable of deoxygenating isobenzofurans and related molecules.

(11)

Cyclotrimerization.

In addition to acetylene, many mono- or disubstituted alkynes undergo cyclotrimerization in the presence of transition metal complexes. Acetylene itself trimerizes to give benzene. Trimerization of unsymmetrically substituted alkynes gives rise mostly to benzenes in which the most sterically demanding substituents occupy positions 1, 2, and 4 around the ring and to a lesser extent a 1,3,5-substitution pattern is also obtained.[34] Although numerous mechanistic pathways have been postulated, depending on the metal involved, a common feature involves intermediacy of metallocyclopentadienes and complexation with a third alkyne which inserts to give a transient metallocycloheptatriene, leading finally to reductive elimination of the metal and the benzene product.

Selective intermolecular co-cycloaddition has been achieved, exploiting the relative unreactivity of phosphine nickel carbonyls towards trimerization of internal alkynes.[35,36] Thus two molecules of acetylene and one molecule of an internal alkyne give a mixture of the unsubstituted and substituted benzenes (eq 12).

Acetyl Fluoride

(MeCOF)

[557-99-3] · C_2H_3FO · Acetyl Fluoride · (MW 62.04) (EtCOF)

[430-71-7] · C_3H_5FO · Propionyl Fluoride · (MW 76.07) (PhCOF)

[455-32-3] · C_7H_5FO · Benzoyl Fluoride · (MW 124.11)

(precursors to acylium salts; acylating agents)

Physical Data: MeCOF: bp 20-21 °C; *d* 1.0024 g cm^{-3}; EtCOF: bp 42-44 °C; *d* 0.972 g cm^{-3}; PhCOF: bp 159-161 °C; *d* 1.140 g cm^{-3}.

Preparative Methods: acetyl fluoride (but not other acyl fluorides) is most conveniently prepared by addition of ***Acetyl Chloride*** to a solution of ***Potassium Fluoride*** in AcOH; reaction is immediate. Warming the solution and condensing the gas gives nearly quantitiative yields.[1] Procedures applicable to the preparation of a variety of acyl fluorides include reaction of the acid chloride or anhydride with nucleophilic fluorides[2] and fluorination of the carboxylic acid.[3]

Handling, Storage, and Precautions: samples of acetyl fluoride sealed in glass ampoules slowly form a pyrylium salt.[4] Acetyl fluoride is a corrosive lachrymator. Use in a fume hood.

Preparation of Acylium Salts.

Addition of Lewis acidic metal fluorides to a variety of acyl fluorides produces acylium salts (**1**), isolable as stable white solids (eq 1).[5] Reaction of acyl fluorides with SO_3 produces acyl fluorosulfates (**2**) (eq 2).[6] Both (**1**) and (**2**) are powerful acylating agents.[5,6]

$$RCOF + MF_x \xrightarrow[-78 \rightarrow 0\ ^\circ C]{F_2CCl_2} RCO^+ MF_{x+1}^- \quad (1)$$

(1)

$$MF_x = BF_3, PF_5, SbF_5, AsF_5$$

$$RCOF + SO_3 \longrightarrow RCO_2SO_2F \quad (2)$$

(2)

Acylation at Carbon.

Acyl fluorides usually have no advantages over acid chlorides for Friedel-Crafts reactions;[7] however, with some poylcyclic aromatic substrates the acyl fluoride-BF_3 system exhibits exceptional regioselectivity (eq 3).[8] Silyl enol ethers are *C*-acetylated by reaction with acetyl fluoride and BF_3 (eq 4).[9] Lower yields are obtained with preformed acetyl tetrafluoroborate. Reaction of Tl^I enolates of β-dicarbonyl compounds with acetyl fluoride in ether gives *C*-acylated products in high yield.[10]

(3)

(4)

Acylation at Oxygen.

Esters of a variety of perfluoro alcohols are obtained by acylation of the metal alkoxides with acyl fluorides.[11] Acetyl fluoride, in the presence of acid catalysts, cleaves certain methyl ethers via an acyl oxonium ion intermediate (eq 5).[12]

Related Reagents.

Acetyl Bromide; ***Acetyl Chloride***; ***Acetyl Methanesulfonate***; ***Chloroacetyl Fluoride***.

Acetyl Hypofluorite[1]

[78948-09-1] · $C_2H_3FO_2$ · Acetyl Hypofluorite · (MW 78.04)

(convertion of alkenes into fluorohydrin derivatives;[2] aromatic fluorination;[3] instrumental in introducing the ^{18}F isotope in sugars and other biologically important compounds for positron emitting tomography studies;[4] fluorination on a carbon α to carbonyl;[5] activation of pyridine derivatives[6])

Physical Data: mp -96 °C; bp approx +53 °C; ^{19}F NMR +168.5 ppm; thermal decomposition to MeF and CO_2.[7]

Analysis of Reagent Purity: AcOF oxidizes iodides to iodine which is then titrated ($AcOF + 2KI + H^+ \rightarrow KF + AcOH + K^+ + I_2$).

Handling, Storage, and Precautions: as with all hypofluorites this reagent should be treated with care. When not in solution, or when very concentrated, it may explode.[8] Solutions of up to 0.3 M in $CFCl_3$ at -78 °C or in MeCN at -45 °C are stable for days, but at rt the half-life is around 2-4 h. No data about the toxicity are available, but some hypofluorite derivatives such as CF_3OF and F_2O are known to be toxic. Use in a fume hood.

Acetyl hypofluorite, prepared in 1981 by reacting F_2 with AcONa,[9] was the first hypofluorite to possess a hydrogen-containing alkyl group in the vicinity of the O-F bond. The fluorine in this reagent is of electrophilic nature, as can be judged from reactions with enol acetates[10] or enolates[5b] when α-fluoro carbonyl derivatives are produced (eqs 1 and 2). Similar conclusions can be drawn from its reactions with unsymmetrical alkenes. Apart from regioselectivity, the addition of AcOF across double bonds is also stereospecific, resulting from a preferential *syn* addition[10,11] (eq 3), a mode characteristic of all reagents with electrophilic fluorine.

(1)

(2)

(3)

The electrophilic nature of the fluorine was also used for aromatic substitution of activated aromatic rings with predominant *ortho* fluorination (eq 4).[3,12] This procedure was used for direct fluorination of the opiatic peptide dermorphine (eq 5).[13]

(4)

(5)

Aromatic fluorination was also achieved via substitution of an Ar-M bond. It seems that the best metals are tin[14] and mercury. The latter was used for synthesis of fluorodopa derivatives (eq 6).[15]

(6)

AcOF was used exclusively for introducing the ^{18}F isotope in order to construct compounds suitable for positron emitting tomography (PET). Among numerous examples, we will mention here the synthesis of 2-deoxy-2-[^{18}F]fluoro-D-glucose[16] and [^{18}F]fluorodopa,[4,17] both used for brain studies, 6-[^{18}F]fluorometaraminol (eq 7) as a heart imaging agent,[18] and [^{18}F]fluoro-2-oxoquasepam (eq 8) with a strong affinity to benzodiazepine receptors.[19]

(7)

(8)

AcOF was also used for activating the inert pyridine ring. The reaction takes advantage of the electrophilic power of the fluorine which is able to attack the nitrogen atom. As a result, the 2-position becomes very susceptible to nucleophilic attacks by either the remaining acetate or nucleophilic solvents, if present (eq 9). The elimination of HF is a strong driving force for the reaction, explaining the speed at low temperatures.[6]

Acetyl Methanesulfonate[1]

[5539-53-7] · $C_3H_6O_4S$ · Acetyl Methanesulfonate · (MW 138.14)

(reagent for ether cleavage,[2] for the cleavage of activated cyclopropanes as partial structures of cyclopropyl ketones,[3-6] and for acetylation of aromatic rings[7])

Physical Data: bp 50 °C/10^{-2} mmHg; mp 33-36 °C.

Solubility: sol MeCN, CH_2Cl_2.

Form Supplied in: not available commercially.

Preparative Methods: can be prepared on a large scale (1 mol) from ***Acetyl Chloride*** and ***Methanesulfonic Acid*** by heating at reflux followed by fractional distillation (85% yield).[1]

Purification: white/colorless solid upon distillation.

Handling, Storage, and Precautions: slightly hygroscopic. However, no particular precautions are required upon exposure to air for a short period of time. Stable if stored at 4 °C for several months. Use in a fume hood.

Ether Cleavage.

Acetyl methanesulfonate (AcOMs) can be used to cleave both acyclic and cyclic ethers.[2] The reaction parallels the Lewis acid promoted cleavage (i.e. S_N1-type process). The reactivity order is tertiary >> secondary > primary ethers. Cyclic ethers can also be cleaved with the expected rate trends. Unsymmetrical ethers give mixtures.

Cyclopropane Cleavage.

Acetyl methanesulfonate is a very efficient reagent for selective opening of the ring in cyclopropyl ketones. In the latter context, AcOMs is the trigger for the cleavage of a cyclopropane followed by spiroannulation yielding a tricyclic intermediate en route to (epi-)cedrone (eq 1).[3]

(1)

If no intramolecular trapping of cationic-type intermediates is possible, AcOMs adds to cyclopropyl ketones regiospecifically, affording enol acetates (eqs 2-5, X = OMs) with good (eq 2) to excellent (eq 3) regio- and stereocontrol of the cyclopropane cleavage.[4] Subtle steric factors seemingly dominate such addition processes as they are consistent with an overall S_N2-type mechanism.[4] Furthermore, if these substrates are combined with AcOMs in the presence of ***Tetramethylammonium Bromide*** or iodide, the parent bromo or iodo enol acetates are the products (eqs 2-5, X = Br or I).[4,5] Activation of the ketone moiety of these substrates by AcOMs is likely to increase the electrophilicity of the cyclopropane, allowing introduction of nucleophiles (Br^- or I^-) which are insufficiently reactive alone. Tetramethylammonium salts are used for these transformations because of their solubility and their potential to effect configurational equilibration in organic solvents.

(2)

(3)

(4)

(5)

3:1

A reaction cascade of three high-yield consecutive steps is triggered by AcOMs in the case of a tricyclooctanone derivative (eq 6).[6,7] If this reaction, which proceeds at room temperature, is run with one equiv of AcOMs (1 h), an enol acetate (eq 6) is obtained with complete stereochemical control. Prolonged reaction time (10 h) and the use of 2.2 equiv of AcOMs leads to cyclization of ring B (eq 7, R = H; after work-up with water). Beneficially, smooth and exclusive C-2 acetylation of the aromatic ring is found to be completed within 24 h when an excess (4-6 equiv) of the reagent is employed (eq 7, R = Ac). As a result, a 2-acetyl-C,18-bisnor-13α,17α-estradiol derivative is assembled. Analogously, ring A acetylation allows a short and clean access to 2-hydroxyestrone 3-methyl ether.[7] The same reference also cites successful acetylations of anisole to *p*-methoxyacetophenone as well as of cyclopentene and cyclohexene to the respective 1-acetylcycloalkenes.

Acetylmethylenetriphenylphosphorane

[1439-36-7] · $C_{21}H_{19}OP$ · Acetylmethylenetriphenylphosphorane · (MW 318.36)

(stabilized ylide for Wittig alkenation of aldehydes; precursor to vinylphosphonium salts; synthesis of 1,2,3-triazoles and pyrazoles; cyclocondensation on α,β,γ,δ-unsaturated carbonyls)

Physical Data: mp 203-205 °C.

Solubility: sol methanol, chlorinated solvents, low pH water.

Form Supplied in: fine white powder.

Preparative Methods: treatment of ***Triphenylphosphine*** with chloro- or ***Bromoacetone*** provides the phosphonium salt (eq 1). Deprotonation with a weak base such as bicarbonate in cold water provides the crude ylide which may by isolated by filtration.

Handling, Storage, and Precautions: may be handled in atmosphere for short periods; will decompose in water at pH > 9.

Wittig Alkenations.

The title ylide is primarily used in the literature to synthesize α,β-unsaturated methyl ketones in a Wittig reaction (eq 2).

This reagent is a close relative to the related stabilized ylide ***(Methoxycarbonylmethylene)triphenylphosphorane*** which will provide an α,β-enoate, while the title reagent provides the corresponding enone from the same aldehyde.[1] The reaction is generally *trans* selective in nonpolar solvents like methylene chloride, chloroform, and aromatics. It is rather quick but not as selective in alcoholic solvents. The stabilized ylides are also rather unreactive to most ketones. The Horner-Emmons-Wadsworth alkenation utilizing a phosphonate ester is used for the same purpose and will react with ketones to provide the trisubstituted alkenes in high yield.

The title reagent is also a critical substrate in the synthesis of a variety of substituted phosphorus compounds. Cooke[2] has carried out metalations at the methyl group with ***n-Butyllithium*** followed by treatment with an alkyl halide to provide the substituted ylide (eq 3). He follows with a hydrolysis of the phosphonium portion to provide a good yield of the saturated ketone. Other workers[3] have also used this synthesis as a route to substituted enones.

Vinylphosphonium Salts.

The neutral form of the ylide is also mildly nucleophilic. It is, however, an ambident nucleophile. It will react with alkyl halides although only methyl or ethyl iodide or benzyl bromide provide synthetically useful yields (eq 4).[4] The primary product is that of *O*-alkylation but this product rearranges on heating to the *C*-alkyl product.[5] It has also been shown that the *O*-alkyl products, which are vinylphosphonium salts, will also react with sodium alkoxide to form alkoxyvinyldiphenylphosphine oxides.[6]

(4)

Heterocycle Synthesis.

The nucleophilicity of phosphorus ylides is also apparent in their reactions with 1,3-dipoles or their equivalents to generate heterocycles. Reaction with alkyl or aryl azides provides a high yield route to 1,2,3-triazoles (eq 5).[7] The initial step of the postulated mechanism is similar to the first step of the Wittig reaction, namely attack of the nucleophilic carbon of the ylide onto the electrophilic end nitrogen of the azide to form a betaine intermediate. Attack of the internal nitrogen onto the carbonyl to form a five-membered ring, followed by elimination of triphenylphosphine oxide, provides the triazole. In similar fashion, treatment of the ylide with hydrazonyl halides provides a useful route to a variety of substituted pyrazoles (eq 6).[8] This mechanism is similar to the triazole formation in that the nucleophilic ylide attacks the electrophilic carbon of the hydrazonyl halide, displacing chlorine. Proton abstraction by added ***Triethylamine*** from the hydrazone, followed by cyclization and elimination of triphenylphosphine oxide, provide the pyrazole.

(5)

One last application is in the reaction of the ylide at the δ-position of an α,β,γ,δ-unsaturated carbonyl system (eq 7). This reaction begins with addition of the ylide to form an enolate/betaine which then attacks the carbonyl of the ylide to form a six-membered ring followed by elimination of triphenylphosphine oxide.[9] Although the reaction goes in low yield it provides an interesting synthesis of some bicyclic systems.

Acetyl Nitrate[1]

[591-09-3] · $C_2H_3NO_4$ · Acetyl Nitrate · (MW 105.05)

(nitrating agent for arenes and selected nonaromatics;[9-13] can functionalize alkenes to β-nitroacetates;[14-17] oxidizes thioethers and disulfides to sulfoxides[22])

Physical Data: colorless, mobile liquid; bp 22 °C/70 mmHg,[2] 2-3 °C/14 mmHg;[3] *d* 1.24 g cm^{-3}.

Solubility: miscible with common organic solvents.

Analysis of Reagent Purity: physicochemical studies indicate a dependence on preparatory method and starting material ratios, as well as age. In commonly used Ac_2O/HNO_3 mixtures, acetyl nitrate, HOAc, and excess Ac_2O are present if the Ac_2O/HNO_3 ratio is >1; if <1, H_2O and even N_2O_5 can be present.[6]

Preparative Methods: a typical approach is to add conc ***Nitric Acid*** (38 mL) slowly to stirred, cooled ***Acetic Anhydride*** (150 mL).[7] In the earliest report,[2] N_2O_5 was dissolved in Ac_2O; though less practical, this is recommended for preparing anhydrous inorganic nitrates.[5] Other methods involve reaction of HNO_3 and ketene,[3] or AcCl and $AgNO_3$ in MeCN in the presence of the substrate to be nitrated.[8]

Handling, Storage, and Precautions: unstable and explosive upon heating.[2,4] Isolation or distillation is not recommended unless extreme care is taken; freshly prepared solutions should be employed. Controlled thermolysis at ~60 °C leads to *N*-oxides, tetranitromethane,[2] and a yellow oil.[5] Highly acidic; avoid skin contact. Reactions should be conducted in a well-ventilated fume hood.

Electrophilic Nitrations.

Solutions of acetyl nitrate behave as NO_2^+ AcO^-, with no sign of acetylation.[9] Its synthetic utility is often quite comparable with that of other nitronium reagents, e.g. reaction with toluene gives a mixture of *o*-, *m*-, and *p*-nitrotoluenes in a 60:3:37 ratio at rt,[9] and biphenyl yields *o*- and *p*-nitro derivatives in a 58:42 ratio (87% yield).[10] Naphthalene and pyrene give the corresponding 1-nitro derivatives, while 3-fluoroanthracene and phenanthrene result in nitration at the 9-position.[11] Regioselectivity of the nitration reaction can be solvent dependent; in most solvents, reaction with phenanthrene leads to 9-nitrophenanthrene, but in CH_2Cl_2 or nitrobenzene the 1-nitro isomer

dominates.[12] Enols can react analogously, as demonstrated with acetoacetate esters (eq 1).[13]

(1)

Addition to Alkenes.

Simple alkenes react with acetyl nitrate to give β-nitroacetates, although nitroalkenes and nitronitrates are often also formed (eq 2).[14]

(2)

Others have found more complex reaction mixtures in this case, and with other cycloalkenes,[15] making the synthetic usefulness doubtful; another example concerns methyl-2-furoate.[16] Reaction of $AcONO_2$ with 4-methylstilbene yielded the DL-*threo* derivative (eq 3),[17] in line with the nitronium acetate character of the reagent. Cyclic dienes[18] also mostly give product mixtures (eq 4).[19]

(3)

(4)

cis:*trans* = 1:7

Other Applications.

Alcohols can be converted to their nitrates (eq 5),[20] and tertiary amines give nitrosamines in fair yields (eq 6).[21]

(5)

(6)

Acetyl nitrate reacts rapidly with thioethers and disulfides to give sulfoxides, even at temperatures far below 0 °C; no further oxidation to sulfones occurs, even with an excess of reagent, and yields are near quantitative (eqs 7 and 8).[22] With sulfides that are susceptible to Pummerer-type reactions with Ac_2O, the use of ***Benzoyl Nitrate*** is preferred.

Acetyl *p*-Toluenesulfonate

[26908-82-7] · $C_9H_{10}O_4S$ · Acetyl *p*-Toluenesulfonate · (MW 214.24)

(selective ether cleavage agent;[1] acylating agent[2])

Physical Data: mp 54-56 °C; *d* 1.092 g cm^{-3}.

Solubility: sol acetonitrile, dichloromethane, toluene.

Form Supplied in: colorless crystals; commercially available, or readily prepared from ***Acetyl Chloride*** and ***p-Toluenesulfonic Acid***.[3]

Analysis of Reagent Purity: NMR spectroscopy; traces of free acid and sulfonic anhydride may be present.

Handling, Storage, and Precautions: the solid is readily hydrolyzed, so it must be protected from contact with moisture; thermal decomposition is also possible.

Ether Cleavage.

Reaction conditions are relatively mild (25-130 °C, 2-48 h, usually in acetonitrile) and added Lewis acid catalysts are not necessary for effective reaction. Higher yields are more often obtained than with other reagents, and cleavage of unsymmetrical ethers occurs with high regioselectivity (eqs 1-4).[1,4,5]

(1)

(2)

(3)

(4)

The mechanism of cleavage of ethers is thought to proceed by initial acylation of the ether oxygen, followed by S_N1-like cleavage to an acetate and an ion pair, which can collapse to give the tosylate. Thus cleavage of mixed ethers should favor cleavage of the bond to the more substituted carbon. In addition, the longer lifetime of a carbocation thus generated allows alternative pathways to compete with immediate ion pair collapse.

Mixed acetate sulfonate diesters are obtained from cyclic ethers. These have useful synthetic applications since the tosylate group is readily displaced by nucleophiles.

Acetylation Agent.

Acetyl *p*-toluenesulfonate is also used as a mild acetylation agent[2] for furans (eq 5), thiophenes (eq 6), and anisoles (eq 7). High yields (75-96%) are readily attained using a 10-50% excess of reagent under mild reaction conditions (25 °C to reflux, 2-24 h, in acetonitrile or benzene). Once again, no Lewis acids are necessary. Acetyl *p*-toluenesulfonate is also a highly reactive acetylation agent for anilines, alcohols, and phenols.

(5)

(6)

(7)

Related Reagents.

Acetyl Methanesulfonate; ***Boron Tribromide***; ***Iodotrimethylsilane***.

Acrolein

[107-02-8] · C_3H_4O · Acrolein · (MW 56.06)

(electrophile in 1,2- and 1,4-addition reactions; diene; dienophile)

Alternate Name: propenal.

Physical Data: mp -87 °C; bp 53 °C; *d* 0.839 g cm^{-3}; n_D 1.4017.

Solubility: sol water, alcohols, most organic solvents.

Form Supplied in: colorless liquid (stabilized with 0.1 wt % hydroquinone); widely available.

Purification: purified by fractional distillation under nitrogen, drying with anhydrous $CaSO_4$, and then distilling under vacuum, preferably in the dark. To avoid formation of diacryl, a small amount of catechol or hydroquinone should be placed in the receiver flask.

Handling, Storage, and Precautions: the liquid is flammable. Polymerization occurs in the presence of base or strong acids or upon exposure to light. Therefore it must be stored in the dark in the presence of 0.1 wt % catechol or hydroquinone. The liquid has a pungent odor and is highly toxic. Skin and mucous membranes become irritated upon exposure, while inhalation may cause lachrymation and an asthmatic reaction. Use in a fume hood.

Oxidations and Reductions.

Each functional group in acrolein can react selectively and in some cases both react. Acetal formation has been achieved using transacetalization conditions.[1] Oxidation with ***Hydrogen Peroxide*** in the presence of a catalytic amount of SeO_2 leads to acrylic acid.[2] while oxidation under controlled pH conditions gives glycidaldehyde in excellent yield.[3] Selective reduction of the alkene can be achieved with ***Octacarbonyldicobalt***/H_2[4] or via treatment with ***Triethylsilane*** in the presence of Wilkinson's catalyst (***Chlorotris(triphenylphosphine)rhodium(I)***) followed by hydrolysis of the silyl enol ether.[5a] Selective reduction using hydrogen and a Pd^{II}/ferrocenylamine sulfide catalyst has been described.[5b]

Addition Reactions.

Acrolein undergoes addition reactions at the carbonyl group (1,2-addition) and/or the electron deficient alkene (1,4-addition). The site of attack depends on the nucleophile and the reaction conditions. Under equilibrating conditions the 1,4-addition product is preferred.

The ratio of 1,2- to 1,4-addition of carbon nucleophiles to acrolein is strongly dependent on the nature of the organometallic species, especially on the polarity of the carbon-metal bond (eq 1). In general, the proportion of 1,2-addition product increases with more electropositive metal counterions. Moreover, due to the high reactivity of aldehydes, 1,2-addition often competes in processes where 1,4-addition is usually the favored pathway.

(1)

Organolithium reagents react with acrolein exclusively via 1,2-addition when the reaction is performed in THF at -78 °C.[6] Grignard reagents give mainly carbonyl addition products.[7] Organoberyllium, -zinc, and -cadmium also add exclusively to the carbonyl group,[8] as do organocerium and -titanium reagents.[9] Low enantioselectivity (24%) was observed in the addition of ***n-Butyllithium*** to acrolein in the presence of a chiral tetraamine ligand (DEB).[10]

Phosphonate anions react at the carbonyl group to yield substituted butadienes ultimately.[11]

Thiols undergo selective 1,4-addition to acrolein, whereas ***Triphenylphosphine*** induces polymerization.[12] Cyanide ion adds to acrolein but it is more efficient to react the α,β-unsaturated imine followed by hydrolysis.[13]

Stabilized carbanions, such as malonate and other active methylene compounds, undergo 1,4-addition (Michael reaction) to give 1,5-dicarbonyl compounds under mild conditions.[14] Phase transfer catalysts have been used to promote the reaction.[14c] When the reaction is carried out between unsaturated aldehydes and (3-ethoxycarbonyl-2-oxopropylidene)triphenylphosphorane, a 3 + 3 cyclohexenone annulation occurs to give cyclohexenones (eq 2).[15] The yield is modest for acrolein, but improves upon substitution at the α- or β-positions.

(2)

Substituents on the malonate can result in additional transformations of the Michael adducts. For example, if the nucleophile has a 2-substituent bearing a ketone, the intermediate aldehyde enolate closes onto the ketone providing a formylcyclopentene in 50% yield.[16] Reaction of bromomalonates with acrolein in the presence of NaOEt results in an efficient route to formylcyclopropanes. Similar products are formed in the reaction of a stabilized *S*-ylide with acrolein (eq 3).[17] Carbene addition to acrolein has also been achieved using nickel catalysts.[18]

(3)

A highly enantioselective rhodium catalyzed version of the Michael addition to acrolein has been recently developed.[19] The catalyst, prepared in situ from $RhH(CO)(PPh_3)_3$ and the chelating chiral diphosphine ligand TRAP (TRAP = 2,2´´-bis[1-(diphenylphosphino)ethyl]-1,1´´-biferrocene), provides high yields and good ee's using 1 mol % of rhodium (eq 4).

(4)

While scattered examples of 1,4-additions of nonstabilized carbanions have been described, the first systematic study of cuprate addition to enals was carried out by Normant.[20] Cuprates derived from organolithium reagents gave low yields,[21] whereas the best results were obtained using cuprates prepared from Grignard reagents. ***Chlorotrimethylsilane*** improved the 1,4-addition process (eq 5).[20]

(5)

Aryl halides react with acrolein in the presence of palladium catalysts to give aryl and diaryl derivatives via a mono or double Heck process respectively.[22]

Organoboranes undergo 1,2- or 1,4-addition to acrolein depending on the R group. Alkylboranes undergo 1,4-addition in a reaction which is catalyzed by the presence of water. There is considerable evidence for a radical chain

mechanism.[23] Allylboranes undergo selective 1,2-addition with a variety of aldehydes including acrolein. Chiral boranes (R^2 = Me, OMe, R^1 = H, Me) derived from α-pinene react to give the alcohols in up to 90% ee (eq 6).[24]

(6)

In contrast, allylic silanes undergo stereoselective 1,4-addition (Sakurai reaction), silyl migration, and ring closure in a novel cyclopentane annulation reaction (eq 7).[25]

(7)

Carbon radicals also add to electron deficient alkenes including acrolein.[26] A key feature of this reaction is the compatibility of several functional groups which would not be tolerated using carbanion chemistry. Furthermore, the reaction can be carried out in organic as well as aqueous media, depending on the mode of radical preparation. With 2-iodoethanol, a conjugate addition-cyclization sequence occurs providing six-membered lactols in good yield (eq 8).[27] It is noteworthy that no elimination of the β-oxygen occurs under these conditions.

(8)

Hydrogen Bromide adds efficiently to the alkene in acrolein.[28] Treatment of acrolein with HBr and ***1,3-Propanediol*** provides a route to γ-bromoacetals,[29a] which have been widely used as β-homoenolate equivalents. Thus γ-ketoaldehydes are prepared by a three-step procedure involving conversion of the bromide to the Grignard reagent, addition of an acid chloride, and hydrolysis of the acetal.[29b]

Aldol Condensation Reactions.

Reaction of the magnesium enolate of a thioamide with acrolein gives predominantly (73-89%) the *syn* aldol adduct.[30] Similar results were obtained with a ketone enolate, though little selectivity was noted for an enolate

derived from an α-alkoxypropionate.[31,32] Selectivities exceeding 50:1 were noted in the reaction of a lithium enolate of a chiral thioester.[33] Asymmetric aldol condensation using an enolate bearing the Evans chiral auxiliary has also been reported with acrolein to give a single diastereomer in high yield (eq 9).[30]

(9)

Pericyclic Reactions.

The ene reaction of (-)-β-pinene with acrolein was shown to proceed at 135 °C in 17 h to give 30% of the ene adduct (a formal conjugate addition).[34] However, Lewis acid catalysis allowed the reaction to be run at a much lower temperature.[35] Thus an alkylidenecycloalkane such as 1-methylene-2,6-dimethylcyclohexane reacts with acrolein in the presence of ***Dimethylaluminum Chloride*** at 0 °C, to provide a decalin system in 57% yield (eq 10). This annulation procedure is based on two sequential ene reactions in which acrolein serves as the double enophile partner.[36]

(10)

β-Alkylation of acrolein has been achieved by indirect multi-step methods. One approach uses a [3,3]-sigmatropic rearrangement of an allylic thionocarbamate as the key step.[37] For example, addition of *n*-BuLi to acrolein, followed by treatment with thiocarbamoyl chloride, provides 2-heptenal after sulfenylation and hydrolysis.

A second method is based on the umpolung strategy. An acetal of 3-phenylsulfonylpropanal, which can be prepared in three steps from acrolein and ***Thiophenol***, can be deprotonated, alkylated, and the acetal hydrolyzed to provide a β-sulfonylated aldehyde, which undergoes a retro-Michael addition to give the (*E*)-β-substituted acrolein.[12]

Cycloadditions.

Acrolein has been used as both a dienophile and a diene in Diels-Alder reactions as illustrated below. The dimer of acrolein is formed under thermal conditions providing a single regioisomer.[38] The dimer is a useful building block in organic synthesis.[38] Cycloaddition between acrolein and vinyl ethers typically requires heating in an autoclave at 160-

200 °C.[39] The reaction temperature can be reduced to 50 °C when mild Lewis acid catalysts such as $Yb(fod)_3$[40] are used, providing a powerful synthetic route to dihydropyrans.[41] The hetero Diels-Alder reaction very efficiently leads to spiroacetal compounds when the appropriate vinyl ether is used (eq 11).[42] Enamines[43] and ynamines[44] also react to yield amino-dihydropyrans and aminopyrans respectively. Both 5,6- and 5,5-spiroacetals can be obtained using acrolein as the diene component.

(11)

There are many examples in which acrolein is used as a dienophile.[45] Electron rich,[46] electron poor,[47] as well as a variety of substituted dienes react smoothly with acrolein at temperatures ranging from rt to 120 °C to yield substituted cyclohexene derivatives, often with complete regiocontrol.[48] Cyclohexadienes,[49] dimethylenehexahydropyrazines,[50] and various furans[51] provide rapid entry into bicyclo[2.2.2]octanes, octahydroquinoxalines, and oxabicyclo[2.2.1] compounds, respectively. While Diels-Alder cycloadditions of dienes with acrolein can be slow at elevated temperatures and atmospheric pressure, rates can be increased by factors of 10-1000 by application of higher pressures[52] or using a Lewis acid catalyst.[53] However, very mild Lewis acids are required since polymerization occurs readily with stronger Lewis acids.[54] The increase in reaction rates is accompanied by improved regioselection. Yb,[40] Fe,[54] W,[55] and Ru[56] based complexes are among the mildest catalysts reported to date (eq 12).

(12)

25 °C, no catalyst, 2700 h	70:30
25 °C, 2 mol% Ru catalyst, 5 h	99:1

There are a few reports of asymmetric cycloadditions with acrolein. A diastereomeric excess of 64% was obtained using an (*S*)-*O*-methylmandeloxy substituted diene.[57] Cycloadditions mediated by a chiral Lewis acid have also been described.[58] An 80% enantiomeric excess was observed in the cycloaddition between cyclohexadiene and acrolein catalyzed by a chiral (acyloxy)borane.

A cycloaddition between acrolein and a pyrilium ion was reported to be highly regioselective and moderately stereoselective, yielding an oxabicyclo[3.2.1]octene.[59]

Acrylic Acid

[79-10-7] · $C_3H_4O_2$ · Acrylic Acid · (MW 72.06)

(acylating agent, electrophile in 1,4-addition reactions, dienophile in Diels-Alder reactions)

Alternate Name: propenoic Acid.

Physical Data: mp -13 °C; bp 139 °C; *d* 1.051 g cm^{-3}; n_D 1.4224.

Solubility: miscible with water, alcohol, ether, acetone, and benzene.

Form Supplied in: colorless liquid (stabilized with 200 ppm hydroquinone monomethyl ether); widely available.

Purification: can be purified by steam distillation, or vacuum distillation through a column packed with copper gauze to inhibit polymerization (this treatment also removes inhibitors such as methylene blue that may be present). Azeotropic removal of the water with benzene converts wet acrylic acid into the anhydrous material.

Handling, Storage, and Precautions: polymerization occurs readily in the presence of oxygen. The liquid is toxic, corrosive, has an acrid odor, and fumes. Use in a fume hood.

Deuterated Acrylic Acid.

(*Z*)- and (*E*)-3-deuterioacrylic acids can be obtained from a stereospecific sodium amalgam reduction of the corresponding (*Z*)- and (*E*)-3-bromoacrylic acids in the presence of D_2O.[1]

Reactions of the Carboxylic Acid Group.

Conversion of acrylic acid to acryloyl chloride[2] and to the mixed anhydride using ***Acetic Anhydride*** have been achieved. Subsequent reaction with alcohols and amines gives esters and amides. Other mild reaction conditions to activate the carboxyl group are known.[4] For example, DCC/DMAP(cat)/alcohol[5] and DEAD/Ph_3P/alcohol systems[6]

have been used successfully. Using ***1,3-Dicyclohexylcarbodiimide***, the reactive intermediate rearranges to an amide in the absence of an external nucleophile.[7] Preparation of the amide by treatment with an in situ prepared phosphazo compound,[8] and amidation catalyzed by Ph_3SbO-P_4S_{10} in the presence of an amine,[9] are among the mildest methods available. The amide and ester adducts have frequently been used as dienophiles (achiral and chiral) in Diels-Alder reactions.[5-7] Synthesis of the analogous thiocarboxylic *S*-acid under mild conditions is best achieved using the Ph_3SbO-P_4S_{10} sulfuration system (eq 1).[10]

(1)

Reactions with the Double Bond.

Functional group transformations of the double bond have also been explored. Selective reduction of the double bond has been achieved in the presence of a variety of catalytic systems. Rh^{II}/H_2,[11] $Mo^0/PhSiH_3$,[12] and Pd^{II}/H_2[13] based systems give high yields and are extremely selective. Treatment of acrylic acid with hydrochloric acid gives 3-chloropropanoic acid,[14] while the Meerwein arylation with an arenediazonium ion yields the corresponding α-bromohydrocinnamic acid derivative.[15] Cyclopropanation using MeLi/LiBr and CH_2Cl_2 yields mixtures of halocyclopropyl ketones and alcohols in very good yield.[16] Regioselective hydrogermylation with trichlorogermane in concentrated hydrochloric acid provides exclusively 3-trichlorogermylpropanoic acid (eq 2).[17]

(2)

The preparation of succinic acid has been achieved from acrylic acid via a regioselective nickel catalyzed β-hydrocarboxylation.[18] Recently, methylmalonic acid was prepared via an α-hydrocarboxylation. Using a catalytic amount of ***Pentacarbonyliron*** in the presence of $Ca(OH)_2$/*i*-PrOH/H_2O, under a CO atmosphere, the diacid was obtained in good yield (eq 3).[19] Oxidation of the double bond to give glyceric acid has been achieved using permanganate oxidation.[20]

Cross Coupling Reactions.

Substituted acrylic acids are obtained via a palladium-catalyzed coupling of aryl or vinyl halides with acrylic acid (Heck reaction).[21] The reaction proceeds in organic[22] as well as aqueous[23] media (eq 4). Similar products are obtained when vinylmercury(II) chlorides are treated with acrylic acid in the presence of a stoichiometric amount of palladium (eq 5).[24]

Addition Reactions to the Double Bond.

Acrylic acid can serve as a Michael acceptor in its reactions with alcohols,[25] thiols,[26] sulfinates,[27] and phospines.[28] Addition of *p*-toluenesulfinate provides 3-(*p*-toluenesulfonyl)propanoic acid, which has been used as a β-acyl anion equivalent upon double deprotonation with ***n-Butyllithium*** at -78 °C.[27b]

The acidity of acrylic acid precludes various nucleophilic addition strategies due to protonation of the nucleophile. While dialkylcopper reagents (R_2CuLi) do not react with acrylic acids, $RCu.BF_3$ are known to add to substituted acid derivatives.[29] Acrylic acid also undergoes an ene reaction with ***Isobutene*** to yield the corresponding adduct in 51% yield.[30] The double bond in acrylic acid can also serve as a radical acceptor. Optically active alanyl radical reacts

with acrylic acid to yield aminoadipic acid with no racemization observed (eq 6).[31]

(6)

Diels-Alder Reaction.

Although acrylic acid has not been as widely used in Diels-Alder reactions as other simple dienophiles, a variety of dienes undergo cycloaddition with acrylic acid. Alkyl-,[32] silyl-,[33] and acetoxy-substituted[34] butadienes, various substituted furans,[35] cyclopentadienes,[36] cyclohexadienes,[37] anthracenes,[38] and pyridones[39] are among the dienes shown to react successfully with acrylic acid.[40] Cyclohexenes, (oxa) bicyclic compounds, and heterocyclic adducts are obtained. The *ortho* and *para* regioisomers usually predominate in reactions of acrylic acid with 1- and 2-substituted butadienes, respectively.[32,41] While the *endo* to *exo* selectivity may vary from poor to good (depending on the diene), repeated fractional recrystallizations of the carboxylic acid adducts often lead to pure products.[34a,35b] Generally, the reactions require stirring for several days at room temperature[35] or, when the product is thermally stable, heating at 100-160 °C for several hours in the presence of hydroquinone (a polymerization inhibitor). Catalysis using Cu^{I} has been reported, while attempted catalysis using Lewis acids such as iron(III) chloride, tin(IV) chloride, and zinc chloride resulted in polymerization.[35a] Recently, ***Diborane*** has been shown to catalyze cycloadditions of acrylic acid via acyloxyboranes.[34b,42] For example, addition of 10 mol% of the ***Borane-Tetrahydrofuran*** complex to the acrylic acid at 0 °C, followed by the diene at -78 °C, resulted in the fast formation of the Diels-Alder adduct. Precomplexation of the borane-THF complex with a monoacylated tartaric acid at 0 °C resulted in the formation of a chiral acyloxyborane, which mediated the reaction between acrylic acid and cyclopentadiene, to give the adduct with 78% enantiomeric excess (eq 7).

(7)

Dipolar cycloadditions with acrylic acid are known but not widely used in synthesis.[43]

Acrylonitrile

[107-13-1] · C_3H_3N · Acrylonitrile · (MW 53.06)

(electrophile in 1,4-addition reactions; radical acceptor; dienophile; acceptor in cycloaddition reactions)

Physical Data: mp -83 °C; bp 77 °C; *d* 0.806 g cm^{-3}; n_D 1.3911.

Solubility: miscible with most organic solvents; 7.3 g of acrylonitrile dissolves in 100 g of water at 20 °C.

Form Supplied in: colorless liquid (inhibited with 35-45 ppm hydroquinone monomethyl ether); widely available.

Purification: the stabilizer can be removed prior to use by passing the liquid through a column of activated alumina or by washing with a 1% aqueous solution of NaOH (if traces of water are allowed in the final product) followed by distillation. For dry acrylonitrile, the following procedure is recommended. Wash with dilute H_2SO_4 or H_3PO_4, then with dilute aqueous Na_2CO_3 and water. Dry over Na_2SO_4, $CaCl_2$, or by shaking with molecular sieves. Finally, fractional distillation under nitrogen (boiling fraction of 75-75.5 °C) provides acrylonitrile which can be stabilized by adding 10 ppm *t*-butyl catechol or hydroquinone monomethyl ether. Pure acrylonitrile is distilled as required.[1a]

Handling, Storage, and Precautions: explosive, flammable, and toxic liquid. May polymerize spontaneously, particularly in the absence of oxygen or on exposure to visible light, if no inhibitor is present. Polymerizes violently in the presence of concentrated alkali. Highly toxic through cyanide effect. Use in a fume hood.

Deuterioacrylonitrile.

Deuterium-labeled acrylonitrile can be obtained by reduction of propiolamide-d_3 with ***Lithium Aluminum Hydride***, followed by D_2O workup. The resulting acrylamide can then be dehydrated with P_2O_5.[1b]

Reactions of the Nitrile Group.

Various functional group transformations have been carried out on the nitrile group in acrylonitrile. Hydration with concentrated ***Sulfuric Acid*** at 100 °C yields acrylamide after neutralization.[2] Secondary and tertiary alcohols produce

N-substituted acrylamides under these conditions in excellent yield (Ritter reaction).[3] Heating in the presence of dilute sulfuric acid or with an aqueous basic solution yields acrylic acid.[4] Imido ethers have been prepared by reacting acrylonitrile with alcohols in the presence of anhydrous hydrogen halides.[5] Anhydrous ***Formaldehyde*** reacts with acrylonitrile in the presence of concentrated sulfuric acid to produce 1,3,5-triacrylylhexahydrotriazine.[6]

Reactions of the Alkene.

Reduction with hydrogen in the presence of Cu,[7] Rh,[8] Ni,[9] or Pd[10] yields propionitrile. Acrylonitrile can be halogenated at low temperature to produce 2,3-dihalopropionitriles. For example, reaction with ***Bromine*** leads to dibromopropionitrile in 65% yield.[11] Also, treatment of acrylonitrile with an aqueous solution of ***Hypochlorous Acid***, gives 2-chloro-3-hydroxypropionitrile in 60% yield.[12] α-Oximation of acrylonitrile has been achieved using Co^{II} catalysts, ***n-Butyl Nitrite*** and phenylsilane.[13]

Nucleophilic Additions.

A wide variety of nucleophiles react with acrylonitrile in 1,4-addition reactions. These Michael-type additions are often referred to as cyanoethylation reactions.[14] The following list illustrates the variety of substrates which will undergo cyanoethylation: ammonia, primary and secondary amines, hydroxylamine, enamines, amides, lactams, imides, hydrazine, water, various alcohols, phenols, oximes, sulfides, inorganic acids like HCN, HCl, HBr, chloroform, bromoform, aldehydes, and ketones bearing an α-hydrogen, malonic ester derivatives, and other diactivated methylene compounds.[15] Stabilized carbanions derived from ***Cyclopentadiene*** and fluorene and 1-5% of an alkaline catalyst also undergo cyanoethylation. The strongly basic quaternary ammonium hydroxides, such as ***Benzyltrimethylammonium Hydroxide*** (Triton B), are particularly effective at promoting cyanoethylation because of their solubility in organic media. Reaction temperatures vary from -20 °C for reactive substrates, to heating at 100 °C for more sluggish nucleophiles. The 1,4-addition of amines has recently been used in the synthesis of poly(propyleneimine) dendrimers.[16]

Phosphine nucleophiles have been reported to promote nucleophilic polymerization of acrylonitrile.[17]

Addition of organometallic reagents to acrylonitrile is less efficient than to conjugated enones. Grignard reagents react with acrylonitrile by 1,2-addition and, after hydrolysis, give α,β-unsaturated ketones.[18] Lithium dialkylcuprate (R_2CuLi) addition in the presence of ***Chlorotrimethylsilane*** leads to double addition at the alkene and nitrile, giving a dialkyl ketone.[19] Yields of only 23-46% are obtained in the conjugate addition of *n*-$BuCu.BF_3$ to acrylonitrile.[20] An enantioselective Michael reaction has been achieved with titanium enolates derived from *N*-propionyloxazolidone (eq 1).[21]

(1)

Acrylonitrile fails to react with trialkylboranes in the absence of oxygen or other radical initiators. However, secondary trialkylboranes transfer alkyl groups in good yield when oxygen is slowly bubbled through the reaction mixture.[22] Primary and secondary alkyl groups can be added in excellent yields using copper(I) methyltrialkylborates.[23] Reaction of acrylonitrile with an organotetracarbonylferrate in a conjugate fashion provides 4-oxonitriles in moderate (25%) yields.[24]

Transition Metal-Catalyzed Additions.

Palladium-catalyzed Heck arylation and alkenylation occurs readily with acrylonitrile (eq 2).[25] Double Heck arylation is observed in the Pd^{II}/montmorillonite-catalyzed reaction of aryl iodides with acrylonitrile.[26]

(2)

Pd^{II} catalyzed oxidation of the double bond in acrylonitrile in the presence of an alcohol (Wacker-type reaction) produces an acetal in high yield.[27] When an enantiomerically pure diol such as ***(2R,4R)-2,4-Pentanediol*** is used, the corresponding chiral cyclic acetal is produced (eq 3).[28]

(3)

Hydrosilation[29a] of acrylonitrile with $MeCl_2SiH$ catalyzed by nickel gives the α-silyl adduct. The β-silyl adduct is obtained when copper(I) oxide is used.[29b] The regioselectivity of the cobalt catalyzed hydrocarboxylation to give

either the 2- or 3-cyanopropionates can also be controlled by the choice of reaction conditions.[30] Hydroformylation of acrylonitrile has also been described.[31]

Cyclopropanation of the double bond has been achieved upon treatment with a Cu^{I} oxide/isocyanide or Cu^{0}/isocyanide complex. Although yields are low to moderate, functionalized cyclopropanes are obtained.[32,33] Photolysis of hydrazone derivatives of glucose in the presence of acrylonitrile provides the cyclopropanes in good yield, but with little stereoselectivity.[34] Chromium-based Fischer carbenes also react with electron deficient alkenes including acrylonitrile to give functionalized cyclopropanes (eq 4).[35]

(4)

Radical Additions.

Carbon-centered radicals add efficiently and regioselectively to the β-position of acrylonitrile, forming a new carbon-carbon bond.[36,37] Such radicals can be generated from an alkyl halide (using a catalytic amount of ***Tri-n-butylstannane***, alcohol (via the thiocarbonyl/Bu_3SnH), tertiary nitro compound (using Bu_3SnH), or an organomercurial (using $NaBH_4$). The stereochemistry of the reaction has been examined in cyclohexanes and cyclopentanes bearing an α-stereocenter.[36] Cr^{II} complexes, vitamin B_{12}, and a Zn/Cu couple have been shown to mediate the intermolecular addition of primary, secondary, and tertiary alkyl halides to acrylonitrile.[38] Acyl radicals derived from phenyl selenoesters and Bu_3SnH also give addition products with acrylonitrile (eq 5).[39]

(5)

Radical additions with acrylonitrile have been used to prepare *C*-glycosides[36,37b] and in annulation procedures.[37c] Acrylonitrile has also been used in a [3 + 2] annulation based on sequential radical additions (eq 6).[40]

(6)

Alkyl and acyl Co^{III} complexes add to acrylonitrile and then undergo β-elimination to give a product corresponding to vinylic C-H substitution.[41] This methodology is complementary to the Heck reaction of aryl and vinyl halides, which fails for alkyl and acyl compounds.[25]

Radicals other than those based on carbon also add to acrylonitrile. Heating acrylonitrile and tributyltin hydride in a 2:3 molar ratio in the presence of a catalytic amount of ***Azobisisobutyronitrile*** yields exclusively the β-stannylated adduct in excellent yield.[42] Hydrostannylation in the presence of a Pd^0 catalyst gives only the α-adduct (eq 7).[42c]

(7)

Treatment of ethyl propiolate with Bu_3SnH in the presence of acrylonitrile results in addition of a tin radical to the β-site of the alkyne followed by addition to acrylonitrile. Use of excess acrylonitrile results in trapping of the radical followed by an annulation reaction, providing trisubstituted cyclohexenes.[43]

Thioselenation of the alkene using ***Diphenyl Disulfide***, ***Diphenyl Diselenide***, and photolysis gives the α-seleno-β-sulfide in 75% yield by a radical addition mechanism.[44] Similarly, ***Tris(trimethylsilyl)silane*** adds to acrylonitrile at 80-90 °C using AIBN to give the β-silyl adduct in 85% yield.[45]

Pericyclic Reactions.

In the presence of a suitable alkene, the double bond in acrylonitrile undergoes a thermally induced ene reaction in low to moderate yield. For example, when (+)-limonene and acrylonitrile are heated in a sealed tube, the corresponding ene adduct is produced in 25% yield.[46]

The thermal [2 + 2] dimerization of acrylonitrile has been known for many years. Good regioselectivity is observed but the yield is low and a mixture of stereoisomers is produced.[47] *Cis*-1,2-dideuterioacrylonitrile was used in this reaction to study the stereochemical outcome of the cycloaddition. It was concluded that a diradical intermediate was involved.[1b]

Other [2 + 2] reactions have been reported. Regioselective cycloaddition between a silyl enol ether and acrylonitrile yields a cyclobutane in the presence of light and a triplet sensitizer.[48a] Reaction between acrylonitrile and a ketene silyl acetal in the presence of a Lewis acid gives either substituted cyclobutanes or γ-cyanoesters depending on the Lewis acid and solvent (eq 8).[48c]

(8)

Dihydropyridines undergo stereoselective cycloaddition with acrylonitrile under photolytic conditions.[48c] The combination of a Lewis acid (***Zinc Chloride***) and photolysis promotes cycloaddition between benzene and acrylonitrile.[48d] Allenyl sulfides undergo Lewis acid catalyzed [2 + 2] cycloaddition with electron deficient alkenes including acrylonitrile with good regioselectivity but little stereoselectivity (eq 9).[49]

(9)

Metal catalysts promote [3 + 2] cycloaddition reactions with acrylonitrile, leading to carbocyclic compounds. Reaction of acrylonitrile with a trimethylenemethane (TMM) precursor in the presence of Pd^0 provides an efficient route to methylenecyclopentanes in moderate yield (40%).[50] A similar yield is obtained when a Ni^0 or Pd^0 catalyzed cycloaddition is employed starting from methylenecyclopropane.[51] Moreover, a variety of substituted methylenecyclopropanes have also been used to furnish substituted methylenecyclopentanes (eq 10).[51b]

(10)

Five-membered heterocycles can be prepared from acrylonitrile by dipolar cycloadditions. Acrylonitrile undergoes efficient cycloaddition with 1,3-dipolar species[52] including nitrile oxides, nitrones, azomethine ylides, azides, and diazo compounds.[53] Cycloaddition of acrylonitrile with an oxopyrilium ylide generates stereoisomeric oxabicyclic compounds with excellent regioselectivity (eq 11).[54]

(11)

The dipolar cycloaddition of acrylonitrile with a hydroxypyridinium bromide is also highly regioselective.[55]

The [2 + 2 + 2] homo Diels-Alder cycloaddition between acrylonitrile and norbornadiene, substituted norbornadienes, or quadricyclane, has also been described under thermal and metal catalyzed conditions.[56] The effect of ligands and substituents on the stereo- and regioselectivity of the nickel catalyzed process has been investigated (eq 12).[56c,d]

(12)

Cobalt catalysts (***Octacarbonyldicobalt***) also promote the cycloaddition of 1,6-diynes with acrylonitrile, yielding cyclohexadienes which are readily aromatized.[57]

Diels-Alder reactions using acrylonitrile have been widely reported with many different dienes. These include alkyl, aryl, alkoxy, alkoxycarbonyl, amido, phenylseleno, phenylthio, and alkoxyboranato substituted butadienes.[58] Reactions between acrylonitrile and furans, thiophenes, and thiopyrans have been reported. In some instances, Lewis

acids accelerate the reaction.[59] Heterodienes including 2-azabutadienes and the 4-(oxa, aza, and thio) derivatives also undergo cycloaddition. Reactive dienes such as *o*-quinodimethanes,[60] benzofurans,[61] and dimethylbenzodioxanes react efficiently with acrylonitrile (eq 13).[62]

Allene

$CH_2=C=CH_2$

[463-49-0] · C_3H_4 · Allene · (MW 40.07)

(used in photochemical, thermal, and transition metal mediated cycloadditions; precursor of allenyl- and propargyllithium; electrophile with cuprates)

Alternate Name: 1,2-propadiene.

Physical Data: mp -136 °C; bp -34 °C; flammable gas.

Solubility: insol H_2O; sol THF, pet ether, benzene.

Form Supplied in: gas (lecture bottle); widely available.

Preparative Method: reaction of ***2,3-Dichloropropene*** with ***Zinc*** in ethanol.[1]

Handling, Storage, and Precautions: flammable gas; handle in a fume hood.

Metalated Allenes.

Allene can be metalated at -70 °C to produce allenyllithium which reacts with alkyl halides to give high yields of terminal allenes (eq 1).[2,3] Generally less than 5% of the alkyne is obtained. The dianion of allene can also be prepared and treated with electrophiles such as alkyl halides and carbonyl compounds (eqs 2 and 3).[4-7] The regiochemistry of the alkylation is dependent on the choice of solvent: more coordinating solvents and solvent combinations typically provide the allene products[6] while less polar solvents produce the substituted alkynes.[4] The intermediate acetylides can be exposed to an additional electrophile to allow the formation of two new carbon-carbon bonds.[3,7]

Photochemical Cycloadditions.

Allene has been used extensively in intermolecular [2 + 2] photocycloaddition reactions.[8] Cyclohexenones (eq 4),[9] cyclopentenones (eq 5),[10] and functionalized enones (eq 6)[11] undergo cycloaddition with allene with excellent and predictable regioselectivity and in uniformly high yields. The stereochemistry of cycloaddition of allene to 4-substituted cyclohexenones has been interpreted by attack of allene on the enone excited state which is substantially pyramidalized at the β-carbon (eq 7).[12,13]

(4)

-78 °C 100% 100:0
25 °C 4:1

(5)

(6)

(7)

13:1

Thermal Cycloadditions.

Allene undergoes various thermal cycloadditions including thermal [2 + 2] cycloadditions (eq 8),[14] Diels-Alder reactions (eq 9),[15,16] and nitrone cycloadditions.[17]

(8)

(9)

Organometallic Catalyzed Reactions.

Allene reacts readily with ***Palladium(II) Chloride*** to form a π-allyl complex[18] and many palladium catalyzed transformations of allene have been reported. Carbopalladation reactions provide ready access to 2-substituted 1,3-dienes (eq 10),[19] bis-stannylation (eq 11) produces high yields of the vinylallylstannanes,[20] and the analogous reaction with bis-silanes has been reported.[21] Substituted acrylates and butenoates are available from the palladium catalyzed carbonylation of allene (eq 12).[22]

Nickel(II) catalysis has been utilized to prepare 4-methyl-4-pentenoic acid from allene[23] and substituted allenes have been prepared from ketones by treatment with a titanacyclobutane (eq 13).[24]

Isopropenyl Stannanes, Silanes, and Germanes.

The reaction of allene with stannyl and silyl cuprates gives isopropenylsilanes[25] and -stannanes[26] (eqs 14 and 15) in excellent yield. Triphenylisopropenylgermane can be prepared from allene and triphenylgermane in the presence of ***Triethylborane***.[27] In addition, haloboration of allene with boron tribromide and anisole produces a 2-bromoallylboronate (eq 16),[28] and electrophilic addition of phenylselenium bromide to allene provides 2-phenylselenoallyl bromide (eq 17).[29]

Allenylboronic Acid

[83816-41-5] · $C_3H_5BO_2$ · Allenylboronic Acid · (MW 83.88)

(propargylating reagent for carbonyl groups; chiral allenylboronic ester as a reagent for enantioselective alkylation;[1] 1,3-asymmetric induction in propargylation of β-hydroxy ketones[2])

Physical Data: mp 150 °C (dec).

Solubility: sol ether, alcohol.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$-Me_2SO-d_6) δ 4.48 (d, *J* = 5.8 Hz, 1H), 4.51 (d, *J* = 7.2 Hz, 1H), 4.83 (dd, *J* = 5.8 and 7.2 Hz, 1H), 6.52 (br s, 2H).

Preparative Method: from ***Propargylmagnesium Bromide*** and ***Trimethyl Borate***.[1]

Handling, Storage, and Precautions: allenylboronic acid can be stored at -20 °C under argon. In air, it catches fire within several minutes. It should only be used in a fume hood.

Allenylboronic Acid.[1]

Treatment of propargylmagnesium bromide with trimethyl borate followed by acidic workup gives, after recrystallization from hexane-ether, a single crystalline boronic acid in 40-60% yield (eq 1).[3] As far as can be described, a single compound results from this preparation.

Allenylboronic acid is an ambident nucleophile and its reactions with carbonyl compounds can be envisioned to occur either at the α or γ position. Treatment of cyclohexanecarbaldehyde with allenylboronic acid in toluene containing 4 equiv. of pentanol and molecular sieves produces exclusively the homopropargylic alcohol (**1**) in 40% yield. This result suggests that the reaction proceeds through the cyclic transition state (**2**).

(1)

(2)

Chiral Allenylboronic Esters.[1]

Condensations of aldehydes with chiral allenylboronic esters provide β-alkynic alcohols with an exceptionally high degree of enantioselectivity (eq 2). The reagents prepared using bulky tartrate esters like 2,4-dimethyl-3-pentyl as the chiral auxiliary are more enantioselective than reagents prepared from ethyl or isopropyl esters of tartaric acid. These results have been rationalized by the transition state shown in structure (**4**), in which the ester alkoxy group exerts a screening influence on the prochiral carbonyl compound such that R´ is positioned as far away from CO_2R as possible.

(3)

R′ = cyclohexyl	R = Et	91% ee
	i-Pr	92% ee
	2,4-dimethyl-3-pentyl	98% ee

(4)

Condensation with aromatic aldehydes appears to be considerably less efficient than the reaction with saturated aldehydes. In addition, only low yields (<50%) of the homopropargylic alcohol are obtained by the reaction with a variety of unsaturated aldehydes with this reagent, indicating that the use of saturated aldehyde is crucial to the success of the asymmetric propargylation reaction. Additional results are summarized in Table 1. This method has been applied to the synthesis of (-)-ipsenol, as summarized in eq 3.[1b,4]

Table 1 Asymmetric Condensation of Allenyl Reagents (**3**) (R = 2,4-dimethyl-3-pentyl)

Aldehyde (equiv.)	Yield (%)	% ee
Hexanal (1.5)	81	94
Hexanal (5.0)	72	97
Cyclohexanecarbaldehyde (1.5)	88	98
Cyclohexanecarbaldehyde (3.0)	89	>99
Isovaleraldehyde (1.5)	78	99
Isovaleraldehyde (3.0)	74	>99
(*S*)-Citronellal (1.5)	74	92
(*S*)-Citronellal (5.0)	90	99
(*R*)-Citronellal (1.5)	67	98

1,3-Asymmetric Induction.[2]

The reaction of allenylboronic acid with carbonyl compounds is slow relative to the reaction of allenylboronic esters.[1] However, the reaction of allenylboronic acid (1.2 equiv.) with β-hydroxy ketones in anhydrous ether at rt in the presence of molecular sieves (5Å for 20 h), followed by treatment with basic ***Hydrogen Peroxide***, yields the *threo* diol (**10**) with excellent levels of 1,3-asymmetric induction (>99%, eq 4). Additional results are summarized in eqs 5-7. The yields in all cases are >90%. The reaction of propargylmagnesium bromide with (**9**) in ether affords a mixture of the *threo* and *erythro* diols, in agreement with related nonselective processes.[5]

(4)

(9) **(10)**

(5)

(6)

(7)

The very high levels of stereoselectivity observed in these reactions strongly suggest the existence of the covalently bonded organometallic (**11**) as a reactive intermediate (eq 8). Indeed, treatment of a mixture of cyclohexanone and *s*-phenethyl

alcohol with allenylboronic acid gave none of the expected homopropargylic alcohol under the above reaction conditions. Furthermore, treatment of a mixture of the ketone (**9**; R = cyclohexyl) and 2-hexanone with allenylboronic acid produced the diol (**10**) as a sole product.

(8)

(11)

Treatment of *threo* diols (**10**) with ***Ruthenium(III) Chloride-Sodium Periodate***[6] gave the corresponding lactones in excellent yield (eqs 5-7).

The use of this method for the preparation of a diastereomer of the β-hydroxy-δ-lactone substituent of the HMG CoA reductase inhibitor mevinolin[7,8] is summarized in eq 9. Unfortunately, however, the product has the (4*S*,6*R*) configuration rather than the most active (4*R*,6*R*) configuration.[7]

Allenyl Chloromethyl Sulfone

[126696-78-4] · $C_4H_5ClO_2S$ · Allenyl Chloromethyl Sulfone · (MW 152.60)

(dienophile whose Diels-Alder adducts give 1,3-dienes with base, thus allowing two-step cyclohomologation of dienes[1])

Physical Data: mp 39-39.5 °C.

Solubility: sol common organic solvents.

Form Supplied in: colorless solid; not commercially available.

Preparative Methods: the reagent is prepared by addition of chloromethylsulfenyl chloride, $ClCH_2SCl$, to ***Propargyl Alcohol*** to give *S*-chloromethylpropargyl sulfenate, $ClCH_2SOCH_2C$&tbond;CH, which via 2,3-sigmatropic rearrangement gives allenyl chloromethyl sulfoxide, $ClCH_2SOCH{=}C{=}CH_2$, which eventually, on oxidation, gives the title reagent (47%).[1]

Handling, Storage, and Precautions: potential alkylating agent; use in fume hood.

Cycloadditions.

Allenyl chloromethyl sulfone is a potent dienophile whose Diels-Alder adducts give 1,3-dienes with bases via the Ramberg-Bäcklund rearrangement, thus allowing two-step cyclohomologation of dienes. Other examples of this class of reagents include chloromethyl tetradeca-1,2-dienyl sulfone [$Me(CH_2)_{10}CH{=}C{=}CHSO_2CH_2Cl$] and chloromethyl 3-methylbuta-1,2-dienyl sulfone [$Me_2C{=}C{=}CHSO_2CH_2Cl$]. As shown in eq 1, allenyl chloromethyl sulfone functions as a synthetic equivalent of 1,2,3-butatriene in Diels-Alder reactions. The synthetic sequence can be used iteratively as shown in eq 2.

It is notable that chloromethylsulfenyl chloride, used in the synthesis of the title reagent (as well as other halomethylsulfenyl bromides), is a versatile reagent for the synthesis of conjugated polyenes, enones, and 1,3-oxathiole 1,1-dioxides.[2]

Allenyllithium

$CH_2=C=CHLi$

[51760-92-0] · C_3H_3Li · Allenyllithium · (MW 45.99)

(allows the preparation of functionalized monosubstituted allenes[1-3] and conjugated allenic ketones;[4] adds regioselectively to vinyl epoxides[5,6])

Physical Data: ^{13}C NMR solution data in THF[7] have been reported. Allenyllithium solutions show a strong IR absorption[8] at 1885 cm^{-1}.

Solubility: at -60 °C, allenyllithium is slightly sol THF-hexane (1:1) but sol ether-THF.[9]

Form Supplied in: prepared in situ and used directly.

Preparative Methods: in situ under nitrogen by reaction of ***n-Butyllithium*** in hexane with ***Allene*** in THF at -65 °C for 10 min,[8-10] or from ***Bromoallene*** by metal-halogen exchange.[10]

Handling, Storage, and Precautions: solutions are unstable and should be kept below -60 °C.[3b]

This reagent adds to a variety of electrophiles to give allenic and/or alkynic compounds depending on both the substrate and the solvent used.

Addition to Halides.

In THF solution, allenyllithium reacts readily with alkyl halides[10] at low temperature to afford mainly monosubstituted allenes along with some alkynic compounds (easily removed by $AgNO_3$ treatment). Addition of 1 equiv. of ***Hexamethylphosphoric Triamide*** suppresses the formation of alkynes.[1,11] Alkylation with functionalized halides has been studied.[2,3] Addition to 1-iodo-2-trimethylsilylethane leads to β-allenylsilane in good yield (eq 1).[2] γ-Chloroallene is easily accessible by alkylation with 1-bromo-3-chloropropane (eq 2).[3]

Condensation of the reagent with ***Chlorotrimethylsilane*** leads to a mixture of silylated allene and alkyne (eq 3).[8,12]

Addition to Carbonyl Compounds.

Cyclopentanone reacts with allenyllithium to afford a 1:1 mixture of α-allenic and β-alkynic alcohols (eq 4).[13] On the other hand, benzophenone gives exclusively homopropargyl alcohol (eq 5).[8] Pure allenic acid is obtained by addition to carbon dioxide (eq 6).[14]

(6)

Addition to Epoxides.

Ethylene Oxide reacts with allenyllithium to afford an equal mixture of β-allenic and γ-alkynic alcohols (eq 7).[15] In the presence of HMPA, ***1,3-Butadiene Monoxide*** reacts with allenyllithium to give β-allenic α´-alkenic alcohols (eq 8).[5] On the other hand, cyclic vinyl epoxides suffer ring opening by means of the S_N2' mechanism in the presence of CuBr.Me_2S (see ***Copper(I) Bromide***) (eq 9).

(7)

(8)

(9)

Addition to Amides.

Reaction with *N*,*N*-dimethylamides at -78 °C affords pure conjugated allenic ketones (eq 10).[4]

(10)

Substituted Allenyllithiums.

Numerous substituted allenyllithium reagents have been prepared.[3b,12] Methylacetylenes with diverse substituents can be metalated at the methyl group to produce 1-substituted allenyllithiums (**1**) (eq 11), e.g. R = Me,[16] *n*-Pr,[17] *i*-Pr,[18] *n*-Bu,[18] *t*-Bu,[18] Et_2N,[19] PhS,[20] R_3Si.[21] Metalation also works well on propargyl ethers,[22] sulfides,[22] selenides,[23] and amines[22] of the type R-C&tbond;C-CH_2X. In addition, most mono-, di-, and trisubstituted allenes can be metalated.[13] An informative study of regiochemistry in allenyllithium reactions has been carried out using 3,3-dimethylallenyllithium.[24]

(11)

(1)

Related Reagents.

Allenylboronic Acid; ***1,3-Dilithiopropyne***; ***3-Lithio-1-triisopropylsilyl-1-propyne***; ***1-Methoxyallenyllithium***; ***Propargylmagnesium Bromide***.

Allylamine

[107-11-9] · C_3H_7N · Allylamine · (MW 57.11)

(used in synthesis of secondary or tertiary allylamines and -amides and heterocyclic compounds[1])

Alternate Name: 2-propen-1-amine.

Physical Data: bp 56.6 °C/756 mmHg; *d* 0.762 g cm^{-3}; mp -88 °C; fp -28 °C;*n* 20D 1.4205; dipole moment 1.31 D (benzene; 25 °C); pK_a 9.49 (H_2O; 25 °C).

Solubility: miscible with water, alcohol, ether, chloroform.

Form Supplied in: colorless liquid, commercially available.

Handling, Storage, and Precautions: corrosive. Highly toxic. Lachrymator. Use only in a chemical fume hood. Use chemical resistant gloves, safety goggles. Do not breathe vapor. Avoid contact with eyes, skin, and clothing. Wash thoroughly after handling. Keep tightly closed. Store in a cool dry place. Extremely flammable.

Allylamine acts as a typical amine towards acylating and alkylating agents and in the formation of imines with aldehydes and ketones. The double bond is also unremarkable in its chemical behavior.

N-Acylation.

Acylations of the amino function can be performed with the usual reagents, such as acid anhydrides,[2] acid chlorides,[3] enol esters,[4] lactones,[5] and carboxylic acids in the presence of molecular sieves[6] or other activating agents (e.g. eq 1).[7] *N*-Allylcarbamates are obtained upon acylation of allylamine with reagents like ***Benzyl Chloroformate*** or ***Di-t-butyl Dicarbonate*** in the presence of base.[8] Another route to carbamates consists of saturation of an allylamine solution with carbon dioxide and reaction of the ionic carbamate thus obtained with ***Benzyl Chloride*** or dimethyl carbonate (eq 2).[9] Iodolactonization of the ionic carbamates leads to oxazolidinones (eq 3).[10] Diacylations of allylamine to *N*-allylimides are known;[2a] an interesting application is the facile preparation of 1,4-disubstituted piperazine-2,4-diones with iminodiacetic acid derivatives (eq 4).[11]

N-Alkylation.

Allylamine can be converted under mild conditions into secondary amines with functionalized alkyl chlorides, bromides, and tosylates.[12] Alkylations through conjugate addition to α,β-unsaturated nitriles[13] and α,β-unsaturated ketones are known (eq 5).[14]

In connection with the search for efficient routes to β-lactam antibiotics, *N*-allylazetidines have been prepared by dialkylation of allylamine. Thus *t*-butyl 2,4-dibromobutyrate led to the azetidine derivative in moderate yield (eq 6).[15] Allylamine attacks the readily available (*R**,*R**)-bromobenzyloxirane (**1**) at the less substituted oxirane carbon and then at the benzylic bromide to give the *trans*-azetidine derivative in reasonable yield (eq 7).[16]

Imine Formation.

Reaction of allylamine with aldehydes[17] (eq 8)[17a] and ketones[18] gives rise to imines. Addition of Lewis acids or molecular sieves may be necessary (eq 9).[18b] Reductive aminations of ketones with allylamine can be performed in the presence of reducing agents like zinc-modified cyanoborohydride (eq 10).[19]

(9)

X = H, Me, F, Cl

R^1 = Me, R^2 = H; R^1 = R^2 = Me; R^1, R^2 = $(CH_2)_{2-4}$

(10)

An important route to β-lactam antibiotics proceeds via condensation of imines with ester enolates to form the β-lactam ring. Allylimines are used in this condensation because the *N*-allyl protecting group from β-lactams can be easily removed by standard methods, thus providing access to β-lactams with a variety of other *N*-substituents. In a highly interesting example of this condensation, the chiral (*S*,*S*)-diazaborolidine (**2**) is used in the asymmetric synthesis of β-lactams from achiral esters and allylimines. Reaction of the (*Z*)-boron enolate, prepared from *S*-*t*-butyl thiopropionate with triethylamine, with *N*-allylimines derived from various aldehydes at -78 °C proceeds with high diastereoselectivity and high enantioselectivity to afford the β-amino acid esters. Treatment of these esters with ***t*-Butylmagnesium Chloride** results in ring closure to the *trans*-substituted β-lactam derivatives (eq 11).[20] In another approach to β-lactams, the allylimines are treated with DBU to afford 2-aza-1,3-dienes which react with acid chlorides to provide the *cis*-substituted β-lactams (eq 12).[21]

Reactions at the C=C-Bond.

The double bond shows the usual reactions, such as addition of bromine[22] or hydrogen halides,[23] Friedel-Crafts reaction (eq 13),[24] Diels-Alder reaction (eq 14),[25] or Pd-catalyzed cyclopropanation with ***Diazomethane*** (eq 15).[26]

B-Allyl-9-borabicyclo[3.3.1]nonane

[53317-08-1] · $C_{11}H_{19}B$ · *B*-Allyl-9-borabicyclo[3.3.1]nonane · (MW 162.07)

(allylating reagent for aldehydes, ketones, acid chlorides, amides, and acid anhydrides;[2] reagent for diastereo- and enantioselective allylation of aldimines;[6,8] diastereoselective allylation of acetals[9])

Alternate Name: allyl-9-BBN.

Physical Data: bp 41.5-42 °C/0.05 mmHg.

Solubility: sol most organic solvents.

Preparative Methods: prepared from ***Allyl Bromide*** and *B*-methoxy-9-BBN according to a literature procedure.[1] Crotyl-9-BBN and 2-methallyl-9-BBN are similarly prepared from the corresponding allylic bromides.

Handling, Storage, and Precautions: the neat liquid is highly flammable and must be stored in the absence of air and moisture. Allyl-9-BBN may be kept as a CH_2Cl_2 or THF solution under N_2 atmosphere.[2] Use in a fume hood.

Allylation of Carbonyl Compounds.[2]

The reaction of allyl-9-BBN with carbonyl compounds occurs cleanly with the allyl group undergoing transfer to the carbonyl carbon and the boron group to the carbonyl oxygen. Aldehydes and ketones react in a 1:1 stoichiometry, while acid chlorides, esters, and *N*,*N*-dimethylamides react with 2 equiv of the allylborane, and acid anhydrides utilize 4 equiv. Simple protonolysis of the boronic esters thus formed, either with water or ***Ethanolamine***, affords excellent yields of the corresponding homoallylic alcohols.[2] The allylation of chiral aldehydes with allyl-9-BBN normally produces low diastereoselectivity via nonchelated Cram transition states.[3] The Cram/anti-Cram stereoselectivity in the allylation of (**1**)-(**3**)[3] and (**4**)[4] is 1:1-1.3:1, with only a slight preference for the *syn* diastereomers.

(1)

(2)

(3)

(4)

Allylation of Imines.

In contrast to the reactions with chiral aldehydes, the reactions with certain aldimines are highly or completely *syn* selective (eq 1).[5,6] The aldimine having a chiral center at the α-position of the nitrogen substituent affords the Cram product (*syn* isomer) with high diastereoselectivity upon treatment with allyl-9-BBN (eq 2).[5,6] The chiral α-imino ester, prepared from *n*-butyl glyoxylate and (*S*)-phenethylamine, reacts with allyl-9-BBN to give the allylation product with 92% de in 92% yield, which is hydrogenated to the butyl ester of L-norvaline.[6,7]

(1)

R = *n*-Pr	96:4
i-Pr	100:0

Aldimines derived from (**2**) gave the nonchelation product either exclusively or predominantly, regardless of the substituents at nitrogen (eq 3).[8] On the other hand, the aldimine derived from (**3**) afforded the nonchelation adduct with good diastereoselectivity only when the (*R*)-phenethylamine group was used as an amine (eq 4).[8]

R = (*S*)-CH(Me)Ph	3 : 97
i-Pr	0 : >99
(*R*)-CH(Me)Ph	0 : >99

Allylation of Acetals.

Treatment of the chiral steroidal acetal (*S*,*R*,*R*) isomer, prepared from the steroidal aldehyde and (2*R*,4*R*)-(-)-pentanediol, with allyl-9-BBN in the presence of ***Titanium(IV) Chloride*** followed by the usual workup gave the (*S*,*S*) isomer exclusively (eq 5).[9] On the other hand, the reaction of the (*S*,*S*,*S*) acetal isomer, prepared from the steroid aldehyde and (2*S*,4*S*)-(+)-pentanediol, with allyl-9-BBN produced an 88:12 mixture of the (*S*,*S*) and (*S*,*R*) isomers, suggesting that the 1,2-asymmetric induction is primarily controlled by the Cram rule rather than the chiral acetal template.

The $TiCl_4$-mediated reaction of the chiral acetal (*S*,*R*,*R*) isomer, prepared from (3*S*)-3-*t*-butyldimethylsiloxybutanol and (2*R*,4*R*)-(-)-pentanediol, with allyl-9-BBN gave the corresponding homoallyl alcohol in 90% yield with predominant formation (90:10) of the chelation product,[10] indicating that the 1,3-asymmetric induction is dictated by chelation rather than the acetal template.

Allyl Bromide

[106-95-6] · C_3H_5Br · Allyl Bromide · (MW 120.99)

(electrophilic allylating agent attacking C, N, O, S, Se, and Te nucleophiles; homoallylic alcohols obtained selectively from aldehydes by various organometallic intermediates; addition reactions provide further reagents of wide applicability)

Physical Data: mp -119.4 °C; bp 71.3 °C; *d* 1.398 g cm^{-3}.

Solubility: miscible with organic solvents; sparingly sol H_2O.

Form Supplied in: yellow to brown liquid.

Purification: wash with water and with aqueous $NaHCO_3$. Dry ($MgSO_4$ or Na_2SO_4) and fractionally distill.

Handling, Storage, and Precautions: highly toxic; cancer suspect agent. Protect from light in brown glass.

Allylating Agent.

Carbon alkylation generally requires nucleophilic carbanions; thus the allylation of PhC&tbond;CH is promoted with powdered ***Potassium Hydroxide*** alone or with ***Tetra-n-butylammonium Bromide*** in dioxane.[1] Dimeric side products (allyl ether, Ph_2C_4) and rearrangement enynes (PhC&tbond;CCH=CHMe; *E/Z*, 3:1) accompany PhC&tbond;$CCH_2CH=CH_2$. Carbanions from acetoacetic esters,[2a,2b] ketones,[2c] malonates (K_2CO_3-Me_2CO or PhH),[3] acetonitrile,[4a] and cyanoacetates[4b] readily undergo allylation (eq 1); the necessary base may be generated electrochemically, as in the use of pyrrolidone anion to bring about allylation of dimethyl 2-(trifluoromethyl)malonate.[5] Perfluoro-2-methyl-2-pentyl carbanion is generated by the addition of F^- (KF or CsF) to $(CF_3)_2CFCF=CFCF_3$; upon allylation (RX; X = Cl, Br, I) the rearranged product $(CF_3)_2C(R)CF_2CF_2CF_3$ results.[6] Mn enolates of dialkyl ketones may be allylated (RBr; THF-sulfolane); thus Pr_2CO gives PrCOCH(R)Et in 98% yield.[7]

$$\text{X-CH}_2\text{-Y} + [\text{X-CH-Y}]^- \xrightarrow{\text{RBr}} \text{X-CHR-Y} \qquad (1)$$

$$\text{X, Y} = \text{R'CO, CO}_2\text{R', CN, H}$$

The homoallylic alcohols $RCH(OH)CH_2CH{=}CH_2$ are formed from the reaction of RCHO and allyl bromide through organometallic intermediates, especially those involving allyl magnesium bromide. Ketones react similarly, but more slowly. The conventional Barbier-Grignard processes have been replaced by a reductive allylation. Thus Al brings about the reaction (i) in the presence of catalytic amounts of $PbBr_2$ in DMF, aq THF, and/or aq MeOH[8a] or (ii) in the presence of $BiCl_3$ in aq THF.[8b] The process may be specific to aldehydes; Pb-Me_3SiCl-Bu_4NBr in DMF promotes allylation of aldehydes without significantly attacking ketones or α-hydroxycarboxylic esters, while esters, lactones, acid anhydrides, and acid chlorides are effectively inert.[9] Correspondingly, homoallylic alcohols are formed from aldehydes and allyl chloride, bromide, or iodide using Zn-$BiCl_3$ or Fe-$BiCl_3$, but ketones, esters, and benzoic acid are unaffected and do not interfere.[10] Fe or Al with $SbCl_3$ in aq DMF behaves similarly.[11] Electrochemical variants are reported in which Bi acts as the reductant towards the aldehyde.[12] Aldehydes and ketones react in the presence of Ph_3Bi to give homoallylic alcohols or their allylic ethers.[13] Zn alone in DMF gives 86% yields with allyl bromide and MeCH=CHCHO;[14a] Cd in DMF similarly shows only 1,2-addition with RCHO or RCOR´ (eq 2).[14b] A complex involving Ph_2CO and Yb provides Ph_2RCOH (R = allyl) with allyl bromide.[15]

(2)

R = H, alkyl; M = Zn, Cd, Al etc.

Asymmetric allylation occurs in a number of appropriately substituted systems. The Schiff base between (+)-camphor and $H_2NCHR´P(O)(OEt)_2$ is metalated (***n-Butyllithium***) and then reacts with allyl bromide to give the (1*S*,4*S*) analog (R = allyl) with >95% diastereomeric excess (eq 3). Sequential hydrolysis provides the (*S*)-ester and the (*S*)-phosphonic acid without appreciable racemization;[16a] (1*R*,2*R*,5*R*)-(+)- and (1*S*,2*S*,5*S*)-(-)-2-hydroxy-3-pinanone behave analogously.[16b] The bis(cyclohexylidene) acetal of D-galactodialdehyde similarly gives Schiff bases with α-alkylated glycine esters; these may be metalated (BuLi) and the anion quenched with allyl bromide with 76% diastereomeric excess.[17] ***Lithium Diisopropylamide*** metalation of a chiral lactam enolate and allylation s imilarly provides a considerable diastereomeric enhancement.[18] Formation of the enol from tetralone with (*R*)-$RCH_2CHPhN(CH_2CH_2OCH_2$-$CH_2OMe)Li$ (R = piperidino) and allylation provides (*R*)-2-allyl-1-tetralone in 92% enantiomeric excess and 89% overall yield; ***Lithium Bromide*** is a necessary co-reagent (eq 4).[19]

(3)

(4)

Similarly, allylation of the lactam by allyl bromide-LDA[20] proceeds stereospecifically to give (**1**).

(1)

Allylation of Ni complexes of some Schiff bases with glycine are reported[21] to yield *S*-α-allylglycine. A three-step synthesis of α-amino acid HCl salts relies upon diastereoselective allylation of a glycine enolate synthon with >97.6% de and in 73-90% yield.[22] *N*,*N*-Dimethylhydrazones of α,β-unsaturated aldehydes[23a] and $RCH_2CH{=}CHCH{=}CHCHO$[23b] metalate (BuLi) and allylate with rearrangement, giving $RCH(R')(CH{=}CH)_nCHO$ analogs (R´ = allyl; *n* = 1 or 2). $Ph_2C{=}NCH_2CO_2$-*t*-Bu undergoes allylation (RBr, 50% aq NaOH, CH_2Cl_2, rt) in the presence of chiral PTC based upon cinchonine; the products show considerable ee (50-60%).[24]

Carbonyl insertion occurs when Me_3P-coordinated π-allyl Pd complexes are treated with CO in CH_2Cl_2 at rt, giving 3-butenoyl derivatives,[25] and allylation of a vinyl rhenium CO complex provides an allyl vinyl ketone complex.[26] Organotin species couple with allyl bromide (catalyzed by Pd complexes); while β-elimination may supervene, CHO, CO_2H, and OH groups do not interfere.[27a] Similar coupling occurs with $RSiMe_3$ or $RSiMe_2F$ and allyl bromide,[27b] but alkenylboranes in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** give alkenes by allyldeboronation.[27c] ***Tetracarbonylnickel*** with allyl bromide (RBr) gives π-allyl nickel bromide complexes. These can act as intermediates in the coupling of allylic systems either symmetrically[28a] or to give substituted alkenes by unsymmetrical coupling (eq 5).[28b]

(5)

π-Allyl nickel bromide complexes allylate C-2 of benzoquinones.[28c] Oxygen-centered attack occurs readily; the K salt of L-ascorbic acid (**2**) gives (allyl bromide-Me_2CO) a lactone (**3**) which with ***Palladium(II) Chloride*** in aq DMF provides (40%) a bicyclic ketone in which the allylic side chain has become the acetonyl ($MeCOCH_2$) residue (eq 6).[29]

(6)

Stannylation of monoalkylated oxiranes by ***Trimethylstannyllithium*** gives lithium alkoxides $XOCH(R)CH_2SnMe_3$ (X = Li) which react conventionally with allyl bromide to give the corresponding allyl ether (X = allyl).[30] Attack at oxygen may also be achieved using other displaced groups. Stannylene acetals of acyclic diols are monoallylated using F^- in a mild, selective, and high yield process.[31]

N-Allylation takes place easily; phthalimide reacts readily with allyl bromide (K_2CO_3-PEG 400; 90 °C).[32] Indoles[33a] and pyrazoles[33b] may be allylated on nitrogen using PTC such as Bu_4NBr (eq 7).

(X = N, CH) (7)

Salts such as Na phenylsulfinate form allyl esters; Al_2O_3, ultrasound, and microwaves all influence the yield.[34] Correspondingly, sulfur,[35,36] selenium,[36] or tellurium[37] attack is preparatively useful (eq 8).

$$RBr + R'X^- \longrightarrow R'XR + Br^- \quad (X = O, S, Se, Te) \quad (8)$$

Alkyl coupling reactions, mediated by Cu, are exemplified by the synthesis of $CF_3CH_2CH{=}CH_2$ using $(CF_3)_2Cu^{III}$(*N*,*N*-diethyldithiocarbamato),[38a] or using FO_2SCF_2I in DMF.[38b]

The allyl system is susceptible to further chemistry, notably epoxidation and other addition processes; the intermediates in such processes may show their own idiosyncratic chemistry[39] as in the cyclization of the thioallyl substituent (**4**) (eq 9), itself obtained by allylation of the thiophenoxide.

Related Reagents.

Allyl Chloride; ***Allyl Iodide***.

Allyl Chloride[1]

[107-05-1] · C_3H_5Cl · Allyl Chloride · (MW 76.53)

(allylating agent which attacks C, O, N, S, Se, Te nucleophiles; organometallic derivatives provide homoallyl alcohols; expected electrophilic addition reactions)

Physical Data: mp -136.4 °C; bp 44.6 °C; *d* 0.938 g mL^{-1}.

Solubility: miscible with organic liquids.

Form Supplied in: colorless liquid, discoloring on standing and exposure to air.

Purification: wash with concd HCl, then with aq Na_2CO_3 and dry ($CaCl_2$). Impurities include isomers and chloropropanes; efficient fractional distillation is essential.[2a]

Handling, Storage, and Precautions: volatile, flammable, toxic, irritant, alkylating agent.

Usually manufactured by high temperature chlorination of propene;[2b] hence the incidence of isomeric and polychlorinated impurities. Allyl chloride allylates ethyl acetoacetate derivatives (40% aq KOH, Bu_4NBr, rt, 3 h) to give 2,2-diallyl analogs (92% yield, 97% pure).[3] Malonic esters are similarly alkylated under dehydrating conditions (RCl, Bu_4NBr, NaOH in PhMe).[4] Alkyl carboxylic acids may be allylated at the α-position when the Na salt (NaH-xylene, 135 °C, 2 h) is treated with ***Lithium Diethylamide*** at 125-135 °C until loss of Et_2NH is complete, followed by treatment with RCl at ~85 °C over some hours.[5] Ruthenium or osmium σ-acetylide complexes (e.g. **1**)[6] undergo allylation (at the alkyne system). Some such substitutions (e.g. methanolysis) are apparently Cu catalyzed;[7,8] an example is the formation of 3-allylpentane-2,4-dione (72%), when Cu + $Cu(ClO_4)_2$ is added to the reagents in Et_2O (eq 1).[8]

(1)

(2)

In the presence of peroxides (e.g. ***1,1-Di-t-butyl Peroxide***) crown ethers add to allyl chloride via the α-hydrogen abstracted radical to form, for example, 2-(3´-chloropropyl)-1,4,7,10-tetraoxacyclododecane (**2**; R = $Cl(CH_2)_3$). While the yields are poor (8-10%) the product is apparently isolable,[9] and affords a route to functionalized crown ethers.

The reductive allylation process (eq 2) occurs with aldehydes in the presence of Bi,[10a,10b] $Al/BiCl_3$,[10b,10c] $Al/PbBr_2$,[11] Zn,[12] and $Fe/BiCl_3$.[10b] Acid chlorides in the presence of Cp_2Sm afford allyl ketones.[13] Dry stirring ***Magnesium*** turnings in an inert atmosphere greatly promotes the formation of allylmagnesium chloride without the formation of biallyl and similar products.[14] In addition to the expected range of Grignard reactions based upon allylmagnesium chloride, allyl chloride reacts with ***Lithium Diisopropylamide*** to form α-chloroallyllithium, which undergoes the expected reactions with RCl, RCHO, R_3SiCl, and R_3SnCl (eq 3).[15]

Allyllithium (RLi) itself is made by cleavage of $RSnPh_3$ (from RBr, Mg, and Ph_3SnCl)[16a,16b] or of allyl aryl ethers (Li, THF, -15 °C) (eq 4).[16c]

The protected glycine ester derivative (**3a**) affords a reagent with 2LiCl.CuCN which allylates with allyl chloride to give the product (**3b**) without loss of the stereochemical identity at the carbon atom α to the protected amino group (eq 5).[17] Allyl chloride also alkylates glycine chiral ester Schiff bases in the presence of chiral Pd complexes.[18] The allylation of the monomenthyl ester of cyclopentane-1,2-dicarboxylic acid by RCl (R = allyl) gives the compound (**4**) in which the allyl halide has approached from the more hindered side of the molecule. Allyl tosylate gives the sterically preferred orientation; the differences in behavior are rationalized in terms of interaction between the Li of the enolate reagent and the Cl of RCl.[19]

(3a) **(3b)**

(4)

Traditional nucleophilic attack is represented by reaction with ArO^- in the synthesis of allyl aryl ethers in a study of

the Claisen reaction,[20] and with ***Sodium Sulfide*** to give R_2S,[21] and in the analogous preparation of R_2Te.[22] Friedel-Crafts allylation of benzene represents an alternative route to the synthesis of propylbenzene after hydrogenation, since rearrangement occurs when propyl halides are subject to this reaction; hydrated ***Iron(III) Chloride*** proved to be a gentle, if inefficient, catalyst for such allylations.[23]

The use of Ru or Rh chlorides on polyethylenimine to promote the addition of $CXCl_3$ to unsaturated systems such as allyl chloride (eq 6) extends the older application of Lewis acids such as ***Aluminum Chloride***.[24] The addition of ***Diborane*** to allyl chloride provides (γ-chloropropyl)boranes which then provide cyclopropane;[25a] with ***Sodium Amide***, allyl chloride gives cyclopropene (low yield).[25b]

Allyl Chloroformate

[2937-50-0] · $C_4H_5ClO_2$ · Allyl Chloroformate · (MW 120.54)

(preparation of allyl carbamates and allyl carbonates;[1a] may be used for preparation of α-allyl carbonyls and α,β-unsaturated carbonyls[4])

Physical Data: bp 109-110 °C; *d* 1.136 g cm^{-3}; fp 31 °C.

Solubility: sol most organic solvents.

Form Supplied in: clear, colorless liquid.

Handling, Storage, and Precautions: keep cold. Reacts with moist air. May contain small amounts of phosgene.

Protecting Group.

Allyl chloroformate has been used to prepare the allyl carbamate protecting groups for amines (eq 1)[1] and the alkyl allyl carbonate group for protecting alcohols (eq 2).[1a] These blocking groups are useful because they are stable to acidic and some basic conditions but are easily removed under aprotic conditions with palladium or nickel catalysis in the presence of nucleophiles (eqs 3 and 4).[1a,2]

(1)

(2)

(3)

(4)

Preparation of α-Allyl and α,α-Diallyl Ketones.

Allyl enol carbonates formed from the reaction of enolates with allyl chloroformate rearrange in the presence of palladium(0) catalysts to provide α-allyl and α,α-diallyl ketones (eq 5).[3]

Preparation of Unsaturated Ketones, Aldehydes, and Nitriles.

Allyl enol carbonates and allyl esters provide good yields of α,β-unsaturated products when treated with palladium(II) and the appropriate ligand. The choice of ligand is critical to the optimal yield of either α-allylated product or unsaturated product (eq 6).[4]

Allylcopper[1]

[37974-18-8] · C_3H_5Cu · Allylcopper · (MW 104.62)

(reagent for allyl transfer to enones,[2] acid chlorides,[3] aldehydes,[3] and imines[4])

Alternate Name: 2-propenylcopper.

Preparative Methods: prepared by reaction of ***Allyllithium*** or allylmagnesium halides and ***Copper(I) Iodide***, or by reaction of allyl halides and activated copper metal.

Handling, Storage, and Precautions: sensitive to air and moisture. Use in a fume hood.

Allylcopper and ***Lithium Diallylcuprate*** were initially prepared by House and Fischer in 1969.[5] Addition of allylcopper to cyclohexenone occurred in excellent yield, but β-substituted enones resulted only in 1,2-addition products (eq 1).

(1)

In a more recent study, Bertz and Dabbagh disclosed that the extent of 1,2-addition in the reaction of allylcopper with cyclohexenone was dependent on the reaction solvent.[6] There have been reports on the difficulties associated with regiocontrol in the reactions of allylcopper and lithium diallylcuprate.[2,3] Hutchinson and Fuchs speculated that lithium diallylcuprate existed as an equilibrium mixture of bis-η^3-allyl and η^1-allyl-η^3-allyl species.[7] Only the η^1-allyl species was able to undergo conjugate addition due to the fact that this complex was formally a 16-electron complex, whereas the 18-electron bis-η^3-allyl complex could not undergo conjugate addition. Lipshutz and co-workers[2] developed a method for the preparation of allylcopper which provided an apparent solution to the problems associated with the reagent generated under the conditions reported by House.[5] Preparation of the neutral allylcopper reagent from ***Allyllithium*** (obtained from transmetalation of allyltributyltin with butyllithium) and ***Copper(I) Iodide*** solubilized by ***Lithium Chloride*** resulted in a reagent that undergoes 1,4-addition with sterically hindered enones (eq 2). The conjugate addition reaction required the presence of ***Chlorotrimethylsilane*** for reproducible results. The

allylcopper reagent could also be obtained from ***Allylmagnesium Bromide*** and soluble copper iodide-***Lithium Bromide*** in THF. The Grignard-derived allylcopper reacted with a hindered cyclopentenone to give the 1,4-adduct in very good yield (eq 3).

(2)

(3)

Lipshutz noted that the allylcopper reagent prepared from soluble copper(I) complexes exhibited atypical reactivity when compared to other less reactive neutral organocopper reagents. 1,2-Addition becomes competitive with 1,4-addition reactions of allylcopper in cases where dialkylcuprate reagents predominately give the 1,4-addition product. Yamamoto and co-workers reported that allylcopper prepared by the method of Lipshutz undergoes conjugate addition to ethyl 4-benzyloxypent-2-enoate, while the same reagent prepared by the method of House did not react (eq 4).[8]

(4)

However, Shultz and Harrington noted that allylcopper prepared by the Lipshutz method did not provide a conjugate addition product in reaction with a 2-amido substituted cyclohexenone.[9] Only copper bromide-catalyzed addition of allylmagnesium bromide provided the 1,4-addition product in modest yield. More recently, Rieke and co-workers have reported the direct preparation of allylcopper from ***Allyl Chloride*** or allyl acetate using activated copper metal generated from the reaction of ***Lithium Naphthalenide*** with soluble ***Copper(I) Cyanide***-lithium bromide.[3] Allylcopper formed in this fashion reacted cleanly with acid chlorides to provide ketones in good yields (eq 5).

(5)

1,2-Addition products could be obtained with aldehydes and ketones, and 1,4-addition reactions with enones were also realized in the presence of trimethylsilyl chloride. Substituted allyl halides readily produce the corresponding allylcopper derivative. Conjugate addition of the substituted allylcopper reagents occurs exclusively by α-attack of the allyl group (eq 6). The activated copper metal method also allows for the generation of substituted allylcopper reagents bearing remote functional groups such as enones, ketones, esters, nitriles, alkyl chlorides, or carbamates.

(6)

Conjugate addition reactions of allylcopper obtained by reaction of allylmagnesium halides with copper(I) salts is also common. Corey and co-workers reported that allylcopper prepared from allylmagnesium chloride and copper iodide added to alkynic esters in a 1,4-fashion to provide the dienyl ester products in good yield.[10] Paquette and co-workers demonstrated that the enolate generated by allylcopper addition to an enone could be trapped by addition of trimethysilyl chloride to the reaction (eq 7).[11] Crimmins and co-workers have been able to trap the intermediate formed by allylcopper addition to an alkynic ester by an intramolecular acylation reaction (eq 8).[12] In this example, the initial allyl addition product isomerizes to the *trans*-propenyl substituent upon work-up. Displacement reactions of allylcopper obtained from allylmagnesium halides have also been used in an improved synthesis of allyl sulfones.[13] Allylcopper has also undergone 1,2-addition to imines to provide homoallylic amines with excellent enantioselectivity (eq 9).[4] The high enantioselectivity of the reaction was attributed to the formation of a rigid chelated complex.

Allyldibutyltin Chloride[1]

[64549-05-9] · $C_{11}H_{23}ClSn$ · Allyldibutyltin Chloride · (MW 309.46)

(versatile reagent, together with other related halides, for the allylation of carbonyl compounds to form homoallylic alcohols,[2] halotetrahydropyrans,[3] allyl ethers,[4] alkenyl-*N*-alkyl carbamates,[5] and esters[6])

Alternate Names: allyldibutylchlorotin; dibutylchloro-2-propenylstannane.

Physical Data: bp 103 °C/15 mmHg; *d* 1.2 g cm^{-3}.

Solubility: insol cold water, sol alcohols and common organic solvents.

Form Supplied in: colorless liquid; commerically unavailable. *Drying:* the usual procedure is vacuum distillation. A saturated aqueous solution of allyldibutyl tin chloride disproportionates to diallyldibutyltin and dibutyltin dichloride; protonolysis of the allyl-tin bond is very slow.

Handling, Storage, and Precautions: very easy to handle without special precautions. Nevertheless, storage in the refrigerator and in dark bottles is recommended. Its toxicity has been determined to be comparable to that of ***Tri-n-butylchlorostannane***. Use in a fume hood.

Preparation of Allyltin Halides.

A list of isolated and well-established allyltin halides is provided in Table 1, together with procedures for their preparation.

Table 1 Preparative Procedure for Allyltin Halides

Compound	bp (°C/mmHg)	Preparative procedure[a]
$Me_2(CH_2{=}CHCH_2)SnCl$	84 85/21	R[8]

$(CH_2{=}CHCH_2)_2SnBr_2$	77 79/2	DS[12]
$(CH_3CH{=}CHCH_2)_2SnBr_2$	104 106/0.2	DS[12]
$(CH_2{=}CHCH_2)SnCl_2Br$	75 78/0.1	DS[2c]

[a] R = redistribution, DS = direct synthesis, RA = reversible allylstannation, C = Sn C bond cleavage.

The general procedures for preparing allyltin halides listed in Table 1 are as follows.

Redistribution (R) reactions of allyl- and mixed allylorgano-tins with organotin or tin(IV) halides (eqs 1 and 2).[1c,2a-d,3a,8]

(1)

(2)

C_4H_7 = *E*-crotyl, *Z*-crotyl, or 1-methylallyl *E*:*Z*, various ratios

Reversible allylstannation (RA), i.e. thermal decomposition of β-organostannoxyalkenes of the type $Bu_{3-n}Cl_nSn$--O--CRR´-CHR´´-CH=CH_2 where n = 1 and 2, R, R´ are alkyl groups, and R´´ is H or Me (eq 3).[2c,7,10-12]

Direct synthesis (DS), i.e. oxidative additions of tin(II) halides to allyl halides (eq 4).[1c,2c,12]

Cleavage (C) of appropriate unsymmetrical organotins (eq 5).[9]

The redistribution reaction is one of the most efficient preparation methods because many allyltin halides can be generated and used in situ,[1c] e.g. the system $Bu_3SnCH_2CH{=}CH_2/SnCl_4$ gives rise to $CH_2{=}CH{-}CH_2SnCl_3$. In the same way, the unstable isomers $R_{3-n}X_nSnCH(CH_3)CH{=}CH_2$ (n = 1-3) can be prepared in situ and then allowed to react with selected substrates.[13]

Allylstannation of Carbonyl Compounds with Allyltin Halides.

When allyldibutyltin chloride is allowed to react with aldehydes and ketones, exothermic additions take place, affording homoallylic alcohols in good yields (eq 6).[2a,c] The reactions occur under mild conditions. They can be carried out neat, in solution, or in the presence of air or water.[14]

The tin atom in allyltin halides possesses enhanced electrophilic character compared to the parent compounds R_3SnAll (All = allyl or allylic group), which are chemically inert towards carbonyl compounds under the same conditions. The Lewis acidity of tin seems to be the driving force for the high reactivity since allylation can be efficiently achieved at -78 °C (eq 7).[15]

The following order of reactivity has been found: $BrCl_2SnAll$ > $BuCl_2SnAll$ > $Bu_2ClSnAll$ >> Bu_3SnAll. Allylstannation of carbonyl compounds by these reagents can be performed in the presence of water to afford homoallylic alcohols directly. It can be carried out even in the presence of an acidic aqueous solution of $HClO_4$ (0.1-4 M).[14d] When crotyltins are used, the stereochemical outcome depends on the acid concentration. As a matter of fact, the stereochemical course of crotylstannation reactions, that is the recovery of *anti* and/or *syn* as well as (*E*) and/or (*Z*) homoallylic alcohols, starting from isomeric mixtures of (*E*/*Z*)-crotyltin derivatives, depends on the experimental conditions. Poor *anti* selectivity (<=66%) results from reactions of some aldehydes with isomeric mixtures of isolated crotyltins,[2d] while *syn* selectivity (72-77%) is encountered when equilibrated mixtures of the system (*E*/*Z*)-$Bu_3SnCrot/Bu_2SnCl_2$ are employed.[2f] (*Z*) Selectivity (89-100%) occurs when the unstable isomer $Bu_2ClSnCH(Me)CH{=}CH_2$ is generated in situ in the presence of the aldehydes (eq 8).[13a,b]

Ph	~100	traces

4-Halo-2,6-dialkyltetrahydropyrans are easily synthesized using allyltin di- and trihalide derivatives (eq 9).[3a-e]

(*E*/*Z*)-4-Halo-2,6-dialkyl-3-methyltetrahydropyrans are produced from the corresponding crotyl halides.[3d] Alkoxides of the type $BuCl_2Sn$-O-CH(CH=CHR)CH_2CH=CH_2 and $BuCl_2$-Sn--O--CH(CH=CHR)CH(R´)CH=CH_2 (R = Me or Pr, and R´ = Me), prepared via allylstannation of α,β-unsaturated aldehydes, give rise to isomeric mixtures of allyl ethers through an intermolecular reaction (eq 10).[4]

(10)

Alkenyl-*N*-alkyl carbamates can be produced in an one-pot synthesis by combining $Bu_2ClSnCH_2CH{=}CH_2$, RCHO, and EtNCO (eq 11).[5]

Adduct A´ is formed through two distinct steps: step (a) deals with the selective allylstannation of the aldehyde to form adduct A (the insertion of EtNCO into the Sn-allyl bond does not occur), while the subsequent step (b) arises due to the ability of tin alkoxides to react with isocyanates.[16]

Allyldicarbonylcyclopentadienyliron[1]

[38960-10-0] · $C_{10}H_{10}FeO_2$ · Allyldicarbonylcyclopentadienyliron · (MW 218.04)

(allyl 1,3-dipole equivalent which undergoes [3 + 2] cycloaddition with electrophilic carbon[2] and heteroatom[3] dipolarophiles; reagent for the Lewis acid-promoted allylation of aldehydes and unactivated ketones;[4] reacts with cationic oxyallyl iron complexes to give [3 + 3] cycloadducts[5])

Physical Data: amber oil which decomposes at ~65 °C.

Solubility: sol all common organic solvents.

Preparative Methods: prepared under an inert atmosphere by the addition of excess ***Allyl Chloride*** to a degassed THF solution of ***Sodium Dicarbonylcyclopentadienylferrate*** at 0 °C.[6] The mixture is stirred for 15 min, warmed to room temperature over 1 h, and concentrated in vacuo. The residue is extracted with pentane, filtered, then concentrated in vacuo to give $Cp(CO)_2Fe(CH_2HC{=}CH_2)$ in 96% crude yield.[7]

Purification: may be protonated with HBF_4 to give the cationic propene complex, $Cp(CO)_2Fe(\eta^2\text{-}H_2C{=}CHMe)^+BF_4^-$, which is precipitated with Et_2O and washed with a large volume of Et_2O. $Cp(CO)_2Fe(CH_2HC{=}CH_2)$ is then regenerated with Et_3N prior to use.[7,8]

Handling, Storage, and Precautions: all manipulations involving $Cp(CO)_2Fe(CH_2HC{=}CH_2)$ should be carried out under an inert atmosphere. Solvents should be thoroughly dried and degassed. The toxicity of allyldicarbonylcyclopentadienyliron has not been fully investigated. For comparative data, see $Cp(CO)_2FeI$ or ***Bis(dicarbonylcyclopentadienyliron)*** (Sigma-Aldrich Material Safety Data Sheets available).

Cycloaddition Reactions.

Allyldicarbonylcyclopentadienyliron (hereafter referred to as allyl-Fp) is a 1,3-dipole equivalent which undergoes [3 + 2] cycloaddition reactions with electron deficient alkenes (eq 1) to give high yields of the corresponding

cyclopentannulation products.[7] The reaction occurs in two steps. Initial attack of the γ-carbon of $Cp(CO)_2Fe(CH_2HC{=}CH_2)$ on the electron-deficient carbon atom generates a zwitterionic iron alkene complex (**1**), which collapses to form the metalated cyclopentane product (see eq 2). Allyl-Fp also reacts with electrophilic heteroatom dipolarophiles such as *N*-tosyl isocyanates and *N*-sulfonylurethanes to give γ-lactams and -sultams, respectively.[3]

(1)

Cyclohexenones react with allyl-Fp to give *cis*-fused hydrindane products.[9] The reaction is promoted by the addition of Lewis acids such as ***Aluminum Bromide***; electron-deficient cycloalkenones such as 1-ethoxycarbonylcyclohexenone undergo cyclopentannulation in the absence of added Lewis acid. These reactions are sensitive to steric effects at the 3-position of the cycloalkenone.

A variety of methods have been developed for demetalation of the cyclopentyl iron complexes.[7] Esters are obtained by oxidation with ***Cerium(IV) Ammonium Nitrate*** (CAN) in ethanol under a carbon monoxide atmosphere (eq 2). Proteolytic demetalation with HCl has been employed to generate cyclopentanes; however, reversal of the cycloaddition is sometimes observed, and is a major drawback of this method.[7,10]

Metal-complexed alkenes have been shown to react with allyl-Fp to give bimetallic condensation products in moderate yields. For simple alkene complexes such as $Cp(CO)_2Fe(\eta^2\text{-}H_2C{=}CHR)^+BF_4^-$ (R = H, Me, Ph), the reaction proceeds readily with little regiospecificity.[10] Acrolein complexes (eq 3) react regiospecifically to give the product of Michael-type addition to the complexed enal.[10] ***Sodium Iodide*** in acetone selectively removes the cationic iron group from the alkene.[10] The alkyl-iron bond is selectively cleaved by treatment with HCl.[10]

A variety of cationic tricarbonyl tropyliumiron complexes add allyl-Fp to give bimetallic hydroazulene complexes via [3 + 2] cycloaddition in moderate to good yields.[11] The cyclopentane ring in the product is *cis*-fused to the seven-membered ring, *trans* to the iron tricarbonyl unit. The product may be further functionalized by addition of electrophiles or nucleophiles.[11c]

In addition to [3 + 2] cycloadditions with two-carbon dipolarophiles, allyl-Fp undergoes a [3 + 3] cycloaddition reaction with cationic oxyallyl iron complexes.[5] The oxyallyl complex is generated in situ by refluxing a CH_2Cl_2 solution of ***Nonacarbonyldiiron*** and an α,α´-dibromo ketone. The yields for the reaction are moderate for tetrasubstituted, trisubstituted, or α,α´-disubstituted ketones; monosubstituted dibromo ketones fail to give cyclic products.

Allylation of Aldehydes and Ketones.

Allyl-Fp also reacts with aldehydes and ketones in the presence of Lewis acids such as ***Boron Trifluoride Etherate***.[4] Under these conditions the cationic iron alkene complex does not undergo internal trapping to give a substituted tetrahydrofuran. Instead, the iron alkene complex is isolated, which may be demetalated with sodium iodide in wet acetone to give the homoallyl alcohol (overall isolated yields range from 50-98%). In this respect the reagent is reminiscent of allylsilane or -stannane reagents. However, the ability to isolate a homoallyl alcohol with iron coordinated to the alkene gives the potential for further elaboration which is not available with silanes and stannanes.

Finally, it must be mentioned that homologs of allyl-Fp, such as methallyl-,[1] 2-[12] or 3-methoxyallyl-,[13] and propargyldicarbonylcyclopentadienyliron,[14] undergo many similar transformations. These related reagents allow for further versatility and unique reactivity.

Related Reagents.

Dicarbonyl(cyclopentadienyl)(isobutene)iron Tetrafluoroborate.

Allylboration of Aldehydes.

The *B*-allyldiisocaranylboranes (Icr_2BAll) condense with aldehydes with exceptional levels of enantioselectivity (98- &egt; 99% ee) to form, upon workup, secondary homoallylic alcohols.[2] While both regioisomers of this reagent (2-$^{d}Icr_2BAll$ and 4-$^{d}Ipc_2BAll$) are derived from the (+)-terpene, they exhibit complementary reactivity to form enantiomeric products (eqs 3 and 4). The degree of enantioselection achieved in the condensation of Icr_2BAll with aldehydes is superior to other means of allylboration[1] (see also ***B-Allyldiisopinocampheylborane***; ***Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate***; ***(R,R)-2,5-Dimethylborolane***).

(3)

(4)

Crotylboration of Aldehydes.

The crotyl analogs of this reagent (Icr_2BCrt) likewise provide very high levels of enantio- and diastereoselectivity (&egt;99% de) when condensed with aldehydes.[3] By varying the geometry of the crotyl group (*Z* or *E*) and the (+)-carene isomer used in the reagent preparation (2- or 3-carene), all four of the possible β-methyl homoallylic alcohol products can be obtained (eqs 5 and 6). As with allylborations, the condensation of *B*-crotyldiisocaranylboranes with aldehydes provide higher levels of enantioselection than the other crotylboration reagents[3] (see also ***B-Crotyldiisopinocampheylborane***; (*Z*) and (*E*)-***Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate***; ***(R,R)-2,5-Dimethylborolane***).

B-Allyldiisopinocampheylborane[1]

(+)-(Ipc_2BAll)

[85116-38-7] · $C_{23}H_{39}B$ · *B*-Allyldiisopinocampheylborane · (MW 324.36) (-)-(Ipc_2BAll)

[106356-53-0]

(reagent for the asymmetric allylboration of aldehydes to produce homoallylic alcohols[2,3])

Solubility: most often used as the crude preparation in Et_2O; however, reactions have also been conducted in CS_2, $CHCl_3$, CH_2Cl_2, toluene, and THF.

Analysis of Reagent Purity: ^{11}B NMR (δ +78, diethyl ether).

Preparative Methods: prepared in three steps from either (+)- or (-)-α-pinene (eq 1) (see also ***B*-Methoxydiisopinocampheylborane**).

Handling, Storage, and Precautions: removal of magnesium salts from the crude reagent preparation is accomplished by solvent exchange into pentane and filtration. Concentration in vacuo provides the neat allylborane as a colorless liquid that can be stored under argon atmosphere for an extended period of time.

Addition to Aldehydes.

Condensation of *B*-allyldiisopinocampheylborane (Ipc_2BAll) with aldehydes occurs in good yield (50-90%) and with excellent enantioselection (83-96% ee) to provide secondary, homoallylic alcohols.[2] Improvements in the original procedure have produced a salt-free reagent preparation that can increase the enantioselectivity of many additions to &egt;99% ee (eqs 2 and 3).[3]

(2)

(3)

Several methods have been employed in the reaction workup to decompose the initial borinic ester adduct (eq 4).[2,4] An oxidative workup procedure (H_2O_2, NaOH) delivers the desired alcohol product along with 2 equiv of isopinocampheol. The elimination workup (*i*-PrCHO, $BF_3.OEt_2$) allows for recovery of the starting α-pinene, whereas the amino alcohol workup (ethanolamine or 8-hydroxyquinoline) precipitates the diisopinocampheylborinate-amino alcohol adducts which are removed by filtration, and which can also be recycled.

The (+)- and (-)-Ipc_2BAll reagents have been condensed with a variety of aldehyde structures[2,5] with no reported reversal of enantiospecificity. Because of this strict fidelity of addition, these reagents have been used in the structure determination of several natural products.[6] In the case of α-substituted aldehydes, however, an erosion of diastereofacial selectivity is sometimes observed for mismatched reactant pairs (eqs 5-7).[7]

(+)-Ipc_2B All 96:4
(-)-Ipc_2B All 5:95

(+)-Ipc_2B All 96:4
(-)-Ipc_2B All 6:94

These reagents have been used for the conversion of C_s symmetrical chains into chiral, nonracemic products. A double condensation with *meso* dialdehydes can produce either optically active diol product (eq 8).[8]

B-Allyldiisopinocampheylborane compares favorably in both yield and enantioselectivity to alternate methods of asymmetric allylboration[1] (see also ***B-Allyldiisocaranylborane***; ***Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate***; ***(R,R)-2,5-Dimethylborolane***).

Addition to Ketones.

Condensation of Ipc_2BAll with methyl ketones proceeds with modest to good enantioselectivity. Unlike with aldehydes, the degree of enantioselection is highly dependent upon ketone structure (eq 9).[2]

B-Methallyldiisopinocampheylborane and Related Reagents.

Derivatives of the reagent containing substituted allyl groups have been used for the synthesis of more highly functionalized homoallylic alcohols (see also ***B-Crotyldiisopinocampheylborane*** and ***B-Allyldiisocaranylborane***). In general, these reagents are prepared in a manner analogous to Ipc_2BAll or by hydroboration of the corresponding diene with diisopinocampheylborane. For example, reagents containing alkyl substituents, such as *B*-methallyldiisopinocampheylborane and *B*-(3,3-dimethylallyl)diisopinocampheylborane, condense with aldehydes to give the corresponding substituted homoallylic alcohols (eqs 10 and 11).[9] An alkenyl-substituted derivative, *B*-2´-isoprenyldiisopinocampheylborane, has been used for the asymmetric isoprenylation of aldehydes (eq 12).[10]

(10)

(11)

(12)

Derivatives containing heteroatoms have allowed for the preparation of allylic 1,2-diols and amino alcohols by this method. Aldehydes react with *B*-[(*Z*)-3-(methoxymethyloxy)allyl]diisopinocampheylborane to give monoprotected diol adducts.[11] 1,2-Diols can be obtained directly by condensation with *B*-[(*E*)-3-((diisopropylamino)dimethylsilyl)allyl]diisopinocampheylborane followed by an oxidative reaction workup (eqs 13 and 14).[12]

(13)

(14)

Amine-containing reagents, such as *B*-[(*E*)-3-(diphenylamino)allyl]diisopinocampheylborane, react in a similar manner to provide 1,2-amino alcohols (eq 15).[13] A further variation on this reagent is where the allylic group is contained in a ring. The cyclohexenyl reagent *B*-(cyclohex-2-enyl)diisopropylcampheylborane and the related cycloheptenyl and cyclooctenyl versions have been described.[14] At low temperatures (< -25 °C), these boranes are stable toward allylic isomerization and transfer with complete diastereoselectivity to provide *erythro* products (eq 16).

Allyldiphenylphosphine Oxide[1]

[4141-48-4] · $C_{15}H_{15}OP$ · Allyldiphenylphosphine Oxide · (MW 242.26)

(reagent for Wittig-Horner reaction;[2] substrate for carbon-phosphorus heterocycle[3] and 1,3-dipolar cycloaddition[4])

Physical Data: mp 108-109 °C;[5] ^{1}H and ^{31}P NMR studies have been reported.[6]

Solubility: sol THF; slightly sol ether; insol hexane.

Form Supplied in: white solid; commercially available.[7]

Preparative Methods: two processes have most commonly been used: (1) rearrangement of allyl diphenylphosphinite[2,8,12] and (2) Arbuzov reaction of alkyl diphenylphosphinite with ***Allyl Bromide***.[9,13] Other new methods have been also developed.[10,14] Structurally related analogs prepared include: 2-methylallyldiphenylphosphine oxide,[15] 2-phenylallyldiphenylphosphine oxide,[15] 1-methoxyallyldiphenylphosphine oxide,[16] crotyldiphenylphosphine oxide,[17] and 1-substituted allylic diphenylphosphine oxide.[18]

Purification: recrystallization from ether/hexane,[2] benzene/petroleum ether,[8] cyclohexane,[9] or benzene.[10]

Handling, Storage, and Precautions: thermally stable up to 150 °C.[11]

Wittig-Horner Reaction.

Lithiated allyldiphenylphosphine oxide condenses with aldehydes in THF-HMPA solution to give (*E*)-1,3-dienes directly and stereoselectively in good yield[2] (for synthesis of 1,3-dienes, see also ***Allylidenetriphenylphosphorane***). This process has been utilized for the synthesis of (*E*)-trienes (eq 1).[19] Condensation with ketones also affords 1,3-dienes (eq 2).[2,20]

(1)

(2)

(*Z*)-Dienes can be prepared with high selectivity by use of a titanium reagent prepared from diphenylphosphinoallyllithium, the metalation product of allyldiphenylphosphine (eqs 3 and 4).[2a,2c]

The Wittig-Horner reaction of structurally related allylic diphenylphosphine oxides has been widely studied by Warren.[18,21] In the absence of HMPA, reaction of lithiated allylic diphenylphosphine oxide with aldehyde affords the Wittig-Horner intermediate alcohol which can be transformed into the 1,3-diene by ***Sodium Hydride*** in DMF (eq 5).[18a,21a,21b]

Geometrically homogeneous crotyldiphenylphosphine oxide can be used to give conjugated diene in which the original (*Z*) or (*E*) geometry is retained.[17] 1-Methoxyallyldiphenylphosphine oxide ylides react at the γ-allylic terminus with aldehydes.[22]

Other Reactions.

Cyclization of allyldiphenylphosphine oxide occurs in the presence of 115% ***Polyphosphoric Acid*** (PPA) at 180-200 °C to give carbon-phosphorus heterocycles in modest yield (eq 6).[3] Allyldiphenylphosphine oxide undergoes 1,3-dipolar cycloaddition with nitrile oxide to give 3,5-disubstituted Δ^2-isoxazolines (eq 7).[4]

O-Allylhydroxylamine

[6542-54-7] · C_3H_7NO · *O*-Allylhydroxylamine · (MW 73.11)

(*O*-allyloximes, pyridine synthesis)

Alternate Name: O-2-propenylhydroxylamine.

Physical Data: bp 80 °C, IR 3350 cm^{-1}. The reagent is typically prepared as the hydrochloride salt which is a white solid that may be recrystallized from EtOH and ether.

Preparative Methods: ***Allyl Bromide*** (39 mL, 0.46 mol) is added dropwise with stirring to a suspension of anhydrous K_2CO_3 (43 g) and commercially available *N*-hydroxyphthalimide (50 g, 0.31 mol) in DMSO (500 mL) at 25 °C. After addition, the mixture is stirred at room temp for 24 h and then poured into cold water (3 L). The precipitate is collected, washed with water, and dried. Recrystallization from EtOH gives *N*-allyloxyphthalimide (87%), mp 56-57 °C. A mixture of *N*-allyloxyphthalimide (10 g, 0.05 mol), hydrazine hydrate (5 mL, 0.1 mol), and EtOH (100 mL) is refluxed for 2 h and then cooled and poured into 3% aqueous Na_2CO_3 (500 mL). The solution is extracted with ether. The ether extract is washed with water and then 5 mL of conc HCl are added. Evaporation gives a solid which is recrystallized from EtOH and ether to afford *O*-allylhydroxylamine hydrochloride as a white solid (eq 1). The free amine can be liberated by distillation from KOH (bp 80 °C)[1] or by treatment with ammonia in situ.[2] It may be conveniently stored as the *N*-allyloxphthalimide intermediate which is converted to *O*-allylhydroxylamine hydrochloride as needed.

Handling, Storage, and Precautions: use in a fume hood.

Synthesis of Pyridines.

The reagent reacts with ketones to provide *O*-allyloximes in generally good yields. These materials may, in turn, be pyrolyzed by heating in a sealed tube at about 180 °C to undergo an electrocyclization which has been proposed to proceed through a nitrile oxide intermediate.[1,2] The final step involves oxidation of a dihydropyridine and therefore it is important *not* to exclude air from the pyrolysis. The intermediate in eq 2 can be derived by allylation of the corresponding oxime; however, this process is generally inferior to the *O*-allylhydroxylamine approach.

(2)

Twofold application of this method to provide bipyridines is unsuccessful. The bridged bipyridine which would be derived from 1,2-cyclooctanedione is better prepared by a stepwise approach wherein the product of eq 2 can be converted to its α-keto derivative and then the second pyridine ring incorporated as before (eq 3).[3,4]

Allylidenetriphenylphosphorane[1]

[15935-94-1] · $C_{21}H_{19}P$ · Allylidenetriphenylphosphorane · (MW 302.36)

(Wittig reagent for 1,3-diene synthesis[2] and Michael addition reaction[3])

Physical Data: ^{13}C and ^{31}P NMR solution studies,[4] X-ray structures of the molybdenum and tungsten complexes,[5] and the heat of formation (ΔH) have been reported.[6]

Solubility: sol THF,[7] toluene.[8]

Form Supplied in: prepared in situ and used directly.

Preparative Methods: this Wittig reagent is generally prepared from ***Allyltriphenylphosphonium Bromide*** or chloride by treatment with ***n-Butyllithium*** or ***Phenyllithium***.[2,3,9] Structurally related analogs have been prepared by the similar methods: 2-butenylidenetriphenylphosphorane;[10] 3-methyl-2-butenylidenetriphenylphosphorane;[10] (*E*)-2-octenylidenetriphenylphosphorane;[11] (*E*)-pentadienylidenetriphenylphosphorane;[11] (*E*)-2,4-hexadienylidenetriphenylphosphorane;[12] 2-alkynylidenetriphenylphosphorane;[12] allylidenetributylphosphorane.[13] γ-Alkyl-substituted allylidenetriphenylphosphorane can be also obtained by the reaction of diisobutylaluminum alkylideneamide with methylidenetriphenylphosphorane.[14]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture.

Wittig Reaction.

Allylidenetriphenylphosphorane usually reacts at the α-carbon with aldehydes to give a mixture of (*E*)- and (*Z*)-1,3-dienes directly in good yield (eq 1).[2] This process has been utilized for synthesis of an intermediate of leukotriene B_4 (eq 2).[15] The Wittig reaction with ketones occurs at higher temperature (eq 3).[16] In contrast, the γ-substitution product is preferentially formed in the condensation with aldehydes, when allylidenetriphenylphosphorane is generated with DBU in refluxing methanol.[17]

(1)

(2)

(3)

Structurally related allylidenetriphenylphosphoranes have been widely employed for the Wittig alkenation reaction.[11-13] Reaction of (*E*)-2-octenylidenetriphenylphosphorane with acrolein gives a 3:2 mixture of (*E*)- and (*Z*)-trienes (eq 4).[11] In this reaction the geometry of the starting (*E*)-2-octenylphosphonium bromide is preserved during both ylide formation and subsequent reaction with aldehyde.

(4)

The stereochemistry of the Wittig alkenation of aldehydes with allylic phosphorus ylides has been extensively studied by Tamura et al.[18] Selective synthesis of (*Z*)-1,3-dienes has been achieved by the condensation of an allyltitanium reagent, generated from allyldiphenylphosphine, with aldehydes[19] (for synthesis of (*E*)-1,3-dienes, see also ***Allyldiphenylphosphine Oxide***).

Conjugate Addition.

Allylidenetriphenylphosphorane reacts with an enone to give a cyclic 1,3-diene (eq 5).[3,20] In this reaction the addition

of the γ-position of the ylide to the β-carbon of the enone occurs first, and then the generated ylide (**1**) undergoes an intramolecular Wittig condensation to produce the 1,3-diene. Strained bridgehead alkene (**2**) has been also successfully synthesized by this method.[20b] In contrast, reaction with a β-chloro-α,β-unsaturated ketone followed by treatment with benzaldehyde yielded triene (**3**).[21]

(1)

(5)

(2)

(3)

Other Reactions.

Addition of allylidenetriphenylphosphorane to benzyne and subsequent treatment with HBr affords cinnamylphosphonium bromide.[22] Silylation with ***Chlorotrimethylsilane*** occurs regiospecifically at the γ-position.[23] Reaction with isocyanate gives 3-pyridylidenephosphorane.[24]

Allyl Iodide

[556-56-9] · C_3H_5I · Allyl Iodide · (MW 167.99)

(allylating agent which attacks C, O, N, S, Se, Te nucleophiles; organometallic derivatives provide homoallyl alcohols; expected electrophilic addition reactions)

Physical Data: mp -99.3 °C; bp 103.1 °C; *d* 1.848 g cm^{-3}.

Solubility: miscible with organic liquids.

Form Supplied in: yellow liquid, discoloring on heating, standing, and exposure to air.

Purification: wash with aq Na_2SO_3 to remove iodine, dry ($MgSO_4$), and distil under reduced pressure (~20 mmHg).[1] Protect from light.

Handling, Storage, and Precautions: store in a light-tight vessel at 0 °C. Volatile, flammable, toxic, irritant alkylating agent. Light sensitive.

Allyl iodide (RI) is usually prepared by ion exchange (NaI-Me_2CO) of allyl chloride or from allyl alcohol using reagents such as ***Diphosphorus Tetraiodide***.[2] The weak C-I bond facilitates both heterolytic and homolytic displacement reactions (eq 1). Thus Barbier-Grignard type processes may also be achieved using Sb,[3] Ga,[4] In,[5] Bi,[6,7] or $BiCl_3$-metal combinations.[7] Cerium powder with allyl iodide provides organocerium species which with ketones give a mixture of secondary alcohol, pinacol dimerization product, and Barbier-Grignard product. With aldehydes the major product is the pinacol product.[8] In contrast, allyl iodide with Al and Ce/Hg in THF at 0 °C under N_2 for 5 h gives excellent yields of the tertiary alcohol with a range of ketones.[9] Other such reductive allylation methods use $CrCl_3$ + 0.5 mol $LiAlH_4$, which seems to provide Cr^{II} which with RI or RBr in THF gives allyl Cr^{II} species. These may lead to biallyl formation or to the Barbier-Grignard reaction with ketones and aldehydes, but not with nitriles or carboxylates (eq 2).

(1)

Allyl chloride behaves similarly, but in DMF and not THF.[10] ***Samarium(II) Iodide*** (THF, N_2, rt) encourages the reaction of aldehydes with RI to give secondary alcohols (eq 3);[11] so also does Sn^{II}, both as the carboxylate[12] and as the halide,[12,13] especially the fluoride.[13] Acyl chlorides similarly react with RI in the presence of SmI_2.[14] The reduction may also be brought about electrochemically; RI (and other allyl halides) provides $Me_2C(R)OH$ with Me_2CO (0.5 M Bu_4NClO_4 in HMPA)[15a] and adds across &cvbond;C=C&dvbond; in diethyl fumarate ($Et_4N^+C_7H_7SO_3^-$ in DMF) to give the 2-allylsuccinate system (eq 4).[15b]

The analogous photochemical addition of RI to benzaldehydes is promoted by lanthanum iodides.[16]

Carbanions (e.g. (**1**), generated from NaH in DMF) allylate without rearrangement (eq 5),[17] while Na salts of penta-2,4-dione enolates allylate exclusively at C-3 (DMSO, RI)[18] and lithio derivatives of silylated acrylate esters (MeLi) show similar specificity of allylation.[19] The stereoselective attack of chiral malonic half-esters,[20] dimethyl tartrate stannylene acetal,[21] chiral imide enolates,[22] and chiral nitro keto imines[23] proceeds well and with high diastereoselectivity. Simple exchange reactions provide radiolabeled products; $Ag^{18}F$ and $Ag^{83}Br$ react with RI in the gas phase to provide high-level $R^{18}F$ and $R^{83}Br$.[24] Iodolactams also undergo stereospecific *N*-allylation.[25] ***Diphenyl Diselenide*** provides PhSeR in the presence of SmI_2.[26]

Allyllithium[1]

[3052-45-7] · C_3H_5Li · Allyllithium · (MW 48.01)

(allylating agent in substitutions and additions; used to attach allyl groups to other metals and nonmetals)

Physical Data: colorless solid, pyrophoric in air.[2] Crystals of complex with ***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine*** showed monomeric ion pairs by X-ray.[3] IR,[4] Raman,[4b] UV,[5] and ^1H,[3,6] ^{13}C,[7] and ^7Li[8] NMR spectra have been reported on solutions.

Solubility: sol in ethers with degrees of association 1.4-10; sparingly sol in alkanes.[2]

Form Supplied in: prepared in situ and used directly.

Preparative Methods: from allyl phenyl ether and Li in THF/ether is recommended for large scale, tin-lithium exchange between allyltins and phenyllithium for pure samples.[9] Halogen-metal exchange is impractical due to fast Wurtz coupling. Allyllithium can also be made at -78 °C by the reaction of ***n-Butyllithium*** with allyl methyl (or phenyl) selenide,[10] and by metallating propene with butyllithium.[11]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas to exclude oxygen and moisture.

Nucleophilic Substitutions at Carbon.

Resonance-stabilized Li reagents such as allyllithium are stronger nucleophiles but weaker bases than alkyllithium reagents, permitting displacement of Br^- and I^- from cyclohexyl and cyclopentyl systems in Wurtz-type couplings (eq 1).[12] The allyl group extends chains by three carbon atoms and can be readily converted into many other groupings. Optically active secondary halides and tosylates react with inversion.[13]

(1)

High-yield displacements also occur at the less-hindered carbons of epoxides (eq 2).[14]

(2)

Nucleophilic Substitutions at Other Nonmetals.

Allyllithium reacts with aryl arylsulfonates at sulfur to give allyl aryl sulfones (eq 3).[15] Similar reactions occur to produce aryl allyl sulfoximines.[16]

(3)

Additions to Double Bonds.

Allyllithium adds to aldehydes[17] and ketones (if aromatic, by electron transfer),[18] allylic alcohols (eq 4),[19] imines,[20] ketenimines,[21] thionolactones,[22] α,β-unsaturated thioamides (by 1,4-addition),[23] and lithium carboxylates.[24]

(4)

Metal Exchange.

Allyllithium is reacted with copper salts to make lithium diallylcuprate, often used for conjugate addition of allyl groups to α,β-unsaturated carbonyl compounds.[25]

Related Reagents.

Allylcopper; ***Allylmagnesium Bromide***; ***Crotyllithium***; ***Lithium Diallylcuprate***; ***Methallyllithium***.

Allylmagnesium Bromide[1]

(X = Br)

[1730-25-2] · C_3H_5BrMg · Allylmagnesium Bromide · (MW 145.29) (X = Cl)

[2622-05-1] · C_3H_5ClMg · Allylmagnesium Chloride · (MW 100.84)

(allylating agents capable of easy addition to carbonyl compounds,[15-23] nitro compounds[57] and nitriles,[58-61] imines[43-50] and aza aromatics,[51-56] unactivated alkenes,[30-42] and of displacement reactions on halo compounds[6,24-28,53,54])

Physical Data: Br: fp -40 °C; *d* 0.851 g cm^{-3} (commercial reagent). Cl: fp -17 °C; *d* 0.995 g cm^{-3} (commercial reagent).

Solubility: Br: very sol ether. Cl: slightly sol ether; sol THF.

Form Supplied in: Br: 1.0 M solution in Et_2O packaged under N_2. Cl: 2.0 M solution in THF packaged under N_2.

Preparative Methods: allylmagnesium bromide and chloride can be easily prepared by direct reaction of ***Magnesium*** with ***Allyl Bromide*** and ***Allyl Chloride***, respectively[2-5] in diethyl ether and/or tetrahydrofuran. An excess of Mg (preferably 10%) is recommended.[6,7] Prior amalgamation of *very pure* Mg[3,4] suppresses the formation of 1,5-hexadiene. An improved preparation[8] uses a THF slurry of Mg, obtained by co-condensation in a rotating solution reactor.[9] Preactivation of Mg by dry stirring in an inert atmosphere is also highly beneficial.[10] Allylpotassium can be readily converted into the magnesium analogs by simply adding a solution of ***Magnesium Bromide*** in THF.[11,12] Most of the work on allylic Grignards has been carried out with the bromide. Indeed, the bromide can be prepared in slightly higher yield than the chloride and shows a greater solubility in ether.[1]

Handling, Storage, and Precautions: both moisture-sensitive; highly inflammable; react violently with water; induce burns. Bottles of these reagents should be flushed with N_2, kept tightly sealed to preclude contact with oxygen, and stored far from sparks. In case of contact with eyes and skin, wash immediately with abundant water.

Structure of Allylmagnesium Halides.

NMR data[3a] of several allylic Grignard reagents support the view that allylMgBr exists as a rapidly equilibrating mixture of the two classical structures (**1**) and (**2**) ($t_{1/2}$ <0.001 s) or as the bridged structure (**3**) (eq 1). This is supported by application of the Saunders isotopic perturbation technique[13] as well as by ^{25}Mg NMR studies.[14]

(1)

(1) **(2)**

(3)

Reactions with Carbonyls.

Allylmagnesium halides react with carbonyl compounds to produce carbinols; 1,2-addition occurs with α,β-unsaturated carbonyls.[1,15d,16-18] Addition takes place also with severely hindered ketones, which with most other Grignards undergo either reduction or enolization. Allylmetallation of carbonyls offers a complementary approach to the aldol reaction for acyclic stereocontrol.[15]

Complex (**4**), prepared by reacting the crystalline chiral complex $Cp(OR^*)_2TiCl$ with allylMgBr, adds to aldehydes to give homoallylic alcohols[19] with 85-94% ee (eq 2).

Homoallylic alcohols have also been synthesized by ring opening of vinylic oxetanes[20] with copper-catalyzed allylmagnesium halides. C_2 homologation of aldehydes and ketones to 2-alkenals uses allylMgBr.[21]

AllylMgBr adds to the C=O of imides to give different products depending upon the imide.[22]

A new synthesis of propenyl ketones involves reaction of an ester with 2 equiv of allylMgCl, furnishing a tertiary bis-homoallylic alcohol that fragments at 80 °C to a mixture of β,γ- and α,β-unsaturated ketones.[23]

Displacement Reactions.

The coupling of allylmagnesium halides with halogenated compounds provides a useful one-step method for introducing an alkenic bond directly into a molecule.[1,15d] Allylic Grignard halides couple with alkyl, allylic, and benzylic halides.[6,24] Sometimes, allylMgCl gives higher yields than the more commonly used allylMgBr.[24a] Alkylation in the presence of ***Copper(I) Iodide*** is much faster.[25]

AllylMgBr couples with fluoroalkenes in a rather unexpected manner.[26] Allylmagnesium halides can be hydroxymethylated in a two-step one-pot procedure by 1-chloro-2-(chloromethoxy)ethane.[27] A new synthesis of dienes, with the double bonds in predetermined positions, involves reaction of an α-chloro ketone with an allyl Grignard in ether at -60 °C followed by treatment with ***Lithium*** powder (eq 3).[29]

(3)

An efficient synthesis of 3-*t*-aminopropanols is based on the regioselective ring opening of tetrahydro-1,3-oxazines with allylMgCl.[28]

Allylmagnesium halides have been used to prepare different organometallics.[1,15d]

Addition to Alkenic Bonds.

Allylmagnesium halides add smoothly to activated and some unactivated double bonds. Intermolecular and uncatalyzed carbomagnesiation of unfunctionalized alkenes, such as ***Ethylene*** and 1-octene, has been reported.[31-33] AllylMgCl[30] reacts with more than 90% regioselectivity with ***1,3-Butadiene*** (Mg at C-2) to afford 2,6-heptadienylmagnesium chloride (**5**) that, with a second carbomagnesiation, leads to 1:2 adduct (**6**), which undergoes a fast ring closure to (**7**) (eq 4).

(4)

The intramolecular carbomagnesiation involving reactive allylic Grignard reagents has been extensively studied.[34-38] The presence of a neighboring hydroxy, alkoxy, or amino group facilitates the addition of allylmagnesium halides.[39-42]

Addition to Azomethine Linkages.

Allylmagnesium halides add to the azomethine linkage easier than the alkyl counterparts. Highly asymmetric syntheses of β- and γ-amino acids with good stereocontrol have been described;[43] the crucial step is the addition reaction of allylMgBr to chiral *N*-benzylidene-*p*-toluenesulfinamides followed by the elaboration of the allylic group (eq 5).

(5)

Resonance stabilization of the allyl anion results in a greater ionization of the carbon-metal bond and hence greater reactivity. This promotes addition to C=N linkages usually unaffected by nonresonance-stabilized organometallic reagents.[44] Thus the reaction of allylmagnesium halides with achiral aldimines affords homoallylamines.[45] The stereochemistry of the addition has been studied.[46]

The addition of allylmagnesium halides to the *O*-protected α-hydroxy-*N*-trimethylsilylimines (**8**), generated in situ, proceeds in a highly *anti* stereocontrolled manner to produce α-amino alcohols[47] that can be oxidized to α-amino acids (eq 6).[48]

AllylMgBr, complexed with ***Cerium(III) Chloride***, adds to chiral (*E*)-alkoxymethyl oxime ether (**9**) to give the corresponding (*S*)-amine derivative stereoselectively, while allyllithium gives mainly the opposite (*R*)-isomer (eq 7).[49]

Allylmagnesium halides also add to imines, iminium salts, *N*-hetero substituted imines (oximes, sulfenimines, etc.), *gem*-amino ethers, *gem*-amino nitriles, ethers, peroxides, disulfides, epoxides, acids and their derivatives, amides, orthoformates, *O*-alkylated oximes.[15d,50]

AllylMgBr adds to the C=N double bond of several aza aromatics to form allylated aza aromatics.[51]

The reaction of 2-hetero substituted benzothiazoles with allylMgBr affords 2-allylbenzothiazole or 2,2-diallylbenzothiazoline or *N*-triallylmethyl-*o*-aminobenzenethiol depending upon the experimental conditions;[52] a novel ring-opening reaction of the benzothiazole system with allylic Grignards has been reported.[53] 2-Alkylbenzoxazoles also react with allylic Grignards, undergoing ring opening to *N*-diallylalkyl-*o*-aminophenols, while 2-chlorobenzoxazole affords the cross-coupling product.[54] Mono and bis addition reactions of the allylic Grignard reagents to the C=N bond of quinoxalines afford high yields of allyldihydroquinoxalines and diallyltetrahydroquinoxalines; dehydrogenation with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** leads to monoallyl- and diallylquinoxalines.[55] Similarly, reaction with pyrimidines furnishes excellent yields of allylpyrimidines.[56]

Reactions with Nitro Compounds and Nitriles.

Allylmagnesium halides react with both aromatic and aliphatic nitro compounds via addition to the nitro group, leading to allylamines or to *N*-hydroxyallylamines (eq 8).[57]

(8)

Allylmagnesium halides add to alkyl, aralkyl, and alkenyl cyanides in a preferred 2:1 ratio to yield trisubstituted primary amines.[58-60] The allyl groups on the carbinamine products are susceptible to catalytic hydrogenation to give *t*-alkyl primary amines, most of which are otherwise difficult to synthesize. Aryl nitriles react with allylmagnesium halides, leading to tetrahydropyridines.[61]

Related Reagents.

Allyllithium; ***Crotylmagnesium Bromide***; ***Methallylmagnesium Chloride***; ***3-Methyl-3-buten-1-ynylcopper(I)***.

Allylmagnesium Bromide-Copper(I) Iodide

[1730-25-2] · C_3H_5BrMg · Allylmagnesium Bromide-Copper(I) Iodide · (MW 145.29)

[7681-65-4] · CuI · Allylmagnesium Bromide-Copper(I) Iodide · (MW 190.44)

(regioselective alkylation;[2] stereo- and regioselective addition to propargylic alcohols;[3] can add to vinylic oxetanes to give homoallylic alcohols[5])

Preparative Methods: allylmagnesium bromide-copper(I) iodide complexes are prepared in situ under anhydrous conditions by reacting ***Allylmagnesium Bromide*** (**1**) with ***Copper(I) Iodide*** (**2**) in varying molar ratios.[1]

Handling, Storage, and Precautions: use in a fume hood.

Regioselective Alkylation.

Treatment of (**1**) (1.3 equiv) with octyl iodide in the presence of (**2**) (10 mol %) gave 1-undecene (eq 1). In the absence of (**2**) the reaction was slow (22% product after 28 h at 0 °C).[2]

(1)

Stereo- and Regioselective Addition to Propargylic Alcohols.

Primary propargylic alcohols undergo regio- and stereoselective additions of (**1**) in the presence of 10 mol % of (**2**) to give allylic alcohols (**3**) (eq 2).[3]

R = H, 60%; R = Me, 79%; R = Ph, 77%; R = Bu, 73%

Negishi et al. used this methodology in a synthesis of stereodefined exocyclic alkenes (**4**) (eq 3).[4]

Synthesis of Homoallylic Alcohols.

Vinylic oxetanes undergo regioselective ring opening to afford homoallylic alcohols (eq 4); preference for the (*E*) isomer was observed.[5]

(4)

R	R'	% yield	*E*:*Z* ratio

Allyl Phenyl Selenide[1]

[14370-82-2] · $C_9H_{10}Se$ · Allyl Phenyl Selenide · (MW 197.14)

(metalated derivatives are ambident nucleophiles;[2,4,6-9,11,15] sigmatropic rearrangements produce allyl alcohols and amines;[9-12] cleavage of Se-C bond provides a source of allyl anions,[13] cations,[6,14,15] and radicals[16,17])

Alternate Name: (2-propenylseleno)benzene.

Physical Data: bp 65-68 °C/1 mmHg;[2] 82-83 °C/3 mmHg.[3]

Solubility: insol water; sol most organic solvents.

Preparative Methods: from ***Allyl Bromide***,[2,4] chloride, or mesylate[4] and sodium benzeneselenolate (prepared by reduction of ***Diphenyl Diselenide***,[2,4] or deprotonation of ***Benzeneselenol***).[3] Numerous other procedures have been used, including the reaction of allylsilanes with ***Benzeneselenenyl Chloride***,[5a] allyl acetates with ***Phenyl Trimethylsilyl Selenide***,[5b] allyl halides with PhSeTl,[5c] and allylamines with PhSeLi (Ru catalyzed).[5d]

Purification: distillation in vacuo[2,3] or chromatography on silica gel[4] before use.

Handling, Storage, and Precautions: the compound is stable indefinitely in the freezer, but will slowly turn yellow at room temperature and in ambient light due to the formation of diphenyl diselenide. The compound is not excessively malodorous when pure, but should be prepared and handled in a fume hood due to the toxic nature of many organoselenium compounds.

Metalation.

Allyl phenyl selenide (**1**) is metalated with ***Lithium Diisopropylamide*** in THF at -78 °C (eq 1).[6,7] The 1-phenyselenoallyllithium (**2**) formed reacts principally at the α-position with alkyl halides and epoxides,[6] and at the γ-position with aldehydes and ketones.[6,8] If (**2**) is treated with ***Triethylaluminum*** prior to reaction with carbonyl compounds, mainly α-hydroxyalkylation is observed.[8] Representative regioselectivities are shown in eq 2.

MeI	18:22
s-BuBr	76:24
Me_3SiCl	82:18
PhCOMe	15:85
PhCOMe, Et_3Al	78:22
EtCHO	12:88
EtCHO, Et_3Al	100:0

Altered reactivity and well-defined regioselectivity can also be achieved by prior conversion to phenylselenoallylstannanes (**3**), which react at the α-position with cationic electrophiles such as iminium salts (eq 3).[9]

Like other stabilized organolithium reagents, (**2**) adds predominantly 1,2 to enones such as cyclopentenone in THF (1,2-adduct, α:γ = 62:18; 1,4-adduct, α:γ = 10:8) but gives exclusively 1,4-addition (α:γ = 81:5) when 1 equiv of ***Hexamethylphosphoric Triamide*** is added.[2]

[2,3] Sigmatropic Rearrangements.

A common application of allylic selenides is oxidation to form transient selenoxides, which undergo facile [2,3] sigmatropic rearrangement at low temperatures. In contrast to sulfur analogs, where the sulfoxide is usually favored, the equilibrium strongly favors the selenenate esters over the selenoxide,[10] so the rearrangement is very clean, requires no trapping reagents, and can typically be performed at 0 °C or lower.

An interesting extension is amination, in which allyl selenides are treated with an *N*-chloroamine (such as anhydrous ***Chloramine-T***) or primary amide or carbamate in the presence of ***N-Chlorosuccinimide***. This forms the selenimide in situ, which rearranges to an *N*-allylsulfonamide, -amide, or -carbamate (eq 4).[11]

Allylselenonium ylides also undergo sigmatropic rearrangements. The diazo-β-lactam (**4**) reacts with (**1**) with copper catalysis to form the allylated selenide (**5**) (eq 5).[12]

Allylic Rearrangement of Allyl Selenides.

Unsymmetrically substituted allyl selenides undergo easy allylic isomerization on irradiation or with acid catalysis, usually to favor primary over secondary selenides.[9,11] Such processes can be applied to the alkylation products of (**2**) to effect regiocontrolled further transformations, such as a second metalation and alkylation,[11] or oxidative,[9] or aminative [2,3] sigmatropic rearrangements.[11] Eq 6 presents an example involving an aminomethylated methallyl selenide.[9]

Allyl Phenyl Selenide as an Allylation Reagent.

The relatively weak C-Se bond in (**1**) and its alkylation products can be exploited to produce anionic and cationic allyl synthons. Treatment of (**1**) with ***n-Butyllithium*** results in Li/Se exchange to form ***Allyllithium***. Other allyl selenides also work.[13]

Allyl selenides (**3**) undergo coupling with organocuprates[6] and Grignard reagents in the presence of nickel catalyst.[14] The reaction of (**1**) with ***Triethylborane*** forms the alkylated allylboronate (**6**) by B to C alkyl transfer with displacement of the PhSe group. This boronate complex can be trapped with aldehydes, or allowed to rearrange to (**7**) before trapping, to give regioisomeric homoallyl alcohols (**8**) and (**9**), in ratios of 94:6, and 9:91, respectively (eq 7).[15]

(7)

There are also reports of allyl radical transfer from (**1**) to carbon[16] and sulfur (sulfonyl) centered radicals.[17]

Related Reagents.

Allyl Phenyl Sulfide.

Allyl Phenyl Sulfide[1]

[5296-64-0] · $C_9H_{10}S$ · Allyl Phenyl Sulfide · (MW 150.24)

(metalated derivatives are ambident nucleophiles; undergo reductive lithiation; precursors to sulfonium salts and sulfur ylides which undergo rearrangement)

Physical Data: bp 48-49 °C/0.43 mmHg; *d* 1.0220 g cm^{-3}.

Solubility: insol water; sol most organic solvents.

Form Supplied in: colorless liquid of 98% purity as obtained commercially.

Preparative Method: from ***Allyl Bromide*** and sodium thiophenolate in ethanol.[2]

Purification: distillation in vacuo prior to use.

Handling, Storage, and Precautions: must be handled in a fume hood due to stench caused by contamination with ***Thiophenol***. The pure sulfide has a more agreeable odor with a sweet overtone. No special precautions are necessary when handling in the atmosphere for weighing and transferring. In order to avoid autoxidation the sulfide should be stored in a well sealed vessel with exclusion of oxygen and moisture at 4 °C.

Metalation.

Treatment of allyl and alkylallyl phenyl sulfides with ***n-Butyllithium*** in THF gives lithiated reagents which predominantly react with alkyl halides in THF at C-α although substantial γ-alkylation takes place in certain cases.[1] α-Regioselectivity is enhanced by replacing phenyl with 2-pyridyl, thiazolyl, *N*-methylimidazolyl and others.[1a,1d] ***Hexamethylphosphoric Triamide*** decreases regioselectivity of alkylation.[1a] Lithiated prenyl phenyl sulfide adds to acetone primarily through C-α in the presence of [2.2.2]cryptate, whereas predominant addition through C-γ takes place in the absence of additives; ***1,4-Diazabicyclo[2.2.2]octane*** and ***N,N,N´,N´-Tetramethylethylenediamine*** have no effect on this regiochemistry.[3] Transmetalation may also be used to enhance regioselectivity in carbonyl addition.[1d] Lithiated allyl phenyl sulfide upon transmetalation with ***Titanium Tetraisopropoxide*** adds through C-α with carbonyl compounds,[4] and to a proline derivative (eq 1),[5] although the lithiated reagent alone reacts in the same way with indene oxide.[6] While the lithiated sulfide reacts with enones in THF at -78 °C to give mixtures of α- and γ-

carbonyl (or 1,2) adducts, HMPA (1.5 equiv.) induces kinetically controlled conjugate (or 1,4) addition through C-α.[7] This observation has been exploited in syntheses of prostaglandins,[8] and estra-1,3,5(10)-triene-6,11,17-trione.[9] The conjugate addition of the lithiated sulfide to 3-methylbutenenitrile in the presence of HMPA proceeds through C-α.[10] Stereoselectivity is rarely observed in addition reactions involving lithiated allyl phenyl sulfide, with exceptions being provided by the reactions involving 3-methylbutenenitrile[10] and the transmetalated sulfide with carbonyl compounds[4] and proline.[5]

Reductive Metalation.

Reductive lithiation with ***Lithium Naphthalenide*** or ***Lithium 1-(Dimethylamino)naphthalenide*** provides an efficient means of replacing the phenylthio group in a wide variety of substituted allyl phenyl sulfides with lithium to give allyllithium reagents not readily obtainable by other methods.[11]

Allylic Displacement.

Allyl phenyl sulfide undergoes displacement by Grignard reagents catalyzed by nickel phosphine complexes.[12] However, regioselectivity in alkylallyl cases is poor. Treatment of allylic sulfides bearing a thiazoline substituent with ***Iodomethane*** generates allylic iodides, a reaction driven by formation of methyliminium intermediates (eq 2).[13] Addition of alkyl radicals, generated from alkyl halides by a mixture of a cobalt(III) complex and zinc, to C-γ of allyl phenyl sulfide (and sulfone, see ***Allyl Phenyl Sulfone***) followed by loss of a phenylthio radical produces the alkylated product in high yield.[14]

Sigmatropic Rearrangements.

When the phenyl group is replaced by methylene attached to a charge-stabilizing group[15] or a group capable of undergoing transmetalation with lithium,[16] lithiation generates an α´-lithiated species which undergoes [2,3]-thia-Wittig rearrangement to homoallylic thiols (eq 3). The use of sulfur cation radicals in organic synthesis is rare. However, the cation radical derived from allyl phenyl sulfide and ***Cerium(IV) Ammonium Nitrate*** couples with silyl enol ethers to give a sulfonium adduct which rearranges to γ,δ-alkenyl-α-phenylthio ketones in high yields (eq 4).[17] Rearrangement of sulfonium ylides generated by the addition of carbenes to allyl sulfides proceeds to give (*E*)-homoallylic sulfides;[1b,1c,18] chirality in relevant cases is thereby transferred from C-1 to C-3 (eq 5).[19] Allyl phenyl sulfide undergoes Lewis acid-catalyzed conjugate addition to propiolic esters to give sulfonium allenes which rearrange to α-allyl-β-phenylthiovinyl esters.[20] The sulfide and related compounds also undergo a catalyzed [3,3]-thio-Claisen rearrangement to give *o*-allylbenzenethiols.[1b,21]

Allyl Phenyl Sulfone

[16212-05-8] · $C_9H_{10}O_2S$ · Allyl Phenyl Sulfone · (MW 182.24)

(metalated derivatives serve as ambident nucleophiles; reacts as a 1,1-allylic dianion or 1,1-allylic dipole equivalent[1])

Alternate Name: 1-phenylsulfonyl-2-propene.

Physical Data: bp 111-113 °C/0.5 mmHg; *d* 1.189 g cm^{-3}.

Solubility: insol water; sol most organic solvents.

Form Supplied in: colorless liquid with purity >98% as obtained commercially.

Preparative Method: from ***Allyl Bromide*** and benzenesulfinate in ethanol according to the original procedure[2] is most straightforward and avoids the use of strong-smelling thiols.

Purification: distillation in vacuo prior to use.

Handling, Storage, and Precautions: the sulfone is a stable compound and is handled without special precaution.

Metalation.

Treatment with ***n-Butyllithium*** in THF produces lithiated allyl phenyl sulfone. Structurally, the lithiated reagent is akin to a lithium dienolate in that it possesses an O-Li contact, and a C-1-S bond which has double bond character, although the X-ray structure of the diglyme solvate indicates that C-1 does not possess full sp^2 character.[3] In THF, the reagent alkylates through C-α in a manner similar to the sulfide and sulfoxide.[1] Carbonyl addition also proceeds in this mode.[4] However, with Michael acceptors, the behavior is intermediate between that of the sulfide and sulfoxide: acyclic unsaturated ketones and unsaturated esters undergo predominantly conjugate (or 1,4-) addition through C-α while cyclic enones preferentially undergo conjugate addition through C-γ.[5,6] The addition proceeds under kinetic control with high diastereoselectivity and is analogous to the sulfoxide reaction (see ***Allyl Phenyl Sulfoxide***).[6c]

However, ***Hexamethylphosphoric Triamide*** causes conjugate addition to both acyclic and cyclic enones through C-α to occur, the latter reaction paralleling that of the lithiated sulfide (see ***Allyl Phenyl Sulfide***).[6] Lithiated allyl phenyl sulfone adds through C-α to a bisepoxide to give a single adduct which, after internal proton transfer, undergoes cyclization to a precursor of brefeldin A (eq 1).[7]

Sulfonyl Leaving Group.

Allylic phenyl sulfones undergo regio- and stereoselective allylic displacement by lithium dialkylcuprates[8] and sodium diethyl malonate in the presence of Pd^0 catalysts[9] in good yields. Like the sulfides, the sulfones undergo radical fragmentation.[10] Addition of tributyltin radical followed by loss of the arylsulfonyl radical affords the allylically transposed stannane. Acid hydrolysis then gives the terminal alkene without contamination with the other regioisomer.[10a,10b] The reaction is not applicable to γ-alkylallylic sulfones. The stannane reacts with *sym*-trioxane in the presence of a Lewis acid catalyst with concomitant destannylation, thereby rendering the allylic sulfone functionally equivalent to a 1,1-dianion (eq 2).[10b] Alkenes are prepared by α-alkylation of lithiated allyl phenyl sulfone followed by conversion into the vinyl sulfone with ***Potassium t-Butoxide*** in THF,[11,12] and then reductive cleavage of the phenylsulfonyl group with lithium in ethylamine.[11] α-Alkylation of lithiated allylic phenyl sulfones bearing other alkyl or functional groups followed by base-induced elimination[13] or reductive cleavage[14] is used in the synthesis of polyenes such as vitamin A and squalene. The weak Lewis basicity of the sulfonyl group enables allylic phenyl sulfones to be activated by Lewis acids in Friedel-Crafts alkylation of aromatic rings with displacement of the phenylsulfonyl group.[15] Thus alkylation of lithiated allyl phenyl sulfone followed by the Friedel-Crafts reaction renders the sulfone functionally equivalent to a 1,1-dipole. A conjugate addition-enolate trapping sequence commencing with DMPU-induced conjugate addition of lithiated prenyl tolyl sulfoxide to 2-methylcyclopentenone provides an adduct which undergoes Lewis acid-catalyzed intramolecular cyclization to a 1,11-epithio steroid (eq 3).[15b] The dipolar characteristic of allylic sulfones is also illustrated in the synthesis of chrysanthemic acid from lithiated prenyl phenyl sulfone.[16] The conjugate adduct with dimethylacrylate undergoes an internal nucleophilic displacement of the phenylsulfonyl group to form the cyclopropane (eq 4). A preparation of prephytoene is carried out in similar fashion.[17] Lithiated allyl phenyl sulfone couples with iodocarbenoids to form 1-iodo-1,3-dienes in high yields and with high stereoselectivity for the *E*-isomer.[18]

Allyl Phenyl Sulfoxide[1]

[19093-37-9] · $C_9H_{10}OS$ · Allyl Phenyl Sulfoxide · (MW 166.23)

(allylic sulfoxides undergo allylic rearrangement to form sulfenate esters, allowing the generation of allylic alcohols; metalated derivatives serve as ambident nucleophiles; precursors to Pummerer intermediates)

Physical Data: bp 103-104 °C/0.36 mmHg; *d* 1.1205 g cm^{-3}.[2]

Solubility: insol water; sparingly sol hexane; sol most other organic solvents.

Preparative Methods: oxidation of ***Allyl Phenyl Sulfide*** in dichloromethane with ***m-Chloroperbenzoic Acid*** acid (1.2 equiv) added slowly as a solution in dichloromethane at -70 °C affords the sulfoxide in high yields with minimal over-oxidation to the sulfone. The *m*-chlorobenzoic acid formed may be removed simply by filtration. Other oxidizing agents such as ***Sodium Bromite***[3] and ***Trifluoroperacetic Acid***[4] afford the sulfoxide in yields greater than 80% and are also highly selective.

Purification: distillation in vacuo prior to use.

Handling, Storage, and Precautions: no special precautions are required. The sulfoxide may be handled normally at the bench for general weighing and transferring. However, for maximum shelf-life it is recommended that it be stored at 4 °C in a sealed vessel with exclusion of oxygen and moisture.

Sulfoxide-Sulfenate Rearrangement.

The important observation by Mislow and co-workers that allyl phenyl sulfoxide and other allylic sulfoxides may be prepared from allylic sulfenate esters, obtained from the corresponding allylic alcohol and an electrophilic sulfenylating agent,[5] in an equilibrating [2,3]-sigmatropic rearrangement was the key to establishing the synthetic utility of these compounds. Conversely, the sulfoxide may be converted into the allylic alcohol by intercepting the intermediate sulfenate ester formed in the equilibrium with the sulfoxide by treatment with a thiophilic reagent typically ***Trimethyl Phosphite***, tertiary phosphine, or secondary amine in methanol, which cleaves the sulfenate ester. Stereocontrol of the rearrangement is dependent on the types of groups attached to the allylic substituent. Selectivity for the (*E*) isomer occurs when R^1 is larger than R^2 (eq 1)[1a,1c] or when both R^1 and R^3 are alkyl groups and R^2 is a proton.[1c,6] In order to achieve (*E*) selectivity for 2,3,3-trisubstituted systems, a substituent at C-1 of the allylic

sulfoxide must have β-branching (eq 2).[7]

(2)

Whilst optically active allyl tolyl sulfoxides may be prepared from allyl Grignard reagents and ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***,[5a,8] the sulfoxide-sulfenate rearrangement causes facile epimerization at the sulfur atom. Racemization is generally less facile when the nonallylic substituent is alkyl rather than aryl.[5a] Thus, approaches to allylic sulfoxides derived from camphor[9] and 10-mercaptoisoborneol[10] have been developed wherein the configurational stability is promoted by a neighboring hydroxyl group. In another approach the rearrangement is not suppressed but rather is rendered highly stereoselective by the use of a bulky arylbiphenyl chiral auxiliary so that the other diastereomer is disfavored on thermodynamic grounds (eq 3).[11]

Metalation.

Treatment of allyl phenyl sulfoxide[12] with ***Lithium Diisopropylamide*** in THF produces the lithiated sulfoxide. Alkyllithium reagents are not generally successful because of competing displacement at sulfur. The lithiated reagent is likely to be structurally akin to a lithium dienolate in that it possesses an O-Li contact, and a C-1-S bond which has double bond character.[12] Reaction with alkyl halides proceeds preferentially at the α-carbon;[1,13] however, regioselectivity is somewhat better than for allyl phenyl sulfide. Subsequent conversion of the α-substituted sulfoxide into the allylically transposed alcohol renders the starting sulfoxide operationally equivalent to a 3-hydroxyvinyl anion.[1c,13] Reaction with cyclic enones is predominant conjugate (or 1,4) addition through the γ-carbon, a regiochemical outcome which is not disrupted by external chelating agents.[14,15] This regioselectivity has been exploited for lithiated allyl *p*-tolyl sulfoxide in a synthesis of pentalenolactone (*E*)-methyl ester[16] and for lithiated 1-pentylallyl phenyl sulfoxide in syntheses of racemic prostaglandin I_2 analogs[14a] and racemic 11-deoxyprostaglandin E_1 (eq 4).[14b] Both the pronounced tendency of the lithiated reagent to undergo conjugate addition and the sigmatropic rearrangement of the neutral reagent to provide the allylic alcohol are well illustrated in the latter synthesis. The vinyl sulfoxide product (**1**) is converted via the intermediate allylic sulfoxide into the allylic alcohol (**2**) by means of ***Potassium t-Butoxide*** in *t*-butanol to give the 13*SR* isomer. The acetate is then converted into the allylically transposed allylic acetate (**3**) by means of $PdCl_2$.2MeCN (see ***Palladium(II) Chloride***) to form the 15*SR* diastereomer. For lithiated (*E*)- and (*Z*)-allylic sulfoxides bearing an alkyl group at C-3, highly stereoselective conjugate additions to cyclopentenone take place to give *syn* and *anti* vinylic sulfoxides such that the configuration at the two new stereogenic centers and at sulfur is rigidly defined by the double bond geometry of the allylic sulfoxide (eq 5).[15b,15d]

(5)

The conjugate addition proceeds under kinetic control[15a] and is explained by invoking a *trans*-decalyl-like transition state model.[15b,15d] By using optically pure allylic sulfoxides, single enantiomeric products are obtained. The use of camphor as the nonallylic substituent enables single enantiomeric allyl sulfoxides to be prepared[9] and these undergo conjugate addition to cyclopentenones with complete face selectivity (eq 6),[9b] albeit in moderate yields (50-60%). The use of an arylbiphenyl chiral auxiliary attached to sulfur affords in some cases higher yields of the adducts with good to excellent diastereoselectivity.[11b]

(6)

Similarly, lithiated reagents from optically pure *p*-tolyl allylic sulfoxides[5a] undergo conjugate addition to a variety of cyclic enones, and the adducts have been converted into (+)-pentalenene,[17] (+)-hirsutene,[18] and (+)- and (-)-13-epoxytrichothec-9-ene.[19] In other cases, configurational integrity of the products is maintained during conversion into bicyclo[2.2.1]heptanones[14d,20,21] and bicyclo[3.3.0.]octanones.[21,22] The regio- and stereoselectivity of reactions of lithiated allyl phenyl sulfoxide with carbonyl compounds is not as pronounced as that with cyclopentenones.[23] Nevertheless, the introduction of additives to modify the reactivity of the reagent has made carbonyl addition a

synthetically useful transformation.[24] Whereas reaction with α-methyl aldehydes gives a mixture of α- and γ-adducts, addition of ***Hexamethylphosphoric Triamide*** enhances α-addition while transmetalation with cadmium(II) encourages γ-addition (eq 7).[24a] This outcome is contrary to that observed with the carbonyl addition of metalated allyl sulfides (see ***Allyl Phenyl Sulfide***). For alkoxyaldehydes, use of lithiated 2-pyridyl allyl sulfoxide gives higher α-selectivity and superior yields,[24b] a reactivity paralleling that of the corresponding sulfide.

HMPA	9:1	75%
$CdCl_2$	1:14	68%

The α-adducts obtained from the reaction of lithiated allyl *p*-tolyl sulfoxide with aldehydes in the presence of HMPA,[24] and of lithiated prenyl phenyl sulfoxide with 1,2-epoxy-2-methyl-3-butene,[25] are converted via the sulfoxide-sulfenate rearrangement into functionalized diols (eq 8).

Vinylthionium Ions.

Polarity reversal may be achieved by converting allyl phenyl sulfoxide into the corresponding vinylthionium ion or equivalent via a Pummerer reaction. Such an electrophilic species also has ambident reactivity and may react with nucleophiles through the α- or the γ-carbon (eq 9).[26]

(9)

Thus allyl phenyl sulfoxide reacts with silyl enol ethers in the presence of ***Trimethylsilyl Trifluoromethanesulfonate*** and ***Diisopropylethylamine*** with high γ-selectivity. The reaction proceeds in good yields, although the scope is limited to the parent allyl system and to 2-alkylallyl aryl sulfoxides (eq 10).[26a]

(10)

In the absence of the silyl enol ether the vinylthionium ion is converted by the tertiary amine in high yield into a quaternary ammonium salt which can be alkylated with dimethyl sodiomalonate in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** in 60% yield.[26b] The use of *N*,*N*-diethyl(trimethylsilyl)amine as the tertiary amine to generate the quaternary salt followed by silyl group removal with ***Trimethylsilyl Trifluoromethanesulfonate*** affords the neutral amine adduct, a masked Mannich derivative, in 90% yield (eq 11).[26b] (α-Trimethylsilyloxy)allyl phenyl sulfide is generated in 53% yield from allyl phenyl sulfoxide and trimethylsilyl ketene acetals in the presence of ***Zinc Iodide*** in acetonitrile via the silyl-Pummerer reaction.[27] Transfer of the silyl group from the ketene acetal to the sulfoxide oxygen leads to a sulfonium intermediate which then traps the liberated silyloxide (eq 12).

Nucleophilic Substitution of the Sulfinyl Group.

Allylic substitution of the sulfinyl and the sulfonyl (see ***Allyl Phenyl Sulfone***) group in 1-alkyl-2-methylallylic sulfoxides and sulfones by lithium dialkylcuprates proceeds with high regio- and stereoselectivity to give trisubstituted alkenes.[28]

Allyltitanium Triphenoxide[1]

[130004-39-6] · $C_{21}H_{20}O_3Ti$ · Allyltitanium Triphenoxide · (MW 368.27)

(reagent for the regioselective allylation of epoxides at the most substituted carbon;[2] the crotyl homolog reacts stereoselectively with aldehydes[3] and ketones[4])

Solubility: reactions are normally performed in THF.

Form Supplied in: not available commercially.

Preparative Methods: the reagent is prepared in situ by reacting the corresponding Grignard derivative in THF at -78 °C -> -30 °C with $ClTi(OPh)_3$.[3] The latter is prepared by refluxing ***Chlorotitanium Triisopropoxide*** and phenol in toluene, with the azeotropic removal of isopropanol. Reactions of the reagent with epoxides are normally performed at -78 °C, while reactions with aldehydes and ketones are started at -100 °C.

Organotitanium Reagents.

The conversion of allyl or crotyl organometallics to derivatives of the general type $RCH{=}CHCH_2TiX_3$ (X = OR´ or NR''_2) or the corresponding titanates $RCH{=}CHCH_2TiX_4MgCl$ (X = OR´ or NR''_2) often results in significant improvements in the chemo-, regio-, diastereo-, and enantioselectivity of these reagents.[1] The increased steric and electronic requirements of the titanated species lead to a synthetically useful modulation of the nucleophilicity, Lewis basicity, and Lewis acidity of these reagents. Also, in the case of crotylmetals, titanation often produces configurationally homogeneous systems, resulting in an enhanced diastereoselectivity during carbonyl additions.

Regioselective Allylation of Epoxides.

The reaction of unsymmetrical epoxides with carbon nucleophiles at their most substituted position is generally a difficult transformation. Normally these epoxides react with organocopper reagents and other similar nucleophiles in an S_N2 manner at their least substituted carbon. In the case of styrene oxides (eq 1), a variety of allyltitanium derivatives,[1d] including $CH_2{=}CHCH_2Ti(OPh)_3$,[2] favor allylation at the most substituted epoxide carbon, presumably via an S_N1-like pathway.

(1)

M =	MgCl	70:30
	$Ti(O\text{-}i\text{-}Pr)_4MgCl$	>99:<1
	$Ti(O\text{-}i\text{-}Pr)_3$	>99:<1
	$Ti(OPh)_3$	>99:<1

Similar reactivity and selectivity is usually not observed with alkyl-substituted epoxides. The use of $CH_2{=}CHCH_2Ti(O\text{-}i\text{-}Pr)_3$ in these cases gives substantial amounts of a hydride reduction product Meerwein-Ponndorf-Verley reduction. A good reagent for this purpose, however, is $CH_2{=}CHCH_2Ti(OPh)_3$, which gives, in high yields, almost exclusively the products of allylation at the most substituted epoxide carbon (eq 2).[2]

(2)

X = O-*i*-Pr, 1:1
X = OPh, 22:1

When the most substituted carbon is chiral, the reaction proceeds with a high degree of inversion of configuration (eq 3).[2]

(3)

trans:*cis* = 10:1

Stereoselective Addition to Aldehydes and Ketones.

Although allyltitanium reagents of the general type $CH_2{=}CHCH_2TiX_3$ (X = OR´ or NR´´$_2$) add to carbonyl compounds in a highly chemoselective manner,[1] the use of the triphenoxy derivative (X = OPh) does not offer any significant advantages over other more readily available variants (e.g. X = O-*i*-Pr). In the case of crotyltitanium species, however, the triphenoxytitanium derivative is one of the most diastereoselective (eq 4).[3]

(4)

X =		
	OPh	85:15
	O-*i*-Pr	80:20
	NEt_2	70:30
	NMe_2	52:48

More bulky phenolic substituents do not result in improved diastereoselectivity (eq 5).[3]

X =	OBu	78:22
	O-*i*-Pr	84:16
	NEt	85:15

R = *t*-Bu	90:10
R = Me	92: 8
R = H	96: 4

A similar reaction takes place with ketones, although the diastereoselectivity depends on the relative size of the large (R_L) and small (R_S) substituents (eq 6).[4]

R =		
	Me	90:10
	Et	74:26
	i-Pr	55:45
	t-Bu	3:97

Allyltributylstannane[1]

[24850-33-7] · $C_{15}H_{32}Sn$ · Allyltributylstannane · (MW 331.11)

(allylating reagent for many compounds, including alkyl halides, carbonyl compounds, imines, acetals, thioacetals, and sulfoximides)

Alternate Name: allyltributyltin.

Physical Data: bp 88-92 °C/0.2 mmHg; fp > 110 °C; *d* 1.068 g cm^{-3}.

Solubility: sol dichloromethane, diethyl ether, THF, toluene, benzene.

Form Supplied in: colorless liquid; widely available.

Purification: distillation.

Handling, Storage, and Precautions: all organotin compounds are highly toxic.

Allylstannanes are widely used as allyl anion equivalents.[1] They are less reactive than the corresponding magnesium or lithium reagents and, hence, can be classified as storable organometallic reagents.[13b] This reduced activity increases the ease of handling in the laboratory; however, higher reaction temperatures or activation with Lewis acids are necessary. The relative reactivities of allyltriphenylsilane, -germane, and -stannane with diaryl carbenium ions are 1, 5.6, and 1600, respectively.[2] Allyltributylstannane is more reactive than ***Allyltriphenylstannane*** by three orders of magnitude. Allyl- and crotyltrialkyltin reagents undergo transmetalation reactions with strong Lewis acids through an S_E2' pathway.[3] Competing transmetalation processes can affect the mechanistic pathway and product distribution.[4] Radical processes can also be exploited in allylation reactions employing stannanes.[5] Because of the high toxicity of organotin reagents, allyltributyltin is more widely used than the more volatile allyltrimethyltin.

Additions to Aldehydes.

Allyltrialkyltin reagents, such as allyltributyltin (**1**), react with carbonyl compounds[1] to form homoallylic alcohols under photolytic,[6] thermal,[7] high pressure,[8] or, more commonly, Lewis acidic conditions.[9] The order of reactivity is aldehydes > methyl ketones > internal ketones. A number of stereochemical issues are important when substituted allylic stannanes are utilized (see ***Crotyltributylstannane*** for details).

Selective conversion of protected α-hydroxy aldehydes (**2**) to monoprotected derivatives of *syn*- or *anti*-1,2-diols by reaction with allyltrialkylstannanes is realized with judicious choice of Lewis acid and protecting group.[10] ***Magnesium Bromide***, ***Titanium(IV) Chloride***, and ***Zinc Iodide*** favor *syn* products (**3**), especially with the benzyloxy derivative (**2a**), while use of ***Boron Trifluoride Etherate*** favors the *anti* products (**4**), particularly with the *t*-butyldimethylsilyl ether (**2b**) (eq 1).

(2a) R = CH_2Ph	**(3a)**	$MgBr_2$	250 : 1	**(4a)**
		BF_3-OEt_2	39 : 61	
(2b) R = $SiMe_2$-*t*-Bu	**(3b)**	$MgBr_2$	21 : 79	**(4b)**
		BF_3-OEt_2	9 : 91	

The ***Tin(IV) Chloride*** promoted allylation of α-methylthio aldehydes with allyltriphenyltin is highly selective for *anti* products, while the selectivity from $BF_3.OEt_2$ mediation is variable.[11] A very mild promoter system, 5 M ***Lithium Perchlorate*** in diethyl ether, was used to allylate dialdose derivatives with high selectivity.[12] Acetals, ethers, and silyl ethers survive the allylation of aldehydes with this promoter.

β-Alkoxy aldehydes, with alkyl groups at C-2, readily form stable chelates with $TiCl_4$, $SnCl_4$, and $MgBr_2$ and consquently show high levels of *anti* selectivity in allylations with allyltributyltin.[13] High levels of diastereofacial selectivity in the Lewis acid mediated additions of allylstannanes to β-alkoxy aldehydes with substituents at C-3 are achieved when (a) the protecting group permits effective bidentate chelation between the aldehyde carbonyl and the ether oxygen and (b) the protecting group provides enough steric bulk to force C-3 substituents into an axial position in the six-membered chelate formed with the Lewis acid. $TiCl_4$ shows the highest *anti* selectivity when the protecting group is benzyl (R = *n*-hexyl; 96:1) and poor selectivity for methyl protection (R = *n*-hexyl; 3.8:1) (eq 2). $SnCl_4$ provides poor selectivities for all C-3 alkyl substituted β-alkoxy aldehydes. These results are consistent with predictions based upon ground state solution structures which show that the preferred conformation for $TiCl_4$ and

$MgBr_2$ chelates has the alkyl group in a pseudoaxial position when the protecting group is ethyl or benzyl. Chelation is not involved in the reactions of α-or β-siloxy aldehydes.[14] In $TiCl_4$ promoted allyltriphenylstannane additions to β-alkoxyaldehydes with a methyl group at C-3, benzyl protection provides superior *anti* selectivity (29:1) to (methylthio)methyl (2:1) and (benzyloxy)methyl (9:1) groups.[15]

Allylation of Ketones.

While irradiation of mixtures of aromatic ketones and allyltrialkylstannanes usually affords coupling products which are allylated at the carbonyl carbon,[6a,b] selective allylation at the α-carbon of aromatic α,β-epoxy ketones is observed (eq 3).[16] Yields of the α-allyl-β-hydroxy aryl ketones are highest when the *para* substituent is an electron-withdrawing group (CN) and lowest when it is an electron donor (MeO). Quinones undergo 1,4-monoallylation with allyltributyltin in the presence of BF_3 etherate (eq 4). However, 4-substituted 1,2-naphthoquinones and sterically hindered 3,5-di-*t*-butyl-*o*-quinones undergo 1,2-addition (eq 5).[17]

(5)

Allyltributylstannane in the presence of BF_3 etherate is a more efficient α-allylating reagent for quinones than the allylsilane-$TiCl_4$ reagent system. Eleutherin and isoleutherin were synthesized, in part, by this method.[18]

Unsymmetrical aryl alkyl α-diketones are regioselectively allylated by allylstannanes at the benzylic carbon under photolytic conditions and allylated at the acyl carbon in the presence of BF_3 etherate (eq 6).[19] Stannylated cyclopentanes are formed from the reaction of allyltributylstannane with aluminum trichloride-activated α,-β-unsatured acyliron complexes.[20] Stereochemistry about the alkene is preserved in this reaction.

(6)

Allylation of Organohalides.

Alkyl halides[21] and selenides[22] are allylated by allylstannes under thermal (with ***Azobisisobutyronitrile***), photochemical (with a tungsten lamp), or palladium-catalyzed conditions in high yield (eqs 7 and 8). Palladium catalyzes many reactions of allyltin reagents with various electrophiles, including allyl halides, aryl iodides and bromides, activated aryl chlorides, acid chlorides, vinyl halides, vinyl triflates, α-halo ketones and esters, and α-halo lactones.[23]

(7)

(8)

Aliphatic, aromatic, and heterocyclic acid chlorides react with allyltrialkylstannanes to give ketones in high yield (eq 9). Functional groups such as nitro, nitrile, haloaryl, methoxy, ester, and aldehyde are tolerated. An alternative palladium-catalyzed ketone synthesis involves the coupling of primary, secondary, or tertiary halides with carbon monoxide and allyltin (eq 10). Allyltributyltin adds to α-alkoxy-β-siloxy acylsilanes, with high *syn* selectivity (*syn*:*anti* = 91:9) in the presence of ***Zinc Chloride***.[24] A monoprotected *syn*-1,2,3 triol results from protiodesilylation. The palladium-catalyzed reaction of α-halo ketones with acetonyl- and allylstannanes produces oxiranes, oxetanes, and tetrahydrofurans in good yield.[25] Most allylic acetates do not react, although cinnamyl acetate and allyl acetate are exceptions.

(9)

(10)

Stille Reaction.

The reaction between phenyl triflates (a vinyl triflate) and allylic stannanes is useful for the synthesis of substituted aromatic compounds (eq 11).[26] The reaction works well with most highly substituted phenols except for hexasubstituted ones.[27] The reaction has been extended to the less expensive aryl fluorosulfonates[28] and aryl arenesulfonates.[29] These reactions proceed in good yield unless the aryl ring contains electron-donating substituents.

(11)

Allylation of Acetals.

In the presence of a Lewis acid, 1,3-dioxolanes can be allylated with allyltributylstannanes or allylsilanes.[30] The Lewis acid promoted cleavage of chiral acetals with allylstannes affords chiral ethers with reported diastereoselectivites of > 500:1 (eq 12).[31] Allylation of monothioacetals and dithioacetals occurs in a highly *syn* selective fashion to form homoallyl sulfides in good yield, particularly with $GaCl_3$ as the Lewis acid promoter.[32]

(12)

Allylation of Imines.

Aldimines are converted to homoallylamines by allyltributyltin with Lewis acid promotion in moderate to high yield.[33] Likewise, β-methyl homoallylamines (predominantly *syn*) result from the reaction of ***Crotyltributylstannane*** with the $TiCl_4$ chelate of aldimines. In the $TiCl_4$-mediated allylstanne addition to (**5**), the Cram product is favored (92:8) (eq 13).[34]

Allyltributyltin is also useful for α-allylations of *N*-acyl heterocycles, including pyridinium salts.[35] Isoquinolines (or dihydroisoquinolines) can be simultaneously acylated and allylated by the addition of α,β,γ,δ-unsaturated acyl chloride and allyltributyltin. The resulting adduct undergoes a Diels-Alder cyclization yielding an isoquinoline alkaloid precursor (eq 14).[36] Acylation and allylation of imidazoles is a particularly useful route to highly substituted 2-allylimidazolines (eq 15).[37]

Acylimininium ions, formed by the reaction of α-alkoxy carbamates with Lewis acids, undergo allyl transfer from allylstannanes or silanes (eq 16).[38]

(16)

Allylation of Sulfoximidoyl Chlorides.

A variety of *S*-allylsulfoximines can be synthesized in high yield by the allylation of sulfoximidoyl chlorides (eq 17).[39] Thiocarbonates are also allylated under photolytic conditions.[40]

(17)

Radical Allylations.

In addition to ionic pathways, radical processes can also be employed in allylations using stannanes.[5,21] The 1,2-asymmetric induction in radical allylations of α-alkoxycarbonyl radicals has been investigated. The observed selectivities, ranging from 1:1 to 99:1, are consistent with transition-state models which incorporate favorable stereoelectronic effects and the minimization of $A^{1,2}$, $A^{1,3}$, and torsional strain.[41] The camphorsultam derivative (**6**) undergoes thermal allylation (10% AIBN, 80 °C, benzene) with stannanes to give the allylated products in excellent yield with diastereoselectivities of 12:1 (eq 18).[42] Allyl transfer to quinones and α,β-epoxy ketones by single electron transfer pathways has also been investigated.[43]

Related Reagents.

Allyltriphenylstannane; ***Crotyltributylstannane***.

Allyl Trichloroacetimidate[1]

[51479-73-3] · $C_5H_6Cl_3NO$ · Allyl Trichloroacetimidate · (MW 202.47)

(delivers allyl group under mild conditions;[2] used in the preparation of N-containing intermediates[1])

Physical Data: bp 74 °C/11 mmHg.

Solubility: sol hexane, ether, dichloromethane.

Preparative Methods: typical procedure:[2] ***Sodium Hydride*** (0.5 g, 21 mmol) is slurried in anhydrous ether (20 mL) under a nitrogen blanket. Allyl alcohol (210 mmol) is introduced in ether (30 mL) dropwise with stirring to the slurry. After 20 min, the homogeneous solution is cooled to 0 °C and ***Trichloroacetonitrile*** (20 mL, 200 mmol) is added over 15 min. The mixture is allowed to warm to 20 °C over 60 min and then concentrated to a syrup. Pentane (20 mL) containing methanol (0.8 mL, 21 mmol) is added followed by vigorous shaking, filtration, and concentration of the filtrate and pentane washings (2 × 20 mL). The product imidate is obtained as a clear liquid (90-97%). No further purification is required. Alternatively, the imidate can be prepared by using sodium methoxide as a catalyst instead of sodium hydride. Other procedures for the preparation of allyl trichloroacetimidate have been reported.[3,4]

Handling, Storage, and Precautions: allyl trichloroacetimidate can be stored in solutions of hexane for up to 2 months at 0 °C. Preparation of allyl trichloroacetimidate should be performed in a well ventilated hood to avoid exposure to trichloroacetonitrile vapors.

O-Allylation and Protecting Group Delivery.

Protecting groups have become an important part of natural and unnatural product chemistry. In oligosaccharide synthesis, they are vital in obtaining the desired compounds because of the various sites at which reaction can occur if hydroxyl groups, for example, are left unprotected. Allyl groups are one of the many substituents used as a protecting group. This group can be delivered to a free hydroxyl group via a trichloroacetimidate derivative. More importantly, the use of allyl trichloroacetimidate allows the protection of an alcohol to take place in the presence of an ester. This is due, in part, to the fact that this reagent is applied under mildly acidic conditions. For example, a rhamnoside is dissolved in dichloromethane and to it is added allyl trichloroacetimidate in cyclohexane followed by a catalytic amount of triflic acid. After 18 h at 20 °C the allylated product is isolated after neutralization with $NaHCO_3$ and

chromatography (eq 1).[2,5]

(1)

Substituted tetrahydrofurans have been prepared by using allyl trichloroacetimidate to generate allyl ether intermediates. For example, the hydroxy ester prepared from ***Methyl Bromoacetate*** and isobutyraldehyde reacts with allyl trichloroacetimidate and a catalytic amount of ***Trifluoromethanesulfonic Acid*** to give the allylic ether ester in 80% yield (eq 2).[6] The resulting tetrahydrofuran-3-one is prepared in four steps with high stereoselection, which is attributed to the use of ***Copper(II) Acetylacetonate*** as the cyclization catalyst.

(2)

7:93

α-Amino acids can be prepared from allylic alcohols using allylic trichloroacetimidates. Thermal 1,3-transposition of the imidate group of allyl trichloroacetimidate is accomplished in refluxing xylene. Oxidation and acidic hydrolysis

afford the corresponding α-amino acid (eq 3).[7] Other acids prepared by this methodology include imidates derived from benzyl alcohol, 4,4-dimethyl-2-pentenol, and 2-butenol.

(3)

Allyl trichloroacetimidate has also been used to deliver an acetaldehyde equivalent in the preparation of β-hydroxy-α-amino acid derivatives. An *anti*-Phe-Leu mimetic was prepared in four steps from the *O*-allyl ether of *N*-phthaloyl-L-phenylalanyl-L-serine. This allyl ether was prepared from allyl trichloroacetimidate and the β-hydroxy-α-amino acid in 60-74% yield (eq 4).[8]

Benzyl groups can be used to protect alcohols in place of the allyl group with comparable yields. For example, under similar reaction conditions, an isopropylidene protected pyranoside was treated with benzyl trichloroacetimidate at room temperature to give a benzyl ether in 82% yield (eq 5).[1,9]

N-Containing Compounds from Imidates.

The synthetic procedure to make allyl trichloroacetimidate has been useful for other allylic imidate systems.[1] For example, geraniol trichloroimidate is prepared by reacting geraniol with sodium hydride in ether. The cooled (-10 °C) solution is treated with ***Trichloroacetonitrile*** followed by work-up with a methanolic-pentane solution to give the corresponding imidate. Amines and amides are prepared from these intermediates. Thermal rearrangement of the imidate, followed by hydrolysis, gives rise to 1,3-transposition of hydroxyl and amino groups. The amine is produced in 61% yield (eq 6).[4,10]

Related imidates can undergo [3,3]-sigmatropic rearrangements by using a palladium(II) catalyst instead of heat. For example, an allyl trichloroacetimidate rearranges to the corresponding amide when catalyzed by ***Bis(benzonitrile)dichloropalladium(II)*** in THF (eq 7).[11] The reaction goes in 8% yield with complete chirality transfer.

Allylic trichloroacetimidates undergo iodocyclization to give the corresponding 4,5-dihydro-1,3-oxazines. The regioselection of the reaction depends on the alkene geometry of the starting allyl imidate (eq 8).[12]

Allyl Trifluoromethanesulfonate

[41029-45-2] · $C_4H_5F_3O_3S$ · Allyl Trifluoromethanesulfonate · (MW 191.16)

(extremely reactive allylating agent;[1,2] attacks a variety of S-, P-, N-, or O-containing molecules;[2] ring expansion reaction[3])

Alternate Name: allyl triflate.

Physical Data: d 1.47 g cm^{-3}.

Solubility: sol chlorinated hydrocarbons.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: IR (neat, cm^{-1}) 2970 (w), 1413 (m), 1281 (s), 1248 (s), 1194 (s), 1149 (m), 913 (m); ^1H NMR (CCl_4, ppm) δ 6.03 (m, 1H), 5.43 (m, 2H), 4.92 (m, 2H); ^{19}F NMR (ppm) φ 74.5 (s).

Preparative Methods: allyl triflate is prepared by the reaction of ***Trifluoromethanesulfonic Anhydride*** (1 equiv) and allyl alcohol (1 equiv) in the presence of pyridine (1 equiv) in carbon tetrachloride at 0 °C.[1] The insoluble pyridine salt is removed by filtration through sodium sulfate, and the resulting solution is used directly for allylation reactions. The yield of the reaction is reported to be 75 ± 5% based on quantitative NMR analysis of aliquots.

Purification: a pure sample may be obtained by distillation (safety shield).[2] The product must be trapped in a cold receiver (-78 °C).

Handling, Storage, and Precautions: allyl triflate must be stored at -78 °C in a vented flask. The half-life of the neat reagent is ~10 min at room temperature, and the reagent in carbon tetrachloride solution completely decomposed in 3 days at room temperature. Allyl triflate reacts violently with nitrogen, or oxygen-containing solvents such as DMSO, DMF, or acetonitrile. The reagent is an extremely reactive allylating agent, and contact or inhalation should be avoided. Use in a fume hood.

S-Allylation-Ring Expansion.[3]

Allyl triflate is an extremely reactive allylating agent and reacts readily with 2-vinylthiapentane (**1**). α-Vinyl-*S*-allylsulfonium salt (**2**) thus obtained undergoes a 2,3-sigmatropic rearrangement upon treatment with a base (***1,8-Diazabicyclo[5.4.0]undec-7-ene***) (eq 1). Two rearrangement products (**3**) and (**4**) were obtained in the ratio of 1:1 that were derived from endocyclic and exocyclic ylides, respectively. Repeated application of this sequence to the eight-membered ring sulfide (**4**) produced medium- and large-sized ring sulfides. No products derived from the endocyclic ylides were observed in the ring expansion sequence from cyclic sulfide (**4**). 2-Vinylthiane also undergoes allylation and a 2,3-sigmatropic rearrangement sequence to produce a 1:2 mixture of cyclic sulfides (**7**) and (**8**) (eq 2). An improved ratio of products (**7**:**8** = 1:24) was obtained by using ***Lithium Diisopropylamide*** at -70 °C for ylide generation, and forcing the rearrangement to occur rapidly under dilute conditions (eq 3). The 2,3-sigmatropic rearrangement of six-membered rings takes place with remarkable stereospecificity,[4] and only the *trans* isomer of nine-membered ring sulfide (**8**) was observed.

C-, *N*-, *O*-Allylation.

5-Chloromercuriuridine (**9**) undergoes a palladium-catalyzed *C*-allylation reaction with allyl triflate (eq 4).[5] Transmetalation of 5-chloromercuriuridine (**9**) and ***Palladium(II) Chloride*** generates the organopalladium(II) complex (**10**), which then reacts with allyl triflate to produce C-5 allyl-substituted uridine (**11**) in 52% yield. *N*-Allylation of *O*-trimethylsilyloxime (**12**) with allyl triflate is a convenient method for nitrone synthesis (eq 5).[6] The initial allylation produces the (*E*)-nitrone, which then isomerizes to the more stable (*Z*)-isomer. Allyl triflate reacts with alcohols to give *O*-allylation products. Alcohols of low nucleophilicity which contain electron-withdrawing substituents such as 2,2-dinitropropanol, 2,2,2-trinitroethanol, and 2,2-dinitro-1,3-propanediol even react with allyl triflate to produce the corresponding allyl ethers in 53%, 33%, and 28% yield, respectively.[1] These etherification reactions were carried out at room temperature in the presence of Na_2SO_4 as a heterogeneous acid scavenger.

Allyltrimethylgermane[1]

[762-66-3] · $C_6H_{14}Ge$ · Allyltrimethylgermane · (MW 158.78)

(allylation reagent for electrophilic[2,3] and nucleophilic reactions[4,5])

Physical Data: bp 101 °C.

Solubility: sol ether, hexane, and dichloromethane; insol H_2O.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: ^{1}NMR or GC.

Preparative Methods: to a solution of MeMgCl (2.3 M, 395 mL) in diethyl ether was added dropwise allyltrichlorogermane (61 g, 0.277 mol) in nitrogen. The mixture was refluxed for 10 h. After quenching with water, the mixture was extracted with diethyl ether. Careful distillation afforded allyltrimethylgermane (68%).[9]

Allylgermanes are nucleophilic species which react with electrophiles with allylic inversion.[1] Lewis acid-catalyzed Michael addition of the substituted allylgermane (**1**) to the unsaturated ester (**2**) takes place at the γ-position of (**1**) with migration of the double bond (eq 1).[2] The stereoselectivity of Lewis acid-promoted allylation of chiral dioxane acetals (**3**) depends on the allylmetal reagent and increases in the order allylsilanes < allylgermanes < allylstannanes, which parallels increased nucleophilicity (eq 2).[3] Similar results were obtained by the reaction of the monothioacetal (**6**) with allylmetal reagents in the presence of ***Trimethylsilyl Trifluoromethanesulfonate*** (eq 3). Allylgermane showed ca. 80% *syn* selectivity irrespective of the stereochemistry of (**6**), while the reaction of allylstannane was highly dependent on the stereochemistry of the reagent. The reaction of less nucleophilic allylgermane proceeds through an S_N1 mechanism involving an oxonium ion, while allylstannane reacts through an S_N2-type mechanism.[6]

Aromatic compounds undergo allylation with allylgermanes by reaction with ***Iodosylbenzene*** in the presence of ***Boron Trifluoride Etherate*** (eq 4).[4] The reaction involves generation of allyliodine(III) species, which can act as an allyl cation equivalent. Allylthallium(III) species, generated from the reaction of allylgermanes with thallium(III) salts, allylate aromatic compounds, alcohols, carboxylic acids, and nitriles.[5]

(4)

The photochemical reaction of allylgermane with 1,4-dicyanonaphthalene gives 1-allyl-4-cyanonaphthalene, which probably involves electron transfer from allylgermane to the electron-deficient 1,4-dicyanonaphthalene (eq 5).[7] Thermal ene reaction of allylgermane with ***Diethyl Azodicarboxylate*** gives a mixture of stereoisomers of vinylgermanes (eq 6).[8]

Allyltrimethylsilane[1]

[762-72-1] · $C_6H_{14}Si$ · Allyltrimethylsilane · (MW 114.26)

(carbon nucleophile for the introduction of allyl groups by Lewis acid-catalyzed or fluoride ion-catalyzed reaction with acid chlorides, aldehydes, ketones, iminium ions, enones, and similar carbon electrophiles)

Physical Data: bp 85-86 °C, *d* 0.717 g cm^{-3}.

Solubility: freely sol all organic solvents.

Form Supplied in: colorless liquid. Methods for the synthesis of allylsilanes in general have been reviewed.[3]

Analysis of Reagent Purity: δ 5.74 (1H, ddt, *J* 16.9, 10.2 and 8), 4.81 (1H, dd, *J* 16.9 and 2), 4.79 (1H, dd, *J* 10.2 and 2), 1.49 (2H, d, *J* 8) and -0.003 (9H, s).[2]

Handling, Storage, and Precautions: inflammable; the vapor is irritating to the skin, eyes, and mucous membranes.

As a Carbon Nucleophile in Lewis Acid-Catalyzed Reactions.

Allyltrimethylsilane is an alkene some 10^5 times more nucleophilic than propene, as judged by its reactions with diarylmethyl cations.[4] It reacts with a variety of cationic carbon electrophiles, usually prepared by coordination of a Lewis acid to a functional group, but also by chemical or electrochemical oxidation,[5] or by irradiation in the presence of 9,10-dicyanoanthracene.[6] The electrophile attacks the terminal alkenic carbon to give an intermediate cation, and the silyl group is lost to create a double bond at the other terminus. Among the more straightforward electrophiles are acid chlorides (eq 1),[7] aldehydes and ketones (eq 2),[8] their acetals (eq 3),[9] and the related alkoxyalkyl halides (eq 4),[10] iminium ions, and acyliminium ions (eqs 5 and 6),[11,12] and tertiary and allylic or benzylic alkyl halides (eqs 7 and 8).[13,14]

(4)

The reaction with acetals does not always need the acetal itself to be synthesized: it can be made in the same flask by mixing the allylsilane, the aldehyde, the silyl ether of the alcohol, and a catalytic amount of an acid such as ***Diphenylboryl Trifluoromethanesulfonate***,[15] ***Trimethylsilyl Trifluoromethanesulfonate***,[16] or ***Fluorosulfuric Acid***.[17]

The further reaction of the double bond in the first-formed product is an occasional complication, as in the formation of tetrahydropyrans from aldehydes when ***Aluminum Chloride*** is the Lewis acid (eq 9),[18] and of piperidines from primary amines and formaldehyde (eq 10).[11]

α,β-Unsaturated esters, aldehydes, ketones, and nitriles generally react in Michael fashion in what is called a Sakurai reaction (eq 11).[19] The intermediate silyl enol ether may be treated with a second electrophile to set up two C-C bonds in one operation (eq 12).[20] Occasionally the silyl group is not lost from the intermediate cation but migrates instead to give a cyclopentannulation byproduct (eq 13).[21]

α,β-Unsaturated nitro compounds initially give nitronic acid derivatives, which can be reduced directly with ***Titanium(III) Chloride*** to give the corresponding ketone (eq 14).[22]

Some electrophiles require a separate activation step, as in the stereospecific reaction of alkenes with benzenesulfenyl chloride (eq 15).[23] The intermediate that actually reacts with the allylsilane is presumably the episulfonium ion. There is a corresponding reaction of epioxonium ions derived from 2-bromoethyl ethers.[24] Intramolecular hydrosilylation of an ester generates an acetal, which reacts with allyltrimethylsilane in the usual way and with high stereocontrol to make an *anti* 1,3-diol derivative (eq 16).[25]

(15)

(16)

The reactions with α- or β-oxygenated aldehydes can be made to give high levels of stereocontrol in either sense by choosing a chelating or nonchelating Lewis acid (eq 17).[26]

Sugar acetals (eq 18)[27] and glycal 3-acetates (eq 19)[28] and related compounds react stereoselectively in favor of axial attack at the anomeric carbon.

The choice of Lewis acid in all these reactions is often important in getting the best results, one Lewis acid being much the best in several cases. Most are used in molar amounts, but some, especially ***Iodotrimethylsilane***, ***Trimethylsilyl Trifluoromethanesulfonate***, and the more powerful trifluoromethanesulfoxonium tetrakis(trifluoromethanesulfonyl)boronate[29] [$TfOH_2^+B(OTf)_4^-$], have the advantage that they can be used in catalytic quantities. In addition to the Lewis acids illustrated, the following less obvious Lewis acids have also been used with one or more of the electrophiles: ***Triphenylmethyl Perchlorate***,[30] titanocene ditriflate,[31] ***Lithium Perchlorate***,[32] ***Tin(IV) Chloride*** in the presence of either ***Tin(II) Trifluoromethanesulfonate***[33] or ***Zinc Chloride***,[34] ***Antimony(V) Chloride***,[35] ***Chlorotrimethylsilane*** combined with indium chloride,[36] ***Ethylaluminum Dichloride***,[37] and ***Diphenylboryl Trifluoromethanesulfonate***.[38] Among carbon electrophiles not illustrated are quinones,[39] cyclopropanedicarboxylic esters,[40] oxetanes,[41] nitriles,[42] dithioacetals,[43] diselenoacetals,[44] the intermediate sulfur-stabilized cation from a Pummerer rearrangement,[45] and propargyl ethers with[46] or without[47] octacarbonyldicobalt complexation.

As a Carbon Nucleophile in Uncatalyzed Reactions.

Some electrophiles do not need Lewis acids, being already cationic and electrophilic enough to react with allyltrimethylsilane. Examples are the dithianyl cation (eq 20),[48] the tricarbonyl(cyclohexadienyl)iron cation (eq 21),[49] (π-allyl) tetracarbonyliron cations,[50] and ***Chlorosulfonyl Isocyanate*** (CSI).[51] Other reagents react directly by cycloaddition, but need further steps to achieve an overall electrophilic substitution, as in the reactions with nitrones (eq 22).[52]

(22)

Although heteroatom (N-, P-, O-, S-, Se-, and halogen-based) electrophiles react with allylsilanes, the products with allyltrimethylsilane itself are usually too simple for this to be an important synthetic method. An exception perhaps is the reaction with ***Palladium(II) Chloride***, which gives the π-allylpalladium chloride cation.[53]

As a Carbon Nucleophile in Fluoride Ion-Catalyzed Reactions.

The reactions with aldehydes, ketones (eq 23),[54] and α,β-unsaturated esters (eq 24)[55] can also be catalyzed by fluoride ion, usually introduced as ***Tetra-n-butylammonium Fluoride*** (TBAF), or other silicophilic ions such as alkoxide. These reactions produce silyl ether intermediates, which are usually hydrolyzed before workup. The stereochemistry of attack on chiral ketones can sometimes be different for the Lewis acid- and fluoride ion-catalyzed reactions.[56] In addition some electrophiles only react in the fluoride-catalyzed reactions, as with the addition to trinitrobenzene giving an allyl Meisenheimer complex.[57]

(23)

(24)

Other Reactions.

Allyltrimethylsilane reacts with some highly electrophilic alkenes, carbonyl compounds, azo compounds, and singlet oxygen to a greater or lesser extent in ene reactions that do not involve the loss of the silyl group, and hence give vinylsilanes in a solvent-dependent reaction (eq 25).[58]

(25)

benzene	18	:	73	:	9
MeCN	6	:	28	:	67

Hydroalumination (and hydroboration) take place regioselectively to place the aluminum (or boron) atom at the terminus, creating a 3-trimethylsilylpropyl nucleophile.[59] Radicals attack allyltrimethylsilane at the terminus, and the intermediate radical reacts further without the trimethylsilyl group being expelled, as the corresponding germanium, tin, and lead groups are.[60] Treatment with strong bases gives trimethylsilylallyl-metal compounds (see

Trimethylsilylallyllithium and ***Allyltrimethylsilylzinc Chloride***).

Allyltrimethylsilylzinc Chloride

[89822-47-9] · $C_6H_{13}ClSiZn$ · Allyltrimethylsilylzinc Chloride · (MW 214.09)

(allylmetal reagent; useful for synthesis of spiro-γ-lactones[1])

Preparative Methods: deprotonation of ***Allyltrimethylsilane*** with ***n-Butyllithium*** in THF at -78 °C or ***s-Butyllithium*** in THF/TMEDA, followed by the addition of ***Zinc Chloride***.[1,2] The reagent is prepared in situ and used directly.

Spiro-γ-lactone Synthesis via Reactions with Carbonyl Compounds.

Although lithiated allyltrimethylsilane adds to simple ketones with good regioselectivity (eq 1),[2] its addition to 17-ketosteroids produces a mixture of α and γ adducts. Transmetalation of allyltrimethylsilyllithium with $ZnCl_2$ leads to a reagent (allyltrimethylsilylzinc chloride) which adds with complete regioselectivity to this type of hindered ketone (eq 2).[1] The resulting silylated homoallylic alcohols can be converted by a simple succession of steps to valuable steroidal γ-lactones. It is interesting to note that the 4-hydroxybutenylsilane obtained by the addition of the allyltrimethylsilyl anion to adamantan-2-one undergoes some unusual transformations[3] in the presence of ***N-Bromosuccinimide***, leading to the oxetane (**1**) via a 4-*exo*-tet ring opening[4] of the intermediate bromonium ion (eq 3). The extent of α and γ selectivity can be fine-tuned by changing the metal, and very high α-regioselectivity is observed using magnesium as the counterion.[5] Similarly, the addition of ***Triethylaluminum*** to the lithium reagent leads to a high α-regioselectivity (eq 4).[6] A stereocontrolled synthesis of *anti*-homoallylic alcohols is possible by preparing the corresponding allylic boronic ester and subsequent reaction with an aldehyde. A stereoselective elimination allows the preparation of either (*E*)- or (*Z*)-dienes (eq 5).[7] The isomeric reagent (**1**) is a useful reagent for the preparation of 2-substituted polyfunctional allylic silanes (eq 6).[8]

Allyltriphenylphosphonium Bromide[1]

[1560-54-9] · $C_{21}H_{20}BrP$ · Allyltriphenylphosphonium Bromide · (MW 383.27)

(conjugate diene-forming reagent, ring-forming reagent[1])

Alternate Name: 2-propenyltriphenylphosphonium bromide.

Physical Data: mp 225-227 °C; pK_a;[3a] ^{1}H,[4a] ^{13}C,[4b] ^{31}P NMR spectra;[4b] MS;[5] X-ray PES spectra.[6]

Solubility: sol acetonitrile; distribution of (**1**) between water and organic solvents.[3b]

Form Supplied in: white powder, mp 222-225 °C.

Handling, Storage, and Precautions: hygroscopic, irritant. Use in a fume hood.

Preparation of allyltriphenylphosphonium bromide (**1**)[1] was accomplished by allowing ***Allyl Bromide*** to react with ***Triphenylphosphine*** in benzene.[2] A couple of drops of methanolic ***Benzyltrimethylammonium Hydroxide***[2c] or ***Triethylamine***[2d] in refluxing acetonitrile converts (**1**) into 1-propenyltriphenylphosphonium bromide (**2**) (eq 1).[2c,d]

The first alkenation reaction was accomplished using ***Phenyllithium*** as the base to convert (**1**) into the phosphorane (**3**)[2a] followed by benzaldehyde to give a 50:50 (*E*):(*Z*) ratio of (**4**) (eq 2).[2a]

The preparation of phosphorane (**3**) for use in alkenation reactions has been accomplished using a large number of base/solvent pairs, such as PhLi/Et_2O,[2] ***n-Butyllithium***/hexane,[7] *n*-BuLi/Et_2O,[8a,b] *n*-BuLi/THF,[8c] ***Methyllithium***/Et_2O,[8d] LiOEt/EtOH,[9] ***Potassium Carbonate***/toluene,[10] and ***1,8-Diazabicyclo[5.4.0]undec-7-ene***/THF[11] (the latter has been used on the fluoroborate, instead of the bromide salt). The aldehyde, in a gaseous state, has also been passed over a solid bed of K_2CO_3 mixed with the phosphonium salt (**1**) suspended in Carbowax 6000 at 150 °C.[12] In a few cases the species used as the base has also contained an aldehydic function, which undergoes the Wittig alkenation reaction and then cyclizes,[13] such as the reaction of (**1**) with sodiopyrrolaldehyde (eq 3).[13a]

Addition-elimination followed by the alkenation reaction has been accomplished with the nucleophilic site on (**3**) being the γ-position (eq 4).[14]

Rings have been formed in reasonable yields via a variety of sequences, such as γ-addition of (**3**) followed by reylidation and the Wittig reaction (eq 5),[15] γ-addition followed by cyclization and proton transfer (eq 6),[16] and alkenation followed by electrocylization (eq 7).[17]

Although this last example is depicted as a Wittig alkenation reaction followed by electrocyclization, it is possible that, as with the example illustrated by eq 5,[15] the reaction involves a γ-addition followed by reylidation and then Wittig alkenation. There is an example of a Wittig alkenation of a ketonic function (a cyclohexanone moiety) by (**3**);[8b] however, there are numerous cases where a compound containing both aldehydic and ketonic functional groups only yields a product from the reaction of the former group.[7c,8d,8e] The ylide (**3**) is generally too stable to react with ketones.

The dianionic phosphonium species (or ylidic anion) (**8**) has been formed by treating (**1**) with 2 equiv of *n*-BuLi.

Reaction with a carbonyl followed by aqueous acid quenching gives a product which arises from γ-addition and alkenation (eq 8).[7n]

Addition of methyldichlorosilane to the double bond of (**1**) has been observed (eq 9).[18] Some high-yield syntheses of π-allylphosphonium ylide complexes have been reported.[19]

With respect to the geometric isomerism of alkenes formed from (**3**), no definitive studies have been undertaken. However, the majority of the products reported gave (*Z*):(*E*) ratios ranging from 60:40 to 100% (*Z*).[7a,7d,7e,7h,7i,7l,8e,13b,13d,20] Three papers reported (*Z*):(*E*) ratios near[10] or at 1.[2a,21] A few papers reported (*Z*):(*E*) ratios around 40:60[7f,8a,12,22,23] or smaller.[11] Altering the solvent polarity was said to change the (*Z*):(*E*) ratio from 20:80 to 70:30; however, no details were reported.[8a]

Related Reagents.

Allyldiphenylphosphine Oxide.

Allyltriphenylstannane[1]

[76-63-1] · $C_{21}H_{20}Sn$ · Allyltriphenylstannane · (MW 391.08)

(widely used allylating agent as an allyl anion equivalent directly or by transmetalating to other allylmetals,[2,3] radical chain transfer reagent, and source of allyl radical[4])

Alternate Names: allyltriphenyltin; (2-propenyl)triphenylstan-nane.

Physical Data: mp 73-74 °C (recryst. from ligroin).[5]

Solubility: sol THF, methylene chloride, chloroform, and benzene.

Form Supplied in: white solid in over 97% purity (microanalysis).

Analysis of Reagent Purity: CH microanalysis, IR,[6] ^{1}H,[7] or ^{13}C NMR spectroscopy.

Handling, Storage, and Precautions: poison by intravenous route; ivn-mus LD_{50}: 100 mg kg^{-1};[8] no significant reactivity with aqueous systems. Use in a fume hood.

Generation of Allyllithium.

Allyllithium may be generated effectively upon treatment of allyltriphenyltin with ***Phenyllithium*** in ether.[2,3] The resulting allyllithium may be further converted into allylboronate complexes upon treatment with trialkylboranes.[3]

Lewis Acid-Mediated Allylation Reactions.

Although allyltriphenyltin has been extensively used as a reagent for nucleophilic allylation under Lewis acid catalysis,[1] it does not appear to offer a particular advantage in terms of yield and reactivity when compared with the same reaction with ***Allyltributylstannane*** (e.g. eq 1).[9]

(1)

A number of highly stereoselective allylation reactions have been developed which involve treatment of Lewis acid-chelated α- or β-heteroatom substituted aldehydes with allytriphenyltin. While α-benzyloxy aldehydes undergo allylation favoring *anti* adducts in the presence of ***Tin(IV) Chloride*** (eq 2), α-thiomethyl aldehydes produce allylated products with high *syn*/*anti* ratios (typically, 94-97:6-3) in excellent yield.[10] β-Alkoxy aldehydes give rise to allyl adducts generally with high *anti* selectivity (e.g. eq 3).[10] Variations in *anti/syn* ratio caused by the different protecting groups as well as Lewis acids have been rationalized on the basis of the conformational preferences of the chelated α-alkoxy aldehydes.[11a] The highly 1,3-diastereoselective allylation reaction has been applied to the total synthesis of (-)-colletol.[11b]

(2)

(3)

P	*anti*/*syn*
MTM	2:1
BOM	9:1
$PhCH_2$	29:1

An allyl group is added stereoselectively to chiral dioxane acetals upon reaction with allyltriphenyltin in the presence of ***Titanium(IV) Chloride***/***Titanium Tetraisopropoxide***, although the use of allyltributyltin in place of allyltriphenyltin gives better diastereoselectivity (eq 4).[12] A $TiCl_4$ catalyzed Michael-type addition of an allyl group onto 1-nitroalkadienes followed by addition of ***Triethylamine*** provides a nitrile oxide equivalent which undergoes intramolecular 1,3-dipolar cycloadditions to give isoxazolines (eq 5).[13] A novel [3 + 2] cycloaddition involving allylstannanes and α,β-unsaturated acyliron complexes has also been reported[14] (see ***trans-Cinnamyltributylstannane***).

(4)

R = Ph, 100%	90:1
R = Bu, 100%	270:1

Allyltriphenyltin can serve as an excellent radical chain transfer agent as well as a source of an allylic radical, as shown in eq 6.[4] Interestingly, when ***Triphenylstannane*** is used instead of allyltriphenyltin, a mixture of α- and β-methylcepham is obtained (eq 7).[4]

Related Reagents.

B-Allyl-9-borabicyclo[3.3.1]nonane; ***Allyltributylstannane***.

Alumina[1]

Al_2O_3

[1344-28-1] · Al_2O_3 · Alumina · (MW 101.96)

(a mildly acidic, basic, or neutral support for chromatographic separations; a reagent for catalyzing dehydration, elimination, addition, condensation, epoxide opening, oxidation, and reduction reactions)

Alternate Name: γ-alumina.

Physical Data: mp 2015 °C; bp 2980 °C; *d* 3.97 g cm^{-3}.

Solubility: slightly sol acid and alkaline solution.

Form Supplied in: fine white powder, widely available in varying particle size (50-200 µm; 70-290 mesh), in acidic (pH 4), basic (pH 10), and neutral (pH 7) forms. *Drying:* the activity of alumina has been classified by the Brockmann scale into five grades. The most active form, grade I, is obtained by heating alumina to 200 °C while passing an inert gas through the system, or heating to ~400 °C in an open vessel, followed by cooling in a dessicator. Addition of 3-4% (w/w) water and mixing for several hours converts grade I alumina to grade II. Other grades are similarly obtained (grade III, 5-7%; grade IV, 9-11%; grade V, 15-19% water).[2,3]

Handling, Storage, and Precautions: inhalation of fine mesh alumina can cause respiratory difficulties. Alumina is best handled under a fume hood and stored under dry, inert conditions.

Introduction.

Alumina is one of the most widely used packing materials for adsorption chromatography and is available in acidic, basic, and neutral forms. Use of the correct type is important to avoid unwanted reactions of the substrate being purified.[1,3] Possessing both Lewis acidic and basic sites, alumina has been found to catalyze a wide range of reactions, generally under conditions that are milder and more selective than comparable homogeneous reactions.[1]

Dehydration and Eliminations.

One of the earliest uses of alumina as a catalyst was for the dehydration of alcohols.[4,5] These reactions generally require high temperature and yield primarily non-Saytzeff products. Complex terpenes have been dehydrated with

Pyridine or ***Quinoline*** doped alumina (eq 1).[6b] Numerous other groups can be eliminated in the presence of alumina, including OR, OAc, O_3SR, O_2SR, and halides.[1,7] Some of these eliminations proceed under mild conditions,[1] often during chromatographic purification (eq 2).[7d] Sulfonates can be eliminated in the presence of acid and base sensitive groups, without skeletal rearrangements. However, a large excess of properly activated alumina is required, and poor stereo- and regiocontrol are observed.[7e] Dehydrohalogenations, particularly dehydrofluorinations, occur readily over alumina (eq 3).[8] Stereoselective syntheses of vinyl halides have been developed that take advantage of desilicohalogenation[9] or deborohalogenation[10] of vinylsilane or vinylboronic acid derived dihalides. Benzol[*c*]thiophene has been synthesized by dehydration of a sulfoxide precursor.[11] The oxidation of selenides to selenoxides and their elimination to alkenes can be accomplished in one step using basic alumina and ***t-Butyl Hydroperoxide*** in THF.[12]

Alumina has been used for various dehydration reactions, including those leading to piperidines,[13] pyrroles (eq 4) and pyrazoles,[14] and other heterocycles.[15] It is also an effective catalyst for the selective protection of aldehydes in the presence of ketones.[16]

(4)

Addition and Condensation Reactions.

Alumina promotes the addition of various heteroatom species, whether by electrophilic or nucleophilic processes. In contrast to the elimination reactions described earlier, alumina also promotes the intramolecular addition of OH and OR groups to isolated (eq 5)[6c] and carbonyl-activated alkenes.[17] It is also reported to catalyze the conjugate addition of other nucleophiles, such as amines.[18] In the presence of alumina, ***Iodine*** can be used to iodinate aromatics, hydroiodinate alkenes, and diiodinate alkynes (eq 6).[19] Hydrochlorinations and hydrobrominations of alkenes and alkynes give the Markovnikov products, with good stereoselectivity.[20]

(5)

(6)

Aldol-type condensations between aldehydes and various active methylene compounds,[21] Michael reactions (eq 7),[22] as well as Wittig-type reactions[23] can be carried out on alumina under mild conditions, often without a solvent. An

interesting nitroaldol reaction-cyclization sequence gives 2-isoxazoline 2-oxides with good diastereoselectivity (eq 8).[24]

(7)

(8)

trans:*cis* = 9:1

Orbital symmetry controlled reactions that have been promoted by alumina include the Diels-Alder,[25] the ene,[26] and the Carroll rearrangement.[27] These reactions proceeded under milder conditions and with greater stereoselectivity. In a spectacular example, chromatographic purification promoted a diastereoselective intramolecular Diels-Alder that produced the verrucarol skeleton (eq 9).[25b]

(9)

Alkylation reactions that have been induced by alumina include per-*C*-methylation of phenol,[28] intramolecular alkylation to yield a spiro-fused cyclopropane,[29] and *S*-[30] and *O*-alkylations (eq 10).[31] The activation of ***Diazomethane*** by alumina has provided methods for the conversion of ketones to epoxides[32] and for the selective monomethylation of dicarboxylic acids.[33] Basic alumina has been used for the generation and trapping of dichlorocarbene.[34]

(10)

Epoxides.

Epoxides can be opened under mild, selective conditions using alumina impregnated with a variety of nucleophiles, such as alcohols, thiols, selenols, amines, carboxylic acids (eq 11),[35] and peroxides.[36] Use is made of this process in a route to (*Z*)-enamines (eq 12).[37] Formation of C-C bonds by intramolecular opening of epoxides has been reported (eq 13),[38] as have alumina catalyzed epoxide formations[23,39] and rearrangements.[40]

(11)

RX = MeO, 66%; PhS, 70%, PhSe, 95%; *n*-BuNH, 73%

(12)

(13)

Oxidations and Reductions.

Posner has shown that Oppenauer oxidations, with Cl_3CCHO or PhCHO as the hydrogen acceptors, are greatly accelerated in the presence of activated alumina.[41] Secondary alcohols are oxidized selectively over primary alcohols (eq 14) and groups susceptible to other oxidants (sulfides, selenides, and alkenes) are unaffected. Even cyclobutanol, which is prone to fragmentation with one-electron oxidants, can be oxidized to cyclobutanone in 92% yield.

(14)

The complementary reduction reaction (Meerwein-Ponndorf-Verley), using isopropanol as the hydride donor, is also facilitated by alumina and allows the selective reduction of aldehydes over ketones.[42] Functional groups that survive these conditions include alkene, nitro, ester, amide, nitrile, primary and secondary iodides, and benzylic bromide.

Air oxidation of a fluoren-9-ol to the fluoren-9-one and thiols to disulfides are accelerated on the alumina surface.[43] Alumina has also been used as a solid support for a variety of inorganic reagents,[44] and for immobilizing chiral catalysts.[45]

Miscellaneous Reactions.

Many rearrangements are catalyzed by alumina.[1] The Beckmann rearrangement[46] of the *O*-sulfonyloxime shown gives the expected amide with activated alumina, and the corresponding oxazoline with basic alumina (eq 15).[46d] Alumina has long been used for isomerization of β,γ-unsaturated ketones to the conjugated ketones.[47] Isomerizations of alkynes to allenes,[48] and allenes to conjugated dienoates[49] have also been reported (eq 16).

(15)

(16)

Alumina promotes the hydrolysis of acetates of primary alcohols,[50] the deacylation of imides,[51] the hydrolysis of sulfonylimines,[52] and the decarbalkoxylation of β-keto esters and carbamates.[53] It can also be used for acylations and esterifications, with high selectivity for primary alcohols over secondary alcohols.[54]

Aluminum[1]

Al

[7429-90-5] · Al · Aluminum · (MW 26.98)

(reducing agent for many functional groups;[1] can aluminate double bonds[2] or insert into carbon-halogen bonds; promotes propargylation of carbonyl compounds; in combination with metallic Sn or $PbBr_2$ mediates Barbier-type allylation of carbonyl compounds or imines)

Physical Data: mp 660.37 °C; bp 2467 °C; *d* 2.702 g cm^{-3}; *E*°(aq) Al^{3+}/Al^0 = -1.66 V.

Solubility: reacts with dil HCl, H_2SO_4, KOH, and NaOH, hot AcOH; insol conc HNO_3.

Form Supplied in: silver-white, malleable, ductile metal; widely available in foil, granules, ingot, pellets, powder, rod, shot, wire.

Handling, Storage, and Precautions: Al foil is moisture sensitive, powder is moisture sensitive and flammable. Aluminum is reputed to be practically nontoxic.

Functional Group Reductions.

Aluminum will reduce ketones or aldehydes to alcohols or saturated hydrocarbons, nitro compounds and Shiff bases to amines, and alkyl halides to alkanes. Aluminum also effects reductive dimerization of ketones and dehalogenation of polyhalogenated compounds. In combination with ***Nickel(II) Chloride*** hexahydrate in THF, metallic Al will reduce acyl chlorides, anhydrides and nitriles, epoxides, and disulfides. Moreover, aluminum exhibits pronounced chemoselectivity in reduction of polyfunctionalized compounds.[3]

Aromatic ketones are especially readily reduced by aluminum. Reduction of 2-methyl-2-phenyl-1-indanone with Al in *i*-PrOH proceeds with diastereoselectivity (*trans*/*cis* ratio in alcohol formed is 90:10) better than that observed with Li, Na, or K.[4] Quinone (**1**) is reduced with Al in 85% H_2SO_4 to the 6,13-dihydro product (**2**) (eq 1) while the 6-hydroxy derivative is formed in reaction of (**1**) with Cu in 96% H_2SO_4.[5]

Reductive dimerization of tetralone to 3,3´,4,4´-tetrahydro-1,1´-binaphthyl is mediated by Al foil activated with ***Mercury(II) Chloride***.[6] A facile reduction of aromatic ketones and aldehydes into corresponding alcohols is readily achieved employing Al powder in combination with $NiCl_2.6H_2O$ in THF.[3]

Reduction of (thiazolyl)(acylaminomethyl)ketones with the reagent prepared from Al dissolved in *i*-PrOH in the presence of ***Aluminum Chloride***,[7a] and oxidation of aluminum tris(3-pentanoxide-1,2-d_5) (from the alcohol, Al shot, and a trace of $HgCl_2$) with benzophenone,[7b] can be considered special cases of modified Meerwein-Ponndorf-Verley and Oppenauer reactions.

Aromatic nitro compounds are reduced to anilines with Al powder in AcOH-HCl[8] or with Al-$NiCl_2.6H_2O$.[3] Reactions of nitrobenzene with Al turnings (heating in aq H_2SO_4)[9a] or Al-Fe alloy (in 50% NaOH)[9b] afford *p*-aminophenol and *N*,*N*´-diphenylhydrazine, respectively.

Al foil activated with $HgCl_2$ and Hg is capable of reducing both aliphatic[10a] and aromatic Shiff bases[10b] to secondary amines. For aromatic substrates, the process is substantially complicated by reductive dimerization of the azomethines. It is this particular reagent (not other metals such as Na, Mg, or Zn) that causes unusual ring contractions of lumazines[11a] and pterines[11b] to theophyllines (eq 2) and guanines respectively, via a radical anion formed upon C=N double bond reduction.

1,2-Dehalogenation occurs when polyhalogenated substrates react with Al turnings in the presence of $AlCl_3$.[12] For alicyclic compounds it is a stereospecific process (eq 3).[12b]

When 2-5% NaOH is added, Al (powder or turnings) reduces 1,1-dibromocyclopropanes or 7,7-dibromonorcaranes

into monobromides with modest *cis* or *exo* stereoselectivity.[13] A small amount of Al powder promotes halide exchange and 3-chlorophthalide is converted almost quantitatively into 3-bromophthalide in a reaction with dry HBr.[14]

On refluxing with an excess of an alkyl or aryl halide, Al inserts into the carbon-halogen bond.[15] Primarily a mixture of sesquihalides (**3**) is formed (eq 4).[15] With alkyl halides,[16] the sesquihalide mixture formed in situ can be easily reduced to produce trialkylaluminum compounds (eq 5).[16c] In case of aryl halides, (**3**) is an excellent reagent for transfer of an aryl moiety from Al to other elements (P, Sn) (eq 6).[17] Mixture (**3**) also reacts with organic halides to form organoaluminum compounds. However, a more versatile method of synthesis involves the reductive replacement of Hg from organomercury compounds with Al (eq 7).[18]

$$\underset{X = Cl,\ Br,\ I}{RX} + Al \longrightarrow \underset{\textbf{(3)}}{R_2AlX} + RAlX_2 \qquad (4)$$

$$2\ Al + 3\ Mg + 6\ BuI + 2\ PhOEt \xrightarrow[\substack{90\text{-}105\ ^\circ C \\ 80\%}]{octane} 2\ AlBu_3 \cdot PhOEt + 3\ MgI_2 \qquad (5)$$

$$Ph_3Al_2Cl_3 + PCl_3 \xrightarrow[91\%]{PhCl,\ rt \rightarrow 180\text{-}200\ ^\circ C,\ 2\ h} Ph_3P + 2\ AlCl_3 \qquad (6)$$

$$3\ [H_2C{=}CH(CH_2)_2]Hg + 2\ Al \xrightarrow[\substack{rt,\ 2\ weeks \\ 100\%}]{sealed\ tube} 2\ [H_2C{=}CH(CH_2)_2CH_2]_3Al + 3\ Hg \qquad (7)$$

Reduction of element-halogen bonds by Al or Al-promoted cleavage of other bonds is widely used in synthesis of organoboron,[19] organosilicon,[20] organogermanium,[21] and organophosphorus compounds,[22] as well as π-complexes of titanium,[23] vanadium,[23b] and zirconium.[24] Al powder in combination with $AlCl_3$ and ***Iodine*** (or ***Iodomethane***) induces borylation of C_6H_6 with ***Boron Trichloride*** to form $PhBCl_2$.[19a] Mixtures of amines and triarylborates are reduced to borazanes by aluminum-iodine.[19b] On electrochemical reduction with a sacrificial Al anode, chlorosilanes undergo dimerization[20a] or cross-coupling if two different chlorosilanes react.[20b] Tetraalkylgermanes are cleaved by the system Al-I_2 to yield iodogermanes.[21]

A mild and neutral reducing system of Al-$NiCl_2$.6H_2O-THF reduces enones to saturated aldehydes (eq 8),[3] nitriles to amines, acid chlorides and anhydrides to aldehydes, disulfides to thiols, and epoxides to the alcohols. Isolated double bonds, carboxylic acids, esters, lactones, primary, benzyl and allyl halides, aliphatic aldehydes and ketones as well as aliphatic nitro compounds are inert to this agent.[3]

In combination with ***Antimony(III) Chloride***, metallic Al smoothly reduces both aliphatic and aromatic aldehydes to alcohols (yield 50-98%). Reduction proceeds chemoselectively and PhCHO is preferably reduced in competition with PhCOMe. Unlike Al-$NiCl_2$, reduction of α,β-unsaturated aldehydes with this system occurs only at the C=O group, leaving C=C double bonds intact.[25]

Reactions of Aluminum Alkoxides and Phenoxides.

A facile method of alcohol dehydration is based on thermal decomposition of the derived Al alkoxide which, depending on the alcohol structure, commences in the range of 200-270 °C.[26] Al foil ($HgCl_2$-activated) in *i*-PrOH promotes deoxygenation of epoxides, giving the corresponding alkenes.[27]

Friedel-Crafts Alkylation Catalyst.

Aluminum catalyzes *ortho*-alkylation of anilines and phenols with alkenes.[28,29] Preformed aluminum anilides or phenoxides exhibit high susceptibility toward alkene attack and usually *o,o´*-dialkylated products predominate.[29a,b] Selective *ortho*-alkylation of phenol can be accomplished using aluminum soft drink cans as the reagent (eq 9).[28]

Alumination Agent.

A facile hydroalumination of carbon-carbon double bonds yielding trialkylaluminum compounds takes place in a three-component mixture consisting of an alkene, hydrogen, and Al (eq 10).[2] The process involves intermediate formation of a dialkylaluminum hydride which adds to the third alkene molecule, affording the trialkylaluminum. To elucidate the mechanism of the reaction, direct synthesis of organoaluminum compounds in the condensed phase from

Al vapor and alkene is of noticeable importance.[30]

$$2\,Al + 3\,H_2 + 3\,H_2C{=}CMe_2 \longrightarrow 2\,(Me_2CHCH_2)_3Al \quad (10)$$

Selective Propargylation.

The problem of propargyl group introduction in various substrates without propargyl-allenyl rearrangement has been addressed using alumination (Al in the presence of $HgCl_2$) of propargylic bromides followed by addition of a carbonyl substrate to the organoaluminum reagent formed in situ.[31] This approach has been used to prepare propargylic alcohols from ketones[32a] and aldehydes,[32b] propargylic ethers from α-chloro ethers[33a] and acetals,[33b] acetals of propargylic carbaldehydes from orthoformates (eq 11),[34] homopropargylic ethers and sulfides from chloromethyl ethers and sulfides.[35] Propargylic compounds prepared in this manner have been used in the synthesis of spirilloxanthin, 3,4-dehydro-rhodopin,[32a] ecdysteroid analogs,[35] and lycorine precursors.[36]

(11)

Aluminum is presumably a unique partner for condensations of this type because, for example, Zn always gives a mixture of alkynic and allenic alcohols.[31,32a]

Aluminum-Tin(0) and Aluminum-Tin(II) Systems.

A strong impetus for current applications of Al in organic synthesis has resulted from a study on allylation of carbonyl compounds mediated by the combination of stoichiometric amounts of metallic Al and ***Tin***, and the observation of extensive acceleration in the presence of water.[37] Typical procedures suggest that a carbonyl compound, allylic bromide, Al, and Sn should be used in a ratio 1:1.2-2:1:1. Allylation with unsymmetrically substituted allylic halides proceeds with complete rearrangement in the allylic unit and shows considerable diastereoselectivity (eq 12).[37a] Intramolecular versions of the reaction have been used in syntheses of five- and six-membered cyclic alcohols.[37c]

(12)

erythro:*threo* = 78:22

A combination of Al powder (2 equiv) and ***Tin(II) Chloride*** (0.1 equiv) in an organic solvent is even more active than the Al-Sn couple and addition of water to the solvent enhances the allylation rate remarkably.[38] Carbonyl compounds are almost inert to allylation if 1 equiv of Al and only 0.1 equiv of Sn is used,[38] whereas metallic Sn or $SnCl_2$ in aprotic solvents convert allylic halides to allylstannanes in situ, which readily allylate carbonyl substrates[39] with complete rearrangement in the entering allylic unit.[39a] It has been established that Al effects both oxidative addition of metallic Sn to allyl halide and reductive regeneration of Sn^0 from Sn^{II} and Sn^{IV} for a recycle use.[38] Thus all allylation reactions in Al-Sn or Al-Sn^{II} systems can be considered as aluminum-promoted and tin-recycled processes.

Al-Sn mediated condensation of aldehydes with α-(bromomethyl)acrylates[40] represents a facile synthesis of α-methylene-γ-butyrolactones (eq 13).[40a] This procedure is more efficient than allylations promoted by Cr^{II} (see ***Chromium(II) Chloride*** and ***Lithium Aluminum Hydride***).[40b]

(13)

Almost exclusive *threo* diastereoselectivity is characteristic of the reactions of cinnamyl chloride with aldehydes promoted by Al-Sn[41a] or Al-$SnCl_2$.[41b] Aldehydes containing a chiral center adjacent to the C=O group afford *threo*

Cram and *threo* anti-Cram products with the former predominating (eq 14) in contrast to magnesium-mediated reactions of the same partners, which give all four possible diastereomers.[41a]

(14)

Unlike other allylation processes mediated by Al-Sn, no isomerization of the allylic unit is observed in the reaction of aromatic aldehydes with CH_2=$CHCF_2Cl$ in the presence of Al-10% $SnCl_2$ in EtOH-AcOH-H_2O. This reaction regiospecifically leads to 1-aryl-2,2-difluoro-3-buten-1-ols.[42]

Aluminum-Lead Bromide.

Three main processes, Barbier-type allylations, reductive coupling of carbonyls, and addition of polyhaloalkanes to carbonyls are mediated by this system which has been extensively studied in the past decade. $PbBr_2$ is used in a catalytic amount (molar ratio Al foil:$PbBr_2$ = 100:1-5), of great importance because of the hazardous properties of lead.

Al-$PbBr_2$ promoted allylation of various carbonyl compounds can be performed at ambient temperature in DMF, aqueous THF, or aqueous MeOH while nonaqueous THF, MeOH, and MeCN are not suitable. A moderate excess of allylic bromide (10-100% relative to carbonyl substrate) is recommended. Under these conditions the addition to α,β-enones proceeds regiospecifically in a 1,2-fashion (eq 15).[43]

(15)

Metallic Al itself does not promote allylation which is, however, mediated by Pb-Bu_4NBr.[44] The observed stoichiometry (carbonyl substrate:CH_2=$CHCH_2Br$:Pb = 1:1:1) suggests that the reaction involves an active organolead(II) rather than organolead(IV) reagent, in contrast to the tin promoted reactions.[38,39] The in situ generated Pb^0 is much more effective than commercially available Pb and turnover of the Pb^0 catalyst in the range 14-77 is attained.[43]

This type of Barbier-type allylation has been applied to C-3 chain elongation of cephalosporins.[45]

Acetals $RCH(OMe)_2$ (**4**) as masked carbonyl compounds also undergo Barbier-type allylation mediated by Al-$PbBr_2$-$AlBr_3$ (molar ratio 1:0.03:0.1) to form homoallylic ethers (**5**).[46] The presence of ***Aluminum Bromide*** is critical because no allylation product is formed in the absence of this co-catalyst. Reaction pathways depend strongly on quantities of reactants and reagents, especially in the case of acetals of aromatic aldehydes. An increase of $AlBr_3$ from 0.1 to 0.5 equiv is accompanied by reductive homocoupling to 1,2-diaryl-1,2-dimethoxyethanes (**6**). If the ratio CH_2=$CHCH_2Br$ to (**4**) is higher than 2:1, commonly used in such processes, diallylation and reductive homocoupling of monoallylated products effectively compete with monoallylation. The results reveal formation of cations (**7**) in the presence of $AlBr_3$ as an acid catalyst. The cations are either further allylated or reduced by Pb^0 to furnish dimers (**6**) (eq 16).[46] Replacement of $AlBr_3$ with ***Trifluoroacetic Acid*** (TFA) (1 equiv) causes a complete shift of the reaction toward formation of homocoupling products (**6**) from arene and heteroaromatic carbaldehyde acetals.[47] To promote homocoupling, although less efficiently, VCl_3 or ***Cobalt(II) Chloride*** or ***Tin(II) Bromide*** can be also employed instead of $PbBr_2$ in the Al-$PbBr_2$-TFA redox system.

An extremely facile procedure for *C*-allylation of imines involves direct mixing of imines and $CH_2{=}CHCH_2Br$ with a catalytic amount of $PbBr_2$ (0.03 equiv) and Al foil (1 equiv) in ether containing ***Boron Trifluoride Etherate*** (1.1 equiv) (eq 17).[48] With almost the same efficiency, aromatic and aliphatic aldimines undergo electroreductive Barbier-type allylation using an Al anode/$PbBr_2$/Bu_4NBr/THF/Pt cathode system where a combination of sacrificial Al anode and Pb^0/Pb^{II} operates as a mediator for anodic and cathodic electron transfer processes, respectively.[49]

Regarding the chemical allylation of imines, $PbBr_2$ and the $BF_3.OEt_2$ couple can be replaced with a catalytic amount (0.05 equiv) of ***Titanium(IV) Chloride***. This system is highly advantageous in chirality transfer from L-valine into a homoallylic amine (diastereomeric ratio greater than 20:1) (eq 18).[50]

(18)

Similar to the transformations observed for acetals,[46,47] introduction of TFA in the Al-$PbBr_2$ system allows reductive dimerization of *N*-alkylimines to vicinal diamines.[51]

Reductive dimerization of allylic as well as benzylic bromides is mediated by the Al-$PbBr_2$ system in DMF. In the case of allylic bromides dimerization is complicated by allylic rearrangement and gives a mixture of isomeric 1,5-hexadienes. Benzylic bromides only give 1,2-diarylethanes.[52] The same reactions are also induced by metallic Pb-Bu_4NBr in DMF.[52]

An Al/$PbBr_2$/$NiCl_2$(bipy) (molar ratio 0.7:0.1:0.1) system promotes reductive dimerization of 2-arylvinyl halides to form 1,4-diaryl-1,3-butadienes, precursors of terphenyl derivatives (eq 19). The process is almost stereospecific and both double bonds in the dimer retain the C=C bond configuration of the starting vinyl halide. The reaction is carried out in DMF or MeOH at ambient temperature with KI (1.5 equiv) added. No dimerization is observed if THF, MeCN, CH_2Cl_2, or C_6H_6 are used as solvent or in the absence of either $NiCl_2$ or $PbBr_2$. The latter can be replaced by $BiCl_3$, $SnBr_2$, or $GeCl_4$, but dimer yields are remarkably decreased.[53]

(19)

Both aromatic and aliphatic aldehydes undergo Al-$PbBr_2$ mediated reductive addition of polyhalomethanes CX_3Y (X = Cl, Br; Y = Cl, Br, CN, $CONH_2$). The reaction (aldehyde:CX_3Y:Al:$PbBr_2$ = 1:2-4:1.2:0.1) is performed in DMF, yielding α-(trihalomethyl)carbinols (**8**) in almost quantitative yield. These can be subjected to further reductive elimination with Al-$PbBr_2$ in MeOH containing aq HCl to produce 1,1-dihaloalkenes (**9**). When carbinols (**8**) react in DMF, reduction of the trihalomethyl group to a dihalomethyl occurs instead of elimination (eq 20).[54] This approach has been used in the stereospecific synthesis of pyrethroid insecticide precursors[54] and arylacetic acids.[55]

In the same way, a CF_3CCl_2 unit can be introduced into aldehydes via a reaction with CF_3CCl_3. This process is chemospecific and no adducts resulting from C-F bond cleavage are formed.[56]

The Al-$PbBr_2$ system is also capable of mediating a facile reductive removal of bromine atoms from 6-bromo- and 6,6-dibromopenicillanate derivatives (in MeOH/aq 1% HBr (9/1)),[57] and has been used in prenylation reactions of *p*-benzoquinones and naphthoquinones.[58]

Aluminum-Bismuth(III) Chloride.

Al powder in combination with catalytic amounts of $BiCl_3$ in aqueous THF at ambient temperature promotes efficient Barbier-type allylation of aldehydes.[59] The reaction occurs with allylic rearrangement in the entering unit and stereoselectively gives the *erythro* product. The reaction involves allylbismuth reagent formation through the oxidative addition of an allylic halide to Bi^0 generated by the reduction of $BiCl_3$ with Al. Metallic Bi is also capable of allylating aldehydes to homoallylic alcohols in aprotic DMF, but not in an aqueous solvent.[60a] Metallic Zn or Fe also can be used with $BiCl_3$ instead of Al.[60b]

The system also induces alkylation of immonium cations. The procedure is experimentally simple due to its being performed in aqueous media.[61] Among other alkylation agents, methyl and benzyl halides have been used for the first

time in this Barbier reaction system (eq 21).[61b]

(21)

Aluminum-Antimony(III) Chloride and Aluminum-Indium(III) Chloride.

Both systems promote Barbier-type allylation of aldehydes. However, in contrast to $InCl_3$, which is required only in a catalytic amount for a reaction in aqueous THF,[62] more than stoichiometric amounts of $SbCl_3$ are used in DMF-H_2O (3:1) and NaI is added to activate allylic bromides (aldehyde:allylic halide:Al:$SbCl_3$:NaI = 1:1.2:2:1.5:1.2).[63] Similar to the Al-$PbBr_2$ system,[58] Al-$InCl_3$ also mediates prenylation of naphthoquinones.[62] Al in combination with a catalytic amount of $SbCl_3$ induces acetalization of carbonyl compounds.[63]

Aluminum-Nickel Alloy.

In alkali medium this reagent is employed for chemical reductions.[64] Al affects liberation of hydrogen which actually plays the role of reducing agent (eq 22).

$$NiAl + 3NaOH \longrightarrow Ni + Na_3AlO_3 + 1.5\ H_2 \qquad (22)$$

Besides reduction of carbonyl compounds, organic halides, and nitriles,[64b] in recent years numerous compounds containing N-N and N-O bonds (hydroxylamines, hydrazines, *N*-nitrosoamines, *N*-oxides) have been reduced to amines.[65] A few heterocycles are also reduced by this reagent, and high temperatures, high pressures, or a hydrogen atmosphere are not required. Corresponding tetrahydro derivatives are produced from pyridines, quinolines, and pyrazines, whereas pyrimidines, pyridazines, oxazoles, and isoxazoles undergo reductive cleavage of C-N, N-N, or N-O bonds to yield saturated diamines or diamino alcohols (see ***Raney Nickel***).[66]

Aluminum Amalgam[1]

Al-Hg

[11146-30-8] · Al · Aluminum Amalgam · (MW 26.98)

(reducing agent for many functional groups,[1] effects reductive dimerization of unsaturated compounds, can cleave carbon-element and element-element bonds.)

Physical Data: shiny solid.

Preparative Methods: ***Aluminum*** turnings (oil-free) are etched with dilute ***Sodium Hydroxide*** to a point of strong hydrogen evolution and the solution is decanted. The metal is washed once with water so that it retains some alkali, then treated with 0.5% ***Mercury(II) Chloride*** solution for 1-2 min, and the entire procedure is repeated. The shiny amalgamated metal is washed rapidly in sequence with water, ethanol, and ether and used at once.[2] Aluminum amalgam (**1**) reacts vigorously with water with liberation of hydrogen in the amount equivalent to the amount of aluminum present and can be used to dry organic solvents (ether, ethanol).[2a] Aluminum amalgam can be also prepared from aluminum foil, which is cut into strips ~10 cm × 1 cm and immersed, all at once, into a 2% aqueous solution of $HgCl_2$ for 15 s. The strips are rinsed with absolute alcohol and then with ether and cut immediately with scissors into pieces ~1 cm square, directly into the reaction vessel.[2b] Before immersion, each strip may be rolled into a cylinder ~1 cm in diameter. Each cylinder is amalgamated, rinsed successively with ethanol and ether and then placed in the reaction vessel.[2c]

Handling, Storage, and Precautions: moisture-sensitive. Precautions should be taken as it readily reacts with water with hydrogen evolution. Can be stored under dry ether. Toxic.

C=C Bond Reduction.

Alkenic substrates are transformed into saturated compounds upon reaction with Al-Hg. Substrates with carbon-carbon double bonds activated by electron-withdrawing substituents are most easily reduced.[3] The reaction may proceed with asymmetric induction and high chemoselectivity, leaving other functionalities unchanged (eq 1).[4] Reduction of 1,3-dienes[5a] and α-nitroalkenes[5b] results in 1,4-addition of hydrogen to the π-system. Aluminum amalgam can also promote reductive dimerization of α,β-unsaturated acid esters.[6a,b]

C=O Bond Reduction.

Cycloalkanones and aldehydes are reduced to the corresponding alcohols (eq 2). Acyclic ketones remain almost inert.[7]

In spite of the ability of carboxylic acid esters to be reduced to alcohols,[8] in oxosuccinic acid esters only the ketone carbonyl group is reduced.[9]

Ultrasound-promoted reduction of the C=O group of *N*-substituted phthalimides leads to hydroxylactams. The ultrasonic irradiation provides rapid fragmentation of the amalgam, giving a reactive dispersion and accelerates the reaction owing to the increase of mass transport between the solution and the Al/Hg surface where reduction occurs. The reaction is highly sensitive to substrate structure and *N*-benzylglutarimide and *N*-benzylsuccinimide are not reduced.[10]

Reductive dimerization of carbonyl compounds to pinacols does not always effectively compete with reduction to alcohols, but in certain cases it becomes the main process (eq 3).[7,11] Factors which determine reduction-dimerization ratios include steric inhibition, torsion strain, and angle strain.[7]

(3)

CH_2Cl_2, reflux, 1-4 h, 21-38%
C_6H_6-EtOH (1:1), reflux, 4 h, 95%
THF-H_2O (9:1), -10 °C → rt, 94%

A special case of reduction involves removal of the carbonyl oxygens from anthraquinones[12a,b] and related compounds[13] with rearomatization (eq 4).[12b]

60-65 °C, 2 h
78%

(4)

C=N Bond Reduction.

Aluminum amalgam reduces Schiff bases to the corresponding amines.[14] Among these reactions of great importance is the reduction of Δ^2-thiazolines to thiazolidines, [15-17] widely used in the synthesis of aldehydes (eq 5),[15] β-hydroxy aldehydes, and homoallylic alcohols.[16]

(5)

Aluminum amalgam also induces reductive dimerization of Schiff bases[14a,18] to produce 1,2-diamines. This process has been used in macrocyclic ring closure.[18a] In respect to reductive dimerization of Δ^1-pyrrolines, aluminum amalgam is much more effective than ***Zinc*** in aqueous NH_4Cl.[18b] Similar to Schiff bases, oximes are also readily reduced to corresponding amines,[19] while reduction of hydrazides provides hydrazines.[20]

NO_2 and N_3 Group Reduction.

Aluminum amalgam reduction is an excellent method for deoxygenation of aliphatic and aromatic nitro groups to produce amines[21] (eq 6).[21d] Nitro alkenes can be chemoselectively reduced, retaining the C=C bond.[21a] In moist ether the reduction can be stopped at the stage of hydroxylamine formation.[22]

(6)

Organic azides are also readily reduced to the corresponding amines. The procedure has been used in a general synthesis of α,β-unsaturated α-amino acids.[23]

Reactions of Carbon-Halogen Bonds.

Organic halides exhibit diverse behavior in reactions with Al-Hg. Thus a trichloromethyl group has been reduced to a dichloromethyl group.[24] At the same time, Al inserts into the C-Br bond of silylated propargyl bromide affording the

allenylaluminum reagent, whereas only direct metalation without rearrangement has been observed in metalation with ***Zinc Amalgam*** (eq 7).[25]

(7)

Mild reductive deacetoxybromination of glycosyl bromides offers an approach to glucals bearing acid-sensitive substituents (eq 8).[26]

(8)

C-O Bond Cleavage.

Ether linkages of various substrates, for example glycosides,[27] 1,3-dioxolanes,[28] tetrahydrofurans,[29,30] and oxiranes,[31] undergo reductive cleavage with formation of alcohols. Among the reactions listed, the reductive cleavage of epoxides (eq 9)[32a] is presumably of the most importance. It has been widely used in the synthesis of prostaglandins,[31a,b,32] steroids,[31c,d] erythronolide B,[33] and vitamin precursors.[34]

Deoxygenation of certain terpene oxides with Al foil activated by $HgCl_2$ has been reported instead of reduction to the desired alcohols.[35]

N-O and N-N Bond Cleavage.

On exposure to excess Al-Hg in aqueous THF at 0 °C for several hours, N-O bonds in bicyclic Diels-Alder adducts are readily cleaved.[36] Mild conditions provide a highly chemoselective process and carbon-carbon double bonds and acid labile functional groups survive, in contrast to the alternative methods employed such as catalytic hydrogenolysis or reduction with ***Zinc-Acetic Acid***.[36a] The reaction occurs with high stereoselectivity and the product is formed with a *cis* disposition of N- and O-containing substituents (eq 10).[36]

Aluminum analgam is also highly effective in reductive cleavage of N-N bonds to produce amines.[37]

Reductive Desulfurization.

The ability of Al-Hg to reduce C-S bonds is widely used in organic synthesis in conjunction with methodology involving reactions of highly reactive α-sulfinyl- and α-sulfonylalkyl carbanions[2b,38] as well as (α-sulfoximidoyl)alkyl carbanions.[39] Removal of the activating sulfur substituent is frequently accomplished using Al-Hg. The methodology offers facile synthetic approaches to ketones,[2b,38,40] enones,[41] di- and triketones,[40,42] hydroxy ketones (eq 11),[43] unsaturated acids,[44] and γ-oxo-α-amino acids.[45]

(11)

Readily removed on treatment with Al-Hg asymmetric sulfinyl and sulfonimidoyl groups may serve as chiral auxiliaries in enantiocontrolled synthesis of 3-substituted cycloalkanones[46] and 3-hydroxy[47] and 3-arylcarboxylic acid esters.[48]

Aluminum amalgam mediated cleavage of C-S bonds plays an important role in sulfoximine-based alkenation of carbonyl compounds via β-hydroxysulfoximines[49] (eq 12).[49b]

(12)

Aluminum amalgam can also be employed in reductive elimination of phenylthio groups from 2-phenylthioalkanones,[50] stereospecific reduction of sulfoximines,[51] selective cleavage of the sulfinyl sulfur-methylene carbon bond in the presence of a disulfide moiety,[52] and reductive scission of S-S and S-N bonds.[53,54]

For some reactions mediated by aluminum activated with mercury(II) chloride, also see ***Aluminum***.

Aluminum Bromide

$AlBr_3$

[7727-15-3] · $AlBr_3$ · Aluminum Bromide · (MW 266.72)

(Lewis acid catalyst similar to $AlCl_3$; useful in oxacycle,[1] cyclopentanone,[3] and conjugated cyclopentenone[4] synthesis; halogenations;[6] reductive deoxygenation of ketones and secondary alcohols;[7] selective ether cleaving reagent;[8] isomerization catalyst;[12] Friedel-Crafts catalyst[16])

Physical Data: mp 97 °C; bp 268 °C; *d* 3.01 g cm^{-3}.

Solubility: sol CS_2, alcohols, ether, acetone, hydrocarbons, nitrobenzene, $Br(CH_2)_2Br$.

Form Supplied in: commercial grade white to yellowish-brown deliquescent solid; colorless is pure. Also available as a 1.0 M solution in CH_2Br_2. Exists as a dimer (Al_2Br_6) in solid and liquid phases.

Handling, Storage, and Precautions: use in a fume hood; fumes strongly in air; violent reaction with H_2O; corrosive to skin. Keep tightly closed and protected from moisture. Decomposes upon heating in air to Br_2 and alumina.

Oxacycle Synthesis.

Unsaturated alcohols react with aldehydes in the presence of $AlBr_3$ to give 4-bromooxacycles in a stereoselective manner (eq 1).[1] Tetrahydropyrans are formed in the all-*cis* configuration. Seven-membered rings are produced as a mixture of isomers at the bromide position. This method has a synthetic advantage over similar allylsilane procedures[2] in that larger rings can be prepared.

(1)

Cyclopentanone Synthesis.

Ring expansion of 1-acyl-1-(alkyl or arylthio)cyclobutanes to cyclopentantones occurs readily in the presence of 1 equiv $AlBr_3$ (eq 2).[3] This method has been used to provide good yields (68-86%) of 2-, 2,4-, and 2,5-substituted cyclopentanones. ***Aluminum Chloride*** and ***Iron(III) Chloride*** were also effective in this conversion; however, $BF_3.Et_2O$ and protic acids do not work.

(2)

Conjugated Cyclopentenone Synthesis.

Decomplexation of 1,3-butadieneiron tricarbonyl complexes by $AlBr_3$ leads to conjugated cyclopentenones under mild conditions.[4] The diene must be unsubstituted at the 4-position but substitution at all other positions is tolerated. This cyclocarbonylation is stereospecific, depending only on the configuration of the diene complex (eq 3). Spirocyclic compounds can be formed using an appropriate precursor (eq 4). The method serves as a valuable alternative to the intramolecular Pauson-Khand reaction. One apparent limitation is that bicyclic cyclopentenones with an angular alkyl group cannot be prepared.

(3)

(4)

Halogenations.

A novel photochemical ring contraction of 1-naphthols to 3-halomethylindanones is promoted by $AlBr_3$ or $AlCl_3$ (eq 5).[5] The halogen substituent is derived from the halogenated solvent. In CH_2Cl_2, chlorides are the major product; in CH_2Br_2, bromides are produced regardless of whether $AlBr_3$ or $AlCl_3$ is used.

(5)

Thiophenes can be regioselectively brominated by $AlBr_3$ in the presence of ***Benzeneseleninyl Chloride*** (eq 6).[6a] Furans are halogenated in low yield and pyrroles are unreactive.

(6)

Bridgehead halogen exchange in polycyclic substrates is catalyzed by $AlBr_3$ in halogenated solvents and proceeds readily in fair to good yield (50-90%).[6b] For bromination, CH_2Br_2 or $CHBr_3$ solvent is used. Iodinations are carried out in MeI or CH_2I_2 and chlorinations in $CHCl_3$ or CCl_4. Bromoalkylation of 1-bromoadamantane occurs when subjected to ethylene or vinyl bromide in the presence of $AlBr_3$ to give 1-bromo- or 1,1-dibromo-2-(1-adamantyl)ethane, respectively.[6c] Yields are dependent on the quality of the $AlBr_3$. Bromination of the bridgehead position of adamantanone by $AlBr_3$/*t*-BuBr (so-called sludge catalyst) provides an improved, high yielding synthesis of 1-bromo-4-adamantanone.[6d]

C-O Bond Cleavages.

Reductive deoxygenation of ketones and secondary alcohols to the corresponding methylene hydrocarbons in excellent yield can be accomplished by the ***Diisobutylaluminum Hydride***/$AlBr_3$ reagent system.[7] In some cases, the addition of a catalytic amount of Cp_2MCl_2 (M = Ti, Zr) or ***Nickel(II) Acetylacetonate*** is required. Diaryl, alkyl aryl, or dialkyl ketones and secondary alkyl or benzylic alcohols undergo this reaction but primary alcohols or phenols do not.

Anhydrous $AlBr_3$ in MeCN or CS_2 is useful for the removal of methyl ethers and in some instances selective cleavage is possible.[8] The 5-MeO group in 3,5,6,7-tetramethoxyflavones and the 3-MeO group in 3,6,7-trimethoxy-5-tosyloxyflavones are selectively cleaved in nearly quantitative yield without debenzylation (eq 7).[8a] It is superior to $AlCl_3$ in some ether cleavages[8b] since it is a stronger Lewis acid and more soluble in organic solvents. An excellent reagent for phenol ether cleavage (except diphenyl ether) is the pyridinium salt of $AlBr_3$.[8c]

(7)

$AlBr_3$ is an efficient reagent for epoxide cleavage giving high yields of the bromohydrin. It does not show much regioselectivity in the case of substituted substrates.[9] The hydroxylation of cyclic acetals with ***Hydrogen Peroxide*** can be catalyzed by $AlBr_3$ as well as with other reagents (especially $SeBr_4$) to give esters of the type

$RCO_2(CH_2)_nOH$ (R = H, aryl, alkyl; *n* = 2-3).[10] Disulfide cleavage with $AlBr_3$ has been reported to give cyclized products in certain systems (eq 8).[11]

(8)

Rearrangements.

The $AlBr_3$ sludge catalyst has been extensively used as an effective isomerization reagent in numerous adamantane, diamantane, and triamantane syntheses (eq 9).[12] A wide variety of polycyclic hydrocarbons can be rearranged to these ring systems. Perhydrogenated phenanthrene rearranges to give mainly *trans*,*syn*,*trans*-perhydroanthracene by the action of $AlBr_3$/HBr in dimethylcyclohexane.[13]

(9)

A facile rearrangement of α-bromoethyldiethylborane (eq 10) occurs when treated with Lewis acids.[14] $AlBr_3$ is very effective for this conversion. $AlCl_3$ or ***Silver(I) Tetrafluoroborate*** also give high yields. The half-life for rearrangement is 0-5 min with these catalysts.

(10)

Diphenylacetylene undergoes dimerization with $AlBr_3$ to give 1,2,3-triphenylazulene.[15] The yield is very dependent on the purity of $AlBr_3$ used. Yields are enhanced by the addition of a small amount of V^{2+} or Ni^{2+}, whereas Ti^{3+}, V^{4+}, Cr^{2+}, Cr^{3+}, Fe^{3+}, or Zn^{2+} almost completely suppress azulene formation.

Friedel-Crafts Reactions.

$AlBr_3$ is a superior reagent for intramolecular Friedel-Crafts cyclization of o-phenylalkanoic acid chlorides ($Ph(CH_2)_nCOCl$; n = 8-15) to the paracyclophanes (eq 11).[16a] Under high dilution conditions, the yields are generally twice as high as that with $AlCl_3$. Negligible yields of medium-sized cyclophanes (n = 8, 5.3%) are obtained. Yields tend to increase with increasing ring size (n = 15, 70%). Other examples of its use as a Friedel-Crafts catalyst and in the Fries rearrangment of phenol esters appear in the literature.[16b-f]

Aluminum *t*-Butoxide[1]

$Al(O\text{-}t\text{-}Bu)_3$

[556-91-2] · $C_9H_{27}AlO_3$ · Aluminum *t*-Butoxide · (MW 246.32)

(metal alkoxide used in Meerwein-Ponndorf-Verley reduction of ketones[2] and Oppenauer oxidation of alcohols[3])

Physical Data: white powder; mp >300 °C (sealed tube); dimeric structure in benzene; can be recryst from benzene; sublimes at 180 °C.

Solubility: v sol organic solvents, especially alcohols, benzene, toluene, and xylene.

Preparative Method: prepared by reacting ***Aluminum*** shavings with dry *t*-butyl alcohol using a catalytic amount of ***Mercury(II) Chloride***.[1c,1e]

Handling, Storage, and Precautions: use in fume hood. Air and moisture sensitive; extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin and should be handled with appropriate caution. Contact via inhalation route is particularly hazardous.

Meerwein-Ponndorf-Verley Reduction.

The reagent has been used for the reduction of 3-keto steroids, affording predominantly the axial alcohol. Thus reduction of the monoethylene ketal of 3,20-pregnanedione with the reagent in *s*-butyl alcohol, followed by transketalization, gave 3β-hydroxy-5β-pregnan-20-one in modest excess over the 3α-epimer.[2] Separation and oxidation of the undesired epimer followed by reduction as above gave, after several cycles, high conversion of the dione to the desired 3β-alcohol (eq 1)

Oppenauer Oxidation.

Aluminum *t*-butoxide is frequently the reagent of choice for this mild oxidation of secondary alcohols to ketones. Since most other oxidizable groups remain unaffected, the method has found wide use in the steroid field, as illustrated by the oxidation of cholesterol to cholest-4-en-3-one (eq 2).[3] The accompanying double bond migration commonly occurs during reactions of steroids of this type.

Aldol Condensation.

The reagent has also found limited use as a base for the aldol condensation of methyl ketones, as illustrated by the preparation of dypnone from acetophenone (eq 3).[4]

Amine Alkylation.

In the presence of catalytic amounts of ***Raney Nickel*** W-2 and aluminum *t*-butoxide, primary and secondary amines are alkylated by alcohols (eqs 4 and 5).[5]

Aluminum Chloride[1]

$AlCl_3$

[7446-70-0] · $AlCl_3$ · Aluminum Chloride · (MW 133.34)

(Lewis acid catalyst for Friedel-Crafts, Diels-Alder, [2 + 2] cycloadditions, ene reactions, rearrangements, and other reactions)

Physical Data: mp 190 °C (193-194 °C sealed tube); sublimes at 180 °C; *d* 2.44 g cm^{-3}.

Solubility: sol many organic solvents, e.g. benzene, nitrobenzene, carbon tetrachloride, chloroform, methylene chloride, nitromethane, and 1,2-dichloroethane; insol carbon disulfide.

Form Supplied in: colorless solid when pure, typically a gray or yellow-green solid; also available as a 1.0 M nitrobenzene solution.

Handling, Storage, and Precautions: fumes in air with a strong odor of HCl. $AlCl_3$ reacts violently with H_2O. All containers should be kept tightly closed and protected from moisture.[1c] Use in a fume hood.

Friedel-Crafts Chemistry.[1,2]

$AlCl_3$ has traditionally been used in stoichiometric or catalytic[3] amounts to mediate Friedel-Crafts alkylations and acylations of aromatic systems (eq 1).

(1)

This is a result of the Lewis acidity of $AlCl_3$ which complexes strongly with carbonyl groups.[4] Adaptations of these basic reactions have been reported.[5] In chiral systems, inter- and intramolecular acylations have been achieved without the loss of optical activity (eq 2).[6]

(2)

Friedel-Crafts chemistry at an asymmetric center generally proceeds with racemization, but the use of mesylates or chlorosulfonates as leaving groups has resulted in alkylations with excellent control of stereochemistry.[7] The reactions proceed with inversion of configuration (eq 3). Cyclopropane derivatives have been used as three-carbon units in acylation reactions (eq 4).[8] In conjunction with triethylsilane, a net alkylation is possible under acylation conditions (eq 5).[9] These conditions are compatible with halogen atoms present elsewhere in the molecule. Acylation reactions of phenolic compounds with heteroaromatic systems have also been accomplished (eq 6).[10]

(3)

(4)

(5)

Treatment of aryl azides with $AlCl_3$ has been reported to give polycyclic aromatic compounds (eq 7),[11] or aziridines when the reactions are run in the presence of alkenes (eq 8).[12]

The scope of Friedel-Crafts chemistry has been expanded beyond aromatic systems to nonaromatic systems, such as alkenes and alkynes and the mechanistic details have been investigated.[13] The Friedel-Crafts alkylation[14] and acylation[15] of alkenes provide access to a variety of organic systems (eq 9). The acylation of alkynes provides access to cyclopentenone derivatives (eq 10).[16] In addition, one can use this chemistry to access indenyl systems[17] and vinyl chlorides.[18] Allylic sulfones can undergo allylation chemistry (eq 11).[19]

(10)

(11)

The use of silyl derivatives in Friedel-Crafts chemistry has not only improved the regioselectivity but extended the scope of these reactions. Substitution at the *ipso* position occurs with aryl silanes (eq 12).[20] The ability of silyl groups to stablize β-carbenium ions (β-effect) affords acylated products with complete control of regiochemistry (eq 13).[21]

(12)

(13)

The use of silylacetylenes gives ynones (eq 14),[22] cyclopentenone derivatives (eq 15),[23] and α-amino acid derivatives (eq 16).[24]

(14)

(15)

(16)

Propargylic silanes undergo acylation to generate allenyl ketones (eq 17),[25] while alkylsilanes afford cycloalkanones (eq 18).[26]

(17)

(18)

Several name reactions are promoted by $AlCl_3$. For example, the Darzens-Nenitzescu reaction is simply the acylation of alkenes. The Ferrario reaction generates phenoxathiins from diphenyl ethers (eq 19).[27] The rearrangement of acyloxy aromatic systems is known as the Fries rearrangement (eq 20).[28] Aryl aldehydes are produced by the Gatterman aldehyde synthesis (eq 21).[29] The initial step of the Haworth phenanthrene synthesis makes use of a Friedel-Crafts acylation.[30] The acylation of phenolic compounds is called the Houben-Hoesch reaction (eq 22).[31] The Leuckart amide synthesis generates aryl amides from isocyanates (eq 23).[32]

(19)

(20)

(21)

(22)

(23)

Amides can also be obtained by $AlCl_3$ catalyzed ester amine exchange which proceeds primarily without racemization of chiral centers (eq 24).[33] The reaction of phenols with β-keto esters is known as the Pechmann condensation (eq 25).[34] Aryl amines are used in the Riehm quinoline synthesis (eq 26).[35] Aromatic systems may be coupled via the Scholl reaction (eq 27)[36] and indole derivatives are prepared in the Stolle synthesis (eq 28).[37] In the Zincke-Suhl reaction, phenols are converted to dienones (eq 29).[38]

(24)

(25)

(26)

(27)

(28)

(29)

Diels-Alder Reactions.

There is some evidence that $AlCl_3$ catalysis of Diels-Alder reactions changes the transition state from a synchronous to an asynchronous one.[39] This also enhances asymmetric induction by increasing steric interactions at one end of the dieneophile. There are many examples of $AlCl_3$ promoted Diels-Alder reactions (eq 30).[40] Hetero-Diels-Alder reactions can be used to generate oxygen (eq 31)[41] and nitrogen (eq 32)[42] containing heterocycles.

(30)

(31)

(32)

$AlCl_3$ can also be used to catalyze [2 + 2] cycloaddition reactions (eq 33)[43] and ene reactions (eq 34).[44]

(33)

(34)

Rearrangements.

$AlCl_3$ catalyzed rearrangement of hydrocarbon derivatives to adamantanes has been well documented (eq 35).[45] Other rearrangements have been used in triquinane synthesis (eq 36).[46]

(35)

(36)

Miscellaneous Reactions.

$AlCl_3$ has been used to catalyze the addition of allylsilanes to aldehydes and acid chlorides (eq 37).[47] Cyclic ethers (pyrans and oxepins) have been prepared with hydroxyalkenes (eq 38).[48] The course of reactions between aldehydes and allylic Grignard reagents can be completely diverted to α-allylation by $AlCl_3$ (eq 39).[49] The normal course of the reaction gives γ-allylation products.

(37)

(38)

(39)

$AlCl_3$ can be used to remove *t*-butyl groups from aromatic rings (eq 40),[50] thereby using this group as a protecting element for a ring position. $AlCl_3$ has also been used to remove *p*-nitrobenzyl (PNB) and benzhydryl protecting groups (eq 41).[51] The combination of $AlCl_3$ and ***Ethanethiol*** has formed the basis of a push-pull mechanism for the cleavage of many types of bonds including C-X,[52] C-NO_2,[53] C=C,[54] and C-O.[55] Furthermore, $AlCl_3$ has been used to catalyze chlorination of aromatic rings,[56] open epoxides,[57] and mediate addition of dichlorophosphoryl groups to alkanes.[58]

Aluminum Cyclohexoxide[1]

$Al(OCy)_3$

[-] · $C_{18}H_{33}AlO_3$ · Aluminum Cyclohexoxide · (MW 324.42) (Al)

[7429-90-5] · Al · Aluminum Cyclohexoxide · (MW 26.98) (CyOH)

[108-93-0] · $C_6H_{12}O$ · Aluminum Cyclohexoxide · (MW 100.18)

(reducing agent for anthraquinone-related ring systems)

Preparative Method: prepared in situ from ***Aluminum*** in refluxing cyclohexanol.[2]

Handling, Storage, and Precautions: use in a fume hood. The reagent should be freshly prepared just prior to use. Many aluminum alkoxides are extremely irritating to skin, eyes, and mucous membranes and should be handled with appropriate caution. Contact via inhalation route is particularly hazardous.

Reduction.

The reagent has been used by several groups for the reduction of anthraquinone and related derivatives to the corresponding anthracene ring systems under what are essentially Meerwein-Ponndorf-Verley reduction conditions.[1] Thus treatment of anthraquinone[2] or tetramethylanthraquinone[3] with the reagent in boiling cyclohexanol afforded anthracene and 2,3,6,7-tetramethylanthracene, respectively, in good yield (eq 1).

The polycyclic aromatic hydrocarbons benz[*a*]anthracene[4] and 2,3,6,7-dibenzanthracene (pentacene)[5] have been prepared in a similar fashion (eqs 2 and 3).

Aluminum Ethoxide[1]

$Al(OEt)_3$

[555-75-9] · $C_6H_{15}AlO_3$ · Aluminum Ethoxide · (MW 162.16)

(reagent for reduction of aldehydes to alcohols;[2] catalyst for conversion of aldehydes to esters[3])

Physical Data: mp 157-160 °C; liq bp 200 °C/6-8 mmHg; mixture of oligomers in solution; physical properties drastically affected by traces of moisture.

Solubility: sol hot xylene, cholorobenzene, other high boiling solvents.

Form Supplied in: available as white powder.

Preparative Method: react ***Aluminum*** filings with absolute ethanol using small amounts of ***Mercury(II) Chloride*** or ***Iodine*** as catalysts.[4]

Handling, Storage, and Precautions: use in a fume hood; air and moisture sensitive; extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes and skin, and should be handled with appropriate caution. Contact via inhalation route is particularly hazardous.

Reductions.

The reagent, while commercially available, may be conveniently prepared prior to use.[4] It has been used in Meerwein-Ponndorf-Verley reductions for the selective conversion of α-halo aldehydes and α,β-unsaturated aldehydes to the corresponding alcohols. For example, reaction of chloral with aluminum ethoxide in ethanol as solvent gives acetaldehyde and the aluminum salt of trichloroethanol. Subsequent treatment of the salt with sulfuric acid liberates trichloroethanol in excellent yield (eq 1).[4] Similar high-yield reductions have been carried out on bromal, cinnamaldehyde, and various halogenated cinnamyl and crotyl aldehydes.[2,5]

(1)

Esters from Aldehydes.

When Tishchenko treated a variety of aldehydes with a catalytic amount of aluminum ethoxide in the absence of solvents, he obtained primarily esters derived from oxidation of one half of the aldehyde and reduction of the other half. Extensive studies later verified this early work.[6] Although alkali metal alkoxides have been used successfully in the Tishchenko reaction for aldehydes lacking α-hydrogens,[3b] aluminum ethoxide is almost invariably the catalyst of choice in those cases where aldol condensations would otherwise predominate. For example, treatment of butanal, 2-ethylbutanal, or octanal with aluminum ethoxide (5% by weight relative to the aldehyde) gave the corresponding esters in good yield (eq 2).[6b] Crossed Tishchenko reactions generally give mixtures of products.

(2)

R = *n*-Pr	81%
R = Et_2CH	70%
R = $Me(CH_2)_6$	69%

Aluminum ethoxide in xylene has also been used to polymerize terephthalaldehyde into high molecular weight chains in a Tishchenko-like process.[7]

Aluminum Hydride[1]

AlH_3

[7784-21-6] · AlH_3 · Aluminum Hydride · (MW 29.99)

(reducing agent for many functional groups; used in hydroalumination of alkynes; allylic rearrangements)

Alternate Name: alane.

Physical Data: colorless, nonvolatile solid in a highly polymerized state; mp 110 °C (dec). X-ray data have also been obtained.[2]

Solubility: sol THF and ether; precipitates from ether after standing for approximately 30 min depending upon method of preparation.

Analysis of Reagent Purity: hydride concentration can be determined by hydrolyzing aliquots and measuring the hydrogen evolved.[3]

Preparative Methods: can be prepared by treating an ether solution of ***Lithium Aluminum Hydride*** with ***Aluminum Chloride*** (eq 1).[4] This affords an ether solution of AlH_3 after precipitation of LiCl. Solutions have to be used immediately otherwise AlH_3 precipitates as a white solid which consists of a polymeric material with ether. The solvent can be removed and the solid redissolved in THF.[5] Alternatively, THF solutions can be prepared directly according to one of the reactions shown in eqs 2-4.[5,6]

$$3\ LiAlH_4 + AlCl_3 \longrightarrow 4\ AlH_3 + 3\ LiCl \qquad (1)$$

$$2\ LiAlH_4 + BeCl_2 \longrightarrow 2\ AlH_3 + LiBeH_2Cl_2 \qquad (2)$$

$$2\ LiAlH_4 + H_2SO_4 \longrightarrow 2\ AlH_3 + Li_2SO_4 + 2\ H_2 \qquad (3)$$

$$2\ LiAlH_4 + ZnCl_2 \longrightarrow 2\ AlH_3 + 2\ LiCl + ZnH_2 \qquad (4)$$

Handling, Storage, and Precautions: solutions of AlH_3 are not spontaneously inflammable.[3] However, since AlH_3 has reactivity comparable to $LiAlH_4$, one should follow similar handling and precautions as those exercised for $LiAlH_4$. Solutions of AlH_3 are prepared in situ but are known to degrade after 3 days, and long term storage of solutions is not possible. Use in a fume hood.

Functional Group Reductions.

Reductions by alane take place primarily by a two-electron mechanism.[7,8] However, evidence for a SET pathway exists.[9] AlH_3 will reduce a wide variety of functional groups.[4] These include aldehydes, ketones, quinones, carboxylic acids, anhydrides, acid chlorides, esters, and lactones, from which the corresponding alcohol is the isolated product. Amides, nitriles, oximes, and isocyanates are reduced to amines. Nitro compounds are inert to AlH_3. Sulfides and sulfones are unreactive, but disulfides and sulfoxides can be reduced. Tosylates are also not reduced by AlH_3.

The reduction of ketones with AlH_3 has selectivity different from other hydride reagents (eqs 5 and 6).[10] The hydroxymethylation of ketones via a two-step procedure has also been accomplished (eq 7).[11] The conversion of α,β-unsaturated ketones to allylic alcohols can be carried out with very good selectivity using AlH_3 (eq 8);[12] however, DIBAL is the reagent of choice for this transformation (see ***Diisobutylaluminum Hydride***).[12c]

(5)

$LiAlH_4$	*trans*:*cis* = 1.9:1
AlH_3	7.3:1

(6)

(7)

(8)

Carboxylic acids and esters are reduced more rapidly by AlH_3 than by $LiAlH_4$, whereas the converse is true for alkyl halides. As a result, acids and esters can be reduced in the presence of halides (eq 9). In addition, esters can be reduced in the presence of nitro groups (eq 10). This stands in contrast to $LiAlH_4$ in which nitro groups are reduced. Acetals can also be reduced to the half protected diol as illustrated in eq 11.[13]

(9)

(10)

(11)

In reductions of amides to amines there is a competition between C-O and C-N bond cleavage which depends upon the reaction conditions. This complication does not occur with AlH_3. A quantitative yield of amine is obtained with short reaction times. Conjugated amides can be cleanly reduced to the allylic amine (eq 12).[6]

(12)

The less basic AlH_3 appears to be better than $LiAlH_4$ for reducing nitriles with relatively acidic α-hydrogens to amines, and enolizable keto esters to diols (eq 13).[6]

(13)

The reduction of β-lactams to azetidines can be accomplished with AlH_3 (eq 14),[14] while ring opening was observed with $LiAlH_4$. AlH_3 can also convert enamines to the corresponding alkenes (eq 15).[15]

(14)

(15)

While alkyl halides are usually inert to AlH_3, the reduction of cyclopropyl halides to cyclopropanes (eq 16)[16] and glycosyl fluorides to tetrahydropyrans (eq 17)[17] are known.

(16)

(17)

Desulfurization of sultones is rapid and proceeds in good yield with AlH_3 while $LiAlH_4$ affords poor yields with long reaction times (eq 18).[18]

(18)

Epoxide Ring Opening.

With most epoxides, hydride attack occurs at the least sterically hindered site to give the corresponding alcohol (eq 19).[19] However, due to the electrophilic nature of AlH_3 compared to $LiAlH_4$, it is possible for ring opening to occur at the more hindered site. With phenyl substituted epoxides, mechanistic studies have shown that attack at a benzylic carbenium ion or a 1,2-hydride shift followed by hydride attack gives products with the same regiochemistry but with different stereochemistry (eq 20).[6,20] The stereoselectivity of AlH_3 mediated epoxide openings has been studied in depth.[21]

(19)

(20)

Hydroalumination.

The addition of AlH_3 across a triple bond has been shown to occur in propargylic systems.[22] When the reactions are quenched with ***Iodine***, AlH_3 gives the 2-iodo-(*E*)-alkene while $LiAlH_4$ gives the 3-iodo-(*E*)-alkene (eq 21). AlH_3 can also be used in conjunction with ***Titanium(IV) Chloride*** to carry out a reaction similar to a hydroboration.[23] Thus 1-hexene is converted to hexane upon aqueous work-up or to the corresponding alcohol upon exposure of the reaction intermediate to oxygen (eq 22). Similar results were obtained with nonconjugated dienes.

Allylic Rearrangements (S_N2').

The S_N2' displacement of a good leaving group to give the rearranged allylic system can be carried out with AlH_3.[24] This reaction appears not to be sterically demanding as a variety of displacements are possible (eq 23).

Preparation of allenes from propargylic systems can also be accomplished.[24] Most systems show a preference for *syn* elimination; however, mesylates prefer an *anti* mode of elimination (eq 24). This same procedure has been used to prepare fluoroallenes (eq 25).[25]

Dialkylaluminum hydrides also behave as hydroalumination reagents (see ***Diisobutylaluminum Hydride***) and are more commonly used than AlH_3.

Aluminum Iodide

AlI_3

[7784-23-8] · AlI_3 · Aluminum Iodide · (MW 407.72)

(cleavage of O-N and S-O bonds;[1] reductive dehalogenation of α-halocarbonyls;[2] deoxygenation of epoxides and vicinal diols;[3,4] ether, acetal, and ester cleaving reagent;[5] iodination of allylic, benzylic, and tertiary alcohols;[4a] hydroiodination of alkenes and alkynes;[6] Friedel-Crafts catalyst[7])

Physical Data: mp 191 °C; bp 382 °C; *d* 3.98 g cm^{-3}.

Solubility: sol CS_2, alcohols, ether, liq. NH_3.

Form Supplied in: white leaflets if pure; commercial grade yellowish to blackish-brown lumps. Exists as the dimer (Al_2I_6) in solid and gas phases.

Preparative Method: some applications require freshly prepared AlI_3. This is conveniently done by heating clean ***Aluminum*** foil with ***Iodine*** in dry MeCN or CS_2 under nitrogen with refluxing for 3 h or until the iodine color disappears. The solution obtained can be directly used for the reaction.

Handling, Storage, and Precautions: use in a fume hood; fumes in moist air; strong exothermic reaction with H_2O; corrosive; moderately toxic. Keep tightly closed and protected from light.

Cleavage of N-O and S-O Bonds.

AlI_3 in MeCN is a general reagent for deoxygenation of *N*-arylnitrones, azoxybenzenes, and *N*-arene *N*-oxides in high yield.[1a] It provides an efficient and facile preparation of *o*-aminobenzophenones by a highly selective reductive cleavage of O-N bonds in 2,1-benzoisoxazoles (eq 1).[1b] Chromone 3-aldonitrones are converted by a facile AlI_3-catalyzed rearrangement to the 3-carboxamides.[1c] Ketoximes undergo Beckmann rearrangement to the carboxamide while aldoximes are readily dehydrated to the nitrile in the presence of AlI_3.[1d] Aryl or alkyl sulfonyl chlorides and sulfoxides are reduced to the disulfide and sulfide, respectively.[1e]

(1)

R^1 = Cl, Br, NO_2, Ac
R^2 = H, Me
R^3 = H, OH

Cleavage of C-X and C-O Bonds.

In the AlI_3-mediated reductive dehalogenation of α-halocarbonyl compounds, aluminum enolates are readily generated and can be trapped via aldol reactions (eq 2).[2] The deoxygenation of oxiranes with AlI_3 proceeds at room temperature in MeCN or benzene to give high yields (typically >90%) of alkenes.[3] With less reactive epoxides the iodohydrin can be isolated. Certain vicinal diols (*cis* and *trans* secondary-tertiary and allylic bis-secondary) are converted to the alkene by this reagent (eq 3).[4a] Bis-secondary *vic*-diols remain unchanged.

(2)

R = aryl, alkyl
R' = H, Ph
X = Cl, Br

(3)

R^1-R^3 = alkyl, allyl

AlI_3 is a highly regioselective ether cleaving reagent, in some cases having a novel cleavage pattern.[5a] Aryl alkyl ethers are cleaved with 1 equiv AlI_3 to give the phenol and alkyl iodide. Selective ether cleavage is possible in the presence of benzoate esters. This method can be improved by the addition of quaternary ammonium iodide salts which give higher yields in shorter reaction times.[5b] AlI_3 exhibits superior regioselectivity over ***Aluminum Chloride*** or ***Aluminum Bromide*** in the cleavage of epoxides to the halohydrin.[5c] It is also an efficient reagent for deprotection of a wide variety of carboxylic esters (2 equiv AlI_3).[5d] Phenol esters, however, undergo Fries rearrangement. A nonaqueous procedure for conversion of acetals to the carbonyl compound is provided using this reagent.[5e] Thioacetals are unreactive under these conditions. Allylic, benzylic, and tertiary alcohols are regioselectively converted to the corresponding iodide by AlI_3. Saturated primary and secondary alcohols are unaffected. Aryl methyl ethers were shown to survive at short reaction times.[4a]

Miscellaneous Reactions.

Good yields of hydroiodinated product are formed by treatment of alkenes and alkynes with AlI_3 and H_2O via in situ generation of ***Hydrogen Iodide***.[6] The use of AlI_3 as a Friedel-Crafts catalyst is limited since it frequently gives lower yields than either $AlCl_3$ or $AlBr_3$. One exception occurs in the isopropylation of benzene.[7] An interesting AlI_3-catalyzed addition of MeCN has been reported (eq 4) but this does not appear to be a general reaction.[8]

Aluminum Isopropoxide[1]

$Al(O\text{-}i\text{-}Pr)_3$

[555-31-7] · $C_9H_{21}AlO_3$ · Aluminum Isopropoxide · (MW 204.25)

(mild reagent for Meerwein-Ponndorf-Verley reduction;[1] Oppenauer oxidation;[13] hydrolysis of oximes;[16] rearrangement of epoxides to allylic alcohols;[17] regio- and chemoselective ring opening of epoxides;[20] preparation of ethers[21])

Alternate Name: triisopropoxyaluminum.

Physical Data: mp 138-142 °C (99.99+%), 118 °C (98+%); bp 140.5 °C; *d* 1.035 g cm^{-3}.

Solubility: sol benzene; less sol alcohols.

Form Supplied in: white solid (99.99+% or 98+% purity based on metals analysis).

Preparative Methods: see example below.

Handling, Storage, and Precautions: the dry solid is corrosive, moisture sensitive, flammable, and an irritant. Use in a fume hood.

NMR Analysis of Aluminum Isopropoxide.

Evidence from molecular weight determinations indicating that aluminum isopropoxide aged in benzene solution consists largely of the tetramer (**1**), whereas freshly distilled molten material is trimeric (**2**),[2] is fully confirmed by NMR spectroscopy.[3]

(1)

(2)

Meerwein-Ponndorf-Verley Reduction.

One use of the reagent is for the reduction of carbonyl compounds, particularly of unsaturated aldehydes and ketones, for the reagent attacks only carbonyl compounds. An example is the reduction of crotonaldehyde to crotyl alcohol (eq 1).[1] A mixture of 27 g of cleaned ***Aluminum*** foil, 300 mL of isopropanol, and 0.5 g of ***Mercury(II) Chloride*** is heated to boiling, 2 mL of carbon tetrachloride is added as catalyst, and heating is continued. The mixture turns gray, and vigorous evolution of hydrogen begins. Refluxing is continued until gas evolution has largely subsided (6-12 h). The solution, which is black from the presence of suspended solid, can be concentrated and the aluminum isopropoxide distilled in vacuum (colorless liquid) or used as such. Thus the undistilled solution prepared as described from 1.74 mol of aluminum and 500 mL of isopropanol is treated with 3 mol of crotonaldehyde and 1 L of isopropanol. On reflux at a bath temperature of 110 °C, acetone slowly distills at 60-70 °C. After 8-9 h, when the distillate no longer gives a test for acetone, most of the remaining isopropanol is distilled at reduced pressure and the residue is cooled and hydrolyzed with 6 N sulfuric acid to liberate crotyl alcohol from its aluminum derivative.

(1)

The Meerwein-Ponndorf-Verley reduction of the ketone (**3**) involves formation of a cyclic coordination complex (**4**) which, by hydrogen transfer, affords the mixed alkoxide (**5**), hydrolyzed to the alcohol (**6**) (eq 2).[4] Further reflection suggests that under forcing conditions it might be possible to effect repetition of the hydrogen transfer and produce the hydrocarbon (**7**). Trial indeed shows that reduction of diaryl ketones can be effected efficiently by heating with excess reagent at 250 °C (eq 3).[5]

A study[6] of this reduction of mono- and bicyclic ketones shows that, contrary to commonly held views, the reduction proceeds at a relatively high rate. The reduction of cyclohexanone and of 2-methylcyclohexanone is immeasurably rapid. Even menthone is reduced almost completely in 2 h. The stereochemistry of the reduction of 3-isothujone (**8**) and of 3-thujone (**11**) has been examined (eqs 4 and 5). The ketone (**8**) produces a preponderance of the *cis*-alcohol (**9**). The stereoselectivity is less pronounced in the case of 3-thujone (**11**), although again the *cis*-alcohol (**12**) predominates. The preponderance of the *cis*-alcohols can be increased by decreasing the concentration of ketone and alkoxide.

This reducing agent is the reagent of choice for reduction of enones of type (**14**) to the α,β-unsaturated alcohols (**15**) (eq 6). Usual reducing agents favor 1,4-reduction to the saturated alcohol.[7]

(14)
BPC = biphenylcarbonyl

(15)
20%, each isomer

The Meerwein-Ponndorf-Verley reduction of pyrimidin-2(1*H*)-ones using ***Zirconium Tetraisopropoxide*** or aluminum isopropoxide leads to exclusive formation of the 3,4-dihydro isomer (eq 7).[8] The former reducing agent is found to be more effective.

Reductions with Chiral Aluminum Alkoxides.

The reduction of cyclohexyl methyl ketone with catalytic amounts of aluminum alkoxide and excess chiral alcohol gives (*S*)-1-cyclohexylethanol in 22% ee (eq 8).[9]

Isobornyloxyaluminum dichloride is a good reagent for reducing ketones to alcohols. The reduction is irreversible and subject to marked steric approach control (eq 9).[10]

Diastereoselective Reductions of Chiral Acetals.

Recently, it has been reported that ***Pentafluorophenol*** is an effective accelerator for Meerwein-Ponndorf-Verley reduction.[11] Reduction of 4-*t*-butylcyclohexanone with aluminum isopropoxide (3 equiv) in dichloromethane, for example, is very slow at 0 °C (<5% yield for 5 h), but in the presence of pentafluorophenol (1 equiv), the reduction is cleanly completed within 4 h at 0 °C (eq 10). The question of why this reagent retains sufficient nucleophilicity is still open. It is possible that the *o*-halo substituents of the phenoxide ligand may coordinate with the aluminum atom, thus

increasing the nucleophilicity of the reagent.

(10)

Chiral acetals derived from (-)-***(2R,4R)-2,4-Pentanediol*** and ketone are reductively cleaved with high diastereoselectivity by a 1:2 mixture of diethylaluminum fluoride and pentafluorophenol.[11] Furthermore, aluminum pentafluorophenoxide is a very powerful Lewis acid catalyst for the present reaction.[12] The reductive cleavage in the presence of 5 mol % of $Al(OC_6F_5)_3$ affords stereoselectively retentive reduced β-alkoxy ketones. The reaction is an intramolecular Meerwein-Ponndorf-Verley reductive and Oppenauer oxidative reaction on an acetal template (eq 11).

(11)

The direct formation of α,β-alkoxy ketones is quite useful. Removal of the chiral auxiliary, followed by base-catalyzed β-elimination of the resulting β-alkoxy ketone, easily gives an optically pure alcohol in good yield. Several examples of the reaction are summarized in Table 1.

Table 1 Reductive Cleavages of Acetals Using $Al(OC_6F_5)_3$ Catalyst

R^1	R^2	Yield (%)	Ratio (*S*:*R*)
C_5H_{11}	Me	83	82:18
i-Bu	Me	61	73:27
i-Pr	Me	90	94:6
Ph	Me	71	>99:1
Ph	Et	78	92:8
c-Hex	Me	89	95:5
		67	81:19 (*trans*:*cis*)

Although the detailed mechanism is not yet clear, it is assumed that an energetically stable tight ion-paired intermediate is generated by stereoselective coordination of $Al(OC_6F_5)_3$ to one of the oxygens of the acetal; the hydrogen atom of the alkoxide is then transferred as a hydride from the retentive direction to this departing oxygen, which leads to the (*S*) configuration at the resulting ether carbon, as described (eq 12).

Oppenauer Oxidation.[13]

Cholestenone is prepared by oxidation of cholesterol in toluene solution with aluminum isopropoxide as catalyst and cyclohexanone as hydrogen acceptor (eq 13).[14]

A formate, unlike an acetate, is easily oxidized and gives the same product as the free alcohol.[15] For oxidation of (**16**) to (**17**) the combination of cyclohexanone and aluminum isopropoxide and a hydrocarbon solvent is used: xylene (bp

140 °C at 760 mmHg) or toluene (bp 111 °C at 760 mmHg) (eq 14).

(14)

Hydrolysis of Oximes.[16]

Oximes can be converted into parent carbonyl compounds by aluminum isopropoxide followed by acid hydrolysis (2N HCl) (eq 15). Yields are generally high in the case of ketones, but are lower for regeneration of aldehydes.

(15)

Rearrangement of Epoxides to Allylic Alcohols.

The key step in the synthesis of the sesquiterpene lactone saussurea lactone (**21**) involved fragmentation of the epoxymesylate (**18**), obtained from α-santonin by several steps (eq 16).[17] When treated with aluminum isopropoxide in boiling toluene (N_2, 72 h), (**18**) is converted mainly into (**20**). The minor product (**19**) is the only product when the fragmentation is quenched after 12 h. Other bases such as potassium *t*-butoxide, LDA, and lithium diethylamide cannot be used. Aluminum isopropoxide is effective probably because aluminum has a marked affinity for oxygen and effects cleavage of the epoxide ring. Meerwein-Ponndorf-Verley reduction is probably involved in one step.

(16)

α-Pinene oxide (**22**) rearranges to pinocarvenol (**23**) in the presence of 1 mol % of aluminum isopropoxide at 100-120 °C for 1 h.[18] The oxide (**22**) rearranges to pinanone (**24**) in the presence of 5 mol % of the alkoxide at 140-170 °C for 2 h. Aluminum isopropoxide has been used to rearrange (**23**) to (**24**) (200 °C, 3 h, 80% yield) (eq 17).[19]

Regio- and Chemoselective Ring Opening of Epoxides.

Functionalized epoxides are regioselectively opened using trimethylsilyl azide/aluminum isopropoxide, giving 2-trimethylsiloxy azides by attack on the less substituted carbon (eq 18).[20]

(18)

Preparation of Ethers.

Ethers ROR´ are prepared from aluminum alkoxides, $Al(OR)_3$, and alkyl halides, R´X. Thus EtCHMeOH is treated with Al, $HgBr_2$, and MeI in DMF to give EtCHMeOMe (eq 19).[21]

Aluminum Thiophenoxide[1]

$Al(SPh)_3$

[15821-77-9] · $C_{18}H_{15}AlS_3$ · Aluminum Thiophenoxide · (MW 354.49)

(used in preparation of phenylthioesters[2] and ketene bis(phenylthio) acetals[3])

Preparative Method: to a solution of 29 mL of 2.35 M ***Trimethylaluminum*** in hexane in 250 mL of deoxygenated xylene is added dropwise 20 mL of ***Thiophenol*** over a 5 min period. The solution is stirred at 25 °C for 10 min and heated at reflux for 48 h. The flask is transferred to a glove bag and the white solid is removed by filtration, washed with benzene, transferred to vials, and dried overnight in a vacuum desiccator.[2]

Handling, Storage, and Precautions: the reagent can be prepared as above and used directly as a suspension in xylene. Use in a fume hood.

Phenylthioesters.[2]

This reagent converts simple esters into phenylthioesters at 5 °C (4 h) or at 25 °C (1 h) in quantitative yields (eq 1).

(1)

$R = Me_2CH$, $R' = Me$; $R = Ph$, $R' = Et$;
$R = cyclohexyl$, $R' = Me$; $R = 3\text{-cyclohexenyl}$, $R' = Me$

The products from α,β-unsaturated esters are contaminated with 3-(phenylthio)thioesters, while using $B(SPh)_3$ in refluxing xylene gave complementary results. A keto group at the 3-position inhibits the reaction while such a group at the 4-position leads to production of the thioacetal of the thioester when 2.5 equiv of the reagent are used.

For preparation of other thioesters, see also dialkylaluminum thiolates such as ***Diethylaluminum Thiophenoxide***.

Ketene Bis(phenylthio) Acetals.[3]

Reaction of the title reagent with carboxylic acids or esters in refluxing benzene or xylene results in simple ketene bis(phenylthio) acetals. Yields are almost quantitative if the acid or ester is branched at the α- or β-position. When there is no branching at the α- or β-positions, an important byproduct is a tris(phenylthio) orthoacetate, a useful precursor of the ketene bis(phenylthio) acetal (eq 2).

(2)

Reaction of the reagent with α,β-unsaturated esters results in a 1,1,3-tris(phenylthio)-1-alkene in 70-85% yield (eq 3).

(*Z*)-β-Aminoacrolein

[25186-34-9] · C_3H_5NO · (*Z*)-β-Aminoacrolein · (MW 71.08)

(pyridine synthesis, Friedländer synthon, β-amino aldehyde)

Alternate Name: 3-amino-2-propenal.

Physical Data: yellow solid, mp 105-106 °C.

Solubility: sol alcohol and water.

Preparative Methods: the reagent is highly reactive towards self-condensation and is best when freshly prepared. One method of preparation involves the reaction of ***Ammonia*** with ***Propargyl Aldehyde*** (propynal) in the presence of ethanol in a sealed tube.[1] This method is somewhat erratic, propargaldehyde is not commercially available, and the stereochemistry of the resulting double bond is most likely *trans*. A modified route, proceeding through 1,1,3,3-tetraethoxypropane, has also been reported.[2] The most satisfactory preparation of β-aminoacrolein involves the partial hydrogenation of isoxazole.[3,4] A solution of commercially available isoxazole (5 g, 0.073 mol) in anhyd MeOH (100 mL) containing 1.0 g of ***Raney Nickel*** was hydrogenated at 40 psi until one equivalent of hydrogen had been absorbed and hydrogen uptake had ceased (eq 1). The mixture was filtered to remove the catalyst and the solvent was evaporated to give 4.2 g (82%) of a yellow solid, mp 96-97 °C. Recrystallization from chloroform-petroleum ether (1:1) gave crystals, mp 104-105 °C.

Handling, Storage, and Precautions: the reagent should be used immediately although it can be stored under inert atmosphere at 0 °C in the dark for several days. Analysis by NMR (D_2O) shows three equal area peaks at δ 5.41 (dd), 7.50 (d), and 8.70 (d). Repurification can be effected by sublimination if necessary. Use in a fume hood.

Pyridine Synthesis.

In a series of three papers, Breitmaier and Bayer demonstrated that the reagent was effective in the preparation of 2,3-substituted pyridines.[5] For example, the Friedländer condensation of β-aminoacrolein with cyclohexanone leads to 5,6,7,8-tetrahydroquinoline in moderate yield (eq 2). The reaction works well for other cyclic ketones but unfortunately fails with cyclobutanone.

This same approach has been extrapolated to the preparation of 3,3´-polymethylene bridged derivatives of 2,2´-bipyridine, albeit in relatively low yields (eq 3).[6]

The reaction may be employed with appropriate diketones to create two pyridine rings simultaneously and represents a direct route to doubly bridged derivatives of 2,2´;6,2´´-terpyridine (eq 4). As expected, the yields are even lower and other routes to these same compounds have been developed.[7]

2-Aminobenzaldehyde[1]

[529-23-7] · C_7H_7NO · 2-Aminobenzaldehyde · (MW 121)

(Friedländer synthon; quinoline synthesis; *o*-amino aldehyde)

Alternate Names: 2-formylaniline; 1-amino-2-formylbenzene.

Physical Data: mp 38-39 °C.

Solubility: sol ether, alcohol.

Preparative Methods: the reagent is best when freshly prepared. At one time it was commercially available but samples more than a few months old were found to be essentially useless due to oligomerization. The propensity of the reagent to self-react and the resulting oligomer structures have been extensively discussed.[1a] A useful preparative method involves ***Iron(II) Sulfate*** reduction of 2-nitrobenzaldehyde.[2] The key to success is limiting the reaction time to 8-10 min and immediate, rapid steam distillation of the reaction product. The precursor is commercially available from a variety of sources and its preparation has also been reported.[3] A supposedly simplified procedure has been suggested but it does not differ significantly from the earlier method.[4]

Purification: can be effected by steam distillation from saturated NaCl solution.

Handling, Storage, and Precautions: the reagent can be stored for periods of up to several months under an inert atmosphere at 0 °C in the dark. The mp is a good general indicator of purity and the NMR spectrum should show an aldehyde proton integrating 1:4 against the aromatic protons. Use in a fume hood.

Quinoline Synthesis.

The reagent is most useful for the preparation of quinolines via the Friedländer condensation where 2-aminobenzaldehyde (2-AB) is the prototype *o*-amino aldehyde reaction partner. The reaction with acetaldehyde to form quinoline was first reported in 1882[5] and involves two dehydration steps, the sequence of which is not well established although initial formation of an imine intermediate appears more likely (eq 1).

The reaction is normally not suitable for the formation of quinolines unsubstituted on the pyridine ring and aldehyde partners are generally unsatisfactory under base-catalyzed conditions. Ketones react more smoothly and even cyclobutanone gives an acceptable yield 2,3-cyclobutaquinoline (eq 2).[6] A review on the Friedländer synthesis which appeared in 1982 gives an extensive compilation of this reaction involving 2-AB as well as other *o*-amino aldehydes.[1b]

The regiochemistry of condensations with unsymmetrical ketones is often pH dependent. In the base-catalyzed reaction of 2-AB with ethyl 3-oxopyrrolidine-1-carboxylate, two products were formed with the dominant one resulting from the more stable enolate or iminate intermediate (eq 3).[7] The same reaction carried out in acetic acid containing sulfuric acid gives a nearly equal mixture of the two regiochemistries.

Activation of the carbonyl component considerably facilitates the reaction and only one regioisomer is observed when 2-AB condenses with acetylacetone (eq 4).[8]

Appropriate β-diketones will condense in a 2:1 fashion to create two quinolines in a single step. Thus 1,2-cyclohexanedione gives a bridged 2,2´-biquinoline (eq 5).[9] In a similar fashion, 1,1´-diacetylferrocene provides a ferrocene substituted with quinoline on each Cp ring.[10]

Friedländer condensations are not limited to simple keto groups. In the reaction of 2-AB with naphthalene-1,3-diol the latter may be considered as a bis-enol (eq 6). Under basic conditions the first step involves condensation between the aldehyde group and the enolate at C-4.[11]

A modification developed by Borsche overcomes some of the difficulties associated with the instability of 2-AB. By employing an arylimine derivative of 2-AB in its place, smooth condensations occur in alkaline ethanolic solution or in the presence of ***Piperidine*** to provide quinolines in yields of 60-90% (eq 7).[12]

1-Aminobenzotriazole

[1614-12-6] · $C_6H_6N_4$ · 1-Aminobenzotriazole · (MW 134.06)

(an important precursor of benzyne, by oxidation with lead tetraacetate;[1] this method of benzyne generation is especially useful for biphenylene formation and other [2 + 2],[1c] [3 + 2],[19] and [4 + 2][22] cycloadditions)

Alternate Name: 1*H*-benzotriazol-1-amine.

Physical Data: colorless to tan solid, mp 83-84 °C;[1c] ^{1}H NMR;[1c] ^{15}N NMR.[2]

Solubility: sol benzene, CH_2Cl_2, $CHCl_3$.

Form Supplied in: commercially available.

Preparative Methods: by amination of benzotriazole with ***Hydroxylamine-O-sulfonic Acid***, or from *o*-nitroaniline by a multistep route.[1c]

Handling, Storage, and Precautions: toxicity and carcinogenicity not known; reacts rapidly with various oxidizing agents to generate benzyne.

Formation of Benzyne.

Campbell and Rees discovered that benzyne is efficiently generated by the ***Lead(IV) Acetate*** (LTA) oxidation of the title compound (**1**), as shown by high yield [4 + 2] trapping with ***Tetraphenylcyclopentadienone*** (**2**) (eq 1).[1] Benzyne is not only formed and trapped efficiently when (**1**) is added to LTA, but also when the order of addition is reversed; the latter is somewhat surprising, since excess (**1**) can function as a nucleophile to destroy benzyne, as observed when oxidation of (**1**) is effected with ***(Diacetoxyiodo)benzene***.[3] A recent modification[4] of the Campbell-Rees method, simultaneous addition of LTA and (**1**) to opposite ports of a stirred flask, has led to improvement in some applications, e.g. [4 + 2] reactions with oxazoles,[4] vinyl isocyanates,[5] and 1,2,4-triazines.[6]

The major advantages of the (**1**) + LTA method, compared with other procedures for generating benzyne, are: (a) the reaction is rapid over a wide temperature range, from at least -70 to +55 °C;[1c] (b) the reagents are compatible with base-sensitive materials and most functional groups; and (c) although all of the aminobenzotriazole substrates must be prepared, the method has considerable demonstrated generality (see below). Disadvantages (side reactions) stem from the powerful oxidizing ability of LTA, and the formation of HOAc in the reaction.

Preparative Methods.

Campbell and Rees also developed two preparative routes to (**1**).[1c] These remain the methods of choice for (**1**), as well as for analogs. The simpler procedure involves amination of benzotriazole with NH_2OSO_3H, which gives a mixture of (**1**) and 2-aminobenzotriazole (**3**) (eq 2).[1c] Compounds (**1**) and (**3**) can be separated by chromatography, although this may not be important in many applications. The reaction of (**3**) with LTA affords *cis,cis*-muconodinitrile, which reportedly does not interfere with the benzyne formed from (**1**).[1c]

The second preparative method for (**1**) is based on an earlier literature report, improved by Campbell and Rees.[1] Diazotization of *o*-nitroaniline followed by treatment with diethyl malonate gives the derivative (**4**); reduction of the nitro group and cyclization via diazotization affords (**5**), which is then hydrolyzed to (**1**) (eq 3).

Analogs of (1).

The known substituted derivatives, benzologs, and heteroaromatic analogs of (**1**) that have been used to generate arynes are displayed as structures (**6**)-(**22**),[1c,5,7-14] along with the related nonoxidative precursor of benzyne (**23**),[15] and the aminotriazene precursor of cycloheptyne (**24**).[16]

(23)[15]

(24)[16]

[2 + 2] Reactions.

One of the most striking and unusual features of the LTA oxidation of (**1**) is the high yield of *o*-biphenylene (**25**) that is formed when the reaction is carried out in the absence of an efficient aryne-trapping agent (eq 4).[1c] The high yield of (**25**) requires that the benzyne concentration exceed [10^{-7}], even if the [2 + 2] reaction occurs at the diffusion-controlled limit. In order to attain such concentrations, a combination of rapid formation and relatively slow side-reaction loss of the aryne is needed.

(4)

(25)

Analogous [2 + 2] homodimerizations have been observed for the arynes generated from (**6**),[1c] (**7**),[1c] (**8**),[7] (**10**),[8] (**13a**) (but not polymer-bound **13b**),[10] (**14**),[11a] (**15**),[11a] and (**23**)[15] (which decomposes thermally to form benzyne). Specific attempts to form [2 + 2] homodimers of arynes derived from (**9**),[8] (**16**),[11b] (**17**)-(**20**),[12b] and (**22**)[14] all failed; cycloheptyne does not react rapidly with itself, and no [2 + 2] homodimer is seen in reactions of (**24**) with LTA.[16]

Crossed aryne [2 + 2] reactions have been observed in LTA oxidations of mixtures of (**1**) + (**8**),[7] (**1**) + (**10**),[8] (**1**) + (**14**),[11a] (**1**) + (**15**),[11a] and, interestingly since no homodimer is formed from (**16**), (**1**) + (**16**)[11b] and (**14**) + (**16**)[11b] (shown in eq 5), but not (**15**) + (**16**).[11b] Angular benzannulation is thought to diminish the lifetime of arynes, making the last reaction especially unfavorable.[11b]

The Campbell-Rees procedure, as well as the anthranilic acid/alkyl nitrite method for generating benzyne, failed to give [2 + 2] product with 1,1-dichloro-2-methylpropene.[17] The bis-aryne precursor (**22**) also failed to give [2 + 2] products with vinyl acetate, or 1,1-dimethoxyethylene.[14] The latter alkene may be too rapidly oxidized by LTA. The homodimerization of benzyne is more rapid than [2 + 2] reactions of (*E*)- and (*Z*)-dichloroethene and vinyl acetate, under the original Campbell-Rees procedure.[18] The modified procedure[4] may lead to improvement.

[3 + 2] Cycloadditions.

The (**1**) + LTA method for generating benzyne is suitable for cycloadditions with mesionic compounds such as 3-phenylsydnone (**26**), which forms indazole (**27**) by extrusion of CO_2 from the initially formed adduct (eq 6).[19] Some related sulfur-containing mesionic species afford isolable adducts that undergo quite different extrusion processes under thermal or photochemical conditions.

(26) (27)

Benzyne from (**1**) + LTA also reacts with CS_2 to give the dithiacarbene intermediate (**28**) (eq 7).[20] The further reactions of (**28**) depend on the reaction conditions.

(28)

[4 + 2] Cycloadditions.

Diels-Alder reactions are often (but not always, cf. thiophene[21]) more successful with the Campbell-Rees than with other benzyne-forming approaches. Further improvements are possible for many [4 + 2] reactions by use of the modified method mentioned earlier,[4] and by carrying out the reactions at lower temperatures.[4b] The inverse temperature/yield relationship of Diels-Alder reactions of cycloheptyne nicely illustrates this point.[16]

A wide range of diene partners has been used for cycloaddition with benzyne derived from (**1**). Oxazoles, depending upon substituents and temperature, can give isolable cycloadducts (e.g. **29**), which can in turn be converted to the analogous isobenzofuran (eq 8).[4] Vinyl isocyanates afford lactams (eq 9).[5,22] Isoquinolines are formed in the reaction with 1,2,4-triazines (eq 10).[6] Compound (**1**) has also been used with metallocyclodienes such as substituted sila-[23] and germacyclopentadienes,[24] and digermacyclohexadienes.[25] The adducts have been used to generate reactive intermediates such as dimethylsilylene (eq 11).[23] Another notable example is the Diels-Alder reaction of azulene; interestingly, simultaneous addition of (**1**) and LTA was used in this study, but no comparison with the original Campbell-Rees conditions was noted. The cycloaddition takes place at the cyclopentadiene site as shown (eq 12).[26]

(8)

(9)

(10)

(12)

The very efficient reaction of benzyne with tetracyclone (**2**; see eq 1) has made it the diene of choice for demonstrating the formation of an aryne, and in some instances this reaction may be the *only* evidence for aryne formation; for example, 2,3-pyridyne from (**17**) was trapped by (**2**) in only 4% yield.[12] Less efficient dienes include furan and anthracene; triptycene was isolated in only 12% yield by Campbell and Rees,[18] but this reaction may have been partly limited by the solubility of anthracene. Limited solubility of the interesting bis-aryne precursor (**22**) also caused difficulties in some of its reactions.[14]

Other oxidizing agents were examined by Campbell and Rees, but none were found to be as good as $Pb(OAc)_4$ for useful aryne applications.[27] ***N-Bromosuccinimide*** apparently generates benzyne efficiently, but the reactive intermediate is largely trapped by rapid reaction with bromine. If a particular application requires the absence of acid, the (hazardous) benzyne precursor (**23**) can be used.

A possible alternative and related benzyne precursor, demonstrated only by reaction with (**2**), in 25% yield, is the nitrosobenzotriazole (**30**) (eq 13).[28]

(*S*)-1-Amino-2-hydroxymethylindoline

[27719-98-8] · $C_9H_{12}N_2O$ · (*S*)-1-Amino-2-hydroxymethylindoline · (MW 164.208)

(stereospecific synthesis of α-substituted α-amino acids from α-keto acids[1])

Physical Data: mp 81.5-82.7 °C (racemate).

Solubility: readily sol methanol, ethanol; insol hexane, ether.

Preparative Methods: 2-hydroxymethylindoline is resolved with (*S*)-(+)-***Mandelic Acid*** to give (*S*)-(+)-2-hydroxymethylindoline, which is then nitrosated and reduced to produce (*S*)-(**1**) (eq 1).[1] (*R*)-(**1**) is also available by a similar procedure.

Purification: recrystallization from methanol/ether.

Handling, Storage, and Precautions: the reagent is very air sensitive. Store under nitrogen or argon at -20 °C. Use in a fume hood.

The enantiospecific synthesis of natural and unnatural α-amino acids has been reviewed.[2] Some of the most successful approaches involve the stereoselective hydrogenation of chiral dehydroamino acid derivatives. Many of these transformations are equivalent to the stereoselective reductive amination of α-keto acids (eq 2).[3] For example, catalytic reduction of the imines of α-keto acids with chiral α-methylbenzylamine gives α-substituted α-amino acids with 12-80% ee (eq 3).[4]

(2)

(3)

Compound (**1**) and its enantiomer provide a variation on the same theme of stereospecific reductive amination. In this case, reduction of a chiral cyclic hydrazone (derived from an α-keto acid and (**1**)) with ***Aluminum Amalgam*** in wet DME proceeds with high stereoselectivity. Reductive cleavage of the N-N bond and ester hydrolysis complete the procedure, which produces α-amino acids with high optical purity (eq 4).[1] The source of chirality is recovered by conversion of the resulting indoline-2-methanol back into (**1**).[1]

Related reagents that have been used successfully for these purposes include (**2**) and (**3**).[1,5] In general, (**3**) appears to generate product with higher enantiomeric purity than either (**1**) or (**2**).

(2)

(3)

Other chiral amine reagents that have been used to effect similar stereospecific reductive aminations include 1,2-diamines[6] and 1,2-amino alcohols (eq 5).[7,8]

Stereospecific reduction of chiral diketopiperazine derivatives from proline and α-keto acids also provide a versatile route to α-amino acids (eq 6).[9,10] The selectivity of the reduction is highly dependent on the nature of the R´ group on the nitrogen atom.

A related synthetic approach involves the biomimetic transamination of α-keto acids with chiral pyridoxamine analogs (eq 7)[11] or achiral pyridoxamine analogs in the presence of a chiral ligand.[12,13]

Related Reagents.

Aminoiminomethanesulfonic Acid

[1184-90-3] · $CH_4N_2O_3S$ · Aminoiminomethanesulfonic Acid · (MW 124.13)

(parent compound and its derivatives guanylate amines; some derivatives give triazoles with azide and aminoiminoethanenitriles with cyanide as nucleophile)

Alternate Name: formamidinesulfonic acid.

Physical Data: mp 131-131.5 °C when highly pure; around 125 °C with dec before purification.

Solubility: sol water; slightly sol methanol, ethanol; insol ether.

Preparative Methods: by the oxidation of thiourea or aminoiminomethanesulfinic acid (formamidinesulfinic acid) with ***Peracetic Acid***. Many substituted aminoiminomethanesulfonic acids can be prepared in the same way.[1,2] Others have utilized ***Hydrogen Peroxide*** with sodium molybdate as a catalyst to oxidize the corresponding thioureas to a variety of monosubstituted aminoiminomethanesulfonic acids; the substituents include phenyl, 2-methylphenyl, 4-fluorophenyl, *n*-propyl,[3] cyclohexylmethyl, *S*-α-methylbenzyl, cyclooctyl, and benzhydryl.[4]

Purification: recrystallize from glacial acetic acid.

Handling, Storage, and Precautions: stable for at least a few weeks at room temperature. After drying, it remains stable for at least 5 months if kept in a freezer. Thiourea and its metabolites (probably oxidized thiourea) are tumorigenic and cause lung edema. All direct contact with the compound should be avoided; for example, a dust mask should be worn. All residues should be destroyed with strong bleach solution. Many substituted thioureas and their metabolites are also biologically active. Use in a fume hood.

Synthesis of Guanidines from Amines.

Aminoiminomethanesulfonic acid (**1**) reacts with a variety of primary amines, including ***t-Butylamine***, to give 50 - 80% yields of the corresponding guanidines (eq 1). This reaction is more facile than guanidine syntheses starting with *S*-alkylisothioureas.[2] Reactions of primary and secondary amines with monosubstituted (phenylamino)- and (*n*-propylamino)iminomethanesulfonic acids also give good to excellent yields of the corresponding guanidines.

Treatment of (*n*-propylamino)iminomethanesulfonic acid with a hindered amine, *t*-butylamine, leads to a good yield of the corresponding triazine instead of the guanidine.[3]

Reaction of aminoiminomethanesulfonic acid with a variety of amino acids gives yields of guanidino acids ranging from 5 -80%. Reactions of some amino acids do not lead to an isolable product. Similar results are obtained with (phenylamino)iminomethanesulfonic acid and (phenylamino)(phenylimino)methanesulfonic acid.[1]

Other Nucleophilic Substitution Reactions.

Nucleophilic substitution of a variety of substituted aminoiminomethanesulfonic acids with cyanide leads to the corresponding aminoiminoethanenitriles in 30-87% yield. A number of substituted aminoiminomethanesulfonic acids react with ***Sodium Azide*** in acetic acid to give the corresponding 5-aminotetrazole. This reaction is subject to pronounced steric hindrance. ***Hydroxylamine*** and ***Cyanamide*** also give nucleophilic substitution of the sulfonic acid group.[5]

Agelasidine-A analogs were prepared in two steps by treatment of a chloroethyl sulfone with ***Ammonia*** followed by aminoiminomethanesulfonic acid (eq 2). Direct displacement of chloride using guanidine furnished the dienyl analog in comparable yield.[6]

Guanylation of 3*R*-methyl-L-arginine with aminoiminomethanesulfonic acid followed by protection with adamantyloxycarbonyl chloride produced the bis-Adoc protected arginine derivative, a key intermediate in the total synthesis of lavendomycin.[7] In contrast, both (3*R*)- and (3*S*)-hydroxy-L-arginine have been prepared by guanylation of the tridentate copper complexes of *threo*- and *erythro*-2-hydroxy-L-ornithine using *S*-methylisothiourea.[8] Aminoiminomethanesulfonic acid has been used in the synthesis of an α-hydroxy ester *C*-terminal homo-L-arginine tripeptide for evaluation as a thrombin inhibitor.[9] The synthesis of a partially modified retro-inverso T-cell epitope

analog required preparation of the malonylarginine intermediate (**2**) using aminoiminomethanesulfonic acid as the guanylating agent (eq 3).[10]

Mtr = 2,3,6-trimethyl-4-methoxybenzenesulfonyl

Conversion of 3,6-bis(*t*-butyldimethylsilyl)-*N*-(3-aminopropyl)normorphine to the corresponding guanidine analog has been accomplished in high yield using aminoiminomethanesulfonic acid. Interestingly, all attempts to convert the N atom of morphine directly to the analogous guanidine were unsuccessful.[11] Guanylation of the *N*-(4´-aminobutyl)cinnamanilide (**3**) with aminoiminomethanesulfonic acid followed by alkylation with prenyl bromide furnished caracasanamide (**4**) in high yield (eq 4).[12] Alternatively, (**4**) could be prepared by reaction of (**3**) with cyanamide (**5**)[12] or from guanylation using the bis-Boc *S*-methylisothiourea (**6**) followed by cleavage with TFA.[13]

(*S*)-1-Amino-2-methoxymethylpyrrolidine[1]

[59983-39-0] · $C_6H_{14}N_2O$ · (*S*)-1-Amino-2-methoxymethylpyrrolidine · (MW 130.19)

(chiral auxiliary; Enders' reagent; diastereo- and/or enantioselective alkylations,[2,3] aldol reactions,[4] Michael additions[5] and reductive or alkylative aminations,[6] resolutions,[7] ee determinations[8])

Alternate Name: SAMP.

Physical Data: bp 186-187 °C; *d* 0.977 g cm^{-3}; *n*20D 1.4650; α20D -80 to -82° (neat).

Solubility: sol H_2O, ether, dichloromethane.

Form Supplied in: colorless liquid or as crystalline colorless oxalate.

Handling, Storage, and Precautions: storage at 0-4 °C under argon atmosphere.

Since the pioneering times of the mid-1970s, (*S*)-1-amino-2-methoxymethylpyrrolidine (SAMP) and its enantiomer RAMP have been among the most powerful chiral auxiliaries in asymmetric synthesis, with a very broad range of applications. As a proline derivative it generally shows high stereoselectivities due to the rigidity of the five-membered ring and the ability to coordinate metal fragments[9] (see also ***(S)-2-Methoxymethylpyrrolidine***, SMP).

The procedure involves the transformation of carbonyl compounds to the corresponding SAMP or RAMP hydrazones, metalation, trapping of the intermediate azaenolates with various electrophiles, and either hydrazone cleavage (carbonyl compounds) or hydrazone reduction/N-N bond cleavage (amines).

The synthetic utility of the SAMP/RAMP hydrazone method is demonstrated in particular in the stereoselective alkylation of aldehyde[2] and ketone[3] SAMP/RAMP hydrazones. A great number of natural products have been synthesized using this method, like the principal alarm pheromone of the leaf cutting ant *Atta texana* (eq 1),[3a] the C(1)-C(15) segment of FK 506 (eq 2),[2b] the amino acid MeBMT (eq 3),[2c] and (-)-methyl kolavenate (eq 4).[3b]

(4)

2,2-Dimethyl-1,3-dioxan-5-one SAMP/RAMP hydrazones[3f-j] were used as dihydroxyacetonephosphate equivalents in the synthesis of C_2 symmetric ketones (eq 5),[3g] aza sugars with novel substitution patterns,[3h] or C_5 to C_9 deoxy sugars.[3i] SAMP hydrazones of 2-oxo esters represent novel phosphoenolpyruvate (PEP) equivalents.[3k,l] α,α-Disubstituted spiroacetals are accessible via the alkylation of ketone SAMP/RAMP hydrazones.[3m]

(5)

The aggregation pheromone of *Drosophila mulleri*, (*S*)-2-tridecanol acetate, is obtainable by alkylation of propiophenone SAMP hydrazone followed by a Baeyer-Villiger reaction of the ketone (eq 6).[3n]

(6)

The relative and absolute configuration of Stigmatellin A, one of the most potent inhibitors of the electron transport chain, was determined via alkylation of diethyl ketone SAMP hydrazone.[3o]

The aldol reaction is the preferred method for the stereoselective synthesis of 1,3-dioxygenated building blocks. In 1978, Enders et al.[4a,b] reported the first enantioselective aldol reaction in the difficult case of α-unsubstituted β-ketols using SAMP and RAMP. Diastereo- and enantiomerically pure *syn*-β-ketols are available by aldol reaction of SAMP/RAMP hydrazones (eq 7).[4c]

The aggregation pheromone of the rice and maize weevil was synthesized by aldol reaction of an enantiomerically pure α-silyl ketone, obtained by the SAMP/RAMP hydrazone method,[10a-d] with various aldehydes (eq 8).[4d]

The utility of the SAMP/RAMP hydrazone method in dia-stereo- and enantioselective Michael additions was demonstrated in the synthesis of 5-oxo esters[5a-e] (eq 9),[5b] δ-lactones (eq 10),[5c,e,f] oxo diesters and dinitriles,[5g] heterocyclic compounds (eq 11),[5h] MIRC (Michael initiated ring closure) reactions,[5i] and 2-substituted 4-oxo sulfones.[5i]

(9)

R= alkyl, aryl

(10)

Organotin reagents can be added to cyclic α,β-unsaturated SAMP/RAMP hydrazones (eq 12).[5k]

Lithiated N-protected SAMP can be used as an ammonia equivalent in Michael and tandem Michael additions to α,β-unsaturated esters (eq 13).[5l] Furthermore, SAMP and RAMP can be employed for the asymmetric synthesis of α- and/or β-substituted primary amines with high regio-, diastereo-, and enantioselectivities.[6] This variant involves hydrazone reduction with a subsequent N-N bond cleavage and can be combined with a prior α-alkylation, as described above.

This method was recently used in the synthesis of different natural products, like the ladybug defence alkaloid harmonine,[6d] α- and β-amino acetals and acids (eq 14),[6e,f] and both enantiomers of the hemlock alkaloid coniine,[6g] utilizing the nucleophilic 1,2-addition of organolithium and -lanthanoid reagents to SAMP/RAMP hydrazones.

The alkylation of SAMP/RAMP hydrazones with heteroelectrophiles leads to enantiomerically pure α-silyl aldehydes and ketones (eq 15),[10a-d] α-sulfenyl aldehydes and ketones (eq 16),[10e] and α-hydroxy aldehydes and ketones (eq 17).[10f]

These very interesting chiral building blocks are employed in aldol reactions,[4d] and in the synthesis of enantiomerically pure vicinal diols (eq 18)[10g,h] and 3-oxo esters and acids bearing quarternary stereogenic centers (eq 19).[10i]

Further applications can be mentioned briefly. SAMP was used in the resolution of 4-demethoxy-7-deoxydaunomycinone,[7] in ee determinations (Scheme 1),[8] as a chelate for tetracarbonylmolybdenum complexes,[11] in intramolecular Heck reactions,[12] as polysilylated hydrazine,[13] in the enantioselective synthesis of isoquinuclidines,[14] and in the conversion of hydrazones to aldehydes[15] and nitriles.[16] The structure of a chiral lithium SAMP hydrazone azaenolate has been determined.[17] In cases where SAMP did not lead to satisfactory inductions, a modified auxiliary, (*S*)-1-amino-2-dimethylmethoxymethylpyrrolidine (SADP),[18] enhanced the stereochemical control.

2-Amino-3-methyl-1,1-diphenyl-1-butanol[1]

(*S*)

[78603-95-9] · $C_{17}H_{21}NO$ · 2-Amino-3-methyl-1,1-diphenyl-1-butanol · (MW 255.36) (.HCl)

[130432-39-2] (R)

[86695-06-9] (.HCl)

[56755-20-5]

(precursor to Itsuno's reagent, a chiral oxazaborolidine catalyst[1] used for the enantioselective reduction of prochiral ketones,[2] oxime *O*-ethers,[2c,d,3] and imines[4])

Alternate Name: 1,1-diphenylvalinol.

Physical Data: mp 94-95 °C; $[\alpha]_{589}$ -127.7° (*c* 0.693, $CHCl_3$) for the (*S*) enantiomer.

Solubility: very sol THF, CH_2Cl_2, MeOH; not very sol water.

Preparative Method: from valine methyl ester hydrochloride and excess ***Phenylmagnesium Bromide*** in 56% yield.[2]

Purification: recrystallization from ethanol-water (10:1).

Handling, Storage, and Precautions: no special information available. In general, however, it is advisable that all reactions with this reagent be conducted in a well ventilated fume hood. Care should be exercised to avoid contact of this reagent and the derived oxazaborolidine catalyst with the eyes and skin.

Stoichiometric Enantioselective Ketone Reduction.

The oxazaborolidine-borane complex (**3**) prepared in situ from diphenylvalinol (**1**) and ***Borane-Tetrahydrofuran*** (2 mol equiv) (eq 1) will enantioselectively reduce a variety of prochiral ketones (eq 2, Table 1).[2] Free oxazaborolidine (**2**) is

ineffective stoichiometrically as an enantioselective reducing agent. The asymmetric catalyst (**3**) works best for the reduction of aryl alkyl ketones, providing very high levels of enantioselectivity (94-100% ee). In the case of dialkyl ketones, the best enantioselectivity (78% ee) is obtained for the reduction of *t*-butyl methyl ketone. Reduction of acylsilanes affords the corresponding carbinols in moderate to high enantioselectivity (50-94% ee).[5]

(2)

Table 1 Stoichiometric Enantioselective Reduction of Prochiral Ketones

n-Pr	Me	55	*R*
i-Pr	Me	60	*R*
t-Bu	Me	78	*R*
Ph	CH_2Cl	96[d]	*S*

[a] Enantiomeric purity based on the optical rotation of the product vs. the maximum value reported. [b] Absolute configuration of the product obtained using the catalyst derived from (*S*)-diphenylvalinol (**1**). [c] Reaction using free oxazaborolidine (**2**). [d] Catalyst derived from (*S*)-diphenylleucinol.

Reduction of α-chloroacetophenone using the catalyst prepared from the related (*S*)-diphenylisoleucinol (**4**) and borane gives (*S*)-chlorohydrin (**5**), which is readily transformed to (*S*)-styrene oxide (eq 3).[3a] The reduction affords the (*S*) enantiomer of (**5**) due to chlorine having a higher priority in nomenclature, not a change in the enantiofacial selectivity of the asymmetric catalyst.

Catalytic Enantioselective Ketone Reduction.

Although free oxazaborolidine (**2**) is ineffective by itself as an enantioselective reducing agent, Corey demonstrated that it can be used catalytically (0.025-0.5 equiv) with excess borane (0.6 mol equiv) for the enantioselective reduction of acetophenone (eq 4).[6] A mechanism was proposed to explain the behavior of the catalyst. Initial coordination between the Lewis acidic ring boron and the ketonic oxygen activates the ketone towards reduction. Intramolecular hydride transfer from the BH_3 coordinated to the ring nitrogen then occurs via a six-membered ring cyclic transition state. In addition, oxazaborolidine (**6**) prepared from α,α-diphenyl-2-pyrrolidinemethanol (eq 5) was reported to be an even better catalyst for the reduction of ketones. For a more detailed discussion, see the entries for α,α-***Diphenyl-2-pyrrolidinemethanol*** and ***Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole***.

(5)

Recently, Katz employed oxazaborolidine (**2**) to catalyze the enantioselective reduction of ketone (**7**) (eq 6). The resultant carbinol was used for the synthesis of optically active helical metallocene oligimers.[7]

(6)

Enantioselective Reduction of Oxime *O*-Ethers.

In addition to the reduction of prochiral ketones, oxazaborolidine (**3**) has been used (both stoichiometrically and catalytically with borane-THF) to catalyze the enantioselective reduction of prochiral ketoxime *O*-ethers to the corresponding amine (eq 7).[2c-d,3] Unlike the ketone reduction described above, the (*S*)-oxazaborolidine catalyst gives (*S*)-amines. The best enantioselectivity is obtained for the case where R = Me (Table 2). Addition of a Lewis acid, such as ***Aluminum Chloride***, to the oxime increases the rate of reduction (complete reaction in 3 h vs. 24 h).

(7)

Table 2 Enantioselective Reduction of Prochiral Ketoxime *O*-Ethers

R_L	R_S	R	Enantiomeric purity[a] (%)	Absolute configuration[b] (%)
Ph	Me	H	0.6	*S*
Ph	Me	Me	99	*S*
Ph	Me	Et	81	*S*
Ph	Me	Bn	95	*S*
Ph	Me	Bn	90[c]	*S*
Ph	Me	Bn	94[d]	*S*
Ph	Me	Bn	89[d,e]	*S*
Ph	Me	TMS	62	*S*
Ph	Me	Ac	8.7	*R*

[a] Enantiomeric purity based on the optical rotation of the product vs. the maximum value reported. [b] Absolute configuration of the product obtained using a stoichiometric amount of the (*S*)-catalyst (**3**). [c] Reduction using 0.25 mol equiv of the catalyst with excess borane THF. [d] Reduction using the catalyst derived from (*S*)-diphenyl-*O*-benzyltyrosenol. [e] $AlCl_3$ added to the ketoxime *O*-ether prior to reduction.

Enantioselective Reduction of Imines.

Oxazaborolidine (**3**) also enantioselectively reduces *N*-substituted ketimines to the corresponding *N*-substituted amine in low to moderate ee (eq 8, Table 3).[4a] In this case the enantioselectivity is the same as the reduction of ketones; thus the (*S*)-oxazaborolidine catalyst gives (*R*)-amines. Oxazaborolidine (**3**) is reported to provide higher enantioselectivity than oxazaborolidine (**6**). An interesting application of this reaction is the preparation of a (a*RS*,*S*) diastereomerically enriched (63% de) sample of the more active atropisomers of the herbicide Metalochlor (eq 9).[4b]

2-Aminonicotinaldehyde[1]

[7521-41-7] · $C_6H_6N_2O$ · 2-Aminonicotinaldehyde · (MW 122)

(1,8-naphthyridine synthesis; Friedländer synthon; β-amino aldehyde)

Alternate Name: 2-amino-3-pyridinecarbaldehyde.

Physical Data: yellow solid, sublimes readily, mp 98-99 °C.

Solubility: ether, ethyl acetate: good; dichloromethane: poor.

Preparative Methods: the reagent is best when freshly prepared. A multistep procedure starting from 2-amino-3-picoline has been improved upon by a simple two-step approach. Sulfamation of nicotinamide with ammonium sulfamate (both commercially available) provides 2-(3´-pyridyl)pyrido[2,3-*d*]pyridimine which may be hydrolyzed in 2 N HCl to provide the reagent (eq 1).[1] Substituted derivatives of the reagent may be prepared via a similar intermediate.[2]

(1)

Handling, Storage, and Precautions: the reagent is somewhat more stable than ***2-Aminobenzaldehyde*** and may be stored for up to several months at 0 °C under an inert atmosphere. Sublimation is a convenient method for the separation of higher oligomers which may accumulate during storage. Use in a fume hood.

1,8-Naphthyridine Synthesis.

The Friedländer condensation of 2-aminonicotinaldehyde with various ketones provides a convenient one-step access to the 1,8-naphthyridine nucleus. Other naphthyridine isomers are available from related pyridine *o*-aminoaldehydes.[1b] The reaction is generally carried out by combining the reactants in ethanol, adding several mL of saturated methanolic KOH and refluxing for 1-4 h. Appropriate diketones will afford two sequential condensations. Reactions with the three isomeric cyclohexanediones are regiospecific and proceed in the direction predicted by the more active methylene position (eq 2).[3-5]

Related Reagents.

(Z)*-β-*Aminoacrolein; ***2-Aminobenzaldehyde***; ***1,3-Cyclohexanedione***; ***Quinoline***.

Ammonia[1]

NH_3

[7664-41-7] · H_3N · Ammonia · (MW 17.03)

(weak base;[2] essential nonaqueous solvent medium for dissolving metal reactions;[3] precursor of organic nitrogen compounds including amines,[4] unsubstituted amides,[5] heterocycles[1,6])

Physical Data: mp -78 °C; bp -33.3 °C/760 mmHg; *d* liq. NH_3 0.682 g cm^{-3} (-33.3 °C/760 mmHg).

Solubility: very sol water (47.8% w/w, 0 °C), methanol, ethanol; also sol chloroform, ether.

Form Supplied in: although gaseous at room temperature, anhydrous NH_3 is usually supplied as the liquified form in stainless steel cylinders which are sometimes fitted with an eductor tube to permit convenient and rapid extraction of liquid NH_3 when the cyclinder is inverted or tipped on its side. NH_3 is also readily available as aqueous solutions (ammonium hydroxide) in various concentrations. *Drying:* commercial anhydrous NH_3 can be used as supplied in many applications though in some cases drying is required to ensure optimum yield. Gaseous NH_3 can be dried by passing through a column of NaOH pellets, whereas liquid NH_3 can be dried using sodium metal (sufficient to obtain a persistent deep-blue coloration) or CaH_2 followed by distillation under nitrogen directly into the reaction vessel.

Handling, Storage, and Precautions: since NH_3 is highly corrosive, cylinders must be equipped with the appropriate stainless steel valves and fittings. As a consequence of its comparatively high enthalpy of vaporization (23.5 kJ mol^{-1}), reactions involving liquid ammonia can be carried out on laboratory scale without the need for external cooling since an insulating layer of ice quickly builds up around the outside of the reaction vessel.

NH_3 is highly toxic; inhalation of the vapor can cause edema of the respiratory tract, spasm of the glottis, and asphyxia. All reactions involving anhydrous ammonia must be conducted in a well-ventilated fume hood.

▪

As a consequence of the lone pair of electrons on the nitrogen, ammonia is both a weak base (K_b 1.8×10^{-5}) and a nucleophile, two properties which account for most of its reagent chemistry.[2] Ammonia reacts readily and reversibly with mineral and organic acids to form salts (eq 1) which, being stable solids, are often used as convenient sources of

ammonia. Since ammonia is an extremely weak acid (pK_a estimated to be ~38),[7] the amide anion is a very strong base.

$$:NH_3 + HX \rightleftharpoons NH_4^+X^- \qquad (1)$$

Ammonia in Dissolving Metal Reactions.

In addition to dissolving a wide range of organic compounds and inorganic salts, anhydrous liquid NH_3 can act as a solvent for the Group 1 and 2 metals, producing deep-blue colored solutions which conduct electricity and are strongly reducing. The physical and chemical properties of such solutions are usually attributed to solvated electrons.[3,8] In the presence of a catalyst such as anhydrous $Fe(NO_3)_3$, solutions of sodium and potassium in liquid NH_3 are conveniently converted into the amide salts ($M^+NH_2^-$), which are very strong bases.[9]

Solutions of Li, Na, and K metals in liquid NH_3, usually in the presence of a proton source like ethanol, have been extensively used for the partial reduction of a variety of benzene derivatives and polyfused aromatic compounds (the Birch reduction);[2] typically, benzene gives 1,4-cyclohexadiene (eq 2) whereas naphthalene is reduced to the tetrahydro derivative. *o*-Methoxybenzoic acid (also its salts and esters) can be converted to 2-alkylcyclohexenones (eq 3).[10] Similar reaction conditions have been utilized for the ring opening of cyclopropanes,[11] the transformation of conjugated enones to the saturated carbonyl compounds[12] or their 2-substituted derivatives,[13] the stereospecific reduction of disubstituted alkynes to (*E*)-alkenes,[14] the hydrodehalogenation of *gem*-dihalides,[15] and the reductive cleavage of polysulfides to thiols.[16]

(2)

(3)

Alkylation of Ammonia.

Direct reactions between ammonia and alkyl halides are complex and generally produce mixtures of the salts of the primary, secondary, and tertiary amines, and also quarternary salts (eqs 4-7). The final composition of the product mixture depends on the relative initial concentrations of the reactants, the nature of the reaction solvent, and the steric requirements of the alkyl groups. The reactions generally exhibit the characteristics of S_N2 type displacements (reaction rate with respect to the alkyl group: primary > secondary > tertiary) and the ease of halogen displacement follows the expected order I > Br > Cl > F.[4b] Reactions carried out in liquid ammonia tend to give mixtures of primary and secondary amines, whereas in methanolic ammonia more complex mixtures of the primary, secondary, and tertiary

amines are obtained.[17] Separation of the various amine products by distillation is usually easier for higher alkyl substituents, e.g. *n*-octyl.[18]

$$:NH_3 + RX \rightleftharpoons RNH_3^+X^- \quad (4)$$

$$R\ddot{N}H_2 + RX \rightleftharpoons R_2NH_2^+X^- \quad (5)$$

$$R_2\ddot{N}H + RX \rightleftharpoons R_3NH^+X^- \quad (6)$$

$$R_3\ddot{N} + RX \rightleftharpoons R_4N^+X^- \quad (7)$$

With dihaloalkanes, intramolecular cyclization will occur to form five- to seven-membered heterocyclic compounds as appropriate, though even in favorable cases, over reaction can occur (eq 8).[19] Tribromoalkanes have also been used to synthesize novel azabicyclic systems (eq 9),[20] and l-azaadamantane (eq 10).[21]

(8)

(9)

(10)

Amination of Aromatic and Heteroaromatic Compounds.

Although amination of simple aryl halides to yield anilines by *ipso* substitution of the halo group is more usually carried out using ***Potassium Amide*** in liquid NH_3, NH_3 itself can also be used but requires elevated temperatures and pressure, and a copper catalyst.[22] Thus, for example, aniline is obtained from chlorobenzene (200 °C, Cu cat.),[23] 3,4-dimethylaniline from 4-bromo-*o*-xylene (195 °C, Cu/CuCl),[24] and *p*-trifluoromethylaniline from *p*-chlorotrifluoromethylbenzene (200 °C, CuCl/KF).[25]

The amination reaction proceeds more smoothly if the benzene ring is activated by strongly electron-withdrawing groups, particularly NO_2, in the *o*- and *p*-positions. The ease of halide displacement follows the sequence F > Br > Cl > I.[22b] Nitro groups have also been displaced from 2,3-dinitrotoluene.[26]

Naphthol derivatives can be transformed to the corresponding amines by treatment with aqueous ammonia in the presence of sulfite or bisulfite ion at elevated temperatures (the Bucherer reaction) (eq 11);[27] the analogous transformation with phenols is known, but is less common.[28]

(11)

Heteroaromatic compounds, particularly pyridines and diazines, are more susceptible to amination with NH_3 than arenes. Although the amination reactions generally proceed under milder conditions, they may also be catalyzed by Cu salts. Typical examples include the Cu-catalyzed conversion of 3-bromopyridine to 3-aminopyridine, and 2-chloro-3-aminopyridine to 2,3-diaminopyridine,[29] the aminolysis of fluoro-[30] and chloropyrazines[31] on treatment with aqueous NH_3 at room temperature and 180 °C respectively, the displacement of the methoxy group in 4-methoxypyrimidone to give cytosine on treatment with methanolic ammonia at 100 °C (eq 12),[32] and the selective transformation of 2,6-dichloropurine to the corresponding 6-amino-2-chloro derivative under similar conditions (eq 13).[33] Treatment of solutions of 3-halo-2-alkylisothiazolium salts in acetonitrile with excess ammonia yields exclusively the *N*-monosubstituted 3-isothiazoles via a ring opening/recyclization process (eq 14).[34] Irradiation of solutions of 6-phenyl- and 6-*t*-butyl-4-halopyrimidines in liq NH_3 with UV light affords the corresponding 4-amino derivatives.[35]

(12)

(13)

(14)

Highly π-electron deficient nitroaza heterocycles (including pyridines, diazines, and their respective benzo compounds) react with ***Potassium Permanganate*** in liq NH_3 to give amino compounds via an S_NH mechanism involving the initial formation of a σ-adduct with NH_3 which is subsequently oxidized by the permanganate.[36] The reactions can be highly regioselective and give high product yields (>80%) (eq 15).[37] For less π-electron deficient compounds, the combination KNH_2/liq NH_3/$KMnO_4$ has been used.[38]

(15)

α-Amino Acids.

Ammonia reacts readily with α-halo carboxylic acids to yield the corresponding α-amino acids (eq 16). The reactions are conveniently carried out using a large excess of ammonia with either ammonium chloride[39] or formaldehyde[40] present to suppress further alkylation. The displacement normally proceeds with inversion of configuration[41] unless the adjacent β-position is substituted.[42]

(16)

Ring-Opening of Epoxides and Aziridines.

Epoxides, possessing a relatively high degree of ring strain, readily open on treatment with ammonia to give 1,2-amino alcohols, usually with a high degree of regio- and stereoselectivity.[43] Consistent with an S_N2 mechanism, nucleophilic attack by the ammonia occurs at the sterically least hindered carbon center of the epoxide, e.g. with propene,[44] butene,[45] and styrene[45,46] oxides (eq 17). The ring opening proceeds in a *trans* fashion with concomitant inversion of configuration, e.g. *trans*-2-butene oxides give *erythro*-amino alcohols, whereas the *cis* compounds afford the diastereoisomeric *threo*-amino alcohols (eq 18).[47] Aminolysis of cyclopentene[48] and cyclohexene[49] oxides produces the corresponding *trans*-amino alcohols; the cyclohexane derivative is also obtained from the reaction of *trans*-chlorohydrin with aqueous ammonia at room temperature.[48] Substitution at the 3-position directs the incoming ammonia to the more distal carbon center (eq 19).[50] With epoxides derived from six-membered ring compounds which have rigid geometries, the amino and hydroxy groups in the resulting product are normally *trans* diaxially related, an important consideration in the stereoselective syntheses of amino sugars.[43,51]

(17)

(18)

(19)

X = OMe, OPh

Ring opening of aziridines by anhydrous NH_3 in the presence of ammonium chloride proceeds smoothly at 100 °C to give 1,2-diamines.[52] The regio- and stereochemical preferences of this reaction have been shown to be similar to those

observed for epoxides.[47]

α-Amino Nitriles.

These key intermediates in the Strecker synthesis of amino acids (see below) can be prepared from the reaction of cyanohydrins with ammonia.[53] α-Amino nitriles (yields 80-95 %) can be conveniently prepared from α-silyloxy nitriles on treatment with ammonia in methanol (eq 20).[54]

(20)

Amidines.

Formamidine Acetate, a relatively nonhygroscopic salt, is conveniently obtained in high yield from the reaction of ***Triethyl Orthoformate*** with ammonia in acetic acid at 115 °C (eq 21). The corresponding acetamidine salt is prepared in a similar fashion using NH_4Cl in ammonia.[55]

(21)

Primary Amides.

Nucleophilic substitution by ammonia at the carbonyl carbon of a carboxylic acid or a related derivative provides a general synthetic route to unsubstituted or primary amides (eq 22).[5] The order of reactivity is carboxylic acids < esters < anhydrides < acyl chlorides.

(22)

$X = OH, OR, Cl, OCOR, OCO_2R$

Since direct reaction between a carboxylic acid and NH_3 requires vigorous reaction conditions (reaction temperatures 170-200 °C), excess NH_3, and continuous removal of the water formed, this method is only suitable for amides derived from thermally stable acids; at higher temperatures, nitrile formation competes. Nonetheless, the primary amides from

a series aliphatic carboxylic acids (C_2-C_{18}) have been prepared by this approach.[56,57] Under similar reaction conditions, cyclic imides (favorable for ring sizes 5 and 6) can be obtained from diacids and NH_3.[58]

Although esters react cleanly with ammonia to give the corresponding amides, the reported conditions to effect the transformation are still reasonably vigorous, e.g. excess conc aq NH_3/NH_4Cl at 100 °C,[59] or liq NH_3 at 165-180 °C.[60] Ethyl cyanoacetate affords cyanoacetamide on shaking with aqueous NH_3.[61] As an alternative method, esters are transformed to primary amides under mild conditions ($CH_2Cl_2/T < 40$ °C) using Me_2AlNH_2 (2 equiv), generated in situ from $AlMe_3$ and NH_3.[62]

The ammonolysis of acyl chlorides has been used extensively as a standard laboratory procedure for the preparation of primary amides, the reactions are rapid and exothermic and usually carried out in solvent.[5,60,63] To ensure completion of reaction, a minimum of a twofold excess of ammonia is required since it reacts with the HCl liberated. Instead of ammonia, ammonium acetate in acetone can be used with acyl chlorides.[64]

Carboxylic acid anhydrides readily undergo ammonolysis to give the corresponding primary amide.[5] With cyclic anhydrides, cyclic imides are formed, e.g. phthalic anhydride gives phthalimide.[58]

Treatment of mixed anhydrides, generated in situ from carboxylic acids and ***Ethyl Chloroformate***, with anhydrous ammonia provides primary amides under mild conditions;[5,65] product yields are claimed to be superior to those obtained using acyl chlorides.[66]

Reactions conditions for the ammonolyses of substituted esters and acyl chlorides can usually be adapted to be compatible with a range of functionality including unsaturation,[67] halo,[68,69] hydroxyl,[70] amino,[71] and acetal groups.[72] For example, α-halocarboximides can be obtained from the corresponding acid chlorides[68] or esters[69] with conc aq NH_3 by maintaining the reaction temperature below 0 °C.

Aromatic or allylic aldehydes can be converted into primary amides by reaction with NH_3 using either ***Nickel(II) Peroxide*** in dry Et_2O at -20 °C,[73] or ***Sodium Cyanide*** and ***Manganese Dioxide*** in isopropanol at 0 °C.[74] Amination of aliphatic and aryl aldehydes has also been accomplished using ***N-Bromosuccinimide*** with AIBN as an initiator in the presence of NH_3; radical substitution of the aldehydic hydrogen by Br generates an acyl bromide which reacts rapidly with the NH_3 present.[75]

Primary amides are obtained from the thermal,[76a] photochemical,[76b] or metal ion (e.g. Ag^+) catalyzed[77] rearrangement of α-diazo ketones in the presence of ammonia (Wolff rearrangement). In cases where the required diazo ketone can be generated in situ from an acyl chloride and ***Diazomethane***, the overall transformation is an homologation (the Arndt-Eistert synthesis) (eq 23).[77]

(23)

The Ugi Reaction.

Ammonia, usually in the form of an ammonium salt of a carboxylic acid, reacts with a mixture of isocyanides and aldehydes to give bis-amides in moderate yield (~50%) (the Ugi reaction) (eq 24).[78] The scope of the reaction is considerably more limited with ammonia than with amines.

Addition of Ammonia to Alkenes and Alkynes.

Since it is intrinsically nucleophilic, NH_3 does not form adducts readily with simple alkenes. Under high temperature (200 °C) and pressures (800-1000 atm), and in the presence of Na metal, ethylene, propene, isobutene, and cyclohexene react with NH_3 to give the corresponding amines in low yield (15-30%).[79] Similarly, 2-phenylethylamine is obtained from styrene in 8% yield.[80] NH_3 does, however, undergo nucleophilic addition to Pd^{II} and Pt^{II} complexes derived from 1,5-dienes; subsequent reduction of the adducts with ***Sodium Borohydride*** releases the amines, e.g. 2-aminohexane (93%) and cyclooctylamine (57%) are obtained from 1,5-hexadiene and 1,5-cycloocatdiene, respectively.[81]

Simple alkenes undergo aminosulfenylation on treatment in turn with ***Dimethyl(methylthio)sulfonium Tetrafluoroborate*** followed by ammonia (eq 25).[82]

Alkenes with electron withdrawing substituents (carbonyl, nitrile, alkoxycarbonyl) are susceptible to Michael addition to form, at least initially, the β-amino adducts. With systems unsubstituted at the β-position, multiple addition usually occurs affording the di- and triadducts even with a large excess of ammonia (eq 26). Thus, the diadduct is the major product from the addition of NH_3 to acrylonitrile at 30 °C even with a significant excess of NH_3. When the reaction is carried out with a large excess of NH_3 (>threefold) at 110 °C for short reaction times, the monoadduct is the major component of the reaction mixture.[83] Ethyl acrylate reacts readily with NH_3 to give the corresponding di- and triadducts which are separable by distillation.[84]

(26)

Substitution at the β-position of α,β-unsaturated systems inhibits multiple addition. Thus crotonic acid,[85] ethyl crotonate,[86] and mesityl oxide[87] all form the corresponding β-amino compounds. 1-Nitropropene and butene also form monoadducts with ammonia which tend to be unstable.[88] Sorbic acid undergoes double addition of NH_3 to give 3,5-diaminohexanoic acid.[89]

As with alkenes, reactions between simple alkynes and NH_3 generally take place under forcing reaction conditions, producing complex product mixtures containing 1,2-diamines, piperidines, etc.[90] Conjugated dialkynes react with NH_3 in the presence of CuCl catalyst to give pyrroles (eq 27).[91]

(27)

Addition of Ammonia to Heterocumulenes.

NH_3 adds across the carbon-carbon double bond of ketenes to give primary amides, usually in good yield (cf. the Wolff rearrangement mentioned above) (eq 28).[92]

(28)

With isocyanates and isothiocyanates, the addition of NH_3 takes place specifically across the carbon-nitrogen double bond, producing ureas[93] and thioureas, respectively (eq 29).[94]

(29)

Amidines.

Alkyl and aryl nitriles react with ammonia in the presence of ammonium salts to give amidine salts, usually in yields

of the order of 80% (eq 30).[95] The reaction between nitriles and $MeAl(Cl)NH_2$, generated in situ from $AlMe_3$ and NH_4Cl, provides an alternative general synthetic route to amidines.[96] Dinitriles of suitable chain length give cyclic imidines on treatment with NH_3 in methanol at 100 °C (eq 31).[97]

(30)

(31)

Addition of Ammonia to Carbonyl Compounds.

Nucleophilic addition of NH_3 to an aldehyde or ketone affords initially a hemiaminal which subsequently dehydrates to an imine (eq 32). Imines which are not readily isolable except those derived from perfluoroalkyl[98] or diaryl ketones[99] usually react further. Condensations of ammonia with (a) formaldehyde yield the polycyclic adduct hexamethylenetetramine (eq 33),[100] (b) *n*-alkanals and arylacetaldehydes form the trimeric hexahydrotriazines (eq 34),[101] and (c) aromatic aldehydes give hydrobenzaminidines (eq 35).[102]

(32)

(33)

(34)

(35)

Reductive Amination.

Catalytic hydrogenation (Ni, Pt, Rh) of mixtures of aldehydes or ketones (usually in ethanol) and NH_3 affords primary amines, presumably by hydrogenation of the intermediate imine (eq 36).[103] Aliphatic carbonyl compounds with at least five carbon atoms (lower molecular weight compounds are too reactive) or aromatic aldehydes are found to be most suitable. Since the primary amines formed initially are potential substrates for reaction, further alkylation may occur giving secondary and tertiary amines.

(36)

Treatment of aromatic aldehydes or aliphatic ketones, which are not soluble in water, with either NH_3/***Formic Acid*** or ***Ammonium Formate*** yields the corresponding primary amines (Leuckart reaction).[104]

Mannich Reaction.

The product mixtures from condensation reactions between ketones which possess at least one α-hydrogen atom, ***Formaldehyde***, and NH_3 are generally more complex than those obtained from the corresponding reactions in which the NH_3 is replaced by a secondary amine such as dimethylamine.[105] Thus acetophenone affords a mixture of the di- and triadducts rather than the expected β-amino ketone (Mannich base) (eq 37).[106] Mannich reactions involving dibenzyl ketones with formaldehyde and NH_3 in a relative molar ratio of 1:5:2 respectively give adamantane-like diaza ketones in good yields (eq 38).[107]

Strecker Synthesis of α-Amino Acids.

Aldehydes react with ***Hydrogen Cyanide*** in the presence of ammonia to yield an α-amino nitrile which on subsequent hydrolysis is converted to an α-amino acid (eq 39).[108] α-Substituted α-amino acids can be prepared from ketones.[109] α-Silyloxy nitriles offer an alternative route to the required intermediate amino nitriles (see eq 20).[54]

Willgerodt Reaction.

Heating mixtures of alkyl aryl ketones with ammonium polysulfide (or sulfur and dry NH_3) affords primary amides or the ammonium salts of the carboxylic acid (eq 40).[110] Side reactions become more pronounced as the chain length increases.

With acyclic and cyclic aliphatic ketones (2 equiv), sulfur, and NH_3, Δ^3-thiazoline derivatives can be obtained. In addition, treatment of methyl ketones, which can only be thiolated on the methyl group (e.g. acetophenone and pinacolone), with a large excess of sulfur (~eightfold) affords Δ^3-imidazoline-5-thiones.[111]

Nitriles.

Gas phase co-pyrolyses of (a) aliphatic mono- or dicarboxylic acids over silica gel at 500 °C[112] or (b) primary alcohols over a 15% Cu/alumina catalyst at 300 °C[113] with NH_3 afford mono- or dinitriles as appropriate in good yield.

Benzaldehydes are converted to the corresponding benzonitriles on treatment with NH_3 in the presence of either ***Iodine***[114] or ***Lead(IV) Acetate***.[115]

Miscellaneous Reactions Involving Ammonia.

Liq NH_3 is found to be a convenient medium and a mild base for the deprotection of FMOC-protected amino acids (eq 41).[116] Removal of N^{α}-benzyloxycarbonyl protecting groups for sulfur-containing peptides by Pd-catalyzed hydrogenolysis proceeds smoothly in liq NH_3 because poisoning of the catalyst is substantially diminished.[117]

α-Acetyl-β-keto esters are readily deacylated on treatment with gaseous NH_3 in dry Et_2O (eq 42).[118]

NH_3 is a participating solvent in ozonolysis reactions; ozonolyses of indene and indole in the presence of NH_3 afford isoquinoline and quinazoline, respectively.[119] Diamines are obtained in 50-60% yield from cyclic alkenes by a sequence involving ozonolysis in methanol and partial reduction of the resulting reaction mixture followed by catalytic hydrogenation over Rh or ***Raney Nickel*** at 200-400 psi/50 °C.[120]

The ***Borane-Ammonia*** complex, prepared in situ from NH_3 and diborane or available commercially, reduces carbonyl compounds rapidly; aldehydes are selectively reduced in the presence of aliphatic and aromatic acyclic ketones.[121] Moreover, the NH_3-BH_3 complex reacts faster than $NaBH_4$ with hindered ketones.

Ammonia in the Synthesis of Nitrogen-Containing Heterocycles.

Ammonia has been used extensively for the introduction of nitrogen atoms into heterocyclic ring systems. Space does not permit an adequate discussion of the various methods. For further details, see the general overview by Jeyaraman[1] and specialist monographs and reviews for systems such as pyridines,[6a,b] pyrroles,[6c,d] and diazines.[122]

Ammonium Formate

HCO_2NH_4

[540-69-2] · CH_5NO_2 · Ammonium Formate · (MW 63.06)

(used as a source of ammonia;[1] a hydrogen source for catalytic transfer hydrogenation reactions;[2,7-9,10-13,17,18] hydrogenolysis of functional groups[3-6,8,14,15,19,20])

Physical Data: mp 119-121 °C; *d* 1.27 g cm^{-3}.

Solubility: sol water, alcohols.

Form Supplied in: crystalline solid.

Analysis of Reagent Purity: base titration.

Handling, Storage, and Precautions: hygroscopic.

Source of Ammonia.

Ammonium formate can be used as a source of nonvolatile ammonia (eq 1),[1] but much of its use is as a hydrogen transfer agent in conjunction with heterogeneous or homogeneous catalysts.[2]

Hydrogenations.

Catalytic transfer hydrogenation of *N*-benzyl protecting groups using 10% ***Palladium on Carbon*** as the catalyst and ammonium formate as the hydrogen source generally gives primary and secondary amines in excellent yields.[3] In the case of 1-benzyl-2,3-dihydroindoles, the one-pot dehydrodebenzylation gave indoles as the major products along with minor amounts of *N*-benzylindoles (eq 2).[4]

Regioselective stepwise debenzylation of 1,3-dibenzyluracils was observed with this catalytic transfer hydrogenation system (eq 3). Functional groups such as esters, alcohols, nonbenzylic ketones or ethers, carboxylic acids, amides, acetals, and nitriles are stable under the reaction conditions.[5]

Interestingly, even *N*-((β-phenylethyl)oxy)carbonyl and 2-phenylethyl benzoates can be deblocked with ammonium formate in the presence of 10% Pd/C or ***Palladium(II) Acetate***.[6]

Aryl ketones are selectively reduced to the secondary alcohols or to the hydrocarbons by careful selection of the reaction temperature and solvent. The alcohol is formed in MeOH at rt[7] and the hydrogenolysis product is produced at 110 °C in acetic acid. Diaryl ketones also provided diarylmethanes under the latter reaction conditions.[8] ***Raney Nickel*** can also participate in the catalytic transfer hydrogenation reaction. The combination of Raney nickel and ammonium formate reduces aryl alkyl ketones to alcohols at rt in >90% yield.[9]

Nitro groups are readily reduced to amines. Alkyl nitro compounds are reduced to the amines with retention of configuration.[10] Certain appropriately substituted nitro compounds do not give amines under the reaction conditions. α,β-Unsaturated nitroalkenes gave oximes (eq 4),[11] γ-nitro ketones gave cyclic nitrones (eq 5),[12] and 2-nitro-β-nitrostyrenes gave indoles (eq 6).[13]

(4)

(5)

(6)

Azides and pyridine *N*-oxides are reduced to amines[14] and pyridines,[15] respectively, with this reaction system. Allyl β-keto carboxylates are decarboxylated to form ketones and propene.[16] Alk-2-ynyl carbonates are hydrogenolyzed to 1,2-dienes (allenes).[17]

Selective reduction of quinoline, isoquinoline, and acridine at the nitrogen containing ring has been reported.[18] Concomitant dehalogenation was also observed with chlorinated isoquin-olines.

Hydrogenolysis of allylic compounds such as esters, nitro compounds, halides, phenyl ethers, carbonates, and vinyl epoxides has provided alkenic products.[19] The reactions required the use of homogeneous Pd catalysts. Use of ***Tri-n-butylphosphine*** as ligand gave excellent selectivity to 1-alkenes. More 2-alkenes were formed (up to 66% in one case) when triarylphosphines or trialkyl phosphites were used.[20]

Ammonium Peroxydisulfate

$(NH_4)_2S_2O_8$

$(NH_4)_2S_2O_8$

[7727-54-0] · $H_8N_2O_8S_2$ · Ammonium Peroxydisulfate · (MW 228.20) $K_2S_2O_8$

[7727-21-1] · $K_2O_8S_2$ · Potassium Peroxydisulfate · (MW 270.32) $Na_2S_2O_8$

[7775-27-1] · $Na_2O_8S_2$ · Sodium Peroxydisulfate · (MW 238.11)

(oxidizing agent for many functional groups;[1] phenols form *p*-hydroxysulfate ester salts (Elbs oxidation), while arylamines give the *o*-aminosulfate esters (Boyland-Sims oxidation)[1m])

Physical Data: E° = -1.92, -1.94 V.[2]

Solubility: sol water, 20 °C: ammonium salt, 2.5 M; potassium salt, 0.17 M; sodium salt, 2.3 M; reasonable solubility in aqueous mixtures with acetonitrile, the lower alcohols, and acetone. Quaternary ammonium salts of peroxydisulfate show much greater solubility in organic solvents.[3]

Form Supplied in: the three salts are commercially available as colorless crystalline solids.

Analysis of Reagent Purity: the commercial materials are typically 98-99% pure and may be analyzed by standard iodometric techniques.

Handling, Storage, and Precautions: the sodium and potassium salts are very stable as dry solids, the ammonium salt less so.[4] Aqueous solutions undergo slow decomposition even at rt.[4] Cases of asthma and skin rashes have been reported among constant users such as hairdressers and industrial workers.

Introduction.

Peroxydisulfate ions are capable of oxidizing virtually all functional groups, even hydrocarbons.[5,6] Mechanistic studies have shown that there are two fundamentally different ways in which this species reacts. At low temperatures (25 °C) and in the absence of catalysts, its reactions are fast only with strong nucleophiles (phenolate ions, amines) and these proceed by simple polar mechanisms. Many other functional groups react so slowly under these conditions as to be essentially inert. At higher temperatures and/or in the presence of catalysts, rapid radical reactions ensue involving the species SO_4^-, the sulfate ion radical. Selectivity can usually be achieved even for this powerful oxidant by careful control of conditions. Peroxydisulfate may be used as a convenient source of peroxymonosulfate, via low-

temperature acid-catalyzed hydrolysis, for use in processes such as the Baeyer-Villiger reaction.[7] The use of the term persulfate should be avoided as it may be confused with peroxymonosulfate (Caro's acid; see ***Monoperoxysulfuric Acid***).

Oxidation of Hydrocarbons.

Conditions for the oxidation of toluene and substituted toluenes can be adjusted, principally by variation in the catalyst (Fe^{II}, Ag^{I}, Cu^{II}) to yield benzaldehyde,[8-11] benzyl acetate,[10,12-14] or benzyl bromide.[12] Benzoic acids and bibenzyls are also formed.[8] Regioselectivity in the oxidation of substituted xylenes has been achieved.[15] Hexamethylbenzene and durene, among others, are converted in 70-90% yield to the corresponding benzyl alcohols via the benzyl nitrates.[16] In the presence of acetates, substituted benzenes and naphthalene are acetoxylated,[17,18] and conditions have been found for conversion of naphthalene to either 1-acetoxynaphthalene or α-(hydroxymethyl)naphthalene acetate.[19] Benzene, fluorobenzene, and anisole may be hydroxylated.[20,21] Quinones are formed from anthracenes, naphthalene, and phenanthrene.[22,23] 9-Methylanthracene gives lepidopterene in good yield (eq 1).[24] Isopropylbenzene reacts with acetate in the presence of Fe^{II} (eq 2).[25]

(1)

(2)

Oxidation of Alkenes.

Glycol diacetates are produced when alkenes and acetates are treated with peroxydisulfate at 60-80 °C in the presence of Cu^{II} or Fe^{II}, sometimes with good stereocontrol.[26-28] Perfluorochlorocarbons add to alkenes at a lower temperature

in the presence of sodium formate (eq 3).[29] A steroidal alkene is oxidized to a ketone (eq 4).[30] Cyclohexene reacts with peroxydisulfate in acetonitrile-water at 60 °C to yield primarily cyclohexanol with a Ag^{I} or Fe^{II} catalyst, but forms cyclopentanecarbaldehyde or the carboxylic acid in the presence of Cu^{II}.[31,32] Alkenes are methoxyselenated by reaction with ***Diphenyl Diselenide*** and peroxydisulfate in methanol,[33] and certain alkenes undergo ring closure initiated by oxidation of diphenyl diselenide (eq 5), where X is an internal nucleophile.[34] Similar reactions have been observed for one disulfide (bis(4-methoxyphenyl) disulfide).[35] Quinolines, among other electrophiles, trap the radicals produced from alkenes to form adducts at either the 2- or 4-position.[31,36] The etheno bridge of 1,N^6-ethenoadenosine is smoothly removed by treatment with peroxydisulfate at pH 7 and 60 °C (eq 6).[37] In the absence of metal ions, under aqueous acidic conditions, peroxydisulfate is hydrolyzed to Caro's acid,[4] which then reacts with alkenes to yield *trans*-glycols.[38]

$$Cl(CF_2)_{7,8}R' + H_2C{=}CHR \xrightarrow[\text{DMF, 40 °C, 52-87\%}]{(NH_4)_2S_2O_8,\ HCO_2Na} R'(CF_2)_{7,8}CH_2CH_2R \quad (3)$$

(4)

(5)

(6)

Oxidation of Alcohols.

Simple primary and secondary alcohols are quantitatively oxidized by peroxydisulfate to the corresponding aldehydes and ketones at 60-80 °C in the absence of catalysts. See also ***Dimethyl Sulfoxide***, ***Dipyridine Chromium(VI) Oxide***, ***Pyridinium Chlorochromate***, ***Pyridinium Dichromate***, ***Tetra-n-propylammonium Perruthenate***, ***Cerium(IV) Ammonium Nitrate***, ***Sodium Dichromate***, ***Silver(I) Carbonate***, ***Nitric Acid***, ***Copper(I) Chloride-Oxygen***, ***Lead(IV) Acetate***, ***Nickel(II) Bromide***, ***Chromium(VI) Oxide***, ***Iodosylbenzene***, and ***Sodium Hypochlorite***. While it is possible to oxidize aldehydes to the corresponding carboxylic acids, this step is relatively slow and, in fact, the aldehyde acts as an inhibitor of further oxidation.[39] Benzyl alcohols (and benzylamines) also give aldehydes under the same conditions,[40] but, in the presence of Ni^{II} and ammonia at room temperature, the benzyl alcohols form the corresponding nitriles in excellent yield.[41] Allylic alcohols can be smoothly converted to the corresponding carbonyl compounds without oxidation of the alkenic bonds by reaction in the presence of a Ni^{II} catalyst, but without ammonia.[42] In the oxidation of a series of substituted 2-phenylethanols, the corresponding bibenzyls were obtained as well as the carbonyl compounds.[43] The intermediate alkoxyl radicals can be trapped by methylquinolines (eq 7),[44] by 4-cyanopyridine,[45] or by *N*-methoxypyridinium fluoroborates.[46] 3-Phenylpropanol cyclizes to a tetrahydrofuran upon reaction with peroxydisulfate in the presence of Cu^{II} (eq 8).[47] Geminal hydroxynitriles undergo rearrangement (eq 9)[48] and a variety of *vic*-glycols are oxidized to the dicarbonyl compounds with Ag^{I} catalysis at moderate temperatures. Both *cis*- and *trans*-glycols react at about the same rate.[49,50]

(7)

(8)

(9)

Oxidation of Ethers.

Ethyl ether undergoes conversion in 60-85% yield to acetaldehyde at 60 °C in water, whereas THF and *p*-dioxane give vinyl ethers.[51] See also ***Ruthenium(VIII) Oxide***. 2,5-Diphenylfuran similarly gives a quantitative yield of *cis*-1,2-dibenzoylethylene (eq 10).[52] The radical from *p*-dioxane, in addition to forming the vinyl ether, may be trapped by 4-methylquinoline.[53]

(10)

Oxidation of Aldehydes and Ketones.

Neither aldehydes nor ketones react rapidly with peroxydisulfate, except in the presence of a metal ion catalyst such as Ag^{I}. Aldehydes are oxidized to the corresponding carboxylic acids. Ketones form the carboxylic acids resulting from cleavage on either side of the carbonyl group.[54] Thus benzaldehyde is converted in about 60% yield to benzoic acid using Ag^{I} in water at 45 °C.[55] Other reactions occur with suitable radical traps. The γ-nitriles are formed in good yield in the presence of ***Sodium Cyanide*** (eq 11).[56] Similarly, acyl radicals may be trapped by quinolines[57] or alkenes[58] to form adducts in good yields.

(11)

Oxidation of Aliphatic Amines.

Aliphatic amines are converted in reasonable yield to the corresponding aldimines (eq 12),[59] while the corresponding amino acids form aldehydes (eq 13).[60] Benzylamine forms the aldimine in the absence of catalyst in 67% yield, but in the presence of Ni^{II}, benzonitrile is formed in 84-97% yield.[61,62] This dehydrogenation of primary amines to the nitrile appears to be a general reaction. See also ***Lead(IV) Acetate***, ***Nickel(II) Peroxide***, ***Sodium Hypochlorite Copper(I) Chloride-Oxygen***. Nitriles as well as other products are formed from primary amines using a Cu^{II} catalyst.[63] Secondary amines yield a variety of products, generally in poor yield,[60,64] but piperidines give good yields (40-60%) of 1,1-bipiperidines.[65]

(12)

(13)

Transformation of Carboxylic Acids to Peroxy Acids and Decarboxylation.

Carboxylic acids are converted (80-90% yield) to the corresponding peroxy acids at room temperature under phase-transfer conditions.[66] See also ***Hydrogen Peroxide***. With Ag^{I} catalysis at 60 °C the acids are decarboxylated, whereas with both Ag^{I} and Cu^{II} the main products are the alkenes and the alcohols.[67,68] Under other conditions (Ti^{III}), coupling products predominate, as found long ago by Fichter.[69,70] Alkanoic acids with favorable alkyl substituents yield δ- and γ-lactones.[71] Lactones can also be formed from certain aromatic systems (eq 14).[72,73] The radicals formed during decarboxylation can be trapped by quinolines, pyridines, or quinones.[74-77]

(14)

Transformations of Amides.

Secondary and tertiary amides are dealkylated to the primary amides at 90 °C (eq 15),[78,79] but 2-pyrrolidinone is oxidized under the same conditions to succinimide in 61% yield.[80] Alkanesulfonamides undergo oxidation at the γ-carbon (eq 16).[81] Biphenyls with *ortho*-substituted secondary amide groups can give a variety of cyclization products (eq 17).[82,83] N-Boc L-tyrosine derivatives, when treated with peroxydisulfate and Cu^{II}, yield the *threo*-β-hydroxy derivative via a cyclic carbamate (eq 18).[84] The scope of this synthesis has been extended to related compounds.[85]

(17)

(18)

Oxidation of Phenols to Hydroquinones and of Aryl Amines to Aminophenols.

These phenols and arylamines undergo similar reactions in alkaline aqueous solution at rt in the absence of catalysts (the Elbs and Boyland-Sims oxidations) (eqs 19 and 20). The sulfate esters can be hydrolyzed to the corresponding phenols in acid. These reactions have been reviewed.[1m] The *ortho-para* distribution in the amine oxidation has been examined recently.[86] The sulfate esters from the amine oxidation are accompanied by varying amounts of coupling products, which predominate in acid solution (see Table F in Behrman[1m]).

+ *o*-isomer (minor) (19)

+ *p*-isomer (minor) (20)

Oxidation of Sulfur Compounds.

Peroxydisulfate converts thiols to disulfides,[87] sulfides to sulfoxides,[88] and sulfoxides to sulfones.[89] This last reaction, however, is very slow so that excellent yields of the sulfoxides are available from the sulfides. See also ***Hydrogen Peroxide***, ***Sodium Periodate***, ***t-Butyl Hypochlorite***, ***Calcium Hypochlorite***, ***Sodium Hypochlorite***, ***Sodium Chlorite***, ***Dimethyldioxirane***, ***Nitric Acid***, ***Sodium Perborate***, and peroxy acids.

Ammonium Sulfide

$(NH_4)_2S$

[12135-76-1] · H_8N_2S · Ammonium Sulfide · (MW 68.14)

(redox agent for alkyl and carbonyl groups in the Willgerodt reaction;[1] reducing agent for nitro functional group;[6] sulfuration agent for many types of functional groups[13])

Physical Data: forms crystals (colorless needles) below -18 °C; decomposes into NH_4SH, NH_3, and ammonium polysulfides at high temperature.

Solubility: sol cold water, ethanol, liquid ammonia; reacts with water to give NH_4SH and NH_4OH.

Form Supplied in: the solution in water (20 wt %) is called ammonium sulfide solution - red and contains about 30% $(NH_4)_2S$, whereas ammonium sulfide - yellow contains 16-20% $(NH_4)_2S$.

Handling, Storage, and Precautions: decomposes into ammonia and ammonium polysulfide in air under light (sunlight); the solution of ammonium sulfide in water is strongly alkaline; keep container tightly closed and in a cool place; odor of NH_3 and H_2S.

Reduction of Carbonyl Functional Groups.

Towards the end of the 19th century, ammonium polysulfide (which usually contains ammonium sulfide) was found to react with aryl alkyl ketones as a redox agent, reducing carbonyls to methylene groups and oxidizing terminal alkyls to carbonyl groups to form the corresponding amides.[1] This reaction is the Willgerodt reaction and has been proposed as a convenient method for the synthesis of amides from ketones, as shown in eq 1.

(1)

Similarly, ammonium sulfide has been widely employed to produce various amides and acids, by acting as a redox agent for many types of compounds; for example, aryl alkyl ketones give the corresponding aryl-substituted amides, with yields according to the substituent, as shown in eq 2.[2] Furthermore, unsaturated carboxylic acids (eq 3),[3] aldehydes (eq 4),[4] carbinols,[5] thiols,[9] amines,[6] alkylbenzenes (eq 5),[7] and alkyl halides (eq 6)[7,8] were also found to

react with ammonium sulfide to give the corresponding amides.

(2)

Yield: X: H > Me > Cl > MeO > I > OH

(3)

(4)

(5)

(6)

Interestingly, Cerwonka et al. reported a ^{14}C-tracer (C*) study showing that the two terminal methyl groups are oxidized to carbonyl groups to give two products and that a short carbon chain is more reactive than a long chain in the molecule (eq 7).[9] Although there have been many reports on the Willgerodt reaction and some reaction mechanisms have been proposed, the exact mechanism is not yet clear.

Reduction of Nitro Functional Group.

Ammonium sulfide is used as a good selective reducing agent of a nitro functional group to an amine. For example, 4-nitrophenylacetic acid is reduced selectively with ammonium sulfide to give 4-aminophenylacetic acid in high yield (eq 8).[10]

Interestingly, 3-nitrofluorene reacts with ammonium sulfide in DMF to give 3-(*N*-hydroxylamino)fluorene selectively and then can be treated with ^{14}C-labeled MeC*OCl to form 3-(*N*-acetylhydroxylamino)fluorene having a ^{14}C-labeled acetyl group (content 98%) in 58% yield (eq 9).[11] This reaction is important as a convenient method to supply ^{14}C-labeled compounds.

(9)

The treatment of 4-chloro-3,5-dinitrotrifluoromethylbenzene with ammonium sulfide in dioxane-H_2O affords the cyclization-dimerization product 1,6-dinitro-3,8-bis(trifluoromethyl)phenothiazine in 25% yield, while similar treatment in the presence of acetone gives 2,2-dimethyl-7-nitobenzothiazoline in 50% yield (eq 10).[12]

(10)

Sulfuration Agent.

The treatment of a gold(II) phosphorus ylide dimer with ammonium sulfide in THF results in the formation of a symmetrical gold(II) phosphorus ylide (60% yield) containing four- and five-atom polysulfide bridges. The coordination geometry about the gold centers in this structure is best described as square planar. The overall configuration of ylide units is shown to be a twisted boat (eq 11).[13]

$$[Au(CH_2)_2P(Ph)Br]_2 \xrightarrow[\text{THF/H}_2\text{O}\ 60\%]{(NH_4)_2S} [Au(CH_2)_2P(Ph)]_2S_9 \quad (11)$$

In the presence of ammonium sulfide, bis(cyclopentadi-enyl)titanium pentasulfide, which is formed by the reaction of bis(methylcyclopentadienyl)titanium dichloride with ammonium sulfide, reacts with acetone to give $(MeCp)_2TiS_4CMe_2$ in 42% yield (eq 12).[14]

(12)

N-Alkyldithiooxamides are synthesized in good yield by reaction of cyanodithioformates with alkylamine and ammonium sulfide (eq 13).[15] Benzoylphenylalkynes react with ammonium sulfide in 60% dioxane-water at 15 °C to give a mixture of the β-hydroxy-α-thiobenzoylstyrene derivative (30%) and (*E*,*Z*)-β,β´-di(α-benzoylstyryl) sulfide (65%), as shown in eq 14, whereas only the β-hydroxy-α-thiobenzoylstyrene derivative is formed with sodium sulfide.[16]

Ammonium Tetrafluoroborate

NH_4BF_4

[13826-83-0] · BF_4H_4N · Ammonium Tetrafluoroborate · (MW 104.84)

(anion exchange reagent for preparation of isolable diazonium salts;[1] weak acid with nonnucleophilic counterion; electrolyte useful for synthetic electrochemistry[2])

Physical Data: mp 220-230 °C (sublimes); *d* 1.871 g cm^{-3} at 15 °C.

Solubility: sol H_2O.

Form Supplied in: white solid; widely available.

Purification: crystallization from water (1 mL g^{-1}) between 100 °C and 0 °C.

Handling, Storage, and Precautions: toxic by ingestion and inhalation. Irritates and can burn skin, eyes, and mucous membranes. Avoid extreme heat. Ammonium tetrafluoroborate is incompatible with acids, oxidizers, and reducing agents. Decomposition products include fluorides, NOX, and NH_3. Use in a fume hood with safety goggles and chemically resistant gloves and clothing. Use a dust respirator if much dust will be produced during use.

General Comments.

There are hundreds of references for the use of ammonium tetrafluoroborate in the patent literature. Only a few of these references are included here, but the reader should be aware of the wide use of ammonium tetrafluoroborate as a mild acid-base catalyst, proton source, or ammonia source. The lack of nucleophilicity of the fluoroborate spectator counteranion is generally advantageous.

Preparation of Arenediazonium Tetrafluoroborates.

Stable, isolable salts are obtained as filterable precipitates when arenediazonium chloride solutions are treated with NH_4BF_4. This is in contrast to arenediazonium salts with other counterions, which are not generally isolated. Thus *p*-bromobenzenediazonium chloride is converted in high yield to *p*-bromobenzenediazonium

tetrafluoroborate (eq 1). Alternatively, the arenediazonium tetrafluoroborate can be prepared from the arylamine in the presence of NH_4BF_4, whereupon the fluoroborate salt precipitates directly. For example, *p*-anisidine is diazotized to provide *p*-methoxybenzenediazonium tetrafluoroborate in nearly quantitative yield.[1]

Acid Catalyst.

In a production of a polymethylated tetrahydropyrimidine from acetone and ammonia, NH_4BF_4 serves as a catalyst. The tetrahydropyrimidine is obtained in 82% yield after 5 h at 50 °C.[3] Further reaction of the aforementioned tetrahydropyrimidine with acetone occurs with NH_4BF_4 catalysis at 70 °C, giving the synthetically useful 2,2,6,6-tetramethylpiperidin-4-one.[4]

Elecrochemical Synthesis.

In an electrolytic oxidation of *p*-acetoxybenzaldehyde from *p*-acetoxytoluene, solutions of NH_4BF_4 in low molecular weight alcohol/carboxylic acid mixtures are effective electrolytes.[2] Various metal alkoxides can be prepared by electrochemical oxidation of the metal with R_4NBF_4/alcohol as the supporting electrolyte.[5] Terephthalaldehyde can be produced electrochemically with the use of NH_4BF_4.[6] Polyfluoroalkyl halides can be converted to perfluorocarboxylic acids by electrochemical initiation of ion-radical reaction with oxygen.[7]

Inversion of Chiral Amines.

Conversion of chiral amines to potassium alkanediazotates, followed by treatment with NH_4BF_4 in refluxing NH_3, leads to inverted amines (eq 2). Percentages of inversion range from 50% to 70%, and yields are modest (18-37%) due to formation of significant amounts of alcohols (configuration predominantly retained) and alkenes.[8]

(2)

Reductive Dehalogenation of Aromatic Iodides.

Treatment of methyl 2-iodobenzoate with excess of ***Copper(II) Trifluoromethanesulfonate*** in aq ammonia provides methyl salicylate in 94% yield. The intermediacy of an arylcopper species was demonstrated by isolation of 98% yield of methyl benzoate in the presence of excess NH_4BF_4 (eq 3).[9]

(3)

Additive in Catalytic Systems.

A zeolite impregnated with NH_4BF_4 catalyzed a 99.5% conversion of methanol to mixtures of hydrocarbons (30.4% propene, 19.3% butenes, and 25.6% C_{5+} aliphatics).[10] Catalytic hydrogenation with a $Ru(acac)_3$/tri-octylphosphine catalyst in the presence of NH_4BF_4 results in a selectivity of 100% (79% conversion) for reduction of succinic anhydride to γ-butyrolactone.[11] In catalytic reductive amination of acetone to produce an *N*-isopropyl arylamine, NH_4BF_4 additive imparts very high selectivity (96.8%) to the Fe_2O_3-promoted copper-chromium catalyst system.[12] An $AlCl_3$ catalyst for production of diphenylamine is improved by addition of NH_4BF_4.[13]

(*S*)-4-Anilino-3-methylamino-1-butanol[1]

[88733-39-5] · $C_{11}H_{18}N_2O$ · (*S*)-4-Anilino-3-methylamino-1-butanol · (MW 194.27)

(tridentate chiral ligand to modify $LiAlH_4$ for the enantioselective reduction of alkyl phenyl ketones[2] and α,β-unsaturated ketones[3])

Physical Data: bp 139-140 °C; [α]23D -13.7° (*c* 1.0, $CHCl_3$).

Solubility: sol THF.

Preparative Methods: β-benzyl *N*-benzyloxycarbonylaspartate[4] is treated with ethyl chloroformate, *N*-methymorpholine, and aniline. Subsequent reduction of the corresponding anilide with $LiAlH_4$ gives the title reagent in overall 80% yield.[2]

Chiral Ligand of $LiAlH_4$ for the Enantioselective Reduction of Alkyl Phenyl Ketones.

Optically active alcohols are important synthetic intermediates. There are two major chemical methods for synthesizing optically active alcohols from carbonyl compounds. One is asymmetric (enantioselective) reduction of ketones.[1] The other is asymmetric (enantioselective) alkylation of aldehydes.[5] Extensive attempts have been reported to modify ***Lithium Aluminum Hydride*** with chiral ligands in order to achieve enantioselective reduction of ketones.[1] However, most of the chiral ligands used for the modification of $LiAlH_4$ are unidentate or bidentate, such as alcohol, phenol, amino alcohol, or amine derivatives.

Unlike many other chiral ligands, (*S*)-4-amilino-3-methylamino-1-butanol (**1**) is designed as a tridentate chiral ligand anticipating a more rigid complex formation with $LiAlH_4$. The chiral reducing reagent is prepared in situ by mixing $LiAlH_4$ and (**1**) in THF. To this chiral reducing reagent is added alkyl phenyl ketone at -100 °C. Optically active (*S*)-*s*-alcohols with 51-88% ee's are obtained in 84-93% yields (eq 1). The results are summarized in Table 1.

Table 1 Enantioselective Reduction of Alkyl Phenyl Ketones

Ketone	Yield (%)	ee (%)
PhCOMe	87	51
PhCOEt	93	68
PhCOPr-*i*	93	77
PhCOBu-*t*	84	86
a-Tetralone	89	88

The ee's of the obtained alcohols increase according to the increase in steric bulkiness of the alkyl substituents of prochiral ketones. Thus the reduction of *t*-butyl phenyl ketone occurs with 86% ee whereas reduction of acetophenone gives 51% ee. The enantioselective reduction of *t*-butyl phenyl ketone and α-tetralone (86 and 88% ee, respectively) are among the most selective of those reported.[6]

After quenching the reaction, the amino alcohol (**1**) is recovered in a yield of over 85% without any racemization.

Chiral Ligand of $LiAlH_4$ for the Enantioselective Reduction of α,β-Unsaturated Ketones.

Enantioselective reductions of α,β-unsaturated ketones afford optically active allylic alcohols which are useful intermediates in natural product synthesis.[7] Enantioselective reduction of α,β-unsaturated ketones with $LiAlH_4$ modified with chiral amino alcohol (**1**) affords optically active (*S*)-allylic alcohols with high ee's. When 2-cyclohexen-1-one is employed, (*S*)-2-cyclohexen-1-ol with 100% ee is obtained in 95% yield (eq 2). This is comparable with the results obtained using $LiAlH_4$-chiral binaphthol[8] and chiral 1,3,2-oxazaborolidine.[9]

When (*S*)-4-(2,6-xylidino)-3-methylamino-1-butanol (**2**) is used instead of (**1**), (*R*)-2-cyclohexen-1-ol is obtained with less enantioselectivity (13% ee) (eq 3).

(2*S*,4*S*)-2-(Anilinomethyl)-1-ethyl-4-hydroxypyrrolidine[1]

[77973-75-8] · $C_{13}H_{20}N_2O$ · (2*S*,4*S*)-2-(Anilinomethyl)-1-ethyl-4-hydroxypyrrolidine · (MW 220.31)

(chiral catalyst for the enantioselective conjugate addition of thiols to α,β-unsaturated ketones[2] and esters)

Physical Data: bp 150-170 °C/2 mmHg; [α]23D -58.1° (*c* 1.03, EtOH).

Solubility: sol toluene, benzene, CH_2Cl_2, CCl_4, ethanol.

Preparative Methods: (2*S*,4*S*)-1-benzyloxycarbonyl-4-hy-droxyproline (*Z*-allohydroxyproline)[3] is acetylated with ***Acetic Anhydride*** and ***Pyridine*** to give the acetate (**1**). The acetate (**1**) is treated with aniline-***1,3-Dicyclohexylcarbodiimide*** and the subsequent removal of the benzyloxycarbonyl group affords (**2**). Acetylation of (**2**) followed by reduction with ***Lithium Aluminum Hydride*** affords (2*S*,4*S*)-2-(anilinomethyl)-1-ethyl-4-hydroxypyrrolidine (**3**) in 60% overall yield from (**1**) (eq 1).[2]

Enantioselective Addition of Thiols to α,β-Unsaturated Ketones and Diisopropyl Maleate.

(2*S*,4*S*)-2-(Anilinomethyl)-1-ethyl-4-hydroxypyrrolidine (**3**) is a chiral amino alcohol which acts as a chiral base catalyst for the enantioselective conjugate addition of aromatic thiols to α,β-unsaturated ketones.[2] When an aromatic thiol is treated with a 2-cycloalkenone in the presence of 1 mol % of amino alcohol (**3**) in toluene at -5 °C, 3-arylthio-1-cycloalkanones with 42-88% ee are obtained in 74-85% yields (eq 2).

(2)

Table 1 Enantioselective Addition of Thiols to 2-Cyclohexenones Catalyzed by Amino Alcohol **(3)**

R	Enone	Yield (%)	ee (%)
		83	77
		75	73
		84	47
		75	83
		74	88
		74	42

The results are shown in Table 1. The reaction between various aromatic thiols and 2-cyclohexen-1-one in the presence of (**3**) affords the adduct in good ee. The best selectivity is observed in the addition of 4-*t*-butylbenzenethiol to 2-cyclohexen-1-one using 1 mol % of (**3**). (*R*)-3-(4-*t*-Butylphenylthio)cyclohexan-1-one is obtained in 88% ee. When cinchonine is employed as a chiral catalyst in the same reaction, the corresponding adduct with (*S*) configuration is obtained in 67% ee.[4]

In the addition of benzenethiol to 2-cyclohexen-1-one, the enantioselectivities using (**3**)[2b] and cinchonidine[4b] are 77 and 54% ee, respectively. Thus (**3**) is more enantioselective than cinchonine and cinchonidine in the addition of RSH to 2-cyclohexen-1-one. However, in the addition of 4-*t*-butylbenzenethiol to a substituted enone (5,5-dimethyl-2-cyclohexen-1-one), the cinchonidine catalyst showed higher enantioselectivity (62% ee)[4] than catalyst (**2**) (42% ee).

Cinchonidine is more enantioselective than (**3**) in the addition to acyclic α,β-unsaturated esters. When benzenethiol is allowed to react with diisopropyl maleate using chiral catalyst (**3**), (*R*)-diisopropyl phenylthiosuccinate with 6% ee is obtained. The same reaction employing cinchonine afforded the (*S*) adduct with 81% ee (eq 3).[5]

(*S*)-2-(Anilinomethyl)pyrrolidine[1]

[64030-44-0] · $C_{11}H_{16}N_2$ · (*S*)-2-(Anilinomethyl)pyrrolidine · (MW 176.25)

(chiral ligand of $LiAlH_4$ for enantioselective reduction of ketones;[2] can form chiral aminals for diastereoselective alkylation,[3,4] 1,2-,[5] and 1,4-additions[6])

Physical Data: bp 111-112 °C/0.55 mmHg; [α]24D +19.7° (*c* 1.04, EtOH).

Solubility: sol ether, THF.

Form Supplied in: colorless oil.

Preparative Methods: reaction of (*S*)-*N*-(benzyloxycarbonyl)proline with (1) ethyl chloroformate and *N*-methylmorpholine, (2) aniline, (3) hydrogenolysis with Pd/C, and (4) reduction with $LiAlH_4$ affords the title compound in 59% overall yield.[2b]

Enantioselective Reduction of Ketones.

(*S*)-2-(Anilinomethyl)pyrrolidine (**1**) is a chiral ligand which, in combination with ***Lithium Aluminum Hydride***, generates a chiral reagent for the enantioselective reduction of ketones. (*S*)-1-Phenylethanol with 92% ee is obtained from the enantioselective reduction of acetophenone with $LiAlH_4$-(**1**) (eq 1).[2a,b] When (*S*)-2-(2,6-xylidinomethyl)pyrrolidine is used instead of (**1**), the ee of the alcohol obtained reaches 95%.[2c] The ee's of aromatic alcohols obtained using $LiAlH_4$-(**1**) are comparable with other highly enantioselective reductions[1] and with highly enantioselective alkylation of aldehydes.[7]

(1)

(2)

Diastereoselective Alkylation of Chiral Keto- and Formylaminals.

Diamine (**1**) forms a chiral ketoaminal by condensation with phenylglyoxal monohydrate. Diastereoselective addition of a Grignard reagent to the ketoaminal and subsequent hydrolysis affords optically active *t*-α-hydroxyaldehydes with >94% ee (eq 2).[3a] Various α-hydroxyaldehydes are synthesized by this method.[3b] Diastereoselectivities are comparable with those of the reactions of chiral 1,3-oxathiane.[8]

(2)

The method has been applied to the diastereoselective synthesis of naturally occurring compounds such as frontalin (84-100% ee)[3c] and (-)-malyngolide (95% ee).[3d] On the other hand, diastereoselective alkylation

of chiral formylaminal with Grignard reagents and the subsequent hydrolysis afford optically active *S*-α-hydroxyaldehydes with moderate stereoselectivity (60% ee).[4]

Diastereoselective 1,2- and 1,4-Additions of Chiral Aminals.

The organolithium reagent derived from a chiral bromoaminal and BuLi adds to pentanal to afford an optically active lactol. Subsequent oxidation affords the optically active lactone with 88% ee (eq 3).[5]

(3)

Diastereoselective 1,4- (conjugate) additions of Grignard reagents to a chiral α,β-unsaturated aminals afford optically active 3-substituted succinaldehydic acid methyl esters with 85-93% ee (eq 4).[6]

(4)

Related Reagents.

p-Anisolesulfonyl Chloride[1]

[98-68-0] · $C_7H_7ClO_3S$ · *p*-Anisolesulfonyl Chloride · (MW 206.65)

(versatile sulfonating agent; useful for the preparation of sulfonamides or as an *N*-protecting group[2])

Alternate Name: 4-methoxybenzenesulfonyl chloride.

Physical Data: mp 40-43 °C.

Solubility: sol acetone, acetonitrile, EtOH, MeOH, dioxane, H_2O.

Form Supplied in: solid; widely available 98% pure.

Handling, Storage, and Precautions: corrosive and a lachrymator. Store at room temperature under anhydrous conditions. Use in a fume hood.

Sulfonating Agent.

4-Methoxybenzenesulfonyl chloride has been employed in the preparation of a wide variety of sulfonamides leading to a number of biologically active compounds.[3,4] The nonprostanoid thromboxane (TXA_2) receptor antagonist (**2**) was prepared from the primary amine in the presence of 4-methoxybenzenesulfonyl chloride (**1**) (1.2 equiv) and excess ***Triethylamine*** (eq 1).[3] Arenesulfonyl chlorides have also been used for the synthesis of sulfonyl cyanides[5] and arylthiocyanates.[6]

The addition of sulfonyl chlorides to alkenes in the presence of a catalytic amount of ***Dichlorotris(triphenylphosphine)ruthenium(II)*** affords 1:1 adducts.[7] Under these reaction conditions it is believed that sulfonyl radicals, which are confined to the coordination sphere of the metal complex, are involved. When the chiral phosphine (-)-DIOP (***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane***) is used as a ligand, the addition of 4-methoxybenzenesulfonyl chloride to styrene proceeds to provide the (*R*) isomer in 40% ee (eq 2).[8]

Arenesulfonyl chlorides have also been cross-coupled in the presence of Pd^0 with both vinyl- and allylstannanes to provide the corresponding sulfones.[9]

Solvolysis of Arenesulfonyl Chlorides.

Kinetics on the solvolysis of various arenesulfonyl chlorides indicate an S_N2 mechanism.[10,11]

Anthranilic Acid

[118-92-3] · $C_7H_7NO_2$ · Anthranilic Acid · (MW 137.14)

(useful benzyne precursor[1]; building block for the synthesis of heterocyclic compounds[2-7])

Physical Data: mp 144-148 °C; *d* 1.412 g cm^{-3}.

Solubility: sol EtOH, AcOEt; partially sol water; insol petroleum ether.

Form Supplied in: yellow powder; widely available.

Benzyne Precursor.

Anthranilic acid can be diazotized to benzenediazonium-2-carboxylate, which is a very useful benzyne precursor. This transformation is usually accomplished under aprotic conditions with ***Isopentyl Nitrite*** (*caution*: isopentyl nitrite is a heart stimulant) (eq 1).[1]

(1)

Synthesis of Heterocycles.

Anthranilic acid reacts with ***Phosgene*** (eq 2)[2] or ***Ethyl 4-Chloroacetoacetate***[3] to afford isatoic anhydride.[2]

(2)

Benzoxazines have been obtained by treatment of a mixture of anthranilic acid and a substituted benzoic acid with ***Phosphorus Oxychloride*** (eq 3).[4]

(3)

Reaction of anthranilic acid with methazonic acid under acid conditions, followed by treatment with sodium acetate/acetic anhydride, leads, in moderate yield, to 3-nitroquinol-4-one (eq 4).[5]

(4)

Acridones can be obtained, by means of the Niementowski modification of the Friedländer synthesis, by heating a mixture of anthranilic acid and a ketone (eq 5).[6]

(5)

Condensation with formanilide yields a benzo-1,3-diazine (eq 6).[7]

(6)

The following interesting reaction between anthranilic acid and a cyclopropylphosphonium salt has also been reported (eq 7).[8]

Antimony(III) Chloride

$SbCl_3$

[10025-91-9] · Cl_3Sb · Antimony(III) Chloride · (MW 228.11)

(Lewis acid catalyst for electrophilic aromatic substitution;[1,2] halo-[3] and stibinodediazoniation[4] of diazonium salts; fluorination of sulfoxides[5,6] and thioethers[7] with DAST)

Alternate Names: antimony trichloride; trichlorostibine.

Physical Data: mp 73 °C; bp 223 °C, 143 °C/70 mmHg; *d* 3.14 g cm^{-3}.

Solubility: sol H_2O (1 g/10.1 mL, at 25 °C); sol acetone, alcohol, benzene, chloroform, 1,2-dichloroethane, dichloromethane; insol pyridine.

Form Supplied in: colorless, hygroscopic crystals which fume in moist air.

Handling, Storage, and Precautions: poisonous; moisture-sensitive, corrosive, and irritant. For best results, anhydrous $SbCl_3$ should be handled in an anhydrous, inert atmosphere (dry box or glove bag in humid laboratories), or manipulated rapidly to minimize contact with air and moisture. Use in a fume hood.

Electrophilic Aromatic Substitution.

Antimony(III) chloride has been used as a Lewis acid catalyst for Friedel-Crafts reactions. Thus treatment of benzene with benzoyl chloride/$SbCl_3$ at 155 °C gives benzophenone in good yield.[1a] However, this conversion and other Friedel-Crafts reactions catalyzed by $SbCl_3$ are slower, require higher temperatures, and give lower yields than with the more reactive Lewis acids ***Aluminum Chloride***, ***Iron(III) Chloride***, and ***Antimony(V) Chloride***.[1] Treatment of benzene with Cl_2/NOCl and molten $SbCl_3$ (135-145 °C) gives chlorobenzene.[2]

Nonaqueous Diazotization/Halodediazoniation, and Stibinodediazoniation.

Treatment of 2-amino-6-substituted purine nucleosides with *t*-butyl nitrite and catalytic amounts of antimony(III)

chloride in a chlorinated hydrocarbon solvent gave 2-chloro-6-substituted derivatives smoothly (eq 1a). The corresponding 2-bromo analogs were obtained when antimony(III) bromide was used in a brominated hydrocarbon solvent (eq 1b).[3] In contrast, diazotization of aniline with pentyl nitrite followed by addition of $SbCl_3$ gave a stable benzenediazonium/$SbCl_3$ salt.[4a] Such antimony salts can also be prepared by aqueous diazotization,[4b-e] and they have been used for the synthesis of a variety of aryl antimony compounds such as phenylstibonic acids.[4]

Fluorination of Sulfoxides and Thioethers.

Antimony(III) chloride is a potent catalyst for the conversion of sulfoxides to α-fluoro thioethers with ***N,N-Diethylaminosulfur Trifluoride*** (DAST).[5] Thioanisole sulfoxide gave fluoromethyl phenyl sulfide in 88% yield (eq 2).[5b] ***Zinc Iodide*** was the catalyst originally reported for this fluoro-Pummerer transformation,[6a] but $SbCl_3$ is markedly superior.[5,6b] Since sulfides afford α-fluoro thioethers directly upon treatment with DAST/$SbCl_3$,[7] prior oxidation of sulfides to their sulfoxides is not necessary for this transformation. Thus thioanisole gave fluoromethyl phenyl sulfide in 94% yield (eq 2) and the more complex 2´,3´-di-*O*-acetyl-5´-adenosyl phenyl (and *p*-anisyl)

sulfides gave the 5´-fluoro derivatives in ~60% yields (eq 3).[7] McCarthy has developed access to terminal vinyl fluorides with derived α-fluoro sulfoxides and sulfones.[6]

(2)

(3)

Antimony(III) Chloride/Reducing Metal Systems.

Zero-valent antimony species prepared by reduction of $SbCl_3$ with aluminum or iron effect allylations of aldehydes with allyl halides at 25 °C to give homoallylic alcohols in high yields.[8a,b] $SbCl_3$/Al or $SbCl_3$/Zn in aqueous DMF (or D_2O/DMF) are efficient systems for the reduction of aldehydes to alcohols.[8b,c] Electroreduction of acetophenone to 1-phenylethanol occurred on a lead cathode in the presence of catalytic $SbCl_3$.[9] Quantitative conversions of aldehydes to their methyl or ethyl acetals have been effected with Al (or Fe)/$SbCl_3$(cat.)/MeOH (or EtOH).[8b]

Antimony(V) Chloride[1]

$SbCl_5$

[7647-18-9] · Cl_5Sb · Antimony(V) Chloride · (MW 299.02)

(Lewis acid,[1] catalyst for Friedel-Crafts reactions, isomerization, and other Lewis acid related chemistry;[1] chlorinating agent; acid system for the preparation of stable carbocation and onium salts[1])

Alternate Name: antimony pentachloride

Physical Data: bp 92 °C/30 mmHg.

Solubility: sol chloroform, carbon tetrachloride.

Form Supplied in: colorless or slightly yellow oily liquid; commercially available.

Handling, Storage, and Precautions: $SbCl_5$ is a corrosive, toxic, and moisture sensitive substance. It can be purified by vacuum distillation. $SbCl_5$ fumes when exposed to atmosphere, and should be stored under anhydrous conditions and handled using proper gloves in a well ventilated hood.

Catalyst in Friedel-Crafts and Related Chemistry.

Aromatic compounds can be readily alkylated under $SbCl_5$ catalysis.[2,3] However, competing chlorination can sometimes complicate the alkylation. The activity of $SbCl_5$ is comparable to that of ***Aluminum Chloride*** and ***Aluminum Bromide*** in the reaction of *s*-butyl chloride with benzene.[2a] It is interesting that dibenzoylchloromethane can be converted to 2-chloro-3-phenylindenone in 80% yield under $SbCl_5$ catalysis (eq 1).[3]

(1)

Both acyl halides and acid anhydrides have been utilized in the acylation of arenes under $SbCl_5$ catalysis.[4,5] Reaction

of 3-acetamidobenzo[*b*]furan with acid chlorides give condensed 1,3-oxazinium salts.[4d] Treatment of the salts with ammonium acetate in acetic acid gives the corresponding benzo[*b*]furano[3,2-*d*]pyrimidines in good yields (eq 2). Similar reactions proceed when 3-acetamidobenzo[*b*]thiophene and indole are used as substrates.[4d] Friedel-Crafts acylation generally requires a stoichiometric amount of Lewis acid. However, catalytic acylation can be achieved with the use of $SbCl_5$ in conjunction with ***Silver(I) Perchlorate***, ***Lithium Perchlorate***, or chlorodiphenylborane.[5] Trichloromethyl phenyl ketones can be readily prepared by reaction of trichlorophosphazoperchloroethane with arenes in the presence of $SbCl_5$ followed by hydrolysis of the reaction mixtures.[6]

(2)

X = O, S, NH; R = Me Ph

Much of the research work on $SbCl_5$-catalyzed halogenation of arenes has focused on chlorination and bromination of perfluoroalkyl substituted aromatics.[7] Iodination of arenes has also been carried out with ***Iodine*** in the presence of $SbCl_5$.[7c]

Reaction of organic disulfides with electron rich aromatic compounds under $SbCl_5$/***Silver(I) Hexafluoroantimonate*** catalysis affords unsymmetrical aryl sulfides in modest yields.[8a] Electrophilic sulfinylation and sulfonation can be similarly effected by $SbCl_5$.[8b-c] Alkyl- and halobenzenes give thiocyano derivatives when treated with a mixture of $SbCl_5$ and $Pb(SCN)_2$ in CCl_4.[9]

Silyl enolates of α,α-dialkoxy ketones react with furans to form [3 + 2] cycloaddition products in the presence of $SbCl_5$ (eq 3).[10] Cycloaddition also occurs when 2,2-dialkoxycyclopropanecarboxylic esters and carbonyl compounds are treated with $SbCl_5$.[11]

(3)

In the presence of $SbCl_5$ and ***Tin(II) Trifluoromethanesulfonate***, α,β-unsaturated thioesters react with silyl enol ethers to form the corresponding Michael adducts stereoselectively in high yields.[12] Successive treatment of lactones with ketene silyl acetals and certain organosilane-based nucleophiles (triethylsilane, allyltrimethylsilane, trimethylsilyl cyanide, etc.) under $SbCl_5/Me_3SiCl/SnI_2$ catalysis affords α-mono- or α,α-disub-stituted cyclic ethers (e.g. eq 4).[13]

Catalyst in Isomerization and Rearrangements.

Along with many other Lewis acids, $SbCl_5$ has been applied to promote the Fries rearrangement.[14] More recently it has been found that the $SbCl_5/AgSbF_6$ system is an efficient catalyst for Beckmann and pinacol rearrangements.[15] In the presence of $SbCl_5$, (*E*)-2-methoxy-2,4-diphenyl-3-butenenitrile can be isomerized to the corresponding γ-methoxy-α,β-unsaturated carbonitriles in good yield.[16] Methyl 6α-chloropenicillanate rearranges to (3*S*)-6-chloro-2,3,4,7-tetrahydro-2,2-dimethyl-7-oxo-1,4-thiazepine-3-carboxylate when treated with $SbCl_5$ in CH_2Cl_2. Under similar conditions, methyl penicillanate and methyl 6β-phthalimidopenicillanate undergo analogous isomerizations (eq 5).[17]

Halogenation.

In addition to its ability as a halogenation catalyst, $SbCl_5$ itself is an excellent chlorinating agent and has been widely applied to chlorination of various organic compounds, including arenes, alkenes, and alkynes.[18-24]

Preparation of Carbocation and Onium Ion Complexes.

$SbCl_5$ has been extensively utilized in the preparation of stable carbocations and onium ions.[25-30] This is facilitated by the ready formation of the stable anion $SbCl_6^-$. The carbocations generated include such stable ions as halophenylcarbenium ions, cyclopropenyl cations, and perchloroallyl cations.[26] Extensive studies have also been carried out on the use of $SbCl_5$ to synthesize onium salts such as alkylidene ammonium salts, 2-azaallenium salts, nitrilium salts,[27] oxonium salts,[28] and sulfonium salts.[29] Reaction of adamantylideneadamantane with $SbCl_5$ gives the

stable chloronium [AdAdCl$^+$][$SbCl_6^-$] salt.[30]

Other Reactions.

1,3-Dithianes can be converted to the corresponding carbonyl compounds in excellent yields in the presence of $SbCl_5$.[31] When epoxides are treated with a catalytic amount of $SbCl_5/AgSbF_6$ in the presence of alkoxytrimethylsilane and triethylsilane, sequential reactions involving rearrangement and reductive condensation give the corresponding ethers in good yields (eq 6).[32] Homologation of ketones with diazoacetic esters can also be catalyzed by $SbCl_5$ (eq 7).[33]

Antimony(V) Fluoride[1]

[7783-70-2] · F_5Sb · Antimony(V) Fluoride · (MW 216.74)

(one of the strongest Lewis acids,[1] used as catalyst for Friedel-Crafts reactions, isomerization, and other acid related chemistry;[1] an efficient acid system for preparation of carbocations and onium ions as well as their salts;[1] a fluorinating agent, and a strong oxidant)

Alternate Name: antimony pentafluoride.

Physical Data: bp 149.5 °C.

Solubility: SbF_5 reacts with most organic solvents, forming solids with ether, acetone, carbon disulfide, and petroleum ether. SbF_5 is soluble in SO_2 and SO_2ClF.

Form Supplied in: viscous liquid; commercially available.

Handling, Storage, and Precautions: SbF_5 is extremely corrosive, toxic, and moisture sensitive. It can be purified by distillation. SbF_5 fumes when exposed to atmosphere. It should be stored under anhydrous conditions in a Teflon bottle and handled using proper gloves in a well ventilated hood.

Antimony pentafluoride is one of the strongest Lewis acids reported and is capable of forming stable conjugate superacid systems with HF and FSO_3H (see ***Hydrogen Fluoride-Antimony(V) Fluoride*** and ***Fluorosulfuric Acid-Antimony(V) Fluoride***).[1] Its complex with ***Trifluoromethanesulfonic Acid*** is, however, less stable and cannot be stored for extended periods of time. Nevertheless, CF_3SO_3H/SbF_5 is also a useful acid system when prepared in situ.[2] The most important properties of SbF_5 include its high acidity, strong oxidative ability, and great tendency to form stable anions.[3] The chemistry of SbF_5 is mainly characterized by these properties. The major applications of SbF_5 in organic synthesis include oxidation, fluorination, and as a catalyst for Friedel-Crafts type reactions and other acid related chemistry, and as a medium for preparation of carbocations and onium ions.[1]

Friedel-Crafts and Related Chemistry.

The use of SbF_5 as a Friedel-Crafts catalyst has significantly expanded the scope of these reactions.[3] This is made possible through the strong Lewis acidity and oxidative ability of SbF_5. Influenced by the strong acidity, compounds of otherwise very weak nucleophilicity such as perfluorocarbons can react readily with aromatics. Furthermore, the strong

oxidative ability of SbF_5 enables unconventional substrates such as methane to be oxidized to form positively charged species, which in turn can be applied as electrophilic reagents. On the other hand, these factors also considerably restrict the use of SbF_5 in organic synthesis since the high reactivity makes it a less selective Lewis acid for many reactions.

Alkylation of arenes proceeds readily under SbF_5 catalysis.[3] In addition to alkyl halides, alkyl esters and haloesters have also been applied to alkylate arenes under the reaction conditions.[4] Perfluoro or perchlorofluoro compounds have been similarly used as alkylating agents in the presence of SbF_5.[5] For example, perfluorotoluene reacts with pentafluorobenzene to form perfluorodiphenylmethane in 68% yield after the reaction mixture is quenched with HF. When H_2O is used in the quenching step, perfluorobenzophenone is obtained in 93% yield (eq 1).[5a]

(1)

Acylation of pentafluorobenzene to form ketones either with acid halides or with anhydrides has been achieved with an excess of SbF_5.[6] In the case of dicarboxylic acid dichlorides or anhydrides as acylating agents, diketones are obtained as the reaction products (eq 2). The reaction of the anhydrides of dicarboxylic acids with aromatic compounds does not stop at the keto acid stage, as is the case when other Lewis acids are used. Using phosgene in place of acid chlorides results in the formation of pentafluorobenzoic acid in good yield.[3]

(2)

Perfluorobenzenium salt can be conveniently prepared from the reaction of 1,4-perfluorocyclohexadiene with SbF_5.[7a-c] In the presence of SbF_5, this salt is able to react with three equivalents of pentafluorobenzene to yield perfluoro-1,3,5-triphenylbenzene (eq 3).[7a-c] When 2,2´-di-*H*-octafluorobiphenyl is used as the substrate, perfluorotriphenylene is obtained in 50% yield (eq 4). Perfluoronaphthlenenium ion also reacts with polyfluorinated arenes in a similar fashion.[7a-c] The above reaction offers a facile approach for the preparation of these perfluorinated polynuclear aromatic compounds. Oxidation of perchlorobenzene with SbF_5 in the presence of pentafluorobenzene leads to the formation of coupling products.[7d]

(3)

(4)

Friedel-Crafts sulfonylation of aromatics with alkane- and arenesulfonyl halides and anhydrides has been studied.[8] Good yields of sulfones are generally obtained (eq 5). In the case of pentafluorobenzenesulfonyl fluoride with pentafluorobenzene, decafluorodiphenyl sulfone is formed along with decafluorodiphenyl.[8c] A convenient approach for synthesizing symmetrical aryl sulfones is to react aromatics with ***Fluorosulfuric Acid*** in the presence of SbF_5 (eq 6).[9] Certain phenylacetylenes react with SO_2 and benzene in the presence of SbF_5 to form benzothiophene *S*-oxides[10] (eq 7). In some cases, 1,1-diphenylvinylsulfinic acids were also obtained as side products of the reaction. Sulfinyl fluoride reacts with arenes similarly under the catalysis of SbF_5 to give sulfoxides (eq 8).[8c]

(5)

(6)

(7)

(8)

Oxidation of elemental sulfur and selenium with SbF_5 leads to the formation of doubly charged polyatomic cations.[11] These cations are able to react with polyfluorinated arenes to form diaryl sulfides or selenides (eq 9).[12a-c] Under similar treatment, polyfluorodiaryl disulfides or diselenides also react with aromatics to form diaryl sulfides and selenides, respectively (eq 10).[12a,12b]

(9)

X = H, F, Br, SMe

(10)

X = F, Cl; Ar = polyfluoroaryl

In the presence of SbF_5, inorganic halides such as NaCl and NaBr can serve as electrophilic halogenating agents.[5b,13] Even deactivated arenes such as 5*H*-nonafluoroindan can be brominated under the reaction conditions (eq 11).[13b]

(11)

Functionalization of alkanes has been achieved under SbF_5 catalysis.[3] Halogenation of alkanes is one of the widely studied reactions in this field.[14] A valuable synthetic procedure is the reaction of alkanes with methylene chloride (or bromide) in the presence of SbF_5 (eq 12).[14d] In these reactions, halonium ions are initially formed, which in turn abstract hydride from hydrocarbons. Quenching of the resulting carbocations with halides leads to the desired haloalkanes.

$$RH \xrightarrow[64\text{-}88\%]{CH_2X_2,\ SbF_5} RX \qquad (12)$$

RH = secondary, tertiary alkanes
X = Cl, Br

In the presence of SbF_5, alkyl chlorides are ionized to form carbocations, which can be trapped with CO.[15] Quenching the reaction intermediates with water or alcohols yields the corresponding carboxylic acids or esters. For instance, halogenated trishomobarrelene reacts with CO in SbF_5/SO_2ClF to give, after treatment with alcohol and water, a mixture of acid and ether (eq 13).[15a]

(13)

Studies have been carried out on the alkylation of alkenes in the presence of SbF_5, especially fluoroalkenes.[16] For example, treatment of 1,1,1-trifluoroethane with SbF_5 in the presence of tetrafluoroethylene yields 90% of 1,1,1,2,2,3,3-heptafluorobutane.[16c] Perfluoroallyl or -benzoyl compounds with varying structures have also been utilized as alkyating agents (eqs 14 and 15).[16b,e-h] At elevated temperatures, intramolecular alkylation was observed in certain cases with perfluorodienes, forming perfluorocyclopentenes or perfluorocyclobutenes (eq 16).[17]

(14)

X = F, CF_3

Acylation of alkenes can also be similarly effected with SbF_5.[18] Reaction of acetyl fluoride with trifluoroethylene produces 1,1,1,2-tetrafluorohexane-3,5-dione in 40% yield.[18a] When antimony pentafluoride is used in excess (more than 6 molar equivalents), 1,1,1,2-tetrafluorobutan-3-one is formed as a side product. Benzoyl fluoride reacts with difluoroethylene to form the expected ketone in 39% yield.[18a] α,β-Unsaturated carboxylic acid fluorides have also been used in reactions with perfluoroalkenes.[18b] In these cases, α,β-unsaturated ketones are obtained (eq 17). Enol acetates of perfluoroisopropyl methyl ketone and perfluoro-*t*-butyl methyl ketone react with acetyl fluoride to provide the corresponding β-diketones (eq 18).[18c]

(18)

Oxygenation of dienes with molecular oxygen to form Diels-Alder-type adducts can be effected by Lewis acids and some salts of stable carbenium ions.[19] In the case of ergosteryl acetate, SbF_5 is by far the most active catalyst (eq 19).[19a]

(19)

Isomerization and Rearrangement.

Isomerization of perfluoroalkenes can be realized with SbF_5 catalysis.[20] The terminal carbon-carbon bonds of these alkenes are usually moved to the 2-position under the influence of this catalyst (eq 20). A further inward shift generally occurs only if H or Cl atoms are present in the 4-position of the alkenes. As a rule, the isomerization leads to the predominant formation of the *trans* isomers. Terminal fluorodienes also isomerize exothermally into dienes containing internal double bonds in the presence of SbF_5. With a catalytic amount of SbF_5, perfluoro-1,4-cyclohexadiene disproportionates to hexafluorobenzene and perfluorocyclohexene. The disproportionation proceeds intramolecularly in the case of perfluoro-1,4,5,8-tetrahydronaphthalene. The starting material is completely converted to perfluorotetralin (eq 21).[20f]

(20)

(21)

Like most Lewis acids, SbF_5 promotes the rearrangement of epoxides to carbonyl compounds,[21] and SbF_5 is an efficient catalyst for this reaction. However, the migratory aptitude of substitutent groups in the reaction under SbF_5 catalysis is much less selective compared to that promoted by weak Lewis acids such as ***Methylaluminum Bis(4-bromo-2,6-di-t-butylphenoxide)***.[21a] Nevertheless, SbF_5 is well suited for the rearrangement of perfluoroepoxides.[21b-e] Excellent yields of ketones are obtained from the reaction. When diepoxides are used, diketones are obtained as the reaction products (eq 22).[21c]

Fluorination and Transformation of Fluorinated Compounds.

SbF_5 is a strong fluorinating agent. However, its use is largely limited to the preparation of perfluoro- or polyfluoroorganic compounds.[22] SbF_5 has also been used for transformation of perfluoro compounds.[22]

When hexachlorobenzene is subjected to SbF_5 treatment, 44% of 1,2-dichloro-3,3,4,4,5,5,6,6-octafluorocyclohex-1-ene is obtained as the major product of the reaction (eq 23).[23] Using $SbCl_5$ as reaction solvent leads to better reaction control, resulting in an increase in the product yield.[23c] In the case of polyfluoronaphthalenes, polyfluorinated tetralins are obtained.[23d] Treatment of hexafluoro-2-trichloromethyl-2-propanol with SbF_5 gives perfluoro-*t*-butyl alcohol in 92% yield (eq 24).[24]

Hydrolysis of CF_3 groups to CO_2H can be induced by SbF_5.[25a] In this reaction, the CF_3-bearing compounds are first treated with SbF_5 and the resulting reaction mixtures are subsequently quenched with water to form the desired products. For example, perfluorotoluene was converted to pentafluorobenzoic acid in 86% yield by this procedure.

When perfluoroxylenes and perfluoromesitylene go through the same treatment, the corresponding di- or triacids are obtained in high yields. It is also possible to partially hydrolyze perfluoroxylenes and perfluoromesitylene through a stepwise procedure and to isolate intermediate products. The hydrolysis procedure is also applicable to other halogen-containing compounds.[25b]

Under SbF_5 catalysis, ***Trifluoromethanesulfonic Anhydride*** is readily decomposed to trifluoromethyl triflate in high yield (eq 25).[26] This method is the most convenient procedure reported for preparation of the triflate.

$$(CF_3SO_2)_2O \xrightarrow[94\%]{SbF_5,\ 25\ ^\circ C} CF_3SO_3CF_3 \qquad (25)$$

Preparation of Carbocations, Onium Ions, and Their Salts.

SbF_5 is a preferred medium for the preparation of carbocations and onium ions.[1] In fact, the first observation of stable carbocations was achieved in this medium.[1,27] By dissolving *t*-butyl fluoride in an excess of SbF_5, the *t*-butyl cation was obtained (eq 26). Subsequently, many alkyl cations have been obtained in SbF_5 (either neat or diluted with SO_2, SO_2ClF, or SO_2F_2). The 2-norbornyl cation, one of the most controversial ions in the history of physical organic chemistry,[28] was prepared from *exo*-2-fluoronorbornane in SbF_5/SO_2 (or SO_2ClF) solution (eq 27).[1] Bridgehead cations such as 1-adamantyl, 1-trishomobarrelyl, and 1-trishomobullvalyl cations have also been similarly prepared with the use of SbF_5.[15a,29]

(26)

(27)

Carbodications have also been studied.[1] One convenient way of preparing alkyl dications is to ionize dihalides with SbF_5 in SO_2ClF (eq 28). In these systems, separation of the two cation centers by at least two methylene groups is necessary for the ions to be observable.[1] Aromatic dications are usually prepared by oxidizing the corresponding aromatic compounds with SbF_5 (eq 29).[1,30] In the case of pagodane containing a planar cyclobutane ring, oxidation leads to the formation of cyclobutane dication which was characterized as a frozen two-electron Woodward-Hoffmann transition state model (eq 30).[31]

(28)

(29)

(30)

SbF_5 has also been found useful in the preparation of homoaromatic cations.[1,32] For example, the simplest 2π monohomoaromatic cations, the homocyclopropenyl cations, can be prepared from corresponding 3-halocyclobutenes in SbF_5 (eq 31).[32a]

(31)

Perfluorocarbocations are generally prepared with the aid of SbF_5.[33] Perfluorobenzyl cations and perfluorinated allyl cations are among the most well studied perfluorinated carbocations. It was reported that in the perfluoroallyl cations containing a pentafluorophenyl group at the 1- or 2-position, the phenyl groups were partially removed from the plane of the allyl triad (eq 32).[33b]

(32)

Use of SbF_5 as ionizing agent offers a convenient route to acyclic and cyclic halonium ions from alkyl halides.[1] Three-membered ring cyclic halonium ions are important intermediates in the electrophilic halogenations of carbon-carbon double bonds.[1] More recently, a stable 1,4-bridged bicyclic bromonium ion, 7-bromoniabicyclo[2.2.1]heptane, has been prepared through the use of SbF_5 involving an unprecedented transannular participation in a six-membered ring (eq 33).[34]

(33)

Other Reactions.

Reaction of α,β-unsaturated carbonyl compounds with diazo compounds generally gives low yields of cyclopropyl compounds. The rapid formation of 1-pyrazolines and their subsequent rearrangement products 2-pyrazolines is the reason for the inefficiency of cyclopropanation of these substrates. However, in the presense of SbF_5, the cyclopropanation of α,β-unsaturated carbonyl compounds with diazocarbonyl compounds proceeds very well to produce the desired products in good yields (eq 34).[35]

Arsenic(III) Fluoride[1]

AsF_3

[7784-35-2] · AsF_3 · Arsenic(III) Fluoride · (MW 131.92)

(arsenating agent;[2] fluorinating agent[3])

Alternate Name: arsenic trifluoride.

Physical Data: mp -5.95 °C (-8.5 °C); bp 57.8 °C (63 °C); d^{15} 2.73 g cm^{-3}.

Solubility: sol ether, THF, C_6H_6, hydrocarbons, alcohols; hydrolyzes in H_2O.

Form Supplied in: colorless, mobile liquid; commercially available.

Analysis of Reagent Purity: ^{19}F NMR, Raman spectrum.[4]

Preparative Methods: several methods exist for the preparation of arsenic trifluoride.[5]

Purification: the reagent can be purified by distillation at atmospheric pressure in an all-glass or iron system.[5]

Handling, Storage, and Precautions: when heated, AsF_3 decomposes to highly toxic fumes containing As^0.[6] Additionally, it will fume in air and is readily hydrolyzed. Contact with skin results in burns similar to those caused by HF.[5a] Since AsF_3 reacts with glass over time, it should be stored in polyethylene or iron containers.[5] This reagent should be handled in a fume hood.

Use as an Arsenating Agent.

Arsenic trifluoride has seen its most extensive use in organic chemistry as an arsenating agent. Usually, the fluoride ligands are exchanged with another ligand such as an amine (eq 1).[7] Cyclic arsenic compounds can be synthesized in moderate to good yields by using bidentate ligands (eq 2).[2a,8]

$$AsF_3 + 2RNH_2 \xrightarrow[0\ ^{o}C\ to\ rt]{toluene} RNHAsF_4 + RNH_2HF \xrightarrow{-HF} RN{=}AsF \quad (1)$$

R = Et (60%), *i*-Pr (63%), *t*-Bu (67%)

R = -$(CH_2)_2$-, -$(CH_2)_3$-, -$(CH_2)_4$-,

Some advantage has been taken of the strength of the silicon-fluorine bond in these exchange reactions (eqs 3 and 4).[2b,9] Not surprisingly, the product cyclopentadienylarsenic difluoride (eq 4) is unstable and polymerizes upon distillation at 30 °C.[9]

$$3\ t\text{-BuSSiMe}_3 \xrightarrow[-196\ ^{o}C\ to\ rt]{AsF_3,} As(S\text{-}t\text{-Bu})_3 \quad (3)$$

(quantitative)

(not isolated)

There is some indication that AsF_3 is less reactive with organic compounds than $AsCl_3$ and the higher homologs (eq 5).[2c,10] Usefully, organoarsenic mono-[11] and difluorides[2c] can be converted to the arsenic hydrides by reaction with

Lithium Aluminum Hydride (eq 6).[11]

(5)

(6)

Importantly, AsF_3 can be added across alkenes in the presence of ***Antimony(V) Fluoride*** (eqs 7 and 8).[12,13] Although stoichiometrically the AsF_3 seems to simply add to the alkene, it is more likely that the reactive species is AsF_2^+SbF-6 in these transformations.[12]

$$AsF_3 + SbF_5 + F_2C{=}CF_2 \xrightarrow[12\ h]{rt} \underset{42\%}{(C_2F_5)_2AsF} + \underset{26\%}{(C_2F_5)_3As} \quad (7)$$

$$AsF_3 + SbF_5 + F_2C{=}CFCl \xrightarrow[6\ h]{rt} \underset{58\%}{(CF_3CFCl)_2AsF} + \underset{14\%}{(CF_3CFCl)_2AsCl} \quad (8)$$

Use as a Fluorinating Agent.

Although milder than SbF_3, AsF_3 can also be used as fluorinating agent. Typically, a ligand exchange reaction occurs in which the fluoride ligands are exchanged for other ligands such as another halide (eq 9).[3,14]

(9)

Fluck et al. have used AsF_3 in several exchange reactions with Et_2N ligands on trivalent phosphorus to generate phosphorus-fluorine bonds (eqs 10 and 11).[15,16]

L-Aspartic Acid[1]

(L)

[56-84-8] · $C_4H_7NO_4$ · L-Aspartic Acid · (MW 133.10) (D)

[1783-96-6] (DL)

[617-45-8]

(chiral reagent used in diastereoselective alkylations[2] and as a ligand for $LiAlH_4$ in asymmetric reductions[3] of enones)

Physical Data: (*S*)-(+),[4a] [α]20D +25°, mp >300 °C (dec.); (*R*)-(-),[4a] [α]20D -24°, mp >300 °C; (±) mp 325-348 °C (dec.).

Solubility: sol in acid and alkali; sol water (1 g/222.2 mL at 20 °C), forming supersaturated solutions easily; insol alcohol.

Form Supplied in: commercially available as a white solid in racemic and optically pure forms.[4]

Diastereoselective Alkylations.

Esters derived from L-aspartic acid have been alkylated at both the α- and β-positions (eq 1).[1,2] β-Alkylations have been more widely used. The amino acid moiety is responsible for the diastereoselection in the β-alkylation process.

Alkylation of cyclic derivatives of L-aspartic acid (**1**) occurs exclusively at the β-position with good to excellent diastereoselection. One application is the synthesis of chiral β-dicarbonyl equivalents.[5] Equivalents of either enantiomer can be prepared depending on whether the alkylation is performed on a lactone (eq 2) or an oxazoline (eq 3).

The most commonly used cyclic derivatives of L-aspartic acid are β-lactams (eq 4).[6] For example, excellent regioselectivity and diastereoselectivity are observed in the alkylation of the dianion of (**3**). Other compounds related to (**3**) have been prepared from L-aspartic acid[7] and used in highly diastereoselective alkylations en route to a variety of natural and nonnatural products[8] including β-lactams,[9] γ-lactams,[10] and dihydroisocoumarin derivatives.[11]

Asymmetric Reductions.

Asymmetric reductions of prochiral ketones to optically active secondary alcohols have been extensively studied.[3] The most common method involves the use of chiral unidentate or bidentate ligands in conjunction with ***Lithium Aluminum Hydride***. However, an (*S*)-aspartic acid derived tridentate ligand has been shown to be very effective in certain cases, presumably due to the rigidity of aluminum complex (**4**) (eqs 5-7).[12]

Unfortunately, the complete enantiofacial differentiation of cyclohexenone (eq 7) appears to be an isolated case, as reaction with 3-methylcyclohexenone afforded the corresponding (*S*)-cyclohexanol in only 28% ee. In the absence of a general trend for the outcome of these reductions, the scope of this method seems limited at this point, as opposed to (*S*)-BINAL-H mediated reductions (see ***Lithium Aluminum Hydride*** and subsequent articles).

2-Azabicyclo[2.2.1]hept-5-en-3-one

(1*R*,4*S*)-(-)-(**1**)

[49805-30-3] · C_6H_7NO · 2-Azabicyclo[2.2.1]hept-5-en-3-one · (MW 109.13) (±)

[61865-48-3] (1*R*)

[79200-56-9] (1*S*)

[130931-83-8]

(building block for the synthesis of carbocyclic nucleosides, GABA inhibitors, etc.)

Physical Data: mp 55-57 °C; bp 102-106 °C/0.25 mmHg.

Solubility: sol H_2O, MeOH, CH_2Cl_2.

Form Supplied in: off-white solid.

Preparative Methods: from reaction of ***Cyclopentadiene*** with either sulfonyl cyanides[1,2] or ***Chlorosulfonyl Isocyanate***.[3] Both enantiomers can be obtained via enzymic kinetic resolution of the racemate.[4]

2-Azabicyclo[2.2.1]hept-5-en-3-one (**1**) has been used as a building block for the synthesis of an array of compounds with potential pharmacological applications. Either enantiomer of *cis*-3-aminocyclopentanecarboxylic acid (**2**) is accessible from a single enantiomer of (**1**) (eq 1). Compound (**2**) has been shown to act as an agonist at the γ-aminobutyric acid (GABA) receptor.[5]

(1)

The (1*R*,4*S*) enantiomer ((-)-**1**) has been used for the preparation of the carbocyclic nucleoside (-)-carbovir (**3**) (eq 2),[6] which has been shown to have similar activity against HIV (RF strain) as AZT (Zidovudine).

Treatment of (**1**) with ***Potassium Monoperoxysulfate*** (oxone) gave an 80% yield of the *exo*-epoxide (**4**) (eq 3), which is of potential use for the preparation of carbocyclic analogs of 2´-or 3´-deoxyribofuranosylamines.

Azidation Polymer[1]

$$\mathbf{P}\text{-}NR_3^+\ N_3^-$$

(used for nucleophilic substitution of azide for halide or sulfonate;[1-6] for introduction of the azide function[1-6])

Physical Data: polymeric resin in form of beads.[2]

Solubility: insol organic solvents, water.

Form Supplied in: available as azide exchange resin, containing ~3.8 mequiv azide ions per gram of resin.

Preparative Methods: the azidation polymer is prepared[2] from Amberlite IR-400 Cl-ion exchange resin (a quaternary ammonium chloride), which is prewashed first with 1.5 times its volume of warm DMF, twice with MeOH, and finally with water. Then the resin is converted into the azide form by washing with twice its volume of 20% aq sodium azide, followed by three washings with deionized water until the eluents give no precipitate with $AgNO_3$ (eq 1). To remove adhered water (which may lead to alcohol product), the resin is washed three times each with 30% MeOH, 60% MeOH, MeOH, 50% MeOH-ether, and ether (or another organic solvent to be used in the nucleophilic substitution reaction). The resin is dried at rt in vacuum and contains ~2.55 mmol azide ions per gram of polymer.

$$\underset{\text{(Amberlite IR-400)}}{\mathbf{P}\text{-}NR_3^+\ Cl^- + NaN_3} \longrightarrow \underset{\text{Azidation polymer}}{\mathbf{P}\text{-}NR_3^+\ N_3^-} \qquad (1)$$

Handling, Storage, and Precautions: the polymer can be stored for several months, preferably either wet with water or wet with the last washing solvent. It is stable to the hammer test and has a friction parameter of 14.4 kg. It should not be treated with acids because toxic HN_3 is formed. *Caution*: when CH_2Cl_2 is used as a solvent for the displacement reaction and the reaction is allowed to proceed for several days, explosive $CH_2(N_3)_2$ may be formed.[2] Handle reagent in a fume hood.

Synthesis of Alkyl Azides.

A typical procedure for nucleophilic displacement of alkyl halides or tosylates with azide ions:[1] to 4.9 g of azidation polymer (12.5 mmol of azide ions) was added 4 mL of CH_2Cl_2 (see above) or another solvent and 0.265 g (1.06 mmol) of *p*-bromobenzyl bromide. The reaction is followed for disappearance of starting benzyl bromide and after 2 h of mild shaking of the slurry in an horizontal cuvette the polymer is filtered and washed with CH_2Cl_2. Mechanical stirring of the

slurry of azidation polymer and substrate is not recommended because shearing of the polymer beads occurs. Evaporation of the combined solvents gave pure (by ^{1}H NMR) *p*-bromobenzyl azide as an oil in 93% yield.

The use of azidation polymer permits displacement of alkyl halides or tosylates by azide ions at room temperature in any organic solvent, usually within hours, as the reaction is followed to the disappearance of starting alkyl halide.[1] After filtration of the polymeric reagent, a solution of pure alkyl azide is obtained. Further purification is usually not necessary. Iodides are displaced faster than bromides, which react faster than tosylates; alkyl chlorides react slowest.[1] In polar solvents (MeCN, DMF) the displacement is faster than in less polar solvents ($CHCl_3$, ether) and secondary halides react slower than primary ones.[1] The more dilute the slurry, the slower the reaction. Even bromoform is converted at rt slowly (22 days for 50% conversion) to highly explosive triazidomethane.[2]

In MeCN, quantitative conversion of *n*-Bu-X to *n*-Bu-N_3 takes place at rt by means of the azidation polymer in the following approximate times:[1] *n*-Bu-I (1 h), *n*-Bu-Br (3 h), *n*-Bu-OTs (24 h), *n*-Bu-Cl (>7 d), Br-$(CH_2)_4$-Br (24 h).

Benzyl chloroformate is converted to benzyl azidoformate at rt.[1] Allyl azides can be prepared readily from allyl bromides using the reagent. For instance, 5-bromo-1,3-pentadiene is converted in 95% yield to 5-azido-1,3-pentadiene.[3]

(2)

o-Azido-4-methoxyacetophenone is obtained from the respective phenacyl bromide.[4] Anhydrothymidine after *N*-alkylation with ethyl triflate followed by reaction with the azidation reagent at 0 °C for 16 h gave the 4-azido- and 2-azidothymidine derivatives (eq 3).[5] 1,2-*cis*-Diols have been converted to 1,2-*cis*-azido alcohol benzoates via the *trans*-chlorohydrin benzoate.[6]

Azidoacetyl Chloride[1]

[30426-58-5] · $C_2H_2ClN_3O$ · Azidoacetyl Chloride · (MW 119.52)

(α-amino carbonyl equivalent suitable for the synthesis of amino azetidinones, has been widely used in the synthesis of β-lactam antibiotics;[1-3] can also be used to acylate a variety of nucleophiles to give amino acid derivatives[4,5])

Alternate Name: AAC.

Physical Data: bp 50 °C/20 mmHg.

Solubility: sol most chlorinated and nonchlorinated organic solvents.

Preparative Methods: prepared by azide displacement of halide from the corresponding haloacetic acid, followed by treatment with ***Thionyl Chloride***.[6,7]

Handling, Storage, and Precautions: α-azido carbonyls have been identified as explosives and, as such, should be treated with extreme caution.[7,8] Use in a fume hood.

β-Lactams.

The formation of azetidinones from the addition of acid chlorides or bromides to imines was reported by Staudinger in the early 1900s,[9] but this reaction attracted relatively little attention until it became associated with the synthesis of β-lactam antibiotics. The use of azidoacetyl chloride (AAC) to make amino azetidinones, first demonstrated in 1966 by Bose et al. (eq 1),[10] was rapidly adopted by a number of industrial groups as one step in the synthesis of commercially important β-lactams (eq 2).[11,12] The rapid development of bacterial resistance created a demand for new antibiotics and since these initial reports AAC has been shown to react with imidates,[13] imines,[14,15] acyclic[16,17] and cyclic thioimidates, and related systems to give naturally occurring, synthetic, bicyclic, and monocyclic β-lactams. The experimental procedure is very simple, involving treatment of the acid chloride and imine with ***Triethylamine*** at or below rt, and appears to have changed little from that originally reported.[10] Because of the danger associated with the preparation of AAC, other derivatives of azidoacetic acid suitable for [2 + 2] cycloadditions have also been prepared.[18,19]

The relative stereochemistry about the C-3-C-4 bond of the azetidinone appears to depend both on the imine and the experimental procedure used. Predominantly or exclusively *trans* adducts are observed from additions to thioformimidates,[20] thiazolines, or thiazines (eq 3),[21,22] and the active configuration of the β-lactam must be obtained via epimerization.[21,22] On the other hand, aldimines give *cis*-azetidinones as the major products.[14,23]

The mechanism of the reaction could involve either a simple [2 + 2] cycloaddition or an imine acylation followed by ring closure.[3,15,24] This is not well understood, and the mechanism may vary with individual examples.

1-Azido-3,3-dimethyl-1-butene[1]

[40168-86-3] · $C_6H_{11}N_3$ · 1-Azido-3,3-dimethyl-1-butene · (MW 125.174)

(used in amination of aromatic and heterocyclic compounds via their lithium derivatives;[2] reaction with alkyllithium compounds leads to alkylated ketones;[3] reaction with sulfoxonium ylides leads to *N*-vinyltriazolines and *N*-vinylaziridines;[4] formation of azirines by thermolysis or photolysis[5])

Solubility: sol most organic solvents.

Form Supplied in: liquid;[6] not available commercially.

Preparative Methods: vinyl azides are prepared in good yield from alkenes by regioselective addition of ***Iodine Azide*** (eq 1) followed by elimination of HI with a base such as ***Potassium t-Butoxide*** or ***1,4-Diazabicyclo[2.2.2]octane***.[6]

Handling, Storage, and Precautions: decomposes on standing; should be handled with care like other azides because of the possibility of explosion.

Amination of Aromatics (NH_2 Transfer).

The reaction of vinyl azides with organolithium or Grignard reagents (RLi or RMgX) proceeds at the *N*-terminal of the azide function to produce an intermediate vinyltriazene, which is usually not isolated but is transformed on workup with dilute acid to an amine when R is aromatic (eq 2). The yield of aminated product is usually only 50-70%, but is the only acid-extractable product; the vinyldiazonium ion byproduct in this reaction is hydrolyzed to an aldehyde or ketone.

While 1-azido-3,3-dimethyl-1-butene often gives better yields, α-azidostyrene and other vinyl azides may also be used (eqs 3 and 4). Theoretically, the reaction of aromatic lithio or Grignard derivatives with any organic azide could lead to NH_2 transfer, but in practice vinyl azides, in particular 1-azido-3,3-dimethyl-1-butene and phenylthiomethyl azide,[7] are reagents of choice.

1,3-Dimethoxybenzene (1.5 g, 11 mmol) is transformed into its 2-lithio derivative by treatment with 1 equiv of ***n-Butyllithium*** in THF at 0 °C for 18 h at rt. Azidostyrene is added at -78 °C and after 2 h at rt the mixture is worked up with 10% HCl and then with KOH to obtain the 2,6-dimethoxyaniline.

Formation of Ketones with Alkyl Transfer.

Unlike the amination of ArLi by means of vinyl azides, the reaction of vinyl azides, including 1-azido-3,3-dimethyl-1-butene, with simple aliphatic RLi compounds leads to alkylated ketones (eq 5).[3] In this case, acid-catalyzed decomposition of the vinyltriazene intermediate produces an alkanediazonium ion and an enamine, with subsequent transfer of the alkyl group to the enamine carbon.

Synthesis of Vinyl Heterocycles.

Reaction of vinyl azides, including 1-azido-3,3-dimethyl-1-butene, with trimethylsulfoxonium ylide leads to *N*-vinyltriazolines. The latter on flash vacuum pyrolysis at ca. 250 °C are transformed into *N*-vinylaziridines in over 90% yield (eq 6).

Formation of Azirines.

In general, vinyl azides are excellent starting materials for azirines via thermolysis or photolysis (eq 7). In the case of terminal vinyl azides, such as 1-azido-3,3-dimethyl-1-butene, heating leads to polymers or nitriles.[5]

Azidomethyl Phenyl Sulfide

[77422-70-9] · $C_7H_7N_3S$ · Azidomethyl Phenyl Sulfide · (MW 165.22)

(reagent for amination of organomagnesium compounds;[1] allows amination and oxidation of α,α-disubstituted ester enolates via 1,2,3-triazol-5-ones;[1b] a synthetic equivalent of methyl azide for the synthesis of methylaziridines;[2] substituted α-azido sulfides undergo Beckmann-type rearrangements to provide lactams and imino thioethers[3,4])

Physical Data: bp 104-105 °C/5 mmHg; *n*20D 1.5904; *d* 1.168 g cm^{-3}; fp 107 °C.

Solubility: freely sol common organic solvents.

Form Supplied in: colorless to light-gold liquid, ~95% pure.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Method: chlorination of ***Thioanisole*** with ***Sulfuryl Chloride*** followed by treatment of the resultant α-chloro sulfide with ***Sodium Azide*** in acetonitrile.[1a]

Handling, Storage, and Precautions: as with all azides of low or moderate molecular weight, heat or shock can cause vigorous, possibly explosive, nitrogen evolution. Distillation should be performed behind a blast shield at reduced pressure and temperatures less than 110 °C. Similar compounds have been shown to decompose with nitrogen evolution at ~120 °C.[5] Striking neat azidomethyl phenyl sulfide with a hammer fails to cause detonation. Storage under nitrogen in an amber bottle in a refrigerator is recommended. It is incompatible with strong acids, bases, and oxidizing agents. When the reagent is used for the amination of organomagnesium reagents, an intermediate triazene is formed. Certain triazenes are known to be carcinogenic,[6] thus caution in handling these intermediates should be exercised. Rinsing glassware with bleach will dispel the disagreeable odor associated with azidomethyl phenyl sulfide, phenylthiomethyltriazenes, and other sulfur-containing byproducts encountered in the use of this reagent. Handle in a fumehood.

Amination of Organomagnesium Reagents.

Treatment of azidomethyl phenyl sulfide with aryl organomagnesium reagents followed by aqueous workup results in the formation of triazenes. These may be converted to anilines by the action of aqueous ***Potassium Hydroxide*** or

aqueous ***Formic Acid*** (eq 1).[1a,c] Transmetalation of aryllithium compounds to organomagnesium compounds with ***Magnesium Bromide*** etherate is required, since the former are unsuitable for this transformation. The phenylthio group appears to accelerate the reaction with the organomagnesium reagent relative to other substituents.[1b] Aliphatic organomagnesium reagents may also be aminated, but acylation of the intermediate magnesiotriazene at low temperature is required prior to cleavage, resulting in the amidated product (eq 2).[1b] A variety of primary and secondary organomagnesium reagents have been amidated, and several different acylating agents have been used.[1b]

The phenylthio group allows regiocontrol in the acylation and subsequent cleavage reaction. Other reagents for

amination of organomagnesium and organolithium reagents have been published, each with its own advantages and limitations.[7] Some representative reagents are $MeONH_2$/MeLi,[8] $ArONH_2$,[9] $(PhO)_2P(O)ONH_2$,[10] $(PhO)_2P(O)N_3$,[11] $ArSO_2N_3$,[12] $Me_3SiCH_2N_3$,[13] vinyl azides,[14] and oxime derivatives.[15] Amidation with TsON(Li)Boc has been accomplished.[16] Introduction of alkylamino, arylamino, or dialkylamino groups by the amination approach has also been studied.[17]

Amination of Ester Enolates.

Lithium ester enolates react with azidomethyl phenyl sulfide to give 3,5-dihydro-4*H*-1,2,3-triazol-5-ones, which may be converted to α-amino amides with aqueous ***Ammonia*** (eq 3).[1b] The ester enolate must be α,α-disubstituted to avoid aromatization of the triazolone. Treatment of the triazolones with methanolic ***Magnesium Methoxide*** results in the formation of α-methoxy amides.[1b] Other azides have been used to prepare triazolones, which undergo similar solvolysis reactions.[18] Other reagents for the amination of enolates have been examined,[7] including BocN=NBoc[19] and trisyl azide.[20]

Dipolar Cycloadditions.

A common strategy for the synthesis of aziridines is the dipolar cycloaddition of azides with alkenes followed by thermal or photochemical decomposition of the resultant triazolines. The synthesis of methylaziridines by this approach would require the hazardous compound methyl azide. Azidomethyl phenyl sulfide is a safer synthetic equivalent of methyl azide, since the phenylthio group can be removed by desulfurization (eq 4).[2]

(4)

Rearrangement of α-Azido Sulfides.

An alternative to the Beckmann rearrangement has been developed involving the protic or Lewis acid promoted rearrangement of α-azido sulfides (eq 5).[3,4] Either lactams or imino thioethers may be formed. The thermal-[5] and base-promoted[21] rearrangement of α-azido sulfides has also been studied (eq 6).[5]

Azidotrimethylsilane[1]

Me_3SiN_3

[4648-54-8] · $C_3H_9N_3Si$ · Azidotrimethylsilane · (MW 115.21)

(azidation of organic halides, acetals, and esters; α- and β-siloxy azides from carbonyl compounds and epoxides; preparation of heterocyclic compounds; effective substitute for hydrazoic acid)

Alternate Names: trimethylsilyl azide; TMSA.

Physical Data: bp 95-96 °C; *n*20D 1.416; *d* 0.868 g cm^{-3}; fp 23 °C; IR ν_{max} 2100 cm^{-1}; ^1H NMR ($CDCl_3$) δ = 0.22.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid.

Preparative Methods: several methods for the synthesis of this azide have been reported.[1] The procedure involving aluminum chloride is not recommended, since an explosive product is formed.[2] Azidotrimethylsilane is now commercially available, and a representative synthetic procedure is as follows. A mixture of ***Sodium Azide*** and ***Chlorotrimethylsilane*** is refluxed in di-*n*-butyl ether for 2 days and the azide is safely distilled directly from the reaction vessel. Purer compound (99% content) is obtained by redistillation of the product.

Handling, Storage, and Precautions: the azide, which decomposes at 500 °C,[1b] is more stable thermally than most organic azides and can be stored in a refrigerator for more than one year. It is moisture sensitive, and should be handled with care since it reacts rapidly with water to release toxic hydrazoic acid. Handle in a fume hood.

Many applications of TMSA in organic synthesis have been reported but only representative examples are described herein.

Substitution Reactions.

Benzyl, allyl, and substituted alkyl halides are converted to the corresponding azides in 60-100% yields via reactions with TMSA under neutral conditions in a nonaqueous solvent (eq 1).[3] By using ***Tin(IV) Chloride*** as a catalyst, secondary and tertiary cyclic and polycyclic halides are similarly transformed into the corresponding azides in 50-92%

yields (eq 1).[4]

$$Me_3SiN_3 + RX \longrightarrow RN_3 + Me_3SiX \qquad (1)$$

R = $ArCH_2$, $CH_2CH{=}CH_2$, CH_2CN, CH_2CO_2Et, *c*-C_5H_9, *c*-C_6H_{11}, 1-, 2-, 3-, and 4-adamantyl
X = Cl, Br

Acyl halides react with TMSA to give trimethylsilyl halides and the corresponding isocyanates in a range of 83-98% yields, which are rearranged from the acyl azides via the Curtius degradation (eq 2).[5] However, a reaction of aroyl chlorides with TMSA in the presence of ***Zinc Iodide*** at 0 °C gives the corresponding azides in 85-96% yields (eq 3).[6]

$$Me_3SiN_3 + RCOX \longrightarrow RN{=}C{=}O + Me_3SiX \qquad (2)$$

R = *c*-C_6H_{11}, Ph, *p*-MeC_6H_4, $CH_2{=}CH(CH_2)_8$-, $MeOCOCH_2CH_2$, phthaloyl, etc.

$$Me_3SiN_3 + ArCOX \xrightarrow[0\ °C]{ZnI_2} ArCON_3 + Me_3SiX \qquad (3)$$

The azide reacts with orthoesters at reflux temperature and acetals in the presence of $SnCl_4$ at -78 °C to give the corresponding azides in 40-70% yields (eq 4).[7]

X = alkyl, aryl, alkoxy

α-Siloxy Azides.

TMSA reacts with carbonyl compounds to give α-siloxy azides in the presence of ***Zinc Chloride*** or ***Tin(II) Chloride***. With aldehydes, α-siloxy azides are obtained in 70-80% yields,[8,9] but the yields of these compounds are very low with most ketones.[9] Carbonyl compounds including ketones are stepwisely or directly converted into *gem*-diazides (30-80%), tetrazoles (40-100%), and nitriles (60-100%), depending on the reaction conditions.[9] The reaction sequences are summarized in Scheme 1.

Scheme 1

β-Siloxy Azides.

The azide reacts with epoxides in the presence of zinc chloride,[8b] titanium and vanadium complexes,[10] zinc tartrate,[11] and ***Aluminum Isopropoxide***[12] to give β-siloxy azides in 80-100% yields (eq 5), which are precursors of β-amino alcohols. With cyclohexene oxide, the *trans* isomer is formed exclusively, regardless of the catalyst used.[8b,10] However, the regio- and chemoselectivity of the reactions of other epoxides depend upon the catalyst.[10-12]

R = Me, R' = H; R = CH_2=CH$(CH_2)_2$, R' = H;
R, R' = -$(CH_2)_n$- (n = 3-5); etc.

Application of this procedure for the regio- and stereoselective synthesis of vinyl azides in the presence of ***Boron Trifluoride Etherate*** complex is summarized in eq 6.[13]

o-Siloxy Isocyanates.

Acyclic anhydrides react with TMSA in a manner similar to acid halides to give equal amounts of trimethylsilyl esters and isocyanates (eq 7).[5b,14] Similarly, cyclic anhydrides react with the azide to give o-trimethylsiloxycarbonyl alk(en)yl isocyanates (eq 8)[14a,15] which are further transformed into 1,3-oxazine-2,6-dione derivatives (70-90%).[14b]

[3 + 2] Cycloaddition.

TMSA, like other alkyl azides, reacts with alkynes and C-hetero multiple bonds to give [3 + 2] cycloaddition products, triazoles and tetrazoles.[1] For example, the reaction of TMSA with 2-butyne gives 4,5-dimethyl-2-trimethylsilyl-1,2,3-triazole in 78-87% yields (eq 9),[16] and TMSA and cyanoferrocene react to give 5-ferrocenyl-2-trimethylsilyltetrazole in 75% yield (eq 10).[17]

(9)

(10)

Fc = ferrocenyl

Lead and Phenyliodoso Azides.

When ***Lead(IV) Acetate*** and phenyliodoso derivatives are used as a catalyst for azidation of alkenic and aromatic compounds (eq 11),[1,18] lead azides and phenyliodoso azides are formed as intermediates.

(11)

Miscellaneous.

A combination of the azide and triflic acid is a highly efficient electrophilic aromatic amination reagent system.[19]

Related Reagents.

Azidotris(dimethylamino)phosphonium Hexafluorophosphate

[50281-51-1] · $C_6H_{18}F_6N_6P_2$ · Azidotris(dimethylamino)phosphonium Hexafluorophosphate · (MW 350.19)

(coupling reagent for amides and peptide synthesis via an acyl azide;[1] in the absence of a nucleophile undergoes a Curtius rearrangement to give the corresponding isocyanate;[1,2] by irradiation gives the iminophosphonium salt;[3,4] diazo transfer reagent[5])

Physical Data: mp >250 °C; IR, $\nu(N_3)$ 2176 cm^{-1}.

Solubility: sol acetone, acetonitrile, DMF.

Form Supplied in: crystalline colorless solid; not available from commercial sources.

Preparative Methods: ***Bromine*** (1 equiv) is added dropwise to ***Hexamethylphosphorous Triamide*** (1 equiv) in dry diethyl ether. After the addition is complete, ***Potassium Hexafluorophosphate*** (1 equiv), dissolved in H_2O is added, and the solid formed is filtered and washed with H_2O. After drying under vacuum, the solid is dissolved in acetone and ***Sodium Azide*** (1.5 equiv) is added. The mixture is stirred overnight at 25 °C, then the sodium bromide formed and the excess of sodium azide is filtered off and the solvent is removed under vacuum.

Purification: by crystallization in a mixture of acetone and diethyl ether.

Handling, Storage, and Precautions: is very stable, not hygroscopic, and can be stored indefinitely under vacuum. The related bromine derivative is an exceptionally safe azide, that does not detonate by shock, friction, rapid heating, or even flame.[5] When used in combination with carboxylic acids, the potential carcinogenic ***Hexamethylphosphoric Triamide*** is a side-product and the reagent must be handled with caution.[6]

Coupling Reagent.

Azidotris(dimethylamino)phosphonium hexafluorophosphate has been used as a condensing reagent for the preparation of peptides.[1] Reaction of α-amino protected amino acids or dipeptides with equimolar amounts of α-

carboxyl protected amino acids or dipeptides and ***Triethylamine*** (2 equiv) in DMF proceed cleanly overnight at -10 to 0 °C, giving the corresponding peptides in good yields (81-97%) (eq 1). Neither acylation of the hydroxy group of serine nor dehydration of the side chain of asparagine is reported during the coupling.[1]

Racemization from azidotris(dimethylamino)phosphonium hexafluorophosphate-mediated couplings is analyzed by different methods. While no racemization is detected by the Anderson[7] and Weinstein[8] methods, the Young[9] method gave some degree (3%) of racemization.

Although azidotris(dimethylamino)phosphonium hexafluorophosphate has not been used in solid-phase peptide synthesis,[10] other commercial phosphonium salt derivatives such as ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (BOP),[11] benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP),[12] or bromotris(pyrrolidino)phosphonium hexafluorophosphate (PyBroP)[13] are commonly used in that strategy.

Isocyanate Formation.

The coupling reaction described above occurs via an acyl azide intermediate, which at 50 °C suffers a Curtius rearrangement to give an isocyanate (eq 2),[1] which can further react with amines to give the corresponding ureas.

Iminophosphonium Salt Formation.

Irradiation of azidotris(dimethylamino)phosphonium hexafluorophosphate in acetonitrile at 254 nm using a Rayonnet

photochemical reactor for 15 h at 25 °C gives the iminophosphonium salt with release of nitrogen (eq 3). This is the first example reported of a Curtius-type rearrangement involving a charged atom.[3,4]

(3)

Diazo Transfer Reagent.

The related compound azidotris(diethylamino)phosphonium bromide has been used for the preparation of diazo products.[5] Active methylene compounds react with azidotris(diethylamino)phosphonium bromide in dry diethyl ether in the presence of only catalytic amounts of base, such as ***Potassium t-Butoxide*** or other alkoxide, yielding the corresponding diazo products in good yields (70-78%) (eq 4).

Aziridine-2-carboxylic Acid[1]

[54080-06-7] · $C_3H_5NO_2$ · Aziridine-2-carboxylic Acid · (MW 87.08)

(building block for chiral amino acids;[2] can be used for synthesis of heterocycles[3])

Physical Data: Li salt: mp 260-268 °C; methyl ester: bp 68 °C/11 mmHg; *n*20D 1.440; nitrile: bp 38 °C/0.1 mmHg; *n*20D 1.475; amide: mp 132-133 °C.

Solubility: esters and nitrile miscible with H_2O, and virtually all organic solvents. Amide and metal salts are soluble in H_2O, lower alcohols, DMF, DMSO.

Form Supplied in: (*S*)-form of Li salt as white solid.

Handling, Storage, and Precautions: free acid is not available, because of its low stability. The only stable aziridinecarboxylic acid is crystalline 3,3-dimethylaziridine-2-carboxylic acid.[4] Salts, esters, and amides are stable.

Synthesis of Derivatives of Aziridine-2-Carboxylic Acids.

Racemic salts, esters, nitriles, and amides are prepared by modified Gabriel synthesis from the reaction of ammonia with vicinal dihalocarboxylic acids.[5] Better yields were obtained by cyclization of β-hydrazinium propionates with base (eq 1).[6]

(1)

Various substituted aziridine-2-carboxylic acids have been prepared from the corresponding azirines with nucleophiles.[7] This method is limited because optically pure aziridines and aziridinecarboxylic acids are not easily

obtained. Amination of electron deficient alkenes with 3,3-pentamethyleneoxaziridine,[8] diphenyl sulfimide,[9] and ***O-(Mesitylsulfonyl)hydroxylamine***[10] yields aziridinemono- and dicarboxylic acids. Aziridinecarboxylic acids can be prepared from serine esters,[11a] but not from threonine esters,[11b] using diethoxytriphenylphosphorane. All these methods give racemic aziridines. However, recent investigations have led to chiral aziridines via chiral oxirane-2-carboxylic esters (eq 2),[12a,b] chiral cyclic sulfamidates (eq 3),[11b] D-ribose and D-lyxose,[12c] or functional group transformations of chiral aziridines.[13] High *cis* stereoselectivity is observed when *N*-trimethylsilylimines react with Li enolates of α-halo esters (eq 4).[14a] Complete control of enantioselectivity can be achieved by proper choice of the metal enolate (eq 5).[14b]

Met = Li, THF, -78 to -50 °C, 35%, 100:0

Met = Li, THF, -78 to -50 °C, 35%, 100:0
Met = Zn, THF, -78 °C to rt, 59%, 0:100

Ring Cleavage of Aziridines.

Aziridinecarboxylic acids are important building blocks in peptide chemistry.[15] They are easily incorporated using serine or threonine derivatives. Convenient syntheses of actinomycin D,[15b] dehydroamino acid containing peptides,[15c] and phosphopeptides have been achieved.[15d] Thiobenzoic acid has been utilized for the cleavage of the aziridine ring to prepare commercially expensive D-cysteine derivatives (eq 6).[16]

The reaction of aziridinecarboxylic acids with HCl[2,5a,d] or HF[17] usually gives mixtures of isomers, depending on the conditions used. Unsubstituted aziridinecarboxylic acid derivatives form regioisomeric mixtures with indole[18] and thiols,[19] with the predominant product arising from attack at C-2. ***Zinc Trifluoromethanesulfonate*** is the only Lewis acid of a large number examined that promotes the reaction of (2*R*)- or (2*S*)-aziridine-2-carboxylates with indoles to obtain optically pure tryptophans (eq 7),[20] albeit in only moderate yield. Only introduction of N-activating groups (acyl, alkoxycarbonyl, sulfonyl) make possible the S_N2-type ring-opening reactions with various nucleophiles.[2] Indole and ***Thiophenol*** lead to attack at C-3, but ***Azidotrimethylsilane*** leads to attack at C-2.

Ring opening of *N*-substituted aziridinecarboxylates with Wittig reagents[2c] (which provide stabilized phosphorus ylides) and organocuprate reagents[2] may be useful for the preparation of amino acids.

Other Reactions.

Activated aziridines react with acetonitrile in the presence of ***Boron Trifluoride Etherate*** leading to imidazolines (eq 8),[2] which yield α,β-diaminocarboxylic acids on standing. Various azabicyclic systems, 1,3-diazabicyclo-[3.1.0]hexan-4-ones, 1,3,4-triazabicyclo[4.1.0]heptan-5-ones (eqs 9 and 10),[3] and 1-azabicyclo[3.3.0]oct-3-enes (eq 11),[21] can be obtained from derivatives of aziridine-2-carboxylic acids.

(9)

(10)

(11)

The Michael addition of acetylenecarboxylates is stereospecific, leading to mostly (*E*) isomers.[22] *C*-Lithioaziridines, accessible by tin-lithium exchange, are converted to aziridinecarboxylic acid derivatives (eq 12).[23]

(12)

Derivatives of aziridinemono-[24] and dicarboxylic acids[25] are halogenated with strong Cl^+ donors like ***t-Butyl Hypochlorite***. The latter gives optically active *cis* and *trans* isomers. ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) was used for the dehydrohalogenation step to yield azirine-2-carboxylic acids in low to moderate yields. Other bases (pyridine, triethylamine, KO-*t*-Bu, NaOMe, etc) and halogens (bromo derivatives) did not alter these results.

Related Reagents.

Ethylenimine.

1,1´-Azobis-1-cyclohexanenitrile

[2094-98-6] · $C_{14}H_{20}N_4$ · 1,1´-Azobis-1-cyclohexanenitrile · (MW 244.34)

(thermally stable radical initiator[1])

Alternate Name: ACN.

Physical Data: mp 114-115 °C.

Solubility: sol benzene, toluene.

Form Supplied in: white solid; widely available commercially.

Purification: recrystallization from methanol.

Handling, Storage, and Precautions: stable indefinitely at rt but prolonged heating at temperatures greater than 80 °C results in rapid decomposition.

ACN has been used as a thermally stable radical initiator. The chair configuration of the cyclohexyl moiety has been given as the reason for its relative thermal stability as compared to other azo-bis(nitrile) derivatives.[1]

Thermal catalysis of ACN-initiated sulfonyl radical-induced addition-cyclization reactions of 1,6 dienes with ***p-Toluenesulfonyl Cyanide*** to give functionalized cyclopentane products as a mixture of stereoisomers in 57-72% yields (eq 1).[2] The *cis* isomer predominated and no cyclohexyl adducts were detected. Photochemically induced cyclization and thermal catalysis with ***Dibenzoyl Peroxide*** gave slightly better yields, with similar stereoselectivity.

(1)

cis:*trans* = 6.3:1

ACN has been used in the key radical cyclization-trapping step in a prostaglandin synthesis (eq 2).[3] Treatment of the iodoacetal and 4 equiv of the β-stannyl enone with ACN in refluxing toluene gives the bicyclic adduct in 72% purified yield. In contrast, the use of 0.1 equiv of ***Azobisisobutyronitrile*** (AIBN) in benzene at 65 °C as an initiator gives only trace amounts of the desired product. Heating at elevated temperatures with AIBN gives the desired adduct as a mixture of anomers in 43% yield after column chromatography.

(2)

ACN has been used for the radical addition of alkyl halides to Liebeskind's tri-*n*-butyltin cyclobutenedione reagent to prepare intermediates in the synthesis of the novel NMDA antagonist (eq 3).[4] Typically, 0.1 equiv of ACN is introduced every 12 h to 2 equiv of dione with various alkyl halides to give the addition product in 21-56% yield. Initiation with AIBN requires longer reaction times.

ACN has been used to introduce a tertiary carbon carrying an electronegative group into the 9-position of anthracene, which can lead to triptycene-type compounds in which the stable rotational isomers can be isolated at room temperature.[5]

Due to its high thermal stability, ACN has also been used in physical organic chemistry for kinetic investigations[1,6] and in polymer chemistry.[7]

Azobisisobutyronitrile

[78-67-1] · $C_8H_{12}N_4$ · Azobisisobutyronitrile · (MW 164.21)

(reagent for initiation of radical reactions)

Alternate Name: AIBN.

Physical Data: mp 103-104 °C.

Solubility: sol benzene, toluene.

Form Supplied in: commercially available as a white powder.

Preparative Method: prepared from the corresponding hydrazine by oxidation with nitrous acid.[1]

Purification: recrystallized from ether.

Handling, Storage, and Precautions: avoid exposure of the reagent to light and heat; store protected from light in a refrigerator or freezer. AIBN is harmful; old or incorrectly stored samples may also present an explosion risk.

Preparation.

Azobisisobutyronitrile (AIBN) and analogs can be prepared by a two-step procedure involving initial treatment of a ketone with ***Hydrazine*** in the presence of ***Sodium Cyanide***, followed by oxidation of the so-formed hydrazine (eq 1).[1,2]

(1)

Use in Radical Chemistry.

AIBN is the initiator most commonly employed in radical reactions, especially those using ***Tri-n-butylstannane***. At temperatures above about 60 °C, AIBN decomposes with evolution of nitrogen to generate isobutyronitrile radicals, which are able to initiate radical chemistry, usually by abstraction of a hydrogen atom from Bu_3SnH or some other donor. The useful working temperature range of AIBN is 60-120 °C, with the half-life at 80 °C being 1 h. In many applications involving C-C bond formation, the radical chemistry is designed to proceed by a chain reaction, and so only small amounts (typically ca. 0.1 equiv) of the initiator is required. For best results, especially at more elevated temperatures, AIBN is best added in portions or as a solution by means of a syringe pump. Typical Bu_3SnH-mediated radical reactions, which involve the use of AIBN as initiator, include cyclizations of alkyl and vinyl radicals (eqs 2 and 3).[3,4]

(2)

(3)

In eq 2, generation of an alkyl radical is achieved by attack of a tributylstannyl radical on a Barton derivative, whereas in eq 3, the vinyl radical required is generated by addition of the stannyl radical to an alkyne. This type of cyclization has been extended to many types of substrate, including those in which a carbonyl group acts as the acceptor (eq 4),[5] and those in which additional types of radical rearrangement or fragmentation occur (eq 5).[5,6] The latter sequence involves addition of the initially formed radical onto the adjacent carbonyl group, followed by reopening of the so-formed cyclopropanoxy radical in regioselective fashion.[6] The reaction effects a one-carbon ring expansion in good chemical yield.

(4)

(5)

AIBN can also be used in combination with many other types of radical-generating systems other than those employing Bu_3SnH. Examples include cyclizations using ***Tris(trimethylsilyl)silane***,[7] ***Thiophenol***,[8] ***Diphenylphosphine***,[9] and carbonylation of radicals using Ph_3GeH and CO under pressure[10] (eqs 6-9).

(6)

(7)

TMTHF = 2,2,5,5-tetramethyltetrahydrofuran

(8)

(9)

For certain types of radical reaction, AIBN may not always give optimal results. Keck and Burnett found in their synthesis of $PGF_{2\alpha}$ that the introduction of the lower side chain, involving radical addition onto a β-stannyl enone, was inefficient when AIBN was used as initiator at 65 °C. By conducting the reaction in refluxing toluene (110 °C), and replacing AIBN with the related ***1,1´-Azobis-1-cyclohexanenitrile*** (ACN), a markedly better yield of the desired adduct was obtained (eq 10).[11]

(10)

For reactions which require temperatures above benzene reflux, ACN, which decomposes markedly slower than AIBN, may be a generally useful alternative to AIBN, although this possibility has not been examined in detail. At elevated temperatures, other alternative initiators such as dialkyl peroxides and peresters should also be considered, although the reactivity of the radicals generated from these initiators is quite different to that of the isobutyronitrile radicals generated from AIBN.

1,1´-(Azodicarbonyl)dipiperidine

[10465-81-3] · $C_{12}H_{20}N_4O_2$ · 1,1´-(Azodicarbonyl)dipiperidine · (MW 252.32)

(selectively oxidizes a variety of alcohols to the corresponding aldehydes or ketones under basic conditions[1])

Physical Data: mp 134-135 °C.

Solubility: insol petroleum ether; slightly sol methanol; sol ethanol, ether, THF.

Form Supplied in: golden-yellow crystals.

Analysis of Reagent Purity: ^{1}H NMR (CCl_4) δ 1.47-1.88 (12H, br), 3.15-3.77 (8H, br); IR (KBr) 1705 cm^{-1}.

Purification: recrystallized from hexane-benzene (10:1).

Handling, Storage, and Precautions: irritant; stable to storage at room temperature.

Oxidation of Alcohols.

A wide variety of primary and secondary alcohols, after being converted into their bromomagnesium salts by treatment with a slight excess amount (1.2 equiv) of *n*-propylmagnesium bromide or ***t-Butoxymagnesium Bromide***, are oxidized with 1.2 equiv of 1,1´-(azodicarbonyl)-dipiperidine in THF at room temperature to afford the corresponding aldehydes or ketones in high yield (eq 1).[1]

The use of *t*-butoxymagnesium bromide is recommended for the oxidation of the substrates having functional groups which react with Grignard reagents. The oxidation of testosterone proceeds smoothly to give 4-androstene-3,17-dione in high yield by the use of *t*-butoxymagnesium bromide (eq 2).[1]

This method has been employed to oxidize a wide range of alcohols incorporating functional groups such as alkenes, epoxides, amines, sulfides (eq 3),[2] allylstannanes (eqs 4 and 5),[3,4] and allenylstannanes (eq 6).[5] Acylstannanes can also be prepared by the oxidation of the lithium salt of 1-stannyl alcohols (eq 7).[6]

Baker's Yeast

(microorganism used as biocatalyst for the reduction of carbonyl groups and double bonds,[1] either under fermenting conditions, immobilized, or ultrasonically stimulated)

Solubility: insol cold and warm H_2O; used as a slurry.

Form Supplied in: yellowish pressed cakes, commercially available as cubes from bakeries or supermarkets, usually produced by brewery companies.

Handling, Storage, and Precautions: the wet cake must be stored in the refrigerator (0-4 °C) and used within the date indicated by the manufacturer.

Baker's Yeast-Mediated Biotransformations.

Baker's yeast (BY, *Saccharomyces cerevisiae*) is readily available and inexpensive, and its use does not require any special training in microbiology. For these reasons, this biocatalyst has enjoyed a wide popularity among organic chemists, so that it can be considered as a microbial reagent for organic synthesis.[2] BY is generally used as whole cells, in spite of the problems connected with rates of penetration and diffusion of the substrates into, and the product from, the cells. However, the crude system is an inexpensive reservoir of cofactor-dependent enzymes such as oxidoreductases.[3] These benefits overcome the complication caused by undesired enzymatic reactions which lead to the formation of byproducts. Well-defined experimental procedures for BY-mediated bioreductions can be found in *Organic Syntheses*.[4] In the usual applications the biotransformations lead to optically active compounds with variable, but generally high, enantioselectivity.[5] The reaction is easily carried out in a heterogeneous medium containing a slurry of the yeast in tap water, in aerobic and fermenting conditions. Typically, the experimental conditions require a variable yeast:substrate ratio (1-40 g $mmol^{-1}$). The yeast is suspended in an aqueous solution of glucose or sucrose (0.1-0.3 M) to start the fermentation and to the fermenting yeast the substrate is added neat or in a suitable solvent, and therefore dispersed into the heterogeneous medium. The reaction is kept at 25-30 °C and, if necessary, additional fermenting BY can be added. At the end, the yeast is filtered off through Celite and the product extracted with organic solvents.

Carbonyl Group Reductions.

Early applications of BY date back to the end of the 19th century and the first examples are reductions of carbonyl compounds.[1c] The widespread applications of this biotransformation are based on some systematic investigations on various ketones[6] and the stereochemical outcome of the reaction is generally described by the so-called Prelog's rule[7] which successfully applies to a great number of structures (eq 1).

The structural variety of carbonyl compounds appears to be almost unlimited since aliphatic, aromatic, and cyclic ketones are good substrates for the bioreduction.[1,5] Also, organometallic carbonyl compounds such as $Cr(CO)_3$-complexed aromatic aldehydes (eq 2)[8] or ketones (eq 3)[9] are enantioselectively reduced by BY.

(2)

(3)

In general, the enantiomeric excess and the configuration of the optically active alcohols are strongly dependent on the structure of the starting carbonyl compound; many examples of diastereoselective reduction have also been reported.[10] The reduction of an epoxy ketone is accompanied by a stereocontrolled epoxide hydrolytic opening to afford a racemic triol, diastereomerically pure (eq 4).[11]

Many experimental procedures have been developed in order to influence the enantioselectivity and the stereochemistry of the products: use of organic media,[12] the addition of various compounds to the incubation mixture,[13] or enclosure in a dialysis tube[14] can be helpful. Immobilized BY can be used in water or in organic solvents for the same purpose.[15] Slight modifications of the substrate can obtain the same result and many examples are available.[16] Several other groups can be present in the carbonyl-containing substrate.[5] For instance, the asymmetric reduction of keto groups in compounds containing a cyclopropyl moiety has been achieved (eq 5).[17]

β-Keto esters are reduced to the corresponding hydroxy esters but, since more oxidoreductases are present in the yeast,[18] occasionally different stereochemistry or lowered enantioselectivity are observed. This is well illustrated by the stereochemical outcome of the reduction of a β-keto ester such as ethyl 4-chloroacetoacetate,[16b] when compared to ethyl acetoacetate (eq 6).[4a]

Both γ- and δ-keto acids are reduced to hydroxy acids, which directly cyclize to the corresponding lactones in the incubation media.[19] The pheromone (*R*)-(+)-hexadecanolide has been prepared in this way by reduction of the corresponding δ-keto acid (eq 7).[20]

(7)

α-Hydroxy ketones are good substrates for the bioreduction and several optically active 1,2-diols have been prepared.[21] The monobenzoate of dihydroxyacetone is reduced to the corresponding optically pure glycerol derivative (eq 8).[22] In many instances, simple protection of the α-hydroxy group may afford the opposite enantiomer.[23]

(8)

Activated Double-Bond Hydrogenation.

Fermenting BY is able to carry out the hydrogenation of double bonds which bear certain functional groups. A compound containing an unsaturated acetal and an ester function is directly transformed enantioselectively in a hydroxy acid, later chemically cyclized to the corresponding lactone (eq 9).[24] Other α,β-unsaturated alcohols and aldehydes are efficiently and enantioselectively converted to the corresponding saturated alcohols.[25] 2-Chloro-2-alkenoates (eq 10)[26] or nitroalkenes (eq 11)[27] are enantioselectively hydrogenated, the stereochemistry of the reaction depending on the double bond configuration.

Acyloin Condensations.

The condensation between furfural or benzaldehyde and a two-carbon unit to afford a hydroxy ketone has long been known.[1b] The extension of the reaction to α,β-unsaturated aldehydes has provided access to optically active functionalized diols (eq 12),[28] which are used as chiral intermediates for the synthesis of natural products.[1b]

Cyclization of Squalene-like Substrates.

Ultrasonically stimulated BY is a source of sterol cyclase, which catalyzes the cyclization of squalene oxide and squalenoid compounds to lanosterol derivatives (eq 13).[29]

Hydrolyses.

The presence of hydrolytic enzymes in BY is well documented.[30] However, the use of the yeast for biocatalytic ester hydrolysis suffers because of the availability of commercially available purified hydrolases. Nonetheless, the hydrolytic ability of fermenting BY has been proposed for the resolution of various amino acid esters (eq 14).[31] The BY-mediated enantioselective hydrolysis has also been applied to the resolution of acetates of hydroxyalkynes[32] and a hydroxybutanolide.[33]

Oxidations.

Reductions are by far the most exploited reactions carried out in the presence of BY. However, a few interesting examples of oxidations are available,[34] such as the dehydrogenation of thiastearates.[35] The regeneration of protected functional groups is possible with BY, which can effect the deprotection of hydrazones[36] and, if ultrasonically stimulated, may release from the oximes the corresponding carbonyl compounds, without further reduction to the alcohols (eq 15).[37]

An attractive reaction has been reported for BY, which is able in ethanol to catalyze the oxidative coupling of various thiols to disulfides (eq 16).[38]

Miscellaneous Reactions.

Many other reactions can be realized in the presence of BY. An interesting hydrolysis-reduction process transformed a derivative of secologanin into two different cyclic compounds, depending on the pH of the incubation.[39] Here, a glucosidase activity afforded the intermediate aldehyde, which could be reduced or rearranged to different products (eq 17).

(17)

With BY, the reduction of α,β-unsaturated aldehydes can act together with a hydration process, affording optically active diols in acceptable yields (eq 18).[40]

(18)

Some cycloaddition reactions have also been carried out in the presence of BY.[41] The asymmetric 1,3-dipolar

cycloaddition of benzonitrile *N*-oxides to various dipolarophiles led to optically active 2-oxazolines (eq 19).[42]

The regio- and enantioselectivity of the reactions depend on the structure of dipolarophiles and the addition of β-cyclodextrin. BY is also able to carry out a Diels-Alder condensation,[41] and a few Michael-type additions are enantioselectively performed in the presence of BY.[43] For example, the addition of amines to α,β-unsaturated esters affords optically active β-amino acid esters (eq 20).[44]

Barium Hydroxide

$Ba(OH)_2$

[17194-00-2] · BaH_2O_2 · Barium Hydroxide · (MW 171.35) (.H_2O)

[22326-55-2] · BaH_4O_3 · Barium Hydroxide · (MW 189.37) (.8H_2O)

[12230-71-6] · $BaH_{18}O_{10}$ · Barium Hydroxide · (MW 315.48)

(used as a base catalyst in a variety of organic reactions such as decarboxylations, aldol or aldol-type reactions, Claisen-Schmidt reactions, Michael additions, and Wittig-Horner reactions)

Physical Data: $Ba(OH)_2.H_2O$, *d* 3.743 g cm^{-3}. $Ba(OH)_2.8H_2O$, mp 78 °C; *d* 2.180 g cm^{-3}.

Solubility: monohydrate is slightly sol water. Octahydrate is freely sol water and methanol, slightly sol ethanol; practically insol acetone.

Form Supplied in: monohydrate, white solid; octahydrate, transparent crystals or white masses.

Handling, Storage, and Precautions: poison; corrosive. May be fatal if swallowed, inhaled, or absorbed through skin. Material is extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin.[1] Incompatible with acids. Absorbs moisture and CO_2 from air. Use only in a chemical fume hood. Avoid contact with eyes, skin, and clothing. Wash thoroughly after handling. Keep container tightly closed.

Introduction.

The octahydrate, $Ba(OH)_2.8H_2O$, is the most common form. Upon dehydration at elevated temperatures (200-500 °C) it is converted to the anhydrous form. On standing at rt, anhydrous $Ba(OH)_2$ is partially rehydrated and the resulting equilibrium water content is related to the dehydration temperature. The solids resulting from such a treatment are referred to in the literature as activated barium hydroxides. An activated $Ba(OH)_2$ is a mixture of anhydrous $Ba(OH)_2$ and the monohydrate in variable ratios. In the crystal structure, the monohydrate is the main component over the solid surface.[1] The most popular activated $Ba(OH)_2$ is sometimes referred to as C-200 (i.e. dehydrated at 200 °C) and was determined to be $Ba(OH)_2.0.8H_2O$.[2]

Partial Hydrolysis of Dimethyl Dicarboxylates.

The monomethyl ester of undecanedioic acid was prepared by partial hydrolysis of the dimethyl ester with methanolic $Ba(OH)_2$ (eq 1). The precipitation of the barium salt of the monoester prevents further hydrolysis to the diacid. The procedure has an advantage over the fractional distillation of partially esterified diacids, particularly for the high-boiling half esters which may disproportionate at elevated temperatures. This method was not satisfactory for low molecular weight half esters because of the higher solubility of their barium salts in methanol.[3]

Ketocarboxylic Acids from Ketodicarboxylic Esters.

The ketodicarboxylate derivative (**1**) was hydrolyzed and decarboxylated when treated with $Ba(OH)_2.8H_2O$ in refluxing ethanol for 20 h to give the crystalline γ-keto acid (**2**) in 98% yield (eq 2).[4]

(1) **(2)**

Monocarboxylic Acids from Dicarboxylic Acid Anhydrides.

In the total synthesis of (±)-pentalenolactone, the intermediate dicarboxylic anhydride (**3**) was converted to carboxyenone (**4**) upon treatment with 1.2 equiv of $Ba(OH)_2.8H_2O$ in water and heating at reflux temperature for 5 h (eq 3). The cleavage of the anhydride, the formation of the enone from the β-methoxy silyl enol ether, and the decarboxylation of the vinylogous β-keto barium carboxylate were all achieved in one operation giving the desired product (**4**) in 99% yield.[5]

Reaction with α-Chlorolactams: a Stereoselective Favorskii-Type Ring Contraction.

Treatment of the bicyclic α-chlorovalerolactams (**5**), (**6**), and (**7**) with aqueous $Ba(OH)_2$ at reflux temperature promoted a Favorskii-type ring contraction to give the octahydroindoles and octahydroisoindoles (**8**), (**9**), and (**10**) respectively. While chlorolactams (**5**) and (**6**) rearrange in a diastereoselective fashion (eqs 4 and 5), (**7**) gave a 1:1 mixture of (**10a**) and (**10b**) (eq 6). The observed diastereoselectivity was attributed to *cis*-1,3 and *cis*-1,2 steric interactions in (**5**) and (**6**), respectively, and the lack of such interactions in (**7**).[6]

Preparation of Diacetone Alcohol.

Heating acetone in a flask fitted with a Soxhlet extractor containing $Ba(OH)_2$ for 95-120 h gave 71% yield of distilled diacetone alcohol (eq 7).[7]

(7)

Heterogeneous Claisen-Schmidt Condensation.

Activated $Ba(OH)_2$ (C-200) was used as a heterogeneous catalyst in Claisen-Schmidt condensations. The method was applied to reactions of various aromatic aldehydes with methyl ketones to give the corresponding styryl ketones. Generally, the aldehyde is mixed with the methyl ketone (2 equiv) and the C-200 catalyst (12%) in ethanol and the mixture is heated at reflux for 1 h. The yields ranged from 25 to 100% (eq 8).[8] The procedure was extended to the synthesis of *o*-hydroxychalcones, e.g. the reaction of *o*-hydroxyacetophenone with benzaldehyde in 96% ethanol and a catalytic amount of C-200 gave *o*-hydroxychalcone in 89% yield (eq 9).[9]

(8)

$R^1 = H$, $R^2 = Ph$, 94-98%; $R^1 = Me$, $R^2 = n\text{-}Pr$, 99-100%; $R^1 = NO_2$, $R^2 = t\text{-}Bu$, 24-25%

(9)

The yields from these reactions were as good as or better than other methods. Secondary reactions such as the Cannizzaro reaction of aldehydes and aldol additions of ketones were not observed. Unlike other methods, protection of the phenol was not necessary and the product did not cyclize to the flavenone. The absence of cyclized products as

well as the (*E*) configuration of the alkenic bond were explained by a rigid transition state in which the carbanion and aldehyde are adsorbed on the insoluble catalyst surface.[9]

Michael Addition to Chalcones.

Partially dehydrated $Ba(OH)_2$ efficiently catalyzed the Michael additions of active methylene compounds to chalcones. The reaction temperature and amount of catalyst determined the isolated product (eq 10). Thus the reaction of chalcone with ethyl acetoacetate (25 mmol each) at rt in EtOH with 5 mg catalyst gave primarily the Michael addition product (**11**) in 90% yield. By increasing the amount of catalyst to 50 mg at rt, the reaction proceeded further to give the cyclic product (**12**) in 95% yield, resulting from Michael addition followed by intramolecular aldol reaction. The dehydrated cyclic adduct (**13**) was the major product (80%) at reflux temperature.[10]

Addition of Diethyl Malonate to Coumarin.

An attempted Michael addition of diethyl malonate to coumarin (**14**) in the presence of solid $Ba(OH)_2$ (C-200) in EtOH gave the unusual 1,2-addition-elimination product (**15**) in 30% yield (eq 11). The result was explained in terms of the structure of the catalyst and the chelation of coumarin to the barium ion of the lattice.[11]

(11)

Synthesis of Δ^2-Isoxazolines and Δ^2-Pyrazolines.

The addition of NH_2OH and $PhNHNH_2$ to chalcone and related enones (**16**) was catalyzed by $Ba(OH)_2$ (C-200) to give good yields of Δ^2-isoxazoline (**17**) and Δ^2-pyrazoline (**18**) derivatives respectively (eq 12). The products were obtained in yields between 65 and 75% and with complete regioselectivity.[12]

(12)

Oxidation of Benzyl Halides to Benzaldehydes.

Benzyl halides were oxidized to benzaldehydes by ***Dimethyl Sulfoxide*** in the presence of activated $Ba(OH)_2$ (C-200) in 1,4-dioxane. The optimum conditions include the use of a 5 M solution of the aryl halide in 1,4-dioxane with 3 equiv of DMSO and about 0.2 equiv of the $Ba(OH)_2$ catalyst, then heating the mixture at 130 °C for 3 h. The reaction does not take place in the absence of the C-200 catalyst. The effect of each variable in the reaction on the yield was studied, but no specific yields were given for isolated products except for $PhCH_2Cl$, which was reported as 100%. The proposed mechanism of the reaction involves an initial displacement of the halide by DMSO followed by elimination of Me_2S with the aid of the basic OH groups on the catalyst surface (eq 13).[13]

Hydrolysis of 2-Alkoxyimidazolines.

In a procedure for the stereoselective synthesis of vicinal diamines, several alkenes were converted into 2-alkoxyimidazolines (**19**) via consecutive reactions with cyanamide/NBS, HCl/EtOH, and Et_3N/EtOH. The intermediates (**19**) were hydrolyzed with $Ba(OH)_2$ at 120 °C for 18 h (eq 14) to give the diamines (**20**) in 79-99% yields for this step and in 61-71% overall yields.[14]

A Skeletal Rearrangement in a 6β,19-Oxido Steroid.

When 6β,19-oxido-2,17-dihydroxyandrosta-1,4-dien-3-one (**21**) was heated at reflux with $Ba(OH)_2.8H_2O$ in pyridine for 22 h, and then worked up under acidic conditions, it rearranged to the furopyranone (**23**) in 80-85% yield (eq 15). The rearrangement included a ring B contraction, a double bond isomerization and a benzylic acid rearrangement. The acidic work-up caused the carboxy intermediate (**22**) to cyclize with the vinyl ether to give (**23**).[15]

(15)

Wittig-Horner Reaction.

Activated $Ba(OH)_2$ (C-200) catalyzed the reactions of aldehydes with triethylphosphonoacetates (**24**) in 1,4-dioxane in the presence of a small amount of water at 70 °C to give the corresponding 3-substituted ethyl acrylates (**25**) (eq 16). The yields of the products from aromatic aldehydes ranged from 0% for indole-3-carbaldehyde to 100% for furfural and *m*-nitrobenzaldehyde. The method was applied to hindered aldehydes such as pyrene-1-carbaldehyde and to unsaturated aldehydes such as *cis*- or *trans*-citral.[16] The reaction was also applied to various aliphatic aldehydes using 2-oxoalkanephosphonates to give the corresponding (*E*)-α,β-unsaturated ketones in high yields and stereoselectivities.[17]

Deacylation of 2-Alkyl-2-halo-1,3-dicarbonyl Compounds.

Treatment of various α-alkyl-α-bromoacetoacetic esters (**26**) with a suspension of anhydrous $Ba(OH)_2$ in absolute ethanol at 0 °C for 30 min effected their deacetylation and gave the corresponding α-bromo esters (**27**) in very good yields without any competing saponification or Favorskii rearrangement (eq 17).[18] The starting α-alkyl-α-bromoacetoacetic esters were prepared from the corresponding acetoacetic esters in two steps (NaH/RX then NaH/Br_2) and used directly in the above reaction. The overall yields for the three-step sequence ranged between 70 and 85%. A similar deacylation of the substituted 4-alkyl-4-chloroheptane-3,5-dione (**28**) was reported in the synthesis of racemic juvenile hormone using $Ba(OH)_2$ in ethanol at 0 °C for 25 min (eq 18) to give the corresponding α-chloro ketone (**29**).[19]

Removal of the *N*-Protecting Benzyloxycarbonyl Group.

The alkynyl amine (**31**) was obtained in 75% yield by removal of the *N*-protecting benzyloxycarbonyl group from the benzyl carbamate (**30**) using 0.15 M $Ba(OH)_2$ in 3:2 glyme-H_2O at reflux temperature for 40 h (eq 19). Other reagents (Me_3SiI, BBr_3, Me_2BBr, BF_3/EtSH, $AlCl_3$/EtSH, MeLi/LiBr, or KOH/EtOH) caused partial destruction of the alkyne.[20]

Ahmed F. Abdel-Magid

Barium Manganate[1]

$BaMnO_4$

[7787-35-1] · $BaMnO_4$ · Barium Manganate · (MW 256.28)

(selective oxidant; oxidizes allylic and benzylic alcohols to aldehydes; diols give dialdehydes, lactols or lactones)

Solubility: insol most organic solvents.

Form Supplied in: dark green crystals or blue-black powder with chunks; widely available.

Preparative Methods: from aqueous solution of $KMnO_4$, $BaCl_2$, NaOH (1 equiv each), and KI (0.12 equiv); dry crystals by azeotropic removal of H_2O with C_6H_6; yield 60% on a 0.041 mol scale.[2b]

Purification: dry as above or at 100 °C for 24 h, or dry in vacuum oven (120 °C, 20 Torr); store in desiccator, and grind just before use.[3]

Handling, Storage, and Precautions: moisture sensitive; indefinitely stable and active; can be stored for months under dry conditions; use in a fume hood.

Oxidation of Alcohols to Aldehydes.

Barium manganate is a stable Mn^{VI} salt which can be regarded as an alternative to ***Manganese Dioxide***. In general, the yields are equal to or better than those obtained using the latter reagent, and the reaction is more rapid. Barium manganate is claimed to be more attractive on a medium to large scale as its preparation is simple, it is easy to handle, no special activation is required for oxidations, product isolation is facile, and less oxidant is required (1:1 to 1:10 compared to 1:5 to 1:50 for MnO_2).[1,2b] Barium manganate is unreactive towards styrene, toluene, 1-heptylamine, and α,β-unsaturated aldehydes and ketones.[2b] However, some aromatic aldehydes are converted to carboxylic acids and some aliphatic aldehydes polymerize on treatment with barium manganate.[4]

Simple allylic or benzylic alcohols are oxidized rapidly at room temperature (eqs 1 and 2); primary and secondary alcohols are also oxidized,[2,5] but the reaction is much slower (eqs 3 and 4).[2b] The reaction also tolerates sensitive functionality such as C&tbond;C triple bonds (eq 5)[2b] and the furan nucleus (eq 6).[6] For the latter reaction, MnO_2 gives a much reduced yield (38%) and two-phase Jones oxidation results in a complex mixture.

(1)

(2)

(3)

(4)

(5)

(6)

The oxidation of benzylic and related diols with barium manganate often produces the corresponding dialdehyde (eqs 7-10),[2] but lactones have been produced in some cases (see next section). As with the oxidation of monohydric alcohols, sensitive functionality is usually compatible with the oxidation conditions.

(7)

(8)

(9)

(10)

Barium manganate oxidation of the diol (**1**) produces the dialdehyde (**2**) (eq 11), which was used in a synthesis of the parent [10]annulene derivative.[7]

(11)

(1) **(2)**

Oxidation of Diols to Lactones.

In some cases the barium manganate oxidation of benzylic diols has been used to prepare the related lactones (eqs 12-14), although in unsymmetrical substrates the reaction often lacks selectivity.[8] Substitution *ortho* to one of the hydroxymethyl groups appears to be important in determining the success of this reaction, as a related substrate which lacks such substitution gives a high yield of the dialdehyde (eq 15).[7]

(12)

(13)

(14)

(15)

The barium manganate oxidation of diol (**3**) has been used as a key step in the total synthesis of cinnamolide (**4**). This reaction can be controlled to give the lactol if 1-2 equiv of the oxidant is used, whereas with excess (10-20 equiv) cinnamolide (**4**) is obtained (eq 16).[9]

(16)

Other Applications.

Barium manganate has found various other applications in synthesis, including the oxidation of thiols to disulfides (eqs 17 and 18).[10] It is noteworthy that an aromatic amino group is unaffected in this oxidation, as aromatic amines have been reported to yield azo compounds with barium manganate (eq 19).[2b]

(17)

(18)

(19)

When hindered phenols are treated with barium manganate, oxidative coupling products are obtained (eq 20).[11]

(20)

Barium manganate is reported to be superior to manganese dioxide for the dehydrogenation of 2-imidazolines to imidazoles (eq 21).[3]

(21)

Longer reaction times also allow some aromatic aldehydes to be oxidized to carboxylic acids (eq 22).[4] Under these conditions, heterocyclic aromatic aldehydes give no oxidation products and aliphatic aldehydes give only polymeric products, which are probably due to aldol reaction pathways.

(22)

Barium manganate is able to oxidatively cyclize benzylideneaminoanilines, -phenols, and -thiophenols to benzimidazoles, benzoxazoles, and benzothiazoles, respectively, at ambient temperature (eq 23).[12]

Benzene(cyclopentadienyl)iron Hexafluorophosphate[1]

[12176-31-7] · $C_{11}H_{11}F_6FeP$ · Benzene(cyclopentadienyl)iron Hexafluorophosphate · (MW 344.02) (BF_4^- salt)

[1277-51-6] · $C_{11}H_{11}BF_4Fe$ · Benzene(cyclopentadienyl)iron Tetrafluoroborate · (MW 285.86) (free cation)

[51364-24-0] · $C_{11}H_{11}Fe$ · Benzene(cyclopentadienyl)iron Hexafluorophosphate

(electrophilically activated arene complex, undergoes nucleophilic addition,[1,2] nucleophilic substitution of aryl halides,[1,3,4] oxidations and substitutions at benzylic protons,[1,5,6] and photochemical or thermal arene removal[3,7])

Physical Data: mp 200 °C (dec).

Solubility: insol H_2O, Et_2O, THF; sol acetone, MeCN; mod sol CH_2Cl_2.

Form Supplied in: yellow solid; not commercially available. Preparative information is available.[2,8]

Handling, Storage, and Precautions: $[(C_6H_6)FeCp]PF_6$ is air stable. No special storage requirements are indicated. Its toxicity is unreported, but is probably low to moderate.

General Description.

Benzene(cyclopentadienyl)iron hexafluorophosphate is the simplest member of the $[(arene)FeCp]^+$ family, which was first prepared in the late 1950s. Although $[CpFeCl(CO)_2]$ was first used as the synthetic precursor, it was soon recognized that ferrocene itself is a more convenient alternative.[1,2,8] ***Aluminum Chloride*** (or other very strong Lewis acid) is needed to produce the cation. ***Aluminum*** powder is often added also to reduce any ferricinium cation generated during the reaction.

Such preparative conditions must necessarily limit the range of aromatic substrates which can be directly coordinated to the $[CpFe]^+$ fragment. Nevertheless, certain arenes which cannot be added directly can be produced subsequent to coordination via substitution or oxidation reactions. Several review articles on arene-iron complexes feature thorough discussions of preparative considerations and the range of usable a romatics.[1]

Nucleophilic Addition Reactions.

The coordination of a metal fragment to an aromatic molecule causes the arene to take on an electrophilic character.[9] This is especially true when the metal fragment is cationic. Hence $[(C_6H_6)FeCp]^+$ undergoes attack by moderate to strong nucleophiles, such as lithium and Grignard reagents (eq 1).[2] Similarly, hydride may be added using ***Sodium Borohydride*** or ***Lithium Aluminum Hydride***. Some ketones have been shown to react as their enolate anions with $[(arene)FeCp]^+$ in the presence of ***Potassium Hydroxide***.[10] Unless it is quite sterically hindered, the arene is the preferred site of attack on $[(arene)FeCp]^+$; the product therefore contains a cyclohexadienyl ring and is a ferrocene analog. The stereochemistry of attack is invariably *exo* with respect to the metal. Substituent effects are typically rather minor.[2] Exceptions include methoxycarbonyl, cyano, nitro, and tosyl substituted benzenes, which show 10-20:1 preferences for *ortho* attack over *meta* and *para*.[11] Liberation of the ring occurs with rearomatization; thus eq 1 represents an overall nucleophilic aromatic substitution.

A variety of metal fragments activate trienes (such as arenes) toward electrophilic attack to varying degrees. In Table 1 the relative kinetic activation afforded by various metal fragments (independent of the coordinated triene and the nucleophile) is compared.[9] This parameter is the electrophilic transferability number (T_E). It may be noted that for a given nucleophile, $[(C_6H_6)Mn(CO)_3]^+$ is expected to react at 1.1×10^4 the rate of $[(C_6H_6)FeCp]^+$. The lesser electrophilicity of the iron cation renders it unreactive toward neutral donors, such as phosphines, which add to the manganese complex.

Table 1 Electrophilic Transferability Numbers (T_E) for Organometallic Fragments

Metal fragment	T_E for trienes
$Fe(C_6H_6)^{2+}$	2.0×10^8
$Ru(C_6H_6)^{2+}$	6.0×10^6
$Os(C_6H_6)^{2+}$	1.5×10^6
$Mn(CO)_3^+$	1.1×10^4
$Re(CO)_3^+$	1.0×10^4
$Mn(CO)_2(PPh_3)^+$	1.6×10^2
$FeCp^+$	1.0
$Cr(CO)_3$	very small

Nucleophilic Substitution Reactions.

The halobenzene and nitrobenzene complexes are subject to substitution of X^- or NO_2^- by soft anionic nucleophiles, such as heteroatom donors.[3,4] This reaction is conveniently conducted in the presence of ***Sodium Carbonate*** (eq 2). Stabilized carbanions behave similarly.[12] Hard carbanions, however, usually undergo addition reactions with $[(PhCl)FeCp]^+$. The ease with which substitution reactions occur for $[(PhCl)FeCp]^+$ is similar to that of 2,4-dichloronitrobenzene. Chloride substitution is of course even more facile for $[(PhCl)Mn(CO)_3]^+$.[13]

(2)

Reactions at Benzylic Sites.

The $[CpFe]^+$ fragment is stable towards oxidation. This allows the elaboration of coordinated methylbenzenes to benzoic acids (eq 3).[5] Conversion to acid derivatives, i.e. esters, acid chlorides, amides, and nitriles, may subsequently be accomplished. In very specialized instances, benzylic carbons can be oxidized to ketones.[14] Coordinated aniline can be oxidized to coordinated nitrobenzene using hydrogen peroxide and acid. Benzylic protons are rendered especially labile by the electron-withdrawing power of $[CpFe]^+$.[6] Hence ring methyls can be alkylated to produce tentacled benzenes (eq 4).[15]

(3)

(4)

Arene Removal Reactions.

The aromatic ligand can be photochemically[7] or thermally[3] removed. The liberated $[CpFe]^+$ fragment is then trapped with 3 mol of coordinating solvent or donor ligands. Alternatively, electron-rich aromatics may be used, facilitating arene exchange. However, the scope of the latter chemistry has not been explored in any detail to date.

Benzenediazonium-2-carboxylate

[1608-42-0] · $C_7H_4N_2O_2$ · Benzenediazonium-2-carboxylate · (MW 148.12)

(benzyne precursor[6])

Alternate Name: 2-carboxybenzenediazonium hydroxide inner salt.

Solubility: insol most organic solvents.

Preparative Method: obtained by diazotization of anthranilic acid;[1] the most useful diazotization agent is ***Isopentyl Nitrite*** (caution, heart stimulant!).

Handling, Storage, and Precautions: can be generated in situ,[2] handled as a suspension of the inner salt[1] or the hydrochloride[3] in ethers or halogenated hydrocarbons, or isolated as a dry solid.[1] Solid benzenediazonium 2-carboxylate decomposes explosively on being heated or scraped against a hard surface. The use of the wet compound is safer, but explosions have been reported during experiments using a slurry of the inner salt[4] or the hydrochloride.[5] The safest procedure is generation in situ by aprotic diazotization, but yields are lower. Preparation and handling should be carried out with good shielding.

Generation of Benzyne.[6]

Benzenediazonium-2-carboxylate decomposes on heating to afford benzyne (eq 1). The decomposition temperature depends on the solvent used.[6] This is one of the simplest and most commonly used procedures for the generation of benzyne for synthetic purposes. When diazotization is carried out in situ, secondary products derived from the reaction of benzyne with the starting materials are obtained. Better yields are obtained if the diazonium salt is prepared previously in a separate flask. However, the scale of work is limited to a few grams by safety reasons. Application of this procedure to the generation of substituted benzynes is limited by the availability of starting anthranilic acids. Most of these reactions are carried out in refluxing DME, THF, or 1,2-dichloroethane.

Nucleophilic Additions.[6]

Most nucleophiles react with benzyne to afford an intermediate aryl carbanion, which can be protonated or trapped with another electrophile. Even ethers, which are frequently used as solvents in these reactions, react with benzyne. For example, THF reacts with benzyne to afford an intermediate betaine, which can undergo attack by nucleophiles (eq 2).[7]

When nucleophile and electrophile belong to the same molecule, annulation takes place. For example, when benzyne is generated from benzenediazonium-2-carboxylate in the presence of enol ethers or enol acetates, benzocyclobutenes are obtained by a formal [2 + 2] cycloaddition (eq 3).[8] These benzocyclobutenes can then be used to generate *o*-quinodimethanes. Halogenated benzocyclobutenes can be obtained in a similar way (eq 4).[9]

(4)

The benzyne dimer biphenylene is a frequent secondary product in benzyne reactions (eq 5).[6]

(5)

The high reactivity of benzyne with nucleophiles makes it necessary to protect nucleophilic centers when other types of reaction, such as cycloadditions, are desired. In particular, nucleophilic nitrogens react very fast with benzyne to afford intermediate betaines, which can undergo a variety of transformations. For example, the aporphine alkaloid nuciferine is transformed into a phenanthrene in moderate yield (eq 6).[10]

(6)

[4 + 2] Reaction with Acyclic Dienes.[6]

Due to the low yields in the first attempts at cycloadditions between benzyne and acyclic dienes,[7] this reaction was rarely used in synthesis until the 1980s. Its resurrection began with the synthesis of anthracyclinones by reaction of benzyne with an exocyclic diene (eq 7).[11]

(7)

Benzyne generated from benzenediazonium 2-carboxylate has been reacted with styrenes to afford low yields of phenanthrenes and/or dehydrophenanthrenes.[12] This reaction has been applied in recent years to the synthesis of aporphinoids. When benzyne was generated in a solution of a protected 1-methylene-1,2,3,4-tetrahydroisoquinoline in DME, the corresponding dehydroaporphine was obtained, the initial dehydrophenanthrene cycloadduct having undergone oxidation under the reaction/work-up conditions. Substituted anthranilic acids can be used as precursors of substituted benzynes, but the yield of the cycloaddition is lower. Remarkably, the reaction works regioselectively when *o*-substituted benzynes are used (eq 8).[13]

(8)

R = H, 60%; R = OMe, 28%

[4 + 2] Reaction with Cyclic Dienes.[6]

Benzyne generated from benzenediazonium-2-carboxylate reacts with most heterocyclic dienes. A typical example is the reaction with furan, which is frequently used as a trapping agent for benzyne (eq 9).[14] Lower yields of cycloadducts are obtained with the less reactive thiophene (see (2-carboxyphenyl)phenyliodonium hydroxide).[15] Silacyclopentadienes also react with benzyne to afford bicyclic compounds (eq 10).[16]

(9)

(10)

A sequence of Diels-Alder/retro-Diels-Alder reactions occurs when benzyne is generated in the presence of 1,2-diazines.[6] Eq 11 shows a particular case which includes a Diels-Alder/retro-homo-Diels-Alder sequence.[17]

(11)

Bridged hydrocarbons can be easily constructed by cycloaddition of benzyne with cyclic dienes such as dimethylfulvene (eq 12).[18] Even aromatic compounds take part in these reactions. Eq 13 shows the formation of benzobarrelene by cycloaddition of benzyne with an anisole derivative.[19]

(12)

(13)

Benzyne cycloaddition is often the method of choice for the synthesis of triptycenes, azatriptycenes, and related compounds (see ***2-Bromofluorobenzene*** and ***2-Bromoiodobenzene***). In eq 14 an azatriptycene is obtained by the addition of benzenediazonium-2-carboxylate to a refluxing solution of the diene in DME.[20] Benzenediazonium-2-carboxylate hydrochloride has been used to generate benzyne in the key cycloaddition step of the synthesis of complex triptycene derivatives. Propene oxide is added to the reaction mixture to trap the HCl. Remarkably, almost quantitative yields were obtained in this cycloaddition step.[21]

(14)

When benzyne is generated from benzenediazonium-2-carboxylate in the presence of isoquinolopyrroline-2,3-diones, the major products are protoberberines (eq 15).[22] This procedure has also been used for the synthesis of compounds

with a yohimban skeleton. The mechanism of these transformations seems to be rather complex.[7] Naphthopyrroline-2,3-diones react in a similar way with benzyne to afford benzophenanthridines (eq 16). This procedure too can be used with substituted anthranilic acids.[23] A different approach to the same group of isoquinoline alkaloids is based on the cycloaddition of benzyne to a pyrone to form a bicyclic intermediate which loses CO_2 in a retro-Diels-Alder reaction (eq 17).[24] Good yields were also obtained using substituted anthranilic acids.

1,3-Dipolar Cycloaddition.

Benzyne generated from benzenediazonium-2-carboxylate also undergoes cycloaddition with 1,3-dipoles such as *N*-oxides (eq 18).[25] 2-Isopentoxy-1,3-benzodithiole is obtained by 1,3-dipolar cycloaddition of carbon disulfide to benzyne, followed by addition of isopentyl alcohol (eq 19).[26]

(18)

(19)

The reactivity of benzyne generated from benzenediazonium-2-carboxylate with dienes can be modified by the addition of Ag^+. 1,3,5-Cycloheptatriene reacts with benzyne to afford, in 36% yield, a mixture of two products, one resulting from an ene reaction and the second by formal [2 + 2] cycloaddition (eq 20).[27] In the presence of Ag^+ only the [4 + 2] adduct was obtained, although the yield fell to 20% (eq 21).[27]

(20)

(21)

Related Reagents.

1,2,3-Benzothiadiazole 1,1-Dioxide; ***Diphenyliodonium Carboxylate***.

Benzenediazonium Chloride[1]

[110-34-5] · $C_6H_5ClN_2$ · Benzenediazonium Chloride · (MW 140.57)

(can form azo compounds by coupling with carbon and hetero nucleophiles,[1a-c,e,f] and a wide variety of benzene derivatives with concomitant dediazoniation;[1] substrate for aromatic substitution)

Alternate Name: phenyldiazonium chloride.

Physical Data: no mp (explodes on heating).

Solubility: very sol H_2O, cold glacial acetic acid; sol abs. ethanol, acetone; insol diethyl ether, $CHCl_3$, benzene.

Form Supplied in: colorless needles, not commercially available. The dry salt can detonate violently and should, therefore, not be isolated as such. Typically, it is prepared by amine diazotization in water or an organic solvent, and the solution or suspension so obtained is used directly.

Analysis of Reagent Purity: usually none (in situ preparation).

Preparative Methods: [1a,b] an aqueous solution of $PhN_2^+Cl^-$ is obtained by adding a stoichiometric amount of $NaNO_2$ at 0-5 °C to the solution obtained from aniline and excess hydrochloric acid in water (eq 1). An excess of nitrite ions at the end of the reaction should be avoided, since they reduce the stability of the diazonium salt solution and can interfere with some further transformations. An excess of HNO_2 is detected with starch-KI paper that turns blue immediately on contact with the reaction solution, and can be destroyed with urea or amidosulfuric acid. A large variety of arenediazonium chlorides and sulfates (using H_2SO_4 instead of HCl) can be prepared by amine diazotization; for less basic and less soluble aromatic amines, the reaction conditions have to be somewhat modified.[2] When the diazotization is carried out with an organic nitrite (typically pentyl nitrite) in an organic solvent such as HOAc, ethanol, or dioxane (eq 1),[3] the solid diazonium salt either separates from the solution or can be precipitated by addition of a nonpolar solvent. The same is true for diazotization of $PhN(SiMe_3)_2$ with NOCl formed in situ from an organic nitrite and Me_3SiCl in dry CH_2Cl_2 (eq 2).[4]

Handling, Storage, and Precautions: dry benzenediazonium chloride explodes on heating, shock, and friction. It deliquesces in moist air with decomposition, but is rather stable in dry air in the dark and in aqueous solution at 0 °C. The decomposition of aqueous solutions of $PhN_2^+Cl^-$ at several temperatures and pH values has been studied by various authors.[5] Less labile than the chloride is the sulfate salt, which does not explode below ca. 100 °C and has a low shock-sensitivity. The salt $(PhN_2^+)_2ZnCl_4^{2-}$, obtained from $PhN_2^+Cl^-$ and $ZnCl_2$, is considered as a stabilized diazonium salt, but an explosion hazard on drying has also been reported.[6] In other arenediazonium salts, both electron-withdrawing and electron-donating *p*-substituents as well as *m*-NO_2, *m*-Br, and *m*-Cl retard the dediazoniation, whereas *m*-MeO and *m*-alkyl groups favor it.[1a,d,7] Arenediazonium salts are stabilized both in the solid state and in solution by complex formation with arenesulfonic acids (especially 1- and 2-naphthalenesulfonic acids),[1a,8] crown ethers, and polyethylene glycols.[1e]

Formation of Covalent Azo Compounds.

The arenediazonium ion reacts at the terminal N atom with a wide range of nucleophiles.[1a,c,7,9] The most important reaction of this type is the synthesis of diarylazo compounds by coupling with phenols, naphthols, aromatic amines, and similar electron-rich aromatic substrates. Electron-rich heteroaromatic and related CH-acidic heterocyclic compounds as well as heteroarenediazonium salts can also participate in this azo coupling reaction which gives access to a great variety of azo dyes and also to azo compounds that are of interest as pharmaceuticals or liquid crystalline materials.[1a,b,f,10,11] In general, the arenediazonium salt is prepared in situ by diazotization of an aromatic amine (see above), and coupled in aqueous solution at pH 3.5-7.0 with another aromatic amine or at pH 5-9 with a phenol derivative. The reaction takes place exclusively at the *p*- and *o*-positions (eqs 3 and 4). The different aspects of this aromatic S_E reaction (mechanism, reactivity, orientation effects) have been studied extensively.[12] In agreement with the electron demand of an aromatic S_E

reaction, the reactivity sequence for substituted phenols and naphthols as coupling components is O^- > NR_2 > NHR > OR &AApprox; OH >> Me.[1a,12] Whereas 1,3,5-trimethoxybenzene couples with PhN_2^+, the more electrophilic 4-nitro- and 2,4-dinitrobenzenediazonium ions are needed for azo coupling with 1,3-dimethoxybenzene and anisole, respectively.[13] With primary or secondary aromatic amines, N-coupling to give triazenes can compete with or dominate over aromatic C-coupling in weakly acidic, neutral or basic solution. The triazenes can undergo an acid-catalyzed intermolecular rearrangement[1a] to the diarylazo compounds. This two-step sequence is sometimes preferred over the direct azo coupling process and has found technical application (eq 5).[14]

(5)

Azo coupling reactions with in situ generated arenediazonium salts have also been performed on azulenes,[15] 2-alkoxy-1,6-methano[10]annulenes,[16] and tropolones.[1c] Since azo compounds can be reductively cleaved into two amine moieties, the azo coupling route allows the regioselective introduction of NH_2 into an electron-rich aromatic substrate.[17] Furthermore, the chemical stability of the azo group allows modifications on the aromatic nucleus before cleavage (eq 6).[18] The transformations of azulene to 1-aminoazulene[19] and of tropolone to 5-aminotropolone[1c] have been realized similarly.

(6)

The covalent azo compounds obtained from ArN_2^+ and CN^- or hetero nucleophiles[1a,c,7,9] are of lesser synthetic importance. Some of them, e.g. *anti*-areneazocyanides (Ar-N=N-CN), *anti*-areneazosulfonates (Ar-N=N-SO_3^-), and

areneazophosphonates ($Ar\text{-}N{=}N\text{-}P(O)(OR)_2$) are thermally stable enough to be useful for further transformations, whereas others split off N_2 more readily to generate aryl radicals by a homolytic pathway. The latter decomposition mode is involved in some synthetically useful transformations of ArN_2^+ salts into functionalized aromatics (see below).

Reduction to Arylhydrazines.

Arenediazonium salts can be converted into arylhydrazines preferably with $SnCl_2$/HCl, Na_2SO_3, or $Na_2S_2O_4$, or by conversion into $Ar\text{-}N{=}N\text{-}SO_3^-$ or $Ar\text{-}N{=}N\text{-}P(O)(OR)_2$ and reduction with Zn/HOAc.[20] While reduction with $SnCl_2$ is most convenient for small-scale preparations, Na_2SO_3 is favored for large batches (eq 7).[21]

(7)

Formation of Arylhydrazones and Formazans.

Arenediazonium salts can be coupled with many active methylene and methine compounds and also with some CH-acidic methyl groups.[22] The reactions are usually carried out in aqueous solution buffered with NaOAc. Alcohol, pyridine, or HOAc are sometimes added for better solubility of the reactants. 1,3-Diketones, β-keto aldehydes, β-keto esters, malonic esters, β-cyano esters, β-cyano sulfones, and malononitriles all react at the active CH_2 group to give arylhydrazones (eq 8).[23] The reaction of $PhN_2^+Cl^-$ with 2 equiv of ethyl acetoacetate yields 3-ethoxycarbonyl-1,5-diphenylformazan[24] with elimination of the acetyl group. Other β-keto esters, oxaloacetic esters, β-keto acids, and malonic acid monoesters behave analogously, the latter two with elimination of CO_2.[22] Acetone (eq 9) and nitromethane also afford formazans, whereas higher nitroalkanes (RCH_2NO_2) as well as activated methyl compounds such as 2-methylpyridine and 9-methylacridine yield the normal arylhydrazones.[22]

(8)

(9)

Methine compounds activated by two electron-withdrawing groups (Z) react with arenediazonium chlorides to give azo compounds that undergo a rapid acid cleavage of the (hetero-)1,3-dicarbonyl system with formation of arylhydrazones (Japp-Klingemann reaction) (eq 10).[25] An aqueous base (NaOH) is sometimes added to facilitate the cleavage reaction. Phenylhydrazones derived from acetoacetic esters can be reduced to amino acid esters und utilized in Fischer-type indole syntheses.[1c,22] By the same sequence, cyclic β-keto esters are cleaved to acyclic o-carboxy-2-arylhydrazono carboxylic esters and can be converted to o-carboxy-α-amino acids or 3-(o-carboxyalkyl)indoles (eq 11).[1c,22,26,27]

Functionalized Arenes from Aromatic Amines via Arenediazonium Salts.

The N_2^+ group of arenediazonium salts can be replaced by H and a variety of functional groups. These straightforward dediazoniation reactions can occur by heterolytic (S_N1), homolytic, and (for certain *o*-substituted ions) aryne mechanisms.[1d,7,28] Table 1 lists some of the more important transformations; further examples can be found elsewhere.[1c,1f,29] The copper(I)-mediated synthesis of ArCl and ArBr from arenediazonium halides (Sandmeyer reaction) has seen various modifications to improve the yield.[30] A particularly efficient approach is the direct conversion of arylamines into ArCl and ArBr with *t*-butyl nitrite and CuX_2 in anhydrous acetonitrile.[31]

Table 1 Arene Synthesis from ArN_2^+ salts. Replacement of N_2^+ by H and functional groups

SO_2, $CuCl_2$; SO_2, HCl; SO_2, CuCl, HCl, HOAc	$ArSO_2Cl$[37]
NaN_3	ArN_3[38]

Biaryl Synthesis.

Biaryls can be obtained when a cold aqueous solution of an arenediazonium chloride is added to a mixture of aqueous NaOH (15-40%) or NaOAc and an aromatic solvent (Gomberg-Bachmann reaction[39]). Benzene and many substituted arenes as well as thiophene and pyridine have been used as coupling partners. There is good evidence that the reaction normally proceeds by a free radical chain mechanism, with aryl radicals as reactive species.[7,40] The yields rarely exceed 45%, and positional isomers are sometimes obtained from substituted arenes (eq 12).[41] Higher yields result when isolated arenediazonium salts (see ***Benzenediazonium Tetrafluoroborate***) are employed under PTC conditions. In view of the drawbacks mentioned, the Gomberg-Bachmann reaction must give way to more efficient and selective procedures for the synthesis of more highly substituted and functionalized biaryls.[42] Appropriately substituted arenediazonium salts (chlorides and sulfates) can undergo intramolecular aryl-aryl coupling to give phenanthrene derivatives (Pschorr cyclization[43]), often in acceptable yield. Fluorenes, fluorenones, and phenanthridones can be obtained analogously. The cyclization is most often copper-catalyzed (eq 13), but several other methods also exist.[42a,43] Copper-mediated cyclization of the isolated arenediazonium BF_4 salts in acetone is also in use.[44]

o-:m-:p-NO_2 = 66.0:6.6:27.4

Arylation of Alkenes.

Arenediazonium chlorides react, in aqueous or H_2O-acetone solution and in the presence of Cu^I or Cu^{II} salts, with alkenes by dediazoniation and addition of Ar-Cl across the alkene bond (Meerwein arylation[1b,1f,45]). Alkenes activated by groups such as acyl, cyano, chloro, aryl, vinyl, and ethynyl are best suited for this reaction (eq 14)[45,46] which proceeds via aryl radicals.[45] Elimination of HCl may lead to a formal substitution product under the reaction conditions. Instead of using the preformed arenediazonium chloride, the Meerwein arylation product can be obtained directly and in improved yield from an arylamine by treatment with an alkyl nitrite and $CuCl_2$ in acetonitrile or acetone solutions that contain the alkene (eq 15).[47]

The reductive β-arylation of α,β-unsaturated carbonyl compounds and acrylonitrile can be realized in the presence of an excess of $TiCl_3$ in a solution of water and a water-miscible organic solvent. The best yields have been obtained with methyl vinyl ketone as the substrate (eq 16).[48] When steric and electronic effects divert the attacking aryl radical to the position α to the carbonyl, a different result is obtained.[49] For the Pd-mediated arylation of unactivated alkenes, see ***Benzenediazonium Tetrafluoroborate***. In contrast to the example in eq 16, simple carbonyl compounds do not undergo an analogous arylation reaction. However, *N*-benzylanilines result when an arenediazonium salt is decomposed by $TiCl_3$ in aqueous acid in the presence of an aldehyde and a primary aromatic amine.[50]

Benzenediazonium Tetrafluoroborate[1]

[369-57-3] · $C_6H_5BF_4N_2$ · Benzenediazonium Tetrafluoroborate · (MW 191.92)

(much higher stability than the corresponding chlorides;[2] shock-insensitive; often used when pure, isolated arenediazonium salts are needed;[1] reagent for introducing aryl, arylazo, arylhydrazono, or amino groups; forms fluoroarenes upon heating;[3] building block for heterocycles)

Alternate Name: phenyldiazonium tetrafluoroborate.

Physical Data: colorless solid after recrystallization; turns pink at 80 °C; decomposes at 114-116 °C.

Solubility: fairly sol polar solvents such as acetonitrile, acetone, pyridine, DMF, DMSO, and HMPA with decomposition; slightly sol water; insol hydrocarbons and Et_2O; solubilized in nonpolar media by crown ethers.

Form Supplied in: 4-nitrobenzenediazonium tetrafluoroborate is widely available (nearly colorless solid). A large variety of arenediazonium BF_4 salts are readily prepared from aromatic amines (see below).

Preparative Methods: [1a,1d,3,4] The most commonly used procedures consist in diazotization of an aromatic amine ($ArNH_2$) with $NaNO_2$ in aqueous HCl or H_2SO_4 followed by precipitation of the salt with added $NaBF_4$ or fluoroboric acid.[5] Alternatively, the diazotization can be carried out directly in 40-50% aqueous HBF_4.[2c] Aromatic amines that do not dissolve in aqueous mineral acids can be reacted with $NO^+BF_4^-$ in an anhydrous organic solvent or in liquid SO_2.[6] This method can also be applied to *N*-(trimethylsilyl)anilines[7] and for the preparation of those salts that are not easily isolated from water.[8] An improved, high-yielding one-pot procedure[9] employs $ArNH_2$, *t*-BuONO, and $BF_3.Et_2O$ in an anhydrous organic solvent, typically CH_2Cl_2.

Handling, Storage, and Precautions: the dry parent salt can be stored for more than a month at rt or for a few years at -20 °C under N_2 in the dark, but decomposes when exposed to direct sunlight. Rapid recrystallization from warm water[2b] or from acetonitrile-Et_2O is possible without decomposition. Although arenediazonium tetrafluoroborates, in contrast to the chloride salts, are renowned in general for their enhanced thermal stability and shock-insensitivity, some care should nevertheless be taken. Some salts are known to decompose while drying, e.g. 3-methoxybenzenediazonium, 2-methylbenzenediazonium, and certain heteroarenediazonium tetrafluoroborates.[3,10] Avoid contact with metals.

General Reactivity Patterns.

Similar to the chloride salts, arenediazonium tetrafluoroborates can be transformed into covalent azo compounds by addition of a nucleophile and into various functionalized arenes by displacement of the N_2^+ group. While the chloride salts are typically prepared in situ in an acidic aqueous or ethanolic solution, the tetrafluoroborates are usually isolated and can be employed as pure compounds in the solvent of choice or in suspension. Their low solubility in nonpolar organic solvents may be a problem, but it can be overcome by phase-transfer techniques.[1c,11]

Addition to Unsaturated Compounds with Retention of N_2.

Diarylazo compounds (Ar^1-N=N-Ar^2) are obtained by coupling of arenediazonium salts with sufficiently electron-rich (hetero)aromatic substrates. The vast majority of these important azo coupling reactions have been carried out in the reaction media obtained by diazotization of aromatic amines with $NaNO_2$ in aqueous HCl or H_2SO_4 (see ***Benzenediazonium Chloride***). Comparisons of reactivity between in situ generated arenediazonium chlorides and tetrafluoroborates (used as isolated salts) are rare.[12] Thus 4-nitrobenzenediazonium chloride reacts only slowly with indole and its 1-, 2-, and 3-Me derivatives in aqueous neutral solution, whereas the corresponding BF_4 salt in H_2O-ethanol undergoes azo coupling rapidly and almost quantitatively (eq 1).[13a] Similarly, several arenediazonium tetrafluoroborates couple smoothly to 2-amino-4-(alkyl or aryl)-1,3-oxazoles in aqueous $NaHCO_3$ solution, whereas neutral or weakly acidic solutions of salts prepared by in situ diazotization give intractable product mixtures.[13b] In other cases, the use of pure, water-free $ArN_2^+BF_4^-$ salts in an organic solvent may be necessary or may simply give better yields. Examples include azo coupling of $PhN_2^+BF_4^-$ with 2-dimethylaminopyrazoles in MeCN[14] and of λ^5-phosphinines in MeOH-benzene (eq 2).[15] Uncommon substrates such as calixarene,[16] ditellurafulvene,[17] sesquifulvalene,[18] and coordinated cyclooctatetraene[19] are also subject to the reaction.

(2)

Azo coupling is promoted by various phase-transfer catalysts such as crown ethers,[20,21] NaOAc,[22] Me_4NCl,[23] and $Na[B(3,5\text{-di-}CF_3\text{-}C_6H_3)_4]$.[24]

Arenediazonium BF_4^- or PF_6^- salts undergo a facile, probably concerted, [2 + 4] cycloaddition to various acyclic methyl- or aryl-substituted 1,3-dienes, and 1,6-dihydropyridazines are isolated (eq 3).[25,26] In contrast, the products isolated with cyclopentadiene result from an initial azo coupling process.[27]

(3)

Azomethine ylides and other 1,3-dipoles also afford cycloadducts with diazonium salts.[28] Ene-type reactions with unsaturated lactones have also been reported.[29]

Addition to Unsaturated Compounds with Loss of N_2 (Introduction of Aryl Groups).

Arylation of alkenic compounds by diazonium salts, yielding saturated or unsaturated products, is known as the Meerwein reaction and is usually catalyzed by copper salts. The procedure can be efficiently applied to intramolecular cyclizations (eq 4).[30] In the presence of iodide ions the reaction takes place without copper salts.[31] Titanium(III) salts also facilitate the addition of alkenic compounds to give reduced products (eq 5).[32] Arylation of ferrocenyl-substituted alkynes and alkenes succeeds without such catalysts.[33]

(4)

(5)

When the thermal decomposition of $ArN_2^+BF_4^-$ is conducted in the presence of pyridine, biaryls are formed in yields up to 30-40% by a radical mechanism, and no ArF is found.[34] Much higher yields of unsymmetrical biaryls can be obtained when arenediazonium BF_4^- or PF_6^- salts are allowed to react with an aromatic compound in the presence of KOAc and a phase-transfer catalyst[35] (eq 6). This procedure often gives better yields than the classical Gomberg-Bachmann-Hey reaction that employs arenediazonium chlorides in a two-phase system. The method also holds promise for the intramolecular version of aryl-aryl coupling (Pschorr cyclization).[11] Titanium(III) salts enhance *ortho* selectivity in the arylation of phenols.[36]

(6)

Diazonium salts add to nitriles with loss of dinitrogen to form *N*-arylnitrilium ions which further react in situ with nucleophiles or aromatics. Hence, intramolecular cyclizations take place starting from *ortho*-substituted diazonium salts (eqs 7 and 8); substituents used are azido,[37] carboxyl,[38] alkylthio,[39] hydroxymethyl,[40] and aryl.[41] In this connection, intermolecular addition of carboxylates to nitrilium ions gives unsymmetrical *N*-arylimides.[42] In place of nitriles, isocyanides also undergo intramolecular cyclizations with *ortho*-substituted diazonium salts.[43] Reactions with carbon monoxide under high pressure[44] or with ***Tetracarbonylnickel***[45] result in the formation of carboxylic acid derivatives.

(7)

(8)

Coupling with Nucleophiles with Retention of N_2 (Introduction of Azo or Hydrazono Groups).

The coupling of diazonium salts with active methylene compounds is known as the Japp-Klingemann reaction, a process applicable to nucleoside synthesis.[46] On the other hand, α-amination of simple esters is achieved through the hydrogenation of azo or hydrazono esters formed from ketene silyl acetals (eq 9).[47] The reaction with enamines likewise leads to α-iminio hydrazones which readily rearrange to heterocycles (eq 10).[48] The nucleophilic addition of ***p-Tolylsulfonylmethyl Isocyanide*** also results in cyclization, affording triazoles.[49] In addition, lithium enolates of α-substituted ketones,[50] Grignard reagents,[50,51] organozinc reagents,[52,53] and allylsilanes[54] produce corresponding azo or hydrazono compounds. ***Potassium Cyanide*** in the presence of ***18-Crown-6*** yields diazo cyanides that act as efficient dienophiles in the Diels-Alder reaction (eq 11).[55]

(10)

(11)

Amines also combine with the terminal nitrogen of diazonium salts to form triazenes (eq 12),[56] the utility of which is summarized in a review.[57] Couplings with ***Difluoramine*** or isopropyl fluorocarbamate yield azides through triazenes as intermediates.[58] Reaction with hydrazonomethanesulfonates or guanidine derivatives give five-membered azacycles.[59] The addition of sodium sulfinates produces arylazo sulfones.[60]

(12)

Coupling with Nucleophiles with Loss of N_2 (Introduction of Aryl Groups).

Arenediazonium salts act as aryl cations toward various nucleophiles. Silyl enol ethers derived from aryl ketones react with diazonium tetrafluoroborates in pyridine to afford α-aryl ketones (eq 13).[61]

(13)

Solvolysis of diazonium tetrafluoroborates in ***Trifluoromethanesulfonic Acid*** results in the formation of aryl triflates

(eq 14).[62] Similarly, decomposition in methanol[63] or ***Trifluoroacetic Acid***[64] leads to the corresponding ethers or esters; the latter is utilized for phenol synthesis. ***Pyridine N-Oxide*** reacts at the oxygen atom to give *N*-(aryloxy)pyridinium tetrafluoroborates.[65] Phenyl ethers and esters can be prepared via the reaction of trimethylsilyl ethers and esters with PhN_2BF_4.[66]

(14)

Unsymmetrical diaryl sulfides are obtained from diazonium fluoroborates and sodium aryl thiolates in DMSO (eq 15).[67] Similarly, aryl thiolesters are formed using thiocarboxylates.[68] Diaryl selenides and diaryl tellurides can be prepared by the reaction of arenediazonium salts with ***Sodium Selenide*** and ***Sodium Telluride*** (eq 16).[69]

(15)

(16)

Controlled thermal decomposition of dry arenediazonium tetrafluoroborates affords fluoroarenes in normally good to high yield (Balz-Schiemann reaction[3]) (eq 17). Typically, the reaction is carried out with the solid salt,[5] but decomposition in suspension or in solution[2b,3,70] has also been reported. Nitroarenediazonium BF_4^- salts are usually mixed with sand, NaF, or $BaSO_4$ to avoid violent decomposition.[3] The BF_3 etherate complex may be useful for an efficient transformation.[71]

(17)

The formation of fluoroarenes proceeds via an aryl cation intermediate that reacts with the BF_4^- ion in the ion pair,[72] and is accelerated by photolysis.[73] In some cases, the use of hexafluoroantimonates or hexafluorophosphates affords better yields.[74] On the other hand, aryl iodides are obtained via the reaction with ***Potassium Iodide/Iodine*** in DMSO.[75] The reactions with trimethylsilyl halides or ***Azidotrimethylsilane*** yield aryl halides or aryl azides, respectively (eq 18).[76] Organic halides such as $BrCCl_3$ and ***Iodomethane*** also act as halogen sources.[77]

(18)

Diazonium fluoroborates transform iminophosphoranes into phosphonium salts.[78] Similarly, sulfones are converted to sulfoxonium salts which can be reduced in situ to sulfoxides with ***Sodium Borohydride***.[79]

Nucleophilic substitution of diazonium salts in the presence of Cu^I salts is known as the Sandmeyer reaction. Nitro-dediazoniation of diazonium tetrafluoroborate with ***Sodium Nitrite*** in the presence of copper powder occurs smoothly (eq 19).[2c] An important access to arenephosphonic acids is provided by the Cu^I-catalyzed reaction of $ArN_2^+BF_4^-$ salts with ***Phosphorus(III) Chloride*** in an organic solvent, followed by hydrolysis (eq 20).[80] The method tolerates a wide range of substituents.[81] The thermal decomposition of arenediazonium salts in dilute aqueous solution in the presence of Cu_2O and a large excess of $Cu(NO_3)_2$ affords phenols in good yield; notably, this method does not require a strongly acidic medium.[82]

(19)

Palladium-Catalyzed Reactions.

Palladium-catalyzed reactions of diazonium salts proceed with nitrogen evolution and provide a mild method to introduce aryl groups.

While the classical, copper salt-catalyzed arylation of alkenes (Meerwein arylation) requires alkene activation by an electron-withdrawing substituent[83] (see ***Benzenediazonium Chloride***), the Pd-catalyzed modification succeeds well not only with acrylic aldehydes and esters, but also with styrene, ethylene, and other non-activated acyclic and cyclic alkenes (eqs 21 and 22).[84] Coupling reactions with isolated $PhN_2^+BF_4^-$ in general give much better yields than with the in situ generated salt $PhN_2^+X^-$ (X = Cl or OAc). In an analogous reaction, silyl-, germyl-, or stannyl-substituted alkenes result in the loss of heteroatom substituents (eq 23).[85-87]

The palladium-catalyzed carbonylation of an arenediazonium tetrafluoroborate with CO in the presence of Et_3SnH or a poly(methylhydrosiloxane) affords substituted benzaldehydes (eq 24).[88] Formation of ArH is sometimes a minor side-reaction, but predominates (81%) in the 2-nitro case. In related Pd-catalyzed reactions, diaryl ketones (eq 25),[89] aryl alkyl ketones,[89] substituted benzoic acids,[90] and mixed arylalkylcarboxylic anhydrides (eq 26)[91] can be obtained. Thermal disproportionation of the latter can be used to prepare homo arenecarboxylic anhydrides.[91]

X = 2-Me, 2-Ph, 4-Me, 4-Cl, 4-NO_2, 4-COMe, 4-CO_2Et, etc

X = 4-I (68%), 3-NO_2 (49%), 4-NO_2 (65%), etc.

Reduction to Arenes.

The removal of an NH_2 function by reductive dediazoniation is an important synthetic operation on the aromatic nucleus. As with other benzenediazonium salts, a number of methods exist for the BF_4^- salts, but the radical-chain reaction with H_3PO_2 is a particularly good method (eq 27).[92] Hydro-dediazoniation with $NaBH_4$ in methanol[93] is also quite convenient, but does not always occur cleanly.[94] Other effective and easily available reducing agents are ***Thiophenol***,[95] hydrosilanes,[96] and hydrostannanes.[96] Decomposition in HMPA[97] or in the presence of crown ethers[98] also gives good results. Catalysis by rhodium phosphine complexes in DMF does not seem very effective.[99]

Benzeneselenol is a unique reagent for producing arylhydrazines from diazonium fluoroborates (eq 28); the reaction is applicable to the synthesis of indazolone from *ortho*-carbamoyl diazonium salts.[100]

Radical Initiation.

Diazonium fluoroborates can be used as radical initiators. Applied examples are alkylation of heteroaromatics with alkyl iodides[101] and polymerization of vinylic compounds.[102]

Benzene-1,2-dithiol

[17534-15-5] · $C_6H_6S_2$ · Benzene-1,2-dithiol · (MW 142.24)

(starting material for the preparation of several organosulfur reagents)

Physical Data: mp 27-28 °C; bp 119-120 °C/17 mmHg; *d* 1.236 g cm^{-3}.

Form Supplied in: deliquescent, bad-smelling solid; commercially available. Aged samples may be contaminated by polymeric disulfides.

Preparative Methods: can be prepared by a number of methods.[1,2]

Handling, Storage, and Precautions: to be kept refrigerated under an inert gas.

The thiol groups of benzene-1,2-dithiol react with a number of reagents to afford compounds of good synthetic potential.

Acyclic Reagents.

The *S*,*S*-dimethyl derivative of the title reagent has been oxidized to the corresponding chiral bis-sulfoxide, which can be viewed as a bifunctional aryl methyl sulfoxide (eq 1).[3]

(1)

Five-Membered Rings.

The carbon atom between the two sulfur atoms in benzodithioles can be activated as a carbocation (**1**), carbene (**2**), or carbanion (**3**).

(1)

(3)

(2)

1,3-Benzodithiolium salts (**1**)[4] are useful for numerous functional group transformations. For example, 1,3-benzodithiolium tetrafluoroborate reacts rapidly with ***Trimethyl Phosphite*** in the presence of ***Sodium Iodide*** to give 2-(*O*,*O*-dimethylphosphonyl)-1,3-benzodithiole. This reagent can be used in Horner-Emmons reactions with various carbonyl compounds for the preparation of benzo-1,4-dithiafulvenes (eq 2).[5a] The double bond of the latter can be hydrogenated under mild conditions and the benzenedithiol eventually removed to generate the aldehyde.[5b] The sequence corresponds to a one-carbon homologation of carbonyl compounds. Other applications include the preparation of 1*D*-aldehydes,[5c] the reduction of sugars,[5d] and the transformation of many carboxylic acid derivatives (eq 3).[5e] 2-Phenyl-1,3-benzodithiolium trifluoromethanesulfonate can be used to convert alcohols into benzyl ethers and benzoates under mild conditions (eq 4).[6]

(2)

(3)

Treatment of the benzenedithiolium tetrafluoroborate with base is one method for generating 1,3-benzodithiole-2-ylidene (**2**).[7] The carbene is also formed as an intermediate in the 1,3-dipolar cycloaddition of carbon disulfide with benzyne.[4] It displays a 6π-electron system and belongs to the class of nucleophilic carbenes capable of reacting with sulfur and selenium metal.[4c]

1,2-Benzenedithiol has found much use in the synthesis of organic metals. A large number of electron-rich compounds have been synthesized with the aim of producing conducting radical cation salts.[8] (**4**), (**5**) and (**6**) are representative compounds derived from the dithiol.

(4)

(5)

(6)

The ability of the two sulfur atoms in benzodithioles to stabilize a negative charge (unlike the parent 1,3-dithiolane that fragments on treatment with bases) makes these reagents useful as umpoled formyl and acyl anion synthons.[9] As with many other sulfur reagents of this type, the oxides exhibit higher reactivity, but the anion of the tetroxide gives aldol-type products only with difficulty because of its stability. The *trans* dioxide of 1,3-benzodithiole can be transformed via a Mannich reaction into the 2-methylene derivative which exhibits dienophilic properties and high diastereoselection in Diels-Alder cycloadditions (eq 5).[10]

(5)

A number of heteroatoms can be included in the five-membered ring in between the two sulfur atoms. Examples include phosphorus[11] and boron.[12] The latter compound has been shown to catalyze Diels-Alder reactions. A large number of complexes of 1,2-benzenedithiol are also well-known and are currently being investigated.[13]

Six-membered Rings.

1,4-Benzodithiin *S,S,S´,S´*-tetroxide is available from 1,2-benzenedithiol or by other methods.[14] These compounds exhibit exceptional reactivity as dienophiles, higher than the bis(phenylsulfonyl)ethylenes (see ***1,2-Bis(phenylsulfonyl)ethylene***; ***1,1-Bis(phenylsulfonyl)ethylene***). The 2-chloro derivative can be used as C_2 synthon in cycloaddition reactions for the preparation of molecules that are difficult to prepare by other methods (eq 6).[15]

(6)

Seven and Higher-Membered Rings.

Sulfur in liquid ammonia is used in one method of synthesis of benzopentathiepine (eq 7).[16a] This sulfide can be used in the synthesis of heterocycles and as a sulfur transfer reagent.[16b] Benzo-1,3,5,2,4-trithiadiazepine is a 10π aromatic system available from benzene-1,2-dithiol via the bis-sulfenyl chloride shown in eq 8.[17] Higher ring systems (thiocrown heterocycles) can also be prepared.[18]

Università di Venezia, Italy

Benzeneperoxyseleninic Acid

[62885-97-6] · $C_6H_6O_3Se$ · Benzeneperoxyseleninic Acid · (MW 205.07)

(reagent for Baeyer-Villiger reaction and oxidizing agent for many functional groups)

Physical Data: mp 52 °C (with explosion).

Solubility: sparingly sol water, chloroform, and acetonitrile.

Form Supplied in: white powder.

Analysis of Reagent Purity: determination of active oxygen iodometrically (19.5%).[1]

Preparative Methods: the method of preparation involves oxidation of ***Benzeneseleninic Acid*** or ***Diphenyl Diselenide*** with 30% ***Hydrogen Peroxide*** used in excess at -10 °C. In a similar way, 2-nitro- and 2,4-dinitrobenzeneperoxyseleninic acids are obtained with 90% H_2O_2.[1] Peroxyseleninic acids are postulated as active intermediates when organic substrates are treated with H_2O_2 or ***t-Butyl Hydroperoxide*** in the presence of areneseleninic acids or aryl diselenides.[2-8]

Handling, Storage, and Precautions: caution: explosion hazard! Benzeneperoxyseleninic acid decomposes when dried in vacuo. It may be stored in a refrigerator for 1 week. Left to stand in air at rt for 3-4 days, it rearranges to benzeneseleninic acid. In the presence of water, it decomposes to benzeneseleninic acid and H_2O_2. This compound should be handled in a fume hood.

Baeyer-Villiger Oxidation.

The treatment of aromatic aldehydes or aryl methyl ketones with benzeneperoxyseleninic acid gives formates or acetates.[1] Similar results are achieved when H_2O_2 is used as a stoichiometric oxidant in the presence of catalytic amounts of bis(2,4-dinitrophenyl) diselenide (DNPDS), which forms 2,4-dinitrobenzeneperoxyseleninic acid in situ. The crude formate or acetate is hydrolyzed to phenol. This method is suitable for the synthesis of phenols substituted with electron-donating groups (eq 1).[7] In a similar manner, α,β-unsaturated aldehydes are oxidized with H_2O_2 in the presence of 2-nitrophenyl diselenide (NPDS) to a mixture of products containing mainly the vinyl formates; hydrolysis then leads to saturated aldehydes or ketones having the carbon chain shortened by one carbon atom (eq 2).[8]

Oxidation of cyclic ketones (eq 3)[5] and epoxidation of alkenes and allylic alcohols is achieved through the intermediate formation of (nonisolated) peroxyseleninic acids.[2-4] Styrene and its analogs are efficiently epoxidized with H_2O_2 in the presence of 2-nitrobenzeneseleninic acid.[6]

Other Oxidations.

Immobilized benzeneperoxyseleninic acid is a possible intermediate when polymer-bound benzeneseleninic acid (in catalytic amounts) and H_2O_2 or *t*-BuOOH are used for oxidations such as epoxidation, diol synthesis, oxidation of benzylic alcohols to carbonyl species, the Baeyer-Villiger oxidation, and the conversion of phenols into quinones.[9]

Aromatic aldehyde *N*,*N*-dimethylhydrazones are oxidized to nitriles (eq 4)[10] with 2-nitrobenzeneperoxyseleninic acid formed in situ from ***o-Nitrobenzeneseleninic Acid*** (NBSA), while aromatic and aliphatic aldoximes in the presence of primary or secondary alcohols are converted into carboxylic esters (eq 5).[11]

Benzeneselenenyl Bromide[1]

[34837-55-3] · C_6H_5BrSe · Benzeneselenenyl Bromide · (MW 235.97)

(electrophilic selenium reagent for alkene synthesis[2-6])

Physical Data: mp 60-62 °C; bp 134 °C/35 mmHg, 107-108 °C/15 mmHg; sublimes at 25 °C/0.001 mmHg.

Solubility: sol organic solvents such as hexane, CH_2Cl_2, ether, THF.

Form Supplied in: dark-red crystals; commercially available.

Preparative Method: can be quantitatively prepared in situ by treatment of ***Diphenyl Diselenide*** with an equimolar amount of ***Bromine***.[2,3,7]

Purification: recrystallization from petroleum ether or sublimation.

Handling, Storage, and Precautions: highly toxic, unpleasant smell.

Reaction with Ketones and Enols.

Benzeneselenenyl bromide (PhSeBr) is a useful electrophilic organoselenium reagent which exhibits similar reactivity to ***Benzeneselenenyl Chloride*** (PhSeCl). Although the reagent can be substituted by PhSeCl in many reactions, there is a significant difference in reactivity between these reagents.[2] Ketones can be efficiently converted into α-phenylseleno ketones through their lithium or copper enolates.[3,8] This reaction is useful for the transformation of saturated ketones to α,β-unsaturated ketones and the β-alkylation of α,β-unsaturated ketones (eqs 1 and 2). Similarly, enol acetates are converted into α,β-unsaturated ketones by using benzeneselenenyl trifluoroacetate ($PhSeOCOCF_3$),[9] which is prepared in situ by treatment of PhSeCl or PhSeBr with ***Silver(I) Trifluoroacetate*** (eq 3).[3,4] Silyl enol ethers react with PhSeBr to provide α-phenylseleno ketones and aldehydes in good yields (eq 4).[10] On the other hand, PhSeBr adds to enol ethers forming bromoselenenylation adducts regioselectively (eq 5).[11] Unlike PhSeCl, PhSeBr does not usually react well with ketones and aldehydes to form α-phenylseleno carbonyl compounds.[3]

(1)

(2)

(3)

(4)

R^1 = H, alkyl

Reaction with Carbanions.

α-Lithiated nitriles[12] and nitroalkanes[13] rapidly react with PhSeBr to afford the corresponding α-phenylseleno compounds, which are oxidized to α,β-unsaturated nitriles and nitroalkanes, respectively (eqs 6 and 7).

Addition to Alkenes.

PhSeBr reacts with alkenes in aprotic organic solvents to provide bromoselenenylation adducts efficiently.[5] This addition is considered to proceed via a seleniranium ion, a selenium-containing 3-membered cyclic cation, and *trans*

adducts are obtained exclusively. For terminal alkenes the regioselectivity of the addition can be controlled by changing the reaction conditions (eq 8).[6] The products can be easily transformed to vinylic selenides,[6] vinylic and allylic bromides,[14a] or α-phenylseleno ketones.[14b] When the reaction is carried out in alcohol or carboxylic acid, oxyselenenylated products of alkenes are obtained in high yields (eq 9).[5,15]

(8)

(9)

R = Me, Et, Ac, etc.

Alkynyl Selenide Synthesis.

Terminal alkynes undergo electrophilic substitution by treatment with the reagent prepared from PhSeBr and ***Silver(I) Nitrite***, providing alkynyl selenides in good yields (eq 10).[16]

(10)

R = Bu, Ph, OCOEt etc.

Reaction with Ketonic Hydrazones.

In the presence of ***t-Butyltetramethylguanidine***, a strong base, ketonic hydrazones smoothly react with PhSeBr to give phenyl vinyl selenides (eq 11).[17] This reaction requires an excess amount of PhSeBr.

(11)

Related Reagents.

A number of chiral electrophilic selenium reagents have been tested for their possible use in asymmetric synthesis (addition to alkenes, eq 9). Diastereomeric excesses as high as 79% have been achieved for (**1**) (R = *N*-(2,4-dinitrophenyl)prolinoyl),[18] and 93% for the triflate derived from (**2**).[19] Little asymmetric induction was seen in the addition of (**3**) to alkenes.[20] See also ***Benzeneselenenyl Chloride***, ***Benzenesulfenyl Chloride***, ***Phenyl Selenocyanate***, ***2-Pyridineselenenyl Bromide***.

Benzeneselenenyl Chloride[1]

[5707-04-0] · C_6H_5ClSe · Benzeneselenenyl Chloride · (MW 191.52)

(electrophilic selenium reagent for alkene synthesis[2-5])

Physical Data: mp 63-65 °C; bp 95-96 °C/6 mmHg, 120 °C/20 mmHg.

Solubility: sol common organic solvents such as hexane, CH_2Cl_2, and THF.

Form Supplied in: orange crystals; commercially available.

Preparative Methods: synthesized in 84-88% isolated yield by the reaction of ***Diphenyl Diselenide*** with ***Chlorine***.[5,6] Conveniently, benzeneselenenyl chloride can be prepared almost quantitatively in situ by treatment of diphenyl diselenide with an equimolar amount of ***Sulfuryl Chloride*** (SO_2Cl_2).[4,7] Reagent prepared in this way may contain significant amounts of SO_2.

Purification: recrystallized from hexane.

Handling, Storage, and Precautions: highly toxic; unpleasant smell.

Electrophilic Selenium Reagents.

Benzeneselenenyl chloride (PhSeCl) is the most common electrophilic selenium reagent and has been widely employed in the synthesis of a variety of natural and nonnatural products (see also ***Benzeneselenenyl Bromide*** (PhSeBr), ***Phenyl Selenocyanate*** (PhSeCN), ***o-Nitrophenyl Selenocyanate*** (*o*-$NO_2C_6H_4SeCN$), ***Benzeneselenenyl Trifluoromethanesulfonate*** (PhSeOTf), and ***Diphenyl Diselenide*** (PhSeSePh)). Other useful electrophilic selenium reagents ($PhSeOCOCF_3$,[2,8] $PhSeNO_2$,[9,10] PhSeF,[11-13] etc.) are usually prepared in situ from PhSeCl or PhSeBr and the corresponding silver salt.

Addition to Alkenes.

Chloroselenenylation.

PhSeCl adds to alkenes to give chloroselenenylation products in high yields.[2,7,14] The addition proceeds exclusively in the *trans* manner due to intervention of a selenium-bridged cation (a seleniranium ion) as a reaction intermediate (eq 1). Reaction with unsymmetrical alkenes generally provides *trans* adducts with high regioselectivity.[14] As shown in eq 2, terminal alkenes undergo chloroselenenylation to give anti-Markovnikov adducts under kinetic conditions and Markovnikov adducts under thermodynamic conditions.[15] These reaction products are useful intermediates for a variety of organic compounds. For example, upon oxidation with ***Hydrogen Peroxide***,[2] chloroselenenylated alkenes are conveniently transformed to vinylic or allylic chlorides via *syn* elimination of the selenoxides. ***Ozone***,[5] ***Sodium Periodate***,[4] peroxy acids,[4,16] and sulfuryl chloride[15] can also be used as an oxidizing agent. When ***N-Chlorosuccinimide*** is employed as oxidizing agent, PhSeCl catalyzes the conversion of alkenes into vinylic or allylic chlorides.[17] There are many other useful applications of chloroselenenylation, such as the transposition of 1,3-enones (eq 3),[18] transformation of allylsilanes to allyl alcohols,[19] and *cis* chlorination of alkenes.[20]

Oxyselenenylation.

Many types of oxyselenenylation reactions of alkenes employing PhSeCl or PhSeBr, such as acetoxy&nbhyph;,[3,21] carboxy-,[22] hydroxy-,[23] alkoxy-,[3,24] and glycosyloxyselenenylation[25] have been reported (eq 4). *Trans* adducts are stereoselectively obtained and are easily transformed to allylic alcohols, ethers, etc., by treatment with hydrogen peroxide. Unsaturated carboxylic acids[26,27] and alcohols[26,28] react with PhSeCl to give lactones and cyclic ethers respectively, in good yields (eqs 5 and 6). The reaction proceeds via intramolecular capture of the seleniranium ion initially formed in the reaction with PhSeCl. The carbonyl[29] and epoxide[30] oxygens as well as the thiol sulfur[31] also react as intramolecular nucleophiles to give 2,6-dideoxyglycosides, cyclic ethers, and cyclic thioethers, respectively. Dienes react with PhSeCl in aqueous acetonitrile to provide cyclic ethers in excellent yields (eq 7).[32]

X = Cl or Br; R = Ac, Me, Et, H, etc. (4)

Amidoselenenylation.

Alkenes efficiently undergo amidoselenenylation upon treatment with PhSeCl in aqueous acetonitrile in the presence of ***Trifluoromethanesulfonic Acid*** as an acid catalyst.[33] The produced β-amidoalkyl phenyl selenides can be converted into allylic amides by oxidation with hydrogen peroxide in good yields (eq 8). The reaction of unsaturated urethanes[34] and *N*-alkenylamides[35] with PhSeCl affords pyrrolidine and piperidine derivatives by intramolecular cyclization (eq 9). Similarly, *N*-alkylalkenamides react with PhSeCl to provide lactams.[36]

(9)

Nitroselenenylation.

In the presence of ***Mercury(II) Chloride*** the reagent prepared from PhSeCl or PhSeBr and ***Silver(I) Nitrite*** smoothly adds to alkenes giving β-nitroalkyl phenyl selenides (eq 10).[9] This reaction is useful for the preparation of 3,4-epoxy-3-nitro-1-alkenes from dienes[10] and 2-nitro-1-alkenylsilanes from 1-alkenylsilanes.[39]

(10)

Cyclization with C-C Bond Formation.

(*Z*,*Z*)-Cyclonona-1,5-diene reacts with PhSeCl in acetic acid to give a bicyclic adduct stereoselectively (eq 11).[40] Similar cyclization of dienes in acetonitrile smoothly proceeds with PhSeI prepared in situ from diphenyl diselenide and ***Iodine***.[37,38] Unsaturated β-keto esters react with PhSeCl to provide cyclohexane derivatives in good yields (eq 12).[41]

(11)

(12)

Fluoroselenenylation.

PhSeF equivalent prepared in situ from PhSeCl or PhSeBr and ***Silver(I) Fluoride*** reacts with alkenes to give β-fluoroalkyl phenyl selenides.[12] The reaction proceeds more smoothly under ultrasound irradiation.[11] The reagent, prepared from diphenyl diselenide and ***Xenon(II) Fluoride***, is also useful for fluoroselenenylation of alkenes.[13] The adducts can be oxidized to allylic fluorides exclusively rather than vinylic fluorides (eq 13).

(13)

Selenosulfonation.

Phenyl areneselenosulfonates ($PhSeSO_2Ar$) react with alkenes to give selenosulfonation adducts in the presence of boron trifluoride etherate[42] or under photochemical conditions (eq 14).[43]

(14)

Addition to Alkynes.

PhSeCl adds to alkynes to form β-chlorovinyl selenides in good yields.[44] The addition proceeds via a selenirenium ion, a selenium-bridged unsaturated cation, and *trans* adducts are exclusively obtained. Similarly, PhSeBr,[45]

$PhSeOCOCF_3$,[2,5] PhSeI,[38b,46] and PhSeF[47] add to alkynes to afford *trans* adducts (eq 15), which can be transformed to many useful synthetic intermediates. For example, 1,4-dichlorobut-2-yne reacts with PhSeCl or PhSeBr, and is converted into dienes, which easily undergo Diels-Alder cycloaddition with methyl vinyl ketone (eq 16).[45b] Areneselenosulfonates ($PhSeSO_2Ar$) also add to alkynes to give similar *trans* adducts.[48] The reaction seems to proceed via a radical intermediate.

(15)

X = Cl, Br, $OCOCF_3$, I, F

(16)

Reaction with Carbonyl Compounds and Their Derivatives.

Aldehydes and ketones directly react with PhSeCl to provide α-phenylseleno aldehydes and ketones, respectively, in good yields, while esters are converted into α-phenylseleno esters via lithium enolate (eq 17).[4] The reaction of PhSeCl with ketones also efficiently proceeds via lithium enolates.[5] These reaction products smoothly undergo oxidative *syn* elimination of the selenium moiety to give α,β-unsaturated carbonyl compounds in high yields. The reaction can be applied to the conversion of γ-lactones into furans[49] as well as to phenol synthesis from cyclohexene derivatives.[50] Similarly, β-dicarbonyl compounds directly react with PhSeCl in the presence of equimolar ***Pyridine***. The α-phenylselenenylation products are smoothly oxidized to the corresponding unsaturated β-dicarbonyl compounds (eq 18).[51] α,β-Unsaturated ketones also directly react with PhSeCl or PhSeBr in the presence of pyridine to form α-phenylseleneno enones.[52] The products undergo further reaction with PhSeCl to form α-halo enones in good yields (eq 19).

(17)

(18)

(19)

Enol ethers[53] and enamines[54] react with PhSeCl to give α-phenylseleno aldehydes in good yields (eq 20). On the other hand, cyclic acetals give the corresponding α-phenylseleno acetals by treatment with PhSeCl (eq 21).[53]

(20)

(21)

$R^2 = H$, alkyl

Reaction with α-Diazo Ketones.

PhSeCl rapidly reacts with α-diazo ketones at room temperature to provide α-chloro-α-phenylseleno ketones, which can be converted into α-chloro-α,β-unsaturated ketones by successive oxidation with hydrogen peroxide.[55,56] PhSeBr,[57] PhSeOAc,[57] PhSeSCN,[57] and PhSeF[58] undergo similar reaction with α-diazo ketones to give the corresponding α-substituted-α-phenylseleno ketones in good yields (eq 22).

Benzeneselenenyl Trifluoromethanesulfonate[1]

[112238-64-9] · $C_7H_5F_3O_3SSe$ · Benzeneselenenyl Trifluoromethanesulfonate · (MW 305.13)

(a highly electrophilic selenium reagent[2-8])

Alternate Name: benzeneselenenyl triflate.

Preparative Methods: usually prepared in situ by the reaction of ***Benzeneselenenyl Chloride*** with ***Silver(I) Trifluoromethanesulfonate*** in dichloromethane or toluene.[2] Two other economical methods are available. The first is the removal of hydrogen chloride from a mixture of benzeneselenenyl chloride and ***Trifluoromethanesulfonic Acid***.[3] The second is the comproportionation reaction of benzeneseleninic anhydride (see ***Benzeneseleninic Acid***) and ***Diphenyl Diselenide*** in the presence of trifluoromethanesulfonic anhydride.[4]

Handling, Storage, and Precautions: moisture sensitive. The dichloromethane solution free of silver chloride and water can be stored at rt for several weeks in the dark.[3]

Addition Reactions.

Benzeneselenenyl triflate is a highly electrophilic selenium reagent due to the poor nucleophilicity of triflate anion. It adds to alkenes having an intramolecular carboxy or hydroxy group to give cyclic products. For example, γ,δ-unsaturated carboxylic acids react with benzeneselenenyl triflate in dichloromethane to give γ-lactones in high yields (eq 1).[2] Under similar reaction conditions, 5- and 6-hydroxyalkenes are transformed to *exo*-cyclized tetrahydrofuran or -pyran derivatives (eq 2).[5,6] This reaction is useful for one-step conversion of acyclic terpene alcohols and derivatives into mono- or polycyclic compounds.[7] In the reaction with phenylacetylene, benzeneselenenyl triflate gives a *trans* adduct, a vinyl triflate, in high yield, which can be easily hydrolyzed to the ketone (eq 3).[4]

(1)

Selenium Polonovski Reaction.

Amine *N*-oxides react with benzeneselenenyl triflate to form selenoxyammonium salts, which rearrange to α-selenoxyamines in the presence of organic bases.[3] The products can be easily converted into secondary or tertiary amine derivatives (eq 4).

O-Glycosylation.

Alcohols efficiently undergo *O*-glycosylation under mild conditions by treatment with 1-thioglycosides and benzeneselenenyl triflate (eq 5).[8] This reaction can be applied to stereo- and regioselective synthesis of α-cyclodextrin derivatives.[9]

Related Reagents.

Benzeneselenenyl *m*-nitrobenzenesulfonate,[10a] benzeneselenenyl *p*-toluenesulfonate,[10b] (phenylseleno)dimethylsulfonium (PhSe+SMe_2) fluoroborate,[11] and (phenylseleno)methylphenylselenonium (PhSe+SeMePh) fluoroborate[12] can be considered as analogs of benzeneselenenyl triflate. (Phenylseleno)dimethylsulfonium (PhSe+SMe_2) fluoroborate reacts with electron-rich aromatic compounds to give the products of electrophilic substitution (eq 6).[11] On the other hand, (phenylseleno)methylphenylselenonium (PhSe+SeMePh) fluoroborate reacts selectively with allylic silanes to give the corresponding allylic selenides, which easily undergo 2,3-sigmatropic rearrangement to allylic alcohols by oxidation (eq 7).[12]

Benzeneseleninic Acid

(R = H)

[6996-92-5] · $C_6H_6O_2Se$ · Benzeneseleninic Acid · (MW 189.07) (R = Se(O)Ph) (anhydride)

[17697-12-0] · $C_{12}H_{10}O_3Se_2$ · Benzeneseleninic Anhydride · (MW 360.13)

(oxidizing agents of many functional groups[1])

Physical Data: acid mp 121 °C; anhydride mp 164-165 °C.

Solubility: both compounds sol chloroform, dichloromethane, THF; the acid is amphoteric and sol in water at low and high pH.

Form Supplied in: both compounds are commercially available white solids.

Purification: the anhydride is readily hydrolyzed and may contain substantial amounts of the acid. It can be regenerated from the latter by heating at 120-130 °C under vacuum (ca. 0.1 Torr) for a few hours.

Handling, Storage, and Precautions: the acid is stable to prolonged storage on the shelf; the anhydride should be kept in a desiccator. Both compounds are toxic and can react vigorously with reducing agents; the acid forms an explosive complex with hydrogen peroxide. Use in a fume hood.

Introduction.

Benzeneseleninic anhydride (BSA) is the more commonly used reagent and benzeneseleninic acid probably functions in at least some cases by generating the anhydride in situ. Excess reagent can be removed at the end of a reaction by washing with aqueous K_2CO_3 or KOH. ***Diphenyl Diselenide*** is the usual byproduct and often requires chromatographic separation.

Oxidation of Alcohols and Phenols.

Primary benzylic alcohols are oxidized to the corresponding aldehydes with BSA in refluxing benzene, chlorobenzene, or THF, while various secondary alcohols afford ketones under similar conditions (eq 1).[2] In principle, it is possible to oxidize 3 mol of the alcohol with 1 mol of the anhydride, but in practice an excess of the latter is generally more efficacious. The reagent can also be generated in situ from a catalytic amount of diphenyl diselenide and ***t-Butyl Hydroperoxide***.[2c] The method is relatively mild and tolerates other easily oxidized groups such as selenide and sulfide. Under more forcing conditions, the product sometimes undergoes dehydrogenation (see below).

(1)

R,R' = alkyl, aryl, H

Phenols are typically oxidized to *o*-quinones with the anhydride and to *p*-quinones with the acid, often with high regioselectivity and in good yield (eq 2).[3] However, the formation of hydroxydienones, or of coupled products, dominates in some cases (eq 3).[4] When the reaction is performed with BSA in the presence of ***Hexamethyldisilazane***, the corresponding *N*-phenylselenoimine is generally obtained, again with high *ortho* selectivity (eq 4). This provides a means for aromatic amination when used in conjunction with reduction of the imine.[5]

2.	7%	82%

(3)

30% 48%

(4)

Dehydrogenation of Carbonyl Compounds.

Ketones, particularly of the steroid or terpenoid variety, produce enones or dienones[6] when heated with the anhydride in chlorobenzene or diglyme at 95-132 °C The method may be used in conjunction with eq 1 to transform alcohols directly to dienones in one step. A further refinement permits the use of catalytic amounts of the anhydride in the presence of a co-oxidant such as iodoxybenzene or *m*-iodoxybenzoic acid (eq 5), which recycles the byproduct diphenyl diselenide.[7] Lactams[2b] and lactones[8] undergo similar dehydrogenations (eq 6), although the former compounds sometimes produce imides[2b] instead.

(5)

(6)

Oxidation of Amines, Hydrazines, and Hydrazones.

Primary amines afford ketones when oxidized with the anhydride under mild conditions (eq 7).[9] Synthetically useful yields are generally limited to non-enolizable ketones, however. Enamides are oxidized to carbinolamides and other hydroxy or keto derivatives,[10] and indolines produce indoles under similar conditions.[11] Benzeneseleninic acid or

anhydride react with ***Hydrazine*** to generate ***Diimide***,[12] whereas various types of 1,2- and 1,1-disubstituted derivatives produce azo compounds[12,13] and tetrazenes,[14] respectively (eqs 8 and 9), at or below rt. This procedure can also be employed to generate the reactive dienophile *N*-phenyl-1,2,4-triazoline-3,5-dione from *N*-phenylurazole,[15] and to oxidize hydroxylamines to nitroso compounds.[13] *N*-Acylhydrazines (hydrazides) and *N*-alkyl- or *N*-arylsulfonylhydrazines (sulfonhydrazides) are converted into selenoesters[12] and selenosulfonates,[16] respectively, when treated with the seleninic acid under mild conditions (eqs 10 and 11).

(9)

(10)

(11)

BSA is a useful reagent for the regeneration of ketones from their hydrazones, oximes, or semicarbazones (eq 12).[13] Phenyl-, *p*-nitrophenyl- and tosylhydrazones react rapidly in warm THF, whereas the 2,4-dinitrophenyl and *N*,*N*-dimethyl derivatives are considerably more resistant. Aldehydes are similarly obtained from their tosylhydrazones or oximes, but not from phenyl- or *p*-nitrophenylhydrazones, which afford *N*-acylazo products instead.

(12)

X = NHAr, NHTs, OH, NHC(O)NH$_2$
R, R' = alkyl, aryl, H

Oxidation of 1,3-Dithiolanes and Thiocarbonyl Compounds.

BSA is also an effective reagent for the deprotection of aldehydes and ketones from their 1,3-dithiolane derivatives (eq 13).[17] The reaction proceeds at or near rt, is applicable to sterically hindered systems, and often gives cleaner results than conventional hydrolytic methods. Moreover, it can be employed under anhydrous conditions, an advantage if other moisture-sensitive groups are present. The similar deprotection of 1,3-dithianes and 1,3-oxathiolanes is, however, generally less efficacious, while selenoacetals afford the parent aldehydes and ketones in typically high yields.[18] The conversion of thiones, xanthates, thionoesters, trithiocarbonates, thioureas, and other thio- and selenocarbonyls into the corresponding carbonyl derivatives can also be accomplished with BSA at rt (eq 14),[19] although enolizable thiones afford more complex products.

(13)

(14)

Miscellaneous Oxidations.

Benzylic hydrocarbons are oxidized to aldehydes in modest to good yields by benzeneseleninic anhydride at elevated temperatures (eq 15).[20] Overoxidation to carboxylic acids and the competing formation of phenylselenenylated derivatives often limits the utility of the method. The comproportionation of benzeneseleninic anhydride with diphenyl diselenide generates electrophilic Se^{II} species in situ. The mixture can thus be employed in the transformation of alkenes to α-phenylseleno ketones or aldehydes.[21] Terminal alkenes afford chiefly the 1-phenylseleno-2-ketone regioisomers (eq 16), whereas the opposite regiochemistry is favored with ethers or esters of allylic alcohols (eq 17). Similarly, the comproportionation of diphenyl diselenide and benzeneseleninic acid,[22] or the reduction of the latter with

Hypophosphorous Acid,[23] in the presence of alkenes results in the addition of PhSeOH to produce β-hydroxy selenides. α-Hydroxylations of polycyclic ketones occur at an adjacent ring junction position when these compounds are heated in refluxing toluene or chlorobenzene with BSA (eq 18).[24] These reactions are, however, sluggish and often produce only modest yields.

(15)

(16)

(17)

(18)

Benzeneseleninic acid reacts with ***Hydrogen Peroxide*** to produce the corresponding perseleninic acid in situ. The latter is in turn a convenient reagent for the oxidation of sulfides to sulfones, aldehydes to carboxylic acids, alkenes to epoxides, and in Baeyer-Villiger reactions (see ***Benzeneperoxyseleninic Acid***).

Benzeneseleninyl Chloride

[57204-85-0] · C_6H_5ClOSe · Benzeneseleninyl Chloride · (MW 207.52)

(introduction of α,β-unsaturation in ketones and esters;[1] oxidation of amines[2] and aldoximes;[3] halogenation of alkenes[4] and aromatic compounds[5] with aluminum halides)

Physical Data: mp 75 °C.

Solubility: sol CH_2Cl_2, THF.

Preparative Method: benzeneseleninyl chloride is obtained from the oxidation of ***Benzeneselenenyl Chloride*** in CH_2Cl_2[1] or CCl_4[6] with ***Ozone***.

Handling, Storage, and Precautions: benzeneseleninyl chloride crystals are extremely hygroscopic and care must be taken to avoid moisture. Solutions in CH_2Cl_2 are stable for weeks when stored at -15 °C. Selenium compounds are potentially toxic and should be handled in a fume hood.

Ketone and ester enolates react with benzeneseleninyl chloride to give α-phenylseleninyl intermediates, which undergo selenoxide elimination to form enones upon warming to room temperature.[1,7] Since the conventional two-step selenenylation/oxidation procedure gives higher yields with fewer byproducts (see ***Benzeneselenenyl Bromide***, ***Benzeneselenenyl Chloride***, and ***Diphenyl Diselenide***), the use of benzeneseleninyl chloride is recommended specifically to avoid competing or preferential oxidation (eq 1).[7]

Primary aryl-substituted amines are oxidized cleanly to ketones and nitriles, presumably via an intermediate seleninamide.[2] Although aldoximes are converted to nitriles in 71-96% yields at rt, comparable results are obtained using readily available benzenesulfenyl chloride or benzeneselenenyl chloride.[3]

The addition of an equivalent of ***Aluminum Chloride*** to a solution of benzeneseleninyl chloride in CH_2Cl_2 produces a complex which chlorinates electron-rich aromatic compounds, such as anisole, diphenyl ether, and *N*,*N*-dimethylaniline, exclusively in the *para* position.[5] This complex also regioselectively chlorinates thiophenes[8] and converts alkenes to vinyl chlorides (eq 2).[4,9] Similarly, a highly efficient brominating complex is formed when aluminum bromide is combined with benzeneseleninyl chloride (eq 3).[8]

Benzeneselenol[1]

[645-96-5] · C_6H_6Se · Benzeneselenol · (MW 157.07)

(a source of selenolate ions; a selenation reagent for organic halides, alcohols, amines, ethers, alkynes, and carbonyl compounds; a mild reducing agent)

Physical Data: bp 73-74 °C/20 mmHg.

Solubility: sol benzene, Et_2O, THF, acetonitrile; insol H_2O, but sol aq NaOH.

Preparative Methods: benzeneselenol is synthesized by the reaction of ***Phenylmagnesium Bromide*** with metallic ***Selenium***, followed by quenching with aqueous hydrochloric acid.[2a] Similar hydrolysis of sodium selenolate prepared by the reduction of ***Diphenyl Diselenide*** with ***Sodium Borohydride*** is a convenient alternative.[2b] In addition, ***Phenyl Trimethylsilyl Selenide*** can be employed as a useful precursor of benzeneselenol upon treating with methanol.[2c] Purification of benzeneselenol is performed by distillation under reduced pressure. ^{1}H NMR ($CDCl_3$) δ 1.54 (PhSeH); ^{13}C NMR ($CDCl_3$) δ 124.46, 126.45, 129.26, 132.71 (PhSeH).

Handling, Storage, and Precautions: pure benzeneselenol is a colorless liquid, but, on exposure to air, the liquid turns yellow to an extent that depends on the concentration of diphenyl diselenide formed by air-oxidation of PhSeH. Thus, it should be stored under nitrogen in the dark, and is conveniently handled using syringe technique. Use in a fume hood.

Generation of Phenylselenolate Ions.

Benzeneselenol has greater acidity than benzenethiol (pK_a = 5.9 (PhSeH); 6.5 (PhSH)),[2b] and therefore it gives lithium or sodium phenylselenolates in the presence of bases such as MeLi (in Et_2O),[3a] NaH (in THF),[3b,c] and aq NaOH.[3d] Alternatively, phenylselenolate ions are prepared by the reduction of ***Diphenyl Diselenide*** with $NaBH_4$ (in EtOH or DMF),[4] Na (in THF, HMPA, or liq NH_3),[3b,c,5] or NaH (in THF or DMF).[6] Sodium selenolate prepared by the $NaBH_4$ reduction of $(PhSe)_2$ is considered to be a complex with triethyl borate of the form $Na^+[PhSeB(OEt)_3]^-$,[4c] and indeed has lower nucleophilicity in comparison with uncomplexed PhSeNa generated by the reduction of $(PhSe)_2$ with Na (or NaH).[3b,c] The selenolate ions are generally much more sensitive to air (molecular oxygen) compared with PhSeH itself. The oxidation of PhSeH or its anions by air or other oxidizing agents such as H_2O_2 or Br_2 provides a general method for synthesis of diphenyl diselenide,[7] which is a key intermediate compound for preparation of

various organoselenium reagents.

Substitution Reactions.

The selenolate ions generated are widely utilized as reagents for introducing a PhSe group into organic molecules. For example, nucleophilic substitution of organic halides by selenolates leads to the corresponding selenides in good yields (i.e. RX + $PhSe^-$ -> RSePh + X^-).[5a,8] A similar reaction using acid halides affords selenoesters,[9] which are utilized as precursors of acyl radicals (eq 1).[10]

Organic sulfonates also undergo displacement by $PhSe^-$ to give selenides.[5a,11] Amines can be converted into selenides via the nucleophilic displacement of corresponding ditosylamides by selenolate ions (i.e. RNH_2 -> $RNTs_2$ -> RSePh),[12] or by reaction with benzeneselenol at high temperatures.[2b]

Upon treatment of esters with selenolate ions, alkyl-oxygen cleavage reaction occurs to provide carboxylic acids and alkyl selenides (i.e. RCOOR´ + $PhSe^-$ -> RCOOH + PhSeR´).[3b,c] The use of lactones as the substrates leads to the synthesis of o-phenylselenenyl carboxylic acids.[4b,5b,6,13] Ring-opening of epoxides also takes place by $PhSe^-$ to give β-hydroxy selenides,[14a-c] which can be converted into allylic alcohols via oxidative elimination of the phenylseleno group (eq 2).[4a] Acyclic ethers undergo C-O bond cleavage upon a similar treatment.[14d] Furthermore, C-C bond cleavage of activated cyclopropanes by $PhSe^-$ can proceed efficiently.[15]

The ring-opening of epoxides[16a] and the alkyl-oxygen cleavage of esters are also attained by the use of benzeneselenol under acidic conditions. For example, alkyl acetates are converted to the corresponding selenides by

the assistance of $BF_3.Et_2O$ (i.e. ROAc + PhSeH -> RSePh).[16b,c] Direct transformation of alcohols to selenides is possible by treatment with PhSeH in the presence of H_2SO_4, HCl, $ZnCl_2$, or $BF_3.Et_2O$ (i.e. ROH + PhSeH -> RSePh).[17]

Other preparative methods of selenides using selenolate ions are the transition metal-catalyzed reactions with organic halides[18a-c] or amines,[18d] and the photostimulated $S_{RN}1$ reactions with aryl or some alkyl halides.[19]

Addition Reactions.

In general, addition of benzeneselenol to unactivated alkenes[20a] hardly proceeds. However, if the alkenes bear a conjugated carbonyl group, such as -CHO, -C(O)R, -COOR, etc., the selenol adds smoothly under acidic,[20b] basic,[20c-f] or neutral[2c] conditions. Similarly, addition to conjugate dienes occurs under neutral conditions to give mainly 1,4-adducts.[21] In the presence of an optically active base such as an alkaloid, the addition of PhSeH to enones proceeds with asymmetric induction (eq 3).[20f]

(3)

Addition of benzeneselenol to alkynes is a useful tool for the synthesis of vinylic selenides. Under neutral conditions, the addition is initiated by a trace amount of oxygen contained in the reaction system, and proceeds by a radical chain mechanism. In this case, anti-Markovnikov-type adducts are formed exclusively (eq 4).[22] Contrary to this, when the same reaction is conducted in the presence of a catalytic amount of ***Palladium(II) Acetate***, Markovnikov-type adducts are obtained selectively in place of anti-Markovnikov adducts.[23] When the oxygen-induced radical reaction of allenes with PhSeH is examined, vinylic selenides are formed via the selective attack of PhSe&bdot; at the central carbon atom of allenes.[24]

(4)

Lewis acid-assisted addition of benzeneselenol to aldehydes and ketones affords synthetically important selenoacetals, which serve as precursors of α-selenoalkyllithiums (eq 5).[25]

Reduction.

Benzeneselenol is not only a selenation reagent as described above, but is also utilized as a mild reducing agent for various classes of organic compounds. The reduction of the carbon-carbon double bond of α,β-unsaturated carbonyl compounds with PhSeH is caused by an introduction of molecular oxygen into the reaction system[26a] or by irradiation with a sunlamp.[26b] The reduction proceeds by a radical chain mechanism, as illustrated in eq 6.

By a similar radical chain mechanism, aromatic aldehydes are reduced to benzylic alcohols at room temperature.[26c] In these reactions, no oxygen incorporation products are formed. This is due to the extremely high hydrogen-donating ability of PhSeH (the rate constant of hydrogen transfer from PhSeH to carbon radicals is estimated as 2.0×10^9 M^{-1} s^{-1} at 20 °C in THF).[27]

In addition, benzeneselenol reduces some nitrogen-containing functional groups such as nitro (NO_2), azo (N=N), and imino groups (C=N) to corresponding amino groups.[28] Organic sulfoxides are reduced to sulfides by treatment with PhSeH as exemplified in eq 7.[29]

Related Reagents.

Methanethiol; ***Methaneselenol***; ***Thiophenol***.

Benzenesulfenyl Chloride[1]

[931-59-9] · C_6H_5ClS · Benzenesulfenyl Chloride · (MW 144.62)

(useful reagent in regio- and stereoselective syntheses,[2] directed alkylation,[3] carbonyl transposition,[4] functionalization of unsaturated groups,[5] sulfenylation of silyl enolates,[6] cycloaddition[7])

Alternate Name: phenylsulfenyl chloride.

Physical Data: bp 88 °C/17 mmHg; 55 °C/3 mmHg; *d* 1.252 g cm^{-3}; n_D^{20} 1.6120.

Solubility: sol pentane, benzene, acetone, $CHCl_3$, CH_2Cl_2, CCl_4.

Form Supplied in: oily, dark red liquid; fumes in air.

Preparative Methods: easily obtained in high yields (90-100%) from ***Thiophenol*** or ***Diphenyl Diselenide*** by chlorination at -5 to 0 °C with chlorine gas[8] or ***Sulfuryl Chloride***.[9] Arenesulfenyl chlorides, including PhSCl, are conveniently prepared from arenethiols and ***N-Chlorosuccinimide*** in dichloromethane solution in quantitative yields and used without isolation in addition reactions to alkenes.[10]

Handling, Storage, and Precautions: extremely hygroscopic and must be carefully protected from moisture. It may be stored for months under dry inert gas in a refrigerator. However, there are two reports on the spontaneous explosion of PhSCl on storage, even in a refrigerator. It is recommended that PhSCl be prepared fresh as needed. Use in a fume hood.

Sulfenylation of Allylic Alcohols.

Sulfenyl (as well as sulfoxide and sulfonyl) groups favor formation of a stabilized carbanion at the neighboring carbon atom by metalation with strong bases, and thus direct sequential alkylation with alkyl halides to the α-position. However, directed γ-alkylation of allylic alcohols can be realized by application of a reversible sulfenate-sulfoxide [2,3]-sigmatropic rearrangement of their benzenesulfenate esters (eq 1).[3,11]

Sequential treatment of an allylic alcohol with ***n-Butyllithium*** and benzenesulfenyl chloride forms the sulfenate ester which spontaneously rearranges to the sulfoxide. The latter is metalated with ***Lithium Diisopropylamide*** (LDA) (*n*-BuLi affords 5-10% of byproducts) and treated with an alkyl iodide to give predominantly an α-alkylated (relative to the sulfoxide group) product. Finally, the alkylated sulfoxide on treatment with ***Trimethyl Phosphite*** and methanol rearranges back to the sulfenate ester and liberates the γ-alkylated allylic alcohol.

Formation of the *trans* isomer is favored, the *trans*:*cis* ratio being 2.7-30.0. Along with the α-alkylation of the sulfoxide, some of the γ-isomer usually forms, the α:γ ratio being 1.1 to >>10 depending on the structure of the sulfoxide. Cyclic allylic alcohols can be alkylated in the same way. The stereochemistry of [2,3]-sigmatropic rearrangements is discussed in Hoffmann's review.[12] The alkylative sulfenate-sulfoxide rearrangement is widely used in stereoselective syntheses of natural products, e.g. to form the side chains of coenzyme ubiquinone-10 and the growth-promoting steroid brassinolide,[13,14] for epimerization of 17-hydroxy-17-vinyl steroids.[15] A transformation of a prostaglandin with 13-*cis*-15β-hydroxy configuration to the inverted natural 13-*trans*-15α-hydroxy configuration (PGE_1) has been achieved employing this rearrangement and *p*-toluenesulfenyl chloride.[16]

The sulfenate-sulfoxide rearrangement can be used for alkylative carbonyl 1,3-transposition in vinyl carbonyl compounds, both acyclic and cyclic. In the case of saturated aldehydes or ketones they are treated at first with ***Vinylmagnesium Bromide*** (or ***Vinyllithium***) to form the allylic alcohol and then sulfenylated as shown in eq 2.[4]

(2)

The sulfoxide formed is lithiated with LDA and sulfenylated with diphenyl disulfide to undergo simultaneous rearrangement and elimination of PhSSPh to yield the enol sulfide. The latter, after hydrolysis with ***Mercury(II) Chloride***, gives the α,β-unsaturated aldehyde. Another example, for a cyclic alkenone, is shown in eq 3.

Phenyl sulfoxides, formed by reaction of 3-trimethylsilylallylic alcohols with PhSCl, have been used for the synthesis of unsaturated aldehydes (eq 4).[17] The α-silyl sulfoxide undergoes a sila-Pummerer rearrangement.

4-Trimethylsilyl-1-buten-3-ol by alkylation of the phenyl sulfoxide produced by reaction with PhSCl, and subsequent

desulfonylation and desilylation by ***Tetra-n-butylammonium Fluoride***, affords (*E*)-1,3-alkadienes in yields >90%.[18]

Sulfenylation of Propargylic Alcohols.

Benzenesulfenates of propargylic alcohols form allene sulfoxides by [2,3]-sigmatropic rearrangement. These can be easily transformed to useful derivatives[2d,e] or cyclized.[2f,h] The starting propargylic alcohols are readily accessible from the reaction of aldehydes or ketones with metal acetylides. Thus β-cyclocitral treated with propynyllithium, followed by PhSCl, after rearrangement affords the triene sulfoxide. Reduction with ***t-Butyllithium*** and methanol (as an internal proton source) yields 72% of the desulfurized hydrocarbon with retention of the double bond configuration (eq 5).[19]

A steroid 17-methylallene sulfoxide has been desulfurized under similar conditions with ***Methyllithium*** to give 72% of the β-methylallene derivative.[20] Trienyl and allenyl phenyl sulfoxides can therefore be desulfurized stereospecifically with retention of configuration using *t*-BuLi or MeLi.

The allene sulfoxide obtained when androst-4-ene-3,17-dione is treated with ***Dipotassium Acetylide*** and PhSCl, is functionalized as shown in eq 6 (only the D-ring of the steroid is shown) to form the corticosteroid structure.[21]

(6)

Phenyl sulfoxides with the *cis*-allenyldiene structure, obtained from corresponding propargylic alcohols, undergo spontaneous electrocyclic ring closure (eq 7).[22] As shown by detailed studies,[22b] the chiral center in the starting propynyl alcohol is stereospecifically transferred to the bridgehead carbon in the cyclized product drimatriene sulfoxide. This type of rearrangement has been used for an enantioselective synthesis of the sesquiterpene (+)-sterpurene.[2h,23]

A tandem [2,3]-sigmatropic rearrangement/Michael addition sequence occurs when the hydroxyphenylpropynol is sulfenylated with PhSCl (eq 8).[24] Other substituted benzofurans are obtained in this way.

Ketones from Arylacetonitriles.[2a]

Secondary aryl, alkyl, or diaryl acetonitriles, on sulfenylation with PhSCl and subsequent oxidative decyanation by ***N-Bromosuccinimide*** and NaOH, afford aryl, alkyl, or diaryl ketones in good yields (eq 9).[25] Four other oxidative decyanation methods were tested;[25b] the one shown is the best.

Reaction with α-Diazo Ketones.[2d]

The mild displacement of diazo nitrogen in α-diazo ketones by PhSCl represents a convenient and regiospecific method for functionalization of both cyclic and acyclic ketones at the α-position with halogen and phenylthio substituents (eqs 10-12).[26] These functionalized ketones are useful for a variety of syntheses, particularly phenylthiocyclopentenone for the synthesis of natural products based on 2,3-disubstituted cyclopentanone.[27]

Addition to Alkenic and Alkynic Compounds.

The most commonly used reaction of PhSCl is the addition to double and triple bonds. The regioselectivity of this reaction is not high and is determined mainly by the steric bulk of neighboring groups. Mixtures of regioisomers are usually formed with anti-Markovnikov adducts predominating, which on standing or refluxing in MeCN undergo conversion to Markovnikov products. Addition to cycloalkenes and alkynes is stereoselective and *trans* isomers form almost exclusively. This fact is consistent with an episulfonium ion intermediate.

Combined chlorosulfenylation-dehydrochlorination reactions have great synthetic utility for the conversion of alkenes to cyclic and acyclic vinyl, allyl, or dienyl phenyl sulfides (eqs 13 and 14).[10] The addition reaction is achieved by simply adding the alkene to a cooled (-50 to -78 °C) solution of PhSCl in CH_2Cl_2 and allowing the mixture to warm to rt. The dechlorination is carried out by briefly heating the β-chloroalkyl sulfides with the amidine base ***1,8-Diazabicyclo[5.4.0]undec-7-ene***. Higher yields on dechlorination are achieved with sulfones quantitatively formed by oxidation of the β-chlorosulfides with peroxy acids.

(13)

(14)

The addition of PhSCl can be used for functionalization of unsaturated groups,[2d] especially the isopropylidene terminus of natural isoprenoids. The synthetic sequence, as shown for the model compound 2-methylbut-2-ene (eq 15), involves addition of PhSCl, dehydrochlorination of isomeric adducts with Et_3N in DMF to methallyl sulfide, oxidation to the sulfoxide, and its rearrangement to the terminal *trans*-allylic alcohol.[5,28a,c] This procedure is used for the synthesis of the biologically important oxygenated terpenes nuciferal, *ar*-turmerone, ipsdienol, neotorreyol, 6-hydroxydendrolasin, 6-oxodendrolasin, and solanesol.[28a,b]

(15)

Complete *cis-trans* alkene isomerization can be achieved by PhSCl addition and dehydrochlorination with *t*-BuOK in

DMSO, which causes *trans* elimination of HCl and formation of vinyl sulfide with inverted configuration.[29]

Selective functionalization of 1,3-dienes by PhSCl involves formation of 1,2-adducts (which convert on heating or storage to 1,4-adducts) and hydrolysis, alcoholysis, or acetolysis of the chlorine in these adducts. The allyl alcohol obtained from the 1,2-adduct may be converted to an epoxide and aldehyde as shown in eq 16.[30]

(16)

Adducts of PhSCl to alkenes and cycloalkenes undergo methylation with $Me_2Zn/TiCl_4$ at the chlorine position with complete retention of configuration (controlled by the episulfonium ion intermediate).[2h,31] This one-pot process is termed carbosulfenylation.

Addition to *O*-Silylated Enols and Alkenols.[2d,i]

Silyl enol ethers react smoothly with PhSCl to give α-keto sulfides.[32] The reaction proceeds by addition of PhSCl to the enol double bond and elimination of chlorosilane.[33] *O*-Silylated dienolates (from unsaturated esters, ketones, and aldehydes) undergo γ-sulfenylation with this reagent,[34] with the exception of γ-chloro-substituted dienolates, which give α-products.[35] This type of reaction may be used for stereoselective synthesis of α-sulfenyl-β-hydroxy esters with the *anti* configuration (eq 17).[6] The latter can be converted into either *syn*- or *anti*-epoxides.

(17)

1-Phenylthiocyclohexanecarbaldehyde, obtained via PhSCl addition to trimethylsiloxymethylenecyclohexane, has been used in stereocontrolled synthesis of allylic alcohols.[36] Benzenesulfenyl chloride adducts of mono- and disubstituted alkenes and cycloalkenes, under ***Zinc Bromide*** catalysis, give stereospecific (*anti*) alkylation of *O*-silylated ester enolates.[37]

t-Butyldimethylsilyl ethers of 1-alkenylcycloalkanols, when treated with PhSCl, readily rearrange to the ring-expanded α-1-phenylthioalkylcycloalkanones via the episulfonium ion (eq 18).[38]

(18)

Cycloaddition.

A range of benzenesulfenyl chloride addition reactions to unsaturated bonds proceeds with simultaneous cyclization to form important compounds, examples of which are depicted below. These reactions include cyclization of isoprenoid β-keto esters (eq 19),[2f,39] homoconjugative cycloaddition to form tricyclenes (precursors of natural sesquiterpenes) (eq 20),[2d,e,7] cyclization of aryloxyphenylalkynes (eq 21),[40] lactonization (eq 22),[2c,41,42] and sulfenocycloamination of unsaturated amides and amines to form lactams, and pyrrolidine and piperidine rings (eqs 23 and 24).[2f,g,43]

Benzenesulfinyl Chloride[1]

(**1**; R = Ph)

[4972-29-6] · C_6H_5ClOS · Benzenesulfinyl Chloride · (MW 160.62) (**2**; R = *p*-Tol)

[10439-23-3] · C_7H_7ClOS · *p*-Toluenesulfinyl Chloride · (MW 173.64) (±)-(**2**)

[116471-91-1]

(preparation of sulfoxides[2] and sulfones;[3] synthesis of chiral sulfinyl-transfer reagents[4,5])

Physical Data: (**1**) mp 38 °C, bp 71-72 °C/1.5 mmHg; d^{25} 1.3470 g cm^{-3}, *n*25D 1.5770; (**2**) mp 54-58 °C, bp 113-115 °C/3.5 mmHg; *n*23.5D 1.6004.

Solubility: sol Et_2O, $CHCl_3$; decomposes in H_2O and alcohol.

Analysis of Reagent Purity: ^1H NMR,[6b] IR.[6c]

Preparative Methods: reaction of ***Sodium Benzenesulfinate*** or sodium *p*-toluenesulfinate with ***Thionyl Chloride***.[6a]

Handling, Storage, and Precautions: it has been reported that arenesulfinyl chlorides should not be distilled above 2 mmHg pressure because of the danger of explosion.[6d] Care also should be taken to avoid exposure of these sulfinyl chlorides to moisture (i.e. air, skin) owing to decomposition and formation of corrosive HCl.

Preparation of Sulfinyl Compounds.

Arenesulfinyl chlorides react with carbon nucleophiles such as enolates and Grignard reagents to produce sulfinylated compounds capable of undergoing further useful transformations;[2] sulfinyl esters react similarly (see ***Methyl Benzenesulfinate***). Incorporation of the sulfinyl group has been used for the regioselective alkylation of ketones via their dianions;[7] the sulfinyl group can be removed reductively with Al(Hg) (eq 1),[8] or eliminated with concomitant formation of a double bond to form α,β-unsaturated ketones (eq 2).[9] This process is one of the better methods of

introducing a double bond into a molecule; this procedure also has found use as an alternative when the popular phenylselenylation-oxidation method was deemed unsuccessful.[10]

Preparation of Unsaturated Sulfoxides and Sulfones.[2,11,12]

Alkenes can be converted directly to allylic sulfoxides with *p*-toluenesulfinyl chloride in the presence of ***Ethylaluminum Dichloride***[13] or ***Zinc Chloride***[14] via an ene reaction. Treatment of the allylic sulfoxides with

trimethyl phosphite in methanol affords the allylic alcohols via sulfoxide-sulfenate rearrangement in higher yields compared to direct oxidation with ***Selenium(IV) Oxide*** (eq 3).[14] Sulfinylation of higher terpenoids with benzenesulfinyl chloride was found to be more regioselective than the procedure of sulfenylation with benzenesulfenyl chloride followed by oxidation.[14]

Allylic sulfinic esters, prepared by reaction of *p*-toluenesulfinyl chloride and an allylic alcohol, rearrange on heating to yield allylic sulfones;[15] sulfinic esters of alkynols rearrange to yield sulfonylallenes (eq 4).[16]

Asymmetric Synthesis.

p-Toluenesulfinyl chloride can be used to prepare menthyl *p*-toluenesulfinates (MenTs) (see ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***), very useful chiral sulfinyl-transfer reagents.[4] Both the (*R*) and the (*S*) isomers can be prepared by reaction of the sulfinyl chloride with either (+)- or (-)-menthol, respectively.[17,18] (See ***Methyl***

Benzenesulfinate for additional discussion on menthyl *p*-toluenesulfinate.) MenTs reacts with a variety of nucleophiles such as metallated esters,[19] dialkylhydrazones,[20] and amides,[21] with inversion of configuration, to form chiral sulfoxides. These substrates are capable of undergoing further enantioselective manipulation to yield optically active compounds in high enantiomeric excess.[22,23]

Chiral vinyl sulfoxides can be prepared from MenTs and metallated vinylic reagents;[24] vinyl sulfoxides are recognized as valuable synthetic intermediates.[11] For example, the conjugate addition of organometallic compounds to enantiomerically pure 2-(*p*-tolylsulfinyl)-2-cyclopentenones occurs with high stereoselectivity; the formation of the desired stereoisomer can be controlled by the presence or absence of a divalent metal complexing agent (eq 5).[24]

Other routes to chiral vinyl sulfoxides utilizing MenTs include a modified Horner-Emmons procedure that usually results in a mixture of (*E*) and (*Z*) isomers (eq 6),[17] and addition of alkynyl Grignard reagents to MenTs followed by stereospecific reduction to either the (*E*) or (*Z*) isomers (eq 7).[25]

(6)

(7)

Recently, a new class of chiral sulfinylating agents have been prepared from oxazolidinones and *p*-toluenesulfinyl chloride (eq 8).[5] These *N*-sulfinyloxazolidinones also react with a wide range of nucleophiles, with inversion of configuration, to form chiral sulfoxides in high yield and enantiomeric excess (ee). These reagents reportedly are purified more easily (crystallization *and* chromatography) than the menthyl esters (crystallization only), and are more reactive than the menthyl *p*-toluenesulfinates.

Benzenesulfonic Anhydride[1]

[512-35-6] · $C_{12}H_{10}O_5S_2$ · Benzenesulfonic Anhydride · (MW 298.33)

(mild sulfonating agent; useful for the preparation of sulfonamides, sulfones, and sulfonate esters)

Physical Data: mp 65-80 °C; 88-91 °C after recrystallization from ether.

Solubility: sol diethyl ether, benzene, toluene; insol H_2O.

Preparative Methods: prepared on a large scale by heating benzenesulfonic acid with excess phosphorus pentoxide mixed with an inert support.[1] An inert support of 1:1 Supercel kieselguhr and Gooch asbestos was mixed with phosphorus pentoxide and slowly added to benzenesulfonic acid, first at rt then heating to 100 °C. The resultant mixture was heated at 100 °C for 5 h, 1,2-dichloroethane was added, and the solution was refluxed for 10 min. After cooling and successive filtrations, benzenesulfonic anhydride was recovered in 70% yield.

Handling, Storage, and Precautions: the reagent can be stored at rt for extended periods under anhydrous conditions. Liquefication occurs upon exposure to air for 2.5 h. Explosive when mixed with 90-95% H_2O_2.

General Reactions.

Arenesulfonic anhydrides have been used as precursors for a variety of substituted sulfones, sulfonate esters, and sulfonamides. The Friedel-Crafts reaction of benzenesulfonic anhydride and benzene in the presence of $AlCl_3$ provided diphenyl sulfone in 99% yield (eq 1).[1] This has proved to be milder and more efficient than the similar reaction using ***Benzenesulfonyl Chloride***.[1,2]

$$(PhSO_2)_2O + PhH \xrightarrow{AlCl_3} PhSO_2Ph \qquad (1)$$

Azoxybenzene is known to rearrange in concentrated sulfuric acid to *p*-hydroxyazobenzene.[3] This acid-catalyzed Wallach rearrangement[4] has been extended by using arenesulfonic anhydrides to furnish the corresponding *p*-

arenesulfonyloxyazobenzenes in reasonable yields (eq 2).[5]

Solvolysis of Benzenesulfonic Anhydride.

Solvolysis of various arenesulfonic anhydrides in aqueous acetone revealed the reaction mechanism to be S_N2 in accord with established results for similar systems.[6]

Benzenesulfonyl Azide

[938-10-3] · $C_6H_5N_3O_2S$ · Benzenesulfonyl Azide · (MW 183.18)

(1,3-dipolar reagent that undergoes cycloaddition to alkenes, enamines and enol ethers;[1] reacts with phosphines and phosphites to form iminophosphoranes[2,3])

Physical Data: mp 105 °C with decomposition.

Solubility: sol most organic solvents.

Preparative Methods: prepared by the reaction of ***Benzenesulfonyl Chloride*** with excess ***Sodium Azide*** in a water-ethanol mixture.[4,5] The formation of ethyl benzenesulfonate as a byproduct may be avoided by addition of neat benzenesulfonyl chloride to an ethanolic solution of sodium azide.[6] A preparation of benzenesulfonyl azide by oxidation of phenylsulfonylhydrazine in the presence of clay-supported iron(III) nitrate (clayfen) has been reported.[7]

Purification: recrystallization from ethanol.

Handling, Storage, and Precautions: crude benzenesulfonyl azide when heated detonates violently.[8] Use in a fume hood.

Dipolar Cycloaddition.

The principal use of benzenesulfonyl azide is in 1,3-dipolar cycloaddition[1] reactions with alkenes and functionally substituted alkenes.[9] The reagent reacts with norbornene to yield an intermediate triazoline which decomposes to an *exo*-aziridine (eq 1).[10,11] In the case of norbornadiene the initially formed aziridine readily rearranges to a ring expanded product (eq 2).[6,12,13]

(1)

(2)

With *N*-methyl-1,2-dihydropyridine, benzenesulfonyl azide affords an isolable aziridine (eq 3).[14] In contrast, *N*-methyl-1,2,3,4-tetrahydropyridine undergoes cycloaddition, decomposition to the aziridine, and then rearrangement to the corresponding amidine sulfonamide (eq 4).[15]

(3)

(4)

The reaction of benzenesulfonyl azide with enol ethers follows a different course. Dihydropyran affords imidate (**1**) in crude quantitative yield and when the imidate is heated it rearranges to lactam (**2**) (eq 5).[16] The more sluggish 6-methoxy derivative reacts in refluxing acetonitrile to afford the lactam product directly (eq 6).

(5)

(1) **(2)**

(6)

With enol ethers of cyclic ketones, benzenesulfonyl azide is one of a variety of sulfonyl azides which effect a ring contraction reaction.[17,18] A triazoline is again assumed to be an intermediate in the process (eq 7).

(7)

Cycloaddition of benzenesulfonyl azide to cobaltacycles leads to the production of substituted pyrroles (eq 8).[19]

(8)

Formation of Iminophosphoranes.

The reaction of benzenesulfonyl azides with triphenylphosphine (eq 9)[3] or with triphenyl or triethyl phosphite[2] leads to the formation of sulfoniminophosphoranes.

Benzenesulfonyl Bromide

[2297-65-6] · $C_6H_5BrO_2S$ · Benzenesulfonyl Bromide · (MW 221.07)

(used as a sulfonating reagent to produce sulfonamides[2-4] and sulfones[5-8])

Physical Data: mp 19.5 °C; bp 76-78 °C/0.17 mmHg.

Solubility: sol CH_2Cl_2, Et_2O, THF, C_6H_6, MeCN.

Preparative Method: prepared by reaction of sodium benzenesulfonate with bromine in 98% yield.[1]

Handling, Storage, and Precautions: by analogy to ***Benzenesulfonyl Chloride***, benzenesulfonyl bromide should be assumed to be an irritant and harmful by skin absorption and ingestion. Benzenesulfonyl bromide is best used immediately following preparation and may be used in situ. The reagent is moisture sensitive and will react with nucleophilic solvents (e.g. alcohols), liberating HBr and therefore should be stored under an inert atmosphere. Use in a fume hood.

Protection of Nitrogen; Formation of Sulfonamides.

Unlike the corresponding arenesulfonyl chlorides (see ***Benzenesulfonyl Chloride*** and ***p-Toluenesulfonyl Chloride***), benzenesulfonyl bromide has been used much less extensively in organic synthesis. Primary amines[2] and imidazoles (eq 1)[3] have been converted to the corresponding benzenesulfonamides and, with indoles, bromination at C-3 occurs with concomitant sulfonamide formation (eq 2).[4]

(1)

(2)

Addition to Unsaturated Compounds.

Benzenesulfonyl bromide undergoes radical-mediated addition to alkenes and alkynes. Addition to alkenes leads to bromo sulfones, which undergo dehydrobromination to give vinyl sulfones (eq 3).[5]

(3)

Addition to vinyl ethers and vinyl esters is regioselective, leading to the corresponding β-alkyloxy/acyloxy sulfone.[6] Addition to alkynes gives vinyl sulfones via a radical pathway. These reactions can be carried out in the presence of peroxide initiators,[7] with Lewis acids such as ***Copper(II) Bromide*** (eq 4),[8] or thermally (eq 5).[8,9]

(4)

(5)

With enynes, mixtures of addition products resulting from 1,2- and 1,4-addition have been observed.[10,11] Radical addition with tricyclic alkanes has also been observed.[12]

Reaction with Arenes.

Benzenesulfonyl bromide reacts readily with trifluoromethanesulfonyl derivatives, yielding the corresponding mixed anhydrides (eq 6)[13] which have been used to convert arenes to aryl phenyl sulfones under Friedel-Crafts-type conditions.

$$PhSO_2Br + CF_3SO_2Ag \xrightarrow[\text{quantitative}]{MeCN,\ 0°C} PhSO_2OSO_2CF_3 + AgBr \quad (6)$$

(used in a range of sulfonating reactions to produce sulfonamides,[5-7] sulfonate esters,[8-10] mixed anhydrides,[13] and sulfones [15-17])

Physical Data: mp 13-15 °C, bp 251.5 °C/760 mmHg, 113-115 °C/10 mmHg; *d* 1.384 g cm^{-3}.

Solubility: sol CH_2Cl_2, Et_2O, THF, C_6H_6, MeCN.

Preparative Methods: prepared by reaction of sodium benzenesulfonate with phosphorus pentachloride or phosphorus oxychloride,[1] or by chlorosulfonation of benzene;[2] also commercially available.

Purification: may be purified by distillation at reduced pressure.

Handling, Storage, and Precautions: benzenesulfonyl chloride is an irritant and harmful by skin absorption and ingestion. The reagent is moisture sensitive and will react with nucleophilic solvents (e.g. alcohols), liberating HCl and therefore should be stored under an inert atmosphere. Use in a fume hood.

Identification of Primary Amines; the Hinsberg Test.

Benzenesulfonyl chloride is used to recognize primary amines. A primary amine will react to form an alkali-soluble benzenesulfonamide (containing an acidic NH), whereas secondary amines form sulfonamides which are insoluble in alkali, and tertiary amines do not react.[3] However, the validity of the test is dependent on reaction velocity, concentration, temperature, and solubility[4] and appropriate precautions must be acknowledged.

Protection of Nitrogen; Formation of Sulfonamides.

Benzenesulfonyl chloride is used to protect amines, indoles and other nitrogen based functional groups (eqs 1-3).[5-7] A variety of bases and solvents can be used, depending on the substrate. Other arene- and alkanesulfonyl chlorides can also be used for this purpose (see ***p-Toluenesulfonyl Chloride*** and ***Methanesulfonyl Chloride***). Sulfonamide cleavage may be achieved under either acidic or basic conditions.

(1)

(2)

(3)

Formation of Sulfonate Esters.

The reaction of phenols,[8] alcohols,[9] and *N*-hydroxy compounds[10] with benzenesulfonyl chloride produces *O*-sulfonate esters, one application of which is as a good leaving group.

The reaction of 1,4- or 1,5-diols with benzenesulfonyl chloride in the presence of a tertiary amine gives cyclic ethers (eq 4).[11] This procedure can be adapted to give cyclic tertiary amines.[12]

(4)

Formation of Mixed Anhydrides.

Benzenesulfonyl chloride will react with carboxylic acids to give mixed anhydrides,[13] which can be utilized in the formation of alkenes via β-lactone formation followed by fragmentation (eq 5).[14] Direct conversion of the hydroxy acid to the alkene can be achieved by the addition of benzenesulfonyl chloride at 45-50 °C in 55-82% yield.

Addition to Unsaturated Compounds.

Benzenesulfonyl chloride will undergo radical addition to alkenes and alkynes under radical conditions (eq 6)[15] or Cu^{II} catalysis (eq 7).[16]

Addition of benzenesulfonyl chloride to trimethylsilyl enol ethers gives β-keto sulfones in good yield (eq 8).[17]

Reaction with Arenes.

Benzenesulfonyl chloride will react with arenes in the presence of ***Aluminum Chloride*** to give biaryl sulfones.[18]

Benzenesulfonyl Isocyanate

[2845-62-7] · $C_7H_5NO_3S$ · Benzenesulfonyl Isocyanate · (MW 183.18)

(derivatizing agent for alcohols and phenols;[1] used to convert (thio)carbonyl compounds to imino derivatives;[2,3] used in the preparation of β-lactams[4] and a wide variety of heterocycles via cycloaddition reactions)

Physical Data: bp 130 °C/9 mmHg; *d* 1.369 g cm^{-3}.

Solubility: sol chlorinated, aromatic, and ethereal solvents; reacts violently with H_2O, basic and protic solvents.

Form Supplied in: colorless liquid; widely available; more expensive than *p*-toluenesulfonyl isocyanate.

Handling, Storage, and Precautions: lachrymator; corrosive; use only in a fume hood; wear protective gloves and preferably a NIOSH-approved respirator. All transfers and reactions should be carried out under anhydrous conditions. Store in a cool dry place, taking care to avoid contamination with protic, basic, or organometallic materials, as these may induce polymerization. Toxicity data for isocyanates are available.[5]

Hydroxy Derivatization.

First prepared by Billetter in 1904, benzenesulfonyl isocyanate has been found to be an excellent reagent for the preparation of highly crystalline carbamates from hindered primary and secondary alcohols and polynitrophenols in very high yield (eq 1).[1] Indeed, the sulfonyl group not only activates the isocyanate moiety relative to alkyl or aryl substituents,[1,6] but these derivatives are also very easily purified (typically by aqueous extraction). Surprisingly, no reports have been made of amine derivatizations, despite a great potential for this purpose.

$$PhSO_2NCO \xrightarrow[85\text{-}100\%]{ROH} PhSO_2NHCO_2R \qquad (1)$$

R = alkyl, aryl

(Thio)carbonyl to Imide Conversion.

This transformation appears quite general, occurring for ketone, amide, oxamate,[2] and thioamide[3] groups. Heating the (thio)carbonyl derivative with benzenesulfonyl isocyanate leads to a formal [2 + 2] cycloaddition, followed by fragmentation, to give the N-protected imine derivative and CO_2 or COS (eq 2). Although this conversion represents an interesting and general method of preparing imines, (thio)imino esters, amidines, etc., note that removal of the benzenesulfonyl group generally requires vigorous reaction conditions that may, in certain circumstances, destroy the imino derivative.

(2)

X = O, S; Y = alkyl, aryl, O, NR^1R^2, S, CO_2R

[2 + 2] and [2 + 3] Cycloadditions.

All isocyanates undergo these reactions to some extent, but benzenesulfonyl isocyanate is several orders of magnitude more reactive for some types of cycloaddition.[6,7] Perhaps the most useful reaction involving this isocyanate is [2 + 2] cycloaddition with enol ethers,[4] ketenes, and thioketenes[8] to afford β-(thio)lactams. This is a very useful entry into N-protected β-lactams, despite the relative difficulty of removing the benzenesulfonyl group without cleaving the β-lactam (eq 3).

(3)

X, Y = H, OR, =O, =S; R^1, R^2 = H, alkyl, aryl

Interestingly, the analogous N,O-ketene acetals give only acyclic products.[9] A number of [2 + 3] cycloadditions have been reported, including the syntheses of indolin-2-ones,[10] dehydroazepinones,[11] and tetrazolones.[7]

Miscellaneous Uses.

The patent literature contains numerous examples of *N*-benzenesulfonyl carbamate and urea compounds (derived respectively from alcohols and amines) exhibiting pharmaceutically[12] and agriculturally useful properties (e.g. imparting H_2O solubility and functioning as a pharmacophore). Benzenesulfonyl isocyanate itself has also been reported in the patent literature to be of use in polymer chemistry as a dehydrating, stabilizing, and crosslinking agent, and as a catalyst or reagent in the preparation of carbodiimides and other isocyanates. See also ***p-Toluenesulfonyl Isocyanate***.

Benzenetellurinic Anhydride[1]

[94971-86-5] · $C_{12}H_{10}O_3Te_2$ · Benzenetellurinic Anhydride · (MW 457.41)

(mild and selective oxidizing agent by itself and as mixed anhydrides;[1-3] catalyst for hydration of ethynyl group;[3] vicinal *syn* diacetoxylating agent of alkenes;[4] electrophiles, as mixed anhydrides, for acetoxytellurinylation of alkenes, cyclofunctionalization of hydroxyalkenes,[5] aminotellurinylation of alkenes, cyclofunctionalization of alkenic carbamates,[6] one-pot synthesis of 2-oxazolidinones from alkenes,[7] amidotellurinylation of alkenes[8] as well as alkynes,[9] one-pot synthesis of 2-oxazolines from alkenes[8] as well as oxazoles from alkynes,[9] and one-pot conversion of allylsilanes to allylamines[10])

Physical Data: mp 220-225 °C.

Solubility: almost insol in common organic solvents except acetic acid. In acetic acid it gradually changes to the mixed anhydride, benzenetellurinyl acetate.

Preparative Methods: benzenetellurinic anhydride is readily obtained as a white solid by alkaline hydrolysis of phenyltellurium trihalides and subsequent acidification with AcOH or by oxidation of ***Diphenyl Ditelluride*** with air or selenous acid.[1] The following arenetellurinic anhydrides are prepared similarly: 4-ethoxybenzene-, mp 234-238 °C (dec); 4-hydroxybenzene-, mp 200 °C (dec); 4-methoxybenzene-, mp 200-205 °C; 4-methylbenzene-, mp 200 °C; 4-phenoxybenzene-, mp 276 °C; 2-naphthalene-, mp 230 °C.[1]

Purification: it was reported that the anhydride could be recrystallized from acetic acid.[11]

Handling, Storage, and Precautions: the anhydride is hygroscopic. It must be dried over P_2O_5 before use and stored as such. Toxicity of this compound is not well-defined. All manipulations are recommended to be done with gloves and in a fume hood.

Oxidation.

Benzenetellurinic anhydride and its congeners[1] readily oxidize thiols to disulfides, phosphines to phosphine oxides, hydroquinones to quinones, thioamides to nitriles, thioesters to esters, xanthates to thioesters, thioureas to carbodiimides, benzyl alcohols to benzaldehydes, and benzoin to benzil, respectively.[2,3] The mixed anhydrides (PhTe(O)OX; X = Ac, $C(O)CF_3$, SO_2CF_3) exhibit similar reactivities as the parent anhydride but also show some different selectivities to thioamides and thioureas to afford thiadiazole and urea derivatives, respectively.[3b]

Catalysis for Ethynyl Hydration.

The *p*-ethoxy congener catalyzes hydration of terminal alkynes in refluxing acetic acid but is inert to internal alkynes (eq 1).[3a]

Vicinal *syn* Diacetoxylation.

Under the catalysis of sulfuric acid, the reagent oxidizes alkenes in AcOH to afford vicinal *syn*-diacetates (eq 2).[4] The reaction was assumed to be initiated by benzenetellurenic acid derivatives generated reductively and to proceed via *trans* acetoxytellurenylation followed by S_N2 displacement of the PhTe group by AcOH.

Electrophiles for Acetoxytellurinylation of Alkenes and Cyclofunctionalization of Hydroxyalkenes.

The reagent and its congeners react with alkenes in AcOH to give acetoxytellurinylation products, which are reduced to Markovnikov-type β-acetoxytellurides. They also induce cyclofunctionalization of hydroxyalkenes to 5-, 6-, and 7-membered cyclic ethers. Treatment of the reagents with AcOH or its anhydride readily afford their mixed anhydrides (eq 3; Ar = Ph, *p*-$MeOC_6H_4$-, 2-naphthyl; X = MeCO), which become soluble in common solvents such as CH_2Cl_2 and $CHCl_3$ and perform the same transformation much more rapidly under the catalysis of Lewis acids such as ***Boron Trifluoride Etherate***. These reactions are highly regio- and *trans* stereoselective (eq 4).[5]

$$[ArTe(O)]_2O + 2\,XOH \longrightarrow 2\,ArTe(O)OX + H_2O$$
$$[ArTe(O)]_2O + X_2O \longrightarrow 2\,ArTe(O)OX \qquad (3)$$

(4)

Electrophiles for Aminotellurinylation, Cyclofunctionalization of Alkenic Carbamates, and One-Pot Synthesis of 2-Oxazolidinones from Alkenes.

The mixed anhydrides of this reagent (eq 3; Ar = Ph, X = MeCO, CF_3CO) with carbamates effect regio- and stereoselective aminotellurinylation of alkenes in the presence of $BF_3.OEt_2$ in $CHCl_3$ to give (2-phenyltellurinyl)alkyl carbamates. The triflate (eq 3; Ar = Ph, X = CF_3SO_2) does it under milder conditions without Lewis acid. This reaction can be extended to cyclofunctionalization of alkenic carbamates into nitrogen heterocycles (eq 5).[6] When the aminotellurinylation is carried out at higher temperature, 2-oxazolidinones are obtained in high yields via a regio- and stereoselective path combined by *trans* addition and intramolecular S_N2 substitution of the PhTe(O) group (eq 6).[7]

(5)

cis: $R^1 = R^4 = n$-Pr, $R^2 = R^3 = H$, 84%
trans: $R^1 = R^3 = n$-Pr, $R^2 = R^4 = H$, 53%

Electrophiles for Amidotellurinylation of Alkenes and Alkynes, and for One-Pot Synthesis of 2-Oxazolines and Oxazoles from Alkenes and Alkynes, respectively.

The mixed anhydride of the reagent (eq 3; Ar = Ph, X = CF_3CO) in the presence of $BF_3.OEt_2$ effects amidotellurinylation of alkenes in MeCN at rt to give 2-acetamidoalkyl phenyl telluroxides, which suffer further intramolecular S_N2 substitution at higher temperature to afford 2-oxazolines in high yields. These reactions are highly regio- and stereoselective (eq 7).[8] The trifluoromethanesulfonic anhydride (eq 3; Ar = Ph, X = CF_3SO_2) combined with MeCN undergoes (*E*) stereoselective amidotellurinylation of alkynes in the presence of a protonic acid. The addition products from terminal alkynes isomerize thermally to (*Z*)-β-acetamidovinyl phenyl telluroxides, whereas those from internal alkynes are transformed into oxazoles via a spontaneous intramolecular cyclization (eq 8).[9]

cis: $R^1 = R^4 = n$-Pr, $R^2 = R^3 = H$, 83%
trans: $R^1 = R^3 = n$-Pr, $R^2 = R^4 = H$, 56%

Electrophile for One-Pot Conversion of Allylsilanes to Allylamines.

In the presence of $BF_3.OEt_2$ in $ClCH_2CH_2Cl$, the mixed anhydride of this reagent (eq 3; Ar = Ph, X = CF_3CO) converts at rt allylsilanes to allyl phenyl telluroxides, which are treated in situ with primary or secondary amines at 65 °C to give the corresponding allylamines. The transformation is highly stereoselective. Thus γ-substituted allylsilanes with arylamine give γ-substituted allylamines but with alkylamine give α-substituted allylamines (eq 9).[10]

(η^6-Benzene)tricarbonylchromium

[12082-08-5] · $C_9H_6CrO_3$ · (η^6-Benzene)tricarbonylchromium · (MW 214.14)

(phenyl cation equivalent[1])

Alternate Name: (benzene)chromium tricarbonyl.

Physical Data: mp 161.5-163 °C.

Solubility: sol THF, ether, benzene.

Form Supplied in: yellow crystals.

Preparative Method: for cases where large quantities are needed, it is easily prepared from the reaction of benzene with ***Hexacarbonylchromium***.[2]

Purification: recrystallized from ether/petroleum ether. Can also be purified by column chromatography on silica gel.

Handling, Storage, and Precautions: slightly air sensitive.

Nucleophilic Substitution.

Treatment of (benzene)tricarbonylchromium (**1**) with various nucleophiles at 25 °C, followed by ***Iodine*** oxidation, effects nucleophilic substitution of hydrogen.[1] Nucleophiles derived from carbon acids having a pK_a > ~22 lead to the arylated products (e.g. **3**) in high yield (eq 1). Nucleophilic addition produces the pentadienylchromium complex (**2**) which converts to the substituted arene upon oxidation. Alternatively, treatment of complex (**2**) with ***Trifluoroacetic Acid*** leads to the cyclohexadiene derivatives (**4-6**) (eq 2).[3] Alkyllithium reagents and Grignard reagents are not arylated under these conditions due to competing deprotonation and addition to the carbonyl ligands.

Nucleophilic Addition/Carbonylation.

Nucleophilic addition to (benzene)tricarbonylchromium, followed by treatment with alkyl iodides in the presence of carbon monoxide, leads to *trans*-5-acyl-6-substituted-1,3-cyclohexadiene derivatives (e.g. **7**) (eq 3).[4] Only very reactive carbanions such as 2-lithio-2-alkyl-1,3-dithiane derivatives will undergo this transformation. When less reactive carbanions are employed, the nucleophile undergoes direct alkylation by the alkyl iodide without incorporation of the benzene ring.

Lithiation.

Treatment of (benzene)tricarbonylchromium with ***n-Butyllithium*** produces the lithiated arene complex (**8**). Treatment of complex (**8**) with electrophiles produces the monosubstituted benzene complexes (e.g. **9**) (eq 4),[5,6] which are converted to the free arenes by treatment with iodine or ***Cerium(IV) Ammonium Nitrate***. (Benzene)tricarbonylchromium thus appears to be substantially more acidic than benzene.

Hydrogenation Catalyst.

(Benzene)tricarbonylchromium catalyzes the hydrogenation of 1,3-dienes (eq 5).[7] The major product is the (*Z*)-alkene resulting from 1,4-addition of hydrogen. Isolated double bonds are not hydrogenated using this catalyst.

(5)

$Z{:}E = 92{:}8$

1,3-Benzodithiol-1-ium Tetrafluoroborate[1]

[57842-27-0] · $C_7H_5BF_4S_2$ · 1,3-Benzodithiol-1-ium Tetrafluoroborate · (MW 240.07)

(formyl[2] and methyl cation[3] equivalent; nucleoside hydroxyl protection group;[4] 1,1-dipole equivalent[11])

Physical Data: mp 150-150.5 °C (dec).

Solubility: sol MeCN and DMF (slowly reacts); insol ether.

Form Supplied in: light brown powder.

Preparative Method: treatment of 2-(3-methylbutoxy)-1,3-benzodithiole[2] with ***Tetrafluoroboric Acid*** in ***Acetic Anhydride*** at 0 °C.

Purification: recrystallized from acetic acid or acetonitrile/ether.

Handling, Storage, and Precautions: can be stored in the absence of moisture and light; no toxicity data is currently available; 1,3-benzodithiol-1-ium perchlorate *[32283-21-9]* is also known,[2] but poses a risk of explosion.

Acyl Cation Equivalent.

Benzodithiolium ions react with a wide range of carbon nucleophiles to afford masked aldehyde and ketone products.[2] Electron-rich arenes (eq 1)[5] and active methylene compounds[6] are useful nucleophiles and 2-substituted benzodithiolium ions lead to good yields of 1-deuteroaldehydes upon reaction with $LiAlD_4$ and subsequent hydrolysis.[7]

(1a)

Ketone products are available by a reaction sequence involving Grignard reagent addition to the parent cation followed by regeneration of the 2-substituted 1,3-benzodithiolium ion via ***Triphenylmethyl Perchlorate*** mediated hydride abstraction. A second Grignard reagent addition and dithiole hydrolysis completes the sequence (eq 2).[8] ***Chloramine-T*** in conjunction with ***Mercury(II) Chloride*** is a superior method for benzodithiole hydrolysis.[7,8a] Reductive cleavage of the benzodithiole unit can be achieved by treatment with ***Sodium-Ammonia***.[8]

(1b)

Methyl Cation Equivalent.

Mild *N*-methylation of guanosine has been achieved employing 1,3-benzodithiol-1-ium tetrafluoroborate as a masked methyl group. Treatment of the *O*-silylated guanosine derivative (**2**) with (**1a**) provided high yields of (**3**), which on exposure to ***Tri-n-butylstannane*** provided the *N*-methyl compound (**4**) (eq 3).[3] This process can be repeated to afford the corresponding *N*,*N*-dimethyl derivative. A related *O*-methylation sequence is not as effective.[3,9]

(3)

Nucleoside Hydroxyl Group Protection.

The benzodithiole group has been used as a selective protecting group for the 5´-hydroxyl group of thymidine (eq 4).[4] No competitive reactions with base residues were noted with any of the nucleosides studied. The benzodithiole protection can be cleaved to reveal the free hydroxyl group with 2% aqueous TFA.

(4)

1,1-Dipole Equivalents.

The parent 1,3-benzodithiole species can be rendered nucleophilic by deprotonation at the 2-position with strong base. A useful reagent for expressing this nucleophilic character is readily available 2-diethoxyphosphinyl-1,3-benzodithiole.[10] Reaction of the 2-lithiated species (**5**) with aldehydes affords excellent yields of ketene dithioacetals suitable for accessing the corresponding substituted benzodithiolium cations for subsequent carbon-carbon bond formation (eq 5).[11]

See also ***2-(3-Methylbutoxy)-1,3-benzodithiolane***.

Benzohydroxamic Acid

[495-18-1] · $C_7H_7NO_2$ · Benzohydroxamic Acid · (MW 137.14)

(precursor to benzoyl nitroso compounds and used in the synthesis of a wide range of heterocyclic compounds[1])

Physical Data: mp 125 °C.

Solubility: sol water; slightly sol other organic solvents.

Form Supplied in: solid; widely available.

Benzohydroxamic acid shows considerable reactivity towards various functional groups. For example, reaction of this reagent with certain alkynic compounds gives 1,3-oxazoles in good yields (eq 1).[1] Benzohydroxamic acid can also be used as a precursor to the Lossen rearrangement (eq 2).[2]

(1)

(2)

Oxidation of benzohydroxamic acid with $Pr_4N^+IO_4^-$ in DMF at 23 °C generates a transient benzoylnitroso compound. If the oxidation is carried out in the presence of a diene, cycloaddition products are formed in high yields (eqs 3-5).

For example, oxidation in the presence of cyclohexadiene gives a [2.2.2] bicyclic adduct.[3] Reductive cleavage of the N-O bond of the cycloadduct with the preservation of both the double bond and the amide carbonyl can be readily accomplished in quantitative yield by treating the adduct with an excess of ***Aluminum Amalgam*** in THF-H_2O at 0 °C.

(3)

(4)

(5)

Eq 6 details the result of a study of the regioselectivity of the [4 + 2] cycloaddition of PhCONO with a 2-substituted 1,3-cyclohexadiene.[4] The ratio of regio adducts is not affected by change in the reaction solvent, temperature, or the source of the nitroso compound.

Benzoic Anhydride

[93-97-0] · $C_{14}H_{10}O_3$ · Benzoic Anhydride · (MW 226.23)

(primarily used as an acylation reagent;[1] can be added to alkynes[2] and carbon-nitrogen double[3] and single bonds[4,5])

Physical Data: mp 42-43 °C; bp 360 °C; *d* 1.199 g cm^{-3}.

Solubility: insol H_2O; sol alcohol, ether, $CHCl_3$, acetone, EtOAc, benzene, toluene, glacial acetic acid, acetic anhydride; slightly sol pet ether.

Form Supplied in: white crystalline solid; widely available.

Purification: benzoic acid is removed by washing with $NaHCO_3$, then water, followed by drying. The reagent can be recrystallized from benzene (0.5 mL g^{-1}) by adding a small amount of pet ether (bp 40-60 °C) and cooling. It can also be distilled at 210-220 °C at 20 mmHg.

Handling, Storage, and Precautions: irritating to eyes, respiratory system, and skin. May decompose on exposure to moist air or water.

Acylation.

The most common use of this reagent is as a protecting group for oxygen[1a,b] and nitrogen[1c] functional groups. The ease of benzoylation and the ready removal of the protecting group under mildly basic conditions render it valuable in organic synthesis.[1a] In addition, this reagent has found many uses as an acylating agent for stabilized carbanions.[1d,e] Its participation in the Friedel-Crafts acylation reaction[1f] is well known and has been extended to processes involving Lewis acid catalysts.[1g] In the presence of ***Titanium(IV) Chloride*** and ***Silver(I) Perchlorate*** as catalysts, this reagent reacts with silyl derivatives of acids and alcohols to give esters via intermediate mixed anhydrides (eq 1).[1h]

(1)

$R^1 = Ph(CH_2)_2$, $R^2 = Ph(CH_2)_3$

Addition Reactions.

Addition of an excess of this reagent to alkynes, promoted by a Lewis acid, results in formation of 1,3-dicarbonyl compounds (eq 2).[2] This reagent can also add across carbon-nitrogen double[3] and single bonds[4] (eqs 3 and 4). Tertiary amines are dealkylated in the presence of metal salts, resulting in the formation of tertiary amides (eq 5).[5]

(2)

(3)

(4)

(5)

Miscellaneous Uses.

This reagent has been shown to decarboxylate α-keto acids upon heating with an excess of pyridine, avoiding Perkin-type condensations.[6] Cyclopropenone oximes have been activated by this reagent to study the Beckmann rearrangement of the *O*-benzoylated derivatives.[7] Substitution of an allylic phenyl ether using this reagent, catalytic ***Palladium(II) Acetate***, and ***Triphenylphosphine*** gives mixtures of allylic benzoates (eq 6).[8]

Benzonitrile Oxide[1]

[873-67-6] · C_7H_5NO · Benzonitrile Oxide · (MW 119.12)

(versatile reagent for regio- and stereoselective construction of heterocycles; synthesis of polyfunctionalized acyclic and cyclic compounds[1])

Physical Data: mp 18-19 °C; bp 113 °C/15 mmHg; *d*224 1.10 g cm^{-3}; *n*22D 1.6172.

Solubility: sol ether, benzene, CCl_4.

Form Supplied in: prepared as described below; not commercially available.

Preparative Methods: the most widely employed methods of benzonitrile oxide (**1**) generation involve triethylamine-mediated dehydrohalogenation of benzhydroxamoyl chloride (**2**) (or bromide), readily accessible through chlorination of benzaldoxime,[2a] or dehydration of α-nitrotoluene with PhCNO[2b,c] or $PhSO_2Cl$ or $ClCO_2Et$ and a catalytic amount of Et_3N (Mukaiyama reaction).[2d] A reaction of (**2**) with alkali metal fluorides also provides a facile quantitative generation of (**1**).[2e] Although (**1**) has been obtained as a crystalline solid,[2f] it is commonly generated in situ.[1] Et_3N almost immediately reacts with (**2**),[3] and should be added very slowly to an ice-cooled solution of (**2**) to maintain a low stationary concentration of (**1**) and thereby suppress its dimerization into 3,4-diphenylfuroxan (**3**).[2a] Benzonitrile oxide can also be generated photochemically by irradiation of (**2**) and ***Hexabutyldistannane***,[4a] or via electrochemical oxidation of benzaldoxime.[4b]

Handling, Storage, and Precautions: usually prepared in situ; readily undergoes dimerization on storage; use in a fume hood.

Introduction.

To simplify the representation of (**1**) as an organic dipole (dipole moment 4.00 D at 15 °C),[1a] the nitrilium betaine formula PhC&tbond;+N-O^- is most commonly used. As implied by this structure, reactions with nucleophiles at the

positively charged N atom or with dipolarophiles across the C-N-O system are common with (**1**).

Reactions with Nucleophiles.

Benzonitrile oxide reacts with O-, C-, N-,[5a-c] and S-nucleophiles[5d] to give benzhydroxamic acid derivatives (eq 1).[5d]

(1)

Nitrogen nucleophiles catalyze dimerization of (**1**),[6a] which may be also promoted under specific acidic conditions (eq 2).[6b] In DMSO, (**1**) undergoes Me_3N-induced polymerization to produce cyclic oligomers.[6c]

(2)

1,3-Dipolar Cycloaddition.

Benzonitrile oxide demonstrates high reactivity towards numerous dipolarophiles containing multiple carbon-carbon and carbon-heteroatom bonds. It is these [$_{\pi}4_s$ + $_{\pi}2_s$] dipolar cycloadditions (DCA) that are responsible for the considerable synthetic potential of (**1**). DCA of (**1**) with alkenes commonly delivers a mixture of isomeric 5- and 4-substituted 3-phenyl-Δ^2-isoxazolines. Regioselectivity depends on dipolarophile structure. From monosubstituted alkenes, 5-substituted heterocycles are predominantly formed[1a,b,7] and in some cases almost complete regiospecificity is achieved (eq 3).[2e]

(3)

Ratios of regioisomers produced from disubstituted alkenes are defined by a combination of polar, steric, and hydrogen-bonding factors.[8] Nevertheless, conformational features, substituent effects, and additives can all affect the regiochemistry of 1,3-DCA reactions (eq 4).[9]

(4)

1,3-DCA of alkenes bearing a chiral residue at the double bond proceed with asymmetric induction.[10] The nature of a substituent in the allylic position of the dipolarophile can affect the ratio of *erythro:threo* products, as shown in eq (5).[10b] The best theoretical model proposed to rationalize such diastereoselectivity assumes conformational control in the transition state of DCA.[10c,e] However, charge transfer and electrostatic effects should not be neglected.[10f]

(5)

	erythro:*threo*
X = H	40:60
X = OCH_2Ph	64:36
X = $OSiMe_3$	71:29

Diastereoselective DCA of (**1**) to chiral acrylic dipolarophiles offers an approach to optically active 2-isoxazolines. Initial studies with chiral sulfonamide (**4**) proceed with 56% de and showed attack of (**1**) to occur on the *re* face of (**4**). This suggested that the major diastereomer resulted from the *s-cis* conformer of (**4**) (eq 6).[11] It is worth noting that generally 1,3-DCA of (**1**) with substrates of type (**4**) takes place with lower selectivity than the corresponding Diels-Alder reactions,[11,12] and Lewis acids retard the 1,3-DCA and decrease yields with no improvement in diastereoselectivity. Higher diastereoselectivity (80-90% de) is observed if bornyl crotonates,[13] chiral imides,[14] alkenes containing a chiral imidazolidine controller,[15] or carbohydrates[16] are employed in DCA with (**1**).

(4) R = cyclohexyl

(6)

78:22

Acryloylsultams such as (**5**)[17a] and (*S*)- and (*R*)-(**6**)[17b] are the best auxiliaries for almost complete asymmetric induction yielding, after reduction, enantiomerically pure isoxazolines (eq 7).

Because the Δ^2-isoxazoline ring can be readily cleaved, this chemistry provides a powerful approach to the synthesis of polyfunctional compounds from alkenes. Upon base-initiated ring-opening, α,β-unsaturated ketones are obtained (eq 8),[18] whereas reductive cleavage offers an approach to β-hydroxy ketones (eq 9),[19] β,γ-enones,[20] β-diketones, and 3(2*H*)-furanones.[21] While the primary products of reduction with ***Raney Nickel***[19,20] are 3-imino alcohols, precursors of β-hydroxy ketones[19] and pyridines,[22] reductive cleavage with ***Lithium Aluminum Hydride*** gives 1,3-amino alcohols.[23] This has been used in the stereoselective synthesis of amino sugars.[23a]

Methodology involving cycloaddition of nitrile oxides to C=C bonds and subsequent cleavage of the resulting Δ^2-isoxazolines has been widely used in natural product synthesis[24] and other synthetic ventures.[25]

1,3-DCA of (**1**) with dipolarophiles containing multiple bonds other than C=C provides a route to various heterocyclic systems.[1a,b,d] Alkynes add (**1**) to produce 3-phenylisoxazoles.[1a,b] Metalated alkynes serve as a handle for introducing a variety of functional groups into the 2-position (eq 10).[26] Alternatively, isoxazoles can be synthesized via DCA of (**1**) with nitroalkenes and subsequent 1,2-elimination of HNO_2.[27]

Compounds containing C=N bonds react with (**1**) to produce 1,3,5-oxadiazepines,[28a] Δ^2-1,2,4-oxadiazolines,[28b] and fused 1,2,4-oxadiazolines.[28c-f] In substrates with both C=C and C=N bonds, the 1,3-DCA takes place across the C=N bond.[28b,c] Nitriles react with (**1**) yielding 3-phenyl-1,2,4-oxadiazoles,[29,30] and the C&tbond;N bond successfully competes with C=C in dipolarophile activity.[30b] Dimerization of (**1**) to furoxan (**3**), a common process under 1,3-DCA conditions, can be considered as a particular case of 1,3-DCA of (**1**) to a C&tbond;N bond.[31]

Benzonitrile oxide also reacts with carbonyl groups to produce 1,4,2-dioxazolines. Uncatalyzed DCA is possible with aromatic carbonyl compounds,[2a,32] while aliphatic substrates react only in the presence of ***Boron Trifluoride Etherate***.[33] Upon treatment with ***Potassium t-Butoxide***, 1,4,2-dioxazolines obtained from arenecarbaldehydes lose PhCN to produce the corresponding arenecarboxylic acids (eq 11).[29] Site-specific or site-selective addition to the C=O group is observed in reactions of (**1**) with quinones[34a] or tropone.[34b]

The C=S bond exhibits high dipolarophilic activity in reactions with (**1**) affording 1,4,2-oxathiazolines.[1a,b,35] Although 3,5-diphenyl-λ^3-phosphinin is inert to (**1**), DCA reaction takes place selectively at the P=C bond after complexation with tungsten pentacarbonyl (eq 12).[36]

Benzophenone Imine

[1013-88-3] · $C_{13}H_{11}N$ · Benzophenone Imine · (MW 181.24)

(reagent for protection of primary amines)

Alternate Name: diphenylketimine.

Physical Data: bp 151-153 °C/10 mmHg.

Form Supplied in: commercially available.

Preparative Methods: prepared by the addition of phenylmagnesium bromide to benzonitrile followed by hydrolysis with MeOH[1] or by reaction of benzophenone with ammonia.[2]

Protected Primary Amines.

Benzophenone imine, a useful protecting group for primary amines (eq 1), is introduced by reaction with the amine salt (CH_2Cl_2, room temperature).[3] The resulting Schiff bases are stable to flash chromatography and have been used in conjunction with other anion-stabilizing groups, especially in the field of amino acid chemistry, to provide activation for proton abstraction.[4] Reaction of protected derivatives with base followed by alkylation with an alkyl halide (cases a (R = H)[5] and d[6,7]), an alkynyl(phenyl)iodonium triflate (case b),[8] or intramolecular alkylation (case c)[9] establish new carbon-carbon bonds at the indicated center.

Benzophenone imine can also serve as a simple protecting group to allow acylation (case e)[10] or formylation (case f)[11] at a remote site. Removal is accomplished with either mild acid or catalytic hydrogenolysis.

Other Reactions.

Michael addition to acceptor-substituted alkenes gives protected β-amino acids, nitriles, and ketones (eq 2).[12]

(2)

Reaction of oxalyl chloride with 1 equiv of *t*-BuOH followed by $Ph_2C{=}NH$ results in a protected α-keto amino ester (starting material in eq 3). This compound can be reacted with nonstabilized, semistabilized, stabilized, or heteroatom-substituted phosphonium ylides to give α,β-dehydroamino acid derivatives (eq 3).[13,14] Other reactions of these products have been reported.[15]

(3)

G = R, Ar, CO_2Et, OMe, Cl, Br

A stereoselective synthesis of β-amino alcohols from the benzophenone Schiff base of α-amino esters has been reported (eq 4).[16] Other reactions from similar protected α-amino acid derivatives include preparations of α- or β-*O*-serine or -threonine glycopeptides,[17] unsymmetrical disulfides of cysteine,[18] and several methods for transesterification[12,19] or related reactions[20] of the benzophenone imines of amino esters.

(4)

Related Reagents.

1,4-Benzoquinone

[106-51-4] · $C_6H_4O_2$ · 1,4-Benzoquinone · (MW 108.10)

(useful as an oxidizing[1] or dehydrogenation agent;[2] can function as a dienophile[3] in the Diels-Alder reaction or as a dipolarophile to prepare 5-hydroxyindole derivatives[4])

Alternate Name: p-benzoquinone.

Physical Data: mp 115.7 °C; *d* 1.318 g cm^{-3}.

Solubility: slightly sol water; sol alcohol, ether, hot petroleum ether, and aqueous base.

Form Supplied in: yellowish powder; widely available.

Handling, Storage, and Precautions: the solid has an irritating odor and can cause conjunctivitis, corneal ulceration, and dermatitis. In severe cases, there can be necrotic changes in the skin. Use in a fume hood.

As Oxidizing or Dehydrogenation Agent.

The ease of reduction of 1,4-benzoquinone to hydroquinone by various compounds renders it useful as an oxidizing or dehydrogenation agent.[2,5] The literature shows that 1,4-benzoquinone prefers to oxidize conjugated primary allylic alcohols over other alcohols (eq 1).[6] Kulkarni has demonstrated the selective oxidation of cinnamyl alcohols to cinnamaldehydes in the presence of secondary or benzylic alcohols. Primary alcohols have been oxidized to the corresponding aldehydes by using 1,4-benzoquinone as the hydrogen acceptor and hydrous zirconium(IV) oxide[7] as a catalyst (eqs 2 and 3).[1]

Nitrogenous compounds can be oxidized by 1,4-benzoquinone in refluxing benzene.[8,9] Aurich reported the conversion of hydroxyamine (**1**) to nitrone (**2**) through the reaction with 1,4-benzoquinone (eq 4).[9] Wiberg used 1,4-benzoquinone to transform tetrazene (**3**) into molecular nitrogen (eq 5).[10] Rossazza reported the oxidation of leurosine at the carbon α to nitrogen (eq 6).[11]

In the oxidation of alkenes with palladium(II) acetate, 1,4-benzoquinone serves as a cooxidant to reoxidize palladium(0) to palladium(II).[12,13] Davidson reported the oxidation of alkene (**4**) to a vinyl acetate with 0.1 equiv of palladium acetate and 1 equiv of 1,4-benzoquinone (eq 7).[14]

Backvall reported that the reaction of 1,3-cyclohexadiene with ***Palladium(II) Acetate*** and 1,4-benzoquinone gave 1,4-diacetoxy-2-cyclohexene in high yield. The stereochemistry of the products was influenced by additives. In the

presence of lithium acetate, the major *trans*-diacetate was obtained in 90% yield.[15] Without the addition of lithium acetate, a 1:1 mixture of *trans* and *cis* isomers was produced. However, the *cis*-diacetate was the major (>93%) product when both lithium acetate and lithium chloride were added (eq 8).[15] When the reaction was carried out in acetic acid containing trifluoroacetic acid and lithium trifluoroacetate, the *trans* isomer of 1-acetoxy-4-trifluoroacetoxy-2-cyclohexene was the major product in 67% yield (eq 9).[16] Similar oxidative 1,4-additions of other dienes, such as 1,3-butadiene, also can be accomplished in a regio- and stereoselective fashion (eq 10).[17] However, 1,4-benzoquinone has a high tendency to undergo Diels-Alder reactions when used as a cooxidant for $Pd(OAc)_2$ in such reactions. Many reactions of this type use only catalytic amounts of 1,4-benzoquinone and stoichiometric amounts of external oxidants, such as $Ce(SO_4)_2$, $Tl(OAc)_3$, and MnO_2.[18]

(8)

(9)

(10)

The combination of 1,4-benzoquinone and a catalytic amount of palladium acetate can transform silyl enol ethers into conjugated enones.[19] This reaction is not only regiospecific (eq 11) but also stereospecific to give the more stable *trans*

acyclic enone (eq 12).

(11)

(12)

Antonsson used ***Manganese Dioxide*** as the oxidant and 0.05 equiv of palladium acetate and 0.20 equiv of 1,4-benzoquinone as catalyst for oxidative ring closure of 1,5-hexadienes to give cyclopentane derivatives in good yield (eq 13).[20] With 1,4-benzoquinone and 10 mol % of ***Palladium(II) Chloride***, a homoallylic alcohol underwent oxidative ring closure to give a γ-butyrolactol (eq 14).[21]

(13)

(14)

The combination of palladium acetate and 1,4-benzoquinone was used in the ring opening of an α,β-epoxysilane to give 19% of oct-2-enal in the presence of oxygen gas (eq 15).[22] Similar reagents are effective in the oxidative coupling of carbon monoxide in methanol to give methyl oxalate (eq 16).[12]

(15)

(16)

As Dienophile.

1,4-Benzoquinone is an excellent dienophile in the Diels-Alder reaction toward electron rich dienes.[23,24] The bicyclic cycloadducts of these reactions are frequently used as the starting materials for the synthesis of natural products. A typical example is demonstrated by Mehta in a total synthesis of capnellene, in which 1,4-benzoquinone is allowed to react with 1-methyl-1,3-cyclopentadiene to give compound (**5**) (eq 17).[25] The cycloaddition of 1,4-benzoquinone and another activated diene is shown in eq 18.[26]

Asymmetric Diels-Alder reactions of 1,4-benzoquinone have been reported. Several examples are shown in eqs 19-21.[3,27,28]

(19)

X = OTBDMS

(20)

(21)

Under high pressure, even electron deficient dienes react with 1,4-benzoquinone. Dauben reported the asymmetric cycloaddition of a chiral dienic ester and 1,4-benzoquinone to produce chiral adducts with moderate enantioselectivity (eq 22).[29]

(22)

Preparation of 5-Hydroxyindoles.

The reaction of 1,4-benzoquinone with certain enamines has been used to prepare 5-hydroxyindole derivatives.[4,30] The first example was reported by Nenitzescu, in which he successfully prepared ethyl 5-hydroxy-2-methylindole-3-carboxylate from 1,4-benzoquinone and ethyl 3-aminocrotonate (eq 23).[4] The ease of the reaction and the availability

of the reactants have made it a popular method for indole synthesis. However, the yields of this type of reaction vary over a wide range (5-90%).

As Reaction Promoter.

In the hydrogenation of nitrobenzene with platinum catalyst in DMSO, addition of 1,4-benzoquinone accelerates the reaction rate.[31]

1,2,3-Benzothiadiazole 1,1-Dioxide[1]

[37150-27-9] · $C_6H_4N_2O_2S$ · 1,2,3-Benzothiadiazole 1,1-Dioxide · (MW 168.17)

(benzyne precursor[1])

Solubility: sol ether.

Preparative Method: by diazotization of sodium 2-aminobenzenesulfinate, which is obtained in three steps from 2-nitroaniline.[2]

Handling, Storage, and Precautions: it can be isolated as yellow-brown needles, but slowly decomposes even at 0 °C and explodes between 45 and 60 °C. A safer alternative is to use it in solution, in which it decomposes smoothly at 10 °C. Preparation and handling should be carried out with good shielding.

Generation of Benzyne.[1]

Decomposition of 1,2,3-benzothiadiazole 1,1-dioxide in ether affords benzyne, nitrogen, and sulfur dioxide (eq 1).[2]

This is a very mild procedure (neutral, relatively low temperature) for the generation of benzyne. However, despite the examples which follow, the time-consuming preparation of 1,2,3-benzothiadiazole 1,1-dioxide has greatly limited its use in synthesis. Moderate yields have been obtained in the reactions of cyclic dienes with benzyne generated in situ from 1,2,3-benzothiadiazole 1,1-dioxide. Furan, for example, traps benzyne efficiently under these conditions to afford the adduct in 54% yield (eq 2).[3]

(2)

2-Pyrone reacts with benzyne to give a bicyclic adduct, which loses CO_2 by a retro-Diels-Alder reaction to afford naphthalene in 36% yield (eq 3).[3]

(3)

Cyclopentadiene derivatives react with benzyne to yield bridged compounds (eq 4).[4]

(4)

Due to the low decomposition temperature of 1,2,3-benzothiadiazole 1,1-dioxide, cycloaddition with less reactive dienes affords complex mixtures with poor yields of cycloadducts. For example, the decomposition of 1,2,3-benzothiadiazole 1,1-dioxide in thiophene leads to a complex mixture with less than a 5% yield of products derived from cycloaddition.[5]

The effect of silver(I) on the course of the reactions of benzyne with polyenes has also been reported.[6] When 1,2,3-benzothiadiazole 1,1-dioxide was decomposed in the presence of 1,3-cyclohexadiene, a complex mixture was obtained. Four products were characterized, giving a total yield of 28% (eq 5). When 1,2,3-benzothiadiazole 1,1-dioxide was added to a silver-diene complex, the yield and selectivity of the reaction were improved (eq 6).

Related Reagents.

Benzenediazonium-2-carboxylate; ***Diphenyliodonium Carboxylate***.

Benzothiazole[1]

[95-16-9] · C_7H_5NS · Benzothiazole · (MW 135.18)

(formyl and acyl anion equivalent;[2] one-carbon homologation of aldehydes via the 2-trimethylsilyl derivative;[3] the *N*-methylbenzothiazolium ring system has been used as a leaving group[4])

Physical Data: mp 2 °C; bp 231 °C/765 mmHg; bp 131 °C/34 mmHg; *d* 1.246 g cm^{-3}; n_D 1.6379.

Solubility: slightly sol H_2O; sol acetone; very sol ethanol, diethyl ether, THF, CS_2.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: ^1H and ^{13}C NMR.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: use in a fume hood. Benzothiazole should be used freshly distilled for best results. Toxic by inhalation, in contact with skin, and if swallowed.

2-Lithiobenzothiazole.[5]

Benzothiazole (**1**) is easily metallated at the 2-position by employing 1.0 equiv of ***n-Butyllithium*** at -78 °C in diethyl ether as solvent.[2a,6] Chikashita et al.[2b] have found that better results can be achieved by adding a 10% excess of *n*-butyllithium and carrying out the reaction in THF as a solvent (eq 1). In fact, when diethyl ether is used as solvent or less than 2 mL THF/mmol benzothiazole, the lithium compound should precipitate and the corresponding suspension becomes very thick, making stirring difficult.

(1)

(1) **(2)**

2-Lithiobenzothiazole (**2**) is stable only below -50 °C. A solution of 2-Lithiobenzothiazole in THF gives rise to a clear orange-colored solution. At temperatures higher than -50 °C a dark-brown solution indicating decomposition of the organolithium compound is observed. Consequently, reactions with this reagent have to be carried out at temperatures lower than -50 °C. 2-Lithiobenzothiazole (**2**) reacts with various electrophiles[7] such as esters or nitriles (eq 2), α-halo ketones (eq 3), and carbonyl compounds[4] to give the intermediate carbinols which can be easily dehydrated to the corresponding alkenes (**3**) as described (eq 4).[2]

(2)

$Z = CO_2Et$, CN

(3)

X = Br, Cl

(4)

(3)

On the other hand, Chikashita et al.[7] suggest that 2-lithiobenzothiazole (**2**) does not react with alkyl halides.

The synthetic utility of the benzothiazole nucleus is demonstrated through the unmasking to the carbonyl function.[2] The methodology involves three steps: (a) methylation of 2-substituted benzothiazoles (**4**), (b) reduction of the resulting salts (**5**), and (c) hydrolysis under mild and neutral conditions to afford the aldehydes (**6**) (eq 5).[2,4] In several cases, however, the efficiency of this unmasking protocol and its compatibility with other protecting groups were not demonstrated.

The *N*-methylbenzothiazolium salts (**5**) also react with organometallic reagents to give 2,2-disubstituted *N*-methylbenzothiazolines which after hydrolysis afford the corresponding ketones (**7**) (eq 6).[2,4]

Corey and Boger have utilized this homologating methodology to devise new carbon-carbon bond-forming reactions[8]

and annulation processes for fused and spiro rings.[9] Another application of benzothiazole chemistry involves the use of the heterocyclic ring as a leaving group. The synthesis of carboxylic acid derivatives via the *N*-methylbenzothiazolium salts (**8**) and (**9**), as outlined in eq 7, takes advantage of this property.[4b]

(7)

2-(Trimethylsilyl)benzothiazole.

This reagent can be prepared in high yield by addition of ***Chlorotrimethylsilane*** to 2-lithiobenzothiazole (**2**) at -78 °C with subsequent gradual warming to room temperature over a 4-5 h period (eq 8).[10]

(8)

2-(Trimethylsilyl)benzothiazole (**10**) reacts with several electrophiles such as acid derivatives and carbonyl compounds in the absence[3a,10] (eq 9) or in the presence of ***Potassium t-Butoxide*** as catalyst[3b] (eq 10).

(9)

(10)

Only one addition of 2-(trimethylsilyl)benzothiazole (**10**) to a chiral aldehyde has been reported[3c] and significant diastereoselection was observed, in contrast to 2-lithiobenzothiazole (**2**) which showed a complete lack of stereoselectivity in the reaction with the same aldehyde (**11**) (eq 11).

(11)

(11) ds = 80%

Since benzothiazole has been shown to be a formyl anion equivalent,[11] this reaction could represent a stereoselective homologation process. However, for this purpose ***2-(Trimethylsilyl)thiazole*** is a more convenient synthetic equivalent since higher stereoselectivity is obtained with this reagent, and the aldehyde release is easier with thiazole than benzothiazole.

2-(Trimethylsilyl)benzothiazole (**10**) has been also used in the synthesis of heteroaromatic phosphines[12] and mesomeric betaines.[13]

1-Benzotriazolyl Diethyl Phosphate

[96338-11-3] · $C_{10}H_{14}N_3O_4P$ · 1-Benzotriazolyl Diethyl Phosphate · (MW 271.21)

(coupling reagent for amides and peptide synthesis[1,2])

Alternate Name: BDP.

Solubility: sol MeCN, DMF, EtOAc, CH_2Cl_2, THF.

Form Supplied in: oil; not available from commercial sources.

Preparative Method: by reaction of diethyl chlorophosphate (1 equiv) and 1-hydroxybenzotriazole (1 equiv) in the presence of triethylamine (1 equiv) in dry THF at 0 °C for 30 min, with 90-95% yields.

Purification: by filtration through a short column of silica gel or cellulose.

Handling, Storage, and Precautions: the oil can be stored in a desiccator with drierite at 4 °C for several weeks without decomposition. Distillation in vacuo leads to decomposition.

1-Benzotriazolyl diethyl phosphate (BDP) has been used as a condensing reagent for the preparation of amides. Typically, equimolar amounts of carboxylic acids, amines, and 1-benzotriazolyl diethyl phosphate, in the presence of triethylamine (2.1 equiv) in a broad range of solvents (the relative coupling efficiency is DMF > MeCN = THF > CH_2Cl_2) react rapidly and cleanly with coupling times in the range of 10-60 min at 25 °C, yielding the corresponding amides in > 90% yields (eq 1).

1-Benzotriazolyl diethyl phosphate is also suitable for hindered carboxylic acids and amines, as well as poorly nucleophilic amines. Thus *N*-cyclohexylbenzamide is obtained from benzoic acid and cyclohexylamine with the addition of 1-benzotriazolyl diethyl phosphate, whereas the use of ***1,3-Dicyclohexylcarbodiimide*** did not yield any trace of the target product. Benzoic acid is readily converted to the corresponding amides by the reaction with 1-benzotriazolyl diethyl phosphate and benzylamine or aniline. Similarly, reaction of acetic acid with sterically hindered *t*-butylamine yielded the corresponding acetamide. Finally, crotonic acid is cleanly converted to the corresponding amides without 1,4-addition side-products.

Additionally, 1-benzotriazolyl diethyl phosphate has been used for the preparation, in solution, of dipeptides and tripeptides. The reaction is carried out as described above with *N*-protected amino acids or dipeptides, and amino acid ester hydrochlorides, in DMF for 4 h, at 25 °C, with a yield superior to 75%. Racemization from 1-benzotriazolyl diethyl phosphate mediated couplings is checked by different methods. Young[3] and Anderson[4] tests gave low degree (<4%) of racemization when DMF is used as a solvent. Other solvents such as THF, EtOAc, and CH_2Cl_2 gave more racemization. Furthermore, the Shiori[5] test gave a higher degree of racemization even in DMF (18%). A related analog, 1-benzotriazolyl diphenyl phosphate, led to 39% of racemization, indicating that the degree of racemization is also dependent on the nature of organophosphate.

1-Benzotriazolyl diethyl phosphate has not been used in solid-phase peptide synthesis,[6] although other commercial triazole derivatives such as ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (BOP)[7] or ***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate*** (HBTU)[8] are commonly used in that strategy.

Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate[1]

[566002-33-6] · $C_{12}H_{22}F_6N_6OP_2$ · Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate · (MW 442.29)

(peptide coupling agent providing high yield and low racemization levels;[1] promotes peptide cyclization[19] and other lactamization,[23] especially β-lactam formation;[24] used to effect various amidification reactions[25-29] and selective esterification;[31] reagent for nucleotidic coupling[32])

Alternate Names: BOP; Castro's reagent.

Physical Data: mp 138 °C (dec.).

Solubility: insol H_2O; sol THF, CH_2Cl_2, MeCN, acetone, DMF, NMP, DMSO.

Form Supplied in: white solid; commercially available. Purity 97-98%.

Analysis of Reagent Purity: ^{1}H NMR (acetone-d_6): 3.0 (d, 18H, J_{H-P} = 10 Hz, NMe_2), 7.9 (m, 4H, arom.). ^{31}P NMR (CH_2Cl_2): +43.7 (s, P^+), -144.2 (septet, PF_6^-). IR (KBr): 1010 (P-N), 840, 770, 560 (PF_6^-).

Preparative Methods: BOP reagent was initially obtained[2a] by reaction of ***Hexamethylphosphorous Triamide*** (tris(dimethylamino)phosphine, TDAP) with CCl_4 in the presence of HOBt (***1-Hydroxybenzotriazole***) followed by precipitation of the phosphonium salt by anion exchange with aqueous KPF_6 solution. It was then prepared[2b,c] by reaction of cheaper $(Me_2N)_3PO$ (HMPA) with $COCl_2$ (phosgene) to generate the chlorophosphonium chloride intermediate, with treatment of the latter with HOBt and base, and precipitation as below. $COCl_2$ was further replaced by $POCl_3$.[2d,e] The crude final product can, if necessary, be purified by recrystallization from a mixture of acetone-ether or CH_2Cl_2 (DCM)-ether.

Handling, Storage, and Precautions: irritant and harmful. Light sensitive. Incompatibility: strong oxidizing

agents. Avoid breathing dust; avoid contact with eyes, skin, and clothing. Keep container closed and store in the dark. Refrigerate. Although BOP is widely used, it is important to stress that the carcinogenic HMPA is a side product and the reagent must be handled with caution. All operations should be carried out in a fume hood.

Peptide Coupling Reagent.

First prepared with the aim to associate both the coupling agent (phosphonium salt as dehydrating agent) and the racemization suppressor (HOBt additive) in the same compound, the BOP reagent has since then been widely developed, mainly in peptide synthesis, as well as in other fields. Mechanistic studies on the probable intermediates (acyloxyphosphonium salt, active ester, symmetrical anhydride, oxazolone, eq 1) during the activation step of carboxylic acids with BOP have been made. Early investigations indicating the intermediacy of a benzotriazolyl active ester,[1a,2b,3] as in activation with the DCC/HOBt (see ***1,3-Dicyclohexylcarbodiimide***) reagent system, were later questioned[1c] in the light of better results obtained with BOP in a number of cases. After further studies, the direct formation of the acyloxyphosphonium salt, presumably through the cyclic complex (eq 1), was postulated as likely.[1c]

Unoptimized initial work in peptide coupling with BOP had already shown high yields and short reaction times, even with bulky amino acids (eq 2) and little if no side reactions with some sensitive amino acids bearing unprotected side chain functional groups.[2]

Unlike DCC, BOP reacts exclusively with carboxylate salts, with carboxylic acids remaining unchanged. The trifluoroacetate anion is not activated by BOP; therefore the trifluoroacetylation side reaction is never encountered.

In usual peptide synthesis (e.g. with the Boc/TFA deprotection strategy), a typical coupling step is conducted as follows: BOP is added to the mixture of the Boc-amino acid (or peptide acid segment) and the C-terminal-protected peptide salt (generally the TFA salt). The solvent can be THF, DCM, MeCN, DMF, or NMP, according to the solubility of the reaction partners, but using as high a concentration as possible. No reaction occurs until the tertiary base, *N*-methylmorpholine, ***Triethylamine***, or preferably ***Diisopropylethylamine*** (DIEA), is added. In every case the reaction mixture has to be kept rather basic in order to ensure a fast coupling. Three equiv of base are necessary to neutralize the carboxylic acid, the amine salt, and the acidic HOBt. In such conditions the coupling rate is so high that racemization is negligible in urethane-protected amino acid coupling and fairly low, albeit not negligible, in segment coupling (see eq 3).[4] The excess of acid and BOP is typically 1.1 mol equiv in solution synthesis.

Racemization in segment coupling has been studied with realistic models[4a] in solution; it appears to be very small when nonhindered amino acids (Ala, Leu, Lys…) are activated, but coupling of segments terminated with bulky residues (Val, Ile, Thr…) are to be avoided (eq 3).[4b]

Segment condensation with BOP is generally peculiarly fast compared with conventional use of the classical DCC/HOBt method, as a few hours are enough to achieve coupling of equimolar quantities of both partners, provided the highest concentration is used (eq 4).[5]

It is very characteristic that this procedure allows the skipping of a separate neutralization step, either in solution or in SPPS (solid phase peptide synthesis) using the Boc/TFA strategy. This is not only time-saving but also useful to minimize diketopiperazine formation during the third step of a synthesis.

The coupling reaction of Boc-Ile-OH with H-His-Pro-OMe . TFA is generally a very low yield reaction as the neutralization of the dipeptide salt is very readily followed by cyclization to cyclo(His-Pro) (eq 5). Using the BOP procedure allows the efficient in situ trapping of the dipeptide amine by the acylating reagent. This feature also makes strategies of segment coupling at a proline residue possible, which are very often restricted by the necessity of using prolyl *t*-butyl esters in order to avoid the cyclization reaction.

This specific ability of BOP for avoiding diketopiperazine formation is illustrated in liquid phase synthesis[5a] as well as in the SPPS.[5c,d,6,7b]

Another facility offered by BOP is the possibility to couple DCHA salts, due to the high rate ratio of amino acid coupling towards dicyclohexylamine (DCHA). This feature is especially useful in SPPS where the small amount of dicyclohexylamide formed is easily washed out. The main application of that procedure lies in the introduction of histidine as the cheap and easily acessible Boc-His(Boc)-OH both in liquid (eq 6)[5a] and solid[7b-d] phase synthesis.

Many peptides have been synthesized in solution,[5a,b,8] stepwise or by segment coupling, using BOP as coupling agent.

In solid phase synthesis, BOP exhibits some distinct advantages, including the suppression of a separate neutralization step previously mentioned; indeed, after TFA treatment and washing, it is convenient to introduce the next Boc-amino acid and BOP as solids, with a minimal volume of solvent and, at last, DIEA. Coupling is generally completed after 15-30 min, with the pH maintained at 8 with excess of acylating reagents (1.5-3M). Finally, the water- and DCM-soluble byproducts, HMPA and HOBt, allow very easy washing of the reaction product, in contrast to DCC condensation where elimination of insoluble urea often remains a problem.

The use of BOP in SPPS, initially limited,[7] has since been widely developed, with Boc/TFA,[9,10] Boc/HF,[11] and mainly Fmoc/piperidine[12-15] deprotection systems. In most cases it compares favorably with other reagents such as DCC, DCC/HOBt, and symmetrical anhydride. As already observed in the liquid phase, some amino acids with side chain functional groups such as Tyr, Thr, Ser (hydroxy group),[2a,9b] or poorly soluble pGlu (γ-lactam)[7d,9c] can be used without protecting groups; other functional groups such as $CONH_2$ (Asn) can lead in some cases to partial dehydration (e.g. β-cyanoalanine)[11,14b,c] or cyclization (succinimide)[9a,30] and need to be protected; such classical dehydration reactions, not observed by others,[1a,2a,b] are sometimes dependent on reactions conditions (e.g. repeated coupling cycles) and must be carefully examined.

Peptide Cyclization.

Various results were provided[16-20] in peptide chain cyclization with BOP, arising either from the reaction conditions or from the ring size, and from the linear precursor conformation.

Better yields and purities are obtained[16] with less powerful coupling agents such as DPPA (***Diphenyl Phosphorazidate***) and NDPP (norborn-5-ene-2,3-dicarboxamidodiphenyl phosphate) in cyclization of tetra- and pentapeptide sequences, despite the need for longer reaction times than with BOP or HBTU (***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate***; 1,1,3,3-tetramethyluronium analog of BOP).

Comparable yields are given for Boc-γ-D-Glu-Tyr-Nle-D-Lys-Trp-OMe cyclizations[17] with BOP ($NaHCO_3$, 4 h, 76%) and MTPA (dimethylphosphinothioyl azide, NEt_3, 36 h, 79%), albeit in different reaction conditions; in this work the reported racemization associated with the use of BOP is not shown.

Cyclization, leading to Gly/Lys-containing peptide macrocycles,[18] has been investigated with a number of coupling reagents. Among them DEPC (***Diethyl Phosphorocyanidate***), DPPA, and BOP are the most effective ones, giving near-quantitative yields.

Macro ring closure of a partly proteinogenic sequence in the synthesis[19] of the cyclodepsipeptide Nordidemnin B was

carried out using BOP in heterogeneous conditions (eq 7).

In SPPS, side chain to side chain cyclization by the BOP procedure not only proceeds more rapidly, but also gives a purer cyclic product than the DCC/HOBt procedure.[20]

The use of BOP has been reported in the final cyclization of cyclosporin,[21b] even if some racemization is observed. The very difficult coupling of *N*-methyl amino acids is achieved in the same work,[21] as in the preceding syntheses.[19] For the coupling of hindered *N*-methyl[22a] and α,α-dialkyl[22b] amino acids, new reagents[22] such as PyBroP, PyCloP, or PyClU seem to be more promising.

Besides the peptide field, cyclization leading to macrocyclic polyether tetralactams (crown ethers) have been carried out with BOP.[23]

β-Lactam Cyclization.

Cyclization of β-amino acids to β-lactams is efficiently effected by treatment with BOP (eq 8).[24a] The present method appears to be limited to the formation of β-lactams from *N*-unsubstituted β-amino acids ($R^1 = R^2 = R^3 = R^5 = H$, $R^4 = Me$, yield 10%).

$R^1 = H, Me;\ R^2 = H, OPh;\ R^3 = H, Me, Ph;$
$R^4 = H, Me, n\text{-}Pr;\ R^5 = CH_2Ph,\ c\text{-}C_6H_{11},\ n\text{-}C_8H_{17}$

In the cephem series, cyclization yields of 80% are obtained with BOP, in DCM at rt, with retention of the initial chirality.[24b]

Amidation.

A number of other various amidation reactions have been conducted using BOP. Such preparations include *N*,*O*-dimethyl hydroxamates of amino acids[25a] and peptides[25b] (precursors of chiral peptidyl aldehydes), heterocyclic amide fragments in the synthesis of macrolide[26] and porphyrin models,[27] dansylglycine anhydride as a mixed sulfonic-carboxylic imide by dehydration-cyclization of dansylglycine,[28] and selective monoacylation of heterocyclic diamine in carbohydrate series (eq 9).[29]

(9)

Esterification.

Treatment of N-protected amino acids with phenol, NEt_3, and BOP in the appropriate solvent (DCM, MeCN, DMF) affords the corresponding phenyl esters in good yield (eq 10).[30]

(10)

P = Boc, Z; AA = Ala, Ile, Phe, Trp, Pro, Ser, Met, Cys(SBn), Lys(εZ)

BOP in combination with ***Imidazole*** (ImH) as catalyst provides a very mild system for selective esterification of polyhydroxy compounds such as carbohydrates; thus trehalose is converted into mono-, di-, and tripalmitate mixtures, with the various quantities of each of them depending on the solvent and acid/alcohol ratio. Monoacylated compounds can be obtained selectively, albeit in moderate yield (31%).[31]

Nucleotidic Coupling and Related Reactions.

BOP has been used as a condensing agent to promote internucleotidic bond formation in phosphotriester

oligodeoxyribonucleotide synthesis.[32] ^{31}P NMR studies[32a] show that a benzotriazolyl phosphate derivative is involved as an active ester intermediate, as with carboxylic acids.[3]

The BOP procedure was applied to the preparation of undecanucleoside decaphosphate.[32b] The same type of activation with BOP is carried out for introducing a phosphonamide bond in dipeptide models[33] with good efficiency (&egt;60%); coupling reactions by activation of phosphinic acid derivatives[34] with BOP give poor yields.

O-Benzotriazol-1-yl-*N,N,N´,N´*-tetramethyluronium Hexafluorophosphate

[94790-37-1] · $C_{11}H_{16}F_6N_5OP$ · *O*-Benzotriazol-1-yl-*N,N,N´,N´*-tetramethyluronium Hexafluorophosphate · (MW 379.29)

(coupling reagent for peptide synthesis[1])

Alternate Name: HBTU.

Physical Data: mp 206-207 °C (dec).

Solubility: sol DMF (0.5 mol L^{-1}). With the tetrafluoroborate counterion the corresponding salt (TBTU) is slightly more soluble (0.6 mol L^{-1}).

Form Supplied in: white solid; widely available.

Purification: by crystallization in a mixture of MeCN and CH_2Cl_2.

Handling, Storage, and Precautions: very stable, not hygroscopic, and can be stored indefinitely. Solutions in DMF (0.45 M) can be stored in an inert atmosphere for weeks. Syntheses of peptides carried out with freshly prepared, 6 and 13 week stored solutions show similar quality of the crude product.[3] Violent decomposition can occur when dried at elevated temperature.[4]

Both *O*-benzotriazol-1-yl-*N,N,N´,N´*-tetramethyluronium hexafluorophosphate (HBTU) and tetrafluoroborate (TBTU) salts have been used as condensing reagents for the preparation of peptides in both solution and solid-phase strategies.[1,4] In solution, reaction of α-amino protected amino acids or dipeptides with equimolar amounts of α-

carboxyl protected amino acids or dipeptides and ***Diisopropylethylamine*** (DIEA) (2 equiv) in DMF proceeds cleanly for 15 min at 0 °C, yielding the corresponding peptides in good yields (80-96%) (eq 1).[1,4]

HBTU activation has been adapted for automated stepwise solid-phase peptide synthesis for both *t*-butoxycarbonyl (Boc) and fluorenylmethoxycarbonyl (Fmoc) strategies.[5] For the former, a simple, effective protocol has been developed, which involves simultaneous in situ neutralization with coupling (extra equivalents of base are required). This protocol is particularly suitable for assembling complex peptides, arising from sequence-dependent peptide chain aggregation. Since aggregation occurs when protonated α-ammonium peptide-resin intermediates are neutralized, simultaneous neutralization and acylation can help to overcome this phenomenon.[6] For Fmoc chemistry, efficient protocols are also available for both batch and continuous-flow systems.[3,7]

Various protected peptide segments have been coupled on solid-phase using a combination of TBTU, HOBt, and DIEA for the syntheses of several small proteins. Coupling yields, using threefold excess of peptide segment and coupling times of ~12 h, are greater than 95%.[8]

Racemization from uronium salt mediated couplings has been determined by analysis of the epimeric products by HPLC using different models. In all cases, racemization is similar or lower than that obtained with carbodiimide and benzotriazole based phosphonium salt methods.[1,2,4,9]

In the absence of the carboxylic component, HBTU reacts with amino groups leading to the formation of a Schiff base (eq 2).[10] Thus in syntheses conducted in solution, the excess of both HBTU and amino component should be avoided. In both solution and solid-phase strategies the sequence of reagent addition is critical. HBTU should be delivered to the carboxylic component for preactivation, prior to the addition of the amine. The Schiff base formation can also occur during slow reactions, such as the preparation of cyclic peptides, where both amino and carboxylic components are in equimolar amounts and an excess of the uronium salt can block the amino group.[11] For the synthesis of cyclic peptides the phosphonium derivatives ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (BOP)[12] and benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP),[13] can be more useful.

(2)

Uronium salts have been used for cyclization of linear peptides in both solution and solid-phase modes. Since this reaction is sequence dependent, there are no general conditions. Thus cyclization in solution with uronium salt methods give, for some peptides, better results than the classical reagent ***Diphenyl Phosphorazidate*** (DPPA),[14] but for another case the converse is true.[15] Furthermore, dehydration of *C*-terminal aspartylamide peptides during cyclization with HBTU has been described. This side-reaction can be prevented by the addition of one equivalent of HOBt.[16] Although good results have been obtained in the solid-phase,[17] guanidino formation side-reactions have also been reported.[11]

Recently, other uronium salts, such as *O*-(*N*-succinimidyl)-*N*,*N*,*N´*,*N´*-tetramethyluronium tetrafluoroborate (TSTU),[4,18] *O*-(*N*-5-norbornene-*endo*-2,3-dicarboximidyl)-*N*,*N*,*N´*,*N´*-tetramethyluronium tetrafluoroborate (TNTU),[4,18] *O*-(2-oxo-1(2*H*)-pyridyl)-*N*,*N*,*N´*,*N´*-bis(pentamethylene)uronium tetrafluoroborate (TOPPipU),[19] ***N-[(Dimethylamino)-1H-1,2,3-triazolo[4,5-b]pyridin-1-ylmethylene]-N-methylmethanaminium Hexafluorophosphate N-Oxide*** (HATU),[20] and *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N´*,*N´*-bis(tetramethylene)uronium hexafluorophosphate (HAPyU)[21] have been described and are commerically available. The uronium salts derived from 7-aza-1-hydroxybenzotriazole (HATU and HAPyU) have been shown to be superior to their benzotriazole analogs in terms of coupling efficiency,[20,21] racemization,[22] and cyclization,[23] in both solution and solid-phase strategies.

(3)

Finally, an X-ray structure determination of HBTU revealed that the solid-state structure differs considerably from the formulation commonly presented in the literature. The solid-state structure is not the *N,N,N´,N´*-tetramethyluronium salt but rather the guanidinium *N*-oxide (**3**).[24]

1-Benzoyl-2-*t*-butyl-3,5-dimethyl-4-imidazolidinone[1]

(2*R*,5*S*)

[97443-91-9] · $C_{16}H_{22}N_2O_2$ · 1-Benzoyl-2-*t*-butyl-3,5-dimethyl-4-imidazolidinone · (MW 274.36) (2*S*,5*S*)

[97443-88-4]

(imidazolidinones for generating the enantiomeric enolates derived from alanine;[2,3] reagents for the preparation of α-methylated amino acids through enolate alkylation, benzylation, and nitroalkene addition[3-5])

Physical Data: (2*R*,5*S*)-(**1**): mp 125 °C; [α]rtD = -47.7° (*c* = 1.04, $CHCl_3$); (2*S*,5*S*)-(**1**): mp 175 °C; [α]rtD = +44.5° (*c* = 1.0, $CHCl_3$).

Solubility: sol THF.

Preparative Method: the imine from (*S*)-alanine *N*-methylamide and pivalaldehyde is cyclized by heating with benzoic anhydride to give mainly *cis*-(**1**) [(2*R*,5*S*)-(**1**)] in modest yields; alternatively, the imine cyclizes to the *trans*-substituted heterocycle by treatment with HCl in MeOH, and subsequent benzoylation produces *trans*-(**1**) [(2*S*,5*S*)-(**1**)] in high yield (eq 1).[2]

Handling, Storage, and Precautions: both diastereoisomers are readily crystallizable compounds which are stable at rt for years.

Alkylations of the Lithium Enolates.

Treatment of the reagents with ***Lithium Diisopropylamide*** (LDA) generates the enolates (**2**) or *ent*-(**2**) (crystal structure of *rac*-TBDMS-(**2**)[6]) which can be alkylated[3,5] to give, for instance, (*R*)-α-methyl-dopa (**3**) or triacetyl (*S*)-α-methyl-dopa.[3]

(2)

ent-**(2)**

rac-TBDMS-**(2)**

(3)

ent-(Ac)$_3$-**(3)**

Benzoylimidazolidinones of Other Amino Acids.

In a similar way, other proteinogenic and nonproteinogenic amino acids have been converted to imidazolidinones (**4**) and alkylated through enolates to give derivatives of α-branched α-amino acids. Examples of the R group in (**4**) are as follows: *i*-Pr,[2-4] Bn,[2] $(CH_2)_2SMe$,[2,7,8] $CH{=}CH_2$,[8] Ph,[2] $(CH_2)_3NHCO_2Bn$,[5] $(CH_2)_4NHCO_2Bn$,[5] CH_2CO_2H,[9] $(CH_2)_2CO_2H$.[9] The limitation of the method is given by the fact that certain amino acid *N*-methylamides, the intermediates on the way from the 3-methylimidazolidinones to free amino acids, are *very* difficult to hydrolyze.[10] Except for the procedure described here and for those methods involving enantioselective catalysis, all other syntheses of amino acids rest upon the use of a covalently attached chiral auxiliary which has to be discarded, recovered, or destroyed after use.[1c]

(4)

The Principle of Self-Regeneration of Stereogenic Centers.[1,11,12]

In the absence of additional chirality the generation of an enolate from a simple amino acid will lead to racemization.[13] There are two ways around this: (i) attachment of a chiral auxiliary, and (ii) diastereoselective generation of an additional stereogenic center which makes sure that the subsequently generated enolate is still chiral. In the case of alanine, described here, the acetal chirality center serves this purpose. The most general case is described in eq 2. Thus an α- or β-amino, -hydroxy-, and -mercaptocarboxylic acid may be converted to one of two diastereoisomeric acetals. The original stereogenic center can now be eliminated without forming an achiral species; subsequent reactions at the newly formed trigonal center should be diastereoselective, so that the product of acetal hydrolysis is nonracemic. The trigonal center at the site of the original stereogenic center may be part of an electrophilic or a nucleophilic double bond system, or may be a radical center. In the overall process, a substituent (mostly a hydrogen) at the one and only chirality center of the starting material is replaced by a new substituent stereoselectively. Since no chiral auxiliary is employed, this has been termed the principle of self-regeneration of the stereogenic center (SRSC). The auxiliary is actually the aldehyde, used for generating the second stereogenic center, and it is removed in the final hydrolysis step.

Oxazoline, oxazolidine, dihydropyrimidine, and 1,3-dioxine derivatives can also be used in this way.

Related Reagents.

(2S,4S)-3-Benzoyl-2-t-butyl-4-methyl-1,3-oxazolidin-5-one; ***t-Butyl 2-t-Butyl-3-methyl-4-oxo-1-imidazolidinecarboxylate***; ***(R)-2-t-Butyl-6-methyl-4H-1,3-dioxin-4-one***; ***(R,R)-2-t-Butyl-5-methyl-1,3-dioxolan-4-one***; ***Diethyl Acetamidomalonate***; ***N-(Diphenylmethylene)aminoacetonitrile***; ***Ethyl N-(Diphenylmethylene)glycinate***; ***Ethyl Isocyanoacetate***; ***Methyl N-Benzylidenealaninate***; ***(R)-Methyl 2-t-Butyl-3(2H)-oxazolecarboxylate***.

(2*S*,4*S*)-3-Benzoyl-2-*t*-butyl-4-methyl-1,3-oxazolidin-5-one[1]

(1)

[104057-64-9] · $C_{15}H_{19}NO_3$ · (2*S*,4*S*)-3-Benzoyl-2-*t*-butyl-4-methyl-1,3-oxazolidin-5-one · (MW 261.32)

(cyclic acetal of *N*-benzoylalanine; reagent for the preparation of enantiopure α-methyl-α-aminocarboxylic acids;[2] precursor to the 4-methylidene derivative;[3a] a radicalophile;[3b] a Michael acceptor;[4] and an ene component for Diels-Alder additions,[5] with formation of more complex α-amino acids)

Physical Data: mp 94.2-94.5 °C; [α]rtD = -29.3° (*c* = 1.0, $CHCl_3$).

Solubility: sol THF, poorly sol hexane.

Preparative Methods: the sodium salt of the pivalaldehyde imine of (*S*)-alanine is cyclized to the oxazolidinone by reaction with PhCOCl in CH_2Cl_2 at low temperature; the *cis*/*trans* ratio in the crude product depends upon the exact reaction conditions, it is usually 4:1; purification by a combination of crystallization and chromatography gives the pure *cis* derivative in 60-70% yield.[2]

Handling, Storage, and Precautions: the solid material is stable for years when stored in a bottle.

Generation of the Enolate and Reactions with Electrophiles.

The enolate of the title reagent (**1**) is generated with lithium amide bases and reacts with electrophiles such as benzylic bromides or tricarbonyl(fluorobenzene)chromium to give the corresponding 4,4-disubstituted derivatives of type (**2**), which are hydrolyzed under acidic conditions[2,6-8] to, for instance, the amino acids[2,7] (**3**) and (**4**).

(2)

(3)

(4)

In the overall process the α-hydrogen of the alanine has been replaced by benzyl or phenyl stereoselectively (an application of the principle of self-regeneration of the stereogenic center). The analogous 2-*t*-butyl-3-benzoyloxazolidinones of valine,[2] phenylalanine,[2] methionine,[2,9] and lysine[6] have also been prepared and alkylated to give α-branched amino acids.

Other Oxazolidine as well as Thiazolidine Derivatives for Branching Amino Acids.

The cyclic derivative of alanine and other amino acids employed most frequently for α-alkylation is not (**1**) but rather the benzaldehyde acetal (**5**), either with a benzoyl[5,10] or with a Cbz[11] group on nitrogen. These compounds were used for the preparation of 2-methyl-2-aminobutanoic acid, α-methylphenylalanine, α-methyllysine, 2-methylaspartic acid, and 2-methylglutamic acid. Bicyclic compounds containing oxazolidinone rings such as (**6**) (from alanine, leucine, and phenylalanine)[12] and (**7**) (from azetidinecarboxylic acid,[13] proline,[14] hydroxyproline,[15] and cysteine[16]) have also been applied to the synthesis of branched amino acids.

(5)

R = Ph, OBn

(6)

(7)

X = $(CH_2)_{0,\ 1}$
X = CHOR
X = S

Finally, the enolates (**8**), (**9**), and (**10**) of oxazolidine and thiazolidine carboxylates have been used for the synthesis of enantiopure α-substituted serine,[17] cysteine,[18] threonine,[17] *allo*-threonine,[17] and β-hydroxyleucine.[19]

(8)

(9)

(10)

α-Bromination-dehydrobromination of oxazolidinone (**1**) (NBS, then DBU) or an alternative preparation starting from cysteine gives the methylene derivative (**11**) which combines with cyclopentadiene and cyclohexadiene in [4 + 2] cycloadditions; these reactions were used for the synthesis of (*R*) and (*S*)-2-aminobicyclo[2.2.1]heptane-2-carboxylic acids as shown in eq (1).[3-5]

(11)

(*R*)- and (*S*)-2-*t*-Butyl-1,3-oxazolidin-5-ones: Chiral Glycine Derivatives.

Since the oxazolidinone enolates are good diastereoselective nucleophiles, and since the products are much more readily hydrolyzed to the free amino acids than those derived from imidazolidinones, it was also desirable to make available the corresponding glycine derivative (**12**). This was achieved by preparative HPLC resolution on Chiraspher, Chiracel OD, or Pirkle columns (up to 10 g per injection, separation factors α up to 2.35).[8,20] The enolate of the 2-*t*-butyl-substituted N-Cbz oxazolidinone was especially useful for the synthesis of a large variety of (*R*)- and (*S*)-threonines; see, for instance, the cyclosporin component MeBmt (**13**)[21] and the *p*-nitrophenylserine (**14**)[22] in eq (2).

Related Reagents.

Benzoyl Chloride[1]

[98-88-4] · C_7H_5ClO · Benzoyl Chloride · (MW 140.57)

(useful acylating agent; preparation of ketones from organometallic compounds;[2,3] preparation of 1,3-dicarbonyl compounds from enolates or enols;[4,5] Friedel-Crafts acylation and related reactions[6] with aromatic and heterocyclic compounds,[7] alkenes,[8] alkynes,[9] enoxysilanes,[10] and silicon compounds;[11] acylation of enol ethers, ketene acetals,[12] and enamines;[13] protection of alcohols as benzoates;[14] protection of amines as benzamides[15])

Physical Data: bp 197.2 °C; mp -1 °C; *d* 1.21 g cm^{-3}.

Solubility: slowly decomposed by water and alcohols; sol most organic solvents.

Form Supplied in: colorless liquid; penetrating odor; widely available.

Purification: the good commercial grade of benzoyl chloride can be purified by distillation. The technical material must be purified as follows: a 50% solution of PhCOCl in ether or cyclohexane is washed with cold 5% aqueous sodium bicarbonate; after drying over $CaCl_2$ the solvent is eliminated under vacuo and the PhCOCl is distilled.[16]

Handling, Storage, and Precautions: use in a fume hood; lachrymatory, irritating to skin, eyes and mucous membranes; toxic by inhalation and ingestion.

Acylation of Organometallic Compounds.[2,3]

PhCOCl reacts with various organometallic reagents to give the corresponding phenyl ketones in variable yields. The first acylation reactions were performed with organocadmium and organozinc compounds (eqs 1 and 2).[3a,b] In THF, organozinc reagents give poor results; however, the yields are clearly improved in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** (eq 3).[3c]

$$\text{MeCdCl} + \text{PhCOCl} \xrightarrow[85\%]{\text{benzene, reflux}} \text{MeCOPh} \qquad (1)$$

$$\text{MeZnI} + \text{PhCOCl} \xrightarrow[80\%]{\text{benzene, 0 °C}} \text{MeCOPh} \qquad (2)$$

$$\text{MeZnCl} + \text{PhCOCl} \xrightarrow[25\ °\text{C}]{\text{THF}} \text{MeCOPh} \qquad (3)$$

no catalyst, 12 h: 10%
5% $Pd(PPh_3)_4$, 30 min: 80%

With the very reactive organomagnesium compounds, the acylation takes place in the presence of $Fe(acac)_3$[3d] or $MnCl_2$[3e] (eqs 4 and 5). It is worthy of note that the 1,2-addition, which is rapid under these reaction conditions (10-20 °C), is completely avoided.

$$\text{PhCOCl} + \text{MeMgCl} \xrightarrow[80\%]{3\%\ Fe(acac)_3,\ \text{THF, rt}} \text{MeCOPh} \qquad (4)$$

$$\text{PhCOCl} + \text{BuMgCl} \xrightarrow[90\%]{3\%\ MnCl_4Li_2,\ \text{THF, 0 °C, 45 min}} \text{BuCOPh} \qquad (5)$$

Organocopper (60% of PhCOMe from $MeCu.PBu_3$)[3f] and cuprate reagents (eq 6),[3g] which are now widely used, give only moderate yields of phenyl ketones. Better yields are obtained at low temperature by using a large excess of organocuprate[3h] or heterocuprate (eq 7).[3i]

$$Me_2CuLi + \text{PhCOCl} \xrightarrow[58\%]{\text{ether, -5 °C}} \text{MeCOPh} \qquad (6)$$

Organomanganese compounds afford excellent yields by the use of a stoichiometric amount of reagents under mild conditions (eq 8).[3j]

Acylation of Enolates, Enols, and Related Reactions.[4,5]

According to the reaction conditions, PhCOCl reacts with ketone enolates to lead to enol benzoates (*O*-acylation, kinetic product) or β-diketones (*C*-acylation, thermodynamic product) (eq 9).[5a]

2 equiv of PhCOCl:	41%	6%
2 equiv of enolate:	9%	33%

PhCOCl very often gives a mixture of the *O*- and *C*-acylated products. To prepare the enol ester (kinetic conditions) a more reactive acylating agent such as ***Acetyl Chloride*** is generally used. Moreover, carboxylic acid anhydrides are generally preferred to acyl halides. Accordingly, PhCOCl is preferred to prepare 1,3-dicarbonyl compounds. Ketones (eq 10),[5b] esters (eq 11),[5c] and more commonly β-keto esters or related CH acidic compounds (eqs 12-15)[5d-g] can be *C*-acylated via the preformed enolate (eq 11) or directly under basic conditions (eq 13).[5e]

(10)

(11)

(12)

(13)

(14)

(15)

Friedel-Crafts Acylation and Related Reactions.[6,7]

Aromatic compounds (eqs 16 and 17)[7a,b] are acylated by PhCOCl in the presence of a Lewis acid such as $AlCl_3$, $TiCl_4$, BF_3, $SnCl_4$, $ZnCl_2$, or $FeCl_3$, or of a strong acid such as polyphosphoric acid or CF_3SO_3H.[6] Metallic Al or Fe and iodine (in situ formation of a Lewis acid) can also act as a catalyst.[6] Various solvents that have been used to perform this reaction are CS_2, CH_2Cl_2, 1,2-dichloroethane, nitrobenzene, and nitromethane.[6] PhCOCl is less reactive than aliphatic carboxylic acid chlorides (with benzene in nitromethane the relative reaction rates are PhCOCl:MeCOCl = 6:100).[7a] As for all electrophilic substitutions, the rate and the regioselectivity of the acylation closely depend on the nature and on the position of the substituents on the aromatic system[6] (eqs 16 and 18[7c]). The nature of the solvent can also exert a strong influence.[6]

(16)

(17)

(18)

The electrophilic acylation of alkenes or alkynes is another example of Friedel-Crafts reactions and is carried out under similar conditions.[6,8,9] With PhCOCl, alkenes can lead to β-chloro alkyl ketones or, more frequently, to the corresponding α,β-ethylenic ketones (eq 19)[8b] according to the reaction conditions.[6,8a] PhCOCl also adds to triple bonds to give a β-chloro vinyl ketone[9] (eq 20).[9b]

$$H_2C{=}CH_2 + PhCOCl \xrightarrow[70\%]{AlCl_3,\ CHCl_2CHCl_2,\ 5\ °C} H_2C{=}CHCOPh \quad (19)$$

$$HC{\equiv}CH + PhCOCl \xrightarrow[\text{65-70\%}]{AlCl_3,\ ClCH_2CH_2Cl,\ 0\ ^\circ C} PhCOCH{=}CHCl \quad (20)$$

Under Friedel-Crafts conditions, PhCOCl reacts with various silicon compounds. Thus β-diketones are easily obtained from enoxysilanes[10a,b] (eq 21).[10c] Conversely, vinyl-, aryl-, and allylsilanes lead to the corresponding vinyl, aryl, and allyl ketones in good yields[11a-c] (eq 22[11d] and eq 23[11e]). Vinylsilanes can lead to a mixture of β-chloro alkyl ketones and conjugated enones; a basic treatment is then necessary to obtain only the enone (eq 23).

(21)

$$PhCH{=}CHSiMe_3 \xrightarrow[\text{2. } Et_3N,\ \text{ether},\ \Delta\ \ \text{73\%}]{\text{1. } PhCOCl,\ AlCl_3,\ \hat{E}\hat{E}CH_2Cl_2,\ 0\ ^\circ C} PhCH{=}CHCOPh \quad (22)$$

$$H_2C{=}CHCH_2SiMe_3 \xrightarrow[\text{90\%}]{PhCOCl,\ AlCl_3,\ CH_2Cl_2,\ -30\ ^\circ C} H_2C{=}CHCH_2COPh \quad (23)$$

Acylation of Enol Ethers, Ketene Acetals,[12] and Enamines.[13]

Enol ethers,[12a] ketene acetals (eq 24),[12b] and enamines (eq 25)[13g] react with PhCOCl to provide the corresponding β-acylated products (eq 24).[12b] The acylation of enamines has been extensively studied (eq 25);[13a-f] the resulting β-acyl enamine is generally hydrolyzed to give β-diketones (eq 25).

$$(MeO)_2C{=}CH_2 + PhCOCl \xrightarrow[\text{55\%}]{Et_3N,\ \text{ether},\ \Delta} (MeO)_2C{=}CHCOPh \quad (24)$$

(25)

Protection of Alcohols as Benzoates[14] and of Amines as Benzamides.[15]

PhCOCl easily reacts with alcohols to give the corresponding benzoates in excellent yields.[14a] The acylation is performed in the presence of an amine, very often pyridine or triethylamine. CH_2Cl_2 or a large excess of amine is generally used as solvent (eq 26).[14d] The reaction has also been performed by phase transfer catalysis (PhCOCl, benzene, Bu_4NCl, 40% NaOH).[14e] Alternatively, the alcohol can be converted to lithium alcoholate (with BuLi), which readily reacts with PhCOCl to give quantitatively the corresponding benzoate (eq 27).[14f] Tributyltin ether prepared by treatment of the alcohol with ***Bis(tri-n-butyltin) Oxide*** has also been used as intermediate.[14g] Benzoates are very often prepared to protect alcohols[14b,c] because they are more stable than acetates and their tendency to migrate to adjacent hydroxyl groups is lower.[14h,i] In most cases the benzoylation of polyhydroxylated molecules is more selective than the acetylation.[14h,i] PhCOCl has also been used to monoprotect diols,[14f] and to acylate a primary alcohol in the presence of a secondary alcohol.[14j] Under similar conditions (pyridine), phenols are converted to aryl benzoates.[14a,k]

(26)

(27)

PhCOCl reacts also easily with primary or secondary amines in the presence of a base, aqueous alkali (Schotten-

Bauman procedure), or tertiary amines (pyridine or Et_3N), to afford the corresponding amides (eq 28).[15b] This reaction is used to protect amines.[15c]

Miscellaneous Reactions.

PhCOCN (see ***Acetyl Cyanide***), which is used as acylating agent (for instance, to protect alcohols)[17a] can be prepared by reacting PhCOCl with ***Copper(I) Cyanide*** (60-65%).[17b,c] Diazoalkanes are readily acylated by PhCOCl to give diazo ketones.[18a,b] These compounds are interesting as intermediates[18c-e] to prepare α-halo ketones, α-hydroxy ketones or arylacetic acids (Arndt-Eistert reaction).[18e] PhCOCl has also been used to prepare volatile acyl chlorides (C_2 to C_6) from the corresponding carboxylic acids.[19] On the other hand, it reacts with sulfoxides to lead generally to the corresponding α-chloro sulfides (Pummerer rearrangement).[20]

Related Reagents.

Acetyl Chloride; ***Acetyl Cyanide***; ***Benzoic Anhydride***.

Benzoyl Isothiocyanate[1]

[532-55-8] · C_8H_5NOS · Benzoyl Isothiocyanate · (MW 163.19)

(reactive isothiocyanate for condensation and cyclization reactions to form thioamides, thioureas, and heterocycles)

Physical Data: bp 133-136 °C/18 mmHg; *d* 1.214 g cm^{-3}.

Solubility: freely sol most organic solvents.

Form Supplied in: liquid or prepared in situ from benzoyl chloride and ammonium thiocyanate.[2]

Purification: distillation in vacuo.

Handling, Storage, and Precautions: toxic; lachrymatory; handle in fume hood. Moisture sensitive; reacts exothermically with strong bases and amines.

Thiourea Synthesis.

The reaction of anilines and aromatic heterocyclic amines with benzoyl isothiocyanate affords the corresponding *N*-aryl-*N*´-benzoylthioureas, which can be hydrolyzed under basic conditions to give good to excellent yields of the *N*-arylthioureas (eq 1).[2,3]

Ar	(1)	(2)
Ph	97%	84%
4-$CF_3C_6H_4$	95%	90%
4-$MeOC_6H_4$	83%	95%
4-$NO_2C_6H_4$	77%	46%

Reactions of benzoyl isothiocyanate with more basic amines or hydrazines often give mixtures of products derived from reaction at the carbonyl, thus giving rise to benzamide or benzhydrazide derivatives.[4]

Synthesis of Thioamides.

Benzoyl isothiocyanate reacts with active methylene compounds to give the expected thioamide derivatives. For example, reaction with ethyl cyanoacetate (as the sodium salt) affords thioamide (**3**) which was readily cyclized with hydrazine to partially protected heterocycle (**4**) in good yield (eq 2).[5] Adducts analogous to (**3**) are obtained starting with malonitrile (40%) and acetylacetone (55%).

Synthesis of Heterocycles.

Benzoyl isothiocyanate is used in a concise synthesis of biologically active isoguanosine (**5**) (eq 3).[6] Other guanosine analogs can be prepared in similar fashion.[7]

Aminoguanidine hydrochloride reacts preferentially at the hydrazino group with benzoyl isothiocyanate to give benzoylthiosemicarbazide (**6**). Cyclization of (**6**) to either thiadiazole (**7**) or to triazole (**8**) is dependent on reaction conditions (eq 4).[8]

A number of pyrimidines can be synthesized employing benzoyl isothiocyanate as a key reagent. Condensation/cyclization reactions of benzoyl isothiocyanate with imidates[9] (eq 5), *S*,*N*- and *N*,*N*-ketene acetals,[10] activated enamines,[11] and acetonitriles[12,13] give rise to structurally diverse pyrimidine derivatives, in moderate to good yields.

Related Reagents.

Ethoxycarbonyl Isothiocyanate; ***Methyl Isocyanate***.

Benzoyl Nitrate[1]

[6786-32-9] · $C_7H_5NO_4$ · Benzoyl Nitrate · (MW 167.12)

(nitrating agent for arenes and some other functionalities; benzoylation may also occur; oxidizes thiols to disulfides, thioethers to sulfoxides, and HCl to chlorine)

Physical Data: not known; presumably liquid at room temperature. *d* 1.3 g cm^{-3} at 0 °C.[2]

Solubility: miscible with common organic solvents.

Form Supplied in: not commercially available.

Preparative Methods: a standard approach is to add an equivalent amount of PhCOCl to a solution of freshly dried $AgNO_3$ in MeCN at -20 °C, and to filter off AgCl. The solution may be kept at -40 °C for some time, but develops a precipitate of benzoic acid.[3] CCl_4 may also be used as a solvent.[4] Alternatively, PhCOCl in MeCN is added dropwise to a rapidly stirred solution of $AgNO_3$ in MeCN plus the required substrate, such as PhR, to be nitrated; eventually this is done at reflux temperature.[3] This is likely to work satisfactorily only if the target reaction is sufficiently rapid.

Purification: kinetic and product studies (such as in the nitration of toluene[4] and also involving substituted analogs of the title reagent) yield an invariant isomer composition of the nitrotoluenes,[3] suggesting that the active ingredient may be N_2O_5, present in equilibrium with benzoic anhydride.

Handling, Storage, and Precautions: unstable above room temperature; stock solution may be stored in the cold,[3] but the use of freshly (or in situ) prepared reagents is recommended. This reagent should be handled in a fume hood.

Electrophilic Nitration (and Benzoylation).

Regular nitration of toluene typically gives a 50% yield of $MeC_6H_4NO_2$, with *o*:*m*:*p* = 62:4:34.[3] In the presence of Al-exchanged mordenite a 99% yield has been claimed, the isomer distribution now being 67:1:32;[5] with H-ZSM 11, selectivity to *para* was even 98%. Further examples include PhR with R = Et, *n*-Pr, *i*-Pr, *t*-Bu; *p*-terphenyl gave a 71% crude yield of $p\text{-}NO_2C_6H_4C_6H_4C_6H_4NO_2\text{-}p$. With *o*-xylene, 3- and 4-nitro-*o*-xylene (28% yield, ratio 32:68) *and* the corresponding benzoyloxy derivatives (16%, ratio 5:95) are formed; the benzoates apparently arise via *ipso* attack of nitronium ion, *p*- or *o*-addition of benzoate ion, and elimination of HNO_2.[6] Thiophene gives 2- and 3-nitrothiophene, in a ratio of ca. 6.[7] Secondary amines can be converted into the *N*-nitro derivative[8] (eq 1). Primary arylamines ($ArNH_2$), however, give ArNHOBz in high yield.[8] Indoles with a free 3-position are converted into their 3-nitro derivatives; 3-methylindole leads to 3-methyl-2-nitroindole, but yields in these reactions are modest (<35%).[9]

(1)

Oxidation.

Benzenethiol is quantitatively converted into PhSSPh.[2] Thiol ethers rapidly give sulfoxides in high yield, without further oxidation to sulfones, even well below 0 °C.[10]

Other Applications.

The oxidative power of the reagent can be directed to effect chlorination. In MeCN with aq. HCl it liberates Cl_2, and when performing the reaction in the presence of e.g. toluene, up to 1.7 mol of chlorotoluene (*o*:*p* = 54:46) per mol of benzoyl nitrate could be obtained.[11] Alcohols (ROH) are converted into $RONO_2$ and PhCOOH.[2]

Thermolysis.

Upon reflux in CCl_4 (9 h) PhCl, $PhCO_2H$, some $PhNO_2$, and CO_2 are produced.[12] In refluxing benzene, biphenyl, benzoic anhydride, $PhCO_2H$, and $PhNO_2$ arise. In both cases radical reactions occur.[13] Controlled gas-phase thermolysis at ca. 290 °C of RCO_2NO_2 can afford RNO_2 in ca. 50% yields.[14]

Benzoyl Trifluoromethanesulfonate

[36967-85-8] · $C_8H_5F_3O_4S$ · Benzoyl Trifluoromethanesulfonate · (MW 254.18)

(reagent for protection of hindered hydroxy groups as their benzoyl esters;[1] reagent effecting ring expansion of bridgehead carbaldehydes;[2,3] a highly reactive benzoylating reagent for Friedel-Crafts acylations[4])

Alternate Name: benzoyl triflate.

Physical Data: bp 92-94 °C/2.2 mmHg; *d* 1.51 g cm^{-3}

Solubility: generated and used in inert solvents such as dichloromethane, carbon tetrachloride, nitromethane, or carbon disulfide.

Preparative Methods: synthesized from ***Benzoyl Chloride*** and ***Trifluoromethanesulfonic Acid***.[1,5] Generation in situ has been achieved with benzoyl chloride and silver triflate,[5a,6] benzoic anyhdride and triflic acid,[5b,7] and reaction of *S*-methyl thiobenzoate with methyl triflate.[8]

Purification: the reagent can be distilled under reduced pressure.

Handling, Storage, and Precautions: very moisture sensitive and corrosive. Darkens on exposure to air, but can be stored at rt under dry nitrogen for several months without appreciable decomposition.

Benzoylation of Sterically Hindered Alcohols.

Benzoyl triflate is a reagent that has successfully been used for protecting sterically hindered alcohols as their benzoyl esters.[1] The reaction proceeds without base but in this case simple ketals and acetals undergo deprotection during the aqueous workup.[1a,b] If other Lewis acid-sensitive functional groups are present in the substrate, e.g. epoxides and spiroacetals, addition of pyridine is essential to prevent substantial decomposition.[1b] Nevertheless, some epoxide functions have been observed to undergo clean ring opening when the carbocation generated by the epoxide opening can be quenched by rearrangement (eq 1).[1a,b]

(1)

Ring Expansion of Bridgehead Carbaldehydes.

Bridgehead carbaldehydes react with benzoyl triflate and triflic acid to give ring-expanded 1,2-diol monobenzoyl esters (eq 2),[2,3] but other strong acids in place of triflic acid give greatly reduced yields.[2b] Unsymmetrical carbaldehydes react to give a mixture of the possible rearranged products,[2] and quenching the reaction with ***Tetra-n-butylammonium Iodide*** in place of water gives the corresponding tertiary iodo benzoate.[3]

(2)

Friedel-Crafts Benzoylation.

Mixed carboxylic-triflic acid anhydrides are highly active Friedel-Crafts acylating agents.[4] Benzoyl triflate can

benzoylate benzene and deactivated chlorobenzene without the addition of a Friedel-Crafts catalyst,[5,6] whereas other sulfonic-carboxylic acid anhydrides fail to react at higher temperatures, even with activated arenes such as anisole. Friedel-Crafts benzoylation is possible in a catalytic cycle[5b,6,9] using benzoyl chloride or benzoic anhydride and 1-10 mol% of triflic acid, which is far superior to other Brønsted or Lewis acids.[5b,9] Substituted benzoyl triflates have been made also; for example, 4-nitro-,[5,6,8,10] 4-methyl-,[8] and 2,4,6-trimethylbenzoyl triflates.[8] Benzoyl triflate has also been used to benzoylate less common heteroaromatic substrates such as 1,3,5,2,4-trithiadiazepine.[7] Although this was low yielding, conventional Friedel-Crafts chemistry had failed completely.

Reaction mixtures of 2-(trifluoromethylsulfonyloxy)pyridine, benzoic acid, and trifluoroacetic acid have also been used to benzoylate arenes, and benzoyl triflate is one of the proposed acylating species in this mixture.[11]

Benzoylation of alkynes[12] has been reported using benzoyl triflate. Both *cis*- and *trans*-vinyl triflates as well as indenones are produced, with the distribution depending on ring and alkyne substituents (eq 3).

R = H	71.5	6.5	22.0
R = NO_2	40.0	60.0	0.0
R = OMe	82.0	1.5	16.5

Reaction with α-diazo ketones[13] was shown to proceed via *O*-benzoylation. Quenching of the reaction with an amine produced triazoles, whereas warming resulted in loss of nitrogen and formation of 1,3-dioxolium salts (eq 4).

Mixed carboxylic-triflic acid anydrides for Friedel-Crafts acylations are not just restricted to aromatic carboxylic acids, and these can have advantages over conventional Friedel-Crafts systems when applied to sensitive substrates.[14] Aliphatic carboxyl triflates[4-8] and trifluoroacetyl triflate[15] have been made, and intramolecular Friedel-Crafts acylation has been achieved using an aromatic acid chloride with triflic acid catalysis.[16]

Related Reagents.

Acetyl Fluoride; ***Benzoyl Chloride***.

Benzyl Bromide

[100-39-0] · C_7H_7Br · Benzyl Bromide · (MW 171.04)

(benzylating agent for a variety of heteroatomic functional groups as well as carbon nucleophiles)

Physical Data: mp -3 to -1 °C; bp 198-199 °C; *d* 1.438 g cm^{-3}.

Solubility: sol ethereal, chlorinated, and dipolar aprotic solvents.

Form Supplied in: 98-99% pure liquid.

Handling, Storage, and Precautions: the reagent is a potent lachrymator and should be handled in a fume hood.

Benzylation of Heteroatomic Functional Groups.

Benzylation of various heteroatomic functional groups is readily achieved with this reagent under a variety of conditions and finds widespread application in organic synthesis, primarily as a protecting group.[1]

Alcohols and phenols are benzylated upon treatment with benzyl bromide under basic conditions. For example, treatment of alcohols with ***Sodium Hydride*** or ***Potassium Hydride*** in ethereal solvent[2] or DMF[3] generates alkoxides, which subsequently undergo Williamson reactions with benzyl bromide. Selective benzylation of a primary alcohol in the presence of a secondary alcohol has been accomplished in DMF at low temperature.[4]

Benzylation of alcohols using ***Potassium Fluoride-Alumina*** and benzyl bromide in acetonitrile at room temperature is effective.[5] Silver oxide in DMF is yet another base system.[6] Of particular interest in carbohydrate applications is the reaction of benzyl bromide with carbohydrate derivatives which have been pretreated with tin reagents. Thus it is possible to benzylate an equatorial alcohol in the presence of an axial alcohol (eq 1)[7] and also to selectively benzylate an anomeric hydroxy through ***Di-n-butyltin Oxide***.[8]

In some instances the sluggish reactivity of sterically hindered alcohols toward benzyl bromide may be overcome through addition of a catalytic iodide source such as ***Tetra-n-butylammonium Iodide***, which generates the more reactive benzyl iodide in situ (see ***Benzyl Iodide***). Benzylation of phenols proceeds well under the conditions described for aliphatic alcohols. Owing to the greater acidity of phenols it is possible to use weaker bases such as ***Potassium Carbonate*** for these reactions.[9]

Benzyl bromide will readily alkylate amino groups. Reactions are normally carried out in the presence of additional base and dibenzylation of primary amines is usually predominant.[10] Selective quaternization of a less hindered tertiary amine in the presence of a more hindered tertiary amine has been described.[11] Amide and lactam nitrogens can be benzylated under basic conditions,[12] as can those of sulfonamides[13] and nitrogen heterocycles.[14]

Thiols,[15] silyl thioethers,[16] and thiosaccharins[17] may be benzylated with benzyl bromide under basic conditions. Thus L-cysteine is *S*-benzylated under basic conditions (eq 2).[18] Benzylation of selenols is likewise possible.[19] A synthesis of benzylic sulfones is possible using ***Benzenesulfonyl Chloride*** and ***Sodium O,O-Diethyl Phosphorotelluroate*** with benzyl bromide.[20]

Although the preparation of benzyl carboxylate esters from benzyl bromide and carboxylate anions is not the most common route to these compounds, the reaction is possible when carried out in DMF[20] or using zinc carboxylates.[21]

Nucleophilic attack on benzyl bromide by cyanide and azide anions is feasible with ion-exchange resins or with the corresponding salts.[22]

Reactions with Active Methylene Compounds.

Enolates of ketones,[23] esters,[24] enediolates,[25] 1,3-dicarbonyl compounds,[26] amides and lactams,[27] as well as nitrile-stabilized carbanions,[28] can be alkylated with benzyl bromide. Cyclohexanone may be benzylated in 92% ee using a chiral amide base.[29] Amide bases as well as alkoxides have been employed in the case of nitrile alkylations.[28b] Benzylation of metalloenamines may be achieved[30a] and enantioselective reactions are possible using a chiral imine (eq 3).[30b] However, reactions between benzyl bromide and enamines proceed in low yield.[31] The benzylation of a ketone via its enol silyl ether, promoted by fluoride, has been observed.[32]

(3)

Reactions with Metals and Organometallics.

Difficulties encountered in the preparation of benzylic metal compounds with active metals are due primarily to the tendency of these compounds to undergo Wurtz coupling (self condensation).[33] Benzylmagnesium bromide may nevertheless be prepared from benzyl bromide and used under standard[34] or Barbier conditions.[35] Benzyllithium cannot be obtained practically from benzyl bromide. Benzylzinc bromide and the cyanocuprate BnCu(CN)ZnBr have both been prepared. The cuprate undergoes 1,2-additions with aldehydes and ketones.[36]

The propensity of benzyl bromide to undergo coupling with organometallic reagents may be used to advantage, as organolithiums,[37] Grignard reagents,[38] organocuprates,[39] organocadmiums,[40] organochromiums,[41] and organoiron reagents[42] are all known to give coupling products. An interesting coupling of benzyl bromide with *N*-methylphthalimide under dissolving metal conditions has been reported (eq 4).[43]

Benzyl Bromomethyl Sulfide

[15960-81-3] · C_8H_9BrS · Benzyl Bromomethyl Sulfide · (MW 217.12)

(introduction of protected mercaptomethyl group via enolate alkylation; synthesis of α-methylene ketones and carboxylic acids[2])

Physical Data: bp 65.5-67 °C/0.2 mmHg.

Solubility: sol CH_2Cl_2, THF.

Preparative Methods: from phenylmethanethiol, paraformaldehyde, and 48% HBr_2 or from benzyl chloromethyl sulfide and anhyd HBr.[3]

Handling, Storage, and Precautions: store cold; use in a fume hood.

Benzyl bromomethyl sulfide alkylates enolates derived from ketones,[2] carboxylic acids,[2] malonates,[3] oxazolidones,[4] and oxazolidyl carboximides,[1] often where ***Benzyl Chloromethyl Sulfide*** (see also ***Chloromethyl Methyl Sulfide*** and ***Chloromethyl Phenyl Sulfide***) proved unsuccessful (eq 1).[2] The alkylation products are debenzylated to give α-mercaptomethyl groups,[1,4] or converted to α-methylene compounds by oxidation to sulfoxides followed by thermolysis (see also ***Dimethyl Disulfide*** and ***Diphenyl Disulfide***).[2,5]

Although benzyl bromomethyl selenide reacts 18 times more slowly than benzyl bromomethyl sulfide, similar alkylation has been achieved with carboxylic acid and amide dianions, enolates of tertiary ketones, and protected amino acid esters (glycine, valine, and alanine).[2] Oxidative debenzylation with Br_2 or SO_2Cl_2 cleanly converts the

selenide to the selenenyl halide, which is conveniently reduced in situ to the diselenide (eq 2). Alternatively, oxidation of the selenide followed by selenoxide elimination mildly generates the alkene (eq 2).[2]

Benzyl 1,3-Butadiene-1-carbamate

(**1**; R = Ph)

[65899-49-2] · $C_{12}H_{13}NO_2$ · Benzyl 1,3-Butadiene-1-carbamate · (MW 203.09) (**2**; R = Me)

[61759-61-3] · $C_7H_{11}NO_2$ · Ethyl 1,3-Butadiene-1-carbamate · (MW 141.08)

(1,3-dienes: useful aminobutadiene equivalents for Diels-Alder reaction,[1] regio- and stereoselective reactions even with poor dienophiles;[2] used in the synthesis of complex heterocyclic natural products[3] and aminoanthraquinones[4])

Physical Data: [5-7] (**1**) mp 74-75 °C; ^{1}H NMR ($CDCl_3$) δ 7.32 (s, Ph), 6.71 (br d, *J* = 9 Hz, =CHNH), 6.26 (dt, *J* = 10, 17 Hz, CH=CH_2), 5.4-5.8 (m, CH=CHNH and NH), 5.15 (s, CH_2Ph), 4.8-5.2 (m, =CH_2); ^{13}C NMR ($CDCl_3$) δ 127.2, 112.5, 134.6, 113.5, 128.3, 128.4, 128.7, 136.0, 153.7, 67.5. (**2**) mp 44-45 °C; ^{1}H NMR ($CDCl_3$) δ 7.7 (br d, NH), 5.3-6.9 (m, vinylic), 4.5-5.1 (m, =CH_2), 4.13 (q, *J* = 7 Hz, Me); ^{13}C NMR ($CDCl_3$) δ 127.6, 112.1, 134.8, 113.2, 14.5, 61.7, 154.1.[2,5]

Solubility: (**1**) readily sol dioxane and toluene; (**2**) sol dioxane.

Preparative Methods: The synthesis of various *N*-acyl-1-amino-1,3-dienes have been described in detail.[6-10] The following, which uses a Curtius rearrangement (eq 1),[7] illustrates the procedure commonly used in the synthesis of (**1**) and (**2**).

Handling, Storage, and Precautions: in general, acyl azides are potentially explosive. Therefore solutions containing acyl azides should not be evaporated to dryness.[5] Both (**1**) and (**2**) are stable solids, which can be stored in a freezer for several months. However, they are acid-sensitive and may be decomposed by traces of deuterium chloride present in chloroform-*d*.[5] In rigorously degassed (oxygen-free) solutions, these diene carbamates are stable for extended periods even at 140 °C and this has been a critical factor in their successful reactivity with poor dienophiles.[2]

Diels-Alder Reactions.

Both (**1**) and (**2**) react with a broad range of dienophiles, providing a variety of amino-functionalized cycloadducts in high yields. Reaction with methyl acrylate yields cyclohexenes with high regio- and stereoselectivity (*endo*) (eq 2).[6] In contrast, with the same dienophile, 2,4-pentanedienoic acid requires longer reaction times and gives a mixture of all the possible stereo- and regioisomers.[1]

The ability to give *endo* selectivity, coupled with their higher reactivity, is, in part, responsible for the versatility of (**1**) and (**2**) in natural product synthesis. The construction of three of the chiral centers found in (±)-pumiliotoxin C was achieved in a single step (eq 3).[11,12] While other dienes exhibited lower stereoselectivities with *trans*-crotonaldehyde,[13,14] (**1**) and (**2**)

gave the *endo* products in 61 and 67% yields, respectively; these were key intermediates in the synthesis of (±)-pumiliotoxin C.[12] Additionally, use of a chiral dienophile, (5*R*)-5-hydroxy-6,6-dimethylhept-2-en-4-one, permitted the asymmetric synthesis of (+)-pumiliotoxin C.[15]

The cycloaddition of benzyl *trans*-1,3-butadiene-1-carbamate (**1**) and ethyl atropate affords the major product *endo*; this was a key intermediate in the synthesis of (±)-tilidine (eq 4).[16] Of significance is the opposite stereoselectivity exhibited by the related *trans*-1-(dialkylamino)-1,3-dienes ($R^1 = R^2 = Me$).[17,18]

The most remarkable feature of dienes (**1**) and (**2**) is their ability to give *endo* cycloaddition products, in good yields, with extremely poor dienophiles such as methyl *trans*-crotonate, *trans*-crotonaldehyde, 2-cyclohexenone, styrene, and 3,4-methylenedioxystyrene.[2,11,19-24] The reaction of (**1**) with phenylacetylene (140 °C, 114 h),[2] however, led to a mixture of 13 products, suggesting an upper limit to the reactivity of these dienes.

To date, Diels-Alder reactions involving (**1**) and (**2**) have been the key step in syntheses of gephyrotoxin,[26] (±)-perhydrogephyrotoxin,[25] (+)-pumiliotoxin,[11,15] (±)-isogabaculine,[27] and (±)-tilidine.[16] In addition, substituted aminoanthraquinones have been synthesized by the regioselective cycloaddition of (**1**) to naphthoquinones followed by aromatization.[4,28] Also noteworthy is the synthesis of epimeric *cis*-decahydroquinoline-5-carboxylic acids, which involved the reaction of (**1**) with *trans*-3-acetylcrotonaldehyde.[29] Additionally, the presence of an easily modifiable phenyl group in (**1**) has led to the generation of a water-soluble diene (eq 5), which has been used in antibody-catalyzed Diels-Alder reactions.[30] Exclusive formation of either isomer (*endo* or *exo*) has been possible, depending on the transition state analog used for the elicitation of catalytic antibodies.[30]

Benzyl Chloride

[100-44-7] · C_7H_7Cl · Benzyl Chloride · (MW 126.59)

(benzylating agent for a variety of heteroatom functional groups and carbon nucleophiles; precursor to benzyl organometallics)

Physical Data: bp 177-181 °C; *d* 1.100 g cm^{-3}.

Solubility: freely miscible in ethereal, chlorinated, and dipolar aprotic solvents.

Form Supplied in: 99% pure liquid.

Handling, Storage, and Precautions: the reagent is a mutagen and possibly a carcinogen. It should be used in a fume hood.

Benzylation of Heteroatom Functional Groups.

Benzyl chloride is a versatile benzylating agent for heteroatom functional groups and is commonly used to introduce this protecting group.[1] Benzylation of alcohols with this reagent is achieved under strongly basic conditions such as KOH, either in an alcoholic solvent[2] or under phase transfer conditions with *n*-Bu_4NHSO_4.[3] Silver oxide in DMF is also effective.[4] A procedure involving $Ni(acac)_2$ has also been reported.[5] Phenols may also be benzylated under basic conditions.[6]

Amino groups are readily benzylated when treated with benzyl chloride in the presence of carbonate or hydroxide base,[5] although dibenzylation of primary amines is a competing reaction.[7] Thiols are benzylated with sodium hydroxide or cesium carbonate in polar solvents such as ethanol or DMF.[8] Dibenzyl sulfide is produced by reaction of benzyl chloride with elemental sulfur and sodium triethylborohydride.[9]

Amides can be *N*-benzylated with this reagent under the influence of strong bases such as metal hydrides.[10] A benzyl carboxylate ester may be formed from benzyl chloride and the corresponding sodium salt of the acid in DMSO.[11]

Benzyl cyanide can be prepared from benzyl chloride and KCN with an ion exchange resin.[12] Benzyl azide is formed by reaction with trimethylsilyl azide in HMPA.[13]

Benzylation of Active Methylene Compounds.

The anions or dianions of β-ketoesters,[14] substituted malonate esters,[15] β-ketoaldehydes,[16] β-diketones,[17] β-ketoamides,[18] and β-ketonitriles[19] all react effectively with benzyl chloride to afford *C*-benzylated products. When the dianion of a β-ketoamide, β-ketoester, or β-diketone is generated and treated with benzyl chloride, benzylation is observed at the least acidic position. Nitrile-stabilized carbanions are readily benzylated in ethereal solvents, ammonia, or DMSO.[15,20] Benzyl chloride also reacts well with carbanions derived from ketones,[21] esters,[22] imines (metalloenamines),[23] oximes,[24] and hydrazones.[23] When benzalacetophenone is treated sequentially with 2 equiv of potassium in ammonia and then with benzyl chloride in ether, a formal conjugate addition of the benzyl group is observed (eq 1).[25] If a second equivalent of benzyl chloride is added, benzylation occurs at both the α- and β-positions.

(1)

Reactions with Metals and Organometallics.

Benzylmagnesium chloride can be prepared satisfactorily by rapid addition of benzyl chloride to magnesium in ether.[26] Benzyl chloride is readily dimerized by lithium naphthalenide,[27] sodium and tetraphenylethane,[28] zinc in the presence of catalytic nickel(II) bromide,[29] with titanocene dichloride and diiodomethane,[30] $(PPh_3)_3CoCl$,[31] and by electrolysis.[32] The cross-coupling reactions of benzyl chloride with other organometallics is demonstrated by the benzylation of organolithiums,[33] as in the case of a directed lithiation product (eq 2),[32a] Grignard reagents,[34] and organocuprates.[35] Vinyl boranes, derived from the addition of boron tribromide to alkynes and subsequent alkylation with organozincs (eq 3),[35a] couple with benzyl chloride under palladium catalysis.[36] Benzyl chloride will add to an α-diketone in the presence of powdered nickel to give the α-ketol (eq 4).[37]

Benzylchlorobis(triphenylphosphine)palladium(II)[1]

(1)

[22784-59-4] · $C_{43}H_{37}ClP_2Pd$ · Benzylchlorobis(triphenylphosphine)palladium(II) · (MW 757.59)

(catalyst for the cross coupling[1] of alkyl-, vinyl-, alkynyl-, and allylstannane groups with acyl chlorides,[2] allyl halides,[3] vinyl triflates, and iodides[4])

Physical Data: mp 166-170 °C.

Solubility: sol THF, benzene, and other organic solvents.

Form Supplied in: crystalline; commercially available.

Preparative Methods: may be prepared from benzyl chloride and $(Ph_3P)_4Pd$ in benzene at room temperature, washed with Et_2O, and dried under vacuum.[5]

Handling, Storage, and Precautions: is an air-stable solid and remains stable in solution. Irritant.

Cross Coupling Reactions with Organostannane Compounds.

Palladium catalysis of cross coupling reactions is well established in organic chemistry.[1] Benzylchlorobis(triphenylphosphine)palladium(II) (**1**), first reported in 1969,[2] is used extensively for these reactions. Other palladium complexes, such as dichlorobis(triphenylphosphine)palladium(II) and ***Tetrakis(triphenylphosphine)palladium(0)***, catalyze cross coupling reactions; however, the title compound generally provides higher yields in shorter reaction times. Most common is the coupling of an organotin compound with an acyl halide to produce ketone products (eq 1), which has many advantages over existing methods of preparing ketones from acyl chlorides. The yields are high, and in many cases, nearly quantitative. Both the organotin compound and the catalyst are air stable. The reaction tolerates a wide variety of functional groups; ester, alkene, nitro, nitrile, halo, methoxy, silyloxy, vinyl ether, and even aldehyde remain intact during the reaction. Sterically hindered acid chlorides will react, and conjugate addition with α,β-unsaturated acid chlorides does not occur. Further, if a vinyl-, aryl-, or alkynyl-trialkylstannane is used, only the vinyl, aryl, or alkynyl group is transferred. With stannanes as substituents on a stereogenic center, the reaction proceeds with stereochemical inversion of the stereogenic center.[6] Acylstannanes can be prepared by the coupling of acyl halides and distannyl species.[7]

Aldehydes can be prepared from acid chlorides and ***Tri-n-butylstannane*** in the presence of (**1**).[8] While this reduction can be performed by mixing the substrate and Bu_3SnH, ester byproducts and other products resulting from radical reactions occur without the palladium catalyst. 1,2-Diketones can be made easily by the reaction of a 1-methoxyvinylstannane and an acid chloride, followed by hydrolysis (eq 2).[9] A similar 2-methoxyvinylstannane was employed in the synthesis of agglomerin A and (±)-carolinic acid.[10] Vinylstannanes and acyl chlorides have been coupled intramolecularly to provide 11-, 12-, 14-, 16-, and 20-membered macrocycles in 32-72% yields.[11]

Allylic halides can be coupled with organostannanes without allylic transposition.[3b] The reaction takes place with inversion of stereochemistry at the allylic carbon, and double bond geometry remains intact for acyclic substrates (eq 3).[3c] In addition, carbon monoxide can be inserted during the course of the reaction to provide ketone products.[3a,12] Vinyl iodides couple in a similar fashion,[4a] and the coupling of vinyl triflates was used in the synthesis of pleraplysillin.[4b]

Ether Cleavage and Formation Reactions.

While the cross coupling reactions of organotin compounds in the presence of (**1**) tolerate a great deal of functionality, cyclic (5-membered or less), allylic and benzylic ethers can be cleaved upon reaction with an acid chloride catalyzed by the presence of trialkyltin chloride (eq 4).[13] Aliphatic and phenolic ethers are not consumed. Complementary to this method of ether substrate cleavage, epoxides, oxetanes, and tetrahydrofurans can be formed by the reaction of bromo ketones and allylic stannanes or α-ketostannanes (eq 5).[14] Other alkylstannanes fail to give cyclic ethers.

Benzyl Chloroformate[1]

[501-53-1] · $C_8H_7ClO_2$ · Benzyl Chloroformate · (MW 170.60)

(protecting agent for many functional groups, especially for the N-protection of amino acids;[7] activates pyridine rings toward nucleophilic attack;[53] reagent for the preparation of other benzyloxycarbonylating agents[3])

Alternate Name: benzyloxycarbonyl chloride (CbzCl).

Physical Data: colorless oily liquid, bp 103 °C/20 mmHg (with slow decarboxylation to benzyl chloride at this temperature); bp 85-87 °C/7 mmHg; mp 0 °C; *d* (20 °C) 1.195 g cm^{-3}; *n*20D 1.5190.

Form Supplied in: widely available.

Preparative Methods: CbzCl can be readily prepared by the reaction of benzyl alcohol and phosgene, either in toluene solution[4] or neat.[1b,5,6] Purification of such freshly prepared CbzCl is often not necessary; indeed, ca. 25% residual toluene solvent does not interfere with derivatization reactions.[4]

Purification: commercial CbzCl is typically better than 95% pure and is often contaminated by benzyl chloride, benzyl alcohol, toluene, and HCl.[2,3] On storage it can undergo a slow HCl-catalyzed decomposition, even at low temperature.[1a,3] It has been recommended[1b,2] that CbzCl which has been stored for long periods be purified by flushing with a stream of dry air to remove dissolved CO_2 and HCl impurities. Filtration and storage over Na_2SO_4 may be followed by distillation; it is important that low temperatures (oil bath <=85 °C)[1b] and high vacuum be used to minimize thermal decomposition.[3]

Handling, Storage, and Precautions: CbzCl is highly toxic and is a cancer suspect agent; it is a lachrymator with an acrid odor and should be handled with caution in a fume hood.

Protection of Amines.

The most widespread application of CbzCl is in the protection of primary and secondary amines as the corresponding benzyl carbamates. These reactions are usually performed either under Schotten-Baumann conditions,[7] by using aq $NaHCO_3$ or aq Na_2CO_3 as base in an organic solvent (eq 1),[8] or in the presence of an organic base (typically Et_3N) in

CH_2Cl_2.[9] The isolation and/or crystallization of amines is often facilitated by Cbz derivatization of the crude amine generated in another reaction.[10] A wide variety of primary and secondary aliphatic amines, including aziridines,[11] azetidines,[12] and other sensitive[7,9] and electron-deficient[8c] amines, can be selectively protected in the presence of alcohol,[8b,13] phenol,[14] and thiol[15] functionality; however, the selective protection of hindered secondary amines over secondary alcohols has proved difficult.[16]

The N-protection of amino acids during peptide synthesis constitutes a major application of this methodology.[1,8a] References to the N-protection of individual amino acids using CbzCl have been tabulated.[1b,e] Use of the *N*-Cbz protecting group generally affords crystalline amino acid derivatives and suppresses racemization at the α-stereocenter during peptide bond formation. The *N*-Cbz group is stable to conditions used for the formation of peptide bonds. Benzyl carbamates are highly complementary to *t*-butyl (i.e. Boc) carbamates in peptide synthesis (see ***t-Butyl Azidoformate***). Schotten-Baumann conditions are most commonly employed for the preparation of *N*-Cbz amino acids (eq 2);[1b,4] racemization at the α stereocenter is suppressed under these basic conditions by the adjacent negatively charged carboxylate group. The use of a lower reaction temperature (-20 °C) has been shown in one case to afford a higher yield of pure *N*-Cbz derivative.[17] One disadvantage of the standard Schotten-Baumann protocol is the need for either the simultaneous addition of CbzCl and aq NaOH, or the sequential addition of small aliquots of these reagents, throughout the course of the reaction. A modified procedure[1b] using $NaHCO_3$ as the base[8d] avoids this inconvenience. A recent report indicates that *N*-Cbz derivatization of a range of α-amino acids can be conveniently achieved, albeit in only moderate yield, by refluxing with CbzCl in ethyl acetate without added base; interestingly, no racemization was observed.[18]

The selective protection of the o-amine in α,o-diamino acids can be achieved by chelation of the α-amino and α-carboxylate functionality by Cu^{II} ion (eq 3).[1b,f,18,19] The Cu^{II} chelate can be cleaved by H_2S,[1f] by thioacetamide,[19] or by use of a chelating ion-exchange resin.[17] Selective protection of the ε-amino group in lysine, the imidazole ring nitrogen in histidine, and the α-amino function in serine, can all be accomplished in homogeneous aqueous medium in the absence of added base using Cbz-imidazolium chloride, a water-soluble benzyloxycarbonylating agent which is prepared in situ from CbzCl and *N*-methylimidazole.[20] Benzyl succinimidyl carbonate, best prepared by reaction of the dicyclohexylammonium salt of *N*-hydroxysuccinimide with CbzCl,[21] is also useful for the *N*-Cbz protection of α-amino acids without the need for added base.

The *N*-Cbz group is stable to a variety of weakly acidic and basic conditions.[22] Benzyl carbamates are most commonly cleaved to the free amine by catalytic hydrogenolysis (H_2/Pd-C)[23] although a plethora of alternate reductive (e.g. transfer hydrogenolysis,[24] Li/liq NH_3[25]), strongly acidic (e.g. HBr/HOAc[26]), and neutral conditions have been employed.[1] The use of transfer hydrogenolysis (cyclohexadiene, 10% Pd-C) allows for the clean deprotection of *N*-Cbz pyrimidines without concomitant reduction of the 5,6-double bond that is observed under standard catalytic hydrogenolysis conditions.[27] The acid stability of the *N*-Cbz group can be manipulated by the introduction of electron-withdrawing or electron-donating substituents onto the phenyl ring. Selective deprotection of an *N*-Cbz group in the presence of an *S*-Cbz moiety can be achieved using HBr/HOAc at rt.[28]

Primary and secondary arylamines can also be *N*-carbamoylated using CbzCl, typically in the presence of aq Na_2CO_3 (eq 4)[29] or pyridine.[30] The protection of electron-deficient anilines can be accomplished using MgO in acetone.[31] Protection of a pyrrole nitrogen can be achieved by initial deprotonation to the potassium salt.[32]

N-Benzyl carbamates prepared as outlined above can also serve as useful intermediates in the overall *N*-methylation of secondary amines, since $LiAlH_4$ reduction of a benzyl carbamate affords the corresponding tertiary *N*-methylamine (eq 5).[33]

Other N-Protection Reactions.

The protection of an amide as its *N*-Cbz derivative can be achieved using CbzCl with Et_3N/DMAP,[34] or by initial deprotonation of the amide using BuLi or $(Me_3Si)_2NLi$.[35] The N-protection of nucleosides is usually ineffective with CbzCl but can be selectively and efficiently accomplished using *N*-Cbz imidazolium salts generated in situ from the reaction of CbzCl with *N*-alkylimidazoles (eq 6).[27,36]

Protection of Alcohols and Phenols.

Protection of alcohols and phenols as the corresponding benzyl carbonates is typically achieved using CbzCl in the

presence of an organic base (e.g. Et_3N,[37] pyridine[38]) in CH_2Cl_2 or ether at low temperature (-20 °C to rt). The selective protection of one secondary alcohol in the presence of other secondary and tertiary alcohols has been accomplished using DMAP at very low temperatures (-40 to -20 °C) for 3 days (eq 7).[39]

(7)

The use of NaH as base allows for the efficient protection of even hindered electron-deficient alcohols (eq 8).[40] A secondary alcohol can be selectively protected over an indole nitrogen.[41] 1-*O*-Methylated 2-deoxyribose sugars can be protected at the 3- and 5-hydroxyl groups[38] while the hemiacetal function is selectively protected over secondary alcohols in 1-unprotected sugars.[42] Both alcohol-[38,43] and phenol-derived[44] benzyl carbonates are efficiently deprotected by catalytic hydrogenolysis; benzyl carbonates are more readily cleaved under these conditions than benzyl ethers.[38] Removal of the *O*-Cbz group can also be achieved by electrolytic reduction.[45]

(8)

Protection of Thiols.

The protection of thiols using CbzCl can be achieved using Et_3N as base.[46] The use of aq $NaHCO_3$ as base allows for the selective protection of the SH group in cysteine (eq 9), while *N,S*-bisprotection is observed under Schotten-Baumann conditions (eq 10).[47] Selective protection of the cysteine SH moiety can also be achieved using Cbz-imidazolium chloride, a water-soluble benzyloxycarbonylating agent prepared in situ from CbzCl and *N*-methylimidazole.[20] Both *N*- and *S*-Cbz groups are deprotected using refluxing CF_3CO_2H[48] or by electrolytic reduction.[45] The use of NaOMe/MeOH at rt for 5-10 min allows for the selective cleavage of *S*-Cbz over *N*-Cbz groups.[28]

Decarboxylative Esterification of Carboxylic Acids.

The preparation of benzyl esters from sterically uncongested carboxylic acids,[49] including α-keto acids[37,50] and malonic acid half esters,[51] can be achieved using CbzCl in the presence of an organic base (Et_3N,[37,50,51] pyridine,[52] or Et_3N/DMAP[49] in CH_2Cl_2 or THF). The lack of reactivity of sterically crowded carboxylic acids[49] allows for the selective esterification of the less crowded of two acid moieties (eq 11).[52] A major attraction of the benzyl ester group is its susceptibility to cleavage to the free carboxylic acid by catalytic hydrogenolysis[1d,23] or transfer hydrogenolysis.[1d]

Activation of Pyridine Ring Towards Nucleophilic Attack.

Pyridine and various 4-substituted pyridines can be activated by CbzCl toward regioselective nucleophilic attack by $NaBH_4$[53] and by alkyl,[54] aryl,[55] and alkynyl[56] Grignard reagents, affording the corresponding 2-substituted 1,2-dihydropyridines (eq 12). Treatment of a 3-substituted pyridine with CbzCl and $NaBH_4$ can afford a mixture of 1,2- and 1,4-reduction products; however, reaction with CbzCl and Red-Al proceeds via regioselective 1,2-reduction at the less crowded α-carbon (eq 13).[57]

Generation of Other Benzyloxycarbonylating Agents.

A variety of other benzyloxycarbonylating agents can be prepared from CbzCl.[3] For example, reaction of CbzCl with sodium benzyl carbonate affords dibenzyl carbonate, a promising stable crystalline alternative to CbzCl for achieving clean and efficient *N*-benzyloxycarbonylation.[3] *N*-Cbz-imidazole, prepared from CbzCl and imidazole, has proved a suitable reagent for the selective protection of primary over secondary amines.[58]

Related Reagents.

4-Bromobenzyl Chloroformate; ***Methyl Chloroformate***; and ***2,2,2-Trichloroethyl Chloroformate***.

Benzyl Chloromethyl Ether[1]

[3587-60-8] · C_8H_9ClO · Benzyl Chloromethyl Ether · (MW 156.61)

(protecting group for alcohols[2] and amines;[3] electrophile in alkylation of carbanions;[4] and source of nucleophilic benzyloxymethyl anion[5])

Physical Data: bp 53-56 °C/1.5 mmHg; 96-99 °C/11 mmHg; *d* 1.13 g cm^{-3}; n_D^{20} 1.5268-1.5279.

Solubility: sol THF, ether, dioxane, dichloromethane, chloroform, benzene, toluene, DMF, DMSO, and acetonitrile.

Form Supplied in: liquid.

Analysis of Reagent Purity: NMR, GC.

Preparative Methods: benzyl alcohol plus aqueous formaldehyde and hydrogen chloride gas;[1,6,7] reaction of benzyl methyl ether with boron trichloride;[8] cleavage of benzyloxymethyl methyl sulfide with sulfuryl chloride.[9]

Purification: distillation.

Handling, Storage, and Precautions: stable indefinitely when kept dry but destroyed by water and other nucleophilic reagents.

Alcohol Protecting Group.

The foremost use for this reagent is as a protecting group for the alcohol functional group. This can be illustrated in a step utilized in the total synthesis of kijanolide (eq 1).[10] An enantioselective synthesis of the taxol side chain used the benzyloxymethyl (BOM) ether for protection of an alcohol group (eq 2).[11]

(1)

(2)

Ethyl lactate can be protected as a BOM ether for subsequent nucleophilic additions to the corresponding aldehyde with high diastereoselectivity.[12] A synthesis of zoapatanol used selective protection of a diol (eq 3).[13] Primary alcohols can be protected selectively in the presence of secondary hydroxy groups,[14] and secondary hydronyls react more quickly than tertiary ones with benzyl chloromethyl ether and base.[15] Removal of this protecting group can be carried out by hydrogenolysis over Pd.

Amine Protecting Group.

2,3,5-Triiodoimidazole reacts with ***Potassium Carbonate*** in DMF followed by benzyl chloromethyl ether to give the 1-BOM derivative in 83% yield.[3] A substituted purine undergoes protection with benzyl chloromethyl ether and ***Sodium Hydride*** (eq 4).[16] Imide nitrogens can be protected in the presence of lactam nitrogens because of the difference in acidity.[17]

Alkylation of Carbanions.

Methyl 2-phenylpropionate can be deprotonated with LDA and alkylated on carbon with benzyl chloromethyl ether.[4] Introduction of the BOM group in both chiral amides (eq 5)[18] and dianions (eq 6)[19] gives good yields. Removal of the benzyl group by hydrogenolysis completes the hydroxymethylation process.

(5)

(6)

Benzyloxymethyl Anion.

Both Grignard and organolithium reagents of the benzyloxymethyl anion can be prepared. The Grignard reagent is formed by reaction with ***Magnesium***.[20] Trapping this species with ***Tri-n-butylchlorostannane*** and reaction of the stannane with ***n-Butyllithium*** gives the organolithium.[20] Addition to electrophiles is predictable (eq 7).[5] Removal of the benzyl group via hydrogenolysis reveals that the ether anion is a masked methanol dianion.

Benzyl Chloromethyl Sulfide

[3970-13-6] · C_8H_9ClS · Benzyl Chloromethyl Sulfide · (MW 172.67)

(protecting group in peptide synthesis,[5] palladium complexes,[10] biologically active iminium compounds,[13] sulfones, and sulfoximes[15])

Alternate Name: benzylthiomethyl chloride; chloromethyl benzyl sulfide; chloromethylthiomethylbenzene.

Physical Data: bp 78 °C/0.2 mmHg; bp 98-99 °C/2.5 mmHg; *n*25D 1.571-1.578.

Solubility: sol most organic solvents.

Preparative Method: the reagent is obtained following the procedure of Fancher.[1] Chloromethylation of phenylmethanethiol with paraformaldehyde in concentrated hydrochloric acid gives the desired benzyl chloromethyl sulfide. To paraformaldehyde (7.5 g) in 50 mL of benzene, 100 mL of concentrated HCl is added in 5 min with stirring. The mixture is kept at 40 °C for a while and phenylmethanethiol (33.75 g) in 50 mL of benzene is added slowly. The resulting mixture is maintained slightly above 40 °C for 2 h. After removing the solvent, the product is purified by distillation under reduced pressure. The unpleasant odor can be in large part suppressed by washing used apparatus immediately with alkaline permanganate. Other methods have been described elsewhere.[2]

Handling, Storage, and Precautions: should only be used in a fume hood.

Protecting Group in Peptide Synthesis.

Methods for the protection of the thiol group of cysteine during peptide synthesis have been prompted in part by evidence that the removal of the *S*-benzyl group from peptides containing *S*-benzylcysteine may be accompanied by side reactions, including fission of the peptide chain[3] and desulfuration.[4] The usefulness of the benzylthiomethyl group as an S-protecting group has been demonstrated by the synthesis of different peptides such as glutathione in pure form and near quantitative yield.[5] The benzylthiomethyl group is stable during the synthesis, and in the final stage can be cleanly removed under standard conditions (mercury(II) acetate in 80% formic acid at rt for 30 min).

Ligand in Mono- and Bimetallic Complexes.

Mono- and bimetallic complexes of short bite ligands such as bis(diphenylphosphino)methane (dppm),[6]

bis(diphenylarsino)methane (dpam),[7] (diphenylarsino)(diphenylphosphino)methane (dapm),[8] and 2-(diphenylphosphino)pyridine (Ph_2py)[9] have received considerable attention recently. These short bite ligands can act in monodentate, bidentate chelating, or bidentate bridging modes in complexes, depending on the nature of the ligand and metal center, and on the oxidation of the metal ion. Only a few bidentate ligands with different donor sites P and S have been reported. Sanger reported the synthesis of some complexes using (phenylthiomethyl)diphenylphosphine as a bridging ligand.[10] However, the coordinating ability of the phenylthiomethyl group seemed weak in bimetallic complexes lacking a metal-metal bond. Based on these observations, it was possible to form a palladium(I) complex containing a metal-metal bond and (benzylthiomethyl)diphenylphosphine as bridging ligand (eq 1).[11] In this case the benzyl group was introduced to enhance the donor ability in the sulfide moiety. Bidentate ligands incorporating a phosphine and a thioether are of interest for the following reasons: (1) when the phosphine and thioether functions are both coordinated to a platinum-group metal, the thioether is expected to be more labile than phosphine, generating a vacant site at the metal center; (2) the generation of heterodinuclear complexes due to preferential coordination of phosphine and thioether to different metals; and (3) the possibility of geometric and coordination isomerism in complexes of these ligands.

$[Pd_2Cl_2(m\text{-}PhCH_2SCH_2PPh_2)_2]$ can react with substituted alkynes (RC&tbond;CR´; R = Ph, R´ = H; R = CO_2Me, R´ = H; R = R´ = CO_2Me) to yield A-frame-type palladium(II) complexes $[Pd_2Cl_2(\mu\text{-}RC\&tbond;CR)(\mu\text{-}PhCH_2SCH_2PPh_2)_2]$ (eq 2).

Complexes of the type $[CpFe(CO)(PPh_3)(CH_2SCH_2Ph)]$ were also synthesized (eq 3).[12] Conformational analyses of

iron complexes of the type $[CpFe(CO)(PPh_3)(CH_2XCH_2R)]$ (R = O, S) were conducted in order to investigate the dependence of conformation on solvent polarity.

Synthesis of 1-*n*-Octyl-2-phenyl-3-(*n*-benzylthiomethyl)imidazolium Chloride.

Imidazolium compounds with alkoxymethyl or alkylthiomethyl groups are potent antimicrobial agents.[13] They can be easily prepared (eq 4).[14]

Preparation of the Sulfoxime Group.

The sulfoxime group (**1**) has a potential for incorporation into enzyme inhibitors. It can mimic the tetrahedral intermediate (**2**) in carboxamide addition reactions, notably with a metalloprotease.[15]

(1)

(2)

In the present case, chloromethyl phenylethyl sulfide serves as precursor for securing the desired β-sulfonimidoylpropionic acid.[16] Like benzyl chloromethyl sulfide, it can be prepared according to the procedure described by Böhme.[2b]

Preparation of Benzylsulfonylmethyl Styryl Sulfones.

Novel unsaturated sulfones have been obtained by the condensation of aryl- and benzylsulfonylmethylacetic acids and aryl aldehydes in the presence of catalytic amounts of benzylamine in glacial acetic acid (Knoevenagel condensation).[17] The products obtained are stable (*E*)-alkenes (eq 5), which are known intermediates in the synthesis of a number of carbocyclic[1b,18] and heterocyclic compounds.[19]

3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium Chloride[1]

[4568-71-2] · $C_{13}H_{16}ClNOS$ · 3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium Chloride · (MW 269.79)

(in the presence of bases, catalyst for the preparation of acyloins and benzoins[2] from aldehydes, and for addition of aldehydes to electrophilic double bonds[3])

Physical Data: mp 141-143 °C.

Solubility: sol H_2O, MeOH, EtOH; slightly sol cold MeCN; insol ether, pentane.

Form Supplied in: colorless crystals, widely available.

Analysis of Reagent Purity: ^{1}H NMR; mp.

Preparative Method: Organic Syntheses procedure.[2]

Handling, Storage, and Precautions: store dry.

Formation of Benzoins and Acyloins from Aldehydes.

Many thiazolium salts catalyze the formation of benzoins from aromatic aldehydes and of acyloins from aliphatic aldehydes in the presence of a base as shown in the preparation of furoin from furan-2-carbaldehyde (eq 1).[2]

(1)

This catalytic reaction has long been known,[4] the most prominent salt being thiamine (vitamin B_1). Other azolium salts[5] and nucleophilic carbenes, or dimers thereof, also catalyze this reaction.[6] Chiral thiazolium salts have been used.[7] The reaction can be performed as a phase-transfer reaction at preparative scale in water.[8] The title reagent (**1**) has been used in the preparative large-scale formation of acyloins and benzoins in the presence of ***Triethylamine*** in ethanol under anhydrous conditions (eq 2).

(2)

Simple aliphatic acyloins,[9] mixed aliphatic acyloins,[10] and acyloins containing other functional groups[11] have been prepared.

Formose Reaction.

A very special case of acyloin formation is observed when formaldehyde is used in that the construction of simple sugars occurs. Only some of the numerous possible products are found in the formose mixture.[12] A similar result has been reported with ethylbenzothiazolium bromide as catalyst.[13]

Addition of Aldehydes to Activated Double Bonds.

This reaction has been reviewed.[3] (**1**) in the presence of bases (e.g. Et_3N or NaOAc) catalyzes the addition of aliphatic and heterocyclic aldehydes to α,β-unsaturated ketones (to yield γ-diketones), esters (to yield γ-ketoesters), and nitriles (to yield γ-ketonitriles), for example (eq 3).[14] This further illustrates the umpolung effect of this reagent on the aldehyde carbonyl reactivity.

(3)

This reaction is used in the synthesis of tri- and polyketones,[15] cyano ketones,[16] 1,4-diketones,[17] and oxocarboxylic esters.[16b,18] Mannich bases (β-dialkylamino ketones) or their quaternary salts can replace the unsaturated ketones.[3] α-Keto carboxylic acids can replace the aldehydes, because these readily decarboxylate under the reaction conditions (eq 4).[19]

(4)

Addition of Aldehydes in Presence of Other Reagents.

The presence of ***Pentacarbonyliron*** changes the reaction pathway to afford different products (eq 5).

(5)

Michael addition of ethyl acrylate to acetoin and transesterification yields the product shown (35%) together with ethyl levulinate (10%).[20] For details on additions of aldehydes in presence of oxidants see ***3-Benzyl-4-methyl-1,3-thiazolium Chloride***.

Related Reagents.

Table 1 shows some widely used 1,3-thiazolium salts analogs of (**1**) that are especially well suited with aromatic aldehydes for the above benzoin preparations and for aldehyde additions to double bonds.[3]

(2)

Table 1 Properties of Some Salts

R	X	CAS No.	MW	Mp (°C)	Empirical formula
Et[a,b]	Br	[54016-70-5]	252.17	84 86	$C_8H_{14}BrNOS$
Me[a,b,c]	I	[16311-69-6]	285.14	85 87	$C_7H_{12}INOS$

[a] Hygroscopic. [b] Widely available. [c] Light sensitive.

Other Reagents.

Sodium Cyanide or ***Potassium Cyanide*** are the classical catalysts for benzoin formation from aromatic aldehydes[21] and they can also be used for the addition of aromatic aldehydes to activated double-bonds.[3] Carboxylic esters and metals such as sodium are used in the classic acyloin condensation[22] and its modern variations.[23] Numerous other acyl anion equivalents have been described.[24]

O-Benzylhydroxylamine Hydrochloride[1]

(base)

[622-33-3] · C_7H_9NO · *O*-Benzylhydroxylamine · (MW 123.15) (.HCl)

[2687-43-6] · $C_7H_{10}ClNO$ · *O*-Benzylhydroxylamine Hydrochloride · (MW 159.62)

(reagent for the preparation of *N*-hydroxyamides[2] (including *N*-hydroxy peptides[3] and *N*-hydroxy β-lactams[4]) and hydroxamic acids;[5] derivatizing agent for ketones,[6-8] aldehydes,[6] and carbohydrates[9])

Alternate Names: O-phenylmethylhydroxylamine hydrochloride; benzyloxyamine hydrochloride; benzyloxyammonium chloride.

Physical Data: white flakes, mp 234-238 °C (subl); hygroscopic.

Solubility: sol H_2O, pyridine; slightly sol alcohol; insol ether.

Analysis of Reagent Purity: ^{1}H NMR (DMSO-d_6 + $CDCl_3$) δ 5.17 (s, 2H, CH_2), 7.42 (s, 5H, C_6H_5), 11 (br, ex NH_2).

Preparative Methods: the free base *O*-benzylhydroxylamine, a liquid of bp 115-119 °C/30 mmHg, is easily prepared from the commercially available hydrochloride salt.[10] For many reactions, however, it is preferable to generate the free base in situ from the salt.

Handling, Storage, and Precautions: store in a cool dry place to preclude contact with moisture and oxygen; may be harmful by inhalation, ingestion, or skin absorption; avoid contact with the eyes.

N-Hydroxyamides and Hydroxamic Acids.

The ease with which an *O*-benzyl moiety can be converted, often through catalytic hydrogenation, to the analogous alcohol allows this reagent to be used as an O-protected equivalent of hydroxylamine. For example, it is especially suited for the preparation of *N*-hydroxyamides (eq 1)[2] (including *N*-hydroxy peptides[3] and *N*-hydroxy β-lactams),[1,4,11] hydroxamic acids (eq 2),[5] and *N*-hydroxyimides (eq 3).[12]

Other functional groups prepared by similar methodology include *N*-alkyl hydroxyureas, *N*-alkyl-*N*-hydroxycarbamates and *N*-alkylhydroxylamines.[13]

O-Benzyloximes.[1]

The reagent is used extensively as a derivatizing agent for preparation of *O*-benzyloximes of ketones,[6-8] aldehydes,[6] and carbohydrates (eq 4).[9] Usually both *syn* (*Z*) and *anti* (*E*) isomers are formed.

(4)

Reaction with *O*-alkyl thiocarboxylates affords alkyl *N*-benzyloxycarboximidates,[14] while enol esters may be converted in the presence of saturated ester functions to their respective ketoximes (eq 5).[15]

N-Benzylhydroxylamine[1]

(base)

[622-30-0] · C_7H_9NO · *N*-Benzylhydroxylamine · (MW 123.15) (.HCl)

[29601-98-7] · $C_7H_{10}ClNO$ · *N*-Benzylhydroxylamine Hydrochloride · (MW 159.62)

(condenses with a wide variety of aldehydes to afford *N*-benzylnitrones;[2] hydroxylamination reagent for allyl esters under palladium(0) catalysis[3])

Physical Data: mp 57 °C; hydrochloride salt, mp 108-110 °C.

Form Supplied in: available commercially as the hydrochloride salt.

Preparative Methods: oxime reduction;[4-7] hydroxylamine alkylation;[8] isoxazole alkylation.[9]

Purification: sublimation.

Handling, Storage, and Precautions: hygroscopic. Use in a fume hood.

For a discussion of this reagent, see ***N-Cyclohexylhydroxylamine***.

(η^4-Benzylideneacetone)tricarbonyliron[1]

[38333-35-6] · $C_{13}H_{10}FeO_4$ · (η^4-Benzylideneacetone)tricarbonyliron · (MW 286.07)

(reagent for the complexation of 1,3-butadienes[5] and 1,3-cyclohexadienes[8] under mild reaction conditions)

Physical Data: mp 88-89 °C.

Solubility: sol hexane, benzene, toluene, diethyl ether, THF, 1,2-dimethoxyethane, chloroform, ethyl acetate.

Form Supplied in: red crystals.

Analysis of Reagent Purity: IR, NMR.

Preparative Methods: conveniently prepared by either thermal[2-4] or photochemical and thermal[1,5,8a] reaction of nonacarbonyldiiron with benzylideneacetone. The best procedure is heating a solution of benzylideneacetone in diethyl ether with an excess of nonacarbonyldiiron at reflux, which provides the (η^4-benzylideneacetone)tricarbonyliron complex $Fe(bda)(CO)_3$ in 81% yield (eq 1).[6,7]

Purification: chromatography on silica gel (ethyl acetate/petroleum ether, 1:9); recrystallization from hexane.

Handling, Storage, and Precautions: should be handled and stored under an inert gas atmosphere of argon or nitrogen. Use in a fume hood.

The $Fe(bda)(CO)_3$ complex serves as a mild source of the tricarbonyliron fragment. The reaction of $Fe(bda)(CO)_3$ and 1,3-dienes occurs at ca. 60 °C with smooth transfer of the tricarbonyliron moiety onto the diene ligand and affords the corresponding tricarbonyl(η^4-1,3-diene)iron complexes in high yields (eq 2).[5]

(2)

The standard procedure for the synthesis of tricarbonyl(η^4-diene)iron complexes involves thermal or photochemical reaction of the diene with ***Pentacarbonyliron***, ***Nonacarbonyldiiron***, or ***Dodecacarbonyltriiron***. Thus tricarbonyliron transfer reagents offer a useful synthetic alternative for the preparation of the tricarbonyliron complexes of dienes which are sensitive towards heat or UV irradiation. For example, tricarbonyl(η^4-8,8-diphenylheptafulvene)iron cannot be prepared by direct reaction of the free ligand with one of the carbonyliron compounds, but is obtained in high yield on transfer complexation with $Fe(bda)(CO)_3$ (eq 3).[2]

(3)

The tricarbonyliron unit can also be used for the protection of labile diene systems in order to achieve selective transformations at other double bonds present in the molecule. Protection of the steroid B-ring diene system of ergosterol derivatives by the tricarbonyliron fragment provides the corresponding diene complex, which has been used for selective reactions at the 22,23-double bond (eq 4).[8]

A broad range of labile diene systems can be complexed using the $Fe(bda)(CO)_3$ reagent and therefore stabilized by the tricarbonyliron fragment.[1,9] These transfer reactions of metal fragments to diene ligands involving the benzylideneacetone ligand have been extended to the $[Fe(CO)_2PPh_3]$ and the $[Fe(CO)_2P(OPh)_3]$ moieties. Using this method the corresponding cycloheptadiene complexes are conveniently prepared in high yields (eq 5).[4,10]

The mechanism of the tricarbonyliron transfer reaction using $Fe(bda)(CO)_3$ has been the subject of extensive investigations.[1,5,10b,11] Low asymmetric inductions (<40% ee) in the complexation of prochiral dienes using optically active $Fe(1\text{-oxadiene})(CO)_3$ complexes have been obtained.[12] Nucleophilic additions to $Fe(bda)(CO)_3$ have also been studied.[6,7,13]

Other Tricarbonyliron Transfer Reagent.

Tricarbonylbis(η^2-*cis*-cyclooctene)iron.

The photolytic reaction of pentacarbonyliron with an excess of *cis*-cyclooctene in hexane solution at -40 °C provides tricarbonylbis(η^2-*cis*-cyclooctene)iron (Grevel's reagent) in 56% yield (eq 6).[14]

(6)

The solid compound can be handled at room temperature, but in solution the complex is labile at temperatures above -35 °C. The advantage of Grevel's reagent compared to $Fe(bda)(CO)_3$ is that the tricarbonyliron transfer reaction occurs under extremely mild conditions at temperatures below 0 °C. Moreover, in contrast to $Fe(bda)(CO)_3$,[5] 1,4-dienes can be complexed using Grevel's reagent with concomitant double bond migration to the conjugated diene system (eq 7).[14a] Useful applications of Grevel's reagent to organic synthesis have been described.[15]

(7)

(η^4-1-Aza-1,3-butadiene)tricarbonyliron Complexes.

More recently, (η^4-1-aza-1,3-butadiene)tricarbonyliron complexes have been shown to represent very useful tricarbonyliron transfer reagents.[16] The tricarbonyliron complexes of the 1-aza-1,3-butadienes can be conveniently prepared by thermal reaction with nonacarbonyldiiron.[17,18] However, the yields of such complexes have been considerably increased by an ultrasound-promoted complexation of the 1-aza-1,3-butadienes at room temperature (e.g. 88% for the cinnamaldehyde/*p*-anisidine imine (eq 8).[16]

(eta-4-Benzylideneacetone)tricarbonyliron

(8)

In contrast to the former reagents, the 1-azadiene complex is stable in the air for months. A smooth transfer of the tricarbonyliron fragment from the 1-azadiene complex to 1,3-dienes is effected in THF at reflux temperature and provides, for example, tricarbonyl(η^4-1,3-cyclohexadiene)iron in 95% yield (eq 9).[16] After the transfer the free 1-azadiene is recovered in more than 95% yield by crystallization.

(9)

The major advantage of the 1-azadiene in comparison with the two former reagents is that the corresponding free ligand can be employed in catalytic amounts. Thus the 1-aza-1,3-butadiene is a useful catalyst for the complexation of 1,3-dienes by nonacarbonyldiiron or pentacarbonyliron. The yield for the 1-azadiene-catalyzed complexation of 1,3-cyclohexadiene is quantitative based on the iron carbonyl source (eq 10).[16]

(10)

Immobilization of the 1-azadiene on a polystyrene resin provides a heterogeneous catalyst which is more easily separated from the reaction mixture and which can be resubmitted to the catalytic complexation.[16] The mechanism of the 1-azadiene-catalyzed complexation has been investigated and it was found that condensation of cinnamaldehyde with *o*-anisidines provides even more efficient catalysts.[19]

Benzylidenetriphenylphosphorane[1]

$Ph_3P=CHPh$

[16721-45-2] · $C_{25}H_{21}P$ · Benzylidenetriphenylphosphorane · (MW 352.41)

(Wittig reagent for the conversion of aldehydes into alkenes[1])

Form Supplied in: usually, Wittig reagents are prepared in situ from the appropriate phosphonium salt. As such, benzyltriphenylphosphonium chloride is available as a white powder or as a mixture with sodium amide, $NaNH_2$.

Preparative Methods: benzylidenetriphenylphosphorane is prepared from benzyltriphenylphosphonium chloride by deprotonation with base.[1,2] Formation of the ylide from this salt has been accomplished with many different base and solvent combinations. In more recent preparations the salt typically is suspended in dry THF under an inert atmosphere and a solution of the base, either BuLi or KHMDS, is added by syringe.[3a,b] Alternatively, the salt and $NaNH_2$ are transferred to a flask in a dry box and then benzene is added.[4a] The ylide can also be generated with alkoxide bases in protic solvents[5] (such as NaOEt/EtOH) or under phase transfer conditions (CH_2Cl_2/H_2O with NaOH).[6]

Purification: benzyltriphenylphosphonium chloride can be recrystallized from absolute ethanol or $CHCl_3$/petroleum ether.

Handling, Storage, and Precautions: benzyltriphenylphosphonium chloride is a slightly hygroscopic solid. It can be dried efficiently under vacuum at elevated temperature (<10 Torr and 40 °C) overnight. Benzylidenetriphenylphosphorane is destroyed rapidly by exposure to oxygen or to moisture, and for this reason is usually prepared immediately before use. When protected from these materials, however, solutions of the ylide are stable for extended periods of time.[7]

Wittig Reagent for the Conversion of Aldehydes into Alkenes.

The reaction between benzylidenetriphenylphosphorane and an aldehyde to form an alkene and triphenylphosphine oxide is experimentally easy to carry out and proceeds under mild conditions at room temperature.[1a] A valuable feature of the Wittig procedure is that, in contrast to many elimination and pyrolytic reactions, it gives rise to alkenes in which the position of the double bond is established unambiguously.[1b] The aldehyde component may contain a wide variety of other functional groups such as hydroxyl, ether, ester, halogen, and terminal alkyne which generally do not interfere with the reaction.[1a,b] The utility of the Wittig reaction is shown by the fact that it has already been used in the synthesis of many alkenes, including a considerable number of natural products.[1b,c,d] Often, excellent selectivity for either the (*Z*)- (with a nonstabilized ylide) or (*E*)-alkene (with a stabilized ylide) can be obtained. In the case of benzylidenetriphenylphosphorane

(a moderated ylide), (*Z*):(*E*) selectivity is often poor,[1b] and apparently quite sensitive to experimental conditions (see Table 1).

Table 1 $Ph_3P{=}CHPh + PhCHO$ ® $PhCH{=}CHPh$

Entry	Base	Solvent	*Z*:*E*
1	PhLi	Et_2O	30:70[8]
2	BuLi	THF	60:40[5]
3	BuLi	C_6H_6	34:66[9]
4	$NaNH_2$	C_6H_6	44:56[4]
5	NaHMDS	C_6H_6	48:52[13]
6	NaOEt	EtOH	66:34[10]
7	NaOEt	EtOH	53:47[11]
8	NaOEt	DMF	74:26[11]
9	KO-*t*-Bu	*t*-BuOH	25:75[12]
10	NaOH	CH_2Cl_2/H_2O	59:41[6]

This ylide is historically important because its reactions with aromatic aldehydes were explored extensively during the first attempts to understand the mechanism of the Wittig reaction.[1a,c] Regrettably, the key reaction $Ph_3P{=}CHPh + PhCHO$ has proved to be the most difficult to control among all of the known Wittig systems. An inspection of Table 1 reveals inconsistencies in a number of the *Z*:*E* ratios for this reaction when the work of different groups is compared.[4-6,8-12] For example, the reported (*Z*) selectivity among the lithium-free entries varies from 25%[12] (entry 9) to 74%[11] (entry 8). Dramatic variations such as these were sometimes cited to support claims of reversal, cation effects, anion effects, electronic effects, or solvent effects in the mechanism of the Wittig reaction.[14] More recent studies are beginning to clarify these mechanistic questions and to explain the origin of selectivity in the Wittig reaction.[15]

Examples of Wittig reactions of benzylidenetriphenylphosphorane with aliphatic aldehydes are uncommon in the literature, and, as with aromatic aldehydes, the (*Z*):(*E*) selectivity is poor. However, if the structure of the substituents at phosphorus in the ylide are varied, then dramatic changes in the selectivity of the reaction are observed. A number of examples of this effect have been published. Two of the most striking examples are shown in eqs 1 and 2.[16]

Benzyl Iodide

[620-05-3] · C_7H_7I · Benzyl Iodide · (MW 218.04)

(benzylating agent for heteroatomic functional groups and enolate anions; precursor to benzylic radicals)

Physical Data: bp 93 °C/10 mmHg; mp 24.5 °C; *d* 1.733 at 25 °C.

Solubility: sol alcohols, ether, and aromatic solvents.

Form Supplied in: 98% pure liquid.

Handling, Storage, and Precautions: potent lachrymator; should be handled in a fume hood.

Benzylation of Heteroatomic Functional Groups.

Benzyl iodide will react with alcohols under basic conditions to afford benzyl ethers and displays higher reactivity than other benzylating agents (see ***Benzyl Chloride***, ***Benzyl Bromide***, ***Benzyl p-Toluenesulfonate***). The reagent is frequently generated in situ, for example from benzyl bromide and tetrabutylammonium iodide in THF, and is useful for benzylation of sterically hindered alcohols.[1] Benzylation under less basic conditions is achieved with CsF and Bu_2SnO in DMF (eq 1).[2] The reagent can also be used to benzylate a phenolic hydroxyl group in the presence of silver oxide.[3] A benzyl penicillanate ester was prepared from the acid and benzyl iodide in the presence of triethylamine in acetone.[4] Benzylation of a thiopyrone in acetone to give the *S*-benzylated thiopyrylium salt has been reported.[5]

Benzylation of Active Methylene Compounds.

Benzyl iodide is reactive toward various enolate anions and has found use in the asymmetric benzylation of such

anions. For example, the enolate derived from a chiral 1,3-oxathiolan-5-one was benzylated to afford, after hydrolysis, a benzylated thioglycolic acid derivative (eq 2).[6]

Chiral acylsultam enolates have been allylated with benzyl iodide with high diastereoselectivity in a route to protected amino acids.[7] An amide derived from ephedrine similarly affords benzylated acids and esters, and the corresponding methyl ketones are also available via this method.[8] Stereoselectivity in these reactions has been attributed to chelation of the metal by the chiral auxiliary. An enantioselective synthesis of L-[3-^{11}C]phenylalanine was achieved through a chiral glycine derivative, where an 8-phenylmenthol ester served as the chiral auxiliary under phase transfer catalysis conditions (eq 3).[9] Asymmetric benzylation of an aldehyde has also been reported using a chiral metalloenamine.[10]

Sulfone stabilized carbanions also react with benzyl iodide.[11] This methodology has been applied to the preparation of polyenes. Likewise, formamidine stabilized carbanions allow access to α-benzylated amines with this reagent.[12]

Radical Reactions.

The benzyl radical has been generated from benzyl iodide and shown to undergo addition to unsaturated mono-[13] and dinitriles.[14] The resultant nitrile-stabilized radical may be further alkylated in the presence of ***Allyltributylstannane*** (eq 4). Oxidative coupling of benzyl iodide with excess ***Allyl Iodide*** in the presence of ***Triethylborane*** and oxygen has also been reported.[15]

Reactions with Organometallics.

Dibenzyl ketone has been prepared in 95% yield by treatment of benzyl iodide with ***Tetracarbonylnickel*** in DMF.[16]

Benzyl Isopropenyl Ether

[32783-20-3] · $C_{10}H_{12}O$ · Benzyl Isopropenyl Ether · (MW 148.20)

(protecting group for compounds with multiple hydroxy groups;[1] acetone enolate equivalent[2])

Physical Data: bp 191-192 °C.[3]

Solubility: sol acetone, benzene.

Preparative Methods: the first reported synthesis of the reagent was accomplished by the pyrolytic decarboxylation of β-benzyloxycrotonic acid.[3] An alternate method for the preparation proceeds via dehydrohalogenation of 2-benzyloxy-1-chloropropane with potassium *t*-butoxide in DMSO (82% yield).[1]

Alcohol Protection.

Benzyl isopropenyl ether (**1**) has been shown to react with free hydroxy groups at rt in benzene in the presence of 10 mol % ***Dichloro(1,5-cyclooctadiene)palladium(II)*** to produce the corresponding mixed benzyl acetals in 85-98% isolated yield (eq 1).[1] The protecting group can also be introduced in comparable yields with catalytic ***Phosphorus Oxychloride*** or ***p-Toluenesulfonic Acid***. Cleavage of the mixed acetal took place at rt in the presence of catalytic 5% ***Palladium on Carbon*** under 1 atm of hydrogen in 92-99% yield. The protecting group was stable to hydride reducing agents (LAH, DIBAL), alkyllithium, and Grignard reagents, and was stable to alkaline hydrolysis conditions (1 M NaOH/THF, 1/1). Exposure to 1 M ***Acetic Acid*** in THF (1/1) effects cleavage of the protecting group.

The primary advantage of this alcohol-protecting group over many similar reagents[4] is the neutral conditions used for its introduction and removal. An alternative method for protecting alcohols as mixed acetals makes use of catalytic ***Cobalt(II) Chloride*** in MeCN at rt.[5] The reported range of yields for this method was slightly lower (68-91%); however, the ready availability and low cost of the cobalt catalyst recommends its use.

A closely related reagent for alcohol protection is 2-phenoxypropene, which was easily prepared from phenyl acetate and Tebbe's reagent in 57% yield.[6] Conversion of alcohols to the corresponding phenyl mixed acetals took place with catalytic phosphorus trichloride. Hydrolytic cleavage with 0.1 M HCl and ether was complete in 30 s.

Acetone Enolate Equivalent.

An early application in which (**1**) was used as an acetone enolate equivalent in a Lewis acid-catalyzed condensation with ketones has been reported.[2] For example (eq 2), condensation of (**1**) with acetone in the presence of ***Boron Trifluoride Etherate*** produced 4-benzyloxy-4-methyl-2-pentanone in 52% yield. This early methodology has largely been eclipsed by advances involving the use of silyl enol ethers.

Benzyllithium[1]

[766-04-1] · C_7H_7Li · Benzyllithium · (MW 98.07)

(benzylating agent in substitutions and additions at carbon; used to attach benzyl groups to other metals and nonmetals)

Physical Data: by X-ray, the DABCO complex forms contact ion pairs with Li over planar benzyl anions[2] and the THF-TMEDA complex has pyramidal benzylic carbon atoms.[3] UV[4] and ^{1}H,[5] ^{13}C,[6] and ^{7}Li[7] NMR studies have been reported.

Solubility: sol ethers; DABCO complex crystallizes from hexane as it forms.[8]

Form Supplied in: prepared in situ and used directly.

Preparative Methods: preparation from benzyl ethyl ether and ***Lithium*** in THF/ether is recommended on a large scale; toluene metalation for pure samples.[8] Metalation of toluene with ***n-Butyllithium***/TMEDA gives 90-91% yield, but contaminated with 5-6% *m*-tolyllithium and 2% each of *o*- and *p*-tolyllithium;[9] metalation of toluene with butyllithium/***Potassium t-Butoxide***, then reaction of the red solid benzylpotassium with LiBr in ether, gives purer product.[10] Preparations from organotin compounds by exchange may be contaminated with organotin compounds.[10] A method involving treatment of benzyl selenides with BuLi at -78 °C should be especially useful for benzyllithiums containing halogens or methoxyls.[11]

Handling, Storage, and Precautions: must be prepared and transferred under an inert gas to exclude oxygen and moisture.

Nucleophilic Substitutions at Carbon.

Resonance-stabilized Li reagents such as benzyllithium are stronger nucleophiles but weaker bases than alkyllithium reagents, permitting displacement of Br^- and I^- from cyclohexyl and cyclopentyl systems in Wurtz-type couplings (eq 1).[12] Optically active secondary halides react with clean inversion.[13]

(1)

Nucleophilic Substitutions at Other Nonmetals.

Cinchonine (an optically active alcohol) can be displaced from phosphinites by benzyllithiums to give optically active phosphines with inversion of configuration (eq 2).[14] The stereoselectivity was much greater with sterically hindered benzyl derivatives.

(2)

Vinyl azide acts as a NH_2^+ equivalent in reaction with benzyllithium (eq 3), providing a method for the amination of such compounds.[15]

(3)

Additions to Double Bonds.

Besides the usual additions to aldehydes and ketones, benzyllithium adds to ketenes as shown in eq 4 to give regiospecific enolates which can be used in aldol condensations.[16] It also adds to a double bond of cyclooctatetraene and then acts as a base, leading to benzylcyclooctatetraene dianion (eq 5).[17]

(4)

(5)

The direction of addition of benzyllithium to vinyl groups depends on the substituents. It adds to the more-substituted carbon of the double bond of allyl alcohol (eq 6),[18] but (in the presence of Cu^{I}) to the less-substituted carbon of the double bond in the epoxyalkene in eq 7.[19]

(6)

(7)

Metal Exchange.

Benzyllithium used in the presence of copper salts may react as lithium dibenzylcuprate.[19] Benzyllithium has been used to make benzylzinc[20] and rare earth benzyl derivatives.[21]

Related Reagents.

Table 1 lists some useful benzyllithium derivatives.[22-30] See also ***Benzylmagnesium Chloride***.

Benzylmagnesium Chloride

(X = Cl)

[6921-34-2] · C_7H_7ClMg · Benzylmagnesium Chloride · (MW 150.89) (X = Br)

[1589-82-8] · C_7H_7BrMg · Benzylmagnesium Bromide · (MW 195.34)

(adds to many unsaturated functional groups; benzyl can displace halide and like groups; can function as a strong base and a Lewis acid[1b-f])

Physical Data: usually prepared or purchased as a solution and used without isolation. Addition of HMPA to an Et_2O solution of BnMgCl causes significant changes in the UV spectrum that indicate ionization to benzyl anions.[2]

Solubility: BnMgCl and BnMgBr are soluble in Et_2O and THF, and insoluble in hydrocarbons.

Form Supplied in: solutions of BnMgCl in Et_2O and THF are commercially available.

Analysis of Reagent Purity: see ***Methylmagnesium Bromide***.

Preparative Methods: [1c,e,3] in spite of the commercial availability of BnMgCl solutions, BnMgCl[4] and BnMgBr are often prepared from reaction of a benzyl halide and Mg, usually in Et_2O or THF.

Handling, Storage, and Precautions: see ***Methylmagnesium Bromide***. Benzyl Grignard reagents do not significantly attack Et_2O or THF at normal reaction temperatures

Preparation.

Yields of routine BnMgCl and BnMgBr preparations often exceed 90%, but those of BnMgI preparations are lower due to competing formation of bibenzyl and other dimers. Yields of Grignard reagents from benzyl chlorides and bromides having α-substituents and certain aryl substituents also are lower. In such cases, yields often are significantly improved by using activated Mg that permits preparation at lower temperatures. A simple activation procedure involves stirring the Mg under nitrogen,[5] but other convenient procedures[6] are available (also see ***Phenylmagnesium Bromide***).

Representative Applications.[1b-f]

A benzyl Grignard reagent is used most frequently in reactions that result in attachment of its organic group to an electrophilic carbon atom of the substrate, most often of a carbonyl group, nitrile, or other unsaturated function. Some reactions[7] of benzyl Grignard reagents, with unhindered carbonyl compounds,[8,9] (eq 1) for example,[8] furnish *ortho*-substituted products. Further reaction of the triene (e.g. **2**) that probably forms initially can provide a product of double addition (**1**), sometimes significant even when excess Grignard reagent is used. *Ortho*- and sometimes small amounts of *para*-substituted products also are found in displacement reactions of benzyl Grignard reagents with reactive alkyl halides.[10] See also ***Benzyllithium*** and ***Methylmagnesium Bromide***.

Benzyl(methoxymethyl)methylamine

(*S*)

[64715-80-6] · $C_{10}H_{15}NO$ · Benzyl(methoxymethyl)methylamine · (MW 165.23) (*R*)

[59919-07-2]

(chiral auxiliary for the enantioselective alkylation of ketones[1] and aldehydes;[2] can form chiral cuprate reagents[3])

Physical Data: (*S*) bp 55-59 °C/0.1 mmHg; mp HCl salt 151-152 °C; $[\alpha]_D^{25}$ -14.4° (*c* 5.7, benzene); HCl salt $[\alpha]_D^{25}$ +19.7° (*c* 2.5, EtOH).

Preparative Method: these chiral methoxy amines are readily prepared from (*S*)- or (*R*)-phenylalanine via reduction followed by methylation.[2]

Handling, Storage, and Precautions: conversion of the freshly distilled amine to its hydrochloride salt is a convenient way to store and handle the compound. The free amine reacts with atmospheric carbon dioxide to produce the respective carbonate. The free amine should be stored tightly sealed under argon or nitrogen immediately after distillation to avoid CO_2 adsorption.

Enantioselective Alkylation.

Both antipodes of this chiral amine have been used in the enantioselective alkylation of ketones and aldehydes via their respective chiral, nonracemic lithioenamines (eq 1). The enantioselectivity in alkylation results from the induced rigidity of the lithioenamine upon chelation with the methoxy group, providing the bias necessary to influence the direction and rate of entry of the electrophile.

Medium-sized cyclic ketones have been enantioselectively alkylated via their chiral lithioenamines to yield 2-alkylcycloalkanones in 80-100% ee.[4] This procedure has also furnished α,α´-dialkyl cyclohexanones in good enantiomeric excess (eq 2).[4] Based on this protocol, regiospecific deuteration of 3-methylcyclohexanones has been achieved with good enantioselectivity.[5]

In contrast with medium-sized cyclic ketones, alkylation of macrocyclic ketones can afford either optical antipode depending on whether the lithioenamine is formed via kinetic (*E*-) or thermodynamic conditions (*Z*-enamine) (eq 3).[6] Optically active α-alkyl macrocyclic ketones have been formed in 30-82% enantiomeric excess, with chemical yields of 62-90%.

In a similar manner, aldehydes can also be enantioselectively alkylated by this procedure. However, the enantiomeric excess obtained is much lower (47%).[2] A special application of this method is the enantioselective alkylation of aldehydes for the construction of quaternary stereogenic centers. An example is the formation of the chiral quaternary carbon in 4-methyl-4-phenylcyclohex-2-en-1-one in high enantiomeric excess using this methodology (eq 4).[7]

Chiral Cuprate Reagents.

This chiral amine has also found application in asymmetric conjugate addition of copper azaenolates to cyclic enones. Lithium azaenolates of optically active acetone imines have been used in the preparation of chiral cuprate reagents.

However, the asymmetric induction is low (17-28% ee) when this amine is employed (eq 5).[3]

Enantioselective alkylation of aldehydes and ketones can also be accomplished using Enders' reagents SAMP and RAMP.[8] In contrast with Meyer's chiral auxiliary, the synthesis of Enders' reagents is lengthy and the recovery is inconvenient because cleavage of the auxiliary does not afford back the reagent. It also generates nitrosoamines (via ozonolysis) which are considered carcinogenic compounds. Therefore, the ease of preparation, availability of the starting material, and efficient cleavage and recovery of this chiral amine make it a convenient chiral auxiliary.

Eduardo A. Véliz & Joseph P. Konopelski

N-Benzyl-*N*-(methoxymethyl)-*N*-trimethylsilylmethylamine[1]

[93102-05-7] · $C_{13}H_{23}NOSi$ · *N*-Benzyl-*N*-(methoxymethyl)-*N*-trimethylsilylmethylamine · (MW 237.42)

(nonstabilized azomethine ylide precursor;[1] reacts with alkenes to give pyrrolidines;[2] alkynes give 3-pyrrolines;[2] carbonyl and thiocarbonyl groups afford 1,3-oxazolidines and 1,3-thiazolidines, respectively[3])

Physical Data: bp 77-80 °C/0.5 mmHg.

Preparative Methods: most conveniently prepared by treatment of benzylamine with chloromethyltrimethylsilane followed by formaldehyde and methanol.[4] Access to higher ether homologs is achieved by replacing methanol with the appropriate alcohol.[5] An alternate procedure involves alkylation of lithium *N*-benzyltrimethylsilymethylamide with methoxymethyl chloride.[2]

Purification: distillation under reduced pressure, although good yields can be obtained with undistilled reagent.

Handling, Storage, and Precautions: the reagent should be handled in a well ventilated fume hood.

1,3-Dipolar Cycloadditions.

N-Benzyl-*N*-(methoxymethyl)-*N*-trimethylsilylmethylamine (**1**) is a valuable reagent for in situ generation of the *N*-benzyl azomethine ylide (**2**). It is generally preferred over alternative silylmethylamine precursors[6-8] because of ease of handling and use. The ylide (**2**) is most conveniently generated from (**1**) using a catalytic amount of ***Trifluoroacetic Acid*** as described by Achiwa.[2] Alternative catalysts include LiF,[3,4] TBAF,[7] Me_3SiOTf-CsF,[5] or Me_3SiI-CsF.[5] Mechanistic studies provide evidence that the reactive intermediate generated from (**1**) with either CF_3CO_2H or F^- is a 1,3-dipolar species.[7,8] Reaction of (**2**) with alkenes provides an efficient convergent route to

pyrrolidine derivatives. Alkynes afford 3-pyrrolines[2] which can be converted into pyrroles.[6a] The ylide (**2**) reacts most readily with electron deficient alkenes and alkynes since this pairing results in a narrow dipole HOMO-dipolarophile LUMO energy gap.[9] Examples of suitable dipolarophiles include unsaturated esters,[2-5] ketones,[2] imides,[2,4] nitriles,[4] and sulfones.[3,4] Cycloaddition occurs with complete *cis* stereospecificity[2-4] (eq 1) which is consistent with a concerted mechanism. Dipolarophiles containing an endocyclic double bond afford fused bicyclic pyrrolidines,[10] whereas substrates with an exocyclic double bond provide access to spirocyclic systems.[11]

Styrenes bearing electron withdrawing aromatic substituents such as CN and NO_2 give high yields of 3-arylpyrrolidines (eq 2).[12] When electron withdrawing groups are absent yields tend to be poor. Vinylpyridines afford 3-pyridylpyrrolidines.[12] The reactivity of alkenes can be enhanced by the introduction of a CF_3 substituent. For example, α-trifluoromethylstyrene gives a high yield of cycloadduct whereas α-methylstyrene is unreactive.[13]

Cycloaddition reactions with aldehydes and ketones afford 1,3-oxazolidines while thioketones give 1,3-thiazolidines (eq 3).[3] Adducts derived from reaction at both the carbonyl and alkenic double bond have been observed with an α,β-unsaturated aldehyde.[3]

Diastereoselective 1,3-Dipolar Cycloadditions.

Several examples of high diastereofacial selectivity with homochiral dipolarophiles have been reported. Cycloaddition of (**1**) with the cyclic dipolarophile (**3**) occurs with complete π-facial selectivity as a result of addition from the side opposite the bulky silyloxymethyl group (eq 4).[14] The key step in an asymmetric synthesis of (*S*)-(-)-cucurbitine involves cycloaddition of (**1**) with the α,β-dehydrolactone (**4**) to give the pyrrolidine (**5**) as a single diastereomer (eq 5).[15]

Double asymmetric induction employing a chiral *N*-α-methylbenzyl analog of (**1**) has been described.[16]

3-Benzyl-4-methyl-1,3-thiazolium Chloride[1]

[4209-18-1] · $C_{11}H_{12}ClNS$ · 3-Benzyl-4-methyl-1,3-thiazolium Chloride · (MW 225.74)

(benzoin condensation catalyst; in the presence of bases, catalyzes the preparation of cyclic acyloins from dialdehydes, and of aromatic esters from aromatic aldehydes)

Physical Data: mp 188 °C; monohydrate 136 °C.[2]

Solubility: sol H_2O, MeOH, EtOH and related solvents; insol ether or pentane.

Analysis of Reagent Purity: ^{1}H NMR, mp.

Preparative Methods: colorless crystals prepared from 4-methyl-1,3-thiazole and benzyl chloride, or benzylthioformamide and chloroacetone.[2]

Handling, Storage, and Precautions: store dry.

Formation of Benzoins and Acyloins from Aldehydes.

Many thiazolium salts catalyze the formation of benzoins from aromatic aldehydes and of acyloins from aliphatic aldehydes, both in presence of bases (eq 1). This catalytic reaction has long been known,[3] the most prominent salt being thiamine (vitamin B_1). For details on the use of other salts, see ***3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium Chloride***. The title reagent is the only one known to catalyze the formation of five- and six-membered cyclic acyloins in the presence of a base (eq 2).[4]

(1)

(2)

Oxidative Reactions.

Aromatic aldehydes in presence of a nitro compound, an alcohol, and a base react in a different way (eq 3). No formation of benzoins is observed, with only the carboxylic esters and nitrobenzene reduction products being formed.[5] Quinones react analogously to nitro compounds.[6] A test for the catalytic activity of azolium salts uses flavin as oxidant and indicator;[7a] details are given in a related bioorganic model study on the reaction of thiamine.[7b]

+ azobenzene + azoxybenzene (3)

Addition of Aldehydes to Electrophilic Double Bonds.[8]

Full details are given under the entry for ***3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium Chloride***. The reagent in the presence of bases catalyzes addition, but shows a tendency to form byproducts (eq 4). In this case the byproduct results from Michael addition to the benzoin instead of to the activated aldehyde.[9]

Reduction and Hydrolysis of the Reagent.

The reagent, like other thiazolium salts, is easily reduced by ***Sodium Borohydride***[10] to the thiazoline and the ring is easily cleaved by aqueous bases.[2b]

Other Reagents.

Acyloins are produced by the action of metals such as sodium on carboxylic esters;[11] benzoins are produced by the catalytic action of cyanides on aromatic aldehydes.[12]

Related Reagents.

3-Benzyl-5-(2-hydroxyethyl)-4-methyl-1,3-thiazolium Chloride; ***3-Benzylthiazolium Bromide***.

Benzyl 4-Nitrophenyl Carbonate

[13795-24-9] · $C_{14}H_{11}NO_5$ · Benzyl 4-Nitrophenyl Carbonate · (MW 273.24)

(reagent for protection of tryptophan nucleus[1])

Physical Data: mp 78-80 °C.

Solubility: sol ether, methanol, chloroform.

Form Supplied in: fibrous powder.

Tryptophan Protection.[1]

Protection of the indole ring on a tryptophan residue, as an acid-stable Cbz derivative, was required for the synthesis of a tetrapeptide target molecule. Thus reaction of a Boc-protected dipeptide fragment with the reagent (**1**) and ***Potassium Fluoride*** solubilized with ***18-Crown-6*** provided the Cbz-protected derivative (eq 1). The naked fluoride ion serves as the base to abstract a proton from the indole ring.

Related Reagents.

Benzyl Chloroformate.

Solubility: sol most polar organic solvents.

Form Supplied in: white crystalline solid; commercially available.

Analysis of Reagent Purity: 99% purity attainable by GLC.

Handling, Storage, and Precautions: no special handling or storage precautions are necessary. There is no known toxicity. It may be harmful by inhalation, ingestion, or skin absorption and may cause skin or eye irritation.

Synthesis of the Chiral Oxazolidinone Auxiliaries.

(*S*)-4-Benzyl- (**1**), (*R*)-4-benzyl- (**2**), (*S*)-4-*i*-propyl- (**3**), (4*R*,5*S*)-4-methyl-5-phenyl- (**4**), (*S*)-4-*t*-butyl- (**8**), and (*S*)-4-phenyl-2-oxazolidinones (**6**) are commercially available. Typical procedures to form these chiral auxiliaries involve the reduction of α-amino acids to the corresponding amino alcohols or the purchase of amino alcohols, followed by formation of the cyclic carbamate (eq 1). A number of high-yielding methods of reduction have been employed for this transformation, including ***Boron Trifluoride Etherate*/*Borane-Dimethyl Sulfide***,[12] ***Lithium Aluminum Hydride***,[1,6,13,14] ***Sodium Borohydride*/*Iodine***,[15] and ***Lithium Borohydride*/*Chlorotrimethylsilane***.[8] Selection among these methods is largely based upon cost of reagents and ease of performance. Reagents for effecting the second transformation include ***Diethyl Carbonate*/*Potassium Carbonate***[12] or ***Phosgene***,[16 -18] with the former being preferable for large-scale production. Ureas,[19,20] dioxolanones,[21] chloroformates,[22] trichloroacetate esters,[22,23] ***N,N´-Carbonyldiimidazole***,[24] and ***Carbon Monoxide*** with catalytic elemental ***Sulfur***[25] or ***Selenium***[26,27] provide alternatives for the transformation of amino alcohols to the derived oxazolidinones.

(1)

Conversion of the appropriate α-amino acids to oxazolidinones may also be performed as a one-pot procedure, obviating the need to isolate the intermediate amino alcohols (eqs 2 and 3).[28,29] Overall isolated yields for these procedures are 70-80%.

(S)-4-Benzyl-2-oxazolidinone

(2)

(3)

Carbamate-protected amino alcohols also yield oxazolidinones upon treatment with base (eq 4)[30,31] or ***p-Toluenesulfonyl Chloride*** (eq 5).[32] The latter reaction requires the protection of the amino group as the *N*-methylated carbamate for selective inversion of the hydroxyl-bearing center.

(4)

(5)

Resolution of racemic oxazolidinones affords either enantiomer of the auxiliary and provides a versatile route to unusually substituted derivatives (eq 6).[33]

(S)-4-Benzyl-2-oxazolidinone

Methods of *N*-Acylation.

Lithiated oxazolidinones add to acid chlorides (eq 7)[6,34] and mixed anhydrides (eq 8)[35,36] in high yields to form the derived *N*-acyl imides. In the latter case the anhydride may be formed in situ with ***Trimethylacetyl Chloride***, and then condensed with the lithiated oxazolidinone selectively at the less hindered carbonyl moiety.

Acryloyl adducts cannot be formed through traditional acylation techniques due to their tendency to polymerize. These adducts may be obtained through reaction of acryloyl chloride with the bromomagnesium salt of the oxazolidinone

auxiliary[9,37] or the *N*-trimethylsilyl derivative in the presence of ***Copper(II) Chloride*** and ***Copper*** powder.[38] These methods yield products in the range of 50-70%.

Methods of *N*-Alkylation.

In analogy with acylation techniques, metalated oxazolidinones add to alkyl halides to afford the *N*-alkylated products in high yields.[39-42]

Enolization of *N*-Acyloxazolidinones.

Various methods have been developed to effect the enolization of chiral *N*-acyloxazolidinones. In alkylation reactions, both ***Lithium Diisopropylamide*** and ***Sodium Hexamethyldisilazide*** deprotonate these imides to provide the (*Z*)-enolates in >100:1 selectivity.[1]

Di-n-butylboryl Trifluoromethanesulfonate with a tertiary amine also provides the (*Z*)-enolates of chiral acyl oxazolidinones in >100:1 selectivity for use in subsequent aldol additions.[6,14] With ***Triethylamine***, ***Diisopropylethylamine*** (Hünig's base), or ***2,6-Lutidine*** the order of addition is of no consequence to enolization.[43] Triethylamine has traditionally seen the greatest utilization in these reactions based upon cost considerations; however, with certain sensitive aldehyde substrates, lutidine provides milder reaction conditions.[44]

The (*Z*)-enolate is also accessed exclusively using titanium enolization procedures.[45,47] Irreversible complexation of ***Titanium(IV) Chloride*** with tertiary amine bases demands complexation of the substrate with the Lewis acid prior to treatment with either triethylamine or Hünig's base. Reactions using Hünig's base occasionally display higher diastereoselectivities, particularly in Michael additions.[7,45] Of the alkoxy titanium species employed in imide enolization, only $TiCl_3$(O-*i*-Pr) is capable of quantitative enolate formation. In these reactions, order of addition of reagents is not significant. These enolates demonstrate enhanced nucleophilicity, albeit with somewhat diminished diastereoselectivity.

Other Lewis acids have been demonstrated to provide moderate levels of enolization, including ***Aluminum Chloride***, ***Magnesium Bromide***, and ***Tin(II) Trifluoromethanesulfonate***.[45,46] However, $SnCl_4$, Me_2AlCl, and $ZrCl_4$ failed to provide detectable enolization.[45]

Enolate Alkylation.

Alkylation of chiral *N*-acyloxazolidinones by simple alkyl and allylic halides occurs through the chelated lithiated (*Z*)-imide enolates to afford products in greater than 93:7 diastereoselectivities (eqs 9 and 10).[1] For small electrophiles such as ***Iodomethane*** and ***Ethyl Iodide***, NaHMDS proved to be the enolization base of choice. On selected substrates, alkyl triflates also demonstrate promise as alkylating agents.[34]

(9)

(10)

For benzyloxymethyl electrophiles, titanium enolates are superior to the corresponding lithium enolates in both yield and alkylation diastereoselectivity (eq 11). Unfortunately, the analogous *p*-methoxybenzyl-protected β-hydroxy adducts cannot be obtained by this method. In other cases the titanium methodology complements the corresponding reactions of the lithium and sodium enolates for S_N1-like electrophiles.[47] It is noteworthy that imides may be selectively enolized under all of the preceding conditions in the presence of esters (eq 12).

(11)

(S)-4-Benzyl-2-oxazolidinone

(12)

Treatment of the silyl enol ethers of *N*-acyloxazolidinones with selected electrophiles that do not require Lewis acid activation similarly results in high induction of the same enolate face (eq 13).[48] The facial bias of this conformationally mobile system improves with the steric bulk of the silyl group.

(13)

Chiral oxazolidinones have also been used to induce chirality in $TiCl_4$-mediated allylsilane addition reactions to α-keto imides (eq 14).[49]

(14)

(S)-4-Benzyl-2-oxazolidinone

Enolate Alkylations with Transition Metal Coordinated Electrophiles.

Coordination of various transition metals to dienes and aromatic compounds sufficiently activates these compounds to nucleophilic addition, resulting in high asymmetric induction at the α-center. However, the manganese complexes of various benzene derivatives couple with lithium enolates in low selectivity at the nascent stereogenic center on the ring (eq 15).[50]

(15)

In contrast, molybdenum and iron diene complexes undergo the same type of reaction with chiral lithium imide enolates, with moderate to good induction at the β-position (eq 16).[51-53]

(16)

Dicobalt hexacarbonyl-coordinated propargyl ethers also combine with imide boron enolates through a kinetic resolution of the rapidly interconverting propargylic cation isomers to afford a 92:8 mixture of isomers at the β-center in 80% yield (eq 17). Stereocontrol of the α-center is 97:3.[54]

(S)-4-Benzyl-2-oxazolidinone

Enolate Acylation.

Acylation of these enolates provides a direct route to β-dicarbonyl systems. Acylations generally proceed with >95% diastereoselection in 83-95% yields, with the valine-derived auxiliary providing slightly higher selectivity (eq 18).[2] The sense of induction is consistent with reaction through the chelated lithium (*Z*)-enolate, and the newly generated stereocenter is retained through routine manipulations.

An alternate approach to these useful 1,3-dicarbonyl substrates may be achieved through enolate orthoester acylation. Titanium enolates have been employed to effect this transformation (eq 19).[45,47] Similarly, treatment of the titanium enolate of β-ketoimide with dioxolane orthoesters results in the formation of a masked tricarbonyl compound (eq 20). Trimethyl orthoacetate and ***Triethyl Orthoacetate*** are not appropriate partners in these coupling reactions.[45,47]

(S)-4-Benzyl-2-oxazolidinone

(19)

(20)

Michael Addition.

Titanium imide enolates are excellent nucleophiles in Michael reactions. Michael acceptors such as ethyl vinyl ketone, ***Methyl Acrylate***, ***Acrylonitrile***, and *t*-butyl acrylate react with excellent diastereoselection (eq 21).[7,45] Enolate chirality transfer is predicted by inspection of the chelated (*Z*)-enolate. For the less reactive unsaturated esters and nitriles, enolates generated from $TiCl_3$(O-*i*-Pr) afford superior yields, albeit with slightly lower selectivities. The scope of the reaction fails to encompass β-substituted, α,β-unsaturated ketones which demonstrate essentially no induction at the prochiral center. Furthermore, substituted unsaturated esters do not act as competent Michael acceptors at all under these conditions.

(21)

X = COEt, CO_2Me, CN >95:5

Various chelated lithium imide enolates have also served as nucleophiles in Michael additions to 3-trifluoromethyl acrylate, favoring the *anti* isomer (eq 22).[55]

(S)-4-Benzyl-2-oxazolidinone

Enolate Hydroxylation.

Treatment of the sodium enolates with the Davis oxaziridine reagent affords the hydroxylated products with the same sense of induction as the alkylation products (eq 23).[5,35] Although high diastereoselectivity may be achieved with ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** (MoOPH), such reactions proceed in lower yields.

Enolate Amination.

Amination likewise can be effected using ***Di-t-butyl Azodicarboxylate*** (DBAD).[4,56] Despite the excellent yields and diastereoselectivity obtained using this methodology (eq 24), the harsh conditions required for further transformation of the resultant hydrazide adducts (***Trifluoroacetic Acid*** and hydrogenation at 500 psi over ***Raney Nickel*** catalyst) limit its synthetic utility.

(S)-4-Benzyl-2-oxazolidinone

(24)

As a method for the synthesis of α-amino acids, the hydrazide methodology has now largely been supplanted by direct enolate azidation (eq 25).[4,57] These adducts are susceptible to mild chemical modification to afford *N*-protected α-amino acid derivatives. Under optimal conditions, yields range from 74-91% and selectivities from 91:9 to >99:1. Imide enolization can be carried out selectively in the presence of an enolizable *t*-butyl ester and suitably protected amino groups.

(25)

Hydrogenation of the azide moiety readily provides the amine using ***Palladium on Carbon*** and H_2 or ***Tin(II) Chloride***. This methodology has been extended to the synthesis of arylglycines (eq 26).[58]

(S)-4-Benzyl-2-oxazolidinone

Failure to use ***2,4,6-Triisopropylbenzenesulfonyl Azide*** results in substantial diazo imide formation. However, optimization for the formation of the α-diazo imide compounds can be achieved with NaHMDS and *p*-nitrobenzenesulfonyl azide, followed by a neutral quench (eq 27).[4] These diazo compounds, however, have failed to demonstrate utility in asymmetric carbenoid chemistry.[59]

Enolate Halogenation.

Enolate halogenation is achieved by reaction of the boryl enolate with ***N-Bromosuccinimide***, affording configurationally stable α-bromo imides in >94:6 diastereoselectivity in 80-98% yield (eq 28).[3,4] The sense of induction suggests halogenation of the chelated (*Z*)-enolate. Introduction of an α-fluoro substituent can be effected by the treatment of imide enolates or α,β-unsaturated enolates with *N*-fluoro-*o*-benzenedisulfonimide (eq 29).[60]

(28)

(29)

R = *n*-Bu, *t*-Bu, Bn, Ph 86-97% de

Displacement of a halide at the α-position with tetramethylguanidinium azide (TMGA) introduces nitrogen functionality with inversion of the original halide configuration and <1% epimerization (eq 30).[3,4]

(30)

In those transformations where other stereogenic centers reside proximal to the prochiral center, auxiliary control is dominant in most cases (eq 31).[61]

(S)-4-Benzyl-2-oxazolidinone

(31)

Aldol Reactions.

The dibutyl boryl enolates of chiral acyloxazolidinones react to afford the *syn*-aldol adducts with virtually complete stereocontrol (eq 32).[6,13,14,43,61-64] Notably, the sense of induction in these reactions is opposite to that predicted from the analogous alkylation reactions. This reaction is general for a wide range of aldehydes and imide enolates.[36,65-69] Enolate control overrides induction inherent to the aldehyde reaction partner.

(32)

Titanium enolates of propionyloxazolidinones also undergo aldol reactions with the same sense of induction as the boryl counterparts, but require two or more equivalents of amine base to afford adducts in marginally higher yields but diminished selectivity (eq 33).[45]

(S)-4-Benzyl-2-oxazolidinone

(33)

Enolization	Yield	Stereoselection
$TiCl_4$, i-Pr_2NEt	87%	94:6
$TiCl_4$, TMEDA	84%	98:2
n-Bu_2BOTf, Et_3N	83%	>99:1

A second entry to dicarbonyl substrates utilizes the aldol reaction to establish the α-methyl center prior to oxidation of the β-hydroxyl moiety. Commonly, this oxidation is performed using the ***Sulfur Trioxide-Pyridine*** complex, which results in <1% epimerization of the methyl-bearing center (eq 34).[2] Interestingly, this procedure procures the opposite methyl stereochemistry from that obtained through enolate acylation of the same enantiomer of oxazolidinone.

(34)

Non-Evans Aldol Reactions.

Either the *syn*- or *anti*-aldol adducts may be obtained from this family of imide-derived enolates, depending upon the specific conditions employed for the reaction. Although the illustrated boron enolate affords the illustrated *syn*-aldol adduct in high diastereoselectivity, the addition reactions between this enolate and Lewis acid-coordinated aldehydes afford different stereochemical outcomes depending on the Lewis acid employed (eq 35).[70] Open transition states have been proposed for the ***Diethylaluminum Chloride*** mediated, *anti*-selective reaction. These *anti*-aldol reactions have been used in kinetic resolutions of 2-phenylthio aldehydes.[71]

(35)

Lewis acid	Yield	A:B:C
$TiCl_4$ (2 equiv)	83%	0:16:84
$SnCl_4$ (2 equiv)	60%	0:13:87
Et_2AlCl (2 equiv)	63%	0:95:5

Enolates derived from α-haloimides also exhibit metal-dependent *syn/anti*-aldol diastereoselection. The derived Li, Sn^{IV}, and Zn enolates afford the *anti* isomer in reactions with aromatic aldehydes, while the corresponding B and Sn^{II} enolates lead to the conventional *syn* products.[72,73] The non-Evans *syn* adducts have also been observed in reactions organized by ***Chlorotitanium Triisopropoxide***.[74,75]

Crotonyl Enolate Aldol Reactions.

Boron enolates of the *N*-crotonyloxazolidinones have been shown to afford the expected *syn*-aldol adducts (eq 36).[76,77] The propensity for self-condensation during the enolization process is minimized by the use of triethylamine over less kinetically basic amines.

α-Alkoxyacetate Aldol Reactions.

The enolates derived from *N*-α-alkoxyacetyloxazolidinones also provide good yields of aldol adducts. Proper choice of reaction conditions leads to either the *syn* (eq 37)[78] or *anti* (eq 38)[46] adducts. In an application of this aldol reaction in the synthesis of cytovaricin, a complex chiral aldehyde was found to turnover the expected *syn* diastereoselectivity of the boron enolate.[66]

(S)-4-Benzyl-2-oxazolidinone

ds of desired to the total amount of other isomers = 77:23

N-Isothiocyanoacetyl Aldol Reactions.

Auxiliary-controlled masked glycine enolate aldol reactions afford the chiral oxazolidine-2-thiones which can be cleaved to provide the *syn*-aldol adducts regardless of aldehyde stereochemistry (eq 39).[79]

N-Haloacetyl Aldol Reactions.

N-Haloacetyloxazolidinones form suitable enolate partners in aldol reactions, although complete aldehyde conversion requires the use of a slight excess of imide (eq 40). The products can be chromatographed to diastereomeric purity.[4,80] Nucleophilic azide displacement of α-halo-β-hydroxy *syn* aldol adducts affords the corresponding *anti* α-amino-β-hydroxy compounds (eq 41).[4,80] Intramolecular displacement of the halogen to form the α-amino product is also

(S)-4-Benzyl-2-oxazolidinone

possible (eq 42).[80]

(40)

(41)

(42)

Acetate Aldol Equivalents.

In contrast to the reliably excellent selectivities of α-substituted dibutylboryl imide enolates, boron enolates derived from *N*-acetyloxazolidinones lead to a statistical mixture of aldol adducts under the same reaction conditions. Acetate enolate equivalents may be obtained from these enolates bearing a removable α-substituent. To this end, thiomethyl- or thioethylacetyloxazolidinones (eq 43)[13] as well as haloacetyloxazolidinones can be submitted to highly selective boron-mediated aldol reactions. Products can be transformed to the acetate aldol products via desulfurization with either Raney Ni[81] or ***Tri-n-butylstannane*** and ***Azobisisobutyronitrile***,[82] or via dehalogenation with ***Zinc-Acetic Acid*** (eq 44).[81] This latter procedure provides several advantages over the sulfur methodology, including ease of imide preparation and improved overall yields.

β-Ketoimide Aldol Reactions.

As has been demonstrated, chiral oxazolidinones provide a gateway into asymmetric β-ketoimides via either an aldol-oxidation sequence, or enolate acylation. These substrates can then undergo an iterative aldol reaction, where chirality is induced by the methyl-bearing α-center. To date, three of the four diastereomeric aldol adducts may be selectively obtained with a variety of aldehydes (eq 45).[36,83-86]

(45)

Reformatsky Reactions.

The Reformatsky reaction of α-halooxazolidinones provides an alternative to the more conventional aldol reaction. Although the traditional zinc-mediated Reformatsky using valine-derived compounds proceeds nonselectively,[87,88] the Sn^{II} modification with 2-bromo-2-methylpropionyloxazolidinone proceeds well (eq 46).[89,90] In this particular case, however, the geminal dialkyl substituents favor the endocyclic carbonyl acyl transfer of the auxiliary by the aldolate oxygen.

(S)-4-Benzyl-2-oxazolidinone

(46)

Acyl Transfer Reactions.

(*S*)-*N*-benzoyloxazolidinones have been used as acyl transfer reagents to effect the kinetic resolution of racemic alcohols.[10] The bromomagnesium alkoxides formed from phenyl *n*-alkyl alcohols selectively attack the exocyclic benzoyl moiety to afford recovered auxiliary and the derived (*R*)-benzoates in >90% ee and >90% yield (eq 47). The scope of this reaction seems to be limited to this class of substrates as selectivity drops with increasing the steric bulk of the alkyl group.

(47)

Sulfinyl Transfer Reactions.

Grignard reagents add to diastereomerically pure *N*-arylsulfinyloxazolidinones with inversion of configuration at sulfur to afford enantiopure dialkyl or aryl alkyl sulfoxides in excellent yields (eq 48).[11] Although broader in synthetic utility

than the menthyl sulfinate esters,[91,92] this methodology is comparable to Kagan's chiral sulfite substrates as a strategy for constructing chiral sulfoxides.[93,94]

(48)

The *N*-arylsulfinyloxazolidinone methodology is readily extended to the formation of sulfinylacetates, sulfinates, and sulfinamides with >95% ee and high yields (eq 49).

(49)

Diels-Alder Reactions.

Chiral α,β-unsaturated imides participate in Lewis acid-promoted Diels-Alder cycloaddition reactions to afford products in uniformly excellent *endo/exo* and *endo* diastereoselectivities (eqs 50 and 51).[9,37,95,96] Unfortunately, this reaction does not extend to certain dienophiles, including methacryloyl imides, β,β-dimethylacryloyl imides, or alkynic imides. Cycloadditions also occur with less reactive acyclic dienes with high diastereoselectivity (eq 52). Of the auxiliaries surveyed, the phenylalanine-derived oxazolidinones provided the highest diastereoselectivities. This methodology has been recently extended to complex intramolecular processes (eq 53).[68,95,97] In this case, use of the

unsubstituted achiral oxazolidinone favored the undesired diastereomer.

(S)-4-Benzyl-2-oxazolidinone

(53)

Staudinger Reactions.

Chiral oxazolidinones have been employed as the chiral control element in the Staudinger reaction as well as the ultimate source of the α-amino group in the formation of β-lactams.[41] Cycloaddition of ketene derived from 4-(*S*)-phenyloxazolidylacetyl chloride with conjugated imines affords the corresponding β-lactams in 80-90% yields with excellent diastereoselectivity (eq 54). The auxiliary can then be reduced under Birch conditions to reveal the α-amino group.

Conjugate Addition Reactions.

α,β-Unsaturated *N*-acyloxazolidinones have been implemented as Michael acceptors, inducing chirality in the same sense as in enolate alkylation reactions. Chiral α,β-unsaturated imides undergo 1,4-addition when treated with diethylaluminum chloride (eq 55). Photochemical initiation is required for the analogous reaction with ***Dimethylaluminum Chloride***.[96]

Organocuprates also undergo conjugate addition with chiral α,β-unsaturated imides.[98] Treatment of the imides derived from 4-phenyl-2-oxazolidinone with methyl- or arylmagnesium halides and CuBr affords conjugate addition products in yields over 80% with few exceptions (eq 56).[8] Reaction diastereoselectivity appears to be contingent upon the use of the 4-phenyloxazolidinone auxiliary. The preceding methodology has been applied to the synthesis of β-methyltryptophan (eq 57).[99]

(S)-4-Benzyl-2-oxazolidinone

Similar chemistry using chiral sultam auxiliaries demonstrates superior yields and selectivities for specific cases of cuprate conjugate additions, but have not yet been extended to the more complex multistep transformation series illustrated above.[100,101] Moderate selectivities have been obtained in alkyl cuprate additions to γ-aminocrotonate equivalents where the nitrogen is derived from the oxazolidinone.[102]

The 4-phenyl-2-oxazolidinone auxiliary has also been employed in the $TiCl_4$-mediated conjugate additions of allylsilanes (eq 58).[103] Analogous reactions using the phenylalanine-derived auxiliary with dimethylaluminum chloride afforded lower selectivities.[104] In these reactions the oxazolidinones perform better than the sultams.

Nucleophilic addition of thiophenol to chiral tiglic acid-derived imides proceeds in excellent yields and diastereoselectivities (eq 59).[105] Complete turnover of both the α- and β-centers results from the use of the (*Z*) rather than (*E*) isomer. Poor β-induction was found with the imides derived from cinnamic acid.

(S)-4-Benzyl-2-oxazolidinone

Dimethylaluminum chloride also catalyzes the ene reactions of chiral α,β-unsaturated imides with 1,1-disubstituted alkenes in moderate yields and selectivities.[104]

Oxazolidinone-Substituted Carbanions.

Oxazolidinone-substituted organostannanes readily undergo transmetalation with alkyllithium reagents to the organolithium derivatives which then can undergo nucleophilic addition reactions. *N*-Substituted oxazolidinones can act in this capacity as both a nitrogen source and source of chirality (eq 60). Although the α-stereoselection in these reactions is excellent, a greater variety of reactant alkylstannanes are available using chiral imidazolidinones in place of oxazolidinones.[39,40,42]

(S)-4-Benzyl-2-oxazolidinone

(60)

Synthesis of Cyclopropanes.

Chiral imide enolates which contain γ-halide substituents undergo intramolecular displacement to form cyclopropanes.[106] Halogenation of γ,δ-unsaturated acyl imides occurs at the γ-position in 85% yield with modest stereoinduction. The (*Z*) sodium enolates of these compounds then cyclize through an intramolecular double stereodifferentiating reaction (eq 61).

(61)

(S)-4-Benzyl-2-oxazolidinone

Stereoselective Cyclizations.

Sultams have been demonstrated to be superior sources of chirality in selected cases of iodolactonizations,[107] oxidative 1,5-diene cyclizations,[108] and Claisen-type rearrangements of β-acetoxyl substrates.[109]

Chiral Ligands.

Bidentate chelation of dirhodium(II) compounds by chiral oxazolidinones creates asymmetric sites on the metal, leading to induction in cyclopropanations and carbon-hydrogen insertion reactions. The oxazolidinones are less effective in this capacity than are the pyrrolidines.[110]

Removal of the Chiral Auxiliary.

In each of the following transformations, the oxazolidinone auxiliary is recovered in high yields (eq 62).

(62)

1a) KOH, MeOH; 1b) LiOH, MeOH or THF; 1c) LiOH, H_2O_2.
2a) $LiAlH_4$; 2b) $LiBH_4$; 2c) $LiBH_4$, H_2O; 2d) $LiBH_4$, MeOH;
2e) $LiAlH_4$, H_2 Lindlar cat., TFA; 2f) Bu_3B, HOAc, $LiBH_4$.

2e) $LiAlH_4$, H_2, Lindlar cat., TFA; 2f) Bu_3B, HOAc, $LiBH_4$.
3a) i) $LiBH_4$, H_2O; ii) DMSO, $(COCl)_2$, Et_3N;
3b) i) $Me_2AlN(OMe)Me$; ii) DIBAL;
3c) i) LiSEt; ii) Et_3SiH, Pd/C.
4a) LiOBn; 4b) $Ti(OBn)_4$; 4c) ROMgBr; 4d) NaOMe;
4e) $Ti(OEt)_4$.
5) i) N_2H_4; ii) isopentyl nitrite, NH_4Cl.
6) $Me_2AlN(OMe)Me$.
7) LiSEt.

Conversion to the Acid.

Hydroxide[6,111] and peroxide[112] conditions saponify acyl imides in excellent yields; however, with sterically hindered acyl groups endocyclic cleavage may predominate upon treatment with ***Lithium Hydroxide***. ***Lithium Hydroperoxide***, however, is highly selective for the exocyclic carbonyl moiety.

Conversion to the Alcohol.

Reduction of acyl imides to their corresponding alcohols is effected by a number of reagents, including ***Lithium Aluminum Hydride***,[1] ***Lithium Borohydride***,[1] $LiAlH_4/H_2$/Lindlar's cat./TFA,[113] $LiBH_4/H_2O/Et_2O$,[114] $LiBH_4$/MeOH/THF,[36] and Bu_3B/HOAc/$LiBH_4$.[77] Although the sole use of $LiAlH_4$ or $LiBH_4$ affords product often in low yields, the addition of an equivalent of H_2O or MeOH greatly enhances reaction efficiency. The MeOH/THF modification occasionally produces more consistent results. The last of the methods outlined above is effective in preventing retro-aldol cleavage in sensitive substrates such as crotyl or α-fluoro aldol adducts (eq 63).

(63)

Conversion to the Aldehyde.

This transformation is accomplished through a two-step procedure. One such variant requires reduction to the alcohol (e.g. $LiAlH_4$, H_2O) and subsequent oxidation (e.g. Swern conditions).[36,85] Alternatively, Weinreb transamination[78,115-117] followed by ***Diisobutylaluminum Hydride***,[78] or conversion to the thioester (see below) and subsequent ***Triethylsilane*** reduction,[86] afford the desired aldehyde in excellent yields. Weinreb transamination proceeds with minimal endocyclic cleavage when there is a β-hydroxy moiety free for internal direction of the aluminum species.

(S)-4-Benzyl-2-oxazolidinone

Conversion to Esters.

Ester formation is readily achieved by conventional alcoholysis with alkoxides such as LiOBn,[1] NaOMe,[6] or ROMgBr (eq 64).[76,118] In hindered cases, endocyclic cleavage becomes competitive. Various titanium(IV) alkoxides have also been employed to effect this transformation.[4,119]

(64)

Conversion to Amides.

N-Acyloxazolidinones may be converted to the primary amide via the corresponding hydrazide.[120] Alternatively, trimethylaluminum/amine adducts form active transamination reagents,[36,117] providing amides of β-hydroxy acyloxazolidinones through intramolecular amine addition of the aminoaluminum species (eq 65).[105]

(65)

Conversion to Thioesters.

The transformation of *N*-acyl imides into thioesters with lithium thiolate reagents proceeds with exceptional selectivity for the *exo* carbonyl moiety even in exceptionally hindered cases.[121] A recent application of this reaction in a complex setting has been reported (eq 66).[68,97] This transformation is significant in that the normally reliable peroxide hydrolysis procedure proved to be nonselective. The recently reported high yield reduction of thioesters to aldehydes[86]

(S)-4-Benzyl-2-oxazolidinone

enhances the utility of these thioester intermediates.

3-(2-Benzyloxyacetyl)thiazolidine-2-thione[1]

[92486-00-5] · $C_{12}H_{13}NO_2S_2$ · 3-(2-Benzyloxyacetyl)thiazolidine-2-thione · (MW 267.36)

(synthon for α-benzyloxy carboxylic esters, amides, or aldehydes;[2,3] enolate precursor for the diastereo- and enantioselective aldol reactions[4])

Physical Data: mp 81.0-82.0 °C.

Form Supplied in: slightly yellow crystals

Preparative Method: methyl 2-hydroxyacetate is converted to methyl 2-benzyloxyacetate (1, NaH; 2, BnBr, DMF, 0 °C to rt, 80%). The acetate is then treated with $LiOH.H_2O$ (1.25 equiv) in THF-H_2O at rt to give 2-benzyloxyacetic acid (99%). The acid is converted to the corresponding acid chloride (oxalyl chloride (2.7 equiv, 60 °C, 1.5 h), which is treated with thiazolidine-2-thione in the presence of triethylamine in dichloromethane to give the title reagent (**1**) (81% from the acid).

Handling, Storage, and Precautions: use in a fume hood.

Diastereo- and Enantioselective Aldol Reactions.

Optically active 1,2-diol units are widely distributed in natural products such as macrolides, polyethers, and carbohydrates, etc. The aldol reactions of the enolates derived from α-alkoxyacetic acid ester derivatives with aldehydes provide a useful way to construct 1,2-diols,[5] and several asymmetric reactions have been developed.

The tin(II) enolate prepared from (**1**), ***Tin(II) Trifluoromethanesulfonate***, and ***1-Ethylpiperidine*** reacts with aldehydes in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) to afford the *anti* aldol adducts in good yields with good selectivities (eq 1). Interestingly, *syn* selective reactions proceed in the absence of TMEDA. Optically active *anti* aldol adducts can be obtained in the presence of chiral diamine (**2**) instead of TMEDA.

Additive	Yield (%)	*syn:anti*	ee (%) *(anti)*
none	62	74:26	-
TMEDA	70	15:85	-
 **(2)**	81	13:87	94

The tin(II) enolate of chiral oxazolidinone derivative (**3**) also works well in the presence of TMEDA to give the *anti* aldol in good yield.[6]

(3)

Optically active *syn* and *anti* diol units can be easily prepared by the asymmetric aldol reaction of aldehydes with silyl

enolates (**4**) and (**5**), respectively, under the influence of chiral tin(II) Lewis acid (**6**).[7,8] Diastereofacial selectivities are controlled simply by choosing the protective group of the α-alkoxy part of ketene silyl acetals (eqs 2 and 3).

(2)

(3)

While stoichiometric amounts of chiral sources are required in the reaction of eqs 2 and 3, the truly catalytic asymmetric version is realized by using a novel catalyst system consisting of tin(II) triflate, chiral diamine (**7**), and tin(II) oxide (eq 4).[9]

(7)

Related Reagents.

Ethyl Mandelate; ***Phenoxyacetic Acid***.

Benzyloxycarbonylhydrazine

(base)

[5331-43-1] · $C_8H_{10}N_2O_2$ · Benzyloxycarbonylhydrazine · (MW 166.18) (.HCl)

[2540-62-7]

(preparation of hydrazides of amino acids for use in peptide synthesis[1])

Alternate Names: carbobenzoxyhydrazine; benzyl hydrazinocarboxylate.

Physical Data: mp 67-69 °C; hydrochloride salt, mp 170-170.5 °C

Preparative Method: prepared by reaction between ***Hydrazine*** and dibenzyl carbonate.[1]

Purification: recrystallization from ethyl acetate/hexane, or from ether.

Peptide Synthesis.

Benzyloxycarbonylhydrazine (**1**) has found use in the preparation of the hydrazides of amino acids and peptides.[1] (**1**) reacts with *N*-protected (phthaloyl or Boc) amino acid chlorides to give the benzyloxycarbonylhydrazide derivatives (**2**) (eq 1).[1] *N*-Deprotection (eq 2) leaves the N-terminus available for coupling to a suitable activated carboxylic acid derivative, giving (**4**) (eq 3); this stepwise elongation procedure may be continued until the desired peptide sequence is obtained. Hydrogenation then affords the peptide hydrazide (**5**) (eq 4). Preparation by this method, where the protected hydrazide is introduced early, at the amino acid stage, avoids the usual need to expose a complex or sensitive peptide ester to hydrazine. Indeed, the hydrazides of *N*-phthaloyl amino acids or peptides were previously inaccessible since hydrazine effects removal of the phthaloyl group rather than reacting with the ester. The hydrazide (**5**) can next be converted to the acyl azide (**6**) (eq 5) in readiness for coupling with an amino component.

N-Benzyloxycarbonyl-L-serine β-Lactone

(R = NH-Cbz) (**1**)

[26054-60-4] · $C_{11}H_{11}NO_4$ · *N*-Benzyloxycarbonyl-L-serine β-Lactone · (MW 221.21) (R = NH-Boc) (**2**)

[98541-64-1] · $C_8H_{13}NO_4$ · *N-t*-Butoxycarbonyl-L-serine β-Lactone · (MW 187.20) (R = NH_3^+ OTs^-) (**3**)

[112839-95-9] · $C_{10}H_{13}NO_5S$ · L-Serine β-Lactone Tosylate · (MW 259.28)

(reagent for the synthesis of β-substituted alanines[1,2])

Alternate Name: (*S*)-3-(*N*-benzyloxycarbonyl)aminooxetan-2-one.

Physical Data: (**1**): mp 133-134 °C, [α]25D = -26.8° (*c* = 1, MeCN); (**2**): mp 119.5-120.5 °C, [α]25D = -26.2° (*c* = 1, MeCN, 24 °C); (**3**): mp 133-135 °C (darkening), dec. 173 °C, [α]25D = -15.9° (*c* = 2.2, DMF).

Solubility: (**1**) and (**2**) sol most organic solvents; (**3**) sol polar aprotic organic solvents and H_2O.

Form Supplied in: white solids.

Preparative Methods: (**1**) is easily made by cyclization of commercially available *N*-Cbz-L-serine (**4**) under modified Mitsunobu conditions, using a preformed complex of dimethyl azodicarboxylate (DMAD) and ***Triphenylphosphine*** (eq 1).[3] The reaction proceeds via hydroxy group activation, and labeling studies show that the 3-hydroxy group is lost in a 4-*exo-tet* cyclization mechanism.[5] The β-lactone must be separated quickly from the reaction mixture,[3] and a slight excess of DMAD improves the yield because unreacted triphenylphosphine can cause polymerization.[6] The Boc (*t*-

butoxycarbonyl) analog (**2**) is prepared similarly, and the *p*-toluenesulfonate (tosylate) salt (**3**) is synthesized from (**2**) by acidic cleavage.[4]

Purification: see Pansare et al.[3,4]

Handling, Storage, and Precautions: the β-lactones (**1**)-(**3**) are stable for many months at 4 °C in dry form. Neutral or slightly acidic solutions of (**1**) and (**2**) are stable for at least 1 day; (**3**) must be used in situ; basic and strongly acidic solutions rapidly decompose these β-lactones. They should be handled in a fume hood.
