N-Cbz-β-lactone (**1**) is a very useful tool for the synthesis of optically active α-amino acids. Unlike other well established procedures,[2] this method does not generate the chiral center at the α-carbon but rather homologates optically pure serine derivatives at the β-carbon. Although this review is limited to the use of *N*-Cbz-L-serine β-lactone to generate L-amino acids in most applications, the corresponding D-serine β-lactones are available analogously from inexpensive D-serine derivatives. Ring-opening of β-lactones can occur in two different modes. Soft nucleophiles (e.g. carboxylate, thiolate) usually attack the β-carbon, whereas hard nucleophiles (e.g. hydroxide, methoxide, organolithium compounds) tend to target the carbonyl group. In certain cases, altering the conditions (e.g. N-substituent, solvent) directs the mode of addition. For example, ammonia in THF at 0 °C attacks the β-position of (**1**) to give the protected α,β-diaminopropanoic acid (**6**), whereas the same nucleophile in acetonitrile reacts with acyl oxygen cleavage to produce serine amide (**5**) (eq 2).[7] However, acetonitrile enhances β-attack by ammonia in the case of the *N*-Boc lactone (**2**).[8]

A variety of heteroatom nucleophiles have proven suitable for the desired ring-opening at the β-position (eq 3), such as Nu^- = NH_3, NMe_3, OAc^-, SBn^-, Cl^-, Br^-, pyrazole, and thiourea (S-attack).[7] Sulfur nucleophiles appear to require protic solvent for good results in this process.

Carbon-carbon bond formation can be achieved with copper-catalyzed Grignard reagents (eq 4), or less cleanly with organolithium-derived cuprate reagents (R_2CuLi or $R_2Cu(CN)Li_2$).[9] Thus Cbz-serine β-lactones behave like chiral enone equivalents, with 1,4-attack of the carbanion at the β-position leading to amino acids and 1,2-attack leading to ketones or even alcohols. Hard organometallics, such as copper-free organolithium or Grignard reagents, react primarily at the carbonyl group, but the organocuprates add at the β-carbon to produce the desired amino acids (**8**) in good to moderate yields. The magnesium plays a key role in this reaction in terms of regioselectivity, optical purity (>99.4 % ee), and yield. The lithium cuprate reagents show less regioselectivity and in certain cases (e.g. R = Ph) can lead to some epimerization at the α-carbon. Temperature control (-23 °C is often ideal) is critical in reactions of (**1**) with organometallic reagents.

(4)

(1) R = alkyl, vinyl, Ph (8)

Acyl-oxygen cleavage of the serine β-lactone, although not desired in most cases, has been employed for the synthesis of (*S*)-2-methyl-4-benzyloxycarbonylaminopyrazolidine (**10**). Methylhydrazine in dichloromethane adds regioselectively to the carbonyl group of (**1**) to afford the hydrazide (**9**), which after several steps affords (**10**) (eq 5).[10]

(5)

(9) (10)

The anionic polymerization of *N*-benzyloxycarbonyl-L-serine β-lactone leads to poly(*N*-acyl-L-serine ester) (M_w = ca. 40 000), from which poly(L-serine ester hydrochloride) can be obtained by hydrogenation.[11]

Other 3-Aminooxetanones.

Various other α-amino-β-lactones have been prepared and used in amino acid syntheses. The Boc derivative (**2**),[6-9,12-14] the tosylate salt (**3**),[4,15] and the recently published *N*-Fmoc-L-serine β-lactone[16] generally exhibit similar reactivity towards nucleophiles (e.g. phosphites[14,16]), and the choice of β-lactone can often be determined by requirements of subsequent synthetic steps. However, some differences have been observed. In addition to the ammonia reaction described above,[7,8] the condensation of β-mercaptoethylamine (**11**) with (**1**) results in nucleophilic attack by nitrogen leading to (**12**), whereas the same nucleophile attacks the tosylate salt (**3**) with reverse chemoselectivity giving the corresponding amino acid (**13**) (eq 6).[7,15] The salt (**3**) has the advantage of producing free amino acids in cases where deprotection of nitrogen may affect the β-substituent.

The L-threonine β-lactone (**14**), in contrast to the serine β-lactones, has been synthesized by carboxyl group activation (4-*exo*-*trig*).[17] Initial experiments have shown that ring opening of such β-substituted lactones tends to proceed by attack at the carbonyl except with certain nucleophiles (e.g. thiourea, halides). However, correct choice of N-protecting group allows the synthesis of a range of other β-substituted α-amino-β-lactones,[17b,c] such as the antiobiotic obaflourin (**15**).[18]

(14)

(15)

In summary, ring opening of serine-β-lactones is an attractive method for generating optically pure β-substituted alanines; the synthesis usually occurs with little or no epimerization.

2-[2-[(Benzyloxy)ethyl]-6,6-dimethylbicyclo[3.3.1]-3-nonyl]-9-borabicyclo[3.3.1]nonane

[81971-15-5] · $C_{26}H_{39}B$ · 2-[2-[(Benzyloxy)ethyl]-6,6-dimethylbicyclo[3.3.1]-3-nonyl]-9-borabicyclo[3.3.1]nonane · (MW 378.41)

(asymmetric reducing agent[1])

Alternate Name: NB-Enantrane®.

Solubility: sol most organic solvents.

Form Supplied in: 0.5M solution in THF; commercially available.

Preparative Methods: NB-Enantrane[2] may be prepared by hydroboration of nopol benzyl ether (commercially available, or from nopol and benzyl bromide[1a]) with ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) (eq 1).

Handling, Storage, and Precautions: NB-Enantrane is an air-sensitive reagent and must be handled under an inert atmosphere. Use in a fume hood.

Asymmetric Reductions.

NB-Enantrane is an analog of ***B-3-Pinanyl-9-borabicyclo[3.3.1]nonane*** (Alpine-Borane[1b]). Since the absolute configuration of nopol is the opposite of (+)-α-pinene, the reagent provides the opposite mode of asymmetric induction. The reagent provides higher asymmetric induction than Alpine-Borane for cases where the two groups flanking the ketone are relatively small, such as methyl or ethyl alkynyl ketones (eq 2).

Reduction occurs via transfer of the tertiary hydride, which is β to the boron. Since this is the hydride added during the hydroboration process, labeled material may be obtained by using labeled 9-BBN in the initial preparation. The absolute configuration of the product may be predicted by using a simple six-membered ring model (**1a**) for the transition state. The larger group is placed away from the reagent in this arrangement.

(1a) favored **(1b)** disfavored

The reagent presumably leads to higher asymmetric induction because of the increased size of the nopol side chain. Brown has shown that replacing the vinylic methyl group of α-pinene with larger groups also leads to higher asymmetric induction (eq 3).[3]

(3)

Borohydride Reagent.

Treatment of NB-enantrane with ***t-Butyllithium*** provides the lithium trialkylborohydride NB-Enantride® (eq 4).[4] This reagent is an effective asymmetric reducing agent for acetophenone and alkyl methyl ketones such as 2-octanone (eq 5). Few reagents show selectivity for such alkyl ketones.

Benzyloxyhydroxamic Acid

[3426-71-9] · $C_8H_9NO_3$ · Benzyloxyhydroxamic Acid · (MW 167.16)

(precursor to a benzyloxy nitroso carbonyl compound which can function as a dienophile in Diels-Alder reactions[1])

Physical Data: mp 65-70 °C.

Solubility: sol water; slightly sol organic solvents.

Form Supplied in: solid; widely available.

Benzyloxyhydroxamic acid generates benzyl nitrosoformate upon oxidation with a tetraalkylammonium periodate. Treatment of in situ generated benzyl nitrosoformate with dienes gives cyclic adducts in good yield. Baldwin and co-workers reported the first total synthesis of tabtoxin by utilizing the Diels-Alder reaction of a benzyl nitrosoformate with a suitable cyclohexadiene.[1] Thus ethyl cyclohexa-1,3-dienecarboxylate reacted with benzyl nitrosoformate (generated in situ from *N*-benzyloxyhydroxamic acid and tetraethylammonium periodate) to yield a single isomer (eq 1). The resulting adduct was then converted to tabtoxin in a few steps.

Recently, Hudlicky[2] and Martin[3] have successfully used [4 + 2] cycloaddition of benzyl nitrosoformate with a substituted cyclohexadiene in synthetic studies directed toward lycoricidine (eqs 2 and 3).

The dimethyl acetals of (*E*)-2,4-pentadienal and (*E*,*E*)- and (*E*,*Z*)-2,4-hexadienals undergo regio- and stereospecific cycloaddition reactions with benzyl nitrosoformate (eq 4).[4] Similarly, this reagent reacts with a 1-silyloxy diene to give regioisomeric cycloadducts in good yield (eq 5).[5]

Martin has reported that benzyloxyhydroxamic acid, as well as other hydroxamic acids such as ***Benzohydroxamic Acid*** and phenylacetohydroxamic acid, is smoothly oxidized to the corresponding acylnitroso compound under Swern conditions ($(COCl)_2$, DMSO, CH_2Cl_2; then NEt_3) at -78 °C. This protocol has also been used to generate chiral nitroso carbamates, which afford [4 + 2] cycloadducts in excellent yield and with high diastereomeric excess (eq 6).[6]

Related Reagents.

Benzohydroxamic Acid; ***Nitrosocarbonylmethane***.

1-(Benzyloxymethoxy)propyllithium

[83876-83-9] · $C_{11}H_{15}LiO_2$ · 1-(Benzyloxymethoxy)propyllithium · (MW 186.18)

(reagent for enantioselective nucleophilic α-hydroxyalkylation; example for several similar reagents)

Form Supplied in: in situ generation at low temperature in THF, ether, or hexane.

Preparative Method: the (preferentially enantioenriched) reagent is generated by tin-lithium exchange of [1-(benzyloxymethoxy)propyl]tributylstannane (eq 1)[1] which proceeds with stereoretention. The lithium carbanion is configurationally stable in THF below approx -40 °C. The nonracemic precursor is obtained by classic[1a] or enzymatic[2] resolution of the α-stannylalkanol, asymmetric reduction[3] of acylstannanes (eq 2), or from chiral (1-chloroalkyl)boronates.[4]

Handling, Storage, and Precautions: solution in THF must be kept under exclusion of air or moisture below -40 °C.

Reactions.

Alkylation[1a] with ***Dimethyl Sulfate*** and carboxylation[5] proceed with complete stereoretention to yield BOM-protected (*S*)-2-butanol[1a] or (*S*)- or (*R*)-2-hydroxybutanoic acid (eq 3).[5] Analogously prepared (*S*)-1-(methoxymethoxy)propyllithium undergoes clean Michael addition to *N*,*N*´,*N*´-trimethylacryloylhydrazide, and the product can be converted to (*S*)-4-hexanolide (eq 4).[6] The acylation of the (*R*) enantiomer by an *N*,*N*-dimethylalkanamide leads to an α-hydroxy ketone, which was converted to (+)-*endo*-brevicomin (eq 5).[7]

The addition of the lithium reagent to aldehydes gives monoprotected *syn*- and *anti*-*vic*-1,2-alkanediols with low diastereoselectivity (eq 6),[8] which is improved in favor of the *syn* diastereomers by lithium-magnesium exchange and by application of β-branched analogs.[8] Higher and opposite diastereoselectivity is achieved with the appropriate tributyltin or tributyllead reagents under Lewis acid catalysis; however, acetal O-protecting groups are not tolerated (eq 7).[9]

Racemates		
M = Li	53:47	75%
M = MgBr	63:37	77%

Racemates		
M = Sn, LA = $TiCl_4$	99:1	90%
M = Pb, LA = $BF_3 \cdot OEt_2$	20:80	54%

The cuprate reagents, derived from 1-(methoxymethoxy)alkyllithium, undergo 1,4-addition to enones[10] and to enals (in the presence of ***Chlorotrimethylsilane***) (eq 8).[11] Enantioenriched reagents racemize under these conditions.[12]

Related Reagents.

1-Lithioalkyl *N*,*N*-dialkylcarbamates are generally accessible by direct deprotonation of alkyl carbamates,[13] either in racemic form or highly enantiomerically enriched (see ***(-)-Sparteine***) (eq 9). Sterically blocked lithiated alkyl benzoates do not permit alkyl substitution at the carbanionic center.[14] Preexisting stereogenic centers in the precursor cause an efficient internal, kinetically controlled, chiral induction in the deprotonation step.[15] This was demonstrated by the synthesis of (2*S*,4*S*)-2-hydroxy-4-pentanolide (eq 10)[15a] from (*S*)-2,3-butanediol and of protected (2*S*,3*S*)-2-hydroxy-3-amino acids (eq 11)[15b] and the chain elongation of 2-amino alkanols.[15b]

Racemic 1-methoxyalkyllithium[16] reagents are easily obtained from monothioacetals by reductive lithiation[17] with lithium salts of radical anions, such as ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN).[18] The method is particularly useful for the preparation of substituted 2-lithiotetrahydropyrans[19] and 2-lithiotetrahydrofurans.[19] The axial lithium compound is preferentially formed from the radical intermediate under kinetic control, irrespective of the relative configuration of the precursor; it epimerizes above -30 °C to form the more stable equatorial epimer (eq 12).[19,20]

(12)

Protected phenylthio- and phenylsulfonyl-2-deoxypyranosides were also subjected to these conditions and substituted by electrophiles via the 1-lithiopyranosides.[21] Both α- and β-1-(3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranosyl)cuprates, prepared by these methods, undergo highly stereoselective conjugate additions to enals and enones (eq 13).[22]

(13)

Even (3,4,6-tri-*O*-benzyl-2-*O*-lithio-α-D-glucopyranosyl)lithium can be generated and added to aldehydes (eq 14).[23]

4-Lithio-1,3-dioxanes[19c,24] derived from chiral 1,3-diols are similarly generated and proved to be versatile building blocks in the stereoselective synthesis of polyols, such as 1,3,5,7,9,10-decanehexaol (eq 15).

(*SP*-4-4)-[(*S*)-[*o*-(1-Benzyl-2-pyrrolidinecarboxamido)-α-phenylbenzylidene]glycinato(2-)-*N,N´,N´´,O*[1]]nickel

[96293-17-3] · $C_{27}H_{25}N_3NiO_3$ · (*SP*-4-4)-[(*S*)-[*o*-(1-Benzyl-2-pyrrolidinecarboxamido)-α-phenylbenzylidene]glycinato(2-)-*N,N´,N´´,O*[1]]nickel · (MW 498.20)

(used in asymmetric alkylations,[1] 1,2-additions,[2] and 1,4-additions[3] to prepare α-amino acids)

Alternate Name: nickel(II) nitrate-(*S*)-*o*-(benzylprolylamino)benzophenone-glycine

Physical Data: diamagnetic, mp 208-212 °C.

Solubility: sol $CHCl_3$; insol MeOH.

Form Supplied in: not commercially available; prepared as a red solid.[1]

Preparative Method: prepared by condensation of (*S*)-*o*-[(*N*-benzylprolyl)amino]benzophenone (BBP) with glycine in the presence of nickel(II) nitrate in methanol.[1]

Purification: purified by sequential chromatography over silica gel and Sephadex LH-20, or by dry flash chromatography.[1]

Handling, Storage, and Precautions: care should be taken in applying samples to purified Sephadex. The addition of basic media can present an explosion hazard.

Alkylations.

The high kinetic stability of the Ni^{II}-BBP-glycine complex (**1**) permits alkylation and halogenation of its derived enolate. Alkylations mediated by powdered alkali in DMF, MeCN, or aqueous acetone have proven superior, though other methods are known (eq 1).[1] Substituents introduced in this fashion kinetically and thermodynamically prefer the face opposite the *N*-benzyl group. Consequently, the (*S*)-proline derived complex instills high (*S*) selectivity in alkylation products. Electrophilic bromination at this site licenses subsequent attack by nucleophiles (eq 2).[5] Electrophilic attack at nitrogen frequently precludes the use of free glycine in this synthesis. The title reagent solves this problem through protection of the amino group as its Schiff's base.[6] Chromatographic separation of the alkylated complexes followed by acidic hydrolysis liberates α-amino acids of high optical purity. As a consequence, (**1**) has been used as a chiral building block for fluorinated phenylalanines and pharmaceutically important radiolabeled amino acids.[1,7,8]

(1) α:β = 9:1

1,2-Additions.

Increased C-H acidity (pK_a = 18.8 in DMSO) facilitates condensation of the complex with aldehydes and ketones, while the use of free glycine is generally problematic.[9,10] The stereochemical outcome at the α-carbon parallels those of alkyl halide alkylations.[11] Thus the Ni^{II}-BBP-glycine complex provides a route to asymmetric aldols and *anti* β-substituted α-aminobutanoic acids (eqs 3 and 4).

1,4-Additions.

Glycine complex (**1**) undergoes asymmetric conjugate addition to α,β-unsaturated esters, nitriles, aldehydes, and ketones.[3] Judicious selection of alkene leads to (*S*)-glutamic acids, though vigorous conditions (concd HCl, 100 °C) are employed for hydrolysis. The high levels of enantioselectivity achieved by this method have culminated in an asymmetric synthesis of proline derivatives (eq 5).[4]

Related Reagents.

Other conceptually related materials used for asymmetric amino acid synthesis include benzophenone imines derived from α-amino esters, α-amino esters temporarily protected as the derived acetals, and bislactim ethers.[12]

N-Benzylquininium Chloride

[67174-25-8] · $C_{27}H_{31}ClN_2O_2$ · *N*-Benzylquininium Chloride · (MW 451.01)

(chiral, nonracemic quaternary ammonium salt; catalyst for a variety of phase transfer reactions under basic conditions[1])

Alternate Names: Quibec; BQC.

Physical Data: mp 180-181 °C, [α]19D -235.5° (*c* = 1.5, H_2O);[2] monohydrate: mp 169-172 °C (dec), $[\alpha]_D$ -212.5° (*c* = 0.5, EtOH).[3]

Solubility: freely sol H_2O, alcohols, acetone; slightly sol EtOAc; sparingly sol $CHCl_3$.[4]

Form Supplied in: solid.

Purification: recrystallized from absolute EtOH.[3]

The combined use of catalytic amounts of *N*-benzylquininium chloride (**1**) with hydroxide bases (NaOH or KOH) has been explored for a variety of phase transfer reactions, including epoxidations, alkylations, and Michael reactions. The degree of stereoselectivity in product formation induced by the reagent can vary widely.[5]

BQC is derived from quinine, which is a member of the *cinchona* family of alkaloids. Ammonium salts derived from quinidine, a diastereomer of (**1**) at the hydroxyl substituent, have been used less frequently in catalysis than BQC. Quinidinium salts often give rise to products with enantioselectivity opposite to that from (**1**). Other related compounds, such as those derived from cinchonine and cinchonidine (which lack the methoxy substituent on the

quinoline nucleus), have found application in organic synthesis. The *cinchona* alkaloids, as well as salt derivatives in which the benzyl group bears various substituents, have also been studied.[6] Results from polymer-bound catalysts have not been promising.[7]

Benzylquininium chloride has shown good to excellent selectivity in the epoxidation of α,β-unsaturated ketones.[8] Oxidation of quinone (**2**) in the presence of (**1**) with aqueous ***t-Butyl Hydroperoxide*** and ***Sodium Hydroxide*** in toluene gave rise to a 95% chemical yield of epoxide (**3**) in 78% ee (eq 1).[2] Recrystallization improved the ee to 100% with 63% mass recovery. Aqueous ***Hydrogen Peroxide*** decreased both the yield (89%) and enantioselectivity (50% ee).

Enantiomerically enriched epoxides have also been generated using (**1**) in the Darzens reaction of α-chloro ketones with aldehydes, as well as through ring closure of racemic halohydrins.[9] The extent of enantioselectivity for both reactions is similar (optical purity 6-8% ±1), suggesting a moderate degree of kinetic resolution occurring in each case.

Benzylquininium chloride has been studied as a catalyst for the asymmetric Michael reaction. Reaction of amidomalonate (**5**) and chalcone (**4**) with catalytic base and a variety of chiral, nonracemic ammonium salts in the absence of solvent produced (**6**) in yields of 41-68% and 20-68% ee (eq 2).[10] The quinine-derived salt (**1**) was of intermediate effectiveness (38% ee, 47% yield) when compared to ephedrine-based catalysts. Although (**1**) was not specifically tested with regard to solvation effects, it is suggested that increased aggregation of reactive species under solid-liquid PTC conditions leads to enhanced organization and selectivity. Low levels of induction have been observed in other systems.[11] A study comparing various chiral alkaloid salts, bases, and reaction conditions on enantioselectivities in the conjugate addition of thiols and nitroalkanes to enones has been reported.[12] Remarkable results have also been obtained in the cinchonium/cinchonidinium-catalyzed reaction of an indanone with methyl vinyl ketone.[13] A direct comparison with a more efficient lanthanum-binaphthol complex has been reported.[14]

(2)

Phase-transfer alkylations have been studied using *cinchona* alkaloid derivatives; however, results have been more promising with the cinchonium/cinchonidinium series than with the quininium/quinidinium group.[15] For example, catalytic asymmetric alkylation in high yield and selectivity has been achieved with *N*-(*p*-trifluoromethylphenyl)cinchonium bromide (*p*-CF_3BCNB) (eq 3).[16] A systematic investigation of reaction variables (catalyst type, solvent, concentration, temperature, stirring rate, leaving group, etc.) has produced a general method to prepare α-amino acids in 44-62% ee.[17]

Benzylsulfonyldiazomethane[1]

[1588-80-3] · $C_8H_8N_2O_2S$ · Benzylsulfonyldiazomethane · (MW 196.22)

(safe, nonexplosive, shelf-stable substitute for diazomethane;[2] performs similar reactions such as ring expansions[3] and Arndt-Eistert syntheses;[4] enables the preparation of various substituted benzyl sulfones)

Alternate Name: BSDM.

Physical Data: mp 98-99 °C; bright yellow solid.

Solubility: sol halogenated organic solvents.

Form Supplied in: not available commercially.

Preparative Methods: from the corresponding urethane via nitrosation with nitrosyl chloride followed by rearrangement on neutral alumina,[2] or via reaction of ethyl benzylsulfonylacetate with tosyl azide in the presence of triethylamine.[5]

Handling, Storage, and Precautions: no toxicological data available; nonexplosive; stable for over 4 months at -20 °C. Use in a fume hood.

Diazomethane Substitute Reactions.

Many reactions of benzylsulfonyldiazomethane (BSDM) are analogous to those of ***Diazomethane***, for which it was developed as a replacement. When treated with BSDM in the presence of ***Titanium(IV) Chloride***, cycloalkanones are converted to the corresponding ring-expanded α-benzylsulfonyl ketones. These are then converted to the synthetically useful vinyl sulfones upon bromination followed by exposure to silver ion (eq 1).[3] BSDM also serves well for the preparation of α-diazo α-sulfonyl ketones, which are Wolff rearrangement precursors (eq 2).[6] The α-benzylsulfonyl diazo ketones are also convertible to α-sulfonyl esters by treatment with alcohols (eq 3).[4]

α-Substituted Sulfones.

When treated with ***Nitrosyl Chloride***, BSDM affords three products, the major one being the α-chloro sulfone. The oxime, also produced, is of interest as a precursor to nitrile oxides (eq 4).[1] Reaction with sulfenyl chlorides affords α-chloro α-sulfenyl sulfones (eq 5),[7] while ***t-Butyl Hypochlorite*** in alcohol solvent enables the synthesis of α-alkoxy α-chloro sulfones, wherein the alkoxy substituent is derived from the solvent (eq 6).[8] Finally, exposure of BSDM to ***p-Toluenesulfonic Acid*** provides the corresponding α-tosylate in 88% yield.[5]

(*S*)-4-Benzyl-2,2,5,5-tetramethyloxazolidine

[144899-42-3] · $C_{14}H_{21}NO$ · (*S*)-4-Benzyl-2,2,5,5-tetramethyloxazolidine · (MW 219.33)

(chirality-controlling auxiliary[1])

Physical Data: colorless liquid; IR,[2] ^{1}H NMR,[1] and ^{13}C NMR[2] spectra are available.

Solubility: very sol in most organic solvents; decomposition occurs in protic solvents.

Handling, Storage, and Precautions: decomposes on silica gel column chromatography; recommended not to be stored for a long time.

Introduction.

(*S*)-4-Benzyl-2,2,5,5-tetramethyloxazolidine is used as a chirality-controlling auxiliary. Its amide derivatives preferentially occupy the *syn* conformation[1] so that one of the π-facial reaction sites of the amide moiety becomes sterically less hindered. This chiral auxiliary will be especially useful for the asymmetric reactions which have to be performed in the absence of metallic additives.

Preparation and Stability.

Since *N*-unsubstituted oxazolidines are labile to hydrolysis, they should be transformed immediately after preparation to amide derivatives, which show much higher stability. Thus reaction of (*S*)-3-amino-2-methyl-4-phenyl-2-butanol[3] with acetone in the presence of a catalytic amount of ***p-Toluenesulfonic Acid*** produces (*S*)-4-benzyl-2,2,5,5-tetramethyloxazolidine. *N*-Acylation using acryloyl, cinnamoyl, and propanoyl chloride (Et_3N, -78 °C) gives the corresponding amides. The *N*-crotonoyl derivative is better obtained by the crotonoylation of (*S*)-3-amino-2-methyl-4-phenyl-2-butanol followed by acetalization with $(Me)_2C(OMe)_2$.

Unsaturated Amides.

Cycloaddition of (*S*)-3-acryloyl-4-benzyl-2,2,5,5-tetramethyloxazolidine with ***Benzonitrile Oxide*** proceeds smoothly at 0 °C to provide the corresponding oxazolidine in a 93:7 diastereomer ratio (eq 1),[4] which is quantitatively reduced with ***Lithium Triethylborohydride*** to give the isoxazoline-5-methanol derivative without loss of enantiomeric purity. A single diastereomer of isoxazoline can be obtained when 3-acryloyl-2,2-dimethyl-4-diphenylmethyloxazolidine is employed.[4]

(1)

Conjugate additions of organocuprates to (*S*)-4-benzyl-3-crotonoyl-2,2,5,5-tetramethyloxazolidine in the presence of ***Chlorotrimethylsilane*** (1.2 equiv) also proceed in a highly diastereoselective manner (eq 2) to give, after the acid-catalyzed hydrolytic removal of the chiral auxiliary, optically pure carboxylic acids with β-chirality.[5]

(2)

Amide Enolates.

The lithium (*Z*)-enolate can be generated from (*S*)-4-benzyl-3-propanoyl-2,2,5,5-tetramethyloxazolidine and ***Lithium Diisopropylamide*** in THF at -78 °C. Its alkylations[6] take place smoothly in the presence of ***Hexamethylphosphoric Triamide*** with high diastereoselectivity (eq 3), and its Michael additions[7] to α,β-unsaturated carbonyl compounds are also exclusively diastereoselective (eq 4). Synthetic applications have been made in the aldol reactions of the titanium (*Z*)-enolates of α-(alkylideneamino) esters.[8]

3-Benzylthiazolium Bromide[1]

[75066-50-1] · $C_{10}H_{10}BrNS$ · 3-Benzylthiazolium Bromide · (MW 256.16)

(in combination with base is a redox catalyst for the oxidation of aldehydes coupled with the reduction of organic compounds[2])

Physical Data: mp 155-156 °C.

Solubility: freely sol methanol; sol ethanol, DMSO, and DMF; sparingly sol chloroform, dichloromethane, and acetone; insol THF, benzene, and ethyl acetate.

Form Supplied in: white columnar crystals.

Analysis of Reagent Purity: ^{1}H NMR (DMSO-d_6, 270 MHz) δ 5.82 (s, 2H, CH_2), 7.41-7.53 (m, 5H, C_6H_5), 8.37 (dd, 1H, H-5, *J* = 3.7 and 2.4 Hz), 8.61 (dd, 1H, H-4, *J*= 3.7 and 1.8 Hz); 10.40 (dd, 1H, H-2, *J* = 2.4 and 1.8 Hz).

Purification: recrystallized from 5:1 benzene/ethanol.

Handling, Storage, and Precautions: the reagent is somewhat hygroscopic and should be dried before use.

Oxidation of Aldehydes to Methyl Esters.

3-Benzylthiazolium bromide, in methanol containing ***Triethylamine***, catalyzes a redox reaction in which aldehydes are oxidized to methyl esters, and certain organic compounds such as acridine, phenazine, azobenzene, and nitrobenzene are reduced.[2] The redox reactions are carried out as follows. Triethylamine (5*n* mmol) and the substrate (4*n* mmol) are added to a frozen solution of a mixture of aldehyde (6*n* mmol) and 3-benzylthiazolium bromide (*n* mmol) in degassed methanol (10*n* mL). The solution, after melting, is stirred under argon at rt for a 20-h period. To increase the yield in the redox reaction, an excess of aldehyde is added. The presence of air in methanol results in the production of methyl esters by oxidation of aldehydes.

The mechanism of this process is outlined in eq 1. The thiazolium salt is first transformed into an ylide by the action of

triethylamine[3] and the ylide then reacts with the aldehyde to form an adduct (active aldehyde)[4] which undergoes a redox reaction with the organic substrate in methanol to give a methyl ester and the reduced form of the substrate (eq 1).

Acridine is reduced by benzaldehyde, 2-furaldehyde, and heptanal in the presence of 3-benzylthiazolium bromide and triethylamine in degassed methanol to give 9,9´-biacridan in satisfactory yields, while aldehydes are oxidized to the corresponding methyl esters (eq 2).[2] The excess aldehydes are converted into α-hydroxy ketones by benzoin condensation.[5] The redox reaction is thought to proceed via the transfer of electrons from the active aldehyde to acridine.

R = Ph	87%	93%
R = 	30%	40%
R = $Me(CH_2)_5$	67%	72%

T^+Br^- = 3-benzylthiazolium bromide

Phenazine and azobenzene are reduced, under similar conditions, to 5,10-dihydrophenazine (eq 3) and hydrazobenzene (eq 4), respectively; the latter is converted into benzidine on treatment with hydrochloric acid after the reaction.[2] Nitrobenzene is reduced to aniline and *N*-benzoyl-*N*-phenylhydroxylamine (eq 5).[2,6]

Benzyl *p*-Toluenesulfonate

[1024-41-5] · $C_{14}H_{14}O_3S$ · Benzyl *p*-Toluenesulfonate · (MW 262.32)

(benzylating agent for heteroatomic functional groups and enolate anions)

Alternate Name: benzyl tosylate.

Physical Data: mp 58 °C.

Solubility: sol alcohols, ether, and aromatic solvents.

Preparative Method: typically prepared from tosyl chloride and benzyl alcohol.[1]

Handling, Storage, and Precautions: may be stored as a crude or purified solid at 0 °C for up to 3 months; potential vessicant. Use in a fume hood.

Benzylation of Heteroatomic Functional Groups.

Phenols are benzylated with this reagent under basic conditions. The regioselectivity, when more than one phenol is present in the substrate, favors the less sterically hindered hydroxy group (eq 1).[2] In the case of phenols where *C*-alkylation commonly accompanies *O*-alkylation, benzyl tosylate gives higher selectivity for *O*-alkylation than ***Benzyl Chloride***.[2] This is illustrated in the benzylation of a phloroglucinol derivative, where benzyl chloride afforded only 18% of the desired product under similar reaction conditions (eq 2).

(1)

Lactams[3] and vinylogous amides[4] can be selectively *N*-benzylated under basic conditions with this reagent (eq 3). Methylamine affords benzylmethylamine when reacted in excess with benzyl tosylate in ether.[5]

Benzyl 3-(Tributylstannyl)acrylate

(*E*)

[86633-19-4] · $C_{22}H_{36}O_2Sn$ · Benzyl 3-(Tributylstannyl)acrylate · (MW 451.22) (*Z*)

[86633-18-3]

(this reagent, along with the corresponding ethyl and methyl esters, are useful partners for Pd^0-catalyzed coupling reactions with a variety of substrates including aryl triflates,[1-3] aryl bromides[4] and iodides,[5,6] vinyl triflates,[7,8] vinyl iodides,[9-13] allylic chlorides,[14] acyl chlorides,[15-17] and sulfonyl chlorides[18])

Physical Data: colorless oil.

Solubility: sol THF, $CHCl_3$.

Preparative Methods: the benzyl acrylates (**1**) and (**2**) can be obtained by nonstereoselective hydrostannylation of benzyl propynoate (eq 1).[15,20] Mixtures of substances (**3**) and (**4**)[10] and of (**5**) and (**6**)[13,21] have been prepared in similar fashion (eq 1). In each case the geometric isomers are chromatographically separable. The stereocontrolled synthesis of (**3**) can be achieved by sequential treatment of (*E*)-1,2-bis(tributylstannyl)ethene with an alkyllithium and $ClCO_2Et$.[22,23] On the other hand, stereospecific syntheses of (**5**) and (**6**) have been achieved by reaction of methyl (*E*)- and (*Z*)-3-chloro (or iodo)acrylates with Bu_3SnCu[24] (see ***Tri-n-butylstannylcopper***).

Handling, Storage, and Precautions: since organotin compounds are toxic,[19] reactions preparing and employing the reagent should be carried out and worked up in a fume hood.

Reaction with Aryl Triflates and Halides.

The Pd^0-catalyzed couplings of reagents (**1**)-(**6**) with aryl triflates[1-3] or halides[4-6] constitute a useful method for the direct incorporation of a 2-(alkyoxycarbonyl)vinyl moiety into aromatic systems. Examples are shown in eqs 2-4.[1,3,6] As indicated by eq 2, the couplings employing the (*Z*) reagents (**2**), (**4**), and (**6**) are generally more sluggish than those employing the corresponding (*E*) isomers. Furthermore, the reaction of (**7**) with (**2**) is not stereoselective.[1] On the other hand, the interesting cross-coupling reaction involving tricarbonyl(iodo-η^5-cyclopentadienyl)methyltungsten and the (*Z*) acrylate (**6**) (eq 4) proceeds in a completely stereoselective fashion, with retention of reagent stereochemistry.[6]

(3)

(4)

Reaction with Vinyl Triflates and Iodides.

The Pd^0-mediated couplings of reagents (**1**)-(**6**) with vinyl triflates[7,8] and iodides[10-13] produce a valuable method for the stereocontrolled synthesis of substituted alkyl 2,4-alkadienoates (eqs 5-8).[8,10,12] This carbon-carbon bond-forming process appears to be stereospecific (eqs 6-8). In contrast, formation of the unsymmetrical divinyl ketone (**9**) via cross-coupling of 1-iodocyclohexene with the (*Z*)-acrylate (**2**) in the presence of CO is not stereoselective (eq 9).[9] The mechanism of this process has been discussed in detail.[9]

(9)

Reaction with Allylic Chlorides.

Reaction of allyl halides with vinylstannanes in the presence of a Pd^0 catalyst provides, efficiently, cross-coupled products. An example of this process involving the (*Z*)-acrylate (**2**) is shown in eq (10).[14] The substitution reaction takes place with overall inversion of configuration, while the stereochemistry of the acrylate moiety is retained.

(10)

Reaction with Acyl and Sulfonyl Chlorides.

Acyl and sulfonyl chlorides react with 3-tributylstannylacrylates in the presence of Pd^0 to give alkyl 4-oxo-2-alkenoates[15-17] and β-alkoxycarbonyl-α,β-unsaturated sulfones,[18] respectively (eqs 11 and 12).[16,18] In each case the configuration of the product is (*E*), regardless of the stereochemistry of the acrylate reagent.[15,17,18] Intramolecular versions of the acyl chloride coupling process have been employed to prepare macrocyclic substances,[25] including the macrodiolide (*R*,*R*)-(-)-pyrenophorin.[25c]

(11)

(12)

Miscellaneous Reactions.

Reagent (**3**) has been used as a dienophile in Diels-Alder reactions[22] and has been converted into the synthetically useful epoxide ethyl (*E*)-3-tributylstannyl-2,3-epoxypropanoate.[26] The methyl acrylates (**5**) and (**6**) have been employed in effecting a highly stereoselective radical substitution process (eq 13),[27] which played a key role in a total synthesis of the natural product bulgecin C.[27]

Benzyl 2,2,2-Trichloroacetimidate

[81927-55-1] · $C_9H_8Cl_3NO$ · Benzyl 2,2,2-Trichloroacetimidate · (MW 252.53)

(reagent for protection of hydroxy groups as benzyl ethers under mildly acidic conditions[1])

Alternate Name: BTCA.

Physical Data: bp 106-114 °C/0.5 mmHg; *d* 1.359 g cm^{-3}

Solubility: reactions are most often carried out in a mixture of cyclohexane/dichloromethane;[1] decomposition by rearrangement to *N*-benzyl trichloroacetamide is accelerated in more polar solvents.

Form Supplied in: colorless oil.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: moisture sensitive.

Hydroxy Group Protection.

The benzyl ether is one of the most versatile and frequently used protecting groups in organic synthesis.[2] The most common way of introducing this group is with a strong base and ***Benzyl Bromide*** using the classical Williamson ether synthesis methodology. Recently, benzyl trichloroacetimidate[3] has found widespread use to protect hydroxy functionalities as their benzyl ethers under mildly acidic conditions,[1,4,5a] when the more conventional strong base-mediated methods either failed or gave lower yields due to side reactions and/or starting material decomposition.

The imidate can be prepared from the sodium alkoxide ion of benzyl alcohol and trichloroacetonitrile according to procedures based on those developed by Cramer[3] in the late 1950s. Substituted benzyl ethers have also been prepared this way, for example using 4-methoxybenzyl trichloroacetimidate,[5] 3,4-dimethoxybenzyl trichloroacetimidate,[6] and 2,6-dichlorobenzyl trichloroacetimidate,[7] and the method has also been applied for the synthesis of allyl[1b] and *t*-butyl ethers,[8] as well as for 2-phenylisopropyl esters[9] for peptide synthesis. The benzyl and 4-methoxybenzyl 2,2,2-trichloroacetimidates are available commercially.

The reaction is performed in nonpolar media to prevent rearrangement of the acetimidate to *N*-benzyl trichloroacetamide, and as an added advantage the solid trichloroacetamide byproduct can simply be removed by filtration. These constraints limit the substrate range to those molecules soluble in this type of solvent; for example, a sugar triol which was insoluble in dichloromethane, when reacted in DMSO yielded very little of the benzylated product desired.[10] It was also noted that differential (primary versus secondary) hydroxy protection in carbohydrates (eq 1) was poor,[10] and the ratio of the 6-OBn to 4-OBn products was at best 2:1.

(1)

The reagent has been used widely in carbohydrate[1,10-14] chemistry. The method was found to be useful in cases where *O*-benzoyl group migration had been observed under basic conditions (eq 2),[11] and has also been applied to inositol derivatives,[15] when the same problem[15a] was encountered.

When *N*-acetyl-protected sugar amines were under investigation[1,12] the *N*-acetyl group was observed to undergo transformation to the *O*-benzyl imidate in competition with OH benzylation (eq 3). It appears for best yields at least 1 equiv of reagent per OH and NAc group is needed, and subsequent hydrolysis and reacetylation of the amine are necessary to obtain are the originally desired material. Similar problems were encountered with the morpholine derived lactams (eq 4),[16a] where mixed products were obtained, but with β-lactams[16b] with *N*-amide protection (eq 5), *O*-benzylation with benzyl trichloroacetimidate proceeded smoothly. BTCA has recently been used to convert diketopiperazines into their bis-benzyl imino ethers.[17]

(4)

(5)

Other classes of molecules which have been benzylated using this reagent include hydroxy ketones,[4] hydroxy halides[4,7,18] and esters[19-23] such as tartrates,[19] hydroxy propionates or butanoates,[20] long alkyl chain hydroxy esters,[21] and hydroxy lactones.[4] Under basic conditions problems such as enolization, aldol reactions, elimination and epoxide formation can cause problems and when 2-substituted esters, such as ethyl (*S*)-lactate,[22] are required as homochiral starting materials, then protection using this method circumvents the considerable risk of racemization that accompanies the use of bases (eq 6).

(6)

Under these benzylation reaction conditions, it has been shown that the *N*-*t*-butoxycarbonyl (N-Boc) (eq 7) and *N*-(2-trimethylsilyl)ethoxycarbonyl (*N*-TEOC) (eq 8) protected amino acid derivatives are converted into their *N*-benzyloxycarbonyl (N-Z) analogs.[24] In most cases yields were moderate, but surprisingly the *t*-butyldimethylsilyloxy and *t*-butyl ester functions are relatively unaffected by the acidic conditions.

(7)

The most frequently employed acid catalyst is TfOH (***Trifluoromethanesulfonic Acid***, or triflic acid), but others that have been used include $BF_3.OEt_2$,[4,8] TMSOTf,[4,16] *p*-TsOH,[6] and TFA.[23,16] Camphorsulfonic acid, pyridinium *p*-toluenesulfonate, and trityl perchlorate have also been investigated in conjunction with the more reactive 4-methoxybenzyl trichloroacetimidate.[5a]

Functional groups sometimes sensitive to acidic conditions such as simple esters,[1,19-23] lactones,[4,5d] acetals,[1,5a,15] epoxides,[5a,13] 2-methoxyethyloxymethyl (MEM) groups,[6] *t*-butyldimethylsilyl ethers,[14,24-27] and orthoformates[15b] are generally unaffected by the catalytic amounts of acid used, although some tertiary alcohols[4] and 1-trimethylsilylalkynes[4] have been noted to give poor yields.

Related Reagents.

Benzyl Bromide; ***Benzyl Chloride***; ***Benzyl Iodide***; ***Benzyl Trifluoromethanesulfonate***; ***3,4-Dimethoxybenzyl Bromide***; ***4-Methoxybenzyl 2,2,2-Trichloroacetimidate***.

Benzyltriethylammonium Chloride[1]

$BnNEt_3^+ Cl^-$

[56-37-1] · $C_{13}H_{22}ClN$ · Benzyltriethylammonium Chloride · (MW 227.81)

(phase transfer catalyst[1])

Alternate Names: TEBA; TEBAC.

Physical Data: mp 185 °C (dec).

Solubility: sol acetone, alcohol, H_2O, 1% aq. NaOH; insol ether, 20% aq. NaOH.

Form Supplied in: anhydrous white solid; monohydrate also available.

Analysis of Reagent Purity: tetraalkylammonium salts can be titrated with potassium 3,5-di-*t*-butyl-2-hydroxybenzenesulfonate and iron(III) chloride.[1a]

Preparative Method: via the reaction of ***Benzyl Chloride*** with ***Triethylamine*** in absolute ethanol.[2]

Purification: precipitation from acetone with ether.[2]

Handling, Storage, and Precautions: highly hygroscopic.

Introduction.

Benzyltriethylammonium chloride is one of many commonly used phase transfer catalysts. Although in specific reactions other phase transfer catalysts have proven superior,[3] TEBA remains the reagent of choice for many reactions.

Catalyst for C-C Bond Formation.

TEBA has been used extensively in the formation of carbenes in heterogeneous systems. Dichlorocarbene[2,4] is formed from ***Chloroform*** and aqueous ***Sodium Hydroxide*** in the presence of TEBA (eq 1).[4a] Dibromocarbenes can also be generated using TEBA.[4b,4d] TEBA has been used as a means of introducing hydroxide or carboxylate ion in alkylations of nitriles,[5] cyanohydrins,[6] Schiff bases,[7] sulfones,[8] malonates,[9] and benzyl ketones.[10] Michael addition reactions[11] have been catalyzed by TEBA, as well as the condensation of *O*-benzoyl cyanohydrins,[12] malonitrile,[13] and sulfones[14]

with benzaldehyde. Condensation of 3-methyl-5-pyrazolone with ***Carbon Disulfide*** and alkyl bromides was realized under phase transfer conditions using TEBA.[15]

(1)

Catalyst for C-N Bond Formation.

TEBA has been used in the alkylation of trifluoroacetamide with α-bromo esters to form, after hydrolysis, α-amino acids (eq 2).[16] TEBA has also been used in the nitration of aromatics,[17] the alkylation of secondary amides,[18] and the dehydration of ureas to form carbodiimides.[19] Reaction of thioamides with dibromoethane and sodium hydroxide catalyzed by TEBA gives thiazolidines.[20]

(2)

Catalyst for C-O Bond Formation.

Benzyl[21] ethers have been formed using TEBA catalysis. TEBA has been used in a variety of oxidation reactions, including permanganate oxidation of longifolene[22] and benzaldehyde,[23] α-hydroxylation of benzyl nitriles giving phenyl ketones,[24] and ***Ruthenium(VIII) Oxide*** catalyzed oxidations of secondary alcohols to ketones with ***Sodium Periodate***.[25]

Catalyst for Carboxylic Acid Functionalization.

TEBA facilitates the solubilization of organic acids, permitting formation of a diacid chloride from an insoluble diacid (eq 3).[26] Organic peroxy acids can also be prepared from the corresponding acid using TEBA and potassium persulfate.[27]

(3)

Catalyst for P-X Bond Formation.

TEBA has been used in the formation of phosphorodiamidates from bis(dimethylamino) phosphorochloridate[28] and phosphate esters[29] or phosphoramidates[30] from ***Diethyl Phosphonite***. Di-*t*-butyl phosphorohalidates have been prepared from di-*t*-butyl phosphite using TEBA, carbon tetrachloride and aq. NaOH.[31]

Miscellaneous Uses.

TEBA has proven very effective in the formation of metal hydrides under phase transfer conditions;[32] for example, $(Ph_3P)_3RuHCl$ and $(i\text{-}Pr_3P)_2IrHCl_2$ are converted to $(Ph_3P)_3RuH_2(H)_2$ and $(i\text{-}Pr_3P)_2IrH_5$,[32a] respectively, upon reaction with hydrogen and aq. NaOH/benzene with TEBA. In metal carbonyl chemistry, TEBA has been used as a phase transfer catalyst.[33] TEBA has also been used in the dibromination of alkenes[34] and azide transfer reactions.[35] Selective tosylation of adenosine has been achieved using ***Di-n-butyltin Oxide***, ***p-Toluenesulfonyl Chloride***, and TEBA (eq 4).[36]

Benzyltriethylammonium Chlorochromate[1]

$[PhCH_2NEt_3]^+[CrO_3Cl]^-$

[106542-73-8] · $C_{13}H_{22}ClCrNO_3$ · Benzyltriethylammonium Chlorochromate · (MW 327.77)

(a mild and neutral oxidizing agent for benzylic and allylic alcohols[1])

Physical Data: mp 89 °C.

Solubility: fairly sol common organic solvents.

Form Supplied in: orange crystalline solid; not commercially available.

Preparative Method: ***Chromic Acid*** (10 g, 0.1 mol) in 3 M HCl (200 mL) is added to an aqueous solution (250 mL) of ***Benzyltriethylammonium Chloride*** (22.7 g, 0.1 mol). The crude product precipitates and can be recrystallized from acetone-water; yield 86%. The reagent prepared according to this procedure was initially described as bis(benzyltriethylammonium dichromate).[2] Later, it was demonstrated that the compound obtained under these conditions is actually benzyltriethylammonium chlorochromate.[3]

Handling, Storage, and Precautions: the reagent is a stable orange crystalline solid. No data have been reported about storage and precautions. Chromium(VI) derivatives are reported to be toxic agents. The reagent should be handled in a fume hood.

Oxidation of Benzylic and Allylic Alcohols.

Benzyltriethylammonium chlorochromate can selectively oxidize benzylic and allylic alcohols to the corresponding carbonyl compounds in almost quantitative yield. Yields are low (30%) for primary alkanols and cycloalkanols. The reaction can be performed in HMPA at 60-80 °C for 4-6 h.[2] Alternatively, the oxidation can be carried out under phase-transfer conditions.[3a] Yields range from 75-

99%.

The reagent can be utilized for the selective oxidation of thiols to disulfides in high yield and this method has been applied to alkanethiols, arylalkanethiols, and arenethiols.[2]

Benzyltriethylammonium Permanganate

$[PhCH_2NEt_3]^+[MnO_4]^-$

[68844-25-7] · $C_{13}H_{22}MnNO_4$ · Benzyltriethylammonium Permanganate · (MW 311.26)

(oxidant, used for the oxidation of alkanes and arenes to alcohols or ketones,[1,2] ethers to esters,[3] primary alcohols to methylene diesters,[4] secondary alcohols to ketones,[4] amines to amides,[5] aldehydes to carboxylic acids,[6] and sulfides or sulfoxides to sulfones[7])

Physical Data: [8] purple solid, decomposes at 101 °C (TDA), 127-129 °C (melting point tube).

Solubility: [8] 4.97 × 10^{-3} M in H_2O; 5.76 × 10^{-2} M in CH_2Cl_2; 4.6 × 10^{-3} M in $CHCl_3$; insol. CCl_4 and toluene.

Analysis of Reagent Purity: ε = 2530 ± 30 L mol^{-1} cm^{-1} at 526 nm[8] or iodometric titration.[1]

Preparative Methods: [1] a solution of ***Benzyltriethylammonium Chloride*** (227.8 g, 1.00 mol) in 200 mL of water is added slowly dropwise to a solution of ***Potassium Permanganate*** (158.0 g, 1.00 mol) in 4.7 L of water. Violet crystals are recovered by filtration and dried under vacuum at rt. Yield: 294.8 g (95%).

Handling, Storage, and Precautions: oxidant, store small amounts (10-100g) in glass vessels at or below rt. Decomposes violently when heated above 50 °C or subjected to shocks.[9,10] Room temperature should not be exceeded when drying under vacuum.[9]

Oxidation of Alkanes and Arenes.[1,2]

Certain alkanes and the benzylic carbon of alkyl-substituted arenes are oxidized by benzyltriethylammonium permanganate in methylene chloride or acetic acid to give alcohols or ketones. Good yields (based on unrecovered starting material) are obtained (25-98%), but the extent of conversion (based on the amount of hydrocarbon used as starting material) is quite low (11-44%). Some typical examples are shown in eqs 1-4.

(1)

(2)

(3)

(4)

Oxidation of Ethers to Esters.[3]

Benzyltriethylammonium permanganate oxidizes ethers to esters in good yield under nonaqueous conditions in reactions that are reminiscent of those reported for ***Ruthenium(VIII) Oxide***. The advantage of using benzyltriethylammonium permanganate is that it does not result in the degradation of aromatic ethers. Examples reported include eqs 5-7.

(5)

(6)

(7)

Oxidation of Alcohols.[4]

The oxidation of secondary alcohols to ketones with this reagent is accompanied by a certain amount of carbon-carbon bond cleavage. Primary alcohols are oxidized to carboxylates, which undergo further reaction with methylene chloride when it is used as the solvent. The principle products are methylene diesters. Examples include those shown in eqs 8-10.

(8)

(9)

Oxidation of Amines.[5]

Tertiary amines are oxidized to *N*,*N*-dialkylamides in good yields. Primary and secondary amines are less selectively oxidized. Examples include eqs 11 and 12.

Oxidation of Aldehydes.[6]

Aldehydes are oxidized by benzyltriethylammonium permanganate to carboxylic acids in organic solvents at rt, e.g. eqs 13 and 14.

(13)

(14)

Oxidation of Sulfides and Sulfoxides.[7]

Sulfides and sulfoxides are oxidized cleanly to the corresponding sulfones by benzyltriethylammonium permanganate under nonaqueous conditions. Examples include eqs 15-18.

(15)

(16)

(17)

(18)

The reactions of benzyltriethylammonium permanganate are very similar to those of other quaternary ammonium and phosphonium permanganates such as ***Tetra-n-butylammonium Permanganate*** and ***Methyltriphenylphosphonium Permanganate***. Similar reactions can also be carried out more simply by use of phase transfer processes which are described under ***Potassium Permanganate***.

Benzyl Trifluoromethanesulfonate[1]

[17674-16-7] · $C_8H_7F_3O_3S$ · Benzyl Trifluoromethanesulfonate · (MW 240.18)

(a highly electrophilic alkylating agent used for the formation of benzyl ethers,[2-7] and for Friedel-Crafts benzylation[13-17])

Alternate Name: benzyl triflate.

Solubility: generated and used in situ in inert solvents such as CH_2Cl_2.

Preparative Methods: from benzyl alcohol, ***Trifluoromethanesulfonic Acid***, and ***2,6-Di-t-butylpyridine*** in CH_2Cl_2. When used in Friedel-Crafts alkylation reactions, it has been made from a benzyl halide and silver triflate.[15,16]

Handling, Storage, and Precautions: generated in situ and used immediately. The compound is extremely readily hydrolyzed. Use in a fume hood.

Introduction of the Benzyl Protecting Group.

Alkyl triflates, such as benzyl triflate, are extremely reactive alkylating agents.[1] Benzyl triflate has been used in carbohydrate chemistry[2-5] for the protection of hydroxy groups as their benzyl ethers, and is particularly useful for protecting the 2-hydroxy group in pyranosides.[2,3] Alkyl triflates have also been used to protect the 1-hydroxy group in sugar acetals without causing anomerization,[4] and the reagent is compatible with acetate,[2,3] isopropylidene,[3] azide,[5] and *t*-butyldimethylsilyl groups.[5] The reagent is also a useful alternative to the benzyl halide/base method for making ethers, when strongly basic conditions need to be avoided[5] (see also ***Benzyl 2,2,2-Trichloroacetimidate***). Benzyl triflate has been used with compounds other than carbohydrates,[6-9] and yields with some base-sensitive compounds can be excellent (eq 1).[6] 4-Nitrobenzyl ethers have also been made via the triflate,[8] as 4-nitrobenzyl bromide is known to be base-sensitive and so not fully compatible with the classical Williamson ether synthesis methodology.

(1)

Problems can arise with the use of benzyl triflate when the substrate is a nitrogen-containing heteroaromatic compound, as significant *N*-alkylation is observed[8,9] (hence the use of the expensive, but highly hindered, 2,6-di-*t*-butylpyridine in the synthesis of the reagent[2,3]). However, *N*-benzylation is sometimes required and benzyl triflate has been used for the protection of the hindered, deactivated N^{im}-3 site in N^{im}-1-Boc protected histidines (eq 2).[10] Other methods for this derivatization need specialized blocking groups to prevent racemization of the substrate under the harsher conditions.

(2)

Benzyl triflate mediated benzylation of alcohols in sulfur-containing compounds such as ethylene dithioacetals can cause problems.[11] The highly electrophilic agent reacts at sulfur initially and causes ring opening of the protecting group (eq 3).

(3)

The thiophilicity of benzyl triflate does mean that thioethers can be conveniently protected as benzylsulfonium triflates (eq 4).[12] In this case, protection of the thioether is necessary to prevent concomitant sulfide-sulfone

oxidation during oxidation of the primary hydroxy group to a carboxylic acid.

Friedel-Crafts Alkylation.

Benzyl triflate, like other alkyl triflates, is an active agent for Friedel-Crafts alkylation of arenes.[13-17] Benzyl triflate can be generated with a benzyl halide and silver triflate,[15,16] and then used to alkylate arenes such as alkylbenzenes,[15] anisoles,[16] and phenols.[16] Reaction occurs at rt without catalysis, but other alkyl triflates are generally less active, sometimes only reacting efficiently with a Lewis acid catalyst.[15] Recently, benzyl triflate has been reported as a decomposition product of *N*-nitroso-*N*-benzyltrifluoromethanesulfonamides, and if this reaction is done in arene solvents such as benzene then Friedel-Crafts alkylation products are obtained.[17]

Benzyltrimethylammonium Dichloroiodate[1]

[114971-52-7] · $C_{10}H_{16}Cl_2IN$ · Benzyltrimethylammonium Dichloroiodate · (MW 348.05)

(iodinating agent for aromatic compounds;[1] chloroiodo addition to unsaturated bonds;[1] α-chlorination of acetyl derivatives[1])

Physical Data: mp 125-126 °C.

Solubility: sol CH_2Cl_2, MeCN, $MeNO_3$, DMSO, DMF; slightly sol MeOH, EtOH, AcOEt; insol C_6H_{14}, Et_2O, CCl_4, $CHCl_3$, C_6H_6, AcOH.

Form Supplied in: yellow needles.

Analysis of Reagent Purity: ^1H NMR (CD_3CN) δ 3.11 (s, 9H, 3 CH_3), 4.48 (s, 2H, CH_2), 7.50 (s, 5H, C_6H_5).

Preparative Methods: to a solution of ICl (16.2 g, 0.1 mol) in CH_2Cl_2 (200 mL) at room temperature is added dropwise over 30 min a solution of benzyltrimethylammonium chloride (18.6 g, 0.1 mol) in water (100 mL); yield 30 g (86%).[2]

Purification: recrystallize from CH_2Cl_2-Et_2O (3:1).

Handling, Storage, and Precautions: stable solid; gradually decomposes in water. This reagent should be handled in a fume hood.

Electrophilic Iodination of Aromatic Compounds.

This solid reagent (**1**) can be used stoichiometrically in place of viscous ***Iodine Monochloride*** to iodinate aromatic compounds (eq 1). The iodinating ability of (**1**) is considerably higher than that of molecular ***Iodine***.

(1)

$R = OH, NH_2, OR^2, AcNH, R^2$

The reaction of phenols with (**1**) in CH_2Cl_2-MeOH in the presence of powdered ***Calcium Carbonate*** or $NaHCO_3$ for several hours at room temperature gives iodophenols in 63-96% yield. Because the presence of MeOH markedly facilitates the reaction, it is assumed that the active species is methyl hypoiodite (MeOI) produced from (**1**) and MeOH. $NaHCO_3$ is used for the iodination of phenols bearing electron-attracting substituents, and $CaCO_3$ is used for the iodination of phenols bearing electron-releasing groups.[2]

The reaction of aromatic amines with (**1**) in CH_2Cl_2-MeOH in the presence of $CaCO_3$ powder at room temperature gives iodo-substituted aromatic amines (73-96% yield). In these cases it is necessary to add $CaCO_3$ powder to remove the HCl generated.[3] The reaction of aromatic ethers with (**1**) in AcOH in the presence of ***Zinc Chloride*** at room temperature gives iodo-substituted aromatic ethers (87-98% yield). The reagent is insoluble in AcOH at room temperature, but the addition of $ZnCl_2$ increases its solubility, allowing the iodination of aromatic ethers to proceed smothly under mild conditions. An equimolar amount of $ZnCl_2$ with respect to (**1**) is required. Thus 2-methylanisole gives 97% yield of 4-iodo-2-methylanisole via the above iodination.[4]

The reaction of acetanilides with (**1**) in AcOH-$ZnCl_2$ at room temperature or at 70 °C gives iodo-substituted acetanilides (60-97% yield). Thus treating acetanilide with (**1**) in AcOH-$ZnCl_2$ at room temperature for 2 h gives a 77% yield of 4-iodoacetanilide.[5]

The reaction of simple arenes with (**1**) in AcOH-$ZnCl_2$ at room temperature or at 70 °C gives iodo-substituted products in 40-99% yield. Thus treating 1,4-dimethylbenzene with 1 equiv of (**1**) at room temperature for 16 h gives a 75% yield of 2-iodo-1,4-dimethylbenzene, and with 2 equiv of (**1**) at 70 °C for 72 h gives a 67% yield of 2,5-diiodo-1,4-dimethylbenzene.[6] The reaction of ethyl 4-aminobenzoate with 1 equiv of (**1**) in CH_2Cl_2-MeOH in the presence of $CaCO_3$ at room temperature for 48 h gives ethyl 4-amino-3-iodobenzoate in 97% yield.[7] The reaction of thiophenes with (**1**) in AcOH-$ZnCl_2$ under mild

conditions gives iodo-substituted thiophenes (39-98% yield). For example, the reaction of 3-methylthiophene with 2 equiv of (**1**) in AcOH in the presence of $ZnCl_2$ at room temperature for 4 h gives a 92% yield of 2,5-diiodo-3-methylthiophene.[8]

Chloroiodo Addition to Unsaturated Bonds.

The reaction of alkenes with (**1**) in CH_2Cl_2 at room temperature gives the chloroiodo adducts in an *anti* stereospecific and regioselective manner (eq 2); in methanol these adducts are obtained along with methanol-incorporated products.[9]

(2)

α-Chlorination of Acetyl Derivatives.

The reaction of aromatic acetyl derivatives with 2 equiv of (**1**) in an appropriate solvent give α-chloro acetyl derivatives (eq 3). Thus the reaction of acetophenone with (**1**) in refluxing $ClCH_2CH_2Cl$-MeOH for 3 h gives a 97% yield of α-chloroacetophenone,[10] and the reaction of 2-acetylpyrrole with (**1**) in THF at room temperature for 12 h gives 2-chloroacetylpyrrole in 85% yield.[11]

Benzyltrimethylammonium Hydroxide

[100-85-6] · $C_{10}H_{17}NO$ · Benzyltrimethylammonium Hydroxide · (MW 167.25)

(quaternary ammonium salt; strong base; phase transfer catalyst[1])

Alternate Name: Triton® B.

Physical Data: none available (generally obtained in solution).

Solubility: sol water, alcohols, hydrocarbons, aromatic hydrocarbons, halogenated solvents.

Form Supplied in: 40 wt % in H_2O; 35-40 wt % in MeOH (Triton B). Typical impurities are amines or benzyl alcohol.

Purification: [2] methanol solution can be decolorized with charcoal, concentrated to a syrup, and dried under vacuum at 75 °C and 1 mmHg pressure. Anhydrous reagent is obtained by drying over P_2O_5 in a vacuum desiccator.

Handling, Storage, and Precautions: hygroscopic solutions; highly toxic; decomposition can occur on heating.[3]

Epoxidations.

Benzyltrimethylammonium hydroxide (**1**) is a common reagent in organic synthesis. It finds use as a catalytic base in the epoxidation of α,β-unsaturated ketones with ***t-Butyl Hydroperoxide***,[4] as demonstrated in a step toward the total synthesis of a complex anthracyclinone (eq 1).[5] The combination of Triton B and either *t*-BuOOH or ***Hydrogen Peroxide*** has been used to advantage in situations where conventional epoxidation conditions have proven either destructive[6] or ineffective.[7] Epoxidations of other α,β-unsaturated systems, such as sulfonates,[8] have also been reported.

Oxidations at Activated Methylenes.

Benzyltrimethylammonium hydroxide has been used as a catalyst for the oxidation of methylene and/or methine groups. The oxidation of a tricyclic ketone to an anthraquinone was accomplished in good yield using this approach (eq 2).[9] Similarly, benzylic anions have been generated and efficiently trapped with air in DMSO.[10]

Dehydrohalogenation.

A variety of 1-bromoalkynes have been prepared through the action of Triton B on 1,1-dibromoalkenes.[11] Both aryl and alkyl substituents were examined, with recoveries ranging from 35 to 87%, and generally above 60% yield (eq 3).

(3)

In an extension of this reaction, a synthesis of propargyl amines using Triton B was developed in which 1,1-dibromoalkenes were dehydrohalogenated, isomerized in situ to bromoallenes, and subjected to nucleophilic attack by primary or secondary amines (eq 4).[12] Yields ranged from 5 to 88%. Attack by methanol was also examined; however, yields were generally low.

(4)

Aldol Condensations.

The aldol reaction has often been carried out with Triton B functioning as base. In the synthesis of a cytochalasin intermediate, a seven-membered ring was closed under the action of Triton B in excellent yield (eq 5).[13] The reagent can effect the double aldol condensation of dibenzyl ketone with benzil, producing tetraphenylcyclopentadienone in excellent yield (eq 6).[14]

The action of Triton B has been used in the synthesis of 2-thiomethylindoles (eq 7).[15] Condensation of various 2-sulfonamido aldehydes with methyl methylsulfinylmethyl sulfide (55-88%) followed by treatment with H_2S and HCl gave rise to the indole products (62-80%).

Conjugate Additions.

Triton B is an effective catalyst for the conjugate addition of carbon acids to Michael acceptors. Such is the case with the reaction of nitromethane and *t*-butyl acrylate mediated by a methanolic solution of (**1**) (eq 8).[16] In the given example, the triester formed was used in the preparation of dendritic macromolecules. Other bases were not as effective.[17] Nitroalkanes have also been added intramolecularly to alkynylamides[18] and intermolecularly to a variety of

unsaturated systems. The addition of a benzonitrile to methyl acrylate in a Michael fashion was reported to occur in excellent yield (eq 9).[19] Heteroatomic nucleophiles have also been added in a 1,4-fashion to conjugated systems.[20]

The addition of nucleophiles to vinylsiloxycyclopropanecarboxylates catalyzed by Triton B was reported to be an efficient method for the preparation of functionalized 4-oxoalkanoates (eq 10).[21] Other catalysts were not as effective.

NuH = malonates, nitroalkanes, thiols

Benzyltrimethylammonium hydroxide also has been utilized in steroid syntheses through the Torgov reaction.[22] A cyclic 1,3-diketone can be *C*-alkylated through a formal S_N2' displacement of an ionizable tertiary hydroxy group (eq 11). Alkylation of 1,3-diketones with halides is also well known.[23]

Eq 12 shows a novel photolytic reaction in which Triton B was used to improve the conversion of an amino enone into a bridged bicyclic compound.[24]

Benzyltrimethylammonium hydroxide has also been used in the conversion of an α-hydroxy-1,1-dichloride to an aldehyde, which was cyclized to generate the tetracyclic compound rhodomycinone (eq 13).[25]

Benzyltrimethylammonium Tetrachloroiodate[1]

[121309-88-4] · $C_{10}H_{16}Cl_4IN$ · Benzyltrimethylammonium Tetrachloroiodate · (MW 418.96)

(chlorinating agent for aromatic compounds;[1] side-chain chlorination of aromatic compounds;[1] chlorine addition to alkenes[1])

Physical Data: mp 106-125 °C (sinters at 106-107 °C, and melts completely at 125 °C).

Solubility: sol MeCN, $MeNO_3$, DMSO, DMF; slightly sol MeOH, EtOH, AcOH, AcOEt, $CHCl_3$, CH_2Cl_2; insol C_6H_{14}, CCl_4, C_6H_6, H_2O.

Form Supplied in: yellow needles.

Analysis of Reagent Purity: ^{1}H NMR (CD_3CN) δ 3.07 (s, 9H, 3 CH_3), 4.40 (s, 2H, CH_2), 7.50 (s, 5H, C_6H_5).

Preparative Methods: chlorine gas is bubbled into a solution of benzyltrimethylammonium chloride (18.6 g, 0.1 mol) and iodine (12.7 g, 0.05 mol) in CH_2Cl_2 (300 mL) for 15 min; yield 40 g (95%).[2] For alternative methods, see Kajigaeshi et al.[3]

Handling, Storage, and Precautions: stable solid, but gradually decomposes with evolution of Cl_2 when in contact with air for a long time. This reagent should be handled in a fume hood.

Electrophilic Chlorination of Aromatic Compounds.

This solid reagent (**1**) is used to chlorinate aromatic compounds (eq 1) and is considerably safer and more convenient to use than toxic gaseous ***Chlorine***.

(1)

$R = OH, NH_2, OR^2, AcNH, R^2$

The reaction of phenols with (**1**) in CH_2Cl_2 at room temperature gives chloro-substituted phenols (66-91% yield). In these cases the chlorination of phenols having an electron-donating groups in the aromatic ring gives polychloro-substituted phenols; however, chlorination of phenols having electron-withdrawing groups can be controlled step by step.[4]

The reaction of aromatic amines with a calculated amount of (**1**) in AcOH at room temperature or at 70 °C gives chloro-substituted aromatic amines (66-99% yield). The active species in these chlorinations may be acetyl hypochlorite (AcOCl). In these cases, chlorination of amines having electron-withdrawing groups in the aromatic ring gives the desired chloro-substituted products, but chlorination of amines having electron-donating groups leads to oxidation products.[5]

The reaction of aromatic ethers with a calculated amount of (**1**) in AcOH or CH_2Cl_2 under mild conditions gives, selectively, chloro-substituted aromatic ethers (71-96% yield). Chlorination of nitroanisoles is unsuccessful.[6]

The reaction of acetanilides with a calculated amount of (**1**) in AcOH at room temperature or at 70 °C gives, selectively, the desired chloro-substituted acetanilides (81-93% yield). Chlorination of nitroacetanilides does not proceed.[7]

The reaction of arenes with a calculated amount of (**1**) in AcOH at room temperature or at 70 °C gives aromatic chlorides (40-99% yield). Thus treating 1,3,5-trimethylbenzene with 1, 2, and 3 equiv of (**1**) gives 1-chloro-, 1,3-dichloro-, and 1,3,5-trichloro-2,4,6-trimethylbenzene, respectively, in good yields.[8] The reaction of thiophenes with (**1**) in AcOH at room temperature or at 70 °C gives chloro-substituted thiophenes. For example, the reaction of 3-methylthiophene with 2 equiv of (**1**) gives 2,5-dichloro-3-methylthiophene in 81% yield.[9]

Side-Chain Chlorination of Aromatic Compounds.

The reaction of arenes with (**1**) in CCl_4 in the presence of AIBN under reflux gives α-chloro-substituted compounds. Thus the reaction of toluene with 1 equiv of (**1**) for 4 h gives benzyl chloride and benzylidene dichloride in 77% and 11% yield, respectively.[3] The reaction of acetophenones (eq 2) with 1 equiv of (**1**) in $ClCH_2CH_2Cl$-MeOH under reflux gives α-chloroacetyl derivatives (95-99% yield). Thus treating acetophenone with (**1**) for 3 h gives a 99% yield of α-chloroacetophenone.[2] The reaction of acetophenones

with 2 equiv of (**1**) in AcOH at 70 °C gives α,α-dichloroacetyl derivatives (66-99% yield). In this fashion, the chlorination of acetophenone with 2 equiv of (**1**) for 5 h gives 2,2-dichloro-1-phenylethanone in 90% yield.[10]

$$\text{Ar-COMe} \xrightarrow[\text{solvent, }\Delta]{n\text{ equiv }(\mathbf{1})} \text{Ar-COCH}_2\text{Cl or Ar-COCHCl}_2 \qquad (2)$$

solvent: $n = 1$, $ClCH_2CH_2Cl$-MeOH; $n = 2$, AcOH

Addition of Chlorine to Alkenes.

The reaction of alkenes with 1 equiv of (**1**) in CH_2Cl_2 at room temperature gives the expected chlorine adducts in a nonstereospecific manner (eq 3). In MeOH or AcOH this reaction produces chlorine adducts along with solvent-incorporated products in a regioselective manner.[11]

Benzyltrimethylammonium Tribromide[1]

[111865-47-5] · $C_{10}H_{16}Br_3N$ · Benzyltrimethylammonium Tribromide · (MW 389.96)

(brominating agent for aromatic compounds;[1] side-chain bromination of aromatic compounds;[1] addition of bromine to π bonds;[1] mild oxidizing agent for many functional groups[1])

Physical Data: mp 100-101 °C.

Solubility: sol CH_2Cl_2, DMSO, DMF; slightly sol MeOH, AcOH, AcOEt, $CHCl_3$; insol hexane, benzene, CCl_4, H_2O.

Form Supplied in: orange-red needles.

Analysis of Reagent Purity: ^{1}H NMR (CD_3CN) δ 3.14 (s, 9H, 3 CH_3), 4.50 (s, 2H, CH_2), 7.52 (s, 5H, C_6H_5).

Preparative Methods: to a solution of benzyltrimethylam-monium chloride (11 g, 0.06 mol) and $NaBrO_3$ (4.5 g, 0.03 mol) in water (100 mL) is added aq. HBr (47%, 0.18 mol) under stirring at room temperature; yield 18.2 g (78%).[2] For an alternative method, see Kajigaeshi et al.[3]

Purification: recrystallize from CH_2Cl_2-Et_2O (10:1).

Handling, Storage, and Precautions: stable solid, but decomposes slightly upon standing for a long time in contact with air or water. This reagent should be handled in a fume hood.

Electrophilic Aromatic Substitution of Bromine.

This reagent (**1**) can be regarded as a solid form of ***Bromine***. The end points of its reactions can be detected by the decolorization of the reagent. Accordingly, the electrophilic bromo substitution of aromatic compounds with (**1**) has been extensively investigated (eq 1).

(1)

$$R = OH,\ NH_2,\ OR^2,\ AcNH,\ R^2$$

The reaction of phenols with a calculated amount of (**1**) in CH_2Cl_2-MeOH at room temperature gives mono-, di-, or tribromo-substituted phenols, selectively.[3] Because the presence of MeOH markedly facilitates the brominations, it can be assumed that the active species is methyl hypobromite (MeOBr) produced from the reaction of (**1**) with MeOH.[4] Polystyrene-bound (**1**) can also be used as the brominating reagent.[5]

The reaction of aromatic amines with (**1**) in CH_2Cl_2-MeOH containing ***Calcium Carbonate*** powder at room temperature gives bromo-substituted aromatic amines.[6] Polystyrene-bound (**1**) is also used for the preparation of polybromo-substituted aromatic amines.[7]

The reaction of aromatic ethers with a stoichiometric amount of (**1**) in CH_2Cl_2-MeOH or AcOH-$ZnCl_2$ under mild conditions gives, selectively, mono-, di-, or tribromo-substituted aromatic ethers.[8] The reagent is only slightly soluble in acetic acid at room temperature, but the addition of ***Zinc Chloride*** increases its solubility, allowing the bromination of aromatic ethers to proceed smoothly under mild conditions. An equimolar amount of $ZnCl_2$ with respect to (**1**) is required.[9]

Bromo-substituted acetanilides have been obtained from the reaction of acetanilides with (**1**) in CH_2Cl_2-MeOH[10] or AcOH-$ZnCl_2$.[11]

Arenes are brominated smoothly by (**1**) in AcOH with the aid of the Lewis acid $ZnCl_2$.[9] The reaction of thiophenes with (**1**) in AcOH-$ZnCl_2$ under mild conditions gives bromo-substituted thiophenes.[12]

Side-Chain Bromination of Aromatic Compounds.

The reaction of arenes with a calculated amount of (**1**) in refluxing benzene in the presence of AIBN gives α-bromo-substituted arenes.[13] The reaction of acetophenones with 1 equiv of (**1**) gives α-bromo-substituted acetophenones and with 2 equiv of (**1**) gives α,α-dibromo-substituted acetophenones.[2]

Addition to Alkenes.

The reaction of alkenes with (**1**) in aprotic solvents gives 1,2-dibromo adducts via a stereospecific *anti* addition; in protic solvents such as MeOH and AcOH it gives the corresponding dibromo adducts along with considerable amounts of solvent-incorporated products in a regioselective manner.[14]

Oxidation with (1).

This reagent has been conveniently used as a mild oxidizing agent in place of liquid bromine. Specifically, the oxidation of primary alcohols or ethers to dimeric esters,[15] α,o-diols or cyclic ethers to lactones,[15] secondary alcohols to ketones,[15] benzyl alcohols to benzaldehydes or benzoic acids,[16] 1,4-benzenediols to 2,5-cyclohexadiene-1,4-diones,[17] sulfides to sulfoxides[18] and thiols to disulfides[19] have been reported. By using (**1**), the haloform reaction of methyl ketones,[20] *N*-bromination of amides,[21] and Hofmann degradation of amides[22] have also been achieved.

(Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate

[82499-43-2] · $C_{35}H_{36}BF_4P_2Rh$ · (Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate · (MW 708.4)

(reagent for catalytic hydrogenation;[9-11] hydrosilylation,[26] hydroboration,[27,28] and aldol condensation[32])

Physical Data: mp 211-212 °C (dec).

Solubility: insol Et_2O, pentane; sol CH_2Cl_2, MeOH, etc.

Form Supplied in: orange crystalline powder. *Drying:* used as supplied in anhydrous solvent.

Analysis of Reagent Purity: ^{31}P NMR indicates presence of free phosphine ligand and phosphine oxides; the characteristic ^{103}Rh coupled doublet (J_{RhP} = 155 Hz) demonstrates pure material.

Preparative Methods: a solution of [Rh(nbd)acac] in THF is treated with fluoroboric acid, followed by addition of 1,4-bis(diphenylphosphino)butane (dppb). The solution becomes deep red and ether is added to precipitate the catalyst, which is then isolated by filtration.[3a] The unpurified product is generally adequately pure for most applications. Recrystallization from methanol can be performed to obtain orange needles of [Rh(nbd)(dppb)]BF_4. Although air-sensitive in solution, the crystalline complex is indefinitely stable when prepared pure and stored under N_2 or Ar below 0 °C. A convenient preparation of the corresponding trifluoromethanesulfonate has been described.[3b] The cyclooctadiene (cod) analog has been characterized by X-ray crystallography,[4] and the dynamic solution structure of related systems has been studied by multinuclear NMR techniques.[5]

Handling, Storage, and Precautions: store under argon in freezer; stable as solid; solutions are air sensitive. Literature describes the use of perchlorate salts but their use cannot be recommended due to risk of detonation. Use in a fume hood.

Introduction.

Homogeneous catalytic hydrogenation with cationic rhodium catalysts has been extensively explored by Schrock and Osborn.[1] Use of these complexes in stereoselective organic synthesis has been a topic of more recent interest, and has been recently reviewed.[2] The reagent of choice for many of these directed hydrogenations has continued to be [Rh(nbd)(dppb)]BF_4 (**1**).

Directed Hydrogenation.

By far the most significant application of (**1**) has been in diastereoselective hydrogenation reactions. The ability of (**1**) to retain a significant level of Lewis acidity under conventional hydrogenation conditions has facilitated the development of directed hydrogenations in which (**1**) engages in prior coordination to heteroatoms situated proximal to the alkene functionality. Scheme 1 shows a general mechanistic scheme by which (**1**) may catalyze hydrogenation.[6] This scheme is derived by analogy to mechanistic steps elucidated in the context of the hydrogenation of *N*-acyl dehydroamino acids, which have been demonstrated to coordinate to (**1**) in a bidentate fashion.

(Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate

Scheme 1

Catalyst (**1**) readily absorbs 2 moles of H_2 to form complex A which may coordinate two solvent molecules.[7] The reversible binding of the substrate then occurs in a bidentate fashion to give complex B. Oxidative addition of dihydrogen then occurs to form the dihydride species C, which then undergoes migratory insertion to form the rhodium alkyl D. Although a primary Rh alkyl is shown in Scheme 1, a secondary Rh alkyl is possible as well. Finally, reductive elimination occurs to give the reduced product with concomitant regeneration of the active catalyst.

At low pressures the addition of hydrogen to a rhodium complex (schematically shown as B) is probably rate-determining, but at higher pressure, pre-equilibria (A to B) can contribute to the rate law. The effect of pressure on mechanism has important implications in the directed hydrogenation of substituted alkenes which can undergo double bond isomerization. This issue has been addressed in synthetic and mechanistic studies employing (**1**) (see below).

An early observation of directed hydrogenation was made by Thompson[8a] using $ClRh(PPh_3)_3$ with a cyclic homoallylic alcohol as reactant; the stereoselectivity of hydrogenation could be enhanced by base so that delivery of hydrogen to the alkene from an alkoxide-coordinated rhodium was postulated. Acyclic diastereoselection was observed in hydrogenation of allylic alcohols with complex (**1**)[8b] and a high level of stereochemical control observed for hydrogenations catalyzed by ***(1,5-Cyclooctadiene)(tricyclohexylphosphine)(pyridine)iridium(I) Hexafluorophosphate*** (**2**).[8c,8d] The ensuing discussion will concentrate on catalysis by complex (**1**).

Cyclic Alkenes.

The directing effect of alcohol substituents is perhaps most dramatically demonstrated with cyclic alkenes in which products are formed via hydrogenation from the more hindered face (Table 1). Entries 1-3 serve to illustrate that the directing alcohol may reside in either the allylic, homoallylic, or bis(homoallylic) position relative to the alkene undergoing hydrogenation, while synthetically useful levels of selectivity are retained.[9] Entry 4 is included to illustrate the dramatic steric congestion which can be overcome in directed hydrogenation reactions employing (**1**). Entries 5[10] and 6[11] illustrate the compatibility of (**1**) with protected amine functionality. In addition, when the alkenes in entry 5 or 6 are reduced under heterogeneous, nondirecting conditions, the other face of each alkene is reduced with high selectivity. Finally, entry 7 demonstrates that hydroxyl directivity in the [2.2.2] bicyclic system is also possible.[12]

Table 1 Hydroxyl-Directed Reductions with Catalyst **(1)**

Entry	Substrate	Major product	Mol % **(1)**	H_2 pressure (psi)	Selectivity
1			3.5	375	>200:1
2, 3			10	1000	R = OH 64:1 R = CH_2OH 19:1
4			10	800	70:1
5			35	15	>19:1
6			10	1400	91:9
7			20	20	>99:1

Other Oxygen Directing Groups.

The Lewis acidity of (**1**) is manifested in coordination to other heteroatom-based functional groups which can direct hydrogenation. Table 2 demonstrates that (**1**) has a sufficient affinity for ethers[11] and esters[13] so that directed hydrogenations can be achieved when these functional groups are proximal to alkenes, although the rates and selectivities are somewhat lower than with the corresponding alcohols. While ketones, acetals, carboxylic acids, and amides have been demonstrated to direct catalytic

hydrogenation with the corresponding Ir^+ catalyst (**2**),[14] these functional groups do not provide good results when (**1**) is employed with cyclic alkenes. The lack of directivity from amides with (**1**) is particularly intriguing given the dramatic coordination properties of this moiety in the Rh^I catalyzed hydrogenation of *N*-acyl dehydroamino acids.[15]

Table 2 Oxygen Heteroatom-Directed Reductions with Catalyst **(1)**

Entry	Substrate	Major product	Mol %	Selectivity
1			2	7:1
2			2	32:1
3			2	7:1
4			2	4:1

Acyclic Alkenes.

Acyclic alkenes also undergo stereoselective hydrogenation with catalysis by (**1**) (Table 3). It is significant to note that, in entry 1,[8b] although high selectivity is observed for the *anti* isomer, about 20% of the product is obtained as the corresponding methyl ketone, indicating that alkene isomerization is a competitive process. Entries 2 and 3 illustrate that either the *syn* or *anti* isomer can be obtained depending on the substitution pattern on the starting alkene.[8] In addition, this study established that alkene isomerization can be effectively suppressed at higher pressures. Entries 4-6 establish the efficiency of (**1**) for the reduction of unsaturated hydroxy esters,[16,17] which are not effectively reduced by (**2**). A model rationalizing the stereochemical outcome of these reductions has been proposed.[18] In this model, simultaneous coordination of the hydroxyl group and the alkene differentiates the diastereotopic faces. This analysis also explains the fact that alkene isomerization at low H_2 pressures contributes to diminished diastereoselectivities. This explanation has been confirmed by independent mechanistic experiments in which entries 2 and 3 were studied employing (**1**) and D_2.[19]

Table 3 Reduction of Acyclic Allylic Alcohols with Catalyst **(1)**

Entry	Substrate	Major product	Mol % **(1)**	H_2 pressure (psi)	Selectivity
1			2	15	32:1
2			17.5	640	13:1
3			17.5	640	10:1
4			0.5	15	99:1
5			10	15	32:1
6			5	15	9:1

Catalyst (**1**) is effective in the directed reduction of homoallylic alcohols as well (Table 4). Entries 1-3 indicate that 1,1-disubstituted alkenes exhibit reasonable levels of diastereoselectivity in directed hydrogenations, although this level depends greatly on substitution pattern.[15,20] Entries 4-8 illustrate homoallylic trisubstituted alkenes undergo directed hydrogenation under catalysis by (**1**) with very high levels of selectivity, and that the configuration of the allylic substituent plays a significant role in modulating the level of selectivity. This study includes a rationale to explain the observed diastereoselectivities based on the principles of allylic strain.[1a,21]

Table 4 Reduction of Acyclic Homoallylic Alcohols with Catalyst **(1)**

Entry	Substrate	Major product	Mol % **(1)**	H_2 pressure (psi)	Selectivity
1			2	15	7:1
2			5	15	10:1
3			5	15	2:1
4			5	15	8:1
5			20	15	32:1
6			20	15	99:1
7			3	15	19:1
8			3	15	10:1

As with cyclic alkenes, nonhydroxylic directing groups can be used in the directed hydrogenation of acyclic alkenes. The selective reductions of 3-substituted itaconate esters illustrate the directing capacity of esters (Table 5). It appears that the presence of coordinating allylic substituents can effect the level of selectivity.[22]

Table 5 Directed Reduction Of Unsaturated Esters

1			2	200:1
2			2	49:1
3			2	17:1
4			5	99:1
5			5	250:1

Applications in Total Synthesis.

Two recent examples of directed hydrogenations employing (**1**) in the total synthesis of complex molecules are illustrated. In eq 1 a simultaneous diastereoselective reduction of the trisubstituted alkene and the α,β-unsaturated ester afforded the illustrated advanced intermediate in the asymmetric total synthesis of ionomycin.[23] In addition, a two-directional application has been utilized in an asymmetric synthesis FK-506 (eq 2).[24]

(Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate

Miscellaneous Applications.

The hydroxyl directed hydrogenation of vinylstannanes and -silanes has been demonstrated to proceed efficiently.[25] The authors present a transition state model which rationalizes the observed results (eqs 3 and 4).

Hydrosilylation.

Rhodium(I) complexes catalyze the asymmetric hydrosilylation of prochiral ketones (eq 5), in the presence of (-)-sparteine.[26] Secondary alcohols are obtained in up to 30% optical yield by this method.

Hydroboration.

[Rh(cod)(dppb)]BF_4 is an efficient catalyst for the hydroboration of a range of vinylarenes.[27,28] Addition of ***Catecholborane*** to various styrene derivatives in the presence of 2 mol % catalyst gives, after oxidative workup, >99% secondary alcohol; in contrast, the corresponding uncatalyzed reaction gives the primary alcohol as the major product (eq 6).

(Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate

Ar = phenyl, 4-F, 4-Cl, 4-Me, 4-MeO, 3-F, 3-Cl
2-Cl, 2-$MeOC_6H_4$, naphthyl

This high regioselectivity is restricted to monosubstituted alkenes, indene, and (*E*)-1-phenylpropene. Analogous reactions with terminal aliphatic alkenes generally lead to primary alcohols as the major product, although alkene isomerization and BH_3-derived products arising from catalyst degradation can be problematic. 1,1-Disubstituted alkenes require longer reaction times, 1,2-disubstituted alkenes are still less reactive, and trisubstituted alkenes are essentially unreactive. This allows preferential hydroboration at the less hindered double bond in limonene (eq 7).[29]

Asymmetric hydroboration of styrenes with the boranes derived from ephedrine and pseudoephedrine catalyzed by [Rh(nbd)(dppb)]OTf gives excellent regioselectivity, but poor enantioselectivity (eq 8). Better optical yields are obtained using rhodium complexes with more rigid [ferrocenyl]diphosphines.[30]

Diastereoselective rhodium-catalyzed hydroborations of allylic alcohol derivatives give results complementary to those observed in the uncatalyzed reaction with ***9-Borabicyclo[3.3.1]nonane***. The *syn* selectivity of the catalyzed reaction increases as the bulk of the R group increases (*syn*:*anti* = 79:21 for R = TBDPS) (eq 9).[29]

R = H, Bn, TBDMS, TBDPS

Exocyclic 1,1-disubstituted alkenes also give complementary selectivity (*syn*:*anti* = 93:7 for R = TBDMS) (eq 10) to that observed with 9-BBN.[29]

R = H, TBDMS

Aldol Condensations.

(Bicyclo[2.2.1]hepta-2,5-diene)[1,4-bis(diphenylphosphino)butane]rhodium(I) Tetrafluoroborate

The rhodium complex has been utilized as a catalyst in aldol condensation of silyl enol ethers and aldehydes[31] or aldehyde equivalents (eqs 11 and 12).[32]

Although this rhodium complex has been studied in hydrocarbonylation and alkene isomerization, other rhodium catalysts give much higher yields and/or offer greater selectivity.

Finally, the ability of (**1**) to induce the isomerization of alkenes has been exploited in synthesis.[33] In the absence of H_2, the dominant product of the isomerization of the illustrated homoallylic silane is the allylic silane shown (eq 13). The reaction is presumably driven by the β-silicon effect.[34]

(catalyst precursor used in the asymmetric hydrogenation of amino acid precursors, as well as in transfer hydrogenation and hydrosilation reactions[2a,b])

Alternate Name: (bicyclo[2.2.1]hepta-2,5-diene)(chiraphos)rhodium perchlorate; (norbornadiene)(chiraphos)rhodium perchlorate.

Physical Data: $^{31}P\{^1H\}$ NMR (CD_3OD) δ 58.4 ppm, J_{Rh-P} = 154 Hz.

Solubility: sol CH_2Cl_2, MeOH, THF/MeOH, and H_2O/MeOH mixtures; sparingly sol THF; insol Et_2O.

Form Supplied in: cationic rhodium-chiraphos complexes are usually prepared in situ or from the procedure given below. In reactions employing the various rhodium-chiraphos complexes, the diene ligand is frequently hydrogenated prior to catalysis to afford the active solvated catalyst precursors $[RhS_2(chiraphos)]^+$.

Preparative Method: ***Bis(bicyclo[2.2.1]hepta-2,5-diene)rhodium Perchlorate*** (0.290 g) and (*S*,*S*)-chiraphos[1,3] (0.308 g) (see ***2,3-Bis(diphenylphosphino)butane***) are dissolved in methylene chloride (5 mL) and THF (5 mL) under nitrogen. Hexane (6 mL) is then added and, after the mixture is allowed to stand at 25 °C for 1 h and then for 2 h at 5 °C, orange-red crystals of [Rh(nbd)(*S*,*S*-chiraphos)]ClO_4 are collected (0.43 g).

Handling, Storage, and Precautions: cationic rhodium-chiraphos complexes are air-sensitive and should be handled and stored under an inert atmosphere.

Hydrogenation.

Rhodium(I) complexes containing chiral phosphine ligands are extremely useful in the preparation of enantiometrically pure amino acids.[2,4] Asymmetric hydrogenation of α-(*N*-acylamino)acrylic acids proceeds in high chemical yields (95-100%) with essentially complete optical purity (eq 1). For example, DOPA, alanine, and tyrosine are obtained from asymmetric hydrogenations catalyzed by rhodium(I)-chiraphos cations with optical yields of 83, 91, and 92% respectively.[2,4,5] Catalyzed hydrogenations of the analogous aliphatic compounds are somewhat less enantioselective.[6] Indeed, hydrogenation of the (*E*) isomers gives products with even lower optical yields (eq 2).

The active herbicidal agent L-phosphinothricin[7] is obtained with enantiomeric excesses up to 91% from the asymmetric hydrogenation of α-acylamidoacrylate precursors (eq 3). While yields of the primary hydrogenation products are quantitative, enantiomeric excesses increase slightly in reactions run in a H_2O/MeOH mixture. Adverse

effects are observed in reactions carried out in THF/MeOH.

Reactions with 1,1,1-trifluoro-2-(acetyloxy)-2-propene provide the first example of a vinyl acetate with a fully saturated substituent geminal to the heteroatom to be hydrogenated asymmetrically with high efficiency (eq 4).[8] Rhodium-chiraphos cations also hydrogenate ketone[9] and epoxide[10] functionalities, albeit with low optical yields, and are, therefore, not synthetically useful. While this rhodium system seems somewhat limited to the preparation of amino acids, other rhodium[11] and ruthenium[12] catalyst precursors are currently available which show enhanced activity and selectivity for a much broader group of hydrogenation substrates.

Transfer Hydrogenation.

Transfer hydrogenation invokes the use of alcohols as a source of hydrogen for the reduction of organic functionalities. While rhodium-chiraphos cations catalyze the asymmetric transfer hydrogenation of acetophenone with high conversion (76%), optical yields are low (8.3%).[13] Slightly higher enantiomeric excesses are obtained for the asymmetric reduction of ethyl phenyl ketone to give the corresponding alcohol (eq 5).[14]

Miscellaneous.

Intramolecular hydrosilation of internally substituted alkenes proceeds rapidly (t = 6 min) in the presence of rhodium-chiraphos cations to give cyclic siloxanes in high yields (eq 6).[15] Basic workup proceeds with retention of configuration converting allylic alcohol derivatives to chiral 1,3-diols. Higher optical yields are obtained for analogous aryl alkenes. Hydroboration of vinylarenes with catecholborane employing cationic rhodium-chiraphos complexes affords secondary alcohols, upon oxidative workup, in high yields but with low optical purity. Much higher

enantiomeric excesses are obtained in reactions using analogous rhodium-BINAP catalyst precursors.[16]

[132014-70-1] · $C_{38}H_{40}F_6O_2P_3Rh$ · (Bicyclo[2.2.1]hepta-2,5-diene)[(*R,R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane]rhodium Hexafluorophosphate · (MW 838.55)

(chiral catalyst precursor for the asymmetric hydrogenation of amino acid precursors as well as for hydrosilations, hydroborations, hydroformylations, alkene migration, and hydrogen transfer reactions[2])

Alternate Name: (bicyclo[2.2.1]hepta-2,5-diene)(DIOP)rhodium tetrafluoroborate; (norbornadiene)(DIOP)rhodium tetrafluoroborate.

Physical Data: while physical data for the title complex are sparse, the analogous cod complex has been characterized fully. Physical data for [Rh(1,5-cod)(DIOP)]ClO_4: mp 183-184 °C (dec); ^1H NMR ($CDCl_3$) δ 1.09 (s, 6H, CH_3), 2.37 (m, 8H, CH_2), 2.71 (m, 4H, CH_2), 3.67 (m, 2H, CH), 4.54 (m, 4H, CH=), 5.26-8.00 (m, 20H, Ph) ppm.

Solubility: sol EtOH, MeOH, CH_2Cl_2; sparingly sol THF; insol Et_2O.

Form Supplied in: cationic rhodium-DIOP complexes are usually prepared in situ or from the procedure given below. In reactions employing the various rhodium-DIOP complexes, the diene ligand is frequently hydrogenated prior to catalysis to afford the active solvated catalyst precursors $[RhS_2(DIOP)]^+$.

Preparative Method: to an acetone (30 mL) solution of $[Rh(1,5\text{-cod})Cl]_2$ (0.27 g, 0.55 mmol) is added ***Silver(I) Perchlorate*** (0.233, 1.15 mmol) and the mixture is allowed to stir for 1 h at ambient temperature. Colorless precipitates are removed by filtration through filter paper and washed with dry acetone. To the pale yellow filtrate and washings is added DIOP (***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane***)[1,3] (0.50 g, 1.15 mmol) in acetone. The crude complex is recrystallized from an acetone-ether mixture to give deep-orange crystals (0.37 g, 45%).[4]

Handling, Storage, and Precautions: cationic rhodium-DIOP complexes are air-sensitive and should be handled and stored under an inert atmosphere.

Hydrogenation.

Asymmetric hydrogenation catalyzed by chiral transition metal complexes is an active research area of synthetic organic chemistry, largely owing to its utilization in Monsanto's L-DOPA synthesis.[2b] Rhodium(I) complexes containing chiral phosphine ligands are used extensively; the standard for evaluating the efficiency of these catalyst precursors is the asymmetric hydrogenation of α-(*N*-acylamino)acrylates.[5] Using the cationic rhodium-DIOP systems, hydrogenation of various precursors of alanine, phenylalanine, tyrosine, DOPA and leucine proceed almost quantitatively with optical yields approaching 95% ee.[6-8] For example, hydrogenation of prochiral thienyl-substituted acylaminoacrylates gives the corresponding saturated propanoic acid derivatives as shown in eq 1.[9]

The naturally occurring amino acid phosphinothricin can be prepared by the asymmetric hydrogenation of α-acylamidoacrylate precursors with enantiomeric excesses reaching 70%.[10] Likewise, Leu-enkephalins and other small peptides can be prepared from asymmetric hydrogenations, although the reactions are only moderately stereoselective (23% ee) using cationic rhodium-DIOP complexes.[11] Although carbonyl functionalities can be stereoselectively reduced to the corresponding alcohols, optical yields are generally much lower than analogous reactions employing

neutral rhodium-DIOP complexes.[12] For instance, methyl 2-acetamido-3-oxobutyrate is hydrogenated en route to an enantioselective synthesis of D- and L-threonine in 90% yield but with enantiomeric excesses of only 18-25% when using cationic rhodium-DIOP systems (eq 2).[13]

(2)

The asymmetric catalytic hydrogenolysis of epoxides can also be accomplished with chiral rhodium complexes. Unfortunately, optical yields using cationic DIOP complexes are low (30%) and epoxides without carboxy functionalities are not hydrogenated under similar conditions.[14] The addition of amines to the catalyst system has been found to enhance yields in the catalyzed hydrogenation of certain prochiral alkenes. Drastic increases in optical yields are observed in the asymmetric hydrogenation of 3-phenyl-3-butenoic acid upon addition of catalytic ***Triethylamine*** (eq 3).[15] Finally, as is generally the case for all asymmetric catalyzed hydrogenations, optical yields are disappointingly low for the reduction of simple alkenes (ca. 15%).[16]

(3)

Amine	Yield (%)	ee (%)
None	6	16.7 *(S)*
Et_3N	78	70.3 *(S)*

Modified DIOP Ligands.

Alkylated[17] and sulfonated[18] analogs of the DIOP ligand, as well as amine[19] and boron[20] derivatives, have been

prepared recently. The corresponding cationic rhodium complexes are active catalysts for the asymmetric hydrogenation of amino acid precursors, generally proceeding with higher optical yields than reactions employing parent catalyst systems.

Alkene Migration.

Cationic rhodium-DIOP complexes are moderately effective for allylic hydrogen migration of secondary and tertiary allylamines to give the corresponding imines and (*E*)-enamines respectively (eq 4).[4] Higher yields are found, however, in reactions employing neutral rhodium systems containing different chiral phosphine ligands.

Miscellaneous.

Cationic rhodium-DIOP complexes are active catalyst precursors for a number of asymmetric reactions including hydrosilation,[21] hydroformylation,[22] hydrogen transfer,[23] and hydroboration (eq 5).[24] Optical yields, however, are generally much lower than reactions employing other chiral phosphines (or their neutral phosphinorhodium counterparts) and are, therefore, not synthetically useful.

1,1´-Binaphthalene-2,2´-dithiol[1]

[102555-71-5] · $C_{20}H_{14}S_2$ · 1,1´-Binaphthalene-2,2´-dithiol · (MW 318.45) (-)

[124414-36-4] (±)

[55441-99-1]

(reagent for the preparation of chiral, atropisomeric organosulfur reagents of C_2 symmetry;[1] used as chiral ligand and in the preparation of chiral crown ethers)

Physical Data: mp 150-151 °C (benzene); (*R*)-(-): [α]22D -85.9°; [α]22546 -103.8° (*c* = 1, $CHCl_3$).

Analysis of Reagent Purity: the presence of the disulfide can be checked by TLC on silica gel, eluting with dichloromethane.

Preparative Methods: the original procedure used Ullman coupling of 1-bromo-2-naphthalenesulfonic acid.[2a] The intermediate 1,1´-binaphthalene-2,2´-sulfonic acid can be resolved with strychnine.[2b] Lithiation of 2,2´-dibromo-1,1´-binaphthalene with *t*-butyllithium, quenching with sulfur,[2c] and reduction of the resulting disulfide is an alternative preparation of the racemic dithiol. More practical procedures entail Newman-Kwart rearrangement of the thioester derived from binaphthol and dimethylthiocarbamoyl chloride, followed by hydrolysis.[3-5] Use of enantiomerically pure binaphthol as starting material gives the enantiomerically pure reagent.[4] Another resolution procedure involves enantioselective oxidation of sulfides which can be further transformed into the dithiol.[6]

Handling, Storage, and Precautions: the reagent oxidizes easily to the disulfide and should be stored under inert atmosphere. Use in a fume hood.

Binaphthalene-2,2´-dithiol is the starting material for the preparation of a number of sulfur-containing heterocycles of

synthetic utility. The basic principle lies in the generation of C_2 symmetric chiral variants of reagents that contain two sulfur atoms. For example, the achiral bis(phenylthio)methane becomes the chiral 1,3-dithiepine (eq 1), still maintaining similar structural features to the acyclic reagent.[7] This dithiepine belongs to the class of reagents that function as formyl anion synthons. The C_2 symmetry is also shared by the bisoxide (it forms stereoselectively as a single pseudoequatorial isomer) and the bis-sulfone. Reaction of the anion of the dithiepine with benzaldehyde gives an 8:2 mixture of diastereoisomers (eq 2).[7]

A single diastereoisomer is obtained in the reduction of the ketone with ***Lithium Aluminum Hydride*** as illustrated in eq 3.[8] The addition of other nucleophiles such as methylmagnesium iodide also gives single adducts.

1,1´-Binaphthalene-2,2´-dithiol

Nucleophile (Nu)	R	Reaction conditions	Diastereomeric ratio	Yield (%)
$LiAlH_4$	H	Et_2O, -78 °C, 45 min	100:0	98
$NaBH_4$	H	EtOH, H_2O, Et_3N, 20 °C, 4 h	86:14	99
MeMgI	Me	THF, Et_2O, 0 °C, 40 min	100:0	98

Monoxidation of the dithiepine gives single diastereomeric sulfoxides with pseudoequatorial configuration (eq 4).[7] In general, the oxides exhibit increased diastereoselectivity with respect to the unoxidized substrates, as in the examples of eq 5.[7]

C_2 symmetric, chiral ketene dithioacetals containing the binaphthyl moiety can be prepared by Peterson alkenation of the title reagent (eq 6).[9] The corresponding bis-sulfone affords one *exo* and one *endo* adduct with cyclopentadiene (eq 7) which, once separated and desulfonylated, give the corresponding norbornenes (see ***1,1-Bis(phenylsulfonyl)ethylene***).[10]

(6)

R = H, Me, Ph

The dithiocine tetraoxide derived from cyclocondensation of binaphthodithiol with dichloroethylene and oxidation (eq 8) is a chiral version of the bis(phenylsulfonyl)ethylenes.[11] These compounds are useful acetylene equivalents in cycloaddition reactions (see ***1,2-Bis(phenylsulfonyl)ethylene***).[9] Indeed, a chiral acetylene equivalent allows the preparation of optically active hydrocarbons which would be difficult to prepare by classical methods. The dithiocine tetroxide reacts with nonsymmetric dienes to give a single crystalline diastereomeric adduct in most cases. Adducts (**1**) and (**2**) were obtained from acyclic and cyclic dienes.

(1)

$R^1 = OMe, R^2 = OTMS$
$R^1 = OMe, R^2 = H$
$R^1 = OTMS, R^2 = H$
$R^1 = Me, R^2 = H$
$R^1 = H, R^2 = OTMS$
$R^1 = H, R^2 = Me$ (8:2 mixture)

(2)

$R^1 = OMe, X = O$
$R^1 = OMe, X = -(CH_2)_2-$

The addition provides only one stereoisomer out of the four possible ones. ***Sodium Amalgam*** reduction in buffered methanol removes the binaphthyl residue to afford the hydrocarbon and recovered starting dithiol.[11]

Finally, it is notable that the title reagent has been used to prepare even larger ring systems such as chiral crown ethers,[3]

and the use of 1,1´-binaphthalene-2,2´-dithiol as ligand for rhodium(I) in the asymmetric hydroformylation of styrene has been described.[12]

(*R*)-1,1´-Bi-2,2´-naphthol[1]

[18531-94-7] · $C_{20}H_{14}O_2$ · (*R*)-1,1´-Bi-2,2´-naphthol · (MW 286.33)

(chiral ligand and auxiliary[1])

Alternate Name: BINOL.

Physical Data: mp 208-210 °C; $[\alpha]^{21}$ +34° (*c* = 1, THF).

Solubility: sol toluene, CH_2Cl_2, $EtNO_2$.

Form Supplied in: white solid; widely available.

Preparative Methods: racemic 1,1´-bi-2,2´-naphthol (BINOL) is most conveniently prepared by the oxidative coupling reaction of 2-naphthol in the presence of transition metal complexes (eq 1).[2] The resolution of racemic BINOL with cinchonine may be performed via the cyclic phosphate (eq 2).[3] An alternative procedure to provide directly optically active BINOL is the oxidative coupling of 2-naphthol catalyzed by Cu^{II} salt in the presence of chiral amines (eq 3).[4] The best procedure uses (+)-amphetamine as the chiral ligand and provides BINOL in 98% yield and 96% ee. Above 25 °C the Cu^{II}/(+)-amphetamine/(*S*)-BINOL complex precipitates while the more soluble Cu^{II}/(+)-amphetamine/(*R*)-BINOL complex is slowly transformed into the former complex. 9,9´-Biphenanthrene-10,10´-diol has also been prepared in 86% yield and with 98% ee by a similar asymmetric oxidative coupling of 9-phenanthrol in the presence of (*R*)-1,2-diphenylethylamine.[5]

Handling, Storage, and Precautions: keep tightly closed, store in a cool dark place; on heating in butanol at 118 °C for 24 h, BINOL lost ~1% of its optical rotation; at 100 °C for 24 h in dioxane-1.2 N HCl, BINOL lost 56% of its rotation; after 24 h at 118 °C in butanol-0.7 N KOH, BINOL lost 20% of its rotation.

Hydrocarboxylation.

The cyclic phosphate resolved according to eq 2 can be used as the chiral ligand in the palladium(II) catalyzed asymmetric hydrocarboxylation of arylethylenes.[6] The 1-arylpropanoic acid is obtained regiospecifically with high enantioselectivity (91% ee) (eq 4).

(R)-1,1´-Bi-2,2´-naphthol

Crown Ethers.

BINOL-derived crown ethers have been reported.[7] Crown ethers containing 3,3´-disubstituted BINOL derivatives are particularly effective for asymmetric synthesis. Thus complexes of these crown ethers (e.g. ***18-Crown-6***) with ***Potassium Amide*** or ***Potassium t-Butoxide*** catalyze asymmetric Michael additions. The reaction of methyl 1-oxo-2-indancarboxylate with methyl vinyl ketone with the 3,3´-dimethyl-BINOL-crown ether/KO-*t*-Bu complex gives the Michael product in 48% yield and with 99% ee (eq 5).[8]

(R)-1,1´-Bi-2,2´-naphthol

Polymerization.

Complexes of BINOL-derived crown ethers with KO-*t*-Bu or BuLi have been used as initiators in the asymmetric polymerization of methacrylates.[9] Thus optically active polymers are obtained with 80-90% isotacticity. Complexes of BINOL with ***Diethylzinc*** or $CdMe_2$ also initiate the asymmetric polymerization of heterocyclic monomers.[10] The chiral initiators selectively polymerize one enantiomer to give an optically active polymer. The unreacted monomer is recovered with 92% ee at 67% conversion in the polymerization of methylthiirane with (*S*)-BINOL/Et_2Zn.

Ullmann Coupling Reaction.

Axially dissymmetric biaryls have been synthesized via an intramolecular Ullmann coupling reaction of BINOL-derived aryl diesters (eq 6).[11] In the example shown, the functionalized binaphthyl is obtained with high ee after hydrolysis of the intermediate 12-membered cyclic diester.

(R)-1,1´-Bi-2,2´-naphthol

100% de

Reduction of Prochiral Ketones.

BINOL has been used as the chiral ligand of the reagent BINAL-H (see ***Lithium Aluminum Hydride-2,2´-Dihydroxy-1,1´-binaphthyl***) for asymmetric reduction.[12] The reagent reduces prochiral unsaturated ketones to the corresponding secondary alcohols in up to 90% yield and >90% ee (eq 7); (*R*)-BINAL-H leads to the (*R*)-alcohols while (*S*)-BINAL-H gives the (*S*)-alcohols.

~100% ee

(R)-1,1´-Bi-2,2´-naphthol

Addition Reactions of Chiral Titanium Reagents to Aldehydes.

The preparation and use of the BINOL-derived titanium complexes in the enantioselective synthesis of some benzhydrols (>90% ee) have been reported (eq 8).[13]

(8)

Cyanosilylation.

The chiral titanium reagent, prepared from the lithium salt of BINOL with $TiCl_4$, has been used as a catalyst for the asymmetric addition of cyanotrimethylsilane to aldehydes.[14] In the example shown, the cyanohydrin is obtained with <=82% ee (eq 9).

(9)

Diels-Alder Reactions.

BINOL and its derivatives are used as the chiral ligand of chiral Lewis acid complexes for enantioselective Diels-Alder cycloadditions. BINOL-$TiCl_2$, prepared from the lithium salt of BINOL with ***Titanium(IV) Chloride***, also catalyzes the enantioselective Diels-Alder reaction of cyclopentadiene with methacrolein (eq 10)[14,15] The *exo* adduct is obtained as the major product (56% yield), but with low enantioselectivity (16% ee). More recently, BINOL-TiX_2 (X = Br or Cl) have been

(R)-1,1´-Bi-2,2´-naphthol

prepared in situ from diisopropoxytitanium dihalides ($(i\text{-PrO})_2TiX_2$, X = Br[16] or Cl[17]) with BINOL in the presence of molecular sieves (MS 4A).[16] The Diels-Alder reaction of methacrolein with 1,3-dienol derivatives can be catalyzed by BINOL-TiX_2. The *endo* adducts are obtained in high enantioselectivity (eq 11).[18] Asymmetric catalytic Diels-Alder reaction of naphthoquinone derivatives as the dienophile (eq 12)[18] can in principle provide an efficient entry to the asymmetric synthesis of anthracyclinone aglycones. The reaction of the 5-hydroxynaphthoquinone with 1-acetoxy-1,3-diene in the presence of MS-free BINOL-$TiCl_2$ (10 mol%) provides the corresponding Diels-Alder product in high chemical yield and with high enantioselectivity (76-96% ee).[18b] The Diels-Alder product is also obtained by the use of 1 equiv of 3,3´-diphenyl-BINOL/borane complex (eq 13); the structure of the intermediate has been proposed.[19]

(R)-1,1´-Bi-2,2´-naphthol

Hetero Diels-Alder Reaction.

Modified BINOL-derived organoaluminum reagents have been used in the asymmetric hetero Diels-Alder reaction of aldehydes (eq 17). The dihydropyrones are obtained with high *cis* diastereoselectivity and enantioselectivity.[23] The hetero Diels-Alder reaction of glyoxylates proceeds smoothly with methoxydienes using BINOL-$TiCl_2$ as a catalyst to give the *cis* product in high enantiomeric excess (eq 18).[18b,24] The hetero Diels-Alder product thus obtained can be readily converted to the lactone portion of HMG-CoA inhibitors such as mevinolin or compactin.

Carbonyl-Ene Reaction.

BINOL-TiX_2 reagent exhibits a remarkable level of asymmetric catalysis in the carbonyl-ene reaction of prochiral

(R)-1,1´-Bi-2,2´-naphthol

glyoxylates, thereby providing practical access to α-hydroxy esters.[16,25] These reactions exhibit a remarkable positive nonlinear effect (asymmetric amplification) that is of practical and mechanistic importance (eq 19).[26] The desymmetrization of prochiral ene substrates with planar symmetry by the enantiofacial selective carbonyl-ene reaction provides an efficient solution to remote internal asymmetric induction (eq 20).[27] The kinetic resolution of a racemic allylic ether by the glyoxylate-ene reaction also provides efficient access to remote but relative asymmetric induction (eq 21).[27] Both the dibromide and dichloride catalysts provide the (2*R*,5*S*)-*syn* product with 97% diastereoselectivity and &egt;95% ee.

Ene Cyclization.

An intramolecular (3,4)-ene reaction of unsaturated aldehydes has been accomplished with the BINOL-derived zinc reagent.[28] Cyclization of 3-methylcitronellal with at least 3 equiv of BINOL-Zn reagent afforded the *trans*-cyclohexanol in 86% yield and 88% ee (eq 22). Asymmetric ene cyclizations of type (2,4) are also catalyzed by the BINOL-derived titanium complexes ((*R*)-BINOL-TiX_2, X = ClO_4 or OTf), modified by the perchlorate or trifluoromethanesulfonate ligand. The 7-membered cyclization of type 7-(2,4) gives the oxepane in high ee (eq 23).

Cationic Cyclization.

A cationic cyclization of BINOL-derived neryl ether has been accomplished with an organoaluminum triflate catalyst.[29] Limonene is obtained in 54% yield and 77% ee (eq 24).

Mukaiyama Aldol Condensation.

The BINOL-derived titanium complex BINOL-$TiCl_2$ is an efficient catalyst for the Mukaiyama-type aldol reaction. Not only ketone silyl enol ether (eq 25),[30] but also ketene silyl acetals (eq 26)[31] can be used to give the aldol-type products with control of absolute and relative stereochemistry.

(R)-1,1´-Bi-2,2´-naphthol

Nitro-Aldol Condensation.

A BINOL-derived lanthanide complex has been used as an efficient catalyst for the nitro-aldol reaction (eq 27).[32] Interestingly enough, the presence of water and LiCl in the reaction mixture is essential to obtain the high level of asymmetric induction and chemical yield.

Carbonyl Addition of Allylic Silanes and Stannanes.

(R)-1,1´-Bi-2,2´-naphthol

BINOL-$TiCl_2$ reagent also catalyzes the asymmetric carbonyl addition reaction of allylic silanes and stannanes.[33] Thus the addition reaction of glyoxylate with (*E*)-2-butenylsilane and -stannane proceeds smoothly to give the *syn* product in high enantiomeric excess (eq 28). The reaction of aliphatic and aromatic aldehydes with allylstannane is also catalyzed by BINOL-$TiCl_2$ or BINOL-Ti(O-*i*-Pr)$_2$ to give remarkably high enantioselectivity.[34]

Claisen Rearrangements.

A modified BINOL-derived aluminum reagent is an effective chiral catalyst for asymmetric Claisen rearrangement of allylic vinyl ethers (eq 29).[35] The use of vinyl ethers with sterically demanding C-3 substituents is necessary for the high level of asymmetric induction.

Alkylation of BINOL-Derived Ester Enolates.

The diastereoselective alkylation of BINOL-derived arylacetates affords the optically active 2-arylalkanoic acids (eq 30).[36]

Alternate Name: BINOL-TiX_2.

Solubility: insol propionitrile; sol toluene, dichloromethane, and nitroethane.

Handling, Storage, and Precautions: titanium is reputed to be of low toxicity.

Introduction.

The (*R*)-1,1´-bi-2,2´-naphthotitanium dihalides (BINOL-TiX_2; X = Br or Cl) are most conveniently prepared in situ from the reaction of diisopropoxytitanium dihalides $(i\text{-PrO})_2TiX_2$; X = Br[2] or Cl[3]) with ***(R)-1,1´-Bi-2,2´-naphthol***

(BINOL) in the presence of molecular sieves (MS 4A) (eq 1).[2] When BINOL is mixed with ***Dichlorotitanium Diisopropoxide*** in the absence of MS 4A, almost no change is observed on the hydroxy-carbon signal of BINOL in the ^{13}C NMR spectrum. However, the addition of MS 4A to the solution of BINOL and $(i\text{-PrO})_2TiCl_2$ leads to a downfield shift of the hydroxy-carbon signal, indicating the formation of the BINOL-derived chiral catalyst. MS (zeolite) serves as an acid/base catalyst[4] and significantly facilitates the alkoxy ligand exchange in the in situ preparation of the chiral catalyst, BINOL-TiX_2. A 1:1 mixture of $(i\text{-PrO})_2TiX_2$ and (*R*)-BINOL in the presence of MS 4A in dichloromethane provides a red-brown solution. The molecularity of BINOL-TiX_2 in dichloromethane is ca. 2.0, depending on the concentration, particularly of homochiral (*R*)(*R*)- or (*S*)(*S*)-dimer which tends to dissociate to the monomer in lower concentration.[5]

The chiral titanium complexes modified by the perchlorate or trifluoromethanesulfonate ligand such as (*R*)-1,1´-bi-2,2´-naphthotitanium diperchlorate (BINOL-$Ti(ClO_4)_2$) or (*R*)-1,1´-bi-2,2´-naphthotitanium ditriflate ((*R*)-BINOL-$Ti(OTf)_2$) can easily be prepared by the addition of ***Silver(I) Perchlorate*** or ***Silver(I) Trifluoromethanesulfonate*** (2 equiv) to BINOL-$TiCl_2$ (eq 2).[6]

Asymmetric Catalysis of Carbonyl-Ene Reaction.

(*R*)-1,1´-Bi-2,2´-naphthotitanium dihalides exhibit a remarkable level of asymmetric induction in the carbonyl-ene reaction of prochiral glyoxylate to provide practical access to α-hydroxy esters, a class of compounds of biological and synthetic importance[7] (eq 3).[2] The catalyst derived from (*R*)-BINOL leads consistently to the (*R*)-alcohol product, whereas the catalyst derived from (*S*)-BINOL affords the (*S*)-enantiomer. Generally speaking, the dibromide is superior to the dichloride in both reactivity and enantioselectivity for the reactions involving a methylene hydrogen shift in particular. On the other hand, the dichloride is lower in reactivity but superior in enantioselectivity for certain reactions involving methyl hydrogen shift. The present asymmetric catalysis is applicable to a variety of 1,1-disubstituted alkenes to provide the ene products in extremely high enantiomeric excess by judicious choice of the dibromo or dichloro catalyst. The reactions of mono- and 1,2-disubstituted alkenes afford no ene product. However, vinylic sulfides and selenides serve as alternatives to mono- and 1,2-disubstituted alkenes, giving the ene products with virtually complete enantioselectivity along with high diastereoselectivity (eq 4).[8] The synthetic advantage of vinylic sulfides and selenides is exemplified by the synthesis of enantiomerically pure (*R*)-(-)-ipsdienol, an insect aggregation pheromone.

(4)

X = S, R = *i*-Bu, 95% *anti*, >99% ee

Positive Nonlinear Effect[5] (Asymmetric Amplification[9]).

A nonclassical phenomenon of asymmetric catalysis by the chiral BINOL-derived titanium complex is the remarkable positive nonlinear effect observed, which is of practical and mechanistic importance.[5] Convex deviation is observed from the usually assumed linear relationship between the enantiomeric purity of the BINOL ligand and the optical yield of the product. The glyoxylate-ene reaction catalyzed by the chiral titanium complex derived from a partially-resolved BINOL of 33.0% ee, for instance, provides the ene product with 91.4% ee in 92% chemical yield (eq 5). The optical yield thus obtained with a partially resolved BINOL ligand is not only much higher than the % ee of BINOL employed but is also very close to the value of 94.6% ee obtained using the enantiomerically pure BINOL. Thus the use of 35-40% ee of BINOL is sufficient to provide the equally high (>90% ee) level obtained with enantiomerically pure BINOL.

(5)

Asymmetric Desymmetrization.[10]

Desymmetrization of an achiral, symmetrical molecule is a potentially powerful but relatively unexplored concept for the asymmetric catalysis of carbon-carbon bond formation. While the ability of enzymes to differentiate between enantiotopic functional groups is well known,[11] little is known about the similar ability of nonenzymatic catalysts to effect carbon-carbon bond formation. The desymmetrization by the enantiofacial selective carbonyl-ene reaction of prochiral ene substrates with planar symmetry provides an efficient access to remote internal[12] asymmetric induction which is otherwise difficult to attain (eq 6).[10] The (2*R*,5*S*)-*syn* product is obtained in >99% ee along with more than

99% diastereoselectivity. The desymmetrized product thus obtained can be transformed stereoselectively by a more classical diastereoselective reaction (e.g. hydroboration).

Kinetic Resolution.[13]

On the basis of the desymmetrization concept, the kinetic resolution of a racemic substrate might be recognized as an intermolecular desymmetrization.[10] The kinetic resolution of a racemic allylic ether by the glyoxylate-ene reaction also provides an efficient access to remote relative[12] asymmetric induction. Both the dibromide and dichloride catalysts provide the (2*R*,5*S*)-*syn* product with >99% diastereoselectivity along with more than 95% ee (eq 7). The high diastereoselectivity, coupled with the high % ee, strongly suggests that the catalyst/glyoxylate complex efficiently discriminates between the two enantiomeric substrates to accomplish effective kinetic resolution. In fact, the relative rates with racemic ethers are quite large, ca. 60 and 700, respectively. As expected, the reaction of (*S*)-ene using the catalyst (*R*)-BINOL-$TiCl_2$ (matched catalytic system) provides complete (>99%) 1,4-*syn* diastereoselectivity in high chemical yield, whereas the reaction of (*R*)-ene using (*R*)-BINOL-$TiCl_2$ (mismatched catalytic system) affords a diastereomeric mixture in quite low yield (eq 8).

Ene Cyclization.[14]

The asymmetric catalysis of the intramolecular carbonyl-ene reaction not only of type (3,4) but also (2,4) employs the BINOL-derived titanium complexes ((*R*)-BINOL-TiX_2; X = ClO_4 or OTf), modified by the perchlorate and trifluoromethanesulfonate ligands.[6] The *trans*-tetrahydropyran is thus preferentially obtained in 84% ee (eq 9). The seven-membered cyclization of type 7-(2,4) gives the oxepane in high ee, where the *gem*-dimethyl groups are unnecessary (eq 10).

(9)

(10)

Mukaiyama Aldol Condensation.

As expected, the chiral titanium complex is also effective for a variety of carbon-carbon bond forming processes such as the aldol and the Diels-Alder reactions. The aldol process constitutes one of the most fundamental bond constructions in organic synthesis.[15] Therefore the development of chiral catalysts that promote asymmetic aldol reactions in a highly stereocontrolled and truly catalytic fashion has attracted much attention, for which the silyl enol ethers of ketones or esters have been used as a storable enolate component (Mukaiyama aldol condensation). The BINOL-derived titanium complex BINOL-$TiCl_2$ can be used as an efficient catalyst for the Mukaiyama-type aldol reaction of not only ketone silyl enol ethers but also ester silyl enol ethers with control of absolute and relative stereochemistry (eq 11).[16]

Carbonyl Addition of Allylic Silanes and Stannanes.[17]

The chiral titanium complex BINOL-$TiCl_2$ also catalyzes the asymmetric carbonyl addition reaction of allylic silanes and stannanes.[18] Thus the addition reaction of glyoxylate with (*E*)-2-butenylsilane and -stannane proceeds smoothly to give the *syn* product in high enantiomeric excess (eq 12). The *syn* product thus obtained can be readily converted to the lactone portion of verrucaline A. The reaction of aliphatic and aromatic aldehydes with allylstannane is also catalyzed by BINOL-$TiCl_2$ to give remarkably high enantioselectivity (eq 13).[19]

Hetero Diels-Alder Reaction.[20]

The hetero-Diels-Alder reaction involving glyoxylate as the dienophile provides an efficient access to the asymmetric synthesis of monosaccharides.[21] The hetero Diels-Alder reaction with methoxydienes proceeds smoothly with catalysis by BINOL-$TiCl_2$ to give the *cis* product in high enantiomeric excess (eq 14).[22] The dibromide affords a higher *cis* selectivity, however, with a lower enantioselectivity, particularly in the *trans* adduct. The product thus obtained can be readily converted to the lactone portion of HMG-CoA inhibitors such as mevinolin or compactin.[23]

X = Cl ,78 (94% ee):22 (>90% ee)
X = Br, 84 (92% ee):16 (50% ee)

Diels-Alder Reaction.[24]

The Diels-Alder reaction of methacrolein with 1,3-dienol derivatives can also be catalyzed by the chiral BINOL-derived titanium complex BINOL-$TiCl_2$. The *endo* adduct was obtained in high enantioselectivity (eq 15).[22a,25] The sense of asymmetric induction is exactly the same as observed for the asymmetric catalytic reactions shown above. Asymmetric catalytic Diels-Alder reactions with naphthoquinone derivatives as the dienophile provide an efficient entry to the asymmetric synthesis of anthracyclinone aglycones (eq 16).[26]

Cyanosilylation.[27]

Another preparative procedure of BINOL-$TiCl_2$ and the use thereof was reported in the asymmetric catalysis of the addition reaction of cyanotrimethylsilane to aldehydes.[28] The dilithium salt of BINOL in ether was treated with ***Titanium(IV) Chloride***, the red-brown mixture was warmed to room temperature, and the ether removed in vacuo. Dry benzene was added and the nondissolved solid was separated via filtration under nitrogen. Removal of the solvent delivered 50% of a sensitive red-brown solid which showed a single set of ^{13}C NMR signals (eq 17). The BINOL-$TiCl_2$ thus obtained was utilized to prepare the cyanohydrin of 3-methylbutanal in <82% ee (eq 18).

Related Reagents.

(*R*)-1,1´-Bi-2,2´-naphthotitanium Diisopropoxide[1]

[123436-17-9] · $C_{26}H_{26}O_4Ti$ · (*R*)-1,1´-Bi-2,2´-naphthotitanium Diisopropoxide · (MW 450.37)

(mild Lewis acid catalyst for asymmetric oxidations[1,2] and allylations[7])

Physical Data: mp 127 °C (dec) (pentane/ether).

Solubility: sol dichloromethane, toluene, and ether.

Handling, Storage, and Precautions: titanium is reputed to be of low toxicity.

(*R*)-1,1´-Bi-2,2´-naphthotitanium diisopropoxide (BINOL-Ti(O-*i*-Pr)$_2$) (**1**), most conveniently prepared by the reaction of ***Titanium Tetraisopropoxide*** with ***(R)-1,1´-Bi-2,2´-naphthol*** through the azeotropic removal of isopropanol, is oxophilic (eq 1). A 1:1 mixture of Ti(O-*i*-Pr)$_4$ and (*R*)-BINOL in dichloromethane provides an orange-yellow solution and on removal of solvent gives a pale yellow solid. The molecularity of the 1:1 titanium-binaphthol species has been determined to be 2.3. However, the X-ray crystal structure is trimeric, containing a C_2 axis of symmetry.[3] This 1:1 complex provides, however, only low enantiomeric excess (ee) in the asymmetric epoxidation of allylic alcohols (eq 2).[1,3] However, the oxidation of sulfides to sulfoxides by ***t-Butyl Hydroperoxide*** proceeds catalytically with (**1**) to afford higher enantioselectivity than Kagan's catalytic method using diethyl tartrate as a chiral ligand (eq 3).[4] As Kagan has already reported, the amount of water added exhibits a significant effect upon ee value. A high ee is obtained when 0.5-3.0 equiv of H_2O was added to the sulfide, while a decrease of ee is observed when less than 0.5 equiv or more than 3.0 equiv of H_2O is used. In the absence of H_2O, only a low ee is obtained. Addition of water to (**1**) provides binaphthol-titanium oxide (BINOL-Ti=O; **2**) (eq 4),[5] which has been reported to serve as an asymmetric catalyst for the Mukaiyama aldol reaction (eq 5).[6]

1,1´-Binaphthyl-2,2´-diyl Hydrogen Phosphate[1]

(*S*)-(+)

[35193-64-7] · $C_{20}H_{13}O_4P$ · 1,1´-Binaphthyl-2,2´-diyl Hydrogen Phosphate · (MW 348.30) (*R*)-(-)

[39648-67-4] (±)

[50574-52-2]

(reagent for optical resolution of a variety of organic bases[2] and helicenes;[3] NMR shift reagent for determining the enantiomeric purity of secondary and tertiary amines;[4] chiral ligand for homogeneous asymmetric catalysts[5,6])

Alternate Name: BNPPA.

Physical Data: (*S*)-(+)-BNPPA: $[\alpha]_D^{20}$ +605° (*c* 1.35, MeOH). (*R*)-(-)-BNPPA: $[\alpha]_D^{20}$ -605° (*c* 1.35, MeOH). Decomposes without melting at ca. 300 °C.

Solubility: racemate: sol ethanol (10 g/100 mL), sol methanol (3 g/100 mL), slightly sol water and other organic solvents. Enantiomer: sol ethanol (6 g/100 mL), sol methanol (2 g/100 mL), slightly sol water and other organic solvents.

Form Supplied in: white solid; racemic and optically active BNPPA are commercially available.

Preparative Methods: racemic BNPPA is obtained by condensation of (±)-binaphthol (see ***(R)-1,1´-Bi-2,2´-naphthol***) and ***Phosphorus Oxychloride*** followed by hydrolysis (eq 1).[1] Racemic BNPPA can be resolved by recrystallization of its cinchonine salt.[1]

Chiral Ligand for Asymmetric Catalysts.

(*S*)-(+)- and (*R*)-(-)-BNPPA are efficient chiral ligands for the Pd-catalyzed hydrocarboxylation of alkenes.[5] Naproxen can be obtained regioselectively in 91% ee (eq 2).

Dinuclear Rh complexes modified with optically active BNPPA catalyze asymmetric carbene reactions with moderate enantioselectivity (eqs 3 and 4).[6]

2,2´-Bipyridinium Chlorochromate[1]

[76899-34-8] · $C_{10}H_9ClCrN_2O_3$ · 2,2´-Bipyridinium Chlorochromate · (MW 292.64)

(mild and selective oxidizing agent for primary and secondary alcohols;[2] can oxidize benzylic methylenes[11])

Alternate Name: BPCC.

Physical Data: mp not available.

Solubility: insol dichloromethane; sol acetone.

Form Supplied in: yellow crystalline solid; widely available.

Handling, Storage, and Precautions: the dry reagent is an air-stable and nonhygroscopic solid; it can be stored for extended periods protected from light and over calcium chloride. Solvents must be anhydrous and free of reducing impurities. 2,2´-Bipyridinium chlorochromate is reputed to be a toxic agent. The reagent should be handled in a fume hood.

Oxidation of Primary and Secondary Alcohols.

2,2´-Bipyridinium chlorochromate (BPCC) is a synthetically useful variant of ***Pyridinium Chlorochromate*** (PCC), in which the presence of the 2,2´-bipyridyl cationic ligand seems to offer special advantages in certain instances. Treatment of primary and secondary alcohols with BPCC in dichloromethane or acetone at rt for 2-4 h affords aldehydes and ketones in good yield (eqs 1-3).[2]

No overoxidation of aldehydes to carboxylic acids has been observed. BPCC is weaker than PCC, and thus 2-4 equiv are required for good yields.[3] However, the use of this reagent greatly simplifies purification of reaction products, since the chromium-containing byproducts are water-soluble granular materials, which can easily be removed by filtration through Celite. BPCC has proven to be efficient for the oxidation of alcohols in molecules containing acid-sensitive groups, due to the buffering effect of the 2,2´-bipyridyl system. Oxidation of citronellol gives citronellal in 89% yield without the cationic cyclization that occurs when unbuffered pyridinium chlorochromate is used.[4] BPCC can also be buffered with sodium acetate, and this is especially useful for oxidations in systems prone to epimerization (eq 4).[5,6]

BPCC can be utilized for the oxidation of unsaturated primary alcohols in polyenes. Thus (2*E*,4*Z*)-2,4,11-dodecatrien-1-ol is smoothly oxidized in dichloromethane at rt to the corresponding unsaturated aldehyde without *E*/*Z* isomerization (eq 5).[7]

A particularly mild oxidant can be obtained by combination of BPCC with neutral ***Alumina***. 1,2-Diols undergo oxidative carbon-carbon cleavage to aldehydes when treated with BPCC alone,[8] but BPCC/alumina (1:1) converts the same 1,2-diol into an α-hydroxy ketone, albeit in moderate yield (eq 6).[9]

BPCC in conjuction with alumina as a buffering agent is effective in oxidizing a primary alcohol in the presence of a silyl ether protecting group (the acidic PCC reagent attacks silyl ethers). 5-(Benzyloxy)-3-[(*t*-butyldiphenylsilyl)oxy]pentan-1-ol is thus converted into the corresponding aldehyde in almost quantitative yield (eq 7).[10]

Oxidation of Benzylic Methylene.

BPCC in acetone is able to perform benzylic oxidation of hydrocarbons to aryl ketones. A large excess of oxidant must be used (16 equiv) and these reactions require 24-28 h (eqs 8 and 9).[11] PCC is also effective for these types of benzylic oxidation.

(8)

(9)

Oxidative Ring Opening of Furan.

PCC is a useful reagent in oxidative ring opening of several furans, but the reagent is less effective in the reactions of reactive furans, such as 5-methoxy derivatives. By contrast, treatment of the same substrate with BPCC effects a smooth cleavage to an α,β-unsaturated γ-keto ester (eq 10).[12]

(10)

Oxidation of Sulfur-Containing Molecules.

BPCC (1 equiv) at rt can oxidize dialkyl sulfides to the corresponding sulfoxides (68-87% yield). However, dialkyl sulfones may be present as a byproduct, especially with primary alkyls (eq 11).[4]

R = *n*-Pr	80%	19%
R = *n*-Bu	87%	2.8%
R = *t*-Bu	68%	0%

Bis(acetonitrile)chloronitropalladium(II)[1]

[77933-52-9] · $C_4H_6ClN_3O_2Pd$ · Bis(acetonitrile)chloronitropalladium(II) · (MW 269.98)

(reagent capable of catalyzing the oxidation of alkenes to ketones,[2] aldehydes,[3] or epoxides[4])

Physical Data: yellow solid, mp 107-109 °C.[2]

Solubility: sol chloroform, benzene, acetonitrile.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) 2.19 (s).[2]

Preparative Method: prepared from the reaction of $Pd(MeCN)_2Cl_2$ (formed from ***Palladium(II) Chloride*** and acetonitrile) with 1 equiv of ***Silver(I) Nitrite*** in ***Acetonitrile***.[2] Removal of the silver chloride after 1 h by filtration and evaporation of the solvent gives the required complex in quantitative yield.

Handling, Storage, and Precautions: the complex should be stored under an inert atmosphere. Palladium compounds are reported to be mildly toxic. Acetonitrile is highly flammable and lachrymatory.

Reactions of Alkenes.

Bis(acetonitrile)chloronitropalladium(II) can act as an efficient catalyst for the oxidation of alkenes to ketones.[2] The reaction frequently gives good yields and high selectivity, even for acid sensitive substrates such as 2-methyl-3-buten-2-ol (eq 1).[5]

(1)

Occasionally the rate for the reaction can be too low. In such situations the rate can be dramatically increased by making the catalyst a cationic palladium complex.[6] This can be achieved by the addition of a silver salt. For instance, if

Silver(I) Hexafluoroantimonate is added to the palladium complex the rate of oxidation of oct-1-ene to octan-2-one in THF shows a 20-fold rate increase over the neutral palladium species. Under these conditions and over longer periods of time, the resultant ketone can undergo oxydehydrogenation to give the α,β-unsaturated ketone. In the case of cyclohexene the reaction can proceed even further to form phenol (eq 2).

If bis(acetonitrile)chloronitropalladium(II) is treated with ***Copper(II) Chloride*** in *t*-butanol at 55 °C, a new catalyst is formed which will catalyze the oxidation of terminal alkenes to aldehydes (60-70% yields) with reasonable selectivity (eq 3).[3]

These conditions also enhance the rate of reaction and by carrying out the reaction in a 1:1 mixture of *t*-butanol and *N*,*N*-diethylpivaloylamide,[7] instead of just *t*-butanol, the selectivity can be changed to favor formation of the ketone (generally with >90% selectivity).

If the alkene being oxidized is more sterically constrained, the hydrogen migration necessary to produce the ketone becomes disfavored and an epoxide is formed instead (eq 4).[8] For this reaction to be efficient, the transformation must be carried out at low-to-moderate concentration. If the epoxidation of norbornene is attempted at high concentration, dimerization occurs to give a tetrahydrofuran adduct.[9]

Bis(acetonitrile)dinitropalladium(II)[1]

[77933-53-0] · $C_4H_6N_4O_4Pd$ · Bis(acetonitrile)dinitropalladium(II) · (MW 280.54)

(reagent capable of catalyzing the oxidation of alkenes to ketones[2,3] and the nitration of alkenes[3])

Physical Data: yellow solid.

Solubility: sol acetone, dichloromethane, acetonitrile; sparingly sol toluene.

Analysis of Reagent Purity: ^{1}H NMR (acetone-d_6): 2.16 ppm (s).[3]

Preparative Method: prepared from the reaction of $Pd(MeCN)_2Cl_2$ (formed from the reaction of ***Palladium(II) Chloride*** and ***Acetonitrile***) with 2 equiv of ***Silver(I) Nitrite*** in acetonitrile. Removal of silver chloride by filtration after 1 h and evaporation of the solvent gives the complex as a yellow solid in quantitative yield.[3]

Handling, Storage, and Precautions: darkening of the complex occurs on extended drying under vacuum or upon recrystallization from acetonitrile and toluene. The complex should be stored under an inert atmosphere. Palladium compounds are reported to be slightly toxic and acetonitrile is highly flammable and lachrymatory.

Oxidation and Nitration of Alkenes.

Bis(acetonitrile)dinitropalladium(II) has been shown to be effective for the catalytic oxidation of alkenes to ketones[2,3] or for the nitration of alkenes.[3] Which of the possible products is obtained is primarily dependent on the choice of solvent.[2] If the reaction is carried out in acetone, formation of the ketone is favored, but if toluene is used the nitration product predominates (eq 1).

The reaction in toluene, however, takes over a week to go to completion because of the sparing solubility of the palladium complex. A more recent study has shown that the same yields and selectivity can be obtained in 5 h by carrying out the reaction in refluxing dichloromethane.[3] It should be noted that nitration with this complex is limited to terminal alkenes. Internal (such as *cis*-2-butene) and cyclic (such as cyclohexene) alkenes react with the complex to give primarily oxidized products.

Bis(acetylacetonato)zinc(II)

$Zn(MeCOCHCOMe)_2(H_2O)$

[14024-63-6] · $C_{10}H_{16}O_5Zn$ · Bis(acetylacetonato)zinc(II) · (MW 263.60)

(catalyst for the coupling of aryl substituted allylic alcohols with β-dicarbonyl compounds,[1] and of organoboranes with organohalides;[2] selective *C*-alkylation of β-diketones;[3] preparation of amino acid derivatives, aminomaleimides,[4] and β-trichloromethyleneamino diones[5])

Alternate Name: $Zn(acac)_2$.

Physical Data: mp: anhydrous: 127 °C; monohydrate: 135-138 °C.

Solubility: dissolves readily in most organic solvents.

Form Supplied in: crystalline; widely available.

Preparative Method: from the reaction of $ZnSO_4.7H_2O$ with acetylacetone (2,4-pentanedione) and NaOH.[6]

Purification: anhydrous: sublimation, 110 °C (0.1 mmHg), recrystallized from *n*-hexane;[6] monohydrate: recrystallized from ethyl acetate.[6]

Handling, Storage, and Precautions: hygroscopic; irritating to eyes, respiratory system and skin. The monohydrate is unstable toward heat, and forms byproducts on dissolution of the hydrate. The anhydrous zinc complex is stable toward heat.

Introduction.

$Zn(acac)_2$ is a widely available catalyst which is prepared through the reaction of $ZnSO_4$, acetylacetone and NaOH, to give either the hydrate or the anhydrous zinc complex.[5] $Zn(acac)_2$ can perform two general types of reactions: (1) stoichiometric reaction at the nucleophilic carbon of the zinc acetylacetonate, and (2) catalytic reaction at the nucleophilic carbon of other β-dicarbonyl substrates.

Stoichiometric Coupling Reactions.

$Zn(acac)_2$ efficiently forms a carbon-carbon bond through the coupling of aryl substituted allylic alcohols with the

nucleophilic central carbon of the acetoacetonate ligand (eq 1).[1] Starting with either (*E*) or (*Z*) allylic alcohols, these reactions give (*E*)-γ,δ-unsaturated ketones through *syn-anti* isomerization of the intermediate π-allyl palladium species. The ***Titanium Tetraisopropoxide*** serves to (1) activate the allylic alcohol toward π-allyl complex formation via an allyl titanate, and (2) activate the coupled dicarbonyl species toward deacylation. An intractable mixture of products occurs when alkyl rather than aryl substituted allylic alcohols are used.[1] Of the various palladium catalysts investigated for this reaction, ***Tetrakis(triphenylphosphine)palladium(0)*** is effective while $PdCl_2$, $Pd(OAc)_2$, and $PdCl_2(PhCN)_2$ are not. $Zn(acac)_2$ can also be prepared in situ by mixing ***Zinc Chloride*** and acetylacetone in the presence of ***Triethylamine***, and can then be used to perform transformations similar to those previously described. This in situ preparation can also be employed to couple allylic alcohols with the zinc enolate of β-keto esters and β-diesters as well as other β-diketones (eq 2).[1]

Unsymmetrical ketones are produced through the carbonylative cross-coupling reaction of aryl iodides or benzyl halides with trialkylboranes mediated by $Zn(acac)_2$ and $PdCl_2(PPh_3)_2$. Typically, yields for this coupling process range from 43-82%.[2] The use of either Et_3B or *B*-alkyl-9BBN derivatives proved to be efficient in the transfer of the desired alkyl group (eq 3).[2] For activation of these coupling reactions, $Zn(acac)_2$ is superior to the acetoacetonate complexes of various other metals (i.e. Li, Mg, Al, Ca, Ti, Mn, Fe, Co, Cu, Mo, and Sn).

$R^1X = PhI, PhCH_2Cl; R^2 = \text{primary or secondary alkyl}$

Selective *C*-alkylation occurs through the addition of various S_N1-type organohalides to the nucleophilic carbon of the $Zn(acac)_2$ (eq 4).[3] This transformation provides yields comparable to those obtained with $Co(acac)_2$, but overall these reagents are less effective than $Co(acac)_3$.[3]

$RX = PhCH_2Br, PhCH(Me)Br, Ph_2CHBr, Ph_3CCl$, 1-bromoadamantane

Catalytic Reactions with β-Dicarbonyl Compounds.

Unsaturated α-amino acid derivatives are obtained through the $Zn(acac)_2$ catalyzed reaction of ethyl cyanoformate with β-diketones, β-keto esters, and β-diesters (eq 5).[4] Similar reactions with β-keto amides result in the formation of cyclic aminomaleimides (eq 6).[4]

$R^1 = R^2 = Me; R^1 = R^2 = Ph; R^1 = Me, R^2 = OEt; R^1 = R^2 = OEt$

R = H, 52%; R = Bn, 90%

$Zn(acac)_2$ also effectively promotes the addition of β-diketones or β-keto esters to trichloroacetonitrile, giving β-trichloromethyleneamino diones in 40-90% yields.[5] The addition of β-dicarbonyl compounds to cyanogen can be achieved with the use of either $Cu(acac)_2$ or $Zn(acac)_2$ (eq 7). These metal catalyzed reactions of cyanogen with β-keto amides give different regioselectivity when compared to catalysis by the ethoxide ion.[7]

Bis(acrylonitrile)nickel(0)[1]

[12266-58-9] · $C_6H_6N_2Ni$ · Bis(acrylonitrile)nickel(0) · (MW 164.82)

(source of nickel(0) useful for the oligomerization of strained alkanes and alkenes,[2] and the cyclooligomerization of alkynes[3])

Alternate Name: $Ni(AN)_2$.

Physical Data: mp 105 °C dec (N_2). The structure of this complex has been thoroughly investigated.[4]

Solubility: sol pyridine, *n*-butylamine. Only sparingly sol most other organic solvents.

Analysis of Reagent Purity: IR: ν_{CN} 2200, $\nu_{C=C}$ 1446 cm^{-1}.[1]

Preparative Methods: under a CO_2 condenser, 2.6 g ***Tetracarbonylnickel*** (caution: extremely toxic, volatile) was refluxed with 25 mL of freshly distilled ***Acrylonitrile*** for 4 h with collection of evolved CO gas. The resultant bright red solid was collected under N_2, washed with methanol and ether, and dried.[5]

Handling, Storage, and Precautions: highly oxygen sensitive: pyrophoric. Special inert-atmosphere techniques must be used.[6] Should be stored at 0 °C.

Oligomerization of Strained Alkanes and Alkenes.

$Ni(AN)_2$ has been shown to react with strained alkanes by oxidative addition of nickel(0) to C-C bonds. These organometallic complexes can go on to form new C-C bonds in the presence of electron-deficient alkenes. Bicyclo[2.1.0]pentane reacts with a catalytic amount of $Ni(AN)_2$ in the presence of acrylonitrile or methyl acrylate to give mixtures of norbornane products and a cyclopentene (eq 1).[7] The norbornane products are formed by insertion of

the activated alkene into the initially formed organometallic complex, followed by reductive elimination of a bridged nickelacyclohexane intermediate. β-Hydride elimination of this intermediate leads instead to the cyclopentene product. Bicyclo[1.1.0]butanes also react to give allylcyclopropanes (see also ***Bis(1,5-cyclooctadiene)nickel(0)***).[8] In addition, the highly-strained 1,8-bishomocubane system has been isomerized in the presence of this catalyst.[9]

R = CN	47%	28%	16%
R = CO_2Me	33%	33%	22%

Quadricyclane (**1**) is isomerized to norbornadiene (**3**) in the presence of $Ni(AN)_2$ in 87% yield (eq 2).[10] The reaction proceeds through organonickel intermediate (**2**), and indeed, addition of an electron-deficient alkene to pure samples of either (**1**) or (**3**) along with the nickel catalyst gives rise to the same adduct (**4**). This [2 + 2 + 2] cycloaddition of norbornadiene is facilitated by the addition of phosphorus ligands, and the steric properties of these ligands influence the stereoselectivity of the reaction (see also ***Dicyanobis(triphenylphosphine)nickel(II)***).[11] Norbornene derivatives can be induced to participate in [2 + 2] cycloadditions,[12] and methylenecyclopropanes react with alkenes to give methylenecyclopentanes (see also ***Bis(1,5-cyclooctadiene)nickel(0)***).[13]

(2)

Cyclooligomerization of Alkynes.

In the presence of a catalytic amount of $Ni(AN)_2$, alkynes can be cyclotrimerized to give benzene derivatives (see also ***Bis(1,5-cyclooctadiene)nickel(0)***).[14] Labeling studies have shown that the [2 + 2 + 2] cyclotrimerization of 2-butyne does not take place through a cyclobutadiene intermediate, but probably occurs via a nickelacyclopentadiene species.[15] When acetylene is used in this reaction, cyclotetramerization occurs to give cyclooctatetraene (see also ***Tetrakis(trichlorophosphine)nickel(0)***).

Other Uses.

This complex can also be used to catalyze the Meerwein arylation reaction[16] between activated alkenes and arenediazonium salts.[17] Acrylonitrile may be selectively dimerized to form 1,4-dicyanobutenes when phosphorus ligands are present.[18] Nitriles are converted into methyl ketones using $Ni(AN)_2$ and ***Trimethylaluminum***.[19]

Bis(allyl)di-μ-bromodinickel

[12012-90-7] · $C_6H_{10}Br_2Ni_2$ · Bis(allyl)di-μ-bromodinickel · (MW 359.33)

(reacts with organic halides by a nickel-radical chain reaction; couples allyl groups, forming macrocycles; generates alcohols from carbonyls)

Physical Data: red solid; sublimation point 80 °C; dipole moment 1.31 D.[1]

Solubility: sol benzene, DMF, and other organic solvents.

Preparative Method: the reagent may be prepared from allyl bromide and $Ni(CO)_4$ or $Ni(cod)_2$ as described below.

Purification: by sublimation.

Handling, Storage, and Precautions: is air and moisture sensitive. It is generally prepared and used in situ. See entries for ***Allyl Bromide***, ***Tetracarbonylnickel***, and ***Bis(1,5-cyclooctadiene)nickel(0)*** for further information.

Synthesis and General Considerations.

The reagent was originally generated from the reaction of $Ni(CO)_4$ with allyl bromide (eq 1).[1] Later, it was found that $Ni(cod)_2$ also works well as the nickel source in the synthesis of (allyl)nickel halides.[2]

(1)

The geometry of the complex consists of two allyl groups bonded through their π-systems to the nickel atoms. Because the center core of Ni_2Br_2 is planar, there are two possible geometries for the complex. In one, the center carbons of the allyl groups are on the same side (*cis*) of the Ni_2Br_2 plane, and in the other, they are on opposite sides (*trans*). Typically, the mixture of these two complexes is used for all subsequent reactions.

The synthesis of the allylnickel halide complex is not restricted to allyl bromide itself. A variety of methyl substituted and cyclic allyl derivatives will form complexes. In contrast to the better known allylpalladium complexes, which are electrophilic, these allylnickel halide complexes are nucleophilic. With unsymmetrically substituted allyl complexes, it is usually the less substituted of the carbons which forms the bond to the electrophile.[3]

Reactions with Alkyl, Aryl, and Vinyl Halides.

Allylnickel halide complexes react with a large variety of organic halides, including primary, secondary, tertiary, vinyl, and aryl compounds, and will do so smoothly, even in the presence of many common functional groups, including alcohols and esters (eq 2). The reactivity order for the X group is I > Br >> Cl. These reactions work only in polar coordinating solvents such as DMF or HMPA.[3-6]

(2)

RX = $PhCH_2Br$, 91%; cyclohexyl iodide, 91%; $H_2C{=}CHBr$, 70%; PhI, 98%

Initially it was believed that a coordinating solvent was needed because the first step is cleavage of the dimer, with the solvent filling-in the now vacant coordination site. Subsequent steps of this reaction are oxidative addition to the RX bond, which proceeds smoothly regardless of the substitution pattern of the R group, followed by reductive elimination of the R-allyl product.[3]

More recently, it has been shown that the mechanism is much more complicated.[7] The reaction goes by a radical chain process; however, it is a nickel and not a carbon radical which is the chain carrying species. This mechanism nicely explains the observed initiation by light, heat, or a reducing agent, the inhibition by an electron acceptor, the reactivity of a large variety of different organic halides, and the racemization observed for secondary halides.

Reaction with Allyl Halides.

One of the more common reactions of an allylnickel halide complex is with an allyl halide to generate a 1,5-hexadiene. A variation of this reaction has been used to couple two allyl groups together to form a macrocyclic ring system (eq 3).[8] This method has proven successful for rings as large as 18. In addition, the reaction

conditions are compatible with a large variety of substitution patterns and functional groups.

(3)

Reaction with Carbonyls.

The allylnickel halide complex will attack an aldehyde or a ketone to generate an alcohol (eqs 4 and 5).[9] However, it will not attack an ester or nitrile. The reaction with a quinone generates an allyl-substituted quinone product, through an initial Michael addition to the α,β-unsaturated system.[10]

(4)

(5)

(via π-allylnickel complex)

Other Reactions.

Tetracarbonylnickel, an allyl bromide derivative, and an alkyne react to generate a cyclopentenone derivative (eq 6).[11,12] It is believed that these reactions go through an allylnickel halide complex as an intermediate.

Bis(allyl)di-μ-chlorodipalladium[1]

[12012-95-2] · $C_6H_{10}Cl_2Pd_2$ · Bis(allyl)di-μ-chlorodipalladium · (MW 365.89)

(prototype substrate for π-allylpalladium reactions,[1] catalyst precursor for allylic alkylations,[1] cross-coupling reactions,[1] diene dimerization,[2] addition of nucleophiles to dienes,[3] conversion of allyl amines to dienes,[4] siloxycyclopropane cleavage,[5] and decomposition of diazo compounds[6])

Physical Data: mp 160 °C.

Solubility: sol benzene, $CHCl_3$, acetone, methanol.

Form Supplied in: pale yellow crystals; widely available.

Analysis of Reagent Purity: IR;[7] MS;[8] ^{13}C NMR;[9] ^{1}H NMR.[10]

Preparative Methods: numerous routes are available.[1] Preferred methods are: reaction of propene with ***Palladium(II) Trifluoroacetate***, followed by counterion exchange with chloride;[11] reaction of ***Potassium Tetrachloropalladate(II)*** with ***Allyl Chloride*** in water;[12] reaction of Na_2PdCl_4, allyl chloride, and CO in water.[13]

Prototype Substrate for π-Allylpalladium Reactions.

Examples of the addition of nucleophiles to bis(allyl)di-μ-chlorodipalladium (**1**) and the homologous unsymmetrical di-μ-chlorobis(crotyl)dipalladium (**2**) are shown below. The latter is included to illustrate aspects of the regiochemistry of nucleophilic attack. The addition of ligands, typically phosphines, is generally required to enhance the electrophilicity of these reagents.[14]

Carbon nucleophiles of pK_a 10-20 have been most studied and often work best with these substrates (eq 1),[1,15] but enamines,[1] cyclopentadiene anions,[1q] enolates (eq 2),[1,16] organotin, -thallium, -zinc, -aluminum, -lithium, and -zirconiums,[1q] as well as Grignards (eq 3)[1,17] and borates,[18] also add to π-allylpalladium complexes. Heteroatom nucleophiles also add successfully; these include amines (eq 4),[1,19] amides,[1q] azides,[1q] magnesium amides,[1q]

sulfonamides,[1q] alcohols,[1q] acids (eq 5),[1,20] nitrites,[1q] sulfinic acids,[1q] thiols,[1q] phosphines,[1q] and phosphites.[1q] Limited use of transition metal nucleophiles is also known.[21]

(1) (1)

(2)

51% 20% (2)

(2) 83%

14% 2% (3)

The use of ***Hexamethylphosphoric Triamide*** and ***Triethylamine*** as ligands in place of the usual phosphines in the addition of ester enolates to (**1**) results in the formation of cyclopropanes via the unusual initial attack at the central carbon atom (eq 6).[22] The process is very limited with respect to nucleophile, however, as only branched ester enolates produce a cyclopropane. ***N,N,N´,N´-Tetramethylethylenediamine*** and ***Carbon Monoxide*** as ligands also promote central carbon attack by ester enolates.[23]

The attack by nucleophiles on π-allylpalladium complexes is generally a stereospecific process, but whether the reaction occurs with retention or inversion with respect to the metal is a complex issue, and strongly depends on the nature of the nucleophile employed.[24]

Insertion Reactions.

CO can be inserted into π-allylpalladium dimers to prepare various β,γ-unsaturated carboxylic acid derivatives (eq 7).[25,26] This process is greatly facilitated by the presence of carboxylate anions. The bridged acetato complex (**3**) works equally as well as (**2**) in this reaction. Similarly, isocyanides,[27,28] CO_2,[29] and SO_2[1q] can also be inserted into these complexes.

(3)

π-Allylpalladium dimers can also react with alkenes (eq 8),[30] dienes,[31] and allenes[1] by an insertion process.

(8)

Reduction.

A variety of metal hydride reducing agents can be employed to reduce π-allylpalladium dimers. These include ***Sodium Borohydride***, ***Sodium Cyanoborohydride***, ***Lithium Triethylborohydride***, ***Lithium Aluminum Hydride***, ***Lithium Tri-t-butoxyaluminum Hydride***, polymethylhydrosiloxane, and R_3SiH (eq 9).[1q,32] Formic acids and formate salts also reduce π-allylpalladium complexes to the corresponding alkenes by the liberation of CO_2 and the in situ formation of a Pd hydride.

The use of stoichiometrically generated π-allylpalladium dimers such as (**1**), (**2**), and (**3**) has largely been obviated by the discovery that the crucial allyl intermediate can be generated catalytically from PdL_4 and an allyl-X compound, where X is a wide variety of leaving groups (see ***Tetrakis(triphenylphosphine)palladium(0)*** for example).[1]

Use as a Catalyst Precursor. Allylic alkylations.

The allylpalladium chloride dimer (**1**) is a particularly useful catalyst precursor for a variety of Pd-mediated processes and possesses a number of significant advantages over PdL_4 complexes. For example, the dimer (**1**) can be employed in conjunction with a ligand L and be subjected to designed in situ reduction to yield a Pd^0-L catalyst. A catalyst generated in this fashion allows rapid access to a great spectrum of Pd^0-L species by obviating the need for individual syntheses of each PdL_4 complex. In addition, the ratio of Pd/L, which is often crucial in defining catalyst performance, can be simply varied. Such variation is obviously not possible with a PdL_4 complex.

The use of (**1**) as a catalyst precursor in a classic π-allyl alkylation is shown in eq 10 as a key step in the preparation of a carbanucleoside, carbovir.[33]

(10)

Significant use of (**1**) as a Pd^0 catalyst precursor has come in the area of asymmetric π-allylpalladium alkylations.[34] A large number of optically active ligands, L*, have been screened in the palladium-catalyzed alkylation step. Particularly promising L* ligands for this reaction include: phosphinoaryldihydrooxazoles (eq 11);[35] ferrocenylphosphines appended with a side chain designed to interact with the incoming nucleophile (eq 12);[36]

phosphinooxazoles;[37] thienyloxazoles;[38] bis-oxazoles;[39] 5-aza-semicorrins;[40] and BINAP.[41]

(11)

(12)

The chloro dimer (**1**) has also been employed in Pd-catalyzed asymmetric hydrosilation of alkenes (eq 13).[42]

(13)

(*S*)

Cross-Coupling Reactions.

The transition metal catalyzed cross-coupling reaction of an organometallic nucleophile and an organic halide constitutes an important carbon-carbon bond forming process. Organometallic compounds of zinc, aluminum, boron, zirconium, magnesium, mercury, copper, tin, silicon, and palladium have all been employed as coupling partners. The dimer (**1**) has served as an excellent catalyst for this process, as illustrated below. The coupling of organotin (eq 14)[43,44] and -zirconium (eq 15)[45] reagents with allyl halides has employed a combination of (**1**) and maleic anhydride to effect cross coupling. The fluoride promoted, Pd-catalyzed, cross coupling of organosilanes and organohalides appears to be a particularly mild and selective way to achieve this reaction. This process allows coupling of alkenylsilanes with alkenyl and allyl halides (eq 16),[46,47] aryl- and heteroarylsilanes with aryl and heteroaryl iodides (eq 17),[48,49] alkyl silicates with aryl halides (eq 18),[50] and ethynyl- and allylsilanes with vinyl, aryl, and allyl halides.[51]

(14)

(15)

(16)

(17)

(18)

In the presence of CO these fluoride-promoted Pd-catalyzed cross-coupling reactions provide unsymmetrical ketones (eq 19),[52,53] including polyaryl ketones.[54]

(19)

The title reagent can also catalyze the stannylation (eq 20)[55,56] and silylation[57,58] of organic halides via cross coupling.

(20)

Diene Dimerization.

The reductive dimerization of isoprene to its head-to-tail dimer has been achieved in high yield using di-μ-acetatobis(allyl)dipalladium (**4**) as the catalyst in combination with phosphine ligands.[2] To achieve optimal selectivity for the desired dimers, a large number of phosphines have been examined in this reaction. Use of the complex (**4**) with the phosphine allows rapid access to each of the desired catalysts, as well as maximum flexibility with respect to Pd/L ratio (eq 21).[2]

(4)

(21)

The organopalladium intermediates in the diene dimerization can also be intercepted by reagents such as ROH,[2] R_3SiSiR_3,[59] and CO_2 (eq 22).[60]

(22)

Codimerization of dienes and alkenes is also possible (eq 23). In this case, (**1**) and Ph_3P-BF_3 are employed as cocatalysts.[61] Complex (**1**) has also been used in the polymerization of butadiene.[62]

(23)

Addition of Nucleophiles to Dienes.

The use of (**1**) with bidentate phosphine ligands and NaOMe to effect in situ Pd reduction allows the selective addition of nucleophiles to 1,3-dienes, including isoprene, without significant competing diene dimerization (eq 24).[3]

(24)

Arenesulfinic acids have also been reported to add to 1,3-dienes in the presence of (**1**) and Ph_3P to yield allylic sulfones (eq 25).[63]

(25)

Preparation of Dienes from Allylic Amines.

Treatment of allylic amines with a catalyst generated from the reaction of (**1**) with $Ph_2P(CH_2)_4PPh_2$ (dppb) and $NaClO_4$ gave the corresponding diene (eq 26).[4] Interestingly, the catalyst generated in this fashion was found to be superior to $Pd(dppb)_2$.

(26)

Siloxycyclopropane Cleavage.

Siloxycyclopropanes undergo C-C bond cleavage and coupling to aryl triflates (eq 27)[5a,b] and acid chlorides (eq 28)[5a,c] in the presence of (**1**) and a phosphine or phosphite ligand. In this fashion, the siloxycyclopropanes serve as synthetically useful homoenolate anions.

Decomposition of Diazo Compounds.

The title reagent decomposes ethyl diazoacetate to the corresponding carbene under mild conditions.[6a] If the decomposition is conducted in the presence of an alkene, a cyclopropane is produced (eq 29).[6a]

Diazo ester (**5**) undergoes ring enlargement via a carbene intermediate with (**1**) as the catalyst (eq 30).[6b]

(30)

Diazo ester (**6**) follows different decomposition pathways depending on the transition metal catalyst employed.[6c] $Rh_2(OAc)_4$ yielded (**7**), while (**1**) gave (**8**) (eq 31).

4,4´-Bis(2-amino-6-methylpyrimidyl) Disulfide

[69945-13-7] · $C_{10}H_{12}N_6S_2$ · 4,4´-Bis(2-amino-6-methylpyrimidyl) Disulfide · (MW 280.37)

(in combination with phosphines, induces lactonization of o-hydroxy acids[1])

Physical Data: mp 207-209 °C.

Solubility: sol benzene, acetonitrile.

Form Supplied in: not available from commercial sources.

Preparative Methods: readily prepared from commercially available 2-amino-4-chloro-6-methylpyrimidine, which is treated with $NaS.H_2O$ (5 equiv) in degassed propylene glycol at 140 °C for 3 h. The solution is diluted with H_2O and neutralized with acetic acid. The collected precipitate is recrystallized from ethanol, giving pure 2-amino-4-mercapto-6-methylpyrimidine, which is dimerized with iodine in boiling methanol containing potassium carbonate.

Purification: by crystallization from ethanol or chromatography on silica gel (chloroform-ethanol, 1:1).

4,4´-Bis(2-amino-6-methylpyrimidyl) disulfide and ***Triphenylphosphine*** form the corresponding thioesters of o-hydroxy acids, which under high dilution conditions and in the presence of ***Silver(I) Perchlorate*** as a thiol scavenger give the corresponding macrolides (eq 1). Optimal conditions involve 1.5 equiv of both the disulfide and the phosphine, and 1.1 equiv of the silver salt, in refluxing dry benzene for 5 h.[1]

2,2´-Dipyridyl Disulfide and related compounds have also been used as a method for macrolide formation; the addition of thiophilic metal cations and/or pyridine derivatives has been found to assist this process.[2]

This oxidation-reduction condensation,[3] using 2,2´-dipyridyl disulfide, constitutes an excellent strategy for the solid-phase synthesis of peptides. This method does not affect amino acids sensitive to oxidation, proceeds under mild conditions without the requirement of basic or acid catalysts, and has the advantages of minimizing both racemization of carboxyl component and side-reactions of certain amino acids.[4] Furthermore, it has been successfully applied to phosphorylation reactions, such as the synthesis of coenzyme A,[5] oligothymidilates, and nucleotide cyclic phosphates,[6] and nucleotides from O^2,2´-cyclouridine.[7]

Bis(benzonitrile)dibromopalladium(II)

[15003-43-7] · $C_{14}H_{10}Br_2N_2Pd$ · Bis(benzonitrile)dibromopalladium(II) · (MW 472.47)

(palladium catalyst used in the codimerization of alkynes and allyl halides;[1-3] synthesis of α-(*Z*)-halomethylene-γ-butyrolactone derivatives;[4-6] isomerization of alkenes[7,8])

Physical Data: dark brown crystals.

Solubility: sol benzene, methanol.

Form Supplied in: not commercially available.

Preparative Method: prepared in 90% yield by reacting $PdBr_2$ in PhCN with prolonged heating at 100 °C. The reaction mixture is filtered while hot and the filtrate cooled to give a brown precipitate. Additional product is obtained by precipitation with cyclohexane.

Purification: recrystallize from low-boiling petroleum ether.

Handling, Storage, and Precautions: usually prepared just prior to use.

Codimerization of Alkynes and Allyl Halides.

The title reagent (**1**) catalyzes the codimerization of alkynes and allyl halides under mild conditions to yield substituted 1,4-pentadienes in one step. This provides a very convenient synthetic method for the preparation of halogen substituted mono- and/or dialkenes (eqs 1 and 2).[1-3]

Metalated (*Z*)-1-bromo-1-trimethylsilyl-1,4-pentadiene, a 4-pentenoyl anion equivalent, has been prepared by this method. This compound shows great utility in the transformation of alkynylsilanes into carbonyl compounds.

Butyrolactone Synthesis.

Butyrolactones are prepared conveniently by intramolecular cyclizations mediated by bis(benzonitrile)dibromopalladium(II), as shown in eq 3.[4-6]

Isomerization of Alkenes and Addition of Amines to Terminal Alkenes.

Isomerization of alkenes by the title reagent is specific for double-bond migration with no detectable skeletal rearrangement (eq 4).

Bis(benzonitrile)dibromopalladium(II) promotes amination of terminal alkenes to give, after reduction, high yields of

amines (eq 5).[8] Internal alkenes may also be aminated, but the yields are moderate to low. The yield of the amination is strongly temperature dependent and, as the temperature increases, there is a steady decrease in the yield.

(5)

Related Reagents.

Bis(benzonitrile)dichloropalladium(II) is similar to reagent (**1**). They are interchangeable in almost all reactions. The former is more reactive.[9]

Bis(benzonitrile)dichloropalladium(II)

$Pd(PhCN)_2Cl_2$

[14220-64-5] · $C_{14}H_{10}Cl_2N_2Pd$ · Bis(benzonitrile)dichloropalladium(II) · (MW 383.57)

(used as an organic solvent-soluble form of $PdCl_2$ and as a Pd^{II} catalyst)

Alternate Name: bis(benzonitrile)palladium chloride.

Physical Data: mp 129-130 °C.

Solubility: sol chloroform, dichloromethane, benzene, toluene.

Form Supplied in: commercially available as an orange-yellow powder.

Handling, Storage, and Precautions: air-stable, not hygroscopic.

General Considerations.

The title reagent is most often used as a soluble source of palladium chloride. Reactions of this and other palladium chloride derivatives are described in the article on ***Palladium(II) Chloride***.

Bis(benzonitrile)dichloroplatinum(II)

[14873-63-3] · $C_{14}H_{10}Cl_2N_2Pt$ · Bis(benzonitrile)dichloroplatinum(II) · (MW 472.25) (*cis*)

[15617-19-3] (*trans*)

[51921-56-3]

(catalyst for hydrogenation of nitro compounds[5,7a] and hydroformylation of alkenes;[13] versatile starting material for complexes of platinum[3])

Physical Data: mp 224 °C (dec).

Solubility: sol dichloromethane.

Form Supplied in: yellow crystalline solid.

Preparative Methods: prepared as a mixture of *cis* and *trans* complexes. The reaction of ***Palladium(II) Chloride*** in benzonitrile at room temperature for 7 h yields a mixture that can be separated chromatographically to yield 26% *trans*- and 58% *cis*-$PtCl_2(PhCN)_2$.[1] An alternate route requires stoichiometric amounts of potassium tetrachloroplatinate(II) and benzonitrile stirred at room temperature for one week. Trituration of the product with hot benzene yields pure *cis*-$PtCl_2(PhCN)_2$ in 60% yield; the cooled benzene solution yields pure *trans*-$PtCl_2(PhCN)_2$ in 20% yield.[2a,b]

Purification: chromatography on silica gel with dichloromethane as eluant,[1] or trituration with hot benzene.[2a,b]

Introduction.

The title reagent is frequently used as the starting material for preparation of organometallic complexes of platinum.[3] The labile ligand, PhCN, can be easily displaced with various phosphorus(III) ligands, thereby modifying or improving the activity of the catalyst. Polymer-supported platinum catalysts are prepared by treating phosphole-containing copolymers with the title reagent. The resulting heterogeneous catalyst can be used in the presence of

Tin(II) Chloride dihydrate to catalyze the hydroformylation of a variety of alkenic substrates.[4]

Hydrogenations.

The homogeneous hydrogenation of aliphatic nitro compounds is catalyzed by platinum metal phosphine complexes. These complexes are formed in situ by treating the title reagent, which possesses the labile ligand PhCN, with a phosphine reagent, for example ***(R)-N,N-Dimethyl-1-[(S)-2-(diphenylphosphino)ferrocenyl]ethylamine*** (PPFA) at 1000 psi (eq 1).[5]

(1)

Platinum catalysts have also been utilized in the reductive *N*-acylation of nitro compounds. The catalyst system requires the platinum catalyst, carbon monoxide, a Lewis acid (***Tin(IV) Chloride***), and a phosphorus(III) ligand. For example, the title reagent, when used in conjunction with ***Triphenylphosphine***, $SnCl_4$, acetic acid, and CO at 60 atm, yields acetanilide in 89% yield from nitrobenzene (eq 2).[7a] When ethanol is used in place of the acetic acid, the resulting product is the carbamate.[7b]

(2)

Carbonylations, Rearrangements, and *N*-Alkylations.

Platinum catalysts have been used for the carbonylation of alkyl, alkenyl, and alkynyl iodides under carbon monoxide pressure. The title reagent, when used in the presence of ***Tri-n-butylphosphine*** and ***Triethylamine***, shows good catalytic activity in the methoxycarbonylation of 1-iodo-1-octyne (eq 3).[6]

(3)

The transformation of a primary amine to a secondary amine has also been catalyzed by the title reagent.[8] Similar transformations have been reported with ruthenium[9a,b] and palladium[10] catalysts. The title reagent, in the presence of the Lewis acid $SnCl_2.2H_2O$ (Sn:Pt = 2.5:1), catalyzes the reaction of *n*-butylamine to give *N*,*N*-dibutylamine in 65% yield (eq 4). Other Lewis acids such as $SnCl_4$, $FeCl_3$, $AlCl_3$ are not effective in this reaction.

(4)

Rearrangements of oxocyclopropanes to vinyl ethers can be accomplished using the title reagent.[12a,b] The rearrangement of cyclopropanes containing the combination of vicinal alkoxy and alkoxy-carbonyl substituents is facile when using $PtCl_2(PhCN)_2$ as the catalyst (eq 5). Other transition metal complexes, e.g. ***Tetracarbonyl(di-μ-chloro)dirhodium*** and $[Ru(CO)_3Cl_2]_2$, are also active catalysts in this system, as are ***Copper Bronze*** and ***Copper(I) Chloride***.

(5)

N-Alkylation and *N*-allylation can be catalyzed by the title reagent in conjunction with $SnCl_2.2H_2O$.[11] Reaction of aniline with an allylic alcohol gives *N*-allylated products (eq 6). The platinum catalyst does not catalyze isomerization of the allylic alcohol to the corresponding aldehyde.

(6)

The hydroformylation of 1-pentene is catalyzed by the title reagent, $SnCl_2.2H_2O$, and a bidentate phosphine ligand under carbon monoxide pressure. When the bidentate ligand is (-)-DIOP (***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane***) the reaction proceeds in 5 h at 100 °C, yielding 75% hexanal, 9% pentane, and 16% 2-pentene.[13]

Bis(benzoyloxy)borane[1]

[94596-93-7] · $C_{14}H_{11}BO_4$ · Bis(benzoyloxy)borane · (MW 254.05)

(reagent for the reduction of tosylhydrazones of aldehydes, ketones, and enones to the corresponding methylene derivatives[1,2])

Physical Data: mp 166-168 °C

Solubility: sol chloroform, THF, and pentane; reacts readily with water and other protic solvents.

Form Supplied in: white crystalline solid

Analysis of Reagent Purity: the technical bulletin *Quantitative Analysis of Active Boron Hydrides*, available upon request from the Aldrich Chemical Company, Milwaukee, WI, USA, describes methodology to determine reagent purity by hydrogen gas evolution.

Preparative Methods: available via the controlled addition of borane-THF complex to benzoic acid at 0 °C.[1a,b] Preparation using borane-dimethyl sulfide complex involves much milder reaction conditions (25 °C).[2]

Handling, Storage, and Precautions: shows good stability that results from adduct formation with solvent (THF or DMS). Solutions of the reagent in THF have shown little decomposition after storage at 0 °C for 10 days.[1b]

Reduction of Tosylhydrazones of Aldehydes, Ketones, and α,β-Unsaturated Aldehydes and Ketones.

Bis(benzoyloxy)borane has been used for the reduction of tosylhydrazones to the corresponding methylene derivatives. This method offers a mild alternative to the classical Wolff-Kishner and Clemmensen reduction procedures which preclude the presence of sensitive functional groups.[3] This reagent is comparable in reactivity to ***Catecholborane***, which had previously been demonstrated to be a very efficient reagent for the reduction of tosylhydrazones.[4] Regiospecific alkene migration occurs during the reduction of α,β-unsaturated derivatives,[5] and allenes result from the reduction of alkynic substrates.[6] Given the commercial availability of catecholborane, it is probably the reagent of

choice for tosylhydrazone reduction. Representative tosylhydrazone reductions employing bis(benzoyloxy)borane are given in eqs 1-4. The reactions are typically complete in 0.5 to 2 h. As with catecholborane a regiospecific and stereospecific rearrangement occurs in the reduction of α,β-unsaturated tosylhydrazones, permitting the preparation of thermodynamically unstable alkenes.[5,6] The related ***Bis(trifluoroacetoxy)borane*** has been used in the reduction of indoles to indolines.[7]

Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium[1]

[12257-42-0] · $C_{14}H_{16}Cl_2Rh_2$ · Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium · (MW 461.00)

(catalyst for valence isomerization[2] and N-heterocyclization;[3] in combination with phosphorus ligands are catalysts for hydrogenation of many functional groups[5,6] and hydroformylation; with chiral ligands are catalysts for asymmetric hydrogenation[7-11])

Alternate Name: dichlorobis(norbornadiene)dirhodium.

Physical Data: mp 240 °C dec.

Solubility: sol chloroform and benzene; insol ether and light petroleum.

Form Supplied in: yellow crystals.

Preparative Methods: ***Rhodium(III) Chloride*** and bicyclo[2.2.1]hepta-2,5-diene in aq ethanol, when shaken for 2 days, give a yellow deposit.

Purification: recrystallized from chloroform and light petroleum.

Handling, Storage, and Precautions: air stable up to 240 °C.

Catalytic Activity.

The rhodium chloride dimer is easily prepared from rhodium trichloride and the diene has been well used as a catalyst for valence isomerization of quadricyclanes to bicyclo[2.2.1]hepta-2,5-dienes (eq 1).[2]

(1)

The reverse isomerization is catalyzed by ***Copper(I) Chloride*** under irradiation.[2c] This cycle has attracted much attention as a solar energy storage system. The rhodium dimer catalyzes the reaction between aminoarenes and alkanals to give quinolines (eq 2).[3] The rhodium dimer is easily transformed into a monomeric neutral form in combination with neutral donor ligands, which turns into a cationic form in the presence of such salts as ***Potassium Hexafluorophosphate*** and $NaClO_4$ (eq 3).

(2)

(3)

These rhodium complexes of two types show high catalytic activities for hydrogenation of many unsaturated groups[5-11] such as C=C, C&tbond;C, C=O, and C=N. In particular, cationic rhodium complexes are efficient under mild conditions (at ambient temperature and 1 atm of H_2).[5] The original rhodium dimer is readily modified into a selection of active catalysts by use of a wide range of phosphorus ligands including chiral,[7-11,13] polymer-supported,[14] and water-soluble types.[15,16]

With a variety of chiral ligands, such substrates as alkenes,[7] ketones,[8] α-keto amides,[9] α-keto esters,[10] and imines[11] are hydrogenated highly enantioselectively (eqs 4-7).

(4)

(5)

(6)

(7)

Hydroformylation of alkenes proceeds with a rhodium catalyst,[12] even asymmetrically.[13] A polymer-supported rhodium catalyst is efficient for hydrogenation of benzenes to cyclohexanes.[14] Water-soluble phosphine ligands are applicable for asymmetric hydrogenation of alkenes[15] and hydroformylation of alkenes.[16]

Related Reagents.

Bis(bicyclo[2.2.1]hepta-2,5-diene)rhodium Perchlorate; ***Chlorotris(triphenylphosphine)rhodium(I)***.

Bis(bicyclo[2.2.1]hepta-2,5-diene)rhodium Perchlorate[1]

[60576-58-1] · $C_{14}H_{16}ClO_4Rh$ · Bis(bicyclo[2.2.1]hepta-2,5-diene)rhodium Perchlorate · (MW 386.64)

(precursor for various cationic rhodium complexes,[2] which are used as catalysts for hydrogenation,[3] allylic hydrogen migration,[4] hydrosilation,[5] and hydroacylation[6])

Alternate Name: $[Rh(nbd)_2]ClO_4$.

Solubility: sol CH_2Cl_2; insol THF, hexane.

Form Supplied in: rust-brown crystals containing 1 mol THF solvent of crystallization.

Preparative Methods: to a mixture of bicyclo[2.2.1]hepta-2,5-diene (nbd, 0.14 g, 1.5 mmol) and ***Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium*** (0.35 g, 0.75 mmol) in CH_2Cl_2 (15 mL) at room temperature is added ***Silver(I) Perchlorate*** (0.315 g, 1.5 mmol) under nitrogen. After stirring for 1 h, precipitated AgCl is filtered off to give a CH_2Cl_2 solution of $[Rh(nbd)_2]ClO_4$. This solution can be directly used for the next reaction,[7] or diluted by THF (15 mL) followed by evaporation of CH_2Cl_2 under vacuum to separate orange needles of $[Rh(nbd)_2]ClO_4$, which are collected and washed with cold THF and then dried in vacuo to afford rust-brown crystals (0.5 g).[8] For another preparation from $[RhCl(C_2H_4)_2]$, see Fairlie and Bosnich.[6]

Handling, Storage, and Precautions: explosive when heated.

Preparation of Cationic Rhodium Complexes.

Cationic rhodium complexes are useful homogeneous catalysts in organic synthesis. In particular, many selective reactions have been accomplished by use of cationic rhodium complexes with various ligands, i.e. phosphines, pyridine derivatives, and bidentate phosphines. These complexes are expeditiously prepared from $[Rh(diene)_2]^+X^-$ by ligand

exchange, where only one diene is replaced by two monodentate ligands or a single bidentate ligand (eq 1).[9] The complexes thus obtained are used as catalysts, or further treated with molecular hydrogen to afford diene-free complexes, which can also be employed as catalysts (eq 2).[2]

$$[Rh(nbd)_2]^+ ClO_4^- \xrightarrow{(S,S)\text{-CHIRAPHOS}} [Rh(nbd)\{(S,S)\text{-CHIRAPHOS}\}]^+ ClO_4^- \quad (1)$$

$$[Rh(nbd)\{(R)\text{-BINAP}\}]^+ ClO_4^- \xrightarrow[\text{MeOH}]{H_2} [Rh\{(R)\text{-BINAP}\}(MeOH)_2]^+ ClO_4^- \quad (2)$$

(*S*,*S*)-CHIRAPHOS

(*R*)-BINAP

Hydrogenation Catalysts.

The cationic rhodium complexes effectively catalyze hydrogenation of carbon-carbon[9] as well as carbon-oxygen[10] multiple bonds. Bidentate phosphine ligands are most frequently used, and certain chiral ligands induce high enantioselectivities.

Asymmetric hydrogenation of dehydroamino acids to optically active α-amino acids has been studied most extensively. The high optical yields (>90% ee) are attained with BINAP,[3] CHIRAPHOS,[8] CAPP,[11] SKEWPHOS,[12] etc. as ligands in hydrogenation of α-(acylamino)cinnamic acid derivatives (eq 3). Itaconic acid is also hydrogenated in the presence of a (*S*,*S*)-CAPP-Rh complex to afford (*R*)-methylsuccinic acid in 95% ee.[11]

(3)

Hydrogenation of ketones is effectively catalyzed by cationic rhodium complexes with phosphine ligands having alkyl substituents on the phosphorus atom, while arylphosphine-rhodium complexes show only a low catalytic activity.[10,13] Another kind of remarkable catalyst is the cationic rhodium complex with (*R*)-(*S*)-BPPFOH, which catalyzes hydrogenation of 3,4-dihydroxyphenyl (*N*-methylamino)methyl ketone hydrochloride in 95% ee to afford the corresponding 2-amino alcohol, e.g. epinephrine (eq 4).[14]

(4)

Isomerization of Allylamines to Enamines.

Allylic hydrogen migration is catalyzed by cationic rhodium complexes. With optically active bidentate phosphines, i.e. BINAP, achiral allylamines isomerize to optically active enamines in high enantiomeric excess (eq 5).[4]

(5)

Hydrosilation.

Asymmetric hydrosilation of prochiral ketones is promoted by cationic rhodium complexes with AMPHOS[15] as well as DIOP[16] to afford the corresponding alcohols in modest to good enantioselectivities. Carbon-carbon double bonds in allylic alcohols are intramolecularly hydrosilated in a highly enantioselective manner. Subsequent H_2O_2 oxidation affords optically active 1,3-diols (eq 6).[5]

(6)

Hydroacylation.

Cationic rhodium complexes which have bidentate phosphine ligands mediate the hydroacylation of substituted 4-pentenals to cyclopentanones (eq 7).[6] Cationic catalysts are superior in activity to neutral ones such as Wilkinson's catalyst.[17]

(7)

For a more detailed discussion of catalytic asymmetric syntheses via rhodium complexes, see those entries that deal specifically with rhodium complexes/optically active ligand combinations.

Related Reagents.

[71049-99-5] · $C_{36}H_{32}FeOP_2$ · Bis(bicyclo[2.2.1]hepta-2,5-diene)rhodium Perchlorate-(*R*)-1-(*S*)-1´,2-Bis(diphenylphosphino)ferrocenylethanol · (MW 598.44)

(catalyst for asymmetric hydrogenation of functionalized carbonyl compounds[2,3] and enol phosphinates[4])

Alternate Name: (**1**): $[Rh(nbd)_2]ClO_4$; (**2**): (*R*)-(*S*)-BPPFOH.

Physical Data: (*R*)-(*S*)-BPPFOH: [α]25D -285° (*c* 0.5, $CHCl_3$); mp 154-155 °C.

Solubility: $[Rh(nbd)_2]ClO_4$: sol CH_2Cl_2; insol THF, hexane.

Form Supplied in: $[Rh(nbd)_2]ClO_4$: rust-brown crystals containing 1 mol THF solvent of recrystallization.

Preparative Method: (*R*)-(*S*)-BPPFOH is prepared from optically resolved (*R*)-*N*,*N*-dimethyl-1-ferrocenylethylamine (**3**) as shown in eq 1.[5] Dilithiation of (*R*)-(**3**) with ***n-Butyllithium*** followed by treatment with ***Chlorodiphenylphosphine*** affords (*R*)-(*S*)-BPPFA stereoselectively. It is treated with an excess of ***Acetic Anhydride*** at 100 °C to give (*R*)-(*S*)-BPPFOAc with retention of configuration. Finally, treatment with BuLi followed by hydrolysis affords (*R*)-(*S*)-BPPFOH in enantiomerically pure form.

Purification: (*R*)-(*S*)-BPPFOH: chromatography on alumina (EtOAc) followed by recrystallization from ethanol.

Handling, Storage, and Precautions: $[Rh(nbd)_2]ClO_4$: ***explosive*** when heated.

Asymmetric Hydrogenation of Functionalized Carbonyl Compounds.

(*R*)-(*S*)-BPPFOH is designed to have a secondary interaction with a carbonyl substrate through the hydroxy group on the side chain of the ferrocene ring. This additional interaction enables a substrate to coordinate to the metal center with preferential recognition of one prochiral face. In addition to the title combination reagent, $[Rh(cod)_2]ClO_4$ and (*R*)-(*S*)-BPPFOH and the isolated complex, [Rh{(*R*)-(*S*)-BPPFOH}(diene)]ClO_4, will be considered together below.

A high optical yield is attained with [Rh{(*R*)-(*S*)-BPPFOH}(cod)]ClO_4 in the hydrogenation of pyruvic acid to afford (*R*)-2-hydroxypropionic acid (eq 2).[2] Addition of 1 equiv of ***Triethylamine*** is necessary to obtain optimal enantioselectivity. The beneficial effect of the hydroxy group on the side chain of the ferrocene ring is demonstrated by the fact that use of (*R*)-1-(*S*)-1´,2-bis(diphenylphosphino)ferrocenylethyldimethylamine ((*R*)-(*S*)-BPPFA), which is analogous to (*R*)-(*S*)-BPPFOH but lacks the hydroxy group, gives a much inferior result. In the case of a simple ketone, e.g. acetophenone or methyl *t*-butyl ketone, the enantioselectivity is around 40-50% ee.

Hydrogenation of aminomethyl aryl ketone hydrochlorides is also catalyzed by [Rh{(*R*)-(*S*)-BPPFOH}(nbd)]ClO_4 to give (*R*)-2-amino-1-arylethanol hydrochlorides in high ee in the presence of triethylamine (eq 3).[3] 3,4-Disubstitution on the aromatic ring by hydroxy or alkoxy groups affords higher selectivity. The principal sympathomimetic hormone, epinephrine, especially is produced in enantiometrically pure form from (*N*-methylamino)methyl 3,4-dihydroxyphenyl ketone hydrochloride.

$R^1 = R^2 = R^3 = H$	52% ee
$R^1 = H$, $R^2 = OH$, $R^3 = Me$	69% ee

Asymmetric Hydrogenation of Enol Phosphinates.

Catalytic asymmetric synthesis of secondary alkyl alcohols in up to 78% ee is accomplished by asymmetric hydrogenation of enol diphenylphosphinates followed by hydrolysis (eq 4).[4] The highest enantioselectivity is obtained in the hydrogenation of 1-phenylvinyldiphenylphosphinate, though in the case of phosphinates derived from dialkyl ketones, selectivities are rather low. Substitution of the diphenylphosphinyl group for other phosphorus-containing functional groups lowers the stereoselectivity. Since enol phosphinates are easily prepared from prochiral ketones, this sequence provides an alternative method for the asymmetric hydrogenation of prochiral ketones.

$R^1 = Ph$, 78% ee (*R*); $R^1 = i$-Pr, 60% ee (*R*); $R^1 = t$-Bu, 39% ee (*S*)

Bis(2,2´-bipyridyl)copper(II) Permanganate

[86609-17-8] · $C_{20}H_{16}CuMn_2N_4O_8$ · Bis(2,2´-bipyridyl)copper(II) Permanganate · (MW 613.79)

(oxidant, used for the oxidation of thiols to disulfides,[1] benzylic alcohols to carbonyl compounds,[2] aromatic amines to azo compounds,[2] benzylamine and oximes to the corresponding carbonyl compounds[2])

Alternate Name: bis(2,2-bipyridine-*N,N´*)copper(2+) permanganate.

Physical Data: purple solid; decomposes at 105-110 °C.[2]

Solubility: sol water, acetone, and methylene chloride.[2]

Analysis of Reagent Purity: λ_{max} (log ε) (H_2O): 290 nm (4.50), 296 (4.59), 306 (4.58), 458, (3.23), 474 (3.28), 491 (3.38), 510 (3.49), 529 (3.57), 552 (3.54), 576 (3.35).

Preparative Methods: ***Potassium Permanganate*** (0.01 mol) dissolved in a minimum of water is added to bis(2,2´-bipyridyl)copper(II) chloride (0.02 mol) in water (25 mL). On cooling a purple precipitate is collected and air dried.[2] The yield is 95%.

Handling, Storage, and Precautions: oxidant, store in a glass vessel at or below rt. The reagent should be filtered and dried on a filter paper, not on a sintered glass funnel. It should be transferred with nonmetallic spatulas; if metallic spatulas are used the reagent may burst into flame.[1]

Oxidation of Thiols to Disulfides.[1]

Bis(2,2´-bipyridyl)copper(II) permanganate can be used to prepare disulfides from the corresponding sulfides. The reactions are carried out in methylene chloride at rt, times range from 5-45 min (eqs 1 and 2).

(1)

(2)

Oxidation of Aromatic Amines to Azo Compounds.[2]

In a somewhat similar reaction, aromatic amines are oxidatively coupled to give azo compounds. The reactions are carried out in refluxing methylene chloride. Some examples are shown in eqs 3 and 4.

(3)

(4)

Oxidation of Benzylic Secondary Alcohols.[2]

Benzyl and cinnamyl alcohols are oxidized to the corresponding aldehydes by this reagent. Of particular interest is the observation that benzylic secondary alcohols are selectively oxidized, as in eq 5.

(5)

Oxidation of Alkenes.[2]

When acetone is used as the solvent, carbon-carbon double bonds adjacent to an aromatic ring are cleaved, as in eq 6.

(6)

Conversion of Oximes to Carbonyl Compounds.

Oximes are converted into the corresponding carbonyl compounds when treated with this reagent (eq 7).

(7)

The reactions of bis(2,2´-bipyridyl)copper(II) permanganate are very similar to those of ***Bis(pyridine)silver(I) Permanganate***. Kinetic studies of the oxidation of aliphatic aldehydes[3] and thioacids[4] by bis(2,2´-bipyridyl)copper(II) permanganate have been reported.

Bis[1,2-bis(diphenylphosphino)ethane]palladium(0)[1]

$(Ph_2PCH_2CH_2PPh_2)_2Pd$

[31277-98-2] · $C_{52}H_{48}P_4Pd$ · Bis[1,2-bis(diphenylphosphino)ethane]palladium(0) · (MW 903.26)

(homogeneous catalyst most widely used in allylic substitution reactions;[5] good catalyst for bulky substrates;[1] slowly dissociating ligand that gives good stereoselectivity[5])

Alternate Names: 1,2-ethylenebis(diphenylphosphine)palladium; bis(diphenylphosphinoethane)palladium(0); ethanediylbisdiphenylphosphinepalladium(0).

Physical Data: mp 234 °C.[2]

Solubility: sol nonprotic solvents.

Form Supplied in: yellow solid.

Analysis of Reagent Purity: ^{31}P and ^{1}H NMR in $CDCl_3$ and ^{31}P NMR in benzene.[3]

Preparative Methods: by reduction of palladium(II) with $NaBH_4$,[2] DIBAL-H, hydrazine, KOH/phosphine,[4] or F^-.[3] Most conveniently prepared in situ from $Pd(dba)_2$ or $Pd(OAc)_2$.[5,6]

Purification: recrystallized from benzene-ethanol[2] or ethanol.[5]

Handling, Storage, and Precautions: air and light sensitive. If stored under nitrogen or argon it is stable for about one month. Avoid inhalation. Use in a fume hood.

General Considerations.

$Pd(dppe)_2$ is a homogeneous catalyst, commercially available but usually prepared in situ because of its sensitivity to oxygen.[5,6] It is often used as a catalyst in allylic substitution reactions. This reaction proceeds via formation of a (π-allyl)palladium(II) complex by oxidative addition of palladium(0) to an allylic substrate. Subsequent nucleophilic attack on the π-allyl gives the product and liberates a palladium(0) complex. The latter complex can then activate a new substrate and this makes the reaction catalytic. The reaction is stereoselective and net retention is generally

observed as a result of a double inversion (eq 1).

With the exception of $Pd(dppe)_2$[1b] there are few zerovalent palladium complexes that offer any advantage over the widely used ***Tetrakis(triphenylphosphine)palladium(0)***. Dppe is a bidentate ligand and therefore sterically less demanding than PPh_3. It is used for bulky substrates and in reactions where it is important to have a stable initial alkene-metal complex.[1a,7]

In allylic substitution reactions, dppe forms a stable (π-allyl)palladium complex and the stability of the complex makes geometrical isomerization possible prior to nucleophilic attack (eq 2).[8,9] If the starting material is *cis*, the *trans* product can be obtained if appropriate reaction conditions are used.[8]

Dppe is used in stereoselective allylic substitution reactions.[10] Because of its slow dissociation from palladium in $Pd(dppe)_2$, only a little Pd(dppe) is present in the solution. This is important because PdL_2 is more nucleophilic than PdL_4[11a] and can displace Pd in (π-allyl)palladium complexes and cause a loss of stereoselectivity (eq 3).[10,11]

(3)

Different ligands afford different products in Pd^0-mediated allylic substitutions.[12] For example, dialkylpalladium complexes with chelating bidentate or monodentate phosphine ligands, respectively, react via different pathways. If a bidentate ligand with a carbon chain of 2-4 carbons between the phosphorus atoms is used, a *cis* complex is obtained.[13] If instead a monodentate ligand or a bidentate ligand with a longer carbon chain is used, a *trans* complex is formed.[14] These different complexes give rise to different products.[15] Dppe favors reductive elimination whereas monodentate ligands favor β-elimination (eq 4). Variations in the carbon backbone can also affect the chelating power of the bidentate ligand and give rise to different product distributions.[12i]

(4)

In general, reactions catalyzed by $Pd(dppe)_2$ are sensitive to the reaction conditions.[16] By varying the temperature,[12j] solvent,[7,16d,17] phosphine to palladium ratio,[5,6,15] the source of $Pd(dppe)_2$,[5,6] or added bases,[18] different products may be obtained.

Reactions with $Pd(dppe)_2$ as the Catalyst.

There are some reactions where it is essential to use $Pd(dppe)_2$ as the catalyst to obtain good results. For example, allylic substitution reactions where primary or secondary amines,[8] Schiff bases,[6,9a] or carbanions[9-19] act as nucleophiles give highest yields using the title reagent. One example is the cyclopropane forming reaction shown in eq 5.[5,12f,20] Another example can be found in an annulation reaction used in a synthesis of alloyohimbone.[21]

$Pd(dppe)_2$ is the best reagent for oxidation of cyclohexene,[22] for CO insertion reactions,[23] in some reactions employing CO_2,[12h,24] for the rearrangement of tetrahydrofurans to cyclopentanones,[7] in the synthesis of 1,3-dienes by elimination of HOAc in an allylic acetate,[5] and for the formation of α,β-unsaturated ketones from allyl enol carbonates.[25] There are other reactions where $Pd(dppe)_2$ can be used but is not always the best catalyst. The title reagent has been used for coupling reactions,[16f,26] in homogenous hydrogenation,[4b] in oxidative homologation,[27] and as a promotor for isomerizations of α-iodocarbonyls involving radical rather than organometallic intermediates.[28]

Bis[1,3-bis(diphenylphosphino)propane]rhodium Tetrafluoroborate[1]

[70196-21-3] · $C_{54}H_{52}BF_4P_4Rh$ · Bis[1,3-bis(diphenylphosphino)propane]rhodium Tetrafluoroborate · (MW 1014.61)

(catalytic decarbonylation of aldehydes[2,3])

Solubility: sol CH_2Cl_2, acetone, MeCN, *m*-xylene, toluene; slightly sol MeOH; insol diethyl ether.

Analysis of Reagent Purity: ^{31}P NMR: δ = 6.4, J_{Rh-P} = 132 Hz (ambient temp, acetone-d_6, downfield from 85% H_3PO_4). Electronic absorption spectroscopy: λ_{max}, nm (log ε$_{max}$) 406 (3.49).

Preparative Method: all manipulations are carried out under a nitrogen atmosphere with use of standard Schlenk techniques. Rh_2Cl_2(1,5-cyclooctadiene)$_2$ (400 mg, 1.63 mmol) is dissolved in 50 mL of degassed acetone to which ***Silver(I) Tetrafluoroborate*** (337 mg, 1.73 mmol) is added to precipitate AgCl. The mixture is stirred for 1 h and filtered. The filtrate is added to an acetone solution of dppp (***1,3-Bis(diphenylphosphino)propane***) (1.58 g, 3.84 mmol). The acetone is partially evaporated under vacuum leaving a precipitate of orange-yellow flakes of $[Rh(dppp)_2]BF_4$ in high yield.

Purification: the product $[Rh(dppp)_2]BF_4$ is recrystallized from a solvent mixture of CH_2Cl_2 and Et_2O by a standard layering technique. The orange-yellow flakes of $[Rh(dppp)_2]BF_4$ are dissolved in a minimum amount of CH_2Cl_2 in a Schlenk tube equipped with a rubber septum. A volume of Et_2O (ca. 3 times the CH_2Cl_2 volume) is carefully layered on top with use of a syringe or cannular tube. The solvents are allowed to slowly diffuse, and large red crystals are isolated. The red crystals are washed with Et_2O and dried under vacuum.[4]

Handling, Storage, and Precautions: the catalyst is air stable in the solid state. However, it is recommended that it be stored under N_2. Decarbonylation reactions *must* be carried out in the absence of oxygen.

Aldehyde Decarbonylation.

The catalyst $[Rh(dppp)_2]BF_4$ decarbonylates aldehydes in a homogeneous solution phase with rates that are more than two orders of magnitude faster than the stoichiometric reagent ***Chlorotris(triphenylphosphine)rhodium(I)***, or the catalytic reagent ***Carbonyl(chloro)bis(triphenylphosphine)rhodium(I)***. A wide variety of aldehydes can be decarbonylated under mild thermal conditions, as shown in Table 1.[5] This decarbonylation reaction occurs with high product yields (based on aldehydes), and total turnovers in excess of 100 000 have been achieved. The catalyst is stable for days, and the reactions are highly selective. A typical reaction with benzaldehyde or heptanal is carried out with approx. 20 mg of $[Rh(dppp)_2]BF_4$ dissolved under an N_2 atmosphere in 30 mL of either neat aldehyde or about 2 mL of aldehyde in *m*-xylene or toluene. The homogeneous solution is stirred at constant temperature and continuously purged with N_2 gas. The products can be collected continuously in a cold trap connected to a reflux condenser.

Table 1 Yield and Conversion for the Decarbonylation of Various Aldehydes[a]

Aldehyde (mmol)	Time (day)	Temp. (°C)	Product	Yield[b] (%)	Conversion (%)[b]
Benzaldehyde (2.45)	2.0	140	Benzene	79	100
Cinnamaldehyde (4.00)	2.0	118	Styrene	95	100
2-Phenylpropanal (64.0)	1.5	175	Ethylbenzene	83	93
Heptanal (1.85)[c]	2.0	118	Hexane	39	46
2-Ethylbutanal (60.8)[c]	1.5	110	Pentane	15	43

[a] 0.02 to 0.05 mmol $[Rh(dppp)_2]BF_4$ catalyst in *m*-xylene or a-methylnaphthalene solvent. [b] The % yield = [(moles decarbonylation product)/(moles aldehyde added)] ´ 100; % conversion = [(moles decarbonylation product)/(moles aldehyde consumed)] ´ 100. [c] These aldehydes are decarbonylated in lower yield (still good activities, Table 2) due to thermal instability.

The activity of the catalyst is dependent on the steric size and electronic inductive properties of the aldehyde substrate.

Compared to other catalysts, $[Rh(dppp)_2]BF_4$ is significantly more active for the decarbonylation of benzaldehyde. $Rh(PPh_3)_3Cl$[6] at 150 °C demonstrates a catalytic activity of 0.60 moles benzene (mol catalyst)$^{-1}$ h^{-1} while the catalytic activity of $[Rh(dppp)_2]BF_4$ at the same temperature is 1.0×10^2. Focusing on the steric size of the substrate, there is a significant rate decrease when the α-carbon atom of the aldehydes is substituted (Table 2). The decarbonylation of tertiary aldehydes is of no synthetic utility as it occurs very slowly, even at 180 °C. *Para* substitution on benzaldehyde (either with electron-withdrawing or electron-donating groups) decreases the catalytic activity. This is in contrast to that observed using $Rh(PPh_3)_3Cl$ (stoichiometric reaction at 100 °C), where a linear Hammet plot was obtained with a positive ρ value.[7]

Table 2 Steric and Electronic Effects of Aldehydes and Catalyst Selectivity

Aldehyde	Only volatile product	Temp (°C)	Catalytic activity (turnover h^{-1})
Heptanal	Hexane	115, 150	31, 330
Benzaldehyde	Benzene	115, 150	11, 90
p-Methylbenzaldehyde	Toluene	115, 150	3.0, 34
p-Methoxybenzaldehyde	Anisole	150	10
p-Chlorobenzaldehyde	Chlorobenzene	150	1.0
2-Ethylbutanal	Pentane	115	5.0
2-Phenyl-2-methylbutanal	2-Phenylbutane	180	1.3
2-Phenylpropanal	Ethylbenzene	115, 150	16, 67
Cinnamaldehyde	Styrene	150	135
a-Methylcinnamaldehyde	*cis*-b-Methylstyrene	150	16

An important characteristic of $[Rh(dppp)_2]BF_4$ is its excellent selectivity. For example, the yield for benzene production from benzaldehyde is 100%. Note that 1-heptanal is converted into 86% hexane and 14% 1-hexene by $Rh(PPh_3)_3Cl$ (stoichiometric reaction, 25 °C); while using $[Rh(dppp)_2]BF_4$ as the catalyst, the only volatile product is hexane.

Additionally, only ethylbenzene is produced from 2-phenylpropanal although the possible unsaturated product, styrene, is very stable. $Rh(PPh_3)_3Cl$ is also known to isomerize double bonds during decarbonylation.[8] For example, α-methylcinnamaldehyde is converted into 91% *cis*- and 9% *trans*-β-methylstyrene at 140 °C. No *trans* isomer is produced using $[Rh(dppp)_2]BF_4$ at 150 °C.

The effect of added reagents on the catalytic activity of $[Rh(dppp)_2]BF_4$ is worth noting. The catalyst will tolerate molar concentrations of ketones, acids, alkenes, and chlorinated aromatics with only a moderate decrease in activity.[1] In general, reagents that can compete for a coordination site on the rhodium atom (i.e. CO, nitriles, phosphines, acid chlorides) will effectively retard the reaction rate. Most importantly, the presence of O_2 irreversibly decomposes the catalyst in solution. Thus all decarbonylations must be carried out under an inert atmosphere such as N_2 gas.

There have been several reports of catalytic aldehyde decarbonylation systems based on Ru^{II} and Fe^{II} tetraphenylporphyrin compounds.[9,10] These catalysts are thought to involve radical pathways and offer an alternative to $[Rh(dppp)_2]BF_4$.

Bis[*N,N*-bis(trimethylsilyl)amino]tin(II)[1]

[59863-13-7] · $C_{12}H_{36}N_2Si_4Sn$ · Bis[*N,N*-bis(trimethylsilyl)amino]tin(II) · (MW 439.46)

(stannylene precursor; reduction of azides to primary amines; insertion with alkyl and aryl halides; enamine synthesis; conversion of esters and carboxylic acids to secondary and tertiary amides)

Alternate Name: tin(II) bis[bis(trimethylsilyl)amide].

Physical Data: mp 37-38 °C, ^{1}H NMR(C_6D_6) δ 0.30; ^{119}Sn NMR(C_6D_6) δ 770.

Solubility: sol hexane, benzene, Et_2O, THF, acetonitrile.

Preparative Methods: a 500 mL round bottomed flask equipped with a nitrogen inlet was charged with 65 mL of dioxane and 40.1 g of anhydrous ***Tin(II) Chloride*** (0.21 mol). This suspension was allowed to stir for 30 min at rt, and was then treated with 71.0 g of ***Lithium Hexamethyldisilazide*** (0.43 mol) in several small portions. During the addition of $LiN(TMS)_2$ the reaction mixture became warm and turned dark red-orange in color. A Vigreux column and vacuum distillation apparutus were attached to the flask, and it was heated at 35 °C for 45 min. The apparatus was then placed under vacuum (0.5 mmHg) and the bath warmed to 85 °C. The forerun, mainly dioxane, was collected with the help of a dry ice acetone bath. Bis[*N,N*-bis(trimethylsilyl)amino]tin(II) distilled as a bright red oil between 105-115 °C (80.4 g, 86%); this material solidified upon standing at rt.[2]

Handling, Storage, and Precautions: is nonpyrophoric but should be handled under a nitrogen atmosphere, and stored in a refrigerator. Since the solid is very soluble in hexane, it is convenient to prepare a hexane solution which may then be transferred via conventional syringe techniques. It readily hydrolyzes to tin(II) oxide, which is of reputed low toxicity. Use in a fume hood.

Stannylene Precursor.

The two silazane ligands on $Sn[N(TMS)_2]_2$ undergo facile metathesis reactions with amines, alcohols, amides, carboxylic acids, amine hydrochloride salts, and related compounds.[1] For example, addition of 2 equiv of piperidine to $Sn[N(TMS)_2]_2$ gives bis(piperidinyl)tin(II) (**1**) as a bridging dimer (eq 1). Subsequent addition of 1 equiv of *t*-BuOH to (**1**) yields tin(II) alkoxyamide (**2**), also as a dimer. Primary amines react with $Sn[N(TMS)_2]_2$ to give tin(II) amines with a cubic structure.[1]

(1)

(1)

(2)

Reduction/Insertion Chemistry.

$Sn[N(TMS)_2]_2$ has been used for the reduction of azides to primary amines.[3] It undergoes insertion reactions with both alkyl and aryl halides, especially bromides and iodides (eq 2).[4]

(2)

Enamine Synthesis.

$Sn[N(TMS)_2]_2$ converts α-unsubstituted aldehydes to *trans*-*N*,*N*-bis(trimethylsilyl)enamines in 22-40% isolated yield (eq 3).[5] It does not react with more hindered α-substituted aldehydes, nor with ketones, esters, nitriles, acetals, terminal alkynes, alkenes, epoxides, or ethers. Addition of a secondary alkylamine to $Sn[N(TMS)_2]_2$ prior to addition of either an aldehyde or a ketone results in formation of a *N*,*N*-dialkylenamine (eq 4).[6]

(3)

(4)

Esters to Tertiary Amides.

Esters can be converted to tertiary amides using reagents derived in situ from $Sn[N(TMS)_2]_2$ (see ***Dimethylaluminum Amide***). For example, addition of 1 equiv of piperidine to $Sn[N(TMS)_2]_2$ generates an unsymmetrical tin(II) amine, which converts methyl 2-phenylacetate to an amide in 74% yield (eq 5).[7] Similarly, addition of both piperidine and *N-t*-butylacetamide to $Sn[N(TMS)_2]_2$ generates a new tin(II) amine via metathesis of both silazane ligands; this reagent converts methyl 2-phenylacetate to its piperidine amide in 93% yield.

(5)

An intramolecular variant of this methodology can be used for the preparation of β-lactams from β-amino esters. Nonsterically encumbered β-amino esters are readily cyclized to β-lactams simply with $Sn[N(TMS)_2]_2$ (eq 6).[8] Substrates with bulky groups on nitrogen or at the β-position of the amino ester are converted to β-lactams in high yield using unsymmetrical tin(II) amines.

(6)

Finally, the ester to tertiary amide transformation can also be effected using the amine hydrochloride salts of volatile amines. Addition of $Sn[N(TMS)_2]_2$ to dimethylamine hydrochloride generates a tin(II) amido chloride, which efficiently converts α-unsubstituted esters to amides (eq 7).[9]

Esters to Secondary Amides.

Tin(II) amines with a cubic structure are formed in the reaction of $Sn[N(TMS)_2]_2$ with primary amines. These tetrameric tin(II) amines are less reactive towards esters than the dimeric tin(II) amines formed from $Sn[N(TMS)_2]_2$ and secondary amines. This lack of reactivity can be circumvented via two procedures, one of which is substrate based and the other, reagent based.[10] In the substrate based approach, a glycol ester reacts with $Sn[N(TMS)_2]_2$ and a primary amine to give an intermediate tin(II) alkoxyamine. Intramolecular delivery of the amino group to the ester provides the secondary amide in high yield (eq 8). In the second approach, simple methyl esters can be converted to secondary amides using a reagent derived from $Sn[N(TMS)_2]_2$, *N*,*N*-dimethylethanolamine, and a primary amine (eq 9). Incorporation of *N*,*N*-dimethylethanolamine as the auxillary ligand appears to retard formation of cubic tetramers and help promote transfer of the primary amino group.

Carboxylic Acids to Secondary or Tertiary Amides.

Carboxylic acids that are less sterically encumbered than pivalic acid can be converted to amides using

$Sn[N(TMS)_2]_2$.[11] For example, reaction of 2-(*t*-butyldimethylsiloxy)-2-phenylacetic acid with $Sn[N(TMS)_2]_2$ and either a primary or secondary amine generates a tin(II) carboxyamine (eq 10). This intermediate is smoothly converted to an amide without racemization of the α-chiral center when heated at reflux for 1 h or stirred at rt overnight.

1,4-Bis(bromomagnesio)butane[1]

[23708-48-7] · $C_4H_8Br_2Mg_2$ · 1,4-Bis(bromomagnesio)butane · (MW 264.53)

(constructing block agent: transformation of many functional groups into cyclopentane, spiro[4.4]nonane, and spiro[4.5]decane synthetic intermediates, and metallacycles)

Solubility: sol THF, ether, and toluene.

Form Supplied in: generally prepared in THF.

Analysis of Reagent Purity: titration.[2]

Preparative Methods: the following preparative method was found to be of general use for the preparation of various 1,*n*-bis(bromomagnesio)alkanes (*n* = 4-6), as well as for primary, secondary, and unsaturated di-Grignard reagents, from the corresponding dibromides.[3] ***1,4-Dibromobutane*** (69 mmol) dissolved in anhydrous THF (150 mL) is added dropwise to ***Magnesium*** turnings (150 mmol) covered with a few mL of the dibromide solution. The exothermic reaction starts within a few minutes and is controlled by the rate of addition of the dibromide, avoiding excessive heating. After an additional 2 to 6 h period, the formation of the reagent is completed (yield ~90%) (eq 1). However, for 1,3-bis(bromomagnesio)propane, this procedure is not suitable, as the elimination product is mostly formed. Therefore, one should refer to the appropriate literature for that particular case.[4]

Handling, Storage, and Precautions: solutions are highly flammable; must be stored in the absence of proton sources, carbon acids, and oxygen. Flasks and Schlenk tubes should be flushed with dry Ar or N_2. Handle with standard syringe technique to prevent contact of the solutions with oxygen and moisture. Solutions can be stored at 0 °C for months.

Synthetic Applications.

1,4-Bis(bromomagnesio)butane is a remarkable annulation reagent. It carries out annulation readily, unlike the pentane or propane analogs. 1,3-Bis(bromomagnesio)propane undergoes hydride transfer and/or addition reaction with electrophiles, furnishing reduction products, α,o-diadducts, and cyclobutane derivatives.[4] With 1,6-bis(bromomagnesio)hexane, 1,6-diaddition compounds are obtained in good yield, while the annulation with carboxylic acid derivatives produces modest yields.

Cyclopentane Derivatives.

The reaction of 1,4-bis(bromomagnesio)butane with esters leads to the formation of cyclopentanols.[5] The application of this annulation process is important for the synthesis of cyclopentanol derivatives substituted with functionalized alkyl groups (eq 2) that are difficult to obtain from the corresponding Grignard reagent and cyclopentanone.[6]

Another advantage of this methodology is the production of *trans*-1,2-disubstituted cyclopentanols with 1,4-bis(bromomagnesio)pentane (eq 3).[3b] This stereoselection is complementary to that obtained by direct addition of an alkyl Grignard to 2-methylcyclopentanone, which gives mainly *cis*-1,2-disubstituted cyclopentanols.[7]

R =	H	77 : 23
	Me	96 : 4
	Cy	95 : 5
	Ph	89 : 11

Lactones undergo the annulation process with 1,4-bis(bromomagnesio)butane.[8] Eq 4 shows annulation on dihydrocoumarin.[9] Yields are higher than observed with ***1,5-Bis(bromomagnesio)pentane***, which also forms products of intermolecular attack and hydride transfer.

(4)

Oximes of 3-alkyl-3-(1-hydroxycyclopentyl)alkan-2-ones were prepared in high yields from 4,4-dialkylisoxazol-5-ones and 1,4-bis(bromomagnesio)butane (eq 5).[3a,10] These results contrast with those obtained for primary Grignard reagents, which produce only the corresponding 5-hydroxy-2-isoxazolines (eq 6).[11]

(5)

(6)

Symmetrically and unsymmetrically substituted cyclic anhydrides are converted in good yield to spirolactones.[12] For unsymmetrical cyclic anhydrides, preferential attack takes place on the more accessible carbonyl group, followed by a second nucleophilic addition to the intermediate ketone, leading to five-carbon annulation (eq 7).[12b] This methodology was successfully used for the construction of linearly fused polyquinane, a class of fused ring compounds containing only cyclopentane rings.[13]

(7)

Organobiscuprates.

In the presence of the ***Copper(I) Bromide***-dimethyl sulfide complex, 1,4-bis(bromomagnesio)butane reacts with 3-

halocycloalk-2-en-1-ones to afford spiro ketones.[14] This annulation methodology was applied, for example, to 1,4-bis(bromomagnesio)pentane and 3-bromocyclopent-2-en-1-one to form *cis*-1-methylspiro[4.4]nonan-2-one (eq 8) (see also ***1,5-Bis(bromomagnesio)pentane***).

(8)

Metallacyclopentanes.

The synthesis of various metallacyclopentanes from metal dihalides and 1,4-bis(bromomagnesio)butane constitutes a useful application of the di-Grignard reagent.[15] These metallacycles may then be used in synthetic applications (see ***1,4-Dilithiobutane***). The formation of chiral 2,5-dimethylborolane illustrates such an approach (eq 9).[16]

1,5-Bis(bromomagnesio)pentane[1]

[23708-48-7] · $C_5H_{10}Br_2Mg_2$ · 1,5-Bis(bromomagnesio)pentane · (MW 278.55)

(constructing block agent: transformation of many functional groups into cyclohexane, spiro[4.5]decane, and spiro[5.5]undecane synthetic intermediates, and α,o-difunctional compounds)

Physical Data: d 0.999 g cm^{-3}.

Solubility: sol THF, ether, and toluene.

Form Supplied in: the reagent is available in THF (0.5 M).

Analysis of Reagent Purity: titration.[2]

Handling, Storage, and Precautions: solutions are highly flammable; must be stored in the absence of proton sources, carbon acids, and oxygen. Flasks should be flushed with dry Ar or N_2. Handle with standard syringe technique to prevent contact of the solutions with oxygen and moisture.

Structure.

The observation of the existence of Schlenk's equilibrium was first confirmed in the preparation of magnesiocycloalkanes.[3,4] During the preparation and use of 1,5-bis(bromomagnesio)pentane at low temperature, $MgBr_2$ precipitates from THF solution (eq 1).[5]

(1)

Synthetic Applications.

Bis(bromomagnesio)pentane mainly undergoes carbon-carbon bond formation with carbon electrophiles to provide α,o-difunctional[6-8] and cyclohexane derivatives.[9-11] However, in the presence of hindered electrophiles, the addition is

accompanied by a reduction process which leads also to the formation of monoaddition adducts.

Reaction with Esters.

The earliest uses of 1,5-bis(bromomagnesio)pentane were as an annulation reagent with carboxylic esters.[9] Reactions with hindered substituted esters form some products derived from intramolecular reduction (eq 2), in contrast to ***1,4-Bis(bromomagnesio)butane***.[12]

(2)

Reaction with Lactones.

Similarly, this reagent led to a general one-pot synthesis of (hydroxyalkyl)cyclohexanols by a double nucleophilic addition to the carbonyl group of lactones. The obtained diols were converted, by appropriate transformations, into spirolactones and spiro ethers (eq 3).[13]

(3)

Seven-carbon annulation using 1,6-bis(bromomagnesio)hexane was achieved with various carboxylic acid derivatives and coumarins. A typical example is given with the synthesis of 3,4-dihydrospiro[2*H*]-1-benzopyran-2,1´-cycloheptane, a spirochroman (eq 4).[14]

(4)

Reaction with Carboxylic Anhydrides.

The reaction of 1,5-bis(bromomagnesio)pentane with cyclic anhydrides gives spirolactones.[5,15] The intermediate carboxylate diminishes the formation of reduction products so that intramolecular Grignard addition takes place almost exclusively (eq 5).

(5)

The reaction of the di-Grignard reagent with bridged bicyclic anhydrides gives good to excellent yields if a stoichiometric or excess amount of reagent is used.[16] The reaction is chemoselective and, for unsymmetrical anhydrides, takes place at the less hindered carbonyl group. Thus reaction of 1,5-bis(bromomagnesio)pentane with *endo*- and *exo*-furan and cyclopentadiene adducts produces bridged bicyclic spirolactones in 80-100% yields. The furan adducts lead, by subsequent distillation, via a retro Diels-Alder reaction, to a convenient synthesis of spirobutenolides (eq 6).[17] This reaction can also be used with primary Grignard reagents and ***1,4-Bis(bromomagnesio)butane***

(6)

The spiroannulation process also works well with heterocyclic anhydrides.[18] Examples are regioselective cyclizations with pyridinecarboxylic, isatoic, and azaisatoic anhydrides (eq 7).

(7)

Reaction with 3-Halocycloalk-2-en-1-ones.

Spiro ketones are formed when the di-Grignard reagent is used, in the presence of CuBr.MeS, with 3-halocycloalk-2-en-1-ones (eq 8).[19] Replacement of the di-Grignard reagent with 1,*n*-dilithioalkane and 2 equiv of copper(I) thiophenoxide leads to more side products.

(8)

This methodology was successfully extended to an unsaturated di-Grignard in a synthesis of the spirosesquiterpene β-vetivone (eq 9).

(9)

1,5-Bis(bromomagnesio)pentane-CuI was also used with alkylidenecyanoacetates. Quaternary-substituted hydrocarbons were obtained, but in very low yields.[20]

α,ο-Difunctional Compounds.

1,5-Bis(bromomagnesio)pentane has been widely used for the preparation of α,o-difunctional compounds. Carbon dioxide, aldehydes, and ketones were usually selected as electrophiles. This procedure is typified by the reaction with cyclohexanone (eq 10).[7b,8,21]

(10)

Reaction with Trialkylboranes.

The reaction of 1,5-bis(bromomagnesio)pentane with trialkylboranes in benzene gives selective boron-magnesium transmetalation to alkylmagnesium bromides (eq 11). The transformation proceeds fast in benzene and toluene, relatively fast in ether, but extremely slowly in THF.[22]

(11)

Related Reagents.

1,4-Bis(bromomagnesio)butane; ***1,4-Dilithiobutane***; ***1,5-Dilithiopentane***.

2,3-Bis(bromomethyl)-1,3-butadiene

[18214-55-6] · $C_6H_8Br_2$ · 2,3-Bis(bromomethyl)-1,3-butadiene · (MW 239.94)

(Diels-Alder diene;[1] preparation of other 2,3-disubstituted 1,3-dienes[2])

Physical Data: mp 57-58 °C.

Solubility: sol pentane, THF.

Form Supplied in: white solid.

Preparative Methods: Zn-Cu[1] or Sn-Cu[3] mediated dehalogenation of tetrakis(bromomethyl)ethylene; thermolysis of a precursor sulfone;[3] and through reaction of allene with $PdBr_2$.[4,5]

Purification: recrystallization from pentane,[1] hexane,[6] or hexane-ethyl acetate.[5]

Handling, Storage, and Precautions: light sensitive; tends to polymerize at room temperature. Stable for months when stored as a solid or as a solution in ether in the dark at 0 °C.

Diels-Alder Diene.

The primary synthetic uses of 2,3-bis(bromomethyl)-1,3-butadiene (**1**) are in Diels-Alder chemistry, in preparation of heterocycles, in the preparation of π-allyl organometallic complexes,[7] and in polymer chemistry. The reactivity of (**1**) is not unlike that of other 1,3-dienes and allylic halides. Diels-Alder reaction of (**1**) with benzoquinone leads to dihydronaphthoquinone (**2**) in 69% yield (eq 1).[8]

(1)

Electron deficient alkynes and diazo compounds are also active Diels-Alder partners (eq 2).[2] Diels-Alder reaction of (**1**) with ***Diethyl Azodicarboxylate*** (DEAD) leads to (**3**). Similarly, treatment of (**1**) with ***Dimethyl Acetylenedicarboxylate*** (DMAD) leads to (**4**).[1] Debromination of these allylic bromides with zinc-copper couple results in the formation of new 1,3-dienes that can be used in additional Diels-Alder reactions.[1]

(2)

2,3-Disubstituted 1,3-Dienes.

Treatment of (**1**) with a variety of nucleophiles leads to mono- or dialkylation (eq 3). Symmetrical 2,3-disubstituted butadienes (**5**) result[1,9] from reaction of (**1**) with NaOMe, NaOAc, NaN_3, or KCN, and further elaboration of these dienes has been accomplished. Addition of unstabilized carbon nucleophiles such as vinylmagnesium chloride leads to polyenes.[1]

(3)

Treatment of tertiary diamines leads to the formation of polyelectrolytes (eq 4).[6]

(4)

Heterocycles.

Treatment of (**1**) with other anions such as Na_2S,[10] NaOH in DMSO,[9] Na_2Se,[11] RNH_2 (R = alkyl or aryl),[9] or stabilized carbanions[2] produces bis(methylene) heterocycles (**6**) (eq 5). There are examples of heterocycles resulting from the treatment of (**1**) with diamines.[12]

(5)

Heterocycles (**6**) participate in Diels-Alder reactions,[2] as well as undergoing (in some cases) intramolecular photochemical [2 + 2] reactions to form [3.2.0]bicyclic systems.[1] Several of the 3,4-dimethylenepyrrolidine compounds have been used as monomers in the synthesis of polypyrroles.[13,14]

[105251-53-4] · $C_{16}H_{25}N_3O_2$ · (1*S*,9*S*)-1,9-Bis[(1-hydroxy-1-methyl)ethyl]-5-cyanosemicorrin · (MW 291.39) (**3**; R = CO_2Me)

[105251-49-8] · $C_{14}H_{17}N_3O_4$ · Dimethyl (1*S*,9*S*)-5-cyanosemicorrin-1,9-dicarboxylate · (MW 291.31)

(chiral ligands for enantiocontrol of metal-catalyzed reactions such as cobalt-catalyzed conjugate reduction of α,β-unsaturated carboxylic esters and amides or copper-catalyzed cyclopropanation of alkenes)[1]

Physical Data: (**1**) mp 75-76 °C, $[\alpha]_D$ -64.7° (*c* 1.0, $CHCl_3$ at rt); (**2**) mp 162 °C, $[\alpha]_D$ -82.0°; (**3**) mp 78-79 °C, $[\alpha]_D$ -145°.

Solubility: insol H_2O; (**1**) sol in all common organic solvents, including *n*-hexane; (**2**) and (**3**) sol CH_2Cl_2, alcohol, THF, and EtOAc, insol hexane, slightly sol diethyl ether.

Form Supplied in: white crystalline solid; (**1**) and (**3**) are commercially available.

Handling, Storage, and Precautions: as crystalline solids, semicorrins of this type are stable at ambient temperature; for longer periods, storage at -20 °C is recommended.

Preparation of Semicorrin Ligands and Metal Complexes.

The crystalline diesters (*S*,*S*)-(-)-(**3**) and (*R*,*R*)-(+)-(**3**) are readily synthesized in enantiomerically pure form starting from L-pyroglutamic acid (-)-(**4**) or its enantiomer (eq 1).[2] By selective transformation of the ester groups, a wide range of semicorrin derivatives with different substituents at the stereogenic centers is accessible.[2,3] Among the various derivatives that have been prepared, semicorrins (**1**) and (**2**) proved to be the most versatile ligands for the stereocontrol of metal-catalyzed reactions.

(1)

Semicorrins form stable chelate complexes with a variety of metal ions such as Co^{II}, Rh^{I}, Pd^{II}, or Cu^{II}. Depending on the metal ion, the ligand structure, and the reaction conditions, mono- or bis(semicorrinato) complexes are obtained.[2,3]

Enantioselective Conjugate Reduction of α,β-Unsaturated Carboxylic Esters and Amides.

Cobalt semicorrin complexes are highly efficient catalysts for the reduction of electrophilic C=C bonds, using ***Sodium Borohydride*** as reducing agent.[1] In the presence of 0.1-1 mol % of catalyst, formed in situ from ***Cobalt(II) Chloride*** and ligand (**1**), esters of β-disubstituted α,β-unsaturated carboxylic acids are cleanly reduced to the corresponding saturated esters in essentially quantitative yield and with high enantioselectivity.[1,3b,4] The best results are obtained in a mixture of ethanol and a polar aprotic solvent such as DMF or diglyme under careful exclusion of oxygen. The reduction of ethyl geranate (eq 2) and the corresponding (*Z*) isomer (eq 3) are typical examples. Both reactions lead to ethyl citronellate with 94% ee. Depending on the double bond geometry, either the (*R*) or (*S*) enantiomer is obtained. The isolated double bond is inert under these conditions. During aqueous workup, the chiral ligand (**3**) forms a catalytically inactive bis(semicorrinato)cobalt(II) complex, and can be recovered by decomplexation with acetic acid.

Even higher selectivities approaching 99% ee have been obtained with primary and secondary carboxamides (eqs 4 and 5).[5] With substrates of this type, the catalyst system can undergo more than 5000 turnovers without significant loss of selectivity. An analogous diene-carboxamide was found to react with high regio- and enantioselectivity to give the corresponding γ,δ-unsaturated amide with a preference of >95:5 over the α,β-unsaturated isomer (eq 5). Tertiary carboxamides react rather sluggishly and with distinctly lower selectivity. The method cannot be applied to α,β-unsaturated ketones because the uncatalyzed nonstereoselective reaction with $NaBH_4$ proceeds at a similar rate as the cobalt-catalyzed process.

(5)

Deuteration experiments showed that the β-H atom in the product stems from borohydride whereas the α-H atom is introduced by proton transfer from ethanol.[3b] Formation of the α-(C-H) bond is nonstereoselective; accordingly, the reduction of analogous substrates with an α- instead of a β-disubstituted double bond leads to racemic products (a mechanistic model rationalizing the stereoselectivity of (semicorrinato)cobalt catalysts is available[1]).

Enantioselective Cyclopropanation of Alkenes.

Semicorrin copper complexes catalyze the reaction of diazo compounds with alkenes leading to optically active cyclopropanes.[1,6] The highest enantiomeric excesses have been obtained with the bulky ligand (**2**). The stable crystalline bis(semicorrinato)copper(II) complex (**5**) serves as a convenient catalyst precursor. The actual catalyst, which is presumed to be a mono(semicorrinato)copper(I) complex, is generated in situ by heating in the presence of the diazo compound or by reduction with ***Phenylhydrazine*** at rt. Alternatively, the catalyst can be prepared from the free ligand and ***Copper(I) t-Butoxide***. Reactions are usually carried out at rt in an apolar solvent such as dichloroethane using 1 mol % of catalyst. The best results are obtained with terminal alkenes or dienes and certain 1,2-disubstituted alkenes which react with alkyl diazoacetates to give the corresponding cyclopropanecarboxylates with high enantioselectivity (eqs 6-8). The relatively poor *trans*/*cis* selectivity is a general problem which is also encountered with other catalysts.[7] Recently, even higher enantiomeric excesses have been achieved with substrates of this type, using cationic Cu^{I} complexes of C_2-symmetric bis(oxazolines) (**6**) (see ***(S,S)-2,2´-(Dimethylmethylene)bis(4-t-butyl-2-oxazoline)***) or 5-aza-semicorrins (**7**).[1,8]

(7) R = $CMe_2OSiR'_3$

(6)

R = Et, 92% ee; *trans*:*cis* = 73:27
R = (+)-menthyl, 97% ee; *trans*:*cis* = 82:18

(7)

R = (+)-menthyl, 97% ee
trans:*cis* = 63:37

(8)

(Semicorrinato)copper catalysts have also been used for intramolecular cyclopropanation reactions of alkenyl diazo ketones (eqs 9 and 10).[9] In this case the (semicorrinato)copper catalyst derived from complex (**5**) proved to be superior to related methylene-bis(oxazoline)copper complexes. Interestingly, analogous allyl diazoacetates react with markedly lower enantioselectivity under these conditions, in contrast to the results obtained with chiral Rh^{II} complexes which are excellent catalysts for intramolecular cyclopropanations of allyl diazoacetates but give poor enantioselectivities with alkenyl diazo ketones (see ***Dirhodium(II) Tetrakis(methyl 2-pyrrolidone-5(S)-carboxylate)***).[7] Moderate enantioselectivities in the reactions shown in eqs 9 and 10 have been reported for (salicylaldiminato)copper catalysts (77% and 34% ee, respectively).[10]

Bis(α-camphorquinone dioximato)cobalt

[67770-21-2] · $C_{20}H_{32}CoN_4O_5$ · Bis(α-camphorquinone dioximato)cobalt · (MW 467.43)

(catalyst for asymmetric cyclopropanation, especially for styrene, butadiene, and conjugated alkenes such as acrylates)

Physical Data: mp 240 °C (under nitrogen).

Solubility: sol hydrocarbons or similar organic solvents.

Form Supplied in: ligand may be available but the catalyst is sensitive to air and must be prepared just before use.

Analysis of Reagent Purity: a change in color from brown to pale brown or yellow indicates decomposition. Only the soluble part should be used.

Preparative Method: $Co(\alpha\text{-cqd})_2$ is prepared from ***Cobalt(II) Chloride*** hexahydrate and the corresponding isomer of camphorquinone dioxime (cqd) (from optically active natural camphor) in ethanol with addition of an aqueous solution of NaOH under nitrogen or argon.[1] This complex is best when freshly prepared before use under nitrogen or preferably under argon. The starting material, L-camphor, is easily obtained in optically pure form.

Handling, Storage, and Precautions: the dry solid must be kept under nitrogen or argon, preferably in the cold. The solution of the catalyst in organic solvents such as benzene, acetone, ethyl acetate, hexanes, or acetophenone deteriorates on standing even under nitrogen. Therefore use just after preparation is recommended.

Although many chiral cyclopropanation catalysts are known, this class of complexes is superior for the alkenes containing vinyl, phenyl, or alkoxycarbonyl groups. Some relevant examples are shown in eqs 1-5. In eq 5, the enantiomeric excess of the product is not known due to the absence of enantiomerically pure isomer. The absolute configuration is not known.

(5)

The related vicinal dioximatocobalt(II) complexes such as $Co(dmg)_2$ and $Co(nqd)_2$ (dmg = dimethylglyoximato, nqd = nopinoquinone dioximato), are also catalytically active but the enantioselectivity varies with the structure of the alkenes.

The steric bulk of the ester alkyl group generally enhances the ee values (eqs 6-8). Thus, the neopentyl ester of diazoacetate gives the highest ee value (88%) for the reaction with styrene (eq 6).

(6)

(7)

(8)

Other than diazoacetates, diazoacetophenone and diazodicyanomethane may also be used for cyclopropanation. The ee values are, however, lower than those obtained for diazoacetates.

Various organic solvents can be used, e.g. benzene, toluene, hexanes, acetone, acetophenone, diethyl ether. However, the substrate must be in large excess to the diazo compounds. The effect of additives has been examined. Pyridine or similar donor molecules retard the catalytic rates and decrease the optical yields.[3]

The enantioselectivity increases upon decreasing temperature. Thus the reaction between 0 and about -30 °C gives the best enantioselectivity in neat alkene.

Related chiral dioximato ligands have also been prepared. Isomeric nopinoquinone dioximato ligands (β- and δ-nqd) are prepared from 1-pinene.[4] The δ-isomer has been found to work to give an enantiomerically opposite isomer relative to the isomer obtainable with cqd by the cyclopropanation.

The enantiomeric purity of the chiral cyclopropanes may be enhanced by recrystallization of the acid obtained after mild alkaline hydrolysis of the chiral ester when the ee values are over 60%.

Related Reagents.

1,2-Bis(chlorodimethylsilyl)ethane[1]

[13528-93-3] · $C_6H_{16}Cl_2Si_2$ · 1,2-Bis(chlorodimethylsilyl)ethane · (MW 215.27)

(reagent for the protection of primary amines as their tetramethyldisilylazacyclopentane or Stabase adducts; used in combination with zinc to form organozinc carbenoids; electrophilic silylating reagent)

Physical Data: mp 36-41 °C; bp 198 °C/734 mmHg.

Form Supplied in: white, waxy solid with a sharp acid odor; 96% pure.

Handling, Storage, and Precautions: the dry solid reacts with moisture to produce hydrogen chloride. Incompatible with strong acids, alcohols, strong bases and strong oxidizers; may be ignited by static electricity; causes severe irritation to the respiratory tract. The reagent therefore should be used in a well ventilated hood.

Protection of Primary Amines.

Few protecting groups exist for the N,N-diprotection of primary amines (see ***1,4-Bis(dimethylamino)-1,1,4,4-tetramethyldisilethylene***). The tetramethyldisilylazacyclopentane or Stabase adduct (**3**) is particularly attractive for this purpose due to its ease of preparation, base stability and facile removal. This cyclic disilane is easily prepared (eq 1) from the commercially available title reagent (**1**).[2] For primary amines with pK_a values between 10 and 11, typical reaction conditions involve the treatment of a dichloromethane solution of the amine with (**1**) in the presence of two equivalents of triethylamine at room temperature. Subsequent workup with aqueous dihydrogen phosphate provides (**3**) in excellent yields.[1] Stabase adducts are quite stable to strongly basic conditions such as ***n-Butyllithium*** and ***s-Butyllithium*** (at -25 °C), ***Lithium Diisopropylamide***, and Grignard reagents making it a superb candidate for use in the alkylation of substrates bearing a primary amine. For example, protected amino acid derivatives are easily alkylated (eq 2).[1,3] After formation of the lithium enolate of the protected ethyl glycinate (**4**) under standard conditions, exposure to various alkyl halides or aldehydes yields alkylation products such as (**5**).[1]

(1)

(2)

In addition to its base stability, this protecting group is readily cleaved under acidic conditions; often upon workup. After quenching the metallated dihydropyridine in eq 3 with the Stabase-protected aminoethyl disulfide (**7**), simple in situ treatment with saturated aqueous ammonium chloride liberates the regioisomeric free amines (**8a**) and (**8b**).[4] However, more vigorous conditions are sometimes required. For example, allylic amine (**11**) was produced by exposure of the crude coupling product of (**9**) and (**10**) to an excess of ethanolic HCl at 0 °C (eq 4).[5] Alternatively, Stabase deprotection can be achieved by reaction with ethanolic ***Sodium Borohydride***, as demonstrated in eq 5. The tertiary alcohol resulting from Grignard addition to aromatic ketone (**12**) was thus deprotected by treatment with $NaBH_4$ in ethanol to afford amino alcohol (**13**).[6]

(6)

(7) + **(3)**

(8a) $R^1 = H$; $R^2 = SCH_2CH_2NH_2$; 16%
(8b) $R^1 = SCH_2CH_2NH_2$; $R^2 = H$; 18%

(9) + **(10)** → **(11)** (4)

Cleavage of Stabase adducts reveals a reactive primary amine that can be utilized in further transformations. Several groups have engineered one-pot, multistep processes that exploit both the protecting power and the acid lability of the cyclic disilane to generate amines in situ. An elegant example of such a transformation is illustrated in the general synthesis of 2-substituted pyrrolidines (**17**) which otherwise are difficult to synthesize (eq 6). Addition of the Stabase-protected Grignard (**14**) to an *N*-methoxy-*N*-methyl amide is followed by treatment of the reaction mixture with ethanolic HCl. Collapse of the intermediate hemiaminal is followed by Stabase cleavage and concomitant cyclization to the imine (**16**) in a single operation. The substituent R may vary from aliphatic to a wide variety of heterocyclic compounds.[7]

A further extension of this concept is shown in the 6-substituted 3-pyridinol synthesis described in eq 7. Treatment of condensation product (**19**) with 1 M HCl initiates Stabase deprotection that is followed by acid-catalyzed

rearrangement of the resulting amino alcohol to pyridine (**20**).[8]

Formation of Organozinc Carbenoids.

When aromatic aldehydes and certain α,β-unsaturated carbonyl compounds are treated with zinc and 1,2-bis(chlorodimethylsilyl)ethane, an organozinc carbenoid results. This two-electron process is postulated to occur as depicted in eq 8. Sequential reaction of the two silicon atoms with the zinc carbonyl complex and subsequent extrusion of the cyclic siloxane (**23**) gives rise to the putative organozinc carbenoid (**24**). When generated in the presence of an alkene, cyclopropanes (**25**) are produced in good yields as in eq 9.[9] When 2 equiv of carbonyl compound are employed, the organozinc carbenoid is trapped by excess carbonyl compound, and the intermediate epoxide is deoxygenated to yield products (**26**) of symmetrical dicarbonyl coupling (eq 10).[10]

(26) R = Me, 86%

Electrophilic Silylation Reagent.

1,2-Bis(chlorodimethylsilyl)ethane is not only an effective amine silylating reagent, but can also be employed in reactions with other anions. For example, when treated with the silver sulfonate salt as in eq 11, the nonafluorobutanesulfonic acid silyl ester (**27**), an extremely powerful silylating reagent, results.[11] Carbanions are also effectively trapped by (**1**). A series of rigid butadiene Diels-Alder precursors such as (**28**) have been prepared in this fashion as outlined in eq 12.[12]

Bis(chloromethyl) Ether

[542-88-1] · $C_2H_4Cl_2O$ · Bis(chloromethyl) Ether · (MW 114.96)

(useful reagent for the chloromethylation of aromatic moieties[1] and for the preparation of oxygen-containing heterocycles[2])

Alternate Names: BCME; α,α´-dichloromethyl ether; 1,1´-dichloromethyl ether; chloromethyl ether; oxybis(chloromethane); *sym*-dichloromethyl ether.

Physical Data: bp 106 °C; mp -41.5 °C; *d* 1.315 g cm^{-3}.

Preparative Method: the large-scale preparation of bis(chloromethyl) ether using paraformaldehyde, hydrogen chloride, and chlorosulfonic acid has been reported by Buc as an *Organic Synthesis* preparation.[3]

Handling, Storage, and Precautions: this agent is a strong irritant to the eyes and respiratory tract and is a known carcinogen.[4] All procedures using this reagent should be carried out in a fume hood.

Aromatic Chloromethylation.

Bis(chloromethyl) ether is an effective reagent for the direct chloromethylation of a variety of aromatic substrates. The reaction occurs via electrophilic aromatic substitution of the oxonium ion generated upon treatment of the reagent with acid catalyst. For example, chloromethylation of *p*-nitroanisole using BCME and ***Zinc Chloride*** in dimethyl sulfide afforded 4-nitro-2-chloromethylanisole in 74% yield (eq 1).[1] The procedure was reported to be superior to chloromethylation using paraformaldehyde and hydrogen chloride, which afforded only poor yields of the desired anisole. A variation of this process using ***Chlorosulfonic Acid*** as the catalyst chloromethylated *p*-nitrotoluene to give 2-chloromethyl-4-nitrotoluene in quantitative yield (eq 2).[5]

(1)

(2)

The chloromethylation of aromatic heterocycles has also been reported. For example, 3,5-dimethylisoxazole was chloromethylated to give 4-chloromethyl-3,5-dimethylisoxazole (eq 3).[6] The synthesis of 5-(halomethyl)-2-pyranones for use as α-chymotrypsin inhibitors have also employed this chloromethylation procedure. Thus treatment of 5-(trifluoromethyl)-2-pyranone with BCME and sulfuric acid gave 3-(chloromethyl)-5-(trifluoromethyl)-2-pyranone in 50% yield (eq 4).[7]

(3)

(4)

Alkylation and Heterocycle Formation.

Oxygen-containing heterocycles have also been prepared using BCME. For example, tetrahydrofurans have been prepared via cyclocondensation of simple alkenes with chloromethoxymethyllithium (eq 5), an agent derived from BCME.[2] Other examples include the preparation of macrocyclic heterocycles. For example, 18-crown-6 coronands have been prepared for use as ionophores via condensation of a bipyrazole with BCME (eq 6).[8]

(5)

(6)

BCME has also been employed in the preparation of symmetrical and unsymmetrical dimethyl ether derivatives (eq 7). Bis(pyridinium and imidazolium) quaternary salts, useful as reversible acetylcholinesterase inhibitors, were prepared via stepwise condensation of the requisite pyridine or imidazole with BCME followed by a second equivalent of amine heterocycle.[9] Likewise, symmetrical dineopentyl ethers have been prepared by Refomatsky reaction using ethyl α-bromo esters, BCME, and zinc (eq 8).[10]

(7)

(8)

Phenols, thiols, phosphines, and pyridines have also been used as nucleophiles with BCME for the synthesis of symmetrical ethers. For example, 4-chlorophenol,[11] 2,5-dimethylbenzenethiol,[12] pyridine,[13] and triphenylphosphine[14] gave, respectively, 90%, 72%, 48%, and 69% yields of the corresponding bis-alkylation products.

(chiral catalyst for asymmetric aldol reactions giving high diastereo- and enantioselectivity;[2] enantioselective synthesis of β-hydroxy-α-aminophosphonates;[3] asymmetric allylation[4])

Solubility: sol dichloromethane, 1,2-dichloroethane, and diethylene glycol dimethyl ether; insol diethyl ether and pentane.

Preparative Method: the complex is prepared in situ by the reaction of bis(cyclohexyl isocyanide)gold(I) tetrafluoroborate[5] with ***(R)-N-[2-(N,N-Dimethylamino)ethyl]-N-methyl-1-[(S)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine***,[6] typically in dichloromethane.[7]

Handling, Storage, and Precautions: prepare under anhydrous conditions and use under a dry inert atmosphere

of nitrogen.

Enantioselective Aldol Reactions.

The development of synthetic methodology for the diastereoselective and enantioselective formation of C-C bonds through the use of catalytic quantities of chiral transition-metal catalysts is a topic of fundamental importance. In 1986, Ito and Hayashi reported an elegant asymmetric synthesis of dihydrooxazolines by the gold(I)-catalyzed aldol reaction (more correctly a Knoevenagel reaction) of an aldehyde with an isocyanoacetate ester in the presence of a chiral ferrocenylamine ligand.[7] The chiral catalyst (*R*)-(*S*)-(**1**) is conveniently prepared in situ as described above.[5,6] The dihydrooxazolines obtained provide a convenient precursor to enantiomerically pure β-hydroxy-α-amino acid derivatives. The *trans* (4*S*,5*R*)-oxazoline in high ee is obtained predominantly in the reaction of aldehydes with α-isocyanoacetate esters catalyzed by (*R*)-(*S*)-(**1**) (eqs 1-3).[7-9] High stereoselectivity is retained with alkyl-substituted α-isocyanoacetate esters (eq 4), although reduced diastereoselectivity and enantioselectivity is often obtained with large α-substituents.[10]

A wide variety of ester functionalities are tolerated (eq 5).[11] A single stereocenter is formed in high ee when formaldeyde is utilized as a reaction component, which leads to an efficient asymmetric synthesis of α-alkylserines (eq 6).[12] The utilization of α-keto esters provides a facile route to β-alkyl-β-hydroxyaspartic acid. Higher diastereo- and enantioselectivity are obtained by the reaction of the α-keto ester with the corresponding *N*,*N*-dimethyl-α-isocyanoacetamide (eq 7).[13] In certain cases, the use of α-isocyanoacetamides is advantageous for improving stereoselectivity in the corresponding reaction with aldehydes.[14] The presence of α-heteroatoms or certain electronegative groups in the aldehyde component of the reaction may lead to dramatic changes in diastereo- and enantioselectivity.[8,11] Opposite product chirality can be obtained in the gold(I)-catalyzed aldol reaction by using the (*S*)-(*R*) enantiomer of (**1**).

Double stereodifferentiation (double asymmetric induction) between a chiral substrate and the chiral ferrocenylamine ligand has been demonstrated (eq 8).[11] The stereocenter (central chirality) as well as the stereoaxis (axial chirality) affects both product diastereoselectivity and enantioselectivity.[15] Chiral cooperativity (or internal cooperativity) refers to individual chirotopic segments of the ligand molecule acting in a cooperative manner to promote a particular diastereo- and enantioselectivity in the product.[8,15-18] The effects of distant stereocenters in ligands analogous to (*R*)-(*S*)-(**1**) upon the stereoselectivity of the gold(I)-catalyzed aldol reaction has been studied.[19,20] Improvements in stereoselectivity can be obtained in certain cases by modification of the terminal *N*,*N*-dimethylamino substituent in the side chain of (*R*)-(*S*)-(**1**),[2,9,10,12,21] (compare eqs 4 and 9) as well as the aryl substituents on phosphorus.[22] Several recent studies have appeared dealing with the elucidation of the stereoselective transition-state geometry.[8,23-25] An elegant study of aldol stereochemistry has important implications on the stereoselective transition-state geometry for the gold(I)-catalyzed aldol reaction.[26] A report has appeared describing the use of a neutral gold(I) ferrocenylamine catalyst for asymmetric aldol reactions, albeit in lower diastereo- and enantioselectivity.[27]

The gold(I)-catalyzed aldol reaction has been applied to the synthesis of several natural products including cyclosporin's unusual amino acid MeBmt, in which two of the three product stereocenters were generated by the reaction of 2-(*R*)-methyl-4-hexenal with ethyl α-isocyanoacetate (eq 10).[28] Although either enantiomer of the *trans*-dihydrooxazole can be obtained by using (*R*)-(*S*)-(**1**) or (*S*)-(*R*)-(**1**), a modest effect due to matching and mismatching of substrate and ligand chirality is

apparent (double stereodifferentiation).[29] Methylation of the *trans*-dihydrooxazole with ***Trimethyloxonium Tetrafluoroborate*** followed by aqueous sodium bicarbonate hydrolysis gives the formamido ester enantiomerically pure after crystallization. The absolute configuration of the two stereocenters formed was confirmed by X-ray crystallography. Careful hydrolysis of the formamido ester to avoid skeletal rearrangement yields MeBmt. In this kilogram scale synthesis, the catalyst can be recovered by precipitation with either diethyl ether or pentane, and can be recycled a number of times without any loss of activity or selectivity.

(10)

The gold(I)-catalyzed asymmetric aldol reaction with the chiral ligand (*R*)-(*S*)-(**2**) has been applied in the synthesis of D-*erythro*- and *threo*-sphingosines (eq 11).[30] The D-*erythro*-sphingosine can be prepared from the *threo* isomer by inversion of the C-3 hydroxyl group.

Chiral β-Hydroxy-α-Aminophosphonic Acids.

An enantioselective synthesis of substituted dihydrooxazolin-4-yl phosphonates was reported by the reaction of an aldehyde with α-isocyanomethylphosphonate ester catalyzed by (*R*)-(*S*)-(**1**) (eq 12).[31] The enantiomeric purity of the product was determined by $^{31}P\{^{1}H\}$ NMR spectroscopy using the chiral solvating reagent (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol. Independently, an asymmetric synthesis of α-aminophosphonic acids was reported using the chiral ferrocenylamine catalyst (*R*)-(*S*)-(**3**) (eq 13).[32]

Asymmetric Allylation.

Asymmetric allylation of β-diketones using the palladium analog of (**1**) has been described.[4] Higher enantioselectivity can be achieved in this case using ferrocenylamines with a modified alkyl side chain.[4] For synthetically useful ferrocenylamine complexes of other metals, see ***(R)-N-[2-(N,N-Dimethylamino)ethyl]-N-methyl-1-[(S)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine***.

Bis(1,5-cyclooctadiene)nickel(0)[1]

[1295-35-8] · $C_{16}H_{24}Ni$ · Bis(1,5-cyclooctadiene)nickel(0) · (MW 275.08)

($Ni(cod)_2$ is a source of nickel(0) useful for the preparation of π-allylnickel halides,[2] for coupling of aryl and alkenyl halides,[3] and for the oligomerization and cycloaddition of strained alkenes,[4] of alkynes,[5] and of 1,3-dienes[6])

Physical Data: mp 60 °C dec (N_2).

Solubility: sol benzene, toluene, THF, ether, DMF, HMPA, *N*-methylpyrrolidinone.

Form Supplied in: yellow-orange crystals of 98+% purity.

Analysis of Reagent Purity: ^{1}H NMR: δ 4.31 (br, =CH), 2.08 (br, CH_2).[1]

Preparative Methods: the standard preparation[2b] is a modification of the original procedure by Wilke and co-workers[7] and involves the reduction of ***Nickel(II) Acetylacetonate***, $Ni(acac)_2$, with ***Triethylaluminum*** in the presence of 1,5-cyclooctadiene (cod) and 1,3-butadiene in toluene. A more convenient preparation utilizes ***Diisobutylaluminum Hydride*** (DIBAL) as the reducing agent.[8] In a typical reaction, 45.4 mL of a 1.0 M THF solution of DIBAL was added to a 250 mL Schlenk flask containing 4.67 g of $Ni(acac)_2$, and 7.93 g cod in THF solution under a nitrogen atmosphere at -78 °C. The resulting dark, reddish-brown solution was warmed to 0 °C and treated with diethyl ether to give a light yellow precipitate. Filtration under nitrogen gave a 72% yield of $Ni(cod)_2$ which was suitable for immediate use. Optional recrystallization from toluene under inert atmosphere gave bright yellow-orange needles with 40% recovery.

Handling, Storage, and Precautions: highly oxygen sensitive. Special inert-atmosphere techniques must be used.[9] Should be stored at 0 °C.

π-Allylnickel Halides.

π-Allylnickel halide complexes are prepared by reaction of allylic halides with $Ni(cod)_2$ in a nonpolar solvent (eq 1).[10] The resulting dimeric species, isolated as a red solid, can be purified by crystallization, stored in the absence of air, and weighed out for reaction like any other moderately air-sensitive compound.[2b] $Ni(cod)_2$ is preferred over

Tetracarbonylnickel for this transformation due to the mildness of conditions required, the extreme toxicity and thermal instability of $Ni(CO)_4$, and the absence of byproducts caused by CO insertion.

(1)

In polar, coordinating solvents such as DMF, HMPA, and *N*-methylpyrrolidinone, π-allylnickel halide complexes react with a wide range of alkyl, alkenyl, and aryl halides[11] to replace a halogen with the allyl group, as shown by the reactivity of π-(2-methallyl)nickel bromide (**1**) (eq 2).[12] These complexes also react with aldehydes and ketones to give homoallylic alcohols,[13] with quinones to produce allylquinones,[14] and with 2-pyridylcarboxylates to give β,γ-unsaturated ketones.[15] However, they do not react readily with esters, acid chlorides, amides, nitriles, or alcohols. Due to this significantly lower reactivity in these reactions, they offer a greater degree of selectivity over their allyllithium, -magnesium, and -zinc counterparts.[16] Mechanistic aspects of the coupling reaction between organic halides and π-allylnickel halides have been investigated and a radical-chain pathway has been proposed.[17]

(2)

(1)

The π-allylnickel halide formation reaction (eq 1) is tolerant to substitution on the allyl halide starting material. 1,1-Dimethylallyl,[13] 2-ethoxycarbonylallyl,[13] 2-methoxyallyl,[18] and 2-trimethylsilylmethyl[19] nickel halide complexes, to name a few, have all been synthesized and utilized in subsequent coupling reactions. Alkene-containing allyl halides have been also used to form dienes.[20] Allyl iodides are more reactive than allyl bromides for the generation of π-allylnickel halides and allyl chlorides are unreactive. Allyl mesylates and trifluoroacetates do not work as well as bromides due to extensive homocoupling of the substrates.[19] α,β-Unsaturated aldehydes and ketones react with $Ni(cod)_2$ in the presence of a trialkylsilyl chloride to give [1-[(trialkylsilyl)oxy]allyl]nickel chloride dimers (**2**) (eq 3).[21] These complexes couple to alkyl halides at the γ-position upon irradiation under a sun lamp to give silyl enol ethers (**3**), making the overall transformation a useful reversed-polarity complement to organocuprate conjugate addition chemistry. Chiral allyl acetals (**4**) have also been utilized to form chiral (*E*)-enol ethers (**5**) which serve as homoenolate equivalents of a new type (eq 4).[22]

(2)

(3)

(3)
60-80% overall

(4)

(4)

(5)

Complexes having π-allylnickel halide-like reactivity may also be used as transient intermediates in polar media without the need for isolation. This type of reactivity is especially important for the intramolecular coupling of allyl groups (see ***Tetracarbonylnickel***). In these cases, allylic tosylates and carboxylates may also be used for the initial oxidative addition of the allyl substrate to nickel.[23] In one interesting group of reactions (eq 5),[24] a π-allyl intermediate undergoes an intramolecular alkene insertion to form a ring followed by β-hydride elimination to give diene (**6**). If carbon monoxide and methanol are included in the reaction mixture, CO insertion, followed by intramolecular insertion of the newly-formed double bond, followed by a final methoxycarbonylation gives rise to keto ester (**7**). The palladium

catalyst ***Bis(dibenzylideneacetone)palladium(0)*** also catalyzes these reactions, but with poor diastereoselectivity. An allylic sulfonium ion (**8**) has shown a similar reactivity and has been utilized in the total synthesis of confertin.[25] Intramolecular coupling with an aldehyde followed by spontaneous lactonization yielded the tricyclic α-methylene-γ-lactone (**9**) (eq 6). Insertion of terminal alkynes into π-allylnickel complexes derived from allylic esters (**10**) has led to a catalytic synthesis of nonconjugated alkenynes (**11**) (eq 7).[26]

(5)

(6)

(7)

Coupling of Aryl Halides.

$Ni(cod)_2$ reacts with a variety of aryl halides in DMF to give diaryl compounds in generally high yields (80-90%) (eq 8).[27]

$$2\ ArX + Ni(cod)_2 \xrightarrow[25\text{-}40\ ^\circ C]{DMF} Ar_2 + NiX_2 + cod \qquad (8)$$

Ortho substituents on the aryl halide drastically reduce the rate of the reaction and an increase in temperature leads only to decomposition of the nickel catalyst. The reaction is tolerant of most functional groups with both electron-donating and electron-withdrawing substituents allowing efficient coupling. Nitro groups, however, destroy the catalytic activity of the nickel complexes.[28] Acidic functionalities such as alcohols, phenols, or carboxylic acids cause reduction of the aryl halide in preference to coupling. The order of reactivity of substrates is I > Br > Cl with phenol *p*-toluenesulfonate esters being completely unreactive. This reaction may be contrasted with the copper-catalyzed Ullmann reaction,[29] which typically requires high temperatures (&egt;200 °C), or a two-step coupling procedure requiring intermediate arylmagnesium or -lithium reagents which are incompatible with many functional groups.

Attempted cross-coupling usually leads to mixtures of products due to extensive symmetrical coupling. Nevertheless, this strategy was utilized in the synthesis of a 2-benzazepine.[30] Intramolecular coupling reactions,[3,31] on the other hand, are generally quite efficient (eq 9)[32] and often benefit from added phosphine ligand (see also ***Tetrakis(triphenylphosphine)nickel(0)***).

(9)

Coupling of Alkenyl Halides.

$Ni(cod)_2$ reacts with alkenyl halides to produce symmetrical 1,3-dienes.[33] These reactions may be carried out in DMF, or in ether with an added ligand such as Ph_3P. Coupling of simple alkenyl halides gives only moderate yields (48-70%) with mixtures of geometrical isomers. Reactions of alkenyl halides bearing electron-withdrawing substituents such as α- and β-haloacrylates, however, are more efficient and highly stereoselective (eq 10).[3] The intramolecular coupling of a simple diiodide has also been shown to be effective (eq 11).[3] Finally, there is one example of the intramolecular coupling of alkyl halides in which α,o-dihaloalkanes are cyclocoupled to give cycloalkanes by a $Ni(cod)_2$-bipyridyl complex.[34]

(10)

(11)

Oligomerization of Strained Alkenes and Alkanes.

3,3-Disubstituted cyclopropenes are known to react with electron-deficient alkenes in the presence of catalytic $Ni(cod)_2$ to give vinylcyclopropanes (eq 12).[35] The mechanism of the reaction begins with oxidative addition of Ni^0 into the C-1-C-3 bond, but there is some dispute as to whether a carbenoid intermediate is involved.[4] Methyl, phenyl, and methoxy groups have all been used as geminal substituents on the cyclopropene; however, the stereochemistry of the starting alkene is not preserved when methoxy is used.[36] Alkyl group substitution on the electron-deficient alkene disfavors this reaction pathway and leads to [2 + 2] cyclodimerization of the cyclopropene.[37] Addition of ligands has also been shown to affect the distribution of products. When the catalyst is modified by the bulky $P(i\text{-Pr})_2(t\text{-Bu})$, a [2 + 2 + 2] cycloaddition is observed (eq 13).[38]

(12)

(13)

Cyclobutenones react with alkynes in the presence of $Ni(cod)_2$ to give substituted phenols. Many substituents are tolerated, but regioselectivity is poor (eq 14). The reaction proceeds by oxidative addition of nickel at the C-1-C-4 bond followed by insertion of the alkyne.[39] Cyclopropenones react to form benzoquinones.[40] This mechanism may involve a nickel-catalyzed [2 + 2] cyclodimerization followed by a thermal isomerization or an alkene methathesis.

(14)

1:1

Norbornene derivatives[41] and cyclobutenes[42] have also been shown to react with alkenes under the influence of $Ni(cod)_2$ catalyst to give [2 + 2] cycloadducts. Norbornadiene substrates can react with electron-deficient alkenes in a [2 + 2 + 2] cycloaddition pathway to give homo-Diels-Alder products (eq 15) (see also ***Bis(acrylonitrile)nickel(0)***).[43] Norbornadiene also forms [2 + 2] cycloadducts with the exceptionally reactive methylene cyclopropane.[44] When this reaction was carried out in the presence of a chiral phosphine ligand, the product was obtained in an enantiomerically enriched form.

(15)

exo:*endo* = 1:2.3

In addition to the ability to undergo [2 + 2] cycloadditions, methylenecyclopropanes have two additional and more useful [3 + 2] modes of reactivity available under nickel catalysis. As shown for the cycloaddition of methylenecyclopropane with an alkene (eq 16), distal ring opening by nickel leads to products of Type A, whereas Type B products are not a direct result of proximal ring opening, but are formed indirectly via reductive dimerization of two alkene units to give a metallacyclopentane followed by a cyclopropylmethyl/3-butenyl rearrangement. The course of the reaction is determined by many factors including the stoichiometry and physical properties of the ligands bonded to nickel, the number, type, and position of substituents on the methylenecyclopropane, and the nature of the substituents on the participating alkene. Because of these many contributing effects, it is difficult to predict which reaction pathway will be followed under any given condition; however, some general reactivity patterns can be deduced.[4]

(16)

While the dimerization and trimerization of methylenecyclopropanes have been investigated,[45] these reactions are not useful from a synthetic standpoint. For this reason the present treatment will consider only the cycloadditions between methylenecyclopropanes and alkenes. The use of low valent nickel complexes, which have the ability to catalyze reactions of both Type A and Type B should be contrasted with the use of palladium(0) catalysts such as ***Bis(dibenzylideneacetone)palladium(0)***[46] or $Pd(\eta^3\text{-}C_3H_5)(\eta^5\text{-}C_5H_5)$[47] which lead exclusively to products of Type A.[4b]

Unsubstituted methylene cyclopropane can form 1:1 adducts with acrylates, crotonates, and maleates to give Type B cycloaddition products in high yields (eq 17)[48] (see also ***Bis(acrylonitrile)nickel(0)***). The use of enantiomerically pure alkyl acrylates in this type of reaction gave products with up to 64% de.[49] Addition of ligands requires higher reaction

temperatures and results in decreased stereoselectivity.[50] Ligand addition also leads to Type A cycloadducts when highly electron-deficient alkenes such as dialkyl fumarates and maleates are used. It is clear that the outcome of these reactions is highly dependent upon the electronic properties of catalyst and substrate.

(17)

cis:*trans* = 9:1

Substitution at the three-membered ring generally gives rise to cycloadducts of Type B.[4b] When (-)-camphorsulfamylacrylate was reacted with 2,2-dimethylmethylenecyclopropane, a methylenecyclopentane was obtained with a diastereomeric excess of 98% (eq 18).[51] When the substituents are phenyl groups, however, Type A cycloaddition results.[4]

(18)

98% de

Substitution at the double bond almost always leads to cycloaddition of Type A. In these reactions there is an added complication of regioselectivity brought about by the intermediacy of a trimethylenemethane-like species. Thus ethyl crotonate reacts with isopropylidenecyclopropane to give a mixture of the alkylidenecyclopentane (**12**) and the 2-substituted methylenecyclopentane (**13**) (eq 19).[52] The use of bulky phosphite ligands and a high ligand:metal ratio favors the formation of 2-substituted methylenecyclopentanes. Alkenes without electron-withdrawing groups favor the formation of alkylidenecyclopentanes.[4,53] The use of triisopropylphosphine/palladium(0) catalysts also leads to this type of product.[4,54] Disubstituted alkynes can also be used in the cycloaddition to produce alkylidenecyclopentenes.[55] When ***Triethylborane*** was added along with the catalyst, systems that normally reacted along a Type A pathway were

induced to react via Type B.[56] An interesting transannular cycloaddition was utilized to prepare a [3.3.3]propellane, although a palladium catalyst was found to be more suitable than nickel (eq 20).[57] Allene can also be oligomerized by $Ni(cod)_2$.[5a,58]

(19)

Finally, some strained alkanes are known to undergo oligomerization in the presence of Ni^0 catalysts (see also ***Bis(acrylonitrile)nickel(0)***). Bicyclo[1.1.0]butanes react by suffering a geminal two-bond cleavage to form an allylcarbene intermediate which may be trapped stereoselectively by an electron-deficient alkene (eq 21).[59] Additionally, a nickel-catalyzed asymmetric vinylcyclopropane-cyclopentene rearrangement has been reported using $Ni(cod)_2$ with chiral phosphine ligands.[60]

(21)

Oligomerization of Alkynes.

The nickel catalyzed intermolecular oligomerizations of alkynes are some of the oldest and best-studied reactions in

organometallic chemistry.[1,5a] Tetramerization and trimerization lead to cyclooctatetraenes and aromatic molecules, respectively. The cycloaddition of two equivalents of alkyne with one equivalent of alkene provides an interesting route to cyclohexadienes.[61] Addition of isocyanides leads to iminocyclopentadienes,[62] insertion of CO_2 gives pyrones,[63] and insertion of isocyanates yields 2-oxo-1,2-dihydropyridines.[64] Finally, hydroacylation of monoalkynes with aldehydes yields α,β-enones.[65]

The synthetic utility of these reactions is greatly increased when they are used intramolecularly with tethered alkynes since more than one ring can be formed and regiochemical problems are drastically reduced.[5b] Tethered diynes react with $Ni(cod)_2$ and CO_2 in the presence of trialkylphosphine ligands to give bicyclic α-pyrones (eq 22).[66] The reaction is catalytic in nickel and works well with three- and four-atom tethers, but the yield suffers when the tether length is raised to five. Tricyclohexylphosphine was found to be the best choice of ligand. When other ligands were used, dimerization of the starting material was observed. It is believed that an electron-donating ligand may be required for strong CO_2 coordination. The reaction is tolerant of many groups on the alkyne terminus including alkyl, hydrogen, and trimethylsilyl. The choice of these groups helps determine the regiochemistry of the CO_2 addition.[67] The use of aldehydes in the reaction allows for the catalytic generation of bicyclic α-pyrans (eq 23).[68] In these cases the structure of the added phosphine ligand does not play a crucial role; however, the length of the tether and the choice of alkyne substituents exert a great influence on the outcome of the reaction. Other products from this reaction such as oxoalkyl-substituted cyclopentenes are explained by various hydrogen transfer isomerizations of a strained 1,2-bis(alkylidene)cycloalkane intermediate.

Diynes undergo cyclization with 2,6-dimethylphenyl isocyanide in the presence of a stoichiometric amount of $Ni(cod)_2$ to yield polycyclic iminocyclopentadienes.[69] In contrast to the previous cycloadditions, this reaction does not require a phosphine ligand, and seven-membered rings can be formed in moderate yields (47%). The products of these reactions could be hydrolyzed to the corresponding cyclopentadienones by ***10-Camphorsulfonic Acid***, used as diene moieties in Diels-Alder reactions, or stereoselectively substituted at the angular position by a 1,4-addition of an alkyllithium reagent.[5b] Enynes may also take part in this reaction to produce iminocyclopentenes with significant diastereoselectivity (eq 24).[70] No reaction occurs when carbon monoxide is used as the cyclization partner; however, there are titanium, zirconium, and cobalt catalysts that are able to carry out such a transformation directly.[71]

(24)

Oligomerization of 1,3-Dienes.

Extensive studies of the catalytic cyclooligomerization of butadiene have shown that many different products can be obtained from the reaction, depending upon the conditions chosen.[6] These products result from the variety of σ- and π-allylnickel intermediates that can be formed during the catalytic cycle (eq 25).[72] Low-temperature NMR studies of the reaction of butadiene with stoichiometric amounts of $Ni(cod)_2$ have shown that the η^1,η^3-octadienyl complex (**14**) is formed after reductive coupling of the two diene units.[73] This intermediate, which is probably important in the catalytic reaction as well, can isomerize to the bis-π-allyl complex (**15**). Reductive elimination to regenerate a nickel(0) species from these and other allylnickel(II) complexes can lead to 4-vinylcyclohexanes (VCH), 1,2-divinylcyclobutanes (DVCB), or 1,5-cyclooctadienes (cod). Insertion of alkenes or dienes into these intermediates leads to larger ring systems.[6a] These intermediates can also be induced to react with carbonyl compounds, but they are much less nucleophilic than π-allylhalide-like complexes.[74]

(25)

Due to the lack of general methods for the production of medium-sized rings, the synthetic value of these reactions lies especially in their ability to generate cyclooctane ring systems. Control of the cyclodimerization of 1,3-dienes to give cyclooctadiene products preferentially is contingent upon the substitution of the diene as well as the composition of the catalyst system, with both of these factors being mutually dependent. The choice of modifying ligand is extremely important in the selectivity of the reaction, with both electronic and steric parameters being important.[75] It has also been shown for some functionalized dienes that the method of generation of the Ni^0 catalyst is important to this selectivity. Catalysts generated from the reduction of nickel(II) salts such as $Ni(acac)_2$ with alkylaluminum derivatives favor formation of VCH derivatives, while aluminum-free reagents such as $Ni(cod)_2$ give preference to the cod products.[76] Several iron and cobalt catalysts have been reported to selectively catalyze cod production, while titanium, iron, and manganese catalysts have led to VCH products. Palladium catalysts, on the other hand, give DVCB products.[5a]

When [4 + 4] cycloadditions occur, simple alkyl substituents on the diene usually give 1,5-disubstituted cod products as a result of initial head-to-tail linking, but mixtures of products are inevitable.[1] Functional groups that can coordinate to nickel act as internal ligands to guide the reaction. Thus methyl 2,4-pentadienoate cyclodimerizes regio- and stereoselectively to give a *trans*-1,2-disubstituted cyclooctadiene (eq 26).[77] While ester and silyl ether substituents worked well in this reaction, amino and amido groups were not tolerated.

(26)

$R = OSiMe_3$, 90%
$R = CO_2Me$, 83%

The synthetic utility of these reactions is significantly enhanced when the cycloadditions are carried out intramolecularly. When the diene units are connected by a tether, the production of byproducts can be essentially

eliminated.[78] Terminally linked dienes undergo Type I [4 + 4] cycloadditions, giving rise to *cis*-fused bicycles when the tether length is three atoms, and *trans*-fused systems when the tether length is increased to four atoms. Diastereoselectivity is observed in these cycloadditions when substitution is made at an allylic position, and the degree of selectivity is related to the size of the substituent (eq 27).[79] A nickel catalyzed intramolecular [4 + 4] cycloaddition was used as the key step in the synthesis of (+)-asteriscanolide (eq 28).[80] Furthermore, when one of the diene fragments is connected at an internal position, bridged ring-systems can be assembled (eq 29).[81] This Type II class of cycloaddition was used in an approach to the taxane skeleton.[82] When trisubstituted dienes are used as substrates for the reaction, angularly substituted bicycles can be obtained.

(27)

R	Yield	Ratio (α:β)
CN	66%	1.6:1
Me	88%	20:1
CH_2OAc	93%	22:1
CO_2Me	65%	65:1

(28)

(29)

These reactions can also be tailored to give 1,4-cyclohexadiene products if an alkyne is tethered to the diene (eq 30).[83] These catalytic [4 + 2] cycloaddition reactions are an attractive alternative to the Diels-Alder reaction because they are very mild, tolerant of a wide array of functional groups, and are exempt from the restrictive electronic substitution requirements of the thermally activated reaction. If the alkyne portion of the molecule is replaced by an alkene, however, a rhodium catalyst must be used.[84] When an allene is used the regiochemistry of the cycloaddition can be controlled by the choice of catalyst (eq 31).[85]

(30)

(31)

Linear dimerizations of 1,3-dienes may be induced by the addition of a hydrogen donor such as an amine, alcohol, or an aminophosphinate ligand to the catalyst.[5a,86] When a chiral aminophosphinate ligand was used, piperylene was dimerized to a 21:70 ratio of the two head-to-head 1,3,6-octatriene isomers having ~90% and 35% ee, respectively.[87]

Other Uses.

Sulfur heterocycles can undergo hydrodesulfurization and ring contraction in the presence of nickel(0) complexes.[88] Symmetrical aromatic ketones may be prepared from aromatic carboxylic acids through the coupling of their *S*-(2-pyridyl) derivatives.[89] Alkenes can be formed from 1,2-diols by the stereospecific cleavage of thionocarbonates.[90] Alkane- and alkenecarboxylic acids can be generated from the reaction of alkenes with a nickel(0) catalyst and CO_2.[91] Geminal dihalides react with nickel(0) catalysts and electron deficient alkenes to give cyclopropanes.[92]

Bis(1,5-cyclooctadiene)rhodium Tetrafluoroborate-(*R*)-2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl[1]

([Rh(cod)$_2$]BF$_4$)

[35138-22-8] · $C_{16}H_{24}BF_4Rh$ · Bis(1,5-cyclooctadiene)rhodium Tetrafluoroborate-(*R*)-2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl · (MW 406.07) ((*R*)-BINAP)

[76189-55-4] · $C_{44}H_{32}P_2$ · Bis(1,5-cyclooctadiene)rhodium Tetrafluoroborate-(*R*)-2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl · (MW 622.68)

(catalyst for asymmetric hydrogenation,[2] isomerization,[3] hydroboration,[4] and intramolecular hydrosilation[5] of alkenes)

Physical Data: [Rh(cod)$_2$]BF$_4$: mp 206-8 °C; (*R*)-BINAP: mp 240-241 °C; [α]25D + 229° (*c* = 0.32, benzene).

Form Supplied in: [Rh(cod)$_2$]BF$_4$: orange-red crystals; (*R*)-BINAP: colorless crystals.

Analysis of Reagent Purity: (*R*)-BINAP: ^{31}P NMR (4:1 C_6D_6-CD_3OD): δ -12.8 (s); mp and optical rotation shown above are also useful for analysis of the purity.

Purification: [Rh(cod)$_2$]BF$_4$: recrystallization from CH_2Cl_2 and ether; (*R*)-BINAP: recrystallization from a mixture of toluene and EtOH.

Handling, Storage, and Precautions: [Rh(cod)$_2$]BF$_4$: hygroscopic; corrosive.

Asymmetric Hydrogenation.

The diene-free cationic rhodium complex of (*R*)-BINAP catalyzes the enantioselective hydrogenation of dehydroamino acids. α-(Benzoylamino)acrylic acid is hydrogenated at rt to afford (*S*)-*N*-benzoylphenylalanine in 100% ee (eq 1).[2] To obtain maximal stereoselectivity the reaction should be carried out under a low concentration of substrate (100% in 0.013 M vs. 62% in 0.15 M) and low initial hydrogen pressure (100% at 1 atm, but 71% at 50 atm).

Optically active homoallylic alcohols are hydrogenated with differentiation of the diastereofaces (eq 2).[6] Use of the matched ligand, i.e. (*R*)-BINAP, gives a product of 96% de, while the mismatched (*S*)-ligand affords low selectivity.

Allylic Hydrogen Migration.

Cationic Rh^I diphosphine complexes are very active catalysts for allylic hydrogen migration of tertiary and secondary allylamines to give the corresponding (*E*)-enamines and imines, respectively. Highly enantioselective isomerization is accomplished by use of (*R*)-BINAP as a diphosphine ligand.[3] Diethylnerylamine, which has (*Z*) geometry, gives (*R*)-(*E*)-diethylcitronellenamine in 95% ee in the presence of 1 mol % of [Rh{(*R*)-BINAP}(cod)]ClO_4, while the isomeric diethylgeranylamine gives (*S*)-(*E*)-diethylcitronellenamine in 96% ee (eq 3). Thus the method presented above offers a desired enantiomer by proper choice of alkene geometry and chirality of BINAP.

$[Rh\{(R)\text{-BINAP}\}(cod)]^+ ClO_4^-$ (3)

Cationic Rh-(*R*)-BINAP complexes also catalyze the allylic hydrogen migration of racemic 4-hydroxy-2-cyclopentenone to 1,3-cyclopentanedione with 5:1 enantiomeric discrimination. The racemate is kinetically resolved to (*R*)-4-hydroxy-2-cyclopentenone of 91% ee at 72% conversion at 0 °C (eq 4).[7]

Asymmetric Hydroboration.

Rhodium complexes are known to catalyze hydroboration of alkenes with unreactive borane derivatives, e.g. catecholborane and oxaborolidine.[8] This reaction proceeds enantioselectively by use of BINAP as a ligand for neutral[9-11] or cationic[4,12] rhodium complexes. Reaction of styrene with catecholborane followed by oxidation affords (*R*)-1-phenylethanol in 96% ee in the presence of (*R*)-BINAP and $[Rh(cod)_2]BF_4$ (eq 5).[4]

Asymmetric Intramolecular Hydrosilation.

Intramolecular hydrosilation of allylic alcohols followed by oxidation is a convenient method for the stereoselective preparation of 1,3-diols.[13] An enantioselective version is achieved by use of diene-free BINAP-Rh$^+$ (eq 6).[5] Both silyl ethers derived from cinnamyl alcohol and its *cis* isomer give (*R*)-1-phenylpropane-1,3-diol in high ee regardless of alkene geometry.

Related Reagents.

Bis(cyclopentadienyl)cobalt

[1277-43-6] · $C_{10}H_{10}Co$ · Bis(cyclopentadienyl)cobalt · (MW 189.12)

(reducing agent; catalyst; source of other organocobalt complexes and of substituted cyclopentanes or cyclopentadienes)

Alternate Name: cobaltocene.

Physical Data: mp 173-174 °C; sublimes 40 °C/0.1 mmHg; paramagnetic.

Solubility: sol petrol and other common org solvents, but reacts with chlorocarbons and oxidizing agents (e.g. nitromethane).

Form Supplied in: black-purple cryst; commercially available; readily synthesized from Co^{II} salts [preferably $Co(NH_3)_6Cl_2$] + CpNa in THF.[1]

Handling, Storage, and Precautions: highly air- and somewhat moisture-sensitive and light-sensitive; indefinitely stable in vacuo or under dry inert atmosphere (N_2, Ar) in the dark; storage in the cold is recommended; toxic.

Catalytic Reactions.

As well as its very facile oxidation to cobaltocenium salts (see ***Bis(cyclopentadienyl)cobalt Hexafluorophosphate***), cobaltocene is a source of $CpCoL_2$ complexes, e.g. the dicarbonyl (L = CO) (eq 1)[2] (see ***Dicarbonyl(cyclopentadienyl)cobalt(I)***) and the bis(ethylene) complex (L = C_2H_4) (eq 2)[3] (see also ***(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)***). Like these diamagnetic complexes ($CpCoL_2$), it catalyzes the reaction of alkynes with nitriles to give 2-substituted pyridines (eq 3),[4] related reactions with isocyanates (eq 4) and carbodiimides,[5] and the closely related alkyne cyclotrimerization.[6] It also catalyzes hydroformylation of alkenes, e.g. 1-octene (eq 5),[7] and is comparable in activity as catalyst to both ***Dicarbonyl(cyclopentadienyl)cobalt(I)*** and ***Octacarbonyldicobalt***, but the last one gives a higher *n*:*i*-nonanal ratio in this reaction.

$$Cp_2Co + CO \longrightarrow CpCo(CO)_2 \qquad (1)$$

$$Cp_2Co + K + 2\,C_2H_4 \xrightarrow[0\ ^\circ C]{Et_2O} CpCo(C_2H_4)_2 + C_5H_5K \qquad (2)$$

RCN + 2 C_2H_2 ⟶ 
(3)

$$PhC{\equiv}CCO_2Me + PhNC{=}O \xrightarrow[\substack{135\ ^\circ C \\ 19\ h}]{Cp_2Co}$$

(4)

$$C_6H_{13}CH{=}CH_2 + CO + H_2 \xrightarrow[\substack{\text{or } CpCo(CO)_2 \\ \text{or } Co_2(CO)_8}]{Cp_2Co}$$

$$C_8H_{17}CHO + C_6H_{13}CHMeCHO \qquad (5)$$

In the presence of base, cobaltocene catalyzes the efficient addition of carbon dioxide to 2-methylbut-3-yn-2-ol (eq 6).[8] In conjunction with copper chelates, it is reported to catalyze polymerization and block copolymerization of methyl methacrylate.[9]

(6)

Stoichiometric Reactions.

As a 19-electron complex, cobaltocene acts as a powerful one-electron reducing agent. Its use as such has been largely confined to the reduction of a wide range of organometallic substrates. Little is known about its ability to reduce metal-free organic substrates apart from its reactions with alkyl halides, including polyhalides, which proceed according to eq 7 and possibly by the steps in eqs 8 and 9. The last step (eq 9) finds support from the addition of the radical &bdot;CMe_2CN, generated from AIBN.[10] The general reaction (eq 7) occurs efficiently with halomethanes and with allylic, benzylic, and propargylic halides, with α-halo esters and ketones and with benzoyl chloride.[11] A related reaction occurs with active hydrogen compounds (e.g. C*H*Cl_3, *H*C_2Ph, *H*CH_2CN, *H*CH_2COMe) in the presence of O_2, apparently via an oxygen adduct of cobaltocene, e.g. eq 10.[12] Interaction of cobaltocene with organomercury[13] and -cadmium[14] reagents also leads to 5-*exo*-substituted cyclopentadiene(cyclopentadienyl)cobalt (eq 11) accompanied by products suggesting radicals (for another route to these 5-*exo*-substituted complexes and some aspects of their behavior, see ***Bis(cyclopentadienyl)cobalt Hexafluorophosphate***).

(7)

(8)

(9)

All such complexes are potential sources of substituted cyclopentadienes, but little attention has been paid to such use. (Trichloromethyl)cyclopentadiene has been liberated by iodine oxidation (eq 12) of the complex prepared from Cp_2Co with CCl_4 or with $CHCl_3/O_2$.[15] However, reactions in which the diene moiety is displaced by other ligands (e.g. Me_2S in the presence of HBF_4[16] or PhC_2Ph[17]) have been carried out without isolation of the metal-free product(s).

The complexes with 5-*exo*-haloalkyl groups undergo ring enlargement on solvolysis (eq 13).[18] In a closely analogous sequence, cobaltocene adds dihaloboranes, e.g. eq 14, to give products which undergo ring enlargement (eq 15) on hydrolysis or on treatment with Lewis acids.[19]

(13)

(14)

(15)

A one-step synthesis of azulene from cobaltocene is reported to proceed in 12-21% yield according to eq 16.[20]

Bis(cyclopentadienyl)cobalt Hexafluorophosphate

[12427-42-8] · $C_{10}H_{10}CoF_6P$ · Bis(cyclopentadienyl)cobalt Hexafluorophosphate · (MW 334.09)

(source of (cyclopentadiene)(cyclopentadienyl)cobalt and its substitution products and, hence, of substituted cyclopentadienes and cyclopentanes)

Alternate Name: cobaltocenium hexafluorophosphate.

Solubility: sol acetone, hot ethanol; sparingly sol ether, water.

Form Supplied in: yellow crystalline solid; available commercially.

Preparative Method: readily synthesized from cobalt(II) salts + CpNa, followed by air + HPF_6 or NH_4PF_6. Salts with a wide range of other counterions may be obtained similarly. The cobaltocenium ion[1] may be precipitated from aqueous solution by a variety of large anions. In addition to PF_6^-, convenient counterions include Br_3^- and I_3^-. The simple halides are hygroscopic, but may be obtained in anhydrous form by removal of water under vacuum.

Handling, Storage, and Precautions: very stable; irritant.

The potential synthetic value of cobaltocenium salts depends on the facile addition of hydride (eq 1)[2] and of (unstabilized) carbon nucleophiles (eq 2)[3] to give (cyclopentadiene)(cyclopentadienyl)cobalt(I) complexes. The unsubstituted $(C_5H_5)Co(C_5H_6)$ is similar in reactivity to ***(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)***. *Exo* substituted derivatives of the type formed in eq 2 are also available from ***Bis(cyclopentadienyl)cobalt***.

They react sluggishly or not at all (depending on R) with triphenylmethyl cations, which in general only abstract *exo*-but in some cases also abstract *endo*-H.[5] However, in many of the cases where they fail it has been found that the products of eq 2 may be converted to substituted cobaltocenium salts by the action of ***N-Bromosuccinimide*** (eq 3)[4] or strong ***Sulfuric Acid***.[5c] Alternatively, thermolysis causes 1,5-H migration (eq 4),[5a,b] making possible subsequent *exo*-H

abstraction (eq 5). However, any further carbanion addition to the resultant monosubstituted cobaltocenium salts will result in isomer mixtures and hence becomes less attractive as a route to disubstituted cyclopentadienes.

(1)

(2)

(3)

(4)

(5)

Methyl and 1,1´-dimethyl derivatives of the cobaltocenium ion are smoothly oxidized by strong oxidants, e.g. ***Potassium Permanganate***, to the corresponding mono- and dicarboxylic acids.[6] The latter, in turn, have been converted to the diacid chlorides,[6b,d] a source of polymers;[7] further conversion by Curtius degradation yields the 1,1´-diaminocobaltocenium ion, itself oxidizable to the dinitro compound.[6b,d] Oxidation of 1,1´-diethylcobaltocenium yields the 1,1´-diacetyl substituted cation[8] and the 1,1´,2,2´-tetracarboxylic acid is formed by oxidation of the dibenzocobaltocenium [bis(indenyl)cobalt(III)] salt with $KMnO_4$.[6a] Such processes are a potential source of substituted cyclopentadienes, as are transformations utilizing the enhanced acidity of α-CH groups. The principle is illustrated by the polysubstitution shown in eq 6.[9]

(6)

A rather remarkable, but low yield, synthesis of azulene is achieved in one step when cobaltocenium hexafluorophosphate is heated with ***Sodium Hydroxide*** (or ***Sodium Amide***), probably via the intermediates included in eq 7.[10]

Bis(η^5-cyclopentadienyl)dihydridozirconium[1]

[37342-98-6] · $C_{10}H_{12}Zr$ · Bis(η^5-cyclopentadienyl)dihydridozirconium · (MW 223.42)

(catalyst for hydrogenation of alkenes and alkynes in combination with hydrogen;[2] catalyst for Meerwein-Ponndorf-Verley type reduction and Oppenauer type oxidation;[3] catalyst for crossed-aldol condensation;[4] catalyst for Tishchenko reaction;[5] reducing agent for organohalogen compounds[6])

Physical Data: polymeric in solid and dimeric $[Cp_2ZrH(\mu\text{-}H)]_2$ in benzene or toluene.[7] The polymeric nature of $[Cp_2ZrH_2]_n$ is suggested by its involatility, insolubility, and insusceptibility to reaction in air. The presence of a Zr-H-Zr bridging system is inferred from the intense broad IR absorption band at 1520 cm^{-1}.[8]

Solubility: insol common solvents.

Form Supplied in: white solid.

Analysis of Reagent Purity: ash (ZrO_2), 55.5%; hydrolyzable H_2, 1.99 g atm mol^{-1}; ^1H NMR (C_6D_6)[7] δ 5.75 (C_5H_5), 3.85 (J = 7.3 Hz), -3.45 (J = 7.3 Hz); IR (KBr disk)[8] 1520, 1300 cm^{-1} (Zr-H).

Preparative Methods: the following method is convenient for the preparation of Cp_2ZrH_2. μ-Oxobis[chlorobis(η^5-cyclopentadienyl)zirconium] ($[Cp_2ZrCl]_2O$) is prepared by the reaction of ***Dichlorobis(cyclopentadienyl)zirconium*** (Cp_2ZrCl_2), available from commercial sources, in dichloromethane and water in aniline.[9] To a solution of $[Cp_2ZrCl]_2O$ in THF is added dropwise ***Lithium Aluminum Hydride*** in THF with stirring under an argon atmosphere. The reaction mixture is stirred for ca. 8 h at rt, filtered, and then washed with THF to give the Cp_2ZrH_2 complex as a white solid (eq 1).[9]

$$2\ Cp_2ZrCl_2 + H_2O \longrightarrow [Cp_2ZrCl]_2O + 2\ HCl$$

$$[Cp_2ZrCl]_2O + LiAlH_4 \longrightarrow 2\ Cp_2ZrH_2 + LiCl + 1/2\ (AlOCl)_2 \qquad (1)$$

Handling, Storage, and Precautions: photosensitive and hydrolyzed by water; should be stored in the dark under

an argon atmosphere.

Reaction with Alkenes.

Alkyl zirconium derivatives, which can be prepared by the addition of Cp_2ZrH_2 to alkenes (hydrozirconation), are easily decomposed by hydrogenolysis to give the corresponding alkanes under mild conditions.[2,10] As a consequence, Cp_2ZrH_2 can be used as a catalyst for the hydrogenation of alkenes to alkanes (eq 2).[2]

(2)

Reaction with Alkynes.

Cp_2ZrH_2-catalyzed hydrogenation of alkynes is also attained (eq 3).[2] Cp_2ZrH_2 reacts with monosubstituted acetylenes to give di-*trans*-alkenyl zirconium complexes, but with diarylacetylene, tetraarylbutadiene complexes are formed (eqs 4 and 5).[11]

(3)

(4)

(5)

Meerwein-Ponndorf-Verley Type Reduction.

Cp_2ZrH_2 catalyzes hydrogen transfer reaction from alcohols to carbonyl compounds.[3] The regioselective 1,2-reduction of α,β-unsaturated carbonyl compounds to allylic alcohols is accomplished in the presence of 2-propanol (eq 6).[12,13] The reagent mediates the chemoselective reduction of keto aldehydes to hydroxy ketones (eq 7).[13] Steroidal diketones, e.g. androst-4-ene-3,17-dione, are reduced to the 17-hydroxy enones with high chemoselectivity (eq 8).[13]

(6)

(7)

(8)

Oppenauer Type Oxidation.

The above discovery (Meerwein-Ponndorf-Verley type reduction) has been extended to the Oppenauer type oxidation.[3] Simple terpenoids, such as geraniol and nerol, are oxidized with retention of stereochemistry of the carbon-carbon double bond to form the corresponding α,β-unsaturated aldehydes (eq 9).[14]

Crossed Aldol Condensation.

Cp_2ZrH_2 catalyzes the selective crossed aldol condensation between alicyclic ketones and aliphatic aldehydes to form the corresponding 2-alkylidenecycloalkanones (eq 10).[4] The reaction of alicyclic ketones with primary alcohols gives 2-alkyl-2-cycloalken-1-ones via the Oppenauer type oxidation followed by crossed aldol condensation (eq 11).[4]

Tishchenko Reaction.

Cp_2ZrH_2 efficiently catalyzes the selective dimerization of aldehydes to esters under mild conditions (eq 12). The crossed dimerization of different kinds of aldehydes is also achieved (eq 13).[5]

(12)

(13)

Dehalogenation of Organohalogen Compounds.

Reductive dehalogenation of organohalogen compounds is achieved by the action of Cp_2ZrH_2.[6] Replacement of hydride in Cp_2ZrH_2 by chloride occurs readily. Thus the reaction of Cp_2ZrH_2 with dichloromethane gives Cp_2ZrCl_2 quantitatively (eq 14).[15]

$$CH_2Cl_2 + Cp_2ZrH_2 \longrightarrow CH_4 + Cp_2ZrCl_2 \qquad (14)$$

Reaction with Alcohols.

Cp_2ZrH_2 readily reacts with alcohols to form the corresponding alkoxy complexes (eq 15).[16]

$$Cp_2ZrH_2 + 2\,ROH \longrightarrow Cp_2Zr(OR)_2 + Zr(OR)_4 \qquad (15)$$

Reaction with Carboxylic Acid and Acetone.

The addition of Cp_2ZrH_2 to excess glacial acetic acid in THF affords $Cp_2Zr(OAc)_2$ (eq 16).[16] Similarly, the slow addition of acetone to a suspension of Cp_2ZrH_2 in THF forms $Cp_2Zr(O\text{-}i\text{-}Pr)_2$ (eq 17).[17]

$$Cp_2ZrH_2 + MeCO_2H \xrightarrow{THF} Cp_2Zr(OAc)_2 \qquad (16)$$

$$Cp_2ZrH_2 + MeCOMe \xrightarrow{THF} Cp_2Zr(O\text{-}i\text{-}Pr)_2 \qquad (17)$$

Reaction with Carbon Monoxide.

The carbonylation of Cp_2ZrH_2 occurs at room temperature to yield an η-formaldehyde-zirconocene complex in a low yield (eq 18).[18] This η-acyl zirconium complex reacts with Cp_2ZrH_2 to form a dinuclear μ-aldehyde-zirconocene hydride complex (eq 19).[18]

(18)

(19)

R = Me, 34%; Ph, 57%

Reaction with Organoborane and Aluminum Complexes.

Cp_2ZrH_2 with ***Borane-Tetrahydrofuran*** or ***Catecholborane*** affords quantitatively $Cp_2Zr(BH_4)_2$ (eqs 20 and 21).[16] When Cp_2ZrH_2 is treated with ***Triethylaluminum*** pale blue product, which is not stable in solution, is obtained. The dinuclear structure is proposed on the basis of ^1H NMR and IR spectra (eq 22).[19]

$$Cp_2ZrH_2 + 2\,H_3B \cdot THF \longrightarrow Cp_2Zr(BH_4)_2 \qquad (20)$$

Kansai University, Osaka, Japan

Bis(η^5-cyclopentadienyl)(diiodozinc)(μ-methylene)titanium[1]

[87370-10-3] · $C_{11}H_{12}I_2TiZn$ · Bis(η^5-cyclopentadienyl)(diiodozinc)(μ-methylene)titanium · (MW 511.28)

(reagent for methylenation of ketones; methylation of nitriles and alkynes; coupling reagent for conversion of benzyl halides to bibenzyl)

Physical Data: δ_H (toluene-d_8) 8.37 (2H), 5.92 (10H).

Solubility: sol THF and toluene at rt; precipitates from THF at -78 °C to give a deep-red $Cp_2TiCH_2.ZnI_2.(THF)_x$ complex.

Analysis of Reagent Purity: concentration can be determined by reaction of originally prepared THF solution with benzophenone to form 1,1-diphenylethylene.

Preparative Methods: $Cp_2TiCH_2.ZnI_2$ is readily generated by the reaction of Cp_2TiCl_2 with $CH_2(ZnI)_2$ in THF.[1]

Handling, Storage, and Precautions: moisture sensitive; must be manipulated under a nitrogen atmosphere; presumably pyrophoric.

Methylenation and Other Reactions.[1]

$Cp_2TiCH_2.ZnI_2$ has been compared[1,2] to the structurally related Tebbe reagent (***μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium***) and reacts in an analogous way with both cyclic and acyclic ketones to give the corresponding alkene (eqs 1 and 2).

(1)

(2)

However, unlike the Tebbe reagent, $Cp_2TiCH_2.ZnI_2$ does not appear to form the methyl ketone, to any significant extent, when it reacts with acid chlorides. For example, reaction of the title reagent with benzoyl chloride affords only small amounts (ca. 20%) of acetophenone, the main product arising from ring-opening of the complexed THF which yields the benzoate of 4-chloro-1-butanol (eq 3). The reagent effects the reductive coupling, presumably via an electron transfer process, of active halides such as benzyl bromide or chloride, and bibenzyls are produced (eq 4).

(3)

(4)

While $Cp_2TiCH_2.ZnI_2$ fails to react with imines, treatment of the reagent with benzonitrile gives acetophenone upon aqueous workup. The observation that α-deuteroacetophenone is formed when D_2O is used in the quenching step supports the intermediacy of a metallocycle (eq 5) in this process.

(5)

Analogous metallocycles are formed when the reagent is allowed to react with alkynes, and hydrolytic cleavage of such intermediates then leads to net *syn* addition of the elements of methane across the original triple bond. The reaction of phenylacetylene with $Cp_2TiCH_2.ZnI_2$ then D_2O is representative (eq 6). However, methylenative dimerization is the

major reaction pathway, and this process involves initial self-condensation of the metallocycle to produce a second intermediate which upon reaction with D_2O affords, when phenylacetylene is used as substrate, a 3:1 mixture of diphenyl-1,5-hexadienes (eq 6).

(6)

The reaction of 1-trimethylsilyl-1-octyne with $Cp_2TiCH_2.ZnI_2$ (eq 7) differs in two respects from that of the preceding alkyne in that: (i) small amounts of an allene are formed (presumably by a β-hydride elimination) and (ii) the principal methylenated dimers have the structures shown, and these probably arise by a process involving insertion into an allylic C-Zn bond. Deuterium-labeling studies are consistent with such mechanistic proposals which involve the intermediacy of a common metallocycle. Some 32% of the product mixture consisted of the same methylated vinylsilane as formed from reaction of the substrate with Cp_2TiCl_2 and $MeAlCl_2$.

Bis(cyclopentadienyl)dimethyltitanium[1]

[1271-66-5] · $C_{12}H_{16}Ti$ · Bis(cyclopentadienyl)dimethyltitanium · (MW 208.14)

(reagent of low basicity and acidity, useful for the methylenation of carbonyl compounds;[2] methylenates highly enolizable ketones,[2] esters[2] and lactones,[2] including aldonolactones[3] and acid-labile substrates;[4] homologs of the reagent perform carbonyl alkylidenations;[5-7] reacts with alkynes[8,9] and nitriles[8-10] and can initiate the ring-opening metathesis polymerization of strained cyclic alkenes;[11] it is a useful precursor for Ziegler-Natta polymerization catalysts,[12] a cocatalyst for alkene metathesis[13] and a catalyst for alkene hydrogenation[14] and the dehydrogenative coupling of silanes[15,16])

Alternate Name: dimethyltitanocene.

Physical Data: mp >90 °C dec.

Solubility: sol most aprotic organic solvents, e.g. Et_2O, THF, CH_2Cl_2, toluene, hexanes.

Form Supplied in: orange crystals; not available commercially.

Analysis of Reagent Purity: ^{1}H NMR (250 MHz, C_6D_6) δ 0.04 (s, 6H), 5.69 (s, 10H).

Preparative Method: [17] a solution of ***Methyllithium*** (2.1 equiv) in Et_2O is added dropwise to a suspension of ***Dichlorobis(cyclopentadienyl)titanium*** in Et_2O (3-5 mL mmol^{-1}) cooled in an ice bath. After 1 h the reaction mixture is quenched with ice water, the ether layer is separated, dried over $MgSO_4$, filtered and evaporated. The resulting bright orange crystals of the reagent, obtained in 95% yield, are dissolved in THF or toluene and stored in the dark, in the refrigerator or freezer.

Handling, Storage, and Precautions: sensitive to oxygen and light, but can be briefly exposed to air and water. In the solid state the reagent is not stable for more than a few hours at rt, but it can be stored for months in the dark as a THF or toluene solution. Although it is stable in solution at rt, the reagent is best stored in a refrigerator.

Methylenation of Carbonyl Compounds.[2]

Although the Wittig reagent[18] $CH_2{=}PPh_3$ (see ***Methylenetriphenylphosphorane***) and several other P-, Si-, or S-stabilized methylene anions[19] are commonly used for the methylenation of aldehydes and ketones, these reagents have several synthetic limitations due to their inherent basicity. Wittig-type alkenations generally fail with readily enolizable carbonyls or substrates that undergo a facile nucleophilic addition or elimination. Furthermore, sterically hindered substrates are often methylenated in low yields, while the alkenation of esters and lactones is usually not possible with these methods. Several Ti-based methylenation procedures[1c] have been developed that avoid most of the problems encountered with Wittig-type processes. The combination of ***Dibromomethane-Zinc-Titanium(IV) Chloride***,[20] particularly Lombardo's reagent,[21] is useful for the methylenation of sterically hindered and highly enolizable aldehydes and ketones. The similar reagent CH_2I_2-Zn-$TiCl_4$[22] is also used for this purpose, while two other variations, CH_2I_2-Zn-Ti(O-*i*-Pr)$_4$ and CH_2I_2-Zn-Me_3Al, allow the chemoselective methylenation of aldehydes in the presence of ketones.[23] Another widely used reagent is the Tebbe reagent (see ***μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium***),[1b,1c,24,25] which is useful for the methylenation of a variety of carbonyls, including aldehydes, enolizable ketones, esters and lactones. This reagent, however, is not suitable for highly acid-labile substrates and requires stringent inert atmosphere techniques due to its high sensitivity to air and water.

Dimethyltitanocene is an experimentally convenient alternative to the Tebbe reagent.[2] It is easier to prepare and handle and is suitable for the methylenation of aldehydes, ketones, esters, and lactones, including highly enolizable and acid-labile substrates. Heating a solution of a carbonyl compound and Cp_2TiMe_2 (1-3 equiv) in the dark at 60-80 °C, in a sealed flask or under argon, results in a clean and efficient methylenation. Unlike the reactions of the Tebbe reagent, this procedure does not require aqueous workup. The product can be isolated by precipitation of the yellow titanium oxide byproduct, filtration and purification by chromatography or distillation. Although the yields for the methylenation of aldehydes are moderate (eq 1),[2] the reaction works well for alkyl and aryl ketones (eq 2),[2] as well as for cyclic ketones (eq 3).[26]

(1)

R = H 48%
R = Me 62%

(2)

(3)

Aldehydes (eq 4)[27] and ketones (eq 5)[2] are methylenated faster than esters or lactones. Due to its suppressed basicity and similarity to the Tebbe reagent[28] and Takai's procedure,[22] Cp_2TiMe_2 also methylenates highly enolizable ketones (eq 6).[2]

(4)

52% @ 62% completion

(5)

(6)

Esters (eq 7)[2] and lactones (eq 8),[29] including aldonolactones (eq 9),[3] are efficiently methylenated with this reagent. Since the resulting enol ether products undergo facile acid-catalyzed hydrolysis, their isolation and purification should be done under basic conditions. Highly acid-sensitive substrates, such as spiroketal lactones (eq 10)[4] which decompose with the Tebbe reagent, can be readily methylenated with Cp_2TiMe_2.

(7)

(8)

(9)

(10)

Alkylidenations of Carbonyl Compounds.

While homologs of the Tebbe reagent are difficult to prepare, the corresponding dialkyltitanocene derivatives are readily prepared from Cp_2TiCl_2 and alkyllithium or Grignard reagents. With the exception of compounds that undergo facile β-hydride elimination, dialkyltitanocenes are adequately stable for isolation in a pure form. Thermolysis of such derivatives in the presence of aldehydes, ketones, esters, lactones, or amides, results in carbonyl alkylidenation. Thus dibenzyltitanocene gives benzylidenation products (eq 11),[5] bis(trimethylsilylmethyl)titanocene forms vinylsilanes (eq 12),[6] while bis(cyclopropyl)titanocene forms cyclopropylidenes (eq 13).[7]

Formation of Titanium Enolates with $(C_5Me_5)_2TiMe_2$.

The pentamethyl-Cp derivative $(C_5Me_5)_2TiMe_2$ behaves differently from Cp_2TiMe_2. Upon thermolysis it forms a reactive titanium methylidene species which undergoes insertion into one of the Cp methyl groups.[30] Rather than carrying out methylenations, $(C_5Me_5)_2TiMe_2$ reacts with ketones to form titanium enolates with a high degree of regio- and stereocontrol (eq 14).[31] It also forms similar enolates from epoxides (eq 15).[32]

(14)

$E:Z = 180:1$

(15)

Reactions with Alkynes.

Although addition-elimination pathways are also possible,[2,8,9] it is likely that the thermolysis of Cp_2TiMe_2 generates the highly reactive intermediate $Cp_2Ti{=}CH_2$, which can be trapped by various substrates. In the case of alkynes, clean quantitative conversions to the corresponding titanacyclobutenes take place.[8,9] Titanacyclobutenes[33] can also be prepared with the Tebbe reagent, and they react with aldehydes, ketones, nitriles, and other electrophiles to give a variety of titanium-free products (eq 16).[8] Interestingly, the reaction of Cp_2TiMe_2 with alkynes under photolytic conditions forms titanacyclopentadienyl derivatives,[34] presumably via a titanocene (Cp_2Ti) intermediate.

Reactions with Nitriles.

Thermolysis of Cp_2TiMe_2 in the presence of nitriles (2 equiv) generates 1,3-diazatitanacycles,[8-10] which can be hydrolyzed to 4-amino-1-azadienes (eq 17).[10]

Ring-Opening Metathesis Polymerization.

Norbornene readily undergoes ROMP with Cp_2TiMe_2 and other dialkyltitanocenes (eq 18).[11]

(18)

Alkene Metathesis.

Among other related systems, the combination of Cp_2TiMe_2 with $WOCl_4$ shows the best catalytic activity for alkene metathesis (eq 19).[13]

(19)

Cp_2TiMe_2, $WOCl_4$	43%	45%
$Cp_2TiClMe$, $WOCl_4$	41%	39%
Cp_2ZrMe_2, WCl_6	30%	36%
Cp_2TiMe_2, WCl_6	39%	16%

Ziegler-Natta Polymerization of Alkenes.

In combination with Al compounds or other acids,[35] dialkyltitanocenes generate cationic titanocene complexes[12] which catalyze the Ziegler-Natta polymerization of alkenes (eq 20).[36-38]

(20)

Hydrogenation of Alkenes.

A variety of dicyclopentadienyl Ti derivatives, including Cp_2TiMe_2, can catalyze the hydrogenation of alkenes, presumably via a Ti-H species (eq 21).[14]

(21)

Reactions with Silanes.

In the presence of catalytic amounts of Cp_2TiMe_2[15] or other similar derivatives,[16,39] hydrosilanes undergo dehydrogenative coupling to form oligomers and polymers (eq 22).[15] Alkene hydrogenation, isomerization, or hydrosilylation occurs when an alkene is present,[40,41] while in ammonia a different type of dehydrocoupling takes place (eq 23).[42]

Bis(cyclopentadienyl)-3,3-dimethyltitanacyclobutane[1]

[80122-07-2] · $C_{15}H_{20}Ti$ · Bis(cyclopentadienyl)-3,3-dimethyltitanacyclobutane · (MW 248.20)

(methylenating agent for alkenation of carbonyl compounds, particularly esters, ketones, and aldehydes;[1a,c] of low basicity and functions without epimerization at α-chiral centers; catalyst precursor in living ring-opening metathesis polymerization[1b])

Solubility: very sol dichloromethane, diethyl ether, and toluene; moderately sol pentane.[2]

Form Supplied in: red crystalline solid.

Analysis of Reagent Purity: by ^{1}H NMR (toluene-d_8, -10 °C)[3] or by bromination in ether at -20 °C followed by quantitation of the 1,3-dibromo-2,2-dimethylpropane product by GC.[4]

Preparative Methods: most often prepared from the Tebbe reagent (**1**) by reaction with isobutene and 4-dimethylaminopyridine in dichloromethane.[3] Alternatively, may be formed in 89% yield from Cp_2TiCl_2 and a 1,3-di-Grignard reagent, which is in turn obtained from 1,3-dibromo-2,2-dimethylpropane in 18% yield.[4,5]

Purification: may be recrystallized by slow cooling of a toluene solution from 0 °C to -78 °C under an inert atmosphere. Recrystallization from diethyl ether is also effective.

Handling, Storage, and Precautions: the title reagent (**2a**) may be stored indefinitely under nitrogen atmosphere, preferably in the dark. Although this titanacycle is moderately air- and water-sensitive, it may be handled in air for brief periods. In solution this complex is labile and will decompose to give the purple dimer $[Cp_2Ti(\mu\text{-}CH_2)]_2$,[6] as well as isobutene and other uncharacterized products. Solutions should be prepared at 0 °C and used immediately.[2]

Reactivity of Titanacyclobutanes.

A number of titanacyclobutane complexes (e.g. (**2a-e**)) have been efficiently prepared from Tebbe reagent (**1**) (***μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium***)[1c,2,7-9] and studied in significant detail (eq

1).[1] Typically pyridine bases are used; ether or tetrahydrofuran as bases give equilibrium concentrations of (**1**) and (**2**).[10] Certain titanacyclobutanes may be prepared in variable yields from 1,3-di-Grignard reagents;[4,5,11] a few examples are shown in eq 2. Very recently a route to titanacyclobutanes via cationic π-allyl species was demonstrated.[12] Also, titanacyclobutanes may be prepared by reaction of alkenes with less stable titanacyclobutanes.[3,8,9] These metallacycles cleave to afford $Cp_2Ti{=}CH_2$ (as the free methylidene or, more likely, an alkene complex[13]) as shown in the ester to vinyl ether conversion of eq 3.[1a,1c,14]

(2a) $R^1 = H$; $R^2, R^3 = Me$
(2b) $R^1 = H$; $R^2 = Me$; $R^3 = n\text{-Pr}$
(2c) $R^1, R^2 = H$; $R^3 = t\text{-Bu}$
(2d) $R^1, R^2 = H$; $R^3 = i\text{-Pr}$
(2e) $R^1, R^2 = (CH_2)_3$; $R^3 = H$

(2)

(2a) $R^1 = R^2 = Me$

(2f) $R^1 = R^2 = H$
(2g) $R^1 = H$; $R^2 = Me$

(3)

The titanacyclobutanes may thus serve as aluminum-free alternatives to the Tebbe reagent for methylenation of a range of carbonyl compounds. Another application which involves retro 2 + 2 cleavage of metallacycles is the ring-opening metathesis polymerization (ROMP) of strained cycloalkenes via substituted methylidene intermediates (see below).[1b] As methylidene sources the titanacyclobutanes offer advantages over (**1**); primarily in avoidance of side reactions due

to acidic aluminum species, ease of workup, and lesser air sensitivity. However, titanacyclobutanes have not been as widely employed because they are not commercially available and preparation requires Schlenk line and glovebox techniques.

The titanacyclobutanes undergo a number of potentially useful reactions in which the carbon skeleton of the ring remains intact in products such as alkanes, 1,3-dibromides, cyclopropanes, and acyloins. These products may be conveniently obtained from titanacycles formed in situ from (**1**).[1a]

Titanacyclobutanes as Methylidene Precursors.

Most titanacyclobutanes, including (**2a-e**), thermally cleave by a retro 2 + 2 process to liberate alkene and afford the reactive methylidene species $Cp_2Ti{=}CH_2$, or an alkene complex thereof, as shown in eq 3.[1f,13,14] Thus much of the chemistry of these metallacycles is qualitatively similar to that of the Tebbe reagent (**1**).[1c] For example, the titanium methylidene so produced affords vinyl ethers from a wide range of esters (eq 3), a conversion which is not possible using Wittig alkylidene phosphorane reagents.[15] Aldehydes and ketones are likewise methylenated and reaction takes place without epimerization at α-chiral centers,[1a] a frequent problem when using highly basic Wittig conditions.[16] Yields in these methylenations are generally good to excellent. The intermediate titanaoxacyclobutanes are not observed in these transformations, although stable analogs having β-alkylidene substitution have been characterized.[17] This methylenation chemistry has been the subject of a recent comprehensive review.[1c]

Different reactivity is observed for the titanacycles with acid chlorides as shown in eq 4.[18] The titanium enolates of methyl ketones which result do not undergo double-bond isomerization, and are useful in the aldol reaction. Although the Tebbe reagent shows similar reactivity, yields are much lower.[19] Reaction of the titanacyclobutanes with sterically hindered ketones also affords titanium enolate complexes; however, these are not active in the aldol reaction.[20] Reaction with anhydrides also gives enolate complexes which are not active in the aldol reaction. By contrast, unhindered imides may be methylenated in good yield with excellent selectivity in unsymmetrical cases.[21]

(4)

Reaction with certain alkyl halides occurs to give titanocene alkyl halides $[Cp_2Ti(Cl)CH_2R]$ via a radical mechanism.[22]

Although α-alkyl substituted titanacyclobutanes (e.g. **2h**, see eq 6) are thermally unstable,[10] α-alkylidene substitution is favorable[23-25] and leads to a versatile synthesis (via titanium vinylidene intermediates) of substituted allenes from ketones as shown in eq 5.[26]

The titanacyclobutanes have also served as precursors in the synthesis of various interesting heterobimetallic μ-methylene complexes[27] and other organometallic species,[28] including titanium methylidene phosphine complexes.[29]

Choice of metallacycle is dictated by reaction conditions and ease of preparation. β-Substituted metallacycles such as (**2c** and **2d**) are especially stable and react at 50-60 °C, whereas β,β-disubstituted titanacycles such as (**2a** and **b**) react at about 0 °C.[1a,13] By contrast, the Tebbe reagent may be used at -40 °C. Titanacyclobutane (**2a**) is particularly convenient for NMR studies due to the simplicity of its spectrum, while (**2b**) is prepared by the same general method using a liquid alkene which is easier to handle than isobutene.

It should be noted that alternate methods for formation of active titanium methylidene species have been developed.[1c] A widely used system for methylenation of ketones[30] is the still undefined mixture formed from $Zn/CH_2X_2/TiCl_4$. Also, thermolysis of Cp_2TiMe_2 provides a clean aluminum-free source of $Cp_2Ti{=}CH_2$ and shows considerable synthetic promise.[31] Except in the case of titanacyclobutanes prepared from strained cycloalkenes (see below), or α-alkylidene substituted cases (see above), the titanacyclobutanes are efficient precursors only for the unsubstituted methylidene species; several approaches to substituted methylidene equivalents of titanium or zirconium have been devised,[1c,32] including a preparation of titanocene vinylcarbene complexes from cyclopropenes.[33]

Reactions Involving Substituted Alkylidene Intermediates: Ring-Opening Metathesis Polymerization (ROMP).[1b]

The titanacyclobutanes were the first metallacycles to demonstrate the requisite reactivity for catalysis of alkene metathesis via alkylidene complex intermediates.[34] However, these species are not useful catalysts for productive metathesis of acyclic alkenes. This is due to the propensity of α-substituted titanacyclobutanes such as (2h) to cleave to the unsubstituted methylidene, as

illustrated by eq 6.[10]

However, titanacyclobutanes formed from strained cycloalkenes will ring open to afford substituted methylidenes. This useful mode of reactivity is illustrated for complex (2i), formed from 3,3-dimethylcyclopropene, which yields titanium alkylidene phosphine complex (3), as shown in eq 7.[9]

Likewise, (2i) reacts with benzophenone to afford 3,3-dimethyl-1,1-diphenyl-1,4-pentadiene.[9] Norbornene affords the extremely stable titanacyclobutane (2j) upon reaction with (1) or even the quite stable titanacycle (2d) under suitable conditions, and this species reacts further with norbornene (benzene solution, 65 °C) to produce ring-opened polynorbornene (*cis*:*trans* ratio 38:62) as

illustrated in eq 8.[35] Because rates of chain transfer and chain termination are very slow relative to initiation and propagation in this system, a living polymerization process occurs. The low polydispersity (below 1.1) of the polynorbornene and the linear increase in molecular weight with time are consistent with this. Another entry into this chemistry involves thermolysis of dimethyltitanonocene.[31b] The living nature of this system allows for end capping of the polymer chains by Wittig-type reactions with, for example, benzophenone[36] or acetone,[37] and also, by sequential addition of different monomers, for the production of block copolymers.[37,38] Other monomer units employed include benzonorbornadiene, 6-methylbenzonorbornadiene, and *endo*- and *exo*-dicyclopentadiene, which have been used to synthesize diblock and triblock copolymers of low polydispersity as illustrated in eq 9.[37] It has been possible to end-cap ROMP polymers with an aldehyde group and to use aldol-group-transfer polymerization to make diblock polymers with poly(vinyl alcohol) or poly(silyl vinyl ether) segments.[38a] ROMP chemistry using titanium methylidene sources has also been used to produce the novel cross-conjugated poly(3,4-isopropylidenecyclobutene) shown in eq 10, which becomes conducting upon oxidative doping.[39]

(2j)

(8)

(9)

(10)

Numerous other ROMP catalysts have been developed,[1d,40] some of which are stable to air and water and are active at room temperature.[41]

It should be noted that in situ formation of a derivative of (2j), which cleaves to give a substituted methylidene, was employed in the synthesis of $\Delta^{9,12}$-capnellene.[42] Certain molybdenum alkylidenes show considerable promise for the stoichiometric[43] or catalytic[44] preparation of cycloalkenes, from unsaturated ketones or dienes, respectively, via metallacyclobutanes which cleave to afford substituted methylidenes.

Reactions Not Involving Methylidene Species.

Alkanes are produced upon acidolysis;[34,45] for example (2a) affords neopentane.[1a] Titanacyclobutanes may be

directly halogenated to afford 1,3-dibromides[1a] as shown in eq 11.[2a] This reaction is typically quantitative, and has been used to assay the titanacyclobutanes.[4]

(11)

By contrast, iodination leads to cyclopropane formation in good yield,[1a] as shown in eq 12, a process which was demonstrated to proceed stepwise with retention of stereochemistry at one carbon and inversion at the other.[46] The titanacycles may be photolyzed, as in eq 13, to afford cyclopropanes via a 1,4-biradical intermediate.[47] Reaction with chemical oxidants such as tetrakis(trifluoromethyl)cyclopentadienone or ferricinium salts also affords cyclopropanes by reductive elimination.[48] Carbonylation leads to reductive coupling of two carbon monoxide units to afford a stable enediolate complex of titanocene which may be converted to a cyclic acyloin upon acidolysis; in the one-pot process of eq 14, metallacycle (2c) is generated in situ from the Tebbe reagent.[1a,2a]

Bis(cyclopentadienyl)diphenyltitanium[1]

[1273-09-2] · $C_{22}H_{20}Ti$ · Bis(cyclopentadienyl)diphenyltitanium · (MW 332.28)

(reagent for the preparation of aryl derivatives via thermolysis and trapping with electrophiles;[2] catalyst for the hydrogenation of alkenes,[3] the polymerization of alkenes,[4,5] the polymerization of silanes,[6] the hydrosilylation of ketones,[7] the silylation of alcohols[8] and aldol condensation[9])

Alternate Name: diphenyltitanocene.

Physical Data: mp 146-148 °C dec.

Solubility: sol most aprotic organic solvents, e.g. Et_2O, THF, CH_2Cl_2, toluene, hexanes.

Form Supplied in: orange-yellow crystals; not available commercially.

Preparative Method: [10,11] a solution of ***Phenyllithium*** (2 equiv) in Et_2O is added dropwise to a suspension of ***Dichlorobis(cyclopentadienyl)titanium*** in Et_2O (3-5 mL $mmol^{-1}$) stirred at rt under N_2. After 1 h, the reaction mixture is cooled to -30 °C and quenched with methanol. Evaporation of the solvents upon warming to rt, addition of Et_2O, filtration, evaporation, and recrystallization from CH_2Cl_2/pentane gives 95% of orange-yellow crystals of Cp_2TiPh_2.

Handling, Storage, and Precautions: sensitive to oxygen and light but can be briefly exposed to air and water; not stable for more than a few days at rt, and decomposes more rapidly in solution; can be stored in the dark in a refrigerator.

Bis(cyclopentadienyl)titanium Derivatives.

The presence of π-bonded cyclopentadienyl substituents on titanium results in a lower Lewis acidity and enhanced thermal stability.[1] A variety of bis(cyclopentadienyl)titanium (Cp_2Ti, titanocene) complexes can be easily prepared from Cp_2TiCl_2, which is commercially available and inexpensive. Among the most widely used *C*-substituted compounds are the dimethyl (see ***Bis(cyclopentadienyl)dimethyltitanium***) and diphenyl derivatives. In general, diaryltitanocenes are less reactive and more thermally stable than the corresponding dimethyl compounds.

Thermolytic Reactions.

Upon heating at high temperatures, diaryltitanocenes undergo extrusion of benzene and formation of a titanocene-benzyne complex, which reacts with alkynes[2,12] to form a benzotitanole adduct. Subsequent reaction of this intermediate with electrophiles gives various titanium-free products (eq 1).[2] Analogous chemistry occurs with the more synthetically versatile zirconocene complexes,[13] while different products are obtained under photochemical conditions.[14] The titanocene-benzyne complex can also be trapped with dinitrogen to form anilines in low yields,[15,16] as well as with carbon dioxide to form benzoic esters upon methanolysis (eq 2).[17]

(1)

Reactions with Alkenes.

Diaryl titanocenes, like their dimethyl analogs, can serve as catalysts for the hydrogenation of alkenes under thermal[3] or photochemical[18] conditions. Also, the parent compound, (Cp_2TiPh_2),[4,5] as well as various analogs with other Cp ligands,[5,19] are useful catalyst components for the isotactic polymerization of propene (eq 3).[5]

Reactions with Silanes.

Similarly to Cp_2TiMe_2 and other related derivatives,[20] Cp_2TiPh_2 catalyzes the dehydrogenative polymerization of hydrosilanes (eq 4).[6] It also catalyzes the hydrosilylation of ketones (eq 5)[7] and the silylation of alcohols (eq 6) and diols (eq 7).[8]

(7)

Aldol Condensation.

Cp_2TiPh_2 is a good catalyst for the self-condensation of aliphatic aldehydes and the mixed aldol condensation of acetophenones with aromatic aldehydes (eq 8).[9]

Bis(cyclopentadienyl)diphenylzirconium[1]

[51177-89-0] · $C_{22}H_{20}Zr$ · Bis(cyclopentadienyl)diphenylzirconium · (MW 375.62)

(precursor of Cp_2Zr;[3,4] precursor of zirconium-benzyne complex[8,9]; insertion reaction into Zr-Ph bond[20])

Alternate Name: diphenylzirconocene.

Physical Data: mp 140 °C dec.

Solubility: sol THF, CS_2; appears to react with $CHCl_3$; reacts with protic solvents.

Analysis of Reagent Purity: IR (nujol cm^{-1}) 1405(m), 1240(w), 1050(m), 1005(m), 980(m), 827(w), 820(s), 775(s), 698(s); ^1H NMR (CS_2) δ: 6.10(s), 6.8-7.3(m); (THF-d_8) δ: 6.18, 6.93(m), 7.23 (m).

Preparative Method: the reaction is conducted under an atmosphere of argon. A suspension of 1.0 g (3.4 mmol) of ***Dichlorobis(cyclopentadienyl)zirconium*** in 20 mL of diethyl ether is cooled to -40 °C. ***Phenyllithium*** (3.0 mL, 2.3 M) is subsequently added dropwise via a syringe over a 45 min period with magnetic stirring, during which time a white crystalline solid separates from solution. Stirring is continued at -40 °C for 1 h and the temperature is slowly allowed to rise to 0 °C. The solvent is then evaporated under reduced pressure and the solid residue is washed with pentane and decanted. The remaining residue is extracted with diethyl ether and the extracts are filtered under nitrogen. Concentration of the filtrate yields 1.0 g (80%) of white crystalline Cp_2ZrPh_2.[2]

Purification: recrystallization at low temperature from diethyl ether; cannot be sublimed.

Handling, Storage, and Precautions: appears to be more stable than the dimethyl analog toward air and moisture. Use in a fume hood.

Precursor of Cp_2Zr.

Reductive elimination of biphenyl from diphenylzirconocene is induced photochemically and gives a zirconocene Cp_2Zr species which has not been characterized but which reacts with various reagents. In the presence of dienes, zirconocene-diene complexes are obtained as stable complexes (eq 1).[3] With alkynes, a dimerization occurs to give zirconacyclopentadienes (eq 2).[4] Reaction of vinylzirconocene with Cp_2Zr affords a dinuclear (alkene)zirconocene complex (eq 3).[5] Coupling of phenyl groups on zirconium is also achieved by the reaction of Cp_2ZrPh_2 with an oxidant such as tetrakis(trifluoromethyl)cyclopentadienone (eq 4).[6]

(1)

(2)

(3)

(4)

Precursor of Zirconium-Benzyne Complex.

Thermolysis of diarylzirconocenes shows a different aspect of their reactivity. When a solution of di-*p*-tolylzirconocene is stirred in degassed absolute benzene at 70 °C for 3 h and treated with bromine, *m*-bromotoluene and bromobenzene are formed in addition to the expected products such as zirconocene dibromide and *p*-bromotoluene.[7] This is due to the formation of phenyltolylzirconocene (eq 5).[7]

(5)

When thermolysis of diphenylzirconocene is carried out at 70 °C under ethylene (20 bar), zirconaindan is formed in excellent yield (eq 6).[8] The zirconaindan compounds can be used for further reactions, e.g. carbonylation (eq 7).[9] The zirconaindan is formed by the coupling reaction of benzyne with ethylene. The coupling reaction with substituted alkenes is highly regioselective (&egt;95%) and stereospecific (eq 8).[10] The alkene moiety of zirconaindans can be replaced by other alkenes as shown in eq 9.[8]

Carbon monoxide coordinated to a transition metal also reacts with benzyne formed in situ to afford a cyclic carbene complex (eq 10).[11] The zirconocene-benzyne complex can be trapped with PMe_3 to form a crystalline complex (eq 11).[12] The benzyne complex reacts with various unsaturated compounds such as nitriles,[12,13] alkynes,[12] ketones,[12] and phosphaacetylene[14] to form five-membered zirconacycles (eqs 12 and 13). Coupling products with alkynes can be converted into heterocycles such as benzothiophene (eq 14).[15] Organic compounds which have an acidic hydrogen react with benzyne to give monophenyl(organo)zirconocene compounds. When the benzyne complex reacts with an ylide or furan, the corresponding monophenyl(organo)zirconocene gives six-membered zirconacycles (eq 15).[16]

(15)

Insertion or Migration Reaction of Cp_2ZrPh_2.

Carbonylation of Cp_2ZrPh_2 at atmospheric pressure occurs rapidly even at -70 °C to give the benzoyl complex $Cp_2Zr(COPh)(Ph)$ in ca. 80% yield (eq 16).[17] The complex formed under kinetic control has a benzoyl oxygen bound to a lateral coordination site, an O-outside complex. This complex isomerizes above -50 °C to the thermodynamically favored O-inside complex.[18] At 70 °C, 1,2-migration of the remaining σ-bonded aryl ligand of the benzoyl complex from zirconium to the acyl-carbon occurs to form a side-on coordinated benzophenone ligand (eq 17).[19] Insertion reactions of diphenylketene, aryl isocyanates, and *p*-tolylcarbodiimide into the Zr-Ph bond are also observed.[20] However, carbon dioxide does not react with Cp_2ZrPh_2 at room temperature at atmospheric pressure. Insertion of NO

gas into the Zr-Ph bond produces a zirconium complex containing the $[ON(Ph)NO]^-$ ligand.[21]

(16)

(17)

Treatment of Cp_2ZrPh_2 with alkynyllithium compounds, RCCLi, affords, after hydrolysis with 3N HCl or iodonolysis with an excess of I_2, migration products, PhCCR, in good yields (eq 18).[22] Insertion reaction of acetonitrile into the Zr-Ph bond is achieved with oxidants such as Ag^+ or Cp_2Fe^+ (eq 19).[23]

Bis(cyclopentadienyl)methylzirconium Tetraphenylborate-Tetrahydrofuran[1]

[100909-50-0] · $C_{39}H_{41}BOZr$ · Bis(cyclopentadienyl)methylzirconium Tetraphenylborate-Tetrahydrofuran · (MW 627.78)

(alkene polymerization agent;[2] can insert carbon monoxide, nitriles, and alkynes;[3] can function as a Lewis acid[4])

Solubility: sol CH_2Cl_2 and 1,2-dichloroethane; reacts with protic solvents.

Analysis of Reagent Purity: ^{1}H NMR (CD_2Cl_2) δ 7.6-6.7 (m, 20H, BPh_4^-), 6.31 (s, 10H), 3.44 (m, 4H, THF), 1.80 (m, 4H, THF), 0.74 (s, 3H).

Preparative Methods: treatment of Cp_2ZrMe_2 with 1 equiv of $AgBPh_4$ in MeCN followed by recrystallization from THF gives $Cp_2ZrMe(THF)^+BPh_4^-$.[3a] Alternatively, it can be obtained directly by treating Cp_2ZrMe_2 with $[HNBu_3][BPh_4]$ or $[Cp'_2Fe][BPh_4]$ ($Cp' = C_5H_4Me$) in THF.[5]

Purification: recrystallization from hot THF gives a relatively stable pale yellow crystalline solid.

Handling, Storage, and Precautions: the dry solid is highly sensitive to moisture and oxygen and should be stored in a dry box; a coordinating solvent, such as MeCN, causes ligand exchange.

Ligand.

Although complexes having ligands other than THF are known,[3a] most descriptions focus on the Lewis acidic THF complex due to there being abundant examples of its use in organic synthesis. The THF-free species Cp_2ZrMe^+, generated as a transient intermediate in CH_2Cl_2 solution, decomposes, principally to Cp_2MeCl.[2a] The THF ligand is labile and generally undergoes rapid exchange with nitriles, small phosphines, pyridine, and other heterocycles. In general, the cationic $Cp_2ZrMe(THF)^+$ complex is more reactive than neutral $Cp_2ZrMeCl$ or Cp_2ZrMe_2 complexes as a result of the increased unsaturation and charge.

Insertion Reaction.

The high insertion reactivity of this complex has been noted and representative insertions are summarized in eqs 1-4.

(1)

(2)

(3)

(4)

The Zr-CH_3 bond of this complex in THF can be cleaved by H_2 to yield the insoluble hydride $Cp_2Zr(H)(THF)^+BPh_4^-$.[6]

The reaction of the cationic methyl complex with stoichiometric amounts of α-picoline yields the η^2-pyridyl complex, $Cp_2Zr(\eta^2\text{-}N,C\text{-picolyl})(THF)^+$, via initial ligand substitution followed by rapid C-H activation/CH_4 elimination ($t_{1/2}$ 6 min, 23 °C, CH_2Cl_2) (eq 5).[7]

Interestingly, use of pyridine itself causes a much slower reaction (hours, 50 °C, CH_2Cl_2). The acceleration of C-H activation by the α-methyl group of α-picoline is considered to be due to steric crowding which enhances the overlap of the *ortho* C-H bond with the Zr LUMO.[8] The C-H activation of a variety of N-heterocyclic compounds[9] can be achieved in CH_2Cl_2 as shown in eqs 6-8. These metallacycles react with alkenes and alkynes to give stable five- or six-membered metallacycles which can be converted to α-substituted heterocycles upon hydrolysis (eqs 9-11).[7a,9,10] The formation of these metallacycles was suggested to be both kinetically and thermodynamically favored.[10a] More importantly, alkenes and *ortho*-substituted pyridines are coupled by catalytic amounts of $Cp_2Zr(Me)^+$ in 1,2-dichloroethane under an H_2 atmosphere (eq 12).[7b]

Lewis Acid Catalyst.

Treatment of $Cp_2Zr(Me)(THF)^+BPh_4^-$ with *t*-BuOH gives $Cp_2Zr(O\text{-}t\text{-}Bu)(THF)^+$ (eq 13), which is an effective catalyst in the Diels-Alder (eq 14) and Mukaiyama aldol reactions (eq 15).[4]

Bis[(η^5-cyclopentadienyl)(μ-nitrosyl)cobalt](*Co -Co*)

Bis[(η^5-cyclopentadienyl)(μ-nitrosyl)cobalt]

[51862-20-5] · $C_{10}H_{10}Co_2N_2O_2$ · Bis[(η^5-cyclopentadienyl)(μ-nitrosyl)cobalt](*Co -Co*) · (MW 308.08)

(starting material for the synthesis of Co(Cp)[1] and Co(NO)[2-4] containing compounds; also used in the preparation of dinitrosoalkane derivatives[12-14] and 1,2-diamines[15,16])

Physical Data: IR (KBr): 1585 s, 1525 ss, br [ν(NO)] cm^{-1}. ^1H NMR (C_6D_6, int. TMS): δ 4.77 [s, C_5H_5].

Form Supplied in: black, air-stable crystals.

Solubility: sol toluene and CH_2Cl_2.

Preparative Methods: ***Dicarbonyl(cyclopentadienyl)cobalt(I)*** (18 g, 0.1 mol) is dissolved in 150 mL of hexane using the Schlenk technique to exclude air. A weak stream of dry NO is passed through the solution. The NO gas can be prepared in a Kipp apparatus from $NaNO_2$ and concentrated sulfuric acid/water (1:1). Traces of NO_2 are removed by a trap kept at -40 °C and by KOH. After 2 h, the color of the reaction mixture turns from red to brown. A black solid is formed. The suspension is brought to a Kieselgel column (30 × 3 cm) and eluted with petroleum ether until the nonreacted red $Co(Cp)(CO)_2$ is completely eluted. The product elutes with CH_2Cl_2 as a dark brown band. The solution is concentrated until crystallization starts. The product is precipitated by addition of petroleum ether, filtered, washed several times with petroleum ether and dried. Yield: 10-10.5 g (65-70%) (see eq 1).[1]

Handling, Storage, and Precautions: solutions of $[Co(Cp)NO]_2$ in toluene or CH_2Cl_2 are air-sensitive. Solid $[Co(Cp)NO]_2$ can be stored without decomposition. Can be sublimed with partial decomposition in high vacuum at 90-100 °C. Handle in a fume hood.

$[Co(Cp)NO]_2$ as the Starting Material for Other CpCo Containing Compounds.

The Co-Co bond in $[Co(Cp)NO]_2$ can be cleaved to give the compounds [(Cp)Co(NO)R],[2] [(Cp)Co(NO)Cl],[3] $[(Cp)Co(NO)GeR_3]$,[4] and $[(Cp)Co(NO)SnR_3]$.[4] $[Co(Cp)NO]_2$ can also be used for the preparation of other compounds such as $[(Cp)CoH]_4$[5] and $[(Cp)Co]_3(NO)_2$.[6] The NO bridges in $[Co(Cp)NO]_2$ can be replaced by carbonyl bridges,[6-8] by methylene bridges,[9] by amido bridges,[10] and by phenylthiolato and diphenylphosphido bridges.[11]

An interesting reaction takes place if $[Co(Cp)NO]_2$ is treated with NO in the presence of alkenes such as norbornene. A unique chelating bis(nitrosoalkane) ligand system is formed in this three-component synthesis (see **1**),[12-14] which can be used for the synthesis of 1,2-diamines.[15,16] Detailed mechanistic studies have been reported.[17-19]

(1)

Chemical[20-22] and electrochemical[23] oxidations as well as chemical[3] and electrochemical[23] reductions of $[Co(Cp)NO]_2$ have been reported. The pentamethylcyclopentadienyl analog $[Co(\eta^5\text{-}C_5Me_5)NO]_2$[3] and the pentaphenylcyclopentadienyl analog $[Co(\eta^5\text{-}C_5Ph_5)NO]_2$[24] of $[Co(Cp)NO]_2$ have been prepared. The structure of $[Co(Cp)NO]_2$ was determined by X-

ray crystallography.[8] Spectroscopic measurements and calculations concerning the electronic structure of $[Co(Cp)NO]_2$ have been reported.[25-33]

Bis(cyclopentadienyl)titanium Bis(trifluoromethanesulfonate)[1]

($Cp_2Ti(OSO_2CF_3)_2$) (**1**)

[76262-87-8] · $C_{12}H_{10}F_6O_6S_2Ti$ · Bis(cyclopentadienyl)titanium Bis(trifluoromethanesulfonate) · (MW 476.20) ($Cp_2Zr(OSO_2CF_3)_2$) (**2**)

[94728-52-6] · $C_{12}H_{10}F_6O_6S_2Zr$ · Bis(cyclopentadienyl)zirconium Bis(trifluoromethanesulfonate) · (MW 519.54) ($Cp^*_2Ti(OH_2)_2^{2+}$) (**3**)

[121266-23-7] · $C_{20}H_{34}O_2Ti$ · Bis(pentamethylcyclopentadienyl)diaquatitanium · (MW 354.37)

(catalyst for Diels-Alder reaction, Mukaiyama crossed-aldol reaction, and Sakurai reaction)

Physical Data: (**1**) red crystals; ^1H NMR (CD_3NO_2) δ 7.06 (s). An X-ray crystal structure has been reported.[2]

Solubility: sol CH_2Cl_2, $MeNO_2$; insol benzene, hexane.

Analysis of Reagent Purity: NMR, elemental analysis.

Preparative Method: [1,2] $Cp_2Ti(OSO_2CF_3)_2$ is prepared by treatment of a 0.06 M THF solution of ***Dichlorobis(cyclopentadienyl)titanium*** with 5.5 equiv of a 0.19 M THF solution of ***Silver(I) Trifluoromethanesulfonate***. After stirring for 15 min the reaction mixture is filtered, the red filtrate is layered with hexane, and the resulting red crystals are collected. Recrystallization from CH_2Cl_2/pentane or THF/hexane affords $Cp_2Ti(OSO_2CF_3)_2$ (25-30%) as red needles. The precursors (Cp_2TiCl_2 and $AgOSO_2CF_3$) are widely available.

Handling, Storage, and Precautions: $Cp_2Ti(OSO_2CF_3)_2$ and $Cp_2Zr(OSO_2CF_3)_2$ can be handled for short periods of time in air, but are best handled and stored in a glove box. Both can be prepared in situ. The pentamethylcyclopentadienyl analog $Cp^*_2Ti(OH_2)_2^{2+}$ is air and water stable. Titanium(IV) is reputed to be

of low toxicity.

General.

The triflate analog of titanocene dichloride, $Cp_2Ti(OSO_2CF_3)_2$, was first prepared in 1980.[2] The trifluoromethanesulfonate ligands were found to be covalently bound to the titanium center in the solid state[2] and in CD_2Cl_2 solution,[1,3] but are easily displaced by various neutral ligands such as water,[4] methyl vinyl ketone (MVK), and nitromethane.[1,3] Recent interest in $Cp_2Ti(OSO_2CF_3)_2$ (**1**), its zirconium analog $Cp_2Zr(OSO_2CF_3)_2$ (**2**), and in the pentamethylcyclopentadienyl diaqua complex $Cp^*_2Ti(OH_2)_2^{2+}$ (**3**),[4] has focused on the ability of these species to function as Lewis acids in various organic transformations.[1,3,5-7] It has been found that very low catalyst loadings are required (0.01-1 mol %) for many transformations which typically require stoichiometric Lewis acids. Although most of the work reported to date has concerned simple substrates and NMR scale reactions, isolated yields are noted to be in the 65-90% range for many of these transformations. The generality of the ability of (**1**)-(**3**) to mediate reactions of more complex molecules remains to be determined.

NMR studies of the interaction of $Cp_2Ti(OSO_2CF_3)_2$ with MVK indicate that the ketone can displace triflate from the titanium center, affording a number of different species including cationic complexes such as $Cp_2Ti(OSO_2CF_3)(MVK)^+$ and $Cp_2Ti(MVK)_2^{2+}$. These cationic complexes are formed reversibly and rapidly, and are believed to account for the observed catalytic activity.[3] In addition, the zirconium complex (**2**), when prepared in THF, is isolated as a THF solvate (**2**.THF).

Diels-Alder Reactions.[1,3,5]

The Diels-Alder cycloaddition between simple 1,3-dienes such as cyclopentadiene and isoprene with α,β-unsaturated carbonyl compounds such as MVK and acrolein is efficiently catalyzed by (**1**)-(**3**) (eqs 1-3). As is typical of Lewis acid-catalyzed Diels-Alder reactions, enhanced *endo* selectivity is observed compared to the thermal reactions. An advantage of these catalysts over other Lewis acids such as ***Titanium(IV) Chloride*** or ***Tin(IV) Chloride*** is that strictly anhydrous conditions need not be maintained, and catalyst loadings of 1 mol % are sufficient to drive the reaction to completion in a reasonable time period (<24 h) for most substrates.[1,3] The addition of up to 10 equiv (vs. catalyst) of water to reactions mediated by the diaqua complex (**3**) has no observed effect on the rate of reaction, nor do the products inhibit catalytic activity.[5]

(1)

(2)

(3)

Mukaiyama Crossed-Aldol Reactions.[1,6]

Catalysts (**1**) and (**2**).THF have also been shown to catalyze the reaction between silyl enol ethers and carbonyls (eqs 4 and 5) (i.e. the Mukaiyama crossed-aldol reaction[8]). Catalyst loadings of 0.5% are sufficient except for highly hindered substrates such as pinacolone, and pivaldehyde reacts only slowly under the typical reaction conditions with a 2,2-dimethylsilyl ketene acetal. The primary advantages of (**1**) and (**2**).THF over other typical Lewis acids such as $TiCl_4$ and ***Boron Trifluoride*** are decreased susceptibility to inhibition by water, and the smooth reaction of silyl enol ethers at low catalyst loadings.

(4)

(5)

Sakurai Reactions.[1,7]

The reaction of allylsilanes with ketones and acetals (the Sakurai reaction[9]) is catalyzed efficiently by (**1**) and (**2**).THF (eqs 6 and 7). As with the Diels-Alder and Mukayama reactions discussed above, very low catalyst loadings are required. In addition to ketones and acetals (eqs 6 and 7), a limited number of orthoesters also react with allylsilanes when catalyzed by (**1**) (eq 8).

Bis(cyclopentadienyl)bis(2,6-dimethylphenylamino)zirconium

[117939] · $C_{26}H_{30}N_2Zr$ · Bis(cyclopentadienyl)bis(2,6-dimethylphenylamino)zirconium · (MW 461.76)

(hydroamination catalyst, precursor to the reactive imido intermediate $Cp_2Zr{=}NAr$)

Alternate Name: bis(cyclopentadienyl)zirconium bis(2,6-dimethylphenyl)amide.

Solubility: insol *n*-hexane and ether; sol toluene and THF.

Preparative Methods: $Cp_2Zr(NHAr)_2$ (**1**) can be prepared by heating Cp_2ZrMe_2 with 2,6-dimethylaniline or by addition of Cp_2ZrCl_2 to a solution containing 2 equiv LiNHAr (eq 1).[1]

Purification: recrystallization from toluene layered with *n*-hexane.

Handling, Storage, and Precautions: $Cp_2Zr(NHAr)_2$ is water sensitive and should be handled and stored under a nitrogen atmosphere in a dry box or using standard Schlenk techniques. Solvents should be free of traces of air and moisture. Zirconium is believed to be of low toxicity; 2,6-dimethylaniline is toxic. Use in a fume hood.

Reactivity.

Thermolysis of (**1**) at 95-110 °C in toluene results in the α-elimination of 1 equiv of 2,6-dimethylaniline and generation of the transient intermediate $Cp_2Zr{=}NAr$.[1,2] This intermediate has been trapped as its ligand adduct $Cp_2Zr(=NAr)(L)$ (L = THF, $OPPh_3$) with Lewis bases, and it reacts with alkynes to give azametallacyclobutenes (**2**) (eq 2). Cycloadditions with a variety of alkynes have been observed and were found to be reversible near 95 °C.

(2)

Catalytic Hydroamination of Alkynes and Allene.

(**1**) also serves as a catalyst for the hydroamination of alkynes.[1,3] For example, heating a toluene solution containing equal amounts of 2,6-dimethylaniline and diphenylacetylene in the presence of 3 mol % of (**1**) to 95-110 °C results in the formation of the *N*-(2,6-dimethylphenyl)enamine (**3**) (eq 3). The rate of production of enamine is slow under these conditions; however, if the reaction is conducted with the exclusion of air and water, complete conversion to the enamine is observed. Additionally, heating allene and 2,6-dimethylaniline with 3 mol % of (**1**) to 90 °C for 6 days results in the formation of the anti-Markovnikov addition product, the 2,6-dimethylphenylimine of acetone.[3] When (**1**) and 2,6-dimethylaniline are heated in the presence of ethylene, allylbenzene, or norbornene, no addition of the amine to the alkene occurs.

Regiochemistry of Additions.

Stoichiometric generation of the reactive imido intermediate $Cp_2Zr{=}NAr$ in the presence of unsymmetrical alkynes results in formation of two regioisomeric azametallacyclobutenes.[3] Regioselectivity comparable to that of the hydroborating reagents disiamylborane and dicyclohexylborane has been observed.[4] The larger substituent on the alkyne exhibits a strong preference to be α to the zirconium center leading primarily to the anti-Markovnikov products after hydrolysis of the metallacycles. The origin of this selectivity is believed to be dictated by the steric interactions between the large nitrogen bound group and the substituent on the alkyne. Generation of $Cp_2Zr{=}NAr$ from (**1**) under catalytic conditions results in an erosion in the regiospecificity of the hydroamination product. This is due to the reversibility of the cycloaddition and the difference in relative rates of protonation of the regioisomeric metallacycles by 2,6-dimethylaniline (which favors protonation of the minor regioisomer for steric reasons).

Formation of α,β-Unsaturated Imines.

(**1**) can be used in a two-step process for the synthesis of α,β-unsaturated imines as illustrated in eq 4.[5] The first step involves synthesis of the azametallacyclobutene. Addition of benzaldehyde or isobutyraldehyde initially gives the addition product which, upon warming, undergoes a [2 + 4] cycloreversion to provide the α,β-unsaturated imine.

Related Reagents.

Chloro(cyclopentadienyl)dimethyltitanium.

Bis(dibenzylideneacetone)palladium(0)

$(PhCH{=}CHCOCH{=}CHPh)_2Pd$

[32005-36-0] · $C_{34}H_{28}O_2Pd$ · Bis(dibenzylideneacetone)palladium(0) · (MW 575.01)

(catalyst for allylation of stabilized anions,[1] cross coupling of allyl, alkenyl, and aryl halides with organostannanes,[2] cross coupling of vinyl halides with alkenyl zinc species,[3] cyclization reactions,[4] and carbonylation of alkenyl and aryl halides[5])

Physical Data: mp 135 °C (dec).

Form Supplied in: solid.

Preparative Method: prepared by adding sodium acetate to a hot methanolic solution of dibenzylideneacetone and $Na_2[Pd_2Cl_6]$, cooling, filtering, washing with MeOH, and air drying.[6]

Handling, Storage, and Precautions: moderately air stable in the solid state; slowly decomposes in solution to metallic palladium and dibenzylideneacetone.

Allylation of Stabilized Anions.

$Pd(dba)_2$ is an effective catalyst for the coupling of electrophiles and nucleophiles, and has found extensive use in organic synthesis (for a similar complex with distinctive reactivities, see also ***Tris(dibenzylideneacetone)dipalladium***). Addition of a catalytic amount of $Pd(dba)_2$ activates allylic species, such as allylic acetates or carbonate derivatives, toward nucleophilic attack.[1] The intermediate organometallic complex, a π-allylpalladium species, is formed by backside displacement of the allylic leaving group, and stereochemical inversion of the original allylic position results. Subsequent nucleophilic attack on the external face of the allyl ligand displaces the palladium in this double inversion process to regenerate the original stereochemical orientation (eq 1).[7] The allylpalladium intermediate can also be generated from a variety of other substrates, such as allyl sulfones,[8] allenes,[9] vinyl epoxides,[10] or α-allenic phosphates.[11] In general, the efficiency of $Pd(dba)_2$ catalysis is optimized through the addition of either ***Triphenylphosphine*** or ***1,2-Bis(diphenylphosphino)ethane*** (dppe).

(1)

The anions of malonate esters,[12] cyclopentadiene,[12] β-keto esters,[13] ketones,[13,14] aldehydes,[14] α-nitroacetate esters,[15] Meldrum's acid,[15] diethylaminophosphonate Schiff bases,[16] β-diketones,[17] β-sulfonyl ketones and esters,[17] and polyketides[18,19] represent the wide variety of carbon nucleophiles effective in this reaction. Generation of the stabilized anions normally is accomplished by addition of ***Sodium Hydride***, ***Potassium Hydride***, or basic ***Alumina***.[15] However, when allyl substrates such as allylisoureas,[14] allyl oxime carbonates,[17] or allyl imidates[20] are used, the allylation reaction proceeds without added base. Nitrogen nucleophiles, such as azide[10] and nucleotide[21] anions, are useful as well.

The coupling reaction generally proceeds regioselectively with attack by the nucleophile at the least hindered terminus of the allyl moiety,[22] accompanied by retention of alkene geometry (eq 2). Even electron-rich enol ethers can be used as the allylic moiety when an allylic trifluoroacetyl leaving group is present.[23] When steric constraints of substrates are equivalent, attack will occur at the more electron rich site.[19] Although this reaction is usually performed in THF, higher yields and greater selectivity are observed for some systems with the use of DME, DMF, or DMSO.[14,16,20] Alternatively, $Pd(dba)_2$ can promote efficient substitution of allylic substrates in a two-phase aqueous-organic medium through the use of $P(C_6H_4\text{-}m\text{-}SO_3Na)_3$ as a phase transfer ligand.[24]

(2)

(*E*) isomer	47%	95 (*E* only):5
(*Z*) isomer	62%	76 (*Z* only):23

Intramolecular reaction of a β-dicarbonyl functionality with a π-allyl species can selectively produce three-,[25] five-,[25] or six-membered[26] rings (eq 3).

(3)

Asymmetric Allylation Reactions.

Employing chiral bidentate phosphine ligands in conjunction with $Pd(dba)_2$ promotes allylation reactions with moderate to good enantioselectivities, which are dependent upon the solvent,[27] counterion,[28] and nature of the allylic leaving group.[27] Chiral phosphine ligands have been used for the asymmetric allylation of α-hydroxy acids (5-30% ee),[29] the preparation of optically active methylenecyclopropane derivatives (52% ee),[22] and chiral 3-alkylidenebicyclo[3.3.0]octane and 1-alkylidenecyclohexane systems (49-90% ee).[27] Allylation of a glycine derivative provides a route to optically active α-amino acid esters (eq 4).[28] The intramolecular reaction can produce up to 69% ee when vicinal stereocenters are generated during bond formation (eq 5).[30]

(4)

(5)

Cross-Coupling Reactions.

Allylic halides,[5,31] aryl diazonium salts,[32] allylic acetates,[33] and vinyl epoxides[34] are excellent substrates for $Pd(dba)_2$ catalyzed selective cross-coupling reactions with alkenyl-, aryl-, and allylstannanes. The reaction of an allylic halide or acetate proceeds through a π-allyl intermediate with inversion of sp^3 stereochemistry, and transmetalation with the organostannane followed by reductive elimination results in coupling from the palladium face of the allyl ligand. Coupling produces overall inversion of allylic stereochemistry, a preference for reaction at the least substituted carbon of the allyl framework, and retention of allylic alkene geometry. In addition, the alkene geometry of alkenylstannane reagents is conserved (eq 6). Functional group compatibility is extensive, and includes the presence of CO_2Bn, OH, OR, CHO, OTHP, β-lactams, and CN functionality.

(6)

Similar methodology is used for the coupling of alkenyl halides and triflates with 1) alkenyl-, aryl-, or alkynylstannanes,[35] 2) alkenylzinc species,[3,36] or 3) arylboron species.[37] This methodology is applied in the synthesis of cephalosporin derivatives (eq 7),[35] and can be used for the introduction of acyl[3,36] and vinylogous acyl[3] equivalents (eq 8).

Intramolecular Reaction with Alkenes.

Palladium π-allyl complexes can undergo intramolecular insertion reactions with alkenes to produce five- and six-membered rings through a metallo-ene-type cyclization.[4] This reaction produces good stereoselectivity when resident chirality is vicinal to a newly formed stereogenic center (eq 9), and can be used to form tricyclic and tetracyclic ring systems through tandem insertion reactions.[38] In the presence of $Pd(dba)_2$ and triisopropyl phosphate, α,β-alkynic esters and α,β-unsaturated enones undergo intramolecular [3 + 2] cycloaddition reactions when tethered to methylenecyclopropane to give a bicyclo[3.3.0]octane ring system (eq 10).[39]

(10)

Carbonylation Reactions.

In the presence of CO and $Pd(dba)_2$, unsaturated carbonyl derivatives can also be prepared through carbonylative coupling reactions. Variations of this reaction include the initial coupling of allyl halides with carbon monoxide, followed by a second coupling with either alkenyl- or arylstannanes (eq 11).[5] This reaction proceeds with overall inversion of allylic sp^3 stereochemistry, and retains the alkene geometry of both the allyl species and the stannyl group. Similarly, aryl and alkenyl halides will undergo carbonylative coupling to generate intermediate acylpalladium complexes. Intermolecular reaction of these acyl complexes with $HSnBu_3$ produces aldehydes,[35,40] while reaction with MeOH or amines generates the corresponding carboxylic acid methyl ester[41] or amides, respectively.[42]

(11)

Palladium acyl species can also undergo intramolecular acylpalladation with alkenes to form five- and six-membered ring γ-keto esters through exocyclic alkene insertion (eq 12).[43] The carbonylative coupling of *o*-iodoaryl alkenyl ketones is also promoted by $Pd(dba)_2$ to give bicyclic and polycyclic quinones through endocyclization followed by β-H elimination.[44] Sequential carbonylation and intramolecular insertion of propargylic and allylic alcohols provides a route to γ-butyrolactones (eq 13).[45]

Bis(dicarbonylcyclopentadienyliron)[1]

[12154-95-9] · $C_{14}H_{10}Fe_2O_4$ · Bis(dicarbonylcyclopentadienyliron) · (MW 353.92)

(dinuclear metal carbonyl catalyst for a variety of carbon-carbon bond forming reactions;[3,7] radical initiator;[19] precursor to alkyl- and acyliron complexes useful in organic synthesis[20])

Physical Data: mp 194 °C (dec); *d* 1.77 g cm^{-3}.

Solubility: very sol $CHCl_3$, pyridine, and alcohol; sol CCl_4 and CS_2; slightly sol pentane; insol H_2O.

Form Supplied in: dark reddish-purple solid; purity >97% widely available.

Handling, Storage, and Precautions: the reagent is stable to air, unaffected by H_2O, and can be stored for long periods of time. Reputed to be very toxic by inhalation and ingestion; avoid breathing of particles or vapors. Use in a fume hood.

Catalysis.

The catalytic properties of bis(dicarbonylcyclopentadienyliron) (Fp_2) are well established.[2] The hydroformylation of alkenes at moderate temperatures (125-175 °C) and pressures of H_2 and CO (50-100 atm) employing catalytic amounts of Fp_2 produces saturated aldehydes.[3,4] Aldehyde formation is regioselective, favoring the formation of branched *iso*-aldehydes over *n*-aldehydes. The reagent catalyzes isomerization of internal alkenes to terminal alkenes; the products are the *iso*- and *n*-aldehydes (eqs 1 and 2).[3] Oxo reactions catalyzed by the dinuclear metal carbonyls of Co or Ru give rise to considerable amounts of alcohols and/or higher aldehydes via aldol condensation or hydrogenation of the aldehyde.[4] Reactions catalyzed by Fp_2 are clean and selective, a result of the considerably weaker acidity and hydrogenating ability of the active metal hydride species.[5] The catalytic activity of the reagent is lower than the other dinuclear metal carbonyl species; thus longer reaction times are necessary.[3] The range of optimum temperatures is narrow. Best results have been observed at 150 °C.

The reagent catalyzes the reaction of cycloalkanes with CCl_4 to give cycloalkyl halides in good yield.[6] The simple addition of CCl_4 to terminal alkenes at moderate temperatures is catalyzed by Fp_2, and results in good yields of 1,1,1,3-tetrachloroalkanes.[7] Similar reactions promoted by mononuclear metal carbonyl catalysts give mixtures of telomer homologs,[8] which are not formed when Fp_2 is employed.[7a] The reaction is completely regiospecific in that CCl_3 is added exclusively at the terminal carbon of the alkene. The reagent also effects the regioselective carbonylation of terminal alkenes in the presence of CCl_4 and CO, offering a convenient regioselective route to 2-alkyl-4,4,4-trichlorobutanoyl chlorides (eq 3).[7a,9] In alcohol solvents the corresponding ester is obtained in nearly the same yield.[7a] Whereas the peroxide catalyzed reaction of ethylene, CO, and CCl_4 results in a telomeric mixture,[10] the Fp_2 catalyzed reaction gives only the 1:1 adduct.[7a] The Fp_2 catalyzed reactions of methyl trichloroacetate with terminal alkenes give good yields of 4-alkyl-2,2-dichloro-γ-butyrolactones (eq 4).[11] The reagent also promotes intramolecular cyclization of allyl trichloroacetate to trichlorinated γ-lactones, albeit in lower yield than when Cu^I salts are employed.[12] The reaction of benzylamine with CCl_4 at moderate temperatures (120-130 °C), using Fp_2 as catalyst, provides a useful route to 2,4,5-triphenylimidazoline derivatives (eq 5).[13] While this reaction is promoted by other catalysts,[14] Fp_2 is the cleanest and most reactive. Perfluoroalkyl-substituted acetals are obtained in excellent yield by the Fp_2 catalyzed coupling of perfluoroalkyl iodides, enol ethers, and alcohols (eq 6).[15]

(6)

The reagent catalyzes the cyclotrimerization of disubstituted acetylenes to benzenes at high temperatures.[16] Butadiene and isoprene are rapidly and selectively cyclodimerized to 4-vinyl-cyclohexenes by the action of Fp_2.[17] Aromatic and aliphatic thioketones are desulfurized and converted to substituted ethylenes by the action of Fp_2 in refluxing benzene.[18]

Radical Promoter.

Fp_2 is an efficient promoter of radical reactions in the manner of organotin compounds. Irradiation of alkyl halides in the presence of a stoichiometric equivalent of Fp_2 leads to C-centered radicals via halogen abstraction by the initially formed 17-electron metal-centered $CpFe(CO)_2$ radical. These carbon radicals can be trapped by alkenes, leading to saturated addition products. Unsaturated addition products can be obtained in the absence of electron-withdrawing substituents on the alkene (eq 7).[19] If no alkenes are present, hydrogen abstraction from solvent leads to alkanes in high yield.

(7)

Alkyl- and Acyliron Complexes.

Treatment of Fp_2 with ***Sodium Amalgam*** generates the $CpFe(CO)_2^-$ anion (Fp^-), a powerful nucleophile which reacts with a variety of electrophilic carbon species.[20] Alkyl- and acyliron (Fp-R and Fp-COR) complexes are readily available on a large scale and have found extensive use in organic synthesis.[21] One-electron oxidants demetalate the alkyl or acyl ligand and lead to a variety of carbonyl compounds,[22] e.g. esters,[23] acids,[23a,24] and amides.[23a,25]

Decomplexation occurs with a high degree of stereoselectivity (eq 8).[26]

(8)

Treatment of alkyliron complexes with ***Triphenylcarbenium Tetrafluoroborate*** results in β-hydride abstraction to give cationic Fp(alkene) complexes.[27] Subsequent liberation of the alkene gives products with a high degree of regio- and stereoselectivity. 2-Alkyliron complexes usually give only the terminal alkene, and 3-alkyliron complexes give only the (*Z*)-alkene (eq 9).[28] Cationic Fp(alkene) complexes, prepared from alkyliron complexes,[27,28] or other routes,[29] react smoothly with lithium enolates and enamines, to give high yields of alkylated products.[30] However, the reactions often show poor regioselectivity. Complexes derived from α,β-unsaturated carbonyl compounds are both highly reactive and highly regioselective with a wide variety of nucleophiles.[31] Vinyl ether complexes, likewise highly reactive and regioselective, are useful vinyl cation equivalents for the vinylation of enolates (eq 10).[31b,32]

(9)

Electrophilic transition metal alkylidene complexes of the type $Cp(CO)_2Fe{=}CRR'^{+}$ ($Fp{=}CRR'^{+}$) smoothly effect the cyclopropanation of alkenes.[33] These iron-carbene complexes are readily prepared by ionization of a leaving group located at the α-position of the alkyliron complex.[34] In particular, the dimethylsulfonium salts offer a chemically mild route to the carbene.[34c,d] Because of the electrophilic nature of the carbene, cyclopropanation is selective for electron rich alkenes (eq 11).[35] High stereoselectivity can be achieved; carbene transfers usually favor higher energy, sterically crowded *cis* products (eq 12).[34d,e,36] Enantioselective cyclopropanations are possible through the use of phosphine substituted iron-carbene complexes possessing a chiral metal center. Optically pure complexes of the type $Cp(CO)(PR_3)Fe{=}CRR'^{+}$ are efficiently prepared from the acyliron complex.[37] While enantioselectivities observed for methylene are low (10-38% ee),[38] ethylidene transfers to various alkenes occur with high selectivity (70-97% ee) (eq 13).[37,39]

Related Reagents.

Dicarbonyl(cyclopentadienyl)(isobutene)iron Tetrafluoroborate; ***Sodium Dicarbonylcyclopentadienylferrate***.

Bis(dichlorotrimethylsilylmethyl)mercury[1]

$Hg(CCl_2SiMe_3)_2$

[18903-82-7] · $C_8H_{18}Cl_4HgSi_2$ · Bis(dichlorotrimethylsilylmethyl)mercury · (MW 512.80)

(by thermal treatment formally transfers **:**$CClSiMe_3$ to alkenes, resulting in cyclopropane formation,[2] and to silanes, inserting into Si-H bond[2])

Physical Data: mp 143-146 °C.

Solubility: sol hexane, benzene, chlorobenzene.

Preparative Methods: reaction of Me_3SiCCl_2Li[3] with $HgBr_2$ at -135 °C in a solvent mixture containing THF, Et_2O, and pentane furnishes the title reagent in 35% yield.[2,4] For this class of silicon-containing organomercurials, the above approach has proven superior to the more classical *t*-BuOK procedure[1] (see also ***Phenyl(trichloromethyl)mercury***).

Purification: recrystallization from hexane.

Handling, Storage, and Precautions: flame-dried glassware and an atmosphere of dry nitrogen are used for the reactions. Organomercury compounds should be carefully handled, and skin contact and inhalation should be particularly avoided. All reactions must be conducted in a well-ventilated hood.

Cyclopropanation of Alkenes.

The synthetic relevance of α-haloorganomercury compounds stems mainly from their utility in preparing cyclopropanes (see also ***Phenyl(trichloromethyl)mercury***) by carbene transfer to simple alkenes. In this respect, bis(dichlorotrimethylsilylmethyl)mercury is quite stable thermally and does not transfer divalent carbon under mild conditions; for example, it was recovered unaltered after heating with cyclohexene at 83 °C for 7 days. However, addition of 1 equiv of ***Diphenylmercury*** results in activation of the reagent with respect to the α-haloorganomercurial.[2,5] The $Hg(CCl_2SiMe_3)_2$-$HgPh_2$ system cyclopropanates cyclooctene at 125 °C under nitrogen (eq 1).[2]

(1)

Insertion into Si-H Bond.

Another common feature of the reactivity of α-haloorganomercurials is their easy reaction with Si-H bonds. Thus insertion of the functional carbene **:**$CClSiMe_3$ into the Si-H bond takes place when a 1:1 mixture of $Hg(CCl_2SiMe_3)_2$-$HgPh_2$ is reacted with an excess of triethylsilane (eq 2).[2] The PhHgCl byproduct was not isolated, but it reacts with the excess of silane under the reaction conditions, furnishing mercury and diphenylmercury.

Bis(diethylaluminum) Sulfate

$(Et_2Al)_2SO_4$

[13747-43-8] · $C_8H_{20}Al_2O_4S$ · Bis(diethylaluminum) Sulfate · (MW 266.27)

(a Lewis acid catalyst for alkene polymerization[1-4] and for promotion of allylstannane additions to various carbon electrophiles[5,6])

Physical Data: none reported.

Solubility: sol hexanes, benzene, and *n*-heptane.

Form Supplied in: white solid; not widely available.

Analysis of Reagent Purity: by elemental analysis.

Preparative Method: the following procedure has proven most efficacious:[3] a flask containing dry pulverized Na_2SO_4 is charged with a solution of ***Diethylaluminum Chloride*** (2 equiv) in *n*-heptane (or benzene). The stirred mixture is heated at reflux for 1 day. The liquid phase is removed by syringe and concentrated under reduced pressure to afford bis(diethylaluminum) sulfate as a white solid.

Handling, Storage, and Precautions: decomposes in air and reacts violently with moisture with evolution of ethane.[3] Use in a fume hood.

Catalyst for Alkene Polymerization.

Bis(diethylaluminum) sulfate has been used in combination with other organometallic complexes to catalyze different types of alkene polymerizations.[1-4] A 1:2 combination of this catalyst and cobalt(II) thiocyanate-bis(triphenylphosphine) effectively polymerizes 1,3-butadiene (and isoprene) to 1,2-syndiotactic polyisobutadiene.[1] A three-component catalyst system containing bis(diethylaluminum) sulfate, ***Tris(acetylacetonato)iron(III)*** and ***Triphenylphosphine*** promotes the production of linear dimers of butadiene.[2] The title reagent has also proven effective as a powerful activator of ***Titanium(III) Chloride*** in the polymerization of propylene.[4]

Catalyst for Allylstannane Addition.

Bis(diethylaluminum) sulfate is a good Lewis acid catalyst for promoting the coupling of allylstannanes with various

electrophiles. For example, it catalyzes the addition of an allyl unit to acetals (eq 1), carbonyl compounds (eq 2), and α,β-unsaturated ketones (eq 3).[5]

Bis(diethylaluminum) sulfate also promotes the coupling of allylstannanes with various allylic species, such as allylic halides (eq 4), ethers (eq 5), and acetates (eq 6).[6] The 1,5-diene products are obtained in good yield, albeit with modest regioselectivity. Many of these allylations are also catalyzed by ***Boron Trifluoride Etherate***, but the yields are generally lower.[5,6]

1,2-Bis(2,5-diethylphospholano)benzene

[136705-64-1] · $C_{22}H_{36}P_2$ · 1,2-Bis(2,5-diethylphospholano)benzene · (MW 362.47)

(ligand for asymmetric catalysis;[1] rhodium complexes are efficient catalyst precursors for highly enantioselective hydrogenation of α-(*N*-acylamino)acrylates,[1,2] enol acetates,[1] and *N*-acylhydrazones[3,4])

Alternate Name: (*R*,*R*)- and (*S*,*S*)-Ethyl-DuPHOS.

Physical Data: bp 138-143 °C/0.045 mmHg; (*R*,*R*)-Ethyl-DuPHOS, [α]25D = -265° (*c* 1, hexane).

Form Supplied in: colorless viscous liquid; both enantiomers available commercially.

Analysis of Reagent Purity: optical rotation, ^{1}H NMR, ^{31}P NMR, ^{13}C NMR.

Preparative Methods: preparation of (*R*,*R*)-Ethyl-DuPHOS requires the use of (3*S*,6*S*)-3,6-octanediol.[1,2] Enantiomerically pure (3*S*,6*S*)-octanediol is obtained in 35-45% overall yields via a simple three-step procedure[5,6] involving the Ru-(*S*)-BINAP-catalyzed asymmetric hydrogenation[7] of methyl propionylacetate to methyl (3*S*)-3-hydroxypentanoate (95% yield, 99% ee), followed by quantitative hydrolysis to the corresponding β-hydroxy acid, and subsequent electrochemical Kolbe coupling (eq 1). This sequence has been used for the synthesis of multigram quantities of (3*S*,6*S*)-octanediol, as well as a series of related chiral 1,4-diols.[2,6] Antipodal (3*R*,6*R*)-octanediol was prepared in a similar fashion by employing the (*R*)-BINAP-Ru catalyst in the first step.[6]

The crystalline (3*S*,6*S*)-octanediol (mp 51-52 °C; [α]25D = +22.8° (*c* 1, $CHCl_3$)) is next converted to the corresponding (3*S*,6*S*)-octanediol cyclic sulfate (mp 80-81 °C; [α]25D = +28.6° (*c* 1, $CHCl_3$)) through reaction with ***Thionyl Chloride***, followed by oxidation with ***Sodium Periodate*** and a catalytic amount (0.1 mol%) of ***Ruthenium(III) Chloride*** (eq 2).[2] The final step involves successively treating 1,2-bis(phosphino)benzene[8] with ***n-Butyllithium*** (2 equiv 1.6 M in hexane), followed by (3*S*,6*S*)-octanediol cyclic sulfate (2 equiv), and then *n*-BuLi (2.2 equiv) to provide the product (*R*,*R*)-Ethyl-DuPHOS in 78% yield after purification by distillation (eq 2). The use of (3*R*,6*R*)-octanediol cyclic sulfate in eq 2 allows the analogous preparation of (*S*,*S*)-Ethyl-DuPHOS. In addition to Ethyl-DuPHOS (R = Et), a series of other DuPHOS derivatives (R = Me, Pr, *i*-Pr, Cy, Bn) have been prepared in this manner.[1,2]

Handling, Storage, and Precautions: somewhat air sensitive and should be handled and stored in a nitrogen or argon atmosphere. Metal complexes generally are sensitive to oxygen in solution. Use in a fume hood.

Catalyst Precursors: Rhodium Complexes.

The cationic rhodium complexes [(cod)Rh(Ethyl-DuPHOS)]$^+$X$^-$ (X = OTf, PF_6, BF_4, SbF_6) serve as efficient catalyst precursors for both enantioselective hydrogenation[1-6] and intramolecular hydrosilylation[9] reactions. These complexes are most conveniently prepared by reacting the ligand, either (*R*,*R*)-Ethyl-DuPHOS or (*S*,*S*)-Ethyl-DuPHOS, with the complexes [$(cod)_2$Rh]$^+$X$^-$ in THF.[2,10] Since the solid rhodium catalysts are less air-senstive than the ligands, they may be weighed quickly in air, although storage under nitrogen or argon is recommended.

Enantioselective Hydrogenations.

α-(*N*-Acylamino)acrylates.

The cationic Ethyl-DuPHOS-Rh catalysts are particularly well-suited for highly enantioselective hydrogenation of α-(*N*-acylamino)acrylates to α-amino acid derivatives (eq 3).[1,2]

(3)

The reactions proceed under mild conditions (1 atm H_2, 25 °C, MeOH) and are extremely efficient (substrate-to-catalyst ratios S/C up to 50 000 have been demonstrated). The breadth of the Ethyl-DuPHOS-Rh catalyst is noteworthy; extremely high enantioselectivities (&egt;99% ee) are achieved over a broad range of substrates (Table 1). Accordingly, the Ethyl-DuPHOS-Rh catalysts can provide practical access to a wide variety of natural, unnatural, nonproteinaceous, and labeled α-amino acids. The absolute configurations of the products are very predictable; (*R*,*R*)-Ethyl-DuPHOS-Rh complexes consistently afford products of (*R*) absolute configuration, while (*S*,*S*)-Ethyl-DuPHOS-Rh complexes provide (*S*)-α-amino acid derivatives. Similarly high ees are obtained with the corresponding carboxylic acid substrates (R^3 = H), as well as with *N*-benzoyl (R^2 = Ph) and *N*-Cbz (R^2 = OBn) α-(*N*-acylamino)acrylates. Significantly, the Ethyl-DuPHOS-Rh catalysts allow hydrogenation of both (*Z*) and (*E*) isomeric α-(*N*-acetylamino)acrylates in high enantiomeric excess (>99% ee) to afford products with the same absolute configuration. Many desirable α-(*N*-acylamino)acrylates are unavoidably synthesized as a mixture of (*E*) and (*Z*) isomers, and a separation step generally is required prior to hydrogenation. When using the Ethyl-DuPHOS-Rh catalysts, however, the need to separate isomeric substrates is often eliminated, thus providing a practical route to many amino acid derivatives.

Table 1 Asymmetric Hydrogenation of a-(*N*-acetamido)acrylates (R^2,R^3 = Me) with Ethyl-DuPHOS Rh Catalyst

1-Naphthyl	>99
2-Naphthyl	>99
2-Thienyl	>99
Ferrocenyl	>99

Enol Acetates.

Several enol acetates are hydrogenated with high enantioselectivities using the Ethyl-DuPHOS-Rh catalysts (eqs 4 and 5).[1] The selectivities are significantly higher than any previously reported for these substrates.[11] The scope of these reactions and substrates bearing β-substituents have not yet been examined.

(4)

(5)

N-Benzoylhydrazones.

The C=N double bond of *N*-benzoylhydrazones may be hydrogenated with high enantioselectivities using the Ethyl-DuPHOS-Rh catalyst systems (eq 6).[3,4]

(6)

Under optimized conditions (0 °C, 60 psi H_2, *i*-PrOH, S/C 500), the (*R*,*R*)-Et-DuPHOS-Rh catalyst predictably provides a variety of *N*-benzoylhydrazine products in high enantiomeric excess and with (*S*) absolute configuration (Table 2).

Table 2 Asymmetric Hydrogenation of *N*-Benzoylhydrazones with Ethyl-DuPHOS Rh Catalyst

R^1	R^2	% ee
Ph	Me	95
Ph	CH_2Ph	84
p-$NO_2C_6H_4$	Me	97
p-BrC_6H_4	Me	96

CO_2Et	Me	89
CO_2Me	Et	91
CO_2Me	Ph	90
$P(O)(OEt)_2$	Ph	90
Cy	Me	72
Et	Me	43

An interesting and potentially useful property of the Et-DuPHOS-Rh catalyst system is the high level of chemoselectivity exhibited in the hydrogenation of *N*-benzoylhydrazones. Little or no reduction of various functional groups including alkenes, alkynes, ketones, aldehydes, nitriles, imines, carbon-halogen, and nitro groups is observed under conditions required for complete reduction of the hydrazones.

Enantioselective hydrogenation of *N*-benzoylhydrazones represents a key transformation in a three-step asymmetric catalytic reductive amination process that involves: (1) treating a ketone with benzoic acid hydrazide; (2) Ethyl-DuPHOS-Rh-catalyzed hydrogenation of the *N*-benzoylhydrazone; and (3) hydrolysis of the product *N*-benzoyl group (3 M HCl) to provide the corresponding hydrazine, or reductive cleavage of the product N-N bond with ***Samarium(II) Iodide*** to directly afford the corresponding amine (eq 7).[4]

Bis(diisopropylamino)aluminum Hydride

[2826-40-6] · $C_{12}H_{29}AlN_2$ · Bis(diisopropylamino)aluminum Hydride · (MW 228.36)

(reducing agent useful for regioselective conjugate reduction of enones;[1] can hydroaluminate double and triple bonds;[2] can reduce carbonyl compounds to alcohols[2b])

Solubility: sol THF, ether, hydrocarbons.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: Al-H stretching frequency (1820 cm^{-1}); aluminum content by titration with EDTA and back titration with $Zn(OAc)_2$; hydrogen content by gas evolution analysis.[2a,2b]

Preparative Methods: easily prepared by the addition of *i*-Pr_2NH to AlH_3 (from reaction of 100% H_2SO_4 with $LiAlH_4$)[3] in THF in a 2:1 molar ratio. H_2 is evolved during the addition. Reaction is complete after 3 h.[3] Highly pure reagent can be made by the reaction of Al metal and *i*-Pr_2NH (1:2 molar ratio) in benzene at 140 °C under 2000 psi H_2 pressure.[4]

Handling, Storage, and Precautions: moisture sensitive.

Regioselective Conjugate Reduction of Enones.

Excellent regioselectivity in the conjugate reduction of some α,β-unsaturated ketones using $(i\text{-}Pr_2N)_2AlH$ has been reported.[1] The 1,4-reduction product is formed almost exclusively for ketones of the type $R^1CH{=}CR^2COR^3$ (R^1 = Me, *t*-Bu, or Ph; R^2 = H or Me; R^3 = Me, *t*-Bu, or Ph) and yields are near quantitative (eq 1). Reactions are typically run in THF at 0 °C (2-4:1 molar ratio hydride:enone) and are complete within 15 min to 1 h. However, the reagent appears to have limited generality. Poor regioselectivities occur in the reductions of methyl vinyl ketone and cyclohexenone. When the enone system is disubstituted at the 4-position (e.g. $Me_2C{=}CHCOMe$ or isophorone), little or no reaction occurs. On the other hand, cyclopentenone undergoes smooth reduction to give the 1,4-product with only traces of the 1,2-product. Similar extents of regioselectivity are obtainable with HBI_2, but this reagent requires elevated temperatures, extended reaction times (9-20 h), a larger excess of hydride (8:1), and gives very poor yields with cyclic ketones.

(1)

Hydrometalation.

Hydroalumination of alkynes by (i-$Pr_2N)_2AlH$ in the presence of a transition metal catalyst (typically 5 mol % ***Dichlorobis(cyclopentadienyl)titanium***) readily takes place to give high yields of the hydrometalated compound.[2] This organometallic species can be further functionalized by quenching the alanate with D_2O or I_2 to give the corresponding deutero or iodo product (eq 2).

(2)

The reaction with alkynes is a stereospecific *syn* addition, giving alkenylaluminum intermediates.[2a,c] Internal alkynes provide high yields (82-95%) of the *cis*-alkene. No trace of the *trans* isomer is observed when the reaction is carried out at 0 °C. A considerable amount of the *trans*-alkene is formed when the temperature is raised to 25 °C at longer reaction times. Terminal alkynes yield a significant amount of alkane (49-54%) along with the alkene after hydrolysis of the alanate. In the case of unsymmetrical alkynes, regiochemistry is likely determined in the formation of the intermediate alkynyltitanium complex, with the subsequent transmetalation being the slow step of this process (eq 3).[2a] The transition metal adds preferentially to form the less sterically hindered complex.

Mono- and disubstituted alkenes are hydrometalated in nearly quantitative yields to provide the alkane upon hydrolytic workup. Tri- and tetrasubstituted alkenes give little or no reaction.[2c] Conjugated dienes react with (i-$Pr_2N)_2AlH$ (1:2 molar ratio) to give mixtures of 1,2- and 1,4-addition products in fair yields (55-60%). An interesting solvent effect was reported in the reaction of 1,5-hexadiene. In THF an 8:1 mixture of alkane and monoene products is formed in 90% yield, whereas cyclization occurs in benzene to give methylcyclopentane (90%).

Nonenolizable carbonyl compounds are quantitatively reduced to the corresponding alcohols (eq 4).[2b] Enolizable ketones are reduced in moderate yields (40-45%) employing a 2:1 molar ratio of (i-$Pr_2N)_2AlH$ to ketone. Stereoselectivity in the reduction of 4-t-butylcyclohexanone decreases when the solvent is changed from THF (92:8 eq:ax alcohols) to benzene (70:30 eq:ax alcohols).

Bis(dimethylamino)methane[1]

[51-80-9] · $C_5H_{14}N_2$ · Bis(dimethylamino)methane · (MW 102.18)

(precursor for the preparation or in situ generation of *N*,*N*-dimethyl(methylene)ammonium salts;[2,3] used for dimethylaminomethylation of active methylene compounds,[1,4] arylstannanes,[5] and electron-rich heterocycles;[6] useful for the preparation of α,β-unsaturated ketones[7])

Alternate Names: N,N,N´,N´-tetramethylmethanediamine; dimethyl(dimethylamino)methylamine; formaldehyde bis(*N*,*N*-dimethylaminal).

Physical Data: bp 85 °C; *d* 0.749 g cm^{-3}; fp -12 °C.

Solubility: sol H_2O, ether.

Form Supplied in: colorless liquid; widely available.

Purification: dried over potassium hydroxide pellets and distilled.

Handling, Storage, and Precautions: highly flammable. Potent lachrymator. Emits toxic fumes under fire conditions. Handle with gloves in a well-ventilated fume hood. Incompatible with acids, acid chlorides, strong oxidizing agents, and carbon dioxide.

Bis(dimethylamino)methane (**1**) can be used for the dimethylaminomethylation of active methylene compounds. Acidic conditions such as ***Trifluoroacetic Acid*** (TFA) (eq 1)[4] or ***Phosphoric Acid*** in ***Acetic Acid*** (eq 2)[8] catalyze the elimination of dimethylamine from (**1**), resulting in the formation of *N*,*N*-dimethyl(methylene)ammonium salts. The in situ use of these salts in the Mannich reaction is usually more convenient than the direct use of the preformed *N*,*N*-dimethyl(methylene)ammonium salts, since the latter are typically hygroscopic and difficult to handle.

Acyl chlorides or ***Chloroiodomethane*** can also be used in combination with (**1**) to accomplish dimethylaminomethylation of activated methylene compounds (eq 3)[9] and silyl enol ethers (eq 4),[10] respectively. The resulting tertiary amine may in some instances be eliminated to produce the corresponding terminal alkene (eq 5).[11] Reagent (**1**) was shown by de Solms[7] to be superior to the classical Mannich base for the preparation of α,β-unsaturated ketones (eq 6).

(5)

(6)

N,*N*-Dimethyl(methylene)ammonium chloride and iodide can be prepared and isolated from the reaction of (**1**) with ***Acetyl Chloride*** (eq 7)[2] or ***Iodotrimethylsilane*** (eq 8),[3] respectively. However, in the reaction of (**1**) with ***Chlorotrimethylsilane***, the formation of *N*,*N*-dimethyl(methylene)ammonium chloride is not observed.[12] Thus in dimethylaminomethylation reactions employing (**1**) and TMSCl, the reactive intermediate is most likely to be the quarternary silylammonium salt (eq 9).

$$\textbf{(1)} \xrightarrow[0\ ^{\circ}C]{AcCl,\ Et_2O} Me_2\overset{+}{N}{=}CH_2\ Cl^- \qquad (7)$$

$$\textbf{(1)} + TMSI \longrightarrow Me_2\overset{+}{N}(SiMe_3)-CH_2-NMe_2\ I^- \longrightarrow Me_2\overset{+}{N}{=}CH_2\ I^- \qquad (8)$$

$$\textbf{(1)} + TMSCl \rightleftharpoons Me_2\overset{+}{N}(SiMe_3)-CH_2-NMe_2\ Cl^- \not\longrightarrow Me_2\overset{+}{N}{=}CH_2\ Cl^- \qquad (9)$$

$$\downarrow \text{indole} \longrightarrow ArCH_2NMe_2 + HCl + Me_2NSiMe_3$$

Dimethylaminomethylations of aryltrialkylstannanes with (**1**) in the presence of silyl chlorides have been reported (eq 10).[5] Reagent (**1**) also reacts with heterocyclic compounds such as *N*-methylpyrroles (eq 11) and indoles (eq 12) in the presence of acetyl chloride or excess ***Sulfur Dioxide*** to provide the corresponding Mannich products.[6]

1,8-Bis(dimethylamino)naphthalene[1,2]

[20734-58-1] · $C_{14}H_{18}N_2$ · 1,8-Bis(dimethylamino)naphthalene · (MW 214.31)

(used as weakly nucleophilic strong base)

Alternate Name: Proton Sponge®.

Physical Data: mp 49-51 °C (45-46 °C).[3]

Solubility: sol most organic solvents.

Form Supplied in: yellow-tan crystals.

Preparative Method: prepared in 82% yield from 1,8-diaminonaphthalene, dimethyl sulfate, and sodium hydride.[3]

Purification: recrystallized from petroleum ether.[3]

Handling, Storage, and Precautions: irritant.

Strong Base.

The strong basic properties of 1,8-bis(dimethylamino)naphthalene (**1**) are attributed to a combination of dipole-dipole repulsions (nitrogen lone pairs), van der Waals repulsions, and steric inhibition of resonance.[4] Relief of strain imposed by the close proximity of the nitrogen lone pairs occurs upon protonation, giving this base one of the highest pK_a values of the aromatic amines (pK_a 12.1; pK_a of *N*,*N*-dimethylaniline 5.1). A variety of stronger Proton Sponge-like aromatic amine bases, such as the 2,7-dimethoxy derivatives (**2**) and (**3**)[5] and the bis(dimethylamino)fluorenyl system (**4**),[6] have been prepared and exhibit pK_a values of 16.1, 16.3, and 13.5, respectively. However, it is observed in these types of systems that the rates of proton transfer to and from the amine base are very slow.[7]

(2) R = Me
(3) R = Et

(4)

The weak nucleophilic character of (**1**) makes this reagent useful for applications involving the neutralization of acid in systems sensitive to Lewis basic reagents. In the phosphorylation of 5-vinyl- and 5-ethynyl-2´-deoxyuridines to the corresponding 5´-triphosphates (eq 1),[8] Proton Sponge effectively promotes formation of the intermediate phosphorodichloridate whereas other bases (TEA, *i*-Pr_2EtN, collidine, DBU, DBN) are ineffective. A phosgene-free synthesis of highly pure isocyanates from carboxylic acids and ***Diphenyl Phosphorazidate*** occurs in good yields only with (**1**) as base (eq 2).[9] Other tertiary amine bases give lower yields and contaminate the product after distillation. The oxidative decarboxylation-deoxygenation of 3-hydroxycarboxylic acids to tri- and tetrasubstituted alkenes (eq 3) makes use of Proton Sponge to eliminate acid-catalyzed alkene isomerization or degradation of the products,[10,11] and the ***Tin(II) Trifluoromethanesulfonate***-promoted addition of aliphatic 1-alkynes to aldehydes (eq 4) proceeds best when performed with this nonnucleophilic base.[12]

(2)

(3)

(4)

1,8-Bis(dimethylamino)naphthalene has particular value in applications involving the use of transition metal catalysts. Its use in palladium-catalyzed arylations (eq 5),[13,14] alkoxycarbonylation (eq 6),[15] and intramolecular cyclizations[16] is noteworthy, giving superior yields compared to other more nucleophilic bases.

Bis(dimethylamino) Phosphorochloridate

[1605-65-8] · $C_4H_{12}ClN_2OP$ · Bis(dimethylamino) Phosphorochloridate · (MW 170.58)

(reagent for protection of alcohols,[1] ketones,[2] thiols[3] and amines;[4] reductive deoxygenation of alcohols and ketones[2])

Physical Data: fp >230 °C; *d* 1.152 g cm^{-3}.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: moisture sensitive; store in a dry, cool environment. Handle in a well-ventilated fume hood.

Protection and/or Reductive Deoxygenation of Alcohols and Ketones.

Bis(dimethylamino) phosphorochloridate constitutes a useful protecting reagent for hydroxyls,[1] thiols[3] and for ketones (i.e. enols).[2] The phosphorodiamidates, prepared by phosphorylation of the corresponding alcoholate or enolate, are stable to various conditions and deprotection is accomplished under mild conditions in nearly quantitative yield.[5]

The phosphorodiamidates of alcoholates are readily reduced in high yield by lithium-ethylamine solution (eq 1).[2] The two-step reductive deoxygenation of ketones (RCOR´ -> RCHOHR´ -> RCH_2R´) has unique advantages over the traditional Wolff-Kishner reduction if the substrate is particularly sensitive to acid/base conditions or if the substrate exhibits severe steric congestion in the vicinity of the carbonyl moiety (eq 2). Bis(dimethylamino) phosphorochloridate[6] (and diethyl phosphate)[7] have been used to trap the kinetic enolate of enediones (e.g. analogs of the Wieland-Miescher ketones) prior to reduction to corresponding alkene.[8]

Glycopyranosyl *N*,*N*,*N*′,*N*′-tetramethylphosphorodiamidates appear to promote highly stereoselective 1,2-*trans*-β-glycosidation reactions.[9] When comparison is made with other phosphorus-containing reagents[10] that promote glycosidations (specifically, the diphenyl phosphate method,[10a] which affords similar reactivity and stereoselectivity), the glycosyl phosphorodiamidates have the advantage of being shelf-stable glycosyl donors (eq 3).[9]

$R^1 = R^2 = Y = Bn, X = H$; $R^1 = R^2 = X = Bn, Y = H$;

R^3 = steroidal alcohols

Bis(dimethylamino)phosphorodiamidate has been employed as a directing agent for the α-lithiation of tetrahydroisoquinolines,[11] the 3-lithiation of 2-furanol,[12] and for the *ortho*-lithiation of phenols[13] and naphthols.[13b] In the case of phenols, the *ortho*-lithiated species prepared by reaction of the derived phosphorodiamidates with ***s-Butyllithium*** at -105 °C can be subsequently trapped (ca. -105 °C) with a variety of electrophiles to afford *ortho*-substituted phosphorodiamidates (eq 4).

(4)

Protection of Primary Amines.

Protection of primary aliphatic amines employing the bis(dimethylamino)phosphoryl group gives *N*-alkylphosphoramides[4] which can be subsequently substituted to afford *N*,*N*´-dialkyl or propargylic phosphoramides (eq 5).[14]

Hydroboration of *N*-alkylpropargylic phosphoramides occurs without nitrogen-boron complexation and with a regioselectivity and stereospecificity similar to that observed with alkynes,[4] while substituted propargylic amines and ethylenic amino ketones are easily prepared from the corresponding phosphoramides.[15]

Isabel Mathieu-Pelta & Slayton A. Evans, Jr.

1,4-Bis(dimethylamino)-1,1,4,4-tetramethyldisilethylene[1]

[91166-50-6] · $C_{10}H_{28}N_2Si_2$ · 1,4-Bis(dimethylamino)-1,1,4,4-tetramethyldisilethylene · (MW 232.52)

(reagent for the protection of primary amines with lower pK_a values, such as substituted anilines, as their tetramethyldisilylazacyclopentane or Stabase adduct; precursor of tetramethyldisilylthiacyclopentane, a sulfur transfer reagent)

Physical Data: bp 100-103 °C/13 mmHg; *d* 0.824 g cm^{-3}.

Preparative Method: the reagent is prepared as a colorless liquid in 90% yield by treating commercially available bis(chlorodimethylsilyl)ethane with 5 equiv of dimethylamine in ether at 0 °C for 5 h.

Handling, Storage, and Precautions: the liquid vapors are heavier than air and may travel a considerable distance to a source of ignition. Vapor-air mixtures are explosive above the flash point of 14 °C. Use in a fume hood.

Protection of Primary Aromatic Amines.[1]

The title reagent is used for the preparation of Stabase derivatives of primary amines, and is particularly useful for the protection of primary aromatic amines with pK_a values of 10-11 (see ***1,2-Bis(chlorodimethylsilyl)ethane***). The protection of substituted anilines is achieved by heating equimolar amounts of the title compound and the anilines in the presence of ***Zinc Iodide*** (0.5 mol %) under a slow stream of nitrogen at 140 °C for 5 h. In many cases the products can be purified by vacuum distillation. Cleavage of the Stabase adducts to the corresponding primary amines can be performed in ether in the presence of 2 equiv of methanol and a small amount of *p*-toluenesulfonic acid monohydrate (0.2 mol %). The tetramethyldisilylazacyclopentane or Stabase adduct (**3**) is a particularly attractive protecting group due to its ease of preparation, base stability, and facile removal (eq 1).

The title compound was utilized to protect 2-amino-6-bromopyridine (**4**) in 72% yield in a sequence to prepare helicopodant (**7**) (eq 2).[2]

(7)

Sulfur Transfer Reagent.

The reagent was used to prepare 2,2,5,5-tetramethyl-2,5-disila-1-thiacyclopentane (**8**) which acts as a sulfur transfer reagent. An example of this reaction is shown in eq 3.[3]

Fatima Z. Basha & Anwer Basha

Abbott Laboratories, Abbott Park, IL, USA

Bis(*N,N*-dimethylformamido)oxodiperoxomolybdenum(VI)

[23319-73-5] · $C_6H_{14}MoN_2O_7$ · Bis(*N,N*-dimethylformamido)oxodiperoxomolybdenum(VI) · (MW 322.13)

(useful as an aprotic oxidant in the oxidation of trimethylsilylated amides to the corresponding hydroxamic acids;[1] catalyst for the epoxidation of alkenes[2,3])

Physical Data: mp 100-102 °C.

Solubility: sol water, $CHCl_3$, CH_2Cl_2; insol ether.

Form Supplied in: yellow powder. *Drying:* the hydrated complex is dried in vacuo over P_2O_5.

Preparative Method: molybdic acid (20 g, 0.15 mol) is dissolved in 30% hydrogen peroxide (100 mL) at 35 °C. The yellow solution is cooled to 15 °C and DMF (21.9 g, 0.3 mol) added. The aqueous solution is partially evaporated under reduced pressure, maintaining the temperature below 35 °C. The resultant yellow crystals are collected by filtration, and washed thoroughly with ether and a small volume of methanol (2 × 25 mL).

Handling, Storage, and Precautions: the complex is stable under storage.

Hydroxamic Acids.

A variety of natural products containing hydroxamic acid functions possess a wide range of biological activities, including the important role of hydroxamic acids in certain iron-transporting systems.[4] Trimethylsilylation of secondary amides activates them towards oxidation to hydroxamic acids by the peroxo-molybdenum complex MoO_5.HMPA.[5] The trimethylsilylation of amides is a well documented process.[6] The derivatives are sensitive to water and protic solvents, being solvolyzed to the parent amide. In order to oxidize trimethylsilylated amides, aprotic oxidants are required. Since molybdenum is known to form stable complexes with hydroxamic acids, there existed the possibility that, after oxidation, the product hydroxamic acid would become complexed with the molybdenum ion, thus avoiding further overoxidation during the reaction. Molybdenum pentoxide complexes are stable, covalent diperoxo species.[7] Several such complexes are known. Two useful ones are MoO_5.HMPA and MoO_5.py.HMPA (see ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)***). These HMPA complexes are more easily prepared because they are insoluble in water, but released HMPA can interfere with workup. The bis(dimethylformamide) complex is the preferred oxidant. It is water soluble and more stable on storage and there is no residual water ligand to interfere with the subsequent oxidation. Furthermore the released DMF ligands interfere less in the workup procedure than HMPA. Since oxidations with these peroxo complexes are thought to involve substrate-molybdenum complex formation,[8] competing strong donor ligands

or very polar solvents competitively inhibit the reaction and oxidations are best carried out in chloroform or, routinely, dichloromethane solutions. Liberation of the uncomplexed hydroxamic acids is accomplished by extraction of the molybdenum ion with warm EDTA at pH 9. Since many of the hydroxamic acids are water soluble, their efficient recovery requires continuous extraction with either chloroform or dichloromethane after adjustment of the pH of the solution to 7.5. Although the yield on oxidation of silylated secondary aliphatic amides is usually only moderate (15-40%), hydroxylation of acetanilides proceeds consistently with yields of 40-50%. The reaction is efficient for oxidation of benzoxazinones (eq 1). The products are useful herbicides because of inhibition of auxin.

Some other substrates are 2-(trimethylsilyloxy)pyridine (eq 2) and 4-quinolone (eq 3) as its trimethylsilyl derivative, giving the corresponding hydroxamic acids in 90% and 55% yield, respectively. In contrast, silylated ureas and carbamates fail to give the desired oxidation products.

Epoxidation Catalyst.[2,3]

A UV and IR examination of the epoxidation of cyclohexene by ***1,1-Di-t-butyl Peroxide***, catalyzed by the complexes of MoO_5 with DMF or HMPA, showed that the mechanism involves the initial, rapid, reaction of the catalyst with *t*-BuOOH to give the Mo peroxo complex which then epoxidizes the alkene via an O transfer. This latter step involves the formation and subsequent cleavage of a fused molybdenadioxacyclopentane ring.

Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III)[1]

[61754-28-7] · $C_{14}H_{22}CoN_5O_4$ · Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III) · (MW 383.29)

(prototype of alkylcobaloximes and model compound for methylcobalamine[1])

Alternate Names: methyl(pyridine)cobaloxime(III); $MeCo^{III}(dmgH)_2py$.

Physical Data: mp 215-220 °C (dec); *d* 1.42 g cm^{-3}; polarographic half-wave potentials (acetonitrile solution, vs $Ag/AgNO_3$ electrode): -1.75, -2.44, -3.01 V; λ_{max} = 438 nm (log ε = 3.17); ^1H, ^{13}C, ^{59}Co NMR, and ESR data,[2] FT-IR and Raman spectroscopy,[3] polarographic properties (dropping mercury electrode),[4] photochemical and radiolytic C-Co bond cleavage,[5] thermal decomposition,[6] and X-ray crystallography[7] have been described.

Solubility: sol many organic solvents (acetone, methanol, methylene chloride); slightly sol THF, benzene, ethyl acetate; almost insol water.

Preparative Method: orange crystals readily available from cobalt(II) chloride, butane-2,3-dione dioxime (dimethylglyoxime, $dmgH_2$), pyridine (py), and dimethyl sulfate or methyl iodide.[8]

Handling, Storage, and Precautions: requires no special handling procedures. It is less light-sensitive than its solutions, which tend to decompose with loss of methyl and formation of cobaloxime(II), but should be stored in amber colored vials under nitrogen. For some reactions the 4-*t*-butylpyridine derivative of methyl(pyridine)cobaloxime(III), i.e. methyl(4-*t*-butylpyridine)cobaloxime(III), is easier to handle especially when column chromatography on silica gel (ethyl acetate, orange band, R_f = 0.4) is required, or in applications which require higher concentrations of alkylcobaloxime(III) in solution or use of nonpolar solvents. Samples have been purified with reversed phase HPLC on a chromsil C_{18} column.[9]
Methyl(pyridine)cobaloxime is readily recrystallized from methanol/water mixtures under a nitrogen atmosphere.

General Preparation of Organocobalt(dmgH)$_2$ Complexes.

Organo-$Co^{III}(dmgH)_2$ complexes were originally developed by Schrauzer as vitamin B_{12} analogs[9,10,11] (see also ***Cobalt Salen Complexes***

and ***Cobalt Salophen Complexes***), and extensive mechanistic studies into their reactions have been carried out.[10,12] The preparation of $RCo^{III}(dmgH)_2$ complexes can be accomplished by reacting $Co^{I}(dmgH)_2$, $Co^{II}(dmgH)_2$, or $Co^{III}(dmgH)_2$ reagents with electrophiles, radicals, and nucleophiles respectively.[10] The most common method for the preparation of $RCo^{III}(dmgH)_2$ reagents is via displacement reactions using supernucleophilic $Co^{I}(dmgH)_2$. $Co^{I}(dmgH)_2$ can be prepared in situ from the readily available $Co^{II}(dmgH)_2$ or $ClCo^{III}(dmgH)_2py$ by reduction with ***Sodium Borohydride***[8,13] or hydrogen gas,[14] electrochemically,[15] or by disproportionation.[16] The reduced $Co^{I}(dm\ gH)_2$ reacts with a variety of substrates including alkyl halides, acyl halides, vinyl halides,[17] alkynyl halides,[18] activated aryl halides,[19] alkyl tosylates, alkyl sulfates, alkyl phosphates,[20] and oxiranes.[21] Allylic halides and propargylic halides may undergo both S_N2 and S_N2' substitution, with steric factors largely determining the course of the reaction (eq 1).[22] For base sensitive substrates, $Co^{II}(dmgH)_2$ can be used in conjunction with Zn metal and an alkylating agent (eq 2).[23]

$Co^{I}(dmgH)_2$ adds to activated alkenes and alkynes, e.g. styrene and acrylonitrile, in alkaline protic solvents to give β-substituted products arising from *trans* addition of the metal ion and a proton from the solvent (eq 3). Under neutral or acidic conditions, $Co^{I}(dmgH)_2$ exists as the protonated hydrido $HCo^{III}(dmgH)_2$ species, and α-substituted products arising from a *cis* addition are isolated (eq 4).[17] 1,3-Dienes that do not possess terminal substituents react to give $allylCo^{III}(dmgH)_2$ complexes (eq 5).[24]

$ClCo^{III}(dmgH)_2py$ reacts with alkyl metals such as Grignard reagents,[25] alkyllithiums, alkylborons, and alkylaluminums, leading to the corresponding organo-$Co^{III}(dmgH)_2$ complexes (eq 6).[26] A one-pot procedure whereby $Co^{I}(dmgH)_2$ is formed in situ from a cobalt(II)

salt, pyridine, and dimethylglyoxime under reducing conditions, followed by the addition of an alkylating agent, can be employed (eq 7).[8]

$$\mathrm{ClCo^{III}(dmgH)_2py} \xrightarrow[79\%]{\text{3 equiv EtMgBr, THF}} \mathrm{EtCo^{III}(dmgH)_2py} \quad (6)$$

$$\mathrm{Co^{II}Cl_2} \xrightarrow[\text{3. } Me_2SO_4 \quad 99\%]{\text{1. 2 equiv } (dmgH)_2\text{, MeOH, py; 2. NaOH}} \mathrm{MeCo^{III}(dmgH)_2py} \quad (7)$$

Methylation.

Methyl(pyridine)cobaloxime(III) is a methylating agent. Due to its covalent nature, the carbon-cobalt bond can be cleaved with nucleophiles, radicals, and electrophiles. For some transformations, photochemical, thermal, or oxidative activation of the carbon-cobalt bond may be required. Thiolates are methylated at room temperature (eq 8).

$$\mathrm{Me[Co^{III}]} + \mathrm{MeS^-Na^+} \xrightarrow[25\ ^\circ\mathrm{C}]{\text{MeOH, dark}} \mathrm{MeSMe} \quad (8)$$

$$[\mathrm{Co}] = \mathrm{Co(dmgH)_2py}$$

Thus in vitro methylation of coenzyme M with abiotic methyl(pyridine)cobaloxime(III) in basic alcoholic solutions and in the presence of cell extracts of *Methanobacillus omelianskii* yields methane, forming a model for methane biosynthesis.[27] Likewise, nucleophiles such as SCN^-, I^-, CN^-, and phosphines readily yield the corresponding methylated products. Electrophilic cleavage of the methyl carbon bond in methyl(pyridine)cobaloxime(III) occurs in the presence of ***Mercury(II) Acetate***, ***Thallium(III) Acetate***, and anhydrous acids, such as ***Trifluoroacetic Acid*** and ***Hydrochloric Acid***.[28] The former reaction mimics environmental formation of methylmercury via methylcobalamine in wastewater of heavily polluted industrial sites (eq 9).

$$\mathrm{Me[Co^{III}]} + \mathrm{Hg(OAc)_2} \xrightarrow[\substack{20\ ^\circ\mathrm{C} \\ 70\text{-}90\%}]{\text{pH 2-5}} \mathrm{[Co^{III}(OAc)]} + \mathrm{MeHgOAc} \quad (9)$$

Efficient and selective methyl transfer reactions from methyl(pyridine)cobaloxime(III) to α,β-unsaturated carbonyl compounds require assistance of palladium salts. Thus 1,4-benzoquinone is monomethylated in 70% yield in the presence of $LiPdCl_4$ (eq 10). Terminal alkenes such as styrene, 1-octene, or acrylates form the corresponding chain elongated (*E*)-alkenes. Substitution of an alkyl group by hydrogen occurs at the sterically less hindered alkenic carbon atom (eq 11).[29]

Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III)

(10)

(11)

Cleavage of alkyl-cobalt bonds with solutions of bromine in the dark has proven to be a useful tool for dealkylation of cobaloximes in both mechanistic and preparative studies.[30] Due to the decreased oxidative power of iodine, alkylcobaloximes are converted to alkyl iodides only when the reaction mixtures are photolyzed.[31] Cobalt(IV) species have been discovered by ESR spectroscopy to be the primary products of photolytic iodination of alkylcobaloximes, and these then fragment to yield alkyl iodides (eq 12).

(12)

Insertion Reactions of Organocobalt(dmgH)$_2$) Complexes.

$RCo^{III}(dmgH)_2$ complexes undergo insertion of molecular oxygen under thermal or photochemical conditions to give alkylperoxycobaloximes ($ROOCo^{III}(dmgH)_2$).[32] The reaction is accompanied by racemization with chiral organocobaloximes.[33] $ROOCo^{III}(dmgH)_2$ complexes can be reduced using $NaBH_4$ or $LiAlH_4$, leading to the corresponding alcohols (eq 13),[15] and can act as sources of oxygen centered radicals.[24] Similarly, sulfur dioxide inserts readily into both primary and secondary alkyl $RCo^{III}(dmgH)_2$ complexes (eq 14). However, phenyl, vinyl, and styryl complexes have been shown to be inert to O_2 and SO_2.[34] Homolysis of $RCo^{III}(dmgH)_2$ complexes in the presence of carbon monoxide does not normally lead to acylcobalt complexes. If the reaction is carried out in an alcoholic solvent, however, then alkoxycarbonyl$Co^{III}(dmgH)_2$ ($ROCOCo^{III}(dmgH)_2$) complexes are formed, where the alkoxy group is derived from the solvent (eq 15).[35]

Homolytic cleavage of $RCo^{III}(dmgH)_2$ complexes in the presence of nitric oxide has been demonstrated. Thus mannosyl bromide yields the corresponding oxime via the mannosylcobaloxime (eq 16).[36] However, either alkyl oximes or nitrates and alcohols can be formed, depending upon the structure of the alkylcobaloximes.[37]

Photolysis of methyl(pyridine)cobaloxime(III) in the presence of alkyl methacrylates leads to selective formation of a dimer.[38] The primary step of this reaction is the formation of the methyl radical, which has been quenched with spin traps such as nitrosodurene or phenyl *t*-butyl nitrone.[39] Methyl radicals add to the β-position of alkyl methacrylates. The persistent cobaloxime(II) radical which is

present in solution traps the adduct radical and regenerates the unsaturation in the product via hydridocobaloxime formation. Hydridocobaloxime is the original catalyst for the dimerization of alkyl methacrylates, adding to the electron deficient acrylate and then formally inserting a second molecule of methacrylate via a radical-generation-alkene-trap-cobaloxime(II)-quench pathway. Subsequent hydridocobaloxime elimination regenerates the catalyst and expels the dimer (eq 17). General radical reactions are discussed in the following sections.

Radical Substitution Reactions.

Reactions between allylCo^{III}(dmgH)$_2$ complexes and organic radicals generally proceed via a S_H2' mechanism. Reactions between nitrogen, sulfur, and carbon centered radicals and allylCo^{III}(dmgH)$_2$ complexes lead to a range of 3-substituted propenes (eq 18).[40] Reaction of organic radicals with the terminal unsaturated carbon in but-3-enylCo^{III}(dmgH)$_2$ complexes gives rise to functionalized cyclopropanes via an intramolecular homolytic displacement (eq 19).[40] Alkyl-, allyl-, and benzylCo^{III}(dmgH)$_2$ complexes have been photolyzed in the presence of sulfur and selenium radical traps to provide the corresponding functionalized products in good yield (eq 20).[41]

Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III)

The allylic $Co^{III}(dmgH)_2$ complex prepared from hydrocobaltation of myrcene undergoes trapping by TEMPO (***2,2,6,6-Tetramethylpiperidin-1-oxyl***) upon irradiation in toluene. The resulting hydroxylamine can then be reduced to both nerol and geraniol (eq 21).[24] This conversion of a 1,3-diene to an allylic alcohol via the hydrocobaltation-oxidation sequence compares favorably with the related method of Suzuki utilizing ***Palladium(II) Chloride***.

Radical Cyclization Reactions.

The ease of homolysis of the Co^{III}-carbon bond can be used to good effect in generating carbon centered radicals which can undergo inter- or intramolecular oxidative addition processes. Various 2-allyloxyethyl halides and tosylates react with $Co^{I}(dmgH)_2$ to give the corresponding tetrahydro-3-furanylmethylcobaloximes, which upon irradiation in benzene lead to products arising from β-elimination (eq 22).[42] $Co^{I}(dmgH)_2$ generated electrochemically catalyzes the cyclization of bromoacetal alkenes to give ring-fused tetrahydrofurans (eq 23).[43] In this case, as well as in other catalytic processes, the cyclizations are terminated reductively. An oxidative process has been developed to produce unsaturated β-oxy-γ-butyrolactones via a $Co^{I}(dmgH)_2$ mediated cyclization of the corresponding vinyl ether bromoacetal (eq 24),[44] and used in an approach to kainic acid (eq 25).[45] Tandem radical cyclizations mediated by $Co^{I}(dmgH)_2$ are also possible, with the option that the process can be intercepted after the first cyclization if desired (eq 26).[46]

(23)

(24)

(25)

(26)

Radical cyclizations have also been initiated via the addition of $Co^{I}(dmgH)_2$ to oxiranes. In this case, irradiation of the intermediate β-hydroxycobaloximes with a sunlamp leads to efficient 6-*exo*-trig cyclizations followed by elimination of $HCo^{III}(dmgH)_2$ (eq 27).[47]

(27)

Intermolecular Radical Addition Reactions.

Alkyl radicals produced from the homolysis of alkyl$Co^{III}(dmgH)_2$ complexes can be trapped in an intermolecular fashion by activated alkenes (eq 28).[48] In these cases the unsaturated products are produced via the β-elimination of cobalt and hydrogen (dehydrocobaltation) from the intermediate cobaloxime. The sp^2-sp^2 coupling reaction between alkenes, involving a novel combination of hydrocobaltation-dehydrocobaltation reactions to and from alkenes, has been demonstrated.[49] This overall transformation is a useful alternative to the Heck reaction which cannot be employed in the case of alkyl halides. Irradiation of glycosylcobaloximes in the presence of various activated alkenes has been shown to give rise to either addition or substitution products depending upon the electronic nature of the substitutents on the alkene substrate (eq 29).[50] Nitroalkyl anions have also been employed in cross-coupling reactions giving rise to the corresponding nitro compounds in good yields (eq 30).[51]

Bis(4,5-dimethyl-2-oxo-1,3,2-dioxaphospholenyl) Oxide[1]

[55894-94-5] · $C_8H_{12}O_7P_2$ · Bis(4,5-dimethyl-2-oxo-1,3,2-dioxaphospholenyl) Oxide · (MW 282.13)

(phosphorylating agent; selective for primary alcohols over secondary alcohols, especially in the presence of triethylamine; used for the preparation of various unsymmetrical phosphodiesters; precursor of the more reactive phosphorylating agents 4,5-dimethyl-2-chloro-2-oxo-1,3,2-dioxaphosphole and 4,5-dimethyl-2-(1´-imidazolyl)-2-oxo-1,3,2-dioxaphosphole)

Alternate Names: bis(1,2-dimethylethylene)pyrophosphate; acetoin enediol cyclopyrophosphate.

Physical Data: mp 84-86 °C.

Solubility: widely sol organic solvents.

Preparative Methods: prepared from 4,5-dimethyl-2-methoxy-2-oxo-1,3,2-dioxaphosphole (**1**) by treatment with pyridine in benzene to form the salt (**2**), followed by reaction with phosgene in benzene (eq 1). The solid (**3**) is recrystallized from CH_2Cl_2/hexanes.[2]

(1)

Handling, Storage, and Precautions: the reagent is hydrolyzed by water.

Phosphorylative Coupling of Two Different Alcohols.

The pyrophosphate (**3**) is used for the preparation of unsymmetrical phosphodiesters in a one-pot operation with no additional activation required. The primary alcohol of a diol can be phosphorylated selectively in the presence of an unprotected secondary alcohol.[3] This selectivity is catalyzed by ***Triethylamine***. Thus the reaction of the monoester (**4**) (derived from the reaction of (**3**) with cyclopentanol) with *trans*-2-hydroxymethylcyclopentanol produces the diesters (**6**) and (**7**) in a 98:2 ratio in the presence of triethylamine (eq 2). With no added base, this ratio is 90:10, while in the presence of imidazole the ratio drops to 80:20.[4] The preparation of unsymmetrical phosphodiesters works best if the first alcohol used is the more hindered of the two alcohols to be utilized. As expected, the triethylamine-induced rate enhancement of phosphorylation of a primary alcohol decreases with increasing steric requirements of the alkyl group in the phosphomonoester (**4**). The byproduct salts (**5**) can be reconverted into the pyrophosphate (**3**) by treatment with phosgene.[3]

(3)

(4) **(5)**

(2)

(6) **(7)**

Aminoethanol derivatives can be effectively phosphorylated and coupled with other alcohols (eq 3).[5] The two

phosphotriesters (**8**) and (**9**) were formed in a ratio of 5:1, and could be separated via chromatography.

Phospholipid Derivatives.

Phosphatidyl-6-D-glucose analogs (**13**) can be prepared from the pyrophosphate (**3**) via initial reaction with diacylglycerol (**10**) to form the phosphomonoester (**11**). Subsequent treatment of (**11**) with a suitably protected glucose derivative (**12**) gave (**13**) in 30-50% overall yield (eq 4).[6] Better yields (55-60%) of the final product were obtained with the triprotected glucose (**12a**). Reaction of the initial adduct (**11**) with 0.5 equiv of 2-(*t*-butyldimethyl-siloxy)glycerol forms the basis of the synthesis of diphosphatidylglycerols (cardiolipins).[7]

Nucleotides.

This phosphorylative method has been applied to the syntheses of di- and tetradeoxynucleotides,[8] as well as phospholiponucleotides (**14**) (eq 5).[9]

Preparation of Other Phosphorylating Agents Derived from (3).

Two more reactive (and less selective) phosphorylating agents can be easily derived from the pyrophosphate (**3**). The phosphochloridate (**15**) is formed from the reaction of (**3**) with phosgene (eq 6).[2] This highly reactive phosphorylating reagent reacts well with poorly nucleophilic or sensitive alcohols in high yields in the presence of triethylamine or pyridine.[10] The second derivative (**16**) is formed from the reaction of either the pyrophosphate (**3**) or the phosphorchloridate (**13**) with imidazole.[2] This reagent, while more reactive than (**3**), exhibits less selectivity than (**3**) in the reactions of primary vs. secondary alcohols. ***Imidazole*** has also been found to catalyze the reaction between alcohols (including secondary) and phosphomonoesters such as (**4**).[4]

Bis(2,4-dinitrophenyl) Carbonate[1]

[7497-12-3] · $C_{13}H_6N_4O_{11}$ · Bis(2,4-dinitrophenyl) Carbonate · (MW 394.21)

(peptide and azapeptide coupling reagent that functions by activating amines, forming derivatives suitable for condensation with N-protected amino acids;[1-4] converts carboxylic acids to activated esters[2])

Alternate Names: carbonic acid bis(2,4-dinitrophenyl) ester; 2,4-dinitrophenyl 2,4-dinitrophenoxyformate.

Physical Data: yellow solid, mp 130-131 °C,[5] mp 148 °C;[2] hygroscopic; X-ray structure.[6]

Solubility: sol EtOAc, pyridine, DMF, $CHCl_3$; moderately sol benzene; insol hexane; dec hot H_2O, EtOH.

Preparative Method: diphenyl carbonate (20 g) is added to a stirred mixture of conc HNO_3 (100 mL) and conc H_2SO_4 (120 mL) at 50-55 °C over 1 h. The resulting suspension is stirred at 50 °C for 3 h, left at rt for 90 h and poured onto ice. The precipitate is washed with iced water and dried in vacuo over P_2O_5. This affords bis(2,4-dinitrophenyl) carbonate (31.2 g, 85%) which recrystallizes from hexane/benzene giving crystals, mp 144-146 °C.[3]

Handling, Storage, and Precautions: store in a cool dry place to preclude contact with moisture; the hazardous and toxicological properties have not been investigated; may explode if heated rapidly.

Peptide and Azapeptide Coupling.

The reagent is used to activate amino groups (eq 1) for subsequent coupling with N-protected amino acids and hydrazides, affording peptide (eq 2) and azapeptide (eq 3) derivatives, respectively.[1-4] Cbz-protected amino acids are coupled without racemization but *N*-acylated amino acids lose all optical activity.[2]

Attempts to prepare azapeptides by activating hydrazides have proved unsuccessful because of the propensity of the intermediate to undergo base-catalyzed cyclization and elimination to stable oxadiazolones (eq 4).[3]

(4)

Activated Esters from Carboxylic Acids.

The reagent is attacked by carboxylate ions, forming unstable intermediates which spontaneously decarboxylate to dinitrophenyl esters (eq 5).[2] These activated esters are good acylating agents and undergo transesterification on reaction with alkoxide or aryloxide ions (eq 6).[2] The mild conditions under which these activated dinitrophenyl esters can be formed makes them preferable intermediates to the analogous 4-mononitrophenyl esters which are less active towards nucleophiles; also 2,4-dinitrophenol is more acidic than 4-nitrophenol and consequently may be easier to separate from the desired reaction product during workup.

1,4-Bis(diphenylhydrosilyl)benzene

[3520-15-8] · $C_{30}H_{26}Si_2$ · 1,4-Bis(diphenylhydrosilyl)benzene · (MW 442.71)

(reducing reagent for esters under radical conditions)

Physical Data: mp 108 °C.

Solubility: sol benzene and THF.

Form Supplied in: white solid.

Preparative Methods: easily prepared by the Grignard reaction of ***Chlorodiphenylsilane*** with *p*-dibromobenzene (eq 1).

Handling, Storage, and Precautions: this reagent is stable in air. Because the toxicological properties are unknown, it should be handled in a well-ventilated hood.

(1)

1,4-Bis(diphenylhydrosilyl)benzene is a useful deoxygenating reagent for esters under radical conditions. Thus the reagent reacts with acetates in the presence of the radical generator ***1,1-Di-t-butyl Peroxide*** (DTBP) at 140 °C to give the corresponding hydrocarbons (eq 2). Acetates derived from primary, secondary, and tertiary alcohols are reduced in high yield.[1] Use of this reagent is preferred compared to monosilanes like ***Triphenylsilane***,[2] since the silicon-containing byproducts are higher boiling and more polar. Consequently, alkane products are easily isolated from reductions with this reagent.

This reduction can be applied to deoxygenation of carbohydrates. Both *O*-acetylfuranoses and pyranoses are converted to the corresponding deoxy sugars (Table 1).[3] Acetylated derivatives of sugars which have an anomeric hydroxy group and *vic*-diols are also deoxygenated without any side reactions.[4]

Table 1

Bis(1,3-diphenyl-2-imidazolidinylidene)[1]

[2179-89-7] · $C_{30}H_{28}N_4$ · Bis(1,3-diphenyl-2-imidazolidinylidene) · (MW 444.58)

(electron-rich alkene; useful for formylation of arenes[1])

Physical Data: mp 285 °C (dec).

Form Supplied in: prepared from 1,2-dianilinoethane and triethyl orthoformate.[2]

Handling, Storage, and Precautions: easily autoxidized; reagent that has oxidized may be upgraded by washing with CH_2Cl_2;[2] store under dry nitrogen; reagent readily reacts with protic solvents, e.g. MeOH,[1] and hydrolyzes in the presence of weak acid[3] or basic[1] media.

Arene Formylation.

Phenols treated with bis(1,3-diphenyl-2-imidazolidinylidene) in refluxing DMF give *para*-substituted cyclic aminals, which upon acid-catalyzed hydrolysis yield the corresponding aldehyde (eq 1).[4,5] Multiple substitution can take place when an additional hydroxy or an acetamido moiety is present (eq 2).[6] The reaction tolerates additional substituents on the phenolic ring, including alkyl, cycloalkyl, dialkylamino, chloro, acetamido, 2*H*-1,2,3-triazolyl, phenyl, and alkoxy groups;[4-6] 8-hydroxyquinoline-7-carbaldehyde was prepared in 52% yield.[6]

α-Substituted Aldehydes.

Addition of CH acidic compounds (e.g. $PhCH_2CO_2Et$ or cyclopentanone) to bis(1,3-diphenyl-2-imidazolidinylidene) gives the α-substituted aminals, which upon hydrolysis provide entry into α-substituted aldehydes (eq 3).[1,7]

(3)

Aminoamidines.

Treatment of a primary amine with bis(1,3-diphenyl-2-imidazolidinylidene) gives the aminoamidine,[8] while dialkylamines and carboxamides react to give the 2-aminoimidazolidine[8] or *N*-(2-imidazolidinyl)carboxamides,[9] respectively (eq 4). Sulfonyl amides or phosphoric amides react to give either sulfonylamidines (78-95%) or phosphorylformamidines (83-100%).[10]

(4)

Homologs of 1,3-Diphenyl-2-imidazolidinone.

Treatment of solutions of bis(1,3-diphenyl-2-imidazolidinylidene) with O_2, S_8, or Se^0 gives, respectively, the imidazolidinone (90%),[7] thioimidazolidinone (85%),[11] or the imidazolidineselenone (62%)[12] (eq 5).

(5)

Carbene Complexes.

Palladium(II)[13,14] and platinum(II)[13] carbene complexes (*trans*) have been prepared from bis(1,3-diphenyl-2-imidazolidinylidene), as illustrated in eq 6.

(+)-*trans*-(2*S*,3*S*)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene[1]

(+)

[71042-54-1] · $C_{31}H_{28}P_2$ · (+)-*trans*-(2*S*,3*S*)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene · (MW 462.51) (-)

[71042-55-1] (±)

[76740-45-9]

(ligand for transition metal catalyzed asymmetric hydrogenation of alkenes,[2] α-keto esters,[3] imines,[4] and β-keto esters;[5] homo-Diels-Alder reactions;[6] hydroarylation[7])

Alternate Name: (+)-NORPHOS.

Physical Data: mp 129-130 °C; [α]20D = +45° (*c* = 1.0, $CHCl_3$).

Preparative Method: trans-(2*S*,3*S*)-bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene (*R*,*R*-NORPHOS) has been prepared by reduction (***Trichlorosilane***) of the phosphine oxide, which was resolved with (-)-dibenzoyltartaric acid.[2]

Handling, Storage, and Precautions: NORPHOS is readily oxidized to the phosphine oxide and should be handled under N_2 or Ar. Use in a fume hood.

Asymmetric Hydrogenation.

Numerous optically active phosphines have been utilized for enantioselective hydrogenations of prochiral substrates.[1] In particular, transition metal complexes of (+)-NORPHOS have found particularly widespread use in asymmetric hydrogenations of a variety of unsaturated functional groups. Rhodium catalysts, prepared in situ from the reaction of $[Rh(diene)Cl]_2$ complexes and (+)-NORPHOS, have been reported for use in asymmetric hydrogenations.[2] The use of 80% ***Formic Acid*** as an alternative to hydrogen gas for catalytic alkene hydrogenations has been described.[8] Reduction of the bicyclo[2.2.1]hept-5-ene backbone of (+)-NORPHOS rapidly occurs under catalytic hydrogenation conditions to give the reduced diphosphine which is the actual ligand involved in catalysis (eq 1).[9] Asymmetric hydrogenation of (*Z*)-α-acetylaminocinnamic acid using a Rh complex of (+)-NORPHOS gave (*S*)-$PhCH_2CH(NHAc)CO_2H$ in quantitative yield and 92% ee (eq 2).[2] Similarly, hydrogenation of (*Z*)-α-acetylamino-2-butenoic acid occurred with 91.4% ee.[10] An additional example of the asymmetric hydrogenation of α-acetylaminoacrylic esters was reported in a synthesis of phosphinothricin in 91% ee (eq 3).[11] High enantiomeric excesses for alkene hydrogenation with (+)-NORPHOS are limited to α-acetylaminoacrylates which are capable of forming a chelate structure involving rhodium, the alkenic double bond, and the acetylamino functional group.

(1)

(2)

(3)

Rhodium complexes of (+)-NORPHOS have also been used for enantioselective hydrogenation of carbon-oxygen and carbon-nitrogen double bonds. Hydrogenation of $PhCH_2CH_2COCO_2Et$ with a catalyst prepared from ***Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium*** and (+)-NORPHOS gave a quantitative yield of $PhCH_2CH_2CH(OH)CO_2Et$ with 96% ee (eq 4).[3] Kinetic resolutions of racemic β-keto esters have been performed using asymmetric hydrogenation in the synthesis of (+)- and (-)-threonine.[5] Enantioselective hydrogenation of imines using a Rh complex of (+)-NORPHOS has been reported. Hydrogenation of $ArN{=}C(Me)CH_2OMe$ occurred with 61%

ee (eq 5).[4] The product enantioselectivity using NORPHOS was comparable to that observed using other diphosphine ligands.

(4)

(5)

Homo-Diels-Alder Reactions.

The enantioselective synthesis of deltacyclenes from norbornadiene and monosubstituted alkynes has been catalyzed by a cobalt catalyst prepared from ***Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS***. 4-Phenyldeltacyclene was obtained in quantitative yield with >98% ee (eq 6).[6]

(6)

Asymmetric Alkene Hydroarylation.

The enantioselective addition of aryl iodides to norbornene has been reported using a palladium(II) complex of (+)-NORPHOS.[7] The reaction of norbornadiene with 4-methoxyiodobenzene proceeded with 40.6% ee (eq 7).

(*R*)- & (*S*)-2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl[1]

[76189-55-4] · $C_{44}H_{32}P_2$ · 2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl · (MW 622.70)

(chiral diphosphine ligand for transition metals;[2] the complexes show high enantioselectivity and reactivity in a variety of organic reactions)

Alternate Name: BINAP.

Physical Data: mp 241-242 °C; [α]25D -229° (*c* = 0.312, benzene) for (*S*)-BINAP.[3]

Solubility: sol THF, benzene, dichloromethane; modestly sol ether, methanol, ethanol; insol water.

Form Supplied in: colorless solid.

Analysis of Reagent Purity: GLC analysis (OV-101, capillary column, 5 m, 200-280 °C) and TLC analysis (E. Merck Kieselgel 60 PF_{254}, 1:19 methanol-chloroform); R_f 0.42 (BINAPO, dioxide of BINAP), 0.67 (monoxide of BINAP), and 0.83 (BINAP). The optical purity of BINAP is analyzed after oxidizing to BINAPO by HPLC using a Pirkle column (Baker bond II) and a hexane/ethanol mixture as eluent.[3]

Preparative Methods: enantiomerically pure BINAP is obtained by resolution of the racemic dioxide, BINAPO, with camphorsulfonic acid or 2,3-di-*O*-benzoyltartaric acid followed by deoxygenation with ***Trichlorosilane*** in the presence of ***Triethylamine***.[3]

Handling, Storage, and Precautions: solid BINAP is substantially stable to air, but bottles of BINAP should be flushed with N_2 or Ar and kept tightly closed for prolonged storage. BINAP is slowly air oxidized to the monoxide in solution.

BINAP-Ru^{II} Catalyzed Asymmetric Reactions.

Halogen-containing BINAP-Ru complexes are most simply prepared by reaction of $[RuCl_2(cod)]_n$ or $[RuX_2(arene)]_2$ (X = Cl, Br, or I) with BINAP.[4] Sequential treatment of $[RuCl_2(benzene)]_2$ with BINAP and sodium carboxylates affords Ru(carboxylate)$_2$(BINAP) complexes. The dicarboxylate complexes, upon treatment with strong acid HX,[5] can be converted to a series of Ru complexes empirically formulated as RuX_2(BINAP). These Ru^{II} complexes act as catalysts for asymmetric hydrogenation of various achiral and chiral unsaturated compounds.

α,β-Unsaturated carboxylic acids are hydrogenated in the presence of a small amount of Ru(OAc)$_2$(BINAP) to give the corresponding optically active saturated products in quantitative yields.[6] The reaction is carried out in methanol at ambient temperature with a substrate:catalyst (S:C) ratio of 100-600:1. The sense and degree of the enantioface differentiation are profoundly affected by hydrogen pressure and the substitution pattern of the substrates. Tiglic acid is hydrogenated quantitatively with a high enantioselectivity under a low hydrogen pressure (eq 1), whereas naproxen, a commercial anti-inflammatory agent, is obtained in 97% ee under high pressure (eq 2).[6a]

(1)

(2)

Enantioselective hydrogenation of certain α- and β-(acylamino)acrylic acids or esters in alcohols under 1-4 atm H_2 affords the protected α- and β-amino acids, respectively (eqs 3 and 4).[2a,7] Reaction of *N*-acylated 1-alkylidene-1,2,3,4-

tetrahydroisoquinolines provides the 1*R*- or 1*S*-alkylated products. This method allows a general asymmetric synthesis of isoquinoline alkaloids (eq 5).[8]

Geraniol or nerol can be converted to citronellol in 96-99% ee in quantitative yield without saturation of the C(6)-C(7) double bond (eq 6).[9] The S:C ratio approaches 50 000. The use of alcoholic solvents such as methanol or ethanol and initial H_2 pressure greater than 30 atm is required to obtain high enantioselectivity. Diastereoselective hydrogenation of the enantiomerically pure allylic alcohol with an azetidinone skeleton proceeds at atmospheric pressure in the presence of an (*R*)-BINAP-Ru complex to afford the β-methyl product, a precursor of 1β-methylcarbapenem antibiotics (eq 7).[10] Racemic allylic alcohols such as 3-methyl-2-cyclohexenol and 4-hydroxy-2-cyclopentenone can be effectively resolved by the BINAP-Ru-catalyzed hydrogenation (eq 8).[11]

(6)

(7)

(8)

Diketene is quantitatively hydrogenated to 3-methyl-3-propanolide in 92% ee (eq 9). Certain 4-methylene- and 2-alkylidene-4-butanolides as well as 2-alkylidenecyclopentanone are also hydrogenated with high enantioselectivity.[12]

(9)

Hydrogenation with halogen-containing BINAP-Ru complexes can convert a wide range of functionalized prochiral ketones to stereo-defined secondary alcohols with high enantiomeric purity (eq 10).[13] 3-Oxocarboxylates are among the most appropriate substrates.[13a,4d] For example, the enantioselective hydrogenation of methyl 3-oxobutanoate proceeds quantitatively in methanol with an S:C ratio of 1000-10 000 to give the hydroxy ester product in nearly 100% ee (eq 11). Halogen-containing complexes RuX_2(BINAP) (X = Cl, Br, or I; polymeric form) or $[RuCl_2(BINAP)]_2NEt_3$ are used as the catalysts. Alcohols are the solvents of choice, but aprotic solvents such as dichloromethane can also be used. At room temperature the reaction requires an initial H_2 pressure of 20-100 atm, but at 80-100 °C the reaction proceeds smoothly at 4 atm H_2.[4c,4d]

(10)

R^1 = alkyl, aryl; R^2 = CH_2OH, CH_2NMe_2, CH_2CH_2OH, CH_2Ac, CH_2CO_2R, CH_2COSR, CH_2CONR_2, $CH_2CH_2CO_2R$, etc.

(11)

R = Me, Et, Bu, *i*-Pr; R′ = Me, Et, *i*-Pr, *t*-Bu

3-Oxocarboxylates possessing an additional functional group can also be hydrogenated with high enantioselectivity by choosing appropriate reaction conditions or by suitable functional group modification (eq 12).[13b,13c]

(12)

The pre-existing stereogenic center in the chiral substrates profoundly affects the stereoselectivity. The (*R*)-BINAP-Ru-catalyzed reaction of (*S*)-4-(alkoxycarbonylamino)-3-oxocarboxylates give the statine series with (3*S*,4*S*) configuration almost exclusively (eq 13).[14]

(13)

Hydrogenation of certain racemic 2-substituted 3-oxocarboxylates occurs with high diastereo- and enantioselectivity via dynamic kinetic resolution involving in situ racemization of the substrates.[15] The (*R*)-BINAP-Ru-catalyzed reaction of 2-acylamino-3-oxocarboxylates in dichloromethane allows preparation of threonine and DOPS (anti-Parkinsonian agent) (eq 14).[16] In addition, a common intermediate for the synthesis of carbapenem antibiotics is prepared stereoselectively on an industrial scale from a 3-oxobutyric ester (**1**) with an acylaminomethyl substituent at the C(2) position.[16a] The second-order stereoselective hydrogenation of 2-ethoxycarbonylcycloalkanones gives predominantly the *trans* hydroxy esters (**2**) in high ee, whereas 2-acetyl-4-butanolide is hydrogenated to give the *syn* diastereomer (**3**).[17]

(14)

(1)
syn:*anti* = 94:6
98% ee

(2)
R = CH_2, $(CH_2)_2$, $(CH_2)_3$
trans:*cis* = 93:7-99:1
90-93% ee

(3)
syn:*anti* = 98:2
94% ee

Certain 1,2- and 1,3-diketones are doubly hydrogenated to give stereoisomeric diols. 2,4-Pentanedione, for instance, affords (*R*,*R*)- or (*S*,*S*)-2,4-pentanediol in nearly 100% ee accompanied by 1% of the *meso* diol.[13b]

A BINAP-Ru complex can hydrogenate a C=N double bond in a special cyclic sulfonimide to the sultam with >99% ee.[18]

The asymmetric transfer hydrogenation of the unsaturated carboxylic acids using formic acid or alcohols as the hydrogen source is catalyzed by Ru(acac-F_6)(η^3-C_3H_5)(BINAP) or [RuH(BINAP)$_2$]PF_6 to produce the saturated acids in up to 97% ee (eq 15).[19]

BINAP-Ru complexes promote addition of arenesulfonyl chlorides to alkenes in 25-40% optical yield.[20]

BINAP-Rh^I Catalyzed Asymmetric Reactions.

The rhodium(I) complexes [Rh(BINAP)(cod)]ClO_4, [Rh(BINAP)(nbd)]ClO_4, and [Rh(BINAP)$_2$]ClO_4, are prepared from [RhCl(cod)]$_2$ or ***Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium*** and BINAP in the presence of $AgClO_4$.[21] [Rh(BINAP)S_2]ClO_4 is prepared by reaction of [Rh(BINAP)(cod or nbd)]ClO_4 with atmospheric pressure of hydrogen in an appropriate solvent, S.[21a] BINAP-Rh complexes catalyze a variety of asymmetric reactions.[2]

Prochiral α-(acylamino)acrylic acids or esters are hydrogenated under an initial hydrogen pressure of 3-4 atm to give the protected amino acids in up to 100% ee (eq 16).[21a] The BINAP-Rh catalyst was used for highly diastereoselective hydrogenation of a chiral homoallylic alcohol to give a fragment of the ionophore ionomycin.[22]

The cationic BINAP-Rh complexes catalyze asymmetric 1,3-hydrogen shifts of certain alkenes. Diethylgeranylamine can be quantitatively isomerized in THF or acetone to citronellal diethylenamine in 96-99% ee (eq 17).[23] This process is the key step in the industrial production of (-)-menthol. In the presence of a cationic (*R*)-BINAP-Rh complex, (*S*)-4-hydroxy-2-cyclopentenone is isomerized five times faster than the (*R*) enantiomer, giving a chiral intermediate of

prostaglandin synthesis.[24]

(17)

Enantioselective cyclization of 4-substituted 4-pentenals to 3-substituted cyclopentanones in >99% ee is achieved with a cationic BINAP-Rh complex (eq 18).[25]

(18)

Reaction of styrene and catecholborane in the presence of a BINAP-Rh complex at low temperature forms, after oxidative workup, 1-phenylethyl alcohol in 96% ee (eq 19).[26]

(19)

Neutral BINAP-Rh complexes catalyze intramolecular hydrosilylation of alkenes. Subsequent ***Hydrogen Peroxide*** oxidation produces the optically active 1,3-diol in up to 97% ee (eq 20).[27]

(20)

BINAP-Pd Catalyzed Asymmetric Reactions.

BINAP-Pd^0 complexes are prepared in situ from ***Bis(dibenzylideneacetone)palladium(0)*** or $Pd_2(dba)_3.CHCl_3$ and BINAP.[28] BINAP-Pd^{II} complexes are formed from ***Bis(allyl)di-μ-chlorodipalladium***, ***Palladium(II) Acetate***, or $PdCl_2(MeCN)_2$ and BINAP.[29-31]

A BINAP-Pd complex brings about enantioselective 1,4-disilylation of α,β-unsaturated ketones with chlorinated disilanes, giving enol silyl ethers in 74-92% ee (eq 21).[29]

(21)

A BINAP-Pd^{II} complex catalyzes a highly enantioselective C-C bond formation between an aryl triflate and 2,3-dihydrofuran (eq 22).[30] The intramolecular version of the reaction using an alkenyl iodide in the presence of $PdCl_2$[(*R*)-BINAP] and ***Silver(I) Phosphate*** allows enantioselective formation of a bicyclic ring system (eq 23).[31]

Enantioselective electrophilic allylation of 2-acetamidomalonate esters is effected by a BINAP-Pd^0 complex (eq 24).[32]

A BINAP-Pd^0 complex catalyzes hydrocyanation of norbornene to the *exo* nitrile with up to 40% ee.[28]

BINAP-Ir^I Catalyzed Asymmetric Reactions.

[Ir(BINAP)(cod)]BF_4 is prepared from [Ir(cod)(MeCN)$_2$]BF_4 and BINAP in THF.[33]

A combined system of the BINAP-Ir complex and bis(*o*-dimethylaminophenyl)phenylphosphine or (*o*-dimethylaminophenyl)diphenylphosphine catalyzes hydrogenation of benzylideneacetone[33a] and cyclic aromatic ketones[33b] with modest to high enantioselectivities (eq 25).

1,4-Bis(diphenylphosphino)butane

[7688-25-7] · $C_{28}H_{28}P_2$ · 1,4-Bis(diphenylphosphino)butane · (MW 426.48)

(ligand for metal-catalyzed lactonization of unsaturated alcohols;[1] allylic substitution;[2] cyclization reactions;[3] carbonylations;[4] alkyne isomerization;[5] alkyne-CO_2 coupling[6])

Alternate Name: dppb.

Physical Data: mp 135-137 °C.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: readily oxidized in solution to the phosphine oxide and should be handled under N_2 or Ar. The compound is air-stable in the solid state.

Lactonization of Unsaturated Alcohols.

Allylic and propargylic alcohols can be converted to lactones by carbonylation using a catalyst prepared from ***Tris(dibenzylideneacetone)dipalladium*** and dppb (eq 1).[1] Lactones are formed with secondary and tertiary alcohols. Primary allylic alcohols give α,β-unsaturated carboxylic acids (eq 2).

(1)

(2)

Allylic Substitution.

Alkylation of allyl acetates by dimethyl malonate derivatives is catalyzed by ***Palladium(II) Acetate***-dppb (eq 3).[2] Alkylation of the Pd(π-allyl) intermediate occurs exclusively at the terminal position. Regioselective addition to the internal position can be accomplished with $(MeCN)_3W(CO)_3$ in pyridine. Allylic azides can be prepared by reaction of ***Sodium Azide*** with allyl acetates using a catalyst prepared from $Pd_2(dba)_3$ and dppb (eq 4).[7] Addition of dimethyl sodiomalonate to 1-chloro-1-vinylcyclopropanes results in methylenecyclopropanes (eq 5).[8]

Cyclization Reactions.

Synthesis of pyrrolidines and furans by intramolecular allylation of alkenes is catalyzed by ***Bis(1,5-cyclooctadiene)nickel(0)***-dppb (eq 6).[3] Macrocyclization to give the 21-membered ring was catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)***-dppb (eq 7).[9]

(6)

(7)

Hydroacylation Reactions.

Carbonylation of vinylarenes with formate esters is catalyzed by $Pd(PPh_3)_4$-dppb under CO. A mixture of linear and branched esters is formed from the reaction of *p*-methylstyrene and *n*-butyl formate (eq 8).[4] Hydroformylation of unsaturated amides is catalyzed by $Rh(PPh_3)_3(CO)H$ and dppb to give nitrogen heterocycles (eq 9).[10]

(8)

(9)

Alkyne Isomerizations.

Isomerization of alkynones to dienones was catalyzed by $Pd(OAc)_2$-dppb (eq 10).[5] The (*E*,*E*)-diene was stereoselectively formed.

(10)

Alkyne-CO_2 Coupling.

Nickel(0) complexes of dppb catalyze the coupling of alkynes with carbon dioxide to give pyrones (eq 11).[6] Bicyclic products can be formed by coupling of CO_2 with diynes.[11]

(2*R*,3*R*)-2,3-Bis(diphenylphosphino)butane[1]

(2*R*,3*R*)

[74839-84-2] · $C_{28}H_{28}P_2$ · 2,3-Bis(diphenylphosphino)butane · (MW 426.48) (2*S*,3*S*)

[64896-28-2]

(ligand for asymmetric hydrogenation of alkenes[2] and β-keto esters;[3] allylic alkylation;[4] hydroarylation[5])

Alternate Name: (*R*,*R*)-CHIRAPHOS.

Physical Data: mp 107-109 °C; [α]20D +195° (*c* = 1.5, $CHCl_3$).

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: is indefinitely stable in air in the solid state. Solutions of CHIRAPHOS are readily oxidized to the phosphine oxide and should be handled under N_2 or Ar.[2]

Asymmetric Hydrogenation.

CHIRAPHOS has been employed in the enantioselective hydrogenation of a variety of unsaturated functional groups. The asymmetric hydrogenation of cinnamic acid derivatives has been extensively studied due to its relevance to the commercial synthesis of amino acids, such as L-Dopa.[1] Hydrogenation of (*Z*)-α-benzoylaminocinnamic acid is catalyzed in quantitative yield and 98% ee by a cationic rhodium complex prepared from $[Rh(cod)_2](ClO_4)$ and (*S*,*S*)-CHIRAPHOS (eq 1).[2] Asymmetric hydrogenations have also been performed using racemic CHIRAPHOS which has been resolved in situ by a substrate-induced kinetic resolution.[6] When racemic CHIRAPHOS (2 equiv) was reacted with complex (**1**) (R = (-)-menthyl), (*S*,*S*)-CHIRAPHOS selectively coordinated to Ir. This resulting (*S*,*S*)-CHIRAPHOS-Ir complex is catalytically inactive for alkene hydrogenation under typical conditions. In the presence of this Ir complex the remaining uncoordinated (*R*,*R*)-CHIRAPHOS is then utilized for rhodium-catalyzed hydrogenation of methyl (*Z*)-α-acetylaminocinnamate (eq 2). The enantiomeric excess using this route is identical to

that observed with authentic (*R*,*R*)-CHIRAPHOS.

(1)

(1)

(2)

Rhodium and ruthenium complexes of CHIRAPHOS are also useful for the asymmetric hydrogenation of β-keto esters. Dynamic kinetic resolution of racemic 2-acylamino-3-oxobutyrates was performed by hydrogenation using ((*S*,*S*)-CHIRAPHOS)$RuBr_2$ (eq 3).[3] The product yields and enantiomeric excesses were dependent upon solvent, ligand, and the ratio of substrate to catalyst. Under optimum conditions a 97:3 mixture of *syn* and *anti* β-hydroxy esters was formed, which was converted to D-threonine (85% ee) and D-allothreonine (99% ee) by hydrolysis and reaction with propylene oxide.

(2R,3R)-2,3-Bis(diphenylphosphino)butane

Allylic Alkylation.

The palladium-catalyzed asymmetric alkylation of 1,3-diphenyl-2-propenyl acetate with dimethyl sodiomalonate produces (**2**) in 86% yield and 90% ee (eq 4).[4] CHIRAPHOS was found to give higher enantioselectivity than both ***2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl*** (BINAP) and ***(+)-trans-(2S,3S)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene*** (NORPHOS). Alkylation using other malonic acid derivatives gave similar optical yields. The product enantiomeric excess was reported to be greatly dependent upon the method of catalyst preparation.

Alkene Hydroarylation.

The enantioselective addition of aryl iodides to norbornene has been reported using a palladium(II) complex of (*S*,*S*)-CHIRAPHOS. The reaction of norbornadiene with 4-methoxyiodobenzene proceeded with 30% ee (eq 5).[5] Enantioselectivities were dependent upon phosphine structure (see ***(+)-trans-(2S,3S)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene***).

1,2-Bis(diphenylphosphino)ethane

[1663-45-2] · $C_{26}H_{24}P_2$ · 1,2-Bis(diphenylphosphino)ethane · (MW 398.42)

(ligand for metal-catalyzed allylic alkylation;[1] decarboxylation of allylic esters;[2] 1,3-diene synthesis;[3] cycloaddition reactions;[4] carbonylation reactions[5])

Alternate Name: DIPHOS; dppe.

Physical Data: mp 140-142 °C.

Solubility: sol THF, $CHCl_3$, CH_2Cl_2, Et_2O, and other organic solvents.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: solutions are readily oxidized to the phosphine oxide and should be handled under N_2 or Ar. Solid samples can be handled in air. DIPHOS exhibits cytotoxic activity.

Allylation.

DIPHOS has been extensively used for palladium-catalyzed addition of nucleophiles to allylic substrates. Addition of enolates to allylic acetates provides a convenient method for the allylation of ketones (eq 1).[1] A variety of nitrogen[6] and sulfur[7] nucleophiles can also be utilized. Addition of diethyl sodiomalonate to vinylcyclopropyl tosylates produces methylenecyclopropanes (eq 2).[8] Regioselective alkylation of allylic dicarbonates occurs at the primary carbonate followed by conversion to vinylcyclopropanes (eq 3).[9] Addition of nucleophiles to propargyl carbonates is also catalyzed by palladium complexes of DIPHOS.[10] β-Keto esters with only one active hydrogen give double alkylation products (eq 4). The reaction of propargylic carbonates with β-dicarbonyl compounds which contain two active hydrogens results in monosubstitution followed by intramolecular *O*-alkylation to form 4-methylene-4,5-dihydrofurans (eq 5).

(3)

Decarboxylation of Allylic Esters.

Palladium-DIPHOS catalyzes the decarboxylation of allyl esters (eq 6).[2] *O*-Allyl dithiocarbonates undergo loss of COS with palladium(0)-DIPHOS to give thioethers.[11] Allyl carbonates and *S*-allyl dithiocarbonates fail to react under similar conditions.

1,3-Diene Synthesis.

Palladium-DIPHOS complexes catalyze the formation of 1,3-dienes from the reaction of allenes, vinyl halides, and nucleophiles (eq 7).[3] Use of benzylic halides leads to substituted vinylarenes.

(7)

Cycloaddition Reactions.

The [3 + 2] cycloaddition of Pd-trimethylenemethane intermediates with alkenes provides access to methylenecyclopentanes (eq 8). Electron-deficient alkenes with ester, nitrile, and sulfone substituents readily undergo reaction. The homo-Diels-Alder cycloaddition of norbornadiene with alkynes is catalyzed by a cobalt-DIPHOS complex (eq 9).[12] Use of optically active phosphines produces deltacyclenes in high enantiomeric excesses (see ***(+)-trans-(2S,3S)-Bis(diphenylphosphino)bicyclo[2.2.1]hept-5-ene*** (NORPHOS)).

(8)

(9)

Carbonylation Reactions.

Palladium-DIPHOS catalyzes the alkoxycarbonylation of 3-chlorobutene in ethanol at 1 atm to give ethyl 3-pentenoate.[5] Carbonylation of propargyl carbonates at 15 atm produces dienoic esters (eq 10).[13]

1,2-Bis(diphenylphosphino)ethane Tetrabromide[1]

[7726-95-6] · $C_{26}H_{24}Br_4P_2$ · 1,2-Bis(diphenylphosphino)ethane Tetrabromide · (MW 718.04)

(reagent capable of effecting the conversion of alcohols and tetrahydropyranyl ethers into bromides rapidly and efficiently in the presence of other sensitive functional groups[1])

Solubility: sol CH_2Cl_2.

Preparative Method: generated in situ by treatment of 1,2-bis(triphenylphosphino)ethane with 2 equiv of bromine in dry dichloromethane at 0 °C under an inert atmosphere.[1]

Handling, Storage, and Precautions: the usual care should be taken to avoid contact of the skin with liquid bromine.

Conversion of Alcohols and THP Ethers to Bromides.

A frequently required synthetic transformation is the conversion of alcohols or protected forms thereof into the corresponding bromides or iodides. Although a myriad of reagents are available for performing this interconversion,[2] many are too harsh to operate successfully on highly sensitive molecules. Some time ago, ***Triphenylphosphine Dibromide*** was recognized to be capable of effecting the formation of bromides directly from tetrahydropyranyl ethers.[3,4] More spectacular still is the ability of 1,2-bis(diphenylphosphino)ethane tetrabromide to effect either of the preceding chemical changes in rapid fashion under extraordinarily mild conditions (eqs 1-3).[1] As can be seen in these examples, double and triple bonds, *t*-butyldimethylsilyl ethers, and carboxylate esters are stable in the presence of this reagent.

Usefully, the phosphorus-containing byproducts of this halogenation are not soluble in a solvent system composed of pentane/ether/dichloromethane (2:1:0.5). In the instances where the bromide product dissolves in this mixture, simple dilution and filtration suffice for isolation purposes.[1]

Although the inertness of the allylic silyl ether moiety demonstrated in eq 3 is noteworthy, the extraordinary mildness of this brominating agent is best reflected in its capability to function as advertized on the sensitive furanocembranoid precursors exemplified in eqs 4 and 5.[5,6] Comparable efficiency was not at all closely approximated by other means.

1,1´-Bis(diphenylphosphino)ferrocene[1]

[12150-46-8] · $C_{34}H_{28}FeP_2$ · 1,1´-Bis(diphenylphosphino)ferrocene · (MW 554.39)

(chelating ligand capable of supporting hydroformylations,[2] cross coupling,[7] allylation,[20] carbonylative coupling,[23] and other catalytic processes employing Group 9 and 10 transition metals)

Alternate Name: dppf.

Physical Data: mp 183-184 °C dec.

Solubility: very sol $CHCl_3$, CH_2Cl_2, and alcohol; sol pentane; insol H_2O.

Form Supplied in: white solid, <97% purity, widely available.

Handling, Storage, and Precautions: the reagent is stable to air, unaffected by H_2O and can be stored for long periods of time. The toxic properties are not known.

Homogeneous Catalysis.

The reagent is an effective supporting ligand for a wide variety of catalytic reactions involving Group 9 and 10 metals. Rhodium-catalyzed hydroformylations of alkenes employing dppf result in higher regioselectivity for the linear aldehyde than when monophosphines are used.[2] The *cis* chelating nature of the ligand, compared to monophosphines, also allows lower ligand/metal ratios. The use of dppf in the rhodium-catalyzed hydroformylation of allyl alcohol, which is a convenient route to 1,4-butanediol, gives higher linear/branched selectivities than ***Triphenylphosphine*** under equivalent conditions (eq 1).[3] Likewise, slightly enhanced regioselectivities favoring the linear product are observed in the dppf supported hydroformylations of methyl acrylate and methyl methacrylate, a useful route to 1,3- and 1,4-difunctional compounds.[4] The dppf ligand demonstrates a very high degree of regioselectivity when employed in the palladium-catalyzed hydroesterification and hydrocarboxylation of perfluoroalkyl and perfluoroaryl alkenes (eq 2). With its use, linear/branched ratios of close to 100 have been observed.[5]

$PdCl_2$(dppf)	1	99

Nickel and palladium phosphine complexes catalyze cross-coupling reactions of organic electrophiles (R-X) and organometallic reagents (R´-M), demonstrating a very high degree of selectivity in product formation (R-R´).[6] This process has been most extensively used in coupling reactions of reagents which lack β-hydrogens, and are not susceptible to β-hydride eliminations. However, the palladium-dppf complex, ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)***, cleanly and selectively catalyzes cross couplings of secondary alkyl organometallic reagents without the usual side reactions of isomerization and reduction observed with other phosphines (eq 3).[7] Likewise, the nickel complex, $NiCl_2$(dppf), is the most selective catalyst for the cross coupling of tertiary alkyl Grignard reagents with vinyl halides.[8] The unprecedented effectiveness of the dppf complexes in catalyzing carbon-carbon bond formation is attributed to the large value of the P-Pd-P bond angle in these rigid ligands.[7b]

M = Mg, $PdCl_2(PPh_3)_2$, 24 h	4%	6%	31%
$PdCl_2$(dppf), 1 h	95%	0%	0%
M = Zn, $PdCl_2(PPh_3)_2$, 24 h	1%	2%	78%
$PdCl_2$(dppf), 20 h	100%	0%	0%

Cross-coupling reactions of organic halides with vinyl Grignards,[9] copper acetylides,[10] and organotin compounds[11] are most efficiently promoted by Pd^{II} dppf complexes, giving high yields, under mild conditions, with little or no homocoupling. The $PdCl_2$(dppf)-catalyzed coupling of dihaloaromatic compounds with ***Bis(1-methoxy-2-methyl-1-propenyloxy)dimethylsilane*** affords a new, simple, high-yield route to conducting polyarenediylvinylenes (eq 4).[12] The direct cyanation of nonactivated aryl halides and triflates with ***Potassium Cyanide*** is catalyzed by various nickel and palladium phosphine catalysts.[13] Again, the bis-chelating ligand dppf has been demonstrated to be the most effective ligand for this reaction, giving high yields of nitriles in a variety of solvents.[13b]

Diphosphine Ni^{II} or Pd^{II} complexes are the most effective catalysts for the preparation of alkylated heterocycles.[14] The $PdCl_2$(dppf)-catalyzed coupling of 2-(methylthio)oxazoles and -oxazolines with organometallic reagents results in high yields of the synthetically useful 2-alkyl or 2-aryl substituted heterocycles (eq 5).[15]

(5)

$L_2 = (PPh_3)_2$	24%	26%
dppf	99%	

The palladium-dppf-catalyzed cross coupling of organoboron compounds with organic halides is a useful method for carbon-carbon bond formation.[16] The hydroboration of haloalkyldienes, followed by intramolecular coupling, affords five- and six-membered rings in high yield.[17] The potential versatility of this process is demonstrated by the ready formation of stereodefined exocyclic alkenes (eq 6). Bipyridines are readily prepared by the palladium-dppf-catalyzed coupling of pyridine boronic acids with substituted halopyridines.[18]

(6)

75%

A particularly useful synthetic process is the catalyzed nucleophilic substitution of allylic compounds.[19] The cross coupling of allylic ethers with Grignard reagents is efficiently catalyzed by the use of nickel and palladium complexes with dppf.[20] The two metals exhibit a useful regioselective divergence (eq 7).[20b] The nickel catalyst leads to carbon-carbon bond formation at the more substituted position while carbon-carbon bond formation occurs at the less substituted position with the palladium catalyst. The use of phosphine ligands other than dppf significantly degrades both the regioselectivity and efficiency of the catalyst. The fact that the isomeric silyl ethers (**1**) and (**2**) give identical product ratios argues strongly for a common π-allylmetal intermediate.

The stereochemical course of the reaction depends on the nature of the carbon nucleophile.[20b,21] A nonstabilized nucleophile such as an alkyl, aryl, or vinyl organometallic gives products with overall inversion of configuration, whereas a resonance stabilized nucleophile such as a malonate yields products with overall retention of configuration (eq 8).

2-Butenylene dicarbamates readily undergo cyclization in the presence of phosphine-palladium(0) catalysts to produce 4-vinyl-2-oxazolidones in high yields.[22] The use of bis-chelating phosphines such as dppf increases the regioselectivity of the reaction, favoring attack of the Pd^0 species on the allylic substrate at the sterically less hindered carbon (eq 9).

The palladium-catalyzed carbonylative coupling of organic halides with terminal alkynes offers a mild, simple, and

selective synthesis of unsymmetrical alkynic ketones.[23] In most cases, $PdCl_2$(dppf) is the best catalyst among a wide range of Pd^{II}-phosphine or Pd^{II}-arsine complexes. The dppf ligand profoundly increases the reactivity of the catalyst, such that selective ketone formation is possible at atmospheric pressures of carbon monoxide. Palladium-catalyzed carbonylative coupling of *o*-iodophenol with phenylacetylene, followed by in situ cyclization, provides a direct entry to the basic skeletons of the biologically active isoflavanones (**3**) and aurones (**4**) (eq 10).[24] The regiochemical outcome of the reaction can be altered by the addition of base to the reaction.

(10)

	(3)	(4)
$Pd(PPh_3)_3$	0%	68%
$Pd(OAc)_2$(dppf)	0%	100%
$Pd(OAc)_2$(dppf), DBU	92%	8%

Macrocyclic lactones having from 12 to 16 members are synthesized by the Pd-phosphine-catalyzed carbonylative coupling of esters having vinylstannane and vinyl triflate termini.[25] These couplings occur under mild conditions, tolerate a range of functional groups, are regiospecific, and are insensitive to ring size. However, formation of linear oligomers results in modest yields of lactone. A polystyrene supported dppf ligand system has been synthesized by copolymerization of styrene, *p*-divinylbenzene, and bis(diphenylphosphino)vinylferrocene.[26] Palladium catalysts supported on this polymer are more selective for large ring lactones, and linear oligomerization is suppressed (eq 11).

1,3-Bis(diphenylphosphino)propane

[6737-42-4] · $C_{27}H_{26}P_2$ · 1,3-Bis(diphenylphosphino)propane · (MW 412.45)

(ligand for metal-catalyzed substitution reactions of aryl and vinyl triflates,[1] halides,[2] and carbonates;[3] carbonylation reactions;[4] Grignard coupling;[5] diene alkylation;[6] macrocycle synthesis[7])

Alternate Name: dppp.

Physical Data: mp 63-65 °C.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: solutions are readily oxidized to the phosphine oxide and should be handled under N_2 or Ar. Solid samples of dppp are air stable.

Substitution Reactions.

Metal complexes of dppp catalyze the substitution of aryl triflates with a variety of reagents. A palladium complex of dppp catalyzes the deoxygenation of phenols via the corresponding triflate (eq 1).[1] A variety of functional groups can be introduced, including acetyl,[2] vinyl,[8] and phosphoryl[9] substituents. These reagents also catalyze the substitution reaction of aryl bromides with vinyl ethers (eq 2).[2] A palladium-dppp complex has been used for the conversion of allylic carbonates to sulfides (eq 3).[3]

(1)

Carbonylation Reactions.

Palladium-dppp complexes catalyze the high-pressure carbonylation of allylic amines to give the corresponding amides (eq 4).[4] Aryl triflates undergo carbonylation in MeOH with the formation of the methyl ester (eq 5).[10] In the presence of alkynes, vinyl triflates are carbonylated to produce alkynyl vinyl ketones.[11] Aldehydes are decarbonylated in high yield by dppp in the presence of ***Carbonyl(chloro)bis(triphenylphosphine)rhodium(I)*** (eq 6).[12]

(5)

(6)

Grignard Coupling Reactions.

The coupling of aryl and alkyl halides with Grignard reagents is efficiently catalyzed by Ni complexes of dppp (eq 7).[5] The substitution of vinyl sulfides with ***Methylmagnesium Bromide*** in the presence of ***Dichlorobis(triphenylphosphine)nickel(II)*** and dppp leads to alkenes.[13]

(7)

Diene Alkylation.

Nucleophilic addition of β-dicarbonyl enolates to dienes is catalyzed by Pd-dppp and NaOMe (eq 8).[6]

Macrocycle Synthesis.

The intramolecular, palladium-catalyzed reaction of allylic carbonates with substituted ethers produces macrocycles in high yield (eq 9).[7] The formation of 11- and 14-membered rings has been reported using dppp in combination with ***Tetrakis(triphenylphosphine)palladium(0)***.[7,14] Intermolecular reactions have also been reported.

Bis(2,2´-bipyridyl)silver(II) Peroxydisulfate

[47386-36-7] · $C_{20}H_{16}AgN_4O_8S_2$ · Bis(2,2´-bipyridyl)silver(II) Peroxydisulfate · (MW 612.36)

(one-electron oxidant capable of oxidizing electron-rich aromatic compounds in nucleophilic solvents)

Physical Data: mp 137 °C (dec).

Solubility: slightly sol acetic acid; increased by increasing concentration of acetate ions.

Analysis of Reagent Purity: contents of Ag^{II} can be assayed conveniently by addition of potassium iodide followed by iodometric titration.

Preparative Methods: oxidation of an aqueous suspension of silver nitrate in the presence of 2 equiv of 2,2´-bipyridyl by potassium peroxydisulfate.[1]

Handling, Storage, and Precautions: should be protected from light.

Aromatic Nuclear Substitution.

Electron-rich aromatic derivatives react with this reagent in acetic acid containing 0.5 M KOAc to give aryl acetates. Some examples of this stoichiometric reaction are given in Table 1. The reaction closely resembles the electrochemical oxidation of aromatic compounds; isomer distributions are quite similar. Of particular interest is the fact that, in many cases, yields higher than 100% were observed. This was explained by assuming Ag^{II} as the primary oxidant of the aromatic compound followed by reoxidation of the formed Ag^{I} by the counterion peroxydisulfate.[2]

Table 1 Nuclear Acetoxylation of Arenes using $Ag^{II}(bipy)_2S_2O_8$ in HOAc/0.5 M KOAc

Substrate	Isomer distribution			Yield (%)
	2-OAc	3-OAc	4-OAc	
Anisole	68	0.6	31	63
Biphenyl	21	0	79	18
Naphthalene[a]	95	5		63
4-Bromoanisole	100	0	0	35
4-Fluoroanisole	0	0	100	35
4-*t*-Butylanisole	100	0	0	63

[a]Isomer distribution refers to 1-acetoxy- and 2-acetoxynaphthalene, respectively.

Aromatic Side-Chain Substitution.

In the case of oxidation of methyl-substituted electron-rich aromatics, benzylic oxidation was observed. For example, 4-methoxytoluene gave, on oxidation in acetic acid/0.5 M KOAc, a mixture of 4-methoxybenzyl acetate and 4-methoxybenzyl alcohol in high yield.[2]

Catalytic Oxidations.

As indicated above, the counterion peroxydisulfate can act as a reoxidant for Ag^{I}. This was used in a catalytic version of the above reactions. Thus using a catalytic amount of either the Ag^{II} complex or AgOAc/2,2´-bipyridyl in acetic acid/0.5 M NaOAc and potassium peroxydisulfate as the oxidant, both nuclear and side-chain substitution can be achieved. The addition of barium acetate is important for a high turnover of the catalyst. For some examples, see Table 2.[2]

Table 2 Catalytic Acetoxylations of Some Aromatic Compounds

Substrate	Product	Yield (%)	Catalyst turnover
1,4-Dimethoxy-benzene	2-Acetoxy-1,4-dimethoxy-benzene	33	87
Anisole	Acetoxyanisoles	39	60
4-Bromoanisole	2-Acetoxy-4-bromoanisole	40	56
4-Methoxy-toluene	4-Methoxybenzyl-acetate	35[a]	75

[a] The byproduct 4-methoxybenzaldehyde, formed when using the pre-formed silver(II) complex as the catalyst, can be avoided by using AgOAc and 2,2¢bipyridyl instead.

1,2-Bis(hydroxymethyl)benzene

[612-14-6] · $C_8H_{10}O_2$ · 1,2-Bis(hydroxymethyl)benzene · (MW 138.17)

(reagent for the protection of carbonyl groups as benzodioxepin acetals)

Alternate Name: 1,2-benzenedimethanol.

Physical Data: mp 64-65 °C.

Solubility: sol most organic solvents.

Preparative Methods: commercially available.

Protection of Carbonyl Derivatives.

The title reagent (**1**) has been used as a protecting group for ketones and aldehydes by their conversion to the corresponding benzodioxepin. It offers the advantage of being removable under neutral conditions by hydrogenation, as opposed to other acetal protecting groups which are typically removed under acidic conditions. With simple ketones the diol is not effective in the formation of the acetals using common acids as catalysts as the yields are low. However, conversion of the diol to the corresponding orthoformate followed by treatment of the orthoformate with acid in the presence of a ketone or aldehyde provides the acetal in good to excellent yield (eq 1).[1] This reaction works with a wide variety of substrates, except very hindered ketones such as camphor.

Alternatively, the use of sulfonated charcoal has been shown to be effective with the diol as a starting material (eq 2).[2]

(2)

This reagent has been used as a protecting group for diethyl β-oxoglutarate, which was used in the synthesis of semivioxanthin (eq 3).[3] Other protecting groups failed due to difficulties encountered in their cleavage. Interestingly, in this case the authors chose to use the diol and tosic acid to obtain the acetal, but in poor yield (36%).

(3)

In the synthesis of an analog of *myo*-inositol 1,4,5-triphosphate, this group was used as a protecting group for a ketone as well as for a phosphoramidite. Thus treatment of the Birch reduction product of anisole with acetic acid and (**1**) provided the protected ketone (eq 4) which was converted to the requisite triol. This was coupled with the phosphoramidite derived from (**1**) and oxidized to the corresponding phosphotriester which was then cleaved to the desired phosphate (eq 5).[4]

(4)

The earliest use of this reagent as a protecting group was in the synthesis of cyclopropanone hydrate. The synthesis required the use of a protecting group that could be removed under neutral conditions. Thus transacetalization of the diethyl acetal derived from bromoacetaldehyde with (**1**) provided the benzodioxepin which was converted to the desired cyclopropane derivative (eq 6).[5]

Related Reagents.

3-Bromo-1,2-propanediol; ***Ethylene Glycol***; ***1,3-Propanediol***.

(η^5,η^5-1*S*,2*R*,4*S*,5*R*-1,4-Bis(indenyl)-2,5-diisopropylcyclohexane)titanium Dichloride

[139561-09-4] · $C_{30}H_{34}Cl_2Ti$ · (η^5,η^5-1*S*,2*R*,4*S*,5*R*-1,4-Bis(indenyl)-2,5-diisopropylcyclohexane)titanium Dichloride · (MW 513.38)

(alkene isomerization; titanium;[4] *ansa*-bis(indenyl) ligand; chiral ligand; C_2 symmetric ligand; asymmetric catalysis[8-10])

Physical Data: mp 264-265 °C (dec 240 °C); *d* 1.339 g cm^{-3}. Dark green crystals from hexane-CH_2Cl_2. [α]23D = +2900° (*c* 0.0202, CH_2Cl_2).

Solubility: sol $CHCl_3$ and CH_2Cl_2; insol hexane.

Preparative Methods: [1] the enantiomerically pure, chiral ligand (**2**) is prepared in two steps from the known (1*S*,2*R*,4*S*,5*R*)-2,5-diisopropylcyclohexane-1,4-diol (**3**) (eq 1).[2,3] It is obtained in 60% yield as a mixture of alkene regioisomers. The chiral titanocene reagent (**1**) is prepared by treatment of (**2**) with 2 equiv of ***n-Butyllithium*** followed by reaction with ***Titanium(III) Chloride*** and subsequent oxidation (HCl/air in $CHCl_3$) of the product (eq 2). It is obtained in 80% yield as a single stereoisomer.

Asymmetric Alkene Isomerization.[1]

The chiral titanocene reagent (**1**) serves as precatalyst for the isomerization of alkene (**4**) (eq 3). Active isomerization catalyst is obtained by in situ reduction of (**1**) with ***Lithium Aluminum Hydride*** (164 °C, 30 min). Treatment of the achiral substrate (**4**) with 2 mol % catalyst produced axially dissymmetric product (*S*)-(**5**) in 44-76% ee (100% yield). The reaction is slow at room temperature (120 h required for complete reaction); faster rates are obtained at higher temperatures, but at the expense of lower product enantiomeric purity.

Other Chiral Cyclopentadienylmetal Complexes.

The chemistry of chiral cyclopentadienylmetal complexes is covered in a review by Halterman.[4] Brintzinger's 1,2-ethylenebis(1-indenyl) ligand is the one most commonly used in the preparation of chiral early metal metallocene catalysts.[5,6] Compared to Brintzinger's ligand, (**2**) has the advantage of producing chiral metallocene complexes as single stereoisomers. A related chiral bis(1-indenyl) ligand developed by Burk and Halterman, possessing the same advantages as (**2**), incorporates a binaphthyl unit as the chiral, enantiomerically pure bridging group.[7]

Other Reactions of Chiral Titanocene Derivatives.

Buchwald has recently reported the catalytic asymmetric hydrogenation of imines[8,9] and unfunctionalized alkenes[10] using chiral titanocene catalysts.

2,6-Bis[(*S*)-4´-isopropyloxazolin-2´-yl](pyridine)rhodium Trichloride[1]

([Pybox-(*S*,*S*)-ip]$RhCl_3$)

[119038-51-6] · $C_{17}H_{23}Cl_3N_3O_2Rh$ · 2,6-Bis[(*S*)-4´-isopropyloxazolin-2´-yl](pyridine)rhodium Trichloride · (MW 510.65) (Pybox-(*S*,*S*)-ip)

[118949-61-4] · $C_{17}H_{23}N_3O_2$ · 2,6-Bis[(*S*)-4´-isopropyloxazolin-2´-yl]pyridine · (MW 301.39)

(highly enantioselective catalyst for hydrosilylative reduction of methyl ketones in combination with Ph_2SiH_2 and $AgBF_4$[5,6])

Alternate Name: [Pybox-(*S*,*S*)-ip]$RhCl_3$.

Physical Data: [Pybox-(*S*,*S*)-ip]$RhCl_3$: mp 279 °C (dec); [α]20D = +543° (*c* 1.09, CH_2Cl_2); Pybox-(*S*,*S*)-ip: white solid, mp 152-153 °C, [α]26D = -116.8° (*c* 1.0, CH_2Cl_2).[6]

Solubility: sol CH_2Cl_2, $CHCl_3$, and alcohols; slightly sol THF and ethyl acetate; insol diethyl ether, benzene, and H_2O.

Form Supplied in: orange solid; synthesized with $RhCl_3(H_2O)_3$ and Pybox-(*S*,*S*)-ip in ethanol at reflux for 3 h. The crude solid was purified by silica gel column chromatography with ethyl acetate and methanol as eluents; TLC R_f = 0.45 (ethyl acetate/methanol = 5:1, Merck Art 5715). *Drying:* although the rhodium compound is nonhygroscopic, it contains some quantity of water or solvents after the purification by chromatography. It should be dried under vacuum (< ca. 1 Torr) for 1 day at 20-60 °C before use.

Handling, Storage, and Precautions: stable in air and moisture.

Enantioselective Reduction of Ketones.

Hydrosilylation of ketones with chiral metal catalysts and hydrosilanes followed by hydrolysis provides optically active secondary alcohols from ketones. Most of the enantioselective hydrosilylations of ketones have been carried out with rhodium catalysts and chiral phosphine ligands. These systems give a middle range of enantioselectivities, especially with diphenylsilane and 1-naphthylsilane.[2] In the 1980s, many splendid results of more than 90% ee were reported with rhodium catalysts of chiral nitrogen-containing ligands such as pyridinethiazolidine[3] and pyridineoxazoline-*t*-Bu,[4,5] which are easily accessible from readily available, optically active amino acids and amino alcohols.

The 2,6-bis(oxazolinyl)pyridine ligand [Pybox-(*S*,*S*)-ip] was also developed as a chiral adjuvant for the asymmetric hydrosilylation of ketones. The Pybox ligand can be synthesized in large scale as a white crystalline solid by condensation of (*S*)-valinol and pyridine-2,6-dicarboxylic acid.[6] Heating of the ethanol solution of Pybox-(*S*,*S*)-ip and ***Rhodium(III) Chloride*** trihydrate gave the stable complex [Pybox-(*S*,*S*)-ip]$RhCl_3$ in 70% yield. Diphenylsilane and the catalytic amount of the Pybox-rhodium(III) complex with the aid of ***Silver(I) Tetrafluoroborate*** reduced aromatic and aliphatic methyl ketones in THF solution at -5 to 25 °C. After hydrolysis of the product silyl ethers in acidic methanol at 0 °C, optically active secondary alcohols were obtained in high yields and high enantioselectivities, e.g. from acetophenone to 1-phenylethanol in 91% yield and 94% ee (*S*) (eq 1; Table 1).[6]

Table 1 Hydrosilylative Reduction of Methyl Ketones with [Pybox-(*S*,*S*)-ip]$RhCl_3$ and Diphenylsilane

(*S*,*S*)-ip]$RhCl_3$ and Diphenylsilane

The stereoselectivity of the reduction of 4-*t*-butylcyclohexanone has been shown to give high proportions (>90%) of the *cis* (equatorial) alcohol in hydrogenations with heterogeneous rhodium catalysts or in transfer hydrogenations with homogeneous rhodium or iridium catalysts.[7] However, the Pybox-rhodium catalyst gave a ratio of 67:33 of the *trans*/*cis* alcohol,[8] similar to that obtained with the Wilkinson catalyst (eq 2).[9] Despite the low axial/equatorial selectivity, the enantioselectivities of the reduction of 2-phenyl- and 2-methoxycarbonylmethylcyclohexanone were extremely high (eqs 3 and 4).[8] Chalcone was also reduced to the allylic alcohol in 71% ee (eq 5).[6]

(5)

In place of diphenylsilane, 1,2-bis(dimethylsilyl)ethane was applied to the reduction of several ketones by the combination of the Pybox-rhodium complex and ***Silver(I) Trifluoromethanesulfonate*** to give the corresponding silyl enol ether exclusively (eq 6).[10]

(6)

Chiral 4-substituted Pybox derivatives (**1**) were synthesized as chiral adjuvants to study remote electronic effects of the substituents in the asymmetric hydrosilylation.[11] The 4-Cl-Pybox-(*S*,*S*)-ip-Rh catalyst afforded the highest result (80% ee (*S*)) for the reduction of 2-octanone to 2-octanol in 88% yield.

2,5-Bis(methoxycarbonyl)-3,4-diphenylcyclopentadienone[1]

[16691-79-5] · $C_{21}H_{16}O_5$ · 2,5-Bis(methoxycarbonyl)-3,4-diphenylcyclopentadienone · (MW 348.35)

(reagent for cycloaddition reactions[1])

Physical Data: mp 169, 175 °C (from pet ether),[1a] 173 °C,[1b] 162-164 °C (from Ac_2O).[1c]

Form Supplied in: orange solid; may contain Diels-Alder dimer as impurity.[1]

Analysis of Reagent Purity: ^{1}H NMR.[1c]

Preparative Method: equimolar amounts of benzil and dimethyl 2-propanone-1,3-dicarboxylate in MeOH or EtOH with OH^- are allowed to react at 25 °C for 1 day to give the intermediate dimethyl 3,4-diphenyl-4-hydroxycyclopent-2-enone-2,5-dicarboxylate in 70-96% yield. Treatment of the intermediate with acid in benzene[1a] or in Ac_2O[1c] with heating gives the dienone in 98% yield containing 3% of the Diels-Alder dimer.[1c]

Cycloaddition Reactions.

As with other cyclopentadienones,[2] the reagent reacts readily in cycloaddition reactions with a variety of dienophiles. Dimerization upon heating to 200 °C has been reported,[1a] but the monomeric reagent is stable at rt. Reactions with dienophiles are typically conducted at temperatures between 20-120 °C. Reactions have been run neat or in inert solvents such as benzene and 1,2-dichloroethane. In the presence of excess dienophile, the reactions are allowed to proceed until the characteristic orange color of the dienone is discharged.

Reactions with dienophiles generally give [4 + 2] cycloaddition (Diels-Alder) products. Additions to substituted styrenes occur with modest to good *endo* stereoselectivity (eq 1), but cycloadditions with electron deficient dienophiles such as ***Maleic Anhydride*** give only the *endo* product.[3] Cycloadditions with *trans*-stilbene, ***Dimethyl Maleate***, and

Dimethyl Fumarate show that the reactions are stereospecific.[4] Kinetic studies of reactions with substituted styrenes gave negative ρ values,[3,5] leading to the classification of reverse electron demand cycloadditions. Cycloadditions with alkenes generally give bicyclic products such as shown in eq 1, but the first-formed products from cycloadditions with alkynes such as ***Dimethyl Acetylenedicarboxylate*** decarbonylate to give aromatic products (eq 2).[1a,3]

Because the dienone is monomeric and highly reactive in [4 + 2] cycloadditions, it has been used to trap intermediate alkene products that are unstable to the reaction conditions. For example, oxidation of the benzadiyne equivalent precursor in eq 3 in the presence of the dienone gives the substituted anthracene shown.[6]

(3)

Mixtures of [4 + 6] and [4 + 2] cycloadducts are obtained in reactions of the dienone with oxepin[7] (eq 4), a 1*H*-azepin,[8] and 1,3,5,7-cyclooctatetraene.[9] Reaction of the dienone with tropone gives [4 + 6] addition products.[3]

(4)

Dipolar cycloadditions as in reactions with diazoalkanes[1b] and with nitrile *N*-oxides[10] give [2 + 3] cycloadducts (eq 5).

Bis(1-methoxy-2-methyl-1-propenyloxy)dimethylsilane[1]

[86934-32-9] · $C_{12}H_{24}O_4Si$ · Bis(1-methoxy-2-methyl-1-propenyloxy)dimethylsilane · (MW 260.40)

(very useful bifunctional protecting agent for various types of H-acidic materials under mild conditions)

Physical Data: 89-90 °C/6.5 mmHg.

Form Supplied in: colorless liquid; not commercially available.

Preparative Method: prepared by treating 2 equiv of methyl lithioisobutyrate with 1 equiv of dichlorodimethylsilane at low temperature in dry THF, followed by distillation of the colorless liquid.

Handling, Storage, and Precautions: moisture sensitive; should be stored under nitrogen in a refrigerator.

The Dialkylsilylene Protecting Group.

Bifunctional compounds containing alcohol, thiol, acid, and amine units may be protected as cyclic dimethylsilylene derivatives, which are analogous to isopropylidene derivatives, by treatment with the title reagent (**1**).[2] Cleavage of the silylene protective group is easily achieved by hydrolysis or solvolysis. It should be noted that the dimethylsilylene group is highly sensitive to hydrolysis and is unstable to column chromatography.

Silylene derivatives have become very useful in synthetic organic chemistry. For example, the cyclic dimethylsilylene derivative (**2**) of *o*-hydroxyacetophenone is useful for [4 + 2] cycloadditions (eq 1).[3] A glycosyl donor and acceptor have been linked as the dimethylsilylene derivative (**3**) and used for stereoselective glycosylation (eq 2).[4] Also, an efficient and stereocontrolled aldol reaction of silylene enolate (**4**) with aldehydes has been reported (eq 3).[5]

(2) (1)

(3)

(2)

(4) (3)

Advantages of Bis(1-methoxy-2-methyl-1-propenyloxy)dimethylsilane.

Dichlorosilanes,[6] bis(trifluoromethanesulfonyl)silanes,[7] and dimethoxysilanes[8] have been used for the synthesis of dialkylsilylene derivatives. These methods, however, have some disadvantages: (i) a strong base or acid catalyst is required; (ii) forcing reaction conditions (high temperature for a long period) are sometimes required; (iii) large amounts of side-products such as inorganic salts, or amine or acid salts, are produced that must be separated from the moisture-sensitive silylene derivatives; and (iv) the yields of the products are not always high. Reagent (**1**), which is much more reactive than other difunctional silyl reagents, allows the ready silylenation of H-acidic materials in the absence of base, and allows isolation of pure products in almost quantitative yields without aqueous workup. The only reaction side-product is methyl isobutyrate, which is volatile.

Bifunctional Protection of H-Acidic Materials.[1,9]

The reaction of (**1**) with H-acidic materials is generally carried out by employing a slight excess of the reagent in an inert solvent such as CH_2Cl_2 or MeCN and usually gives a high yield of the corresponding silylene derivatives. Furthermore, addition of catalytic amounts of dichlorodimethylsilane induces a slightly exothermal reaction, leading to the rapid formation of the silylenes. A wide range of 1,2-, 1,3-, and 1,4-difunctional compounds give the corresponding silylenes in high yields (eqs 4-8). Monofunctional alcohols and carboxylic acids can also be linked via the dimethylsilylene group forming dialkoxy- and diacyloxydimethylsilane, respectively (eqs 9 and 10).

[90290-05-4]

(chiral auxiliary with C_2 symmetry;[1] used as a chiral auxiliary for alkylations, acylations, reductions, cycloadditions, and radical additions)

Physical Data: colorless oil; bp 110-115 °C/15 mmHg; for *S*,*S*-form, $[\alpha]_D$ = +7.8° (*c* = 3.0, EtOH).

Solubility: sol methylene chloride, chloroform, ethanol.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: ^{13}C NMR (δ 27.7, 56.7, 58.8, 76.1 ppm).

Handling, Storage, and Precautions: irritant; use only in a fume hood.

Chiral Amines with C_2 Symmetry.

trans-2,5-Dimethylpyrrolidine (**1**)[2] was the first chiral amine possessing C_2 symmetry used as a chiral auxiliary in asymmetric synthesis.[1,2a] Since that time a number of related systems have been developed including the title compound (**2**) and (**4**).[1] These amines were developed as C_2-symmetric analogs to the commercially available prolinol derivative (**5**). While proline-derived chiral auxiliaries have been widely used in asymmetric synthesis,[3] the C_2-symmetric chiral auxiliaries often give enhanced stereoselectivity when compared directly to the prolinol derivatives. Unfortunately the preparation of the C_2-symmetric compounds is more tedious and, at the time of writing, none are commercially available. For example, the standard route to chiral pyrrolidines (**2**) and (**3**) involves the resolution of *trans*-*N*-benzylpyrrolidine-2,5-dicarboxylic acid,[4] although other preparations have been reported.[5] In general,

pyrrolidines (**2**) and (**3**) have been used interchangeably and will be the primary focus of this entry.

(1) R = Me
(2) R = CH_2OMe
(3) R = $[CH_2O]_2Me$

(4)

(5)

Alkylation of Amides Derived from *C*$_2$-Symmetric Pyrrolidines.

Alkylation of amides derived from either pyrrolidine (**2**) or (**3**) are highly stereoselective (eq 1).[4a] The reaction is successful for a large variety of amide derivatives[4a,6] and alkylating agents.[7] Upon hydrolysis of the amide, chiral acids are produced (eq 2). This method has been used to prepare α-amino[6d] and α-hydroxy acids.[6a] The diastereoselectivity observed is greater than for amides derived from prolinol (**5**).[3] While the degree of the stereoselectivity is almost identical for amides derived from either (**2**) or (**3**), the method for removal of the chiral auxiliary does differ (eq 2). In keeping with earlier results from the prolinol-derived amides,[3] the hydrolysis is best effected via the hydroxymethyl derivative (**10**). For derivative (**8**) this means that the methyl ether is first cleaved with either ***Boron Trichloride***[4a] or ***Boron Tribromide***.[8] In the case of the methoxymethyl derivative (**9**), refluxing in aqueous acid simultaneously effects both cleavage of the methoxymethyl ether and hydrolysis to the chiral acid.

(2)

(10)

Reduction of α- and β-Ketoamides Derived from C_2-Symmetric Pyrrolidines.

By analogy to the alkylation reaction discussed above, acylation of the enolate derived from amide (**8**) produces the β-ketoamide (**11**) as a single diastereomer (eq 3).[9] Subsequent reduction of the ketone produces either the *syn*[9] or *anti*[10] β-hydroxyamides with high diastereoselectivity (eqs 4 and 5). Pyrrolidine-derived α-ketoamides have also been shown to react stereospecifically with reducing agents,[11] as well as with other organometallic reagents.[12]

(3)

(4)

(5)

Cycloaddition Reactions.

Chiral acrylamides derived from pyrrolidines (**2**) or (**3**) undergo stereoselective [4 + 2] cycloaddition reactions with a

variety of cyclic dienes.[8a,13] Similarly, nitroso compounds derivatized with pyrrolidine (**2**) and generated in situ give cycloadducts with a high degree of stereoselectivity (eq 6).[8a,14] Intramolecular [2 + 2] cycloadditions involving pyrrolidine-derived keteniminium salts have been shown to produce chiral cyclobutanones.[4b]

(6)

Other Reactions.

Other reactions in which pyrrolidines (**2**) and (**3**) have been used as chiral auxiliaries include radical additions,[8b] electrocyclizations,[15] and Wittig rearrangements.[7b]

Patrick G. McDougal

2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide[1]

[19172-47-5] · $C_{14}H_{14}O_2P_2S_4$ · 2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide · (MW 404.45)

(reagent for the conversion of carbonyl into thiocarbonyl groups[1])

Alternate Name: Lawesson's reagent.

Physical Data: mp 228-229 °C.

Solubility: modestly sol boiling organic solvents such as toluene, chlorobenzene, anisole, dimethoxyethane.

Form Supplied in: yellowish evil-smelling crystals; typical impurity is P_4S_{10}.

Analysis of Reagent Purity: FTIR spectrum.[1c]

Preparative Methods: reaction of P_4S_{10} with anisole in excess refluxing anisole.[2]

Purification: recrystallization from boiling toluene.

Handling, Storage, and Precautions: can be stored for months at rt if moisture is excluded. Prolonged heating in solution causes decomposition (polymerization). It is toxic and should be handled under a fume hood since hazardous H_2S is easily liberated with moisture.

Thionation of Carbonyl Compounds.

Lawesson's reagent (LR) is a most powerful reagent for the thionation of a wide variety of carbonyl compounds. Ketones, enones, carboxylic esters, thiolocarboxylic esters, amides, and related substrates are conveniently transformed into the corresponding thiocarbonyl compounds.[1] In some cases, follow-up products are isolated since certain thiones

are labile under the reaction conditions. Compared with P_4S_{10}, from which it is easily prepared,[2] LR exhibits several advantages. Its reactivity is significantly higher and it is sufficiently soluble in hot organic solvents, allowing homogeneous reaction conditions to be applied. Therefore many carbonyl compounds can be successfully thionated with LR but not with P_4S_{10}, or at least thionated in higher yields. Several reagents with structures similar to LR, which are even more reactive or more selective than LR, have been developed and are used in particularly difficult cases (see ***2,4-Bis(methylthio)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide***). The workup procedure depends on the reaction conditions applied, in particular on the solvent, and the products formed. If DME is used, the reaction mixture can be poured into water and the product extracted as usual. Low boiling hydrocarbons are best evaporated and the residue, which contains the product together with 2,4,6-tris(4-methoxyphenyl)cyclotriphosphoxane 2,4,6-trisulfide, is subjected to column chromatography. High boiling solvents such as tetralin or trichlorobenzene should be removed by flash chromatography in order to avoid thermal decomposition of the labile thiones.

Thioketones.

Thioketones of different types have been obtained from the corresponding ketones. Lawesson, who discovered LR to be a powerful reagent for the conversion of C=O into C=S groups, described the preparation of diaryl thioketones.[3] Substituents such as Me, Br, NO_2, or NMe_2 do not affect the good yields of up to 98% (eq 1).

(1)

Recently, the diferrocenyl thioketones (**1**) and (**2**) were prepared from the corresponding ketones.[4] Alkyl aryl and dialkyl thioketones (**3**),[3] (**4**),[5] (**5**)[6] are formed in good yields if enethiolization is unfavored or impossible, whereas mainly enethiols are obtained from cycloalkanones (eq 2).[7]

(1) 71% **(2)** 90%

(3) 83%

(4) 85%

(5) 85%

(2)

2-Cyclohexenones are thionated with LR (eq 3),[7] but only the vinylogous dithioester (**6**) is a stable compound. Acyclic enones (chalcones) give on reaction with LR the enethione dimers (eq 4).[8]

(6)

(3)

(4)

Again, stable enethiones are formed if an electron donating substituent (e.g. NR_2) is present in the β-position (eq 5).[9] Certain isolable 2,5-cyclohexadienethiones can be further transformed into bicyclohexadienylidenes (eq 6).[10]

(5)

(6)

The thioanalogs of natural products such as the steroid (**7**)[11] or the colchicine alkaloid (**8**)[12] have also been prepared by use of LR.

(7) 96%

(8) 33%

Thio Analogs of Dicarbonyl Compounds.

In general, the most labile thiono analogs of α-dicarbonyl compounds cannot be prepared by any thionation procedure. However, thioacenaphthoquinone (**9**) as well as thioanthraquinone (**10**) were obtained from the quinones and LR.[13] Even α-thioxo thioamides are available (eq 7),[14] whereas 2,2,5,5-tetramethyl-4-thioxo-3-hexanone, which itself cannot be prepared from the corresponding diketone, reacts with LR to yield 3,4-di-*t*-butyl-1,2-dithiete, the valence isomer of the open-chain dithione (eq 8).[15]

(9) 70%

(10) 65%

(7)

(8)

Thioketones with pronounced steric hindrance are obtained on reaction of cyclobutane-1,3-diones with LR (eq 9).[16]

(9)

Diketones with remote C=O groups can be transformed by LR into the mono- or dithiones.[17]

Thiono Esters and Lactones.

Although thiono esters can be conveniently prepared via imidates,[18] the introduction of LR for the thionation of esters[3] represents a great advance in synthetic methodology since ordinary esters are used as educts and P_4S_{10} only reacts with esters if enforced reaction conditions are applied, under which many thiono esters decompose. Facile conversion of aliphatic and aromatic esters (eq 10),[3,19] α,β-unsaturated esters,[20] and lactones[21] to the corresponding thiono derivatives is effected in high yields (eqs 11 and 12).[22,23]

(10)

(11)

(12)

Thiono esters and lactones are important intermediates in modern organic synthesis since they easily undergo useful follow-up reactions. Ethers are formed on reduction with ***Raney Nickel***[24] or ***Tri-n-butylstannane*** (eq 13).[25]

(13)

Macrocyclic bis-thionolactones have been prepared with LR. These were converted by reduction with ***Sodium Naphthalenide*** into the radical anions, which gave bicyclic systems through radical dimerization and subsequent methylation (eq 14).[26] This method was successfully applied by Nicolaou et al.[27] in the total synthesis of hemibrevetoxin B. One of the crucial steps of the synthesis was the preparation of the bis-thiono ester (**11**), which was achieved by using LR together with tetramethylthiourea in xylene at 175 °C.[27]

(14)

(11) 49%

Dithioesters and Related Compounds.

Thioesters are transformed into the corresponding dithioesters on reaction with LR.[3,20,28] Again the yields are nearly quantitative even if steric hindrance can be expected (eq 15).[3]

(15)

The reaction is completed within 5-15 min if tetralin at 210 °C is used as solvent.[28] Also, dithio-γ-lactones,[21,28] including dithiophthalides[29] and dithio-α-pyrones,[30] are formed smoothly whereas the hitherto unknown simple β- or δ-dithiolactones cannot be prepared, neither with LR nor by any other method. Interestingly, dithiopilocarpine is formed as a mixture of diastereomers on reaction of pilocarpine with LR (eq 16), i.e. both oxygen atoms of (**12**) are replaced by sulfur.[31] In an interesting sequence of thionation and rearrangement reactions, three different thiono analogs of 1,8-naphthalic anhydride were prepared (eq 17).[32]

(16)

(12)

2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide

(17)

Thioamides and Related Compounds.

Thioamides are the most stable thiocarbonyl compounds and have been prepared, for a century, from amides and P_4S_{10} under rather drastic conditions. However, even for this purpose LR has turned out to be a superior reagent. High yields are obtained for all types of thioamides[1,33] and -lactams[1,33,34] including the elusive unsubstituted acrylothioamide (eq 18)[35] and thioformamides or thioamides bearing sensitive substituents such as NO_2, Z-NH,[36] or OH (eq 19).[33]

(18)

(19)

β-Lactams are also smoothly transformed[34] (eq 20),[37] which is important for the preparation of thio analogs of β-lactam antibiotics or azetidines. Furthermore, endothio oligopeptides became conveniently available only after LR had been introduced as reagent[1,38,39] (eq 21).[40]

Recently the cyclopeptide [D-cysteine]^{8}cyclosporin has been prepared from [D-serine]^{8}cyclosporin via selective thionation with LR at the 7-position followed by intramolecular sulfur transfer.[41]

Miscellaneous Reactions of LR.

Under particular conditions, certain carbonyl compounds and other substrates react with LR to form thiophosphonates or heterocycles, which fact throws some light on the mechanism of thionation reactions with LR.[1] Carbinols undergo nucleophilic substitution with LR to form the corresponding thiols.[42] The redox properties of LR can be utilized to prepare dithiolactones from dialdehydes (eq 22),[43] α-oxo thioamides from nitro ketones (eq 23),[44] or sulfides from sulfoxides.[45]

Bis(*N*-methylsalicylaldimine)nickel[1]

[14322-02-2] · $C_{16}H_{16}N_2NiO_2$ · Bis(*N*-methylsalicylaldimine)nickel · (MW 327.00)

(used in conjunction with triisobutylaluminum for alkyne coupling,[2] allene synthesis,[3] and conjugate reduction of α,β-enones[5])

Alternate Name: $Ni(mesal)_2$.

Physical Data: mp 195-198 °C, *d* 1.45 g cm^{-3}, λ_{max} 354 nm (solid).

Solubility: sol alcohol, ether, benzene, $CHCl_3$; slightly sol hexane.

Form Supplied in: olive-green solid, not commercially available.

Preparative Method: easily prepared from a 2:2:1 mixture of salicylaldehyde, methylamine, and nickel acetate in alcohol solution at 60 °C for 1 h. The green solid can be recrystallized from alcohol or from chloroform/petroleum ether.[1]

Handling, Storage, and Precautions: stable, nonhygroscopic; nickel compounds are cancer suspect agents.

Triisobutylaluminum-Bis(*N*-methylsalicylaldimine)nickel.

$Ni(mesal)_2$ modifies reactions of ***Triisobutylaluminum***, allowing for greater selectivity in reactions of alkynes. The two reagents are premixed, typically in a 50:1 Al:Ni molar ratio, in the reaction vessel before addition of substrates, but no isolation of the combined reagent is necessary. Note that most reactions are carried out in the absence of solvent.[2] Caution: triisobutylaluminum is pyrophoric and moisture sensitive.

Alkyne Coupling.

By itself, (i-Bu)$_3$Al promotes the coupling of 1-alkynes to give a complex mixture of i-butylalkenes, 1,3-dienes, and trisubstituted benzenes (eq 1). Catalytic amounts of Ni(mesal)$_2$ accelerate the reaction and show a preference for formation of head-to-tail dimers and benzene products (eq 2).[2] Nickel metallacyclopentadienes are proposed intermediates.

Allene Synthesis.

Ni(mesal)$_2$ catalyzes the cross-coupling reaction of allenic bromides with trialkylaluminum or Grignard reagents (eq 3).[3] The method is fairly general. Triisobutylaluminum was used in two-fold molar excess to the allene and 1 mol % Ni(mesal)$_2$ catalyst was added. When an enantiomerically enriched sample of the bromoallene was used as substrate, the reaction was found to occur with predominant retention of configuration in the allenyl moiety.[4]

Reduction of α,β-Unsaturated Ketones.

Triisobutylaluminum alone leads to both 1,2-reduction products and 1,2-addition products on reaction with α,β-unsaturated ketones. In contrast, the same reaction catalyzed by 3 mol % $Ni(mesal)_2$ leads predominantly to reduction of the C-C double bond (eq 4).[5] The reaction is carried out in pentane at rt using a 1:1 molar ratio of enone and *i*-Bu_3Al.

$R^1 = Me, R^2 = H$	96%	0%
$R^1 = H, R^2 = Me$	77%	23%

2,4-Bis(methylthio)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide

[82737-61-9] · $C_2H_6P_2S_6$ · 2,4-Bis(methylthio)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide · (MW 284.38)

(reagent for the conversion of carboxylic acids into dithioesters and carbonyl groups into thiocarbonyl groups)

Alternate Name: Davy's reagent.

Physical Data: mp 125-136 °C.

Solubility: sol hot aromatic hydrocarbons, chlorobenzene.

Form Supplied in: pale yellow, evil-smelling crystals.

Analysis of Reagent Purity: ^{1}H NMR spectrum: δ = 2.86 (d, J = 20 Hz, CH_3).

Preparative Method: reaction of P_4S_{10} with methanethiol or methanol.[1]

Purification: washing with cyclohexane.

Handling, Storage, and Precautions: should be stored in the cold with exclusion of moisture. It is very toxic and must be handled under a hood or in glove-boxes due to its intolerable odor and the hazardous methanethiol which is easily liberated with moisture.

Introduction.

2,4-Bis(methylthio)-1,3,2,4-dithiadiphosphetane 2,4-disulfide as well as the analogous ethylthio, isopropylthio, and benzylthio derivatives have been introduced as reagents for syntheses by Davy and Metzner. These compounds (Davy's reagent, DR) can be used in the same way as Lawesson's reagent, LR (see ***2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide***), for the thionation of carbonyl groups. DR is, however, considerably more reactive and in many cases more selective than LR. Furthermore, it exhibits the unique ability to transform carboxylic acids into dithiocarboxylic esters in one step. Similar dithiadiphosphetane disulfides with arylthio substituents have been

designed in order to achieve an even improved effectiveness in thionation reactions and also to produce a more conveniently handled reagent compared with the obnoxious DR. The so-called Japanese reagent (JR), 2,4-bis(phenylthio)-1,3,2,4-dithiadiphosphetane 2,4-disulfide,[3] has recently found considerable synthetic application.

Transformation of Carboxylic Acids into Dithiocarboxylic Esters.[2,4]

Dithioesters bearing functional groups such as C=C double bonds,[2] halogen,[2,5] nitro,[6] or phenoxy groups[2] are obtained with yields of up to 68% on reaction of aliphatic (eq 1)[2b] or aromatic (eq 2)[5b] carboxylic acids with DR in boiling chlorobenzene. Acid chlorides can also be used as starting material.[2b,4] Isolation and handling of pure DR can be avoided by using a one-pot procedure (eq 3),[7] which consists of first reacting methanol or ethanol with P_4S_{10} followed by addition of the carboxylic acid and further P_4S_{10}. The above mentioned JR enables one to prepare phenyl dithiocarboxylates in extremely short reaction times (eq 4).[3]

(1)

(2)

(3)

(4)

Thionation of Carbonyl Compounds.

Diaryl thioketones[8] and 2,4-bis(diphenylmethylene)cyclobutane-1,3-dithione[9] were obtained on reaction of the corresponding ketones with DR. On the other hand, JR was utilized to thionate selectively the carbonyl group of benzil monophenylimine.[10] If carboxylic esters or lactones are reacted with DR, dithiocarboxylic esters[4] or dithiolactones[4,8] are formed, i.e. the carbonyl group is thionated and the alkoxy group is substituted by an alkylthio group. Bis(5-methyl-2-thienyl) disulfide is produced in this way from a butenolide (eq 5).[4]

(5)

A systematic study on the thionation reactions of primary, secondary, and tertiary amides and lactams with DR compared with LR and 2,4-bis(4-phenoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-disulfide, the so-called Belleau's reagent (BR),[11] has been performed.[12] Generally, good yields are obtained with whichever reagent is used, but each reagent may exhibit advantages in a special case. DR has been mainly utilized for the preparation of simple thioamides (eq 6).[8]

(6)

JR has found application in endothiopeptide synthesis.[3,13,14] One carbonyl group of a cyclohexapeptide is selectively thionated with JR (eq 7).[15] The cyclic thiopeptide exhibits enhanced effectiveness as an inhibitor of triosephosphate isomerase (TIM). This results from the pronounced alteration of the backbone conformation which is due to different hydrogen bridges. Belleau's reagent, BR, can be used similarly to JR to prepare thiooligopeptides selectively[16,17] or thiono esters of the carbohydrate series (eq 8).[18]

Bis(methylthio)(trimethylsilyl)methane

[37891-79-5] · $C_6H_{16}S_2Si$ · Bis(methylthio)(trimethylsilyl)methane · (MW 180.40)

(reagent used for synthesis of bis(methylthio)ketene acetals from aldehydes and ketones;[1] acyl anion synthon for conjugate additions to enones and enoates;[2] useful for one-carbon homologations[3])

Physical Data: bp 67-70 °C/10 mmHg.

Solubility: insol H_2O; sol organic solvents.

Preparative Methods: prepared from lithiobis(methylthio)methane by silylation with chlorotrimethylsilane (eq 1).[1] Both bis(methylthio)methane and ***Chlorotrimethylsilane*** are commercially available.

Handling, Storage, and Precautions: use in a fume hood.

Lithiobis(methylthio)(trimethylsilyl)methane.

The anion is generated by treatment of the title compound with ***n-Butyllithium*** in THF at -60 °C (eq 2). This species is well-behaved at low temperature. Useful reactions of this anion are discussed in the following sections.

Thioketene Acetals.

The lithio reagent readily converts aldehydes and ketones into the corresponding bis(methylthio)ketene acetals via a Peterson alkenation sequence.[1] Aromatic aldehydes give excellent yields under these conditions (eq 3), and certain enolizable ketones such as acetophenone and cyclohexanone also react accordingly (eq 4). Alternative methods for preparing these acetals include a Horner-Wittig process that uses phosphonate derivatives[4] and an alkylative process involving CS_2 and MeI.[5] Relative to these alternatives, the title reagent offers advantages of ease of reagent preparation and control of regioselectivity. The phosphonate reagents are more nucleophilic, however, and avoid competitive deprotonation.

(3)

(4)

Reaction of the lithio species with α-oxo ketones and aldehydes allows the formation of β,β-disubstituted enones, useful intermediates for the preparation of unsaturated 1,5-diketones (eq 5).[6]

(5)

Acyl Anion Conjugate Additions.

The lithio reagent readily undergoes 1,4-addition to unsaturated substrates (eq 6), in direct contrast to the corresponding ***RL031-***, which is a poor Michael donor.[2] The initial Michael adducts can also be alkylated to provide highly functionalized products. Very good levels of diastereoselectivity have been observed in the 1,4-addition and enolate alkylations of cyclic enoates (eq 7)[7] and acyclic enones (eq 8).[8]

(6)

(7)

(8)

Other effective Michael donors of this type include lithiobis(phenylthio)(trimethylsilyl)methane,[9] lithio(methoxy)(phenylthio)(trimethylsilyl)methane,[10] and lithio(methylthio)(methylsulfoxido)methane.[11] The isolated yields with lithiobis(phenylthio)(trimethylsilyl)methane are generally superior to those with the title reagent, but the latter compound is more readily available and easier to handle than those listed above.

One-Carbon Homologations.[3]

The bis(methylthio)ketene acetals are useful synthetic intermediates because they are readily converted into *S*-methyl

thioesters (eq 9)[12] or the corresponding carboxylic acids and esters.[13a]

(9)

This acetal methodology was used for a 1,3-carbonyl transposition in a synthesis of (±)-myodesmone (eq 10),[13b] and for a one-carbon homologation en route to vitamin B_{12} (eq 11).[14]

(10)

(11)

A particularly useful transformation is the fluoride-induced removal of the trimethylsilyl group to provide a mixed *O*,*S*-acetal that is easily converted into the corresponding aldehyde (eq 12).[10]

Bis(methylthio)(trimethylstannyl)methane

[62762-48-5] · $C_6H_{16}S_2Sn$ · Bis(methylthio)(trimethylstannyl)methane · (MW 271.00)

(precursor to acyl anion equivalent with 1,4-addition selectivity; dianion equivalent[1])

Physical Data: bp (distillation) 93-95 °C/7 mmHg; *n*20D 1.5548.

Preparative Methods: commercially available bis(methylthio)methane is deprotonated by ***n-Butyllithium*** in THF/hexane at -60 to 0 °C. The resulting lithio derivative is quenched at -40 °C with 1 equiv of ***Chlorotrimethylstannane***. An aqueous workup followed by vacuum distillation affords the bis(methylthio)(trimethylstannyl)methane reagent in 82% yield.[2] The analogous ***Bis(methylthio)(trimethylsilyl)methane*** can be prepared by a similar procedure.[3]

Handling, Storage, and Precautions: organotin compounds should be considered toxic and should be handled with appropriate care. Use in a fume hood.

1,4-Additions.

In contrast to lithiated 1,3-dithianes and related dithioacetals which undergo only 1,2-addition reactions with cyclic enones, lithiated bis(methylthio)(trimethylstannyl)methane furnishes 1,4-addition products in good yield. The reagent is metalated with ***Lithium Diisopropylamide*** in THF/HMPA at -78 to -30 °C; conjugate addition reactions (eq 1) are carried out from -78 to 25 °C. If the intermediate enolates are alkylated in situ with alkyl iodides, the products are predominantly the *trans*-2,3-disubstituted cycloalkanones (eq 2). The ***Bis(methylthio)(trimethylsilyl)methane*** reagent behaves similarly under these conjugate addition and alkylation reaction conditions.

Dianions.

The intermediate enolates can also be converted to dilithium derivatives by transmetalation (***Methyllithium***, THF, -100 °C) after removal of the diisopropylamine. The dilithium species can then be treated sequentially with electrophiles (eq 3). The dithioacetal anion is the more reactive nucleophile.

Bismuth(III) Oxide[1]

Bi_2O_3

[1304-76-3] · Bi_2O_3 · Bismuth(III) Oxide · (MW 465.96)

(oxidizing agent specific for conversion of α-hydroxy ketones to diketones[1])

Physical Data: mp 820 °C; *d* 8.9 g cm^{-3}.

Solubility: insol water and organic solvents; sol acids.

Form Supplied in: amorphous yellow powder.

Handling, Storage, and Precautions: no special precautions.

Oxidation of α-Hydroxy Ketones to 1,2-Diketones.

Bismuth(III) oxide is a specific reagent for the oxidation of α-hydroxy ketones to the corresponding diketones.[2,3] The oxidation is generally carried out in acetic acid at about 100 °C. Bismuth(III) oxide is soluble in acetic acid under these conditions and forms bismuth triacetate, the active oxidizing agent, which becomes reduced to metallic bismuth. Oxidation of simple α-hydroxy ketones is rapid, but more highly substituted compounds may require several days for complete reaction. Reaction of bismuth(III) oxide with α-hydroxy ketones is confined to examples possessing an α-hydrogen atom. It has been suggested that the oxidation proceeds via an enediol intermediate. Bismuth triacetate may act as an acylating agent towards alcohols and amines. This reaction occurs only at high temperatures (200 °C no solvent) and would not normally interfere with the oxidation of α-hydroxy ketones.

In a typical procedure the α-hydroxy ketone, dissolved in acetic acid, is heated on a steam bath with 1.2 equiv of bismuth(III) oxide. During the course of the reaction black metallic bismuth precipitates. Unhindered substrates are normally oxidized in under an hour under these conditions. The reaction mixture is filtered to remove bismuth and excess reagent; water is added and the product is extracted into ether. Yields of greater than 90% may be obtained. Sugars are not oxidized by the reagent and neither is

ascorbic acid. The presence in the reaction mixture of certain polyhydroxy compounds, such as glucose and catechol, inhibits the oxidation of α-hydroxy ketones owing to the formation of bismuth-containing compounds with these materials.[1]

Bis(4-nitrophenyl) Carbonate

[5070-13-3] · $C_{13}H_8N_2O_7$ · Bis(4-nitrophenyl) Carbonate · (MW 304.22)

(peptide coupling reagent;[1] reagent for formation of carbamate linked cytosines[2])

Physical Data: mp 144-145 °C.

Solubility: sol chloroform and THF.

Form Supplied in: off-white powder.

Peptide Coupling Reagent.

N-Protected amino acids can be converted into activated 4-nitrophenyl esters suitable for peptide coupling reactions. Reaction of the N-protected amino acid in acetic acid and pyridine with 1.5 equiv of the reagent under reflux for 3 h affords the activated ester following loss of CO_2 from the intermediate mixed anhydride (eq 1).[1]

Formation of Carbamate-Linked Cytosine Oligomers.[2]

Reaction of the 5´-protected aminocytosine derivative (**1a**) with the reagent in DMF and Et_3N afforded an activated 4-nitrophenyl carbonate derivative. Following purification, reaction of this compound with another monomer unit, (**1b**), provided the linked dimer (**2**) (eq 2). This compound was elaborated further into a carbamate-linked hexameric cytosine oligomer which was found to conjugate strongly to native DNA strands.

Formation of Ureido Sugars.[3]

A variety of 2-amino sugars can be converted into ureido derivatives in reasonable yields (50-83% for two steps). For example, methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside is first reacted with the reagent to afford a 4-nitrophenyl carbamate intermediate which, upon further reaction with a variety of secondary amines in CH_2Cl_2 at room temperature for 5-24 h, provides the ureido sugar. In a similar manner, symmetrical and unsymmetrical *N*,*N*´-disubstituted ureas can be prepared by the sequential addition of amines to the reagent.[4]

Bis(*p*-nitrophenyl) Hydrogen Phosphate

[645-15-8] · $C_{12}H_9N_2O_8P$ · Bis(*p*-nitrophenyl) Hydrogen Phosphate · (MW 340.19)

(acid catalyst[1,2] for preparation of nucleosides[3,4] and nucleoside acetals[1,5])

Physical Data: mp 175-175.5 °C;[6] pK_a 2.79 (H_2O),[7] pK_a 1.7 (50% EtOH).[8]

Form Supplied in: yellow crystals.

Preparative Methods: treat freshly distilled $POCl_3$ with finely powdered sodium *p*-nitrophenoxide, followed by partial alkaline hydrolysis of the corresponding tris(*p*-nitrophenyl) phosphate;[6] *p*-nitrophenol treated with $POCl_3$ in acetonitrile.[9]

Purification: recrystallization from H_2O to yield white needles.[6]

Nucleoside Synthesis.

Effective catalytic reagent for the preparation of nucleosides by fusion of purines with fully *O*-acetylated sugars.[3] This is superior to ***p-Toluenesulfonic Acid*** (except for synthesis of phenylborate nucleosides[10]), ethyl polyphosphate, or ***Zinc Chloride***. An example of the method[4] is the fusion of purine (**1**) with tetra-*O*-acetyl-D-ribofuranose (**2**), at 170-180 °C for 15 min under reduced pressure (water pump), to yield two nucleosides (**3**) and (**4**) (eq 1). The major product (**3**) is the triacetyl derivative of a naturally occurring nucleoside antibiotic nebularine.

Acetal Synthesis.

The reagent is used as an acid catalyst for the conversion of purines and pyrimidine ribonucleosides to their corresponding 2´,3´-*O*-isopropylidene (acetonide) derivatives, in the presence of 2,2-dimethoxypropane (effective for maintaining the anhydrous conditions necessary of such conversions). An example of the method[1] is the preparation of 2´,3´-*O*-isopropylidene uridine (eq 2).

Bis(*p*-nitrophenyl) hydrogen phosphate is superior to ***p-Toluenesulfonic Acid*** as a catalyst for the reaction because it has twice the lipophilic area, making its salts with nucleosides correspondingly more soluble in acetone. This procedure has been extended to a range of acetals other than isopropylidene, with greater or lesser stability to acid.[5]

Bis(*o*-nitrophenyl) Phenylphosphonate

[73404-18-9] · $C_{18}H_{13}N_2O_7P$ · Bis(*o*-nitrophenyl) Phenylphosphonate · (MW 400.28)

(coupling reagent for peptide[1,2] and carboxamide synthesis[3])

Preparative Method: readily prepared from *o*-nitrophenol and phenylphosphonic dichloride ($PhP(O)Cl_2$).[1]

Peptide and Carboxamide Synthesis.

Condensation of the tetrabutylammonium salt of *N*-benzoyl-L-leucine with glycine ethyl ester, the components in the Young's test,[4] in DMF in the presence of bis(*o*-nitrophenyl) phenylphosphonate proceeds to give the corresponding dipeptide in 82-93% yield without racemization.[1] Employment of quarternary ammonium salts[5] enables the reaction to proceed smoothly because of increased solubility[6] and nucleophilicity of the carboxyl component. The coproducts are *o*-nitrophenol and the phosphonate ammonium salt, which means that no free base such as tertiary amines need to be utilized, which often cause serious problems such as racemization during condensation (eq 1).[4] This method has been efficiently applied to more complex hexaglycine and leucine-enkephalin (L-Tyr-Gly-Gly-L-Phe-L-Leu) peptides.[2]

(1)

Preparation of both peptides and carboxamides have been simplified by the use of phase-transfer conditions in which the tetrabutylammonium carboxylic acid salts are formed in situ.[3] Thus treatment of free acids and amines in aqueous CH_2Cl_2 (or aqueous THF) with bis(*o*-nitrophenyl) phenylphosphonate in the presence of *n*-$Bn_4N^+HSO_4^-$ (or *n*-$Bn_4N^+Br^-$) gave corresponding carboxamides and peptides. An example of the method[3] is the preparation of an arylamide in quantative yield (eq 2).

Bis(*p*-nitrophenyl) Phenylphosphonate

[38873-91-5] · $C_{18}H_{13}N_2O_7P$ · Bis(*p*-nitrophenyl) Phenylphosphonate · (MW 400.28)

(efficient peptide coupling agent causing little racemization[1,2])

Physical Data: mp 99-101 °C.[3]

Form Supplied in: off-white to tan granules.[3]

Preparative Method: heat phenylphosphonic dichloride ($PhP(O)Cl_2$) with 2 equiv of 4-nitrophenol at 160 °C for 4 h.[4]

Purification: recrystallize from CCl_4 (mp 94-96 °C).[4]

Handling, Storage, and Precautions: hygroscopic; store in a cool dry place. Incompatible with strong oxidizing agents, acids, and bases.[3]

Peptide Synthesis.

Bis(*p*-nitrophenyl) phenylphosphonate (see also ***Bis(o-nitrophenyl) Phenylphosphonate***) has been used as a coupling reagent in the condensation of the tetrabutylammonium salt of *N*-benzoyl-L-leucine with glycine ethyl ester. These are the reactants used in the Young's test,[5] which is known as the most severe racemization test. The most favorable solvent used in the coupling was DMF and the reaction proceeded to the corresponding dipeptide in 93% yield, at below 0 °C with little racemization (95-97% L-isomer) (eq 1).

The advantage of using the tetrabutylammonium salt in the coupling reaction was that it increased both solubility[6] and nucleophilicity of the carboxylic component, enabling the reaction to take place without using tertiary amines, which play a major role in causing racemization. The quarternary ammonium salts were prepared by the reaction of alkaline *n*-$Bn_4N^+HSO_4^-$ or Bu_4N^+ OH^- on the carboxylic acid.[1]

This method has also been efficiently applied to the synthesis of opioid agonist leucine-enkephalin[2] (L-Tyr-Gly-Gly-L-Ppe-L-Leu) without protection of the phenolic hydroxy group in the tyrosine residue.[2]

Bis(*p*-nitrophenyl) Sulfite

[35887-81-4] · $C_{12}H_8N_2O_7S$ · Bis(*p*-nitrophenyl) Sulfite · (MW 324.29)

(preparation of *p*-nitrophenyl esters for use in peptide synthesis)

Physical Data: mp 98-100 °C; bp 172-174 °C/11 mmHg.

Solubility: sol MeCN.

Preparative Method: by the reaction of ***p-Nitrophenol*** with ***Thionyl Chloride*** in the presence of ***Pyridine*** in benzene at 0 °C.[7]

Purification: recrystallization from chloroform/hexane. Several recrystallizations are required to obtain the reagent in a pure form.

Handling, Storage, and Precautions: may be stored as a solution in acetonitrile at -30 °C; under these conditions, decomposition occurs only slowly. Decomposition and reaction products are *p*-nitrophenol and sulfur dioxide. Handle with gloves and in a fume hood.

Bis(*p*-nitrophenyl) sulfite is used to prepare activated *p*-nitrophenol esters.[1-5] These esters have found exclusive application as a method for carboxyl activation. The *p*-nitrophenol activated esters are stable and their major application is in the synthesis of peptide bonds. The activated ester is prepared by the reaction of a peptide or *N*-protected amino acid in pyridine with bis(*p*-nitrophenyl) sulfite (eq 1).

Some racemization has been observed where the amino acid is not a glycine or proline residue. An example of the use of this reagent is in the preparation of a cyclic peptide (eq 2).[4]

The *p*-nitrophenol esters are stable to acid (such as anhydrous TFA) but are moisture sensitive. Therefore, some hydrolysis of the ester occurs in the amine deprotection (eq 3). Following amine deprotection, further treatment with a base such as pyridine results in amide formation, to give the corresponding peptide (eq 4).

Carboxyl activation by other aryl esters based on halogen-substituted phenols has been investigated. Those derived from 2,4,5-trichlorophenol have found the widest application.[6] Pentafluorophenyl esters have also been prepared and react preferentially in the presence of *p*-nitrophenol esters.[8] Where the hydrogenolysis of benzyloxycarbonyl groups is required in the presence of acyl esters, the halogen-substituted acyl esters are preferred, as traces of unremoved *p*-nitrophenol can give rise to reactive *p*-aminophenol. It is also possible to prepare *p*-nitrophenol esters from *p*-nitrophenol and ***1,3-Dicyclohexylcarbodiimide***[9] or tris-*p*-nitrophenyl phosphite.[10]

Bis(2-oxo-3-oxazolidinyl)phosphinic Chloride[1]

[68641-49-6] · $C_6H_8ClN_2O_5P$ · Bis(2-oxo-3-oxazolidinyl)phosphinic Chloride · (MW 254.57)

(reagent for activating carboxyl groups,[1] converting acids to esters[2] (including thioesters[3] and phosphoesters[4]), amides[5] (including peptides[6-8] and β-lactams[9,10]), and anhydrides;[11] reagent for kinetic resolution of racemic carboxylic acids and alcohols[12])

Alternate Names: *N,N*-bis(2-oxo-3-oxazolidinyl)phosphordiamidic chloride; *N,N*-bis(2-oxo-3-oxazolidinyl)phosphorodiamidic chloride; phosphoric acid bis(2-oxooxazolidide)chloride; BOP-Cl; BOPDCl.

Physical Data: white powder, mp 195-198 °C; hygroscopic.

Solubility: slightly sol CH_2Cl_2, MeCN, THF, DMF; dec H_2O.

Form Supplied in: white to off-white powder, typically 97% pure.

Analysis of Reagent Purity: IR (KBr): 1775 (C=O), 765 (P-Cl) cm^{-1}.

Purification: the outcome of reactions can be greatly affected by the purity of the reagent; commercial samples may require to be washed with cold water and recrystallized from MeCN prior to use.[13]

Handling, Storage, and Precautions: store in a cool dry place under nitrogen to preclude contact with moisture and oxygen. Use only in a chemical fume hood. Wear suitable protective clothing and eye/face protection. Causes burns and is harmful if swallowed, inhaled, or absorbed through skin.

Carboxyl Group Activator.

BOP-Cl[1] is used for a direct, one-pot conversion of carboxylic acids into esters (eq 1)[2] (including thioesters[3] and phosphoesters[4]), amides (eq 2),[5] and anhydrides (eq 3).[11] Conditions for minimizing side reactions and optimizing yields of both esters and amides are reported.[2,5] Advantages offered over previously used reagents, such as ***N,N´-Carbonyldiimidazole***, carbodiimides, and unsymmetrical anhydrides, include good yields (typically >80%), mild reaction

conditions, and tolerance of both steric bulk and a wide range of functional groups.

(1)

(2)

(3)

The mechanism of these reactions is assumed to involve displacement of chloride by the carboxylate anion to give a phosphorodiamidate (eq 4). Subsequent nucleophilic attack of an alcohol, amine, or a carboxylate anion affords phosphorodiamidic acid and esters, amides, and anhydrides, respectively (eq 5).

(4)

(5)

For lactonization (eq 6),[14] including the synthesis of macrolactones,[15] BOP-Cl is a useful reagent.

(6)

Chemo- and regioselective acylation with BOP-Cl is illustrated by the formation of 5´-benzoyldeoxyadenosine in good yield (eq 7).[16]

(7)

For the synthesis of oligonucleotides, BOP-Cl is an effective coupling reagent, allowing phosphotriesters to be prepared in high yields without detectable side reactions (eq 8).[17]

DMT = 4,4'-dimethoxytrityl

(8)

β-Lactams may be prepared either by condensation of imines with carboxylic acids (eq 9)[9] or by cyclization of β-amino acids (eq 10).[10]

(9)

(10)

BOP-Cl has been used quite extensively for the synthesis of peptides.[6-8] It is particularly useful for coupling *N*-alkyl-α-amino acids with minimal racemization (eq 11),[18,19] although the quality of BOP-Cl employed in these reactions can significantly affect yields,[13] and the analogous azide, BOP-N_3, has been proposed as an alternative reagent.[20] Racemization can sometimes be suppressed by inclusion of additives such as ***1-Hydroxybenzotriazole*** (HOBt) or ***Imidazole*** (eq 12),[21] although under certain conditions HOBt can induce epimerization.[22]

(11)

Cbz-Gly-D/L-Phe-L-Val-OMe (12)

	Yield (%)	Epimerization (%)
with HO-*t*-Bu	88	0.0
with imidazole	96	0.8
without HO-*t*-Bu or imidazole	78	5.6

Problems, notably racemization and poor yields due to oxazolone formation, are encountered when coupling *N*-acyl amino acids with BOP-Cl;[6] ***1,3-Dicyclohexylcarbodiimide*** (DCC) is a better reagent to use in such cases. Some limitations of BOP-Cl for peptide couplings have been discussed;[7] it is not recommended for β-branched α-amino acids (e.g. Boc-Val) or for couplings in which the nucleophile is a primary amine.[8]

Kinetic Resolution.

BOP-Cl is a condensation agent for the kinetic resolution of racemic carboxylic acids and alcohols with chiral alcohols (eq 13) and carboxylic acids, respectively.[12]

Bis(*o*-phenylene) Pyrophosphite

[16421-86-6] · $C_{12}H_8O_5P_2$ · Bis(*o*-phenylene) Pyrophosphite · (MW 294.14)

(reagent for peptide synthesis[1])

Physical Data: mp 72 °C; bp 156 °C/0.25 mmHg; *n*20D 1.5090 (supercooled liquid).

Preparative Method: reaction of ***Catechol*** with ***Phosphorus(III) Chloride*** gives *o*-phenylene phosphorochloridite, which upon hydrolysis affords bis(*o*-phenylene) pyrophosphite (**1**).[2]

Purification: purified by distillation at reduced pressure.

Handling, Storage, and Precautions: may be stored indefinitely in a stoppered bottle.

Peptide Synthesis.

The reagent (**1**) was introduced as a substitute in peptide synthesis for the widely used, but less easily prepared, ***Tetraethyl Pyrophosphate***. Heating a mixture of an *N*-protected (Cbz or phthaloyl) amino acid and an amino acid or peptide ester with 1.1 equiv of (**1**) in pyridine effects amide bond formation (eq 1).[1] The amino acid or peptide ester may be used as its hydrohalide or tosylate salt. The method is experimentally simple and has the additional advantage that the crude product is generally of sufficient purity for preparative purposes. Prereaction of (**1**) with either coupling partner to give the active ester or the phosphoramidite intermediate is possible but offers no advantage.

While no racemization was detected in couplings involving *N*-Cbz-protected amino acids, use of *N*-protected dipeptides as carboxyl components resulted in extensive racemization, presumably by the oxazolone mechanism. The method is also unsuitable for the synthesis of tyrosine peptides without prior protection of the phenolic hydroxy group, since *O*-phosphorylation may occur.

Synthesis of cyclic peptides using (**1**) was studied by Miller and Smith.[3] Use of diethyl phosphite as solvent rather than pyridine was found to be necessary; the method gave better results than ***1,3-Dicyclohexylcarbodiimide*** (DCC) for cyclization of penta- and hexapeptides, but was not suitable for cyclization of tripeptides.

1,2-Bis(phenylsulfonyl)ethylene[1]

(*Z*)

[963-15-5] · $C_{14}H_{12}O_4S_2$ · 1,2-Bis(phenylsulfonyl)ethylene · (MW 308.37) (*E*)

[963-16-6]

(powerful dienophiles and synthetic equivalents of acetylene and ethylene in Diels-Alder cycloadditions;[2] react as Michael acceptors with substitution of a phenylsulfonyl group[3])

Alternate Name: BPSE.

Physical Data: (*Z*) mp 100-101 °C; (*E*) mp 219.5 °C.

Solubility: the (*Z*)-isomer is more soluble than the (*E*)-isomer in most solvents. In Diels-Alder cycloadditions conducted in dichloromethane, the (*Z*)-isomer affords quite insoluble adducts; conversely, the (*E*)-compound leads to more soluble products.

Form Supplied in: colorless solids; commercially available.

Analysis of Reagent Purity: purity with respect to one another can be checked by ^{1}H NMR. The vinyl protons of the (*Z*)-isomer appear at 6.82 ppm and those of the (*E*)-isomer at 7.37 ppm in $CDCl_3$.

Preparative Methods: (*Z*)-1,2-bis(phenylsulfonyl)ethylene is prepared by oxidation of the corresponding thioether,[2] which is prepared from (*Z*)-1,2-dichloroethylene[4] or, for large quantities, from 1,1-dichloroethylene.[4b] A mixture of the (*Z*)- and (*E*)-1,2-dichloroethylenes can also be used, but the (*E*)-isomer is unreactive under standard conditions.[4b] Under more drastic reaction conditions (DMF, 70-90 °C), (*E*)-1,2-dichloroethylene also affords the substitution product [57% (*E*), 14% (*Z*)].[4c] The preparation of the (*E*)-isomer is accomplished by sunlight-iodine catalyzed isomerization of the (*Z*)-isomer.[2]

Handling, Storage, and Precautions: the (*Z*)-isomer should be stored protected from direct light because it isomerizes to the (*E*)-form.

Cycloadditions.

1,2-Bis(phenylsulfonyl)ethylenes [(*Z*)- and (*E*)-BPSE] are most commonly used as synthetic equivalents of acetylene in cycloaddition reactions (eq 1).[2,5] A number of dienes have been prepared via this route which are otherwise not readily accessible.[6]

(1)

The preparation of both the *syn*- and the *anti*-sesquinorbornatrienes was possible because of the different stereochemistry by which the (*Z*)- and (*E*)-isomers add to 8,9-dehydroisodicyclopentadiene (eq 2).[7] Further studies on these molecules have been reported, including the preparation of deutero derivatives via the deuterated (*Z*)-BPSE.[8] Use of (*E*)-BPSE in the preparation of a natural product is described in eq 3.[9]

(2)

The choice of the solvent for cycloadditions is often crucial. While both reagents are not reactive towards furan in refluxing benzene,[10] they react smoothly at rt in quantitative yields in dichloromethane.[2,11]

Generally, the (*E*)-isomer is more reactive in cycloadditions than the (*Z*)-isomer. For example, the reaction of (*E*)-BPSE with cyclopentadiene in dioxane is 100 times faster than that of the (*Z*)-isomer.[12] A few dienes (1,3-cycloheptadiene and cyclooctatetraene are examples) react only with the former. With cyclopentadiene in dioxane, (*E*)-BPSE is twice as reactive as ***Maleic Anhydride***,[12] but cases have been reported where (*E*)-BPSE failed to react while maleic anhydride did react. Styrene, homobarrelene, and other polycyclic dienes are examples.[13] High pressure (10-12 kbar) can be used to increase reactivity.[14] Examples are the preparations of derivatives of *syn*-sesquinorbornatriene[14a] and of the C_{4v} [4]peristylane tetraketone (eq 4).[14c]

(4)

The desulfonylation of cycloadducts can be performed with ***Sodium Amalgam*** (1.5-6%) in methanol buffered with suspended sodium dihydrogen phosphate.[2] Because the reaction is heterogeneous, sonication has been proved beneficial.[13a] ***Samarium(II) Iodide*** in HMPA has also been used.[15] Other reducing agents and reaction conditions, such as ***Magnesium-Methanol***,[16] afford mixtures of saturated and unsaturated hydrocarbons. ***Lithium*** or ***Sodium*** metal in liquid ammonia effectively gives solely the saturated adduct, making the title reagent equivalent to ethylene in cycloaddition reactions.[17]

When treated with base, the Diels-Alder adducts give vinyl sulfones. In one example, the vinyl sulfone was further reacted with nucleophiles in a synthesis of ibogamine (eq 5).[18]

(5)

Substitution of one vinyl hydrogen with chlorine gives reagents that can be considered equivalents of the unstable bis(arylsulfonyl)alkynes (eq 6).[19]

(6)

The parent and substituted bis(arylsulfonyl)alkenes, such as the one prepared in eq 6, are good Michael acceptors[20] and react with heteroatomic nucleophiles and Grignard reagents.[3,21] The products correspond to the formal substitution of one of the phenylsulfonyl groups. In eq 7, the product of the Michael addition cyclizes to a dihydrofuran upon deprotonation with ***Lithium Diisopropylamide***.[21a]

Both isomeric reagents are also reactive dipolarophiles.[22] For example, they react with azomethine ylides,[22a,b] nitrones,[22c] and diazoalkanes (eq 8).[22d]

C_2-Symmetrical chiral versions of these reagents (**1**) and (**2**), which maintain the chemical properties associated with the achiral reagents, are available (see ***1,1´-Binaphthalene-2,2´-dithiol***).[23]

(1)

(2)

These reagents are stable towards racemization and are readily available from the respective dibenzo- or dinaphtho-2,2´-dithiols. In cycloadditions with nonsymmetrical dienes they afford a single diastereoisomer in most cases.

1,1-Bis(phenylsulfonyl)ethylene[1]

[39082-53-6] · $C_{14}H_{12}O_4S_2$ · 1,1-Bis(phenylsulfonyl)ethylene · (MW 308.37)

(powerful Michael acceptor and dienophile; reagent for two-carbon homologation of ketones; synthetic equivalent of ethylene in Diels-Alder reactions and of ethylene 1,2-dipole in cycloadditions)[1]

Alternate Name: 1,1-BPSE.

Physical Data: mp 124-126 °C.

Form Supplied in: colorless solid.

Analysis of Reagent Purity: depending upon the method of preparation, it may contain bis(phenylsulfonyl)methane and 1,1,3,3-tetrakis(phenylsulfonyl)propane as impurities. In a few cases, isomerization to (*E*)-1,2-bis(phenylsulfonyl)ethylene has been observed.[2,3a] The chemical shift of the vinyl protons is 7.19 ppm ($CDCl_3$).

Preparative Methods: the reagent can be prepared via careful oxidation of the corresponding ketene dithioacetal[3a] or via Mannich condensation of bis(phenylsulfonyl)methane with paraformaldehyde and a secondary amine followed by elimination with acids.[3]

Handling, Storage, and Precautions: keep dry and refrigerated; potential alkylating agent; use in a fume hood.

Addition Reactions.

The two geminal phenylsulfonyl groups impart to the double bond of 1,1-BPSE a strong electrophilic nature which manifests most evidently in Michael additions.[1b] Heteroatomic nucleophiles such as amines, alcohols, and thiols add in nonpolar solvents even without added base.[1b,3a] Water, either under acid or base catalysis, and strong nucleophiles in protic solvents can cleave the double bond with eventual formation of 1,1,3,3-tetrakis(phenylsulfonyl)propane.[1b,4] 1,1-BPSE adds to carbon nucleophiles generated from active methylene compounds using different bases[5] (eq 1),[5d] including fluoride ions,[5d] or under Lewis acid catalysis.[5a] Neutral carbon nucleophiles[6] such as enol ethers (eq 2)[6c] and enamines[6a] also add smoothly with no need of extra activation. Enantiomerically pure enamino esters give, after

hydrolysis, ketones which display stereochemistry opposite to that obtained with ***Phenylsulfonylethylene*** (eq 3).[6d] Ynamines react similarly, but in this case the likely zwitterionic intermediate cyclizes to a [2 + 2] cycloadduct (eq 4).[7]

(1)

R = COMe, COPh, SO_2Ph, NO_2, etc.

(2)

(3)

(4)

Enolizable ketones and imines also react with 1,1-BPSE even without base catalysis.[6] Since the nucleophile is presumably the enol, the regiochemistry of the addition is opposite to that obtained with enolates (eq 5).[6b]

(5)

Cycloadditions.

The title reagent forms Diels-Alder adducts with dienes such as 1,3-cyclohexadiene (**1**),[8a,b] cycloheptatriene (**2**),[8a] norbornadiene (**3**),[6a,8c] quadricyclane (**4**),[6a,8a,c] 2-acetoxy-1,3-cyclopentadiene (**5**),[8a] and *N*-benzoylindole-2,3-quinodimethane (**6**).[8d] In cases where two regioisomers can form, the results are in accordance with the stereochemistry expected on the basis of orbital coefficients.[8a,d]

(1)

(2)

(3)

(4)

(5)

(6)

Due to the polarization of the reagent, [2 + 2] cycloadducts and products arising from dipolar rearrangements have been observed in reactions with strained alkenes. Benzonorbornadiene is an example (eq 6).[6a] The desulfonylation reaction can be performed with ***Aluminum Amalgam*** or ***Sodium Amalgam*** in such a way as to obtain sequential mono- and bisdesulfonylation (see also ***1,2-Bis(phenylsulfonyl)ethylene***).

Chiral variants of the title reagent having a 2,2´-binaphthyl residue in the place of the two phenyl rings have been proposed (see ***1,1´-Binaphthalene-2,2´-dithiol***).[9]

Bis(phenylthio)methane[1]

[3561-67-9] · $C_{13}H_{12}S_2$ · Bis(phenylthio)methane · (MW 232.36)

(lithio derivative is formyl anion equivalent[2] but chief uses are in synthesis of phenyl vinyl sulfides[3] and α-(phenylthio) ketones[4])

Physical Data: mp 38 °C.

Solubility: sol THF, diethyl ether; insol H_2O.

Form Supplied in: yellow crystals (white when pure).

Preparative Methods: all methods begin with benzenethiol (***Thiophenol***, PhSH). An early approach involved reaction of ***Diiodomethane*** with PhSNa (generated from PhSH and NaOH in ethanol).[2] Dichloromethane (CH_2Cl_2) has replaced the more expensive CH_2I_2 in more recent methods either in the presence of triethylamine[3] or under phase-transfer conditions with ***Potassium Carbonate*** and ***Benzyltriethylammonium Chloride***.[5] The hydrogen chloride-catalyzed reaction of benzenethiol with ***Dimethoxymethane*** is an effective procedure.[6]

Purification: recrystallize from petroleum ether.

Handling, Storage, and Precautions: irritating to mucous membranes and upper respiratory tract. Precautions should be followed to avoid inhalation, ingestion, contact with the eyes, or absorption through the skin. Stench. Store in a cool dry place. The toxicological properties appear not to have been thoroughly investigated but exposure can cause nausea, headache, and vomiting.

Introduction.

As reagents for nucleophilic acylation, bis(phenylthio)methane (**1**) and ***1,3-Dithiane*** were introduced into synthetic methodology at about the same time. Application of (**1**) to the synthesis of aldehydes involves a sequence of steps (eqs 1-3) analogous to those of 1,3-dithiane. In practice, however, the sequence beginning with 1,3-dithiane is the standard method for nucleophilic acylation while that based on (**1**) is rarely employed. Nevertheless, there are a number of novel transformations involving derivatives of (**1**) and it is the applications of these reactions that comprise the major portion of the present account. Before examining these reactions, a brief discussion of the metalation of (**1**) (eq 1) and the reactions of its lithio derivative (**2**) is in order.

Metalation of (1) and Nucleophilic Reactivity of (2).

With a pK_a of 30.8 (in DMSO),[7] (**1**) is a somewhat stronger acid than 1,3-dithiane (pK_a = ca. 39 in DMSO) and is readily metalated with ***n-Butyllithium*** in THF (eq 1).[2,3] The resulting clear yellow solution of bis(phenylthio)methyllithium (**2**) is stable at 0 °C for at least 12 h. Early studies in which sodium amide in liquid ammonia was used in the metalation step gave lower yields of subsequent alkylation products.[8] Reaction of (**2**) with primary alkyl halides gives high yields of phenyl thioacetal derivatives of aldehydes (**3**) (eq 2).[2,9,10] Secondary alkyl halides are less effective alkylating agents but 3-chloro-1-butene, which is a relatively unhindered secondary allylic halide, gives the desired alkylation product in almost quantitative yield and without allylic rearrangement (eq 4).[11]

(4)

Dialkylation is difficult and requires the presence of metal-complexing agents to enhance the reactivity of the organometallic in the second alkylation step. Thus metalation of 1,1-bis(phenylthio)ethane (**4**)[12] in hexane containing TMEDA, followed by addition of a variety of primary alkyl halides, produced compounds of type (**5**) in synthetically useful yields (eq 5).[13] Similar results were obtained using a procedure in which ***Sodium Amide*** was added to a THF-HMPA solution of (**4**) and a primary alkyl halide.[14]

(5)

Bis(phenylthio)methyllithium (**2**) reacts with ethylene oxide to give the product of nucleophilic ring opening (eq 6).[15] Lithio derivative (**2**) reacts with epibromohydrin by displacement of halogen, leaving the epoxide ring intact.[10]

(6)

A number of studies directed toward synthetic applications of (**1**) have described reactions of lithio derivative (**2**) with aldehydes and ketones as a key step.[2-4,16,17] As exemplified in (eq 7), such reactions proceed readily.[9a] Addition of (**2**) to α,β-unsaturated aldehydes seems to be exclusively 1,2[3,18] but a mixture of 1,2- and 1,4-addition products are observed with α,β-unsaturated ketones. The tendency toward 1,4-addition is more pronounced with (**2**) than with ***2-Lithio-1,3-dithiane*** and is increased in the presence of HMPA (eq 8).[19] 1,4-Addition predominates in reactions of the cuprate reagent derived from (**2**).[20]

(7)

Preparation of Phenyl Vinyl Sulfides.

Copper(I) Trifluoromethanesulfonate (triflate) is an effective reagent for promoting carbocation formation by cleavage of a phenylthio substituent from bis(phenylthio) acetals (eq 9).[21] Deprotonation of the resulting α-phenylthio carbocation yields a phenyl vinyl sulfide. Reaction conditions have been developed for the effective synthesis of phenyl vinyl sulfides by alkylation of (**1**) followed by copper(I) triflate-induced elimination (eq 10).[3]

A novel fragmentation occurs when (**6**) (derived from (**2**) and 1,2-epoxycyclohexane) as its lithium alkoxide is treated with excess (4 equiv) of copper(I) triflate.[22] The product is a phenyl vinyl sulfide (eq 11).

Preparation of α-(Phenylthio) Ketones.

The adducts of (**2**) with aldehydes and ketones give α-(phenylthio) ketones on treatment with copper(I) triflate in refluxing benzene containing *N*-ethyl-*N*,*N*-diisopropylamine (eq 12).[4] The adducts of cyclic ketones yield ring-expanded α-(phenylthio) ketones as illustrated by the example in eq 13. The reaction is believed to proceed by Cu^{I}-promoted ionization of one of the phenylthio substituents, followed by epoxide formation, then hydride or alkyl group migration.

(12)

(13)

A similar transformation occurs when adducts of (**2**) with aldehydes and ketones are treated with ***p-Toluenesulfonic Acid*** in refluxing benzene.[9a] The adducts of (**2**) with cyclic ketones undergo an analogous rearrangement via a carbenoid mechanism when converted to their dianions by reaction with two equivalents of ***Methyllithium*** or ***s-Butyllithium*** in THF at 0 °C.[23] The α-(phenylthio) ketones formed by this procedure can serve as precursors to enones (by oxidation and thermal elimination of the resulting sulfoxide)[9b] and α-(phenylthio) enones (by Pummerer rearrangement).[16]

Bis(methylthio)methane as an Analogous Reagent.

Deprotonation of bis(methylthio)methane with *n*-butyllithium affords bis(methylthio)methyllithium, which has been used several times as a formyl anion equivalent. Addition of bis(methylthio)methyllithium to cyclic vinylogous esters[24] affords, after aqueous acid hydrolysis, 3-bis(methylthio)methylcyclohexenones (eq 14).[25] Thioacetal hydrolysis provides the 3-formylcyclohexenone.

(14)

Epoxide opening by bis(methylthio)methyllithium, tosylate formation, deprotonation and intramolecular tosylate displacement affords cyclopropanone thioacetals in good yields via a one-pot procedure (eq 15).[26] Reaction of a carbohydrate *N*-acetylaziridine with bis(methylthio)methane and acetic acid gave in high yield the *S*-alkylation product (eq 16) via the presumed pathway shown. Clean inversion of configuration at C(7) was observed.[27]

(15)

Electrophilic thionium ion intermediates have been accessed via thioacetals derived from bis(methylthio)methane.[28] Successive deprotonation/alkylation steps lead to the cyclization substrates in eqs 17 and 18. In the former, the bracketed thionium ion arises from treatment of the thioacetal with ***p-Toluenesulfinic Acid*** in warm acetonitrile. Cyclization and elimination steps yielded the 4-substituted indole.[28a] Treatment of the thioacetal in eq 18 with ***Dimethyl(methylthio)sulfonium Tetrafluoroborate*** provides the spirocyclic enone shown via initial thionium ion trapping by the vinylsilane, followed by allylic sulfide activation and cyclization involving the enol silyl ether.[28b] These applications highlight the nucleophilic *and* electrophilic behavior of the thioacetal linkage.

Bis(*N*-propylsalicylideneaminato)copper(II)

[14077-15-7] · $C_{20}H_{24}CuN_2O_2$ · Bis(*N*-propylsalicylideneaminato)copper(II) · (MW 387.97)

(catalyzes decomposition of diazo ketones to carbenoids;[2] promotes electron transfer reactions[4])

Alternate Name: bis[2-(*N*-propylformimidoyl)phenolato]copper.

Physical Data: green or greenish-brown needles; mp 127-128 °C.

Solubility: sol alcohol, dioxane, chloroform, and benzene; insol water, pet ether.

Preparative Method: by one-pot reaction of *n*-propylamine with the bis(salicylaldehato)copper complex prepared from copper(II) acetate and salicylaldehyde.[1]

Purification: recrystallization from cyclohexane or chloroform-ethanol.[1]

Handling, Storage, and Precautions: irritant. The copper chelate can be stored at rt in the absence of moisture.

Diazo Ketone Decomposition.

In the synthesis of the natural sesquiterpene (±)-α-chamigrene, construction of the spirocyclic skeleton involved an intramolecular ketocarbenoid addition via thermal copper-catalyzed diazo ketone decomposition, followed by dissolving-metal reduction of the cyclopropane ring in the product (eq 1).[2,3]

It was discovered that insoluble copper salts typically employed for such decompositions, e.g. ***Copper(II) Acetate*** and ***Copper(I) Chloride***, reacted instead with the acetal protecting group. Use of the more soluble copper chelate avoided this problem, giving the tricycloketone intermediate in 66% yield.[3] With relatively nonfunctionalized systems (eq 3), the more traditional copper salt catalysts are as effective as the title reagent; thus ***Copper*** powder could be employed in a similar diazo ketone decomposition which ultimately led to the spirocyclic (-)-acorenone B (eq 2).[3,5]

Electron Transfer Reaction.

The reagent, and other similar chelated copper(II) complexes, catalyzes the oxidation of 3,5-di-*t*-butylcatechol by O_2. The catalytic behavior is related to the electron transfer reactions between the complex and two-electron donors such as catechols and ascorbic acid (eq 4).[4]

Bis(*N*-propylsalicylideneaminato)cobalt(II)

(R = *n*-Pr)

[100031-33-2] · $C_{20}H_{24}CoN_2O_2$ · Bis(*N*-propylsalicylideneaminato)cobalt(II) · (MW 383.35) (R = *i*-Pr)

[41754-09-0]

(catalyst for the conversion of arylglyoxals to α-aryl-α-hydroxyacetic esters[1])

Physical Data: mp 226-234 °C (R = *i*-Pr).[2]

Solubility: sol $CHCl_3$, benzene, and dioxane; slightly sol ethanol and cyclohexane; insol petroleum ether.

Form Supplied in: red crystals.

Preparative Methods: a solution of bis(salicylaldehyde)cobalt(II) dihydrate and a slight excess of propylamine in methanol is heated at reflux in the presence of a trace amount of formaldehyde for 10 to 40 min.[3] As the mixture is cooled, red crystals separate out. The crystals are filtered quickly and dried in vacuo.

Purification: recrystallization from *i*-PrOH/$CHCl_3$ (*i*-Pr).[4]

Handling, Storage, and Precautions: unlike the *N*-*i*-propylsalicylidene Co^{II} complex, the *N*-*n*-propylsalicylidene Co^{II} complex is readily oxidized by oxygen in the atmosphere.[3] It is thus necessary to carry out the above procedure in an oxygen-free atmosphere.

α-Phenyl-α-hydroxyacetic Ester.

Bis(*N*-*n*-propylsalicylideneaminato)cobalt(II) catalyzes the highly selective transformation of phenylglyoxal to α-phenyl-α-hydroxyacetic ester (eq 1).[1] After a solution of phenylglyoxal (**1**) (1.0 mmol) and *N*-*n*-propylsalicylidene

Co^{II} complex (**2a**) (0.2 mmol) in a mixture of *i*-PrOH (40 mL) and 1,2-dichloroethane (20 mL) was heated at 60 °C for 8 h under oxygen atmosphere, the metal complex was separated, and the solvent was evaporated to afford a 97:3 mixture of *i*-propyl mandelate (**3**) and *i*-propylphenyl glyoxylate (**4**) in 93% yield. *N*-*i*-Propylsalicylidene Co^{II} complex (**2b**) also catalyzes this transformation; however, a lower yield (31%) of *i*-propyl mandelate (**3**) was obtained. The hydroxocobalt(III) complex, $Co^{III}(OH)$,[5] which is generated from irreversible oxidation of the Co^{II} complex in alcoholic solvents, is believed to be the reactive catalytic species.

Bis(pyridine)iodonium(I) Tetrafluoroborate[1]

[15656-28-7] · $C_{10}H_{10}BF_4IN_2$ · Bis(pyridine)iodonium(I) Tetrafluoroborate · (MW 371.91)

(iodinating agent for the selective functionalization of unsaturated compounds;[2-4] can also mediate C-C bond formation[5])

Physical Data: mp 149-151 °C (dec).[6]

Solubility: sol CH_2Cl_2, DMSO, MeCN, pyridine, DMF; modestly sol $CHCl_3$; insol ether, THF, hexane.

Analysis of Reagent Purity: spectroscopic data: IR,[6] NMR (^1H, ^{13}C).[6]

Preparative Method: prepared by the reaction of HgO/HBF_4-SiO_2[7] with iodine and pyridine in dry CH_2Cl_2 at rt.[2,6] Solids are filtered off, and the reagent is isolated by precipitation from CH_2Cl_2 solution by addition of cold ether, repeating the operation several times until a negative test for mercury(II) is obtained (i.e. absence of precipitation of mercury by treatment of an aliquot with $NaBH_4$/NaOH).[2]

Purification: recrystallization from CH_2Cl_2-$CHCl_3$ (white solid).

Handling, Storage, and Precautions: can be safely stored under a nitrogen atmosphere (in the dark at 4 °C) for long periods of time (up to 3 months has been observed) without changing either properties or physical appearance.

Reaction with Alkenes.

Ipy_2BF_4 reacts readily with alkenes in CH_2Cl_2 to afford 1,2-disubstituted products arising from addition of iodine and pyridine.[6] Synthetically more important is the reaction of alkenes with Ipy_2BF_4 in the presence of nucleophiles, which provides a general method for the vicinal iodofunctionalization of alkenes. In this regard, HBF_4 (used as commercially available 54% ethereal soultion) is usually added to the reaction mixture to avoid the competitive formation of products

from pyridine acting as nucleophile (eq 1).[6] ***Tetrafluoroboric Acid*** was selected to neutralize pyridine on the basis of its low nucleophilic character. As an alternative, the use of ***Boron Trifluoride Etherate*** has been reported.

(1)

A variety of nucleophiles participate in this reaction, and the nature of the nucleophile is important in determining the experimental protocol. Typical inorganic salts (e.g. Br^-) behave as efficient nucleophiles in this reaction using dioxane:water (10:1 v/v) as solvent, so that addition of HBF_4 is not required. A different and representative procedure can be followed for nucleophiles that can be used as solvents; for instance, MeCN reacts at -30 °C with alkenes and Ipy_2BF_4-HBF_4 (1:2 molar ratio), furnishing 2-iodoamides after hydrolysis. On some occasions, CH_2Cl_2 can be employed as the solvent, allowing a reduction in the amount of nucleophile. Oxygenated compounds (for instance methanol) and arenes can also be employed as nucleophiles following the latter approach.

Remarkably, reaction of alkenes with Ipy_2BF_4-HBF_4 in CH_2Cl_2 (-60 °C, 30 min) in the absence of nucleophile produces iodofluorinated compounds in high yield. The regioselectivity of the process is illustrated in the reaction of 1-hexene (eq 2).[3] Regarding the stereochemistry of the reaction, it was found that cyclohexene leads exclusively to *trans*-1-fluoro-2-iodocyclohexane in 89% yield. This mild iodofluorination process is quite general with respect to the structure of the alkene and has been nicely adapted to fluoroiodinate the less reactive esters of acrylic acid. The regio- and stereoselectivity shown together with other features of this process are compatible with an initial electrophilic attack of iodine to the alkene followed by ring opening of the resulting iodonium ion via nucleophilic attack of one fluoride ion liberated by BF_4^-.[8]

(2)

Carbon-carbon bond formation can also be mediated by the title reagent, providing routes to carbocycles. Reaction of difunctional α,δ-arylalkenes with Ipy_2BF_4-HBF_4 results in a diastereoselective and high-yield intramolecular six-membered ring construction (eq 3).[9] The regio- and stereochemistry found can be rationalized in terms of a chairlike transition state for the attack of electrophilic iodine to the difunctional compound, in agreement with the Stork-Eschenmoser hypothesis.[10] The reaction of 1,5- and 1,6-dienes took place in a related manner. It was found that, besides intramolecular carbon-carbon bond formation, concomitant fluorine incorporation into the cyclized products took place (e.g. 1,5-hexadiene gives 1-fluoro-4-iodocyclohexane as the major reaction product). Interestingly, cyclizations also occur when using ***Trifluoromethanesulfonic Acid*** instead of HBF_4; thus 1,5-hexadiene furnishes 4-iodocyclohexene in 70% yield.

(3)

Reaction with 1,3-Dienes.

Nucleophiles react with conjugated dienes in the presence of Ipy_2BF_4-HBF_4, furnishing products derived from 1,2- and/or 1,4-addition.[11,12] The structure of the starting diene and, in some cases, the reaction temperature were decisive factors in determining the addition pattern. Terminal dienes (i.e. 1,3-butadiene, isoprene, 2,3-dimethyl-1,3-butadiene) cleanly afford 1,2-addition products (eq 4).[11] Exceptions to this trend were found when working with C_6H_6 and MeCN as nucleophiles, where 1,4-addition products were observed.[12]

(4)

Thus reaction of 1,3-butadiene with Ipy_2BF_4-HBF_4 in MeOH at -40 °C furnished CH_2=CH-CH(OMe)CH_2I in 86% yield. Similar behavior was noticed for 2,3-dimethyl-1,3-butadiene (78% yield of the 1,2-addition product) without evidence for the formation of the 1,4-regioisomer. Internal dienes, such as 1,3-cyclooctadiene and 2,4-hexadiene, were found to undergo exclusively 1,4-addition irrespective of the nature of the nucleophile (Nu: Cl, OCHO (from DMF), MeCONH (from MeCN); NO_2^-).[11] In fact, 1,3-cyclooctadiene reacted with MeOH, under related conditions to those described for 1,3-butadiene, affording the 1,4-regioisomer in 58% yield. Experimental conditions were also described to isomerize 1,2-addition products (kinetic control) to their 1,4-regioisomers (thermodynamic control).[12]

Reaction with Alkynes.

This process has been studied in some detail. Alkynes react with Ipy_2BF_4 and nucleophiles (i.e. RCO_2H, Cl^-, py, ArH,

Br^-, I^-) to give 1,2-iodofunctionalized alkenes in moderate to good yield.[2,13,14] Addition products are generally formed as single regio- and stereoisomers; this fact enhances the synthetic utility of this reaction. The regiochemistry can be predicted by taking into account polar effects exerted by the substituents onto the triple bond; PhC&tbond;CH, *n*-BuC&tbond;CH, and PhC&tbond;CMe thus incorporated nucleophiles at the underlined carbon atom. With respect to stereoselectivity, the situation is somewhat more complicated but still some helpful generalizations are possible. Thus terminal alkynes furnished products derived from an *anti* addition of iodine and the nucleophile. For internal acetylenes the outcome was affected by the nature of the nucleophile; *syn* addition occurs for the strong nucleophile I^-, whereas weaker nucleophiles (RCO_2H, Cl^-, py, ArH) give rise to *anti* addition products.[2,14] Competition between *anti* and *syn* addition was noticed for borderline nucleophiles like Br^-. The same observation was made for reactions of weaker nucleophiles (RCO_2H) with internal alkynes bearing a bulky substituent on the sp carbon (PhC&tbond;C-*t*-Bu).[2] An ionic mechanism that involves participation of a vinyleneiodonium ion was proposed to account for the observed selectivity.

Taking advantage of their reactivity towards the reactive Ipy_2BF_4-HBF_4 in CH_2Cl_2 solution, alkynes were successfully employed to alkylate aromatic compounds. This type of Friedel-Crafts alkylation reaction had been rarely observed before (eq 5).[14] Efficient nucleophiles that take part in this alkylation include C_6H_6, C_6D_6, alkylbenzenes, anisole, and naphthalene. Bromobenzene gives only a modest yield (20%) of adduct on reaction with phenylacetylene. The alkyne component can be modified (*n*-BuC&tbond;CH; PhC&tbond;CMe), maintaining the same regioselectivity pattern in the addition. The intramolecular version of the process is also known.[9]

(5)

The influence of polar effects of the substituents to control the regiochemistry was clearly shown when alkynyl sulfides were used as starting materials (eq 6).[15]

(6)

Based on this special reactivity of Ipy_2BF_4, a new one-pot procedure to prepare iodinated alkynes from alkynes was reported.[16] Room temperature reaction of both components, alkyne and Ipy_2BF_4, in the presence of MeONa-MeOH

affords good yields of products. This process is very clean and is compatible with the presence of several functional groups on the alkyne molecule. The iodoalkynes thus obtained undergo a number of interesting addition reactions; among these the iodofunctionalized product arising from incorporation of isopropanol as nucleophile is of particular interest (eq 7).[17]

As depicted, treatment of Ph(*i*-PrO)C=CI_2 with excess ***s-Butyllithium*** followed by reaction of the metalated intermediate with an electrophile established an easy approach to the stereoselective elaboration of highly functionalized tetrasubstituted alkenes. The nature of the incorporated electrophile can be widely modified (H, D, allyl, MeS, Me, MeCHOH), leading always to the formation of a sole stereoisomer, that showing a *trans* relationship for the electrophile and the *i*-PrO group. The intermediate carbenoid species displayed unusual thermal stability in THF up to -20 °C and, remarkably, could be coupled in the presence of ***Copper(I) Chloride*** (THF, -60 °C), furnishing 1,4-diisopropoxy-1,4-diphenyl-1,2,3-butatriene in quantitative yield.[17] From a synthetic point of view, the second iodine atom can also be replaced. This can be done in a stepwise manner (eq 8)[17] or in a one-pot procedure (eq 8).[18] The former allows the preparation of functionalized enol ethers with defined stereochemistry.

(8)

To enlarge the scope of the reactions of addition to 1-haloalkynes, the corresponding chloro and bromo derivatives were brought to react with Ipy_2BF_4 in the presence of different nucleophiles to afford stereoselectively the related 1-halo-1-iodo-1-alkenes.[19,20]

A distinctive feature of the reactivity of 1-iodoalkynes has recently been reported. It was shown that these iodoalkynes react with catalytic amounts of Ipy_2BF_4-HBF_4 to yield head-to-tail dimers through an unprecedented coupling reaction (eq 9).[5] The reaction works well either when R is an aryl group or when it contains a conjugated carbon-carbon double bond. Also, it was found that the reaction involving *p*-substituted arylalkynes is quite sensitive to the nature of substituent, and the observed trend of reactivity suggests an electrophilic mechanism. Under the reported reaction condition, no evidence for further oligomerization was found.

(9)

Reaction with Aromatic Compounds.

Ipy_2BF_4 has proven to be an excellent reagent to achieve the iodination of aromatic compounds.[4,21] The structure of the iodinated products can be predicted according to aromatic electrophilic substitution rules. The reaction of Ipy_2BF_4 with arenes takes place at room temperature in the presence of HBF_4 or CF_3SO_3H in CH_2Cl_2, furnishing monoiodo

derivatives with great regioselectivity and high yield. One of the major merits of the procedure lies in its ability to iodinate a wide range of arenes, from very activated compounds such as 1,3,5-trimethoxybenzene to deactivated systems such as nitrobenzene (almost all previously reported iodinating agents failed to react with nitrobenzene) (eq 10),[4] as well as heteroarenes such as indole, for which only catalytic amounts of acid are required. Use of either acid gives comparable results when the starting aromatic compound is activated (eq 11), whereas triflic acid is the acid of choice to iodinate deactivated aromatics.

(10)

(11)

Benzaldehyde is also efficiently iodinated in 80% yield under similar conditions to those reported for nitrobenzene, without formation of oxidation products. In summary, the reported 21 examples[4] demonstrate that this is a general and reliable procedure which overcomes the well documented limited scope of aromatic iodination. Moreover, conditions were optimized to regioselectively prepare polyiodinated compounds at room temperature. In particular, reaction of Ipy_2BF_4 with C_6H_6 and CF_3SO_3H in CH_2Cl_2 provides an easy synthetic entry into a complete set of rarely accessible benzene derivatives (eq 12).[22]

(12)

Finally, Ipy_2BF_4 is the reagent of choice to prepare 3,5-diamino-4-iodopyrazole through direct iodination of the corresponding pyrazole.[23]

Bis(pyridine)silver(I) Permanganate

[82503-38-6] · $C_{10}H_{10}AgMnN_2O_4$ · Bis(pyridine)silver(I) Permanganate · (MW 385.01)

(oxidant, useful for the oxidation of polycyclic aromatics and alkynes to diketones,[1] primary benzylic alcohols to aldehydes,[2] secondary alcohols to ketones;[2] for the oxidative coupling of amines;[3] and the deoximation of oximes[3])

Physical Data: purple solid, decomposes at 104-105 °C.[2]

Solubility: sol acetone, chloroform and dichloromethane; sparingly sol benzene and pyridine.[2]

Analysis of Reagent Purity: elemental analysis.[2]

Preparative Method: pyridine (3 mol) is added to $KMnO_4$ (1 mol) dissolved in a minimum of distilled water followed by $AgNO_3$ (1 mol) in 1.7 L of distilled water. The purple precipitate (90%) is washed with water and then benzene. After drying over $CaCl_2$ it is recrystallized from acetone/benzene.[2] The visible spectrum resembles that of potassium permanganate and the IR displays a strong band at 900 cm^{-1}.

Handling, Storage, and Precautions: slowly reduced by polar solvents such as acetone, chloroform, and dichloromethane; less soluble, but more stable in benzene and pyridine;[2] insensitive to hammer blows, but ignites above 80 °C;[2] store small amounts (10-50 g) in glass vessels at or below rt.

Oxidation of Polycyclic Aromatic Hydrocarbons.[1]

Polycyclic aromatic hydrocarbons such as naphthalene, anthracene, and phenanthrene are converted into diketones when oxidized by bis(pyridine)silver permanganate as illustrated in eqs 1 and 2. The conditions employed are mild (rt in CH_2Cl_2) and the yields are uniformly high.

(1)

(2)

Oxidation of Alkynes.[2]

Nonterminal alkynes are also oxidized to diketones, while terminal alkynes undergo coupling, as illustrated in eqs 3 and 4. The conversion of benzocyclobutadienes into diketones is accompanied by carbon-carbon bond cleavage (eq 5).[2]

(3)

(4)

(5)

Oxidation of Primary Alcohols.[2]

Primary benzylic alcohols are converted into the corresponding aldehydes in good yield when oxidized by bis(pyridine)silver permanganate in benzene (eqs 6 and 7).

(6)

(7)

Oxidation of Secondary Alcohols.[2]

Secondary alcohols are converted into the corresponding ketones by use of this reagent (eqs 8 and 9).

(8)

(9)

Oxidative Coupling of Amines.[2]

When treated with this oxidant, substituted anilines undergo a coupling reaction (eqs 10 and 11). Other primary amines are oxidized to aldehydes. For example, benzylamine gives benzaldehyde in 95% yield.

(10)

(11)

Oxidation of Oximes.[3]

Oximes are converted by bis(pyridine)silver permanganate into the corresponding aldehydes or ketones (eqs 12 and 13).

(12)

(13)

In most respects the reactions of bis(pyridine)silver permanganate are very similar to those of ***Bis(2,2´-***

bipyridyl)copper(II) Permanganate. The latter has, however, been reported to be more stable and easier to handle.[4]

Bis(3-salicylideneaminopropyl)aminecobalt(II)[1]

[15306-22-6] · $C_{20}H_{23}CoN_3O_2$ · Bis(3-salicylideneaminopropyl)aminecobalt(II) · (MW 396.36)

(catalyst for the homogeneous oxygenation of phenols with dioxygen in organic media)

Alternate Name: Co(Salpr).

Solubility: sol MeOH, CH_2Cl_2, $CHCl_3$, C_6H_6, THF, C_5H_5N and DMF.

Form Supplied in: green crystals.

Preparative Method: prepared under nitrogen from bis(salicylaldehydehydato)cobalt(II) dihydrate and bis(3-aminopropyl)amine.[2,3] The long green prisms are collected by suction, washed with cold methanol, and dried in a vacuum desiccator.

Purification: may be recrystallized from methanol if necessary; normally used without further purification.

Handling, Storage, and Precautions: store in a sealed container under an inert atmosphere.

Oxidation of 4-Substituted 2,6-Di-*t*-butylphenols to Quinols.

Co(Salpr), which binds dioxygen reversibly (1 O_2:2 Co), catalyzes the regioselective oxidation of 4-substituted 2,6-di-*t*-butylphenols in methanol to *p*-quinols, via alkylperoxycobalt(III) complexes and hydroperoxy intermediates, in high

yields (eq 1).[2,4-10] The peroxy complexes give the quinols quantitatively upon treatment with silica gel.[2] Either the complex or intermediate may be isolated. The regioselectivity of dioxygen incorporation depends on the nature of the substituent in the 4-position of the phenols.[9] In methanol, with 4-alkyl substituents, the oxygenation takes place in the 4-position (eq 1), and with 4-aryl substitution, oxygenation occurs exclusively at the 2-position (eq 2).[2,9] Complex product mixtures are obtained in benzene or chloroform.

(1)

(2)

4-Alkyl-2,6-di-*t*-butylphenols give *p*-quinols in alkaline ethanol (cf. eq 1) and epoxy-*p*-quinols in DMF containing *t*-BuOK (eq 3).[10] The 4-aryl-substituted phenols afford *o*-quinols at low temperature (cf. eq 2), epoxy-*o*-quinols at 40 °C, and cyclopentadienones at 70 °C (eq 4).[10]

(3)

2,6-Di-*t*-butylphenols bearing electron-withdrawing groups at the 4-position are oxygenated exclusively at the 2 position with Co(Salpr) in CH_2Cl_2, to give the corresponding 3,5-di-*t*-butyl-6-hydroperoxy-2,4-cyclohexadienone derivatives (cf. eq 2; Ar = COR; CN; C=NR; C(R)=NOMe).[11,12] The 4-cyanophenol ultimately affords 3-cyano-2,5-di-*t*-butylcyclopentadienone (eq 5), and the imines also yield products resulting from intramolecular decomposition of the peroxy-*o*-quinolato Co^{III}(Salpr) intermediates (eq 6).[12]

Oxidation of Alkyl Substituted Phenols to *p*-Benzoquinones.

Oxygenation of alkyl substituted phenols without a substituent *para* to the oxygen functionality in the presence of Co(Salpr) affords *p*-benzoquinone derivatives.[13-15]

Oxygenation of *t*-Butylphenols with an Unsaturated Side Chain.

The oxygenation of 4-alkenyl-2,6-di-*t*-butylphenols with Co(Salpr) in dichloromethane followed by filtration through a short column of silica gel affords the intermediate hydroperoxyquinone methides and *p*-acylphenols (eq 7).[9] The yields of the products depend on the nature of the alkenyl substituent. With 2-alkenyl-4,6-di-*t*-butylphenols, cleavage of the double bond to form only 2-acyl-4,6-di-*t*-butylphenols is observed.[9] These results indicate that dioxygen is incorporated exclusively into the alkenyl side chain. Each sp hybridized carbon atom is oxidized to a carbonyl group (1,2-dione) during the oxygenation of 4-alkynyl-2,6-di-*t*-butylphenols.[9,16]

Oxidative Phenolic Coupling.

Carpanone, a lignan with five contiguous asymmetric centers, is synthesized in excellent yield by the Co(Salpr) catalyzed oxidation of *trans*-2-(1-propenyl)-4,5-methylenedioxyphenol (eq 8).[17] Co(Salpr) and Co(Salen) (***Salcomine***) are more effective catalysts than either Fe(Salen) or Mn(Salen).

Oxidative Cyclization to Flavanones and 1,3-Benzodioxoles.

Co(Salpr) in methanol under nitrogen promotes the conversion of 1-(2-hydroxyphenyl)-3-phenyl-1,3-propanediones to retro-Claisen reaction products and flavanones.[18] Similarly, 2´-hydroxychalcones are also converted to flavanones (eq 9).[19] Substituted 2´-hydroxyacetophenone 4-bromophenylhydrazones are oxygenated readily in the presence of Co(Salpr) in ethanol to give 2-(4-bromophenylazo)-1,3-benzodioxoles in good yield (eq 10).[20]

(9)

(10)

Other Applications.

Co(Salpr) and other cobalt-Schiff base complexes, in primary or secondary alcohols under dioxygen, catalyze the oxygenation of alkenes substituted with an aromatic or an electron-withdrawing group to ketones without double bond cleavage (eq 11).[21]

N,N´-Bis(salicylidene)ethylenediaminenickel(II)[1]

[14167-20-5] · $C_{16}H_{14}N_2NiO_2$ · *N,N´*-Bis(salicylidene)ethylenediaminenickel(II) · (MW 324.99)

(catalyst for alkane chlorination,[2] alkene epoxidation,[4] DNA oxidation,[5] Michael addition,[7] and radical cyclization[8])

Alternate Name: Ni(salen).

Physical Data: mp 337 °C, *d* 1.325 g cm^{-3}.

Solubility: insol H_2O; slightly sol benzene and ether; sol acetone, acetic acid, pyridine, $CHCl_3$, and CH_2Cl_2.

Form Supplied in: commercially available as an orange powder.

Preparative Method: easily and cheaply prepared from ethylenediamine, salicylaldehyde, and $Ni(OAc)_2$.[1]

Handling, Storage, and Precautions: low sensitivity to air and water; cancer suspect agent; handle with care.

Alkane Chlorination.

Ni(salen) catalyzes the chlorination of saturated hydrocarbons, such as adamantane and cyclohexane, and the benzylic position of arenes.[2] Reactions are carried out under phase-transfer conditions using aqueous ***Sodium Hypochlorite*** adjusted to pH 11 and CH_2Cl_2 solutions of the alkane (0.4 M) and catalyst (0.01 M). An 8.5:1 preference for chlorination at tertiary compared to secondary positions has been observed. Small amounts of ketone side products arise from hydrolysis of *gem*-dichloro compounds.

Alkene Epoxidation.

Ni(salen) is a highly efficient catalyst for alkene epoxidation using aqueous NaOCl adjusted to pH 9.3 under phase-transfer conditions (eq 1).[3,4] As little as 0.013 mol % catalyst can be used with respect to alkene. The reaction is highly sensitive to pH. Epoxidation and alkene chlorination are both enhanced at lower pH, and pH 9.3 was found to give an optimal epoxidation rate while minimizing chlorination.[4] Arylalkenes (styrenes, stilbenes) are the best substrates for this reaction, giving virtually quantitative conversion to epoxides, while alkylalkenes give relatively large percentages of chlorinated products. Use of optically active salen analogs fails to give enantioselectivity in epoxidation.[3]

(1)

DNA Oxidation.

Ni(salen) is among the most active of a series of nickel(II) complexes as a catalyst for DNA oxidation. Form I supercoiled plasmid DNA is readily converted to Form II nicked DNA by single-strand cleavage in the presence of ***Iodosylbenzene*** or magnesium monoperoxyphthalate (MMPP).[5] Reactions typically involve use of 100 µM Ni(salen) and 1 mM oxidant at pH 6.8-7.0 for 5 min (PhIO) to 2.5 h (MMPP) at 25 °C.

A derivative of Ni(salen) bearing water-solubilizing groups (**1**) is an excellent reagent for oxidative alkylation of guanine residues in accessible sites of DNA structures.[6] In the presence of $KHSO_5$ as oxidant, a hairpin deoxyoligonucleotide showed specific reactivity at the G's located in the hairpin. The alkylation reaction gives rise to site-specific strand scission upon treatment with piperidine. Since the cleavage reaction is presumed to give clean phosphate ends, this method can be used for site-specific cleavage and synthesis of altered oligonucleotides.

(1)

Michael Addition.

Ni(salen) and related Schiff base complexes catalyze the Michael addition of β-keto esters to methyl vinyl ketone.[7] For example, use of 1 mol % nickel catalyst in benzene gave excellent yields (84-96 %) of addition products when methyl vinyl ketone was used as the enone with various β-dicarbonyl compounds (eq 2). However, other Michael acceptors such as cyclohexenone gave considerably lower yields. Use of optically active Schiff base ligands gave low enantioselectivity (6% ee).

(2)

Radical Cyclization.

Ni^{II}(salen) undergoes reversible reduction to a nickel(I) species at a carbon cathode in DMF at a potential where 6-halo-1-hexynes are not electroactive. Thus Ni(salen) can be used as an electrocatalyst for the intramolecular cyclization of haloalkynes.[8] Reactions are carried out in DMF with 0.1 M tetraethylammonium perchlorate as electrolyte. Controlled potential electrolysis at -1.00 V gave excellent conversions of 6-halo-1-phenyl-1-hexyne to the

corresponding benzylidenecyclopentane (eq 3). Halide reduction was a minor competing process (6-17%).

Bis(tetrabutylammonium) Dichromate[1]

(n-$Bu_4N)_2Cr_2O_7$

[56660-19-6] · $C_{32}H_{72}Cr_2N_2O_7$ · Bis(tetrabutylammonium) Dichromate · (MW 700.92)

(mild selective oxidizing agent for benzylic and allylic alcohols;[2] can oxidize carbon-halogen bonds[3])

Alternate Name: TBADC.

Physical Data: mp 139-143 °C.

Solubility: sol dichloromethane, chloroform.

Form Supplied in: orange crystalline solid; widely available.

Preparative Method: a concentrated aqueous solution (300 mL) of ***Potassium Dichromate*** (29.4 g, 0.1 mol) is added to a saturated aqueous solution (300 mL) of ***Tetra-n-butylammonium Bromide*** (64.4 g, 0.2 mol). TBADC precipitates and can be removed by filtration (62.8 g, 90% yield).

Handling, Storage, and Precautions: reported to be a toxic agent. The reagent should be handled in a fume hood.

Oxidation of Benzylic and Allylic Alcohols.

TBADC is a neutral and mild oxidizing reagent, soluble in organic solvents. It can be used for the selective oxidation of benzylic and allylic alcohols to the corresponding carbonyl compounds. The reactions are performed in refluxing dichloromethane for 1-3 h with a stoichiometric amount of oxidant; yields range from 78 to 90% (eqs 1 and 2);[2] (*E*)/(*Z*) isomerization is observed in the oxidation of allylic alcohols.

(1)

(2)

$X = H, Cl, OMe, NO_2; R = H, Me, CO_2Et$

Unactivated alcohols resist attack by the oxidant, being only slightly oxidized (10-20%) after 24 h at reflux.[2a]

Oxidation of Carbon-Halogen Bonds.

TBADC, acting as an oxidizing nucleophile, efficiently converts benzylic and allylic halides into the corresponding carbonyl compounds in boiling chloroform. The yields are generally excellent (eq 3).[3,4] The reactions are faster for bromides than for chlorides, and in the presence of an excess of oxidant.[3]

(3)

$R^1 = alkyl, aryl; R^2 = H, Me; X = Cl, Br$

Secondary alkyl bromides afford ketones in high yields, while primary alkyl bromides give a mixture of products with the corresponding aldehydes formed in very low yield.[3] Methyl 3,5-bromomethylbenzoate undergoes selective oxidation at one of two benzylic bromomethyl groups to form the corresponding aldehyde upon treatment with TBADC (0.66 equiv) in refluxing chloroform for 1 h, albeit in a moderate yield. The dialdehyde is obtained as a byproduct (eq 4).[4]

Bis[*N*-(*p*-toluenesulfonyl)]selenodiimide

[60123-29-7] · $C_{14}H_{14}N_2O_4S_2Se$ · Bis[*N*-(*p*-toluenesulfonyl)]selenodiimide · (MW 417.36)

(allylic amination of alkenes and alkynes,[1] 1,2-diamination of 1,3-dienes[2])

Physical Data: mp 115-117 °C.

Preparative Methods: ***Selenium*** metal is allowed to react with 2 equiv of anhydrous ***Chloramine-T*** (TsNClNa) in $CHCl_2$ under N_2 for 24 h.[1] Also prepared by adding an ether solution of *N*,*N*-bis(trimethylsilyl)-*p*-toluenesulfonamide to an ether solution of selenyl chloride and stirring for 3 h.[3]

Handling, Storage, and Precautions: readily hydrolyzed by water; must be kept rigorously dry.

Allylic Amination and Diamination.

The title compound (**1**) effects allylic amination of alkenes (eq 1)[1] and alkynes (eq 2).[1] The reaction occurs via an initial ene reaction to form (**2**) followed by a [2,3]-sigmatropic rearrangement. Nitrogen insertion takes place without net rearrangement of the double bond and generally occurs at the most substituted allylic position (eq 3).[1]

Compound (**1**) has been utilized in the total synthesis of gabaculine (**6**).[4] Upon treatment with (**1**), alkene (**3**) afforded a mixture of allylic amine derivatives (**4**) and (**5**) in 45% yield (eq 4). Compound (**1**) has also been used effectively in the syntheses of both β-apopicropodophyllin analogs[5] and daunosamine analogs.[6]

(4)

Trialkylsilyl enol ethers have also been aminated by (**1**), providing access to α-amino ketone derivatives (eq 5).[7] The products of the amination have the NHTs group in an axial orientation due to interactions between the π orbital and the σ* orbital of the C-N bond.[8] Compound (**1**) was used to aminate silyl enol ether (**7**) in the synthesis of the benzomorphanone core structure (**8**) (eq 6).[9]

(5)

Compound (**1**), prepared from selenium oxychloride (**9**) and *N*,*N*-bis(trimethylsilyl)toluenesulfonamide (**10**) (eq 7), has been isolated and utilized in [4 + 2] cycloaddition reactions with dienes.[3] For example (**1**) reacts regioselectively with isoprene to yield 3,6-dihydro-1,2-selenazine (**11**) (eq 8).[3]

In cases where (**1**) is prepared from chloramine T, the reaction with 1,3-dienes directly produces 1,2-disulfonamides (eq 9)[2] rather than Diels-Alder adducts. Initially, the [4 + 2] adduct (**12**) is probably formed, which is then cleaved by traces of *p*-toluenesulfonamide to afford (**13**). This intermediate subsequently undergoes [2,3]-sigmatropic rearrangement to (**14**), which hydrolyzes in situ to yield disulfonamide (**15**). It has been suggested that the reagent prepared from selenium and chloramine T is actually $(TsNNa)_2SeCl_2$.[10] Cyclic dienes afford exclusively the *cis*-1,2-disulfonamides (eq 10).[2]

(10)

Compound (**1**) has been used to prepare 3-vinyl-1,2,5-selenadiazole (**17**) from 1,2-diamine (**16**) via a cyclocondensation reaction (eq 11).[11]

Bis[*N*-(*p*-toluenesulfonyl)]sulfodiimide[1]

[851-06-9] · $C_{14}H_{14}N_2O_4S_3$ · Bis[*N*-(*p*-toluenesulfonyl)]sulfodiimide · (MW 370.46)

(can act as an enophile in ene reactions[4-6] and as a dienophile in Diels-Alder reactions;[2,10-12] participates in [2 + 2][4] and [3 + 2][15,16] cycloaddition reactions; cycloadds to ynamines[17])

Physical Data: bright yellow solid; mp 48-50 °C.

Solubility: sol benzene, toluene, chloroform, and methylene chloride.

Preparative Methods: a convenient in situ method for the synthesis of bis[*N*-(*p*-toluenesulfonyl)]sulfodiimide (**1a**) is by treating ***N-Sulfinyl-p-toluenesulfonamide*** with dry ***Pyridine*** in benzene (eq 1).[2] An alternative procedure is the reaction of SCl_2 or S_2Cl_2 with *p*-toluenesulfonamide in the presence of a base such as pyridine or triethylamine (eq 2).[3]

Handling, Storage, and Precautions: extremely sensitive to moisture and should be stored in a desiccator and handled only in a dry box or glove bag. Typically the title compound is generated and used in situ.

Ene Reaction or Allylic Amination.

Some years ago it was discovered that sulfur diimide (**1a**) is a highly reactive enophile, converting a wide variety of alkenes into sulfinamides under mild conditions. For example, (**1a**) reacts with allylbenzene at 10 °C to afford sulfinamide (**3**) in 91% yield (eq 3).[4,5] This reactive intermediate spontaneously undergoes a [2,3]-sigmatropic rearrangement to produce the diaminosulfane (**4**). It was also shown that the N-S-N bond is readily cleaved using Na_2SO_3 to give the allylic sulfonamide (**5**) in excellent yield.[5a]

In a similar study, cyclic compounds, such as methylenecyclohexane, were shown to react with sulfur diimide (**1a**) to give principally disulfenamide (**7**) and initial ene product (**6**) as a minor component (eq 4).[6] These sulfenamide intermediates are slowly hydrolyzed with K_2CO_3 to the corresponding allylic sulfonamides.

The allylic amination sequence has been applied to an elegant total synthesis of racemic gabaculine (**11**).[7] Treatment of cyclohexenyl derivative (**8**) with (**1a**) followed by basic hydrolysis affords predominantly allylic sulfonamide (**9**) (eq 5).

(5)

In similar fashion, the allylic sulfonamide moiety was also introduced in a synthesis of *N*-tosyldaunosamine (**12**), a derivative of the carbohydrate daunosamine (eq 6).[8]

(6)

In a unique synthesis of functionalized 1,2,5-selenadiazole rings, homoallylic sulfonamide (**13**) was combined with (**1a**) to give bis(sulfonamide) (**14**) in 50% yield (eq 7).[9] This sequence represents an extension of the methodology of Sharpless and Kresze to an alkenic substrate which already contains a sulfonamide group on the homoallylic carbon (see above).

Diels-Alder Reactions.

Sulfur diimide (**1a**) is a highly reactive dienophile in regioselective [4 + 2] cycloadditions of unsymmetrical dienes.[1b,2,10] For instance, the Diels-Alder reaction of (**1a**) with (*E*)-piperylene (eq 8) and isoprene (eq 9) afforded C-3 and C-5 substituted 3,6-dihydrothiazin-1-imines, respectively, while chloroprene gave the 5-substituted cycloadduct (eq 10).[11]

(10)

As an application of this methodology, (*E*,*E*)-2,4-hexadiene and (**1a**) react in benzene to produce a separable mixture of 3,6-dihydrothiazin-1-imines (**15a**) and (**16a**) (91%) in a 1.1:1 ratio,[12] while the cycloaddition with the bis(carbamate) (**1b**) afforded a 1:8 mixture of adducts (**15b**) and (**16b**), respectively (eq 11).[13] This Diels-Alder strategy was also applied to isomeric (*E*,*Z*)-2,4-hexadiene. Reaction of this diene with (**1a**) gave a 1:7 mixture of cycloadducts (**17a**) and (**18a**) (75%), while addition of bis(carbamate) (**1b**) to (*E*,*Z*)-2,4-hexadiene yielded 2.4:1 mixture of adducts (**17b**) and (**18b**) (65%) (eq 12).

(11)

	b = CO_2Me	71%	1:8

(12)

(**17**) (**18**)

R:	**a** = Ts	75%	1:7
	b = CO_2Me	65%	2.4:1

The 3,6-dihydrothiazin-1-imines generated from these hetero Diels-Alder processes were shown to be valuable intermediates in the stereocontrolled synthesis of unsaturated vicinal diamines.[12] Refluxing *cis*-dihydrothiazine-1-imines (**15**) and (**17**) (in either the sulfur diimide series or the bis(carbamate) series) in benzene stereoselectively produced stable thiadiazolidines (**19**) and (**21**) (eqs 13 and 14), respectively, via a novel transannular [2,3]-sigmatropic process.[13] Reduction of (**19**) and (**21**) with ***Sodium Borohydride*** gave (*E*)-*threo* vicinal diamine derivative (**20**) and (*E*)-*erythro* compound (**22**), respectively, in excellent yields.

In contrast, *trans*-dihydrothiazin-1-imines (**16**) and (**18**) (in both the sulfur diimide and bis(carbamate) series) reacted with ***Phenylmagnesium Bromide*** to give initial allylic sulfinimine products which underwent facile [2,3]-sigmatropic rearrangement through an envelope-like transition state to afford sulfenamides (**23**) and (**24**) (eqs 15 and 16), respectively.[13] Desulfurization of sulfenamides (**23**) and (**24**) with ***Trimethyl Phosphite*** cleanly afforded the corresponding protected diamines in good yields.

(23) R = Ts 83%
CO_2Me 92%

(15)

(24) R = Ts 71%
CO_2Me 94%

(16)

The methodology for the stereoselective synthesis of unsaturated vicinal diamines was also applied in an attempted total synthesis of biotin (**25**).[14] The Diels-Alder cycloaddition of (*E*,*E*)-diene (**26**) with (**1b**) occurred in high yield to produce a 7.7:1 mixture of epimeric 3,6-dihydrothiazin-1-imines (**27**) and (**28**) (eq 17). Heating adducts (**27**) and (**28**) in toluene induced the [2,3]-sigmatropic rearrangement, giving thiadiazolidines (**29**) and (**30**) in quantitative yield (eq 18). The mixture was readily separated and thiadiazolidine (**29**) was reduced, cyclized, and protected to afford urea (**31**) which unfortunately could not be converted to biotin.

(25)

Other Cycloaddition Reactions.

Sulfur diimide (**1a**) and vinyl ether (**32**) combine to afford an unstable [2 + 2] cycloadduct which spontaneously undergoes a [1,5]-hydrogen shift to produce substituted diaminosulfane (**33**) (eq 19).[4]

It has been shown that the periselectivity between ene reactions and [2 + 2] cycloadditions is delicately influenced by alkene geometry and stereoelectronic effects of the substituents.[1a] However, the periselectivity between a [2 + 2] and a [3 + 2] cycloaddition pathway was found to be dependent on the reaction temperature. For instance, if (**1a**) is added to diphenylketene at -15 °C, a reversible [2 + 2] cycloaddition takes place (eq 20), but at higher temperatures a [3 + 2] cycloaddition was observed (eq 21).[15]

(20)

(21)

Another illustration of a rare [3 + 2] cycloaddition of (**1a**) is the reaction with diphenylfulvene to give cycloadduct (**34**), albeit in only 30% yield (eq 22).[16]

(22)

Sulfur diimide (**1a**) also cycloadds to ynamines in a [2 + 2] process in a novel synthesis of 1,4-diaza-1,3-butadienes (eq 23).[17]

(23)

N,N´-Ditosyltellurodiimide.

Sulfur diimide (**1a**) and the corresponding selenodiimide (see ***Bis[N-(p-toluenesulfonyl)]selenodiimide***) have been utilized to synthesize *N*-tosylimines, but both procedures can occasionally suffer a lack of chemoselectivity since these reagents both also undergo Diels-Alder and ene reactions. Trost has developed an analogous procedure using tellurodiimide (**36**) (eq 24)[18] which does not undergo these undesired side reactions. Tellurodiimide (**36**), generated from ***Tellurium*** metal and ***Chloramine-T***, was combined with aldehyde (**35**) to afford *N*-tosylimine (**38**), presumably via a cycloaddition to a four-membered ring (**37**) followed by cycloreversion (eq 24).

trans-1,2-Bis(tributylstannyl)ethylene[1]

[14275-61-7] · $C_{26}H_{56}Sn_2$ · *trans*-1,2-Bis(tributylstannyl)ethylene · (MW 606.11)

(versatile vinyl anion synthon: efficiently monotransmetalated by alkyllithium reagents[2] and higher order organocuprates;[7,8] palladium-catalyzed coupling with a variety of electrophilic partners affords substituted vinylstannanes)

Physical Data: bp 170-86 °C/0.3 mmHg;[3a] colorless oil; ^{1}H NMR,[3a] IR.[3a]

Solubility: sol THF, DMF.

Analysis of Reagent Purity: TLC.[4]

Preparative Method: prepared in high yield by the reductive hydrostannation of tributylstannylacetylene with ***Tri-n-butylstannane*** and catalytic ***Azobisisobutyronitrile***.[2,3a,5]

Purification: can be purified by distillation[3] or by preparative reverse-phase chromatography.[4]

Handling, Storage, and Precautions: organostannane reagents are potentially toxic.[6] Their preparation and use must therefore be conducted, wearing appropriate protective clothing, in a well ventilated fume hood. The reagent should be stored under an inert atmosphere and protected from light.

Transmetalation.

Alkyllithium reagents efficiently transmetalate (*E*)-1,2-(bistributylstannyl)ethylene (**1**) to afford (*E*)-1-lithio-2-(tributylstannyl)ethylene, which exhibits reactivity typical of vinyllithium reagents.[2,3]

Higher order cyanocuprates ($Me_2CuCNLi_2$ and $Me(2\text{-Th})CuCNLi_2$) rapidly transmetalate (*E*)-1,2-(bistributylstannyl)ethylene in high yield at ambient temperature to afford the corresponding vinylcuprates ($n\text{-}Bu_3SnCH{=}CH)(Me)Cu(CN)Li_2$[7] and ($n\text{-}Bu_3SnCH{=}CH)(2\text{-Th})Cu(CN)Li_2$,[8] thus providing a very convient method for the preparation these useful reagents.[7-9]

Cross-Coupling Reactions.

Stille et al. pioneered the palladium-catalyzed cross-coupling reaction of organostannanes with a variety of electrophilic partners. These reactions proceed under mild conditions which are often compatable with typically sensitive functional groups.[1]

Palladium-catalyzed coupling of (*E*)-1,2-(bistributylstannyl)ethylene with appropriate electrophiles can afford either mono- or disubstituted products. The product distribution is readily and predictably controlled by the stoichiometry of the reactants. Coupling of (**1**) with 1 equiv of an allylic (eq 1),[10a] aromatic,[11] or vinyl halide[12] provides the corresponding substituted vinylstannane. Symmetrical stilbenes are prepared when 2 equiv of aryl halide are used.[13]

(1)

Macrocylization of the highly functionalized divinyl diiodide (**2**) (eq 2)[14] to rapamycin (**3**) is an elegant and unique example of the use of this reagent.

(2)

β-Stannyl enones are prepared in moderate yield by the palladium-catalyzed coupling of (*E*)-1,2-(bistributylstannyl)ethylene with acyl chlorides (eq 3).[15] Coupling of the product with a second acyl chloride provides a route to unsymmetrical 1,4-butanediones. The intermediate 1,4-butenediones are efficiently reduced in situ by a palladium hydride species generated during the course of the reaction.[15] Symmetrical 1,4-butanediones are prepared directly when 2 equiv of acid chloride are used.[15]

(3)

Aluminum Chloride-promoted coupling of (*E*)-1,2-bis(tributylstannyl)ethylene with acid chlorides provides an alternate, and often higher yielding, route to β-stannyl enones.[3b,16]

Bis(tri-*n*-butyltin) Oxide

$(n\text{-}Bu_3Sn)_2O$

[56-35-9] · $C_{24}H_{54}OSn_2$ · Bis(tri-*n*-butyltin) Oxide · (MW 596.20)

promotes the oxidation of secondary alcohols and sulfides with Br_2; O- and N-activations; dehydrosulfurizations; hydrolysis catalyst)

Physical Data: bp 180 °C/2 mmHg; *d* 1.170 g cm^{-3}.

Solubility: sol ether and hexane.

Form Supplied in: colorless oil.

Handling, Storage, and Precautions: $(Bu_3Sn)_2O$ should be stored in the absence of moisture. Owing to the toxicity of organostannanes, this reagent should be handled in a well-ventilated fume hood. Contact with the eyes and skin should be avoided.

Oxidations.

Benzylic, allylic, and secondary alcohols are oxidized to the corresponding carbonyl compounds by using $(Bu_3Sn)_2O$-***Bromine***.[1] This procedure is quite useful for selective oxidation of secondary alcohols in the presence of primary alcohols, which are inert under these conditions (eqs 1-3).[2] $(Bu_3Sn)_2O$-***N-Bromosuccinimide*** can also be applied to the selective oxidation of secondary alcohols (eq 4).[3]

(1)

(2)

(3)

(4)

$(Bu_3Sn)_2O$-Br_2 oxidizes sulfides to sulfoxides in CH_2Cl_2 without further oxidation to sulfones, even in the presence of excess reagent (eq 5).[4] This procedure is especially useful for sulfides having long, hydrophobic alkyl chains, for which solubility problems are often encountered in the ***Sodium Periodate*** oxidation in aqueous organic solvents. Oxidation of sulfenamides to sulfinamides can be achieved without formation of sulfonamides using the reagent (eq 6).[4]

(5)

(6)

$(Bu_3Sn)_2O$-Br_2-***Diphenyl Diselenide*** in refluxing $CHCl_3$ transforms alkenes into α-seleno ketones (eq 7).[5]

(7)

O- and N-activations.

$(Bu_3Sn)_2O$ has been used in the activation of hydroxy groups toward sulfamoylations, acylations, carbamoylations, and alkylations because conversion of alcohols to stannyl ethers enhances the oxygen nucleophilicity. Tributylstannyl ethers are easily prepared by heating the alcohol and $(Bu_3Sn)_2O$, with azeotropic removal of water. Sulfamoylation of alcohols can be achieved via tributyltin derivatives in high yields, whereas direct sulfamoylation gives low yields (eq 8).[6] This activation can be used for selective acylation of vicinal diols (eq 9).[7] In carbohydrate chemistry this approach is extremely useful for the regioselective acylation without the use of a blocking-deblocking technique (eq 10).[8] The order of the activation of hydroxy groups on carbohydrates has been investigated, and is shown in partial structures (**1**), (**2**), and (**3**).[9] Regioselective carbamoylation can also be accomplished by changing experimental conditions (eq 11).[10] On the other hand, alkylations of the tin derivatives are sluggish and less selective than acylations under similar conditions. Regioselective alkylation of sugar compounds, however, can be carried out in high yield by conversion to a tributyltin ether followed by addition of alkylating agent and quaternary ammonium halide catalysts (eq 12).[11]

(8)

(9)

(10)

(1)
most reactive

(2)
next most reactive

(3)
least reactive

This O-activation is also effective for intramolecular alkylations such as oxetane synthesis (eq 13).[12] Similar N-activation has been used in the synthesis of pyrimidine nucleosides (eq 14).[13]

Dehydrosulfurizations.

The thiophilicity of tin compounds is often utilized in functional group transformations. Thus conversion of aromatic and aliphatic thioamides to the corresponding nitriles can be accomplished by using $(Bu_3Sn)_2O$ in boiling benzene under azeotropic conditions (eq 15).[14]

Hydrolysis.

Esters are efficiently hydrolyzed with $(Bu_3Sn)_2O$ under mild conditions (eq 16).[15]

Transformation of primary alkyl bromides or iodides to the corresponding primary alcohols is achieved in good yield by using $(Bu_3Sn)_2O$-***Silver(I) Nitrate*** (or ***Silver(I) p-Toluenesulfonate***) (eq 17),[16] whereas this method is not applicable to secondary halides due to elimination.

$(Bu_3Sn)_2O$ is a useful starting material for the preparation of tributyltin hydride, which is a convenient radical reducing reagent in organic synthesis. Thus ***Tri-n-butylstannane*** is easily prepared by using exchange reactions of $(Bu_3Sn)_2O$ with polysiloxanes (eq 18).[17]

Related Reagents.

Tri-n-butyl(methoxy)stannane.

Bis(tributyltin) Peroxide[1]

[63256-88-2] · $C_{24}H_{54}O_2Sn_2$ · Bis(tributyltin) Peroxide · (MW 612.07)

(mild nonalkaline source of dinucleophilic peroxide; reacts with alkyl triflates to deliver dialkyl peroxides, often in higher yields than obtained from the reaction of alkyl mesylates with hydrogen peroxide and a base)

Physical Data: unstable liquid.

Solubility: sol CH_2Cl_2.

Form Supplied in: must be freshly prepared.

Preparative Method: addition of ***Tri-n-butyl(methoxy)stannane*** to an ether-methanol solution of anhydrous ***Hydrogen Peroxide*** at 0 °C followed by removal of ether and methanol in vacuo at 0 °C.[1]

Purification: attempted purification by rapid column chromatography on silica gel or Florisil led to decomposition.

Handling, Storage, and Precautions: thermally unstable, but can be stored for 1 day neat at -20 °C. The reagent is presumed to be a strong oxidizing agent and, as with organic peroxides in general, there is a potential for explosion. The use of a safety shield is mandatory during preparation and use. Reaction with water releases anhydrous H_2O_2 that is hazardous.

Peroxide Transfer.

$Bu_3SnOOSnBu_3$ reacts with alkyl triflates to generate dialkyl peroxides in good yields. In many cases, as in the reaction with isopropyl triflate (eq 1), dialkyl ethers are formed as byproducts. Other syntheses of secondary dialkyl peroxides give significantly lower yields. For example, base-catalyzed alkylation of hydrogen peroxide with isopropyl mesylate gives diisopropyl peroxide in low yield (eq 2).[2] ***Silver(I) Trifluoroacetate***-assisted alkylation of 2-butyl hydroperoxide with 2-butyl bromide gives a low yield of dialkyl peroxide (eq 3).[3]

Cyclic dialkyl peroxides are obtained from the reaction of alkyl ditriflates with $Bu_3SnOOSnBu_3$ (eq 4). For volatile dialkyl peroxides, isolation is simplified and yields improved by using 1,2,4-trichlorobenzene as solvent. The reaction is conducted in vacuo, and the product is efficiently removed from the reaction mixture and collected in a cold trap (-78 °C). This protocol is essential for the preparation of 2,3-dioxabicyclo[2.2.1]heptane, the strained nucleus of prostaglandin endoperoxides, because this peroxide is unusually reactive (eq 5). It is noteworthy that pure 2,3-dioxabicyclo[2.2.1]heptane, mp 63-64 °C, is stable toward bis(tri-*n*-butyltin) peroxide.

(5)

An ether, tetrahydropyran, is the major product of the reaction of $Bu_3SnOOSnBu_3$ with pentane 1,5-bistriflate. The relative preference for cyclic ether formation in the reaction of bistriflates is 5, 6 > 7 > 8-membered rings while that for cyclic peroxide formation is 4 &LLt; 5, 6 > 7-membered rings. The product ratios of cyclic peroxide versus cyclic ether indicate an important role for stereoelectronic preferences in the kinetically controlled partitioning of a monoalkylperoxytin precursor between two oxonium ion intermediates (eq 6).[4]

Bis(2,2,2-trichloro-1,1-dimethylethyl) Phosphorochloridate

[17677-92-8] · $C_8H_{12}Cl_7O_3P$ · Bis(2,2,2-trichloro-1,1-dimethylethyl) Phosphorochloridate · (MW 435.33)

(phosphorylating reagent)

Physical Data: mp 81-82 °C.

Solubility: crystallized from pentane.

Form Supplied in: colorless solid.

Preparative Methods: the reagent[1] is conveniently prepared by the reaction of 2-trichloromethyl-2-propanol with PCl_3 in pyridine solvent to afford bis(2,2,2-trichloro-1,1-dimethylethyl) chlorophosphite (71%). The chlorophosphite is oxidized with ***(Diacetoxyiodo)benzene*** to give 65% of the desired phosphorochloridate (eq 1). This overall procedure represents an improved synthesis of the phosphorochloridate when compared to the different methods reported in the literature, which give mixtures of bis(2,2,2-trichloro-1,1-dimethylethyl) chlorophosphite and 2,2,2-trichloro-1,1-dimethylethyl dichlorophosphite.[2,3]

Handling, Storage, and Precautions: moisture sensitive; store in a cool, dry environment. Handle in a well-ventilated fume hood.

Phosphorylating Reagent.

Nucleoside derivatives are selectively phosphorylated and protected at the 5´-OH group using bis(2,2,2-trichloro-1,1-dimethylethyl) phosphorochloridate.[4] The chemospecificity favors the 5´-phosphorylated oligonucleotides which are formed exclusively, in presence of a free 3´-OH group (eq 2).[5] Compared to those of other alkylmono- and dichlorophosphate reagents,[6] the 2,2,2-trichloro-1,1-dimethylethyl group exhibits unusual stability towards acids and bases, which is a distinct advantage, especially when considering the different transformations required for effective oligonucleotide synthesis.[7,8] The bis(2,2,2-trichloro-1,1-dimethylethyl) group can be readily removed by the supernucleophilic cobalt(I) phthalocyanine anion $[Co^1Pc]^-$.[9]

Bis(2,2,2-trichloroethyl) Azodicarboxylate

[38857-88-4] · $C_6H_4Cl_6N_2O_4$ · Bis(2,2,2-trichloroethyl) Azodicarboxylate · (MW 380.83)

(a reactive dienophile,[2] diene,[7] and enophile[8])

Physical Data: mp 110-111 °C.

Solubility: sol in a wide range of organic solvents.

Form Supplied in: slightly yellow plates.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) displays a singlet at δ 5.05.

Preparative Method: commercially available.[1]

Purification: recrystallize from pentane.

Handling, Storage, and Precautions: as with all azo compounds, caution should be exercised to avoid exposure of the material to heat. Store in a brown bottle.

Reaction as a Diels-Alder Dienophile.

Bis(2,2,2-trichloroethyl) azodicarboxylate (**1**) is most often used as a Diels-Alder dienophile.[2] Its relatively high reactivity occasionally makes it preferable to the less reactive diethyl or dimethyl analogs, since the times and temperatures needed to achieve reaction are often reduced. For example, the Diels-Alder reaction illustrated (eq 1) required 5 days to reach completion when dimethyl azodicarboxylate was used, in contrast to just 1 h with (**1**).[2]

The bis(carbamate) cycloadducts are often highly viscous materials. Attempts to characterize them by ^{1}H NMR can be difficult by virtue of the several dynamic processes which occur on the NMR timescale.[3] To obtain a well-resolved spectrum requires that it be recorded at an elevated temperature.[3]

Most often, bis(carbamates) serve as precursors to azo compounds and the latter, in turn, to a host of theoretically interesting materials, reactive intermediates, and precursors to natural products.[2,4] While hydrolytic methods can also be used, the trichloroethoxy group is most often cleaved reductively, usually with ***Zinc-Acetic Acid***,[5] or with a ***Zinc/Copper Couple*** in the presence of a proton donating solvent,[2b,4] or via an electroreductive process.[6] The presence of a proton donor leads to the formation of an intermediate hydrazo compound, which requires further oxidation to generate the azo linkage. Occasionally, the azo compound is initially isolated as a copper complex and then freed by making the solution basic, often by using aqueous ammonia.[5] In the absence of a proton donor, the hydrazo compound is bypassed. In this case, oxidation of the intermediate dicarboxylate salt leads directly to the azo functionality.[2,6] Regardless of the method, yields are sometimes variable, and experimentation is often required to achieve optimal conversion.

Reaction as a Diene.

Interestingly, (**1**) can also serve as a diene. Thus when irradiated (eq 2) (350 nm), a novel [4 + 2] cycloaddition occurs between (**1**) and a variety of glycals.[7] Reaction times are quite long (e.g. 18 h to 2 weeks), but the yields are uniformly good (73-85%). Once again, the increased reactivity of (**1**) relative to other commonly used azodicarboxylates is apparent. For example, while the photoreaction (eq 2) requires 1.5 weeks, it fails to occur using dibenzyl azodicarboxylate. Treatment of the adducts with a catalytic amount of *p*-TsOH in methanol affords the corresponding methyl glycosides which, when exposed to zinc dust in acetic acid and acetone, followed by acetic anhydride/pyridine, generate 2-amino glycosides in good to excellent yields (60-97%; 75% for the case shown).

(2)

Reaction as an Enophile.

When used as an enophile, (**1**) provides a novel route to allylic amines.[8] Ene reactions with diethyl and dimethyl azodicarboxylate have also been reported, but the yields are low. In contrast, use of the trichloroethyl derivative affords ene adducts in 60-88% yield and allows generation of both cyclic and acyclic *N*-acylamines under mild conditions (eq 3).

Bis(2,2,2-trichloroethyl) Phosphorochloridate

[17172-53-6] · $C_4H_4Cl_7O_3P$ · Bis(2,2,2-trichloroethyl) Phosphorochloridate · (MW 379.22)

(phosphorylating reagent)

Physical Data: mp 45-47 °C.

Form Supplied in: colorless solid.

Handling, Storage, and Precautions: may decompose on exposure to air or water. Store in a dry, cool environment. Corrosive material and it should be handled in a well-ventilated fume hood.

Phosphorylating Reagent.

Phosphorochlorides have been widely used for the direct introduction of a phosphate group in hydroxy amino acids.[1] The use of the 2,2,2-trichloroethyl group for the phosphate protection[2] in phosphoserine derivatives[3] constitutes an efficient method for effective phosphopeptide synthesis.[4] Nucleotides are selectively protected as the 5´-OH phosphate ester derivatives[5,6] with bis(2,2,2-trichloroethyl) phosphorochloridate (eq 1).[7]

B = thymine, 4-thiothymine, and uracyl; R^1 = H, OH; R^2 = H, COMe, COPh

The isolated esters are stable in alkaline medium,[8] and selective cleavage of the 2,2,2-trichloroethyl group to afford the phosphate nucleotides occurs upon treatment with ***Zinc*** metal[9,10] (in DMF or acetic acid media) in presence of other protecting groups.[11] Bis(2,2,2-trichloroethyl) phosphorochloridate has also been successfully used as a phosphorylating agent for carbohydrates (eq 2),[12,13] and for the preparation of forskolin derivatives.[14]

Preparation of Mixed Trialkyl Phosphates.

In a general transesterification method designed to prepare mixed trialkyl phosphates,[15] reactions of bis(2,2,2-trichloroethyl) phosphorochloridate with different alcohols, in pyridine solvent, and in presence of fluoride ion (***Cesium Fluoride*** or ***Tetra-n-butylammonium Fluoride***), afford the mixed trialkyl phosphates (eq 3).[16] Reactions with diols give cyclic phosphates (eq 4).[16] The 2,2,2-trichloroethyl group has been also conveniently used for the preparation of mixed triesters of nucleotides.[17]

Bis(trichloromethyl) Carbonate[1]

[32315-10-9] · $C_3Cl_6O_3$ · Bis(trichloromethyl) Carbonate · (MW 296.73)

(a phosgene surrogate)

Alternate Name: triphosgene.

Physical Data: mp 81-83 °C; bp 203-206 °C.

Solubility: sol methanol, ethanol, benzene, diethyl ether, hexane, THF, ethyl acetate; dec slowly in cold water.

Form Supplied in: white crystalline solid

Handling, Storage, and Precautions: the reagent is somewhat moisture sensitive, but scrupulously anhydrous conditions are not necessary. Rapid handling of the reagent in open air, in the absence of a glove bag or dry box, is usually satisfactory. This reagent should only be handled in a fume hood.

Introduction.

Phosgene gas is a versatile reagent for organic synthesis, which has been used in carbonylation, chloroformylation, chlorination, and dehydration reactions, to name a few.[1] However, because of the high toxicity of ***Phosgene***, it has not been used widely. Surrogates for phosgene have long been sought. ***Trichloromethyl Chloroformate*** (diphosgene) was introduced as one such phosgene substitute.[2] To the extent that diphosgene is a highly toxic, hygroscopic, and noxious liquid, it is not a fully satisfactory phosgene substitute. On the other hand, bis(trichloromethyl) carbonate (triphosgene; **1**) is a crystalline solid compound, is not very hygroscopic, and can substitute for phosgene in a plethora of chemical reactions. Triphosgene has been known since 1880,[3] but its synthetic utility had not been exploited until recently.

Carbonylation.

The formation of oxazoles,[4] quinazolinediones (eq 1),[5] carbonates (eq 2),[6] urea analogs,[7] and isocyanates (eq 3)[1] have been reported with triphosgene. The reactions give good to excellent yields and often require only 1/3 equiv of

triphosgene.

(1)

(2)

(3)

Chloroformylation.

The use of triphosgene in the formation of chloroformates with both hydroxy compounds (eq 4) and substituted amines (eq 5) has been reported.[1]

(4)

(5)

Dehydration.

Synthesis of isocyanides from formamides (eq 6) is the only example of a dehydration reaction reported for

triphosgene to date.[1]

N-Carboxyamino Acid Anhydrides.

Synthesis of *N*-carboxyamino acid anhydrides (NCAs) is accomplished by the reaction of the zwitterionic unprotected amino acid with triphosgene at elevated temperatures (eq 7).[8] Wilder and Mobashery reported a milder version of this reaction, utilizing *N*-*t*-butoxycarbonyl-α-amino acids; in the presence of a stoichiometric quantity of ***Triethylamine*** and 1/3 equiv of triphosgene (eq 8) the reaction is believed to proceed via a chloroformic *N*-*t*-butoxycarbonyl-α-amino acid anhydride intermediate to give the corresponding NCA.[9] There are many synthetic routes to NCAs;[10] however, the use of triphosgene in the preparation of NCAs provides a facile, safe, mild, and practical entry to these important molecules.

Chlorination.

Triphosgene has been used in the synthesis of acyl chlorides (eq 9).[1] Also, it has been shown to react with a variety of aldehydes to give α-chloro chloroformates (eq 10).[11] Goren et al. have shown that triphosgene mediates chloride substitution reactions on activated alcohols (eq 11);[12] this reaction involves the formation of an intermediary chloroformate species en route to the chlorinated product. The generality of the reaction was shown for benzylic (eq

12), allylic, and propargylic systems. This reaction proceeds primarily via S_N2, with some contribution by S_N1 and/or S_Ni mechanisms.[12] Chlorination with triphosgene is considerably milder than the typical chlorination reactions with ***Thionyl Chloride***, ***Phosphorus(III) Chloride***, ***Phosphorus(V) Chloride***, ***Oxalyl Chloride***, and the like; for example, acid-labile functionalities, such as *t*-butyl carbamate (BOC), benzhydryl, and *p*-methoxybenzyl groups, can be tolerated in the triphosgene-mediated reactions, whereas they do not normally survive reactions with other chlorination reagents.

(9)

(10)

(11)

(12)

Oxidation.

Palomo et al. have demonstrated that primary and secondary alcohols are readily oxidized by triphosgene in the presence of ***Dimethyl Sulfoxide*** (DMSO) in good to excellent yields;[13a] the reaction is applicable to both activated (eq 13) and unactivated alcohols (eq 14). This reaction is a variation of the one reported by Barton with phosgene gas,[14] and it is an excellent alternative to Swern-type oxidations. Indeed, in some respects, oxidation of alcohols by triphosgene is superior to the widely used Swern oxidation. The triphosgene reaction tolerates acid-labile functionalities and is not as sensitive to residual moisture as oxalyl chloride used in the Swern oxidation. An

additional advantage of the method of Palomo et al. is the ease of handling of triphosgene, and the fact that the reaction is amenable to large-scale synthesis. The breadth and scope of this reaction have been investigated with a large variety of alcohol substrates.[13b] See also ***Dimethyl Sulfoxide-Triphosgene***.

Bis(trichloromethyl)mercury[1]

$Hg(CCl_3)_2$

[6795-81-9] · C_2Cl_6Hg · Bis(trichloromethyl)mercury · (MW 437.33)

(source of **:**CCl_2 by thermal treatment;[2,3] furnishes cyclopropanes by reaction with alkenes[4])

Physical Data: mp 141 °C.

Solubility: sol ether, THF, $CHCl_3$; insol cold H_2O, petroleum ether.

Analysis of Reagent Purity: IR,[5] Raman,[5] NMR (^{13}C and ^{119}Hg),[6] and NQR (^{35}Cl).[7]

Preparative Method: reaction of ***Mercury(II) Chloride*** ($HgBr_2$ has proven to be unreactive) with ***Sodium Trichloroacetate*** (1:2 molar ratio) in dry monoglyme at reflux for 1 h affords $Hg(CCl_3)_2$ as a crystalline solid after purification.

Purification: recrystallization from $CHCl_3$.

Handling, Storage, and Precautions: flame-dried glassware and an atmosphere of dry nitrogen are used for the reactions. Organomercury(II) compounds should be carefully handled and skin contact and inhalation should be particularly avoided. All reactions must be conducted in a well-ventilated hood.

Pyrolysis.

Gas phase pyrolysis of $Hg(CCl_3)_2$ at 350 °C gave mainly C_2Cl_4 and minor amounts of C_2Cl_6.[2,3] Similar pyrolysis in the presence of excess cyclopentadiene yields chlorobenzene, originated from addition of **:**CCl_2 to the C=C bond of the diene. Further and compelling evidence for carbene generation under pyrolytic conditions arises from investigations by matrix isolation techniques after the gas phase pyrolysis, allowing characterization of the intermediate species.[2,3]

Cyclopropanation of Alkenes.

A major reaction of some α-haloorganomercurials is their ability to cyclopropanate alkenes.[1] When dealing with $Hg(CCl_3)_2$, the reaction takes place at elevated temperatures and gives only modest yields (eq 1).[4] Yields can be slightly improved by raising the temperature. Thus, for example, running the reaction in an autoclave for 15 min, cyclohexene yields 25% of cyclopropanation at 200 °C, but 36% at 250 °C.[4]

(1,3-dielectrophile used mainly for the synthesis of five-, six-, and seven-membered heterocycles functionalized with oxo and hydroxy groups in the 1,3-position)

Alternate Names: active malonates (AMEs); magic malonates.

Physical Data: mp: R = H, 152-153 °C (toluene);[1,2] R = Me, 84-85 °C (EtOH);[1] R = Et, 101-102 °C (EtOH);[1] R = *i*-Pr, 95-96 °C (EtOH);[1] R = *t*-Bu, 132 °C (*n*-PrOH);[3] R = Ph, 97-98 °C (*n*-BuOH);[1] R = Bn, 106-107 °C (*i*-PrOH).[1] Other analogs: R = *n*-Pr,[4,5] *n*-Bu,[4,6] *s*-Bu,[7] *i*-Bu,[7] 4-methoxyphenyl,[8] 4-chlorobenzene,[7] 4-methoxybenzyl,[7] hexyl,[9] and 3-thienyl.[9]

Preparative Method: from the corresponding malonic acid and 2,4,6-trichlorophenol in the presence of phosphorus oxychloride. The reaction is preferably carried out with an excess of malonic acid (molar

ratio 1:1.6). The free malonic acids are readily obtained in about 90% yield by a modified saponification procedure[10] from the diethyl malonates (most of them are commercially available).[1,5]

Handling, Storage, and Precautions: the crude esters are quite unstable and should be used within 2 weeks. Crystallized material can be stored for 6-12 months (depending on the purity).

Reactions.

The vast majority of substrates which have been reacted with active malonic esters (AMEs, magic malonates) represent 1,3-dinucleophiles leading to six-membered heterocycles. Most of these condensations have been carried out thermally, by fusion at 150-250 °C, depending on the reactivity of the substrate. In some cases, bromobenzene, anisole or diphenyl ether have been used as solvents. However, for some substrates (mostly *N,N´*-dinucleophiles) a cold method exists which is useful for compounds which undergo transformations at higher temperature.

The reaction of acyclic and cyclic ketones leads to 4-hydoxy-2-pyrones. Thus the reaction of diethyl ketone with benzyl-AME yields the 3-benzyl-6-ethyl-5-methyl derivative which can be debenzylated with $AlCl_3$ at 150 °C (eq 1).[11] This is the starting material for the synthesis of two natural products (edulitin and obtusifolin). This compound cannot be obtained by using the unsubstituted AME, since (as a phenolic compound) it will react with further AME. Also the *t*-butyl group can be removed with $AlCl_3$; however, the corresponding *t*-butyl-AME gives lower yields with various substrates, and its preparation requires more steps.[3]

(1)

Phenols react with AMEs to yield 4-hydroxycoumarins.[12] The reaction of 3-methoxyphenol with 4-methoxyphenyl-AME (eq 2) affords a coumarin which on cyclodehydrogenation leads directly to coumestrol dimethyl ether.

(2)

Enamines or azomethines react to yield 4-hydroxy-2-pyridones (eq 3).[13] The reaction temperature is strongly dependent on the structure of the substrate: a β-enamino ester ($R^1 = CO_2Et$) will react in refluxing bromobenzene, while acetophenone anil requires 240-250 °C. Cyclic substrates afford bicyclic hydroxypyridones (eq 4).[14]

(3)

(4)

Even 2-alkylpyridines react with AMEs to give 2-hydroxy-4-quinolizines (eq 5).[1] The presence of an activating group in the side chain ($R^1 = CO_2Et$, CN, COR) is helpful, but not necessary. Many five- or six-membered heteroaromatic systems bearing a 2-alkyl side chain react in this way.[15]

(5)

2-Aminopyridine is very reactive and gives pyridopyrimidines even with diethyl malonates if heated to 200 °C. However, in the presence of a substituent in position 6 the reaction requires higher temperatures and leads to formation of naphthyridine derivatives. With AMEs the reaction proceeds at rt to pyridopyrimidines which can then be rearranged quantitatively to naphthyridines (eq 6).[16]

(6)

N,*N*´-Disubstituted amidines (and similar substrates which bear only one removable hydrogen atom) condense with AMEs to give cross-conjugated mesomeric betaines (eq 7).[17] The reaction has been extended to cyclic amidines (e.g. 2-alkylaminopyridines), leading to bicyclic compounds (**1**) and (**2**).[18] The reaction with five-membered 2-amino heterocycles has been studied extensively by Glennon et al.[5,7,19,20] Because of the biological activity found in this series, about 150 derivatives have been synthesized since 1973,[19] including those bearing a sugar moiety (R^1) at the nitrogen.[20]

(7)

X, Y, Z = CH, CR, N

(1)

X = CH, CR, N
Y = O, S

(2)

Alternatives.

α-Carbonyl acid chlorides (ketene carbonyl chlorides) represent an effective alternative to AMEs; however, the number of described derivatives is limited. One of their advantages is their much lower molecular weight. On the other hand, the liberation of HCl sometimes brings problems. Bis(pentachlorophenyl) malonates have been proposed as an alternative.[21] However, they are less reactive, and very insoluble, and the liberated pentachlorophenol is more difficult to remove. Attempts to prepare mixed anhydrides from malonic acids, ethyl chloroformate, and triethylamine result in the formation of diethyl malonates.[22] An explanation for this unusual reaction has been described.[23]

Related Reagents.

Bis(tricyclohexyltin) Sulfide-Boron Trichloride

[13121-76-1] · $C_{36}H_{66}SSn_2$ · Bis(tricyclohexyltin) Sulfide-Boron Trichloride · (MW 768.36)

[10294-34-5] · BCl_3 · Bis(tricyclohexyltin) Sulfide-Boron Trichloride · (MW 117.17)

(functions as a conveniently prepared in situ form of boron trisulfide; a powerful sulfurating agent for the conversion of carbonyl units into their corresponding thiono carbonyl analogs, e.g. thioaldehydes, thioketones, β-thiolactams, thiolactams;[1] thiophenes;[2] the analogous bis(tricyclohexyltin) selenide-boron trichloride reagent is useful for selenation of carbonyl compounds to selenoaldehydes and selenoketones[1])

Physical Data: bis(tricyclohexyltin) sulfide: mp 130-132 °C; BCl_3: mp -107 °C; bp 12.5 °C.

Solubility: bis(tricyclohexyltin) sulfide: insol water; highly sol nonpolar organic liquids; less sol alcohol. Boron trichloride: Lewis acid, partially dissolves in aprotic organic liquids.

Form Supplied in: bis(tricyclohexyltin) sulfide: solid >97% pure; boron trichloride: gas (lecture bottle) 99.95% pure; more conveniently as a 1.0 M solution in dichloromethane, heptane, hexanes, or *p*-xylene.

Preparative Method: bis(tricyclohexyltin) sulfide: prepared in quantitative yield by treating tricyclohexyltin chloride with $Na_2S.9H_2O$ in refluxing ethanol (95%) for 2 h; recrystallization from CH_2Cl_2/MeOH affords pure material, mp 130-132 °C.[1]

Purification: bis(tricyclohexyltin) sulfide: by recrystallization.

Handling, Storage, and Precautions: bis(tricyclohexyltin) sulfide: irritant; stable solid. Boron trichloride (dichloromethane solution): corrosive; moisture sensitive; stored in nitrogen-filled pressure bottles kept cold in a refrigerator.

Chemistry.

Treating the tin sulfide reagent with a dichloromethane (or other) solution of ***Boron Trichloride*** in anhydrous toluene, at reflux, produces a highly reactive in situ form of boron trisulfide (eq 1). A potent form of boron triselenide is similarly derived from the corresponding tin selenide reagent (eq 2). [Bis(tricyclohexyltin) selenide is prepared in quantitative yield by treating tricyclohexyltin chloride with Na_2Se in anhydrous THF for 2 h. Recrystallization from CH_2Cl_2/MeOH affords pure material, mp 130-132 °C.][1] Other Group 14 organometallic sulfides[1] have been used as the chalcogen source with comparable efficacy (eq 3) and variations of the technique continue to be developed.[3-5]

$$3\ (Cy_3Sn)_2S + 2\ BCl_3 \longrightarrow 6\ Cy_3SnCl + 'B_2S_3' \qquad (1)$$

$$3\ (Cy_3Sn)_2Se + 2\ BCl_3 \longrightarrow 6\ Cy_3SnCl + 'B_2Se_3' \qquad (2)$$

$$3\ [R_3M]_2S + 2\ BCl_3 \longrightarrow 6\ R_3MCl + 'B_2S_3' \qquad (3)$$

R = Me, Ph; M = Si, Sn
R = *n*-Bu; M = Sn

If the in situ form of boron trisulfide is prepared in the presence of carbonyl-containing substrates, the carbonyl units are converted into their corresponding thiono analogs (eq 4); esters and lactones, however, generally are not converted in the process.

(4)

R^1, R^2	
nonenolizable aldehydes	65%
enolizable aldehydes	80% (as trimers)
nonenolizable ketones	85%
β-lactams, lactams	90%
lactones, esters	generally unreactive

The selenium analogs are similarly prepared, though isolation of the selenones, due to their inherent instability, is limited to hindered nonenolizable derivatives such as fenchone (eq 5).

With some diketones such as 1,4-diones, thiophenes are the products (eq 6).[2] Though no mechanism is presented, a thione intermediate that enolizes, cylizes, and then dehydrates to the aromatic system might be possible.

Bis(trifluoroacetoxy)borane

$(CF_3CO_2)_2BH$

[-] · $C_4HBF_6O_4$ · Bis(trifluoroacetoxy)borane · (MW 237.85) (THF complex)

[75626-03-8] · $C_8H_9BF_6O_5$ · Bis(trifluoroacetoxy)borane · (MW 309.96)

(useful as a selective reducing agent, especially in the presence of strong acids)

Preparative Method: involves treatment of certain complexes of borane, such as ***Borane-Tetrahydrofuran***, ***Borane-Dimethyl Sulfide***, or ***Borane-Pyridine***, with ***Trifluoroacetic Acid*** in a suitable solvent such as tetrahydrofuran (THF), dichloromethane, or trifluoroacetic acid. Excess trifluoroacetic acid can be present because the title reagent is stable to protonolysis of the B-H bond.[1]

Handling, Storage, and Precautions: generated and employed in situ; normally not isolated and stored.[1,2] Hydrogen is evolved during reagent generation. The reagent causes the cleavage and oligomerization of THF.[1-3] Thus the use of borane-THF for reagent generation, or the use of THF as solvent, is not recommended for reactions at temperatures above 25 °C.[2] Use in a fume hood.

General Information.

Reductions of organic compounds with borohydride reagents in carboxylic acid media have been recognized for many years for diverse applications.[4] However, reductions with borane complexes in carboxylic acid media have received considerably less attention. Because the title reagent is stable to strong acids, such as trifluoroacetic acid, reductions can be performed in acidic media without the need for a large excess of boron hydride reagent.[1,2] The title reagent, which has been explored in some detail,[2] is applicable to a narrow class of reductions.

Reduction of Indoles to Indolines.

The reduction of indoles to indolines by use of hydride reagents is facilitated by activation of the indole, usually by protonation. The species reduced is actually the 3*H*-indolenium ion. Bis(trifluoroacetoxy)borane in trifluoroacetic acid,[1,2] and certain borane complexes (borane-THF,[1,2,5-8] borane-dimethyl sulfide,[1,2,6,9] and borane-pyridine[1,6,10]) in trifluoroacetic acid, offer a rapid, mild, convenient, high-yield method for this conversion. The benefits of this method are particularly realized in the reduction of indoles bearing basic amine groups.[1,2,5-8] High stereochemical control for the *cis* indoline can be obtained for the reduction of indoles bearing a 2,3-fused ring;[1,2,5-8] however, under certain conditions other stereochemical results can be obtained.[6,7] The mild, rapid reduction of tryptophan derivatives[10a,b] permits the selective reduction of Trp residues within peptides and proteins.[10b-d] Some representative examples are

depicted in eq 1,[1] eq 2,[9] eq 3,[5] and eq 4.[10a]

(1)

(2)

(3)

Reductive Deoxygenation of Carbinols.

Diaryl and triaryl carbinols are reduced to the corresponding hydrocarbon species by bis(trifluoroacetoxy)borane in trifluoroacetic acid, rapidly and in good yields (eqs 5 and 6).[2,11] In certain β-aryl-β-hydroxy tertiary amines, an enammonium-iminium rearrangement mechanism occurs, which can afford surprisingly effective stereochemical control (eq 6).[11] Diaryl ketones are directly deoxygenated to the corresponding diaryl hydrocarbons, via carbinol intermediates.[2,12] It is also possible with borane-pyridine and trifluoroacetic acid to deoxygenate monoaryl carbinols and ketones (eq 7).[12] Similarly, alkynic carbinols, in the form of dicobalt hexacarbonyl complexes, are reductively deoxygenated by using borane-dimethyl sulfide in trifluoroacetic acid; yields are moderate to good for the three steps of complex formation, reduction, and decomplexation (eq 8).[13] Ethers prone to forming carbocations in trifluoroacetic acid, such as trimethyl orthobenzoate and acyliminium ion precursors (eq 9), are also readily reduced.[2] By the same token, adducts from aldehydes or ketones and thiols are reduced to sulfides by using pyridine-borane and trifluoroacetic acid (eq 10).[14]

(9)

$$Ph(CH_2)_2CHO + BuSH \xrightarrow[CF_3CO_2H,\ 74\%]{BH_3 \cdot py} Ph(CH_2)_3S(CH_2)_3Me \quad (10)$$

Reduction of Other Functional Groups.

As suggested above, the title reagent readily reduces aldehydes and ketones to alcohols.[2] Imines are also readily reduced to amines (eq 11).[2,15] Cyclohexanone oxime is reduced to the hydroxylamine in 70% yield;[2] another example is shown in eq 12.[16] Tosylhydrazones are reduced to tosylhydrazines (eq 13) or the corresponding hydrocarbon (eq 14).[2] Certain diaza heterocycles, such as quinoxaline and quinazoline, are reduced (eq 15).[2] Many other functional groups and organic moieties are relatively inert to the reducing conditions: nitro, aryl/benzyl ether, nitrile, ester, carboxamide, acid, acid chloride, amidine, imide, alkene, alkyne, sulfoxide, disulfide, quinoline, isoquinoline, pyrrole, and benzofuran.[2,10]

N,O-Bis(trifluoroacetyl)hydroxylamine

[684-78-6] · $C_4HF_6NO_3$ · *N,O*-Bis(trifluoroacetyl)hydroxylamine · (MW 225.05)

(conversion of aldehydes to nitriles[1])

Physical Data: mp 62 °C (subl, sealed tube; transition 50 °C);[1] mp 40-50 °C.[2]

Solubility: sol ether, benzene, hot CH_2Cl_2; insol cold CH_2Cl_2.

Analysis of Reagent Purity: ^{19}F NMR (δ -73.7 (s), -74.5 (s)); IR (1848, 1706 cm^{-1}); elemental analysis.

Preparative Method: addition of ***Trifluoroacetic Anhydride*** (2.2 equiv) to ***Hydroxylamine*** hydrochloride.

Purification: recrystallized from CH_2Cl_2.

Handling, Storage, and Precautions: hygroscopic; should be dried in a vacuum desiccator.

Conversion of Aldehydes to Nitriles.

In 1959, Pomeroy and Craig reported a new method for direct conversion of aldehydes to nitriles using pyridine and either trifluoroacetohydroxamic acid or *N,O*-bis(trifluoroacetyl)hydroxylamine, with the latter reagent providing higher yields of products (eq 1).[1] The reagent was prepared by refluxing $HONH_2.HCl$ with excess TFAA, followed by removal of volatiles and recrystallization from CH_2Cl_2. More recently, a modification of this procedure has been reported.[2] A mechanism proceeding through a cyclic, four-membered intermediate has been proposed.[3]

Since its first report, this reagent has been used extensively for the aldehyde to nitrile transformation in several complex substrates. Early examples included steroidal systems and mitomycin derivatives.[4] *N,O*-Bis(trifluoroacetyl)hydroxylamine can also be applied to the conversion of α-formyl ketones to the corresponding ketonitriles (eq 2).[5]

Other examples have demonstrated the compatibility of *N,O*-bis(trifluoroacetyl)hydroxylamine with a variety of potentially sensitive functional groups. An optically active cyclobutanecarbaldehyde was converted to the corresponding nitrile with no apparent epimerization.[6] α,β-Unsaturated aldehydes attached to thiazine or dihydrothiazine rings are also amenable to conversion into the corresponding α,β-unsaturated nitriles.[7] The reaction can be carried out in the presence of ester groups,[7,8] as exemplified by an early step in the synthesis of steganacine (eq 3).[8] Unsaturated aldehydes at the terminus of conjugated polyene systems have also been successfully converted to nitriles.[9] 1,3-Dithiane-2-carbaldehyde has been converted into the corresponding cyano-1,3-dithiane (eq 4).[10]

1,3-Bis(triisopropylsilyl)propyne

[82192-59-4] · $C_{21}H_{44}Si_2$ · 1,3-Bis(triisopropylsilyl)propyne · (MW 352.75)

(precursor of a stereoselective bulky C_3 nucleophile, functionalized Peterson reagent[1])

Alternate Name: 1,3-bis(TIPS)propyne.

Physical Data: bp 130-135 °C/0.08 mmHg; *d* 0.846 g cm^{-3}.

Solubility: both the reagent and its lithio derivative are soluble in ether or THF.

Analysis of Reagent Purity: GC at 210 °C on a glass capillary column coated with OV-17; TLC on silica (hexanes, R_f 0.75). ^1H NMR ($CDCl_3$, 80 MHz): δ = 1.63 (s, CH_2), 1.3-0.9 (m, 2 TIPS).

Preparative Method: 1,3-bis(TIPS)propyne is prepared in quantitative yield by silylation of ***3-Lithio-1-triisopropylsilyl-1-propyne*** with ***Triisopropylsilyl Trifluoromethanesulfonate***.[2]

Purification: by distillation or chromatography.

Handling, Storage, and Precautions: no special precautions required; the reagent is not changed when stored for several months at ambient temperature. The Li derivative is handled under inert gas using simple syringe equipment.

Generation of Lithio-1,3-bis(triisopropylsilyl)propyne.

The main use of the title reagent is as a precursor of the lithium derivative. 1,3-Bis(triisopropylsilyl)propyne is cleanly lithiated by treatment with 1 equiv of ***n-Butyllithium*** in THF at -20 °C (15 min) to what is probably an equilibrium mixture of propargylic and allenic species (**1**) and (**2**) (eq 1).[3] The bulky triisopropylsilyl (TIPS) group serves as a controlling group in the addition of (**1**/**2**) to electrophiles.

(1)

Formation of (*Z*)-enynes.

The lithio derivative reacts with aliphatic aldehydes (RCHO, -78 °C -> rt, few h) to form the (*Z*)-enynes R-CH=CH-C&tbond;C-TIPS (**3**) in good yield (57-79%) and high isomeric purity (*Z*:*E* &AApprox; 20:1, eq 2). The intermediate addition product formed by attack of (**2**) on the aldehyde has *erythro* configuration[2] and undergoes *syn* elimination of silanolate to give (**3**) by the pathway generally observed in Peterson reactions in alkaline media.[4]

The method was used for attachment of the *cis* enyne side chain in a synthesis of gephyrotoxin,[5] and for the preparation of (*Z*)-non-3-en-1-yne, a building block in the synthesis of prostaglandins and of 11-HETE methyl ester.[6]

Formation of (*E*)-Enynes.

The stereoselectivity of the reaction can be reversed simply by adding 5 equiv ***Hexamethylphosphoric Triamide*** to the solution of (**1**/**2**) prior to addition of the aldehyde. Under these conditions the reaction is complete within a few seconds at -78 °C, and (*E*)-enynes (**4**) are isolated in 60-65% yield with high *E*:*Z* selectivity (20:1 to 10:1, eq 3). Evidence has been presented that the action of HMPA is exerted in the addition to the aldehyde, not in the elimination step.[2] A *threo* propargylic intermediate is presumably formed by attack of an ion pair similar to (**1**) onto the aldehyde. The method was used for the introduction of the *trans* enyne side chain in a synthesis of laurenyne.[7]

The stereochemical preferences of these reactions are less pronounced with aromatic aldehydes. For example, the reaction of (**1**/**2**) with benzaldehyde in THF gives a 2:1 mixture of *Z*:*E* enynes (-20 -> 0 °C, 1 h, 67%), whereas in the presence of 1 equiv HMPA mostly the (*E*)-enyne is obtained (1:9 selectivity, -78 °C, 10 s, 78%).

Enynes and Dienynes from Other Bis(silyl)propynes.

Corresponding Li reagents containing a less bulky silyl group at the propargylic carbon generally show lower selectivity for (*Z*)-enynes, e.g. the Li derivatives of 1,3-bis(trimethylsilyl)propyne, 1-trimethylsilyl-3-triethylsilyl-1-propyne, 1-trimethylsilyl-3-*t*-butyldimethylsilyl-1-propyne (TMS-C&tbond;C-CH_2-SiR_3 with R_3 = Me_3, Et_3, *t*-$BuMe_2$).[8] Selectivity could be improved by using a Mg or Ti counterion instead of Li.[8-10] Cinnamaldehyde, cyclohexanone, and *cis*- and *trans*-hydrindanones[11] likewise underwent the reaction.

1-Trimethylsilyl-3-triisopropylsilyl-1-propyne (TMS-C&tbond;C-CH_2-TIPS, **5**) was found to give essentially the same results (yield and stereoselectivity) as bis(TIPS)propyne in two cases of direct comparison (crotonaldehyde, cinnamaldehyde).[12] Scrambling of the silyl groups did not occur. Compound (**5**) is available from TMS-C&tbond;C-CH_2Br by reaction with ***Magnesium*** in the presence of 0.5% ***Mercury(II) Chloride*** followed by silylation with TIPS-OTf (76%). Silane (**5**) can also be prepared from propargyl bromide by reaction with (1) Mg/0.5% $HgCl_2$, (2) TIPS-OTf, (3) *n*-BuLi, (4) TMS-Cl (two-pot procedure, 63% overall).[12]

Using the lithio reagent obtained from (**5**) in THF, (*Z*)-dienynes were prepared in good yield and stereoselectivity from several α,β-unsaturated aldehydes (eq 4) (Table 1).[12,13] In the corresponding Wittig reactions, the yields and isomeric purity of enynes were far lower. Oxirane and aziridine groups are compatible with the reaction conditions (eq 5) (Table 2).[12]

(4)

(5)

Table 1 TMS-Protected Dienynes from a,b-Unsaturated Aldehydes (eq 4)

[a] In the presence of 1 equiv $Ti(O\text{-}i\text{-}Pr)_4$.

Table 2 TMS-Protected Enynes from Oxirane (Aziridine) Carbaldehydes (eq 5).

X	R^1	R^2	R^3	Yield (%)	Z: E
O	H	Ph	H	60	1.5:1
O	Ph	H	Ph	63	1:1.5
O	H	Ph	Ph	75	>20:1
NCH_2Ph	Ph	H	H	73	>20:1

The preparation of (*Z*)-enynes by alternative methods (Wittig-Horner and others) is possible;[14-16] and is also possible for (*E*)-enynes (Wittig).[17-19]

Epoxide Opening.

The lithio propyne derivative (**1**/**2**) adds to epoxides in spite of its bulkiness. The TIPS group near the reaction center is useful for preventing secondary reactions in a polyepoxide substrate. Thus while the simple monoadduct (**6a**) from *cis*-benzene trioxide and 3-lithio-1-TIPS-1-propyne was formed as a minor product only (always accompanied by products (**7a**), (**8a**), (**9a**)), the monoadduct (**6b**) was isolated in 48% yield (two diastereomers) from the reaction with (**1**/**2**) along with 10% (**7b**); bisadducts (**8b**/**9b**) were not formed (eq 6).[20]

2,5-Bis(trimethylsilyloxy)furan[1]

[77220-06-5] · $C_{10}H_{20}O_3Si_2$ · 2,5-Bis(trimethylsilyloxy)furan · (MW 244.44)

(diene for use in cycloadditions;[3] building block for quinones[3] and heterocycles[4-6])

Physical Data: bp 42-43 °C/0.01 mmHg.

Solubility: insol H_2O; sol aprotic organic solvents.

Preparative Methods: readily prepared by the reaction of ***Succinic Anhydride***, ***Triethylamine***, ***Zinc Chloride***, and ***Chlorotrimethylsilane*** in MeCN (eq 1). It can also be prepared in 66% yield using succinic anhydride, ***Trimethylsilyl Trifluoromethanesulfonate*** and triethylamine.[2]

Handling, Storage, and Precautions: very unstable to air and moisture.

Cycloadditions.

The title reagent is very reactive in Diels-Alder reactions, affording adducts with ***Dimethyl Acetylenedicarboxylate*** and ***Ethyl Acrylate*** in good to excellent yields. The resulting adducts can be desilylated with ***Sodium Fluoride*** in wet acetonitrile (eq 2).[3]

2,5-Bis(trimethylsilyloxy)furan also reacts with tetrachlorocyclopropene in carbon tetrachloride for 3 days to afford a bicyclic adduct in 33% yield (eq 3).[4]

(3)

Nucleophilic Additions.

2,5-Bis(trimethylsilyloxy)furan reacts with carbonyl compounds in the presence of a Lewis acid to form an anhydride which upon workup affords a dilactone (eq 4). This one-step procedure constitutes a facile entry to the 3,7-dioxabicyclo[3.3.0]octane system.[5] This reaction is successful with both aldehydes and ketones.

(4)

2,5-Bis(trimethylsilyloxy)furan reacts with methyl vinyl ketone to produce a novel diketo acid (eq 5). This reaction may be conducted either thermally or in the presence of a Lewis acid such as ***Titanium(IV) Chloride*** at -78 °C.[6]

N,O-Bis(trimethylsilyl)acetamide

[10416-59-8] · $C_8H_{21}NOSi_2$ · *N,O*-Bis(trimethylsilyl)acetamide · (MW 203.43)

(powerful silylating agent; reacts with a wide range of functional groups)

Alternate Name: BSA.

Physical Data: bp 71-73 °C/35 mmHg.[1,2]

Solubility: very sol most organic solvents.

Form Supplied in: liquid; rapidly contaminated with trimethylsilylacetamide and acetamide if exposed to moist air. *Drying:* extreme moisture sensitivity; should be kept in a sealed container.

Preparative Method: made by the reaction of acetamide with a large excess of ***Chlorotrimethylsilane*** in the presence of ***Triethylamine***.[1,2]

Handling, Storage, and Precautions: no special handling and storage procedures; all work must be carried in an efficient fume hood.

Bis(trimethylsilyl)acetamide.

Bis(trimethylsilyl)acetamide (BSA) has been formulated as *N,N*-bis(trimethylsilyl)acetamide as well as the imidate form. The NMR spectra of a number of silylamide derivatives (^{13}C, ^{29}Si, ^{14}N, and ^{17}O) have been investigated. Whereas BSA is seen to exist in the imidate form, some analogs, for example bis(trimethylsilyl)formamide, exist in the *N,N*-bis(trimethylsilyl) form, and the product obtained by the interaction of ***1,2-Bis(chlorodimethylsilyl)ethane*** with BSA is also clearly in the alternative form.[3] Trimethylsilyl derivatives of hydroxamic acids are formed in reactions using ***Hexamethyldisilazane*** and are similar in structure to BSA.[4] This entry will concentrate on examples from the more recent literature.

Protection of Functional Groups.

Early reports of the use of BSA concentrated on the preparation of derivatives of a number of functional group types in

order to facilitate chromatographic analysis. The trimethylsilylation of amides, ureas, amino acids and dipeptides, carboxylic acids, enols and hindered phenols were reported under mild reaction conditions.[1,2] Substituted ureas are converted into their monosilylated derivatives because of the lone electron pair involvement and so ***N,N´-Bis(trimethylsilyl)urea*** is close in energy to BSA. By the same token, one of the trimethylsilyl residues in BSA is replaced more easily than the second. The conversion of *N*-haloamides into the *N*-haloimidic trimethylsilyl esters, for example *N*-chloroacetamide into *N*-chloroacetimidic trimethylsilyl ester, was probably the first reported use of BSA.[5] Part per billion traces in water of environmentally important phenols and carboxylic acids have been determined by concentration using macroreticular resins and subsequent derivatization using BSA before gas chromatography.[6] It has been claimed that trimethylsilylation of trichothecines prior to gas chromatography is best achieved by using bis(trimethylsilyl)trifluoroacetamide (BSTFA) rather than BSA.[7]

Protection of Hydroxy Groups.

The first example of the use of the trimethylsilyl group for the protection of a sterically hindered hydroxy group involved a 14-hydroxy steroid which was treated with bis(trimethylsilyl)acetamide in DMF at 78 °C.[8] Since that time a wide variety of alcohols have been protected using BSA. The product from the enantioselective hydroboration-oxidation of *N*-benzyloxycarbonyl-1,2,3,6-tetrahydropyridine was converted into its trimethylsilyl ether (TMS ether) in order to allow isolation by gas chromatography.[9] The osmylation of unsaturated ester components of insect pheromones, followed by a reductive workup and silylation with BSA, has been used to allow identification using GC-MS.[10] Bis(trimethylsilylation) using BSA has been shown to be the most convenient method for the protection of a range of biologically important dihydroarenediols prior to characterization using GC-MS.[11] High yields have been reported with other secondary alcohols using BSA,[12] including the example shown in eq 1.[13] The method has been used to effect the trimethylsilylation of an aldol product,[14] Ninhydrin reacts with allyltrimethylsilane and trimethylsilyl triflate in acetonitrile to give the expected 2,2-bis(trimethylsilyloxy)indan-1,3-dione. However, using BSA the major product incorporated an acetamido residue.[15] The replacement of an acetoxy group by an amido group (eq 2) presumably occurs via an oxonium species.[16]

(1)

(2)

Bis(trimethylsilyl)acetamide has also been used to provide temporary protection of hydroxy and carboxy groups in a

number of coupling reactions involved in the preparation of cephalosporins and penicillins, as shown in eq 3.[17] The protection of nucleoside hydroxy groups prior to reduction using tributyltin hydride-AIBN has been reported.[18] The same method has also been used in connection with nucleoside coupling reactions.[19] Transglycosylation catalyzed by trimethylsilyl triflate has also been carried out on trimethylsilyl-protected nucleosides (eq 4), in which the prior protection was effected using BSA.[20] In the case of 6-oxopurineribonucleoside synthesis, the 7β-isomer is first formed and eventually affords the 9β-isomer, presumably by way of the 7,9-diribonucleoside.[21] It has been shown that BSA causes the debromination of some purine nucleosides in the presence of ***Potassium Fluoride*** and a crown ether.[22]

The silylation of tertiary alcohols in good yields has been reported, e.g. di-*t*-hydroxyadamantane.[23] The preparation of

2-methyl-2-trimethylsilyloxynonadecane was achieved in 84% yield using a combination of BSA, chlorotrimethylsilane, and ***N-(Trimethylsilyl)imidazole***.[24] 2-Methyl-2-trimethylsilyloxypentanone, a prototype for a series of compounds that are valuable intermediates used in a study of diastereoselective aldol reactions, can be prepared in good yield using BSA.[25] Even highly hindered silanols react with BSA as indicated in eq 5.[26] It is of interest to note that BSA has been used to reduce the influence of free hydroxy groups on surfaces. Difficult Diels-Alder reactions that require high temperatures and are carried out in sealed glass tubes may suffer from decomposition of the diene on the surface of the glass. Silylation with BSA is then worth investigating.[27] It has also been shown that the charcoal carrier for tungstic acid-***Tri-n-butylchlorostannane***, which is used in the catalyzed hydrogen peroxide epoxidation of alkenes, is improved by treatment with BSA. Decomposition of the hydrogen peroxide, catalyzed by surface hydroxy groups, is then less troublesome.[28]

(5)

Formation of Trimethylsilyl Enol Ethers.

The silylation of enolizable aldehydes and ketones has been carried out using BSA in HMPA in the presence of very small amounts of metallic sodium. The method is highly regio- and stereoselective, giving the (*Z*)-isomer that results from kinetic control.[29] With more easily enolized compounds the reaction proceeds readily in the absence of other additives. In the case of the bis(trimethylsilylation) of oxindole (eq 6) the effect is evidently related to the gain in resonance energy on silylation at oxygen.[2] Similarly, the conversion of glutaconic anhydride into the silylated α-pyrone (eq 7) was achieved in very high yield using BSA.[30] The product is a very useful Diels-Alder diene. Other highly functionalized dienes have been prepared and used in Diels-Alder syntheses of highly functionalized naturally occurring anthraquinones. The dienes shown in eqs 8 and 9 were used in the syntheses of ceroalbolinic acid[31] and xantholaccaic acid,[32] respectively.

The protection of phenols was one of the first examples of the use of BSA, including the trimethylsilylation of 2,6-di-*t*-butylphenol.[2] 2,6-Di-*t*-butyl-4-vinylphenol has been protected with BSA and then polymerized by both cationic and radical initiators before liberating the free phenolic groups by cleavage with acid.[33] A number of calixarene trimethylsilyl ethers have been prepared from the phenols using BSA.[34] Calix[4]arene has been converted into a mixture of tris- and tetrakis(trimethylsilyl) ethers by heating the phenol with BSA in acetonitrile.[35]

Protection of Carboxy Groups.

As with hydroxy compounds, the conversion of carboxy groups into their trimethylsilyl derivatives is valuable in connection with GC-MS. The method has been used, for example, in assaying a perhydroindole ACE inhibitor.[36] Amino acid hydrohalides are silylated in almost quantitative yields by BSA in THF at reflux. Other methods require higher temperatures. The free amino acid can be isolated after treatment with water and another important feature is that no racemization was observed.[37] The use of BSA in peptide coupling reactions has been reported,[38] including examples where hydroxy amino acids are involved.[39] A coupling reaction involved in a total synthesis of the immunostimulating peptide FK156 also involved the formation of a peptide TMS ester.[40] The trimethylsilylation of (*E*)-3-bromoacrylic acid proceeds in good yield (eq 10) and has been used in conjunction with a protected alanyl anion in the synthesis of an unsaturated α-amino acid.[41] The bis(trimethylsilyl) ester of squaric acid, formed using BSA (eq 11), has been shown to be in dynamic equilibrium. The trimethylsilyl groups undergo rapid intermolecular migration, as established by crossover experiments.[42]

(10)

(11)

Reactions at Nitrogen.

The protection and activation of a number of nitrogen functional groups has been achieved using BSA, for example the silylation of aziridines.[43] Treatment of primary and secondary amines with BSA and then with a chloroformate gives good yields of carbamates.[44] Conversion of the guanine derivative into the bis(trimethylsilyl) derivative and the ***Trimethylsilyl Trifluoromethanesulfonate*** nucleoside coupling reaction (eq 12) was part of a synthesis of AzddMAP.[45] Similarly, the conversion of sulfoximines into their TMS derivatives, prior to deprotonation and reaction with a range of electrophiles, can be carried out in almost quantitative yields using BSA.[46] The preparation of the 1,3,4-oxadiazoline shown in eq 13 was achieved in 60-65% yield.[47]

(12)

(13)

The increased volatility on silylation of pyrimido[4,5-*i*]imidazo[4,5-*g*]cinnoline has been investigated in connection with flash vacuum pyrolysis studies.[48] It has been reported that dihydropyrimidines and dihydro-*s*-triazines were dehydrogenated under vigorous trimethylsilylation conditions.[49] Apparently the reaction does not proceed in the absence of oxygen or in the presence of free radical inhibitors. Aromatic isocyanates react with BSA to give silylated azauracils as shown in eq 14, which are desilyated on treatment with ethanol.[50] We also note that BSA and other bis(trimethylsilyl)amides are converted into nitriles in high yields by treatment with ***Tetra-n-butylammonium***

Fluoride. Lewis acids, or ***Iron(II) Phthalocyanine***,[51] and a range of bis(trimethylsilyl)amides react with ***Phosgene*** to form acyl isocyanates.[52] Arylsulfonylacetonitriles undergo carbon-carbon coupling reactions when heated in BSA at 120-140 °C.[53] A range of silylnitronates have been prepared using BSA or the trifluoro analog (BSTFA). The products (eq 15) are useful intermediates for the synthesis of isoxazolidines.[54]

(14)

(15)

The Control of Protic Acids.

There are a number of examples where protic acids have been shown to have a deleterious effect on reactions and where partial or complete control is advantageous. The rearrangement of the benzylpenicillin sulfoxide to the cephalosporanic acid derivative (eq 16) gave the best yield using ***Hydrogen Bromide*** and ca. 30 mol % of BSA.[55] Similarly, the preparation of eight-membered oxygen heterocycles that are present in a number of marine natural products, has been achieved in moderate yields by Lewis acid promoted acetal-alkene cyclizations in the presence of BSA as shown in eq 17.[56] The same principle has been used to control Friedel-Crafts alkylation reactions involving, for example, methyl chloromethoxyacetate and *N*-methylindole.[57] In the absence of BSA a considerable amount of the indole derivative was converted into its dimer while the major product was methyl bis(1-methyl-3-indolyl)acetate. In the presence of BSA the formation of the dimer was suppressed and the initial product, methyl 1-methyl-3-indolylacetate, isolated in a 90% yield. Control in the highly diastereoselective alkylation of 1-methylindole using chiral pyrrole derivatives was achieved in a better yield when using BSA (eq 18).[58]

(16)

(17)

(18)

95% de

Use has also been made of the oxophilicity of silicon, as compared to the azaphilicity of protons, in Mannich reactions of bis(aminol ethers) with heterocycles such as 2-methylfuran where a proton is liberated during the reaction.[59] The bis(methoxymethyl) derivative from *t*-butylamine gave an iminium salt when treated with hydrogen chloride in ether. In duplicate reactions using 2-methylfuran, one (eq 19) was treated with BSA while the other, in the absence of BSA, was worked up using Hünig's base and gave the expected secondary amine after a hydrolytic work up in 80% yield. Evidently in the first reaction the BSA reacted with the hydrogen chloride produced and gave chlorotrimethylsilane.

The reaction between triflic acid and *N*-trimethylsilyl-1,3-oxazolidin-2-one has been shown to afford trimethylsilyl triflate in a high yield, whereas the reaction of BSA with triflic acid gave only a 43% yield of trimethylsilyl triflate.[60] Despite that finding, in situ catalytic reactions involving trimethylsilyl triflate (eq 20)[58b] and trimethylsilyl fluorosulfonate (eq 21)[61] can be carried out in high yields when a catalytic amount of the acid is added to BSA.

Reactions of the Anion from Bis(trimethylsilyl)acetamide.

The deprotonation of BSA using ***Lithium Diisopropylamide*** was used to generate the protected acetamide enolate ion for use in the synthesis of the dienone shown in eq 22.[62] It has been shown subsequently that the same product can be prepared by the reaction of the anion, generated from *n*-butyllithium and BSA, with 2,6-dibromo-1,4-benzoquinone.[63] The anion has also been used in reactions with a number of carbonyl compounds, including benzophenone.[64]

(22)

Reactions of Phosphorus Compounds.

A number of papers report the conversion of chlorophosphites, dichlorophosphites, and their thio analogs into trimethylsilyl derivatives.[65] The reaction between bromodifluorophosphine and BSA at -80 °C results in formation of an unstable product with a P-N bond together with bromotrimethylsilane.[66] Nucleoside phosphonates have been converted into the related bis(trimethylsilyl) phosphites by treatment with BSA. Subsequent reaction with an acyl chloride and triethylamine then rapidly affords the corresponding acyl phosphonate.[67] The Michael addition of phosphonous acids and esters by way of intermediate silyl alkyl phosphonites has been used in the preparation of phosphinic acids (eq 23).[68] The coupling of an activated acid with an acylphosphoranylidene in the presence of BSA (eq 24) has been used in the synthesis of the vicinal tricarbonyl portion of the immunosuppressant macrocyclic lactone FK-506.[69] The coupling in that case gave the required product in a 91% yield.

(23)

(24)

Metal Catalyzed Reactions of Allylic Esters.

Hexacarbonylmolybdenum catalyzed elimination of acetic acid in the presence of BSA is effective in a high yield route to conjugated dienes,[70] and BSA has been used as a base in an unexpected palladium catalyzed tandem elimination-cycloaddition reaction.[71] The alkylation of malonic esters with allylic acetates using hexacarbonyl molybdenum and BSA (eq 25) has been reported to give high yields.[72] β-Keto esters are also alkylated using palladium(0) catalysis. In reactions of 2-hydroxymethyl-2-propen-1-ol diacetate with methyl 4-methylcyclohexanone-2-carboxylate, the use of BSA gave the monoalkylated product whereas using DBU resulted in the formation of the bicycloannulation product.[73] The palladium catalyzed alkylation of sodium dimethyl malonate with a silylated allene acetate in the presence of BSA (eq 26) proceeds via the silylated ester.[74] The silylation step is necessary because of the sensitive nature of allenyl acetates. A stereoselective total synthesis of isolobophytolide used BSA to convert an allylic pivalate into the corresponding enol trimethylsilyl derivative and this was then used in the intramolecular allylation of a sulfonyl acetate anion using ***Tetrakis(triphenylphosphine)palladium(0)*** as catalyst.[75]

Bis(trimethylsilyl)acetylene

[14630-40-1] · $C_8H_{18}Si_2$ · Bis(trimethylsilyl)acetylene · (MW 170.40)

(nucleophile in Friedel-Crafts type acylations and alkylations; lithium trimethylsilylacetylide precursor; cycloaddition substrate)

Alternate Name: BTMSA.

Physical Data: mp 26 °C; bp 136-137 °C; *d* 0.752 g cm^{-3}.

Solubility: sol all commonly used organic solvents.

Form Supplied in: clear liquid; widely available.

Preparative Method: from acetylene by treatment with ***n-Butyllithium*** followed by ***Chlorotrimethylsilane***.[1]

Handling, Storage, and Precautions: the liquid is flammable and an irritant. Use in a fume hood.

Friedel-Crafts Alkylation/Acylation and Related Reactions.

Bis(trimethylsilyl)acetylene (BTMSA) can be added to a variety of Lewis acid-activated electrophiles. The most common variation which has been used in several total syntheses is the addition of BTMSA to acid chlorides in the presence of ***Aluminum Chloride*** to afford α,β-alkynic ketones in good yields (eq 1);[2,3] this complements the method by which monosubstituted alkynes are added to carboxylic acid anhydrides, esters and tertiary amides (see ***n-Butyllithium-Boron Trifluoride Etherate***). In addition to acid chlorides, BTMSA can be added to optically active acetals in the presence of ***Titanium(IV) Chloride*** to afford, after cleavage of the chiral template, α-hydroxyalkynes in excellent yield and high enantiopurity (eq 2).[4] BTMSA can also be added to the oxonium ion intermediate resulting from the treatment of tri-*O*-acetyl-D-glucal with ***Tin(IV) Chloride*** to give the α-alkynylated pyranose in excellent yield as a single stereoisomer (eq 3).[5] In a related example, it has been shown that BTMSA can be added to γ-lactols in the presence of ***Boron Trifluoride Etherate*** to afford highly substituted tetrahydrofuran-3-carboxylates in high stereoselectivity.[6]

(1)

(2)

(3)

In addition, treatment of δ-methoxyproline derivatives[7] and γ-methoxy-γ-lactams[8] under the Lewis acid/BTMSA conditions gives δ-alkynic prolines and γ-alkynic γ-lactams, respectively. BTMSA will undergo a 1,4-addition to ethylenic acyl cyanides in the presence of $TiCl_4$ to give γ,δ-alkynic acyl cyanides in good yield (eq 4).[9] BTMSA will also add to tertiary[10] or activated halides in the presence of Lewis acids (eq 5).[11]

(4)

(5)

Concerning noncarbon electrophiles, addition of BTMSA to arylsulfonyl chlorides in the presence of aluminum chloride affords ethynyl sulfones[12] which have been used as Michael acceptors and Diels-Alder dienophiles.[13] It is presumed that the Lewis acid catalyzed processes summarized above proceed via a silicon-stabilized vinyl cation, which then loses the trimethylsilyl moiety to afford the alkynic products.

Trimethylsilylacetylide Alkylation Reactions.

While BTMSA adds to a number of electrophiles under Lewis acid-catalyzed conditions, this reagent can also be used as a trimethylsilylacetylide precursor. In this regard, it has been reported that treatment of BTMSA with ***Methyllithium***-LiBr complex in THF gives quantitative formation of lithium trimethylsilylacetylide (eq 6).[14] The utility of this reagent lies in its ability to provide access to a diverse group of protected, terminal alkynes. For example, this reagent, which is formed in situ, can be added to aldehydes to give secondary α-hydroxy alkynes,[14] ketones to afford tertiary α-hydroxy alkynes (eq 7),[15] epoxides to form β-hydroxy alkynes,[16] or alkyl halides to give monoalkylated alkynes.[17] Lithium trimethylsilylacetylide can be brominated with ***Bromine*** and coupled with copper acetylides to give 1,3-diynes[18] or iodinated with ***Iodine Monochloride***[19] and coupled with arylcopper reagents to afford aryl alkynes in good yields.[20] This lithium acetylide intermediate has also been transmetalated with ***Zinc Bromide*** and coupled with a vinyl iodide in the presence of Pd^0 to give a 1,3-enyne[21] (eq 8) or with ***Diethylaluminum Chloride*** and coupled with an enone in the presence of a nickel catalyst to afford a γ,δ-alkynic ketone (eq 9).[22]

(6)

(7)

(8)

(9)

Cycloaddition Reactions.

BTMSA is a powerful substrate in a variety of cycloaddition reactions. The most common use of this reagent in that sense involves the transition metal-catalyzed [2 + 2 + 2] cycloaddition.[23] BTMSA can be added to 1,5-hexadiyne in the presence of a cobalt catalyst to afford the highly strained, versatile synthetic intermediate 4,5-bis(trimethylsilyl)benzocyclobutene (eq 10).[24] When this reaction is run on a diyne with a properly tethered vinyl group the initial adduct isomerizes to the corresponding *o*-xylylene and undergoes an intramolecular [4 + 2] cycloaddition to afford complex polycycles in high yields (eq 11);[25] this method was used in a concise total synthesis of (±)-estrone.[26] Varying the BTMSA acceptor in this reaction gives a number of polycyclic heterocycles including 2*H*-pyrans,[27] 2,3-dihydro-5(1*H*)-indolizinones,[28] anthraquinones,[29] tetrahydroisoquinolines (eq 12)[30] and 1,3-diazabiphenylenes (eq 13).[31]

(13)

BTMSA can also be added to several dienes in Diels-Alder fashion. Pretreatment of hydrocarbon dienes such as 1,3-butadiene with catalytic $Et_2AlCl/TiCl_4$ followed by addition of BTMSA at 60 °C gives the corresponding bis(trimethylsilyl)cyclohexadienes in high yields.[32] BTMSA can be added to α-pyrone in decalin at 165 °C to give 1,2-bis(trimethylsilyl)benzene in good yield,[33] as well as to 6*H*-1,3-oxazin-6-ones in refluxing decalin to afford 3,4-bis(trimethylsilyl)pyridine in moderate yield.[34] In addition, BTMSA can be added to 4-phenyloxazole in the presence of catalytic triethylamine at 250 °C to give 3,4-bis(trimethylsilyl)furan in excellent yield.[35] BTMSA has also been used in other cycloadditions including cyclopropenation involving bis(methoxycarbonyl)carbene,[36] [2 + 2] cycloaddition with dichloroketene to give silylated cyclobutenedione,[37] 1,3-dipolar cycloaddition with pyridinium dicyanomethylides to afford silylated indolizines,[38] and with nitrile oxides to give isoxazoles.[39]

Miscellaneous Reactions.

In addition to BTMSA being used as an acetylide synthon, it can also be converted to the corresponding alkynyl(phenyl)iodonium tosylate[40] and treated with nucleophiles such as 1,3-dicarbonyl compounds.[41] 1-Nitro-2-(trimethylsilyl)acetylene has been prepared from BTMSA and undergoes a series of cycloadditions analogous to BTMSA itself.[42] In addition, BTMSA will undergo hydroboration with dialkylborane to afford 1-substituted 1,2-bis(trimethylsilyl)ethenes[43] or with ***Borane-Dimethyl Sulfide*** to give an acylsilane.[44] Finally, it was reported that BTMSA could be treated with cyclopropylcarbene-chromium complex to give silylated 3-methoxy-2-cyclopentenone in good yield.[45]

Related Reagents.

Trimethylsilylacetylene.

(1*E*,3*E*)-1,4-Bis(trimethylsilyl)-1,3-butadiene

[22430-47-3] · $C_{10}H_{22}Si_2$ · (1*E*,3*E*)-1,4-Bis(trimethylsilyl)-1,3-butadiene · (MW 198.45)

(building block for the stereodefined construction of conjugated polyenyl chains[1-4])

Physical Data: bp 46-49 °C/15 mmHg; *n*20D 1.4679.

Analysis of Reagent Purity: GC/MS, IR, ^{1}H and ^{13}C NMR.

Preparative Methods: coupling of the Grignard reagent derived from (*E*)-2-(trimethylsilyl)-1-bromoethylene with the same bromo derivative leads to the silyldiene in 51% yield;[5] a higher yield (62%) is obtained by reaction of bis(trimethylsilyl)methyllithium with (*E*)-3-(trimethylsilyl)-2-propenal.[6] Other procedures involve the Pd^0-catalyzed demercuration of bis[(*E*)-(2-trimethylsilylvinyl)]mercury, prepared from (*E*)-2-(trimethylsilyl)-1-lithioethylene and $HgCl_2$ (77% yield),[7] or the reaction of (*E*)-1,4-bis(trimethylsilyl)-2-butene with *n*-BuLi and TMEDA and subsequent oxidation with $HgCl_2$ of the isolated bis-lithiated species, stabilized by complexation with TMEDA (57% yield).[8]

Handling, Storage, and Precautions: conveniently stored at -15 °C for several months, without appreciable isomerization.

Electrophilic Substitutions.

A highly selective substitution of a trimethylsilyl group is readily performed with acyl chlorides in the presence of ***Aluminum Chloride*** to obtain silylated ketones with high retention of configuration (>98%). Dicarbonyl compounds are prepared with a one-pot procedure, by simply adding the second acyl chloride after completion of the first step, without isolation of the monosubstitution product (eq 1).[1]

(1E,3E)-1,4-Bis(trimethylsilyl)-1,3-butadiene

The versatility of this approach is illustrated by the synthesis of polyunsaturated fatty acids of special interest. Ostopanic acid, a cytotoxic fatty acid,[9] is directly obtained by acylation reactions with the appropriate acyl chlorides,[2] whereas β-parinaric acid methyl ester, an interesting fluorescent probe for biological membranes,[10] is prepared by a selective double acylation, followed by reduction and dehydration reactions (eq 2).[3]

Moreover, unsaturated keto silanes and diketones obtained according to eq 1 can be easily reduced to saturated keto silanes or 1,6-dicarbonyl compounds;[11] unsaturated keto silanes can be transformed into enantiomerically enriched hydroxy derivatives by reduction and enzymatic kinetic resolution.[12] Monosilylated unsaturated sulfides, precursors of a variety of dienylsilanes,[13] can be also obtained by chemoselective electrophilic substitutions.[4]

Halogen Addition.

Bromine addition leads to a tetrabromo derivative which can be bromodesilylated to (1*Z*,3*Z*)-1,4-dibromobutadiene (eq 3).[14]

(3)

Cycloaddition Reactions.

Diels-Alder reactions with ***Maleic Anhydride*** (eq 4)[5,6] lead to cyclic allylsilanes, which can undergo further interesting elaborations.[6]

(4)

Related Reagents.

(1E,3E,5E)-1,6-Bis(trimethylsilyl)-1,3,5-hexatriene; ***2,3-Bis(trimethylstannyl)-1,3-butadiene***; ***(E)-1-Trimethylsilyl-1,3-butadiene***; ***2-Trimethylsilylmethyl-1,3-butadiene***.

(1*E*,3*E*,5*E*)-1,6-Bis(trimethylsilyl)-1,3,5-hexatriene

[133683-82-6] · $C_{12}H_{24}Si_2$ · (1*E*,3*E*,5*E*)-1,6-Bis(trimethylsilyl)-1,3,5-hexatriene · (MW 224.49)

(building block for the stereodefined construction of conjugated polyenyl chains[1-6])

Physical Data: bp 71-73 °C/0.75 mmHg.

Analysis of Reagent Purity: GC/MS, IR, ^{1}H and ^{13}C NMR.

Preparative Methods: conveniently prepared by means of the cross-coupling reactions of 2 equiv of the Grignard reagent derived from (*E*)-2-(trimethylsilyl)-1-bromoethylene with (*E*)-1,2-dichloroethylene (75% yield) or with (*E*)-2-phenylthio-1-chloroethylene (55% yield),[7] in the presence of $NiCl_2$(dppe) in THF at rt. [2-(Trimethylsilyl)-1-bromoethylene is commercially available in an (*E*)/(*Z*) 87/13 ratio. The mixture is distilled two or three times on a Fisher column MMS 202 at 50-52 °C/42 mmHg and fractions enriched in (*Z*)-isomer are collected. The (*E*)-isomer is recovered and purified by simple distillation (bp 54-55 °C/42 mmHg, stereoisomeric purity 98-99%)].

Handling, Storage, and Precautions: can be stored at -15 °C for several months, without isomerization.

Electrophilic Substitutions with Acyl Chlorides.

The reaction of the trienylsilane with equimolar amounts of acyl chloride and ***Aluminum Chloride*** at 0 °C in CH_2Cl_2 affords unsaturated keto silanes with high retention of configuration (>98%). Subsequent substitution of the second silyl group with another acyl chloride in the same reaction flask at rt leads to the diketone derivative (eq 1).[1]

The highly efficient synthetic potential of the bis-silylated triene is illustrated by the synthesis of the (6*E*)-isomer of leukotriene B_3[2] and of SM-9064, a potential LTB_4 antagonist (eq 2).[3] The key step of the synthesis of both compounds is represented by the double acylation of the bis-silylated triene with the appropriate acyl chlorides [(6*E*)-LTB_3: nonanoyl chloride and methylglutaryl chloride; SM-9064: 3-(*p*-methoxyphenyl)propanoyl chloride and methylsuccinyl chloride]. Other steps require reduction with ***Sodium Borohydride*** of the diketo ester intermediates and, in the case of SM-9064, the amide formation reaction with ***Pyrrolidine*** in methanol.

Unsaturated keto silanes and diketones prepared according to eq 1 can be further transformed into saturated keto silanes or 1,8-diketones by means of Pd-catalyzed selective hydrogenation reactions.[4]

Polyunsaturated secondary alcohols, obtained by reduction of keto silanes, can be kinetically resolved with a high (>97%) enantioselectivity by lipase-catalyzed transesterification with ***Vinyl Acetate***.[5] A representative example is reported in eq 3.

(1E,3E,5E)-1,6-Bis(trimethylsilyl)-1,3,5-hexatriene

Electrophilic Substitutions with Sulfur Derivatives.

Reaction of the bis-silylated triene with ***Benzenesulfenyl Chloride*** in THF at rt leads to the trienyl sulfide with inversion of configuration at the terminal double bond (*Z*,*E*,*E*/*E*,*E*,*E* = 90/10).[6] The substitution reaction with the commercially available *S*-phenyl carbonochloridothioate leads to the corresponding monosilylated thioester with high retention of configuration. A straightforward decarbonylation reaction with Ni^0 in DMF[8] affords the corresponding sulfide (*E*,*E*,*E*/*Z*,*E*,*E* = 85/15) (eq 4).[6]

Related Reagents.

(1E,3E)-1,4-Bis(trimethylsilyl)-1,3-butadiene; ***(E)-1-Trimethylsilyl-1,3-butadiene***.

N,O-Bis(trimethylsilyl)hydroxylamine

[22737-37-7] · $C_6H_{19}NOSi_2$ · *N,O*-Bis(trimethylsilyl)hydroxylamine · (MW 177.39)

(protected hydroxylamine synthon for the formation of isocyanates,[6] hydroxamic acids,[6] *N*-phosphinoylhydroxylamines,[12] and oximes[13])

Physical Data: bp 137-139 °C, 78-80 °C/100 mmHg; *d* 0.830 g cm^{-3}; flash point 28 °C.

Solubility: sol THF, ether, pentane, CH_2Cl_2.

Form Supplied in: liquid; widely available, but expensive.

Analysis of Reagent Purity: ^1H NMR (benzene-d_6) δ 0.16 (s, 9, $NSiMe_3$), 0.25 (s, 9, $OSiMe_3$), 4.6 (br s, 1, NH).[1-3]

Preparative Methods: can be prepared in 69% yield by treating dry ***Hydroxylamine*** with 2 equiv ***Chlorotrimethylsilane*** and 2 equiv ***Triethylamine***.[3] A safer preparation, which avoids the use of the explosive solid, hydroxylamine, uses the reaction of hydroxylamine hydrochloride with excess ***Hexamethyldisilazane*** (71-75% yield).[1,2] Alternatively, neutralization of hydroxylamine hydrochloride with ethylenediamine followed by addition of chlorotrimethylsilane can be used.[4]

Handling, Storage, and Precautions: flammable, corrosive liquid; hydrolyzed by moist air. Avoid inhalation and prevent contact with skin and eyes. The reagent should be stored under argon at 0-4 °C. Use in a fume hood.

Nucleophilic Reactions.

N,O-Bis(trimethylsilyl)hydroxylamine is a protected, lipophilic form of hydroxylamine. It reacts with a variety of electrophiles predominantly by attack on the nitrogen nucleophilic center. Reaction with acid chlorides (1 equiv) in the presence of triethylamine gives *N,O*-bis(trimethylsilyl)hydroxamic acids by *N*-acylation.[6] A related reagent, tris(trimethylsilyl)hydroxylamine, gives the same product in high yields, also by *N*-acylation.[5,6] Hydrolysis gives the free hydroxamic acids, whereas thermal fragmentation affords isocyanates (eq 1).[6]

Excess ***Acetyl Chloride*** (and presumably other acyl chlorides) reacts with *N,O*-bis(trimethylsilyl)hydroxylamine to give *O*-acetyl acetohydroxamate in 88% yield after hydrolytic workup.[7] Isocyanates react exothermically with *N,O*-bis(trimethylsilyl)hydroxylamine to give *N,O*-bis(trimethylsilyl)-*N*-hydroxyureas in high yields.[8] Carboxylation of *N,O*-bis(trimethylsilyl)hydroxylamine with ***Carbon Dioxide*** in THF followed by silylation gives a tris(trimethylsilyl) derivative of *N*-hydroxycarbamic acid.[9] This intermediate rearranges in high yield to afford an *N*-trimethylsilyloxy isocyanate (eq 2).[10]

Reaction of *N,O*-bis(trimethylsilyl)hydroxylamine with ***Diketene*** affords the explosive *N,O*-bis(trimethylsilyl) derivative of acetoacetylhydroxamic acid. Deprotection and cyclization gives an isoxazole (eq 3) whose dianion serves as a useful β-keto amide synthon.[11]

(3)

Phosphorus analogs of hydroxamic acids, prepared from phosphinic chlorides and *N*,*O*-bis(trimethylsilyl)hydroxylamine, tend to be unstable. The stable *O*-sulfonyl derivatives of the phosphinoylhydroxylamines undergo base-induced, Lossen-type rearrangement to phosphonamidates by aryl group migration from P to N (eq 4).[12]

(4)

Deprotonation of *N*,*O*-bis(trimethylsilyl)hydroxylamine with ***n-Butyllithium*** or ***Potassium Hydride*** at low temperature yields the nitrogen centered anion *N*,*O*-bis(trimethylsilyl)hydroxylamide.[6,13] At higher temperatures the oxyanion *N*,*N*-bis(trimethylsilyl)hydroxylamide is formed by rearrangement.[1,14] Each reacts with acyl chlorides chemospecifically by *N*-acylation and *O*-acylation, respectively. The oxyanion also reacts with silyl halides,[1a] methyl iodide,[1] and sulfonyl chlorides[14] chemospecifically on oxygen. In a Peterson-type one-pot reaction, oximes and oxime derivatives can be prepared effectively from the N-anion of *N*,*O*-bis(trimethylsilyl)hydroxylamine and an aldehyde or ketone (eq 5).[13] Oximes of sterically hindered ketones can be formed in high yields by this procedure.

Bis(trimethylsilyl) Malonate[1]

[18457-04-0] · $C_9H_{20}O_4Si_2$ · Bis(trimethylsilyl) Malonate · (MW 248.43)

(reagent useful in the synthesis of β-keto acids[2-4] and methyl ketones[3])

Physical Data: bp 63-66 °C/1 mmHg; *d* 0.974 g cm^{-3}.

Preparative Method: commercially available; alternatively, it can be easily prepared from malonic acid by a number of silylation procedures.[5]

Handling, Storage, and Precautions: flammable liquid, moisture sensitive.

Synthetic Applications.

In the homologation of activated carboxylic acid derivatives to β-keto acids, bis(trimethylsilyl) malonate has been shown to be a useful alternative to conventional methods.[4] However, despite the mild reaction conditions and generally high product yields, the reagent has seen limited use in organic synthesis.

The lithio derivative (**1**) adds smoothly to a variety of acid derivatives, including acid chlorides, mixed anhydrides, or HOBT esters, to provide β-keto acids following mild aqueous hydrolysis.[2] Thus benzoylacetic acid was obtained in 92% yield upon treatment of (**1**) with ***Benzoyl Chloride*** (eq 1).

In the presence of lithium or magnesium salts, bis(trimethylsilyl) malonate can be acylated with acid chlorides under milder conditions.[3] Metal complexation enhances the acidity of malonates such that tertiary amines can be used as bases.[3b] The β-keto acids can be isolated after a mild aqueous workup, or the corresponding methyl ketone can be obtained directly using more vigorous conditions (eq 2).

5-Acetyl-2-chloro-3-nitropyridine, an intermediate in the synthesis of analogs of the inotropic agent isomazole, was prepared from the corresponding acid chloride using this methodology (eq 3).[6]

The α-substituted β-keto acid (**2**), an intermediate useful in the synthesis of chiral 2-methyl-3-hydroxybutyrolactones, was obtained via the reaction of the anion derived from methyl bis(trimethylsilyl) malonate (eq 4).[7]

Bis(trimethylsilyl)mercury[1]

$Hg(SiMe_3)_2$

[4656-04-6] · $C_6H_{18}HgSi_2$ · Bis(trimethylsilyl)mercury · (MW 346.97)

(precursor to trimethylsilyllithium;[2] debrominates 1,2- and 1,3-dibromides;[3] source of trimethylsilyl radical;[4] useful reagent for preparation of metal-silicon bonds[5])

Physical Data: mp 102-104 °C.

Solubility: sol diethyl ether, tetrahydrofuran, benzene, hexane, and carbon disulfide.

Form Supplied in: yellow crystals.

Preparative Methods: original procedure involves shaking ***Sodium Amalgam*** with ***Bromotrimethylsilane***.[6] The resulting bis(trimethylsilyl)mercury is readily purified by sublimation at 60 °C in vacuo. Several alternative procedures have been described.[7]

Handling, Storage, and Precautions: mercury and its organic derivatives are highly toxic and should be handled in an efficient fume hood. Bis(trimethylsilyl)mercury is air sensitive.

Treatment of bis(trimethylsilyl)mercury with ***Lithium*** metal in an ether or hydrocarbon solvent provides ***Trimethylsilyllithium*** (eq 1).[2] This method has proved particularly useful for the generation of this lithium reagent free from additives such as HMPA.[8]

$$Hg(SiMe_3)_2 + 2\,Li \longrightarrow 2\,Me_3SiLi + Hg \qquad (1)$$

Bis(trimethylsilyl)mercury can be utilized for the conversion of 1,2- and 1,3-dibromoalkanes into alkenes and cyclopropanes respectively (eqs 2 and 3).[3] 1,2-Diiodides react in a similar fashion. Adamantene has been generated and trapped in situ with dienes using this methodology.[9]

(2)

(3)

Photolysis of bis(trimethylsilyl)mercury with UV light leads to the formation of a trimethylsilyl radical.[4] Generation of this species in the presence of imines leads to the production of 1,2-diamines via an addition-dimerization process (eq 4).[10] Under similar conditions, polyfluorinated alkenes undergo an addition-elimination reaction, producing the corresponding vinyl silanes (eq 5).[11] The dealkylation of ethers such as anisole with bis(trimethylsilyl)mercury was originally speculated to involve the trimethylsilyl radical. However, more recent evidence suggests that this reaction proceeds predominantly via direct attack of the reagent on the ether linkage (eq 6).[12]

(4)

(5)

(6)

A number of organometallic complexes containing metal-silicon bonds have been prepared using

bis(trimethylsilyl)mercury as a source of the trimethylsilyl ligand.[5] Complexes derived from transition metal, lanthanide, and main group elements have all been synthesized using this chemistry.

Bis(trimethylsilyl)methane[1]

$(Me_3Si)_2CH_2$

[2117-28-4] · $C_7H_{20}Si_2$ · Bis(trimethylsilyl)methane · (MW 160.41)

(precursor of $(Me_3Si)_2CHLi$ and Me_3SiCH_2Li, which are useful in Peterson alkenation reactions[3])

Physical Data: bp 132-133 °C; *d* 0.752 g cm^{-3}; *n*20D 1.41710.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; commercially available.

Analysis of Reagent Purity: ^1H NMR.

Purification: by distillation.

Handling, Storage, and Precautions: the reagent can be stored in a glass bottle.

Formation of Trimethylsilylmethyl Anion.

The carbon-silicon bond of bis(trimethylsilyl)methane can be cleaved by ***Sodium Methoxide*** in HMPA to form trimethylsilylmethylsodium, which subsequently reacts with ketones to form alkenes (eq 1).[2]

(1)

Similar reaction of bis(trimethylsilyl)phenylmethane (eq 2) gave triphenylethylene in 79% yield. Lithium methoxide

can be used instead of sodium methoxide.

(2)

Formation of Bis(trimethylsilyl)methyllithium.

Bis(trimethylsilyl)methane can be metalated with ***Methyllithium***[3] or ***n-Butyllithium***[4] in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** to produce $(Me_3Si)_2CHLi$, which is a useful Peterson alkenation reagent (eq 3).

(3)

Related Reagents.

Tris(trimethylsilyl)methane.

Bis(trimethylsilyl) Monoperoxysulfate

[23115-33-5] · $C_6H_{18}O_5SSi_2$ · Bis(trimethylsilyl) Monoperoxysulfate · (MW 258.44)

(strong oxidant; Baeyer-Villiger oxidant in nonprotic solvents;[1,2] oxidizes alkenes to ketones,[2] sulfides to sulfoxides,[2] and pyridine to its *N*-oxide[3])

Physical Data: colorless viscous liquid at -30 °C. ^{1}H NMR (CD_2Cl_2, 200 MHz, -30 °C) δ 0.38 (s);[2] (-50 °C) 0.28 (s) and 0.42 (s) due to nonequivalence of the Me_3Si groups.[4] ^{13}C NMR (CD_2Cl_2, 50 MHz, -30 °C) δ 0.53 (s).[2]

Solubility: sol CH_2Cl_2, CCl_4, and diethyl ether; sparingly sol petroleum ether.

Analysis of Reagent Purity: the oxidation of I^- to I_2 serves for the determination of the peroxide content (iodometric titration). Moreover, bis(trimethylsilyl) monoperoxysulfate is a sufficiently strong oxidizing agent to oxidize Cl^- or HCl gas to Cl_2 in CH_2Cl_2 solution at -20 °C.[3]

Preparative Method: the reagent is conveniently prepared[1,3] by adding dropwise a solution of ***Sulfur Trioxide*** (1 equiv or slightly less) in dry CH_2Cl_2 to a solution of ***Bis(trimethylsilyl) Peroxide***[6] in dry CH_2Cl_2 at -30 °C, followed by stirring further for 30 min at this temperature (eq 1). The yield is quantitative and the crude reagent can be used directly for oxidation reactions. Use of more than 1 equiv of SO_3 affords bis(trimethylsilyl) peroxydisulfate.[3]

Handling, Storage, and Precautions: the reagent should be handled below -20 °C under anhydrous conditions and used immediately after preparation. It decomposes (explosion) on warming to rt, with the evolution of sulfur trioxide.[5] The reagent rearranges at rt in CH_2Cl_2 solution to the isomeric trimethylsilyl methoxydimethylsilyl sulfate within 1-2 d;[5] the rearrangement is slower at -30 °C and requires about 36 h for complete conversion.[2] The reagent undergoes hydrolysis in the presence of water to form hexamethyldisiloxane and peroxymonosulfuric acid.[3,5] A good fume hood, a safety shield, and all safety precautions required for peroxides are essential.

Baeyer-Villiger Oxidations.

Bis(trimethylsilyl) monoperoxysulfate is a convenient reagent for Baeyer-Villiger oxidations under mild conditions, in which high yields (88-98 %) of esters or lactones are obtained from the corresponding ketones (eq 2).[1,2] Usually 3-5 equiv of the reagent are required and the reaction is complete within a few hours (3-8 h). Its solubility in CH_2Cl_2 makes it a useful reagent for Baeyer-Villiger oxidations in nonprotic solvents, unlike ***Monoperoxysulfuric Acid*** (Caro's acid) or ***Potassium Monoperoxysulfate*** (Oxone). An important advantage of this reagent over monoperoxysulfuric acid is the fact that after oxygen transfer the byproduct, bis(trimethylsilyl) sulfate, is not acidic and therefore undesirable side products are usually minimized.

(2)

Bis(trimethylsilyl) monoperoxysulfate in CH_2Cl_2 oxidizes 4-heptanone, benzophenone, fluorenone, adamantanone, and tetracyclone to their corresponding Baeyer-Villiger rearrangement products in high yield.[1] Acetophenone gives mainly phenyl acetate, together with an appreciable amount (20 %) of methyl benzoate, despite the poor migratory aptitude of the methyl vs. phenyl group in Baeyer-Villiger oxidations.[2] Cyclohexanone affords ε-caprolactone in high yield, along with small amounts of γ-caprolactone.[2] Through the use of ^{18}O-labeled $Me_3SiOSO_2{}^{18}O{}^{18}OSiMe_3$ it was shown that this reaction proceeds via an intermediate dioxirane.[2]

The limitations of this reagent in Baeyer-Villiger oxidations are that α,β-unsaturated ketones react sluggishly and that double bonds are epoxidized.[1]

Alkene Oxidations.

Bis(trimethylsilyl) monoperoxysulfate in CH_2Cl_2 at low temperature oxidizes alkenes to ketones in high yield via the intermediacy of the corresponding epoxide (eqs 3 and 4). Addition of ketones to the reaction mixture remarkably increases the rate of this reaction.[2]

(3)

(4)

Heteroatom Oxidations.

Bis(trimethylsilyl) monoperoxysulfate reacts instantaneously with sulfides such as methyl *p*-tolyl sulfide to give the corresponding sulfoxide and bis(trimethylsilyl) sulfate (eq 5).[2] The reagent oxidizes pyridine to pyridine *N*-oxide at -30 °C in CH_2Cl_2 solution (eq 6).[3]

1,2-Bis(trimethylsilyloxy)cyclobutene

[17082-61-0] · $C_{10}H_{22}O_2Si_2$ · 1,2-Bis(trimethylsilyloxy)cyclobutene · (MW 230.45)

(a suitable reagent for annulation processes[1,2] and 4-keto ester synthesis[3])

Physical Data: bp 88-92 °C/13-14 mmHg; *d* 0.89 g cm^{-3}.

Solubility: sol hydrocarbons and ethers.

Form Supplied in: not commercially available.

Preparative Methods: prepared as a colorless liquid by acyloin condensation of ***Diethyl Succinate*** (dispersed Na in toluene or Et_2O, reflux) using ***Chlorotrimethylsilane*** as trapping agent.[4] An *Organic Synthesis* preparation is available.[4c]

Handling, Storage, and Precautions: use in a fume hood; the compound is stable for years if stored in a tightly screw-capped bottle. Prolonged exposure to moist air leads to decomposition.

Cyclopentane Annulation by Geminal Acylation.

1,2-Bis(trimethylsilyloxy)cyclobutene (**1**) reacts in an aldol-type reaction with aldehydes and acetals in the presence of ***Boron Trifluoride Etherate***. The adducts are easily converted into 2- or 2,2-substituted 1,3-cyclopentanediones in high yields via a pinacol rearrangement (eq 1). Acetals of cyclic ketones lead to spiro[4.*n*] ring systems.[1,5a] This two-step geminal acylation provides an efficient and general annulation procedure which can be carried out in a one-pot process. Cyclic acetals (dioxolanes, dioxanes), in the presence of a large excess of $BF_3.OEt_2$, provide a superior yield of the cyclopentanediones.[6] With ***Tetra-n-butylammonium Fluoride*** catalysis the reactions stop at the butanone stage.[7] Starting from thioacetals, the rearrangement can be carried out under mild, neutral conditions (***Mercury(II) Chloride***).[8]

(1)

(1)

o-Alkynyl acetals react with (**1**) directly to give polycyclic unsaturated ketones (eq 2); a different pathway is observed for a terminal alkyne (eq 3).[9]

Differently functionalized cyclopentenones, β-hydroxy-cyclopentanone, or β-alkylidenecyclopentanones are obtained when the butanone is modified prior to the rearrangement.[1,5d] The spiroannulation is stereoselective because of equatorial preference of the aldol-type reactions and complete inversion during the pinacol rearrangement (eq 4).

$n = 1$, 24 h, 58%; $n = 2$, 144 h, 87%

(2)

Reductive Succinoylation.

In the presence of ***Tin(IV) Chloride***, (**1**) and an acetal undergo two successive reactions, involving ring cleavage of the aldol adduct (eq 5).[3,5g] Reaction of the enol silyl ether with carbon or sulfur electrophiles leads to 5-substituted 4-keto esters.[1,3] Also 5-alkoxy-1,4-diketones can be obtained.[3,10]

Cyclohexane Annulation.

Photochemical cycloaddition of (**1**) to 2-cyclopentenones and 2-cyclohexanones (except 2-alkyl-2-cyclohexenones) leads to tricyclo[4.3.0.0[2,6]]nonane-2-ones and tricyclo[4.4.0.0[2,7]]decane-2-ones, respectively.[2] With 5-alkyl-2-cyclohexenones the addition occurs *trans* to the 5-substituent (eq 6).[11] Subsequent to manipulation (reduction, organometallic, or Wittig reaction) of the keto function in the adduct, oxidative α-diol cleavage provides a facile entry into bicyclo[4.3.0]nona-2,5-diones and bicyclo[4.4.0]deca-2,5-diones.[2,11,12] The respective *cis*-hydrindanes and *cis*-decalanes, such as (**2**), are functionalized at three positions vicinal to the ring junction.

(2)

Cyclobutane Derivatives.

Reagent (**1**) can be transformed into 1,2-cyclobutanedione, *cis*-1,2-cyclobutanediol, 2-aminobutanone, and 2-*t*-alkyl-2-hydroxybutanone.[13] β-C-Glycosides are available upon ***Titanium(IV) Chloride***-mediated reaction of (**1**) with glycosyl acetates.[14]

2,3-Bis(trimethylsilyloxy)-1,3-butadiene.

This is obtained upon thermolysis (180 °C, 84%) of (**1**) and can be used in Diels-Alder reactions with alkynic esters.[15]

2,3-Bis(trimethylsilyloxy)-1,3-cyclohexadiene

[59733-54-9] · $C_{12}H_{24}O_2Si_2$ · 2,3-Bis(trimethylsilyloxy)-1,3-cyclohexadiene · (MW 256.54)

(useful for Diels-Alder reactions giving highly functionalized [2.2.2] bicyclic systems)

Physical Data: bp 102-103 °C/12 mmHg.

Solubility: sol C_6H_6, Et_2O.

Preparative Method: by the sequential silylation of 1,2-cyclohexanedione with a weak base and ***Trimethylsilyl Trifluoromethanesulfonate***[1] or under strongly basic conditions.[2,3]

Handling, Storage, and Precautions: silyl enol ethers are susceptible to hydrolysis under basic and especially acidic conditions or in the presence of fluoride ion and other silyl specific nucleophiles (e.g. DMSO, DMF). Precautions should therefore be adopted to protect such enol ethers from moisture.

Silyl enol ethers are significantly more electron-rich than normal alkenes and this property dominates their reactivity.[4] They react with a wide variety of electrophiles, usually in the presence of a Lewis acid. It was also recognized, particularly by Danishefsky,[5] that these functional groups can serve as convenient surrogates for ketones in hetero-Diels-Alder reactions (eq 1).

1,2-Diketones, somewhat more difficult materials to work with, can also be utilized in related reactions. The diketones,

by virtue of dipole repulsion, exist largely as the keto-enol form. Attempts to directly silylate cyclohexane-1,2-dione using LDA as the base were reported to be complicated by competing self-condensation.[2] Sequential silylation, however, led to the bis(silyloxy)diene.[2] Alternatively, with the bulky silicon base ***Sodium Hexamethyldisilazide***, self-condensation was less problematic (eq 2).[3] The bis(silyloxy)diene can also be directly prepared under less basic conditions from the dione using Me_3SiOTf/NEt_3 (eq 2).

(2)

Reetz has shown that 2,3-bis(trimethylsilyloxy)-1,3-cyclohexadiene, an electron-rich diene, reacts readily in a Diels-Alder fashion with a variety of activated dienophiles (eq 3). In these reactions, *endo* addition was exclusively observed.[3]

(3)

Related bis-2,3-silyloxy-1,3-dienes also undergo Diels-Alder reactions with various dienophiles, including heterodienophiles such as diazo compounds and imines (eqs 4 and 5).[6,7]

(4)

(5)

The products of these Diels-Alder reactions, bis(1,2-silyloxy)-1-alkenes, can undergo further synthetic elaboration. Although such reactions have not been described for the cyclohexane-1,2-dione derivatives, structurally related species may be desilylated to regenerate the 1,2-dione (eq 6).[3] The high electron density in the bis(1,2-silyloxy)-1-alkenes makes them suitable educts for inverse electron demand Diels-Alder reactions (eqs 7 and 8).[8,9] Finally, the silyl enol ether can undergo normal electrophilic addition to imines, leading to α-hydroxy carbonyl compounds (eq 9).[10]

Bis(trimethylsilyl) Peroxide[1]

[5796-98-5] · $C_6H_{18}O_2Si_2$ · Bis(trimethylsilyl) Peroxide · (MW 178.38)

(a masked form of 100% hydrogen peroxide;[2] synthon of HO^+ for electrophilic hydroxylation;[3,4] source of Me_3SiO^+ for electrophilic oxidations;[4-6] a versatile oxidant for alcohols, ketones, phosphines, phosphites, and sulfides[1,2,7])

Physical Data: bp 41 °C/30 mmHg;[7] *n*20D 1.3970.[1b]

Solubility: highly sol aprotic organic solvents.

Form Supplied in: colorless oil; used as an anhydrous and protected form of hydrogen peroxide; 10% solution in hexane or in CH_2Cl_2.

Analysis of Reagent Purity: ^{1}H NMR (s) δ 0.18 ppm;[3] ^{29}Si NMR δ 27.2 ppm.[8]

Preparative Methods: obtained in 80-96% yields by reaction of ***Chlorotrimethylsilane*** with ***1,4-Diazabicyclo[2.2.2]octane***.$(H_2O_2)_2$,[3] ***Hexamethylenetetramine***.H_2O_2,[8] or ***Hydrogen Peroxide-Urea*** in CH_2Cl_2.[9]

Handling, Storage, and Precautions: thermally stable; can be handled in the pure state and distilled;[8] rearranges at 150-180 °C.[1c]

Electrophilic Oxidations.

Bis(trimethylsilyl) peroxide (**1**) functions as an electrophilic hydroxylating agent for aliphatic, aromatic, and heteroaromatic anions.[3] Reaction of their lithium or Grignard compounds with (**1**) often affords trimethylsiloxy intermediates, which undergo desilylation with HCl in methanol to give the corresponding alcohols in good yields. In the presence of a catalytic amount of ***Trifluoromethanesulfonic Acid***, (**1**) reacts with aromatic compounds to produce the corresponding phenols after acidic workup.[10] In these reactions the Me_3SiO^+ moiety is considered as a synthon of the hydroxyl cation (i.e. OH^+).

Lithium or Grignard enolates of vinyl compounds react with (**1**) to produce the corresponding α-hydroxy ketones

upon acidic workup.[4] Treatment of enolate anions derived from carboxylic acids and amides with (**1**) in THF at rt gives the corresponding α-hydroxy derivatives in 31-58% yields.[11] Furthermore, stereoselective synthesis of silyl enol ethers with retention of configuration is accomplished by oxidation of (*E*)- and (*Z*)-vinyllithiums, prepared from the corresponding bromides and *s*-BuLi, with (**1**) in THF at -78 °C.[6] Heterocyclic silyl enol ethers, such as 3-(trimethylsiloxy)furan and 3-(trimethylsiloxy)thiophene, can be obtained by reaction of (**1**) with 3-lithiofuran and 3-lithiothiophene, respectively.[5] In some reactions involving nucleophiles and (**1**), silylation may compete with siloxylation;[3] the outcome depends upon the counterion.[4]

Oxidative Desulfonylation and Selective Baeyer-Villiger Oxidation.

Aliphatic, alicyclic, and benzylic phenyl sulfones react with *n*-BuLi and then with (**1**) in situ to give aldehydes or ketones in 66-91% yields (eq 1).[12] On the other hand, reaction of ketones with (**1**) in the presence of a catalyst, such as ***Trimethylsilyl Trifluoromethanesulfonate***,[2] ***Tin(IV) Chloride***, or ***Boron Trifluoride Etherate***,[7] in CH_2Cl_2 gives esters in good to excellent yields (eq 2). This Baeyer-Villiger oxidation proceeds in a regio- and chemoselective manner: the competing epoxidation of a C-C double bond does not occur.

$$RR'C{=}O + Me_3SiOSiMe_3 + PhSO_2Li \quad (1)$$

(2)

catalyst = $Me_3SiSO_3CF_3$, $SnCl_4$, $BF_3 \cdot OEt_2$

Oxidation of Alcohols, Sulfur, and Phosphorus Compounds as well as Si-Si and Si-H Bonds.

Bis(trimethylsilyl) peroxide acts as an effective oxidant for alcohols in the presence of ***Pyridinium Dichromate*** or $RuCl_2(PPh_3)_3$ complex as the catalyst in CH_2Cl_2.[13] By this method, primary allylic and benzylic alcohols can be selectively oxidized to α-enals in the presence of a secondary alcohol.

Sulfur Trioxide reacts with (**1**) in CH_2Cl_2 at -30 °C, affording ***Bis(trimethylsilyl) Monoperoxysulfate***, an oxidant useful for the Baeyer-Villiger oxidation.[14] In addition, sulfides can be converted to sulfoxides or sulfones by use of (**1**) in benzene at reflux.[1b,15,16] This peroxide can also oxidize phosphines and phosphites to the corresponding oxyphosphoryl derivatives with retention of configuration at the phosphorus center in high yields.[1b,17] Furthermore, it converts the P=S and P=Se functionalities to the P=O group with inversion of configuration at the phosphorus center.[17] The $CF_3SO_3SiMe_3$ or Nafion-$SiMe_3$ catalyzed oxidation of nucleoside phosphites to phosphates under nonaqueous conditions is applied to the solid-phase synthesis of oligonucleotides.[18,19]

Reactions between (**1**) and disilanes containing fluorine atoms or possessing ring strain proceed readily at ambient temperature to generate the corresponding disiloxanes.[20] Oxidation of hydrosilanes (R_3SiH) with (**1**) gives a mixture of R_3SiOH and $R_3SiOSiMe_3$. The ratio of R_3SiOH to $R_3SiOSiMe_3$ tends to decrease in the order $Et_3SiH > PhMe_2SiH > Me_3SiSiHMe_2$.

Isomerization of Allylic Alcohols and Formation of 1-Halo-1-alkynes.

Isomerization of primary and secondary allylic alcohols to tertiary isomers proceeds in CH_2Cl_2 at 25 °C in the presence of a catalyst that is prepared in situ by activation of ***Vanadyl Bis(acetylacetonate)*** or $MoO_2(acac)_2$ with (**1**) (eq 3).[21] On the other hand, terminal alkynes react with (**1**) in the presence of copper or zinc halides in THF at -15 °C to afford terminal 1-halo-1-alkynes in 40-85% yields.[22] By the same method, 1-cyano-1-alkynes are obtained in 65% yield by use of copper cyanide.

Bis(trimethylsilyl) Peroxide-Vanadyl Bis(acetylacetonate)[1]

$Me_3SiO\text{-}OSiMe_3.V(O)(acac)_2$

[-] · $C_{16}H_{32}O_7Si_2V$ · Bis(trimethylsilyl) Peroxide-Vanadyl Bis(acetylacetonate) · (MW 443.54) $(TMSO)_2$

[5796-98-5] · $C_6H_{18}O_2Si_2$ · Bis(trimethylsilyl) Peroxide-Vanadyl Bis(acetylacetonate) · (MW 178.38) $VO(acac)_2$

[3153-26-2] · $C_{10}H_{14}O_5V$ · Bis(trimethylsilyl) Peroxide-Vanadyl Bis(acetylacetonate) · (MW 265.16)

(reagent for the transposition of allylic and allenic alcohols)

Physical Data: $Me_3SiOOSiMe_3$: bp 40-41 °C/28 mmHg;[2] $VO(acac)_2$: mp 255 °C (dec).

Solubility: sol dichloromethane.

Preparative Method: prepared in situ from bis(trimethylsilyl) peroxide (colorless liquid) and $VO(acac)_2$ (blue-green crystals).

Handling, Storage, and Precautions: bis(trimethylsilyl) peroxide is reported to be a reasonably stable, distillable liquid. Vanadyl acetylacetonate is air-sensitive and should be refrigerated under dry nitrogen or argon. See ***Bis(trimethylsilyl) Peroxide*** and ***Vanadyl Bis(acetylacetonate)***.

Isomerization of Primary and Secondary Allylic Alcohols.

The title reagent, prepared in situ by the addition of bis(trimethylsilyl) peroxide[2,3] to a dichloromethane solution of vanadyl bis(acetylacetonate) (3:1), is effective in catalyzing the allylic transposition of both cyclic and acyclic primary and secondary allylic alcohols to tertiary allylic alcohols in good yields (eqs 1-3). The conversion of primary allylic alcohols to secondary allylic alcohols is less effective (eq 4). The reaction is catalytic in vanadyl bis(acetylacetonate) (10 mol %), and produces only the (*E*)-alkenes in the secondary alcohols studied. It is noteworthy that this reagent shows no propensity to give epoxides from the allylic alcohols, in contrast to the Sharpless epoxidation reagent, ***t-Butyl Hydroperoxide***/$VO(acac)_2$.[4] $MoO_2(acac)_2$, with or without added $Me_3SiOOSiMe_3$, also catalyzes these allylic isomerizations but with inferior yields (e.g. 76% and 35%, respectively, for the transformation in eq 1).

(1)

(2)

(3)

(4)

Allylic isomerization of geraniol (or nerol) gives linalool (eq 5) in 68-70% yield, with only trace formation of α-terpineol. This evidence suggests that the isomerization does not proceed via a free allylic cation. Further support for a primarily suprafacial vanadium-assisted allylic rearrangement is provided in eq 6, where (*S*)-(-)-3-methyl-2-cyclohexen-1-ol (40% ee) gives (*R*)-(+)-1-methyl-2-cyclohexen-1-ol (29% ee), with retention of hydroxy facial orientation.

Isomerization of Secondary Allenic Alcohols.[2]

The $VO(acac)_2$-$Me_3SiOOSiMe_3$ catalytic system also effects allylic transposition in α-allenic alcohols. (*E*)-4-Phenyl-3-buten-2-one is produced in 81% yield from the addition of 10 mol % of the catalyst to a dichloromethane solution of 1-phenyl-2,3-butadien-1-ol (eq 7). However, in substrates where both allylic and allenic rearrangement is possible, the allylic transposition dominates (eq 8). In this particular case, the use of the catalyst $MoO_2(acac)_2$ at 5 mol % is more effective in promoting the isomerization to either of the two products, and without the use of the bis(trimethylsilyl) peroxide.[2] At 25 °C, $MoO_2(acac)_2$ gives 90% yield of the dienone (10 min), whereas at -78 °C, the allylic rearranged trienol product is formed in 94% yield (10 min).

Bis(trimethylsilyl) Selenide

[4099-46-1] · $C_6H_{18}SeSi_2$ · Bis(trimethylsilyl) Selenide · (MW 225.34)

(synthesis of unsymmetrical selenides;[6] generation of selenoaldehydes;[7] reduction of sulfoxides, selenoxides, and telluroxides[4])

Physical Data: bp 45-46 °C/5.3 mmHg.

Solubility: sol Et_2O and THF.

Handling, Storage, and Precautions: is an air-sensitive, colorless oil. Because of the strong odor and the release of toxic hydrogen selenide on exposure to moisture, handling of bis(trimethylsilyl) selenide should be performed in a well-ventilated hood. It can be stored at -20 °C in an argon-flushed glass vessel for about a month; after this time, amorphous selenium (red color) is gradually deposited on the vessel.

Synthesis of Bis(trimethylsilyl) Selenide.

In the initial studies, bis(trimethylsilyl) selenide was synthesized by the following two methods: silylation of ***Sodium Selenide***[1] (or ***Lithium Selenide***[2]) with ***Chlorotrimethylsilane*** (eq 1) or reaction of bromobenzene, ***Magnesium***, and ***Selenium*** with chlorotrimethylsilane (eq 2).[3]

$$\mathrm{Se} \xrightarrow[\text{liq. } NH_3]{\text{Na (or Li)}} \underset{(\text{or } Li_2Se)}{Na_2Se} \xrightarrow[C_6H_6 \text{ (or } Et_2O)]{Me_3SiCl} \underset{83\%}{(Me_3Si)_2Se} \quad (1)$$

$$\mathrm{PhBr} + \mathrm{Mg} + \mathrm{Se} \xrightarrow{\mathrm{Et_2O}} \mathrm{Se(MgBr)_2} + \mathrm{Ph_2Se} \xrightarrow[\text{rt, 24 h}]{\mathrm{Me_3SiCl}} \underset{39\%}{(\mathrm{Me_3Si})_2\mathrm{Se}} \quad (2)$$

However, the former method requires the troublesome manipulation involved in preparing sodium selenide (or lithium selenide) in liquid ammonia[1b] and conducting the silylation in benzene (or diethyl ether). The latter method is inefficient and results in a low yield of the desired disilyl selenide. Thus a one-pot, high-yield procedure based on the ***Lithium Triethylborohydride*** reduction of elemental selenium has been developed, as depicted in eq 3.[4] In this method, both preparation of Li_2Se and silylation with Me_3SiCl are performed in THF. Technically important is the use of selenium shot; if selenium powder is utilized, the yield of Li_2Se decreases sharply. Moreover, addition of small amount of ***Boron Trifluoride Etherate*** (1.6 mol %) accelerates the silylation of Li_2Se.[5]

$$\mathrm{Se} \xrightarrow[\text{THF}]{\mathrm{LiBEt_3H}} \mathrm{Li_2Se} \xrightarrow[\text{THF}]{\mathrm{Me_3SiCl}} \underset{95\%}{(\mathrm{Me_3Si})_2\mathrm{Se}} \quad (3)$$

Recently it has been reported that the reaction of ***Lithium Diselenide*** (Li_2Se_2) with 2 equiv of chlorotrimethylsilane affords bis(trimethylsilyl) selenide in 73% yield with the concomitant formation of elemental selenium (eq 4).[5]

$$\mathrm{Se} \xrightarrow[\text{cat. PhC}\equiv\text{CPh}]{\text{Li, THF}} \mathrm{Li_2Se_2} \xrightarrow[\text{THF}]{\mathrm{Me_3SiCl}} \underset{73\%}{(\mathrm{Me_3Si})_2\mathrm{Se}} + \mathrm{Se} \quad (4)$$

Synthesis of Unsymmetrical Selenides.

Bis(trimethylsilyl) selenide reacts with equimolar amounts of ***n-Butyllithium*** to generate $Me_3SiSeLi$, alkylation of which then provides trimethylsilyl alkyl selenides. Similar treatment of Me_3SiSeR^1 with BuLi / R^2X successfully leads to unsymmetrical selenides in good yields (eq 5).[6] Use of acid chlorides in place of alkyl halides results in the formation of selenoesters.

Generation and Diels-Alder Reaction of Selenoaldehydes.[7]

Direct conversion of aldehydes to selenoaldehydes has been achieved by treatment with bis(trimethylsilyl) selenide in the presence of a catalytic amount of butyllithium (eq 6).[7a]

A mechanistic proposal includes addition of $Me_3SiSeLi$ to aldehydes, followed by elimination of Me_3SiOLi to generate selenoaldehydes, which undergo Diels-Alder reaction with dienes. Aldehydes bearing a conjugate diene unit provide intramolecular Diels-Alder adducts (eq 7).[7b]

Reduction of Sulfoxides, Selenoxides, and Telluroxides.

Bis(trimethylsilyl) selenide is useful as a two-electron reducing agent for the reduction of sulfoxides, selenoxides, and telluroxides to corresponding sulfides, selenides, and tellurides, respectively (eq 8).[4]

Bis(trimethylsilyl) Sulfide[1]

[3385-94-2] · $C_6H_{18}SSi_2$ · Bis(trimethylsilyl) Sulfide · (MW 178.44)

(reduction of S, Se, and Te oxides;[4] formation of thiocarbonyl derivatives under mild conditions;[7] formation of allylsilanes from ketones or allylic alcohols[13])

Alternate Name: TMS_2S.

Physical Data: bp 164 °C; *d* 0.846 g cm^{-3}.

Solubility: sol diethyl ether, THF, CH_2Cl_2, MeCN, and aromatic solvents.

Form Supplied in: colorless cloudy liquid, commercially available.

Handling, Storage, and Precautions: avoid strong oxidizing agents. The reagent is moisture sensitive, flammable, and decomposes to CO, CO_2, H_2S, and sulfur oxides. Stench, mucous membrane (lungs, eyes) and skin irritant. Store in cool dry place free of oxygen. Use in a fume hood.

Reducing Agent.

Bis(trimethylsilyl) sulfide (TMS_2S) is used to reduce aromatic nitro groups[2] to amines and the oxides of sulfur, selenium, and tellurium. Conditions for nitro group reduction (eq 1) are forcing; however, yields are good. Reactions of TMS_2S with primary aliphatic nitro groups[3] result in the formation of the thiohydroxamic acids (eq 2) which can be isolated or carried further to the nitrile. Secondary alkyl nitro derivatives provide oximes. Sulfoxides are reduced[4] to sulfides, selenoxides to selenides, and telluroxides to tellurides. Conditions are mild and work well on both the aliphatic and aromatic oxides.

(1)

(2)

Sulfur Transfer Reagent.

Alkyl sulfides[5] can be formed from the corresponding alkyl halides using TMS_2S. Thioaldehydes,[6] thioketones (eq 3),[7] thioamides,[8] thioacid anhydrides,[9] thioacylsilanes,[10] divinyl sulfides (eq 4),[11] and thiranes (eq 5)[12] are also produced from TMS_2S and their respective carbonyl or alkenic compounds, in combination with the reagents shown.

(3)

(4)

(5)

Silicon Transfer Reagent.

Bis(trimethylsilyl) sulfide can transform[1b] alcohols, acids, and amines into their silylated counterparts. Enol silanes[13] are also formed under the influence of this silyl transfer reagent.

N,N´-Bis(trimethylsilyl)urea[1]

[18297-67-7] · $C_7H_{20}N_2OSi_2$ · *N,N´*-Bis(trimethylsilyl)urea · (MW 204.42)

(large-scale silylating reagent for alcohols and carboxylic acids;[1b] does not require acid or base catalysis and the urea byproduct is insoluble in CH_2Cl_2, which aids in the reaction workup)

Alternate Name: BSU.

Physical Data: mp 232 °C (dec).

Form Supplied in: white powder.

Handling, Storage, and Precautions: when using, wear protective clothing to prevent contact with eyes and skin. May cause irritation if inhaled, ingested, or comes in contact with skin. Toxicological properties have not been thoroughly investigated. Store in a cool dry place, under an inert atmosphere to prevent hydrolysis.

The use of a trimethylsilyl group as a protecting group in organic synthesis has become a widely used procedure, due to the fact that it may be easily removed under mild conditions.[1] The reagents which have been developed for its introduction are ***Chlorotrimethylsilane***,[2] ***Hexamethyldisiloxane***,[3,4] ketene methyl trialkylsilyl acetals,[5] ***Triethylsilyl Perchlorate***,[6] and allylsilanes.[7] However, problems exist with the above procedures, which include the necessity for acid[3,4,7] or base[2,6] catalysis, the silylating agent is not readily accessible,[5] or a gas is produced during the reaction which may cause problems when working on a large scale.[7]

As a silylating agent, *N,N´*-bis(trimethylsilyl)urea has primarily been used in industry for large-scale production of pharmaceuticals such as prostaglandins and semisynthetic penicillins and cephalosporins.[1b] Not until recently has this reagent been utilized in the laboratory as a silylating agent for smaller-scale organic transformations. Researchers have found that *N,N´*-bis(trimethylsilyl)urea can be generally used for the *O*-silylation of alcohols and carboxylic acids.[8]

The use of *N,N´*-bis(trimethylsilyl)urea as a silylating agent has many advantages over other reagents which perform the same purpose. The reaction conditions that are employed are very mild (0-40 °C, CH_2Cl_2). The urea byproduct formed is neutral and also precipitates out of solution, lending to easy reaction workups, and the reactions generally

proceed in excellent yields (>85%). The generality of this reagent is demonstrated in the following transformations of primary, secondary, and tertiary alcohols and carboxylic acids (eqs 1-4). This transformation is not limited to just alkanols, as aryl alcohols can also be transformed to their TMS ethers easily in high yields.

As a silylating agent *N,N´*-bis(trimethylsilyl)urea has been employed in the derivatization of carboxylic acids in peptide synthesis due to the solubility properties of the silylating agent and the urea byproduct.[9]

N,N´-Bis(trimethylsilyl)urea has also been employed in the silylation of primary amines, which are generated in situ and will readily add to arylethylene oxides to give β-hydroxyamines in good to excellent yields (eq 5).[10]

Related Reagents.

Bis(trimethylstannyl) Benzopinacolate

[39157-60-3] · $C_{32}H_{38}O_2Sn_2$ · Bis(trimethylstannyl) Benzopinacolate · (MW 692.03)

(reagent for radical mediated formation of C-C and Sn-X (X = C, O, N, etc.) bonds)

Alternate Name: TINPIN.

Physical Data: mp 122-124 °C.

Solubility: slightly sol petroleum ether; sol benzene, CH_2Cl_2.

Form Supplied in: not commercially available.

Preparative Method: prepared as a colorless solid by photolysis of a mixture of ***Hexamethyldistannane*** and benzophenone.[1]

Handling, Storage, and Precautions: avoid exposure of the reagent to light and heat; store protected from light in a refrigerator or freezer. Organotin compounds are highly toxic.

Preparation and Thermolysis.

Bis(trimethylstannyl) benzopinacolate (TINPIN) is prepared in the form of colorless crystals by photolysis of a mixture of benzophenone and $Me_3SnSnMe_3$ in benzene.[1] On thermolysis, TINPIN undergoes homolytic C-C cleavage, resulting in the formation of a (trimethylstannyloxy)diphenylmethyl radical, which can undergo further cleavage to give benzophenone and a trimethylstannyl radical (eq 1).

Radical C-C Bond Formation.

Under typical radical conditions, employing ***Tri-n-butylstannane*** and ***Azobisisobutyronitrile*** or $Me_3SnSnMe_3$, the intermolecular addition of alkyl radicals to *O*-benzylformaldoxime is inefficient. Hart and Seely overcame this problem by employing TINPIN in place of these conventional tin reagents (eq 2), a particularly interesting example being the synthesis of a *C*-glycosidic product starting with a glucosyl bromide (eq 3).[2]

(2)

(3)

An interesting extension of this work, employing a functionalized oxime derivative, allowed the synthesis of a novel dinucleoside (eq 4).[3]

(4)

The report of Hart and Seely also mentions that TINPIN is a highly effective replacement for Bu_3SnH for the intermolecular radical addition of cyclohexyl iodide to ethyl acrylate (eq 5). The reaction is remarkable in that high yields of the desired adduct are obtained without the use of a large excess of acrylate radical acceptor. It is thought that this may be a radical nonchain process, involving trapping of the initial adduct radical by a (trimethylstannyloxy)diphenylmethyl radical, followed by a thermal retroaldol process to give the observed product (eq 6).[4]

(5)

product (6)

The TINPIN reagent has also been employed in an intramolecular [3 + 2] radical-mediated addition reaction, enabling the synthesis of the cyclopenta[*b*]benzofuran ring system of the natural product rocaglamide (eq 7).[5] This stereoselective transformation involves initial attack of a trimethylstannyl radical on the thioamide group, followed by cyclopropane opening, double intramolecular radical cyclization, and final expulsion of the tin radical.

(7)

Formation of Tin-Heteroatom Bonds.

TINPIN is a highly effective reagent for the formation of stannylated derivatives from a range of heteroatom containing systems, including benzoquinone and NBS (eqs 8 and 9).[1,6]

(8)

(9)

Examples of other systems which are effectively bis-stannylated include benzil and azobenzene.

2,3-Bis(trimethylstannyl)-1,3-butadiene

[19312-27-5] · $C_{10}H_{22}Sn_2$ · 2,3-Bis(trimethylstannyl)-1,3-butadiene · (MW 379.66)

(synthon for the 2,3-dianion of 1,3-butadiene)

Physical Data: low-melting solid, bp 65-66 °C/0.8 mmHg (distillation); stable indefinitely at -20 °C under nitrogen

Preparative Methods: [1] treatment of either 2,3-dichloro-1,3-butadiene or commercially available ***1,4-Dichloro-2-butyne*** with 2 equiv ***Trimethylstannyllithium*** in THF affords 1,4-bis(trimethylstannyl)-2-butyne as the kinetic product. This alkyne can be isomerized to 2,3-bis(trimethylstannyl)-1,3-butadiene by a catalytic amount of either ***Methyllithium*** or trimethylstannyllithium and 2 equiv of HMPA in THF (eq 1). Therefore either dihalide can serve as precursor to either stannane. A one-pot synthesis can be accomplished in 70% yield. It may be advantageous to prepare the trimethylstannyllithium reagent with lithium wire containing 1% sodium.[2]

Handling, Storage, and Precautions: organotin compounds should be considered toxic and should be handled with appropriate care.

Lithium Reagents.

The divergence of kinetic and thermodynamic control among lithium reagents derived from Sn/Li transmetalation of 2,3-bis(trimethylstannyl)-1,3-butadiene can have profound synthetic implications (eqs 2 and 3). The monolithiated butadiene is less stable than the isomeric lithiated allene; their common dilithio species appears to be propargylic. Thus 2-lithio-3-(trimethylstannyl)-1,3-butadiene can furnish diene products, alkyne products, or mixtures depending on whether the lithium reagent is handled under strictly kinetic conditions or is allowed to equilibrate.

Monosubstitution Reactions.

A solution of 2-lithio-3-(trimethylstannyl)-1,3-butadiene is prepared at -78 °C in THF and then transferred by cannula (jacketed, -78 °C) to a solution of electrophile in THF, ether, or pentane at -78 °C. In this manner, silicon halides, positive halogen sources, sulfenylating reagents, primary alkyl halides, some secondary alkyl halides, elemental selenium, and carbon dioxide afford good yields of monosubstitution products.

When the 2-lithio-3(trimethylstannyl)-1,3-butadiene reacts with simple carbonyl electrophiles (eq 4; M = Li), diene products predominate with varying amounts of contamination by allenic substitution. If the lithiobutadiene is first transformed to the Grignard reagent by exchange with ***Magnesium Bromide*** (eq 4; M = MgBr), allenes are obtained.

M = Li	R = Me	69%	18%
M = MgBr	R = Me		82%
M = Li	R = CH_2CH_2Ph	52%	
M = MgBr	R = CH_2CH_2Ph	14%	80%

The most effective organocopper species for conjugate addition reactions is derived from 2-lithio-3-(trimethylstannyl)-1,3-butadiene using ***Copper(I) Iodide-Tributylphosphine***. The reaction yield of 64% is based on chalcone (eq 5). No allenic products are formed, but the Gilman reagent requires 2 equiv lithiobutadiene.

Disubstitution Reactions.

Since Sn/Li transmetalation of the stannylated butadienes is faster than the reaction of many electrophiles with methyllithium, some double derivatizations can be carried out in situ by simply adding 2-3 equiv of MeLi to a solution of 2,3-bis(trimethylstannyl)-1,3-butadiene and 2 equiv of electrophile in THF at -78 °C. Silicon halides, elemental selenium, and primary iodides are appropriate electrophiles for such reactions. Sequential disubstitution reactions may be carried out providing the first substituent is stable to methyllithium in THF.

Diels-Alder Reactivity.

Compared to the parent butadiene (k_{rel} = 1), 2,3-bis(trimethylstannyl)-1,3-butadiene is a poor Diels-Alder diene (k_{rel} = 0.05).

Bis[trinitratocerium(IV)] Chromate[1]

$[Ce(NO_3)_3]_2CrO_4$

[93250-25-0] · $Ce_2CrN_6O_{22}$ · Bis[trinitratocerium(IV)] Chromate · (MW 768.26)

(mild oxidizing reagent capable of oxidizing several functional groups;[2,3] releases alcohols from allyl and propargyl silyl ethers[4] and carbonyl compounds from acetals[4])

Alternate Name: BTNCC.

Solubility: sol DMSO, DMF; moderately sol H_2O; sparingly sol EtOH, MeCN; insol PhH.

Form Supplied in: yellow-orange solid.

Preparative Method: to a solution of ***Potassium Dichromate*** (0.02 mol) in H_2O (100 mL), ***Cerium(IV) Ammonium Nitrate*** (0.02 mol) in H_2O (50 mL) is added, and the mixture diluted with H_2O (150 mL). The resulting precipitates are filtered, triturated with acetone, separated, and dried in air (70%).

Handling, Storage, and Precautions: stable at elevated temperatures (>200 °C) and to storage at rt for months. Chromate is a cancer suspect agent. Work with this reagent should be conducted in a fume hood.

Introduction.

Reactions with this reagent (BTNCC) proceed in dry benzene and residual oxidant can be separated by simple filtration. Drawbacks of other Ce^{IV} oxidations,[1,5] such as cleavage reactions, strong acidic conditions, and the necessity of employing polar solvents or cosolvents, are not encountered with this reagent.

Oxidations.

Hydroquinones, α-hydroxy ketones, and primary and secondary saturated and benzylic alcohols are converted to their quinones, α-diketones, and carbonyl compounds, respectively, in high yields (eqs 1-3).[2,4] Allyl, propargyl, and deactivated benzyl alcohols remain intact.

(1)

(2)

(3)

Benzyl silyl ethers are quantitatively converted to aldehydes (eq 4).[4]

(4)

Smooth oxidation of thiols to disulfides (eq 5) in high yield[3] occurs with this mild reagent.

(5)

Deprotection Reactions.

This reagent releases alcohols from propargyl and allyl silyl ethers without further oxidation (eq 6).[4] Saturated silyl ethers remain intact.

(6)

Deprotection of acetals proceeds well to produce carbonyl compounds (eq 7).

(7)

A brief comparison between this reagent, ***Cerium(IV) Ammonium Nitrate*** (CAN),[5,6] and ***Pyridinium Chlorochromate*** (PCC)[3,7] is shown in Table 1.

Table 1 Comparison of Cerium Reagents

Bis(triphenylphosphine)[1,2-bis(diphenylphosphino)ethane]palladium(0)

$(Ph_3P)_2Pd(Ph_2PCH_2CH_2PPh_2)$

[74790-18-4] · $C_{62}H_{54}P_4Pd$ · Bis(triphenylphosphine)[1,2-bis(diphenylphosphino)ethane]palladium(0) · (MW 1029.42)

(useful for trimethylenemethane cycloadditions;[1,2] sulfonylation or amination with epoxy nitro compounds;[3] allylic alkylation and amination of nitro compounds;[4,5] rearrangement of 2,3-epoxy ketones to β-diketones;[6,7] alkylation of enol stannanes;[8] opening of vinyloxetanes;[9] and macrocyclizations[10,11])

Solubility: sol THF, toluene, DMF, and MeCN.

Form Supplied in: generated in situ.

Preparative Method: in situ by the addition of slightly more than 1 equiv of ***1,2-Bis(diphenylphosphino)ethane*** (dppe) to 1 equiv of ***Tetrakis(triphenylphosphine)palladium(0)***.

Handling, Storage, and Precautions: as with most palladium(0) catalysts, this reagent should be used under an inert atmosphere and should not be allowed to sit for long periods of time in solution prior to use.

Trimethylenemethane Cycloadditions.

Trimethylenemethane (TMM) cycloaddition is an important tool in the synthesis of five-membered carbocycles.[1] The use of bis(triphenylphosphine)[1,2-bis(diphenylphosphino)ethane]palladium(0) (**1**; 3-9 mol %) with (2-acetoxymethylallyl)trimethylsilane (**2**) generates the TMM-Pd complex which, in turn, undergoes a [3 + 2] cycloaddition specifically with alkenes bearing an ester, lactone, nitrile, ketone, or sulfone moiety (eq 1). *Trans*-alkenes provide mainly the *trans* stereoisomer (95:5, *t:c*) while *cis*-alkenes isomerize to give a mixture of *cis* and *trans* products. The presence of 0.5-1 equiv of dppe in relation to palladium prolongs the lifetime of the catalyst and prevents the deposition of palladium black. An alternative catalytic system, which employs palladium(II), does not produce a significant difference in yields. However, the use of catalytic palladium(II) has two advantages: (1) the nature of the ligands of palladium(II) can easily be altered and (2) palladium(II) is not air-sensitive.

(1)

E = CO_2Me **(2)** *trans*:*cis* = 95:5

Trost extends his TMM methodology to include intramolecular [3 + 2] cycloadditions (eq 2).[2] With the use of catalyst (**1**), bicyclic compounds are effectively prepared in one step from acyclic substrates. Concomitant formation of five-membered rings yields only the *cis*-fused bicyclo[3.3.0]octanes (*n* = 1). Moderate yields are obtained for the formation of a six-membered ring (*n* = 2), and the ratio of *cis* to *trans* fused ring systems is 2:1. For the intramolecular reaction with TMM, ***Bis[1,2-bis(diphenylphosphino)ethane]palladium(0)*** is an efficient catalyst. The use of $(dppe)_2Pd$ and added dppe, or the use of ***Tetrakis(triphenylphosphine)palladium(0)*** with additional triphenylphosphine, produces the cyclized substrate in significantly lower yields. Catalytic ***Palladium(II) Acetate*** (5 mol %) with ***Triisopropyl Phosphite*** in the presence of ***N,O-Bis(trimethylsilyl)acetamide*** gives superior yields over catalyst (**1**) for the substrate in which *n* = 2, $R^1 = CO_2Me$ and $R^2 = SO_2Ph$.

(2)

BSA = *N,O*-bis(trimethylsilyl)acetamide

$n = 1$, $R^1 = Ac$, $R^2 = CO_2Me$	51%
$n = 2$, $R^1 = Ac$, $R^2 = SO_2Ph$	43-70%, *cis*:*trans* = 2:1
$n = 2$, $R^1 = CO_2Me$, $R^2 = SO_2Ph$	73%, *cis*:*trans* = 1.5:1

Epoxide Opening with Nucleophilic Substitution.

In the presence of (**1**), which is generated in situ, β-alkyl-β,γ-epoxynitro compounds undergo epoxide opening, and subsequent displacement of the nitro group by various nucleophiles results (eq 3).[3] Nucleophiles that efficiently displace the nitro group are ***Sodium Benzenesulfinate*** and ***Piperidine***. Nucleophilic attack on the π-allyl intermediate is regiospecific for five-membered ring substrates, but only marginal regioselectivity is observed for the reaction of the six-membered ring substrates (eq 3). The absence of dppe results in a slight decrease in the yield of the desired product by 5-10%.

(3)

$n = 1$, Nuc = $PhSO_2^- Na^+$	60%	100:0
	83%	100:0
$n = 2$, Nuc = $PhSO_2^- Na^+$	47%	55:45
	56%	64:36

Allylic Alkylation/Amination and Denitration of Nitro Compounds.

In a closely related study, complex (**1**) catalyzes substitutions of allylic nitro compounds with secondary amines and stabilized carbanions such as malonic and β-keto esters.[4] For cyclic allylic nitro compounds, the use of triphenylphosphine provides higher yields than when dppe is used as the co-ligand. Generally, five-membered ring substrates produce a single regioisomer in moderate yields, while the six-membered substrate gives a mixture of two regioisomers (eq 4). In the palladium-catalyzed allylic alkylation and amination of primary nitro compounds, mixtures of regioisomers and diastereomers are produced unless a sterically hindered alkene is used (eq 5). In this reaction, preferential bond formation occurs at the primary allylic carbon.

Compound (**1**) is also used for the catalysis of the denitroamination of α-nitroalkenes (eq 6).[4,5] Normally, α-nitroalkenes are excellent Michael acceptors. However, in the presence of (**1**) and a secondary amine, allylic amination occurs accompanied by denitration. In acyclic substrates the regiospecific nucleophilic attack occurs at the less hindered carbon, and β-hydride elimination yields only the (*E*) isomer. This same type of reaction proceeds with ***Sodium Benzenesulfinate*** as the nucleophile and ***Triethylamine*** as the base. Again, only the (*E*) isomer is produced as a result of nucleophilic attack at the least hindered site. The dppe ligand is thought to have two functions in the denitrosulfonylation. Dppe is believed not only to serve as an additional ligand for palladium, but also to function as a base in the isomerization of the α-nitroalkenes to the active allylic species.

Rearrangements.

The rearrangement of 2,3-epoxy ketones to β-diketones is also facilitated by (**1**) (eq 7).[6] Treatment of 2,3-epoxy ketones with catalytic ***Tetrakis(triphenylphosphine)palladium(0)*** and dppe in equimolar amounts produces β-

diketones in moderate to excellent yields. This methodology presents a fairly mild procedure for the preparation of β-diketones under neutral and aprotic conditions as opposed to the strongly basic conditions of the Claisen condensation. The addition of dppe significantly improves the yields of β-diketone products, and the use of dppe is necessary to obtain a reasonable reaction rate and to avoid metal precipitation, which deactivates the catalyst. In a similar manner, diethyl (2,3-epoxy-4-oxoalkyl)phosphonates rearrange to give diethyl (2,4-dioxoalkyl)phosphonates promoted by the (dppe)Pd(PPh_3)$_2$ catalyst system (eq 8).[7]

(7)

(8)

Alkylations.

Polyalkylation of enolates presents a problem for synthetic chemists. One procedure that promotes monoalkylation with high regioselectivity uses (**1**) to catalyze the coupling of enol stannanes with allyl acetates (eq 9).[8] Enol stannanes are alkylated with bifunctional silicon conjunctive reagents. Generally, the regioselectivity for alkylation with compound (**3**) favors alkylation α to the silicon. 3-Acetoxy-1-(trimethylsilyl)-1-propene can be used as an alternative to compound (**3**).

(9)

Oxetane Opening with Allylic Alkylation.

Vinyloxetanes are alkylated through nucleophilic opening of the oxetane to yield homoallylic alcohols (eq 10).[9] Although the formation of disubstituted alkenes can be accomplished simply with $Pd(PPh_3)_4$, synthesis of trisubstituted alkenes requires the use of compound (**1**). Various nucleophiles can take part in this general reaction, yet only stabilized enolates (β-diketones, malonates, and β-cyano esters) produce successful formation of trisubstituted alkenes.

(10)

Macrocyclization.

Macrocyclization is accomplished by generating the π-allylpalladium species from the allylic pivalate with compound (**1**) (eq 11).[10] Intramolecular phenylsulfonylacetate attack of the π-allylpalladium species at the least hindered carbon generates the macrocyclic product used as an intermediate in the synthesis of isolobophytolide. A key step in the synthesis of antibiotic A26771B also employs this macrocyclization methodology (eq 12).[11] In this cyclization the intermediate π-allyl palladium species is generated from an acetate which is allylic to an enol ether. This methodology offers an alternative route to macrolactone formation. The conditions of this cyclization are tolerated by enol ethers, sulfones, esters, alkenes and hydroxy groups.

Bis(triphenylphosphine)copper(I) Borohydride[1]

$(Ph_3P)_2CuBH_4$

[16903-61-0] · $C_{36}H_{34}BCuP_2$ · Bis(triphenylphosphine)copper(I) Borohydride · (MW 602.97)

(selectively reduces acid chlorides to aldehydes,[2,4] tosyl- and trisylhydrazones to alkanes,[5] aldehydes and ketones to alcohols,[6] and aromatic azides to anilines[7])

Alternate Name: (tetrahydroborato)bis(triphenylphosphine)copper.

Physical Data: mp 172-174 °C (dec) (from $CHCl_3$/ether);[2] 177 °C (dec) (from $CHCl_3$/ethanol);[3] recrystallizing from benzene/ethanol gives a stable 1:1 complex with benzene, mp 187 °C (dec),[3] as white needles.

Solubility: sol THF, $CHCl_3$, CH_2Cl_2, benzene; slightly sol acetone; insol ether, ethanol, and water.

Form Supplied in: commercially available as a white solid, or is easily prepared.

Preparative Method: by adding ***Copper(I) Chloride*** to a stirring solution of 2 equiv of ***Triphenylphosphine*** in chloroform. Once the copper chloride is dissolved the mixture is treated with a suspension of ***Sodium Borohydride*** (1 equiv) in ethanol for at least 15 min to ensure complete reaction. The solution is washed with water and dried over anhydrous magnesium sulfate. Diethyl ether is added to precipitate the reagent as fine white needles (90% yield).[2]

Purification: can be recrystallized from $CHCl_3$/ether or $CHCl_3$/ethanol mixtures.

Handling, Storage, and Precautions: stable to air and water. It should be handled in a well-ventilated hood; contact with the eyes and skin should be avoided.

Reductions of Acid Chlorides to Aldehydes.

Bis(triphenylphosphine)copper(I) borohydride selectively reduces many acid chlorides to aldehydes (eq 1) in good yields (Table 1).[2,4a] Acetone is the best solvent for these reductions, and addition of 2 equiv of triphenylphosphine to the reaction mixture increases yields. It is thought that 1 equiv binds to the bis(triphenylphosphine)copper(I) chloride byproduct and the second equiv traps the BH_3 given off in the reaction.[4a] Formation of an acylphosphonium salt as an intermediate in the reduction has also been postulated.[4c]

(1)

Table 1 Reduction of Acid Chlorides to Aldehydes with Bis(triphenylphosphine)copper(I) Borohydride (eq 1)

Acid chloride	Aldehyde	Yield (%)
Benzoyl	Benzaldehyde	78 83
Cinnamoyl	Cinnamaldehyde	77 78
4-Nitrobenzoyl	4-Nitrobenzaldehyde	57
Pivaloyl	Pivaldehyde	60
4-Chlorobenzoyl	4-Chlorobenzaldehyde	80
Decanoyl	Decanal	79
Cyclohexanecarbonyl	Cyclohexanecarbaldehyde	72
a-Acetoxypropionyl	a-Acetoxypropionaldehyde	23
Crotonyl	Crotonaldehyde	33

Reduction of *p*-Toluenesulfonylhydrazones (Tosylhydrazones) and 2,4,6-Triisopropylbenzenesulfonylhydrazones (Trisylhydrazones) to Alkanes.

The reduction of aldehydes and ketones to the corresponding alkanes can be achieved via the *p*-toluenesulfonylhydrazone derivative using the title reagent.[5] Tosylhydrazones of ketones (eq 2) are reduced consistently in good yield and tosylhydrazones of aldehydes are reduced in slightly lower yields (Table 2).[5a] The *p*-toluenesulfonylhydrazones derived from aromatic and α,β-unsaturated aldehydes and ketones cannot be reduced by this method. Sterically hindered hydrazones such as camphor tosylhydrazone are also reduced only with difficulty and in low yields.

(2)

Table 2 The Reduction of Tosylhydrazones Using Bis(triphenylphosphine)copper(I) Borohydride (eq 2)

Tosylhydrazone of	Product	Yield (%)[a]
Cholestanone	Cholestane	70
Adamantanone	Adamantane	84
4-*t*-Butylcyclohexanone	4-*t*-Butylcyclohexane	74
Palmitaldehyde	Hexadecane	48
Nonanal	Nonane	56
4-Nitrobenzaldehyde	4-Nitrotoluene	0
Cinnamaldehyde	Allylbenzene	0
Camphor	Camphane	0

[a] Yield determined by GLC analysis.

A typical procedure involves mixing an equimolar ratio of the hydrazone and bis(triphenylphosphine)copper(I) borohydride in refluxing chloroform; benzene, toluene, and acetone may also be used. The reaction is usually complete in 2 h. Excess triphenylphosphine does not improve yields, as is the case for the reduction of acid chlorides to aldehydes. The reductions of 2,4,6-triisopropylbenzene (trisyl) hydrazones proceed in only moderate yields at rt. Increased temperature reduces the yields of trisylhydrazone reductions.

The reduction of a tosylhydrazone using this reagent has been performed in the synthesis of naturally occurring 12-tridecanolide (eq 3).[5b] The reduction of an aldehyde to the corresponding alkane via the tosylhydrazone, in the presence of other reducible and sensitive functional groups, has been demonstrated in the conversion of the 16-membered macrolide antibiotic tylosin to 20-dihydro-20-deoxytylosin (eq 4).[5c]

(3)

Reduction of Ketones and Aldehydes to Alcohols.

Strong acid-catalyzed reduction of aldehydes and ketones with the title reagent can be carried out with high chemo- and stereoselectivity.[6] While aldehydes were not reduced at room temperature in acetone under neutral conditions by using bis(triphenylphosphine)copper(I) borohydride, aromatic aldehydes such as 4-nitrobenzaldehyde containing strong electron-withdrawing groups were reduced quantitatively in chloroform or dichloromethane in the absence of a catalyst. In the presence of a strong acid catalyst, however, aldehydes and ketones are generally reduced (eq 5) in high yield to the corresponding alcohol (Table 3).[6]

Table 3 Representative Acid-Catalyzed Reductions of Aldehydes and Ketones with Bis(triphenylphosphine)copper(I) Borohydride (eq 5)

Carbonyl compound	Acid	Equivalents of $(Ph_3P)_2CuBH_4$	Product	Yield (%)
4-*t*-Butylcyclohexanone	HCl (g)	1	4-*t*-Butylcyclohexanol	91 (94% *trans*)
	0.3 $AlCl_3$	1		92 (92% *trans*)
3,3,5-Trimethylcyclohexanone	$AlCl_3$	1.5	3,3,5-Trimethylcyclohexanol	86 (72% *trans*)
Camphor	HCl (g)	1	Isoborneol	0
	$2AlCl_3$	2		73 (98% *exo*)
Nonanal	HCl (g)	1	Nonanol	94
4-Nitrobenzaldehyde	none	1	4-Nitrobenzylalcohol	98
Cinnamaldehyde	HCl (g)	1	Cinnamyl alcohol	99
Cyclohexenone	HCl (g)	1		0

Typical conditions necessary to effect the reduction of aldehydes and ketones is to bubble gaseous hydrogen chloride through a dichloromethane solution of the carbonyl compound and 1 equiv of bis(triphenylphosphine)copper(I) borohydride at room temperature for 10 min. Sterically hindered ketones are not reduced under these conditions. A strong Lewis acid such as ***Aluminum Chloride***, however, will catalyze the high yield reduction of hindered ketones such as camphor and 3,3,5-trimethylcyclohexanone. The steric size of the reductant contributes to its good stereoselectivity in the reduction of ketones. α,β-Unsaturated aldehydes are easily reduced under these conditions to the primary allylic alcohol, but α,β-unsaturated ketones give complex mixtures of products.

Reduction of Aromatic Azides to Anilines.

Bis(triphenylphosphine)copper(I) borohydride can be used as an alternative reagent to ***1,3-Propanedithiol*** for the selective reduction of aromatic azides to aromatic amines.[7] One equiv of the reducing agent in chloroform at rt reduces aromatic azides in good yields (eq 6). Aromatic rings substituted with electron-withdrawing groups are reduced in 30 min, while aromatic rings substituted with electron-donating groups are reduced more slowly (Table 4).[7] The rates of these reductions increase in refluxing chloroform or in the presence of an acid catalyst. Aliphatic azides are not affected under the conditions necessary to reduce the more activated aromatic azides.

$$ArN_3 \xrightarrow[CHCl_3,\ rt]{(Ph_3P)_2CuBH_4} ArNH_2 \qquad (6)$$

Table 4 The Reduction of Aromatic Azides to Aromatic Amines with Bis(triphenylphosphine)copper(I) Borohydride (eq 6)

Azide/amine	Reaction time (h)	Yield (%)
4-Nitrophenyl	0.5	95
2-Nitrophenyl	0.5	83
4-Methyl-3-nitrophenyl	3	74
4-(Phenylazo)phenyl	14	69
4-Ethoxycarbonylphenyl	18	85

Bis(triphenylphosphine)copper(I) Cyanoborohydride

$(Ph_3P)_2CuBH_3CN$

[51321-47-2] · $C_{37}H_{33}BCuNP_2$ · Bis(triphenylphosphine)copper(I) Cyanoborohydride · (MW 627.98)

(selective, mild reducing reagent for the conversion of acid chlorides to aldehydes under neutral conditions, and reduction of aldehydes and ketones to alcohols in acidic media)

Alternate Name: μ-bis(cyanotrihydroborato)tetrakis(triphenylphosphine)dicopper(I).

Physical Data: white, nonhydroscopic solid, mp 176-177 °C; exists as a dimer.[1]

Solubility: sol acetone, $CHCl_3$, and THF; insol water, ethanol, and ether.

Preparative Method: from treating ***Copper(II) Sulfate*** or ***Copper(I) Chloride*** sequentially with excess ***Triphenylphosphine*** and ***Sodium Cyanoborohydride*** in ethanol.[2] The reagent is synthesized in an analogous manner to those described for the preparation of the corresponding BH_4 derivative, ***Bis(triphenylphosphine)copper(I) Borohydride***, substituting $NaBH_3CN$ for $NaBH_4$.[3]

Functional Group Reductions.

Under neutral conditions this reagent selectively reduces alkyl and aryl acid chlorides to aldehydes without further conversion to alcohols (Table 1).[2]

Table 1 Reduction of Acid Chlorides to Aldehydes in Acetone

Acid chloride	Aldehyde (% yield)
PhCOCl	84
p-ClC_6H_4COCl	92
p-$NO_2C_6H_4COCl$	48
$Me(CH_2)_8COCl$	82
PhCH=CHCOCl	61

In acidic (pH 3) media, aldehydes and ketones (except diaryl) are reduced to alcohols (Table 2). Reduction of 4-*t*-butylcyclohexanone under these conditions provides the *trans* isomer with 94:6 selectivity (eq 1).[2] The stereoselectivity of this reduction is among the highest observed for hydride reagents.[4]

Table 2 Reduction of Aldehydes and Ketones to Alcohols in Acidic THF (pH 3)

Carbonyl compound	Alcohol (% yield)
o-ClC_6H_4CHO	77
m-$NO_2C_6H_4CHO$	83
$Me(CH_2)_8CHO$	84
$MeCO(CH_2)_5Me$	74
PhCOMe	68
Ph_2CO	32

The ease and convenience of conducting reactions coupled with the excellent chemoselectivity possible under neutral conditions recommend this reagent for conversion of acid chlorides to aldehydes. No other functional groups are known to be reduced at ambient temperature.

Bis(triphenylphosphine)nickel(0)[1]

$Ni(PPh_3)_2$

[33991-60-5] · $C_{36}H_{30}NiP_2$ · Bis(triphenylphosphine)nickel(0) · (MW 538.27)

(source of nickel(0) useful for the formation of carbonates from epoxides[2] and the coupling of alkenyl boranes with allylic epoxides[3])

Physical Data: mp 155-157 °C dec. (N_2).

Solubility: sol benzene, toluene, MeCN, THF.

Analysis of Reagent Purity: ^1H NMR: (C_6D_6) δ 7.67 (m), 7.13 (m); ^{31}P NMR: (C_6D_6) δ -22 ppm from $(MeO)_3PO$.

Preparative Methods: by the ***Sodium Amalgam*** reduction of ***Dibromobis(triphenylphosphine)nickel(II)***.[4] In the standard preparation, 22.3 g of $Ni(PPh_3)_2Br_2$ were added to a mixture of sodium amalgam (1.73 g Na, 0.075 g-atom in 300 mL Hg) and 500 mL acetonitrile. After removal of Hg and solvent, the precipitate was dissolved in benzene to remove the insoluble Hg occluded NaBr. Concentration of the dark brown benzene solution in vacuo gave 13-15 g of red-brown $Ni(PPh_3)_2$ (74-84%) which could be used without further purification. Optional recrystallization from benzene (or toluene)/hexane is possible but significant loss of the product occurs due to high solubility. Sodium amalgam reductions of similar systems have been problematic and ***n-Butyllithium*** was found to be a superior reducing agent.[5]

Handling, Storage, and Precautions: highly oxygen sensitive. Special inert-atmosphere techniques must be used.[6] Should be stored at 0 °C.

Reactions of Epoxides.

Bis(triphenylphosphine)nickel(0), $Ni(PPh_3)_2$, can react with epoxides by oxidative addition of Ni^0 into the strained C-O bond. Insertion of CO_2 into these organonickel complexes leads to alkenyl carbonates. Thus reaction of 1-chloro-2,3-epoxypropane (**1**) with $Ni(PPh_3)_2$ in the presence of CO_2 catalytically produced chloromethylene carbonate (**2**) in good yield (eq 1).[2]

(1)

Alkenylboranes also react with these organonickel complexes to give alcohols in overall catalytic coupling reactions. When the hexenylborane (**3**) was reacted with 3,4-epoxy-1-butene (**4**) and the catalyst, a mixture of the two coupling products (**5**) and (**6**) was produced in 85% yield (eq 2).[3] The regioselectivity of the reaction was found to depend upon the nature of the catalyst used. When metal complexes such as ***Bis(dibenzylideneacetone)palladium(0)***, ***Tetrakis(triphenylphosphine)palladium(0)***, or $Ni(PPh_3)_n$ were used the predominant product was (**5**), whereas when ***Palladium(II) Chloride*** or ***Nickel(II) Acetylacetonate*** were used the formation of (**6**) was favored. Overall, the palladium complexes proved to be superior catalysts for this transformation. The best yield (92%) was obtained using $Pd(dba)_2$.

Other Uses.

Allene has been cyclooligomerized in the presence of a catalytic amount of $Ni(PPh_3)_2$ into a mixture of isomers with a cyclic pentamer being the major product.[4] The linear dimerization of ethylene and propene also takes place when this nickel complex along with ***Diethylaluminum Chloride*** is used as the catalytic system.[7]

Related Reagents.

Bis(triphenylphosphine)palladium(II) Acetate

$Pd(PPh_3)_2(OAc)_2$

[14588-08-0] · $C_{40}H_{36}O_4P_2Pd$ · Bis(triphenylphosphine)palladium(II) Acetate · (MW 749.09)

(catalyst for various reactions, for example coupling reactions, dimerizations, cyclizations, carbonylations, and reductions)

Physical Data: lemon-yellow amorphous crystals; mp 136 °C (dec.).

Solubility: sol acetonitrile, benzene, dioxane, DMF, DMSO, THF; low sol petroleum ether.

Form Supplied in: commercially available solid.

Handling, Storage, and Precautions: store under argon at -18 °C; air and moisture sensitive; hygroscopic.

General Considerations.

This reagent has mainly been used in coupling reactions and cyclizations, but also for reductions, and carbonylations. Although commercially available, the catalyst is easily prepared by mixing ***Palladium(II) Acetate*** with an excess of ***Triphenylphosphine*** in benzene.[1] There is also evidence that mixing $Pd(OAc)_2$ with 2 equiv of PPh_3 generates a species with the same properties as $Pd(OAc)_2(PPh_3)_2$ (**1**). In most catalytic reactions, complex (**1**) generates Pd^0 in situ, which is the active catalyst.[2] Reagents able to do similar reactions as (**1**) are described in the following text.

Coupling and Dimerization Reactions.

Catalyst (**1**) has been used to couple and dimerize many types of substrates. For example, isoprene in the presence of (**1**), ***Formic Acid***, ***Triethylamine*** and an alcohol dimerizes to generate predominantly 1,6-diene (**2**) and 1,7-diene (**3**) (eq 1). The formic acid serves as a hydrogen donor. These two isomers were used to prepare the terpenes α,β-citronellol and linalool.[3] Under similar reaction conditions, alkynes react with iodobenzene to give alkenes.[4]

(1)

Although the most commonly used catalyst for Heck arylation and vinylation reactions[5] is $Pd(OAc)_2$, there are several examples where (**1**) has been used. For example, 2-bromopropene reacts with styrene (eq 2)[6a] or phenylacetylene (eq 3)[6b] to yield dienes or enynes, respectively.

(2)

(3)

Reagent (**1**) catalyzes the coupling between fluorinated vinyl iodides and 1-alkynes to give excellent yields of fluorinated enynes.[7] The use of Dichlorobis(triphenyl-phosphine)palladium(II) (**4**) and ***Tetrakis(triphenylphosphine)palladium(0)*** as catalysts give similar results. Various substituted aryl bromides react with trimethylsilylacetylene in the presence of (**1**) to give terminal alkynes (eq 4).[8] In some cases, (**4**) has been used in place of (**1**). The corresponding aryl propargyl alcohols (which are easily converted to terminal alkenes) are made by ***Tetraethyl Pyrophosphate*** catalyzed cross-coupling of aryl halides with propargyl alcohol.[9]

(4)

R = a variety of substituents

The coupling of aryl iodides with α,β-unsaturated ketones[10a,b] and aldehydes[10c] (eq 5) is catalyzed by (**1**). This reagent nicely catalyzes the coupling of vinyl and aryl triflates with various terminal alkynes in the presence of a base (eq 6).[11,12] Addition of *n*-Bu_4NCl increases the yield.

Cyclizations.

Complex (**1**) catalyzes the cyclization of 1,6-enynes to five-membered rings. Either 1,3- or 1,4-dienes are formed depending on the substituents (eqs 7 and 8).[13] When ***Diacetatobis(tri-o-tolylphosphine)palladium(II)*** is used the yield increases.

(8)

These cyclizations can be performed with full stereocontrol.[14] Functionalized butenolides are obtained with high stereo- and regioselectivity in a one-pot hydroarylation cyclization when α,β-alkynic esters are reacted in the presence of formic acid, ***Tri-n-butylamine***, and catalyst (**1**).[15]

Reductions.

Vinyl and aryl triflates are reduced in high yields with catalytic amounts of (**1**).[16] The reaction shown in eq 9 is used in a route to angelicin.[17]

(9)

Carbonylations.

If ***Carbon Monoxide*** is present in place of formic acid, an insertion of a CO unit into the metal-carbon bond in the intermediate occurs to produce the corresponding acid. Vinyl alcohols and phenols, after conversion to triflates, undergo one-carbon homologation to the corresponding α,β-unsaturated and aromatic acids.[18] Vinyl triflates work best with the title catalyst, but with aryl triflates, better results are obtained with ***Palladium(II) Acetate*** and ***1,1´-Bis(diphenylphosphino)ferrocene*** (dppf) as an added ligand. Oxalic acid esters can be made from alcohols under 20-50 atm of CO employing (**1**) in stochiometric amounts (**4** gave no reaction).[19] The use of ***1,4-Benzoquinone*** as a reoxidant makes it possible to use (**1**) in catalytic amounts. For example, treatment of methanol with 1 mol % of (**1**) and carbon monoxide at a pressure of 1000 psi and 65 °C gives the methyl ester of oxalic acid in high yield.[20]

(*R*)-3,3´-Bis(triphenylsilyl)binaphthomethylaluminum

[118724-91-7] · $C_{57}H_{43}AlO_2Si_2$ · (*R*)-3,3´-Bis(triphenylsilyl)binaphthomethylaluminum · (MW 843.16)

(chiral Lewis acid for asymmetric hetero-Diels-Alder,[2,3] Diels-Alder,[6] and ene reactions,[7] Claisen rearrangement,[8,9] and polymerization[10])

Solubility: sol toluene and CH_2Cl_2; slightly sol hexane.

Form Supplied in: prepared and used in situ.

Preparative Methods: can be prepared by treatment of (*R*)-3,3´-bis(triphenylsilyl)binaphthol[1] in CH_2Cl_2 or toluene with a 1 M hexane solution of ***Trimethylaluminum*** room temperature for 1-2 h.[2] This reagent can be also generated in situ by discrimination of its racemates with optically active (-)-bromocamphor.[3]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Asymmetric Hetero-Diels-Alder Reaction.

This chiral organoaluminum reagent has been developed for effecting the hetero-Diels-Alder reaction of aldehydes and siloxydienes with high enantioselectivity.[2,4] Thus reaction of benzaldehyde with 1-methoxy-2-methyl-3-trimethylsiloxy-1,3-pentadiene under the influence of 10 mol % of the chiral aluminum reagent affords *cis*-dihydropyrone as a major product in 95% ee (eq 1). The enantioselectivity is highly dependent on the bulk of the triarylsilyl moiety of the aluminum reagent. Thus replacement of the triphenylsilyl group by the tris(3,5-xylyl)silyl

group enhances the enantio as well as *cis* selectivity, but replacement by trimethylsilyl groups lowers the enantioselectivity. This chiral aluminum reagent is generated in situ by discrimination of racemic organoaluminum reagents with (-)-bromocamphor by diastereoselective complexation, and utilized as a chiral Lewis acid for the asymmetric hetero-Diels-Alder reaction.[3]

Asymmetric Diels-Alder Reaction.

Although the asymmetric Diels-Alder reaction of cyclopentadiene with methacrolein is quite disappointing (17-23% ee) with the chiral aluminum reagent,[5] the use of α,β-unsaturated esters as dienophiles gives good enantioselectivity (eq 2).[6]

Asymmetric Ene Reaction.

The enantioselective activation of carbonyl groups with the chiral aluminum reagent also enabled the asymmetric ene reaction of electron-deficient aldehydes with various alkenes (eq 3).[7] In the presence of powdered 4 &AAring; molecular sieves, the chiral aluminum reagent can be utilized as a catalyst without loss of enantioselectivity.

(R)-3,3´-Bis(triphenylsilyl)binaphthomethylaluminum

Asymmetric Claisen Rearrangement.

The enantioselective activation of an ether oxygen with the chiral organoaluminum reagent allows for the first example of the asymmetric Claisen rearrangement of allylic vinyl ethers.[8] This method provides a facile asymmetric synthesis of various acylsilanes and acylgermanes from allylic α-(trimethylsilyl)vinyl ethers and allylic α-(trimethylgermyl)vinyl ethers, respectively (eq 4). Among various trialkylsilyl substituents of the chiral aluminum reagent, use of the bulkier *t*-butyldiphenylsilyl group results in the highest enantioselectivity.

Notably, the asymmetric Claisen rearrangement of *cis*-allylic α-(trimethylsilyl)vinyl ethers with the chiral aluminum reagent produced optically active acylsilanes with the same absolute configuration as those from *trans*-allylic α-(trimethylsilyl)vinyl ethers (eq 5).[9]

Asymmetric Polymerization.

(R)-3,3´-Bis(triphenylsilyl)binaphthomethylaluminum

The chiral organoaluminum catalyst is utilized for asymmetric polymerization of racemic α-methyl and β-methyl β-lactones.[10] Optically active polymers possessing negative optical rotation values are produced, suggesting that (*S*) enantiomers of racemic β-lactones are preferentially activated by the aluminum catalyst.

9-Borabicyclo[3.3.1]nonane Dimer[1]

[70658-61-6] · $C_{16}H_{30}B_2$ · 9-Borabicyclo[3.3.1]nonane · (MW 244.03)

(highly selective, stable hydroborating agent;[1,3] anti-Markovnikov hydration of alkenes and alkynes;[1d] effective ligation for alkyl-, aryl-, allyl-, allenyl-, alkenyl- and alkynylboranes;[1a,4,5] forms stable dialkylboryl derivatives, borinate esters, and haloboranes;[1f] organoboranes from hydroboration and organometallic reagents;[1,5] precursor to boracycles;[1,11] can selectively reduce conjugated enones to allylic alcohols;[1a,30] organoborane derivatives for α-alkylation and arylation of α-halo ketones, nitriles, and esters;[1b] vinylation and alkynylation of carbonyl compounds;[1a,46] conjugate addition to enones;[1a,47] homologation; asymmetric reduction;[1,8] Diels-Alder reactions;[1a,18,50] enolboranes for crossed aldol condensations;[1a,20,52] Suzuki-Miyaura coupling[1a,54-57])

Alternate Name: 9-BBN-H.

Physical Data: mp 153-155 °C (sealed capillary); bp 195 °C/12 mmHg.[1,3]

Solubility: sparingly sol cyclohexane, dimethoxyethane, diglyme, dioxane (<0.1 M at 25 °C); sol THF, ether, hexane, benzene, toluene, CCl_4, $CHCl_3$, CH_2Cl_2, SMe_2 (ca. 0.2-0.6 M at 25 °C); reacts with alcohols, acetals, aldehydes, and ketones.[1,3]

Form Supplied in: colorless, stable crystalline solid; 0.5 M solution in THF or hexanes.

Analysis of Reagent Purity: the melting point of 9-BBN-H dimer is very sensitive to trace amounts of impurities. Recrystallization from dimethoxyethane is recommended for samples melting below 146 °C. The dimer exhibits a single ^{11}B NMR (C_6D_6) resonance at δ 28 ppm and ^{13}C NMR signals at 20.2 (br), 24.3 (t), and 33.6 (t) ppm.[1,3]

Handling, Storage, and Precautions: the crystalline 9-BBN-H dimer can be handled in the atmosphere for brief periods without significant decomposition. However, the reagent should be stored under an inert atmosphere, preferably below 0 °C. Under these conditions the reagent is indefinitely stable. In solution, 9-BBN is more susceptible both to hydrolysis and oxidation, and contact with the open atmosphere should be rigorously avoided. Many 9-BBN derivatives are pyrophoric and/or susceptible to hydrolysis so that individuals planning to use 9-BBN-H dimer should thoroughly familiarize themselves with the special techniques required for the safe handling of such reagents prior to their use.[1b] The reagent should be used in a

well-ventilated hood.

Organoboranes from 9-BBN-H.

First identified by Köster,[2] 9-BBN-H dimer is prepared from the cyclic hydroboration of 1,5-cyclooctadiene (eq 1).[3] As a dialkylborane, 9-BBN-H exhibits extraordinary steric- and electronic-based regioselectivities which distinguish these derivatives from the less useful polyhydridic reagents (Table 1).[4]

(1)

Table 1 Boron Atom Placement in the Hydroboration of Simple Alkenes

	Bu		Ph		i-Pr	
BH_3	94	6	81	19	43	57
t-$HxBH_2$	94	6	94	6	34	66
9-BBN-H	99.9	0.1	98.5	1.5	0.2	98.8

	$SiMe_3$		CH_2Cl			
BH_3	40	60	60	40	50	50
Sia_2BH	95	5	95	5	52	48
9-BBN-H	100	0	98.9	1.1	80	20

However, in contrast to other dialkylborane reagents (e.g. ***Disiamylborane*** or ***Dicyclohexylborane***) which must be freshly prepared immediately prior to their use, 9-BBN-H dimer is a stable crystalline reagent[1,3] which is commercially available in high purity. This feature of the reagent facilitates the control of reaction stoichiometry at a level unattainable with most borane reagents. The remarkable thermal stability of 9-BBN derivatives permits hydroborations to be conducted over a broad range of temperatures (from 0 °C to above 100 °C) either neat or in a variety of solvents.[4] The *B*-alkyl-9-BBN products can frequently be isolated by distillation without decomposition and fully characterized spectroscopically.[1,4,5] The integrity of the 9-BBN ring is retained even at elevated temperatures (200 °C), but positional isomerization in the *B*-alkyl portion can take place at ca. 160 °C.[6]

Like most other dialkylboranes, 9-BBN-H exists as a dimer, but hydroborates as a monomer (eq 2).[7] In general, the rates of hydroboration follow the order $R_2C{=}CH_2$ > $RHC{=}CH_2$ > *cis*-RHC=CHR > *trans*-RHC=CHR > $RHC{=}CR_2$ > $R_2C{=}CR_2$.[1,4] For relatively unsubstituted alkenes the dissociation of the 9-BBN-H dimer is rate-limiting ($T_{1/2}$ at 25 °C &AApprox; 20 min) so that the hydroborations of typical 1-alkenes are normally complete in less than 3 h at room temperature. Competitive rate studies have revealed that electron-donating groups enhance the rates within these groups, e.g. for *p*-$XC_6H_4CH{=}CH_2$, k_{rel} = 1 (X = CF_3), 5 (X = H), 70 (X = OMe).[4c]

$$[9\text{-BBN-H}]_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} 2\,[9\text{-BBN-H}] \qquad (2)$$

$$9\text{-BBN-H} \xrightarrow[k_2]{\text{alkene}} \text{R-9-BBN}$$

Hydroborations of more substituted alkenes such as α-pinene[8] or 2,3-dimethyl-2-butene[4b] with 9-BBN-H are slower (k_2 is rate-limiting) and require heating at reflux temperature in THF for 2 and 8 h, respectively, for complete reaction to occur. However, the enantioselective reducing agent[8a] Alpine-borane® (see ***B-3-Pinanyl-9-borabicyclo[3.3.1]nonane***) is formed quantitatively as a single enantiomer, the process taking place with complete Markovnikov regiochemistry, exclusively through *syn* addition from the least hindered face of the alkene (eq 3).

(3)

While the monohydroboration of symmetrical nonconjugated dienes with 9-BBN-H is thwarted by competing dihydroboration because these remote functionalities act as essentially independent entities, with nonequivalent sites the chemoselectivity of the reagent can be excellent (eq 4).[4] Also, whereas the monohydroboration of conjugated dienes is not always a useful process because of competitive dihydroboration, highly substituted dienes and 1,3-cyclohexadiene produce allylborane products efficiently. In contrast to the monohydroboration of allene itself, which gives a 1,3-diboryl adduct, 9-BBN-H is an effective reagent for the preparation of allylboranes from substituted allenes.[4g] For example, excellent selectivity has been observed for silylated allenes where hydroboration occurs *anti* to the silyl group on the allene and at the terminal position (eq 5).[9] It is also important to note that the diastereofacial selectivities of 9-BBN-H can be complementary to those obtained with Rh-catalyzed hydroborations (eq 6).[10]

(4)

(5)

(6)

9-BBN-H	11:89
CatBH, $ClRh(PPh_3)_3$	96:4

Medium-ring boracycles are efficiently prepared by the dihydroboration of α,o-dienes with 9-BBN-H followed by exchange with borane.[11] In this process 9-BBN-H is particularly useful because it not only fixes the key 1,5-diboryl relationship, but also the 9-BBN ligands do not participate in the exchange process (eq 7).

Unlike most dialkylboranes, 9-BBN-H hydroborates alkenes faster than its does the corresponding alkynes, a feature which leads to the competitive formation of 1,1-diboryl adducts in the hydroboration of 1-alkynes with 9-BBN-H employing a 1:1 stoichiometry (eq 8).[1,12,13] In some cases, the (*E*)-1-alkenyl-9-BBN derivative can be efficiently prepared by employing either a large excess of the alkyne[12,13] or through the use of 1-trimethylsilyl derivatives.[6] However, these vinylboranes are now perhaps best prepared through the dehydroborylation of their 1,1-diboryl adducts with aromatic aldehydes (eq 8).[12]

By contrast, 9-BBN-H effectively monohydroborates internal alkynes to produce the corresponding vinylboranes in >90% yields.[1,13] Compared to 1-alkynes, their 1-silyl counterparts also produce better yields of vinylboranes but, in contrast to normal internal alkynes, produce *vicinal* rather than *geminal* diboryl adducts with dihydroboration.[6,13,14] Larger silyl groups can effectively be used to redirect the boron to the internal position producing the silyl-Markovnikov vinylborane, exclusively, without competitive dihydroboration.[6] For 1-halo-1-alkynes, hydroboration with 9-BBN is slow, but the (*Z*)-1-halovinylboranes (eq 9) are produced cleanly and these are protonolyzed to provide *cis*-vinyl halides.[15] The isomeric (*Z*)-2-bromovinyl-9-BBN derivatives are available from the bromoboration of 1-alkynes with *B*-Br-9-BBN[16] (see ***9-Bromo-9-borabicyclo[3.3.1]nonane***). It is important to point out that the preference of 9-BBN-H to hydroborate alkenes in the presence of alkynes can have useful synthetic applications (eq 10).[17]

(9)

(10)

Organometallic reagents can provide very useful entries to many *B*-substituted 9-BBN derivatives. These are particularly important for organoboranes which cannot be prepared by hydroboration.[5] Both *B*-alkoxy and *B*-halo derivatives serve as useful precursors to *B*-alkyl, -allyl, -aryl, -vinyl or -alkynyl-9-BBN derivatives (eqs 11-16). *B*-Halo-9-BBN derivatives are effectively vinylated with organotin reagents.[18] However, *B*-MeO-9-BBN is superior to its *B*-halo counterparts for secondary and tertiary alkyllithium reagents where the latter undergo some reduction to 9-BBN-H through β-hydride transfer from the organolithium.

(11)

(12)

(13)

(14)

(15)

(16)

Hydroboration of the byproduct alkene gives isomeric *B*-alkyl-9-BBN products.[5b] Generally, hydrocarbon solvents are

preferable to ether or THF for this process because the greater stability of the intermediate methoxyborate complexes (i.e. Li[R(MeO)-9-BBN]) at -78 °C in these solvents prevents the product from being formed and competing with *B*-MeO-9-BBN for the alkyllithium reagent prior to its complete consumption.[5b] The complex is stable for alkenyl and alkynyl derivatives which require $BF_3.Et_2O$ to remove the methoxy moiety. The procedure has also been used for the preparation of *cis*-vinyl-9-BBN derivatives[19] since the normal route to such derivatives based upon the hydroboration of 1-haloalkynes, followed by hydride-induced rearrangement gives ring expansion products competitively with (*Z*)-1-halovinyl-9-BBNs.[20] Similar behavior has been observed for the reaction of α-methoxyvinyllithium with *B*-alkyl-9-BBNs (see ***1-Methoxyvinyllithium***).[21]

Derivatives of 9-BBN.

Like other boron hydrides, a variety of proton sources (ROH, RCO_2H, RSO_3H, HX (X = Cl, Br, OH, SH, $O_2P(OH)_2$, NHR)) as well as boron halides can be effectively employed to prepare useful derivatives from 9-BBN-H.[1d,5b,22] The synthetic value of *B*-MeO-9-BBN lies principally in the preparation of *B*-alkyl derivatives through organometallic reagents as described above. As a byproduct in other processes, it is also easily converted to 9-BBN-H with BMS (eq 17).[22]

(17)

Efficient procedures have been developed for the preparation of *B*-Cl-9-BBN from 9-BBN-H (HCl in Et_2O)[5b] and *B*-Br-9-BBN (BBr_3 in CH_2Cl_2),[23] the latter being a useful reagent for ether cleavage, the bromoboration of 1-alkynes, and for conjugative additions to enones (see ***9-Bromo-9-borabicyclo[3.3.1]nonane***). 9-BBN triflate is highly useful in formation of enolboranes for stereoselective crossed aldol reactions[24] (see ***9-Borabicyclononyl Trifluoromethanesulfonate***). The *B*-acyloxy-9-BBN derivatives have been employed in conjuction with borohydrides for the reduction of carboxylic acids to aldehydes[25] (see ***Lithium 9-boratabicyclo[3.3.1]nonane***). Amine complexes of 9-BBN-H and borohydride derivatives are easily prepared from the addition of amines or metal hydrides to 9-BBN-H.[26] *B*-Alkyl-9-BBNs and their borohydrides are very selective reducing agents and, with chiral terpenoid or sugar appendages, can also effectively function as enantioselective reagents (eq 18)[8,27] (see ***B-3-Pinanyl-9-borabicyclo[3.3.1]nonane*** and ***Potassium 9-Siamyl-9-boratabicyclo[3.3.1]nonane***). 9,9-Dialkylborate derivatives of 9-BBN are also highly selective reducing agents[28] (see ***Lithium 9,9-Dibutyl-9-borabicyclo[3.3.1]nonanate***), transferring a bridgehead hydride with rearrangement to bicyclo[3.3.0]octylboranes. This process is best accomplished with ***Acetyl Chloride*** and provides a highly versatile entry to these organoboranes for subsequent conversions (eq 19).[29]

(18)

(19)

Functional Group Conversions with 9-BBN-H.

9-BBN-H selectively reduces acid chlorides, aldehydes, ketones, lactones, and sulfoxides at 25 °C.[1e] Alcohol rather than amine products are produced as the major products from tertiary amides, while primary derivatives are not reduced effectively. Reduction is slow with esters, carboxylic acids, nitriles, and epoxides, and does not occur with nitro compounds, nor with alkyl or aryl halides. At 65 °C, carboxylic acids and esters are cleanly reduced to alcohols, the former being significantly slower (18 vs. 4 h). Moreover, 9-BBN-H is a highly selective reducing agent for the reduction of enones to allylic alcohols (eq 20).[30]

(20)

As noted earlier, *B*-substituted-9-BBN derivatives are available from a variety of sources and organoboranes serve as a versatile entry to other functionalities. Their oxidative conversion to alcohols with alkaline ***Hydrogen Peroxide*** or ***Sodium Perborate***[31] is quantitative and occurs with complete retention of configuration, making the process highly useful.[1] The 9-BBN moiety is oxidized to *cis*-1,5-cyclooctanediol (eq 21), a compound which can be removed from less polar products through extraction with water, selective crystallization, or by chromatography.[1] The monooxidation of 9-BBN derivatives with anhydrous ***Trimethylamine N-Oxide*** (TMANO) produces 9-oxa-10-borabicyclo[3.3.2]decanes (eq 22),[14] many of which are air-stable and undergo useful coupling reactions.

(21)

(22)

Anomalous oxidation products are observed from the oxidation of tetraalkylborate salts (i.e. Li(R_2-9-BBN)), which produces bicyclo[3.3.0]octan-l-ol as a co-product through a skeletal rearrangement which occurs during the oxidation process.[32] Moreover, the alkaline hydrogen peroxide oxidation of 1,1-di-9-BBN derivatives gives primary alcohols rather than aldehydes because of their solvolysis prior to oxidation.[6,13]

While the protonolysis of *B*-alkyl-9-BBNs, like other trialkylboranes, with carboxylic acids takes place only at temperatures above 100 °C, *B*-vinyl derivatives are readily cleaved by HOAc at 0 °C with complete retention of configuration.[1,13] This can be combined with other 9-BBN processes (e.g. thermal isomerization or dehydroborylation) to give remarkable overall conversions (eq 23).[6] The hydrolysis of allylic and alkynic 9-BBN derivatives is more facile, occurring even with water or alcohols.[5c,32]

In the absence of light, molecular bromine readily cleaves *B*-(*s*-alkyl)-9-BBN derivatives through a hydrogen abstraction process, to give excellent yields of the corresponding alkyl bromides, the 9-BBN moiety being converted to 9-Br-9-BBN (eq 24).[33] However, bicyclo[3.3.0]octylborinic and -boronic acids are produced from *B*-Me- and *B*-MeO-9-BBN through this radical bromination under hydrolytic conditions where the facile 1,2-alkyl migration of a ring B-C bond occurs (eq 25).[1b,34] This latter compound serves as a convenient source of 9-oxabicyclo[3.3.1]nonane through base-induced iodination via an S_E2-type inversion.[35]

Mechanistically similar to the oxidation of 9-BBN derivatives with TMANO, the amination of *B*-alkyl-9-BBN proceeds through ring B-C migration rather than through *B*-alkyl migration (eq 26).[36] Similar behavior is observed for the thermal reaction of organic azides with these derivatives. Dichloroboryl derivatives have proved to be more versatile and general for the synthesis of amines, including optically active derivatives.[37]

(26)

Carbon-Carbon Bond Formation via 9-BBN Derivatives.

Consistent with the versatility of organoboranes in synthetically useful chemical transformations, most conversions with 9-BBN derivatives are very efficient and occur with strict stereochemical control.[1] Of particular importance are those which involve the formation of new carbon-carbon bonds because valuable R groups can often be selectively transferred to the substrates without competition from the 9-BBN ring. For example, whereas only one of the alkyl, vinyl or aryl groups can be transferred from BR_3 to the anions derived from α-halo ketones, esters and nitriles, these reactions are ideally suited to *B*-R-9-BBN derivatives which transfer the *B*-R group selectively (eq 27).[1a,38] The vinylogous γ-alkylation of γ-bromo-α,β-unsaturated esters efficiently leads to γ-substituted-β,γ-unsaturated esters, the double bond transposition being commonly observed in the kinetic protonation of enolates with extended conjugation. Both sulfur ylides and α-bromo sulfones undergo related alkylations.[1a]

(27)

Base-induced eliminations of γ-haloalkyl-9-BBN derivatives give cycloalkanes (C_3 to C_6)[1b] with inversion of configuration at both carbon centers.[1,39] 1,1-Diboryl adducts from the dihydroboration of 1-alkynes with 9-BBN-H serve as useful precursors to *B*-cyclopropyl-9-BBN derivatives by a similar process (eq 28).

The carbonylation of *B*-alkyl-9-BBNs at 70 atm, 150 °C in the presence of ethylene glycol produces intermediate boronate esters which are oxidized with alkaline hydrogen peroxide to give high yields of the corresponding carbinols (Scheme 1).[40] In the presence of hydride-reducing agents (e.g. $LiHAl(OMe)_3$ or ***Potassium Triisopropoxyborohydride***), the carbonylation of *B*-R-9-BBN derivatives can be carried out at atmospheric pressures at 0 °C, producing an intermediate α-alkoxyalkylborane which can be further reduced with ***Lithium Aluminum Hydride***. This results in homologated organoboranes and, after oxidation, alcohols. Alternatively, the intermediate α-alkoxyalkylborane can be directly oxidized to produce aldehydes (Scheme 1).[1a,38c,41]

Scheme 1

As a useful alternative to carbonylation, the Brown dichloromethyl methyl ether (DCME) process has been effectively used for the synthesis of 9-alkylbicyclo[3.3.1]nonan-9-ols.[42] The ketone bicyclo[3.3.1]nonan-9-one (eq 29)[42b] has also

been prepared from a hindered *B*-aryloxy-9-BBN derivative, with simple *B*-alkoxy-9-BBN derivatives failing to undergo this process. However, most borinate esters are smoothly converted to ketones through this process, including germa- and silaborinanes (eq 30).[11e,f] In these cases, 9-BBN-H provides the essential 1,5-diboryl relationship which allows the formation of borinane by the exchange reaction described earlier.

(29)

(30)

Allylboration with 9-BBN derivatives (see ***B-Allyl-9-borabicyclo[3.3.1]nonane***) is an efficient process, resulting in the smooth formation of homoallylic alcohols (eq 31).[43] Alkynylboranes also undergo 1,2-addition to both aldehydes and ketones.[44] As with other reactions producing *B*-alkoxy-9-BBN byproducts, the conversion of these to alcohols with ***Ethanolamine*** also results in the formation of an alkane-insoluble 9-BBN complex which is conveniently removed, thereby greatly simplifying the workup procedure.

(31)

Vinyl derivatives of 9-BBN uniquely undergo Grignard-like 1,2-additions to aldehydes to produce stereodefined allylic alcohols (eq 32).[12,45] The thermal stability of the 9-BBN ring system, as well as its resistance to serve as a β-hydride source, facilitates this highly effective process. These vinylboranes are also the borane reagents of choice for the conjugate additions to enones which can adopt a *cisoid* conformation, providing a convenient entry to γ,δ-unsaturated

ketones from enones (eq 33).[46] Alkynylboranes undergo a related addition-elimination process with β-methoxyenones, giving enynones (eq 34).[47]

(32)

(33)

(34)

Vinyl(methoxy)-9-BBN ate complexes undergo an unusual homocoupling reaction when treated with ***Zinc Chloride*** (0.5 equiv) (eq 35).[48] Related intermediates, formed through the Cu^{I}-catalyzed addition of stannylborate complexes to 1-alkynes, can be coupled either through catalytic palladium or stoichiometric copper chemistry to produce stereodefined vinylstannanes (eq 36).[49]

(35)

(36)

Both vinyl- and alkynyl-9-BBN derivatives are effective dienophiles in Diels-Alder cycloadditions, leading to boron-functionalized cyclohexenes in a selective manner (eqs 37 and 38).[18,50] Silylated allenylboranes add selectively as allylboranes to aldehydes, a reaction which has been effectively used to prepare the steroid nucleus through a Hudrlik elimination followed by a Bergman rearrangement (eq 39).[51]

(37)

cis:*trans* = 92:8

(38)

(39)

Stereodefined 9-BBN enolboranes which contain a directing chiral auxiliary undergo highly selective crossed aldol condensations as do other dialkylboryl systems (eq 40).[20,52] The conjugate addition of *B*-Br-9-BBN also produces enolboranes which condense with aldehydes to produce, after the elimination of the elements of *B*-HO-9-BBN, α-bromomethyl enones stereoselectively (eq 41).[53]

(40)

(41)

While catechol- and disiamylborane derivatives were originally employed in the Pd-catalyzed cross coupling of organoboranes to unsaturated organic halides under basic conditions (Suzuki-Miyaura coupling), 9-BBN has recently found an important place in this process. Initially, *B*-(primary alkyl)-9-BBNs, with added bases (NaOH, TlOH, NaOMe, or K_3PO_4), were found to undergo efficient coupling with iodobenzene using ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)*** as the catalyst.[54] However, while secondary alkylboranes may require

this catalyst, ***Tetrakis(triphenylphosphine)palladium(0)*** is perfectly satisfactory for the coupling of *n*- or *i*-alkyl-9-BBN derivatives to unsaturated bromides, iodides, or triflates under basic conditions (eqs 42-45).

(42)

(43)

(44)

(45)

Several recent applications include the syntheses of pharmaceuticals, pheromones, and prostaglandins, with complete retention of configuration being observed with alkenyl substrates.[54b,55] Either carbon monoxide or ***t-Butyl Isocyanide*** can be used to prepare ketones through the sequential formation of two new carbon-carbon bonds with this reaction.[56] Moreover, vinyl-9-BBNs (eqs 46-48) are also smoothly cross-coupled with retention of configuration to these substrates and, with these now being readily available, their expanded use in this process should flourish.[12,57] It is important to mention that vinyl vs. primary alkyl group transfer is favored by oxygenated ligation on the borane.[52b,58]

9-Borabicyclononyl Trifluoromethanesulfonate

[62731-43-5] · $C_9H_{14}BF_3O_3S$ · 9-Borabicyclononyl Trifluoromethanesulfonate · (MW 270.08)

(Lewis acid for the preparation of vinyloxyboranes[1-4] and boryl azaenolates;[5-8] catalyst for coupling silyl enol ethers and acetals;[9] catalyst for isomerization of epoxides to allylic alcohols[10])

Alternate Name: 9-BBNOTf.

Physical Data: bp 81 °C/2.5 mmHg.

Solubility: sol common inert organic solvents such as Et_2O, CH_2Cl_2, and hexane.

Form Supplied in: 0.5 M solution in hexane.

Preparative Method: equimolar amounts of ***9-Borabicyclo[3.3.1]nonane*** and ***Trifluoromethanesulfonic Acid*** are mixed in hexane and stirred at 20 °C for 24 h after which time the product is isolated by vacuum distillation.[1]

Handling, Storage, and Precautions: use in a fume hood; the neat liquid as well as solutions are moisture and air sensitive; therefore the material should be stored and transferred under a dry inert atmosphere.

Vinyloxyborane Enolates.

9-Borabicyclononyl vinyloxyboranes are conveniently prepared from active methylene carbonyl-containing compounds utilizing 9-BBNOTf in combination with a sterically hindered amine base. Typically the base, either ***Diisopropylethylamine*** or ***2,6-Lutidine*** (2,6-lut), and 9-BBNOTf are premixed in Et_2O or CH_2Cl_2 at -78 °C and then the carbonyl component is added. Enolate generation is allowed to occur over the next 15-30 min at temperatures ranging from -78 °C to 0 °C, resulting in the formation of vinyloxyboranes which are suitable nucleophiles for reaction with aldehydes in a crossed aldol reaction. Other boryl triflate reagents have been shown to have similar or complementary utility in this process (see ***Di-n-butylboryl Trifluoromethanesulfonate*** (Bu_2BOTf) and ***Dicyclopentylboryl Trifluoromethanesulfonate*** ($(c\text{-}C_5H_9)_2BOTf$)).

With unsymmetrical methyl ketones, use of 9-BBNOTf and 2,6-lut results in the regioselective formation of the

vinyloxyborane at the more substituted carbon. However, if Bu_2BOTf and *i*-Pr_2NEt are used, the regioselectivity of vinyloxyborane formation is reversed (eq 1).[1]

Bu_2BOTf, *i*-Pr_2NEt	100:0
9-BBNOTf, 2,6-lut	12:88

The relative stereochemistry of the two new chiral centers formed in the aldol product is a direct consequence of the vinyloxyborane enolate geometry with *Z*(O) enolates affording the 2,3-*syn* aldol products and the *E*(O) vinyloxyboranes leading to the 2,3-*anti* isomers. As a result, a number of studies have examined the effects of various boron reagents and amines on the geometry of the resulting enolate. For example, when the vinyloxyboranes of ethyl cyclohexyl ketone are generated with $(c\text{-}C_5H_9)_2BOTf$ or 9-BBNOTf in the presence of *i*-Pr_2NEt, and then treated with benzaldehyde, the ratio of crossed aldol products varies dramatically. As shown in eq 2, the enolate derived from $(c\text{-}C_5H_9)_2BOTf$ yields a preponderance of the 2,3-*anti* aldol product while that from 9-BBNOTf produces almost exclusively the 2,3-*syn* isomer.[11] When the ethyl ketone contains a sterically demanding *t*-butyl group, generation of the enolate with 9-BBNOTf and Et_3N produces predominately the *E*(O) vinyloxyborane. However, when the leaving group on the boron reagent is changed from triflate to iodide, the *Z*(O) vinyloxyborane predominates (eq 3).[2]

$R_2 = (c\text{-}C_5H_9)_2$	86:14	88%
9-BBN	<3:97	79%

Several propionate synthons initially developed for the preparation of natural products containing polypropionate fragments have also been successfully utilized in combination with 9-BBNOTf to prepare vinyloxyboranes of *Z*(O) geometry. Generation of the enolate from *S*-phenyl propanethioate with 9-BBNOTf and *i*-Pr_2NEt followed by condensation with various model aldehydes gave predominately the 2,3-*syn* aldol products (eq 4).[3] These results are complementary to the cross aldol products obtained from *S*-*t*-butyl propanethioate. Treatment of the latter with $(c\text{-}C_5H_9)_2BOTf$, *i*-Pr_2NEt, and an aldehyde yields predominately the 2,3-*anti* aldol product (see ***Dicyclopentylboryl Trifluoromethanesulfonate***).

Further extension of this methodology has led to the development of chiral masked propionate equivalents in which the boryl triflate generates chiral vinyloxyboranes of defined enolate geometry. Upon reaction with an aldehyde the chiral enolate is able to exert an influence on the absolute stereochemistry of the two newly formed chiral centers in the crossed aldol product. The α-hydroxy ethyl ketones derived from the enantiomers of hexahydromandelic acid are examples of such reagents. For additional examples see ***Di-n-butylboryl Trifluoromethanesulfonate***. This reagent forms the *Z*(O) vinyloxyborane stereospecifically with 9-BBNOTf, Bu_2BOTf, and $(c\text{-}C_5H_9)_2BOTf$. Upon exposure to a sterically demanding aldehyde such as isobutyraldehyde, the reaction proceeds only with the enolates generated from 9-BBNOTf and Bu_2BOTf. Excellent stereoselection is achieved in both cases (eq 5). The fact that the reaction does not proceed with the bulky cyclopentyl ligands on the vinyloxyborane has been attributed to steric congestion in the transition state.[4]

R_2 =	9-BBN	>100:1
	Bu_2	>100:1
	$(c\text{-}C_5H_9)_2$	no reaction

Boryl Azaenolates.

The azaenolate of a chiral 2-ethyloxazoline was prepared with 9-BBNOTf and *i*-Pr_2NEt (eq 6). Subsequent condensation with aldehydes afforded predominately the 2,3-*syn* aldol products. The stereoselectivity of this reaction was rather low, ranging from 40 to 60% de.[5]

R =	Et	2.3:1	44%
	i-Pr	2.3:1	42%
	i-Bu	4.0:1	50%

A number of methyl substituted nitrogen-containing heteroaromatics have been examined as azaenolate precursors in reactions with benzaldehyde. The azaenolates were generated with 9-BBNOTf and *i*-Pr_2NEt in CH_2Cl_2 and, as shown in Table 1, many of the compounds are good substrates. 2-Methyl-4-phenyloxazole reacts selectively at the 2-position when the boron enolate is condensed with benzaldehyde. This contrasts to the lithium enolate in which condensation occurs exclusively at the 5-position (eq 7).[6] Similar results were observed with 2-methylthiazole, as shown in eq 8. Thus the regioselective functionalization of these methyl substituted five-membered heteroaromatics is achieved by judicious choice of the reaction conditions utilized for azaenolate generation.

Table 1 Aldol Reaction of Heteroaromatics with Benzaldehyde

Heteroaromatic	Yield (%)	Heteroaromatic	Yield (%)
	88		88
	79		79
	0		0

9-BBNOTf, *i*-Pr_2NEt	70%	0%
n-BuLi	0%	58%

9-BBNOTf, *i*-Pr_2NEt	77%	0%
n-BuLi	18%	52%

Reaction of 2,4-lutidine with benzaldehyde gave aldol-like products arising from condensation at both the 2- and 4-positions. The regioselectivity of the reaction could be controlled by the choice of boryl triflate and amine utilized. 9-BBNOTf and *i*-Pr_2NEt produced an azaenolate which reacted with benzaldehyde exclusively at the 4-position while use of Bu_2BOTf and Et_3N generated an azaenolate which reacted solely at the 2-methyl group (eq 9).[7]

(9)

9-BBNOTf, *i*-Pr_2NEt	0:100	73%
Bu_2BOTf, Et_3N	100:0	68%

Nitrile derivatives also react with 9-BBNOTf and *i*-Pr_2NEt to produce an azaenolate which was condensed with various substituted benzaldehydes to yield β-hydroxy nitrile products.[8] The yields were low when aliphatic aldehydes were utilized as reactants, thus limiting the scope of this reaction.

Mukaiyama Reaction Catalyst.

β-Alkoxy ketones are produced when 9-BBNOTf is used to catalyze the coupling of enol silyl ethers with acetals (eq 10).[9]

(10)

Allylic Alcohols from Epoxides.

Epoxides are isomerized to allylic alcohols in the presence of 9-BBNOTf and 2,6-lut. The reaction proceeds most efficiently when the substrate is treated with equimolar equivalents of the triflate and amine reagents. When the possibility of producing regioisomeric alkenes exists, as in the example shown in eq 11, both are observed.[10]

Borane-Ammonia[1]

$NH_3.BH_3$

[13774-81-7] · BH_6N · Borane-Ammonia · (MW 30.86)

(strong chemo- and stereoselective, hydride-like reducing agent with greater hydrolytic stability than $NaBH_4$ in protic solvents (including water) and higher solubility in aprotic organic solvents; useful for the reduction of carbonyls and carbon-nitrogen double bonds)

Solubility: very sol methanol, THF, toluene, and dichloromethane; sol water and diethyl ether; insol hexane.[1]

Form Supplied in: waxy solid; commercially available as 90% technical grade.

Handling, Storage, and Precautions: explodes when heated; use in a fume hood. Borane-ammonia thermally decomposes to aminoborane with the evolution of hydrogen.[1] Heating the solid reagent presents an explosion hazard. $BH_3.NH_3$ is hygroscopic and undergoes slow degradation in the presence of moisture to ammonia and hydrogen gas. Bottles of ammonia borane should be stored in the cold, flushed with nitrogen, sealed to avoid contamination by atmospheric moisture and opened carefully due to potential pressure build-up. Because of its greater purity, indistinguishable reactivity and thermal and hydrolytic stability, the commercially available reagent borane-*t*-butylamine[1] should be substituted for borane-ammonia whenever possible.

Carbonyl Reductions.

Borane-ammonia is a non-ionic dative complex with reducing properties equivalent to ***Sodium Borohydride***. It is a mild reducing agent which is useful in a wide range of solvents (including water) at temperatures as low as -50 °C. Aliphatic and aromatic ketones, aldehydes, and enones are reduced, affording the corresponding alcohols in 65-97% isolated yields.[1] It is capable of transferring all three hydride equivalents and excess reagent can conveniently be hydrolyzed by quenching with dilute HCl. Because of its being intermediate in reactivity between the electrophilic reagent borane and the nucleophilic hydride reagents, $BH_3.HN_3$ exhibits unique stereo- and chemoselective reactivity.

Stereoselectivity.

In the reduction of 4-*t*-butylcyclohexanone, $BH_3.HN_3$ in methanol at -50 °C affords a high ratio (96:4) of axial hydride delivery.[2a] Stereoselective carbonyl reductions have been reported in the synthesis of lubimin,[3] and in the stereospecific reduction of a protected octulopyranosylonic acid.[4]

The reduction of (*S*)-γ-methytetronic acid in methanol/water (eq 1) gave a 25:75 ratio of the *cis*:*trans* hydroxy lactones (a ratio opposite to that observed with catalytic hydrogenation over rhodium).[5a] Six-member-ring analogs of tetronic acids were found to be reducible with $BH_3.NH_3$ but not with sodium borohydride or sodium cyanoborohydride.[5b]

Diastereoselectivity has been observed in the reduction of an acyclic sterically hindered α-keto ester (eq 2).[6]

Reductions of aromatic ketones with $BH_3.NH_3$ complex and chiral ***18-Crown-6*** derivatives afford 63-80% yields of the corresponding alcohols with enantiomeric excesses of 28-67%.[7]

Chemoselectivity.

The reduction of a 1:1 molar mixture of benzaldehyde and acetophenone with 1 hydride equivalent affords a 98:2 ratio of benzyl alcohol to phenylethanol.[2b] The relative reduction rates decrease in the order aliphatic aldehyde > aromatic

aldehyde > hexanone > pentanone > arylketone > enone. Thus ketones may be reduced selectively in the presence of enones,[8,2b] and aliphatic aldehydes in the presence of ketone and/or lactone moieties.[9a,9b]

Reduction of Imines.

In the reduction of 4-substituted cyclohexyl imines, iminium salts, and enamines with $BH_3.NH_3$,[10] in contrast to the case with carbonyl reduction, equatorial attack of hydride is favored affording the corresponding reduced amines in 60-89% yield.

Related Reagents.

Sodium Borohydride; ***Sodium Cyanoborohydride***.

Borane-Dimethyl Sulfide[1]

$BH_3.SMe_2$

[13292-87-0] · C_2H_9BS · Borane-Dimethyl Sulfide · (MW 75.96)

(hydroborating and reducing agent)

Alternate Name: BMS.

*Physical Data: d*204 = 0.801 g cm^{-3}.

Solubility: sol dichloromethane, benzene, toluene, xylene, hexane, diethyl ether, diglyme, DME, and ethyl acetate; insol but reacts slowly with water; reacts with alcohols, acetone.

Form Supplied in: neat complex, colorless liquid, ca. 10 M in BH_3; contains slight excess of dimethyl sulfide.

Analysis of Reagent Purity: active hydride is determined by hydrolysis of an aliquot in glycerol-water-methanol mixture and measuring the hydrogen evolved according to a standard procedure.[3a] ^{11}B NMR (CH_2Cl_2) δ -20.1 ppm (*q*, J_{B-H} = 104 Hz).[4]

Preparative Method: ***Diborane*** generated by the reaction of ***Sodium Borohydride*** with ***Boron Trifluoride Etherate*** in diglyme[3] is absorbed in ***Dimethyl Sulfide***.

Purification: commercial reagent can be purified and freed of excess dimethyl sulfide by vacuum transfer.[2]

Handling, Storage, and Precautions: use in a fume hood; flammable liquid with stench; reacts with atmospheric moisture forming a crust of boric acid. Store and handle under nitrogen or argon. Stable indefinitely when kept at 0 °C. Stable for prolonged periods at rt.

Introduction.

Borane-dimethyl sulfide (BMS) parallels ***Borane-Tetrahydrofuran*** in hydroboration and reduction reactions. Its advantages are stability, solubility in various solvents, and higher concentration.

Hydroboration.

Directive effects and stereoselectivity in the hydroboration of representative alkenes with BMS are shown in Figure 1.[5,6]

Oxidation of organoborane intermediates with a standard alkaline hydrogen peroxide in the presence of dimethyl sulfide requires a higher concentration of alkali to suppress slow concurrent oxidation of dimethyl sulfide. When its presence is not desirable, it can be removed by selective oxidation with sodium hypochlorite.[7] The oxidation of primary trialkylboranes with ***Pyridinium Chlorochromate*** in methylene chloride and with ***Chromium(VI) Oxide*** in acetic acid provides the corresponding aldehydes and acids, respectively. The method works best for α-alkyl-substituted alkenes undergoing hydroboration with high regioselectivity (eq 1).[8] BMS finds application for the synthesis of various hydroborating and reducing agents derived from hindered alkenes and other precursors.[9]

(1)

The reaction of internal alkynes with BMS (also with ***Borane-Tetrahydrofuran***) can be controlled to give the corresponding (*Z*)-alkenylborane. Photochemical isomerization of such alkenylboranes has been reported (eq 2).[10]

(2)

The hydroboration of cyclic dienes with BMS gives mixtures of products. Dihydroboration predominates for seven- and eight-membered ring dienes, whereas cyclopentadiene and 1,3-cyclohexadiene give mainly the homoallylic and allylic organoborane, respectively.[11] Acyclic α,o-dienes are transformed into bora heterocycles by cyclic hydroboration with ***9-Borabicyclo[3.3.1]nonane*** and BMS (eq 3).[9c,12]

The hydroboration reaction tolerates many functional groups. A high level of acyclic diastereoselection is achieved in certain highly functionalized alkenes with BMS (eq 4)[13a] and also with borane-THF.[13b,c] Vinylic and allylic derivatives containing oxygen, sulfur, or nitrogen substituents react with high regioselectivity, placing boron at the β-position (Figure 2).[6,14] Although such organoboranes are prone to elimination reactions, pure products can often be obtained by a careful control of the reaction conditions.

Generally, the hydroboration of allylic amines and sulfides proceeds only to the monoalkylborane stage due to intramolecular complexation.[15,16] The amino group can be protected by Boc, benzyloxycarbonyl, trimethylsilyl, or phosphoramido groups[14,17,18] (eq 5).[17] Allylic *N*-phosphoroamidates are readily transformed into γ-haloamines via hydroboration-halogenolysis.[18]

The hydroboration of β-monosubstituted enamines with BMS in THF affords [(2-dialkylamino)alkyl]boranes as the major product, which can be transformed into the corresponding boronates, boronic acids, amino alcohols, or alkenes, depending on the reaction conditions (eq 6).[16,19] Aldehydes and ketones can be stereoselectively transformed into (*E*)- or (*Z*)-alkenes by this method (eq 6).[19]

Directive effects in the addition of BMS to vinylic and allylic silicon derivatives are opposite to those observed for the oxygen and nitrogen derivatives (Figure 3).[20]

Several stereodefined organoboranes containing two different metals, boron and silicon, in a 1:3 relationship have been synthesized and transformed into 1,3-diols.[21] The hydroboration of alkynylsilanes provides a convenient access to acylsilanes (eq 7).[20b,22]

Following the analogy to cyclic hydroboration of dienes with 9-BBN/BMS, pharmacologically important 1-silacyclohexan-4-one has been synthesized via cyclic hydroboration of the divinylsilane derivative.[23,24]

Reduction of Functional Groups:[1,25,26] Carboxylic Acids and Derivatives.

Carboxylic acids,[16,27] thioacids,[28] and amino acids[29] are transformed into the corresponding alcohols, thiols, and amino alcohols. Aromatic acids are reduced in the presence of trimethoxyborane.[30] They may also undergo reduction to hydrocarbons.[31] Oxidation of the intermediate alkoxyboranes yields aldehydes.[27a] Since alkoxyboranes are readily prepared from alcohols,[32] the PCC oxidation of alkoxyboranes may be advantageous if water-sensitive groups are present (eq 8).[27a,32b]

Carboxylic groups can be protected from BMS reduction as trialkylsilyl esters.[33] Aliphatic esters and lactones are rapidly reduced in refluxing THF. Aromatic esters react at a slower rate.[26] Site selective reductions of α-hydroxy esters in the presence of other ester groups have been achieved in both aliphatic and aromatic systems[34] (eq 9).[34a,b]

Amides and lactams are reduced to amines[35] (eq 10).[35b] α,o-Amido esters undergo reductive cyclization.[36] Formylation-reduction of primary amines provides convenient access to monomethylated amines.[37] For the isolation of amines, a decomplexing agent such as BF_3 is added, or the amine is isolated as a hydrochloride salt.[26] Alternatively, if a theoretical amount of BMS is used in refluxing toluene, neither distillation of dimethyl sulfide nor a decomplexing agent is necessary.[38] Both aliphatic and aromatic nitriles undergo fast reduction.[26]

Ketones and Derivatives.

BMS is used as a source of borane in asymmetric reductions of prochiral ketones and derivatives catalyzed by oxazaborolidines (see ***Borane-Tetrahydrofuran***). It is also used for the synthesis of the catalysts.[39]

In stoichiometric ratios, BMS is a highly selective reducing agent for α-halo ketones and α-halo imines.[40] In the reduction of aldoximes and ketoximes, the reagent offers the advantage of a simpler isolation procedure as compared to reductions with borane-THF.[1b] Selective reduction of an aldehyde in the presence of a ketone and α,β-unsaturated aldehydes and ketones to the corresponding allylic alcohols has been demonstrated.[1a] Acetals are tolerated by the reagent and serve as protective groups for ketones in selective hydroborations and reductions. Efficient acetal opening is achieved upon activation with ***Trimethylsilyl Trifluoromethanesulfonate*** (eq 11).[41]

(11)

Cleavage of Single Bonds.

Simple ethers appear to be stable to BMS, for example THF is not cleaved when refluxed with BMS for long periods. However, methoxy groups attached to aromatic rings may undergo cleavage to phenols.[35c]

BMS is an efficient reagent for the direct reduction of ozonides to alcohols in methylene chloride solution.[42]

Other Applications.

BMS is used for the synthesis of various borane complexes, e.g. with amines,[43] phosphines,[44] azo compounds,[45] and oligonucleotides.[46] A novel staining method for transmission electron microscopy is based on the reduction (BMS)-oxidation of ester groups in polymeric materials.[47]

Borane-Pyridine[1]

[110-51-0] · C_5H_8BN · Borane-Pyridine · (MW 92.93)

(mild reducing agent with greater hydrolytic stability than $NaBH_4$ in protic solvents and higher solubility in aprotic organic solvents; in solution with a weak organic acid or complexed with Lewis acids it is useful for reductive aminations, reduction of carbonyls, heterocycles, tosylhydrazones, and oximes; in strong acid it converts aldehydes to symmetrical ethers; weak hydroborating agent)

Physical Data: mp 10-11 °C; bp (dec).

Solubility: very sol methanol, THF, toluene, dichloromethane; sol water, diethyl ether; insol hexane.[1]

Form Supplied in: viscous liquid.

Handling, Storage, and Precautions: hydrolytically stable in neutral aqueous solution. Excess reagent may be decomposed with dilute HCl.[1] Use in a fume hood.

Reductive Amination.

Borane-pyridine in neutral or acidic solution is an inexpensive and less toxic alternative to ***Sodium Cyanoborohydride*** for the reductive amination of aldehydes and ketones.[2] Side products in reductive aminations of aldehydes, related to the presence of cyanide in cyanoborohydride, may be avoided using borane-pyridine in ethanol.[3] Borane-pyridine in acetic acid/toluene affords higher yields and product quality compared to ***Sodium Borohydride*** in the 3-aminofluoranthene tagging of aliphatic ketones and aldehydes.[4] Due to its solubility in aqueous solvent, borane-pyridine is the reagent of choice for the reductive methylation of proteins with formaldehyde[5] and is useful for the immobilization of proteins on

oxidized agarose beads in neutral aqueous media.[6]

Carbonyl Reductions.

Borane-pyridine is less reactive than borane complexes of primary and secondary amines and in aprotic solvents generally affords lower stereo- and chemoselectivity.[1,7a,7b] However, reduction rates are accelerated by weak organic acids. For example, the chemoselective reduction of the 2-oxo moiety of 2,5-diketogluconic acid in aqueous solution at 0 °C affords a 92:8 mixture of 2-ketogulonic to 2-ketogluconic acids in 79% yield.[7c] Polymers of 2- and 4-vinylpyridine-borane complexed with ***Boron Trifluoride Etherate***, or uncomplexed in acetic acid solution, exhibit enhanced reactivity and chemoselectivity in the reduction of aliphatic and aromatic ketones, enones, and aldehydes.[8,9]

Carbonyl Deoxygenation.

Borane-pyridine is effective for the reduction of tosylhydrazones of aryl carbonyl derivatives, affording the corresponding tosylhydrazines in 91-98% yields.[10a] This is a key feature in a procedure for the deoxygenation of aromatic ketone tosylhydrazones without the intermediate mercuration stage required for metal hydride reduction.[10b]

Other Functional Group Reductions.

Borane-pyridine in acetic acid reduces quinoline and indole at rt to 1,2,3,4-tetrahydroquinoline and indoline in 71 and 86% yields, respectively.[1] The indole rings of protein tryptophan residues are reduced under these conditions.[5] In ethanol/10% HCl solution, borane-pyridine converts aromatic and aliphatic oximes to hydroxylamines in the presence of ester, nitrile, nitro, amide and halide moieties.[11a] Its solubility in water facilitates the reduction of phosphorylacetaldehyde oximes to phosphorylhydroxylamines.[11b] Borane-pyridine in TFA reduces aliphatic and aromatic aldehydes to symmetric ethers in 55-87% yields. The reduction of aldehydes in alcohol produces unsymmetrical ethers. Aryl ketones are reduced directly to arenes, while dialkyl ketones are reduced to the corresponding alcohols.[12a,12b] Benzyl heptyl sulfide was obtained in 73% yield by the reduction of benzaldehyde with borane-pyridine/***Aluminum Chloride*** in the presence of 1-heptanethiol in dichloromethane.[12c]

Borane-pyridine has also been used as a weak hydroborating agent, for the reductive hydrogenolysis of aryl halide and the reduction of ozonides.[1]

Borane-Tetrahydrofuran[1]

[14044-65-6] · $C_4H_{11}BO$ · Borane-Tetrahydrofuran · (MW 85.94)

(hydroborating and reducing agent)

Physical Data: d_4^{20} = 0.898 g cm^{-3} for 1 M solution in THF.

Solubility: sol THF; reacts violently with water.

Form Supplied in: solution in THF 1 M in BH_3, stabilized with 0.005 M sodium borohydride.

Analysis of Reagent Purity: ^{11}B NMR: δ -0.7 ppm (J_{B-H} = 103 Hz).[5] Active hydride is determined by hydrolysis of an aliquot in a mixture of glycerol and water (1:1) and measuring the hydrogen evolved according to a standard procedure.[6a] Boric acid formed by hydrolysis is determined by titration with standard sodium hydroxide in the presence of mannitol.

Preparative Methods: ***Diborane*** is conveniently generated by the reaction of ***Sodium Borohydride*** with ***Boron Trifluoride Etherate*** in diglyme and absorbed in THF.[2] The solution, ca. 2 M in BH_3, may contain traces of boron trifluoride, which poses problems only on rare occasions.[3] Diborane synthesis has been reviewed.[4]

Handling, Storage, and Precautions: use in a fume hood; air- and moisture-sensitive, flammable liquid; handle and store under nitrogen or argon. Commercial solutions are stable over prolonged periods when stored at 0 °C under nitrogen. Unstabilized solutions can be kept for several weeks under those conditions. However, in such solutions the BH_3 concentration may slowly decrease due to the cleavage of THF by borane.[6b]

Introduction.

The stoichiometry, directive effects, stereochemical and mechanistic aspects of the hydroboration of alkenes, dienes, alkynes, and functional derivatives are discussed in detail in monographs and reviews[1,7,8] (see also ***Borane-Dimethyl Sulfide***). Here, transformations of major synthetic importance involving organoboranes produced by hydroboration with borane-THF are outlined.

Hydroboration-Oxidation: Synthesis of Alcohols.

Oxidation of the intermediate organoborane with alkaline ***Hydrogen Peroxide***, the standard procedure, proceeds with complete retention of configuration to give alcohols in excellent yields (eq 1).[9]

Many functional groups are tolerated.[10] Other oxidation procedures are known.[11] Generally, functional groups in isolated positions do not affect the hydroboration of double or triple bonds. However, proximate substituents may dramatically influence the regioselectivity of addition and stability of the organoborane product.[12-15]

Hydroboration-Elimination: Synthesis of Alkenes.

Enamines,[16] certain homoallylic alcohols,[17] and heterocyclic compounds[18] have been transformed into alkenes or dienes by elimination or fragmentation of the organoborane intermediate (eq 2).[17]

Synthesis of Hydroperoxides.

The low-temperature autoxidation of organoboranes in THF leads to the formation of diperoxyboranes, which provide the corresponding alkylhydroperoxides in excellent yields upon treatment with hydrogen peroxide. Two of the three alkyl groups on boron are utilized (eq 3).[19] The reaction involves a radical chain and the configurational integrity of the alkyl group is not retained.

$$R_3B + O_2 \xrightarrow[-78\ ^\circ C]{THF} (ROO)_2BR \xrightarrow{H_2O_2} 2\ ROOH + ROH \quad (3)$$

81-95%

Hydroboration-Protonolysis: Noncatalytic Stereospecific Hydrogenation.

Trialkylboranes undergo protonolysis by treatment with carboxylic acids.[20] The first alkyl group is readily cleaved. Complete removal of alkyl groups requires heating with acid. The protonolysis proceeds with retention of configuration (eq 4). Internal alkynes can be transformed into (*Z*)-alkenes (see also ***Borane-Dimethyl Sulfide***).

(4)

38%

Contrathermodynamic Isomerization of Alkenes.

Thermal isomerization of alkylboranes at 150-170 °C results in migration of the boron atom to the least hindered position.[21] In aliphatic systems, boron migrates along the carbon chain to the terminal position; however, it cannot pass quarternary centers. Treatment of the isomerized organoborane with a high boiling alkene brings about displacement,[22] and oxidation yields the primary alcohol (eq 5).[23]

$$Me(CH_2)_{13}CH{=}CH(CH_2)_{13}Me \xrightarrow[\text{diglyme, 160 °C, 12 h}]{\substack{1.\ BH_3 \cdot THF \\ 2.\ 2\ C_{14}H_{29}CH{=}CH_2}} \quad (5)$$

$$3.\ H_2O_2,\ NaOH$$

$$Me(CH_2)_{28}CH_2OH + s\text{-}C_{30}H_{61}H + C_{30}H_{60}$$

66% 13% 21%

Functional groups unreactive to borane, e.g. ethers, do not interfere; however, the direction of migration may be influenced by reactive groups, e.g. hydroxy.[24]

Amination: Synthesis of Primary and Secondary Amines.

Trialkylboranes are converted by hydroxylamine-*O*-sulfonic acid to primary amines. The reaction proceeds with complete retention of configuration (eq 6).[25a]

(6)

Other aminating reagents are also known.[26] Secondary amines can be prepared by the reaction of trialkylboranes with organic azides.[27] For better utilization of R groups in these reactions, $RBMe_2$ and $RBCl_2$ can be used, respectively.[25b,26]

Halogenolysis.

Alkylboranes are readily converted into the corresponding alkyl chlorides by radical reaction with ***Trichloramine***.[28a] The reaction is not stereospecific; however, with other reagents, e.g. dichloramine T, the stereochemical integrity of the alkyl group is retained.[28b] Brominolysis and iodinolysis of trialkylboranes proceed under mild conditions in the presence of a base.[29] The yields of primary alkyl bromides and iodides are excellent. Three alkyl groups are utilized in the brominolysis and two in the iodinolysis. Secondary alkyl groups react with predominant inversion of configuration (eq 7). In contrast, the dark bromination proceeds with complete retention of configuration (eq 7).[30]

(7)

X = Br, base = NaOMe	75%	25%
X = I, base = MeOH	80%	20%

Mercuration.

Mercury(II) salts react with primary trialkylboranes to yield organomercurials (eq 8).[31] Mercuration of secondary alkylboranes is sluggish.

$$RCH{=}CH_2 \xrightarrow[\text{3. } H_2O,\ NaCl\ \ 91\text{-}97\%]{\text{1. } BH_3 \cdot THF\ \ \text{2. } Hg(OAc)_2} 3\ RCH_2CH_2HgCl \qquad (8)$$

Sulfuridation: Synthesis of Thioethers, Alkyl Thio- and Selenocyanates.

Trialkylboranes are cleaved by dialkyl and diaryl sulfides, producing mixed thioethers (eq 9).[32] The reaction is catalyzed by air. Alkyl thio- and selenocyanates are obtained by treatment of trialkylboranes with iron(III) thio- and selenocyanate, respectively.[33]

$$R_3B + MeSSMe \xrightarrow[74\text{-}94\%]{} RSMe + R_2BSMe \qquad (9)$$

Synthesis of Mono- and Dialkylboranes.[34]

Several valuable hydroborating and reducing agents,[34] e.g. ***Thexylborane***, ***Disiamylborane***, ***Dicyclohexylborane***, ***9-Borabicyclo[3.3.1]nonane*** (9-BBN, eq 10),[35] and borinane,[36] are synthesized by hydroboration of the corresponding alkenes or dienes with the reagent.

(10)

Single Carbon Homologation: Carbonylation, Cyanidation, Dichloromethyl Methyl Ether (DCME) Reaction; Synthesis of Alcohols, Aldehydes, and Ketones.

Trialkylboranes react with carbon monoxide at 100-125 °C in diglyme. The reaction proceeds stepwise and the migration of alkyl groups can be controlled to give products of one, two, or three group transfers (eq 11).[37] Cyanidation[38] and the DCME reaction[39a] lead to the same products under milder conditions. Highly hindered tertiary alcohols can be prepared. Annulation and spiroannulation of 1-allylcyclohexenes have been achieved.[39b] All reactions proceed with retention of configuration of alkyl groups. Functional groups, such as ether, ester, nitro, and chloro are tolerated. Unsymmetrically substituted ketones can be obtained by the reaction of trialkylboranes with acyl carbanion equivalents.[40]

(11)

Coupling; Synthesis of Alkanes, Cycloalkanes and (*E*)-Alkenes.

Treatment of trialkylboranes with alkaline ***Silver(I) Nitrate*** solution results in coupling of the alkyl groups.[41] Yields for coupling of primary and secondary groups are in the range of 60-80% and 35-50%, respectively.

α-Alkylation of Esters, Ketones and Nitriles.

Trialkylboranes react with carbanions generated from α-halo esters, ketones, and nitriles, transferring the alkyl group from boron to carbon.[42] Two different groups can be introduced consecutively, starting with α,α-dihalonitriles.[42d] The anions are generated by hindered bases, e.g. *t*-butoxide, or better, 2,6-di-*t*-butylphenoxide for sensitive compounds (eq 12).

α-Diazocarbonyl compounds react with trialkylboranes directly in the absence of bases at -25 °C.[43] Mild conditions are advantageous when functionalities labile to bases are present (eq 13).[43a]

α-Bromination-Alkyl Group Transfer: Synthesis of Hindered Tertiary Alcohols.

The photochemical α-bromination of trialkylboranes with bromine proceeds readily. Weak bases such as water or THF are sufficient to induce the migration of alkyl groups from boron to the α-brominated carbon. All three alkyl groups may be utilized. It is possible to halt the reaction after the first group migration. Highly hindered tertiary alcohols can be prepared (eq 14).[44]

(14)

Addition to Carbonyl Compounds: Synthesis of Unsymmetrical Ketones.

Unlike Grignard and alkyllithium compounds, trialkylboranes are inert to carbonyl compounds. The air-catalyzed addition to formaldehyde is exceptional.[45] Alkyl borates are more reactive and can transfer primary alkyl groups to acyl halides. The reaction provides highly chemoselective boron-mediated synthesis of unsymmetrical ketones (eq 15).[46]

$$s\text{-}R^1{}_3B + R^2Li \longrightarrow s\text{-}R^1{}_3\bar{B}R^2\,Li^+ \xrightarrow{R^3COX} R^3COR^2 + s\text{-}R^1{}_3B + LiX \quad (15)$$

57-88%

β-Alkylation of Conjugated Carbonyl Compounds and Oxiranes.

Trialkylboranes undergo radical conjugate addition to various α,β-unsaturated carbonyl compounds, such as enals, enones, quinones, unsaturated nitriles, crotonaldimines, and ynones, and also to alkenyl- and alkynyloxiranes[47] (eq 16).[47b]

Functional Group Reductions.[48]

The reactivity order of representative functional groups toward borane-THF is[49a] carboxylic acids > aldehydes > ketones > alkenes >> nitriles > epoxides > esters > acid chlorides. Acid anhydrides, amides, lactones, acetals, oximes, oxime ethers, imines, and hydrazones are also reduced. Nitro compounds, organic halides, sulfones, sulfonic acids, disulfides, thiols, alcohols, phenols (hydrogen evolution), and amines are stable to borane-THF.[49]

Carboxylic Acids and Derivatives.

Borane-THF is the reagent of choice for the reduction of carboxylic acids to alcohols.[50-56] Selective reduction in the presence of esters, halogen derivatives, nitrileLane, C.s, amides, lactones, nitro compounds, amino, phenolic, and other groups is possible (eq 17).[51] Carboxylic acid salts are reduced with 2 equiv of BH_3.THF.[52]

Aromatic acids containing electron-donating groups may undergo overreduction to hydrocarbons.[57] Other carboxylic groups can also be converted into the methyl group via the reduction of *N*-acyl-*N*´-tosylhydrazines.[58] Isotopically labeled chiral methyl groups have been obtained by a sequence of reactions involving BD_3.THF.[59]

Acid anhydrides are reduced to alcohols at a slower rate than carboxylic acids.[60] Aliphatic esters and lactones react slowly (6-12 h at 0 °C) to give alcohols or ethers.[49,61-65]

The reduction of amides to amines is another major synthetic application of the reagent. The reactivity order is tertiary > secondary >> primary. All types of amides and lactams are reduced rapidly and quantitatively by excess of borane in refluxing THF.[66-69]

A large-scale preparation of an intermediate in the synthesis of nitrobenzyl-DOTA, an efficient chelating agent for metal ions, used in biochemical studies, is shown in eq 18.[70]

Nitriles are readily reduced with an excess of borane in refluxing THF to give the corresponding amines upon acid hydrolysis of the intermediate borazines.[66,71] Less reactive functional groups are tolerated. The initial intermediate *N*-borylimine can be alkylated to give carbinamines (eq 19).[72] Cyanohydrins are reduced to amino alcohols; however, α-aminonitriles undergo decyanation.[73]

Ketones and Derivatives.

Although aldehydes and ketones are readily reduced by borane,[49] other reagents of higher selectivity are widely used for that purpose. In some cases, however, the use of borane may be advantageous, as demonstrated in the synthesis of ciramadol involving a stereoselective reduction of 2-(α-dimethylamino-*m*-hydroxybenzyl)cyclohexanone[74a] and in highly diastereoselective keto boronate reduction (eq 20).[74b]

34:1 (20)

The asymmetric reductions of prochiral ketones are now dominated by catalytic reactions[75] and highly selective stoichiometric reagents.[76] Borane-THF reacts with chiral amino alcohols to give asymmetric reducing agents and serves as a source of BH_3 in enantioselective reductions of prochiral ketones catalyzed by oxazaboralidines and oxazaphospholidines (eq 21).[77] Catalysts of type 2 are best studied and new modifications are prepared.[75,78]

(21)

R,R' = Ph, Me cat. 1, 94% ee; cat. 2, 97% ee
R,R' = *i*-Pr, Me cat. 1, 60% ee; cat. 3, 92% ee

cat. 1

cat. 2

cat. 3

Oximes react with borane in refluxing THF to give the corresponding hydroxylamine derivatives (see also ***Borane-Dimethyl Sulfide***).[79] Oximes of aryltrifluoromethyl ketones are reduced at room temperature (not with BMS).[80] Oxime ethers and acetates react under mild conditions.[81] ***Aluminum Hydride*** (alane) is also a convenient reagent for these

reductions.[82] Reagents for asymmetric reduction of prochiral ketoxime *O*-alkyl ethers and imines are prepared from borane-THF and chiral amino alcohols.[75,77a,83]

Cleavage of Single Bonds.

Epoxides react slowly with borane-THF to yield mixtures of products.[84] In the presence of small amounts of sodium borohydride or boron trifluoride, the reaction is greatly accelerated and the epoxide ring is cleanly opened. Although anti-Markovnikov products predominate, the regioselectivity is high only in certain cases, e.g. styrene and indene epoxides give 2-phenylethanol and indan-2-ol, respectively.[84,85] In contrast, the reduction of *s*-cisoid α,β-unsaturated epoxides with borane-THF proceeds stereoselectively with the double bond shift to give allylic alcohols of (*Z*) configuration (eq 22).[86] Similarly, α,β-unsaturated aziridines are reduced to (*Z*) allylic amines.[87] Acetals and tetrahydropyranyl ethers undergo reductive cleavage[88] (eq 23).[88c]

(22)

(23)

Imidazolidines and oxazolidines are also cleaved,[89] whereas thiazolidines appear to be stable to the reagent at rt.[90]

Nitro Compounds.

The nitro group itself is stable to the reagent; however, aci nitro salts and α,β-unsaturated nitro compounds are reduced to the corresponding hydroxylamines.[91,92]

Other Applications.

Borane-THF reacts with Grignard reagents, arylmercury, arylthalium, and allyl- and propargyllithium compounds to give organoboranes which can be oxidized to the corresponding alcohols, phenols, and 1,3-diols.[93] The reagent is used for blocking tertiary amine groups in Friedel-Crafts cyclizations and oxidative phenol coupling reactions in alkaloid syntheses.[94] It activates α,β-unsaturated acids in the reaction with 1,3-dienes[95] and is used in the synthesis of catalysts for asymmetric Diels-Alder and aldol reactions.[75] Trialkylboranes are useful intermediates in the synthesis of compounds labeled with various isotopes for medical applications.[96]

Related Reagents.

Borane-Ammonia; ***Borane-Dimethyl Sulfide***; ***Borane-Pyridine***; ***Diborane***.

Boric Acid

H_3BO_3

[10043-35-3] · BH_3O_3 · Boric Acid · (MW 61.83)

(reacts with alcohols to form borate esters;[1] catalyzes dehydration,[2] hydrolysis,[3] decarboxylation,[4] and condensation reactions;[5] useful in carbohydrate chemistry[6])

Physical Data: mp 169 °C; *d* 1.435 g cm^{-3}. Heating boric acid above 100 °C gradually produces metaboric acid, HBO_2; at higher temperatures all water is lost and boron oxide, B_2O_3, results.

Solubility: sol cold water (1 g in 18 mL), boiling water (1 g in 4 mL), cold alcohol (1 g in 18 mL), boiling alcohol (1 g in 6 mL), glycerol (1 g in 6 mL), acetone (1 g in 15 mL).

Form Supplied in: white solid, widely available (see also ***Sodium Tetraborate***).

Purification: recrystallize three times from water (3 mL g^{-1}) with filtering. Dry over metaboric acid in a desiccator.

Handling, Storage, and Precautions: boric acid is hygroscopic. It is an irritant to eyes, skin, and mucous membranes, and should be handled with the appropriate precautions to eliminate contact with these areas. Death has resulted from ingestion of 5 to 20 g in adults. Use in a fume hood.

Borate Esters.

Trigonal borate esters are readily formed by condensing alcohols with boric acid; the reaction is driven by azeotropic removal of water. Borate esters are stable under a variety of anhydrous reaction conditions and can serve as a method of protecting alcohols.[1] The reactivity of carbonyl compounds can be enhanced by intramolecular coordination with an adjacent borate ester.[7] Borate esters are intermediates in boric acid-catalyzed dehydrations of primary, secondary, and tertiary alcohols.[2] Carbocation-derived rearrangements are a potential problem with this method.[8]

Imine Hydrolysis.

Imines can be hydrolyzed in quantitative yields by using boric acid in refluxing ethanol.[3] Imines that are susceptible to intra- and intermolecular attack in the presence of other catalysts have been successfully hydrolyzed using boric acid.[9] Conversion of isoxazolines into β-hydroxy ketones and β-hydroxy esters involves hydrogenolysis of the N-O bond and imine hydrolysis in a single step.[10] In the presence of boric acid, racemization is inhibited (eq 1).[10a]

Additive (2-5 equiv)	(1)	:	(2)
acetate	91	:	9
phosphate	94	:	6
boric acid	100	:	0

Decarboxylation.

Boric acid has been used to catalyze the decarboxylation of β-keto esters and β-imino esters.[4,11] A convenient method for the production of γ-keto esters from diethyl α-acylsuccinates in high yield is shown in eq 2.[4] The conventional method of saponification, decarboxylation, and reesterification produced low yields.

Condensation.

Boric acid catalyzes the self-condensation of aldehydes and ketones to produce α,β-unsaturated enones.[12] Yields were much higher than those reported with other acid or base catalysts. Under similar conditions, aldehydes which are not readily susceptible to aldol condensation, dismutate to form esters (Tischenko reaction).[13] A catalytic amount of boric acid/sulfuric acid mixture has been used to synthesize aryl esters (eq 3) in good yields.[5] The reaction was unsuccessful using mineral acids or boric acid alone.

(3)

Indole can be condensed directly with various carboxylic acids in the presence of boric acid.[14] Traditional methods were found to be unsatisfactory due to low yields and the production of 3-acylated and 1,3-diacylated side products.

Carbohydrate Chemistry.

In alkaline solution, boric acid catalyzes the isomerization of aldoses into ketoses.[6] During the synthesis of mono- and diacylglycerides, the use of boric acid to remove acetal[15] and trityl[16] protecting groups minimizes undesired acyl group migrations.[17] The reductive acetylation of azidopyranosides to form *N*-acetylaminopyranosides is improved in the presence of boric acid.[18]

Boron Tribromide[1]

BBr_3

[10294-33-4] · BBr_3 · Boron Tribromide · (MW 250.52)

(Lewis acid used for deprotection of OH and NH groups; cleaves ethers or esters to alkyl bromides; bromoborates allene and alkynes)

Physical Data: mp -45 °C; bp 91.7 °C; *d* 2.650 g cm^{-3}.

Form Supplied in: colorless, fuming liquid; a 1.0 M solution in dichloromethane and hexane; $BBr_3.Me_2S$ complex is available as either a white solid or a 1.0 M solution in dichloromethane.

Purification: by distillation.

Handling, Storage, and Precautions: BBr_3 is highly moisture sensitive and decomposes in air with evolution of HBr. Store under a dry inert atmosphere and transfer by syringe or through a Teflon tube. It reacts violently with protic solvents such as water and alcohols. Ether and THF are not appropriate solvents.

Removal of Protecting Groups.

BBr_3 is highly Lewis acidic. It coordinates to ethereal oxygens and promotes C-O bond cleavage to an alkyl bromide and an alkoxyborane that is hydrolyzed to an alcohol during workup (eq 1).[2]

$$R^1OR^2 \xrightarrow{BBr_3} R^1Br + Br_2BOR^2 \xrightarrow{H_2O} R^1Br + R^2OH \quad (1)$$

BBr_3 has been widely used to cleave ethers because the reaction proceeds completely under mild conditions. In a special case, BBr_3 has been used to cleave acetals that cannot be deprotected by usual acidic conditions.[3] Because alkyl aryl ethers are cleaved at the alkyl-oxygen bond to give ArOH and alkyl bromides, BBr_3 has been most generally used for the demethylation of methyl aryl ethers,[2,4] for example as the final step of zearalenone synthesis (eq 2).[5] Problems are sometimes encountered in attempts to deprotect more than one nonadjacent methoxy group on one aromatic ring, and when stable chelates are formed.[6] The presence of a carbonyl substituent facilitates the selective deprotection of polymethoxyaryl compounds (eq 3).[7]

The cleavage of mixed dialkyl ethers occurs at the more substituted carbon-oxygen bond. Methyl ethers of secondary or tertiary alcohols give methanol and secondary or tertiary alkyl bromides selectively by the reaction with BBr_3,[8] although the addition of ***Sodium Iodide*** and ***15-Crown-5*** ether can change this selectivity (eq 4).[9] In contrast, methyl ethers of primary alcohols are generally cleaved at the Me-O bond, as demonstrated in Corey's prostaglandin synthesis (eq 5).[10]

BBr_3 has been also used for the deprotection of carbohydrate derivatives[11] and polyoxygenated intermediates in the synthesis of deoxyvernolepin,[12] vernolepin,[13] and vernomenin.[13] Although one of the model compounds is deprotected cleanly (eq 6),[14] application of BBr_3 to more highly functionalized intermediates leads to cleavage of undesired C-O bonds competitively (eq 7).[12,13]

(7)

For the complete cleavage, 1 mol of BBr_3 is required for each ether group and other Lewis-basic functional groups. Sometimes it is difficult to find reaction conditions for the selective cleavage of the desired C-O bond. Recently, modified bromoboranes such as ***B-Bromocatecholborane***,[15] dialkylbromoboranes,[16] ***Bromobis(isopropylthio)borane***,[17] and ***9-Bromo-9-borabicyclo[3.3.1]nonane***,[18] have been introduced to cleave C-O bonds more selectively under milder conditions. $BBr_3.SMe_2$ is also effective for ether cleavage and has the advantage of being more stable than BBr_3. It can be stored for a long time and handled easily. However, a two- to fourfold excess of the reagent is necessary to complete the dealkylation of alkyl aryl ether.[19]

Amino acid protecting groups such as benzyloxycarbonyl and *t*-butoxycarbonyl groups are cleaved by BBr_3. However, the hydrolysis of the ester function also occurs under the same reaction conditions.[20] Debenzylation and debenzyloxymethylation of uracils proceed successfully in aromatic solvents, but demethylation is more sluggish and less facile (eq 8).[21]

(8)

Substitution Reactions.

BBr_3 reacts with cyclic ethers to give tris(o-bromoalkoxy)boranes which provide o-bromoalkanols or o-bromoalkanals when treated with MeOH or ***Pyridinium Chlorochromate***, respectively (eq 9).[22] Unfortunately, unsymmetrically substituted ethers such as 2-methyltetrahydrofuran are cleaved nonregioselectively. Generally, ester groups survive under the reaction conditions for ether cleavage, but the ring opening of lactones occurs under mild conditions to give o-halocarboxylic acids in good yields (eq 10).[23]

(9)

(10)

In the reaction with methoxybenzaldehyde, bromination of the carbonyl group takes place more rapidly than demethylation; therefore benzal bromide formation is generally observed in the reaction with aromatic aldehydes.[24] Cleavage of *t*-butyldimethylsilyl ethers or *t*-butyldiphenylsilyl ethers occurs at the C-O bond to give alkyl bromides.[25] Alcohols can be converted to alkyl bromides by this method.

In a special case, BBr_3 is used for the bromination of hydrocarbons. Adamantane is brominated by a mixture of ***Bromine***, BBr_3, and ***Aluminum Bromide*** to give 1,3-dibromoadamantane selectively.[26] Tetrachlorocyclopropene[27] and hexachlorocyclopentadiene[28] are substituted to the corresponding bromides by BBr_3 and, in the latter case, addition of $AlBr_3$ and Br_2 is effective to improve the result.[29]

Reduction of Sulfur Compounds.

Alkyl and aryl sulfoxides are reduced by BBr_3 to the corresponding sulfides in good yields.[30] Addition of ***Potassium Iodide*** and a catalytic amount of ***Tetra-n-butylammonium Iodide*** is necessary for the reduction of sulfonic acids and their derivatives.[31]

Transesterification of Esters or Conversion to Amides.

Transesterification reactions of carboxylic esters or conversion into the amides is promoted by a stoichiometric amount of BBr_3.[32]

Removal of Methyl Sulfide from Organoborane-Methyl Sulfide Complexes.

Methyl sulfide can be removed from $BrBR_2.SMe_2$ or $Br_2BR.SMe_2$, which are prepared by the hydroboration reaction of alkenes or alkynes with $BrBH_2.SMe_2$ or $Br_2BH.SMe_2$, by using BBr_3.[33] The resulting alkenyldibromoboranes are useful for the stereoselective synthesis of bromodienes (eq 11).[34]

(11)

Bromoboration Reactions.

BBr_3 does not add to isolated double bonds, but reacts with allene spontaneously even at low temperature to give (2-

bromoallyl)dibromoborane,[35] which provides stable (2-bromoallyl)diphenoxyborane by the addition of anisole.[36] The diphenoxyborane derivative reacts with carbonyl compounds to give 2-bromohomoallylic alcohols in high yields (eq 12). Bromoboration of 1-alkynes provides (*Z*)-(2-bromo-1-alkenyl)dibromoboranes stereo- and regioselectively (eq 13),[37] which are applied for the synthesis of trisubstituted alkenes,[38] α,β-unsaturated esters,[39] and γ,δ-unsaturated ketones,[40] bromodienes,[41] 1,2-dihalo-1-alkenes,[42] 2-bromoalkanals,[43] and β-bromo-α,β-unsaturated amides.[44]

(12)

(13)

Chiral Bromoborane Reagents.

Complexes made from chiral 1-alkyl-2-(diphenylhydroxymethyl)pyrrolidines and BBr_3 are effective catalysts for asymmetric Diels-Alder reactions.[45] Bromoboranes prepared from chiral 1,2-diphenyl-1,2-bis(arenesulfonamido)ethanes[46,47] are used to prepare chiral allylic boranes,[47,48] allenylic borane,[49] propargylic boranes,[49] and enolates.[46,47,50] The *B*-bromodiazaborolidinene (**1**), prepared from 1,2-diphenyl-1,2-bis(*p*-toluenesulfonamido)ethane, is particularly effective in these applications. The reagents prepared from (**1**) are highly effective for the enantioselective synthesis of homoallylic alcohols (eq 14),[48] homopropargylic alcohols (eq 15),[49] propadienyl carbinols (eq 16),[49] and aldol condensation products (eq 17).[46]

Boron Trichloride[1]

BCl_3

[10294-34-5] · BCl_3 · Boron Trichloride · (MW 117.17)

(Lewis acid capable of selective cleavage of ether and acetal protecting groups; reagent for carbonyl condensations; precursor of organoboron reagents)

Physical Data: bp 12.5 °C; *d* 1.434 g cm^{-3} (0 °C).

Solubility: sol saturated and halogenated hydrocarbon and aromatic solvents; solubility in diethyl ether is approximately 1.5 M at 0 °C; stable for several weeks in ethyl ether at 0 °C, but dec by water or alcohols.

Form Supplied in: colorless gas or fuming liquid in an ampoule; $BCl_3.SMe_2$ complex (solid) and 1 M solutions in dichloromethane, hexane, heptane, and *p*-xylene are available.

Handling, Storage, and Precautions: a poison by inhalation and an irritant to skin, eyes, and mucous membranes. Reacts exothermically with water and moist air, forming toxic and corrosive fumes. Violent reaction occurs with aniline or phosphine. All operations should be carried out in a well-ventilated fume hood without exposure to the atmosphere. The gas can be collected and measured as a liquid by condensing in a cooled centrifuge tube and then transferred to the reaction system by distillation with a slow stream of nitrogen.

Cleavage of Ethers, Acetals, and Esters.

Like many other Lewis acids, BCl_3 has been extensively used as a reagent for the cleavage of a wide variety of ethers, acetals, and certain types of esters.[2] Ether cleavage procedures involve addition of BCl_3, either neat or as a solution in CH_2Cl_2, to the substrate at -80 °C. The vessel is then stoppered and allowed to warm to rt. Whereas the complexes of BCl_3 with dimethyl ether and diethyl ether are rather stable at rt, they decompose to form $ROBCl_2$ or $(RO)_2BCl$ with evolution of alkyl chloride upon heating to 56 °C.[1] Diaryl ethers are unreactive. Mixed dialkyl ethers are cleaved to give the alkyl chloride derived from C-O bond cleavage leading to the more stable carbenium ion. The transition state is predominantly S_N1 in character, as evidenced by partial racemization of chiral ethers[1,2] and the rearrangement of allyl phenyl ethers to *o*-allylphenols.[3] BCl_3 can be used for the deprotection of a variety of methoxybenzenes including hindered polymethoxybenzenes and *peri*-methoxynaphthalene.[1,2,4] When methoxy groups are *ortho* to a carbonyl group, the reaction is accelerated by the formation of a chelate between boron and the carbonyl oxygen atom (Scheme 1).[4a-c]

Scheme 1 Demethylation of aromatic ethers by BCl_3 in CH_2Cl_2

The reagent is less reactive than ***Boron Tribromide*** for ether cleavage; however, the type and extent of deetherification can be more easily controlled by the ratio of substrate to BCl_3 as well as the reaction temperature and time. The transformation of (-)-β-hydrastine (**1**) to (-)-cordrastine II is efficiently achieved by selective cleavage of the methylenedioxy group in preference to aromatic methoxy groups.[5] The demethylation of (-)-2-*O*-methyl-(-)-inositol in dichloromethane proceeds at -80 °C without cleavage of a tosyl ester group.[6] Methyl glycosides are converted into glycosyl chlorides at -78 °C without effecting benzyl and acetyl protecting groups.[7]

One of the difficulties with the use of BCl_3 arises from its tendency to fume profusely in air. The complex of BCl_3 with dimethyl sulfide is solid, stable in air, and handled easily. By using a two- to fourfold excess of the reagent in dichloroethane at 83 °C, aromatic methoxy and methylenedioxy groups can be cleaved in good yields.[8]

Another application of BCl_3 is for the cleavage of highly hindered esters under mild conditions. *O*-Methylpodocarpate (**2**) and methyl adamantane-1-carboxylate are cleaved at 0 °C.[9] The highly selective displacement of the acetoxy group in the presence of other potentially basic groups in 2-cephem ester (**3**) provides the corresponding allylic chloride. On the other hand, treatment of (**3**) with an excess of BCl_3 results in the cleavage of the acetoxy and *t*-butyl ester groups.[10]

(2)

R = Me → H; 90%
BCl_3, CH_2Cl_2, 0 °C

BCl_3 (1 equiv), CH_2Cl_2, -5 °C
(2) R = *t*-Bu → H, X = OAc → OH; 68%
BCl_3 (3 equiv), CH_2Cl_2, rt

Tertiary phosphines are cleaved at the P-C bond to give diphenylphosphine oxides. Workup with ***Hydrogen Peroxide*** provides diphenylphosphinic acids (eq 1).[11]

Condensation Reactions.

Boron trichloride converts ketones into (*Z*)-boron enolates at -95 °C in the presence of ***Diisopropylethylamine***. These enolates react with aldehydes with high *syn* diastereoselectivity (eq 2).[12] A similar condensation of imines with carbonyl compounds also provides crossed aldols in reasonable yields.[13] The reaction was extended to the asymmetric aldol condensation of acetophenone imine and benzaldehyde by using isobornylamine as a chiral auxiliary (48% ee).[14]

(2)

(*N*-Alkylanilino)dichloroboranes (**5**), prepared in situ from *N*-alkylanilines and boron trichloride, are versatile intermediates for the synthesis of *ortho*-functionalized aniline derivatives (eqs 3-5).[15] The regioselective *ortho* hydroxyalkylation can be achieved with aromatic aldehydes.[16]

The reaction of (**5**) with alkyl and aryl nitriles and ***Aluminum Chloride*** catalyst provides *ortho*-acyl anilines.[16] When chloroacetonitrile is used, the products are ideal precursors for indole synthesis.[17] Use of isocyanides instead of

nitriles provides *ortho*-formyl *N*-alkylanilines.[18] Although these reactions with BCl_3 are restricted to *N*-alkylanilines, the use of ***Phenylboron Dichloride*** allows the *ortho*-hydroxybenzylation of primary anilines.[19]

Analogously, boron trichloride induces *ortho* selective acylation of phenols at rt with nitriles, isocyanates, or acyl chlorides (eq 6).[20] The efficiency and regioselectivity of these reactions are best with BCl_3 among the representative metal halides that have been examined. In both the aniline and phenol substitutions the boron atom acts as a template to bring the reactants together, leading to cyclic intermediates and exclusively products of *ortho* substitution. A similar *ortho* selective condensation of aromatic azides with BCl_3 provides fused heterocycles containing nitrogen.[21]

(6)

Aldehydes and ketones condense with ketene in the presence of 1 equiv of boron trichloride to give α,β-unsaturated acyl chlorides.[22] Aryl isocyanates are converted into allophanyl chlorides, which are precursors for industrially important 1,3-diazetidinediones (eq 7).[23]

(7)

Synthesis of Organoboron Reagents.

General method of synthesis of organoboranes consists of the transmetallation reaction of organometallic compounds with BX_3.[24] Boronic acid derivatives [$RB(OH)_2$] are most conveniently synthesized by the reaction of $B(OR)_3$ with RLi or RMgX reagents, but boron trihalides are more advantageous for transmetalation reactions with less nucleophilic organometallic reagents based on Pb,[25] Hg,[26] Sn,[27] and Zr[28] (eqs 8 and 9).

$$Ph_4Sn + 2\,BCl_3 \longrightarrow 2\,PhBCl_2 + Ph_2SnCl_2 \qquad (8)$$

(9)

Redistribution or exchange reactions of R_3B with boron trihalides in the presence of catalytic amounts of hydride provides an efficient synthesis of RBX_2 and R_2BX.[29] Another convenient and general method for the preparation of organodichloroboranes involves treatment of alkyl, 1-alkenyl, and aryl boronates with BCl_3 in the presence of ***Iron(III) Chloride*** (3 mol %).[30] Organodichloroboranes are valuable synthetic reagents because of their high Lewis acidity, and their utility is well demonstrated in the syntheses of piperidine and pyrrolidine derivatives by the intramolecular alkylation of azides (eq 10)[31] or the synthesis of esters by the reaction with ***Ethyl Diazoacetate***.[32] The various organoborane derivatives, R_3B, R_2BCl, and $RBCl_2$, all react with organic azides and diazoacetates. However, especially facile reactions are achieved by using organodichloroboranes ($RBCl_2$).

(10)

Dichloroborane and monochloroborane etherates or their methyl sulfide complexes have been prepared by the reaction of borane and boron trichloride.[33] However, hydroboration of alkenes with these borane reagents is usually very slow due to the slow dissociation of the complex. Dichloroborane prepared in pentane from boron trichloride and trimethylsilane shows unusually high reactivity with alkenes and alkynes; hydroboration is instantaneous at -78 °C (eq 11).[34]

Direct boronation of benzene derivatives with BCl_3 in the presence of activated aluminum or $AlCl_3$ provides arylboronic acids after hydrolysis (eq 12).[35] Chloroboration of acetylene with boron trichloride produces dichloro(2-chloroethenyl)borane.[36] Similar reaction with phenylacetylene provides (*E*)-2-chloro-2-phenylethenylborane regio- and stereoselectively.[37]

The syntheses of thioaldehydes, thioketones, thiolactones, and thiolactams from carbonyl compounds are readily achieved by in situ preparation of B_2S_3 from bis(tricyclohexyltin) sulfide and boron trichloride (eq 13).[38] The high sulfurating ability of this in situ prepared reagent can be attributed to its solubility in the reaction medium.

Related Reagents.

Bis(tricyclohexyltin) Sulfide-Boron Trichloride.

Boron Trifluoride-Acetic Acid

$BF_3.(MeCO_2H)_2$

(BF_3)

[7637-07-2] · BF_3 · Boron Trifluoride-Acetic Acid · (MW 67.81) ($BF_3.MeCO_2H$)

[-] · $C_2H_4BF_3O_2$ · Boron Trifluoride-Acetic Acid · (MW 127.86) ($BF_3.(MeCO_2H)_2$)

[373-61-5] · $C_4H_8BF_3O_4$ · Boron Trifluoride-Acetic Acid · (MW 187.91) ($MeCO_2H$)

[64-19-7] · $C_2H_4O_2$ · Boron Trifluoride-Acetic Acid · (MW 60.05)

(mild Lewis acid)

Physical Data: solid monoacetic acid complex; liquid diacetic acid complex, *d* 1.353 g cm^{-3}.

Solubility: decomposes in water exothermically.

Form Supplied in: liquid diacetic acid complex 98%.

Preparative Methods: boron trifluoride monoacetic acid complex is made by passing ***Boron Trifluoride*** into anhydrous ***Acetic Acid*** in dichloroethane until a solid is produced; the liquid diacetic acid complex remains in solution. A solid with a composition of ca. 80 mol % absorption can be obtained by passing boron trifluoride into anhydrous acetic acid.[2]

Handling, Storage, and Precautions: extremely corrosive to the eyes and skin. If swallowed causes severe internal irritation and damage. Toxic irritating vapor. All work must be carried out in an efficient fume hood.

Desilylation Reactions.

These reactions are based on the well-known stabilization of a β-carbenium center by silicon. The conversion of allylsilanes into terminal alkenes using the boron trifluoride-diacetic acid complex has been studied in considerable detail. The reaction occurs by protonation, followed by nucleophile induced desilylation. The principle involved is shown in eq 1.[1] The stereochemical implications were considered in a detailed account, and in the deuteration-desilylation sequence shown in eq 2 the structure shown is the major product.[2] The method has been used as part of a total synthesis of carbocyclic cytochalasans, where the conversion of an endocyclic alkene into an exocyclic isomer was achieved in an 80% yield.[3] Protonation-desilylation of alkynes to give allenes in yields ranging from 70 to 97%

evidently can be rationalized as involving a β-vinyl cation. An example is shown in eq 3.[4]

(1)

(2)

(3)

The formation of β-silicon-stabilized cations from γ-hydroxysilanes results from the normal pattern of pinacol rearrangements where hydride and phenyl migration is common. Desilylation then also affords an alkene.[5] Where the alkyl group is a ring residue, only hydride migration was observed, as shown in eq 4. Where a suitably positioned aryl residue can cyclize onto a second carbenium center, Friedel-Crafts cyclization takes place (eq 5). The full paper reports an additional number of interesting examples and also indicates that, while precedent might suggest that cyclopropane formation should be possible, none was observed.[6]

(4)

(5)

The phenyldimethylsilyl group can be converted in two steps into a hydroxy group and as such can be regarded as a masked hydroxy group. The first step involves the proto-desilylation of the phenyl group, which is then followed by a peracid-mediated rearrangement into a hydroxy group, with retention of configuration.[7] The sequence works well for primary, secondary, and tertiary silanes; the presence of ketone and ester functions does not cause a problem. Examples are shown in eqs 6-8.[7] The proto-desilylation-oxidation sequence has also been used in a formal synthesis of thienamycin.[8]

(6)

(7)

(8)

Destannylation Reactions.

The absence of cyclopropane formation in the silicon-based reactions reviewed above prompted an investigation of related tin chemistry. A large number of examples have been reported where cyclopropanes are formed in good yields and with remarkable stereoselectivity.[9] The yields are high even when the reacting centers are fully substituted (eq 9) and inversion of configuration occurs at both reacting centers. In the case of secondary benzyl alcohols the cyclopropanes are formed apparently with complete stereospecificity (eq 10).[9a]

(9)

(10)

Miscellaneous Reactions.

Many of the other reactions using boron trifluoride/acetic acid complexes have been covered in the article on ***Boron Trifluoride-Acetic Anhydride***, which should be read in conjunction with this article. The hydrolysis of nitriles is an example,[10] but in the case of the hydrolysis to benzamide derivatives acylation α to the amide residue is not possible, and so as shown in eq 11, the addition of acetic anhydride would have been superfluous.[11] The Fries rearrangement is also discussed in connection with reactions of boron trifluoride and acetic anhydride, but in those cases the liberated phenolic group is acylated. Reaction also occurs using the boron trifluoride diacetic acid complex, as shown in eq 12.[12]

(11)

(12)

There are a large number of methods for the cleavage of ethers and esters that are based on boron trifluoride reagents and many of these are covered in other articles. An example that uses the boron trifluoride-acetic acid complex is concerned with protection of carboxy groups in peptides by means of the diphenylmethyl group.[13] The S-S bond in cystine is stable to the deprotection conditions.

Boron Trifluoride-Dimethyl Sulfide[1]

$BF_3.SMe_2$

[353-43-5] · $C_2H_6BF_3S$ · Boron Trifluoride-Dimethyl Sulfide · (MW 129.93)

(reagent for the cleavage of benzyl ethers and carbamates)

Physical Data: solid at -78 °C, liquid at rt; P_{satn}(25 °C) 217 mmHg.[2a]

Solubility: sol most organic solvents such as pentane.

Form Supplied in: liquid complex sealed under nitrogen; commercially available.

Preparative Methods: made by the addition of equimolar amounts of the two components at -78 °C.[2a] Dissociation of the complex reported as 96.2% at 12 °C and 97.4% at 34 °C.[2a] Also formed when crystalline bromodimethylsulfonium tetrafluoroborate is aspirated at rt to give a colorless product without change in crystal form.[2b] The reagent system is normally assembled by adding a large excess of dimethyl sulfide to an excess of boron trifluoride etherate.[2c]

Handling, Storage, and Precautions: moisture-sensitive; use with carefully dried apparatus. All work must be carried out in an efficient fume hood.

Introduction.

A number of boron trifluoride-type reagents have been used for the cleavage of ethers and related compounds, and a review of the earlier work on ether cleavage exists.[3] Carbon-oxygen bond cleavage using boron trifluoride combined with a sulfide or a thiol is based on the principle that a hard acid will interact with the oxygen and that the sulfur, being a soft nucleophile, will attack carbon. Small variations in the balance between the electrophilic and nucleophilic components can result in important changes in reactivity. Although the boron trifluoride-dimethyl sulfide complex is commercially available, the majority of the work reported has used ***Boron Trifluoride Etherate*** in combination with ***Dimethyl Sulfide***.[2c] A number of related reagent systems are compared in this entry. It will be seen that, although boron trifluoride together with a thiol can cause ether cleavage, there are certain functionalities, notably the carbonyl group in aldehydes and ketones and the alkene residue in α,β-unsaturated esters, that are themselves reactive to the system. The reagent system ***Aluminum Chloride-Ethanethiol*** (or dialkyl sulfide) is much more reactive than the boron-based systems and is thereby less selective.[4] For example, aluminum chloride in the presence of ethanethiol demethylates methyl ethers and cleaves methylenedioxy derivatives,[4b] but it also dehalogenates *o*- and *p*-bromoanisole in addition to cleaving the ether.[4e] Ethyl 4-bromobenzoate gives the acid in 92.5% yield using aluminum chloride-

dimethyl sulfide.[4d] On the other hand, the system which uses aluminum chloride and ***Sodium Iodide*** in acetonitrile has been used to demethylate aliphatic methyl ethers selectively in the presence of phenolic methyl ethers.[5] The use of aluminum chloride in the presence of *N*,*N*-dimethylaniline has been recommended recently as a reagent for the cleavage of benzyl and allyl ethers.[6] The regioselective debenzylation of poly-*O*-benzylated monosaccharides has been achieved using ***Tin(IV) Chloride*** and ***Titanium(IV) Chloride***. Three appropriately located metal chelating groups are necessary for selective debenzylation to proceed.[7] Recent general reviews on the cleavage of ethers[8] and on the chemical deprotection of esters[9] have been published.

Dealkylation of Ethers.

The combination of an aliphatic thiol such as ethanethiol and boron trifluoride etherate has been used to remove benzyl groups. However, although that method works well it does suffer from an incompatibility with certain functional groups.[2c] The presence of an α,β-unsaturated ester in the same molecule can result in Michael addition as well as debenzylation (eq 1).[10] Boron trifluoride in the presence of dimethyl sulfide, being a milder reagent, does not cause this type of complication, as shown in eq 2.[11]

It is clear that boron trifluoride in the presence of a thiol will convert an aldehyde or ketone into the related thioacetal. For example, 4-benzyloxyacetophenone is converted into the ethyl thioacetal of 4-hydroxyacetophenone in 84% yield by $BF_3.OEt_2$-EtSH, whereas using $BF_3.OEt_2$-Me_2S gives 4-hydroxyacetophenone in 97% yield.[2c] The conversion of an acetal to a dithioacetal has also been reported using, for example 1,3-propanedithiol in the presence of BF_3; also known is the conversion of a dithiane into the related acyclic dithioacetal by using an excess of ***Methanethiol*** and BF_3.[12] It has also been found that the double bond in substituted styrenes is cleaved by boron trifluoride etherate-ethanethiol when an electron-withdrawing group is present at the β-position (eq 3).[13] It is of interest to note that, although the system using a thiol does not result in benzyl ester cleavage, the removal of an acetyl group from a highly functionalized pyrrole has been reported (eq 4).[14]

(3)

(4)

In a series of papers on the synthesis of benzopyrone derivatives, benzyl protection-deprotection of phenolic hydroxy groups has been a standard protocol.[15] It should be noted that in this series the yields of the debenzylated products are poor unless the boron difluoride complex is preformed. The example (eq 5) shown is part of a fulvic acid synthesis.[15c]

(5)

In the example shown in eq 6, the benzylic ether is part of a ring.[16] A number of other examples are recorded,[17] including cases where complex functionality and stereochemistry are unaffected by the procedure, as illustrated in eq 7.[18]

(6)

(7)

The method has also been used successfully to remove the methoxymethyl (MOM) group (eqs 8 and 9),[19,20] and should be compared once again with the use of boron trifluoride etherate-ethanedithiol (eq 10), which was used in a total synthesis of bruceantin.[21]

Cleavage of Benzyl Carbamates.

The removal of the benzyloxycarbonyl (Cbz) group from nitrogen can be achieved successfully using boron trifluoride etherate in the presence of either a thiol or dimethyl sulfide. The carbamates derived from secondary amines are cleaved more rapidly than those from primary amines using the ethanethiol method, even when using $BF_3.OEt_2$ as the solvent. The procedure allows reasonable selectivity, as shown in eq 11.[10]

In another interesting example, the removal of the Cbz protecting group and concomitant intramolecular 1,4-addition of

the resulting amine to the spiroenone gave racemic dihydrooxocrinine in a single operation (eq 12).[22]

Boron Trifluoride-Acetic Anhydride[1]

$BF_3.Ac_2O$

(BF_3)

[7637-07-2] · BF_3 · Boron Trifluoride-Acetic Anhydride · (MW 67.81) (Ac_2O)

[108-24-7] · $C_4H_6O_3$ · Boron Trifluoride-Acetic Anhydride · (MW 102.09)

(a mild Lewis acid catalyst, mainly used for the acylation of enolizable ketones and aromatic compounds)

Physical Data: see ***Acetic Anhydride*** and ***Boron Trifluoride***.

Solubility: BF_3 gas: very sol H_2O to form two hydrates; with a large excess of H_2O it slowly reacts to form fluoroboric acid; sol most organic solvents and forms well-defined complexes with ethers, alcohols, amines, and phosphines.

Form Supplied in: prepared in situ.

Preparative Methods: BF_3 gas: prepared by heating boron trioxide with calcium fluoride, ammonium fluoroborate, or potassium fluoroborate with conc sulfuric acid.[2]

Handling, Storage, and Precautions: all forms of BF_3 are extremely corrosive to eyes and skin. All work must be carried out in an efficient fume hood.

Acylation Reactions of Ketones.

A major use of the reagent system has been concerned with the conversion of enolizable ketones into 1,3-diketones. The reactions are carried out by treating a mixture of the carboxylic anhydride and ketone with a Lewis acid catalyst system based on ***Boron Trifluoride***.[2] The main catalyst systems used involve: (i) saturation of the reaction mixture with gaseous boron trifluoride, (ii) the use of either the solid (1:1) or liquid (1:2) complexes formed between boron trifluoride and acetic acid (see ***Boron Trifluoride-Acetic Acid***) to which sometimes is added a protic acid such as ***p-Toluenesulfonic Acid***, and (iii) the use of ***Boron Trifluoride Etherate***. Where different isomeric products are possible, the reactions carried out under different conditions sometimes lead to different products or product ratios. For example, in the reaction of 3-methylbutanone with acetic anhydride under different reaction conditions, the two possible products are formed in the proportions shown in eq 1.[3] Reaction conditions that use boron trifluoride diethyl etherate as the catalyst are less strong than the others and it is then not unusual for reaction not to occur at an α-carbon that carries two alkyl substituents.

Reaction conditions	(1):(2)
BF_3 gas, rapid saturation, 0-10 °C	7.0:3.0
BF_3 gas, slow saturation, 0-10 °C	3.7:6.3
$BF_3 \cdot (AcOH)_2$, 25 °C	0.2:9.8
$BF_3 \cdot (AcOH)_2$, TsOH, 25 °C	0.0:10.0

The rapid saturation of the reaction mixture with boron trifluoride leads to the formation of the product derived from the kinetic enol, whereas in the presence of a protic acid the product formed from the thermodynamic enol may be the exclusive product. It is assumed that in the first case the nucleophile is the boron complex of the enol, while in the latter case an enol ester is involved (eq 2). In both sequences the final product is the boron difluoride complex (**3**) and in a number of examples such a complex has been isolated.[4] This explains why, in most of the reactions, 100 mol % of catalyst is required. The formation of the diketone (**2**) (eq 1) shows, however, that it is not a requirement that a complex of type (**3**) is formed. In many of the examples reported the boron difluoride complex was not observed because the hydrolytic sequences that were used gave the 1,3-diketone directly. Checked procedures have been published.[5] They include the preparation of pentane-2,4-dione in which the isolation of the product was facilitated by formation of the copper(II) complex.[5a] Reactions of cyclohexanone with a variety of anhydrides[6] include the reaction with 3-nitropropanoic anhydride[6b] and, in the case of homoveratric anhydride, reaction resulted in the formation of an octahydrophenanthrene derivative.[6c] Recent reports include the preparation of 1,3-diketones for use in an alkene synthesis involving the elimination of nitro and keto groups.[7] The acylation of benzyl methyl ketone[8] and pinacolone[9] proceed in good yield as expected. In the latter case the diketone was required in a tripyrrin-α-carboxylic acid synthesis.[10] The acetylation of aromatic ketones sometimes results, eventually, in the formation of heterocyclic derivatives. For example, the acetylation of acetophenone under forcing conditions can lead to the formation of 2,4-diphenyl-6-methylpyrylium fluoroborate,[11] and 4-(2-hydroxyphenyl)butane-2,4-dione was converted into 3-acetyl-2-methylchromone.[12]

(2)

In accord with the suggested mechanisms, the expected enol acetate was isolated in low yield in an acetylation of butanone. On the other hand, it was not possible to form the enol acetate from acetophenone, and so it was concluded that a boron difluoride enol complex was involved.[2] The treatment of cyclohexanone with acetic anhydride and 14 mol % of boron trifluoride gave 1-acetoxycyclohexene in 22% yield, which was converted into 2-acetylcyclohexanone in 76% yield (eq 3).[2] Enol acetates have also been shown to afford boron difluoride complexes and acetyl fluoride on treatment with acetic anhydride and boron trifluoride.[13] Similarly, in a reaction of boron trifluoride with the enol benzoate derived from dibenzoylmethane, benzoyl fluoride was isolated along with the boron difluoride complex (eq 4).[13] Other enol acetates and enol benzoates have been converted into β-diketones by saturating the enol esters with boron trifluoride.[14] Boron difluoride complexes have also been isolated in reactions of chroman-4-one and its thia analog.[15]

(3)

(4)

A further improvement to the experimental method was achieved by the rapid addition of the ketone-anhydride mixture to a solid boron trifluoride-acetic acid complex. In this way the acetylation of cyclohexanone was improved to afford an 86% yield of 2-acetylcyclohexanone.[16] The inverse addition method also gave an excellent yield of 2-butanoylcyclopentanone (eq 5).[16] The method has been used for the acylation of a wide range of cyclic ketones, including five- to eight-membered ring ketones,[17] including the example shown in eq 6.[17a] The acetylation of 3-methylcyclopentane-1,2,4-trione has also been reported.[18] The functionalization of 5,8-dimethoxy-1-tetralone (eq 7) was used as part of a daunomycinone aglycon synthesis.[19]

(5)

(6)

(7)

1,3-Diketones are important intermediates in the synthesis of substituted pyrroles and, as a result, improvements to the original procedures have been reported. Another recent improvement was established in the preparation of precursors required for octaalkylporphyrin synthesis. The classical work-up procedure involving steam distillation was replaced by

the hydrolysis of the boron fluoride complex with methanolic sodium hydroxide solution.[20] For example, boron trifluoride gas was bubbled through a mixture of pentan-2-one and propanoic anhydride and the complex was isolated in 89% yield; hydrolysis then gave the diketone in 80% yield (eq 8). The advantage of the acetylation procedure for the preparation of 3-methylpentane-2,4-dione from butanone, as compared with the alkylation of acetylacetone, has been noted as one of the steps in a study of the pentapyrrolic sapphyrins. The methylation of pentane-2,4-dione was found to lead to an impure product, whereas there were no detectable impurities in the acetylation of butanone.[21] A reaction of benzenesulfonylacetone with acetic anhydride and the boron trifluoride acetic acid 1:1 complex led to acetylation at the terminal methyl group in 85% yield.[22] The electron-withdrawing effect of the benzenesulfonyl group apparently does not favor enolization towards the methylene group. The self-condensation of anhydrides has been reported under mild conditions,[23] while under more forcing conditions diketones are formed.[24] Enolizable aldehydes are not *C*-acylated by an anhydride in the presence of a boron trifluoride reagent, but good yields of the *O*,*O*-diacylated products are obtained.[25]

(8)

Reactions of steroidal ketone acetals, for example the ethylene acetals derived from cholestanone and androstan-17β-ol, give the related 2-acetyl enol ethers in good yield.[26] In rigid systems, such as those found in steroids, the direction of the kinetically favored enolization of a ketone depends on the stereochemistry of the ring junction. With 3-keto steroids the 2,3-enol is formed more rapidly with a *trans*-5,6-ring junction, whereas the formation of the 3,4-enol is favored when the ring junction is *cis*. This effect is exemplified in eqs 9 and 10.[27] Cholestenone is converted into a dienol acetate by acetic anhydride in the presence of boron trifluoride diethyl etherate; further reaction leads to the formation of a mixture of diastereomeric diketones.[27,28]

Acetylation of Nitriles and Amides.

The reaction between boron trifluoride and phenylacetonitrile in the presence of aqueous acetic acid had been shown to afford phenylacetamide in high yield.[29] This result led to an investigation of the reaction of phenylacetamide and phenylacetonitrile with acetic anhydride in the presence of the boron trifluoride-diacetic acid complex. Both reactions gave the same product after an aqueous workup as shown in eqs 11 and 12.[30] The suggested mechanism involves hydrolysis of phenylacetonitrile to phenylacetamide followed by *C*- and *N*-acylation. However, in view of the fact that *p*-tolunitrile and *p*-nitrobenzonitrile both afford the related benzamides on quenching the reaction mixtures with aqueous alkali, but not in the absence of an aqueous workup, it is suggested that the mechanisms probably involve an acylnitrilium species as shown in eq 13.

(12)

(13)

Friedel-Crafts Acylation Reactions.

Since a carboxylic anhydride and boron trifluoride constitute a mild Friedel-Crafts acylating system, it is not surprising that nucleophilic aromatic substrates such as toluene, mesitylene, and anisole have been acetoacetylated,[31a] as has fluorene[31b] and η^5-(acetylcyclopentadienyl)tricarbonylmanganese.[31c] The expected 1,3-diketones are formed when a sufficient excess of acetic anhydride is present in the reaction mixtures. The process is illustrated with anisole in eq 14.[31a] The acetylation of thiophene gives the so-called 2-triacetylthiophene,[32] but the product is in fact identical with the boron difluoride complex formed in the acetylation of 2-acetylthiophene.[33] Fries rearrangement reactions may be involved in some reactions of phenols; in the case of the acetylation of 4,8-dimethoxy-1-naphthol it was possible to isolate the initial *O*-acylated phenol in very high yield.[34] Reactions involving a wide variety of electron-rich heterocyclic compounds have been reported but, not surprisingly, low yields are sometimes obtained when electron-

withdrawing groups are present.[35] Normally the yields are good,[36] although it may be that destruction of labile heterocycles such as indole and pyrrole requires that great care is taken to avoid the presence of strong protic acids. Acetylation of 2-ethoxycarbonyl-5-hydroxybenzo[*b*]furan occurs in high yield at the 4-position.[37] The acylation of 1-benzenesulfonylpyrrole is of great interest because reaction occurs predominantly at the 2-position using boron trifluoride etherate as the Lewis acid (eq 15), while the regioselectivity is reversed using ***Aluminum Chloride***.[38]

(14)

(15)

The acylation of a number of heterocyclic arylacetic acid derivatives has been used to great advantage in benzannulation reactions that proceed by way of α-pyrone derivatives.[39] The protocol is exemplified in eq 16[39e] and has also been used in a synthesis of the staurosporine aglycon.[39f]

(16)

Alkylation and Acetoxylation Reactions.

The Pomeranz-Fritsch isoquinoline synthesis, where an acetal is cyclized to afford an isoquinoline after the loss of an alcohol, can be carried out using the boron trifluoride-diacetic acid complex in the presence of trifluoroacetic anhydride.[40] In many cases the conversion of quinones into acetoxyhydroquinone acetates is best achieved using boron trifluoride etherate together with acetic anhydride.[41a] Thus 1,4-naphthoquinone is converted into 1,2,4-triacetoxynaphthalene in 81% yield by this method,[41b] and although 2,5-dimethyl-1,4-benzoquinone reacts similarly, the related 2,6-dimethyl-1,4-benzoquinone apparently does not.[41c]

Cleavage and Rearrangement Reactions.

A large number of rearrangement reactions are initiated by boron trifluoride complexes in the presence of acetic anhydride, including the synthesis of functionalized and optically active pyrans from (+)-(*R*,*R*)-diethyl tartrate as indicated in eq 17.[42] The reaction of 1,4,5,5-tetramethylcyclopentene with paraformaldehyde and acetic anhydride in the presence of boron trifluoride etherate has been used in an approach to necrodane-type monoterpenes.[43] Other examples include the conversion of bicyclic into monocyclic[44] and tricyclic into bicyclic systems,[45] the acetolysis of glycosides resulting in the formation of the fully acetylated acyclic derivative,[46] the unusual migration of nitrogen in the dienone-phenol rearrangement of an *N*-methoxy-β-lactam,[47] and the cleavage of the tetrahydrofuran ring in compound (**4**) which gave the diacetate (**5**) (eq 18) with inversion of configuration at C-20.[48] Among other interesting reactions are the synthesis of adamantanone derivatives (eq 19)[49] and a one step synthesis of the twistane system (eq 20).[50]

(20)

Protection and Deprotection Reactions.

There are a number of cases where the acetylation of hydroxy and amino groups is difficult to achieve and where the use of acetic anhydride in the presence of boron trifluoride etherate has been successful. Two representative examples are carbazole[51] and a hindered 17β-hydroxy steroid.[52] The demethylation-acetylation of methyl ethers has been carried

out using the same system but with the addition of ***Lithium Bromide***,[53] while a number of steroidal alcohols have been regenerated from their ethers in the absence of lithium bromide. Thus cholesterol methyl ether gave the corresponding acetate in 93% yield after 15 h at 0 °C, while the related 7β-methoxycholest-4-ene was more resistant to cleavage and gave the acetate after 50 h. The retention of configuration indicates homoallylic participation and, in accord with that suggestion, it was found that saturated steroidal methyl ethers gave mixtures of epimeric acetates and elimination products.[54] Acetic anhydride in the presence of catalytic boron trifluoride etherate in THF at low temperature has been reported more recently to give good chemoselectivity in the acetylation of the polyhydroxy tumor inhibitor oridonin. Among the wide range of additional examples, alcohols were shown to be acetylated in the presence of phenols.[55] The removal of the methoxymethyl group from indoles proved difficult. The involvement of the lone pair electrons in the aromatic system diminishes the hydrolytic lability of what would otherwise be an aminol ether; as a result, the reaction conditions that were found to be necessary restrict the substituent types that may be accommodated at other positions.[56] The deblocking of the anomeric position, protected as the 2-trimethylsilylethyl ether, has been achieved in high yields in examples drawn from mono-, di-, and trisaccharides.[57] The method is exemplified in eq 21. In the absence of acetic anhydride, the product with a free anomeric hydroxy group is obtained.

Boron Trifluoride Etherate

$BF_3.OEt_2$

($BF_3.OEt_2$)

[109-63-7] · $C_4H_{10}BF_3O$ · Boron Trifluoride Etherate · (MW 141.94) (BF_3.MeOH)

[373-57-9] · CH_4BF_3O · Boron Trifluoride-Methanol · (MW 99.85)

($BF_3.OEt_2$: easy-to-handle and convenient source of BF_3; Lewis acid catalyst; promotes epoxide cleavage and rearrangement, control of stereoselectivity; BF_3.MeOH: esterification of aliphatic and aromatic acids; cleavage of trityl ethers)

Alternate Names: boron trifluoride diethyl etherate; boron trifluoride ethyl etherate; boron trifluoride ethyl ether complex; trifluoroboron diethyl etherate.

Physical Data: $BF_3.OEt_2$: bp 126 °C; *d* 1.15 g cm^{-3}; BF_3.MeOH: bp 59 °C/4 mmHg; *d* 1.203 g cm^{-3} for 50 wt % BF_3, 0.868 g cm^{-3} for 12 wt % BF_3.

Solubility: sol benzene, chloromethanes, dioxane, ether, methanol, THF, toluene.

Form Supplied in: $BF_3.OEt_2$: light yellow liquid, packaged under nitrogen or argon; BF_3.MeOH is available in solutions of 10-50% BF_3 in MeOH.

Preparative Methods: $BF_3.OEt_2$ is prepared by passing BF_3 through anhydrous ether;[1a] the BF_3.MeOH complex is formed from $BF_3.OET_2$ and methanol.

Purification: oxidation in air darkens commercial boron trifluoride etherate; therefore the reagent should be redistilled prior to use. An excess of the etherate in ether should be distilled in an all-glass apparatus with calcium hydroxide to remove volatile acids and to reduce bumping.[1b]

Handling, Storage, and Precautions: keep away from moisture and oxidants; avoid skin contact and work in a well-ventilated fume hood.

Addition Reactions.

$BF_3.OEt_2$ facilitates the addition of moderately basic nucleophiles like alkyl-, alkenyl-, and aryllithium, imines, Grignard reagents, and enolates to a variety of electrophiles.[2]

Organolithiums undergo addition reactions with 2-isoxazolines to afford *N*-unsubstituted isoxazolidines, and to the carbon-nitrogen double bond of oxime *O*-ethers to give *O*-alkylhydroxylamines.[3] Aliphatic esters react with lithium acetylides in the presence of $BF_3.OEt_2$ in THF at -78 °C to form alkynyl ketones in 40-80% yields.[4] Alkynylboranes, generated in situ from lithium acetylides and $BF_3.OEt_2$, were found to react with oxiranes[5] and oxetanes[6] under mild conditions to afford β-hydroxyalkynes and γ-alkoxyalkynes, respectively. (1-Alkenyl)dialkoxyboranes react stereoselectively with α,β-unsaturated ketones[7] and esters[8] in the presence of $BF_3.OEt_2$ to give γ,δ-unsaturated ketones and α-acyl-γ,δ-unsaturated esters, respectively.

The reaction of imines activated by $BF_3.OEt_2$ with 4-(phenylsulfonyl)butanoic acid dianion leads to 2-piperidones in high yields.[9] (Perfluoroalkyl)lithiums, generated in situ, add to imines in the presence of $BF_3.OEt_2$ to give perfluoroalkylated amines.[10] Enolate esters add to 3-thiazolines under mild conditions to form thiazolidines if these imines are first activated with $BF_3.OEt_2$.[11] The carbon-nitrogen double bond of imines can be alkylated with various organometallic reagents to produce amines.[12] A solution of benzalaniline in acetone treated with $BF_3.OEt_2$ results in the formation of β-phenyl-β-anilinoethyl methyl ketone.[13] Anilinobenzylphosphonates are synthesized in one pot using aniline, benzaldehyde, dialkyl phosphite, and $BF_3.OEt_2$;[14] the reagent accelerates imine generation and dialkyl phosphite addition. Similarly, $BF_3.OEt_2$ activates the nitrile group of cyanocuprates, thereby accelerating Michael reactions.[15]

The reagent activates iodobenzene for the allylation of aromatics, alcohols, and acids.[16] Allylstannanes are likewise activated for the allylation of *p*-benzoquinones, e.g. in the formation of coenzyme Q_n using polyprenylalkylstannane.[17]

Nucleophilic silanes undergo stereospecific addition to electrophilic glycols activated by Lewis acids. The glycosidation is highly stereoselective with respect to the glycosidic linkage in some cases using $BF_3.OEt_2$. Protected pyranosides undergo stereospecific *C*-glycosidation with C-1-oxygenated allylsilanes to form α-glycosides.[18,19] α-Methoxyglycine esters react with allylsilanes and silyl enol ethers in the presence of $BF_3.OEt_2$ to give racemic γ,δ-unsaturated α-amino acids and γ-oxo-α-amino acids, respectively.[20] β-Glucopyranosides are synthesized from an aglycon and 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose.[21] Alcohols and silyl ethers also undergo stereoselective glycosylation with protected glycosyl fluorides to form β-glycosides.[22]

$BF_3.OEt_2$ reverses the usual *anti* selectivity observed in the reaction of crotyl organometallic compounds (based on Cu, Cd, Hg, Sn, Tl, Ti, Zr, and V, but not on Mg, Zn, or B) with aldehydes (eq 1a) and imines (eq 1b), so that homoallyl alcohols and homoallylamines are formed, respectively.[23-28] The products show mainly *syn* diastereoselectivity. $BF_3.OEt_2$ is the only Lewis acid which produces hydroxy- rather than halo-tetrahydropyrans from the reaction of allylstannanes with pyranosides.[29] The $BF_3.OEt_2$ mediated condensations of γ-oxygenated allylstannanes with aldehydes (eq 1c) and with activated imines (eq 1d) affords vicinal diol derivatives and 1,2-amino alcohols, respectively, with *syn* diastereoselectivity.[30,31] The activated imines are obtained from aromatic amines, aliphatic aldehydes, and α-ethoxycarbamates. The reaction of aldehydes with α-(alkoxy)-β-methylallylstannanes with aldehydes in the presence of $BF_3.OEt_2$ gives almost exclusively *syn*-(*E*)-isomers.[31]

(d) X = NHR^2, Y = OH or derivative

The reaction of α-diketones with allyltrimethylstannane in the presence of $BF_3.OEt_2$ yields a mixture of homoallylic alcohols, with the less hindered carbonyl group being allylated predominantly.[32] The reaction between aldehydes and allylic silanes with an asymmetric ethereal functionality produces *syn*-homoallyl alcohols when ***Titanium(IV) Chloride*** is coordinated with the allylic silane and *anti* isomers with $BF_3.OEt_2$.[33]

Chiral oxetanes can be synthesized by the $BF_3.OEt_2$ catalyzed [2 + 2] cycloaddition reactions of 2,3-*O*-isopropylidenealdehyde-D-aldose derivatives with allylsilanes, vinyl ethers, or vinyl sulfides.[34] The regiospecificity and stereoselectivity is greater than in the photochemical reaction; *trans*-2-alkoxy- and *trans*-2-phenylthiooxetanes are the resulting products.

2-Alkylthioethyl acetates can be formed from vinyl acetates by the addition of thiols with $BF_3.OEt_2$ as the catalyst.[35] The yield is 79%, compared to 75% when $BF_3.OEt_2$ is used in conjunction with ***Mercury(II) Sulfate*** or ***Mercury(II) Oxide***.

α-Alkoxycarbonylallylsilanes react with acetals in the presence of $BF_3.OEt_2$ (eq 2).[36] The products can be converted into α-methylene-γ-butyrolactones by dealkylation with ***Iodotrimethylsilane***.

(2)

The cuprate 1,4-conjugate addition step in the synthesis of (+)-modhephene is difficult due to the neopentyl environment of C-4 in the enone, but it can occur in the presence of $BF_3.OEt_2$ (eq 3).[37]

(3)

The reagent is used as a Lewis acid catalyst for the intramolecular addition of diazo ketones to alkenes.[38] The direct synthesis of bicyclo[3.2.1]octenones from the appropriate diazo ketones using $BF_3.OEt_2$ (eq 4) is superior to the copper-catalyzed thermal decomposition of the diazo ketone to a cyclopropyl ketone and subsequent acid-catalyzed cleavage.[38]

(4)

$BF_3.OEt_2$ reacts with fluorinated amines to form salts which are analogous to Vilsmeier reagents, Arnold reagents, or phosgene-immonium salts (eq 5).[39] These salts are used to acylate electron-rich aromatic compounds, introducing a fluorinated carbonyl group (eq 6).

(5)

R = Et; X = Cl, F, CF_3 **(1)**

(6)

Xenon(II) Fluoride and methanol react to form ***Methyl Hypofluorite***, which reacts as a positive oxygen electrophile in the presence of BF_3 (etherate or methanol complex) to yield anti-Markovnikov fluoromethoxy products from alkenes.[40,41]

Aldol Reactions.

Although ***Titanium(IV) Chloride*** is a better Lewis acid in effecting aldol reactions of aldehydes, acetals, and silyl enol ethers, $BF_3.OEt_2$ is more effective for aldol reactions with anions generated from transition metal carbenes and with tetrasubstituted enol ethers such as (*Z*)- and (*E*)-3-methyl-2-(trimethylsilyloxy)-2-pentene.[42,43] One exception involves the preparation of substituted cyclopentanediones from acetals by the aldol condensation of protected four-membered acyloin derivatives with $BF_3.OEt_2$ rather than $TiCl_4$ (eq 7).[44] The latter catalyst causes some loss of the silyl protecting group. The pinacol rearrangement is driven by the release of ring strain in the four-membered ring and controlled by an acyl group adjacent to the diol moiety.

The reagent is the best promoter of the aldol reaction of 2-(trimethylsilyloxy)acrylate esters, prepared by the silylation of pyruvate esters, to afford γ-alkoxy-α-keto esters (eq 8).[45] These esters occur in a variety of important natural products.

$BF_3.OEt_2$ can improve or reverse the aldehyde diastereofacial selectivity in the aldol reaction of silyl enol ethers with aldehydes, forming the *syn* adducts. For example, the reaction of the silyl enol ether of pinacolone with 2-

phenylpropanal using $BF_3.OEt_2$ gives enhanced levels of Felkin selectivity relative to the addition of the corresponding lithium enolate.[46,47] In the reaction of silyl enol ethers with 3-formyl-Δ^2-isoxazolines, $BF_3.OEt_2$ gives predominantly *anti* aldol adducts, whereas other Lewis acids give *syn* aldol adducts.[48] The reagent can give high diastereofacial selectivity in the addition of silyl enol ethers or silyl ketones to chiral aldehydes.[49] In the addition of a nonstereogenic silylketene acetal to chiral, racemic α-thioaldehydes, $BF_3.OEt_2$ leads exclusively to the *anti* product.[49]

1,5-Dicarbonyl compounds are formed from the reaction of silyl enol ethers with methyl vinyl ketones in the presence of $BF_3.OEt_2$ and an alcohol (eq 9).[50] α-Methoxy ketones are formed from α-diazo ketones with $BF_3.OEt_2$ and methanol, or directly from silyl enol ethers using iodobenzene/$BF_3.OEt_2$ in methanol.[51]

(9)

α-Mercurio ketones condense with aldehydes in the presence of $BF_3.OEt_2$ with predominant *erythro* selectivity (eq 10).[52] Enaminosilanes derived from acylic and cyclic ketones undergo *syn* selective aldol condensations in the presence of $BF_3.OEt_2$.[53]

(10)

Cyclizations.

Arylamines can undergo photocyclization in the presence of $BF_3.OEt_2$ to give tricyclic products, e.g. 9-azaphenanthrene derivatives (eq 11).[54]

Substituted phenethyl isocyanates undergo cyclization to lactams when treated with $BF_3.OEt_2$.[55] Vinyl ether epoxides (eq 12),[56] vinyl aldehydes,[57] and epoxy β-keto esters[58] all undergo cyclization with $BF_3.OEt_2$.

β-Silyl divinyl ketones (Nazarov reagents) in the presence of $BF_3.OEt_2$ cyclize to give cyclopentenones, generally with retention of the silyl group.[59] $BF_3.OEt_2$ is used for the key step in the synthesis of the sesquiterpene trichodiene, which has adjacent quaternary centers, by catalyzing the cyclization of the dienone to the tricyclic ketone (eq 13).[60] Trifluoroacetic acid and trifluoroacetic anhydride do not catalyze this cyclization.

Costunolide, treated with $BF_3.OEt_2$, produces the cyclocostunolide (**2**) and a C-4 oxygenated sesquiterpene lactone (**3**), 4α-hydroxycyclocostunolide (eq 14).[61]

(14)

Other Condensation Reactions.

BF_3.MeOH and BF_3.OEt_2 with ethanol are widely used in the esterification of various kinds of aliphatic, aromatic, and carboxylic acids;[62] the reaction is mild, and no rearrangement of double bonds occurs. This esterification is used routinely for stable acids prior to GLC analysis. Heterocyclic carboxylic acids,[63] unsaturated organic acids,[64] biphenyl-4,4´-dicarboxylic acid,[65] 4-aminobenzoic acid,[63] and the very sensitive 1,4-dihydrobenzoic acid[65] are esterified directly.

The dianion of acetoacetate undergoes Claisen condensations with tetramethyldiamide derivatives of dicarboxylic acids to produce polyketides in the presence of BF_3.OEt_2 (eq 15).[66] Similarly, 3,5-dioxoalkanoates are synthesized from tertiary amides or esters with the acetoacetate dianion in the presence of BF_3.OEt_2 (eq 16).[66]

(15)

(16)

R = *n*-C_9H_{19}, $ClCH_2$, Ph

Aldehydes and siloxydienes undergo cyclocondensation with $BF_3.OEt_2$ to form pyrones (eq 17).[67] The stereoselectivity is influenced by the solvent.

(17)

solvent:	CH_2Cl_2	1:2.3
	PhMe	7:1

$BF_3.OEt_2$ is effective in the direct amidation of carboxylic acids to form carboxamides (eq 18).[68] The reaction is accelerated by bases and by azeotropic removal of water.

(18)

Carbamates of secondary alcohols can be prepared by a condensation reaction with the isocyanate and $BF_3.OEt_2$ or ***Aluminum Chloride***.[69] These catalysts are superior to basic catalysts such as pyridine and triethylamine. Some phenylsulfonylureas have been prepared from phenylsulfonamides and isocyanates using $BF_3.OEt_2$ as a catalyst; for example, 1-butyl-3-(*p*-tolylsulfonyl)urea is prepared from *p*-toluenesulfonamide and butyl isocyanate.[70] $BF_3.OEt_2$ is an excellent catalyst for the condensation of amines to form azomethines (eq 19).[71] The temperatures required are much lower than with ***Zinc Chloride***.

(19)

Acyltetrahydrofurans can be obtained by $BF_3.OEt_2$ catalyzed condensation of (*Z*)-4-hydroxy-1-alkenylcarbamates with aldehydes, with high diastereo- and enantioselectivity.[72] Pentasubstituted hydrofurans are obtained by the use of ketones.

Isobornyl ethers are obtained in high yields by the condensation of camphene with phenols at low temperatures using $BF_3.OEt_2$ as catalyst.[73] Thus camphene and 2,4-dimethylphenol react to give isobornyl 2,4-dimethylphenyl ether, which can undergo further rearrangement with $BF_3.OEt_2$ to give 2,4-dimethyl-6-isobornylphenol.[73]

The title reagent is also useful for the condensation of allylic alcohols with enols. A classic example is the reaction of phytol in dioxane with 2-methyl-1,4-naphthohydroquinone 1-monoacetate to form the dihydro monoacetate of vitamin K_1 (eq 20), which can be easily oxidized to the quinone.[74]

R = H or COMe

(20)

$BF_3.OEt_2$ promotes fast, mild, clean regioselective dehydration of tertiary alcohols to the thermodynamically most stable alkenes.[75] 11β-Hydroxysteroids are dehydrated by $BF_3.OEt_2$ to give $\Delta^{9(11)}$-enes (eq 21).[76,77]

(21)

Epoxide Cleavage and Rearrangements.

The treatment of epoxides with $BF_3.OEt_2$ results in rearrangements to form aldehydes and ketones (eq 22).[78] The carbon α to the carbonyl group of an epoxy ketone migrates to give the dicarbonyl product.[79] The acyl migration in acyclic α,β-epoxy ketones proceeds through a highly concerted process, with inversion of configuration at the migration terminus.[80] With 5-substituted 2,3-epoxycyclohexanes the stereochemistry of the quaternary carbon center of the cyclopentanecarbaldehyde product is directed by the chirality of the 5-position.[81] Diketones are formed if the β-position of the α,β-epoxy ketone is unsubstituted. The 1,2-carbonyl migration of an α,β-epoxy ketone, 2-cycloheptylidenecyclopentanone oxide, occurs with $BF_3.OEt_2$ at 25 °C to form the cyclic spiro-1,3-diketone in 1 min (eq 23).[82]

$R^1 = Me, H; R^2 = Me, Ph$

The migration of the carbonyl during epoxide cleavage is used to produce hydroxy lactones from epoxides of carboxylic acids (eq 24).[83] α-Acyl-2-indanones,[84] furans,[85] and Δ^2-oxazolines[86] (eq 25) can also be synthesized by the cleavage and rearrangement of epoxides with $BF_3.OEt_2$. The last reaction has been conducted with sulfuric acid and with tin chloride, but the yields were lower. γ,δ-Epoxy tin compounds react with $BF_3.OEt_2$ to give the corresponding cyclopropylcarbinyl alcohols (eq 26).[87]

(25)

(26)

Remotely unsaturated epoxy acids undergo fission rearrangement when treated with $BF_3.OEt_2$. Hence, *cis* and *trans* ketocyclopropane esters are produced from the unsaturated epoxy ester methyl vernolate (eq 27).[88]

(27)

Epoxy sulfones undergo rearrangement with $BF_3.OEt_2$ to give the corresponding aldehydes.[89] α-Epoxy sulfoxides, like other negatively substituted epoxides, undergo rearrangement in which the sulfinyl group migrates and not the hydrogen, alkyl, or aryl groups (eq 28).[89]

(28)

α,β-Epoxy alcohols undergo cleavage and rearrangement with $BF_3.OEt_2$ to form β-hydroxy ketones.[90] The rearrangement is stereospecific with respect to the epoxide and generally results in *anti* migration. The rearrangement of epoxy alcohols with β-substituents leads to α,α-disubstituted carbonyl compounds.[91]

The $BF_3.OEt_2$-induced opening of epoxides with alcohols is regioselective, but the regioselectivity varies with the nature of the substituents on the oxirane ring.[92] If the substituent provides charge stabilization (as with a phenyl ring), the internal position is attacked exclusively. On the other hand, terminal ethers are formed by the regioselective cleavage of the epoxide ring of glycidyl tosylate.[92]

A combination of cyanoborohydride and $BF_3.OEt_2$ is used for the regio- and stereoselective cleavage of most epoxides to the less substituted alcohols resulting from *anti* ring opening.[93] The reaction rate of organocopper and cuprate reagents with slightly reactive epoxides, e.g. cyclohexene oxide, is dramatically enhanced by $BF_3.OEt_2$.[94] The Lewis acid and nucleophile work in a concerted manner so that *anti* products are formed.

Azanaphthalene *N*-oxides undergo photochemical deoxygenation reactions in benzene containing $BF_3.OEt_2$, resulting in amines in 70-80% yield;[95] these amines are important in the synthesis of heterocyclic compounds. ***Azidotrimethylsilane*** reacts with *trans*-1,2-epoxyalkylsilanes in the presence of $BF_3.OEt_2$ to produce (*Z*)-1-alkenyl azides.[96] The *cis*-1,2-epoxyalkylsilanes undergo rapid polymerization in the presence of Lewis acids.

Other Rearrangements.

$BF_3.OEt_2$ is used for the regioselective rearrangement of polyprenyl aryl ethers to yield polyprenyl substituted phenols, e.g. coenzyme Q_n.[97] The reagent is used in the Fries rearrangement; for example, 5-acetyl-6-hydroxycoumaran is obtained in 96% yield from 6-acetoxycoumaran using this reagent (eq 29).[98]

(29)

Formyl bicyclo[2.2.2]octane undergoes the retro-Claisen rearrangement to a vinyl ether in the presence of $BF_3.OEt_2$ at 0 °C (eq 30), rather than with HOAc at 110 °C.[99]

(30)

$BF_3.OEt_2$ is used for a stereospecific 1,3-alkyl migration to form *trans*-2-alkyltetrahydrofuran-3-carbaldehydes from 4,5-dihydrodioxepins (eq 31), which are obtained by the isomerization of 4,7-dihydro-1,3-dioxepins.[100] Similarly, α-alkyl-β-alkoxyaldehydes can be prepared from 1-alkenyl alkyl acetals by a 1,3-migration using $BF_3.OEt_2$ as catalyst.[101] *Syn* products are obtained from (*E*)-1-alkenyl alkyl acetals and *anti* products from the (*Z*)-acetals.

(31)

The methyl substituent, and not the cyano group, of 4-methyl-4-cyanocyclohexadienone migrates in the presence of $BF_3.OEt_2$ to give 3-methyl-4-cyanocyclohexadienone.[102] $BF_3.OEt_2$-promoted regioselective rearrangements of polyprenyl aryl ethers provide a convenient route for the preparation of polyprenyl-substituted hydroquinones (eq 32), which can be oxidized to polyprenylquinones.[103]

(32)

The (*E*)-(*Z*) photoisomerization of α,β-unsaturated esters,[104] cinnamic esters,[105] butenoic esters,[106] and dienoic esters[106] is catalyzed by $BF_3.OEt_2$ or ***Ethylaluminum Dichloride***. The latter two reactions also involve the photodeconjugation of α,β-unsaturated esters to β,γ-unsaturated esters. The BF_3.MeOH complex is used for the isomerization of 1- and 2-butenes to form equal quantities of *cis*- and *trans*-but-2-enes;[107] the $BF_3.OEt_2$-acetic acid complex is not as effective.

The complex formed with $BF_3.OEt_2$ and ***Epichlorohydrin*** in DMF acts as a catalyst for the Beckmann rearrangement of oximes.[108] Cyclohexanone, acetaldehyde, and *syn*-benzaldehyde oximes are converted into ε-caprolactam, a mixture of *N*-methylformamide and acetamide, and *N*-phenylacetamide, respectively.

The addition of $BF_3.OEt_2$ to an α-phosphorylated imine results in the 1,3-transfer of a diphenylphosphinoyl group, with resultant migration of the C-N=C triad.[109] This method is less destructive than the thermal rearrangement. The decomposition of dimethyldioxirane in acetone to methyl acetate is accelerated with $BF_3.OEt_2$, but acetol is also formed.[110] Propene oxide undergoes polymerization with $BF_3.OEt_2$ in most solvents, but isomerizes to propionaldehyde and acetone in dioxane.[111]

Hydrolysis.

$BF_3.OEt_2$ is used for stereospecific hydrolysis of methyl ethers, e.g. in the synthesis of (±)-aklavone.[112] The reagent is also used for the mild hydrolysis of dimethylhydrazones.[113] The precipitate formed by the addition of $BF_3.OEt_2$ to a dimethylhydrazone in ether is readily hydrolyzed by water to the ketone; the reaction is fast and does not affect enol acetate functionality.

Cleavage of Ethers.

In aprotic, anhydrous solvents, BF_3.MeOH is useful for the cleavage of trityl ethers at rt.[114] Under these conditions, *O*- and *N*-acyl groups, *O*-sulfonyl, *N*-alkoxycarbonyl, *O*-methyl, *O*-benzyl, and acetal groups are not cleaved.

$BF_3.OEt_2$ and iodide ion are extremely useful for the mild and regioselective cleavage of aliphatic ethers and for the removal of the acetal protecting group of carbonyl compounds.[115,116] Aromatic ethers are not cleaved, in contrast to other boron reagents. $BF_3.OEt_2$, in chloroform or dichloromethane, can be used for the removal of the *t*-butyldimethylsilyl (TBDMS) protecting group of hydroxyls, at 0-25 °C in 85-90% yield.[117] This is an alternative to ether cleavage with ***Tetra-n-butylammonium Fluoride*** or hydrolysis with aqueous ***Acetic Acid***.

In the presence of $BF_3.OEt_2$, dithio-substituted allylic anions react exclusively at the α-carbons of cyclic ethers, to give high yields of the corresponding alcohol products (eq 33).[118] The dithiane moiety is readily hydrolyzed with ***Mercury(II) Chloride*** to give the keto derivatives.

(33)

Inexpensive di-, tri-, and tetramethoxyanthraquinones can be selectively dealkylated to hydroxymethoxyanthraquinones by the formation of difluoroboron chelates with $BF_3.OEt_2$ in benzene and subsequent hydrolysis with methanol.[119] These unsymmetrically functionalized anthraquinone derivatives are useful intermediates for the synthesis of adriamycin, an antitumor agent. 2,4,6-Trimethoxytoluene reacts with cinnamic acid and $BF_3.OEt_2$, with selective demethylation, to form a boron heterocycle which can be hydrolyzed to the chalcone aurentiacin (eq 34).[120]

(34)

Reductions.

In contrast to hydrosilylation reactions catalyzed by metal chlorides, aldehydes and ketones are rapidly reduced at rt by ***Triethylsilane*** and $BF_3.OEt_2$, primarily to symmetrical ethers and borate esters, respectively.[121] Aryl ketones like acetophenone and benzophenone are converted to ethylbenzene and diphenylmethane, respectively. Friedel-Crafts acylation-silane reduction reactions can also occur in one step using these reagents; thus ***Benzoyl Chloride*** reacts with benzene, triethylsilane, and $BF_3.OEt_2$ to give diphenylmethane in 30% yield.[121]

$BF_3.OEt_2$ followed by ***Diisobutylaluminum Hydride*** is used for the 1,2-reduction of γ-amino-α,β-unsaturated esters to give unsaturated amino alcohols, which are chiral building blocks for α-amino acids.[122] α,β-Unsaturated nitroalkenes can be reduced to hydroxylamines by ***Sodium Borohydride*** and $BF_3.OEt_2$ in THF;[123,124] extended reaction times result in the reduction of the hydroxylamines to alkylamines. Diphenylamine-borane is prepared from sodium borohydride, $BF_3.OEt_2$, and diphenylamine in THF at 0 °C.[125] This solid is more stable in air than BF_3.THF and is almost as reactive in the reduction of aldehydes, ketones, carboxylic acids, esters, and anhydrides, as well as in the hydroboration of alkenes.

Bromination.

$BF_3.OEt_2$ can catalyze the bromination of steroids that cannot be brominated in the presence of HBr or sodium acetate. Hence, 11α-bromoketones are obtained in high yields from methyl 3α,7α-diacetoxy-12-ketocholanate.[126] Bromination (at the 6α-position) and dibromination (at the 6α- and 11α-positions) of methyl 3α-acetoxy-7,12-dioxocholanate can occur, depending on the concentration of bromine.[127]

A combination of $BF_3.OEt_2$ and a halide ion (tetraethylammonium bromide or iodide in dichloromethane or chloroform, or sodium bromide or iodide in acetonitrile) is useful for the conversion of allyl, benzyl, and tertiary alcohols to the corresponding halides.[128,129]

Diels-Alder Reactions.

$BF_3.OEt_2$ is used to catalyze and reverse the regiospecificity of some Diels-Alder reactions, e.g. with *peri*-hydroxylated naphthoquinones,[130] sulfur-containing compounds,[131] the reaction of 1-substituted *trans*-1,3-dienes with 2,6-dimethylbenzoquinones,[132] and the reaction of 6-methoxy-1-vinyl-3,4-dihydronaphthalene with *p*-quinones.[133] $BF_3.OEt_2$ has a drastic effect on the regioselectivity of the Diels-Alder reaction of quinoline- and isoquinoline-5,8-dione with piperylene, which produces substituted azaanthraquinones.[134] This Lewis acid is the most effective catalyst for the Diels-Alder reaction of furan with methyl acrylate, giving high *endo* selectivity in the 7-oxabicyclo[2.2.1]heptene product (eq 35).[135]

(35)

α-Vinylidenecycloalkanones, obtained by the reaction of ***Lithium Acetylide*** with epoxides and subsequent oxidation, undergo a Diels-Alder reaction at low temperature with $BF_3.OEt_2$ to form spirocyclic dienones (eq 36).[136]

(36)

Other Reactions.

The 17-hydroxy group of steroids can be protected by forming the THP (*O*-tetrahydropyran-2-yl) derivative with 2,3-dihydropyran, using $BF_3.OEt_2$ as catalyst;[137] the yields are higher and the reaction times shorter than with *p*-toluenesulfonic acid monohydrate.

$BF_3.OEt_2$ catalyzes the decomposition of β,γ-unsaturated diazomethyl ketones to cyclopentenone derivatives (eq 37).[138,139] Similarly, γ,δ-unsaturated diazo ketones are decomposed to β,γ-unsaturated cyclohexenones, but in lower yields.[140]

(37)

$BF_3.OEt_2$ is an effective reagent for debenzyloxycarbonylations of methionine-containing peptides.[141] Substituted 6*H*-1,3-thiazines can be prepared in high yields from $BF_3.OEt_2$-catalyzed reactions between α,β-unsaturated aldehydes, ketones, or acetals with thioamides, thioureas, and dithiocarbamates (eq 38).[142]

(38)

α-Alkoxy ketones can be prepared from α-diazo ketones and primary, secondary, and tertiary alcohols using $BF_3.OEt_2$ in ethanol.[143] Nitrogen is released from a solution of α-***Diazoacetophenone*** and $BF_3.OEt_2$ in ethanol to give α-ethoxyacetophenone.[143]

Anti-diols can be formed from β-hydroxy ketones using ***Tin(IV) Chloride*** or $BF_3.OEt_2$.[144] The hydroxy ketones are silylated, treated with the Lewis acid, and then desilylated with ***Hydrogen Fluoride***. *Syn*-diols are formed if ***Zinc Chloride*** is used as the catalyst.

$BF_3.OEt_2$ activates the formal substitution reaction of the hydroxyl group of γ- or δ-lactols with some organometallic reagents (M = Al, Zn, Sn), so that 2,5-disubstituted tetrahydrofurans or 2,6-disubstituted tetrahydropyrans are formed.[145]

A new method of nitrile synthesis from aldehydes has been discovered using *O*-(2-aminobenzoyl)hydroxylamine and $BF_3.OEt_2$, achieving 78-94% yields (eq 39).[146]

(39)

Carbonyl compounds react predominantly at the α site of dithiocinnamyllithium if $BF_3.OEt_2$ is present, as the hardness of the carbonyl compound is increased (eq 40).[147] The products can be hydrolyzed to α-hydroxyenones.

(40)

Optically active sulfinates can be synthesized from sulfinamides and alcohols using $BF_3.OEt_2$.[148] The reaction proceeds stereospecifically with inversion of sulfinyl configuration; the mild conditions ensure that the reaction will proceed even with alcohols with acid-labile functionality.

Related Reagents.

See entries for other Lewis acids, e.g. ***Zinc Chloride***, ***Aluminum Chloride***, ***Titanium(IV) Chloride***; also see entries for ***Boron Trifluoride*** (and combination reagents), and combination reagents employing boron trifluoride etherate, e.g. ***n-Butyllithium-Boron Trifluoride Etherate***, ***Cerium(III) Acetate-Boron Trifluoride Etherate***, ***Lithium Aluminum Hydride-Boron Trifluoride Etherate***, ***Methylcopper-Boron Trifluoride Etherate***

Boron Trifluoride[1]

[7637-07-2] · BF_3 · Boron Trifluoride · (MW 67.81)

(strongly oxophilic Lewis acid)

Physical Data: gas, mp -127 °C; bp -100 °C/35 mmHg.[1,2]

Solubility: very sol water, and forms a mono- and dihydrate; it is only partially hydrolyzed to fluoroboric acid. Also sol most organic solvents such as pentane; forms complexes with compounds that contain heteroatoms with lone pair electrons.

Form Supplied in: gas in cylinders or lecture bottles; widely available.

Preparative Method: made by heating calcium fluoride with boron trioxide or from potassium fluoroborate with concentrated sulfuric acid. The product may be contaminated by silicon tetrafluoride unless the starting materials are free from silicon.[1b,2]

Purification: via distillation and aromatic addition compound formation.[40]

Handling, Storage, and Precautions: a monel metal valve or stainless steel regulator is recommended. Extremely moisture sensitive; should be used with carefully dried apparatus. Irritant, slowly hydrolyzes to give HF. All work must be carried out in an efficient fume hood.

Introduction.

Boron trifluoride acts as a Lewis acid but its major reactivity relates to the fact that the boron reagent is oxophilic, whereas ***Aluminum Chloride*** is mostly known for its reactions with halides.[3] Thus many of the reactions of boron trifluoride involve alcohols, ethers, carboxylic acids, and esters; the water which is frequently eliminated coordinates with the boron trifluoride. Esters are formed in the presence of boron trifluoride by the interaction of acids with alcohols,[4] acids with ethers,[5] and amides with alcohols and phenols.[6] Thus phenyl acetate is rapidly formed when phenol and acetamide are treated with boron trifluoride. Propene, in the presence of boron trifluoride, reacts with carboxylic acids to form isopropyl esters,[7] and with phenol to form the isopropyl ether.[8] When salicylic acid is treated with boron trifluoride and then propene the ester, isopropyl salicylate, is formed rapidly. With an excess of propene, isopropyl 2-hydroxy-3,5-diisopropylbenzoate is formed in an almost quantitative yield.[7] Ketones that are enolizable are converted into β-diketones in the presence of carboxylic anhydrides and boron trifluoride.[9] Similarly, phenyl alkyl

ethers afford alkyl phenols.[10,11] Benzidine and Beckmann rearrangements and the rearrangement of phenyl acetate to 4-hydroxyacetophenone have all been studied using boron trifluoride.[3] A number of the early investigations have been repeated.

Friedel-Crafts Alkylation Reactions.

Alcohols react with benzene[12] or naphthalene[13] to give alkylated products. The alkylation of benzene using cyclohexanol (eq 1) gives moderate yields, but no other alcohols give better results; for example, both 1-propanol and 2-propanol give mono- and 1,4-diisopropylbenzene in a combined yield of ca. 38%.[12a] The reactions of isobutanol with benzene in the presence of boron trifluoride, not unexpectedly, give *t*-butyl- and 1,4-di-*t*-butylbenzene.[12e] Similarly, naphthalene is alkylated in good yield using cyclohexanol (eq 2).[13]

(1)

(2)

The alkylation of aromatic hydrocarbons using alkyl fluorides has also been investigated. Although the reactivity of boron trifluoride is lower than that of the other boron halides, the yields are usually better when using the fluoride. Methyl, ethyl, propyl, isopropyl, *t*-butyl, and cyclohexyl fluorides were shown to alkylate aromatic compounds in good yields. For example, benzene and cyclohexyl fluoride give the expected product in 85% yield.[12b] Normally, alkylation does not occur using alkyl halides other than the fluorides, and mixed halides afford products containing halogen. Although the reaction of cyclohexyl fluoride was successful, an attempted reaction using cyclohexyl bromide with toluene was unsuccessful.[12b] The preparation of cumene in high yield can be achieved using 2-fluoropropane in a reaction with benzene (eq 3); the lack of reactivity of other halogens is exemplified by the reaction of 1-chloro-3-fluoropropane, in which the product is 1-chloro-2-phenylpropane, and by eq 4, where the bromine is retained using 1-bromo-2-fluoroethane.[14]

(3)

(4)

The use of alkenes as sources of the electrophiles involved in Friedel-Crafts alkylations has also been studied. In early examples the yields obtained were not as good as in alkylations using alcohols. For example, the yield of 2-cyclohexylnaphthalene is only 35% using cyclohexene.[13] On the other hand, the intramolecular alkylation of 1-(2-tolyl)-(*E*)-pent-3-ene gives 1,5-dimethyl-1,2,3,4-tetrahydronaphthalene in 95% yield, and the example shown in eq 5 was used in a synthesis of 1,3,6,8-tetramethyltriphenylene.[15] Related to this latter reaction, gaseous boron trifluoride has been shown to form a complex with nitromethane, which is particularly effective in catalyzing proton-initiated cascade cyclizations like the one shown in eq 6.[16]

(5)

(6)

Diastereoselective alkylation reactions of furans have been studied using diacetoxypyrrolidinones as sources of an

acyliminium ion. Good yields and some diastereoselection were observed when using ***Zinc Bromide*** or ***Chlorotrimethylsilane*** as the Lewis acid but, unfortunately, no diastereoselection was observed using boron trifluoride.[17]

Friedel-Crafts Acylation Reactions.

The acylation of particularly electron-rich aromatic compounds can be achieved by a number of procedures; the number of options available that allow formylations to be carried out are fewer. The Vilsmeier protocols apply only to nucleophilic aromatic substrates, for example indoles and pyrroles. Formylation reactions using carbon monoxide, hydrogen chloride, and aluminum chloride function as if ***Formyl Chloride*** were produced. It is known, however, that formyl chloride is unstable at temperatures above -60 °C. On the other hand, ***Formyl Fluoride***, which may be prepared by the interaction of anhydrous hydrogen fluoride with the mixed anhydride of formic and acetic acids, and removed as it is formed (bp -29 °C), has been used in conjunction with boron trifluoride. Alkylbenzenes are formylated at low temperatures. In an alternative procedure, formyl fluoride and boron trifluoride are passed into a solution of the aromatic hydrocarbon in carbon disulfide.[18] Thus benzene gives benzaldehyde (56%), mesitylene gives mesitaldehyde (70%), and naphthalene gives a 1:5 mixture of α- and β-naphthaldehydes.

In other acylation reactions, acyl fluorides and boron trifluoride afford ketones with better regioselectivity than that observed with aluminum chloride as the Lewis acid. A reaction of isobutyryl fluoride with 2-methylnaphthalene gives an excellent yield of the product shown in eq 7.[19]

(7)

Boron trifluoride can, however, give rise to difficulties as a result of side-chain acylation, as exemplified in eq 8.[20] Carboxylic acids have been used in reactions of phenols[21] and aryl ethers together with boron trifluoride. Dealkylation of an ether residue *ortho* to the introduced acyl group is frequently encountered, as in the synthesis of baeckeol (eq 9).[22] Advantage of this effect was also taken in a synthesis of the naturally occurring phenol aurentiacin, as shown in eq 10.[23]

(8)

(9)

(10)

Carbonyl Group and Related Transformations.

The conversion of aldehydes and ketones into the related *gem*-difluoro compounds is effected by treatment with ***Molybdenum(VI) Fluoride*** at rt in the presence of catalytic amounts of boron trifluoride. The yields with ketones are significantly better than with aldehydes.[24] The acylation of enolizable carbonyl compounds was mentioned in the introduction.[9] A checked procedure for the acetylation of acetone, which affords pentane-2,4-dione in 80-85% yield, has been reported.[25] In general, it has been established that better yields of β-diketones are obtained if the intermediate boron difluoride complexes are isolated.[26] The boron difluoride complexes, isolated in yields of 75-92%, give the β-diketones in yields of 76-95%; the procedure is exemplified in eq 11. In another study, evidence was presented that implicated two mechanisms for the acetylation of ketones.[27] One route involves the formation of the enol acetate and the other involves the direct acetylation of the boron enolate. Thus the enol acetate derived from cyclohexanone is formed and isolated in 22% yield in a reaction in which cyclohexanone is allowed to interact with acetic anhydride in the presence of 14 mol % of boron trifluoride gas. The enol acetate was subsequently shown to afford 2-acetylcyclohexanone in 76% yield when treated with acetic anhydride and boron trifluoride. On the other hand, attempts to form the enol acetate from acetophenone were unsuccessful.

(11)

The alkylation of β-keto esters using an alcohol as the source of the electrophile can be effected by using boron trifluoride (eq 12).[28]

(12)

Beckmann rearrangements using boron trifluoride[3] have been investigated in more detail. For example, benzophenone oxime affords a 1:1 complex in 98% yield when boron trifluoride is passed into a solution of the oxime in light petroleum. The complex rearranges to *N*-phenylbenzamide in 83% yield when heated to 140-150 °C. The related benzophenone oxime *O*-methyl ether-boron trifluoride complex also gives *N*-phenylbenzamide at a lower temperature but in lower yield.[29] The isomerization of *syn*- to *anti*-arylaldoximes has also been reported via the boron trifluoride complexes.[30]

Cation-Assisted Rearrangement Reactions.

A number of interesting cyclization reactions leading to naturally occurring polycyclic ring systems have been investigated using boron trifluoride. The cedrane ring system is formed (eq 13) when the enol acetate is treated as shown; reaction of the ketone with ***Methyllithium*** then gives racemic cedrol.[31] In a detailed study of the reactions of an acetoxymenthadiene (eq 14), it was shown that racemic camphor can be obtained in 90% yield when a 0.1 % solution in wet dichloromethane is treated with boron trifluoride at room temperature for 10 min. Lower yields are obtained when higher concentrations of the diene are used, and boron trifluoride etherate fails to afford any of the required product as do other Lewis acids.[32] A Lewis acid-assisted fragmentation followed by a 1,2-methyl shift, driven by the enolate, is involved in the terpene rearrangement leading to the nootkatane skeleton shown in eq 15.[33] Rearrangement reactions of glycidic esters have been studied using boron trifluoride and are found to proceed in high yields.[34] For example, ethyl β-phenylglycidate gives ethyl phenylpyruvate, isolated in 80% yield as the 2,4-dinitrophenylhydrazone.

Diels-Alder Reactions.

Lewis acid-catalyzed Diels-Alder reactions are well known, and a number of examples have been studied using boron trifluoride. The regioselectivity of the reaction of unsymmetrical dienes with unsymmetrically substituted quinones can be directed in favor of either regioisomer depending on the catalyst used. This is exemplified in eq 16.[35] The regioselectivity has been explained on the basis that boron is capable of forming a tetracoordinate complex, whereas tin can complex via the more basic oxygen and the adjacent methoxy group. The analogous reaction using piperylene (penta-1,3-diene) shows, as expected, slightly improved regioselectivity. A study of diastereoselective Diels-Alder reactions using acrylate esters of 3,4-*O*-methylene-β-D-arabinoside has involved the use of a number of Lewis acids, including boron trifluoride.[36]

Miscellaneous Reactions.

The nitration of benzene derivatives using methyl nitrate in nitromethane in the presence of a Lewis acid leads to the formation of significant amounts of chlorinated products when using chlorine-containing Lewis acids. Side-chain nitration is also a problem sometimes. On the other hand, the nitrations of tetra- and pentamethylbenzenes proceed efficiently when boron trifluoride is used. Pentamethylbenzene affords the nitro derivative in an almost quantitative yield and durene gives mononitrodurene in 97% yield. When using a 3:1 excess of methyl nitrate and boron trifluoride, durene converts quantitatively into dinitrodurene.[37]

The reduction of alcohols using a trialkylsilane in the presence of a protic acid can be complicated by skeletal rearrangement and alkene formation as a result of carbenium ion formation. This problem is significantly reduced when using boron trifluoride as the acid (eq 17).[38] The preparation of peptide isosteres (eq 18) and related model compounds (eq 19) is achieved by the reductive elimination of γ-oxygenated-α,β-unsaturated carboxylates using boron trifluoride complexes of alkenylcopper reagents.[38]

(18)

(19)

Finally, it is of interest to note that α-difluoroamino fluoroimines fragment to α-difluoroamino fluorides in dichloromethane in the presence of boron trifluoride (eq 20).[39]

Boron Triiodide[1]

BI_3

[13517-10-7] · BI_3 · Boron Triiodide · (MW 391.52)

(strong Lewis acid with labile, nucleophilic iodine atoms; cleaves ethers,[2] esters,[3] silanes,[4] halides,[5] and alcohols to alkyl iodides; reductively cleaves sulfonyl[6] and sulfinyl[7] groups to disulfides)

Physical Data: mp 50.5 °C; *d* 3.350 g cm^{-3}.

Solubility: sol hydrocarbons, CH_2Cl_2, $CHCl_3$, CCl_4, CS_2; reacts with oxygenated solvents.

Form Supplied in: volatile white solid (frequently has a pinkish color due to traces of I_2).

Preparative Methods: BI_3 of extremely high purity can be prepared in 25% yield by treating I_2 in heptane at 80 °C with KBH_4 (which has been recrystallized from H_2O).[8] Recrystallized $NaBH_4$ can also be used; if traces of chloride or bromide can be tolerated then $LiBH_4$ in hexane can be used.[9]

Purification: BI_3 has a vapor pressure similar to that of I_2 and can be purified by sublimation from Cu powder at 60 °C (in vacuo). Commercial material is usually contaminated with traces of other halides. While the presence of small amounts of BI_2Br and/or BI_2Cl does not usually interfere with most organic reactions, these impurities are not easily removed by sublimation or distillation.

Handling, Storage, and Precautions: use in a fume hood; reacts expositively with H_2O; traces of moisture result in the liberation of I_2 so the formation of any color indicates improper handling. BI_3 is also light sensitive; it photolyzes below 360 nm. It should be stored under an inert atmosphere in the dark.

Ether Cleavages.

All of the boron trihalides, except the fluorides, will cleave ethers with varying degrees of efficacy.[10] However, the nucleophilic character of iodine coupled with the strong Lewis acidity of boron makes boron triiodide the most potent of these reagents. It is a powerful reagent for the cleavage of C-O bonds in ethers, esters, and alcohols, resulting in the formation of alkyl iodides under mild conditions. Aryl alkyl ethers are cleaved to phenols (eq 1). Diaryl ethers are unreactive. BI_3 reacts at least an order of magnitude faster than ***Boron Tribromide*** in ether cleavages.[1] This is especially useful in the cleavage of the ethers of higher alkyl groups (eq 2).

(1)

(2)

The initial products of ether cleavage are the alkyl halide and a borate ester, $(RO)_3B$. The borate esters are usually inert to further displacement but, because the iodide is more nucleophilic than the other halides, warming the borate esters (60-80 °C) in the presence of BI_3 will result in the complete conversion of all the alkyl residues to iodides (eq 3).[2]

(3)

Other Cleavages.

Kabalka[3] and co-workers have shown that an attenuated form of BI_3, $BI_3.NEt_2Ph$, will cleave a variety of compounds containing C-O single bonds at elevated temperatures. Solutions of this reagent are prepared by reacting the commercially available amine-borane complex with I_2 in benzene at 80 °C for several hours. The reagent cleaves ethers,[11] esters,[3] and geminal diacetates.[11] Esters[3] are cleaved to an activated acyl intermediate RCOX which can be used to prepare acids, other esters, and amides (eq 4).

(4)

$R^1 = Ph,\ o\text{-}C_6H_4OH,\ o\text{-}C_6H_4Br,\ C_3H_7,\ \text{-}(CH_2)_2\text{-}CH{=}CH_2$

$R^2 = Me,\ Et,\ Bu,\ Bn$

$H\text{-}Z = H_2O,\ MeOH,\ EtOH,\ PhNH_2,\ PhCH_2NH_2$

Sulfinyl and sulfonyl compounds react with BI_3[6] and $BI_3.NEt_2Ph$[7] to afford disulfides (eq 5).

Sulfoxides are deoxygenated by $BI_3.NEt_2Ph$.[7] Sulfides are also cleaved by BI_3. Methionine reacts to yield a complex mixture of C-S bond cleavage products including homocysteic acid, homoserine, and homoserine lactone.[12]

Substitution Reactions.

As a powerful electrophile, BI_3 will effect aromatic and aliphatic substitution reactions on alkyl and aryl halides and silanes (eq 6).[4] Alkyl halides (R-Cl and R-Br) also undergo substitutions reactions in CH_2Cl_2 and CCl_4 solution, producing iodides without alkyl rearrangement. In CCl_4 the reaction is second order in alkyl halide.[5] At elevated temperatures the *ipso* substitution of aryl iodides occurs readily, resulting in borinic iodides eq 7).[13] The direct borylation of benzene is a photochemical process which most likely involves the formation of I&bdot; and I_2B&bdot; radicals (eq 8).[14]

Boron Tris(trifluoroacetate)[1]

$B(OCOCF_3)_3$

[350-70-9] · $C_6BF_9O_6$ · Boron Tris(trifluoroacetate) · (MW 349.86)

(mild Lewis acid)

Alternate Name: tris(trifluoroacetoxy)borane.

Physical Data: mp 88 °C (dec).

Solubility: decomposes in water exothermically; sol organic solvents.

Preparative Methods: obtained in quantitative yield by the interaction of BCl_3 or BBr_3 with trifluoroacetic acid.[2]

Handling, Storage, and Precautions: extremely corrosive to the eyes and skin. If swallowed causes severe internal irritation and damage. Toxic irritating vapor. All work must be carried out in an efficient fume hood.

Deprotection of the N-Terminus of Amino Acids and Peptides.

The major use of tris(trifluoroacetoxy)borane has been to remove protecting groups used during the synthesis of peptides and α-amino acids.[3] Although a number of boron-derived reagents, such as ***Boron Tribromide*** and ***Boron Triiodide***, are good reagents for the removal of the Z-group (benzyloxycarbonyl) from N-terminal residues in dichloromethane, the partial removal of ester groups has been reported. A further disadvantage is that dichloromethane is not a good solvent for long peptides. On the other hand, the hydroxy groups of serine or threonine and the thiol residue of cysteine are reported not to be attacked by the boron halides. The original communication indicated that a number of important functional groups were unaffected by tris(trifluoroacetoxy)borane.[3] The groups included methyl and ethyl esters, methyl ethers, and the amide bond. Benzyl esters were reported, however, to be deprotected. An example is shown in eq 1, in which it was pointed out that optical purity was maintained, but the presence of acid-sensitive groups precludes the use of this method.[4]

Since the first report, tris(trifluoroacetoxy)borane has been used in a number of peptide syntheses, for example the synthesis of the peptide fragment of the human myelin basic protein.[5] The method has been particularly useful in the final removal of protecting groups in those syntheses using the Merrifield technique.[6] The deprotection of side chains in peptides required in an investigation of human dihydrofolate reductase used the method successfully.[7] Protection with the Z-group and eventual deprotection has been used in structure elucidation, for example in the case of the peptide antibiotics herbicolin A and B.[8] In general, there have been few problems reported concerning the use of tris(trifluoroacetoxy)borane. However, although the deprotection shown in eq 2 was achieved very efficiently, the analog in which the unnatural tryptophan was present gave rise to a complex mixture.[9]

A synthesis of new inhibitors of enkephalin metabolism with improved protection from in vivo enzymic degradation has involved the modification of the C-terminal amino acid by the incorporation of a β-amino acid residue.[10] For the *N*-methyl derivative shown in eq 3, the *t*-butyl ester was removed using tris(trifluoroacetoxy)borane with simultaneous deprotection of the hydroxyamino group.

In the total synthesis of the antitumor antibiotic acivicin, an α-amino acid, the protective group removal was effected in 56% yield by using ***Boron Trichloride***.[11a] However, when tris(trifluoroacetoxy)borane was used to remove the Z-group and to cleave the oxazolidinone ring, the yield in the final step was improved to 89% (eq 4).[11b]

Friedel-Crafts Reactions.

The other use of tris(trifluoroacetoxy)borane has been in Friedel-Crafts reactions.[12] In principle the reagent can function as an acylating agent, but only in the case of a reaction using mesitylene (eq 5) did the reaction stop at that stage and afford 2,4,6-trimethyltrifluoroacetophenone (**1**). It is presumed that this effect is related to a steric problem. With benzene a low yield of 1,1,1-trifluoro-2,2,2-triphenylethane was obtained, but with a more nucleophilic aromatic compound such as anisole, a 90% yield of 1,1,1-trifluoro-2,2,2-tris(*p*-methoxyphenyl)ethane (**2**) was obtained (eq 6). With even more nucleophilic substrates, such as 1,3-dimethoxybenzene and phenol, the 1,1-diaryl-2,2,2-trifluoroethanol derivative was obtained. In the example shown, the product (**3**) was isolated in 82% yield (eq 6).

Boron Trisulfide

B_2S_3

[12007-33-9] · B_2S_3 · Boron Trisulfide · (MW 117.80)

(sulfuration agent of carbonyl to thiocarbonyl group;[1] sulfuration agent of phosphine oxide to phosphine sulfide;[8] dehydrogenating agent;[11] synthetic reagent for boroles[14])

Physical Data: monoclinic colorless crystals; mp 563 °C (dec); *d* 1.55 g cm^{-3}.

Solubility: sol ethanol, but decomposes.

Form Supplied in: white solid.

Handling, Storage, and Precautions: the dry solid is very flammable under air and immediately reacts with water to give boric acid and hydrogen sulfide.

Sulfuration Agent of Carbonyl to Thiocarbonyl Functional Group.

Boron trisulfide is used as a sulfuration agent in synthetic chemistry; it is especially efficient for the conversion of carbonyl to thiocarbonyl. 1,3,4,6-Tetrathiapentalene-2,5-dione is sulfurized with boron trisulfide in toluene under reflux to give a mixed carbonyl-thiocarbonyl compound. When a solid mixture of 1,3,4,6-tetrathiapentalene-2,5-dione and boron trisulfide is heated at 100 °C for long time, 1,3,4,6-tetrathia-2,5-dithione is formed as a yellow solid (eq 1).[1]

(1)

Boron trisulfide has advantages over ***Phosphorus(V) Sulfide*** for converting non-enolizable ketones such as 2-pyrones and 4-pyrones to the corresponding thiones (eq 2).[2] Boron trisulfide is very active and often effective at rt. 4-Selenapyranthione is formed from 4-selenapyranone by treating with boron trisulfide in chloroform (eq 3).[3]

(2)

(3)

The reaction of boron trisulfide with aromatic aldehydes and aliphatic aldehydes gives a good yield of the corresponding thioaldehyde trimer via the monomer (eq 4).[4]

(4)

Steliou has reported that the treatment with ***Bis(tricyclohexyltin) Sulfide-Boron Trichloride*** converts carbonyls into the thiocarbonyl analogs in high yield. The intermediate formation of boron trisulfide has been postulated. This sulfurating method is efficient even with highly hindered ketones inert to direct sulfuration (eq 5).[5] The yields of the thiocarbonyl compounds obtained are shown in Table 1.

Table 1 Sulfuration of Various Carbonyl Compounds using Bis(tricyclohexyltin) Sulfide

Carbonyl compound	Yield (%)	Carbonyl compound	Yield (%)
Trimethylacetaldehyde	65	2-Adamantanone	72
Benzaldehyde	85	(±)-Camphor	95
p-Anisaldehyde	95	(-)-Fenchone	90
p-Nitobenzaldehyde	83	Coumarin	94
4,4¢Bis(dimethylamino) benzophenone	90	Pentacyclo[6.2.1.$0^{2,7}$.$0^{5,9}$]-undecane-3,6-dione	84
Di-*t*-butyl ketone	65	1,4-Diphenyl-3-methyl-2-azetidinone	90
e-Caprolactam	92		

Some orthoesters are also conveniently sulfurized with boron trisulfide to give the corresponding thioesters (eq 6).[6]

(6)

When methyl benzoate and boron trisulfide are refluxed under nitrogen for 28 h, the sulfurized cyclization product 2,3,4,5-tetraphenylthiophene is obtained (eq 7).[4,7] Boron trisulfide reacts with acyl complexes $(C_5H_5)Fe(CO)_2COR$ to give dithiocarboxylate complexes $(C_5H_5)Fe(CO)_2SCSR$ and $(C_5H_5)Fe(CO)SSCR$. Generally, the reactions with boron trisulfide are faster than those with phosphorus pentasulfide (eq 8).[8]

(7)

(8)

Sulfuration Agent for Other Compounds.

Boron trisulfide transforms tertiary phosphine oxides into the corresponding phosphine sulfides with net retention of configuration at phosphorus (eq 9).[9] Sulfoxides are reduced to give sulfides, presumably through an intermediate sulfothioxide (eq 10).[10]

(9)

R	R¹	R	R¹
Me	Me	Ph	Pr
Me	Bn	Ph	Bn
Bn	Bn	Ph	Ph
Me	Ph	*p*-Tol	*p*-Tol

Dehydrogenating Agent.

Boron trisulfide behaves as a dehydrogenating agent with organic molecules containing labile hydrogens such as alcohols[11] and thiols[12] to give the corresponding orthoester and orthothioester. Moreover, several nitrogen bases, e.g. aniline and *N*,*N*-dimethylhydrazine, react with boron trisulfide under nitrogen in the dark to form tris(phenylamino)boron and tris(*N*,*N*-dimethylhydrazo)boron respectively (eq 11).[13] Catechol also reacts with boron trisulfide to give 2,2´-*o*-phenylenedioxybis(1,3,2-benzodioxaborole), while only the hydroxy function of salicylic acid reacts to give a quantitative yield of tris(*o*-carboxylphenoxy)borane. Phthalic acid, succinic acid, and maleic acid are not sulfinated by boron trisulfide (eq 12).[14]

Related Reagents.

2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide; ***Bis(tricyclohexyltin) Sulfide-Boron Trichloride***; ***Bis(trimethylsilyl) Sulfide***.

Bromine[1]

[7726-95-6] · Br_2 · Bromine · (MW 159.81)

(powerful brominating and oxidizing agent; can initiate/participate in ring cleavage and rearrangement)

Physical Data: mp -7 °C; bp 59 °C; *d* 3.12 g cm^{-3}.

Solubility: sol H_2O, acetic acid, alcohol, ether, chloroform, carbon tetrachloride, carbon disulfide, hydrocarbon solvents (pentane, petroleum ether).

Form Supplied in: dark, red-brown, volatile liquid; also available as a 1 M solution in carbon tetrachloride.

Analysis of Reagent Purity: by iodometric titration.[79]

Purification: several methods have been described.[80]

Handling, Storage, and Precautions: bromine is an extremely corrosive and toxic reagent in both liquid and vapor form. As a liquid, it produces painful burns and blisters when spilled on the skin. Such burns should be flushed with water and neutralized with a 10% solution of sodium thiosulfate in water. Medical attention should be sought immediately. Protective clothing is therefore a must, including laboratory coat and apron, protective gloves, and a full-face respirator equipped with a NIOSH-approved organic vapor-acid gas canister. Bromine should be stored in a cool, dry area. It is incompatible with combustibles, liquid ammonia, alkali hydroxides, metals (including aluminum, mercury, magnesium, and titanium), and some types of rubber and plastic.[2] Use in a fume hood.

Halogenations.

Bromine is a very powerful brominating agent that has found utility in a variety of systems. While the bromination of alkanes is usually not a viable synthetic method,[3] alkylbenzenes can be brominated at the benzylic position under radical conditions (eq 1).[4] ***N-Bromosuccinimide*** (NBS) can also be used for this transformation.

(1)

Electrophilic aromatic substitution occurs in the presence of Lewis acids to provide brominated aromatics.[5] Monobromination usually occurs due to the deactivating nature of the bromine. However, highly reactive aromatics, such as phenols, anilines, and polyalkylbenzenes, are frequently polybrominated, even in the absence of catalysts.

Bromine has been used in the bromination of heterocycles. However, the unique reactivity patterns of each heterocyclic ring system create a discussion beyond the scope of this review. The reader is directed to reviews on the subject.[1a,6]

The addition of bromine to alkenes[7] proceeds with formation of the cyclic bromonium ion (**1**), which can then be intercepted by an anionic species (Y^-), to give the product derived from *anti* addition (eq 2). In the case of bromine itself, this gives rise to *trans* vicinal dibromides (eq 2; Y = Br). Variations from ideality are not uncommon due to weakened, unsymmetrical bridging in the bromonium ion (eq 3),[8] transannular interactions (eq 4),[9] and substrates susceptible to rearrangements. Brominations in the presence of crown ethers[10] and zeolites[11] have been investigated to improve selectivity. Conjugated dienes give predominantly 1,4-addition, while alkynes are less susceptible to electrophilic attack.[12]

(2)

(3)

(4)

The addition of bromine to alkenes has been used as the first step in the oxidation of alkenes to 1,3-butadienes (eqs 5 and 6).[13,14] Alkenes can also be protected[15] or purified[16] by bromination and subsequent regeneration of the double bond.

(5)

(6)

Alkenes bearing an electron-withdrawing group at one terminus are frequently converted to the α-bromo analogs via a bromination/dehydrobromination sequence (eqs 7 and 8).[17,18]

(7)

(8)

Cyclic bromonium ions (**1**) can be opened by a variety of other nucleophiles. Thus bromination of alkenes in aqueous systems can lead to bromohydrins. However, NBS has been shown to be superior to bromine for this transformation, presumably due to the minimization of competing bromide ion in the reaction mixture.[19] Alcohols react to give vicinal bromo ethers, in both inter- and intramolecular fashion (eq 9).[20]

(9)

Bromolactonization of alkenic acids has been the subject of extensive investigation.[21] Cyclizations can be performed on the carboxylic acid salts as well as the free acids. Thallium(I) salts have proven to be especially efficacious.[21b,22] Treatment of the mercury(II) salts with bromine proceeds via a radical mechanism and provides the expected products in substrates where normal bromolactonization conditions lead to rearrangement (eq 10).[23] Other sources of electrophilic bromine can also give different products (eq 11).[21b]

(10)

(11)

The enol lactonization of alkynic acids can be performed to give either the (*E*)- or (*Z*)-bromo enol isomers depending on reaction conditions (eq 12).[24]

(12)

Alkenic amides cyclize under standard conditions to form lactones rather than lactams.[25] Bromolactamization can be achieved, however, by introduction of substituents on the amide nitrogen that serve to lower its pK_a (eqs 13 and 14).[26,27]

(13)

(14)

R = Me, *cis*:*trans* = 23:77
R = CbzNH, *cis*:*trans* = 70:30

Electron-rich alkenes, such as enol ethers[28] and enamines,[29] can be brominated to furnish the β-bromo compounds (eq 15).

(15)

Bromine has been used for brominations α to carbonyl groups.[30] Carboxylic acids are brominated in the presence of phosphorus or phosphorus trihalides in the classical Hell-Volhard-Zelinski reaction (eq 16).[31] Variations on this include brominations in thionyl chloride[32] and in polyphosphoric acid.[33] The less reactive carboxylic esters are frequently converted to the acid halide, α-brominated, and subsequently re-esterified in one pot.[34,35]

(16)

The bromination of ketones is believed to occur via acid-catalyzed enolization, followed by electrophilic attack on the enol form.[30] Unsymmetrical ketones can give rise to mixtures of bromo ketones due to mixtures of enols, and several approaches to overcome this shortcoming have been reported. Radical bromination in the presence of epoxides (as acid scavengers) allows for substitution at the more highly substituted position (eq 17).[36] Silyl enol ethers of aldehydes and ketones react with bromine (or NBS) to give the α-brominated carbonyl compounds (eq 18).[37] This, combined with the ability to regiospecifically prepare silyl enol ethers (kinetic vs. thermodynamic), makes for an extremely useful technique for the preparation of α-bromo carbonyl compounds.

(17)

hν, epoxide	100: 0
dark, no epoxide	60:40

(18)

Sulfoxides are best α-brominated with a combination of bromine and NBS in pyridine.[38]

Bromine has been used in the halogenation of organometallic reagents. Organomagnesium,[39] organolithium,[40] and organoaluminum[41] reagents react to give the compounds in which the metal has been replaced by bromine. Organoboranes can react with bromine in several ways. Bromination in the presence of sodium methoxide gives the corresponding alkyl bromides.[42] Photobromination (in the absence of strong base) gives an initial α-bromo organoborane that can either give the corresponding alkyl bromide[43] or rearrange to a new organoborane.[44] Organoboranes can also be converted to alkyl bromides in aqueous media.[45] Alkenic bromides have been prepared from alkenylboronic esters with inversion of configuration (eq 19).[46]

(19)

Enolates of ketones[47] and esters[48] can be brominated by treatment with bromine (eq 20), as can the anions of terminal alkynes.[49] The high reactivity of bromine, however, is sometimes a problem; milder sources of electrophilic bromine (such as ***1,2-Dibromoethane***) are occasionally used in its place.

(20)

Oxidations.

Bromine reacts with secondary alcohols to give ketones. Since ketones are subject to bromination themselves (see above), the α-bromo ketones can sometimes be undesirable byproducts. However, in cases where there are no α-protons, this can provide an excellent method of oxidation (eq 21).[50]

(21)

Primary alcohols are oxidized to either aldehydes or, more commonly, esters. An especially attractive corollary to this involves the oxidation of acetals to esters (eq 22).[51]

(22)

The addition of coreactants has provided a number of selective bromine-based oxidants. Both bromine/***Hexamethylphosphoric Triamide*** (HMPA)[52] and bromine/***Bis(tri-n-butyltin) Oxide*** (HBD)[53] have shown a preference for the oxidation of secondary vs. primary alcohols (eq 23), while bromine/nickel carboxylates[54] convert 1,4-diols to γ-butyrolactones by selective oxidation of the primary alcohols (eq 24).

(23)

(24)

Tetrahydrofurans have been prepared from alcohols or diols by bromine/silver(I) salts (eq 25)[55] or bromine/DMSO,[56] respectively.

(25)

Bromine has demonstrated its superiority in the oxidation of enediol bis-trimethylsilyl ethers to α-diketones (eq 26).[57]

(26)

A number of other functional groups are oxidized by bromine; however, they do not appear to have gained widespread use. These include cyclohexenones,[58] ethers,[59] hydrazines,[60] oximes,[61] tertiary amines,[62] thiols,[63] sulfides,[64] and organoselenium reagents.[65]

Rearrangements.

Bromine reacts with a number of functional groups to effect bond cleavage or other skeletal rearrangements. In the classical Hofmann rearrangement,[66] treatment of primary amides with bromine in the presence of base gives isocyanates, carbamates, or amines, depending on the reaction conditions (eq 27).[67]

(27)

In the Hunsdiecker reaction,[68] treatment of silver salts of carboxylic acids with bromine furnishes the alkyl(aryl) bromides with one less carbon atom. Improvements that do not require the preparation of the dry silver salts include the use of mercury(II) salts (Cristol-Firth modification) (eq 28),[69] thallium(I) salts,[70] and photostimulation.[71]

(28)

Three-membered rings are especially susceptible to reaction with bromine. Cyclopropanes are opened to give 1,3-dibromopropanes,[72] while cyclopropenylethanol derivatives rearrange in the presence of bromine to give 3-methylenetetrahydrofurans (eq 29).[73] Trimethylsilyl cyclopropyl ethers are opened to give β-bromo ketones (eq 30).[74] Epoxides can give either bromohydrins[75] or α-bromo ketones,[76] depending on the reaction conditions.

(29)

(30)

Mercury(II)-mediated cyclization of dienes allows access to bromine-containing natural products.[77] Thus, in the synthesis of aplysistatin, the key step was the cyclization of an acyclic precursor to the required bromoperhydro[1]benzoxepine ring system (eq 31).[78]

(31)

Bromine Azide[1]

BrN_3

[13973-87-0] · BrN_3 · Bromine Azide · (MW 121.92)

(used like ***Iodine Azide*** in additions to multiple bonds;[1-5] for introduction of the azide function;[1-5] in synthesis of aziridines,[3,6,7] vinyl azides,[4a] and azirines[7])

Alternate Name: azido bromide.

Physical Data: orange-red liquid, mp -45 °C;[1b] explosive when neat;[8] therefore should be prepared in situ in solution. Odor resembles that of the free halogen.

Solubility: sol most organic solvents.

Analysis of Reagent Purity: by titrimetric analysis.[1b]

Preparative Methods: BrN_3 is not available commercially, but can be prepared in situ from NaN_3, Br_2, and HCl, preferably in CH_2Cl_2 or ether.[2] It can also be prepared from NBS, HN_3, and *t*-BuOH in $CHCl_3$[3a] or from NBS and NaN_3 in DME-H_2O.[3b] Typical procedure for addition to alkenes:[2] to a well-stirred slurry of 32.5 g (0.5 mol) of NaN_3 in 100 mL of CH_2Cl_2 (or pentane) at 0 °C add 25 mL of 30% aq HCl, followed by 8.0 g (0.1 mol) of Br_2. After 30-60 min of further stirring, decant and dry the organic layer. Add 0.1 mol of alkene in $MeNO_2$ (ionic addition) or pentane (radical addition). Warm the mixture to 20 °C and stir for 8-24 h, then wash in turn with water and 5% aq sodium thiosulfate until colorless, and chromatograph (neutral alumina) or crystallize to afford the bromoazide adduct in 35-95% yield.

Handling, Storage, and Precautions: explosive liquid[1b] (see ***Iodine Azide***); use in a fume hood. After reaction with multiple bonds, the mixture should be washed with sodium bisulfite until colorless, to destroy excess BrN_3. Dilute solutions of BrN_3 in organic solvents can generally be handled safely.[1b] Keep away from strong reducing agents.

Additions to Alkenes.

Additions of BrN_3 to alkenes are much more influenced by solvent polarity than additions of IN_3 and lead to different regioisomeric adducts, depending upon the polarity of the solvent. Ionic additions, proceeding via a three-membered ring bromonium species, are achieved in polar solvents, such as $MeNO_2$-CH_2Cl_2, or in the presence of acid catalysts

and are usually stereospecific for aliphatic alkenes. Radical additions proceed by N_3 radical attack on the C=C double bond and are favored in nonpolar solvents such as pentane, in the presence of light or radical initiators, or when the reaction mixture is purged with N_2 to remove O_2, a radical inhibitor. Thus styrene reacts with BrN_3 in $MeNO_2$ to produce the regioisomer opposite to that formed in pentane solution (eq 1).[2]

Such differences also exist for the behavior of IN_3 vs. BrN_3. Thus while IN_3 addition in MeCN to benzo[*b*]thiophene 1,1-dioxide leads to the *trans*-3-azido-2-iodo adduct, BrN_3 addition in CH_2Cl_2 affords the *trans*-2-azido-3-bromo product.[9]

In polar solvents the addition of BrN_3 to simple alkenes, such as *cis*- and *trans*-2-butene, proceeds stereospecifically *anti*.[2] Steroid 2-enes[2] and 5-enes[3a] afford the β-azido-α-bromo diaxial adducts via α-bromonium species, while radical addition to 2-cholestene gives a mixture of regioisomers (eq 2).

On the other hand, BrN_3 additions to steroid enones can lead to α-azido-β-bromo steroids or to *cis* adducts. Thus podocarp-6-enes give 7α-azido-6β-bromo adducts.[5b]

Enol ethers lead to formation of α-azido ethers as a mixture of stereoisomers.[2] However, reaction of sugar 2-enes with BrN_3 in the presence of ***Dibenzoyl Peroxide*** (radical reaction) led, after treatment with ***Mercury(II) Acetate***, to formation of 2-acetoxy-3-azido sugars.[10]

Aromatic or other substituents on a double bond, which can stabilize a positive charge well, can lead to a mixture of stereoisomers.[2b] In polar nucleophilic solvents (MeCN, DMF, HOAc, MeOH), reaction of BrN_3 with alkenes leads to solvent participation (eq 3).[11]

(3)

While ionic addition of BrN_3 to 3,3,3-triphenylpropene proceeds with phenyl migration, the radical addition to this alkene gives mainly the unrearranged product.[12]

Addition of BrN_3 to allenes at -65 °C leads, like IN_3, to a mixture of allylic azides, while addition at rt apparently proceeds via radicals to afford an unstable vicinal diazide.[13]

Synthesis of Aziridines.

BrN_3 addition to alkenes, followed by reduction with LAH or Ph_3P-H_2O, is a convenient method for the synthesis of aziridines (eq 4).[3,14]

(4)

Synthesis of Vinyl Azides and Azirines.

Bases, like ***Potassium t-Butoxide***, cause stereospecific elimination of HBr from the adducts; the resulting vinyl azides[4a] provide useful routes for the synthesis of azirines or ketones, or for amination of aromatic compounds (see ***Iodine Azide***).

Bromine-*t*-Butylamine

Br_2.*t*-$BuNH_2$

(Br_2)

[7726-95-6] · Br_2 · Bromine-*t*-Butylamine · (MW 159.81) (*t*-$BuNH_2$)

[75-64-9] · $C_4H_{11}N$ · Bromine-*t*-Butylamine · (MW 73.14)

(reagent for *ortho* bromination of phenols[1])

Alternate Name: bromine-2-methyl-2-propylamine.

Solubility: sol toluene.

Preparative Method: prepared in situ by addition of bromine to a solution of *t*-butylamine in toluene at -20 to -30 °C.

Handling, Storage, and Precautions: bromine-*t*-butylamine is prepared in situ, and is not generally stored. No particular hazards have been reported for this reagent combination (other than the corrosivity and toxicity hazards associated with bromine and *t*-butylamine), but the 1:1 complex between bromine and trimethylamine has been reported[2] to explode when heated in a sealed tube. This reagent should be handled in a fume hood.

Ortho Bromination of Phenols.

The combination of ***Bromine*** and ***t-Butylamine*** has been used for the selective *ortho* bromination of phenols.[1,3] Little or no *para* bromination is usually observed. The yields are generally good when 2,6-dibromination is desired (eq 1)[1] or when one of the *ortho* positions is blocked (eq 2).[4]

(1)

(2)

For substrates in which both *ortho* positions are open (eq 3),[1] or for highly activated substrates (eq 4),[5] it is sometimes difficult to obtain monobrominated products. In these cases less than 1 equiv of bromine has often been employed. Yields are then calculated on moles of bromine used.

(3)

(4)

It has been speculated[1,6] that the source of selectivity with the Br_2.*t*-$BuNH_2$ reagent is due to the formation of a hypobromite intermediate which undergoes intramolecular bromine transfer.

An interesting use of the selective properties of this reagent is demonstrated in the chemoselective bromination of phenol (**1**) in the presence of a trisubstituted alkene to give bromide (**2**) in 85% yield. Compound (**2**) was used in a total synthesis of mycophenolic acid.[7]

(1) X = H
(2) X = Br

For other reagents useful for the *ortho* bromination of phenols see ***2,4,4,6-Tetrabromo-2,5-cyclohexadienone***.

Bromine Chloride

BrCl

[13863-41-7] · BrCl · Bromine Chloride · (MW 115.36)

(powerful brominating and/or bromochlorinating agent)

Physical Data: mp ca. -66 °C; bp ca. 5 °C.[1]

Solubility: sol H_2O, methylene chloride, chloroform, carbon tetrachloride, carbon disulfide, ether.

Form Supplied in: while bromine chloride (occasionally referred to incorrectly as chlorine bromide) is commercially available, it is more commonly prepared in the laboratory on demand.

Preparative Methods: these include the reaction of Br_2 and Cl_2 in solution;[2,3] reaction of HCl gas with either *N*-bromoacetamide (NBA)[4] or *N*-bromosuccinimide (NBS)[5] in halogenated solvents; reaction of NaBr with either Cl_2[6,7] or chloramine-T[7] in aqueous solution. Appropriate literature reference(s) should be consulted for particular applications.

Handling, Storage, and Precautions: as a source of positive halogen, all precautions associated with the use of halogens (see ***Bromine***, ***Chlorine***) should be observed. Protective clothing is a must, and in the case of gaseous BrCl (or preparations using corrosive gaseous reagents) the use of a respirator is advised. Use in a fume hood.

Bromination of Sulfones.

Bromine chloride has been used successfully in the photochemical bromination of sulfones. With 1 equiv of BrCl, tetrahydrothiophene 1,1-dioxide gave a 72% yield of the 2-bromo isomer, while diethyl sulfone gave a mixture due to α- and β-bromination.[2] Attempts to effect bromination using other conditions (***Bromine***, Br_2/Lewis acid, NaOBr, ***N-Bromosuccinimide***, dioxane dibromide) were unsuccessful. Thietane 1,1-dioxide (**1**) has been brominated in the 3-position (eq 1),[3,8] but the product was reported to be contaminated with some of the 3-chloro compound.[9]

(1)

Bromination of Aromatic Rings.

Bromine chloride has been used as an alternative to Br_2 in the electrophilic bromination of aromatic rings.[6] In this case, chlorine was not incorporated onto the ring.

Addition to Alkenes.

The addition of BrCl to alkenes is governed by a combination of steric and stereoelectronic effects.[5,10,11] Thus while (**2**) reacts with BrCl to give a mixture of isomers (eq 2), the sterically more demanding (**3**) gives a single compound (eq 3).[5a] Steroids, with their highly rigid framework, also demonstrate excellent regio- and stereoselectivity (eqs 4 and 5).[4,5]

(2)

(3)

(4)

(5)

Bromination of Organoboranes Under Ionic Conditions.

When organoboranes are treated in the dark with BrCl (or Br_2) in the presence of H_2O, good yields of alkyl bromides are obtained.[7] This method works best for the synthesis of primary bromides from terminal alkenes (eq 6). In this sense it complements the radical bromination of organoboranes, which has been shown to prefer secondary alkyl groups.

(6)

Related Reagents.

Bromine; ***N-Bromoacetamide***; ***N-Bromosuccinimide***; ***Chloramine-T***; ***Chlorine***; ***N-Chlorosuccinimide***; ***Sodium Bromide***.

Bromine-1,4-Diazabicyclo[2.2.2]octane

[5770-70-7] · $C_6H_{12}Br_4N_2$ · Bromine-1,4-Diazabicyclo[2.2.2]octane · (MW 431.79)

(mild oxidizing agent for oxidizing benzyl alcohols and secondary alcohols to benzaldehydes and ketones;[1] selectively oxidizes sulfides to sulfoxides;[2] oxidizes monothioacetals to aldehydes[3])

Alternate Name: DABCO.2Br_2; 1,4-diazabicyclo[2.2.2]octane, compound with Br_2.

Physical Data: mp 155-160 °C (dec).

Solubility: insol most organic solvents and water.

Form Supplied in: yellow amorphous solid (not commercially available).

Preparative Method: prepared by adding excess ***Bromine*** to solutions of ***1,4-Diazabicyclo[2.2.2]octane*** in benzene, carbon tetrachloride, or water[1-4] (95% yield obtained on 50 mmol scale).[4]

Handling, Storage, and Precautions: thermally stable in neutral or basic media; decomposes in acidic media. Nonhygroscopic and stable to air, water, and light. This reagent should be handled in a fume hood.

Introduction.

DABCO.2Br_2 is one of several complexes of halogens with amines, such as ***Chlorine-Pyridine***[5] and bromine/quinoline,[2] that are used as oxidants for organic molecules. This reagent is more convenient to use because it is readily prepared and is very stable to air, water, light, and basic media.[1-4] Acidic media decompose it. This stable complex allows for the more accurate measuring of active bromine, especially for small scale reactions. X-ray studies of DABCO.2Br_2 show that it exists as a novel complex of multiple

DABCO and bromine units.[6] Hudlický has reviewed this reagent and alternative oxidation reagents.[7]

Selective Oxidation of Alcohols.

DABCO.2Br_2 oxidizes benzyl alcohol and secondary aliphatic alcohols (eq 1) to benzaldehyde (97%) and ketones (36-71%) in acetonitrile or refluxing methylene chloride.[1] Primary alcohols are oxidized less readily (ca. 10%). Optimum yields are obtained after 3-6 h. Superior yields (62-100%), better selectivity, and shorter reaction times (2-60 min) are observed when bromine/HMPA is used as an oxidant.[8]

(1)

Oxidation of Sulfides to Sulfoxides.

DABCO.2Br_2 oxidizes sulfides to sulfoxides in 70% aqueous acetic acid without over-oxidation to sulfones.[2] Yields for substrates ranging from dibutyl sulfide to thianthrene (eq 2) varied between 70 and 95%. The reaction is fast enough to be used as a method to prepare ^{18}O-enriched sulfoxides from sulfides.[2] Sulfides can also be oxidized to sulfoxides with ***Dipyridine Chromium(VI) Oxide***, ***Manganese Dioxide***,[9] and ***Sodium Periodate***.[10]

(2)

Other Applications.

DABCO.2Br_2 oxidizes monothioacetals to aldehydes (eq 3) in 40-83% yield.[3] No aldehydes were obtained when 3-chloroperoxybenzoic acid, sodium periodate, and selenium dioxide-hydrogen peroxide were used as oxidants.

Bromine-1,4-Dioxane[1]

[15481-39-7] · $C_4H_8Br_2O_2$ · Bromine-1,4-Dioxane · (MW 247.91)

(reagent for bromination of phenols,[2] aromatic amines,[3] α-bromination of aldehydes[4] and ketones[5])

Alternate Name: dioxane dibromide.

Physical Data: mp 60 °C.

Solubility: sol 1,4-dioxane, THF, and ether.

Preparative Methods: a 1:1 complex between 1,4-dioxane and bromine has been prepared and isolated on a 2 mol scale by the addition of bromine to 1,4-dioxane.[6] The reagent has also been prepared in situ.[3,7]

Handling, Storage, and Precautions: the complex is reported to be volatile (much material was lost on drying).[6] It can be stored at 0 °C. This material should only be handled in a fume hood.

Aromatic Brominations.

Bromine and 1,4-dioxane form a stable 1:1 complex, which has been referred to in the literature as dioxane dibromide. This complex is a mild brominating agent which has been used for bromination of activated aromatic systems. Yanovskaya et al. have reported[2] the bromination of phenol to give *p*-bromophenol in 88% yield. Schlegel et al. were able to monobrominate 1,3-dimethoxybenzene in high yield (eq 1).[8] In this case, reaction with bromine was reported to give a mixture of products.

(1)

Aromatic amines can be monobrominated to give the *p*-bromo compounds in moderate to good yields (eq 2).[3] The yields are highest for tertiary amines.

(2)

The bromination of 5-hydroxybenzimidazole is reported[9] to proceed at lower temperature and in higher yield with bromine-1,4-dioxane than with bromine alone (eq 3).

(3)

α-Bromination of Aldehydes and Ketones.

Bromine-1,4-dioxane is useful for the α-bromination of carbonyl compounds. Aldehydes have been brominated in moderate to good yields (eq 4).[4]

(4)

Hydroxy-substituted acetophenones can be brominated selectively on the alkyl side chain in good yields without

aromatic bromination using this reagent (eq 5).[5] A commonly used reagent for this transformation is ***Copper(II) Bromide***. Use of bromine-1,4-dioxane has the advantage that no heavy metal waste is generated.

(5)

Other Applications.

Bromine-1,4-dioxane has also been used for the one-pot preparation of α-bromoacetals of aryl alkyl ketones,[7] for the conversion of thiocarbonyl compounds to their oxygen analogs,[10] for the hydrolysis of dithioacetals,[10] for the oxidation of thiols to disulfides,[10] and for the bromination of 1-trimethylsilylindene.[11]

Related Reagents.

Bromine; ***Bromine-t-Butylamine***; ***N-Bromosuccinimide***; ***Copper(II) Bromide***; ***Phenyltrimethylammonium Perbromide***; ***Pyridinium Hydrobromide Perbromide***; ***2,4,4,6-Tetrabromo-2,5-cyclohexadienone***.

Bromine Monofluoride[1]

BrF

[13863-59-7] · BrF · Bromine Monofluoride · (MW 98.90)

(adds bromine and fluorine atoms across double and triple bonds;[2] brominates aromatic rings;[3] converts carbonyls, through their hydrazones[4] or dithiolanes,[5] to the CF_2 group; converts benzylic dithiocarboxylates and orthothioesters to $ArCF_3$[6])

Physical Data: mp -33 °C (dec to Br_2 and BrF_3); has not been isolated in pure form; orange-red crystals at low temperatures.[7,9]

Preparative Methods: unlike most organic reagents, the notation [BrF] has been designated to indicate a two-step reaction taking place when a mixture of two different agents, one a source of electrophilic bromine and the other of nucleophilic fluorine, is reacted with a substrate. The true molecule BrF can be prepared in situ by reaction between the corresponding elements[7] and by reacting bromine with BrF_3.[8] Many, but not all, reactions of [BrF] and BrF are quite similar.

Bromofluorination of Alkenes.

Adding the elements of bromine and fluorine across double bonds by using ***N-Bromosuccinimide*** (NBS), or similar N-Br derivatives, and anhydrous ***Hydrogen Fluoride*** is an established procedure employed extensively in steroid chemistry (eq 1).[10] The addition proceeds with relatively good regio- and stereospecificity (*anti* addition). Olah suggested replacing anhydrous HF, which is inconvenient for laboratory use, with the easier to handle HF.py[2a] (eq 2). Many variations on this procedure have since appeared. These include the following combinations: NBS-Et_3N/3HF,[11] NBS-AgF/CaF_2,[12] NBS-Bu_4NF,[13] NBS-NH_4HF_2/ultrasound,[14] and 1,3-dibromo-5,5-dimethylhydantoin (DBH)/SiF_4.[15]

(1)

$$MeCH{=}CH_2 \xrightarrow{NBS,\ (HF)_x \cdot py} MeCHFCH_2Br$$

(2)

$$PhC{\equiv}CPh \xrightarrow{NBS,\ (HF)_x \cdot py} PhCBr{=}CFPh$$

The combination of agents which results in [BrF] is also used for converting carbonyls, through their hydrazones, into the CF_2 group (eq 3).[4] The same eventual results can also be achieved through the action of [BrF], made from NBS or DBH with HF.py, on various dithiolanes (eq 4).[5] A somewhat similar process is the reaction of [BrF] with methyl aryldithiocarboxylates, which can be directed to give either $ArCF_3$ or the thioethers $ArCF_2SMe$ (eq 5).[6a] Trifluoromethylarenes are also obtained when [BrF] is reacted with aryl orthothioesters (eq 6).[6b] An interesting variation is the reaction with arylxanthates, which forms aryltrifluoromethyl ethers (eq 7).[16]

$$Ph_2C{=}O \xrightarrow{H_2NNH_2} Ph_2C{=}NNH_2 \xrightarrow{NBS,\ (HF)_x \cdot py} Ph_2CF_2 \quad (3)$$

(4)

(5)

(6)

(7)

The molecular BrF, prepared in situ from the elements, adds across double bonds with similar results to [IF] (see ***Iodine Monofluoride***), but it also adds to very deactivated enones and ynones (eq 8).[2c] The strong electrophilicity of the bromine in molecular BrF is the driving force behind the very efficient bromination of practically any deactivated aromatic compounds without the need for any Friedel-Crafts catalyst (eq 9).[3]

Bromine-Silver(I) Oxide

Br_2-Ag_2O

(Br_2)

[7726-95-6] · Br_2 · Bromine-Silver(I) Oxide · (MW 159.81) (Ag_2O)

[20667-12-3] · Ag_2O · Bromine-Silver(I) Oxide · (MW 231.74)

(oxidant; used to form tetrahydrofurans from alcohols via insertion into unactivated C-H bonds)

Physical Data: none available; reagent generated in situ.

Solubility: used as suspension in pentane, $CHCl_3$, CCl_4, or THF; marginally sol aqueous media.

Form Supplied in: generated in situ from ***Bromine*** and ***Silver(I) Oxide***.

Handling, Storage, and Precautions: reagent is generated in situ. Carrying out reaction in the dark is recommended by some authors, but is apparently unnecessary. Freshly prepared Ag_2O[6] (from Ag_2NO_3 and aq. NaOH followed by drying at 40-45 °C) is preferred to commercial samples.

Formation of Cyclic Ethers.

Remote functionalization of unactivated carbons using alcohol derivatives such as nitrites or hypohalites is well precedented.[1] A related process can be effected directly using the free alcohols in the presence of silver(I) oxide and bromine at room temperature. For example, 1,3,3-trimethylcyclohexanol underwent conversion to the bicyclic ether in 75% yield (eq 1).[2] The original report suggested that cyclization occurred via silver-assisted heterolytic cleavage of an intermediate hypobromite, with concomitant insertion of electrophilic oxygen into a δ C-H bond. A homolytic mechanism was considered less likely because the reaction proceeded readily in the dark and was unaffected by radical inhibitors. However, subsequent studies provided evidence for the intermediacy of alkoxyl radicals in the form of characteristic decomposition products,[3] racemization at the site of insertion,[4] and stereochemical dependence on hydrogen vs. deuterium abstraction.[5]

(1)

Primary and secondary alcohols led to mixtures of tetrahydrofurans and ketones or aldehydes (eq 2).[6] In some cases, yields were improved by carrying out the reaction in indirect daylight rather than in the dark. Cyclization of a benzylic alcohol to an *ortho* methyl group was found to be restricted to tertiary alcohols.[7] In an examination of the reaction of two secondary alcohols with bromine and other silver(I) salts, it was noted that the ratio of THF to ketone was sensitive to the acidity of the medium, with the addition of 1 equiv of trifluoro- or trichloroacetic acid leading to nearly complete selectivity for the ketone.[8] A more recent competition study has shown that the reaction is highly selective for methine carbons over methylenes or methyls (eq 3).[9]

(2)

dark	61%	14%
daylight	71%	15%

(3)

The observation of an induction period and a sigmoid curve for appearance of cyclic ether led to the suggestion of a possible autocatalytic mechanism.[10] In support of this, it was found that addition of 2 equiv of dimethyltetrahydrofuran eliminated the induction period and improved the yield of cyclization product. However, others have attributed this effect to the presence of peroxide impurities which could serve as initiators for a radical decomposition of the hypobromite intermediates.[11]

Overall, the fate of aliphatic alcohols in the presence of this reagent is analogous to that seen with ***Lead(IV) Acetate***, although the yields of cyclic ethers typically appear to be higher. The preponderance of evidence seems to favor a homolytic mechanism. The likely role of the silver salts is to facilitate the cyclization of the intermediate δ-bromo alcohols.[11,12]

Bromine Trifluoride[1]

BrF_3

[7787-71-5] · BrF_3 · Bromine Trifluoride · (MW 136.90)

(forms in situ bromine monofluoride,[2] oxidative fluorination on heteroatoms[3] and polyfluoroaromatics,[4] substituting aliphatic halogens[5] and tertiary hydrogens with fluorine,[6] brominating aromatic rings,[7] converting carbonyls through their azines and thioesters[8] to the CF_2 group)

Physical Data: mp 8.8 °C; bp 126 °C; d_{liq} 2.49 g cm^{-3}.

Form Supplied in: commercially supplied in cylinders as a volatile liquid, pale yellow when pure; orange-red crystals at low temperatures; dec at high temperature to Br_2 and BrF_5.[9]

Handling, Storage, and Precautions: use in a fume hood; BrF_3 can be stored in stainless steel or Teflon containers. It reacts violently with water and many oxygen-containing organic solvents.

Introduction.

The organic chemistry associated with BrF_3 is still in its infancy. The high reactivity of the reagent is one of the reasons that, until recently, its chemistry was not strongly developed. However, its commercial availability and the ease of preparation from the corresponding elements are changing this situation.

Bromofluorination of Alkenes.

When BrF_3 is mixed with bromine, the active species is ***Bromine Monofluoride***, which can be added to alkenes (eq 1)[2] or can brominate deactivated aromatic rings (eq 2).[7] Martin used BrF_3 to prepare compounds with hypervalent heteroatoms, many of them unattainable otherwise (eq 3).[3] A key step in Lemal's unique synthesis of perfluorocyclopentadiene also involved an oxidative fluorination (eq 4).[4] BrF_3 is capable of electrophilic fluorination and it can substitute halogens, as well as unactivated tertiary hydrogens whose bond with carbon is relatively electron rich (eqs 5 and 6).[5,6]

$$\underset{\substack{cis\\trans}}{CHCl{=}CHCl} \xrightarrow{BrF_3,\ Br_2} \underset{\substack{threo\\erythro}}{CHFCl\text{-}CHBrCl} \qquad (1)$$

$$PhNO_2 \xrightarrow{BrF_3,\ Br_2} m\text{-}BrC_6H_4NO_2 \qquad (2)$$

(3)

(4)

(5)

(6)

Recently, bromine trifluoride found promising use as a tool for converting carbonyls to the important CF_2 group. Aldehydes and ketones are converted through their easy-to-make azines (eq 7), while esters give the corresponding thioesters to form eventually α-fluoromethylene ethers (eq 8).[8]

Bromine-Triphenyl Phosphite[1]

$Br_2.P(OPh)_3$

$Br_2.P(OPh)_3$

[76934-05-9] · $C_{18}H_{15}Br_2O_3P$ · Bromine-Triphenyl Phosphite · (MW 470.10) (Br_2)

[7726-95-6] · Br_2 · Bromine-Triphenyl Phosphite · (MW 159.81) ($P(OPh)_3$)

[101-02-0] · $C_{18}H_{15}O_3P$ · Bromine-Triphenyl Phosphite · (MW 310.29)

(reagent for the conversion of alcohols[3a,d] and phenols[5] to alkyl and aryl bromides, and aldehydes[6] to 1,1-dibromoalkanes)

Alternate Names: bromotriphenoxyphosphonium bromide;[2] triphenyl phosphite dibromide; dibromotriphenoxyphosphorane.

Physical Data: Br_2: mp -7.2 °C; bp 59.5 °C; *d*254 3.1023 g cm^{-3}. $(PhO)_3P$: mp ca. 25 °C; bp 360 °C; *d*204 1.1844 g cm^{-3}; *n*20D 1.590.

Solubility: Br_2: sol H_2O (0.214 M L^{-1}); very sol alcohol, ether, $CHCl_3$, CCl_4, CS_2. $(PhO)_3P$: insol H_2O; dec in hot H_2O; sol usual organic solvents.

Form Supplied in: not available in final form $Br_2P(OPh)_3$;[2] prepared in situ. The starting materials, Br_2 and $(PhO)_3P$, are both widely available; Br_2: dark red diatomic liquid; purity &egt;99.5%; $(PhO)_3P$: liquid which solidifies in the cold; purity &egt; 97%; typical impurities: $(PhO)_3PO$, PhOH.

Analysis of Reagent Purity: ^{31}P NMR δ: Br^- $Br+P(OPh)_3$ +4 ± 0.5; $(PhO)_3P$ +128 ± 1; $(PhO)_3P=O$ -18 ± 0.5.

Preparative Methods: the reagent is mainly prepared in situ[3a,b] or precipitated and washed just before use.[3c,e]

Handling, Storage, and Precautions: $Br_2P(OPh)_3$ is very hygroscopic and corrosive. Br_2 is a corrosive liquid with a suffocating odor which vaporizes rapidly at rt. $(PhO)_3P$ is harmful as a solid or liquid, is an irritant and is moisture sensitive; store in a cool dry place. This reagent should be handled in a fume hood.

Synthesis of Alkyl Bromides from Alcohols.

Alkyl bromides are prepared conveniently and in good yield from saturated alcohols,[3a] either by adding bromine to a mixture of the alcohol and triphenyl phosphite (eq 1) or by first preparing the triphenyl phosphite dibromide and then adding the alcohol (as in eq 3).

$$(PhO)_3P + ROH \xrightarrow[\text{0 °C then rt, 76-92\%}]{Br_2} RBr + OP(OPh)_3 + HBr \quad (1)$$

$$R = n\text{-Bu},\ t\text{-Bu},\ -(CH_2)_3-,\ MeCH(CO_2Et)-,\ PhCH_2CH_2-$$

In the preparation[3b] of optically active (-)-2-Bromo-3-methylbutane from (+)-3-methylbutan-2-ol (eq 2) without rearrangement, $(PhO)_3PBr_2$ proved to be less effective than ***Triphenylphosphine-Carbon Tetrabromide*** and particularly inferior compared to ***Triphenylphosphine Dibromide*** despite a better overall yield (eq 2).

(2)

$(PhO)_3P, Br_2$	20%	55.6%
Ph_3P, CBr_4	39.3%	10%
Ph_3P, Br_2	42.3%	1.4%

Unsaturated alkenic,[3a,e] alkynic and allenic[3c,d] alcohols are converted into bromides by treating an equimolar mixture of each of them and pyridine with the previously generated $(PhO)_3PBr_2$ reagent (eq 3). This procedure avoids the addition of Br_2 and HBr to multiple bonds present in the substrate; Br_2 reacts first with the phosphite alone and pyridine acts as HBr scavenger. This method gives improved and more consistent yields (37-76%) and purer products than the conventional PBr_3 procedure.

(3)

This reagent can also be used to convert hydroxy groups into bromides in carbohydrates[3f-h] and nucleosides.[3i] Carbon skeletal rearrangement is observed with hindered compounds such as the protected glucose (**1**) from which the 6-bromo derivative (**2**) is obtained instead of the expected 3-bromo derivative (eq 4). In all cases tested the migration of the hydroxy protecting group proceeds with retention of configuration.[3h] In spite of low yields, this reaction offers a new route to deoxy sugars after hydrogenolysis of the bromide intermediate.

(4)

In the nucleoside field,[3i] a double activation has been performed, probably via the C-6-oxyphosphonium species, to give in one pot both a 5´-bromide and 6-phenylthioether (eq 5).

(5)

Ph_3PBr_2 effects also such conversions, but in some cases the removal of the $OPPh_3$ byproduct is problematic. This observation is quite general in the use of these reagents: the disadvantages of $(PhO)_3PBr_2$ are that phenol is produced as a byproduct and usually a mixture of phosphorus species is formed, but in many cases this reagent compares favorably with PPh_3-based reagents at the purification stage.

Synthesis of Aryl Bromides.[5]

Thermolysis of the tetraphenoxyphosphonium bromide obtained[4b] from $(PhO)_3P$ (2 parts) and Br_2 (eq 6) provides bromobenzene (eq 7). Other aryl bromides are also produced from $(PhO)_3$+POAr´ Br^- obtained by reacting Ar´OH with $(PhO)_3PBr_2$ (Ar´Br yields: Ar´ = 4-$NO_2C_6H_4$, 82%; 4-ClC_6H_4, 45%; 4-MeC_6H_4, 51%).

$$2\,(PhO)_3P \xrightarrow[\text{PhCl, 0 °C}]{Br_2} (PhO)_4PBr + (PhO)_2PBr \qquad (6)$$

$$(PhO)_4PBr \xrightarrow[\text{250 °C, 92\%}]{} PhBr + (PhO)_3PO \qquad (7)$$

Synthesis of 1,1-Dibromoalkanes.

Aliphatic and aromatic aldehydes[6] are converted into 1,1-dibromoalkyl derivatives using the $(PhO)_3PBr_2$ reagent with moderate to good yields (50-91%) (eq 8).

(8)

R = *n*-C_6H_{13}, 70%; MePrCH, 56%; Cy, 55%; *t*-Bu, 50%; $BnOCH_2$, 64%; Ph, 64%; 3-O_2N-4-Cl-C_6H_3, 91%; (*S*)-Me(OBn)CH, 62%

The use of this reagent is limited since substrates which are sensitive to Lewis acids, such as furfural, acrolein, and *O*-isopropylideneglyceraldehyde, undergo decomposition under these conditions; however, chiral (*S*)-2-benzyloxypropionaldehyde could be converted into the dibromo derivative without noticeable racemization.

---

1. Castro, B. R. *OR* **1983**, *29*, 1.
2. The reactive entity, the addition compound of the halogen and the phosphite, is in fact a mixture of several phosphorus species in equilibrium. The ratio of each component depends on the reaction conditions (solvent,

temperature, sense of the addition, etc.) as unequivocally shown by physical measurements:4 ^{31}P NMR4c,d clearly indicates the ionic tetracovalent nature of the phosphorus in $(PhO)_3$+PBr Br^- (δ ^{31}P = +4 ± 0.5 ppm).

N-Bromoacetamide

[79-15-2] · C_2H_4BrNO · *N*-Bromoacetamide · (MW 137.96)

(bromohydration and bromofluorination of alkenes; oxidation of alcohols)

Alternate Name: NBA.

Physical Data: mp 102-105 °C.

Solubility: sol $CHCl_3$, H_2O, acetone, THF; insol ether, hexane.

Form Supplied in: white needles; commercially available.

Preparative Method: *N*-bromoacetamide has been prepared by the reaction of acetamide with bromine and 50% aqueous potassium hydroxide at 0 °C.[1]

Purification: NBA can be recrystallized by dissolving in chloroform (10 mL g^{-1}), adding hexane (10 mL g^{-1}) and cooling to 0 °C. The purity of NBA may be determined by the standard bromide-thiosulfate titration method.[1]

Handling, Storage, and Precautions: *N*-bromoacetamide should be stored in the refrigerator, and protected from light and moisture to avoid decomposition. NBA is an irritating solid and precautions should be taken to avoid inhalation of the powder or contact with skin.

Bromohydration of Alkenes.

Although more expensive than ***N-Bromosuccinimide***, *N*-bromoacetamide is particularly effective for the electrophilic bromination of alkenes when a milder bromination reagent is needed, or when the ease of removal of the byproduct (acetamide) provides an advantage. The standard conditions for this reaction involve addition of NBA to a solution of the alkene in aqueous acetone, dioxane, or THF mixtures at 0 °C,[2] although for less reactive alkenes catalytic sulfuric acid has been added.[3] More recently, NBA has been chosen for the bromohydration of particularly reactive alkenes (eqs 1 and 2)[4,5] and for the synthesis of sensitive 1,2-anhydro sugars (glycal epoxides).[6] The reaction of alkenes with NBA in acetic acid has also been used for the preparation of bromoacetates.[7]

(1)

(2)

Bromofluorination of Alkenes.

Alkenes are converted to the corresponding 1,2-bromofluorides using NBA and anhydrous HF in ether.[8] This method has been especially useful for the synthesis of fluorinated steroids, fluorinated amino acids (eq 3), and other fluorine analogs of biologically important molecules.[9,10]

(3)

Oxidation of Alcohols.[11]

NBA has mild reactivity for the oxidation of alcohols in aqueous dioxane or THF at room temperature but is generally only of preparative value for the oxidation of secondary alcohols. Although the use of *N*-bromoacetamide and other *N*-bromoamides for the oxidation of alcohols has largely been displaced by chromium reagents and activated dimethyl sulfoxide reagents, the ease of handling and the unreactivity of the byproduct acetamide may favor the use of NBA in particular applications. In addition, secondary alcohols in different environments are oxidized at appreciably different rates by NBA and the selective oxidation of axial alcohols in the presence of equatorial alcohols has frequently been achieved in the steroid field.[12]

N-Bromoacetamide-Silver Acetate-Acetic Acid

(MeCONHBr)

[79-15-2] · C_2H_4BrNO · *N*-Bromoacetamide-Silver Acetate-Acetic Acid · (MW 137.96) (AgOAc)

[563-63-3] · $C_2H_3AgO_2$ · *N*-Bromoacetamide-Silver Acetate-Acetic Acid · (MW 166.91) (HOAc)

[64-19-7] · $C_2H_4O_2$ · *N*-Bromoacetamide-Silver Acetate-Acetic Acid · (MW 60.05)

(*cis* dihydroxylation of alkenes)

For information on the individual components see ***N-Bromoacetamide***, ***Silver(I) Acetate*** and ***Acetic Acid***.

The mixture of *N*-bromoacetamide (NBA) with silver acetate serves as an extremely useful means of executing *cis* dihydroxylation of alkenes from the more hindered face, via the corresponding 1,2-diacetoxyalkane (eq 1).[1] In particular, the method offers an improvement over the previous reagents used to carry out most hindered dihydroxylations namely ***Iodine-Silver Acetate*** (the so-called Woodward hydroxylation[2]); under the latter conditions, the reaction represented in eq 1 produces a mixture of diastereoisomers. The use of NBA furnishes a single diol in all reactions of cyclohexenes except where methylcyclohexenes are employed; in the reaction of these substrates a product mixture very similar to that seen under Woodward conditions is obtained (Table 1), but yields of diol are improved.

(1)

Table 1 Preparation of *cis*-1,2-Diols using NBA

Alkene	Diol	Yield (%)
	 33:67	100 (65)[a]
	 30:70	85 (65)[a]
	 45:55	85 (60)[a]
	 70:30	50 (0)[a]

[a] Yields obtained using I_2, AgOAc.

The NBA-AgOAc mixture is also effective in the hydroxylation of prochiral acyclic alkenes and has been thus employed in studies towards total synthesis of daunosamines (eq 2).[3,4] In these studies, reaction of (**1**) gave the desired L-*lyxo* stereoisomer in excess; use of Woodward conditions gave this isomer in minor amounts (4:1 *xylo*:*lyxo*) while ***Osmium Tetroxide*** gave only a slight preponderance of *lyxo* (1:2 *xylo*:*lyxo*).[3]

(2)

Contrary to one report, NBA-AgOAc is not claimed to effect bromoacetoxylation of alkenes.[5]

Bromoacetone[1]

[598-31-2] · C_3H_5BrO · Bromoacetone · (MW 136.98)

(acetonylation; synthesis of heterocycles)

Alternate Name: 1-bromo-2-propanone.

Physical Data: bp 40-42 °C/13 mmHg;[2] 63.5-64 °C/50 mmHg;[3] 37-45 °C/12 mmHg;[4] 138-140 °C;[5] *n*15D 1.4697.

Solubility: sol most organic solvents; the use of nucleophilic solvents has to be avoided due to the high reactivity of the reagent for nucleophilic substitution.

Preparative Methods: bromoacetone is most conveniently prepared by bromination of ***Acetone*** with ***Bromine*** in aqueous acetic acid (eq 1)[2] or in aqueous medium in the presence of potassium chlorate (eq 2).[3] The yields are never excellent but these procedures are recommended due to the ease of operation and the inexpensive starting materials. However, it has been reported that acetone is brominated to give bromoacetone in almost quantitative yields by bromination with (*Z*)-5-nitro-2-furylvinylpyridinium tribromide[5] or 6-chloroperfluorohexanesulfonyl bromide.[6]

Handling, Storage, and Precautions: strong lachrymator; strong alkylating agent; toxic; strong vesicant; only use in a well-ventilated hood. The stability of bromoacetone is notably dependent upon its purity.[3] In the absence of any stabilizer the crude product appears to keep much better than the purified material, but the

situation is reversed when a trace of magnesium oxide is present. Complete decomposition occurs after several months on standing at rt in the dark. Pure bromoacetone can be kept over a trace of magnesium oxide as colorless liquid for years. Traces of water (0.01%) seem to stabilize this reagent.[3]

Introduction.

Like α-halo ketones in general, bromoacetone is an extremely versatile reagent or building block in organic chemistry.[1] A major application of bromoacetone is its use as an acetonylation reagent for a whole range of nucleophilic heteroatoms, e.g. oxygen, sulfur, nitrogen, phosphorus, and halides. Nucleophilic additions across the carbonyl group are also observed. In the former application, two major reactions are utilized in ring closure reactions with difunctional and polyfunctional substrates. To a lesser extent, aldol-type reactions of bromoacetone have been reported. Bromoacetone has been isolated from the red alga *Asparagopsis taxiformis*.[7]

Acetonylation of Oxygen Nucleophiles.

Reaction of bromoacetone with aqueous sodium hydroxide gives hydroxyacetone.[8] In this case the mechanism may occur by direct substitution or via rearrangement of the corresponding hydroxyepoxide. Phenolates easily substitute bromoacetone (eq 3).[9] When applied to functionalized phenols, e.g. pyrocatechol,[10] 5-bromosalicaldehyde (eq 4),[11] or 2-acetamidophenol (eq 5),[12] benzodioxanes,[10] 2-acetyl-5-bromobenzofuran,[11] or 4-acetyl-3-methyl-4*H*-1,4-benzoxazine[12] are produced, respectively. Also phenolic *p*-*t*-butylcalix[4]arenes are tetraacetonylated with bromoacetone.[13] Esterification of fatty acid chains by bromoacetone is quantitatively accomplished in the presence of quaternary ammonium salts (eq 6).[14]

(5)

(6)

R = fatty acid chain

Acetonylation of Sulfur Nucleophiles.

Thiolates react smoothly with bromoacetone to afford α-sulfenylated acetones (eq 7).[15,16] However, lower alkyl thiolates give very low yields.[17] The substitution product with sodium thiolate undergoes cyclocondensation with ammonia in the presence of an aldehyde or ketone to yield 3-thiazolines.[18] Potassum thiocyanate[19] and thioacetic acid[20] undergo acetonylation by bromoacetone, the latter substitution product undergoing cyclization to 2,4-dimethylthiazole (eq 8).[20] This thiazole synthesis can also be accomplished in a one-step process.[20]

(7)

R = alkyl, 1-naphthyl

(8)

Thioamide-type compounds, e.g. pyrrolidine-2-thiones[21] and 2,4-dihydro-5-methyl-4-phenyl-3*H*-1,2,4-triazole-3-thione,[22] react with bromoacetone at sulfur. These acetonylated compounds are useful for desulfurization and further elaboration into (±)- hygrine (eq 9),[21] or can be cyclized into 1*H*-thiazolo[3,2-*b*]-*s*-triazolium salts.[22] Also thiourea reacts similarly with bromoacetone to give 2-amino-4-methylthiazole directly (eq 10).[8,23]

(9)

(10)

Acetonylation of Nitrogen Nucleophiles.

Primary amines are mono- or diacetonylated by bromoacetone (eq 11).[24,25] The diacetonylated compounds are useful substrates for the acid-catalyzed ring closure to tetrahydropyridin-3-ones (eq 11).[24,25] When mixed at rt for 4 days with excess primary amines, e.g. isopropylamine, bromoacetone is converted to the corresponding α-(*N*-alkylamino)imine, which undergoes cyclocondensation with ethyl acetoacetate to give pyrroles.[26] Secondary amines also give rise to nucleophilic substitution of the halogen in bromoacetone.[27-29] Heating of *N*-methyl formimidate with bromoacetone in toluene/1,2-dimethoxyethane gives access to the corresponding *N*-methylformamide (eq 12), which is a precursor for 1-(*N*-methylamino)-2-propanone.[30]

(11)

(12)

Imide-type compounds, e.g. thiazolidine-2,4-dione[31] and phthalimide,[32] are acetonylated by bromoacetone, while tosylamides[33] and 2-imidazolinones[34] are similarly alkylated at nitrogen. Quaternizations at nitrogen of pyridines (eq 13)[35,36] and other aza heterocycles, such as 2,4-dimethylthiazole (eq 14),[37] have been performed with bromoacetone. Some of these salts are useful for further cyclization into fused heterocycles, e.g. pyrrolothiazoles.[37]

(13)

(14)

Acetonylation of Carbon Nucleophiles.

Active methylene functions of malonates (eq 15),[38] dicarboxylic esters (eq 16),[39] β-keto esters (eq 17),[40] β-diones,[41] and β-oxo sulfones (eq 18)[42] are alkylated by bromoacetone.

(15)

(16)

(17)

(18)

The methylcopper-catalyzed hydroalumination of 2-cyclohexenone with ***Diisobutylaluminum Hydride*** generates an aluminum enolate, which is trapped by bromoacetone to afford α-acetonylated cyclohexanone (eq 19).[43]

(19)

Enamines are useful nucleophiles towards bromoacetone, affording 1,4-dicarbonyl compounds (eq 20).[4,44,45] A convenient route to methyl ketones from bromoacetone consists of the reaction with boranes, e.g. tri-*n*-butylborane, in the presence of the potassium salt of 2,6-di-*t*-butylphenol (eq 21).[46]

(20)

Reactions with Phosphorus Reagents.

The reaction of α-halo ketones and trialkyl phosphites is extremely complex and usually leads to vinyl phosphates and β-ketophosphonates according to Perkov and Arbuzov reaction mechanisms.[48] However, the reaction of bromoacetone with trimethyl phosphate in methanol is a suitable entry to dimethyl 1-methylvinyl phosphate (eq 22).[48,49] It has been reported that bromoacetone reacts with triethyl phosphite in ether at -70 °C in the presence of hydrogen chloride to give the adduct across the carbonyl group (eq 23).[50] Phosphines, e.g. 2-anisyldiphenylphosphine, give nucleophilic substitution, the resulting phosphonium salt being a precursor for phosphorus heterocycles (eq 24).[51]

Addition Reactions across the Carbonyl Group.

Grignard reagents add to the carbonyl function of bromoacetone at low temperature.[52,53] These adducts can be used for further elaboration, such as in the synthesis of homologated tertiary alcohols (eq 25).[52] Acetalization of bromoacetone occurs smoothly under the usual conditions.[54] The dimethyl acetal of bromoacetone is converted into 3-bromo-2-methoxypropane, a suitable acetonylation reagent (eq 26).[54]

(26)

The oxime of bromoacetone is readily formed upon reaction with ***Hydroxylamine*** and is shown to be a suitable building block, after protection of the hydroxy function, for the synthesis of oxazaphospholines and 2-methylazirine (eq 27).[55] Bromoacetone condenses with ***p-Toluenesulfonylhydrazide*** to give the *syn-N*-tosylhydrazone exclusively,[56] while with ***Phenylhydrazine*** it gives rise to the *s-anti*-(*E,E*)-1,2-dihydrazone.[47]

(27)

Aldol-Type Reactions.

The condensation of bromoacetone with aldehydes in the presence of ***Tin(II) Trifluoromethanesulfonate*** and a tertiary amine affords aldol-type adducts in which the bromo atom is retained in the final product (eq 28) allowing further elaboration, i.e. oxirane formation.[57,58]

Aldol condensation with removal of the halogen is obtained under reducing conditions with ***Cerium(III) Chloride*** and ***Tin(II) Chloride*** (eq 29).[59]

Synthesis of Heterocycles.

The condensation of bromoacetone with various multifunctional reagents leads to a whole range of heterocycles. In many cases the condensation proceeds by consecutive reactions, the order of which is not easily determined. Furans are obtained from bromoacetone by reaction with α-(tri-*n*-butyltin) ketones (eq 30)[59-61] and the sodio salt of ***Ethyl Acetoacetate*** (eq 31).[62] Furanones are obtained by condensation of bromoacetone with phosphonates under Wittig-Horner conditions,[63] while isocoumarins and benzofurans are accessible by reaction of bromoacetone with 3,5-dimethoxybenzoic acid[64] or 5-bromosalicaldehyde.[11] The reaction of bromoacetone with enamino thioketones leads to thiophenes (eq 32),[65] which are also accessible from the same bromo ketone and ketones in the presence of ***Sodium Sulfide***.[66] Dithiins result from the cyclocondensation of bromoacetone with ***1,2-Ethanedithiol***[67] and thiazolines are produced from bromoacetone, sodium sulfide, and ammonia.[18] Thiazoles are accessible from bromoacetone via Hantzsch condensation with thioureas (eq 33),[8,23,68] or by a one-pot synthesis with thioacids in the presence of ammonium acetate and acetic acid.[20] Thienoazepines are formed upon condensation of enaminothiones with bromoacetone.[69]

(30)

R = H, Me

(31)

(32)

Ar = Ph, 4-BrC$_6$H$_4$, 4-MeOC$_6$H$_4$, 4-ClC$_6$H$_4$, 4-MeC$_6$H$_4$

(33)

R = Me, Ph, Bn

Imidazoles result from a three-component reaction, consisting of bromoacetone, ammonia, and imidates under pressure (eq 34),[70] while functionalized imidazoles are formed upon reaction of bromoacetone with functionalized isothiourea derivatives.[71]

(34)

Pyrroles are accessible from the reaction of bromoacetone with *N*-vinyliminophosphoranes (eq 35)[72] or lithiated aldimines or ketimines.[73] In addition, the condensation of acetone dicarboxylic methyl ester with ***Ethanolamine*** and bromoacetone gives access to pyrroles.[74] Ethoxycarbonylacetamidine can be used as substrate for a pyrrole synthesis as well.[84]

(35)

Bromoacetone is an especially useful building block for the construction of fused heterocycles. Cyclocondensation of heterocycles containing an amidino functionality with an exocyclic amino group, e.g. 3,9-dialkylguanines,[76] 3-methylguanine (eq 36),[77] 2-aminothiazole,[75] and 2-aminopyridines (eq 37),[83] readily condense with bromoacetone to give heterocycles with a fused imidazole ring. Pyrimidines also react with bromoacetone to give ring-fused heterocycles, e.g. 6-azaindolizines,[78,79] while 4-aminopyrimidines give rise to imidazo[1,2-*c*]pyrimidines.[80] 8-Aminoquinoline cyclocondenses with bromoacetone to produce fused heterocycles, which can be further elaborated to indolizinoquinoxalines.[81] Other examples leading to different fused heterocycles have been reported.[82,85]

Bromoacetyl Chloride

[22118-09-8] · C_2H_2BrClO · Bromoacetyl Chloride · (MW 157.39)

(bifunctional building block;[1-8] ketene precursor;[9-12] bromoacetylating agent[13,14])

Physical Data: bp 127-128 °C; *d* 1.908 g cm^{-3}.

Form Supplied in: colorless liquid, 98% pure or in lower grades [contaminated with $BrCH_2C(O)Br$ and $ClCH_2C(O)Cl$]; widely available.

Handling, Storage, and Precautions: readily hydrolyzed with formation of HCl; corrosive; lachrymator. This reagent should only be handled in a fume hood.

Bifunctional Building Block.

Bromoacetyl chloride has been used extensively as a bifunctional two-carbon building block.[1-8] Since both C-1 and C-2 are electrophilic, it can be used to link two nucleophilic units. Examples of intermolecular couplings[1-4] include sequences to prepare α-amino ketones,[1] α-heterosubstituted amides,[2] α-heterosubstituted esters (eq 1),[3] and Wittig-type reagents (eq 2).[4] Where both nucleophilic functionalities are on the same molecule, cyclic compounds result. Such intramolecular couplings[5-8] have been employed in syntheses of heterocycles such as morpholin-3-ones (eq 3),[5] aza-β-lactams,[6] and benzodiazepines.[7]

(1)

(2)

(3)

Ketene Precursor.

Treatment of bromoacetyl chloride with Et_3N in the presence of a suitable trapping agent (e.g. an imine) gives products derived from the expected intermediate ketene.[9-11] Such cycloaddition reactions with imines produce β-lactams (eq 4);[9] other heterocyclic compounds have also been prepared by this method.[11] Ketene itself may be prepared and distilled in solution by reaction of $BrCH_2C(O)Cl$ with pentacarbonylmanganate anion.[12]

(4)

Bromoacetylating Agent.

Bromoacetyl chloride has been used as a reagent for the introduction of bromoacetyl groups.[13,14] There is some interest in preparing compounds bearing a bromoacetyl group (typically bromoacetamides) as possible pharmacological agents.[13] These compounds would be expected to be alkylating agents which could be anti-cancer drugs (by alkylation of DNA) or enzyme inhibitors (by alkylation of HO- or HS-containing residues in the active site.) The bromoacetyl group has also been used as a hydroxy-protecting group in carbohydrates.[14]

Bromoacetylium Hexafluoroantimonate

$BrCH_2CO^+SbF_6^-$

[54854-60-3] · $C_2H_2BrF_6OSb$ · Bromoacetylium Hexafluoroantimonate · (MW 357.68)

(bromoacetylating agent)

Physical Data: mp 82 °C.

Preparative Method: prepared by treating $BrCH_2COF$ with antimony pentafluoride in Freon 113.[1a] Pure $BrCH_2CO^+SbF_6^-$ is obtained by washing the crude product with excess dry Freon 113.

Handling, Storage, and Precautions: corrosive and moisture sensitive. Store in a Teflon or a Nalgene bottle under anhydrous conditions. Use in a fume hood.

Bromoacetylium hexafluoroantimonate has been used to bromoacetylate aromatic compounds (eq 1). It reacts readily with benzene, toluene, *p*-xylene, and mesitylene to generate the corresponding bromoacylated products in high yields. In the case of toluene a 3.8:31.1:95.1 isomer distribution ratio is obtained for the *ortho*, *meta*, and *para* isomers.[1b]

Bromoallene[1]

[10024-18-7] · C_3H_3Br · Bromoallene · (MW 118.96)

(useful reagent for synthesis of terminal alkynic compounds[2] and substituted allenes[3])

Physical Data: bp 73 °C; *d*204 1.5508 g cm^{-3}; *n*204 1.5212.

Solubility: sol most common organic solvents.

Form Supplied in: liquid; not available from common commercial suppliers.

Analysis of Reagent Purity: IR (cm^{-1}): 3080, 3005, 1961, 1740, 1432, 1078, 862, 681, 603, 519.[1] UV (nm (ε)): 269 (72), 192 (7780).[1] ^1H NMR (ppm): 5.95 (t, 1H, *J* = 6 Hz), 4.93 (d, 2H, *J* = 6 Hz).[4] ^{13}C NMR (ppm): 206.5, 86.8, 81.2.[4]

Preparative Methods: a tedious preparation[5] of bromoallene by isomerization of propargyl bromide in the presence of copper(I) bromide has been improved[6] and pure bromoallene can be obtained by removing the side product (propargyl bromide) with diethylamine (eq 1). Bromoallene has also been prepared by flash vacuum pyrolysis of bromocyclopropene[4] or by phase transfer catalysis using $CHBr(CH_2Br_2)$,[7] but in both cases reaction mixtures contained a significant amount of propargyl bromide.

Bromoallene as an Electrophile.

The hydroalumination of 1-alkene followed by treatment with bromoallene in the presence of a catalytic amount of ***Copper(I) Chloride*** leads to terminal alkynic compounds (eq 2).[2]

(2)

This bromide was also subject to nucleophilic substitution by the anion of ***Ethyl Acetoacetate*** in a basic medium, but it was found that propargyl bromide (see ***Propargyl Chloride***) gives identical results. A carbene mechanism was proposed (eq 3).[8]

(3)

Formation of substituted allenes by reaction of bromoallene with 1-alkynylzinc chlorides and a Pd^0 catalyst is very useful. However, propargylic bromide or acetate can be used and seems more suitable for the preparation of unsymmetrical diallenes (e.g. R = *t*-BuCH=C=CH-) (eq 4).[3]

(4)

Bromoallene in Electrophilic Substitution via Metallic

Derivatives.

Allenylmagnesium Bromide.

Although this compound was earlier prepared from propargyl bromide, bromoallene may be used to synthesize allenylmagnesium bromide. It has been well established that propargyl or allenyl bromide deliver the same allenyl Grignard derivative (eq 5).[9]

(5)

By a preferential attack at the 3-position (S_E2' type mechanism), this organometallic gives exclusively or mainly the alkynic compound when added to most electrophiles in ether (eq 6).[10] A reversal of reactivity may be encountered with polar aprotic solvents or with other organometallic compounds such as allenylzinc bromide (eq 7) or cadmium derivatives.[10]

(6)

(7)

The addition of Cu^I salts leads to allene products (eq 8).[11]

(8)

Cycloadditions.

Bromoallene gives a [4 + 2] cycloaddition by reacting with hexachlorocyclopentadiene, leading to the 5-bromomethylene adduct (eq 9).[12] A 1,3-dipolar cycloaddition with benzonitrile oxide[13] as well as photochemical cycloadditions of 9,10-phenanthraquinones[14] to bromoallene have also been investigated.

4-Bromobenzenesulfonyl Azide

[6647-76-3] · $C_6H_4BrN_3O_2S$ · 4-Bromobenzenesulfonyl Azide · (MW 262.08)

(1,3-dipolar reagent that undergoes cycloaddition to vinyl and alkynyl ethers[1])

Physical Data: mp 54.5-56 °C.

Solubility: sol most organic solvents.

Preparative Method: by the reaction of ***4-Bromobenzenesulfonyl Chloride*** with excess ***Sodium Azide*** in a water-ethanol mixture.[2,3]

Purification: crystallization from ethanol.

Handling, Storage, and Precautions: should be used in solution. Azides are prone to violent detonation upon thermal, electrical, and mechanical shock.

Dipolar Cycloaddition.

The principal use of *p*-bromobenzenesulfonyl azide is in 1,3-dipolar cycloaddition reactions with functionally substituted alkenes. The reagent has been used at ambient temperature and pressure to convert simple trimethylsilyl[4] and methyl[5] enol ethers of cyclic ketones to ring-contracted *p*-bromobenzenesulfonimidates, and thence to the corresponding amides, esters, or acids (eqs 1 and 2).

At high pressure (~15 kbar) the normally more sluggish *t*-butyldimethylsilyl enol ethers of cyclic ketones react in good yield to afford the ring contracted product (eq 3).[6,7]

(3)

The chemo-, regio-, and stereoselectivity of the ring contraction process has been demonstrated with a variety of dienol ethers obtained by dissolving metal reduction of aromatic methyl ethers (eqs 4 and 5).[8]

(4)

(5)

Methyl enol ethers which are unreactive under ambient conditions react in good yield to afford the corresponding *p*-bromobenzenesulfonimidates under the influence of low-wattage ultrasound (eqs 6 and 7).[9]

Cycloaddition of *p*-bromobenzenesulfonyl azide to alkynyl ethers affords equilibrium mixtures of triazole and diazocarboximidate. In the case of the ether in which both the carbon and the oxygen substituents of the alkynyl ether are methyl, only the triazole is found (eq 8).[10]

4-Bromobenzenesulfonyl Chloride

[98-58-8] · $C_6H_4BrClO_2S$ · 4-Bromobenzenesulfonyl Chloride · (MW 225.52)

(N-protection of amines; formation of sulfonamides, sulfonate esters, and carbodiimides)

Alternate Name: BsCl.

Physical Data: mp 73-75 °C.

Solubility: sol Et_2O, THF, petroleum ether and 1,4-dioxane.

Preparative Method: reaction of sodium *p*-bromobenzenesulfonate with ***Phosphorus(V) Chloride*** gives a 90% yield.[1]

Handling, Storage, and Precautions: harmful by skin absorption and ingestion and causes burns. The reagent is moisture sensitive and will react with nucleophilic solvents, e.g. alcohols, liberating HCl and therefore should be stored under an inert atmosphere.

Protection of Nitrogen, Formation of Sulfonamides.

p-Bromobenzenesulfonyl chloride (BsCl) has been widely used to N-protect amines (eqs 1 and 2)[2,3] (see also ***p-Toluenesulfonyl Chloride*** and ***Benzenesulfonyl Chloride***). Due to the relatively high molecular weight, *p*-bromobenzenesulfonyl derivatives have a higher melting point and may be more readily crystallizable than lower molecular weight derivatives.

(1)

(2)

The electron-withdrawing nature of the *p*-bromobenzenesulfonyl group has been used, via the sulfonamide derivative of a pyridone, in inverse electron demand Diels-Alder reactions to great effect.[4]

Disulfonamides can be prepared from primary amines (eq 3), thereby converting the amine into a better leaving group.[5] The syntheses of sulfonamides derived from sulfamates have also been reported.[6]

(3)

Formation of Sulfonate Esters.

The reaction of hydroxy groups with *p*-bromobenzenesulfonyl chloride gives *p*-bromobenzenesulfonates (brosylates) (eq 4).[7] The brosylate ester transforms the hydroxy functional group into a good leaving group and this has been exploited in synthesis. Inositol derivatives[8] have been prepared using brosylates in preference to the corresponding 4-methylbenzenesulfonates, the latter being a less effective leaving group in this particular case.

(4)

The reaction of β-hydroxy acids with *p*-bromobenzenesulfonyl chloride in the presence of a tertiary amine gives β-lactones (eq 5).[9,10] Brosylate esters of oximes have been manipulated in the Beckmann rearrangement of erythromycin derivatives[11] as an alternative to both 4-methylbenzenesulfonate esters and benzenesulfonate esters.

(5)

Formation of Carbodiimides.

p-Bromobenzenesulfonyl chloride reacts with ureas to form carbodiimides in good yield (eq 6).[12]

(6)

Reaction with Alkenes and Arenes.

p-Bromobenzenesulfonyl chloride will undergo desulfonylative coupling to alkenes and arenes using Pd^{II} catalysis (eq 7).[13]

4-Bromobenzyl Chloroformate

[5798-78-7] · $C_8H_6BrClO_2$ · 4-Bromobenzyl Chloroformate · (MW 249.49)

(N-protecting agent for α-amino acids)

Alternate Name: *p*-bromobenzyloxycarbonyl chloride.

Physical Data: mp 12 °C; *d* (20 °C) 1.5588 g cm^{-3}; *n*20D 1.6004.

Preparative Methods: not commercially available. It may be prepared[1] by the addition of a solution of 4-bromobenzyl alcohol in dioxane to a solution of excess ***Phosgene*** in toluene followed by stirring at rt for 24 h. Removal of the solvent by distillation in vacuo at 60 °C leaves a straw-colored oil. Three recrystallizations from hexane at -50 °C gives pure 4-bromobenzyl chloroformate in 78% yield as colorless needles. In a closely related alternate preparative procedure,[2] the crude oily product, obtained in 98% yield, was used in a preparative reaction without further purification.

Handling, Storage, and Precautions: although no details are available, the high toxicity and suspected carcinogenic properties of the closely related ***Benzyl Chloroformate*** suggest that 4-bromobenzyl chloroformate should be handled with caution.

N-Protection of α-Amino Acids.

Treatment of an α-amino acid[1] or an oligopeptide[3] with a dioxane solution of 4-bromobenzyl chloroformate and aq $NaHCO_3$ affords the *N*-(4-bromobenzyl) carbamate derivative in moderate to good yield (eq 1). Use of aq NaOH as the base gives similar results.[4] The resulting *N*-(4-bromobenzyloxycarbonyl)-α-amino acids have higher melting points than the corresponding *N*-benzyloxycarbonyl-α-amino acids[1,5] (see ***Benzyl Chloroformate***). Their highly crystalline nature allows for facile repeated recrystallization,[1,5] which makes them well-suited for use in the quantitation of α-amino acid racemization. The 4-bromobenzyl carbamate moiety is stable to the basic conditions (aq NaOH, ethanol) used to hydrolyze a methyl ester,[4] but is still readily cleaved by hydrogenolysis.[5]

Protection of Carboxylic Acids.

Given the utility of benzyl chloroformate for the protection of carboxylic acids as their benzyl esters it is likely that the preparation of 4-bromobenzyl esters using 4-bromobenzyl chloroformate would be possible, although such chemistry has not yet been reported. Such a protection method would be useful, since it has been demonstrated that 4-bromobenzyl esters are 5-7 times more stable than the corresponding benzyl esters to acidic hydrolysis. For example, they are stable to 50% CF_3COOH used to cleave *N*-Boc-protected α-amino acids; they are cleaved quantitatively by exposure to HF (0 °C, 10 min).[6]

Bromobis(isopropylthio)borane[1]

[89449-88-7] · $C_6H_{14}BBrS_2$ · Bromobis(isopropylthio)borane · (MW 241.01)

(mild Lewis acid capable of converting methoxyethoxymethyl (MEM) ethers into isopropylthiomethyl ethers;[1] deprotection of MEM ethers;[1] and cleavage of mono methoxymethyl (MOM) (or MEM) ethers of 1,2- and 1,3-diols[1])

Physical Data: bp 75-80 °C/2 mmHg; light-yellow oil.

Solubility: sol most organic solvents such as pentane, CH_2Cl_2, etc.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 3.64 (hept, 2H, *J* = 6.8 Hz, CH), 1.385 (d, 12H, *J* = 6.8 Hz, Me).

Preparative Method: [1] to a stirred mixture of 3.57 g (0.010 mol) of bis(isopropylthio)lead[2] in 20 mL of pentane under argon at 25 °C is added a solution of 0.95 mL (0.010 mol) of ***Boron Tribromide*** in 10 mL of pentane. After the mixture is stirred for 20 min, 10 mL of CH_2Cl_2 is added and the mixture is heated under reflux for 2.5 h. The reaction mixture is cooled to 25 °C and the white precipitate ($PbBr_2$) is removed by filtration under argon. The filtrate is distilled under argon to remove solvents and then distilled under reduced pressure: 2.13 g (90% yield) of a yellow oil; bp 75-80 °C/2 mmHg.

Handling, Storage, and Precautions: should be stored under argon at 0 °C. The compound has an unpleasant odor and reacts rapidly with water and other protic solvents.

Bromobis(isopropylthio)borane converts various MEM ethers into the corresponding isopropylthiomethyl ethers. Among several examples shown below, treatment of the MEM ether of cholesterol in CH_2Cl_2 at -95 °C with 3-5 equiv of (*i*-PrS)$_2$BBr for 5 min followed by the addition of ***4-Dimethylaminopyridine*** (DMAP) (2 equiv/equiv of boron reagent) and stirring the mixture at -95 °C for 15 min, then at -50 °C for 10 min, before quenching with aqueous potassium carbonate gives an 89% yield of the isopropylthiomethyl ether of cholesterol along with a 9% yield of cholesterol (eq 1).[1] Presumably, DMAP displaces isopropylthiolate anion from the boron complex, thereby providing a reactive S-nucleophile to attack the dioxymethylene carbon of the boron-coordinated MEM ether.

(1)

MEM = $-CH_2OCH_2CH_2OMe$

(1a) 84%

(1b) 89%

(1c) 90%

Under different conditions, $(i\text{-PrS})_2BBr$ cleaves MEM ethers into the corresponding alcohols. For example, in the absence of DMAP, reaction of MEM ether (**1c**) with 1.5 equiv of $(i\text{-PrS})_2BBr$ in CH_2Cl_2 at -95 °C for 5 min followed by treatment with aqueous sodium bicarbonate provides an 88% yield of the corresponding alcohol and only a 2% yield of the isopropylthiomethyl ether.

Bromobis(isopropylthio)borane also cleaves mono MOM (or MEM) ethers of 1,2- and 1,3-diols to the corresponding diols.[1] Treatment of glycol mono MOM ethers with 1.2 equiv of $(i\text{-PrS})_2BBr$ in CH_2Cl_2 at -78 °C followed by methanol at 23 °C for 1 h affords excellent yields of the corresponding diols (eqs 2-4). It should be noted that these glycol mono MOM ethers under conventional acid-catalyzed processes (using protic or Lewis acids) produce cyclic diol formals as the major product.

(2)

MOM = CH_2OMe

$n = 1$, 73%
$n = 2$, 96%
$n = 6$, 82%

(3)

(4)

Deprotection of MEM ethers with other Lewis acidic boron reagents (such as 2-chloro-1,3,2-dithiaborolane[3] and ***Bromodimethylborane***[4]) to the corresponding alcohols has also been reported.

9-Bromo-9-borabicyclo[3.3.1]nonane[1]

[22086-45-9] · $C_8H_{14}BBr$ · 9-Bromo-9-borabicyclo[3.3.1]nonane · (MW 200.91)

(selective reagent for the cleavage of ethers[2] and deoxygenation of sulfoxides;[3] adds regioselectively and stereoselectively to terminal alkynes;[4] undergoes conjugate addition to α,β-unsaturated ketones;[5] converts vinyltins to vinylboranes[10])

Alternate Name: Br-9-BBN.

Physical Data: colorless liquid; bp 54-59 °C/0.3-0.4 mmHg; mp -17 °C; *d* 1.315 g cm^{-3}.

Solubility: sol pentane, CH_2Cl_2; dec ethers, alcohols.

Form Supplied in: 1.0 M solution in CH_2Cl_2.

Analysis of Reagent Purity: the reagent exhibits a single resonance in its ^{11}B NMR (neat) spectrum at δ 83.9 (s) ppm.[2]

Handling, Storage, and Precautions: the reagent is pyrophoric and reacts violently with moisture and protic solvents. Individuals should thoroughly familiarize themselves with the special handling techniques required for such reagents prior to use.[1] Use in a well-ventilated fume hood.

Selective Cleavage of Ethers.

In methylene chloride solution, Br-9-BBN readily cleaves a variety of common ethers at 25 °C.[2] For dibutyl ether the reagent reacts smoothly to produce 1-bromobutane quantitatively in 24 h. This behavior contrasts to that of polyfunctional reagents such as ***Boron Tribromide*** whose rate is markedly slowed after two of its three bromides have been used. The bromine is selectively transferred to tertiary and secondary vs. primary groups, the process occurring with 73% inversion in the case of (*R*)-(-)-2-methoxyoctane (eq 1). Alkyl aryl ethers are also selectively cleaved, with no Claisen products from allyl phenyl ether as is observed with ***Boron Trichloride***. One of the methoxy groups in

hydroquinone dimethyl ether can be selectively cleaved with the reagent, whereas the methylenedioxy moiety must be completely removed with two equivalents of the reagent under more forcing conditions.

(1)

Deoxygenation of Sulfoxides.

Br-9-BBN rapidly and cleanly deoxygenates sulfoxides with no accompanying rearrangement in CH_2Cl_2 at or below 0 °C.[3] The reagent gives isolated yields which equal or exceed those from either ***Boron Tribromide*** or ***Bromodimethylborane***, all of which provide the corresponding sulfides in excellent yields even with polyfunctionalized substrates (eq 2).

(2)

Addition to Terminal Alkynes.

The *syn* bromoboration of terminal acetylenes with Br-9-BBN provides a simple route to (*Z*)-2-bromovinylboranes (eq 3).[4] The addition is highly regioselective (98-99%) even for functionalized substrates such as propargyl bromide. Reaction occurs over ca. 3 h at 0 °C in CH_2Cl_2 and both ester and alkenic functionalities can be tolerated in the alkyne. The process has been effectively used in the asymmetric synthesis of (-)-ipsenol.[4b]

(3)

The (*Z*)-2-bromovinyl-9-BBN adducts undergo additional conversions which lead to stereoselective carbon-carbon bond formation. For example, the iodination of the alkynyl borate complexes derived from these vinylboranes produces the corresponding (*Z*)-brominated enynes in 53-72% yield for representative combinations (eq 4).[6] However, it must be mentioned that for certain applications (e.g. oxidation,[7] halogenation,[8] Pd-catalyzed cross coupling[9]) the use of the 1:1 adducts derived from the addition of BBr_3 to 1-alkynes is preferable to the corresponding 9-BBN derivatives.

(4)

Conjugate Addition to α,β-Unsaturated Ketones and Aldol Reactions.

Br-9-BBN undergoes 1,4-addition to conjugated enones to produce γ-brominated (*Z*)-enolboranes which undergo stereoselective crossed aldol reactions with a variety of aldehydes.[5] Elimination occurs under the reaction conditions leading to α-bromomethylated enones in good overall yields (50-60%) in a one-pot sequence (eq 5). The stereochemistry and successful substrates suggest that the addition takes place through the *cisoid* form of the starting enone.

(5)

Vinylboranes from Vinylstannanes.

Like Cl-9-BBN, Br-9-BBN undergoes transmetalation with vinylstannanes to produce vinylboranes (eq 6), the *trans*-1,2-bis-9-BBN derivative being less stable than its BMe_2 or catecholboryl analog (see ***B-Bromocatecholborane***).[10]

Bromo(*t*-butyl)(methoxy)phenylsilane

[94124-39-7] · $C_{11}H_{17}BrOSi$ · Bromo(*t*-butyl)(methoxy)phenylsilane · (MW 273.24)

(reagent for the protection of primary, secondary, and tertiary alcohols; reacts selectively with primary hydroxy groups in dichloromethane; *t*-butylmethoxyphenylsilyl ethers are highly reactive towards F^-, allowing for selective removal in the presence of other silyl protecting groups[1])

Alternate Name: bromo-(1,1-dimethylethyl)methoxyphenylsilane.

Physical Data: bp 97-102 °C/1 mmHg; *d* 1.201 g cm^{-3}; fp 106 °C.

Solubility: sol most organic solvents.

Form Supplied in: clear liquid.

Handling, Storage, and Precautions: corrosive, lachrymator; the reagent is light and moisture sensitive and should be handled under an inert atmosphere. Use in a fume hood.

Reactivity.

Bromo(*t*-butyl)(methoxy)phenylsilane reacts with primary, secondary, and tertiary alcohols in DMF, in the presence of ***Triethylamine***, to give the corresponding silyl ethers in good yield (eqs 1 and 2). Under the same conditions, enolizable ketones may be converted efficiently to silyl enol ethers (eq 3).

(1)

(2)

(3)

In the case of secondary alcohols, silylation can be achieved in dichloromethane in the presence of a small amount of DMF (0.02 equiv). This accelerating effect of DMF has been rationalized based on the involvement of a more reactive hexacoordinated silicon species. Chemoselective silylation of primary alcohols can be achieved when dichloromethane is used as the only solvent (eq 4).[1]

(4)

Stability.

One of the most striking and useful features of the *t*-butyl(methoxy)phenylsilyl ether group is its sensitivity to fluoride. Removal of this protecting group can be achieved using ***Tetra-n-butylammonium Fluoride*** (1M solution in THF) in

dry dichloroethane (10% v/v), in the presence of primary or secondary *t*-butyldimethylsilyl or *t*-butyldiphenylsilyl ethers (eqs 5 and 7).[1] Selective cleavage of a *t*-butyldimethylsilyl ether in the presence of a *t*-butyl(methoxy)phenylsilyl ether is possible under acidic conditions (eqs 6 and 8).

The *t*-butyl(methoxy)phenylsilyl protecting group is compatible with reactions such as PCC oxidation,[2] acylation, tosylation, $NaBH_4$ reduction, benzylation, and hydrogenolysis.

Note that the use of this reagent on chiral molecules will produce diastereoisomers; this may complicate interpretation of NMR spectra.

3-Bromocamphor-8-sulfonic Acid[1]

(1*S*)

[46472-20-2] · $C_{10}H_{15}BrO_4S$ · 3-Bromocamphor-8-sulfonic Acid · (MW 311.19) (1*R*)

[5344-58-1] (1*S*) (NH_4^+ salt)

[55870-50-3] · $C_{10}H_{18}BrNO_4S$ · Ammonium 3-Bromocamphor-8-sulfonate · (MW 328.22) (1*R*) (NH_4^+ salt)

[14575-84-9] (±) (NH_4^+ salt)

[122519-23-7]

(chemical resolutions;[1] starting material for the preparation of chiral reagents[2])

Alternate Names: α-bromocamphor-π-sulfonic acid; 3-bromocamphor-9-sulfonic acid.

Physical Data: free acid: mp 195-196 °C; (1*R*): $[\alpha]_D$ 88.3° (*c* 2.6, H_2O). NH_4^+ salt: mp 284 °C (dec); (1*R*): $[\alpha]_D$ 84.8° (*c* 4, H_2O)

Solubility: the ammonium salt is sol in water, slightly sol in EtOH, but essentially insol in acetone and Et_2O. The free acid is sol in EtOAc, MeCN, and 5% aq. NaOH.

Form Supplied in: both enantiomers are commercially available as ammonium salts.

Preparative Methods: by sulfonation of bromocamphor with ***Chlorosulfonic Acid*** in $CHCl_3$.[3] Alternatively, fuming ***Sulfuric Acid*** can be used as both the solvent and sulfonating agent.[4] Recently, an improved preparation with an easier isolation procedure was reported (34% yield).[5] The acid can be prepared by passing a solution of the NH_4^+ salt in H_2O through a Dowex resin (H^+) column.[6] Alternatively, it can be obtained by adding ***Acetyl Chloride*** to a suspension of the ammonium salt in a 2:1 mixture of $CHCl_3$ and absolute EtOH.[7] The corresponding sulfonyl chloride is readily prepared from the acid or the NH_4^+ salt upon treatment with ***Phosphorus(V) Chloride*** and ***Phosphorus Oxychloride***.[8,9]

Purification: crystallized from H_2O.

Handling, Storage, and Precautions: a 0.5 M solution of the free acid in dry MeCN is stable for at least 30 days at 5 °C in a closed vessel under N_2.[6]

Chemical Resolution of Compounds Containing Basic Groups.

3-Bromocamphor-8-sulfonic acid has been widely used as a resolving agent for compounds containing basic groups. A number of primary (**1**),[10] secondary (**2**),[11] and tertiary (**3**) amines[12] as well as oxazolines (**4**)[6] have been resolved by the formation of diastereomeric salts derived from 3-bromo-8-camphorsulfonic acid.

(1)

(3)

(2) Flecainide

(4)

The optical resolution of racemic *p*-hydroxyphenylglycine with 3-bromocamphor-8-sulfonic acid has also been achieved.[13] This resolving agent has also been widely used in the preparation of optically pure chromium[14] and cobalt complexes.[15]

Preparation of Chiral Reagents.

3-Bromocamphor-8-sulfonic acid has been used as a starting material for the synthesis of chiral reagents.[16] Although the oxidation of sulfides to sulfoxides can be accomplished with the oxaziridine (**5**) or (**6**), other camphor-derived oxaziridines (**7** and **8**) are the reagents of choice to accomplish this transformation (eq 1).[2,9,17]

B-Bromocatecholborane

[51901-85-0] · $C_6H_4BBrO_2$ · *B*-Bromocatecholborane · (MW 198.81)

(mild Lewis acid capable of selective cleavage of ether, ester and carbamate protecting groups;[1,2] catalyst for Diels-Alder reactions[3,4])

Alternate Name: 2-bromo-1,3,2-benzodioxaborole.

Physical Data: mp 47 °C; bp 76 °C/9 mmHg; fp 41 °C.

Solubility: sol dichloromethane.

Form Supplied in: colorless solid which fumes in air.

Preparative Method: can be conveniently prepared by treating ***Catechol*** with ***Boron Tribromide***.[1,2,5] The reagent is isolated by distillation as a moisture-sensitive, low-melting solid.

Handling, Storage, and Precautions: flammable solid, moisture sensitive; may be conveniently stored and dispensed as a 0.2 M solution in dichloromethane. If properly protected from moisture, these solutions are stable for a period of months.[1] Use in a fume hood.

Cleavage of Ether, Ester, and Carbamate Protecting Groups.

B-Bromocatecholborane has been used to cleave a variety of ether, ester, and carbamate protecting groups.[1,2,6-9] The reactions typically proceed at rt in dichloromethane using 1-2 equiv of the reagent. ***Boron Trifluoride Etherate*** has been used as a coreagent.[2] After the cleavage of carbamate protecting groups the product amines should be freed of reactive bromide byproducts immediately upon workup in order to avoid problems of *N*-alkylation, especially when a reactive halide (e.g. benzyl bromide from cleavage of the Cbz protecting group) is involved.[1]

A series of competition experiments were performed in order to determine the relative reactivity of a number of common protecting groups towards *B*-bromocatecholborane. The results of these experiments suggest the following

tentative order of reactivity: MOM and MEM ethers > *t*-Boc > Cbz and *t*-Bu ethers > benzyl ethers > allyl ethers > *t*-Bu esters and secondary alkyl ethers > benzyl esters and primary alkyl ethers >> alkyl esters.[1] Selective cleavage of multifunctional substrates is possible when sufficient differences in reactivity exist; however, an excess of the reagent may be necessary when coordinating groups are present (eqs 1-4).[1,7]

(1)

(2)

(3)

(4)

B-Chlorocatecholborane has been used for similar transformations.[1,9-11] This reagent is observed to be less reactive than the bromo analog and may be preferable when higher selectivity is required.[1]

Diels-Alder Reactions.

B-Bromocatecholborane also functions as a catalyst for the Diels-Alder reaction (eq 5).[3,4] It is a very effective catalyst with a wide variety of dienophiles including α,β-unsaturated aldehydes, ketones, esters, thioesters, and nitriles. Turnover was seen with all dienophiles tested with the exception of acrylonitrile.[3]

(5)

In a comparison of the Diels-Alder reaction of cyclopentadiene with a variety of α,β-unsaturated esters and thioesters catalyzed by ***Aluminum Chloride*** or *B*-bromocatecholborane, the latter reagent afforded higher levels of *endo* selectivity.[4]

Related Reagents.

Boron Tribromide; ***Bromodimethylborane***.

Bromo(crotyl)(cyclopentadienyl)(nitrosyl)molybdenum

[133684-62-5] · $C_9H_{12}BrMoNO$ · Bromo(crotyl)(cyclopentadienyl)(nitrosyl)molybdenum · (MW 326.04)

(reagent for stereocontrolled synthesis of β-methyl homoallyl alcohols via crotyl addition to aldehydes)

Physical Data: mp ~150 °C (with dec).

Solubility: sol most polar organic solvents; very sol methylene chloride.

Form Supplied in: orange crystals; currently no commercial source.

Handling, Storage, and Precautions: indefinitely stable at rt under nitrogen or argon. The crystals can be handled in air for short periods with no significant decomposition.

Additions of crotyl organometallics to aldehydes provide a particularly effective route for the stereocontrolled synthesis of β-methyl homoallyl alcohols. CpMo(NO)(halide)(η^3-crotyl) reagents complement the crotylboron and crotyltitanium reagents, which are more reactive but can be more sensitive to decomposition by moisture (particularly the titanium complexes). As solids they have an indefinite shelf life and solutions are not particularly air-sensitive, although they are best handled under an inert atmosphere.

There are several methods of reagent preparation;[1-4] the most useful involves several straightforward steps via high yield reactions from the (*E*)- or (*Z*)-crotyl halide (eq 1).[4] (*Z*)-***Crotyl Chloride*** can be prepared readily from *cis*-2-butenol (commercially available or from hydrogenation of 2-butynol) by reaction with ***Triphenylphosphine*** and ***Hexachloroacetone***.[5]

Since the (*E*)-crotyl complex is the stable form and the half-life for conversion of (*Z*) to (*E*) is ~0.4 days at rt in solution, the steps involving addition of crotyl halide and LiCp to the (*Z*)-crotyl complex are best carried out at 0 °C. An alternate efficient route to the (*Z*)-crotyl complex is via hydride reduction of $[CpMo(CO)(2\text{-butyne})_2]BF_4$ under an atmosphere of CO to yield the $CpMo(CO)_2$(crotyl) complex[6] followed by treatment with NO^+ and halide.[2] The various halides can be easily interconverted by treatment with excess NaX or LiX in acetone. Another preparation uses the commercially available $[CpMo(CO)_3]_2$ as the starting organomolybdenum reagent with *cis*- or *trans*-crotyl halides.[7] Liebeskind[8] has reported that use of diphenylphosphinates instead of halides may be useful for analogs of crotyl reagents.

When the (*Z*)-crotyl reagent is initially prepared it usually contains some (<15%) of the (*E*)-isomer. Since the (*Z*)-isomer is less soluble (particularly for the iodide and bromide), recrystallization (CH_2Cl_2/pentane at -15 °C) allows separation of 99% pure material. This step is often not necessary because the (*Z*)-isomer reacts much faster with aldehydes than the (*E*)-isomer; consequently, the de of the product is not affected to a great degree. This feature appears to be common to other crotyl reagents, since (*Z*)-crotyl boronates also react faster than their (*E*)-analogs.[9] One should note in this preparation that the addition of NO^+ yields exclusively the isomer with the NO group *trans* to the methyl group. This tends to weaken the Mo-C bond on the methyl-substituted terminus of the crotyl ligand. An η^1-crotyl is thus readily formed (*k* &AApprox; 0.5 s^{-1} at 25 °C). This allows interconversion of conformers of the reagent in solution. Characterization by NMR can be complicated by the presence of resonances for two conformers (*exo*:*endo* &AApprox; 2:1 for the (*Z*)-crotyl-iodide complex).

The reactivity of the CpMo(NO)(halide)(crotyl) complexes decreases in the order OTs > Cl > Br >> I. The iodide and bromide readily form large crystals from methylene chloride and are more easily handled than the chloride and tosylate. The greater reactivity of the bromide thus may make it the reagent of choice. The (*Z*)-crotyl complex yields the *syn*-homoallylic alcohol (eq 2), whereas the (*E*)-crotyl complex yields the *anti*-isomer (eq 3), as one might anticipate based on a chair-like transition state. With the racemic crotyl complexes, both of the enantiomers of (**2**) and (**3**) shown in eqs 2 and 3 are produced as well.

The reaction rates are slow by comparison with those of allyltitanium reagents, which are often used at low temperatures. The reactions are faster in methylene chloride than in chloroform. Since they are second-order reactions, the more concentrated the solutions, the higher the rate. The reactions are effective for alkyl, aryl, and α,β-unsaturated aldehydes, but not for ketones. Room temperature reactions typically require less than an hour for CpMo(NO)(Br)[(*Z*)-crotyl] and 12 hours for CpMo(NO)(Br)[(*E*)-crotyl]. The reaction rates with α-substituted aldehydes are slower and the more reactive tosylate may be required; nevertheless, the selectivity of the reaction with the bromide is high, but may take several days.

After attack of the crotyl on the bound aldehyde, a proton is required to remove the newly formed homoallylic alcoholate from molybdenum. In initial reports, methanol was added to the reaction mixture as a proton source. With slower reacting alcohols, problems can sometimes be encountered owing to hemiacetal or acetal formation. The water present in wet methylene chloride is sufficient to provide the needed proton for the alcohol and also generates a relative insoluble [CpMo(NO)X(OH)] dimer. The convenience of this reagent lies in the facility with which the reagent can be removed from the reaction mixture by filtration (or passage through a short silica gel column), which yields a solution of product and any remaining starting aldehyde. This approach also does not require carefully dried solvents.

Enantiomerically pure (neomenthylCp)Mo(NO)(Cl)[(*E*)-crotyl] complexes produce the *anti*-β-methyl homoallylic alcohols in high enantiomeric purity (>98% ee; 92% de).[1] Although it has been unsuccessful with the parent CpMo(NO)(X)(allyl) complex, the crotyl and 2-methallyl complexes can be resolved as the camphorsulfonate complexes and converted back to the halides.[10,11] These reactions also yield the *anti*-β-methyl homoallylic alcohols in high ee.

Variants of these reagents have been utilized by Liu et al. in stereoselective 1,3-diol (eq 4) and 1,3,5-triol syntheses.[7,12,13]

2-Bromo-2-cyano-*N,N*-dimethylacetamide[1,2]

[15430-62-3] · $C_5H_7BrN_2O$ · 2-Bromo-2-cyano-*N,N*-dimethylacetamide · (MW 191.03)

(monobrominating agent selective for α-carbon of enolizable ketones[2])

Physical Data: mp 53-54 °C; bp 134-135 °C/0.3 mmHg.

Solubility: sol ethanol, benzene, chloroform, ethyl acetate, and THF; insol petroleum ether and hexane; slightly sol hot ether, isopropyl alcohol, and H_2O. It is stable at rt in neutral or acidic solution, but unstable in basic media.

Form Supplied in: colorless solid.

Preparative Method: via bromination of 2-cyano-*N,N*-dimethylacetamide with Br_2 in AcOH/Ac_2O at 8-10 °C.[3]

Handling, Storage, and Precautions: the reagent is fairly stable at rt. For long storage, keep at 0-10 °C, shielded from light. This reagent should be handled in a fume hood.

Regioselective Bromination.

This reagent is effective for the introduction of one bromine atom into ketones. Monobromination occurs regioselectively at the α-carbon of ketones on the side favorable to enolization. The reaction proceeds on refluxing the ketone substrate with an equimolar amount of the reagent, usually in benzene (eqs 1-8).[2] As the reaction most likely involves a radical mechanism,[2] nonpolar solvents are preferred. During the course of the reaction, the reagent is debrominated to 2-cyano-*N,N*-dimethylacetamide, which can be easily isolated and recycled to the original reagent through bromination.[2]

This highly selective reagent does not react with esters and does not add to carbon-carbon double bonds. Allylic bromination is not observed with this reagent. Bromomalononitrile shows reactivity similar to the reagent, but reacts with difficulty and in lower yield in some cases.[2] In the literature only a few examples of brominating reagents have appeared bearing bromine-carbon bonds, such as 2,2-dibromomalononitrile,[4] 2,2,2-tribromoacetophenone,[5] and ***5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione***.[6]

5-Bromo-1,3-cyclopentadiene

[41851-49-4] · C_5H_5Br · 5-Bromo-1,3-cyclopentadiene · (MW 145.00)

(Diels-Alder reaction;[1] 1,5-hydride shift;[2] bromocyclopentadienyl anion[3])

Physical Data: reactive intermediate typically stored in CCl_4 solution under nitrogen at -78 °C.

Form Supplied in: not commercially available.

Preparative Method: the compound may be prepared[1a] by addition of ***N-Bromosuccinimide*** to a solution of ***Thallium(I) Cyclopentadienide*** in dry CCl_4 at 0 °C.

Diels-Alder Reaction and 1,5-Hydride Shift.

Bromocyclopentadiene reacts with ***4-Phenyl-1,2,4-triazoline-3,5-dione*** (eq 1)[1a] and ***Dimethyl Acetylenedicarboxylate***[1b] to form the Diels-Alder adduct stereospecifically. The 5-iodo analog reacts similarly, while 5-chlorocyclopentadiene produces both chlorine epimers.[1]

5-Halocyclopentadienes are much more prone to dimerization than ***Cyclopentadiene*** itself (dimerizing about 10^3 times faster).[1a] However, the cycloaddition of halocyclopentadienes with electrophilic dienes is slower than with cyclopentadiene.[1a]

The presence of halogen on the cyclopentadiene ring slows the rate of 1,5-hydride shift and, although iodine rapidly migrates around the ring, bromine does not.[2]

Bromocyclopentadiene Anions.

Both potassium[2] and thallium[3] bromocyclopentadienyl derivatives have been reported.

3-Bromo-1,1-dichloro-1-propene

(R = Br)

[36469-73-5] · $C_3H_3BrCl_2$ · 3-Bromo-1,1-dichloro-1-propene · (MW 189.87) (R = CH_2OH)

[42134-33-8] · $C_4H_6Cl_2O$ · 4,4-Dichloro-3-buten-1-ol · (MW 141.00)

(chloroalkene annulating agent for synthesis of cycloalkane carboxylic acids,[1] halogenated vinyl epoxides,[2] halogen-substituted allylglycines,[3] and 1,1-dichloro terminal alkenes[4])

Physical Data: R = Br: bp 65-66.5 °C/17 mmHg; n_D^{20} 1.5363; d_{25} 1.7593 g L^{-1}. R = CH_2OH: bp 80-81.5 °C/10 mmHg.

Form Supplied in: R = Br: not available commercially; pale yellow liquid. R = CH_2OH: not available commercially; liquid.

Preparative Methods: R = Br: can be prepared by ***N-Bromosuccinimide***/***Dibenzoyl Peroxide*** bromination in CCl_4 of 1,1-dichloropropene with >60% yield.[1,2,5] Other methods of preparation are ***Hydrogen Bromide*** bromination of 1,1,3-trichloropropene (***Copper(I) Chloride***/***Copper(II) Chloride*** or ***Iron(III) Chloride*** catalyzed halogen exchange, 90% yield)[6] or 1,1-dichloropropen-3-ol (65% yield).[7] NMR, dipole moment, and IR studies of the reagent show that it exists in a *gauche* conformation in solution.[8] R = CH_2OH: can be prepared by the condensation of ***Chloral*** (hypnotic, sedative) and ***Malonic Acid***,[9] followed by acetylation (***Acetyl Chloride***/***Pyridine***), ***Zinc*** dechloroacetoxylation, and ***Lithium Aluminum Hydride*** reduction to produce 4,4-dichloro-3-buten-l-ol in 30% yield.[1]

Electrophilic Reactions.

These substituted alkenes are known for their utility in chloroalkene annulation reactions, which provide a useful synthesis of cycloalkanecarboxylic acids.[1,10] One example is the octalincarboxylic acid synthesis outlined in eq 1. A 1,1-dichloroalkene intermediate (**2**) is formed by alkylation of ***1-Pyrrolidino-1-cyclohexene*** (**1**) with 3-bromo-1,1-dichloro-1-propene. The ketone intermediate (**2**) is then converted to a mixture of isomeric octalincarboxylic acids (**3**) in two steps. First, ***Vinylmagnesium Bromide*** yields an allylic alcohol which then undergoes cyclization to (**3**) on treatment with ***Formic Acid*** at reflux. The *cis,cis*- and *cis,trans*-2-decalincarboxylic acids were obtained after

hydrogenation of (**3**) with Pt catalyst in acetic acid.

(1)

(3)

A related procedure employing 4,4-dichloro-3-buten-1-ol provides an efficient route to cyclopentanecarboxylic acid (**6**) (eq 2).[1,10] 4,4-Dichloro-3-buten-1-ol is first converted to the mesylate (**4**) (with ***Methanesulfonyl Chloride***), which in turn is used to alkylate deoxybenzoin to form ketone (**5**). Reduction of ketone (**5**) to the alcohol followed by formolysis (97% HCOOH, reflux overnight) results in cyclization to give *trans,trans*-2,3-diphenylcyclopentanecarboxylic acid (**6**).

(2)

(6)

Advantages of this methodology are the inertness of the chloroalkene side chain toward a variety of reagents and the relatively mild formolysis conditions required for cyclization. Chloroalkene reagents may be homologated to allow for generation of rings with more than six members. The method is general and has been used with other related

haloalkene reagents.[11]

3-Bromo-1,1-dichloro-1-propene is also used to form halovinyl epoxides. A haloallylsulfonium salt (**8**) is prepared by reaction of tetrahydrothiophene (**7**) with 3-bromo-1,1-dichloro-1-propene in anhydrous acetone (eq 3).[2] Halogenated vinyl epoxides (**9**) are formed upon condensation of (**8**) with RCHO (R = MeCH=CH-, CH_2=C(Me)-, Ph). Other allylic chlorides and bromides have also been used in this reaction.[2]

(3)

(**9**)

Halogenated allylic reagents have been used to synthesize substituted allylglycines.[3] Diethyl formamidomalonate (**10**) was alkylated with 3-bromo-1,1-dichloro-1-propene to form intermediate (**11**) (eq 4). The amino acid (**12**) is then obtained by hydrolysis with dilute HBr (reflux, 4 h).

(4)

The 1,1-dichloropropen-3-yl ester of hexanoic acid has been found to be an antagonist of insect juvenile hormone.[4] This ester is prepared (93%) by reaction (K_2CO_3/55 °C/3 h/HMPA) of 3-bromo-1,1-dichloro-1-propene with hexanoic acid. Several patents have been filed for 1,1-dichloroalkene-substituted compounds which have antitumor, herbicide, or pesticide activity and are prepared using 3-bromo-1,1-dichloro-1-propene.

Nucleophilic Reactions.

It has been demonstrated that the 1,1-dichloroalkene moiety may also be introduced into organic molecules via conversion of the reagent to a nucleophile.[1,10] For example, 4,4-dichloro-3-buten-1-ylmagnesium bromide, obtained from bromide (**13**) ($Cl_2C{=}CH(CH_2)_2OH/PBr_3$), reacts with deoxybenzoin to yield alcohol (**14**) (eq 5). Formolysis of (**14**) in refluxing HCO_2H then provides the same cyclopentanecarboxylic acid (**6**) as was obtained in chemistry described earlier where $Cl_2C{=}CH(CH_2)_2OMs$ was employed as an electrophilic reagent (eq 2). The overall yields of the two reactions are similar and the same advantages of chloroalkene side-chain inertness and mild formolysis conditions apply. Other related chloroalkene reactions have been described in the literature.[11]

3-Bromo-4,5-dihydro-5-hydroperoxy-4,4-dimethyl-3,5-diphenyl-3*H*-pyrazole[1]

[76847-41-2] · $C_{17}H_{17}BrN_2O_2$ · 3-Bromo-4,5-dihydro-5-hydroperoxy-4,4-dimethyl-3,5-diphenyl-3*H*-pyrazole · (MW 361.24)

(oxygen-atom transfer reagent; heteroatom and alkene oxidation[2])

Physical Data: mp 77-80 °C (dec).

Solubility: sol $CHCl_3$, CH_2Cl_2, ether, acetone.

Analysis of Reagent Purity: [3] gravimetric analysis gives 96% of bromine theoretical yield. Analysis of gaseous products (thermolysis) shows an N_2 to O_2 ratio of 1:1. IR (KBr): stretching absorptions for OOH and N=N at 3250 and 1540 cm^{-1}, respectively. ^1H NMR ($CDCl_3$): -0.05 (s, 3H), 1.68 (s, 3H), 7.2-7.8 (m, 11H). ^{13}C NMR ($CDCl_3$): 19.9, 23.0, 25.8, 48.6, 102.4, 119.7, 125.7, 128.2, 128.3, 129.1, 132.1, 135.4, 138.9.

Preparative Method: [3] to a slurry of 2.0 g (8.0 mmol) of 4,4-dimethyl-3,5-diphenyl-4*H*-pyrazole in anhydrous ether at 0 °C is carefully added in small portions 6 g (159 mmol) of 90% ***Hydrogen Peroxide*** (caution: danger of explosion!). The solution is allowed to warm to rt and 1.17 g (4.1 mmol) of ***1,3-Dibromo-5,5-dimethylhydantoin*** is added as a powder, portionwise, over a 20-30 min period in the dark. The resulting solution is kept at -20 °C for 48 h, after which it is washed with cold 10% sodium bicarbonate and dried over anhydrous magnesium sulfate. Filtration and removal of the solvent under reduced pressure at 0 °C affords the crude product as a yellow oil; recrystallization from CH_2Cl_2/petroleum ether (below -20 °C) yields white crystals of the desired reagent in 75% yield.

Handling, Storage, and Precautions: should be stored at low temperature. Crystals have been kept at -30 °C for years with little or no detectable decomposition. Solutions of the hydroperoxide *must* contain small amounts of *cis*- or *trans*-3-hexene to prevent self-induced decomposition. Addition of 2 µL of the unreactive alkene per 1 mL of solvent stabilizes the reagent. All normal precautions used in the handling of peroxidic materials should be followed.

Heteroatom and Alkene Oxidation.[2]

3-Bromo-4,5-dihydro-5-hydroperoxy-4,4-dimethyl-3,5-diphenyl-3*H*-pyrazole (**1**) is one of the most reactive organic hydroperoxides known.[1] As an electrophilic oxygen-atom transfer reagent, its reactivity in heteroatom oxidation (eq 1)[2] is similar to that of flavin hydroperoxides and ca. two orders of magnitude faster than acyclic azo hydroperoxides.[4] Both *N*- and *S*-oxidation have been found to be first order in (**1**) and in substrate, respectively. No external proton source was required. The reactivity of (**1**) can be estimated[1] to be ca. 10^5 that of ***Hydrogen Peroxide*** and ***t-Butyl Hydroperoxide*** for *N*-oxidation. Heteroatom oxidation has been found[4b] to be an order of magnitude slower in acetone-d_6 than in $CDCl_3$.

Azo hydroperoxide (**1**) has been found to be of sufficient reactivity to epoxidize alkenes (eq 2) in good yield under mild conditions.[2] The selectivity is essentially identical to that of peroxy acids. The reactivity of (**1**) is comparable to that of ***2-Hydroperoxyhexafluoro-2-propanol*** and roughly two orders of magnitude lower than that of ***Peracetic Acid***.[1] Representative product yields and second order rate constants for heteroatom and alkene oxidation are listed in Table 1.

Table 1 Product Yields and Second Order Rate Constants for the Reaction of (**1**) with Sulfides, Amines, and Alkenes in $CDCl_3$ at 34 °C[2]

Substrate	*Oxide yield (%)*	k_2 ($M^{-1}s^{-1}$)	*Substrate*	*Oxide yield (%)*	k_2 ($M^{-1}s^{-1}$)
BnSMe	93	fast	2,3-Dimethyl-2-butene	94	0.0039
PhSMe	94	0.95	1,2-Dimethyl-cyclohexene	85	0.0021
BnSPh	90	0.80	2-Methyl-2-butene	79	0.00028
Ph_2S	92	0.010	1-Methylcyclohexene	72	0.00021
Et_3N	100	0.48	Cyclopentene	41	0.000032
$BnNMe_2$	97	0.16			
N-Methyl-morpholine	95	0.05			
$PhNMe_2$	90	0.0011			

Oxygen-atom transfer reagent (**1**) offers the following advantages: (a) high reactivity with normal selectivity; (b) mild reaction conditions with neutral products; and (c) long-term storage. Limitations for this reagent center on its synthesis. The procedure[3] must be followed in detail and the method has not been extended to additional compounds. Conc H_2O_2 is required in the preparation which greatly increases the difficulty in the preparation of labeled reagent. The newer generation[4b,5] of cyclic azo hydroperoxides are of equal reactivity but are prepared by the reaction of oxygen with 3,4-dihydro-2*H*-pyrazoles (eq 3). Thus these compounds can be prepared readily with ^{17}O or ^{18}O enriched oxygen for use as labeling reagents.[4a]

Bromodimethylborane[1]

Me_2BBr

[5158-50-9] · $C_2H_6BBr_2$ · Bromodimethylborane · (MW 120.78)

(mild Lewis acid capable of selective cleavage of ethers[2,3] and acetals;[4,5] deoxygenation of sulfoxides[6])

Physical Data: mp -129 °C; bp 31-32 °C; *d* 1.238 g cm^{-3}; fp -37 °C.

Solubility: sol dichloromethane, 1,2-dichloroethane, hexane.

Form Supplied in: colorless liquid.

Preparative Method: can be conveniently prepared by treating ***Tetramethylstannane*** with ***Boron Tribromide***.[7]

Handling, Storage, and Precautions: flammable liquid, moisture sensitive; typically stored and dispensed as a 1.5-2 M solution in dichloromethane or dichloroethane. Solutions of this sort are stable for a period of months if stored at -15 °C and properly protected from moisture.

Cleavage of Ethers.

Bromodimethylborane (Me_2BBr) reacts with primary, secondary, and aryl methyl ethers,[2] in addition to trityl,[8] benzyl,[2,8] and 4-methoxybenzyl[9] ethers, to regenerate the parent alcohol in good to excellent yield (e.g. eq 1). The tertiary methyl ethers examined afforded the corresponding tertiary bromides.[2] The reaction is typically carried out in dichloromethane or 1,2-dichloroethane between 0 °C and rt, in the presence of 1.3-4 equiv of Me_2BBr. The reaction is usually complete in a matter of hours. ***Triethylamine*** (0.1-0.15 equiv per equiv of Me_2BBr) is often added as an acid scavenger. 4-Methoxybenzyl ethers are more reactive and are cleaved at -78 °C, whereas aryl methyl ethers require elevated temperatures to react. Other functional groups including acetates, benzoates, alcohols, ethyl esters, and *t*-butyldiphenylsilyl ethers are recovered unchanged under the standard reaction conditions.

Bromodimethylborane is also effective for the cleavage of cyclic ethers.[2,3] Epoxides react at -78 °C while the analogous four- to seven-membered ring heterocycles react between 0 °C and rt. In contrast to other boron-containing Lewis acids, Me_2BBr reacts via a predominantly S_N2 mechanism. Tetrahydrofuran derivatives which are substituted at the 2-position give rise to primary bromides as the major or exclusive products. The nature of the substituent has a quantitative influence on the outcome of the reaction via steric effects and/or complexation to the reagent. It is of interest to note that tetrahydrofurans can be cleaved in the presence of acyclic ethers (eq 2).[3]

It is also of considerable interest to note that no β-elimination of the hydroxy group was observed in the ring-opening of 2-(ethoxycarbonylmethyl)tetrahydrofurans (eq 3),[3] whereas *C*-glycosides bearing more acidic protons on the aglycon react with Me_2BBr to generate acyclic alkenes (eq 4).[10]

Bromodimethylborane has also been used in conjunction with ***Tetra-n-butylammonium Iodide*** to bring about the fragmentation of iodomethyl ether derivatives (eq 5).[11]

Cleavage of Acetals.[4,5]

Cyclic and acyclic acetals react with Me_2BBr at -78 °C to generate the parent aldehydes and ketones in excellent yield (e.g. eq 6). Primary, secondary, and tertiary (2-methoxyethoxy)methyl (MEM), methoxymethyl (MOM), and (methylthio)methyl (MTM) ethers also react at -78 °C to give, after aqueous workup, the corresponding alcohol. It is interesting to note that even tertiary MEM ethers cleanly regenerate the parent alcohol without formation of the corresponding bromide or elimination products (eq 7). Treatment of an acetonide with Me_2BBr gives the parent diol in high yield (eq 8).

(7)

(8)

Tetrahydropyranyl (THP) and tetrahydrofuranyl (THF) ethers are converted to the corresponding alcohols by Me_2BBr at rt (eq 9), although the acetals are cleaved at -78 °C (see below).

(9)

Bromodiphenylborane (Ph_2BBr) and ***9-Bromo-9-borabicyclo[3.3.1]nonane*** (Br-9-BBN) can often be used in place of Me_2BBr for the cleavage of acetals;[4,5] however, the purification of products from reactions employing Me_2BBr is facilitated by the volatility of Me_2B-containing byproducts, thus making Me_2BBr the reagent of choice in most instances.

Interconversion of Functional Groups.

The reaction of Me_2BBr with MEM and MOM ethers is believed to proceed via α-bromo ether intermediates. It is possible to trap these intermediates with nucleophiles such as thiols, alcohols, and cyanide. An example of the utility of this sequence is the conversion of a readily prepared MOM ether into an MTM ether (eq 10).[12]

(10)

While THP and THF ethers are converted to the corresponding alcohols by Me_2BBr at rt, the acetal is cleaved at -78 °C.[13] The initial products of the reaction are acyclic α-bromo ethers. These can be trapped with a variety of nucleophiles to generate stable ring-opened products (eq 11).[13] This reaction has been extended to glycosides which, although less reactive, behave in a similar fashion.[14,15]

Benzylidene acetals are recovered unchanged when treated with Me_2BBr under conditions which are used to cleave other acetals.[16] It is, however, possible to cleave benzylidene acetals to generate hydroxy-*O*,*S*-acetals in excellent yield, by treatment with Me_2BBr at -78 °C followed by ***Thiophenol*** (eq 12).[16] Sterically encumbered bromoboranes optimize regioselective complexation of boron to the least hindered oxygen atom and are, therefore, the reagents of choice for this process (eq 12).[16] These experiments demonstrate that benzylidene acetals do indeed react with Me_2BBr at -78 °C, like other acetals.

Me_2BBr	68%	17%
Ph_2BBr	96%	-
9-BrBBN	90%	-

Treatment of glycoside benzylidene acetals with a variety of disubstituted bromoboranes, followed by ***Borane-Tetrahydrofuran***, generates 4-*O*-benzyl-6-hydroxypyranosides in excellent yield (eq 13).[16]

(13)

Acetals derived from ***Dimethyl L-Tartrate*** react with Me_2BBr to generate α-bromo ethers which react further with cuprate reagents to give optically active secondary alcohol derivatives (eq 14).[17] The alcohols may be liberated by treatment with ***Samarium(II) Iodide*** or by a straightforward sequence of reactions (mesylation and elimination to form an enol ether followed by exposure to methoxide in refluxing methanol). Selectivity is enhanced by the use of Ph_2BBr and by careful control of the reaction temperature at each step.

(14)

Me_2BBr, 80%	34:1
Ph_2BBr, 62%	82:1

Miscellaneous Reactions.

Bromodimethylborane can also be used to convert dialkyl, aryl alkyl, and diaryl sulfoxides to the corresponding

sulfides (eq 15).[6] Typically, the sulfoxides are treated with 2.5 equiv of Me_2BBr in dichloromethane at -23 °C for 30 min and at 0 °C for 10 min. Bromine is produced in the reaction and must be removed in order to avoid possible side reactions. This is accomplished by saturating the solution with propene prior to introducing the reagent or by adding cyclohexene. Phosphine oxides and sulfones failed to react under the conditions used to deoxygenate sulfoxides.

(15)

Bromodimethylborane has also been used as a catalyst for the Pictet-Spengler reaction (eq 16)[18] and to catalyze the 1,3-transposition of an allylic lactone.[19]

3-Bromo-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one[1]

(R = *t*-Boc) (3*S*,5*S*,6*R*)

[112741-51-2] · $C_{21}H_{22}BrNO_4$ · 3-Bromo-4-*t*-butoxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one · (MW 432.31) (R = *t*-Boc) (3*R*,5*R*,6*S*)

[127420-01-3] (R = Cbz) (3*S*,5*S*,6*R*)

[111934-06-6] · $C_{24}H_{20}BrNO_4$ · 4-Benzyloxycarbonyl-3-bromo-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one · (MW 466.33) (R = Cbz) (3*R*,5*R*,6*S*)

[117527-28-3]

(electrophilic glycine equivalent useful for the preparation of α-substituted-α-amino acids in high enantiomeric excess[2])

Alternate Name: 3-bromo-5,6-diphenylmorpholin-2-one.

Physical Data: white solid, decomposes upon heating.

Solubility: sol THF, CH_2Cl_2.

Preparative Methods: *N*-*t*-Boc- and *N*-Cbz-3-bromo-5,6-diphenyl-2,3,5,6-tetrahydrooxazin-2-ones are not commercially available. They are prepared by addition of 1 equiv of ***N-Bromosuccinimide*** to a solution of the parent oxazinone (commercially available[3] as the individual enantiomers or as racemates) in CCl_4 at reflux. Upon cooling of the reaction mixture to 0 °C and filtering off the succinimide, the CCl_4 is removed under reduced pressure and the bromooxazinone is obtained in essentially quantitative yield as a white solid and is used without further purification.[2]

Handling, Storage, and Precautions: generally prepared immediately prior to use. Chromatography on silica gel results in decomposition.

General Reactivity.

The *N*-protected 3-bromo-5,6-diphenyl-2,3,5,6-tetrahydrooxazin-2-ones serve as chiral electrophilic glycine equivalents. They are prepared as discussed above to yield the *anti*-diastereomer exclusively (eq 1).[2] The bromide is subject to displacement by a variety of reagents under a range of conditions to afford the substituted oxazinone generally with the newly introduced substituent oriented *anti* to the C(5) and C(6) phenyl groups. Deprotection of the heterocyclic amino acid precursor is accomplished by scission of the benzylic carbon-heteroatom bonds via reductive or oxidative cleavage. The deprotection routes afford the amino acid zwitterion or *N*-*t*-Boc amino acid directly but also result in destruction of the chiral auxiliary. Hydrogenolysis of the bromooxazinone with deuterium[4c] or tritium[4a,b] using ***Palladium(II) Chloride*** as catalyst occurs with net retention of configuration to afford the chiral isotopically labeled glycine (eq 2). Ease of preparation and introduction of the isotope in the final step make this a valuable synthesis of chiral glycines.

(1)

(2)

Coupling with Allylsilanes.

Allyltrimethylsilanes react with the bromooxazinone in the presence of ***Zinc Chloride*** in THF to afford the allylated heterocycles with high selectivity (eq 3).[2] The coupling is presumed to take place by an S_N1 mechanism in which the Lewis acid promotes expulsion of bromide resulting in iminium ion formation. The heterocyclic iminium ion then undergoes attack by the nucleophile on the least hindered face, giving the *anti* diastereomer. Hydrogenolysis of the Cbz protected oxazinone (20-50 psi) affords the amino acid zwitterion in good yield and high chemical purity (eq 4).

(3)

(4)

The amino acids can also be liberated by dissolving metal reduction.[2] Treatment of the oxazinone with ***Lithium*** or ***Sodium*** metal in liquid ammonia at -33 °C effects deprotection (eq 5). Ion exchange chromatography yields the zwitterionic amino acid free of inorganic salts. This procedure has the advantage of permitting the synthesis of amino acids possessing unsaturated side chains. When the dissolving metal reduction is carried out on the *t*-Boc protected oxazinone, the *N*-*t*-Boc amino acid is obtained directly (eq 6).

(5)

(6)

Coupling with Tin Acetylides.

Trialkyltin acetylides react with the bromooxazinone in the presence of $ZnCl_2$ to furnish the alkyne-substituted heterocycle (eq 7).[5] Hydrogenation of the Cbz-protected acetylide adducts yields the aliphatic amino acids in good yield and high enantiomeric excess (eq 8).[5b] Dissolving metal reduction affords the (*E*)-vinylglycines, though some racemization is observed. The use of sodium metal in the deprotection results in higher chemical yields (71-80%) and lower enantiomeric excess (56-68%) while the use of lithium metal gives better enantiomeric excess (65-98%) but much lower chemical yields (16-20%) (eq 9).[5a]

(7)

(8)

(9)

Coupling with Electron-Rich Arenes.

Electron-rich aromatics such as trimethoxybenzene, furan, and 2-methylfuran also couple the bromooxazinone in the presence of $ZnCl_2$ to afford the 3-aryloxazinones stereoselectively (eq 10).[2a,6] This process introduces a third benzylic carbon-heteroatom bond into the molecule and thereby precludes the reductive deprotections described. An alternative oxidative deprotection was developed.[6] Removal of the *t*-Boc protecting group followed by acid catalyzed opening of the heterocycle and subsequent oxidative cleavage with ***Sodium Periodate*** affords the arylglycines in moderate yield (eq 11).

(10)

(11)

Coupling with Silyl Enol Ethers and Silyl Ketene Acetals.

Silyl enol ethers can couple to the bromooxazinone to give both the *syn* and *anti* diastereomers.[2,7] The reaction can proceed via the S_N1 mechanism discussed above or by a Lewis acid assisted S_N2 displacement of the bromide. The reaction conditions can be manipulated to favor the S_N1 (stronger Lewis acids, more polar solvents) or S_N2 path (weaker Lewis acids, less polar solvents) (eqs 12 and 13).[2a]

$ZnCl_2$, CH_2Cl_2	1	45

Coupling with Organozincs and Organocuprates.

Alkylzinc chlorides and alkyl- and arylcuprates couple with the bromooxazinones with a high degree of diastereoselection but in lower yields.[2,6] Reduction of the bromide to the parent oxazinone is a significant side reaction and is attributed to the reaction taking place via an electron-transfer, radical-radical coupling.[2a] Substituted phenyl and naphthyl glycines have been prepared by coupling of the bromide with the corresponding organocuprate and employing the oxidative deprotection described above (eqs 14 and 15).[6]

(14)

(15)

1-Aminocyclopropane-1-carboxylic Acids.

These amino acids are prepared by a multistep procedure involving treatment of the bromooxazinone with ***Trimethyl Phosphite*** to give the corresponding phosphonate at the 3-position. Ylide formation and condensation with an aldehyde produces the α,β-dehydrooxazinone adduct possessing the (*E*) configuration (eq 16). Cyclopropanation with either ***Diazomethane*** or ***Dimethylsulfoxonium Methylide*** occurs with little diastereoselectivity. In contrast, cyclopropanation with (diethylamino)phenylsulfoxonium methylide is highly selective (eq 17).[8] Unexpectedly, delivery of the methylene occurs on the face of the heterocycle *syn* to the phenyl rings. The reason for this selectivity has not yet been determined. Deprotection with Li^0/NH_3 yields the *N*-*t*-Boc-1-aminocyclopropane-1-carboxylic acids (eq 18).

(16)

(17)

(18)

The α,β-dehydrooxazinone adducts can also undergo 1,3-dipolar cycloadditions as demonstrated in the synthesis of *S*-(-)-cucurbitine (eqs 19 and 20).[9]

For the complementary synthesis of α-substituted-α-amino acids via a chiral glycine enolate equivalent see ***4-t-Butoxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4H-oxazin-2-one***.

2-(2-Bromoethyl)-1,3-dioxane[1]

(**1**; R,R = $-(CH_2)_3-$)

[33884-43-4] · $C_6H_{11}BrO_2$ · 2-(2-Bromoethyl)-1,3-dioxane · (MW 195.06) (**2**; R,R = $-(CH_2)_2-$)

[18742-02-4] · $C_5H_9BrO_2$ · 2-(2-Bromoethyl)-1,3-dioxolane · (MW 181.03) (**3**; R,R = Me,Me)

[36255-44-4] · $C_5H_{11}BrO_2$ · 3-Bromopropionaldehyde Dimethyl Acetal · (MW 183.04)

(a group of bifunctional three-carbon reagents having the capacity to serve as electrophiles or as nucleophiles;[1] once the latent carbonyl is unmasked, annulation reactions of various types can be implemented; the application range of these reagents can be further enhanced by initial bromide displacement with nucleophiles possessing useful functionality)

Physical Data: (**1**) bp 67-70 °C/2.8 mmHg, *d* 1.431 g cm^{-3}; (**2**) bp 68-70 °C/8 mmHg, *d* 1.542 g cm^{-3}; (**3**) bp 58-60 °C/17 mmHg, *d* 1.341 g cm^{-3}.

Form Supplied in: all three acetals are colorless, commercially available liquids.

Preparative Methods: 3-bromopropionaldehyde acetals are prepared by bubbling anhydrous gaseous ***Hydrogen Bromide*** into a dichloromethane solution containing ***Acrolein*** and the alcohol or diol at or below rt.[2] More recently, the discovery has been made that ***Chlorotrimethylsilane*** can promote the conjugate addition of NaX (X = Br, I, SCN) to α,β-unsaturated acetals.[3]

Handling, Storage, and Precautions: these bromides are recognized to possess irritant properties and should therefore invariably be handled with gloved hands inside an efficient hood. It is also advisable that these reagents be refrigerated for long-term storage in order to minimize the potential for acid liberation.

As Electrophile in Alkylation Reactions.

These three-carbon bifunctional reagents have proven to be very serviceable electrophiles in a variety of settings. Doubly activated anions such as those derived from β-diketones,[4] β-keto esters (eq 1),[5] malonate esters,[6] and phosphono esters[7] are readily homologated by this means. This level of activation is hardly necessary as demonstrated

by the fact that anions derived from esters,[8] nitriles (eqs 2 and 3),[9] imines,[10] and isocyanides[11] behave comparably. Generally, the carbonyl group is subsequently unmasked and utilized in further chemical transformations. Where (**2**) and (**3**) are concerned, aqueous acid suffices to accomplish the hydrolysis. Dioxanes derived from (**1**) are much less reactive and often require prior conversion to the dimethyl acetal.[12] Sulfur-containing nucleophiles including α-sulfonyl,[13] thioallyl,[14] and 1,3-dithianyl anions[15] are also readily alkylated. In addition to (**4**) (eq 4), it has proven possible to prepare polyprenols stereoselectively,[14] to produce substituted 1,5-dienes, and to synthesize estrone in a modest number of steps.[15b]

(7) (5)

Alkynyl anions have frequently been combined with (**1**)-(**3**).[19] For example, the directness with which (**8**) is constructed underscores the abbreviated route that produces both diastereomers of (**9**) (eq 6).[20] Similarly, the generation of enediyne (**10**) is central to the successful realization of an intramolecular [2 + 2 + 2] cycloaddition that gives rise to diene (**11**) (eq 7).[21] Allenyllithiums have proven equally effective (eq 8).[22]
