(7)

(11)

2-(2-Bromoethyl)-1,3-dioxane

(8)

Since the lateral metalation of methyl-substituted aromatics can often be directly implemented, introduction of a functionalized sidechain is made possible by reaction of these anions with (**2**) and (**3**).[23] When dianions such as (**12**) and (**13**) are involved, chemoselectivity is manifested such that C-C bond formation is heavily favored kinetically (eqs 9 and 10).[24,25]

(9)

(10)

The (η^5-cyclohexadienylidene)$_2$[Cr(CO)$_3$]$_2$ dianion (**14**) reacts regioselectively with (**2**) to give intermediate (**15**); its further treatment, as shown in eq 11, leads ultimately to the doubly functionalized aromatic product (**16**).[26] The discovery has been made that the condensation of (**2**) with the anion of ethyl phenylsulfinylfluoroacetate leads to the α-

fluoro acrylate (**17**) (eq 12).[27]

(14)

(11)

(15) **(16)** 49%

(12)

(17)

Alcohols and amines are also capable of condensing with these halo acetals. The conversion of a suitably protected hydroxyproline to (**18**) (eq 13)[28] and of the methylamino derivative to arecolone (**19**) are illustrative (eq 14).[29]

2-(2-Bromoethyl)-1,3-dioxane

(13)

(18)

(14)

(19)

Use as Grignard Reagents.

The Grignard reagents derived from (**1**)-(**3**) exhibit a stability order that parallels their hydrolytic behavior. That derived from (**1**) is thermally stable,[12] while the dimethyl acetal (**3**-MgBr) is too labile to be useful.[30] Since the magnesium reagent derived from (**2**) decomposes at rt and above,[30,31] it must be generated and used below 25 °C. As expected, examples of simple additions of (**1**-MgBr) and (**2**-MgBr) to aldehydes[32] and ketones[33] abound. In the first instance, this process has evolved into a facile means for preparing 5-substituted butyrolactones.[34] The conversion of ketone (**20**) to norbisabolide (**21**) shows that ketones can be analogously processed (eq 15).[35] Clever use has been made of this condensation reaction in a total synthesis of clavukerin A,[36] where Grob fragmentation of adduct (**22**) was utilized to obtain the functionalized 3-cycloheptenone (**23**) (eq 16).

(15)

(20)

(21)

2-(2-Bromoethyl)-1,3-dioxane

(16)

These Grignard reagents can be condensed directly with activated halides (eq 17).[37] Alternatively, related carbon-carbon bond formation can be realized by promoting the coupling with ***Dilithium Tetrachlorocuprate(II)*** (eq 18).[38]

(17)

2-(2-Bromoethyl)-1,3-dioxane

(18)

The presence of acetal oxygen atoms has been recognized to moderate the chemical reactivity of these Grignard reagents. As seen in eq 19, addition to cyclic enones at -78 °C affords principally the product of conjugate addition without the benefit of a Cu^{I} salt.[39] Additionally, these organometallics are widely known to react with acid chlorides to produce ketones without significant further conversion to tertiary alcohols.[12a,40] The substantial synthetic latitude provided by this process is reflected in eqs 20-22.[41-43]

(21)

2-(2-Bromoethyl)-1,3-dioxane

Other notable uses of (**2**-MgBr) can be found in syntheses of estafiatin (1,6-addition to tropone),[44] eupolauramine (displacement of an aryl oxazoline),[45] substituted eudistomins (capture by a nitrile group),[46] a tripeptide ACE inhibitor (addition to a thio ester),[47] the 1,7-dioxaspiro[5.5]undecane subunit of milbemycin β_3 (directed oxirane cleavage),[48] and the lipophilic sidechain of the cyclic hexadepsipeptide antibiotic L-156,602 (addition to an α-chloroboronate).[49]

Use as a Cuprate.

As noted above (eq 18), (**1**-MgBr) and (**2**-MgBr) give coupling reactions with halides and tosylates under conditions of copper catalysis.[38,50] Cuprate formation also results in successful condensation with allylic acetates (eq 23),[51,52] epoxides,[53] vinyl epoxides (eq 24),[54] and alkynes (eq 25).[55] Conjugate addition to α,β-unsaturated ketones can also be realized in this way,[56] this process often constituting the first step of an annulation sequence.

high yield

(23)

(24)

(25)

Annulation Reactions.

The keto acetals formed upon Cu^{I}-promoted 1,4-addition of acetal-containing Grignard reagents have found wide application in cyclopentene annulation.[57] When no α-substituent is present, the aldol condensation leads to a conjugated bicyclic enone (eq 26).[58] Dehydration is, of course, not spontaneous when an angular group is already in place; in such cases, dehydration must be implemented separately (eq 27).[59]

(26)

(27)

When the site of connectivity is external to an aromatic ring, cyclodehydration results in the elaboration of a six-membered ring.[60] Depending upon the method employed and the degree of substitution, the annulated ring may be singly unsaturated (eq 28)[61] or fully aromatic (eq 29).[62]

2-(2-Bromoethyl)-1,3-dioxane

(28)

(29)

Pyridoannulations are also possible (eq 30).[63] Other nitrogen-containing rings have been elaborated either by radical means (eq 31)[64] or via the involvement of *N*-acyliminium ions (eq 32).[65] The potential for spirocyclic ring construction has been explored as well (eq 33).[66]

Allied Compounds.

The lithium derivative of (**1**) has been satisfactorily generated by exposure of the iodide to ***t-Butyllithium*** in *n*-pentane-ether (3:2) at -78 °C.[67] Bromo acetals (**1**)-(**3**) are quite amenable to functional group exchange in the manner represented by (**24a-h**).[68-73] Of these, (**24b**)[69] has held particular fascination as a consequence of its ability to serve as a reaction partner in [3 + 2] cycloadditions (eq 34).[69d] The dithianyl acetals of type (**25**) are notably serviceable as cyclohexane annulating agents (eq 35).[72b,74] Ynamine acetal (**26**) has found similar application (eq 36).[75]

The Ohio State University, Columbus, OH, USA

2-(2-Bromoethyl)-2-methyl-1,3-dioxolane[1]

(**1**; X = Br)

[37865-96-6] · $C_6H_{11}BrO_2$ · 2-(2-Bromoethyl)-2-methyl-1,3-dioxolane · (MW 195.06) (**2**; X = I)

[53750-51-9] · $C_6H_{11}IO_2$ · 2-(2-Iodoethyl)-2-methyl-1,3-dioxolane · (MW 242.06) (**3**; X = Cl)

[57398-28-4] · $C_6H_{11}ClO_2$ · 2-(2-Chloroethyl)-2-methyl-1,3-dioxolane · (MW 150.60)

(methyl vinyl ketone equivalent; alkylating agents for attaching a 3-ketobutyl group to various nucleophiles; the derived organometallic reagents attach this group to electrophilic centers such as carbonyl groups; major use in the synthesis of monoprotected 1,4-, 1,5-, and 1,6-diketones and related 1,*n*-difunctional compounds)

Physical Data: X = Cl: bp 40-43 °C/1 mmHg; 73-74 °C/14 mmHg. X = Br: bp 42-46 °C/0.4 mmHg; 64-68 °C/9 mmHg; 84-88 °C/12 mmHg, 88-94 °C/27 mmHg. X = I: decomposes on distillation.

Preparative Methods: X = Br or I: addition of methyl vinyl ketone to a two-phase mixture of benzene and conc aq HX, followed by drying of the benzene phase, addition of ethylene glycol, and removal of water with a Dean-Stark trap.[1b,2] X = Cl: acetalization of 4-chloro-2-butanone with ethylene glycol;[3] the chloro ketone was made by acylation of ethylene[4] but, presumably, can also be made as above. Other preparations of these and related 4-halo-2-butanone acetals have been reported.[5]

Purification: X = Cl or Br: vacuum distillation from a trace of sodium bicarbonate; X = I: filter through a small plug of alumina; the acetal should not be distilled.

Handling, Storage, and Precautions: even purified samples contain some β-halo ketone which slowly loses HX, catalyzing further decomposition. Store at <=0 °C.

Electrophilic 3-Ketobutyl Reagent.

Attachment of a 3-ketoalkyl chain to the α-position of a preexisting ketone gives a 1,5-diketone which, upon treatment with base, undergoes aldol condensation to give a 2-cyclohexen-1-one.[6] In the case of relatively acidic ketones (such as β-dicarbonyl compounds), chain attachment can be effected by Michael addition of their enolates (generated with a

catalytic amount of base) to an alkyl vinyl ketone, generally in a protic solvent. With simple ketones, however, the high basicity of the enolate causes polymerization of the alkyl vinyl ketone. Furthermore, enolate equilibration often occurs, resulting in attachment of the chain to both the α- and α´-carbons. Compounds (**1**) and (**2**) have found some use in solving these problems in the case of α,β-unsaturated ketones (eq 1).[7]

Reagents (**1**) and (**2**) have found little use in alkylation of unsymmetrical saturated ketones, presumably because they are insufficiently electrophilic to trap regiospecifically generated enolates. The high nucleophilicity of metallated enamines[8] and hydrazones,[9] along with the possibility for controlling the site of anion formation,[10] may extend the utility of β-haloacetals as annulating agents.[11] Reagents for bis-annulation have been prepared by alkylating acyclic carbonyl compounds with (**1**).[12] The variation in eq 2 exploits the synthetic equivalence of 2-alkylpyridines and 2-cyclohexen-1-ones.[13]

2-(2-Bromoethyl)-2-methyl-1,3-dioxolane

(2)

Alkylation of the anions of α-arylnitriles with (**1**) and (**2**), followed by ***Diisobutylaluminum Hydride*** reduction leads to 5,5-ethylenedioxy aldehydes which have been cyclized to (spiro) 4,4-disubstituted 2-cyclohexen-1-ones.[14] A related approach to spiro compounds involves alkylation of a lactone with (**2**).[15]

1,4-Diketones, useful as precursors of 2-cyclopenten-1-ones, furans, and other heterocycles, have been prepared by alkylation of terminal acetylides with (**1**) followed by regioselective hydration.[16] Alternatively, 1,4-diketones can be made by alkylation of α-tosyl isocyanide carbanions with (**1**) followed by hydrolysis;[17] both strategies have been used to make *cis*-jasmone. Presumably the pairing of (**1**) with other acyl anion equivalents[18] represents a general approach to differentially protected 1,4-diketones.

A variety of very basic carbanions have been alkylated with (**1**) and (**2**), including sulfoxide and sulfone anions,[19] dianions from β-dicarbonyl compounds[5d,i,12,20] and β-keto sulfoxides,[21] and carboxylic acid dianions.[22] Alkylation of allylic carbanions[23] with (**1**) or (**2**) has been used in syntheses of bridged dioxabicyclo[3.2.1]octanes[5d,i,23b,c] including (1*S*,5*R*)-frontalin (**14**) (eq 3).[23c]

Nucleophilic 3-Ketobutyl Reagent.

Addition, at 25 °C, of a THF solution of (**1**) (containing ***1,2-Dibromoethane*** as an entraining agent) to excess ***Magnesium*** gives the Grignard reagent (**15**);[24a] ultrasonication is beneficial.[25] Reagent (**15**) reacts with electrophiles very slowly, presumably due to internal coordination of magnesium by the dioxolane ring. Its reaction with cyclohexanones or even aldehydes (used in syntheses of several natural products)[26] typically requires several hours at 25 °C. The lithium reagent from (**1**), made using ***t-Butyllithium*** in THF-Et_2O-pentane at -95 °C, is more reactive than (**15**), and gives 1,2-addition to a hindered α,β-unsaturated ketone within 1 h at 25 °C.[27] For use with cyclopentanones or aromatic ketones, (**15**) is prepared in benzene-THF (2:1); even in this solvent, complete consumption of 6-methoxy-1-tetralone required 4 h. An α-oxo group was then introduced, giving (**17**),[24a,24d] a precursor of (**18**), previously prepared[28] by Robinson annulation of the relatively inaccessible 6-methoxy-2-tetralone (eq 4). A more direct procedure was devised where the α-oxygen function is present before attachment of the ketobutyl group. Thus, for example, treatment of 2-benzoyloxycyclohexanone with (**15**) gave (**21**) directly,[24b] presumably via hydride shift[24c] in (**20**) (cf. the Serini reaction).[29] These reactions are examples of annulations in which a 3-ketobutyl unit is attached to a ketone at the carbonyl carbon, rather than next to it (eq 5).

Several approaches to terpenes employ acid-catalyzed rearrangements in adducts between (**15**) and bicyclic alkoxyketones (eq 6).[25a,30]

2-(2-Bromoethyl)-2-methyl-1,3-dioxolane

Ketones result from the reaction of (**15**) with acid chlorides at low temperatures;[24a] this idea is used in several syntheses of *cis*-jasmone (eq 7).[5e,31]

In the presence of copper(I) salts, (**15**) adds in conjugate fashion to α,β-unsaturated ketones[32a] and α,β-unsaturated lactones,[32b] leading to monoprotected 1,6-dicarbonyl compounds. This reaction has been used for annulation of a five-membered ring onto a preexisting ring (eq 8).[32a]

2-(2-Bromoethyl)-2-methyl-1,3-dioxolane

The Grignard reagent, in the presence of copper salts, has been used for nucleophilic substitution reactions with halides and sulfonate esters,[33] epoxides,[34] and β-lactones (alkyl-oxygen fission).[35]

Wittig reaction using the triphenylphosphonium salt from (**1**) (best prepared at 15 kbar pressure)[36] is employed in two syntheses of optically active brevicomins from carbohydrate-derived aldehydes.[37] The analogous diphenylphosphinyl carbanion also has synthetic utility for Wittig-Horner reactions.[38]

2-Bromofluorobenzene[1]

[1072-85-1] · C_6H_4BrF · 2-Bromofluorobenzene · (MW 175.00)

(starting material for coupling reactions; useful benzyne precursor)

Physical Data: bp 156-157 °C; bp 58-82 °C/50 mmHg; *d* 1.601 g cm^{-3}; *n*20D 1.5340.

Solubility: sol dichloromethane.

Form Supplied in: liquid; widely available.

Coupling Reactions.[1]

2-Bromofluorobenzene reacts with palladium in DMF containing ***Tri-n-butylamine*** to yield 2,2´-difluorobiphenyl (eq 1).[2]

(1)

Ullmann-type Coupling.

2-Bromofluorobenzene can be coupled with amines using a copper catalyst (eq 2).[3]

Generation of Benzyne.[4]

Benzyne can be generated by treatment of 2-bromofluorobenzene with lithium amalgam or ***Magnesium***(eq 3). This procedure for benzyne generation has been used for the synthesis of bridged polycyclic molecules such as triptycene (eq 4).[5]

An alternative procedure for the generation of benzyne is based on the use of ***n-Butyllithium***. Under these conditions, benzyne reacts with pyrroles in a [4 + 2] cycloaddition (eq 5).[6]

Very efficient cycloaddition occurs when benzyne is generated from 2-bromofluorobenzene and magnesium in the presence of a furan. This method has been applied to the synthesis of analogs of the antitumor agent ellipticine (eq 6).[7]

(6)

Benzyne generated by the same procedure has reacted with isoindoles to yield dibenzoazanorbornanes (eq 7).[8]

(7)

Germacyclopentadienes react with benzyne to afford dibenzogermanorbornanes (eq 8).[9] Silacyclopentadienes react with benzyne similarly (eq 9).[10]

(8)

(9)

Bromoform

$CHBr_3$

[75-25-2] · $CHBr_3$ · Bromoform · (MW 252.73)

(used in the synthesis of mono- and dibromocyclopropanes,[1] allenes[2] and cumulenes,[3] cyclopentadienes and fulvenes, α- and β-bromo-α,β-unsaturated carbonyl compounds, 1,1,3-tribromides, tribromomethyllithium carbonyl adducts, isocyanides,[4] α-hydroxy and α-aminoaryl acetic acids)

Alternate Name: tribromomethane.

Physical Data: mp 8.5 °C; bp 146-150 °C; *d* 2.827 g cm^{-3}.

Solubility: sol acetone, benzene, chloroform, ethanol, ether, petroleum ether.

Form Supplied in: commercially available with inhibitors present.

Analysis of Reagent Purity: technical (94%) and high purity (99+%).

Preparative Method: by reaction of acetone with sodium hypobromite.

Purification: wash with concentrated sulfuric acid and then water. The liquid is dried over $CaCl_2$ or K_2CO_3 then fractionally distilled.

Handling, Storage, and Precautions: store in closed containers away from light. Diphenylamine and ethanol are commonly used inhibitors. Do not breathe vapors as addiction may occur. Suspected cancer agent; lachrymator. Use in a fume hood.

Dibromocyclopropanes.[5]

Bromoform is a routinely used precursor to dibromocarbene which can be generated by many different methods (eq 1).[6] Dibromocarbene adds stereospecifically to alkenes[7] and its reactivity towards alkyl substituted alkenes is analogous to that of dichlorocarbene: tetrasubstituted > trisubstituted > unsymmetrical disubstituted > symmetrical disubstituted > monosubstituted alkenes.[8] Dibromocarbene has been prepared by treatment of bromoform with ***Potassium t-Butoxide***.[9] The yields of dibromocyclopropanes obtained using this method are typically no more than 70% for good cases and are usually lower. For example, reaction of cyclooctene with bromoform and potassium *t*-butoxide gave a 52-65% yield of dibromide (eq 2).[10] Dibromocarbene has also been generated by adsorbing a mixture of alkene and bromoform on basic

Alumina.[11] At elevated temperatures, ***Potassium Carbonate*** can generate dibromocarbene from bromoform in the presence of ***18-Crown-6***. Cycloheptatriene at 140 °C with these reagents gave 1-bromobenzocyclobutane in 18-45% yield (eq 3).[12]

(3)

A significant improvement in the rate and yield of halocyclopropanes is realized if phase transfer catalysts[13] like triethylbenzylammonium chloride are used.[14] Yields for dibromocyclopropanes, however, while generally less than 50%, can be somewhat improved if a considerable excess of bromoform and 24-96 h reaction times are used.[15] Addition of a small amount of ethanol to the reaction mixture often results in 10-30% increase in the yield of dibromocyclopropanes. In a typical procedure, 50% aqueous NaOH is added over 10 min to a stirred mixture of bromoform, alkene, triethylbenzylammonium chloride (TEBA) and a small amount of ethanol at 40-45 °C. After 3 h at the same temperature the mixture is diluted with dichloromethane and poured into water. An extractive work-up and concentration of the organic phases provides the crude product which is typically purified by distillation. For this method a two- to three-fold molar excess of bromoform to alkene or the converse is ordinarily used.[16]

It has been observed that the nature of the phase transfer catalyst (PTC) can have a profound effect on the yield of product obtained.[17] For example, reaction of allylic bromides with bromoform can give either cyclopropanes or substitution products depending on the type of catalyst used (eq 4). When the phase transfer catalyst cetrimide [$(C_{16}H_{33})NMe_3Br$] is used, the cyclopropane product predominates. The product ratio is reversed when tetraphenylarsonium chloride (Ph_4AsCl) is used as the catalyst and the substitution pathway is preferred.[18] When α,β-unsaturated carbonyls are used, the choice of phase transfer catalyst also impacts the product distribution obtained between the cyclopropyl product and that of Michael addition.[19] For systems where only ring formation is expected, the reaction selectivities between different alkenes are not affected by alteration of the phase transfer catalyst.[20] The use of an optically active phase transfer catalyst has led to unprecedented but low levels of asymmetric induction.[21]

PTC	Product ratio cyclopropane:substitution
cetrimide	92:1
Ph_4AsCl	1:91

Dibromocarbene is also made via Seyferth's reagent.[22] The reagent, ***Phenyl(tribromomethyl)mercury***, is typically prepared from bromoform, a phenylmercury(II) halide, and potassium *t*-butoxide.[23] Another procedure for the synthesis of phenyl(tribromomethyl)mercury[24] using a phase transfer catalyst, ***Potassium Fluoride***, and ***Sodium Hydroxide*** has also been reported.[25] Using these types of methods, the carbene is released with elimination of phenylmercury(II) halide.[26] The ring expansion of 1-methylindenes into 3-bromo-1-methylnaphthalenes is accomplished in moderate yields (~55%) by reaction of the dibromocarbene released from this type of mercury reagent (eq 5). The same reaction using bromoform/potassium *t*-butoxide gave a 2-bromo-1-methylnaphthalene in only 14% yield.[27] An alternative to other straightforward syntheses of monobromocyclopropanes[28] from alkenes (eq 6) uses ***Diethylzinc-Bromoform-Oxygen***.[29]

(5)

(6)

syn:*anti* = 62:38

Once having obtained the dibromocyclopropanes resulting from addition of dibromocarbene to different types of double bonds, chemists have been able to prepare a myriad of different structures (see also ***Chloroform*** and ***Iodoform***).

Allenes and Cumulenes.

Allenes have been prepared by reaction of dibromocyclopropanes with ***Magnesium***, but in low yield.[30] The use of

alkyllithiums leads to improved yields with ***Methyllithium*** being the reagent of choice.[31] 9,9-Dibromobicyclo[6.1.0]nonane is converted to 1,2-cyclononadiene with methyllithium (eq 7)[10,32,33] while the lower homolog, 8,8-dibromobicyclo[5.1.0]octane, leads to a complex mixture of products.[34] This is due, in large part, to intramolecular carbenoid insertions competing with allene formation. This property has been used to gain entry into the tricyclo[4.1.0.0^{2,7}]heptene ring system (eq 8).[35]

(7)

(8)

Reaction of dibromocarbene with allenes leads to cumulenes upon treatment of the intermediate dibromocyclopropane with methyllithium.[36,37] An example of the utility of this approach is shown in eq 9.[38,39]

(9)

Cyclopentadienes and Fulvenes.

The Skattebøl rearrangement occurs when conjugated dienes are converted into 1,1-dibromo-2-vinylcyclopropanes and then treated with MeLi at -78 °C. The major products are typically cyclopentadienes with small amounts of vinylallenes (eq 10). The ratio of products vary with the substitution on the starting vinylcyclopropane.[40] An example of the Skattebøl rearrangement in the synthesis of an optically active cyclopentadiene is shown in eq 11.[41,42]

(10)

(11)

Similar treatment of 3,3,3´3´-tetramethyl-2,2,2´,2´-tetrabromobicyclopropyl with methyllithium yields a diallene as the major product (eq 12). When the dimethylbicyclopropyl analog is used, a fulvene is the major product with a diallene being a minor product (eq 13). This change in product distribution is believed to result from the difference in rates of allene formation versus that of rearrangement to a cyclopentylcarbene.[40,43]

(12)

(13)

α-Bromo-α,β-Unsaturated Carbonyl Compounds.

Addition of dibromocarbene to a silyl enol ether has been shown to generate α-bromo-α,β-unsaturated carbonyl compounds after thermal or acid-catalyzed rearrangement of the intermediate dibromocyclopropane (eq 14).[44,45]

(14)

β-Bromo-α,β-Unsaturated Esters.

Reaction of unsubstituted ketene trialkylsilyl acetals with bromoform and a catalytic amount of ***Triethylborane*** affords 3-bromoacrylate (eq 15). The same conditions using a substituted ketene acetal provides a 2-dibromomethyl ester (eq 16).[46]

(15)

(16)

1,1,3-Tribromides.

Unlike chloroform, which adds under radical conditions across the double bond through the C-H bond,[47] bromoform typically reacts through one of the C-Br bonds (eq 17),[48] although mixtures of products are often obtained.[49]

(17)

Tribromomethyllithium.

Bromoform is converted in situ into ***Tribromomethyllithium*** upon treatment with lithium dicyclohexylamide. The anion reacts with cyclohexanone to afford the corresponding tribromomethyl alcohol (eq 18).[50]

(18)

Isocyanides.

The use of phase transfer catalysis in the Hofmann isocyanide synthesis[51] is reported to result in improved yields.[52] Either chloroform or bromoform can be used. Bromoform is often used in the preparation of low-boiling isocyanides since the products can be easily removed from the reaction mixture (eq 19).

(19)

α-Hydroxyarylacetic and α-Aminoarylacetic Acids.

A one-pot synthesis of α-hydroxyarylacetic acids from bromoform, an aryl aldehyde, and ***Potassium Hydroxide*** occurs with ***Lithium Chloride*** as catalyst (eq 20).[53] By a similar process, α-aminoarylacetic acids can be made using bromoform, an aryl aldehyde, and ***Ammonia*** with potassium hydroxide and ***Lithium Amide*** as catalyst. This method reportedly gives higher yields than other single-pot procedures.[54]

2-Bromoiodobenzene

[583-55-1] · C_6H_4BrI · 2-Bromoiodobenzene · (MW 282.91)

(starting material for coupling reactions; useful benzyne precursor)

Physical Data: mp 9-10 °C; bp 257 °C/754 mmHg; 120-121 °C/15 mmHg; *d* 2.257 g cm^{-3}; *n*20D 1.6618.

Solubility: sol acetone.

Form Supplied in: liquid; widely available, sometimes stabilized with copper.

Coupling Reactions.

2-Bromoiodobenzene selectively couples with arenes,[1] alkenes,[1] and alkynes[2] to afford *ortho*-substituted bromobenzenes in which the bromine atom can be used for further synthetic manipulation.

Suzuki Coupling.[3]

2-Bromoiodobenzene has been coupled with phenylboronic acids to afford biaryls using ***Tetrakis(triphenylphosphine)palladium(0)*** as catalyst (eq 1).[4]

Castro Coupling.[5]

Coupling of 2-bromoiodobenzene with ***Phenylethynylcopper(I)*** yields a (phenylalkynyl)arene (eq 2).[6]

Heck Reaction.[7]

Palladium(II) Acetate-catalyzed coupling of 2-bromoiodobenzene with ***Acrylic Acid*** leads to 2-bromocinnamic acid (eq 3).[8]

Coupling with vinylzinc derivatives has also been reported.[9]

Coupling with allylsilanes often presents problems as a result of a lack of regioselectivity. However, a regioselective palladium-catalyzed coupling with allyltrifluorosilanes has been achieved (eq 4).[10]

Eq 5 shows the synthetic potential of this reaction.[11] Coupling of 2-bromoiodobenzene with ***Trimethylsilylacetylene***, followed by lithium-bromine exchange with ***n-Butyllithium***, reaction with the monoacetal of *p*-quinone, desilylation, and treatment with base, afforded a spirovinyl ether.

(5)

The different selectivities of the two halogens allows stepwise selective coupling. An application to the synthesis of angular phenylenes has recently been developed (eq 6).[12]

(6)

The same strategy has been used for the synthesis of a leukotriene analog (eq 7).[13]

Generation of Benzyne.[14]

Treatment of 2-bromoiodobenzene with metallic ***Lithium*** in ether affords benzyne (eq 8),[15] which in the absence of a trapping agent trimerizes to triphenylene.[15]

Benzyne can also be generated by treatment of 2-bromoiodobenzene with a Grignard reagent. Nucleophilic addition of a second equiv of the Grignard reagent to benzyne affords an arylmagnesium bromide which can be reacted with an allyl halide (eq 9).[16]

1-Bromo-2-iodo-2-butene[1]

[147644-04-0] · C_4H_6BrI · 1-Bromo-2-iodo-2-butene · (MW 260.90)

(organopalladium Heck annulation)

Handling, Storage, and Precautions: as a low molecular weight allylic halide, this reagent can be expected to be lachrymatory; irritating to, and absorbed through, the skin and mucous membranes; especially hazardous via inhalation; suspect carcinogen. As an iodoalkene, it can be expected to be photochemically and/or thermally labile and susceptible to oxidation in air. Use in a fume hood.

Annulation.

In a new approach to *Strychnos* alkaloids, Rawal deployed 1-bromo-2-iodo-2-butene for construction of ring E via *N*-alkylation followed by Pd-catalyzed cyclization (intramolecular Heck reaction). Thus the reagent of (*Z*) configuration led to racemic dehydrotubifoline with correct exocyclic double bond stereochemistry (eq 1).[1] Prior model experiments demonstrated the stereospecific nature of the cyclization (eqs 2 and 3).[2] The requisite diastereomeric iodoalkenes were obtained by regio- and stereoselective addition of ***Tri-n-butylstannane*** to 2-butyn-1-ol, followed by iododestannylation (eqs 4 and 5).[2]

(*Z*)-3-Bromo-1-iodopropene

[133834-87-4] · C_3H_4BrI · (*Z*)-3-Bromo-1-iodopropene · (MW 246.87)

(bifunctional reagent employed in a cyclopentenone annulation method[1,2])

Physical Data: colorless liquid, distillation temperature (bulb-to-bulb) 25-45 °C/0.2 mmHg.

Solubility: insol H_2O; sol pentane, Et_2O, THF, CH_2Cl_2, $CHCl_3$.

Preparative Methods: (*Z*)-3-bromo-1-iodopropene (**3**) is readily prepared[1] by treatment of the corresponding alcohol (**2**) with ***Triphenylphosphine Dibromide*** in CH_2Cl_2 (eq 1).[3] Although a number of useful procedures for the synthesis of (**2**) have been reported,[4] probably the most convenient involves reduction of methyl (*Z*)-3-iodopropenoate (**1**)[5] with ***Diisobutylaluminum Hydride*** (eq 1).[1]

(1)

Handling, Storage, and Precautions: when stored in a freezer over copper wire under an inert atmosphere, this reagent is stable for months. It decomposes upon exposure to heat and/or light. A slight pink coloration does not affect its reactivity, but the reagent should be distilled from dried basic alumina and copper wire just prior to use. This substance is a lachrymator and should be prepared and handled only in a fume hood.

Cyclopentenone Annulations.

The use of reagent (**3**) in performing cyclopentenone annulations involves three steps: alkylation of a carbonyl compound with (**3**), ***n-Butyllithium***-mediated ring closure[6] of the resultant keto vinyl iodide to a tertiary allylic alcohol, and oxidative rearrangement of the latter species with a Cr^{VI} reagent to afford the 2-cyclopenten-1-one. The method is illustrated by the conversion of keto ester (**4**) into the bicyclic enone (**7**) (eq 2).[2] In those cases in which

direct alkylation of a ketone substrate is problematic, nitrogen-containing analogs (e.g. *N*,*N*-dimethylhydrazones)[7] may be employed effectively (eq 3).[2]

This annulation method played a key role in a recent total synthesis of the tetraquinane diterpenoid (±)-crinipellin B (**8**).[1] Attempts to effect conversion of the intermediate (**9**) into the enone (**10**) via the application of a number of known

cyclopentenone annulation methods[8] were unsuccessful.[1] However, alkylation of (**9**) with (**3**) and subsequent treatment of the resultant product with *n*-BuLi produced, efficiently, the allylic alcohol (**11**). Oxidation of (**11**) afforded the enone (**12**) as the major product (eq 4).[1] Interestingly, the latter reaction, in addition to effecting the expected transformation (enone formation), caused oxidative conversion of the (hindered) silyl ether group into the corresponding ketone function. The tetracyclic enone (**12**) served as a suitable intermediate for the total synthesis of (**8**).[1]

1-Bromo-1-lithio-2-phenylcyclopropane

[107887-79-6] · C_9H_8BrLi · 1-Bromo-1-lithio-2-phenylcyclopropane · (MW 203.01)

(highly reactive organolithium compound, generated at low temperature in solutions of THF or diethyl ether; reacts with electrophiles at temperatures below -85 °C)

1-Bromo-1-lithio-2-phenylcyclopropane, which is generated in situ by treatment of 1,1-dibromo-2-phenylcyclopropane with ***Methyllithium***, undergoes spontaneous rearrangement to phenylallene under α-elimination of ***Lithium Bromide*** (eq 1).[1,2]

(1)

Solutions of 1-bromo-1-lithiocyclopropanes[3] can be generated in THF or diethyl ether or in mixtures of THF/diethyl ether and THF/diethyl ether/pentane at -110 to -85 °C. The bromine-lithium exchange of 1,1-dibromocyclopropanes turns out to be the most versatile method. Solutions of ^{13}C,^{6}Li-labeled 1-bromo-1-lithiocyclopropanes have been studied by NMR spectroscopy.[4] Solutions of such carbenoids react with a variety of electrophiles. When 1-bromo-1-lithiocyclopropanes are added to benzophenone the formation of cyclobutanones results via a spontaneous rearrangement of oxaspiropentanes (eq 2).[5]

A stereoselective bromine-lithium exchange occurs upon treatment of 7,7-dibromonorcarane with ***n-Butyllithium*** to give *exo*-7-bromo-*endo*-7-lithiobicyclo[4.1.0]heptane (eq 3). A slight excess of dibromocyclopropane relative to butyllithium is required to achieve stereoselectivity. The *exo*-lithium stereoisomer, which is the favored product of a kinetically controlled lithiation, undergoes another bromine-lithium exchange reaction with dibromonorcarane to give ultimately the thermodynamically favored *endo*-lithium carbenoid (eq 4). The configuration of the latter reagent is proven by carboxylation (eq 3).[6]

The following representative 1-bromo-1-lithiocyclopropanes have also been prepared by bromine-lithium exchange reactions:[12] 1-bromo-1-lithio-2-phenylcyclopropane (**1**),[6,7] 1-bromo-1-lithio-2,2-dimethylcyclopropane (**2**),[5] 13-bromo-13-lithiobicyclo[10.1.0]tridecane (**3**),[8] *endo*-7-bromo-*exo*-7-lithio-1-methoxybicyclo[4.1.0]heptane (**4**),[9] *exo*-9-bromo-*endo*-9-lithiobicyclo[6.1.0]nonane (**5**),[10] and *trans*-2-benzyloxymethyl-1-bromo-1-lithiocyclopropane (**6**).[7,11]

(1)

(2)

(3)

(4)

(5)

(6)

The treatment of *endo*-7-bromo-*exo*-7-(trimethylstannyl)bicyclo[4.1.0]heptane results in an exclusive tin-lithium exchange reaction to give *endo*-7-bromo-*exo*-7-lithionorcarane (eq 5).[13]

(5)

Related Reagents.

Bromomagnesium Diethylamide

[5856-91-7] · $C_4H_{10}BrMgN$ · Bromomagnesium Diethylamide · (MW 176.34)

(aldol condensation; Claisen ester condensation)

Alternate Name: diethylaminomagnesium bromide.

Preparative Method: has been prepared from ***Ethylmagnesium Bromide*** and diethylamine in anhydrous ether by mixing at 0 °C, then stirring at rt followed by a 15 min reflux.[1,2]

Handling, Storage, and Precautions: use in a fume hood.

Although bromomagnesium diethylamide has been shown to be an effective base for the Claisen ester condensation of certain esters, its use is limited by its tendency to react with the ester group to form amides.[3,4] The related reagent ***Bromomagnesium Diisopropylamide*** does not suffer from this drawback and has been used more frequently.

Diethyl succinate has been successfully condensed with trifluoroacetophenones using bromomagnesium diethylamide (eq 1).[5,6]

The condensation of (-)-menthyl acetate with alkyl phenyl ketones,[1,7] dialkyl ketones,[8] or aromatic aldehydes[8] gives optically active β-hydroxy esters which can be hydrolyzed to the optically active β-hydroxy acids (eq 2). Synthetic yields are 30-80% and optical yields are 16-60%. As the size of R increases, the optical yield decreases.[7]

Bromomagnesium Diisopropylamide

[50715-01-0] · $C_6H_{14}BrMgN$ · Bromomagnesium Diisopropylamide · (MW 204.39)

(thermodynamic enolate generation; aldol condensation; Claisen ester condensation)

Alternate Names: diisopropylaminomagnesium bromide; BMDA.

Preparative Methods: prepared from ***Diisopropylamine*** and ***Methylmagnesium Bromide*** or ***Ethylmagnesium Bromide*** using either THF or ether as the solvent. In THF a 1.5 M solution was prepared at 80 °C and stored at 50 °C (presumably to prevent precipitation).[1] A refluxing 0.5 M THF solution of BMDA was reported to be stable for several hours.[2] In ether, preparations have been reported at rt; however, BMDA is practically insoluble in ether and was used as a slurry.[3,4]

Handling, Storage, and Precautions: use in a fume hood.

Ester Condensations.

BMDA has been examined as a base for the Claisen ester condensation[3,5-7] and was found to be an excellent condensing agent for mixed condensations of methyl benzoate and methyl 2-furoate with aliphatic esters.[5] A small study of BMDA's use in the Dieckmann cyclization of diesters seemed to show no obvious advantage over other bases.[7] Intramolecular condensations using BMDA have been reported (eqs 1 and 2).[8,9] Thiolactones have been condensed with ***Diethyl Oxalate*** (eq 3).[10]

(1)

(2)

(3)

Nitrile Condensations.

The condensation of nitriles using BMDA has been investigated. Although acetonitrile gave very poor yields, reactions of propio-, valero-, and phenylacetonitriles proceeded in 65-80% yields (eq 4). The reactions were carried out in refluxing ether. When the reactions were carried out in refluxing *n*-butyl ether, they were more complex and cyclic trimers of the pyrimidine and pyridine classes were formed.[11]

(4)

Aldol Condensations.

BMDA has found utility in a number of aldol condensations where other bases have failed. In Kishi's synthesis of monensin, BMDA was used to couple the left and right halves of the molecule (eq 5).[1]

(5)

In a synthesis of the taxane ring system, Holton used BMDA to effect the intramolecular condensation to give (**2**) in 90% yield (eq 6).[12] Other reagents resulted in a retro Michael reaction.

Annunziata et al. found magnesium bases such as BMDA superior in diastereoselectivity to lithium bases for the aldol condensation of the enantiomerically pure 3-*p*-tolylsulfinylmethyl-4,5-dihydroisoxazoles (eq 7).[13]

Similarly, Nokami et al. reported the condensation of another *p*-tolylsulfinyl compound with propargyl aldehyde (eq 8).[14]

Enolate Generation.

Krafft and Holton reported the examination of a number of bases for the preparation of enolates. This examination showed that BMDA was the best base for the preparation of thermodynamic enolates. The enolate was trapped with ***Chlorotrimethylsilane*** and the product obtained in 85-95% yields with ratios of thermodynamic:kinetic product (**4:5**) of ca. 97:3 (eq 9).[4] ***Lithium Diisopropylamide*** gave a 1:99 ratio of (**4:5**). Other bases examined gave predominately (**4**); however, the ratios of (**4:5**) were inferior to BMDA. This procedure has been used in the synthesis of the taxane ring system,[12] intermediates for reserpine (trapped with ***t-Butyldimethylchlorosilane***),[15] dihydropallescensin D,[16] and other systems.[17] Thermodynamic enolates have also been trapped with ***N-Phenyltrifluoromethanesulfonimide*** to give vinyl triflates.[18,19] Scott and Stille observed that the use of excess BMDA with 2-methylcyclohexanone led to lower

ratios of thermodynamic:kinetic product when the enolate was trapped with either TMSCl or *N*-phenyltriflimide.[19]

Carey and Helquist used BMDA to generate enolates in their synthesis of fused cyclopentanones (eq 10).[20]

It should be noted that since BMDA can also promote aldol condensations, the use of BMDA to form enolates of ketones that are not relatively sterically hindered can lead to aldol products as the only reaction.[12,21]

Chiral Sulfoxides.

One synthetic route to optically active α-sulfinyl esters is the displacement of the *O*-menthyl group of an optically active sulfinate ester (eq 11).[22-24] When R = Me the ratio of diastereomers was 1:1 and when R = Et the ratio was 3:7. A similar reaction with cyclic ketones has been reported (eq 12).[21] When *n* = 1 the ratio of diastereomers was 3.0:1 and with *n* = 2 the ratio was 1.6:1.

(12)

Other Reactions.

BMDA has proven useful for the functionalization of cubanes. Treatment of (**6**) with BMDA in refluxing THF gave the diester (**7**) as the product,[2] whereas at rt the monoester (**8**) is formed (eq 13).[2,25]

(13)

BMDA metalates (diphenylphosphinyl)ferrocene exclusively *ortho* to the diphenylphosphinyl group (eq 14).[26]

(14)

BMDA has been reported to be complementary to LDA in the acylation of 2-acyl-1,3-dithianes (**9**) (eq 15). When

R = aryl, LDA gave predominately *O*-acylation (**11**), whereas BMDA gave exclusive *C*-acylation (**10**). When R = Me, LDA gave 100% *O*-acylation and BMDA gave 78% *C*-acylation.[27]

Bromomagnesium Hexamethyldisilazide

[50916-70-6] · $C_6H_{18}BrMgNSi_2$ · Bromomagnesium Hexamethyldisilazide · (MW 264.59)

(base for selective formation of magnesium enolates)

Physical Data: white solid from ether of composition $Mg_2Br_2[N(SiMe_3)_2]_2.2Et_2O$, mp 98 °C.

Solubility: sol benzene, cyclohexane, and toluene; very sol ether.

Preparative Method: ***Hexamethyldisilazane*** is added to ***Ethylmagnesium Bromide*** in ether. Cooling to -20 °C produces white crystals in good yield.[1]

Reaction with Carbonyl Compounds.

Although seldom used in comparison with ***Bromomagnesium Diisopropylamide***, bromomagnesium hexamethyldisilazide has the unique feature of high solubility in organic solvents.

Bromomagnesium hexamethyldisilazide and bromomagnesium diisopropylamide were the most effective of several magnesium bases examined for selective formation of the more substituted silyl enol ether from ketones (eq 1). Less-hindered ketones gave mainly aldol products.[2]

The reagent reacts with hindered esters to give isolable complexes, with no evidence for enolate formation (eq 2).[3]

Bromomethane[1]

CH_3Br

[74-83-9] · CH_3Br · Bromomethane · (MW 94.95)

(methylates C, N, O, P, S, Se, and Te nucleophiles; forms metal-Me systems which act as bases or which attack >C=O, -C&tbond;N)

Alternate Name: methyl bromide.

Physical Data: mp -93.66 °C; bp 3.56 °C; *d* 1.732 g cm^{-3} (0 °C).

Solubility: miscible with most organic solvents, sparingly with aqueous media.

Form Supplied in: colorless mobile liquid.

Purification: gas passed through conc. H_2SO_4 and dried with P_2O_5.

Handling, Storage, and Precautions: usually available in cylinders or as a solution in Et_2O or MTBE. Potent alkylating agent; high toxicity. Use in a fume hood.

Introduction.

CH_3Br is usually prepared by the bromination of methane[1a] or by the interaction of MeOH with ***Hydrogen Bromide***.[1b] Methyl bromide is the archetypal alkylating agent, either directly as a source of $Me^{\delta+}$ or through organometallic intermediates giving $Me^{\delta-}$. The alkyl group may also undergo substitution, usually selectively (e.g. bromination; 90% of the bromide is converted, giving a mixture of CH_2Br_2 and $CHBr_3$ (96:4, using $[Br_2]/[CH_3Br]$ = 10:1)).[1a]

Methylating Agent.

CH_3Br reacts readily with many nucleophiles including C-, O-, N-, and S-based systems; increased reactivity is often achieved through formation of the conjugate base (e.g. ROH -> RO^-). In this way, 2,3-dimethylcyclohexanone provides 2,2,3-trimethylcyclohexanone (eq 1).[2]

(1)

Ru-coordinated dibenzotetrathiacyclodecane dianion is methylated at the position α to sulfur,[3] and bridged annulene dianions (e.g. **1**) are correspondingly attacked.[4] Unsubstituted or monosubstituted malonic esters are methylated in the absence of solvent, forming the carbanion by adding NaOEt and distilling out the EtOH.[5]

(1)

Other carbanions which may be methylated include the perfluoro-2-methylpentyl carbanion[6] and lithiated phenanthrene-9-carbamate, which provides the 10-Me analog.[7] Superacids (***Tetrafluoroboric Acid***, ***Boron Trifluoride***, or ***Trifluoromethanesulfonic Acid***) allow the carbonylation of MeCl or MeBr, giving a mixture of AcOH and AcOMe; this process is cheaper than those involving Rh catalysis.[8]

Asymmetric induction is achieved in the methylation of enones of α-aryl-substituted ketones, esters, and lactones by using chiral phase-transfer catalysts derived from cinchonine, cinchonidine, or their dihydro analogs.[9] Similarly, $CpFe(CO)(PPh_3)(COCH_2R)$ is deprotonated (***n-Butyllithium***) to form exclusively the (*E*)-enolate; alkylation of this substitutes the α-position of the acyl ligand. The greatest stereoselectivity of attack is shown by more bulky electrophiles.[10] A study of the methylation of lithiated silacyclopentenes reflects many uses of MeBr as a small electrophile which shows little influence by steric factors. Thus the allylic carbanion formed when silacyclopentene (**2**) (Ar = *p*-*t*-BuC_6H_4; R = R´ = H) reacts with ***t-Butyllithium*** is deuterated (D_2O) or methylated (MeBr) at the α-position (eq 2) (R = D or Me), whereas ***Triisopropylsilyl Chloride*** attacks at the γ-position to give the rearranged product (**3**) (R = H, R´ = *i*-Pr_3Si).[11]

(2)

The methylation of aminobenzothiazoles (MeBr-DMF) on nitrogen exemplifies the use of aprotic solvents to encourage alkylation; it is accompanied by formylation at C-2 in these substrates.[12] $[Mo(N_2)_2(Et_2PCH_2CH_2PEt_2)_2]$ reacts with MeBr to provide the *N*,*N*-dimethylhydrazine derivative $[Mo(NNMe_2)_2(Et_2PCH_2CH_2PEt_2)_2]Br$.[13]

Organometallic Reagents.

The Grignard reagent ***Methylmagnesium Bromide*** is formed readily and quantitatively in Et_2O. The reaction with carbon-11 CO_2 is the first step in a synthesis of $Me^{11}CH_2I$ via labelled EtOH in a convenient one-pot process (eq 3).[14]

$$MeBr + Mg \longrightarrow MeMgBr \longrightarrow Me^{11}CO_2H \longrightarrow Me^{11}CH_2OH \longrightarrow Me^{11}CH_2I \quad (3)$$

Similar reactions with carbonyl compounds[15a] are widely used to incorporate methyl groups, while the corresponding processes often occur with great diastereoselectivity.[15b] The ring opening of epoxides proceeds in good yield with no loss of chirality both in systems such as (**4**) (Z = SO, SO_2, CO_2R) with RMgBr + CuI in Et_2O-THF at -60 °C which provide $EtCH(OH)CH_2Z$ (eq 4)[16] and in the reaction between either (*R*)- or (*S*)-glycidol with (RMgBr + $2LiCl/CuCl_2$) in THF at -5 °C when, for example, (*S*)-glycidol gives (*S*)-butane-1,2-diol in 70% yield and with 97% ee (eq 5).[17]

Bromomethanesulfonyl Bromide

[54730-18-6] · $CH_2Br_2O_2S$ · Bromomethanesulfonyl Bromide · (MW 237.89)

(converts alkenes into 1,3-dienes[1-7] including 1-vinyl-1-cycloalkenes,[1,3] 3-methylene-1-cycloalkenes,[1,3] 2-alkyl-1,3-butadienes;[1,6] also converts silyl enol ethers into α-methylene ketones[1,5] and alkynes into enynes[1])

Physical Data: bp 68 °C/0.55 mmHg;[2] *n*20D 1.5706.[1]

Solubility: sol CH_2Cl_2, Et_2O; insol H_2O.

Analysis of Reagent Purity: ^{1}H NMR (60 MHz) δ 5.05 (s, 2H).

Preparative Methods: to a stirred suspension of *sym*-trithiane (0.73 mol) in water was added Br_2 (7.1 mol) dropwise to maintain a reaction temperature of 35-40 °C. Cooling by ice bath may be required. After the addition of Br_2 is complete, the reaction is stirred for an additional 15 min. The product is extracted into CH_2Cl_2, washed with 5% sodium bisulfite solution, and dried. Concentration and distillation yields bromomethanesulfonyl bromide in 42-48% yield as a pale yellow liquid.[1,2]

Handling, Storage, and Precautions: reactive sulfonylating agent: avoid contact with skin and mucous membranes. Stable at 25 °C for at least 2 weeks. Decomposes forming CH_2Br_2 and SO_2. Use in a fume hood.

Addition to Alkenes.

Light-initiated bromosulfonylation of alkenes occurs readily at -20 °C via a radical chain reaction and is generally more efficient than the thermal reaction (see also ***Benzenesulfonyl Bromide***). Regioselective addition of sulfonyl bromides with mono-, 1,1-disubstituted, and 1,1,2-trisubstituted alkenes occurs to give the more substituted alkyl bromide.[1,3] Chemoselective addition to alkenes is observed with nonconjugated dienes: monoalkyl > 1,1-dialkyl > 1,1,2-trialkyl. Subsequent treatment of the adducts with base yields α,β-unsaturated sulfones (eq 1). Stereoselectivity with terminal alkenes is observed, favoring the (*E*) configuration.[1,3]

α,β-Unsaturated bromomethyl sulfones are converted into 1,3-dienes upon further treatment with base via a vinylogous Ramberg-Bäcklund reaction.[1-7] Employing this procedure, a variety of 1,3-diene products have been prepared (Table 1).

Table 1 Diene and Enyne Synthesis using Bromomethylsulfonyl Bromide

Alkene	1,3-Diene (*E*:*Z*)	Yield (%)
n-$C_6H_{13}CH{=}CH_2$	n-$C_5H_{11}CH{=}CHCH{=}CH_2$ (2:1)	61

$B(OR)_2$	$B(OR)_2$	

81

The γ-deprotonation of α,β-unsaturated sulfones may occur *syn* or *anti* to the sulfonyl group, which would give a mixture of dienes from unsymmetrical precursors. The regioselectivity observed appears to be controlled by steric factors (***Potassium t-Butoxide*** deprotonates at the less hindered position) and by coordination of the alkali cations to the sulfonyl group (***Lithium t-Butoxide*** favors deprotonation *syn* to the sulfonyl group even when sterically hindered).

By this procedure, allylsilanes[1,4] and 2-propenyl boronates[7] are transformed into 1-trialkylsilyl-1,3-butadiene and electron-deficient 1,3-butadienyl-2-boronic esters, respectively (Table 1). However, reaction of allylstannanes with bromomethylsulfonyl bromide does not give the adduct but yields only allyl bromomethyl sulfone and stannyl bromides.[1,4]

Trimethylsilyl enol ethers are transformed into α-keto bromomethyl sulfones by bromomethylsulfonyl bromide in good yield. Subsequent treatment with ***1,5-Diazabicyclo[4.3.0]non-5-ene*** yields a mixture of α-methylene ketones and 1,3-oxathiole 3,3-dioxide heterocycles, depending on the solvent and reaction conditions.[1,5] Good yields of α-methylenecycloheptanone can be obtained (eq 2).

1-Bromomethoxy-4-chlorobutane

[53970-36-8] · $C_5H_{10}BrClO$ · 1-Bromomethoxy-4-chlorobutane · (MW 201.49)

(bromomethylating agent)

Physical Data: bp 94 °C/5 mmHg.

Preparative Method: can be prepared by treating 4-chloro-1-butanol with ***Paraformaldehyde*** and dry ***Hydrogen Bromide***.[1] Subsequent aqueous workup, separation, and distillation provides the desired product in 49% yield.

Handling, Storage, and Precautions: is much less volatile and therefore more convenient and safer compared to traditional halomethylating agents such as ***Chloromethyl Methyl Ether***, but it is still a potential carcinogenic compound. Thus, caution should be exercised while handling this compound. Use in a fume hood.

1-Bromomethoxy-4-chlorobutane is primarily used as a bromomethylating agent.[1] It is a safer halomethylating reagent compared to the traditionally used agents such as chloromethyl methyl ether, which is highly volatile. 1-Bromomethoxy-4-chlorobutane reacts readily with arenes under ***Zinc Chloride*** or ***Titanium(IV) Chloride*** catalysis to produce bromomethylated arenes in good yields with THF as the byproduct, the formation of which facilitates the reaction (eq 1).

(1)

1-Bromomethoxy-4-chlorobutane can also serve as a precursor to the δ-chlorobutyl carboxonium ion, which can be further utilized for the alkylation of tetrahydrofuran and tetrahydrothiophene (eq 2).[2]

(2)

Related Reagents.

Bromomethyl Methyl Ether; ***Chloromethyl Methyl Ether***.

1-Bromo-3-methyl-2-butene

[870-63-3] · C_5H_9Br · 1-Bromo-3-methyl-2-butene · (MW 149.03)

(alkylating (prenylating) agent)

Alternate Names: prenyl bromide; isoprene hydrobromide.

Physical Data: bp 59-60 °C/60 mmHg; *d* 1.293 g cm^{-3}; fp 32 °C.

Form Supplied in: colorless liquid stabilized with silver wool.

Preparative Method: is readily prepared by treatment of ***Isoprene*** with ***Hydrogen Bromide*** (eq 1).[1-3]

Handling, Storage, and Precautions: flammable liquid; corrosive; use in a fume hood.

Alkylating Agent.

Enantiomerically pure (2*S*)-1-phenylsulfonylalkan-2-ols are available from the ketones by asymmetric reduction with ***Baker's Yeast***. Alkylation of the dianion from these sulfonyl alcohols with 1-bromo-3-methyl-2-butene provides the (*S*,*S*)-alcohol in 66% yield (eq 2). Phenylseleno cyclization followed by oxidation-elimination afforded enantiomerically pure 2,5-disubstituted tetrahydrofurans.[4]

(2)

64:36

The anion derived from a trimethylsilyl (TMS)-capped alkynic Schiff base can be alkylated quite readily with 1-bromo-3-methyl-2-butene (eq 3). The imine can then be converted to an *N*-acetyl group, followed by introduction of the second nitrogen atom via the Ritter reaction. After deprotection, the *gem*-dimethyl diamino product was obtained.[5]

(3)

Intramolecular cyclization of allylic propiolates derived from *O*-alkylation of a carboxylic acid with various allylic halides has been used to study stannyl radical additions. The products resulting from radical addition to the propiolate lead to moderate yields of α-methylene-γ-butyrolactones after treatment of the vinyl α-tributylstannyl intermediate with HCl or HI in ether or benzene for several hours (eq 4).[6] A competing pathway with the radical cyclization is simple addition of tin hydride across the propiolate.

(4)

Treatment of the pyrido[2,3-*d*]pyrimidine nucleus with 1-bromo-3-methyl-2-butene in DMF afforded the N-8 alkylated

system in good yield (eq 5).[7-12]

(5)

Derived Grignard Reagents.

3-Bromo-1-(phenylsulfonyl)-1-propene (a mixture of *cis*/*trans* isomers, 1:4), which is available from ***Allyl Phenyl Sulfone***, reacts with prenylmagnesium bromide to give *trans*-2-substituted cyclopropyl sulfones (eq 6). It is interesting that the Grignard reagent from 1-bromo-3-methyl-2-butene yields only the *trans*-2-(α,α-dimethylallyl)cyclopropyl phenyl sulfone. Alkyl Grignard reagents failed to yield the cyclopropyl sulfones. This represents an interesting cyclopropane synthesis via addition of unsaturated organometallics to alkenyl sulfones.[13]

(6)

Nickel Coupling.

Treatment of 1-bromo-3-methyl-2-butene with excess ***Tetracarbonylnickel*** in benzene yields μ-3-methylbut-2-enylnickel bromide (eq 7). This π-allylnickel intermediate undergoes cross-coupling with aryl bromides in polar solvents such as DMF in quite good yield. This methodology was used in the synthesis of various vitamin K analogs,[14] as well as in the synthesis of (+)-epicamphorenone and (+)-epi-β-santalene.[15]

1-Bromo-3-methyl-2-butene

Derived Copper Reagents.

Allyltriphenylstannane compounds have been used to make allyl lithium reagents which are useful for the synthesis of difficult-to-prepare cuprates. Reaction of the cuprate derived from 1-bromo-3-methyl-2-butene with an unstable 3-furan tosylate afforded perillene in modest yield (eq 8).[16,17]

Derived Phosphorus Reagents.

Alkylation of diphenylmethylphosphine oxide with 1-bromo-3-methyl-2-butene provided an unsaturated phosphine, which upon further deprotonation afforded an anion which added to a cyclohexenyl methyl ketone to yield a mixture of *erythro* (53%) and *threo* (4%) products (eq 9). Elimination of $Ph_2PO_2^-$ from the *erythro* intermediate afforded (*Z*)-α-bisabolene.[18] A related synthesis of disubstituted alkenes relies on a hydride reduction to establish the correct stereochemistry prior to the elimination step.[19]

(9)

Addition of the Wittig reagent derived from ***Triphenylphosphine*** and 1-bromo-3-methyl-2-butene (γ,γ-dimethylallyltriphenylphosphonium bromide) to 2,3-indolinedione (eq 10) afforded an (*E*)/(*Z*) mixture of indolinones which are the major components from the rhizomes of *Cimicifuga dahurica* Maxim.[20]

$R^1 = CH{=}CMe_2;\ R^2 = H$
$R^1 = H;\ R^2 = CH{=}CMe_2$ (10)

Sigmatropic Rearrangements.

Adducts derived from the alkylation of phenols with 1-bromo-3-methyl-2-butene have been used as substrates for thermal rearrangements leading to natural products, as well as being used in mechanistic studies (eq 11). Depending on the reaction temperature, several reaction pathways are possible, leading to both normal and abnormal Claisen rearrangement products. Interestingly, in the case cited the abnormal rearrangement product leads to the natural product anisoxide.[21]

Base-catalyzed rearrangements of quaternary ammonium salts, derived from the reaction of tertiary amines with allylic halides (such as 1-bromo-3-methyl-2-butene), generally proceed via a [3,2]-sigmatropic rearrangement in aprotic solvents (eq 12). There is, however, often a competing 1,2-Stevens rearrangement. Treatment of diallylammonium cations with base in protic solvent led to a series of events (double bond isomerization, [3,3]-sigmatropic rearrangement, hydrolysis) ultimately yielding an aldehyde in excellent yield.[22]

R = CH_2=CH-, Me_2C=CH-, Ph—≡

(12)

α-Allokainic and α-kainic acids are neurophysiologically interesting constituents of algae. *N*-Alkylation of the bis(ethoxycarbonyl) (*Z*)-enoate with ^{13}C-labeled 1-bromo-3-methyl-2-butene provided mechanistic evidence for a concerted ene reaction (eq 13). The desired *N*-alkylation could not be achieved using the corresponding tosylate or chloride.[23]

(Bromomethyl)chlorodimethylsilane[1]

[16532-02-8] · $C_3H_8BrClSi$ · (Bromomethyl)chlorodimethylsilane · (MW 187.54)

(allylic,[2] propargylic,[3] and homoallylic[4] bromomethylsilyl ethers are used for regio- and stereoselective introduction of hydroxymethyl[2-4] or methyl[2c,d] groups through radical cyclization; derivatizing agent for electron capture GC[5])

Physical Data: bp 133-135 °C; bp 130 °C/740 mmHg; *d*204 1.386; *n*20D 1.466.

Solubility: sol most organic solvents including benzene, THF, methylene chloride, chloroform, and pyridine.

Form Supplied in: commercially available colorless liquid with 98% (GC) purity.

Analysis of Reagent Purity: GC analysis appears best; the following spectroscopic information may also be used: FTIR (vapor phase at 225 °C): 2978 (w), 1392 (w), 1264 (m), 822 (s) cm^{-1};[6] ^1H NMR ($CDCl_3$) δ 0.58 (s, 6H), 2.65 (s, 2H); ^{13}C NMR ($CDCl_3$) δ 0.27, 16.47.

Handling, Storage, and Precautions: moisture-sensitive; toxicological properties have not been thoroughly investigated; symptoms of exposure may include burning sensation, coughing, wheezing, laryngitis, shortness of breath, headache, nausea, and vomiting.[7] Use in a fume hood.

Use as a Source of α-Silyl Radicals.

Treatment of hydroxy groups with $(BrCH_2)Me_2SiCl$ in the presence of ***Triethylamine*** often with a catalytic amount of ***4-Dimethylaminopyridine*** provides the (bromomethyl)dimethylsilyl ether derivatives in high yield. α-Silyl radicals generated from (bromomethyl)dimethylsilyl derivatives of cyclic allylic alcohols undergo highly regio- and stereoselective 5-*exo* radical cyclization reactions to provide the corresponding siloxanes (eq 1).[2,8] These five-membered siloxanes can be efficiently oxidized to 1,3-diols[2a-d,8] by the use of Tamao's conditions[9] or cleaved to β-methyl alcohols with ***Potassium t-Butoxide-Dimethyl Sulfoxide*** (eq 1).[2c,d] Radicals generated from the (bromomethyl)dimethylsilyl ethers of acyclic alcohols also exhibit similar regioselectivity during radical cyclization.[2a] Formation of *trans*-3,4-disubstituted 1-sila-2-oxacyclopentanes is generally favored (eq 2).[2a] However, propensity toward increased 6-*endo* cyclization, as is observed in the cyclization of 2-sila-5-hexen-1-yl radicals,[10] can be clearly manifested in certain α-silyl radicals (eq 3).[2a,11] This 6-*endo* mode of cyclization is observed for α-silyl radicals with

appropriate structural bias (eq 4).[12] Detailed studies on the factors that affect these two competing modes of cyclization of allylic α-silyl radicals have resulted in the development of new methodology for the introduction of an angular hydroxymethyl group (eq 5).[13,14]

(4)

(5)

(Bromomethyl)dimethylsilyl propargylic ethers undergo highly regio-, stereo-, and chemoselective radical cyclization.[3,15] The α-silyl radicals cyclize in a 5-*exo* fashion to provide siloxanes with an exocyclic alkene having *trans* stereochemistry between the newly formed C-C and C-H bonds (eq 6).[15] This stereochemical preference is reversed when a substituent at the distal sp carbon is a TMS or phenyl group. When there are competing sites for addition between alkenic and alkynic carbons by the 5-*exo*-mode of cyclization, these α-silyl radicals preferentially attack an sp (5-*exo*-dig) over sp^2 carbon (5-*exo*-trig).[15]

(6)

The mode of cyclization of α-silyl radicals generated from homoallylic (bromomethyl)dimethylsilyl ethers is highly dependent upon the substitution pattern on the distal alkenic carbon.[4] Thus while those with unsubstituted distal alkene carbons provide seven-membered siloxanes (7-*endo*) (eq 7),[4] those having substituted carbons undergo a 6-*exo*-mode of radical cyclization in a highly regio- and stereoselective manner (eq 8).[4] These six-membered siloxanes provide,

upon Tamao oxidation,[9] branched chain 1,4-diols (eq 8).[4]

Generation of Chloro(lithiomethyl)dimethylsilane.

Treatment of (bromomethyl)chlorodimethylsilane in THF/ether with 1 equiv of ***n-Butyllithium*** in hexanes at -120 °C produces chloro(lithiomethyl)dimethylsilane. This lithiated derivative spontaneously eliminates LiCl to give an

intermediate silaethylene species, which undergoes dimerization to afford 1,1,3,3-tetramethyl-1,3-disilacyclobutane (45%), together with a small amount of 1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane (15%) (eq 9).[16]

(9)

Silazole Synthesis.

(Bromomethyl)dimethylsilyl derivatives obtainable from 2-mercaptoimidazoles and -benzimidazoles undergo cyclodehydrohalogenation, in the presence of a slight excess of a proton sponge (***1,8-Bis(dimethylamino)naphthalene***), providing silazoles (eq 10).[17]

Bromomethylenetriphenylphosphorane[1]

$Ph_3P{=}CHBr$

[39598-55-5] · $C_{19}H_{16}BrP$ · Bromomethylenetriphenylphosphorane · (MW 355.21)

(Wittig reagent for the formation of 1-bromoalkenes from aldehydes and ketones; terminal alkynes are formed by elimination of HBr)

Solubility: sol THF and ether; reacts with water and other acidic protons.

Preparative Method: by using strong base to deprotonate the salt bromomethyltriphenylphosphonium bromide, which is available commercially or synthetically.[2]

Handling, Storage, and Precautions: the ylide is generally prepared in situ and used immediately, but can be stored under nitrogen for short periods. The ylide will decompose upon exposure to air or water.

Preparation of the Ylide and Stereoselectivity.

The Wittig reaction of bromomethylenetriphenylphosphorane forms 1-bromoalkenes from carbonyl compounds with complete regioselectivity. Unlike most phosphorus ylides, treatment of the starting phosphonium salt with butyllithium does not give the desired bromo-substituted ylide, but forms $Ph_3P{=}CH_2$ via halogen-metal exchange.[2,3] The use of PhLi and lithium piperidide are also not recommended.[2,4] Bromomethylenetriphenylphosphorane has been cleanly prepared from the dry bromomethyl phosphonium salt using either ***Potassium t-Butoxide*** in THF[5] or ***Potassium Hexamethyldisilazide*** in toluene.[6] With these bases the Wittig reaction with aldehydes and ketones proceeds in good yield and often, in the case of aldehydes, with high (*Z*) selectivity. Table 1 gives results for the ylide prepared using *t*-BuOK at low temperature (eq 1),[5] and shows that (*Z*)-bromoalkenes were prepared with good selectivity. When 2 equiv of base were used in these reactions, terminal alkynes were formed as the final product.[5]

Table 1 Wittig Reaction of Bromomethylenetriphenylphosphorane with Aldehydes

Aldehyde	Yield (%)	(*E*:*Z*) Ratio
PhCHO	71	83:17
a-NaphthylCHO	81	86:14
$PhCH_2CH_2CHO$	47	86:14
PhCH=CHCHO	72	77:23

High selectivity was also reported in the reaction of the bromo-substituted ylide (prepared from KHMDS in toluene) with an α-keto amino acid derivative (eq 2), which gave a 95:5 (*Z*:*E*) ratio of bromoalkenes in 80% yield.[6]

(2)

Synthetic Uses.

The bromoalkene products of the Wittig reaction have most often been used for the preparation of alkynes or in palladium-catalyzed coupling reactions. HBr elimination with an excess of strong base (***Lithium Diisopropylamide*** or *t*-BuOK) gives terminal alkynes in good yield. The overall transformation (RCHO to RC&tbond;CH) has been used in the synthesis of leukotriene B_4 (eq 3),[7] derivatives of vitamin D_3,[8] and methynolide intermediates.[9] Palladium(0) coupling of 1-bromoalkenes with alkynes has also been reported, such as in the synthesis of antitumor agent CI-920[10] and carotenoids.[11]

A useful alternative to the Wittig reaction for vinyl halide synthesis is the reaction of ***Bromoform*** with $CrBr_3/LiAlH_4$ in the presence of an aldehyde.[12] The organochromium intermediate formed in situ reacts with aliphatic and aromatic aldehydes to give bromoalkenes with good (*E*) selectivity in 55-70% yield. This transformation, however, requires 6 equiv of the expensive chromium reagent. For preparation of vinyl bromides from ketones, addition of lithiated methylene bromide to the carbonyl group followed by reduction with ***Zinc-Acetic Acid*** gives 1-bromoalkenes in good yield.[13]

Bromomethyllithium[1]

$BrCH_2Li$

[92533-92-1] · CH_2BrLi · Bromomethyllithium · (MW 100.87)

(converts aldehydes or ketones to oxiranes;[1] $B(OR)_3$ to $BrCH_2B(OR)_2$;[1] $R^1B(OR^2)_2$ to $R^1CH_2B(OR^2)_2$[1])

Physical Data: stable at -110 °C in the presence of LiBr; unstable at higher temperatures; unstable even at -130 °C in the absence of LiBr.[4,5]

Preparative Methods: preferably by addition of MeLi/LiBr or *n*-BuLi solution dropwise to a vigorously stirred solution of CH_2Br_2 and the substrate in THF cooled with a dry ice-acetone bath.[1]

Handling, Storage, and Precautions: see ***n-Butyllithium*** and ***Dibromomethane***. The reagent must be generated under an inert atmosphere of nitrogen or argon.

Oxirane Formation.

Aldehydes and ketones are efficiently converted to oxiranes by $BrCH_2Li$ generated by addition of BuLi to CH_2Br_2 in the presence of the carbonyl compound in THF cooled with a -78 °C bath (internal temperature below -65 °C), followed by standing at rt for 15 h (eq 1).[1]

With $BrCH_2Li$ the yields were uniformly high in all four examples illustrated (eqs 2-5). The first three transformations had been carried out previously with ***Chloromethyllithium***, with reported yields of 91-99%[2] and replicated yields of 88-

93%.[1] However, with the last example, ethyl levulinate, $ClCH_2Li$ yielded only 40% oxirane and $BrCH_2Li$ yielded 93%. Thus $BrCH_2Li$ appears to be the more selective reagent, at least with regard to interfering ester functionality.

(2)

(3)

(4)

(5)

The first reported generation of $BrCH_2Li$ from CH_2Br_2 and BuLi in the presence of a ketone yielded only 20% of the corresponding oxirane.[3] Present knowledge implies that there was an error in experimental procedure, possibly mere failure to allow enough time for oxirane ring closure. The use of Li dispersion with CH_2Br_2 yielded 35-52% of oxiranes in eight examples, 95% in one,[3] and is clearly not a practical method.

It is also possible to preform the $BrCH_2Li$ in the presence of LiBr in THF-Et_2O-pentane at -115 °C.[4] The reagent is unstable in the absence of LiBr or above -110 °C.[4,5] Although the preformed reagent gives satisfactory yields of oxiranes, this method is obsolete for any known practical purpose.

Boronic Esters.

Dropwise addition of BuLi to a mixture of CH_2Br_2 and ***Triisopropyl Borate*** in THF stirred below -65 °C (-78 °C bath) results in the formation of an addition compound of $BrCH_2Li$ with the borate, which is converted by anhydrous acid to diisopropyl (bromomethyl)boronate (eq 6).[1] This preparation is easily scaled up to 2-mol batches.

(6)

With simple boronic esters, $BrCH_2Li$ adds to the boron atom to form a borate complex, which on warming to rt rearranges to form the homologous boronic ester (eqs 7 and 8).[1] Unexpectedly, the presence of oxygen functionality has a severely adverse effect on boronic ester homologation with $BrCH_2Li$ (eq 9).[1] This result contrasts with the previous finding with $ClCH_2Li$, which accomplished the conversion of eq 9 in 90% yield.[2]

(7)

(8)

Homologs of Bromomethyllithium.

Although the first attempt to use BuLi to generate $BrCH_2Li$ from CH_2Br_2 in the presence of a ketone gave an anomalous poor result,[3] similar treatment of $MeCHBr_2$, Me_2CBr_2, $PhCHBr_2$, or $EtOCHBr_2$ readily yielded the corresponding oxiranes.[6] Typical examples are illustrated (eqs 10 and 11). It should be noted that where both the carbonyl compound and the halide are unsymmetrical, diastereomeric mixtures result.

Several examples of RCHBrLi have also been preformed at -115 °C and reacted with carbonyl compounds to form oxiranes or bromohydrins.[4,7]

Bromomethyl Methyl Ether

$MeOCH_2Br$

[13057-17-5] · C_2H_5BrO · Bromomethyl Methyl Ether · (MW 124.96)

(alkylating agent; formaldehyde equivalent;[1-8] alcohol protecting group[9-14])

Alternate Name: BMME.

Physical Data: bp 87 °C; *d* 1.531 g cm^{-3}.

Form Supplied in: colorless to light yellow liquid.

Handling, Storage, and Precautions: lachrymator, possible carcinogen, handle with care. Extremely destructive to tissue of mucous membranes, eyes, and skin. Wear respirator, chemical-resistant gloves, and safety goggles.

Alkylating Agent.

Bromomethyl methyl ether (BMME) has been used in the preparation of α-methylene ketones[1] and lactones.[2] Reaction of a silyl enol ether with 1.5 equiv of BMME in the presence of 5 mol% of ***Tin(II) Bromide*** leads to good yields of α-methylene ketones after treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) (eq 1). The reaction is thought to proceed via an intermediate stannane complex which is attacked by bromide ion to give an α-bromomethyl ketone. The reaction can be carried out in a one-pot operation, and proceeds in modest to good yields.

In the course of their synthesis of the pseudoguaianolide aromaticin, Lansbury et al. used BMME as a latent formaldehyde equivalent. Alkylation of the functionalized lactone (eq 2) with BMME (***Lithium Diisopropylamide***, HMPA) was followed by hydrolysis to a hydroxy acid and in situ elimination of the methoxy group. Careful quenching of the reaction was necessary to avoid methanol addition to the newly formed α-methylene lactone.

(2)

Williams[3] utilized bromomethyl methyl ether in an enantioselective synthesis of 2,6-diamino-6-(hydroxymethyl)pimelic acid (eq 3). The chiral oxazinone was first alkylated with iodobutene followed by subsequent alkylation with bromomethyl methyl ether. The bis-alkyl adduct was then converted to the desired product after a number of steps.

(3)

Schank[4] studied the alkylation of sulfinate anions (eq 4) with bromomethyl methyl ether. Alkylation occurs predominantly on the sulfinyl oxygen to give an unstable compound along with minor amounts of *S*-alkylated product. The unstable compound rearranges upon heating to give the product.

(4)

Alcohol Protecting Group.

Eqs 5-7 illustrate the use of bromomethyl methyl ether for forming the methoxymethyl ether (MOM) protecting group.[9-14] Typically the alcohol is reacted with BMME in the presence of ***Diisopropylethylamine*** (DIEA) as an acid scavenger.

2-Bromo-2-methylpropionyl Bromide[1]

[20769-85-1] · $C_4H_6Br_2O$ · 2-Bromo-2-methylpropionyl Bromide · (MW 229.90)

(useful reagent for the preparation of ketenes,[1,2] amides,[3,4] alkynic ketones,[5] and macrocyclic amides[6,7])

Physical Data: bp 162-164 °C; *d* 1.860 g cm^{-3}.

Solubility: sol polar aprotic and nonpolar solvents; reacts with protic solvents.

Form Supplied in: colorless liquid, widely available.

Handling, Storage, and Precautions: should be handled in a dry atmosphere. Hydrogen bromide is evolved upon exposure to water and protic solvents. A well-ventilated fume hood should be used when handling this compound. Adequate skin and eye protection should also be worn.

Preparation of Ketenes.

Treatment of 2-bromo-2-methylpropionyl bromide with ***Zinc*** turnings in ethyl acetate affords dimethylketene in 46-54% yield (eq 1).[1] The dimethylketene is obtained as a 9-10% solution in ethyl acetate by distillation of the reaction mixture at 300 mmHg. Treatment of 2-bromo-2-methylpropionyl bromide with propargyl alcohol affords the propargyl ester, which is converted to the ketene acid upon treatment with zinc dust in benzene (eq 2).[2] The transformation of the propargyl ester to the ketene acid occurs by formation of the zinc enolate, followed by a [3,3]-sigmatropic rearrangement.[2a]

(1)

(2)

Preparation of Amides.

A variety of aromatic and aliphatic amines react with 2-bromo-2-methylpropionyl bromide to afford the corresponding amides.[3] These amides have then been used in a variety of subsequent reactions that take advantage of the bromocarbon functionality. For example, treatment of 6-amino-1,3-dihydro-2*H*-indol-2-one with 2-bromo-2-methylpropionyl bromide afforded the intermediate acyl derivative, which was cyclized to 5,7-dihydro-3,3-dimethylbenzo[1,2-*b*:5,4-*b*´]dipyrrole-2,6-(1*H*,3*H*)-dione upon treatment with ***Aluminum Chloride*** (eq 3).[4]

(3)

Preparation of Alkynic Ketones.

Treatment of phenyl(trimethylsilyl)acetylene with 2-bromo-2-methylpropionyl bromide in the presence of aluminum chloride afforded 4-bromo-4-methyl-1-phenylpent-1-yn-3-one (eq 4).[5] This alkynic ketone could also be made from phenylacetylene and 2-bromo-2-methylpropionyl bromide using dichlorobis(triphenylphosphine)palladium(II)-***Copper(I) Iodide*** as catalyst. This alkynic ketone served as a key precursor to the natural product bullatenone.

(4)

Preparation of Macrocyclic Amides.

Treatment of ethylenediamine with 2-bromo-2-methylpropionyl bromide in chloroform in the presence of ***Pyridine*** afforded *N,N´*-ethylenebis(2-bromoisobutyramide) (eq 5), which served as a precursor to macrocyclic nitrogen-sulfur compounds.[6] These macrocycles were then used as ligands for transition metals. Several other macrocyclic nitrogen ligands have been prepared using 2-bromo-2-methylpropionyl bromide.[7]

2-Bromo-1-methylpyridinium Iodide[1]

[52693-56-8] · C_6H_7BrIN · 2-Bromo-1-methylpyridinium Iodide · (MW 299.94)

(dehydrative coupling and activation of alcohols)

Preparative Methods: the title reagent (**1a**) as well as the chloro analog (**1b**) can be prepared by adding 1.2 equiv of MeI to an acetone solution of 2-bromo- or 2-chloropyridine at 0 °C. After stirring for 3 days at rt the precipitated pyridinium salt is filtered off and washed with dry ether. Further drying under vacuum results in 80-90% yield of the pyridinium salt as a colorless solid which may be used without further purification.[2b,c]

General.

The reagent (**1a**) is a member of the widely used 2-halo-*N*-alkylpyridinium salts pioneered by Mukaiyama in the mid-1970s. Two general uses have arisen: dehydrative coupling and conversion of alcohols to leaving groups followed by subsequent nucleophilic displacement. Several variants of (**1**) exhibit analogous reactivity and this discussion will include some of these alternative reagents. The uses of 2-halo-*N*-alkylpyridinium salts up to 1979 have been reviewed.[1]

Dehydrative Coupling.

The C-2 bromide of (**1a**) (as well as the corresponding chloride of **1b**) is easily displaced by carboxylates in the presence of an amine base to generate 2-acyloxypyridinium salts (**2**) which, in turn, can acylate a variety of nucleophiles to provide esters,[2] amides,[3] thiolesters[4] (eq 1), and 3-acylthiazolidine-2-thiones.[5] The reactions generally proceed well in a variety of solvents, including diethyl ether, dichloromethane, acetonitrile, pyridine, and toluene. As bases, ***Triethylamine***, ***Tri-n-butylamine***, and ***2,6-Lutidine*** give good results. It was found that less basic pyrimidinone derivatives such as (**7**) and (**8**) allow the reaction to be carried out under essentially neutral conditions.[6]

(7) R = H
(8) R = Me

(9)

Ring closure via intramolecular acylation to produce lactones[7] (including macrocyclizations[8]) and β-lactams[9] have also been demonstrated with (**1b**). These dehydrative processes have two outstanding characteristics: a number of

functional groups can tolerate the mild reaction conditions, and even hindered nucleophiles may be acylated. For example, pivalic acid (**10**) may be converted to its *t*-butyl ester (**12**) in 54% yield (eq 2). However, the steroidal alcohol (**9**) was acylated in only 10-15% yield using 2-bromo-1-ethylpyridinium iodide after 5 days at 100 °C.[10] The mildness of the conditions was demonstrated in the macrolactamization which produced (**13**) in 81% yield using (**1b**) with Et_3N in CH_2Cl_2 at 20 °C.[11]

(2)

(13)

Activation of Alcohols.

This aspect of the Mukaiyama reagents has not been studied as intensely as dehydrative coupling. In many respects the activation of alcohols by 2-halo-1-methylpyridinium salts mirrors that of the ***Triphenylphosphine-Diethyl Azodicarboxylate*** (Mitsunobu reagent). That is, alcohols are converted to good leaving groups and can then undergo invertive substitution with nucleophiles (eq 3). Thus activated, both primary and secondary alcohols have been

displaced with Grignard reagents,[12] trichloroacetic acid/Et_3N[13] (to eventually induce the equivalent of the Mitsunobu process), iodide (-> R-I) and chloride ion (-> R-Cl),[14] sulfides (-> R-SR),[15] sodium *N*,*N*-dimethyldithiocarbamate (-> R-SH),[16] and azide ion (-> R-NH_2).[17] With secondary alcohols, complete inversion normally occurs. The 2-chlorobenzoxazolium salt (**17**) plays the same role as (**14**) in several of the processes.

(3)

(16)

(17)

Other Uses.

These reagents also promote the following: reductive elimination of β-hydroxy sulfides to give alkenes,[18] preparation of nucleosides,[19] phosphorylation,[20] carbocation formation as a prelude to cationic cyclizations,[21] Beckmann and pinacol rearrangements,[22] preparation of isothiocyanates,[23] carbodiimides,[24] and isocyanates from amines,[25] and dehydration of amides to give nitrile and isocyanides.[26] None of these latter processes have been utilized beyond their original descriptions.

Bromonium Di-*sym*-collidine Perchlorate[1]

[4836-12-8] · $C_{16}H_{22}BrClN_2O_4$ · Bromonium Di-*sym*-collidine Perchlorate · (MW 421.72)

(reactive electrophilic brominating agent; activates alkenes towards nucleophilic reagents;[2] reagent for bromocyclization,[3,4] useful in the preparation of *cis*-α-alkylamino alcohols)

Alternate Names: bromonium dicollidine perchlorate; bis(collidine)bromonium perchlorate.

Physical Data: mp 230 °C.

Solubility: sol chloroform; insol ether.

Form Supplied in: fine colorless crystalline powder.

Preparative Method: it is important in the preparation of this reagent to be sure that conditions are anhydrous, otherwise bromine tends to be reliberated. Silver di-*sym*-collidine perchlorate is prepared by adding *sym*-collidine (20 mL) to a solution of silver nitrate (9 g) and sodium perchlorate (11 g) in 100 mL of water, while stirring vigorously, to give a curdy white precipitate. After washing repeatedly with water, the product is washed with ethanol and ether and finally dried under vacuum over P_2O_5. The yield is quantitative. Silver di-*sym*-collidine perchlorate (13.47 g, 30 mmol) is suspended in 150 mL of chloroform and 1 mL of *sym*-collidine. Bromine (1.65 mL, 30 mmol) is added. Silver bromide rapidly precipitates and is filtered through Celite. The clear pale-yellow filtrate gives a fine, white crystalline precipitate on the addition of ether. The crystals are dried under high vacuum.

Handling, Storage, and Precautions: perchlorates are potentially powerful explosives. This compound detonates on strong heating and so due precautions[1] must be taken. The compound is stored under anhydrous conditions. This reagent should be handled in a fume hood.

Preparation of Glycosides and Nonreducing Disaccharides.[1]

Reaction of D-glucal triacetate (**2**) with equimolar amounts of methanol and bromonium di-*sym*-collidine complex (**1**) dissolved in chloroform gives virtually quantitative yields of acetylated methyl 2-deoxy-2-bromoglycosides. Unlike pyridine or 2-methylpyridine, the steric hindrance to *N*-glycoside formation provided by the methyl groups at the 2- and 6-positions of *sym*-collidine is required for successful *O*-glycoside synthesis. If 2,3,4,6-tetra-*O*-acetyl-β-D-glucose (**3**) is used as the alcohol, the 2-deoxy-2-bromo disaccharide heptaacetate (**4**) is formed (eq 1). Deacetylation with ***Triethylamine*** in aqueous methanol followed by hydrogenolysis with ***Palladium on Carbon*** as the catalyst affords β-D-glucopyranosyl-2-deoxy-α-D-*arabino*-hexopyranoside (2-deoxyneotrehalose), isolated as the crystalline heptaacetate (**5**).

(1)

Bromocyclization[3] of Unsaturated Thiocarbamidates.

This reagent can effect the stereo- and regiospecific functionalization of alkenes to furnish *cis*-1,2-methylamino alcohols in protected form. For example, unsaturated thiocarbamates, prepared as shown in eq 2, on treatment with bromonium dicollidine perchlorate cyclize to bromocarbamates. This cyclization has been successfully applied to several cyclic and acyclic unsaturated alcohols using methyl, benzyl, and *t*-butyl isothiocyanates. In all cases the condensation step (**6** to **7**) is essentially quantitative. The product (**8**) can be converted into *cis*-α-alkylamino alcohols by reduction of the bromine with ***Tri-n-butylstannane*** followed by alkaline hydrolysis. When R is a *t*-butyl group it can be removed in high yield by treatment with ***Trifluoroacetic Acid*** at 25 °C. The value of these transformations for the synthesis of aminocyclitols is illustrated by the conversion of bromocarbamate (**9**) to (±)-sporamine (**10**) in three steps (TFA; *n*-Bu_3SnH; aqueous NaOH, 25 °C) in better than 90% overall yield (eq 3). Sporamine is the aminocyclitol portion of the broad-spectrum antibiotic sporacin A.

(2)

(3)

Bromolactamization.

Esoaminuroic acid (**11**), an amino sugar, is present in esomycin A, which is an antifungal antibiotic isolated from *Streptomyces*. The key step in its synthesis is the transannular bromolactamization of an unsaturated amide (eq 4).[4]

(4)

N-(*R*)-*p*-Methoxyphenethylamides were subjected to the bromolactamization sequence involving the use of ***Trimethylsilyl Trifluoromethanesulfonate*** as the amide silylating agent, and bromonium dicollidine perchlorate as electrophile. The desired [3.2.1] lactams were the only cyclization products, with yields exceeding 75% (eq 5). No [2.2.2] lactams were formed in detectable quantities. It may be noted that the *N,O*-bis(*t*-butyldimethylsilyl) derivative gave more [2.2.2] product, particularly at higher temperature.[5]

(*E*)-1-Bromo-2-phenylthioethylene[1]

(*E*)-(**1**; X = Br)

[17101-82-5] · C_8H_7BrS · (*E*)-1-Bromo-2-phenylthioethylene · (MW 215.11) (*Z*)-(**2**; X = Br)

[17101-71-2] (*E*)-(**3**; X = Cl)

[26620-11-1] · C_8H_7ClS · (*E*)-1-Chloro-2-phenylthioethylene · (MW 170.66)

(building blocks for stereospecific synthesis of alkenes and dienes)

Alternate Name: 2-bromovinyl phenyl sulfide.

Physical Data: (**1**) bp 44.5-45 °C/0.04 mmHg; (**2**) bp 59-60 °C/0.04 mmHg; (**3**) bp 119-120 °C/15 mmHg.

Analysis of Reagent Purity: GC/MS, IR, and ^{1}H NMR.

Preparative Methods: (i) 3-phenylthioacrylic acid is first formed by thiophenol addition to propiolic acid, and is then subjected to a one-pot bromine addition and subsequent decarboxylative dehalogenation. This gives a ca. 1:4 mixture of (**1**) and (**2**) (overall yield 69%);[2] (ii) by a PTC reaction between thiophenol and 1,2-dibromoethylene (only isomer (**2**), yield 48%);[3] and (iii) by addition of sulfenyl chloride to acetylene (only compound (**3**), yield 73%).[4]

Purification: by distillation; the isomeric mixture of (**1**) and (**2**) is separated into its components by careful distillation,[5] or by flash chromatography (silica gel; petroleum ether eluent).

Handling, Storage, and Precautions: if refrigerated (-10 to 0 °C) they can be stored for several weeks without isomerization. Avoid inhaling; use in a fume hood.

Synthesis of Stereodefined Alkenes.

Reagents (**1**), (**2**), and (**3**) can be subjected to two, sequential, cross-coupling reactions with Grignard reagents in the presence of a Ni^{II} or Pd^{II} catalyst, with the substitution of the halogen and phenylthio group (eqs 1 and 2) yielding stereodefined alkenes.[1,5,6]

(E)-1-Bromo-2-phenylthioethylene

The substitution of the phenylthio group is much slower than the replacement of the halogen, and can be performed only using longer reaction times and an excess of Grignard reagent. In order to prepare nonsymmetrical alkenes, it is necessary to use a different Grignard reagent after completion of the first step.[6] Often, it is unnecessary to isolate the vinyl sulfide intermediate and the procedure can be performed successfully in one pot. Moreover, the isomeric purity of the final product is higher than 99% in the case of the (*E*) isomers, and slightly lower for the (*Z*) isomers (95-98%). In the second step of the procedure (e.g. the substitution of the phenylthio group), Ni catalysts cannot be replaced by Pd catalysts.

An application of the described method is the synthesis of many monoalkenic insect sex pheromones in high isomeric purity (>98%), and in isolated overall yields in the range 65-75% for the (*Z*) isomers and 80-90% for the (*E*) isomers.[5] The procedure can also be applied to the synthesis of pheromones with an alkenyl acetate structure (eqs 3 and 4), using Grignard reagents derived from 1-halo-o-tetrahydropyranyloxyalkanes in the first step, and acetylating the tetrahydropyranyl-protected alkenols after the second cross-coupling step.[5]

Synthesis of Stereodefined Alkenyl Sulfides.

The substitution of the halogen atom occurs at a rate much greater than the phenylthio group; thus alkenyl sulfides can be conveniently obtained (eqs 5-7).[3,5,6]

(5)

(6)

(7)

It is worth noting that the use of a Pd catalyst in the reaction leading to (*Z*) isomers gives better stereochemical results. The phenylthio group of alkenyl sulfides is easily converted to a carbonyl group.[7]

Alkenyl sulfides can be also obtained in an enantioselective manner (51-57% ee) by a cross-coupling reaction of (**1**) or (**2**) with a secondary Grignard reagent in the presence of chiral Ni^{II} or Pd^{II} catalysts, at 0 °C or at rt, in THF or ether (eq 8).[3] The best results are obtained with the complex of the chiral phosphine PPFA (PPFA = ***(R)-N,N-Dimethyl-1-[(S)-2-(diphenylphosphino)ferrocenyl]ethylamine***).

(8)

Occasionally, when secondary organomagnesium reagents are used, isomerization of the secondary alkyl/primary alkyl group is observed. Iron(III) complexes, for example ***Tris(dibenzoylmethide)iron(III)*** and $Fe(DPM)_3$ (DPM = dipivaloylmethide), completely suppress this isomerization process.[8]

The cross-coupling process leading to (*Z*)-alkenyl sulfides can also be performed with other organometallic compounds, e.g. by combining (**2**) with 9-alkyl-9-BBN in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** (as catalyst) and a base,[9a] or with (dialkoxyboryl)methylzinc reagents in the presence of the same catalyst.[9b]

Reagent (*E*)-(**3**) can be transformed into vinyl selenides by action of MeSeLi or PhSeNa (eq 9), with retention of configuration.[10]

(E)-1-Bromo-2-phenylthioethylene

(9)

R = methyl, phenyl

Synthesis of Stereodefined Dienes.

1,3-Dienes.

1-Trimethylsilyl-1,3-dienes.

(1*E*,3*E*)- and (1*E*,3*Z*)-1-trimethylsilyl-1,3-dienes can be obtained by the appropriate cross-coupling reaction between (**1**) or (**2**) and (*E*)-2-trimethylsilylvinylmagnesium bromide (eqs 10 and 11) in the presence of $NiCl_2$(dppe).[11]

(10)

(11)

These compounds can be employed in the synthesis of more complex targets, since both the phenylthio and the trimethylsilyl groups can be substituted in different ways (e.g. the trimethylsilyl group can be replaced by acyl groups using acyl chlorides in the presence of $AlCl_3$).[1]

1-Phenylthio-1,3-dienes.

Reagents (**1**) and (**2**) react with 1-alkenyl-1,3,2-benzodioxaborole in the presence of $Pd(PPh_3)_4$ and a base to yield 1-phenylthio-1,3-alkadienes or -1,3,5-alkatrienes (eqs 12 and 13).[12] These intermediates are easily converted into important natural products, e.g. *cis*(C_{10})-allofarnesene, by the substitution of the arylthio group with a Grignard reagent in the presence of Ni^{II} complexes.

(12)

(E)-1-Bromo-2-phenylthioethylene

(13)

(*E*,*Z*)- and (*Z*,*E*)-Dienes.

Reagent (**2**) can give ***Phenylthioacetylene***,[2] to which (*Z*)-dialkenylcuprates are added (eq 14).[13]

(14)

The arylthio group of the resulting (*E*,*Z*)- and (*Z*,*E*)-1-phenylthio-1,3-dienes can be substituted by a Grignard reagent in the presence of $NiCl_2$(dppe) to yield the corresponding dienes (eq 15). A variety of pheromones having a conjugated diene structure can be prepared using this approach.[13]

(15)

1,4-Dienes.

Phenylthiopentadiene.

Reagent (**2**) is converted (eq 16) by a cross-coupling reaction with ***Allylmagnesium Bromide*** in the presence of $NiCl_2$(dppe) to a 1-phenylthio-1,4-diene.[14] This compound can be easily metalated with ***n-Butyllithium*** to give phenylthiopentadienyllithium, which can be reacted with various C-electrophiles, or can be first transmetalated and then reacted with C-electrophiles. The stereo- and regiochemistry of the process can be properly tuned.

(16)

Synthesis of Sulfoxides.

Vinyl Sulfoxides.

Reagents (**1**), (**2**), and (**3**) can be oxidized by ***m-Chloroperbenzoic Acid*** to the corresponding sulfoxides, which react in two different ways (eq 17), according to the organometallic reagent employed.[15]

(17)

Organocuprates give the cross-coupling process with substitution of the halogen group. Grignard reagents attack the sulfur atom with substitution of the whole halovinyl moiety. Starting with optically active halovinyl aryl sulfoxides, alkyl aryl or diaryl sulfoxides can be obtained in a highly enantioselective manner.[16]

Vinylstannanes.

Reagent (**3**) can generate vinylstannanes after *m*-CPBA oxidation to sulfoxides, and subsequent treatment with ***Hexamethyldistannane*** (eq 18) in the presence of $Pd_2(dba)_3/PPh_3$.[17]

(18)

Recently, reagent (**3**) has been transformed into 1-bromo-1-phenylthio-1,3-butadiene, thus leading to a general approach to conjugated (*E*,*E*)-dienes, through sequential coupling reactions.[18]

Related Reagents.

Phenylthioacetylene.

3-Bromo-1,2-propanediol[1]

[4704-77-2] · $C_3H_7BrO_2$ · 3-Bromo-1,2-propanediol · (MW 154.99)

(carbonyl protecting group which can be cleaved under neutral conditions[2])

Physical Data: bp 92-94 °C/1.5 mmHg; *d* 1.769 g cm^{-3}.

Form Supplied in: widely available as 95% or 98% pure; viscous colorless liquid.

Preparative Method: prepared according to the procedure of Winstein and Goodman.[4] Epibromohydrin (**1**) is treated with a catalytic amount of *p*-toluenesulfonic acid in H_2O at refluxing temperature for 7 h (eq 1). Distillation of the final product gives a 65% yield of the desired diol (**2**).

Handling, Storage, and Precautions: harmful liquid and fumes (CO, CO_2, HBr); incompatible with strong oxidizing agents; corrosive; irritant; use in fume hood only; refrigerate.[3]

Synthetic Utility.

The transformation of aldehydes and ketones to cyclic acetals is a commonly used method for the protection of the carbonyl functional group. The cleavage of these acetal protecting groups is usually accomplished with acidic media, rendering acid incompatible functional groups unsuitable for schemes employing such deprotection steps. The development of 3-bromo-1,2-propanediol as a protecting group for carbonyls stemmed from the need for a protecting group which could be removed under neutral conditions in high yields. 4-*t*-Butylcyclohexanone (**3**) in the presence of bromoglycol (**2**) and catalytic ***p-Toluenesulfonic Acid*** in refluxing benzene gives 98% of acetal (**4**) (eq 2).

Deprotection of the bromomethylethylene acetal (**4**) is accomplished by treating it with ***Zinc*** dust in refluxing methanol for 12 h to afford 89% of 4-*t*-butylcyclohexanone (**3**) (eq 2).[2]

(2)

Under acidic conditions, α,β-saturated ketones can be selectively protected in the presence of their α,β-unsaturated counterparts. For example, exposure of enedione (**5**) to 3-bromo-1,2-propanediol and *p*-toluenesulfonic acid in refluxing benzene gives a mixture of isomeric acetals (**6a** and **6b**) and the monoprotected compound (**7**). Treatment of this mixture with *p*-toluenesulfonic acid and acetone gives pure (**7**) in 74% overall yield (eq 3).[5]

Formation of this acetal has also been used to shift the double bond of an α,β-unsaturated enone. For example, treatment of enone (**8**) with 3-bromo-1,2-propanediol under standard conditions gives a mixture of acetals (**9** and **10**) (eq 4). The mixture of isomers can be deprotected without separation with zinc in refluxing methanol for 18 h. Enone (**11**) is isolated in 37% yield after chromatographic separation of the alkenic isomers.[6]

Stability of the Acetal.

The bromomethylethylene acetal moiety is stable to a variety of reagents that react with carbonyl groups. For example, treatment of acetal (**4**) with ***m-Chloroperbenzoic Acid***, ***Ammonia***, ***Sodium Borohydride***, ***Methyllithium***, or ***Chromium(VI) Oxide*** gives a quantitative recovery of the starting material.[2] On the other hand, while there are many hydroxy, amino, and carbonyl protecting groups that are stable to the reductive conditions employed to remove this protecting group,[2,7] the β-halo ethers (**12** and **13**) are incompatible with such conditions.

3-Bromo-2-propen-1-ol

[37675-33-5] · C_3H_5BrO · 3-Bromo-2-propen-1-ol · (MW 136.98)

(used in palladium-catalyzed cross-coupling reactions with alkynes)

Physical Data: bp 94-97 °C/55 mmHg. *cis* isomer: bp 81 °C/25 mmHg; d^{25} 1.6623. *trans* isomer: bp 87 °C/25 mmHg; d^{25} 1.6567.

Analysis of Reagent Purity: satisfactory microanalytical data reported.[1]

Preparative Methods: by alkaline hydrolysis of 1,3-dibromopropene,[1,2] by hydrobromination of methyl propiolate followed by reduction,[3] or by sequential hydrostannylation and bromination of propyn-3-ol.[4]

3-Bromo-2-propen-1-ol has been widely used in palladium-catalyzed cross-coupling reactions of hydroxylated alkynes. Synthetic routes to leukotriene B_4,[5] leukotriene E_4 metabolites,[4] lipoxin A_1,[6] coriolic acid, and dimorphecolic acid[7] have utilized such reactions as pivotal steps (eqs 1-4, respectively). Intermediates for the preparation of other arachadonic acid metabolites have also been prepared by this method (eq 5).[8]

Trienals derived from linolenic acid may be prepared using the process (eq 6).[9]

Oxidation of bromopropenal gives the highly unstable 3-bromopropenal that may be converted in situ to the corresponding dimethyl acetal (eq 7), which has been examined as a substrate for Heck reactions with alkenes.[4]

3-Bromopropionyl Isocyanate

[18926-24-4] · $C_4H_4BrNO_2$ · 3-Bromopropionyl Isocyanate · (MW 177.99)

(derivatizing agent for alcohols,[1] phenols,[2] and arylamines;[3] brominating agent potentially present in *N*-bromosuccinimide brominations;[4] bifunctional cyclization reagent[5])

Alternate Name: 3-bromopropanoyl isocyanate.

Physical Data: volatile liquid.

Solubility: sol chlorinated, aromatic, and ethereal solvents; reacts violently with H_2O, and with basic and protic solvents.

Form Supplied in: prepared from ***N-Bromosuccinimide*** as needed.[6]

Handling, Storage, and Precautions: lachrymator; corrosive; use only in a fume hood; wear protective gloves and preferably a NIOSH-approved respirator. All transfers and reactions should be carried out under anhydrous conditions. Store in a cool dry place, taking care to avoid contamination with protic, basic, or organometallic materials, as these may induce polymerization. Toxicity data for isocyanates are available.[7]

Derivatization of Alcohols, Phenols, and Amines.

Like other isocyanates, 3-bromopropionyl isocyanate reacts rapidly with N- or O-nucleophiles to give urea and carbamate derivatives, respectively (eq 1).[8] Crystalline materials are obtained from primary and unhindered secondary alcohols, while tertiary alcohols give alkenes via elimination.[1] Phenols react extremely well, except those containing multiple nitro groups.[2] Anilines afford ureas, unless hindered or containing more than one amino group.[3] Aliphatic amines usually cause elimination of HBr from the isocyanate, thus yielding *N*-acryloylurea impurities.[3] Note that the presence of the Br atom in these derivatives simplifies crystal structure determination by heavy atom methods.

(1)

R^1 = primary or secondary alkyl, aryl; YH = OH, NH_2, NHR^2

Isomeric Brominating Agent Present in *N*-Bromosuccinimide Reactions.

Much recent interest in elucidating the exact nature of the radical chain carriers in *N*-bromosuccinimide reactions (π-versus σ-centered radicals)[9] and their respective chemoselectivities has led in turn to a greater understanding of the radical chemistry of 3-bromopropionyl isocyanate. Indeed, radical scavengers form adducts with 3-bromopropionyl isocyanate in several solvents.[4,10] The current status of the debate holds that the rate of intramolecular cyclization of 3-bromopropionyl isocyanate (3.7×10^6 at 328 K) is more consistent with a σ-centered radical (eq 2).[11]

(2)

Bifunctional Cyclization Reagent.

This molecule contains two reactive centers (isocyanate and bromide) of appreciably different reactivity. Thus far, this relationship has been exploited in the preparation of dihydrouracil antibacterial agents (eq 3).[5] It must also be noted that the bromine substituent may be eliminated to give an acryloyl moiety,[3] which may

give additional modes of reactivity.

2-(3-Bromopropyl)-2-methyl-1,3-dioxolane

(**1**; X = Br, R,R = $-CH_2CH_2-$)

[24400-75-7] · $C_7H_{13}BrO_2$ · 2-(3-Bromopropyl)-2-methyl-1,3-dioxolane · (MW 209.08) (**2**; X = Cl, R,R = $-CH_2CH_2-$)

[5978-08-5] · $C_7H_{13}ClO_2$ · 2-(3-Chloropropyl)-2-methyl-1,3-dioxolane · (MW 164.63) (**3**; X = I, R,R = $-CH_2CH_2-$)

[3695-28-1] · $C_7H_{13}IO_2$ · 2-(3-Iodopropyl)-2-methyl-1,3-dioxolane · (MW 256.08) (**4**; X = I, R,R = Me,Me)

[88794-75-6] · $C_7H_{15}IO_2$ · 5-Iodo-2-pentanone Dimethyl Acetal · (MW 258.10)

(alkylating agents for attaching a 4-ketopentyl group to various nucleophiles; the derived organometallic reagents attach this group to electrophilic centers such as carbonyl groups; the major use has been for synthesis of monoprotected 1,5- and 1,6-diketones and related 1,*n* difunctional compounds)

Alternate Name: 5-bromo-2-pentanone ethylene acetal.

Physical Data: bp (**1**), 94-97 °C/10 mmHg; (**2**), 79-81 °C/8 mmHg; (**3**), 70-72 °C/2 mmHg; (**4**) 100 °C/11 mmHg.

Preparative Methods: acetalization of the 5-halo-2-pentanone (made by opening 2-acetylbutyrolactone with HX).[1] 5-Chloro-2-pentanone is commercially available, and has been converted to 5-iodo-2-pentanone by treatment with sodium iodide/acetone.[1g,2] Alternatively, (**2**) is treated with sodium bromide/ethyl bromide to give (**1**);[3a] (**1**) or (**2**) may be treated with sodium iodide to give (**3**).[3b-d]

Purification: vacuum distillation from a trace of sodium bicarbonate.

Handling, Storage, and Precautions: store at <=0 °C; use in a fume hood.

Electrophilic 4-Ketopentyl Reagent.

2-(3-Bromopropyl)-2-methyl-1,3-dioxolane

Alkylation of ketone enolates with (**1**) gives 1,6-diketone monoacetals.[4] Similarly, enolate equivalents, namely the anions of acetone dimethylhydrazone[5a] and acetylmethylenetriphenylphosphorane,[5b] have been alkylated with (**1**) to give, after partial hydrolysis, 7,7-ethylenedioxy-2-octanone. These substances can be cyclized to acetylcyclopentenes (eq 1).[4a]

(1)

Alkylation of (**8**) followed by acetalization/deacetalization leads to the tricyclic alkaloid intermediate (**11**) (eq 2).[6]

2-(3-Bromopropyl)-2-methyl-1,3-dioxolane

Alkylation of nitriles[7] and α-aminonitriles[8] with 5-halo-2-pentanone acetals is well established. A nonstereoselective synthesis of (-)-pumiliotoxin-C (**15**) starts with the alkylation of (**12**) (eq 3).[8c]

o-Halo-2-alkanone acetals have been used in the synthesis of *n,m*-dihydroxy-2-alkanones which, upon internal acetalization, give various bridged dioxabicyclic insect pheromones (see ***2-(2-Bromoethyl)-2-methyl-1,3-dioxolane***). Stereoselective alkylation of lactone (**16**)[9] (derived from L-lactic acid) with (**4**) is the basis of an enantioselective synthesis of (-)-frontalin (**18**) (eq 4).[1g] A different approach to (**18**) involves Sharpless epoxidation of (**21**) derived from alkylation of malonic ester with (**1**) (eq 5).[10a] Several examples of alkylation of monoanions of 1,3-dicarbonyl and 2-cyanocarbonyl compounds with 5-halo-2-pentanone acetals are known.[10]

(4)

(5)

A short synthesis of (+)-*endo*-brevicomin (**25**) involves alkylation of the dianion of (**22**) (readily available from ***Baker's Yeast*** reduction of 2-propionyl-1,3-dithiane), followed by chemoselective monohydrolysis of (**23**) and stereoselective reduction (eq 6).[11a] Other 1,3-dithianes have been alkylated with 5-halo-2-pentanone acetals in connection with syntheses of insect substances[11b,c] and the macrocyclic lactone zearalenone.[11d] A synthesis of (*E*)-9-keto-2-decenoic acid (queen substance) relies on alkylation of a 1,3-disulfone with (**3**).[12]

5-Halo-2-pentanone acetals have been used to alkylate lithium and sodium acetylides,[1b,c,13] allenyllithiums,[14] alkenyllithiums[15] and -cuprates,[16] allylic lithiums,[17] 3-furyllithiums,[18] and an allylic phosphonate anion.[19] Several of these applications lead to dioxabicyclic insect pheromones.[13a,b,16b,17b,19]

Nucleophilic 4-Ketopentyl Reagent.

Feugeas and Normant noted in 1963 that the Grignard reagents (**26a**) and (**26b**) (from (**1**) and (**2**), respectively) could be prepared in THF but not in diethyl ether (where dioxolane ring cleavage occured).[20] Despite this caveat, at least three other groups have prepared (**26a**) in diethyl ether[21] and, to further complicate the picture, a fourth group has claimed that, even in THF, the preparation of (**26b**) is capricious.[22] It is likely that the key to success in both solvents is temperature control[23] and the use of freshly distilled (**1**) or (**2**);[21a] the use of Rieke ***Magnesium***[24] has been recommended,[25] as has also the use of ***1,2-Dibromoethane*** as an entraining agent.[26a] In two reports,[1b,22] reaction of (**26b**) with aldehydes produces, in addition to the expected secondary alcohol, large amounts of ketone, presumably via Oppenauer-like intramolecular hydride transfer. Reaction of (**26**) with ketones frequently gives low yields of tertiary alcohols;[27] in one case this has been traced to production of large amounts of secondary alcohol,[27c] presumably via β-hydride transfer. Despite these problems, reaction of (**26**) with aldehydes and ketones has often been used successfully in natural products synthesis;[21,27a,b,28] for example, in the synthesis of monomorine I(**29**) (eq 7).[28a]

The corresponding lithium reagent (**30**) has been prepared by reaction of (**1**) in diethyl ether with ***Lithium*** containing 1-2% sodium,[29] or with lithium-arene radical anions.[30] Reagent (**30**) reacts more rapidly than (**26**) with aldehydes and ketones, and reacts selectively with a variety of electrophiles.[30a] Townsend and co-workers used both (**26a**)[25a] and (**30**)[29a] with equally good results in syntheses of averrufin (**33**) (eq 8).

2-(3-Bromopropyl)-2-methyl-1,3-dioxolane

The relatively low reactivity of (**26**) allows the reaction with acid chlorides[31a] and anhydrides[31b,c] to be stopped after monoaddition, enabling preparation of 1,5-diketone monoacetals. Reagent (**26a**) has been paired successfully with enol lactones[21c,31c,32] in the Fujimoto-Belleau reaction (eq 9).

2-(3-Bromopropyl)-2-methyl-1,3-dioxolane

Simple esters, such as ethyl formate, consume 2 mol of the Grignard reagent (producing secondary alcohols),[33] but monoaddition to oxalate esters can be effected at -40 °C, leading to α-keto esters; this latter process has been used in syntheses of anatoxin A.[25b,c] Reactions of (**26a**) and (**26b**) with hemi-aminals and immonium salts,[34a] carbon disulfide,[34b] triphenyltin chloride,[34c] and trimethyl borate[34d] have been reported.

The Grignard reagent (**26a**) in the presence of copper salts has been used for nucleophilic substitution reactions with saturated alkyl halides and sulfonate esters,[26] and with allyl[35] and propargyl[36] halides and sulfonates (1,3-substitution). The triphenylphosphonium ylide derived from (**1**)-(**3**) has been treated with carbonyl compounds to make alkenes.[2,3b,37] For example, deprotonation of (**36**) with ***Sodium Amide*** in benzene, filtration (to produce a salt-free ylide), and reaction with acetaldehyde gives, in 35% overall yield, (**39c**) (contaminated by 5% of (**39t**), an intermediate in the synthesis of cinerolone.[37a] The Horner-Wittig variant, employing the diphenylphosphine oxide (**37**), has the advantage that either *cis*- or *trans*-alkenes may be prepared (eq 10). Very high levels of isomer purity may be achieved since the intermediate *erythro*/*threo* hydroxy compounds are crystalline and easily separated by chromatography.[1a]

N-Bromosuccinimide[1]

[128-08-5] · $C_4H_4BrNO_2$ · *N*-Bromosuccinimide · (MW 177.99)

(radical bromination of allylic and benzylic positions; electrophilic bromination of ketones, aromatic and heterocyclic compounds; bromohydration, bromoetherification, and bromolactonization of alkenes)

Alternate Names: NBS; 1-bromo-2,5-pyrrolidinedione.

Physical Data: mp 173-175 °C (dec); *d* 2.098 g cm^{-3}.

Solubility: sol acetone, THF, DMF, DMSO, MeCN; slightly sol H_2O, AcOH; insol ether, hexane, CCl_4 (at 25 °C).

Form Supplied in: white powder or crystals having a faint odor of bromine when pure; widely available.

Purification: in many applications the use of unrecrystallized material has led to erratic results. Material stored for extended periods often contains significant amounts of molecular bromine and is easily purified by recrystallization from H_2O (AcOH has also been used). In an efficient fume hood (caution: bromine evolution), an impure sample of NBS (200 g) is dissolved as quickly as possible in 2.5 L of preheated water at 90-95 °C. As filtration is usually unnecessary, the solution is then chilled well in an ice bath to effect crystallization. After most of the aqueous portion has been decanted, the white crystals are collected by filtration through a bed of ice and washed well with water. The crystals are dried on the filter and then in vacuo. The purity of NBS may be determined by the standard iodide-thiosulfate titration method.

Handling, Storage, and Precautions: should be stored in a refrigerator and protected from moisture to avoid decomposition. One of the advantages of using NBS is that it is easier and safer to handle than bromine; however, the solid is an irritant and bromine may be released during some operations. Therefore, precautions should be taken to avoid inhalation of the powder and contact with skin. All operations with this reagent are best conducted in an efficient fume hood. In addition, since reactions involving NBS are generally quite exothermic, large-scale operations (>0.1 mol) should be approached with particular caution.

Introduction.

N-Bromosuccinimide is a convenient source of bromine for both radical substitution and electrophilic addition reactions. For radical substitution reactions, NBS has several advantages over the use of molecular ***Bromine***, while ***1,3-Dibromo-5,5-dimethylhydantoin*** is another reagent of use. ***N-Chlorosuccinimide*** and ***N-Iodosuccinimide*** generally do not facilitate analogous substitution reactions. For electrophilic substitutions, ***Bromine***, ***N-Bromoacetamide***, ***Bromonium Di-sym-collidine Perchlorate***, ***1,3-Dibromoisocyanuric Acid***, and ***2,4,4,6-Tetrabromo-2,5-cyclohexadienone*** also have applicability and the analogous halogenation reactions are generally possible using NCS, NIS, and I_2. Possible impurities generated during NBS brominations include conjugates of succinimide and, if basic conditions are employed, β-alanine (formed by the Hofmann reaction) and its derivatives may be isolated.

Allylic Bromination of Alkenes.[2]

Standard conditions for allylic bromination involve refluxing of a solution of the alkene and recrystallized NBS in anhydrous CCl_4 using ***Dibenzoyl Peroxide***, irradiation with visible light (ordinary 100 W light bulb or sunlamp[3]), or both to effect initiation. Both NBS and the co-product succinimide are insoluble in CCl_4 and succinimide collects at the surface of the reaction mixture as the reaction proceeds.[4] High levels of regioselectivity operate during the hydrogen-abstraction step of the chain mechanism, such that allylic methylene groups are attacked much more rapidly than allylic methyl groups.[5] However, a thermodynamic mixture of allylic bromides is generally isolated since both the allylic radical and the allylic bromide are subject to isomerization under the reaction conditions.[6] High levels of functional group selectivity are characteristic of this reaction, for example alkenic esters may be converted to allylic bromides prior to intramolecular cyclization (eq 1).[7] Brominations of α,β-unsaturated esters (eq 2)[8] and lactones (eq 3) are also successful.[9]

(1)

(2)

(3)

Benzylic Bromination of Aromatic Compounds.

Using the conditions described above, NBS also effects the bromination of benzylic positions.[10] Bromine is also regularly used for benzylic bromination (eq 4);[11] however, many functional groups are sensitive to the generation of HBr during the reaction, including carbonyl groups which suffer competing acid-catalyzed bromination. These considerations render NBS as the reagent of choice for bromination of polyfunctional aromatic compounds. Selectivity can be anticipated with polyfunctional molecules based on the predicted stabilities of the radical intermediates (eq 5).[12] Accordingly, the use of NBS allows the bromination of alkyl groups attached to sensitive heterocyclic compounds (eq 6).[13] Complications which may arise from this method include *gem*-dibromination (eq 7)[14] of methyl substituents as well as in situ elimination of the product benzylic bromide (see also ***1,3-Dibromo-5,5-dimethylhydantoin***).

(4)

(5)

(6)

(7)

The regioselective cleavage of benzylidene acetals using NBS has been used widely in the synthesis of natural products from carbohydrates (eq 8)[15] and other chiral materials (eq 9).[16] It is rather important that the reaction be conducted in anhydrous CCl_4 (passage through activated alumina is sufficient), since in the presence of water the hydroxy benzoate is formed.[17] Barium carbonate is generally added to maintain anhydrous and acid-free conditions, and the addition of $Cl_2CHCHCl_2$ often improves solubility of the substrate. Selectivity is usually very high in cases in which a primary bromide can be produced, but may also be obtained in systems such as shown in eq 10.[18] As alkoxy substituents serve

to further stabilize the adjacent radicals, these reactions proceed with high selectivity in the presence of other functional groups. Other applications in the carbohydrate field include the cleavage of benzyl ethers and benzyl glycosides (to the corresponding glycosyl bromides) and the bromination of pyranoses in the 5-position.[19]

(8)

(9)

(10)

Unsaturation and Aromatization Reactions.[20]

Unsaturated aldehydes, esters, and lactones can be accessed via strategies involving radical bromination and subsequent elimination. The allylic bromination of unsaturated lactones may be followed by elimination with base to obtain dienoic and trienoic lactones (eqs 11 and 12).[21] Conversion of an aldehyde to the enol acetate allows the radical bromination at the C_β position to proceed smoothly and, upon ester hydrolysis, the α,β-unsaturated aldehyde is obtained (eq 13).[22]

(11)

(12)

(13)

The direct bromination of β-alkoxylactones at the β position initially generates the α,β-unsaturated lactones (eq 14); however, the required radical abstraction is not so facile and further bromination of the α,β-unsaturated lactone proceeds competitively to afford the mono- and dibrominated products.[23] NBS is also used for the oxidative aromatization of polycyclic compounds, including steroids and anthraquinone precursors (eq 15).[24]

(14)

(15)

α-Bromination of Carbonyl Derivatives.

Although simple carbonyl derivatives are not attacked in the α-position under radical bromination conditions, substitution by electron-donating groups stabilizes the radical intermediates by the capto-dative effect[25] and thus facilitates the substitution reaction which has been applied to a number of useful synthetic strategies. Protected glycine derivatives are easily brominated by NBS and benzoyl peroxide in $CHCl_3$ or CCl_4 at reflux to afford the corresponding α-bromoglycine derivatives.[26] These compounds are stable precursors of *N*-acyliminoacetates, which may be alkylated by silyl enol ethers in the presence of Lewis acids, organometallic reagents, and other nucleophiles to afford novel α-amino acids (eq 16).[27] Diketopiperazines and related heterocycles are also substituted in good yields (eq 17).[28] Furthermore, in contrast to aldehydes which undergo abstraction of the aldehydic hydrogen (see below), *O*-trimethylsilylaldoximes are readily brominated at the α-position under radical bromination conditions and can be converted to substituted nitrile oxides (*O*-trimethylsilylketoximes react similarly).[29]

(16)

(17)

The use of NBS in the presence of catalytic ***Hydrogen Bromide*** has proven to be more convenient than Br_2 for the conversion of acid chlorides to α-bromo acid chlorides.[30] The reaction of the corresponding enolates, enol ethers, or enol acetates with NBS (and other halogenating agents) offers considerable advantages over direct acid-catalyzed

halogenation of ketones and esters.[31] Although both reagents may afford the α-brominated products in high yields, NBS is more compatible than is bromine with sensitive functional groups and has been used in the asymmetric synthesis of α-amino acids.[32] The bromination of cyanoacetic acid proceeds rapidly with NBS to afford dibromoacetonitrile[33] and, similarly, β-keto esters, β-diketones, and β-sulfonyl ketones may be reacted with NBS in the presence of base to afford the products of bromination and in situ deacylation (see ***N-Chlorosuccinimide***).[34] (5*E*)-Bromovinyluridine derivatives are readily prepared by bromodecarboxylation of the corresponding α,β-unsaturated acids with NBS (eq 18).[35]

(18)

Reaction with Vinylic and Alkynic Derivatives.

NBS is a suitable source of bromine for the conversion of vinylcopper and other organometallic derivatives to the corresponding vinyl bromides.[36] Vinylsilanes, prepared from the corresponding 1-trimethylsilylalkyne by reduction with ***Diisobutylaluminum Hydride***, can be isomerized from the (*Z*) to the (*E*) geometry by irradiation with NBS and ***Pyridine***, thus making (*E*)-vinylsilanes readily available stereoselectively in three steps from the corresponding alkyne (eq 19).[37] Allylsilane can be brominated by NBS under radical conditions, whereas more reactive allylsilanes are bromodesilated by NBS in CH_2Cl_2 at -78 °C.[38] 1-Bromoalkynes can be prepared under mild conditions by reaction with NBS in acetone in the presence of catalytic ***Silver(I) Nitrate***.[39]

(19)

Bromination of Aromatic Compounds.

Phenols, anilines, and other electron-rich aromatic compounds can be monobrominated using NBS in DMF with higher yields and higher levels of *para* selectivity than with Br_2.[40] *N*-Trimethylsilylanilines and aromatic ethers are also selectively brominated by NBS in $CHCl_3$ or CCl_4.[41] *N*-Substituted pyrroles are brominated with NBS in THF to afford 2-bromopyrroles (1 equiv) or 2,5-dibromopyrroles (2 equiv) with high selectivity, whereas bromination with Br_2 affords the thermodynamically more stable 3-bromopyrroles.[42] The use of NBS in DMF also achieves the controlled bromination of imidazole and nitroimidazole.[43] Thiophenes are also selectively brominated in the 2-position using NBS in acetic acid-chloroform.[44]

Bromohydration, Bromolactonization, and Other Additions to C=C.[45]

The preferred conditions for the bromohydration of alkenes involves the portionwise addition of solid or predissolved NBS (recrystallized) to a solution of the alkene in 50-75% aqueous DME, THF, or *t*-butanol at 0 °C. The formation of dibromide and α-bromo ketone byproducts can be minimized by using recrystallized NBS. High selectivity for Markovnikov addition and *anti* stereochemistry results from attack of the bromonium ion intermediate by water. Aqueous DMSO can also be used as the solvent; however, since DMSO is readily oxidized under the reaction conditions, significant amounts of the dibromide byproduct may be produced.[46,47] In the bromohydration of polyalkenic compounds, high selectivity is regularly achieved for attack of the most electron-rich double bond (eq 20).[48] With farnesol acetate, squalene, and other polyisoprenes, choice of the optimum proportion of water is used to effect the selective bromohydration at the terminal double bond (eq 21),[49] and the two-step sequence shown is often the method of choice for the preparation of the corresponding epoxides.[50]

(20)

(21)

Bromoetherification of alkenes can be achieved using NBS in the desired alcohol as the solvent. The reaction of 1,3-dichloropropene with NBS in methanol yields an α-bromo dimethyl acetal in the first step in a convenient synthesis of cyclopropenone.[51] Using propargyl alcohol the reaction depicted in eq 22 has been extended to an annulation method for the synthesis of α-methylene-γ-butyrolactones.[52] Intramolecular bromoetherification and bromoamination reactions are generally very facile (eq 23).[53] In natural products synthesis, bromoetherification has been used for the synthesis of cyclic ethers (by subsequent debromination, see ***Tri-n-butylstannane***) and for the protection of alkene appendages as cyclic bromoethers (regenerated by reaction with zinc).[54]

(22)

(23)

NBS is also an effective reagent for bromolactonization of unsaturated acids and acid derivatives with the same high stereo- and Markovnikov selectivity (see also ***Iodine***). Dienes, such as the cycloheptadiene derivative shown, may react exclusively via *syn*-1,4-addition (eq 24).[55] Alkynic acids are converted to the (*E*)-bromo enol lactones by NBS in a biphasic medium, whereas the combination of bromine and silver nitrate afford the (*Z*)-bromo enol lactones (eq 25).[56] α,β-Unsaturated acylprolines react with NBS in anhydrous DMF to afford the corresponding bromolactones having diastereomeric excesses up to 93%, which can be converted to chiral α-hydroxy acids by debromination followed by acidic hydrolysis (eq 26).[57] In contrast to alkenic amides, which generally react with NBS to afford bromolactones (via the cyclic iminoether derivatives), alkenic sulfonamides readily undergo cyclization on nitrogen when reacted with NBS to afford the bromosulfonamides in high yields.[58] *N*-Methoxyamides have also proven effective for bromolactamization, leading to diketopiperazines (eq 27)[59] (see also ***Bromonium Di-sym-collidine Perchlorate***).

(24)

(25)

(26)

(27)

Addition of NBS to an alkene in the presence of aqueous ***Sodium Azide*** affords fair yields of the corresponding β-bromoazides, which can be converted by ***Lithium Aluminum Hydride*** reduction to aziridines.[60] Intermolecular reactions of alkenes with NBS and weaker nucleophiles can be achieved if conducted under anhydrous conditions to avoid the facile bromohydration reaction. In this manner, bromofluorination of alkenes has been extensively studied using ***Pyridinium Poly(hydrogen fluoride)***, triethylammonium dihydrogentrifluoride or tetrabutylammonium hydrogendifluoride as the fluoride ion source.[61]

Oxidation and Bromination of Other Functional Groups.

Conjugate bases of other functional groups can be α-brominated with NBS. Nitronate anions of aliphatic nitro compounds react with NBS to afford the *gem*-bromonitro compounds in high yield.[62] The α-bromination of sulfoxides can be performed in the presence of pyridine and proceeds more satisfactorily using NBS in the presence of catalytic Br_2 than with either reagent alone.[63] NBS also reacts with sulfides to afford sulfoxides when methanol is used as a solvent, or to form α-bromo sulfides in anhydrous solvents.[64] NBS is a favored reagent for the deprotection of dithianes and dithioacetals to regenerate carbonyl groups (eq 28)[65] (see also ***N-Chlorosuccinimide*** and ***1,3-Diiodo-5,5-dimethylhydantoin***).

(28)

In polar media, NBS effectively oxidizes primary and secondary alcohols to carbonyl compounds via hypobromite or alkoxysuccinimide intermediates. Although this transformation is more commonly effected by the use of chromium reagents or activated ***Dimethyl Sulfoxide***, the most notable application of NBS and related reagents lies in its selectivity for the oxidation of axial vs. equatorial hydroxy groups in steroid systems (see ***N-Bromoacetamide***).[66] Often, a single secondary alcohol may be converted to the ketone in the presence of many other alcohol groups.

Under radical conditions, aldehydes are readily oxidized by NBS to acid bromides.[67] The oxidation of aldoximes to nitrile oxides using NBS and ***Triethylamine*** in DMF is superior to the use of aqueous hypochlorite.[68] Tosylhydrazones are cleaved by reaction with NBS in methanol,[69] and hydrazines and hydrazides are oxidized to azo compounds.[70]

N-Bromosuccinimide-Dimethylformamide

(NBS)

[128-08-5] · $C_4H_4BrNO_2$ · *N*-Bromosuccinimide-Dimethylformamide · (MW 177.99) (DMF)

[68-12-2] · C_3H_7NO · *N*-Bromosuccinimide-Dimethylformamide · (MW 73.09)

(mild selective bromination reagent[1] for reactive electron-rich aromatic hydrocarbons, heterocycles, phenols, and anilines)

Alternate Name: NBS-DMF.

Physical Data: see individual entries for ***N-Bromosuccinimide*** and ***N,N-Dimethylformamide***.

Handling, Storage, and Precautions: NBS (recrystallized from water and dried under vacuum) should be freshly dissolved in DMF (dried over molecular sieves) immediately before use. Note: use of old NBS and undried DMF may reduce yields in some cases.

Aromatic Hydrocarbons.

The main advantage of NBS-DMF is that monobromination usually occurs cleanly with 1 equiv of reagent at rt in high yields (80-98%). At least three alkyl groups must be present on a benzene ring, or two on a naphthalene ring; however, unsubstituted anthracene,[1] biphenylene,[2] and pyrene[1] are sufficiently reactive (eqs 1-3).

(1)

(2)

(3)

Phenols and Anisoles.

Selective monobromination of a phenol[1,3] is achieved, particularly if the DMF is dry (eqs 4 and 5). However, in some cases, dibromination also occurs (eq 6).[4] A difference in regiochemistry was observed[5] between the phenols (eq 7) and anisoles (eq 8). Anisoles, even with several methoxy groups, can also be selectively monobrominated;[6-9] an example is given in eq 9.

(4)

(5)

(6)

(7)

(8)

(9)

Anilines.

These are normally rather difficult to selectively brominate without oxidation; however, several examples[1,10-13] have now been reported with NBS-DMF (for example eq 10).

(10)

Five-Membered Ring Heterocycles.

Furans,[14] imidazoles,[15] and thiophenes[16] have now been brominated with NBS-DMF. In the thiophene shown in eq 11, 1.1 equiv of NBS gives the monobromide in 56% yield, while 2.4 equiv gives the dibromide in 70% yield.

(11)

Oxidation.

Hydroquinone is oxidized by NBS-DMF to *p*-benzoquinone.[1] It has been recently found[17] that dimethyldihydropyrene also forms the quinone when >2 equiv of NBS in *wet* DMF are used (eq 12).

Side Products.

In general the above reactions are fairly clean, and the main side product is usually the dibromide. The mildness, selectivity, ease of use, and ready availability of both NBS and DMF makes the use of this reagent a convenient option over alternatives such as the more reactive ***Thallium(III) Acetate-Bromine***,[18] or ***Copper(II) Bromide***,[19] or bromine itself (which is often not selective).

N-Bromosuccinimide-Dimethyl Sulfide[1]

(NBS)

[128-08-5] · $C_4H_4BrNO_2$ · *N*-Bromosuccinimide-Dimethyl Sulfide · (MW 177.99) (DMS)

[75-18-3] · C_2H_6S · *N*-Bromosuccinimide-Dimethyl Sulfide · (MW 62.13)

(converts allylic and benzylic alcohols to bromides under neutral conditions;[1] slowly converts primary alcohols to bromides;[1] oxidizes primary and secondary alcohols to aldehydes or ketones[2])

Alternate Name: NBS-DMS.

Physical Data: reagent is formed in situ. See entries for ***N-Bromosuccinimide*** and ***Dimethyl Sulfide***.

Solubility: sol methylene chloride, carbon tetrachloride, toluene.

Preparative Method: freshly prepared by dissolving *N*-bromosuccinimide (5.4 g, 30 mmol) in methylene chloride (100 mL) at 0 °C under argon and slowly adding excess dimethyl sulfide (2.23 g, 36 mmol). Stir the resultant yellow slurry for 1 h at 0 °C before use.[3] Oxidation and bromide replacement reactions are typically carried out between -25 and 0 °C in methylene chloride.

Handling, Storage, and Precautions: use protective clothing; use in a fume hood.

Conversion of Alcohols to Bromides.

The principal use for NBS-DMS is to convert allylic and benzylic alcohols to allylic and benzylic bromides (see ***N-Chlorosuccinimide-Dimethyl Sulfide*** (NCS-DMS)). Eqs 1-3[1,3,4] illustrate typical replacements of the hydroxy group of a primary allylic alcohol without rearrangement. This reaction is a much milder way of introducing bromide than the standard ***Phosphorus(III) Bromide*** reaction, which is incompatible with acid-sensitive functionalities because it generates HBr. In some cases, secondary allylic alcohols (eqs 4 and 5) tend to undergo an S_N2' displacement of the

allylic alcohol and rearrange to the primary allylic bromides. In these examples[5,6] bearing a sulfoxide or sulfone, the rearrangements proceed with high (*E*) selectivity.

(1)

(2)

(3)

(4)

(5)

NBS-DMS is also a mild and practical reagent for synthesizing benzylic bromides from benzylic alcohols. As in the case of allylic alcohols, it is superior to PBr_3 when sensitive functionality is involved because no HBr is produced. Reactions of NBS-DMS proceed rapidly in high yield and high purity (eq 6).[7]

(6)

NBS-DMS is also capable of converting alkyl alcohols to bromides in reasonable yields. Eq 7 shows an example of this type of conversion that occurs at 20 °C in 36 h[1] (see also ***Carbon Tetrabromide*** and ***Triphenylphosphine Dibromide***).

(7)

Oxidation of Primary and Secondary Alcohols.

Oxidations using NBS-DMS are part of a larger family of sulfonium ion-type oxidations (see also ***Dimethyl Sulfoxide-Oxalyl Chloride*** and ***Dimethyl Sulfide-Chlorine***), and are carried out in a similar manner to the NCS-DMS oxidation.[8] The reactions take place in 2 h at temperatures between 0 °C and -78 °C. The sulfoxonium ion intermediate is decomposed with ***Triethylamine*** to generate the carbonyl compound (eqs 8 and 9), as with NCS-DMS. This reagent is not useful for oxidizing allylic or benzylic alcohols because of the bromide replacement reaction described above.[2]

N-Bromosuccinimide-Hydrogen Fluoride

(NBS)

[128-08-5] · $C_4H_4BrNO_2$ · *N*-Bromosuccinimide-Hydrogen Fluoride · (MW 177.99) (HF)

[7664-39-3] · FH · *N*-Bromosuccinimide-Hydrogen Fluoride · (MW 20.01)

(reagent for the bromofluorination of alkenes and fluorination of dithioesters)

Alternate Name: NBS-HF.

Physical Data: NBS: mp 173-175 °C; *d* 2.098 g cm^{-3}. HF: mp -83.1 °C; bp 19.54 °C; *d* 0.991 g cm^{-3}.

Solubility: NBS: sol water, acetone, alcohol, acetic acid, ethyl acetate. HF: sol water, alcohol, benzene, pyridine; slightly sol ether.

Form Supplied in: NBS: off-white to yellow crystalline material; widely available. HF: widely available as aqueous solutions, or anhydrous solutions in pyridine (70% HF, 30% pyridine).

Handling, Storage, and Precautions: NBS: eye protection and rubber gloves should be worn when handling this material. This reagent should only be handled in a fume hood. Absorbed through the skin; high concentrations are destructive to mucous membranes and the tissues of upper respiratory systems. HF: eye protection and rubber gloves should be worn when handling this material. This reagent should only be handled in a fume hood. Corrosive, highly irritating, and poisonous. Should not be stored in glass containers; will etch glass. Causes severe burns, which may not be immediately apparent. Extremely destructive to mucous membranes and tissues of the upper respiratory system. Pyridine solutions are moisture sensitive.

Fluorination and Bromofluorination of Alkenes.

N-Bromosuccinimide used in conjunction with poly(hydrogen fluoride)/tertiary amine reagents bromofluorinates alkenes[1] and polymeric alkenes (eq 1).[2] In ether, using HF/pyridine, the products exhibit typical Markovnikov

regioselectivity, with the bromide adding to the least substituted end of the alkene.[3] Bromofluorination also occurs with NBS and liquid ***Hydrogen Fluoride***, but these conditions are more harsh and are more difficult to carry out due to the need for low temperature and high pressure.[4] The reaction is stereoselective, giving *anti* addition products (eq 2).[3,5a] This reaction can be done with HF supported on crosslinked poly(styrene-*co*-4-vinylpyridine) or poly-4-vinylpyridinium, and exhibits the same regio- and stereoselectivity as that with HF supported on pyridine.[5] If ***Silver(I) Fluoride*** is added to the reaction after completion, *vic*-difluorides can be formed by exchange of the bromofluoroalkane to the difluoride.[1] If any water is present, the vicinal halohydrin can also be formed.[6]

(1)

(2)

In the reaction of NBS-HF/pyridine, several factors influence the stereoselectivity.[3,7] Normal *anti* selectivity results from the NBS-HF complex reacting with one face of the alkene, thus preventing fluoride ion from adding in a *syn* fashion. If the concentration of HF is increased, the complexing effects are lessened, and fluoride can add to the carbocation from either face.[7] The reaction of 1-phenyl-4-*t*-butylcyclohexene demonstrates the selectivity, reacting to give two *anti* products, resulting from complexation on either face of the alkene (eq 3).[3c] In addition to concentration, the diastereoselectivity for bromofluorination of alkenes is dependent on solvent effects[7] and alkene geometry.[4,8]

(3)

For large cyclic alkenic compounds containing an oxirane group, bromofluorination fails to give the expected α-bromo-β-fluoro compound, due to competing complexation with the oxirane ring. Instead, a mixture of bicyclic ethers substituted with bromine and fluorine is produced (eq 4).[9]

NBS-HF/pyridine or poly-4-vinylpyridinium reacts with diazoalkanes and diazo ketones to give the α,α-bromofluoroalkanes and ketones (eq 5).[10] Hydrazones of aldehydes and ketones also react under these conditions, giving the *gem*-difluoro compounds, with the fluoride substituents replacing the hydrazone, in effect allowing the transformation of carbonyls to *gem*-difluoro compounds (eq 6).[11]

NBS-HF/pyridine has also been used for the fluorination of dithioesters of aromatic acids, which react to give trifluoromethyl substituted aromatic compounds (eq 7).[12] This reaction can also be carried out on sulfides where one of the substituents is $ArCF_2$, to give trifluoromethylaryl compounds.

N-Bromosuccinimide-Sodium Azide

(NBS)

[128-08-5] · $C_4H_4BrNO_2$ · *N*-Bromosuccinimide-Sodium Azide · (MW 177.99) (NaN_3)

[26628-22-8] · N_3Na · *N*-Bromosuccinimide-Sodium Azide · (MW 65.01)

(source of BrN_3 in conversion of alkenes to β-bromoalkyl azides and, upon reduction, to aziridines)

Physical Data: for physical data see ***N-Bromosuccinimide*** and ***Sodium Azide***.

Introduction.

Sodium azide-*N*-bromosuccinimide can transfer an azido group and a Br atom to C=C double bonds. Reduction of the resulting β-bromoalkyl azides with ***Lithium Aluminum Hydride*** produces aziridines. This combination has been used as an in situ source of bromine azide BrN_3 and is a good substitute for the classical method of Hassner,[1,2] which requires the synthesis of potentially explosive[3] BrN_3 in acetonitrile or pentane.

Scope and Limitations.

The reaction is usually carried out at temperatures around -5 °C, by adding NBS in small portions to a mixture (4/1 or 3/1) of organic solvent (DME, THF, or DMF) and water in which is dissolved an excess of NaN_3 and the suspended alkene. It has been successfully carried out up to a molar scale.[4] It is still unclear if BrN_3 is effectively formed or if the azido anion reacts with the intermediate bromonium ion resulting from the interaction of the alkene with NBS. 1,1-Disubstituted,[5] 1,2-disubstituted,[6] trisubstituted,[6,7] and tetrasubstituted[4,8] alkenes (eqs 1-5) as well as indenes (eq 6)[9,10] and allylic alcohols (eq 7)[10] are transformed in reasonably good yields (40-60%) to the corresponding β-bromoalkyl azides.

The reaction is difficult with less reactive C=C double bonds. For example, monosubstituted alkenes give poor yields of 1-bromoalkyl azides and bromohydrins are formed.[6] This results from the reaction with HOBr, formed along with N_2 by the decomposition of BrN_3 in water. The same process is also observed with 7-methoxyindene (eq 6).[9] Phenanthrene does not react[11] and is recovered in high yield under these conditions. Again, decomposition of BrN_3 by water is responsible for this failure, since preformed bromine azide in CH_2Cl_2 adds to the 9,10-C=C double bond (eq 8).[11] In some cases, e.g. 9,9a-dihydro-3*H*-pyrrolo[1,2-*a*]indoles (eq 9)[12] and 1,4,5,8,9,10-hexahydro-4a,9a-methanoanthracene and related derivatives (eq 5),[4,8] aromatization totally or partially competes with the formation of the β-bromoalkyl azide. In some other cases, loss of HBr occurs during the purification of the crude mixture (eq 8)[11] or even during the reaction (eq 10).[13] In such cases the vinyl azides first generated are able to react further with BrN_3 to produce β-bromo-α,α-bis(alkylazido)alkanes (eq 10).[13]

Regioselectivity (rs).

The addition is highly regiospecific with terminal[5,6] and trisubstituted[6] alkenes and produces the β-bromoalkyl azide in which the bromine atom is attached to the least substituted carbon atom (rs >95%; eqs 1-5). This is remarkable, since preformed BrN_3 reacts in a nonregioselective manner with terminal alkenes in acetonitrile and leads to an 8/2 mixture of β-bromoalkyl azides, in which the product bearing the bromine atom at the least substituted carbon prevails (Markovnikov rules).[6] The higher electronegativity of Br compared to that of I and probably to that of N_3 explains why,

under similar conditions, BrN_3 possesses a much higher propensity than its iodo analog to react in a radical process.[2] The high polarity of the medium in the NaN_3-NBS reaction favors the ionic process.[6] This reagent adds regioselectively to indenes (eq 6)[9,10] and nonregioselectively to dialkyl substituted C=C double bonds bearing two different alkyl substituents (eqs 3 and 4)[6] and to 2-cyclopenten-1-ol (eq 7).[14]

Stereoselectivity (ss).

The addition of the Br atom and N_3 moiety is *anti* stereospecific (ss >98%) with tri- and tetrasubstituted alkenes (eqs 3 and 4) and, therefore, the whole process NaN_3-NBS, $LiAlH_4$ allows the highly stereoselective synthesis of aziridines which possess the same stereochemistry as their parent alkenes. This occurs[6] with a much higher stereoselectivity than observed in the conventional BrN_3, $LiAlH_4$ method,[2] due to the absence of radical reactions, and therefore more closely resembles the reaction IN_3, $LiAlH_4$.[2]

Asymmetric induction is very poor with 2-cyclopenten-1-ol (eq 7)[14] but very high with 1,4,5,8,9,10-hexahydro-4a,9a-methanoanthracene (eq 5).[8] In the latter case the ionic addition to the tetrasubstituted double bond is sterically controlled by the cyclopropane ring and, after reductive cyclization, affords a compound in which both three-membered rings are on the same face of the tricyclic derivative.[14]

Chemoselectivity.

NaN_3-NBS proved to be more reactive toward tetra- than disubstituted double bonds (eq 5).[4,8] It also reacts chemoselectively on the terminal nonfunctionalized C=C double bond of geranyl and farnesyl acetates as well as of squalene,[7] which possess two, three, and six identically trisubstituted C=C double bonds, respectively (eqs 11 and 12). Presumably, the polyene is coiled in the highly polar medium used (DME-H_2O) and presents its terminal double bond to the attack of the extensively solvated bromonium ion.[7] A similar explanation was previously given to rationalize the high chemoselective addition of BrOH towards the same polyalkenes.[15] Interestingly, the conventional BrN_3 method[7] as applied to geranyl and farnesyl acetates not only produces the corresponding β-bromoalkyl azides in very low yields but also shows very little terminal preference. Poor chemoselectivity is also observed if squalene is reacted with IN_3 under conventional conditions.[16]

The NaN_3-NBS, $LiAlH_4$ method proved, for aziridine synthesis from alkenes, to be superior to the alternative method of epoxide ring opening by azide ion followed by reaction of the corresponding tosylate with $LiAlH_4$.[17]

trans-Bromotetracarbonyl(ethylidyne)tungsten

[50726-31-3] · $C_6H_3BrO_4W$ · *trans*-Bromotetracarbonyl(ethylidyne)tungsten · (MW 402.84)

(couples with alkynes[1])

Alternate Name: trans-bromotetracarbonyl(methylmethylidyne)tungsten.

Physical Data: solid at 25 °C; mp dec; yellow crystals.

Solubility: sol pentane, THF, Et_2O.

Form Supplied in: not commercially available.

Preparative Methods: prepared from the reaction of pentacarbonyl(1-methoxyethylidene)tungsten and ***Boron Tribromide***[2] or tetramethylammonium acetyl(pentacarbonyl)tungstate and ***Oxalyl Bromide***.[3]

Purification: after synthesis, *trans*-bromotetracarbonyl(ethylidyne)tungsten is purified by chromatography on silica gel at -30 °C using 1:1 pentane-dichloromethane as an eluent, followed by recrystallization from pentane at -78 °C. Purification by extensive washing with pentane at low temperature is apparently sufficient for use in alkyne coupling reactions.[1]

Handling, Storage, and Precautions: unstable above 35 °C; decomposes in air.

Reactions with Alkenes and Alkynes.

Coupling of diynes and *trans*-bromotetracarbonyl(ethylidyne)tungsten leads to ring-fused phenol derivatives in moderate yield (eq 1).[1] The reaction is most efficient for the construction of indanols, and less so for preparation of tetrahydronaphthols and benzocyclobutanols. A similar reaction pathway is observed for the analogous carbene complex;[4] involvement of carbene complexes in these processes has not been ruled out. Cyclization of enynes is less

efficient, leading to pentadienyltungsten complexes having the sickle geometry (eq 2).[5] Enynes having methylene group tethers did not display the reactivity depicted in eq 2. Additional reactions of *trans*-bromotetracarbonyl(ethylidyne)tungsten with unsaturated hydrocarbons include alkyne polymerization and ring opening metathesis polymerization (ROMP) of cycloalkenes.[6]

(1)

(2)

Ligand Exchange.

A limited number of synthetic transformations have been reported employing *trans*-bromotetracarbonyl(ethylidyne)tungsten; however, substitution of the CO ligands for phosphine ligands provides a more stable carbyne complex (eq 3). These ligand-modified complexes have been the focus of considerable investigation.[7]

1-Bromo-1,2,2,2-tetrafluoroethyl(phenyl)mercury[1]

[42201-75-2] · $C_8H_5BrF_4Hg$ · 1-Bromo-1,2,2,2-tetrafluoroethyl(phenyl)mercury · (MW 457.62)

(excellent source of tetrafluoroethylidene, **:**$CFCF_3$; cyclopropanates alkenes; inserts into Si-H bonds; reacts with C=S bonds)

Physical Data: mp 121-122 °C.

Solubility: sol THF, benzene, dichloromethane.

Analysis of Reagent Purity: spectroscopic data: IR, NMR (^{1}H and ^{19}F).[2]

Preparative Method: prepared in 65% yield by reaction of PhHgCl with CF_3CHFBr in dry THF in the presence of MeONa-MeOH.[2,3]

Purification: recrystallization from hexane (colorless prisms).

Handling, Storage, and Precautions: flame-dried glassware and an atmosphere of dry nitrogen are used for the reactions. Organomercury(II) compounds should be carefully handled and skin contact and inhalation should be particularly avoided. All reactions must be conducted in a well-ventilated hood.

Cyclopropanation of Alkenes.

The reagent was introduced[3] as an attractive alternative source of divalent **:**$CFCF_3$ to circumvent problems of volatility and toxicity[4] associated with $Hg(CFBrCF_3)_2$[5] and $Hg(CFClCF_3)_2$.[6] In this context, $PhHgCFBrCF_3$ has proven to be a valuable and synthetically useful reagent for transferring tetrafluoroethylidene to alkenes. Its reaction with several representative alkenes has been studied; for instance, cyclopropanation of cyclooctene occurs with almost quantitative yield (isomer ratio based on ^{19}F NMR data) (eq 1).

As anticipated, thermal treatment of $PhHgCFBrCF_3$ transfers the **:**$CFCF_3$ species and eliminates PhHgBr with no evidence of competitive PhHgF formation being observed.[7,8] Another interesting feature is that the yield of cyclopropane formation and mercury elimination correlates well and, thus, side reactions do not take place.[9] Reactions were carried out in sealed tubes and similar results are obtained for acyclic mono- and disubstituted alkenes. Allylsilane is also a good partner for $PhHgCFBrCF_3$, affording the corresponding cyclopropane in 93% yield; however, in the case of vinylsilane the yield is quite low (16%) and does not correlate well with the amount of PhHgBr recovered from the reaction mixture (60%). Finally, $PhHgCFBrCF_3$ is superior to $PhHgCFClCF_3$ as a source of **:**$CFCF_3$; the latter requires longer reaction times (typically 5 days at 140 °C).[10]

Insertion into Si-H Bond.

Thermal reaction of Et_3SiH with $PhHgCFBrCF_3$ furnishes $Et_3SiCHFCF_3$ in 53% yield after 24 h at 155 °C in a sealed tube,[2] the result of insertion of divalent carbon into the Si-H bond.[1]

Reaction with Thiobenzophenone.

The C=S bond of thiobenzophenone reacts with the organomercury reagent at 155 °C for 40 h in a sealed tube, affording $Ph_2C{=}CFCF_3$ and sulfur (eq 2).[2] The expected thiirane ring is not isolated, although it is presumably formed; instead it probably undergoes, under the reaction conditions, sulfur extrusion to the observed alkene, as depicted (eq 2).

1-Bromo-3-tetrahydropyranyloxy-1-propyne

Br-C&tbond;C-CH_2OR

(**1**; R = -$CH(CH_2)_4O$)

[14420-47-4] · $C_8H_{11}BrO_2$ · 1-Bromo-3-tetrahydropyranyloxy-1-propyne · (MW 219.08) (**2**; R = $SiMe_3$)

[56958-33-9] · $C_6H_{11}BrOSi$ · 1-Bromo-3-trimethylsilyloxy-1-propyne · (MW 207.14)

(alkoxymethylalkynylating agent; propargyl alcohol cation equivalent)

Physical Data: (**1**) bp 69 °C/0.8 mmHg; (**2**) bp 34-36 °C/2 mmHg.

Solubility: sol any common organic solvent.

Preparative Methods: by protection of 3-bromo-2-propynol: (**1**) with ***3,4-Dihydro-2H-pyran*** and a catalytic amount of 10 N HCl,[1] scale 0.5 mol, yield 60%; (**2**) by treatment with ***Sodium Hydride*** and ***Chlorotrimethylsilane***,[2] scale 0.5 mol, yield 70%. 3-Bromo-2-propynol is prepared from ***Propargyl Alcohol*** and ***Bromine*** in basic medium,[3] scale 0.5 mol, in quantitative yield. Conversely, 1-tetrahydropyranyloxy-2-propyne can be brominated with ***N-Bromosuccinimide*** and ***Silver(I) Nitrate*** in acetone[4] (scale 3 mmol, yield 59%).

Handling, Storage, and Precautions: use in a fume hood; store in the absence of moisture, preferably over K_2CO_3, at 0 °C in the dark.

Electrophilic Propargylation with (1).

A limited number of nucleophiles have been reacted with this reagent to date; an example is sodium diethyl phosphite, which leads to phosphonates (eq 1).

(1)

Vinylcopper reagents lead to enynols (eq 2) provided that 1.2-2 equiv of TMEDA are added[4] to prevent the formation of diene and diyne.

(2)

Vinyl zincacyanocuprates derived from tin also react (eqs 3 and 4).[5] The starting copper reagents are made in situ via stannyl cupration. A Cadiot-Chodkiewicz coupling, with a terminal alkyne, leads to the corresponding diynol.[6]

(3)

(4)

Electrophilic Propargylation with (2).

Vinylcopper reagents react similarly (eq 5) and are used to prepare (*Z*,*E*)-dienols of high purity (after LAH reduction). The reaction described in eq 2 with this reagent affords the same alcohol (82% yield). Also, the use of (**2**) in eq 4 leads to the corresponding silylated enynol in 65% yield.

(5)

Higher Homolog.

The compound Br-C&tbond;C-$(CH_2)_2OSiMe_3$ is prepared analogously from the bromo alcohol.[4] Vinyl cuprates derived from acetylene react better if they are first converted to the vinylcopper species with CuI (eq 6).[7]

Bromo(*o*-tolyl)bis(triethylphosphine)nickel(II)

[26521-33-5] · $C_{19}H_{37}BrNiP_2$ · Bromo(*o*-tolyl)bis(triethylphosphine)nickel(II) · (MW 466.06)

(Ullmann[1] and cross-coupling[2] reactions; halogen exchange of aryl and vinyl halides;[1,3] oligomerization reactions[4])

Physical Data: mp 102-103 °C.

Solubility: sol benzene, diethyl ether, THF, DMF, ethanol, DMSO, acetone, cyclohexane, cumene, nitromethane, dichloromethane.

Form Supplied in: brown, air stable, crystalline solid.

Preparative Method: prepared in 67% yield by treating a benzene solution of dibromobis(triethylphosphine)nickel(II) with an ethereal solution of *o*-tolylmagnesium bromide.[2,5]

Purification: recrystallization from ethanol.

Handling, Storage, and Precautions: although no special precautions are reported, this complex is likely to be toxic, as with many nickel reagents.[6]

Biaryl Syntheses and Cross-Coupling Reactions.

As part of a study examining the syntheses of biaryls under nickel catalysis,[1] the title reagent (**1**) and other nickel(II) complexes were found to react with aryl halides to give biaryls via a radical chain process and were thus proposed as intermediates in nickel(0)-catalyzed Ullmann coupling reactions. The reactions of (**1**) are most efficiently conducted in a sealed, evacuated tube at 70 °C with a nonpolar organic solvent such as benzene or toluene. In a similar study (**1**) was found, upon treatment with ***Methyllithium*** and heating in hexanes, di-*n*-butyl ether, or 1,2-dimethoxyethane, to provide *o*-xylene, suggesting that nickel(II) species are intermediates in the cross coupling of Grignard reagents and aryl halides with nickel(0) reagents.[2]

Halogen Exchange with Aryl and Vinylic Halides.

A number of nickel complexes have been found to catalyze the substitution of aryl halides with nucleophiles such as amines, phosphines, and cyanide.[7] Reagent (**1**) is well suited for the exchange of aryl and vinyl halides with more electronegative halides (eqs 1-4). These reactions are most frequently carried out in refluxing benzene or THF in the presence of an appropriate ammonium halide salt.[1,3] In cases where *cis*- or *trans*-vinyl halides are used (eqs 3 and 4), no detectable isomerization is observed.

(1)

(2)

(3)

(4)

Oligomerization Reactions.

The cyclodimerization of butadiene to provide 2-methylenevinylcyclopentane (eq 5) is carried out quite efficiently with (**1**) and other nickel catalysts.[4] This process is best carried out at an elevated temperature in benzene in the presence of (**1**) and methanol. The use of protic reagents other than methanol leads to a diminished yield of 2-methylenevinylcyclopentane and the formation of other cyclodimerized products.

5-Bromo-2,2,5-trimethyl-1,3-dioxane-4,6-dione

[34817-42-0] · $C_7H_9BrO_4$ · 5-Bromo-2,2,5-trimethyl-1,3-dioxane-4,6-dione · (MW 237.05)

(brominating agent;[1-4] transfer alkylating agent;[1] used to synthesize 1,2-diketones[5])

Physical Data: colorless crystalline solid, mp 86 °C.

Solubility: commonly used in THF solution.

Preparative Methods: by treating a chloroform solution of 2,2,5-trimethyl-1,3-dioxane-4,6-dione[6] with ***Bromine*** and anhydrous ***Sodium Fluoride***.

Purification: recrystallization from 2-propanol.

Handling, Storage, and Precautions: good laboratory practice should be sufficient when handling this reagent. The reagent is a relatively stable brominating agent and no special measures are required for its storage.

Bromination.

Addition of the anion of 3,3-dimethylthietane 1,1-dioxide (**1**) to a THF solution of the title reagent (**2**) afforded the bromo sulfone in good yield (eq 1).[2] Alternative reagents such as ***Bromine***, ***N-Bromosuccinimide***, and ***1-Chlorobenzotriazole*** did not effect the required transformation. Similarly, deprotonation of keto ester (**3**) and treatment with (**2**) afforded α-bromo ketone (**4**) stereoselectively. The addition of norbornene improved the efficiency of the reaction (eq 2).[3] Treatment of azlactone (**5**) with (**2**) in the presence of ***Potassium Carbonate*** afforded the corresponding unsaturated azlactone via bromination and concomitant dehydrobromination. Reagents such as bromine, ***Sulfuryl Chloride***, NBS, ***2-Pyrrolidone Hydrotribromide***, ***1,3-Dibromo-5,5-dimethylhydantoin***, and 1-chlorobenzotriazole were, however, more effective for this transformation (eq 3).[4]

(1)

(2)

(3)

Transfer Alkylation.

Deprotonation of methyl 3-(methoxycarbonyl)-3,5-heptadienoate (**6**) with LDA in THF solution and treatment with (**2**)

resulted in α-bromination and precipitation of the corresponding lithium salt of (**2**). Subsequent introduction of HMPA effected dissolution of this salt and resulted in S_N2'' alkylation. The product of this reaction can be smoothly hydrolyzed and subsequently decarboxylated (eq 4).[1,2]

Diketone Synthesis.

Treatment of (**2**) with potassium acetate and subsequent pyrolysis has afforded butane-2,3-dione (eq 5).[5]

Bromotrimethylsilane[1]

Me_3SiBr

[2857-97-8] · C_3H_9BrSi · Bromotrimethylsilane · (MW 153.09)

(mild and selective reagent for cleavage of lactones, epoxides, acetals, phosphonate esters and certain ethers; effective reagent for formation of silyl enol ethers; can function as brominating agent)

Alternate Name: TMS-Br.

Physical Data: bp 79 °C; *d* 1.188 g cm^{-3}; *n*20D 1.4240; fp 32 °C.

Solubility: sol CCl_4, $CHCl_3$, CH_2Cl_2, $ClCH_2CH_2Cl$, MeCN, toluene, hexanes; reactive with THF (ethers), alcohols, and somewhat reactive with EtOAc (esters).

Form Supplied in: colorless liquid, packaged in ampules.

Analysis of Reagent Purity: well characterized by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy.

Preparative Methods: although many methods are reported,[1] only a few are provided here: ***Chlorotrimethylsilane*** undergoes halogen exchange with either ***Magnesium Bromide***[2] in Et_2O or ***Sodium Bromide***[3] in MeCN, which allows in situ reagent formation (eq 1); alternatively, ***Hexamethyldisilane*** reacts with ***Bromine*** in benzene solution or neat, to afford only TMS-Br with no byproducts (eq 2).[4] TMS-Br may also be generated by reaction of hexamethyldisiloxane and ***Aluminum Bromide*** (eq 3).[5] However, it should be noted that the reactivity of in situ generated reagent appears to depend upon the method of preparation.

$$Me_3SiCl \xrightarrow[\text{or NaBr, MeCN}]{MgBr_2,\ Et_2O} Me_3SiBr + LiBr \text{ or } NaBr \qquad (1)$$

$$Me_3Si\text{-}SiMe_3 + Br_2 \longrightarrow Me_3SiBr \qquad (2)$$

$$Me_3SiOSiMe_3 + AlBr_3 \longrightarrow Me_3SiBr \qquad (3)$$

Purification: by distillation.

Handling, Storage, and Precautions: extremely sensitive to light, air, and moisture; fumes in air due to hydrolysis (HBr), and becomes discolored upon prolonged storage (free Br_2).

Ester Cleavage.[6]

Although esters are readily cleaved with ***Iodotrimethylsilane***, reaction of esters with TMS-Br under similar conditions gives somewhat lower yields of silyl esters or acids upon hydrolysis (eq 4). Lactones, however, react with TMS-Br at 100 °C to afford o-bromocarboxylic acids after hydrolysis of the silyl ester (eq 5).[7]

(4)

(5)

Ether Cleavage.

THF[8] reacts with TMS-Br, thereby rendering ethereal solvents incompatible with the reagent. Smooth removal of the methoxymethyl (MOM) protecting group can be accomplished with TMS-Br at 0 °C (eq 6).[9] Whereas acetals, THP and silyl ethers are slowly cleaved with TMS-Br, the reagent generated in situ effects selective MOM ether cleavage in the presence of an acetonide.[10] The majority of published ether cleavages have been accomplished with TMS-I, although limited data show that the more vigorous conditions necessary for ethyl ether cleavage also result in bromide formation.[8]

(6)

Cleavage of Epoxides.

Epoxide opening with TMS-Br occurs to provide the primary alkyl bromide at -60 °C (eq 7).[8]

(7)

Cleavage of Acetals.

Acetals can be cleaved by analogy to ethers, providing the parent carbonyl species.[3c,6b] Glycosyl bromides have been prepared from the corresponding acetate by reaction with TMS-Br in $CHCl_3$ at rt (eq 8).[11] In conjunction with $CoBr_2$ and ***Tetra-n-butylammonium Bromide***, TMS-Br converts the glucopyranose to the α-D-glucoside in the presence of an alcohol (eq 9).[12]

(8)

(9)

An interesting solvent effect was noted in the cleavage of the acetonide moiety in some nucleoside derivatives (eq 10).[13] In CH_2Cl_2, TMS-Br converted the acetonide to the anhydrouridine within 1.5 h, but in MeCN the bromide is formed after 10 min.

Formation of Enol Ethers.[14]

Bromotrimethylsilane with ***Triethylamine*** in DMF is an effective medium for production of thermodynamic (*Z*) silyl enol ethers (eq 11).

Formation of Alkyl Bromides.[6b]

Alcohols react with excess TMS-Br (1.5-4 equiv) at 25-50 °C to form the alkyl bromide and hexamethyldisiloxane (eq 12). Benzylic and tertiary alcohols react faster than secondary alcohols.

Reaction with Acid Chlorides.[15]

Acid bromides may be prepared from acid chlorides by reaction with TMS-Br (eq 13).

Cleavage of Phosphonate Esters.[16]

Compared to the reactivity of TMS-I with phosphonate and phosphate esters, TMS-Br is more selective and will cleave phosphonate esters even in the presence of carboxylic esters and carbamates. Benzyl ester protecting groups on aryl phosphates are selectively removed with TMS-Br.[17] The reaction of phosphonate esters with TMS-Br proceeds through a mechanism similar to ester cleavage, providing a silyl ester which is subsequently hydrolyzed with MeOH or H_2O (eq 14).

(14)

Reaction with Amines.

Amines react with TMS-Br to form isolable adducts, which react readily with ketones to form enamines under mild conditions (eq 15).[18]

(15)

Conjugate Addition.

α,β-Unsaturated ketones undergo conjugate addition with TMS-Br. Treatment of the intermediate with ***p-Toluenesulfonic Acid*** and ethylene glycol provides β-bromoethyldioxolanes (eq 16).[19]

(16)

Bromolactonization.

o-Unsaturated carboxylic acids react with TMS-Br in the presence of a tertiary amine in DMSO yielding bromolactones, resulting from *cis* addition across the double bond (eq 17).[20]

(17)

Ylide Formation.

Methylenetriphenylphosphorane reacts with TMS-Br to provide the corresponding ylide (eq 18).[21]

(*Z*)-2-Bromo-1-(trimethylsilyloxy)ethylene

[64556-66-7] · $C_5H_{11}BrOSi$ · (*Z*)-2-Bromo-1-(trimethylsilyloxy)ethylene · (MW 195.13)

(reagent used as a precursor of (*Z*)-(trimethylsilyloxy)vinyllithium, α-bromo aldehydes, and α-disilylketene)

Physical Data: bp 48-49 °C/15 mmHg.[1]

Solubility: sol Et_2O, THF and most organic solvents; fairly sol cold water.

Analysis of Reagent Purity: ^1H NMR (C_6D_6) (*Z*) isomer: 6.37 (d; *J* = 3.8); 5.02 (d; *J* = 3.8); 0.05 (s). (*E*) isomer: 6.61 (d; *J* = 11.4); 5.52 (d; *J* = 11.4); -0.06 (s).

Preparative Methods: addition of ***Bromine*** to trimethylsilyl vinyl ether in CH_2Cl_2 or Et_2O at -60 °C, followed by dehydrobromination with ***Triethylamine*** (50%)[1] or by reaction of trimethylsilyl 2,2-dibromoethyl ether with two equiv of ***n-Butyllithium*** in Et_2O from -70 °C to rt (86%)[2] (*Z*/*E*:95/5).[3]

Purification: vacuum distillation.

Handling, Storage, and Precautions: must be stored at -20 °C in the absence of moisture (flushing with dry Ar or N_2). It turns pale yellow on storage. It is instantaneously hydrolyzed by dilute acidic aqueous solutions.

(*Z*)-2-Bromo-1-(trimethylsilyloxy)ethylene (**1**) is used essentially as a precursor of ***(Z)-2-(Trimethylsilyloxy)vinyllithium*** (eq 1).[3]

(1)

(Z)-2-Bromo-1-(trimethylsilyloxy)ethylene

Reagent (**1**) has been condensed with allylic alcohols in the presence of a catalytic quantity of a Lewis acid (such as ***Boron Trifluoride Etherate***) to achieve a new synthesis of α,β-unsaturated aldehydes (eq 2).[4] This reaction is analogous to the widely used Müller-Cunradi-Pieroh reaction[5] except that the oxidation state of the cationic species is one unit lower and that of the nucleophilic species is one unit higher. Thus condensation with β-ionol leads to an α-bromo aldehyde which was transformed into β-ionylideneacetaldehyde by dehydrobromination, using ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.[4]

(2)

The reaction of (**1**) with ***Lithium Diisopropylamide*** followed by treatment with ***Chlorodimethylsilane*** was reported to give the disilylketene (**2**) in a modest yield,[6] instead of the expected alkynic ether (**3**) (eq 3).[2] The hydridosilylketene (**2**) is transformed by flash vacuum thermolysis (FVT) to trimethylsilylacetylene by expulsion of dimethylsilanone.[6]

(Z)-2-Bromo-1-(trimethylsilyloxy)ethylene

(3)

It is noteworthy that compounds homologous with (**1**) couple with Grignard reagents in the presence of nickel-phosphine complexes to produce alkylated and arylated enol ethers (eq 4).[7]

2-Bromo-3-trimethylsilyl-1-propene

[81790-10-5] · $C_6H_{13}BrSi$ · 2-Bromo-3-trimethylsilyl-1-propene · (MW 193.16)

(synthon for CH_2=-CCH_2TMS[1-3] and CH_2=CBr-CH_2;[2] for synthesis of 1-trimethylsilylmethyl-substituted 1,3-butadienes[4])

Alternate Name: 2-bromoallyltrimethylsilane.

Physical Data: bp 46-50 °C/20 mmHg,[3] 64-65 °C/38-39 mmHg.[1]

Solubility: sol alcohol, acetone, ether, THF, pentane; insol water.

Preparative Methods: (1) reaction of ***2,3-Dibromopropene*** with lithium (trimethylsilyl)cuprate in HMPA at 0 °C (63-90%);[3,5] (2) reaction of 2,3-dibromopropene with ***Trichlorosilane*** in the presence of ***Triethylamine*** and ***Copper(I) Chloride***, followed by treatment with ***Methylmagnesium Bromide*** (63-71%).[1,3,6]

Handling, Storage, and Precautions: no special requirements, except refrigeration in a brown bottle is recommended for long-term storage.

Synthon for CH_2=-CCH_2TMS.

The 1-trimethylsilylmethylvinyl anion CH_2=C(M)CH_2TMS (**2**) (M = Li, Mg, Cu, etc.), readily prepared from 2-bromo-3-trimethylsilyl-1-propene (**1**) under typical conditions, allows the introduction of the synthetically useful 1-trimethylsilylmethylvinyl group to a wide variety of substrates. Ring opening of 1-butene oxide with the Grignard reagent (**2**) (M = MgBr) in the presence of ***Copper(I) Iodide*** gives only one regioisomer. Subsequent desilylative oxidation of this allyl alcohol to α-methylene-γ-lactones provides further utility of (**1**) as a 1-hydroxymethylvinyl anion equivalent, i.e. CH_2=-CCH_2OH (eq 1).[1] Alternatively, the alcohol from *trans*-2,3-epoxybutane provides a route to the unstable six-membered β,γ-unsaturated lactone (eq 2).[7] The copper-catalyzed 1,4-addition to the typically unreactive mesityl oxide proceeds smoothly. The versatility of the allylsilane moiety is again illustrated in the ***Ethylaluminum Dichloride***-induced cyclization of the adduct to a tertiary cyclopentanol in high yield (eq 3).[2]

Addition of (**2**) to α,o-substituted aldehydes and ketones is an efficient entry to inter- and intramolecular [3 + 2] cycloaddition approaches to methylenecyclopentanes.[8] For example, chemoselective addition of the Grignard reagent (**2**) to the aldehyde (**3**), followed by acetylation and treatment with a palladium(0) catalyst, gives a bicyclo[3.3.0]octane (eq 4).[3] Similarly, the ketosulfone (**5**), which derives from the lithium reagent (**2**) (M = Li) and the ketodithiane (**4**), cyclizes to the perhydroindanone system (eq 5).[9] This methodology has also been extended to the synthesis of methylenetetrahydrofurans, e.g. in the formation of the phyllanthocin ring system (eq 6).[10] Lewis acid-mediated cycloadditions, both inter- and intramolecular, have also been developed.[11,12] An intermolecular case which generates the zizaene skeleton is depicted in eq 7.[11]

(6)

(7)

The tin analog of (**2**) (M = Me_3Sn) undergoes smooth coupling with various aryl bromides and acyl chlorides to produce 2-substituted allylsilanes (eq 8).[13] Interestingly, the organozinc reagent (**2**) (M = ZnCl) has been shown to equilibrate to the allyl isomer (**6**) and react as such with electrophiles to produce vinylsilanes.[14a] However, it is possible in some cases to control the product distribution with the choice of catalyst (eq 9).[14b]

Synthon for CH_2=CBr-CH_2.

Lewis acid-mediated addition of the silyl bromide (**1**) to electrophiles provides a convenient way to introduce the CH_2=$CBrCH_2$ moiety. In the case of carbonyl substrates, aldehydes react well while aliphatic ketones require higher concentration and aromatic ketones fail to participate. High stereoselectivity is achieved in many cases, e.g. in the addition to aldehyde (**7**). The subsequent conversion of the adduct by carbonylation to a α-methylene-γ-butyrolactone illustrates the synthetic versatility of the vinyl bromide unit (eq 10).[2] Conjugate addition to enones has also been demonstrated.[2,15] In the case of 1-acetylcyclopentene, intramolecular Barbier reaction of the *cis* isomer of the adduct gives an excellent yield of the cyclopentanol (eq 11).[2] Thus by combining the nucleophilic properties of the allylsilane with the ability to effect transmetalation of the vinyl bromide unit, the silyl bromide can serve also as a synthon for CH_2=-C--CH_2. Furthermore, the vinyl bromide moiety can be a source of a vinyl radical. The synthesis of a propellane ring skeleton is made possible using this strategy (eq 12).[16]

(7)

(10)

(11)

+ *trans* isomer

(12)

85%

Under Lewis acidic conditions, the silyl bromide (**1**) and α,α´-dimethoxylated amides undergo a [3 + 3] type annulation which is useful for the construction of the piperidine skeleton (eq 13).[17] The silyl bromide (**1**) is also an excellent reagent for the stereoselective introduction of a functionalized allyl group at the anomeric center of the glucosides (eq 14).[6,18]

(13)

(14)

Coupling Reactions to Dienes and Enynes.

The silyl bromide (**1**) participates readily in copper or transition metal-mediated coupling reactions to produce 1,3-butadienes, which are very useful synthetic intermediates. For example, 2,3-bis[(trimethylsilyl)methyl]-1,3-butadiene (**8**), derived from the oxidative dimerization of cuprate (**2**) (M = Cu) is useful for rapid construction of multicyclic systems via tandem Diels-Alder reactions, as depicted in eq 15.[19] The diene 2-dimethylaminomethyl-3-trimethylsilylmethyl-1,3-butadiene (**9**) functions similarly in the synthesis of a [6,7] ring system (eq 16).[20]

(15)

(16)

Nickel-catalyzed cross coupling of Grignard reagent (**2**) (M = MgBr) with other vinyl bromides provides an easy access to isoprenylsilanes that display high reactivity and regioselectivity toward various dienophiles, as illustrated in the

synthesis of a dihydropyran (eq 17).[4] Carbopalladation of allene with the silyl bromide (**1**) in the presence of a nucleophile also produces dienes. In one case the allylsilane unit is used to generate a cyclohexyl ring (eq 18).[21]

(17)

(18)

Palladium-catalyzed coupling of the silyl bromide to the terminal alkyne (**10**) gives the propargylic allylsilane (**11**), which is a key intermediate in the synthesis of a 10-membered cyclodiynol analog (**12**) of the antitumor agent neocarzinostatin (eq 19).[22]

3-Bromo-1-trimethylsilyl-1-propene

[84673-88-1] · $C_6H_{13}BrSi$ · 3-Bromo-1-trimethylsilyl-1-propene · (MW 193.16)

(preparation of functionalized vinylsilanes[1])

Physical Data: bp 88-90 °C/63 mmHg.

Solubility: insol H_2O; sol most common organic solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: GLC, NMR.

Preparative Methods: bromination (***Phosphorus(III) Bromide***, 0 °C;[2,3] ***N-Bromosuccinimide-Dimethyl Sulfide***[4]) of 3-(trimethylsilyl)allyl alcohol, which in turn can be prepared by ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** reduction of 3-trimethylsilylpropargyl alcohol.[5] Allylic bromination of ***Allyltrimethylsilane*** gives a mixture of the title compound and its regioisomers, which is also useful for some applications.[6]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: stable in air, and should be kept in a tightly capped bottle.

Use as an Electrophile.

The allylic bromide and congeners serve as excellent alkylating agents of enolate anions, providing a useful synthetic route to a variety of substituted vinylsilanes. The lithium enolate of 2-methylcyclohexanone reacts with the trimethylsilyl allylic iodide in excellent yield, and subsequent oxidation of the vinylsilane group smoothly gives a 1,5-diketone (eq 1).[1]

(1)

The S_N2 regioselectivity of the nucleophilic displacement of the bromide group is due to the steric bulk of the silyl group, and is general not only for lithium enolates but for other enolates,[7] lithioenamines, cuprates, and enamines (eq 2).[8]

(2)

The vinylsilanes thus obtained have been used as substrates of polyene cyclization (eq 2),[4,9] and intramolecular acylation (eq 3);[2] the vinylsilane moiety was found to be more electrophilic than the simple allyl group.

(3)

Use as a Nucleophile.

Reduction of the bromide with a low-valent metal generates a nucleophilic allylating reagent, which undergoes highly S_E2'-selective allylation reactions. Thus the reaction of a regioisomeric mixture of the bromide with ***Chromium(II) Chloride*** in the presence of an aldehyde proceeds via a trimethylsilyl allylic chromium reagent with excellent regio- and stereoselectivity to give a β-hydroxysilane (eq 4).[6] Similarly, allylic lead and zinc reagents prepared in situ undergo regio- and chemoselective addition to carbonyl compounds[10] or imines.[11]

(4)

The reaction of the silyl allylic bromide with ***Triphenylphosphine*** readily provides an allylic phosphonium salt, which upon treatment with ***n-Butyllithium*** and an appropriate carbonyl compound (e.g. acetone, cyclohexanone, fluorenone) gives 1-trimethylsilylbutadiene derivatives (eq 5).[3]

(*E*)-(2-Bromovinyl)diisopropoxyborane[1]

[119441-89-3] · $C_8H_{16}BBrO_2$ · (*E*)-(2-Bromovinyl)diisopropoxyborane · (MW 234.93)

((*E*)-vinylation reagent, useful for synthesis of (*E*)-alkenes, α,β-unsaturated ketones, and α,β-unsaturated esters)

Physical Data: bp 73 °C/12 mmHg.

Solubility: sol ether, THF, CH_2Cl_2, and $CHCl_3$.

Form Supplied in: colorless liquid; not available commercially.

Analysis of Reagent Purity: purity is analyzed by ^{1}H NMR ($CDCl_3$): δ 1.17 (d, *J* = 6 Hz, 12H), 4.22-4.56 (m, 2H), 6.37 (d, *J* = 15 Hz, 1H), 7.06 (d, *J* = 15 Hz, 1H).

Preparative Methods: by the bromoboration of acetylene with tribromoborane,[2] followed by the addition of isopropanol to the resulting 2-(bromovinyl)dibromoborane (eq 1).[3,4] The reagent is isolated by distillation under nitrogen. Large quantities may be prepared and stored in a refrigerator.

Handling, Storage, and Precautions: moisture sensitive; can be handled in air for a short time but is gradually hydrolyzed to the boronic acid by moisture. It should be stored in a refrigerator under a dry inert gas and transferred by syringe. After prolonged storage it should be distilled under a dry inert gas before use. Sensitive to both base and acid; base treatment causes rapid decomposition by β-elimination.

Synthesis of (*E*)-Alkenes via Palladium-Catalyzed Stepwise Cross-Coupling Reactions.

Cross-coupling reactions of alkenylboranes with organic halides are known to proceed in the presence of a palladium

catalyst and an appropriate base.[5] In the absence of base, (*E*)-(2-bromovinyl)diisopropoxyborane reacts with organozinc compounds as a simple organic halide to give (*E*)-(1-alkenyl)diisopropoxyboranes. Subsequent addition of base and an organic halide promotes the coupling reaction between the alkenylborane and the organic halide to provide (*E*)-alkenes stereoselectively (eq 2).[4] Though the isolation of the alkenylborane intermediate is possible, the reaction can be carried out without isolation of any intermediates. Alkynyl, alkenyl, alkyl, and aryl groups can be introduced on to both sides of the double bond. This method is an alternative to the cross-coupling reaction of alkenylboranes prepared by the hydroboration of alkynes, and is preferable especially when an alkyne is difficult to synthesize or has functional groups that are sensitive to hydroboration reactions.

α,β-Unsaturated Ketones.

This methodology is effective for the synthesis of α,β-unsaturated ketones using α-alkoxyalkenylzinc chlorides in the first cross-coupling step.[6] The reaction proceeds under mild conditions, and is applicable for the synthesis of polyenones such as pseudoionone (eq 3).

This reaction has been applied to the synthesis of prostaglandin B_1(PGB_1).[7] Stepwise cross-coupling of (1-methoxy-1-pentenyl)zinc chloride with (*E*)-(2-bromovinyl)-diisopropoxyborane followed by 3-bromo-2-[6-(methoxycarbonyl)hexyl]-2-cyclopenten-1-one (**1**) provides 15-dehydro-PGB_1 directly in a one-pot operation (eq 4).

α,β-Unsaturated Esters.

A sequence involving cross-coupling and alkoxycarbonylation reactions of (*E*)-2-(bromovinyl)diisopropoxyborane gives α,β-unsaturated esters.[8] Isolation of alkenylborane intermediates is not necessary, but removal of the solid generated in the first step is required. The second step is carried out under a carbon monoxide atmosphere after the addition of the other reagents (eq 5).

α-Bromovinyl Methyl Sulfone

[35495-31-9] · $C_3H_5BrO_2S$ · α-Bromovinyl Methyl Sulfone · (MW 185.05)

(dienophile equivalent to allene in cycloaddition reactions via Ramberg-Bäcklund reaction of the adducts;[1] gives aziridines with primary amines in DMSO[2])

Physical Data: bp 63-64 °C/0.4 mmHg.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Preparative Method: prepared by bromination-dehydrobromination of methyl vinyl sulfone in 80% yield.[1]

The reaction of α-bromovinyl methyl sulfone with cyclopentadiene affords a mixture of the expected cycloadducts which, upon treatment with ***Sodium Methoxide*** in DMSO, give 5-methylene-2-norbornene via the Ramberg-Bäcklund rearrangement in over 90% yield. Using 2N ***Sodium Hydroxide*** as the base, the adducts give, besides the expected 5-methylene-2-norbornene, 37-59% yield of the rearranged adduct (eq 1).[1] The latter product arises from a radical rearrangement.

(1)

The action of ***Dimethyl Sulfoxide*** and a primary amine on α-bromovinyl methyl sulfone gives aziridines (eq 2).[2]

(1-Bromovinyl)trimethylsilane[1]

[13683-41-5] · $C_5H_{11}BrSi$ · (1-Bromovinyl)trimethylsilane · (MW 179.13)

(undergoes lithium-halogen exchange in the presence of alkyllithium;[2] used as a dienophile in [4 + 2] cycloaddition reactions;[3] used in palladium-catalyzed reactions;[4] substrate for cyclopropanation[5])

Alternate Names: 1-(trimethylsilyl)vinyl bromide; 1-bromo-1-(trimethylsilyl)ethylene.

Physical Data: bp 124 °C/745 mmHg; *d* 1.156 g cm^{-3}.

Solubility: completely miscible with THF and Et_2O.

Form Supplied in: clear liquid.

Analysis of Reagent Purity: ^1H and ^{13}C NMR can be used.

Preparative Methods: prepared, in good yield, from the reaction of ***Vinyltrimethylsilane*** with ***Bromine*** at low temperature followed by dehydrohalogenation in the presence of an amine base.[1] Alternative syntheses and reagents, i.e. (1-bromovinyl)triphenylsilane and (1-bromovinyl)triethylsilane, are also known.[2a]

Handling, Storage, and Precautions: store in a dry area.

Vinyltrimethylsilane Metal.[2]

1-Trimethylsilylvinyl metal species are mostly used as acyl anion equivalents and as hindered vinyl anion substitutes. ***1-(Trimethylsilyl)vinyllithium*** is easily accessible from (1-bromovinyl)trimethylsilane by treatment with ***n-Butyllithium*** at -78 °C in ether (eq 1).[2a] Other solvents and alkyllithiums can also be used for the metal-halogen exchange.[2b] The use of (1-chlorovinyl)trimethylsilane or the direct reaction of (1-bromovinyl)trimethylsilane with lithium metal are not proper methods for generating the lithium species.[2c]

(1-Bromovinyl)trimethylsilane

(1)

The corresponding Grignard reagent is made by reaction of ***Magnesium*** with (1-bromovinyl)trimethylsilane in THF (eq 2).[2d] It has the same general uses as the lithium analog (***1-(Trimethylsilyl)vinyllithium***). Furthermore, it has been shown to react with allylic acetates, in the presence of palladium catalysts, to give the corresponding dienes in moderate to low enantiomeric excess when the catalyst was chiral (eq 3).[6] Generally, Grignard reagents will add to the carbonyl of the acetate group in preference to allylic substitution. The authors described 1-(trimethylsilyl)vinylmagnesium bromide as a soft stabilized anion to explain this peculiar reactivity.

(2)

(3)

This Grignard reagent has also been reacted with ***Carbon Dioxide***[2f] and the cuprate of this Grignard reagent adds to alkynyl compounds and provides a practical synthesis of 1,3-butadienes (eq 4).[2g]

(4)

[4 + 2] Cycloaddition Reactions.[3]

A number of substituted vinyltrimethylsilanes react with dienes and nitrile oxides in Diels-Alder[6] and 1,3-dipolar cycloadditions.[3] The trimethylsilyl group has a deactivating effect. This reaction with ***Benzonitrile Oxide*** gives 3-phenyl-5-trimethylsilylisoxazole (eq 5).

(5)

Palladium-Catalyzed Reactions.[4]

Numerous nucleophiles react with (1-bromovinyl)trimethylsilane in the presence of palladium complexes. The bromine has been substituted by phenylthio,[4a] vinyl,[4b] and aryl[4c] groups. This approach gives reasonable yields of the desired products. However, the substitution reactions sometimes lack regiospecificity. For example, a mixture of regioisomers was obtained in eq 6. Two mechanisms have been proposed for the formation of the β-substituted product. One involves an elimination step to give ***Trimethylsilylacetylene*** as an intermediate, which then undergoes catalyzed additions with the nucleophile at either the α- or β-positions.[4a] The other mechanism involves the formation of a pentacoordinated palladium intermediate, leading to the formation of isomeric products.[4c]

(6)

Substrate for Cyclopropanation.[5]

Dichlorocarbene adds to vinyltrimethylsilane, and the adduct is a source of 1-chlorocyclopropene, a reactive dienophile for Diels-Alder reactions.[5b] Dichlorocarbene also reacts with (1-bromovinyl)trimethylsilane[5a] to form (1-bromo-2-dichlorocyclopropyl)trimethylsilane. β-Elimination in the presence of ***Tetra-n-butylammonium Fluoride*** gives 1-bromo-2-chlorocyclopropene, another reactive dienophile (eq 7).

(7)

Related Reagents.

(2-Bromovinyl)trimethylsilane; ***1-(Trimethylsilyl)vinyllithium***; ***(E)-2-(Trimethylsilyl)vinyllithium***; ***Vinylmagnesium Bromide***.

(2-Bromovinyl)trimethylsilane

[13682-94-5] · $C_5H_{11}BrSi$ · (2-Bromovinyl)trimethylsilane · (MW 179.13) (*E*)

[41309-43-7] (*Z*)

[70737-20-1]

(for introduction of the β-(trimethylsilyl)vinyl moiety; the resulting alkenylsilanes undergo useful electrophilic substitutions of the TMS group[1])

Alternate Name: 1-bromo-2-trimethylsilylethylene.

Physical Data: (*E*)-isomer: bp 54-55 °C/56 mmHg; *d* 1.16 g cm^{-3}. (*Z*)-isomer: bp 50-52 °C/56 mmHg.

Form Supplied in: (*E*)-isomer, typically containing ca. 10% (*Z*)-isomer.

Analysis of Reagent Purity: ^{1}H NMR (CH=CH) of (*E*)-isomer: δ 6.48 (s); (*Z*)-isomer: δ 6.35, 6.50, 6.86, 7.01 (AB pattern, *J* = 9 Hz).

Preparative Methods: (*E*)-isomer: by the sequence of eq 1,[2] or more directly from the readily available ***Vinyltrimethylsilane***[3] (eq 2).[4] (*Z*)-isomer: by bromination-debromosilylation of 1,2-bis(trimethylsilyl)ethylene (eq 3).[5]

Purification: An 87:13 (*E*):(*Z*) mixture was enriched to 98-99% (*E*) by fractionation.[6]

Handling, Storage, and Precautions: use in a fume hood.

Introduction.

Methods for the introduction of the β-(trimethylsilyl)vinyl moiety into organic frameworks using (2-bromovinyl)trimethylsilane (**1**) may be grouped into two broad categories: those which employ (**1**) as an electrophilic component, or organometallic derivatives of (**1**) as nucleophilic reaction components.

As Nucleophilic Component.

The first such reagent[7] prepared from (**1**) was (*E*)-β-(trimethylsilyl)vinylmagnesium bromide (**2**) (eq 4).[2] This undergoes expected reactions with a number of electrophiles (eqs 5-8)[2,8,9] as well as coupling with (**1**) (eq 9).[10]

(8)

(9)

In addition, coupling of the Grignard (**2**) with both alkenyl and alkyl halides has been promoted by metal ion catalysis (eqs 10-12).[5,11] Under copper(I) catalysis, (**2**) reacts with conjugated enones in a 1,4-fashion (eq 13),[11,12] and the diorganocuprate derived from (**2**) behaves in a similar fashion (eq 14).[13]

(10)

(11)

(12)

(13)

(14)

As Electrophilic Component.

Although an example of coupling between (**1**) and a lithium diorganocuprate is known (eq 15),[14] most substitution reactions of this nature employ palladium catalysis. In this way, organomagnesium (eq 16),[11] as well as organozinc (eqs 17 and 18),[15,16] alkynyltin (eq 19),[15b] and alkenylaluminum compounds (eq 20)[15] have been effectively used as coupling agents. Although the commonly available 9:1 (*E*)/(*Z*) mixture of (**1**) was utilized in these couplings, the alkenylsilane products were obtained in high stereoisomeric (*E*) purity.[15] The cross-coupling of an alkenylzinc reagent with (**1**) was used for a direct synthesis of a dihydrobenzisoquinoline (eq 21).[17]

(15)

(16)

(17)

(18)

(19)

(20)

(21)

Couplings of more highly ionic organometallic coreactants with (**1**) have also proven amenable to palladium catalysis. These procedures are often tolerant of accompanying electrophilic functionalities (eqs 22 and 23).[18,19] Palladium catalysis has also been utilized for the formation of (*E*)-β-(trimethylsilyl)vinyl sulfides from (**1**) (eq 24).[20] A stereoisomeric purity of >99% was observed for the product. Although (**1**) has generally been found to be much more reactive than its (*Z*)-isomer (**3**) is cross-coupling reactions,[15,20] the latter has been efficiently employed in the stereospecific transformation of eq 25.[21]

(22)

(23)

(24)

(25)

In behavior separate from those described above, (**3**) undergoes electrophilic substitution of the TMS group characteristic of alkenylsilanes[1] when treated with acyl chloride-***Aluminum Chloride*** mixtures (eq 26).[5]

(26)

Related Reagents.

(E)-1-Lithio-2-tributylstannylethylene; ***(E)-2-(Trimethylsilyl)vinyllithium***.

Brucine[1]

[357-57-3] · $C_{23}H_{26}N_2O_4$ · Brucine · (MW 394.47)

(reagent for the resolution of acids, alcohols, and other neutral compounds[1])

Physical Data: colorless needles (acetone/water) mp 178 °C; $[\alpha]_D$ -79.3° (*c* 1.3, EtOH).

Solubility: very sol methanol, ethanol, and chloroform; mod sol ethyl acetate or benzene.

Form Supplied in: colorless needles or plates. The free base, which is available from multiple commercial sources, is usually hydrated. Dihydrated and tetrahydrated forms have been characterized. Anhydrous brucine can be obtained by heating at 100-120 °C in vacuo for 24 h. The hydrated forms can be used for most applications.

Purification: the commercial reagent is often used without further purification. However, the reagent can be purified by recrystallization from ethanol/water (1:1).[2] Recovered reagent[3] should be purified before reuse.

Handling, Storage, and Precautions: EXTREMELY POISONOUS. Oral LD_{50} in rats is 1 mg kg^{-1}. Handle in well-ventilated hood only.

Introduction.

The alkaloid brucine has been a key resolving agent for over a century, in spite of its highly toxic nature. The group of chiral bases represented primarily by brucine, its homolog strychnine, and the cinchona alkaloids quinine, quinidine, cinchonidine, and cinchonine, has been extremely useful for the resolution of all types of acids.[1] No empirical rules have emerged from all of this work to help in predicting the optimal resolving agent for a given type of acid. Acid resolution is still primarily an empirical process that requires the evaluation of several diastereomeric salts. An inherent limitation to the use of alkaloids as resolving agents for acids is the availability of only one antipode, which sometimes

allows the practical isolation of only one of the acid enantiomers in a pure form. Nevertheless, there are reports of resolutions with brucine that are so efficient that the less crystalline enantiomer can be isolated directly from the mother liquors (see below for examples). In other cases, pairs of pseudoenantiomeric cinchona alkaloids (i.e. quinine and quinidine, cinchonine and cinchonidine), or brucine and another alkaloid, display opposite selectivities for the enantiomers of a racemic acid (see below).[1a]

Resolution of Acids.

The number of acids resolved with brucine is too large to attempt to list even a small portion of them in this synopsis. An excellent tabulation of all published resolutions with brucine up to 1972 is available.[1a] Only a few representative examples will be described here (eqs 1-4).[4-9] In all these cases, the resolved acids were obtained in high yield and with almost absolute enantiomeric purity. The solvents most frequently used for brucine resolutions are acetone and alcohol solvents. However, water, hexane, and others have also been used as cosolvents.

(1)

(2)

(3)

(4)

Additional types of carboxylic acids that have been successfully resolved with brucine are represented by structures (**1**)-(**5**).[10-14]

(1)

(2)

(3)

(4)

(5)

As mentioned above, one of the limitations of using naturally occurring resolving agents is that only one enantiomer of the compound being resolved may be readily accessible by resolution. However, many examples have been described where brucine and some other alkaloid favor crystallization with opposite enantiomers of a given acid. For example, resolution of acid (**6**) with brucine yields the (+)-enantiomer, while cinchonidine provides material that is enriched in the (-)-enantiomer of the acid.[15] Similarly, diacid (**7**) is resolved into its (-)-enantiomer by brucine and into its (+)-enantiomer by strychnine.[16] The (+)-enantiomer of acid (**8**) can be obtained with brucine, while the (-)-enantiomer crystallizes with cinchonidine.[17] Additional examples of the same phenomenon can be found in the literature.[1a]

(6)

(7)

(8)

Resolution of Alcohols.

Although not a well exploited use of brucine, a variety of secondary benzylic alcohols have been resolved by complexation and crystallization with brucine (eq 5).[18] About a dozen alcohols were obtained in close to enantiomeric purity by this procedure.[18] Also resolved by crystallization of their brucine inclusion complexes were a series of tertiary propargylic alcohols (eq 6).[19] In this case, the enantiomer that does not crystallize with brucine can be obtained in almost complete optical purity from the mother liquors.

(5)

(6)

A more traditional and general approach to the resolution of alcohols is the formation of the corresponding hemiphthalate or hemisuccinate esters, followed by resolution of these acidic derivatives with brucine or some other chiral base (eqs 7-9).[20-23] The resolved alcohols are liberated by alkaline hydrolysis of the esters. High enantiomeric purity is frequently achieved by this procedure, which has been applied successfully to primary, secondary, and tertiary alcohols.

(7)

Resolution of Ketones.

Brucine has not been used very extensively for the resolution of neutral compounds. However, in some cases, ketones or ketone derivatives may form diastereomeric inclusion complexes with brucine, providing an opportunity for their resolution. For example, the cyanohydrin of a bicyclic ketone has been resolved by this procedure (eq 10).[24] Following resolution of the cyanohydrin, the ketone was regenerated and determined to be of 94% ee.

(10)

Resolution of Sulfoxides.

Although it can be considered as the resolution of an unique type of carboxylic acid, some racemic sulfoxides containing carboxylic acids have been resolved via diastereomeric crystalline complexes with brucine (eq 11).[25]

(11)

Chiral Catalysis.

Brucine has been utilized as chiral catalyst in a variety of reactions. For example, its incorporation into a polymer support provides a chiral catalyst for performing enantioselective benzoin condensations.[26] It has also been used as a chiral catalyst in the asymmetric synthesis of (*R*)-malic acid via the corresponding β-lactone, which results from the asymmetric cycloaddition of chloral and ketene (eq 12).[27] Though brucine yields malic acid with 68% ee, quinidine was found to be a more selective catalyst (98% ee).

(12)

(*R*)-malic acid

Brucine has been used as an enantioselective catalyst in the kinetic resolution of alcohols. For example, an azirinylmethanol was reacted with 0.5 equiv of ***Acetic Anhydride*** in the presence of 25 mol % brucine. The resulting acetate was found to possess 24% ee (eq 13).[28]

(13)

24% ee
absolute stereochemistry
unknown

Brucine has been used to produce enantiomerically enriched compounds by selective reaction with or destruction of one of the enantiomers. The optical purity of the resulting compound is usually modest, although some exceptions have been described. For example, dibromo compound (**9**) was obtained (enriched in the (-)-enantiomer) by selective destruction of the (+)-enantiomer with brucine in chloroform.[29] The resolution of (±)-2,3-dibromobutane may have also been a case of enantioselective destruction,[30] although more recent reports suggest that it is more likely a case of enantioselective entrapment in the brucine crystals (eq 14).[31]

(9)

(14)

Miscellaneous.

Brucine greatly accelerates the decarboxylation of certain β-oxo carboxylic acids at rt (eq 15),[32] as well as the decarbalkoxylation of β-oxo esters.[33] In some cases the products of these reactions possess some (modest) enantiomeric excess.[34]

1,3-Butadiene

[106-99-0] · C_4H_6 · 1,3-Butadiene · (MW 54.09)

(co-monomer in synthetic elastomers and polymers, polybutadiene rubber, chloroprene, and nylon intermediate;[1] 4π partner in Diels-Alder reactions[2])

Alternate Names: butadiene; α,γ-butadiene; bivinyl; divinyl; vinylethylene; biethylene.

Physical Data: bp -4.5 °C/760 mmHg; mp -109 °C; fp <-7 °C; ρ-64 0.650.

Solubility: sol common organic solvents.

Form Supplied in: widely available in compressed liquid phase. Supplied in several grades ranging from 99.0-99.8% purity. Sizes available range incrementally from lecture bottles (100 g) to large gas cylinders (61 kg).

Preparative Methods: butadiene sulfone (2,5-dihydrothiophene 1,1-dioxide), a crystalline, nonhygroscopic, commercially available solid, can be used to generate 1,3-butadiene in situ: heating the sulfone at 100-130 °C induces loss of SO_2.[3b,3c]

Handling, Storage, and Precautions: extremely flammable liquid and gas. Avoid polymerization initiators. Relatively nontoxic. Suspected chronic carcinogen. Acutely irritating to respiratory tract. 1,3-Butadiene (**1**) is used in the laboratory by condensing the gas directly into a reaction vessel, or by forming a saturated solution of the gas in the reaction solvent. For reactions run below rt (e.g. Lewis acid-catalyzed reactions), normal reaction flasks can be used. For higher temperature reactions, sealed tubes are required to prevent escape of (**1**). A particularly convenient, reusable apparatus is available from Ace Glass, Inc., and consists of a heavy-walled glass tube sealed on one end and threaded on the other. The threaded end can be sealed with a heavy Teflon plug fitted with an O-ring.

Reactivity.

1,3-Butadiene (**1**) participates as the 4π partner in $[_{\pi}4_s + _{\pi}2_2]$ cycloaddition reactions with a variety of dienophiles. The majority of these cycloadditions are normal Diels-Alder reactions ($HOMO_{diene}$-$LUMO_{dienophile}$ controlled).[2,3a] Theoretical predictions on the mechanism of Diels-Alder reactions of butadiene have pointed towards a synchronous concerted mechanism.[4] 1,3-Butadiene (**1**) is typically less reactive than substituted butadienes, except when steric

factors prevent the diene from attaining the reactive *s-cis* conformation. For example ***Tetracyanoethylene*** reacts more slowly with (**1**) than with (*E*)-1-methyl-1,3-butadiene (103×), 2-phenyl-1,3-butadiene (191×), or (*E*)-1-methoxy-1,3-butadiene (50 934×).

Lewis Acid-Catalyzed Cycloadditions.

Friedel-Crafts type catalysts are reported to facilitate the cycloaddition reactions of (**1**) with α,β-unsaturated carbonyl compounds.[5] With methyl vinyl ketone (eq 1), cycloaddition was effected in the presence of less than 1 molar equivalent of ***Aluminum Chloride***, ***Tin(IV) Chloride***, ***Boron Trifluoride***, ***Iron(III) Chloride***, or ***Titanium(IV) Chloride*** for 1 h at 25 °C. For comparison, the uncatalyzed reaction required 8-10 h at 140 °C in a sealed tube (75%). ***Acrolein***, ***Methyl Vinyl Ketone***, and ***Acrylic Acid*** all underwent effective catalyzed Diels-Alder reactions with (**1**) in good yields. The principal limitation of this reaction is polymerization of the 1,3-diene. For example, 2,3-dimethylbutadiene and cyclopentadiene underwent polymerization and dimerization, respectively, under these conditions.

(1)

In the cycloaddition of (**1**) with 2,5-cyclohexadienones in an approach to *cis*-clerodanes, the facial selectivity depended on the length of the carboxylate side-chain (eq 2).[6] When the carboxylate was a significant distance from the ring (*n* = 2), cycloaddition occurred *syn* to the less bulky methyl group to afford the *anti* cycloadduct. Facial selectivity eroded with *n* = 1, and was reversed when the carboxylate was directly attached to the ring, to afford exclusively the *syn* diastereomer.

(2)

Lewis acids have also been used to catalyze the cycloaddition of (**1**) with alkynes (eq 3).[7] A mixture of $TiCl_4$ and ***Diethylaluminum Chloride*** promoted the [4 + 2] cycloaddition of phenyl(trimethylsilyl)acetylene and (**1**) to afford the

dihydrobenzene adduct in 84% yield, which could be aromatized thermally to afford the *ortho*-disubstituted benzene in 92% yield. Cycloaddition of cycloalkenones with butadiene in the presence of $AlCl_3$ affords the expected *cis*-fused systems for *n* = 2, 3, 4 (eq 4).[8] Partial or total isomerization of the *cis* adduct to the more stable *trans* isomer was observed with R = H.

A highly regioselective and moderately stereoselective cycloaddition of (**1**) with the γ,δ-double bond of a dienone was effected by $AlCl_3$ catalysis in 37% yield (eq 5).[9] The cycloadduct formally arising from approach of butadiene *syn* to the enone ring predominated initially, and was shown to isomerize to the more stable *anti* product under the reaction conditions. Contrasteric facial selectivity was observed in the Lewis acid-catalyzed cycloaddition of (**1**) with γ-alkoxycycloalkenones (eq 6).[10] When *n* = 1, cycloaddition at rt in the presence of catalytic $AlCl_3$ afforded predominately the *syn* cycloadduct (76%; 13:1 *syn/anti*). Under similar reaction conditions with *n* = 2, the *syn* cycloadduct was also the major product (10:1 *syn/anti*). The divergence of these results with those obtained with γ-alkylcycloalkenones was discussed, and a tentative theoretical model was proposed to account for the *syn* selectivity.

Montmorillonite K10 exchanged with Fe^{III} has been reported to catalyze the Diels-Alder reaction of butadiene with acrolein (eq 7).[11] Cycloaddition occurs at rt in high yield in the presence of 1.8 g catalyst per 15 mmol cycloaddition partners. Other dienes reacted with equal facility with acrolein under these conditions.

Asymmetric Diels-Alder Reactions.

Cycloaddition of (**1**) with a methacrylate dienophile using a camphor lactam imide in the presence of Lewis acid affords the cyclohexenecarboxylate cycloadduct in 61% yield with 85:15 π-facial selectivity.[12] Presumably the steric bulky of the coordinated metal forces the methacrylate to adopt an *s-trans* conformation as shown (eq 8), and cycloaddition occurs from the less crowded bottom face of the complex. A pyrrolidin-2-one auxiliary containing the bulky 5-(trityloxymethyl) group was effective at asymmetric induction in the Lewis acid-catalyzed cycloaddition of (**1**) with a fumarate dienophile (eq 9).[13] The cyclohexenedicarboxylate was obtained in 52% yield and 96% de. Other dienophiles and Lewis acids were examined and found to be equally effective, giving high *endo* selectivity (&egt;97:3) and excellent diastereoselectivity (&egt;94% de).

(9)

Carbohydrate-based chiral auxiliaries have proven effective in cycloadditions with (**1**).[14] The auxiliary derived from 3-*O*-acryloyldihydro-D-glucal (eq 10; R = pivaloyl) afforded the (*S*)-cyclohexenecarboxylate (8:92 *R/S*), whereas the pseudoenantiomeric system, 3-*O*-acryloyldihydro-L-rhamnal (eq 11; R = pivaloyl), afforded the (*R*)-cycloadduct (95:5 *R/S*). Complexation of the titanium catalyst to each of the ester carbonyl oxygens was postulated to rigidify the acryloyl group, locking it in the conformation depicted. In both cases, cycloaddition presumably occurs to the less hindered face of the acrylate away from the bulky 4-*O*-pivaloyl group.

(10)

(11)

Chiral titanium-based catalysts have been used in asymmetric Diels-Alder reactions of (**1**). A mixture of $TiCl_4$ and ***Titanium Tetraisopropoxide*** was used with a tartrate-derived auxiliary in the cycloaddition of (**1**) with a quinone (eq 12) to afford the expected bicyclic system in 88% yield and 63% ee.[15] Other dienes underwent stereoselective cycloadditions with better asymmetric induction. A similar catalyst system was used in the cycloaddition of (**1**) with fumarate[16] and acrylate[17] derivatives. The catalyst was prepared by alkoxy exchange with the tartrate-derived auxiliary and ***Dichlorotitanium Diisopropoxide***, and was treated with the cycloaddition partners at rt for 24 h to afford the cyclohexenecarboxylate in 81% yield and in 93% optical purity (eq 13). Other dienes underwent asymmetric cycloaddition with equal success. A model was proposed for the catalyst-dienophile complex.

The C_2-symmetric hydrobenzoin complexed with $TiCl_4$ promoted the cycloaddition of (**1**) with ***Dimethyl Fumarate*** to afford the cyclohexenedicarboxylate in 78% yield with a modest 60% ee (eq 14).[18] Carboxylic ester dienophiles have typically participated ineffectively in asymmetric Diels-Alder reactions.

Applications in Synthesis.

Butadiene is a widely used reagent in organic synthesis. It is primarily used as the 4π participant in the Diels-Alder construction of carbocyclic and heterocyclic six-membered rings,[2] although numerous other uses have been recorded.

Butadiene cycloaddition was a key step in the synthesis of constrained phenanthrenamine derivatives that are active as noncompetitive NMDA antagonists.[19] Reaction of dihydronaphthalenecarboxylic acid with (**1**) in toluene at 110 °C in the presence of polymerization inhibitor afforded the tricyclic adduct in 60% yield (eq 15). Hydrogenation of the resulting double bond afforded the hydrophenanthrenecarboxylic acid, which was converted to a variety of tetracyclic structures where the carboxylate was converted to an amine by modified Curtius rearrangement.

(15)

Three reports have described the use of butadiene in the asymmetric construction of the C-28-C-34 fragment of the immunosuppressant FK-506.[20-22] In the first report (eq 16), the acrylate ester of (*S*)-(+)-pantolactone was reacted with (**1**) in the presence of $TiCl_4$ to afford the cyclohexenecarboxylate in excellent yield and in 91% de.[20] In the second report, the same Diels-Alder reaction was performed with a chiral sultam auxiliary under $EtAlCl_2$ catalysis to give the cyclohexenecarboxylate in 86% yield in 93% ee (eq 17).[21] In the third report, an acryloyl-(*S*)-2-hydroxysuccinimide underwent cycloaddition with (**1**) under catalysis by $TiCl_4$ to afford the cyclohexenecarboxylate in 85% yield in 98% ee (eq 18).[22] The double bond of all three cycloadducts was subsequently converted to the *anti*-diol of FK-506. A cycloaddition reaction identical to that shown in eq 16 was used as a key step in the asymmetric synthesis of the cyclohexane ring of (+)-phyllanthocin.[23] In this instance the cycloaddition proceeded in 70% yield and in 97% ee.

(16)

(17)

(18)

A β-pinene-derived dienophile was used as the 2π cycloaddition partner with (**1**) in an approach to the morphine skeleton (eq 19).[24] Thermal cycloaddition occurred stereoselectively from the face opposite the substituted bridge to afford the adduct in 82% yield. Cycloaddition was also effected in lower yield under Lewis acid-catalyzed conditions

($Cu(BF_4)_2$, CH_2Cl_2, 25 °C, 12 h, 34%). Further elaboration of the cycloadduct afforded the *cis*-Δ^6-1-octalone acetal possessing the required absolute configuration at three contiguous stereogenic centers for conversion to morphine-related compounds. In a synthetic approach to analogs of the potassium channel activator aprikalim, butadiene was used in a hetero Diels-Alder reaction for the construction of a thiopyran ring (eq 20).[25] Thus reaction of the thiocarbonyl group of an α-thioketo ester (generated in situ) with (**1**) afforded the desired thiopyran in 65% yield.

An asymmetric Diels-Alder reaction of (**1**) with a phenylalaninol-derived auxiliary was used to construct the B-ring of (+)-compactin and (+)-mevinolin (eq 21).[26] Cycloaddition of the (*E*)-crotonic acid derivative with butadiene in the presence of catalytic Et_2AlCl afforded the desired cycloadduct in 56% yield and greater than 95% de. The auxiliary was removed and the desired *cis*-isomer of the 2-methyl-4-cyclohexenecarboxylate was obtained by base-promoted epimerization of the *trans*-isomer (65:35 *cis/trans* equilibrium mixture). Use of the corresponding (*Z*)-crotonoyl auxiliary was not examined as the (*Z*) configuration of the alkene is not preserved under the reaction conditions.[27]

A rapid and stereospecific construction of the 2-azabicyclo[3.3.1]nonane ring system characteristic of *Strychnos* alkaloids was initiated with a Diels-Alder reaction of β-nitrostyrene and (**1**) (eq 22).[28] After reduction of the nitro group and *N*-acylation, the desired aminocyclohexene was obtained in 63% overall yield. Subsequent elaboration to the 2-azabicyclo[3.3.1]nonane system involved a high-yielding stereoselective Heck reaction. Butadiene sulfone was used for in situ generation of (**1**) in an approach to cephalotaxine analogs. In a key step, a β-nitrostyrene dienophile was treated

with butadiene sulfone at 135 °C to afford the butadiene cycloadduct in 74% yield (eq 23).[29]

Miscellaneous Reactions.

The novel dienophile 2-trimethylsilylvinyl-9-BBN was shown to undergo facile Diels-Alder reaction with butadiene to afford the 2-trimethylsilylcyclohexenol in 85% yield after oxidation of the intermediate trialkylborane (eq 24).[30] The cycloadduct was shown to be a precursor to 5-trimethylsilyl-1,3-cyclohexadiene and -1,4-cyclohexadiene, thus making the dienophile an acetylene equivalent.

Catalytic osmylation was used to convert 1,3-butadiene to a polyol with good control of relative stereochemistry (eq 25).[31] Under standard osmylation conditions, (**1**) was converted to the 2,3-*anti*-tetraol in 80% yield in a 5:1 *anti/syn* ratio. The stereoselectivity of this reaction is consistent with previous findings on the osmylation of allylic alcohols and ethers.

1,3-Butadiene Monoxide

[930-22-3] · C_4H_6O · 1,3-Butadiene Monoxide · (MW 70.09)

(ambident electrophile)

Alternate Names: 3,4-epoxy-1-butene; butadiene epoxide; vinyl epoxide; vinyloxirane.

Physical Data: bp 70 °C; *d* 0.9006 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: clear liquid.

Preparative Method: few attempts have been reported to epoxidize conjugated dienes. Recently, a manganese catalyst was employed in a method developed to epoxidize butadiene selectively in one step (eq 1).[1]

Handling, Storage, and Precautions: the flammable liquid, flash point -50 °C, is a possible carcinogen and should be used in a fume hood.

Nucleophilic Opening at C(1).

Butadiene monoxide is a versatile four-carbon synthon in organic synthesis.[2] With the careful choice of reagents one can selectively react nucleophiles at three sites on the carbon backbone. α-Selenobenzyllithiums react at the C(1) position and the resulting intermediates have been transformed into cyclopropanes (eq 2).[3] Aminolead reagents displayed even greater selectivity for attack at the C(1) position (eq 3).[4]

Nucleophilic Opening at C(2).

In Et_2O, allylcerium reagents were found to be more regioselective in additions to the 2-position of butadiene monoxide than allyllithium reagents (eq 4).[5] In THF the yields and product ratios were comparable. ***Vinylmagnesium Bromide*** also adds selectively at the 2-position provided 2-3 equiv of the Grignard reagent are employed (eq 5).[6]

(5)

Nucleophilic Opening at C(4).

The S_N2' reaction of organocopper reagents with vinyloxiranes has recently been reviewed.[7] A number of S_N2' reactions with butadiene monoxide have been facilitated by a palladium catalyst.[8] A recent example is found in the synthesis of a linear diene alcohol that was further converted into a cyclopropane-containing eicosanoid of marine origin (eq 6).[9] Under standard metalation conditions enol carbamates are readily lithiated, and these acyl anion equivalents also react selectively at the C(4) position without a catalyst (eq 7).[10]

(6)

Functionalization at C(2).

The proton at the 2-position of butadiene monoxide can be selectively deprotonated with ***t-Butyllithium-N,N,N´,N´-Tetramethylethylenediamine*** and silylated with ***Chlorotrimethylsilane***.[11] A similar and perhaps more useful reaction involves the reductive metalation of epoxides by various metals.[12] Employing ***Chromium(II) Chloride***, the 2-position of butadiene monoxide can be functionalized with reasonable selectivity (eq 8).[12a]

Related Reagents.

Ethylene Oxide; ***Isoprene Epoxide***; ***Propylene Oxide***.

2,3-Butadienenitrile

[1001-56-5] · C_4H_3N · 2,3-Butadienenitrile · (MW 65.07)

(reactive in transformations involving nucleophilic conjugate addition,[1] radical addition,[2] and dipolar addition, especially with nitrones[3])

Alternate Names: allenecarbonitrile; cyanoallene; cyanopropadiene.

Physical Data: bp 50-51.5 °C/50 mmHg.

Solubility: sol EtOH, THF, toluene, chloroform, benzene.

Analysis of Reagent Purity: IR 1970, 2230 cm^{-1}.

Preparative Methods: this reagent is not commercially available, but at least two preparative methods have been reported. One proceeds through a Wittig reaction between cyanomethylidenetriphenylphosphorane and ketene.[4] However, the procedure to be recommended involves the formation of 3-butynenitrile and its isomerization in situ to 2,3-butadienenitrile (eq 1).[5] The indicated product mixture can be produced on a scale near 100 g, and its fractional distillation affords pure 2,3-butadienenitrile.

Purification: vacuum distillation.

Handling, Storage, and Precautions: this reagent has been reported[6] to cause severe allergic reactions in some individuals. Handling with double, heavy-duty rubber gloves is recommended. This reagent should only be handled in a fume hood.

Procedures Involving Nucleophilic Conjugate Addition to 2,3-Butadienenitrile.

Transformations in which this reagent behaves as a conjugate addition electrophile are well known. For example, eq 2[1] shows an unsaturated amino acid synthesis based on this concept.

(2)

A similar process underlies the [2 + 2] cycloaddition between 2,3-butadienenitrile and cyclohexanone morpholine enamine (eq 3).[7]

(3)

A more sophisticated exploitation of this chemistry is incorporated in the procedure[8] for alkylation *ortho* to aromatic

amino nitrogen (eq 4). This protocol delivers an intermediate cyano ketone through nucleophilic addition of the hydroxamate anion to 2,3-butadienenitrile and subsequent [3,3]-sigmatropic rearrangement and tautomerization. ***Formic Acid*** treatment of the cyano ketone then produces the 2-substituted indole. Likewise, a mechanistically related sequence carried out on a substrate incapable of tautomerization and rearomatization delivers carbocyclic products (eq 5).[9]

(4)

(5)

2,3-Butadienenitrile can also function in a formal sense as the nucleophilic component in the conjugate addition to

Methyl Vinyl Ketone depicted in eq 6.[10] However, this transformation also occurs by way of conjugate addition of methoxide to this reagent, followed by reaction of the derived allylic nitrile anion with methyl vinyl ketone and base-induced ejection of methoxide to deliver the observed product.

(6)

Transformations Involving Radical Addition to 2,3-Butadienenitrile.

Several transformations in which radicals add to 2,3-butadienenitrile have been reported. For example, 1-adamantyl engages the central carbon in the reagent to provide a modest yield of the corresponding 2-substituted 2-butenenitrile (eq 7).[2] Related reactions are shown in eqs 8[11] and eq 9.[6]

(7)

99:1

(8)

61:39

(9)

Dipolar Additions of Nitrones to 2,3-Butadienenitrile.

Eq 3 formally constitutes a cycloadditive process involving this reagent. However, among cycloadditions involving 2,3-butadienenitrile, dipolar additions of nitrones are the most commonly encountered (eqs 10 and 11).[3] When the nitrone carries a sterically demanding group on the nitrogen, *cis* stereoselectivity is eroded (eq 11).

(10)

(11)

A transformation reminiscent of eq 4 is illustrated in eq 12.[12] Formation of the nitrone occurs in situ, and initiates a sequence involving dipolar addition, [3,3]-sigmatropic rearrangement, and further transformation into the 2-vinylindole indicated through a one-pot procedure.

1,3-Butadienyl-2-lithium

[84531-04-4] · C_4H_5Li · 1,3-Butadienyl-2-lithium · (MW 60.02)

(reagent for carbon-carbon bond forming reactions with carbonyls[1,2] and α,β-alkenyl esters[3,4])

Preparative Methods: 1,3-butadienyl-2-lithium is synthesized by transmetalation of 1,2-butadienyl-2-tributyltin (eq 1)[1] or by the Shapiro reaction of 2,4,6-(*i*-Pr)$_3$C$_6$H$_2$SO$_2$NHN=CMeCH=CH$_2$ with ***Methyllithium*** (eq 2).[2] 3-Methyl-1,3-butadienyl-2-lithium has been prepared by lithium-bromine exchange.[5].

Analysis of Reagent Purity: 1,3-butadienyl-2-lithium is synthesized and used direclty without further isolation or purification.

Handling, Storage, and Precautions: use in a fume hood.

Reaction with Aldehydes and Ketones.

1,3-Butadienyl-2-lithium reacts with aldehydes and ketones. Dienyl carbinols are generally obtained as major products, along with small amounts of allenyl carbinols (eq 3). Compared with ***1,3-Butadienyl-2-magnesium Chloride***, a stronger

preference for dienyl products is observed (Table 1).[1]

Table 1 Reaction of 1,3-Butadienyl-2-lithium with Carbonyl Compounds

Carbonyl compound	Yield and selectivity (%) (diene/allene)	Selectivity by 1,3-butadienyl-2-magnesium chloride (diene/allene)
PhCHO	80 (91:9)	39:61
$Me(CH_2)_5CHO$	61 (100:0)	
PhCH=CHCHO	76 (19:1)	7:9
PhCOMe	70 (9:1)	19:81
PhCOPh	73 (1:1)	0:100

1,3-Butadienyl-2-lithium undergoes Michael addition to α,β-alkenyl esters. The reaction with methyl 2-(trimethylsilyl)propenoate affords the corresponding lithium enolate, which upon alkylation yields a series of α-silyl esters (eq 4).[3]

Treatment of the Michael adduct with an aldehyde followed by Peterson alkenation furnishes the dienyl α,β-alkenyl ester (eq 5).[4] Stereoselectivities of the products vary with the substrate (*E*/*Z* = ca. 3:1 to *Z* only).[4]

(5)

Substituted 2-lithiobutadienes which have been prepared include 3-methyl-,[5] 3-trimethylstannyl-,[6] 3-trimethylsilyl-,[6] 3-hexyl-,[6] and 4-methoxy-1,3-butadienes.[7]

Related Reagents.

1,3-Butadienyl-1-lithium

[4843-71-4] · C_4H_5Li · 1,3-Butadienyl-1-lithium · (MW 60.02) (*E*)

[91892-10-3]

(reagent for single-step introduction of the 1,3-butadienyl group)

Solubility: sol THF and ether.

Preparative Method: (*E*)-1,3-butadienyl-1-lithium was generated from (*E*)-butadienyltributylstannane and BuLi in hexane at -78 °C for 15 min.[1] Concentration of the reagent solution can be determined by titration.[2]

Handling, Storage, and Precautions: the reagent is moisture- and air-sensitive. All solvents must be dried before use.

1,3-Butadienyl-1-lithium Reagents.

A common approach for the preparation of the 1,3-butadienyl-1-lithium reagents is transmetalation of butadienyltrialkylstannanes with ***Methyllithium***[3] or ***n-Butyllithium***.[1,3-7] Rapid transmetalation proceeds with complete retention of diene configuration (eq 1). The butadienylstannanes are commonly prepared by hydrostannylation of alkynes,[3-5] or addition of (phenylthio)(trimethylstannyl)cuprate to alkynes.[3]

(1)

$R^1 = R^2 = H$; $R^1 = Me$, $R^2 = H$; $R^1 = H$, $R^2 = OEt$; $R^3 = Me$, Bu

A convenient method for the preparation of 4-alkoxy-[8a] and 4-silyloxy-1,3-butadienyl-1-lithium[8] derivatives is bromine-lithium exchange with ***t-Butyllithium*** (eq 2).

(2)

$R^1 = H, Me; R^2 = H, Me; R^3 = Et, SiMe_3$

Metal-halogen exchange between equimolar quantities of (*E*,*E*)-1-bromo-1-(trimethylsilyl)penta-1,3-diene and ***s-Butyllithium*** (THF-cyclohexane, -78 °C, 30 min) affords lithiated species (eq 3).[9]

(3)

Exchange of one bromine atom in unstable 1,4-dibromobutadiene occurs with *s*-BuLi (1 equiv) or *t*-BuLi (2 equiv) (eq 4), whereas the use of *n*-BuLi favors polymer formation.[10] Both bromine atoms are exchanged with an excess of *t*-BuLi (4 equiv).

(4)

1,3-Dienyl ethers are readily lithiated at C-1 using *t*-BuLi (R = Me),[11a] *s*-BuLi (R = MOM),[11b] or *n*-BuLi and ***Potassium t-Butoxide*** in THF (R = Me, Ph; diene:*t*-BuOK:*n*-BuLi ratio is 1:1.04:1.10).[11c] The butadienyl-1-potassium formed first is subsequently transmetalated. The metalation of ethers and (*E*)-dienylic sulfides occurs with retention of configuration (eqs 5 and 6), while in the case of (*Z*)-dienylic sulfides the structure of the products depends on both reaction conditions and the *S*-alkyl substituent: higher temperatures and more bulky thioalkyl groups promote inversion of configuration (eq 7).[11c]

(5)

(6)

(7)

Higher temperatures also promote side reactions (1,4-addition of BuLi) and tar production. Treatment of butadienyl monosulfides with alkyllithium (*n*-, *s*- or *t*-Bu) reagents in THF in the absence of *t*-BuOK gives insignificant metalation even in the presence of TMEDA (***N,N,N´,N´-Tetramethylethylenediamine***). The main reaction is 1,4-addition of R^2Li to the conjugated diene (eq 8). On the other hand, 1,4-bis(methylthio)buta-1,3-dienes are monolithiated with *n*-BuLi in THF-TMEDA mixtures at low temperature.[12] When (1*Z*,3*E*)-bis-sulfides are used, lithium is introduced exclusively at the (*E*) double bond (eq 9).

(8)

(9)

Reactions of 1,3-Butadienyl-1-lithium Reagents.

The 1,3-butadienyl-1-lithium reagents (4-lithio-1,3-pentadiene,[3,13] 1-alkoxy-,[11] and 1-alkylthio-1,3-butadienyl-1-lithium[11c]) react smoothly with a variety of electrophiles (halides, methyl thiocyanate, aldehydes, and ketones) and produce the corresponding substituted dienes (eqs 10 and 11).

(10)

(11)

RX = OMe, SMe, *t*-BuS, PhO

Electrophilic substitution at the lithiated carbon proceeds with retention of configuration. Yields of the substituted dienes are as high as 90% for methylation and 60-75% for alkylation with higher alkyl halides and carbonyl compounds.

Lithiobutadienyl alkyl and silyl ethers are suitable intermediates in the synthesis of polyethylenic aldehydes and ketones (eq 12). These are important building blocks in natural product synthesis (polyene and macrolide antibiotics and terpenes). Starting from (*E*)-lithiated ethers and aldehydes or ketones, exclusively (*E*)-isomers are obtained.[7,8] An exception is benzophenone, which gives some loss of stereochemistry.[8b] Yields of the dienols (dieno ketones) are 70-90%.

$R^1 = R^2 = H$; $R^5 = SiMe_3$, Et
$R^1 = Me$, $R^2 = H$; $R^1 = H$, $R^2 = Me$

(12)

The condensation of lithiated dienol ethers with conjugated carbonyl compounds and the hydrolysis of the intermediate adduct leads in one pot to polyconjugated ketones. Use of the lithiated dienol ether is recommended over that of the lithiodioxolane (eq 13).[8a]

Reaction of 1,3-butadienyl-1-lithium with chloro ketones is used for the sequential introduction of two neighboring 1,3-butadienyl groups on a cyclohexane ring (eq 14).[4,6] The silylated product undergoes thermal [5,5]-sigmatropic rearrangement to form a macrocyclic enol ether, giving cyclotetradecatrienone after hydrolysis.[1]

A mixed cuprate derived from a lithiodiene and *n*-PrC&tbond;CCu in ether-$(Me_2N)_3P$ reacted with an unsaturated ketone to yield the 1,4-addition product (eq 15).[5]

(15)

Lithiated 1,3-butadienyl 1,4-disulfides can be alkylated or cyclized to form thiophenes, depending on reaction conditions (eq 16).[12]

(16)

1,3-Butadienyllithium derivatives are suitable intermediates for transmetalation reactions (eqs 17 and 18). The 1-trimethylsilyl-1,3-pentadienyl-1-lithium is transmetalated to the corresponding magnesium derivative by interaction with freshly prepared ***Magnesium Bromide*** (obtained from the reaction of Mg with $BrCH_2CH_2Br$ in 3:1 ether-benzene solvent).[9] The reaction of cyclopentadienyldicarbonyliron iodide with 4-bromobutadienyl-1-lithium proceeds with the retention of configuration.[10]

(17)

(18)

Related Reagents.

1,3-Butadienyl-2-lithium; ***1,3-Butadienyl-2-magnesium Chloride***; ***1,3-Butadienyl-1-magnesium Chloride***.

1,3-Butadienyl-2-magnesium Chloride

[32657-89-9] · C_4H_5ClMg · 1,3-Butadienyl-2-magnesium Chloride · (MW 112.84)

(reagent for a variety of carbon-carbon bond forming reactions with carbonyls, epoxides, and alkyl and aryl halides; precursor of organotin and organosilicon compounds via transmetalation reactions)

Analysis of Reagent Purity: the IR spectrum of a THF solution of 1,3-butadienyl-2-magnesium chloride showed a strong absorption of a conjugated diene at 1600 cm^{-1}. A butadienyl, rather than allenyl, structure is also indicated by the ^1H NMR spectrum.[1] The concentration of 1,3-butadienyl-2-magnesium chloride is determined by titration with 1 M HCl.

Preparative Method: 1,3-butadienyl-2-magnesium chloride is synthesized by Grignard reaction of 4-chloro-1,2-butadiene with ***Magnesium*** in ether (eq 1)[1] or 2-chloro-1,3-butadiene (chloroprene) with magnesium in the presence of ***1,2-Dibromoethane*** and a catalytic amount of ***Zinc Chloride*** in THF (eq 2).[2] The experimental procedure is as follows: to a flask equipped with a mechanical stirrer under nitrogen were charged magnesium turnings, well activated by scratching (0.15 mol), 0.5 mL of 1,2-dibromoethane, and 5 mL of THF. On cooling, $ZnCl_2$ (3 mol%) was added. To this mixture was added a small amount of freshly distilled chloroprene (ca. 1 g), and the solution was stirred vigorously with heating until initiation occurred. Several drops of dibromoethane may be added to assist initiation. After initiation occurred, chloroprene (100 mmol) in THF (100 mL) was added dropwise at a rate to maintain gentle reflux. An additional 3 h of reflux ensured complete reaction. 1,3-Butadienyl-2-magnesium chloride is generally used directly for further reactions as the solution.

Carbon-Carbon Bond Forming Reactions.

1,3-Butadienyl-2-magnesium chloride is suitable for a variety of carbon-carbon bond forming reactions with carbonyl compounds,[3] epoxides, and alkyl and aryl halides.[4] The reaction generally gives a mixture of regioisomers. The selectivity depends significantly upon the substrate, solvent (as well as co-solvent) and additive. When the dienyl Grignard reagent is treated with acetaldehyde, the reaction affords an 84:16 mixture of 1,3-dienyl alcohol and allenyl alcohol (eq 3).

1,3-Butadienyl-2-magnesium chloride also induces the ring opening of epoxides and Michael reactions (eq 4). 1,3-Butadienyl-2-magnesium chloride reacts with alkyl halides to yield the corresponding alkylated products, which are available for intra- and intermolecular Diels-Alder reactions. The cross-coupling reaction with alkyl and aryl halides proceeds in the presence of catalytic ***Dilithium Tetrachlorocuprate(II)*** or Pd^0, as shown in eq 5.

Transmetalation.

Treatment of 1,3-butadienyl-2-magnesium chloride with ***Dichlorodimethylsilane*** gives, via transmetalation, the corresponding 2-silylated butadiene, which is an intermediate for the preparation of a monomer of side-chain liquid

crystalline polymers.[5] The reaction of 1,3-butadienyl-2-magnesium chloride with ***Tri-n-butylchlorostannane*** affords a 1,3-butadienyl-2-stannyl compound and with ***Benzeneselenenyl Chloride*** gives 2-phenylseleno-1,3-butadiene (eq 6).[6,7] The former is a useful precursor for ***1,3-Butadienyl-2-lithium***.[6]

Related Reagents.

1,3-Butadienyl-2-lithium; ***1,3-Butadienyl-1-lithium***; ***1,3-Butadienyl-1-magnesium Chloride***.

1,3-Butadienyl-1-magnesium Chloride

[114073-55-1] · C_4H_5ClMg · 1,3-Butadienyl-1-magnesium Chloride · (MW 112.84) (*E*)

[112564-81-5] (*Z*)

[112564-82-6]

(reagent for single-step introduction of the terminal 1,3-butadienyl group to various organic skeletons)

Solubility: sol THF, dioxane, DMF, 1,2-diethoxyethane, diethylene glycol dimethyl or diethyl ether, as well as in combinations of these solvents with aliphatic (*n*-hexane, *n*-octane) or aromatic (benzene, xylene) hydrocarbons.[1]

Preparative Method: [2,3] a mixture of ***Magnesium*** (24 g, 1.0 mol) and zinc chloride (6.8 g, 0.05 mol) was dried at 130 °C for 2 h under vacuum. Dried THF (30 mL) and ***1,2-Dibromoethane*** (2.0 mL) were added and the mixture was stirred vigorously under an argon atmosphere. After the exothermic reaction had subsided, the reaction mixture was diluted by additional THF (350 mL), and then a solution of 1-chloro-1,3-butadiene (44 g, 0.5 mol) and 1,2-dibromoethane (4 mL) in THF (70 mL) was added dropwise over 1 h and the mixture was heated under reflux for 2 h. The concentration of the reagent solution is determined[4] by titration using 1,10-phenanthroline as indicator. The average yield of 1,3-butadienyl-1-magnesium chloride was about 70%.

Handling, Storage, and Precautions: the reagent is moisture sensitive. Solvents must be carefully dried before use, and the preparation and reactions should be carried out under nitrogen or argon atmosphere.

Addition to Carbonyl Compounds.

Treatment of ketones or aldehydes with 1,3-butadienyl-1-magnesium chloride after hydrolytic work-up gave excellent yields of alcohols containing the 1,3-butadienyl group: 80-98% for aldehydes and aliphatic and alicyclic ketones, and approximately 70% for aromatic ketones and enones (eq 1).[1-3] In these reactions the initial stereochemical (*E*)/(*Z*) ratio, of the 1,3-butadienyl group of the Grignard reagent was found to be retained in the reaction products.

(1)

$R^1 = H$; $R^2 = n$-Hept, i-Pr, MeCH=CH-
$R^1 = Me$; $R^2 = Et$, Ph, Me
$R^1, R^2 = -(CH_2)_4-$, $-(CH_2)_5-$, $-(CH_2)_3-CH=CH-$

Butadienylmagnesium chloride usually reacts at the carbonyl group of conjugated ketones, whereas in the presence of ***Copper(I) Iodide*** (addition of 50 mol % CuI forms the butadienylmagnesium Cu^I complex), 1,4-addition is observed (eq 2).

(2)

Grignard analogs of higher 1,3-dienes (penta-, hepta-, octa-)[1] or their silylated derivatives (e.g. (*E*,*E*)-1 bromo-1-(trimethylsilyl)penta-1,3-diene)[5] react with carbonyl compounds in a similar manner (eq 3).

For the introduction of the butadienyl moiety, Grignard reagents are preferred to the lithium derivatives due to the lower basicity of the former. The silylated pentadienyl Grignard reagent in eq 3 was superior to both the precursor lithium reagent and pentadienyllithium itself.[5]

Coupling with Alkyl Halides.

The coupling of 1,3-butadienyl-1-magnesium chloride with alkyl bromides or iodides is catalyzed by CuI and proceeds under mild conditions (eq 4).[3] The stereochemistry of the dienyl moiety is retained in the reaction product. The coupling reaction with 5-bromo-2-methyl-1-penten-3-yne was accompanied by allene formation (eq 5).[6]

X = Br, I
R = Me(CH$_2$)$_4$, R^{1}O(CH$_2$)$_7$, Ph; R^1 = THP, Et

The configuration of the introduced butadienyl group corresponds to the configuration of the starting chlorobutadiene (for purification and isomerization of (*Z*)- and (*E*)-1-chlorobuta-1,3-dienes, see Onishchenko[7]). A mixture of (*Z*)- and (*E*)-isomers of the butadienyl derivatives obtained after reaction of butadienylmagnesium chloride with ketones and aldehydes could be transformed by the action of alkyllithium reagents, ***Dimethylphenylsilyllithium***, ***Trimethylstannyllithium***, or ***Lithium Diethylamide***, into the pure (*E*)-diene with simultaneous lengthening of the chain (eq 6).[2]

4-Substituted-(*Z*,*Z*)-butadienyl cuprates can be prepared by addition of cuprates to alkynes. These form 1,4-disubstituted (*Z*,*Z*)-butadienes with typical electrophiles (alkyl halides, enones, CO_2) (eq 7).[8]

Related Reagents.

1,3-Butadienyl-2-lithium; ***1,3-Butadienyl-1-lithium***; ***1,3-Butadienyl-2-magnesium Chloride***.

Butadiyne

(R = H)

[460-12-2] · C_4H_2 · Butadiyne · (MW 50.06) (R = $SiMe_3$)

[4526-07-2] · $C_{10}H_{18}Si_2$ · 1,4-Bis(trimethylsilyl)buta-1,3-diyne · (MW 194.42)

(butadiyne is an intermediate for synthesis of substituted 1,3-diynes.[1-3] The silylated derivative is used for Friedel-Crafts acylation,[5-7] for the synthesis of heterocycles,[8-11] and for the preparation of (*Z*)-methyl-1,4-bis(trimethylsilyl)-1-buten-3-yne derivatives;[12] hydrosilation gives access to vinylsilane derivatives;[13] trimethylsilylbuta-1,3-diynyllithium may be acylated or alkylated[14-17] and used in the synthesis of (*Z*)- or (*E*)-enyne derivatives[15,18,19])

Physical Data: R = H: mp -36 to -35 °C; bp 10 °C. R = $SiMe_3$: mp 107-108 °C.

Solubility: R = H or $SiMe_3$: sol most organic solvents.

Preparative Methods: R = H: from dehydrochlorination of 1,4-dichloro-2-butyne with sodium or potassium hydroxide.[4] R = $SiMe_3$: by dimerization of trimethylsilylacetylene under copper catalysis and in the presence of TMEDA.[5]

Handling, Storage, and Precautions: R = H: irritant, extremely flammable, and potentially explosive. Readily polymerizes above 0 °C. THF solutions can be stored for at least 3 d at -20 °C; storage of large quantities should be avoided. R = $SiMe_3$: stable white solid.

Alkylation and Acylation Reactions of Butadiyne.

Formation of the mono- or bis-sodium anion of butadiyne can be achieved directly from ***1,4-Dichloro-2-butyne*** with 3 or 4 equiv of sodamide.[1,2] This avoids isolation of the highly unstable parent compound. Alkylation or acylation in situ with alkyl halides or carbonyl compounds is then possible (eq 1). The mono- or bis-lithium anion can also be produced in situ by deprotonation and elimination of (*Z*)-1-methoxybut-1-en-3-yne with either 2 or 3 equiv of ***n-Butyllithium*** (eq 2).[3]

Conjugated Diynones.

1,4-Bis(trimethylsilyl)buta-1,3-diyne has been used in Friedel-Crafts acylation reactions under Lewis acid catalysis (eq 3).[5-7]

Diels-Alder Reactions.

1,4-Bis(trimethylsilyl)buta-1,3-diyne has been used with varying degrees of success as a dienophile in Diels-Alder cycloadditions (eq 4).[8-10]

Synthesis of Pyrazoles and Isoxazoles.

1,4-Bis(trimethylsilyl)buta-1,3-diyne has been used for the synthesis of pyrazoles and isoxazoles;[11] for example, reaction with ***Hydrazine*** gives the indicated pyrazole (eq 5).

(*Z*)-Methyl-1,4-bis(trimethylsilyl)-1-buten-3-yne Derivatives.

Zirconium catalyzed carbometalation of 1,4-bis(trimethylsilyl)buta-1,3-diyne with ***Trimethylaluminum*** followed by addition of electrophiles gives access to the title derivatives (eq 6).[12]

(6)

Vinylsilanes.

Hydrosilation of 1,4-bis(trimethylsilyl)buta-1,3-diyne gives access to a range of vinylsilane derivatives.[13]

Trimethylsilylbuta-1,3-diynyllithium.

Treatment of 1,4-bis(trimethylsilyl)buta-1,3-diyne with ***Methyllithium-Lithium Bromide*** selectively produces trimethylsilylbuta-1,3-diynyllithium (eq 7).[14] This reagent combines with various electrophiles to produce substituted 1,3-diynes (e.g eq 8).[15-17] The same anion can be synthesized from (*Z*)-4-trimethylsilyl-1-methoxybut-1-en-3-yne by deprotonation and elimination with 2 equiv of *n*-BuLi (eq 2).[3]

(7)

(8)

Hydrogenation.

Hydrogenation of siladiynes selectively reduces the triple bond which is furthest from the silicon protecting group, yielding silyl protected *cis*-enynes.[16,18] Formation of the corresponding *trans*-enyne derivatives is possible by hydroalumination.[7,17,19]

2,3-Butanediol[1]

[513-85-9] · $C_4H_{10}O_2$ · 2,3-Butanediol · (MW 90.12) (2*R*,3*R*)

[24347-58-8] (2*S*,3*S*)

[19132-06-0]

(resolution of enantiomers;[2] determination of enantiomeric purity by ^{13}C NMR;[3] asymmetric aldol reactions;[4] asymmetric cleavage of chiral acetals;[5] asymmetric β-elimination of chiral alkynic acetals;[6] asymmetric allylations;[7] cyclization of chiral dienic acetals;[8] enantioselective epoxidation;[9] diastereoselective cyclopropanation;[10] boronic ester homologation[11])

Physical Data: bp 179-182 °C; *d* 0.99 g cm^{-3}.

Solubility: sol H_2O, alcohol, ether, acetone.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: avoid breathing vapor. Avoid contact with eyes, skin, and clothing. Hygroscopic. Air sensitive. Store under nitrogen in a cool dry place.

Resolution of Enantiomers.

The availability of optically pure tartrate-derived diols has led to their widespread use in asymmetric synthesis. Mixtures of diastereomeric acetals prepared from (2*R*,3*R*)-(-)-2,3-butanediol are usually easily separated. Resolution of DL-camphor[12] was one of its earliest uses, but many nonracemic mixtures have been separated more recently.[2,13-15] Acetals prepared from this reagent also give distinct ^{13}C NMR spectra which can be interpreted to determine the enantiomeric purity of the starting ketones.[3,16-23]

Enantiomeric Monoacetalization of Diones.[24]

The acid-catalyzed monoacetalization of diones with (2*R*,3*R*)-(-)-2,3-butanediol forms a separable mixture of

diastereomeric acetals. Retro-Claisen fragmentation of the β-keto acetals with TsOH in benzene under reflux, followed by transesterification with methanol, provides a route to optically active 2,3-disubstituted cycloalkanones (eq 1).[24b]

Asymmetric Aldol Reactions.[4]

Acetals prepared from (2*R*,3*R*)-(-)-2,3-butanediol react cleanly with α-silyl carbonyl compounds in the presence of ***Tin(IV) Chloride*** to give the crossed aldol products with high ee (eq 2).[4b] The product can be converted into an optically active β-hydroxy ketone by Swern or ***Pyridinium Chlorochromate*** oxidation, Baeyer-Villager oxidation, and methanolysis in an overall yield of 70%. The asymmetric aldol reaction is also catalyzed by ***Boron Trifluoride***.

Diastereoselective Nucleophilic Addition.

(2*R*,3*R*)-(-)-2,3-Butanediol α-keto acetals react with Grignard reagents[25] with poor stereoselectivity, but reduction of β-keto acetals with ***Lithium Aluminum Hydride*** occurs with good de (eq 3).[26]

(3)

Asymmetric cleavage of chiral acetals by R_2CuLi/BF_3 gives the corresponding ring-opened products with high de (eq 4).[5] The diastereoselectivity of this ring opening is due to an unfavorable 1,3-diaxial interaction. A similar interaction in the β-elimination reaction of chiral alkynic acetals with Grignard reagents gives alkoxyallenes with very high de (eq 5).[6]

(4)

(5)

Asymmetric allylations of protected cyclopentenonecarbaldehydes proceed with high de. Subsequent anionic oxy-Cope rearrangement provides a convenient route to the prostaglandins (eq 6).[7]

(6)

Asymmetric Diels-Alder Reaction.[27,28]

The chiral aluminum diolates prepared from ***Ethylaluminum Dichloride*** and 2,3-butanediol catalyze the Diels-Alder reaction of methacrolein and cyclopentadiene in good yield, but the ee is very low. The catalyst prepared from (*S*)-1,1-diphenyl-1,2-dihydroxypropane gives superior results, with 74% ee.[27]

Intramolecular Cyclization.

The $SnCl_4$-catalyzed cyclization of dienic acetals derived from (2*R*,3*R*)-(-)-2,3-butanediol occurs with a high degree of asymmetric induction (eq 7).[8]

(7)

Enantioselective Epoxidation.

Asymmetric epoxidation of aliphatic alkenes with molybdenum(VI) (oxo-diperoxo) reagents in the presence of either (2*S*,3*S*)- or (2*R*,3*R*)-2,3-butanediol in nitromethane gives high ee, probably because of an efficient kinetic resolution of the oxiranes formed (eq 8).[9] This method makes possible asymmetric syntheses of epoxides not available by other routes (e.g. Sharpless epoxidation).

(8)

Diastereoselective Cyclopropanation.[10]

Diastereoselective Simmons-Smith cyclopropanation of 2-cyclohexen-1-one acetals of 2,3-butanediol occurs with good de (eq 9).[10a]

(9)

Boronic Ester Homologation.[11,29]

Dichloromethaneboronic esters of (2*R*,3*R*)-2,3-butanediol react with alkyllithium reagents to give a borate complex which rearranges diastereoselectively in the presence of ***Zinc Chloride*** with the introduction of a chiral center adjacent to boron (eq 10).[11a]

(10)

Substitution Reactions.

Both (2*R*,3*R*)- and (2*S*,3*S*)-2,3-butanediol have been used as starting materials for the preparation of optically pure compounds, such as (2*R*,3*R*)-***2,3-Bis(diphenylphosphino)butane***,[30] (2*S*,3*R*)-3-bromo-2-butanol,[31] and (*R*)-acetoin.[32]

2,3-Butanedione

[431-03-8] · $C_4H_6O_2$ · 2,3-Butanedione · (MW 86.09)

(cyclocondensations; reacts with Wittig reagents; condensations)

Alternate Name: biacetyl.

Physical Data: mp 2.4 °C; bp 88 °C/760 mmHg; *d* 0.981 g cm^{-3}; fp <21 °C.

Solubility: sol water (25 g/100 mL); miscible with alcohol and ether.

Form Supplied in: yellowish green liquid; quinone odor.

Purification: dried over anhydrous $CaSO_4$, $CaCl_2$, or $MgSO_4$, then vacuum distilled under nitrogen. The middle fraction is taken and stored at dry ice temperature in the dark (to prevent polymerization).

Handling, Storage, and Precautions: highly flammable, moderately toxic.

Cyclocondensations.

2,3-Butanedione (**1**) reacts with 1,3-dimethylurea in refluxing benzene containing 10% ***Trifluoroacetic Acid*** to form a bis adduct, 4,4´-methylenebis(1,3,5-trimethyl-4-imidazolin-2-one), whose structure has been confirmed by X-ray analysis (eq 1).[1]

Reaction of (**1**) with malononitrile catalyzed by ***Sodium Ethoxide*** furnishes the 1,5-dimethyl-3,7-dioxo-2,8-diaza-*cis*-bicyclo[3.3.0]octane-4,6-dicarbonitrile (eq 2).[2] On the other hand, ***Piperidine***-catalyzed condensation of (**1**) with 2-cyanacetamide forms 4,5-dimethyl-5-hydroxy-2-oxo-3-pyrrolinecarbonitrile (eq 3).[3]

Condensation of (**1**) with 4,5-diamino-2-thioxo-6-oxotetrahydropyrimidine,[4] 3,4-diamino-2-(methylthio)-5-cyanothiophene,[5] and amidrazone,[6] individually, affords 6,7-dimethyl-4-oxo-2-thioxotetrahydropteridine, 2-(methylthio)thieno[3,4-*b*]pyrazine, and triazine derivatives, respectively (eqs 4-6).

(4)

(5)

(6)

Condensation of (**1**) with an aldehyde (RCHO) in liquid ***Ammonia*** at 50-60 °C/20-25 atm furnishes the 4,5-dimethylimidazole (eq 7),[7] whereas condensation with ***Hydroxylamine*** or its HCl salt in EtOH forms the corresponding 4,5-dimethyl-1-hydroxyimidazole oxide (eq 8).[8]

(7)

(8)

Biacetyl (**1**) with dihydrazino thiophosphites in a 1:1 ratio forms thiophosphatetraazacycloheptadienes (eq 9),[9] whereas stirring with tris(trimethylsilyl) phosphite in benzene at rt furnishes the 3-trimethylsiloxy-2-butene-2-[bis(trimethylsilyl)] phosphate (eq 10).[10]

(9)

(10)

Reaction with Wittig Reagents.

2,3-Butanedione (**1**) undergoes the Wittig reaction with propylenetriphenylphosphorane to furnish a mixture of *cis*- and *trans*-3-methyl-3-hexen-2-ones in a 45:55 ratio (eq 11),[11] whereas stirring (**1**) with excess ***Cyanomethylenetriphenylphosphorane*** provides the bis Wittig adduct (*E*,*E*)-3,4-dimethylmuconononitrile (eq 12).[12]

(11)

(12)

Reaction of (**1**) with ***Diazomethane*** in ether containing excess methanol or 1 mol of ***Boron Trifluoride*** provides 2-methyl-1-epoxybutan-3-one (eq 13),[13] and with ***Diphenyldiazomethane*** furnishes 2-methyl-1,1-diphenyl-1,2-epoxybutan-3-one (eq 14).[14]

(13)

(14)

Reaction of (**1**) with *p*-cresol furnishes the benzofuro[3,2-*b*]benzofuran (eq 15).[15]

(15)

Condensation with Dimethyl 1,3-Acetonedicarboxylate.

The dione (**1**) undergoes the Weiss-Cook process with ***Dimethyl 1,3-Acetonedicarboxylate*** to form tetramethyl 1,5-dimethyl-*cis*-bicyclo[3.3.0]octane-3,7-dione-2,4,6,8-tetracarboxylate (eq 16) in excellent yield.[16]

(16)

Acid-catalyzed reaction of (**1**) with *cis*-1,2-cyclohexanediol forms normal mono- and diacetals, whereas stirring with *trans*-cyclohexanediol provides a different bisacetal, represented in eq 17.[17]

(17)

Reaction of (**1**) with 2 equiv of allylzinc, prepared from ***Allyl Bromide***, followed by acidic hydrolysis gives the γ-ethylenic α-hydroxy ketone (eq 18).[18]

(18)

Thermal-mediated reaction of (**1**) with 1,1-diethoxyethene gives 2,2-diethoxy-4-acetyl-4-methyloxetane (eq 19);[19] furthermore, (**1**) reacts with acetoxyphenylketene (generated in situ by reacting 2-acetoxyphenacyl chloride with ***Triethylamine*** in the cold) to give the β-lactone, which rearranges to a tricyclic orthoester lactone at temperatures above 130 °C (eq 20).[20]

(19)

(20)

Biacetyl (**1**) condenses with malonic acid in the presence of ***Titanium(IV) Chloride*** in pyridine-THF to furnish the α-carboxy-β,γ-dimethyl-γ-hydroxy-$\Delta^{\alpha,\beta}$-butenolide (eq 21),[21] a very useful precursor for the synthesis of eudesmane and certain elemane sesquiterpenes.

2-Butanone Ethylene Acetal

[126-39-6] · $C_6H_{12}O_2$ · 2-Butanone Ethylene Acetal · (MW 116.16)

(reagent for production of cyclic acetals by acid-catalyzed transacetalization[1])

Alternate Names: 2-methyl-2-ethyldioxolane; MED.

Physical Data: bp 116-117 °C; *d* 0.929 g cm^{-3}.

Solubility: miscible with organic solvents.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: the reagent is a flammable liquid; it is an irritant.

Transacetalizations.

The reagent (MED) has been employed for the syntheses of cyclic acetals from ketones as an alternative to ethylene glycol.[1] In the initial report of the reagent, superior selectivity in acetal formation over that observed with ***Ethylene Glycol*** was noted.[1] MED also has been reported to be superior to the analogous transacetalization reagent prepared from acetone (2,2-dimethyl-1,3-dioxolane).[1] The transacetalization reactions appear to be more subject to steric effects than to electronic effects.

Several general methods initially reported[1] have been used extensively. In a typical application, MED is employed in large excess, often as the solvent, although cosolvents such as benzene and CH_2Cl_2 have been employed. In some cases, acetalization reactions have been conducted with excess MED and a small amount of ethylene glycol. In cases where monoacetalization of a di- or polyketone is desired, a stoichiometric amount of MED may be employed, but monoacetalizations of diketones are usually conducted with excess MED. Reactions are generally run at reflux for several hours with ***p-Toluenesulfonic Acid*** (TsOH) as the catalyst. Hindered ketones have been acetalized employing MED as solvent at reflux for several days,[1] but some transacetalization reactions have been conducted over extended periods at rt.

The selectivity of transacetalizations with MED has been studied. Simple saturated ketones are acetalized more readily

than α,β-unsaturated ketones.[1] Thus the Wieland-Mischer ketone reacts with MED to give the monoacetal shown in eq 1 in 95% yield with 2% of the diacetal;[2] when the reaction was conducted with ethylene glycol, the monoacetal was produced in 78% yield, the diacetal was formed in 10% yield, and 12% of unreacted diketone remained. The enhanced reactivity of MED with simple ketones over that observed with α,β-unsaturated ketones can be used in a chemical separation scheme; for example, reaction of a 1:1 mixture of the saturated and unsaturated ketones shown in eq 2 with 0.5 equiv of MED in benzene at reflux with TsOH catalysis resulted in the acetal of the saturated ketone and unreacted unsaturated ketone as the only products observed.[3]

(1)

(2)

Steric and ring strain effects can overwhelm electronic effects in transacetalizations with MED. Thus a mixture of monoacetals was produced from the diketone shown in eq 3,[4] and transacetalization of Δ^4-androstene-3,17-dione with MED gave the monoacetal shown in eq 4.[1] The double bond migrations shown in these reactions are common for transacetalizations of α,β-unsaturated ketones with MED as they also are in ethylene glycol acetalizations. The product composition reflects the stability of the double bonds; for example, an equilibrium mixture of acetals was obtained from 2-cyclohexenone (eq 5).[5] An advantage of MED transacetalization of α,β-unsaturated ketones over direct ethylene glycol acetalization is seen in the 2-cyclohexenone reaction; when the acetalization was conducted with ethylene glycol, the mixture of unsaturated acetals was obtained with the ether product as a minor impurity.[5]

(3)

(4)

(5)

Monoacetalization of a 1,3-dione proceeds in good yields, as shown in eq 6.[6] In this reaction an eightfold excess of MED was used in CH_2Cl_2 solvent with ***10-Camphorsulfonic Acid*** as the catalyst.

(6)

The transacetalization reactions with MED appear to provide kinetic products as demonstrated in the transacetalization of Δ^4-androstene-3,16,17-trione (eq 7).[7] Reaction in the presence of excess MED with TsOH catalysis at reflux for 5 min gave monoacetal (**1**) in 66% yield. Slow distillation of the reaction mixture over 30 min gave (**1**),(**2**), and (**3**) in 7%, 30%, and 13% yields, respectively. Heating the reaction mixture at reflux for 5 h gave triacetal (**3**) in 43% yield.

(7)

a) $R^1 = -OCH_2CH_2O-$, $R^2 = R^3 = O$
b) $R^1 = R^2 = -OCH_2CH_2O-$, $R^3 = O$
c) $R^1 = R^2 = R^3 = -OCH_2CH_2O-$

α,β-Butenolide[1]

[497-23-4] · $C_4H_4O_2$ · α,β-Butenolide · (MW 84.07)

(can be transformed into derivatives of 2-furanol including esters[2] and silyl ethers;[3] provides 3-(1´-hydroxyalkyl)-2(5*H*)-furanones by regioselective aldolization;[4] undergoes highly regio- and stereoselective reactions with sulfinylallyl anions;[5] serves as keystone for the convergent assembly of lignans[6] and prostaglandin analogs[7] through tandem vicinal difunctionalization[8])

Alternate Names: γ-crotonolactone; 2(5*H*)-furanone; but-2-en-4-olide.

Physical Data: bp 86-87 °C/12 mmHg; mp 5 °C; *d* 1.185 g cm^{-3}. A pK_a value of 18.8 has been determined for its equilibrium acidity in DMSO (pK_{HA}), but this may not be correct.[9]

Solubility: sol most organic solvents, e.g. CCl_4, CH_2Cl_2, Et_2O, toluene, THF, MeOH, and MeCN.

Form Supplied in: colorless or pale yellow liquid, commercially available; expensive.

Preparative Methods: obtainable by oxidation of furfural[10] or by dehydrobromination of α-bromo-γ-butyrolactone[10a,11] at very low cost.

Handling, Storage, and Precautions: avoid contact with skin or eyes; do not inhale or ingest; vapor is irritating to the eyes and upper respiratory track. It should be stored at 4 °C or below. Use in a fume hood.

Tautomerism.

In the free state, isomerization of α,β-butenolide (**1**) to β,γ-butenolide (**2**) or 2-furanol (**3**) does not occur to any detectable amount (eq 1). According to MO calculations the order of decreasing stability is (**1**) > (**2**) > (**3**).[12] In practice, (**3**) may not even exist. On the other hand, (**2**) is easily prepared in multigram quantities although it isomerizes to (**1**) at a rate of 3% per month on standing at rt.[10a]

(1)

Derivatives of 2-Furanol.

Acid chlorides lacking α-hydrogens and alkyl chloroformates are converted into esters and carbonates by using ***Triethylamine*** as a base (eq 2).[2] Similarly, noncarbon electrophiles such as ***Phosphorus Oxychloride***[10b] and silylating agents[3] readily afford the corresponding furanol derivatives. 2-Trialkylsilyloxyfurans thus obtained (eq 3)[13] can be subsequently transformed into a variety of 5-substituted 2(5*H*)-furanones (see ***2-Trimethylsilyloxyfuran***).

(2)

(3)

Reactions of 2-Furanolates with Carbon Electrophiles.

The alkylation of α,β-butenolide by conversion to lithium 2-furanolate (***Lithium Diisopropylamide***/THF, -78 °C) and subsequent in situ reaction with prenyl bromide in the presence of HMPA, leads to a mixture of mono- and bis-α-alkylated lactones in low yield.[14] Under similar conditions, aldol condensation with aldehydes is only modestly regioselective, giving α- and γ-adducts in a 3:1 ratio.[15] In contrast, high regioselectivity and yields of 3-(1´-

hydroxyalkyl)-2(5*H*)-furanones are obtained with dialkylboron 2-furanolates (eq 4).[4] The α regioselectivity is explained by the intervention of a boron-containing six-membered chelate. This method has served as key step in the synthesis of the marine antimicrobial bromobeckerelide.[16]

(4)

In certain cases γ regioselectivity is also attainable. Thus base-induced condensation of α,β-butenolide with 5-aryl-2-furaldehydes affords 4-ylidenebutenolides (eq 5).[17] Likewise, alkali metal 2-furanolates undergo γ-selective conjugate addition to enones (eq 6).[18]

(5)

(6)

Bromination.

5-Bromo-2(5*H*)-furanones can be conveniently prepared from the corresponding α,β-butenolides by radical bromination (eq 7).[19] They are useful for the synthesis of alfatoxins[20] and other bioactive substances.[21] For an alternative viable method for preparing 5-bromo-2(5*H*)-furanones, see ***2-Trimethylsilyloxyfuran***.

(7)

Michael Acceptor.

A variety of carbon and noncarbon nucleophiles undergo conjugate addition to α,β-butenolides.[22] These include organocopper reagents,[23] stabilized carbanions,[24] amines,[25] and thiols[22,26] among others.[27] Ambident allylic anions derived from γ-substituted allyl sulfoxides add to butenolide in a highly regio- and diastereoselective manner (eq 8).[5a] The relative configuration at the allylic carbon in the product is determined by the geometry of the starting sulfoxide. A *trans*-decalyl-like transition state accounts for both the regio- and stereochemical features of this process.[5a] This chemistry has been applied to the synthesis of enantiomerically enriched β-alkyl-γ-butyrolactones (eq 9).[5b]

(8)

(9)

Tandem Vicinal Difunctionalization.

An initial conjugate addition of a nucleophile, and subsequent capture of the resulting enolate with a suitable electrophile, enables rapid introduction of two vicinal substituents.[6,8] The intermolecular process leads invariably to *trans*-α,β-disubstituted lactones (eqs 10 and 11).[6a,28] Moreover, when aldehydes are used as electrophiles, aldolization can be effected in a highly *syn* stereoselective fashion by using ***Zinc Bromide*** as additive (eq 11).[28] The intramolecular version of this process, known as type II Michael-initiated ring closure (MIRC), provides *cis*-fused lactones (eq 12).[29]

(10)

Not surprisingly, this methodology has been widely exploited for convergent access to various types of lignans[6,28-30] and prostaglandin analogs.[7] Applications to the synthesis of enantiomerically pure lignans have also been reported.[22,31]

Cycloaddition Reactions.

Although α,β-butenolide and its substituted analogs undergo various concerted reactions, such as Diels-Alder[32] and [2 + 2] cycloadditions,[33] relatively few synthetic applications are known.[34] A noteworthy example is the 1,3-dipolar addition to diazomethane.[23a,b] This process leads to pyrazolinolactones which on thermolysis afford the corresponding 4-methyl-2(5*H*)-furanones in good yields (eq 13).[23b,35] Thus replacement of the β hydrogen by a methyl group can be achieved in just two steps. Other substituents can be installed in this manner by selecting the appropriate diazoalkane, diazo ester or diazo ketone.[13,35]

Related Reagents.

γ-Butyrolactone; ***Dihydro-5-(hydroxymethyl)-2(3H)-furanone***; ***(R)-Pantolactone***; ***β-Propiolactone***; ***2-Trimethylsilyloxyfuran***; ***β-Vinyl-α,β-butenolide***.

3-Butenyl-1-magnesium Bromide

[7103-09-5] · C_4H_7BrMg · 3-Butenyl-1-magnesium Bromide · (MW 159.31)

(nucleophilic Grignard reagent used as a synthetic equivalent of the 3-butenyl anion)

Solubility: normally prepared in THF and used in situ.

Handling, Storage, and Precautions: Grignard reagent sensitive to moisture. Normally prepared and used immediately.

Nucleophilic Additions.

This reagent, like the analogous organolithium reagent, is employed in synthetic chemistry as a synthetic equivalent of the 3-butenyl anion and also as a synthon for the 3-oxopropyl anion. The reagent is normally used in ether solvents, typically diethyl ether or THF, and is readily prepared under standard conditions for Grignard reagent formation by dropwise addition to ***Magnesium*** turnings, with external cooling following reaction initiation. Four principal types of addition reaction are seen: addition to carbonyl groups and their various derivatives, conjugate addition to α,β-unsaturated ketones, displacements of halides and other leaving groups from alkyl or even aryl substrates, and addition to epoxides with ring cleavage. Metal-metal exchange is also observed.

Addition to prochiral carbonyl groups of aldehydes and ketones is common, as in the representative examples shown in eqs 1-4,[1-4] and often takes place with high stereoselectivity. Interestingly, addition to ***γ-Butyrolactone*** takes place successfully to give the hemiacetal (eq 5).[5] In contrast, simple esters have been shown to undergo double addition leading to carbinols; this property has been utilized in a clever synthesis of functionalized dienes by use of α-silyl-β,γ-unsaturated esters as substrates; an in situ Peterson elimination then takes place upon alkoxide formation to give the conjugated dienes (eq 6).[6] *N,O*-Dimethylhydroxamates have been used to limit nucleophilic addition to 1 equiv of reagent, giving the ketonic product.[7]

(5)

(6)

Imines are also successful substrates for the copper-catalyzed addition of 3-butenylmagnesium bromide in the presence of Lewis acids (eq 7). The δ,ε-unsaturated amine products may be cyclized by intramolecular aminoselenation to produce pyrrolidine derivatives.[8]

(7)

Copper-catalyzed conjugate addition is an equally general and successful procedure, and was employed by Ley in his synthesis of ajugarin I in a highly stereoselective reaction (eq 8).[9] In this case it was essential to add the enone, in ethereal solution, dropwise to a solution of the organometallic. Corresponding reactions with similar oxoacetals are much less stereoselective.[10] Other representative examples are given in eqs 9-11.[11-14]

(8)

(9)

(10)

(11)

There are relatively few examples of nucleophilic substitution reactions involving this reagent. Whiting has reported

the efficient displacement of a secondary pivaloyloxy group (eq 12),[15] and an interesting displacement of chloride from an α-chlorinated glycine derivative is shown in eq 13.[16] The reagent has also been used at -20 °C for selective aromatic nucleophilic substitution of one cyanide group from tetrafluoroterephthalonitrile in 60% yield.[17]

The corresponding addition to epoxides can be very efficient. For example, addition to (*R*)-(-)-1-nonene oxide in the presence of ***Copper(I) Bromide*** occurs at -10 °C to give the enantiomerically pure secondary alcohol in 90% yield (eq 14),[18] and the THP ether of glycidol undergoes addition under similar conditions, again in 90% yield (eq 15).[19]

3-Butenyl-1-magnesium bromide has also been used to generate the corresponding organozinc species by metal exchange using ***Zinc Chloride***. The organozinc species was used in enantioselective addition to aldehydes catalyzed by a spirotitanate derived from (*R*,*R*)-tartaric acid.[20]

Although 3-butenylmagnesium bromide is known to be in equilibrium with small amounts of cyclopropylmethylmagnesium bromide,[21] cyclopropyl products are not observed.

Related Reagents.

2-(2-Butenylthio)benzothiazole

[89805-98-1] · $C_{11}H_{11}NS_2$ · 2-(2-Butenylthio)benzothiazole · (MW 221.37)

(allylic electrophile which allows efficient control of the chemo-,[1] regio-, and stereoselectivity[2,3] in the C-C coupling process by reaction with organocopper reagents)

Solubility: sol all solvents except water.

Form Supplied in: white oils or solids; not commercially available.

Preparative Methods: 2-allyloxybenzothiazoles are prepared by reaction of potassium allyloxides with 2-chlorobenzothiazole in dry ether at rt.[2] 2-Allylthiobenzothiazoles are prepared by reaction of allylic alcohols with 2,2´-dithiobis(benzothiazole) and triphenylphosphine or with benzothiazole-2-thiol, diethyl azodicarboxylate, and triphenylphosphine in dry toluene at rt.[3]

Handling, Storage, and Precautions: store at 5 °C. Safety and handling data not available.

2-Allylthiobenzothiazoles.

The reaction of these substrates with organocopper reagents, prepared by reaction of Grignard reagents with ***Copper(I) Bromide***, leads to C-C coupling products (eq 1).

2-(2-Butenylthio)benzothiazole

Efficient regiocontrol of this process (α- or γ-substitution) depends on the nature of the organometallic reagent. High ratios of RMgX:CuX, which favor the formation of organocuprates, give only α-substituted products, whereas lower ratios, which favor the formation of organocopper reagents RCu, afford exclusively γ-substituted products (eq 2).[3] γ-Substitution occurs independently of the steric hindrance of the R^2 group in the allylic sulfide (eq 3).

These features have been applied to a simple synthesis of California red scale pheromone[4] starting from the

benzothiazole sulfide/benzyl ether of (*S*)-(-)-citronellol (eq 4).

Stereodivergent pathways relative to other allylic systems (e.g. allylic acetates)[5] have been found[6] in the reactions of cyclic allylic sulfides or ethers of benzothiazole with organocopper reagents. In this case the S_N2' process occurs with *syn* stereochemistry (eq 5) and is due to the anchimeric coordination of the organometallic reagent with the heterocyclic moiety. This has been utilized for regio- and stereocontrolled access to branched-chain sugars.

The importance of coordination in dictating the stereo- and regioselectivity is further demonstrated[7] by the reactions of α,β-enoates γ-substituted by a *S*-benzothiazolyl group with organocopper reagents to give, in a anti-Michael fashion, α-alkylated-β,γ-enoates (eq 6).

2-(2-Butenylthio)benzothiazole

The control of chemo-, regio-, and stereochemistry in the reactions of allylic electrophiles with two different leaving groups with organocopper reagents is difficult to achieve since many chemo-, regio-, and stereochemical reactions occur together with the desired one.[8] These difficulties can be overcome by using the benzothiazolyl group as one of the leaving groups which is selectively replaced. This has been used for a synthesis of homoallylic pivalates (eq 7).[1]

2-Allyloxybenzothiazoles.

Coupling of these reagents with allylic Grignard reagents in the presence of CuBr allows regioselective synthesis of 1,5-dienes, thus overcoming the difficulties found for different allylic electrophiles.[9] The C-C coupling occurs exclusively in a head-to-tail fashion. Contrary to this the same electrophiles, when complexed with CuBr before the addition of the allylic Grignard reagent, give only 1,5-dienes derived from head-to-head coupling process (eq 8).[10]

t-Butoxyacetylene

[89489-28-1] · $C_6H_{10}O$ · *t*-Butoxyacetylene · (MW 98.16)

(thermal and Cu^I-catalyzed dimerization;[1] synthesis of silylketenes;[2] synthesis of macrocyclic lactones via ketene intermediates[3])

Physical Data: bp ca. 23 °C/22 mmHg.

Solubility: sol organic solvents.

Form Supplied in: pale yellow liquid.

Analysis of Reagent Purity: ^{1}H NMR, ^{13}C NMR, IR, and gas chromatography.

Preparative Methods: bromination of ethyl vinyl ether and displacement by *t*-butanol provides a mixed acetal (eq 1); substitution of ethoxy by chloride and dehydrochlorination then gives rise to β-bromovinyl ether (eq 2), which upon dehydrobromination with base generates *t*-butoxyacetylene (eq 3).[4] The overall yield from ethyl vinyl ether is 34%. This substance has also been prepared by bromination of *t*-butoxy vinyl ether followed by stepwise elimination of HBr.[5] The preparation of *t*-butoxyacetylene from an appropriate 1-chloro-1-fluoroalkene has also been reported.[6]

(1)

(2)

Purification: distillation at 23 °C/0.5 mmHg, collecting material at -78 °C, followed by redistillation at 23 °C/22 mmHg, collecting at 0 °C.

Handling, Storage, and Precautions: *t*-butoxyacetylene should be used as distilled for best results (clear liquid). It turns pale yellow upon storage at -10 °C (freezer) and is stable for a few months under these conditions.

Dimerization.

The Cu^I-catalyzed oxidative dimerization of *t*-butoxyacetylene under modified Hay conditions has been found to proceed smoothly (eq 4).[1a] The resulting 1,4-di-*t*-butoxy-1,3-butadiyne is interesting with respect to its polymerization properties. The controlled polymerization of *t*-butoxyacetylene via tungstacarbene compounds has been reported.[7] Thermal dimerization of *t*-butoxyacetylene under mild conditions, so that the generated low concentration of the parent ketene prevents its oligomerization, provides 3-*t*-butoxycyclobutenone in good yield (eq 5) which in turn can be hydrolyzed to 1,3-cyclobutanedione.[1b]

Synthesis of Silylketenes.

The *C*-silylation of *t*-butoxyacetylene has been achieved by deprotonation and subsequent silylation (eq 6).[2] Thermally induced elimination of isobutylene from these derivatives via a retro-ene type rearrangement delivers silylketenes at much lower temperature than from the corresponding ethoxyacetylene compounds (eq 7).[8] In the case of 1-*t*-butoxy-2-(trimethylsilyl)acetylene, thermolysis at 50-55 °C in the presence of diphenylamine provided *N*,*N*-diphenyl(trimethylsilyl)acetamide in high yield (eq 8).[2] The *C*-alkylation of *t*-butoxyacetylene can be carried out in a similar manner.[3a,4]

(6)

R = Me, *t*-BuMe$_2$, *t*-BuPh$_2$

(7)

R = *t*-BuMe$_2$, *t*-BuPh$_2$

(8)

Macrocyclic Lactones.

Addition of substituted *t*-butoxyacetylene derivatives to refluxing MeCN and ***Triethylamine*** under high-dilution conditions produces macrocyclic lactones in 57% yield via a ketene intermediate (e.g. eq 9).[3a] Similar lactonizations are shown in eqs 10 and 11. As indicated, the cross-coupling of *t*-butoxyacetylene with conjugated enynes (eq 10) is more efficient than that with simple alkynes (eq 11).[3b]

t-Butoxybis(dimethylamino)methane[1]

(**1**; R = *t*-Bu) (*t*-BAE)

[5815-08-7] · $C_9H_{22}N_2O$ · *t*-Butoxybis(dimethylamino)methane · (MW 174.33) (**2**; R = Me) (MAE)

[1186-70-5] · $C_6H_{16}N_2O$ · Methoxybis(dimethylamino)methane · (MW 132.24)

(aminal esters reactive as aminomethylenating reagents (formylating reagents) for CH_2- and NH_2-acidic compounds. The *t*-butyl analog is somewhat more reactive than the methyl derivative; bis(dimethylamino)carbene can be generated from both compounds)

Alternate Name: Bredereck's reagent.

Physical Data: (**1**) bp 50-52 °C/12 mmHg; *n*20D = 1.4250. (**2**) bp 128 °C/760 mmHg; 32-33 °C/25 mmHg; *n*20D = 1.4158.

Solubility: miscible with nonpolar aprotic waterfree solvents (benzene, toluene, cyclohexane, diethyl ether, etc.); react with protic solvents like water (hydrolysis to DMF) or alcohols (alcoholysis affords DMF acetals). Even common solvents like acetonitrile or acetone which are weakly CH-acidic react with the aminal esters on heating.

Form Supplied in: colorless to weak yellow, strong amine-smelling liquids.

Analysis of Reagent Purity: the best method is ^{1}H NMR spectroscopic examination of a neat sample.

Handling, Storage, and Precautions: both compounds should be handled in a fume hood, with strict exclusion of atmospheric moisture. They should be stored in tightly sealed containers in a refrigerator under an atmosphere of dry nitrogen or argon.

Introduction.

Alkoxybis(dimethylamino)methanes can be obtained in good yields from *N*,*N*,*N*´,*N*´-tetraalkylformamidinium salts and alcohol-free alkoxides.[2] The reactions have to be conducted in inert, strictly anhydrous solvents like cyclohexane,

hexane, ether, or THF, in which unfortunately both reagents are insoluble. As a consequence it is necessary to use relatively large amounts of the solvent and long reaction times (eq 1). In the patent literature it is claimed that by the use of a mixture of DMF and mesitylene as solvent, the yields can be improved to about 95%.[3]

(1)

X	R	Solvent	Reaction time (h)	Yield (%)
$MeSO_4$	Me	Ether	1-2	62
$MeSO_4$	*t*-Bu	Cyclohexane	1-2	70
Cl	*t*-Bu	Ether	24	75

In another method,[4] bis(dimethylamino)acetonitrile is used as the starting compound. Alcohol-free alkoxides suspended in absolute ether substitute the cyano group to give the corresponding aminal ester (eq 2). In contrast to the aforementioned method, less solvent and shorter reaction times are needed because the nitrile is soluble in ether and the product yields are normally 5-20% higher.

(2)

The purity and stability of the product are determined by the quality of the metal alkoxide. Traces of alcohol catalyze the disproportionation of the aminal ester to the corresponding DMF acetal and tris(dimethylamino)methane (eq 3),[5] which may complicate spectroscopic investigations. For preparative purposes the disproportionation reaction can be disregarded; at higher temperatures the orthoamides interconvert very rapidly to the aminal ester, and usually the condensation reactions of aminal esters are not affected by the equilibrium.

(3)

Reactions.

The reactivity of aminal esters is very similar to that of ***Tris(dimethylamino)methane***. In the first step of the reaction the compounds dissociate, forming strong basic alkoxide anions which set up an equilibrium with the XH_2-acidic compounds (eq 4). The HX^- anions thus formed combine with the formamidinium ions. β-Elimination of dimethylamine from the adduct is the final step of the condensation reaction.

Because of their high reactivity with XH_2-acidic compounds, aminal esters have found widespread application as formylating reagents; especially with CH_2-acidic ketones such as simple dialkyl ketones,[6-9] aryl alkyl ketones,[6,10-16] heteroaryl alkyl ketones,[17-19] 1-alkenyl alkyl ketones,[20] α-dialkylamino ketones,[21] α-glycosyl alkyl ketones,[22] cycloalkanones,[10,11,16,20,23 -28] 4-piperidinones,[29] and steroidal ketones.[30,31] If an additional acidic functional group is present (e.g. an NH_2 group), this may also be aminomethylenated by the reagent,[10] in some cases accompanied by ring closure.[32] The resulting difunctional compounds formed have been transformed into various types of product. Eqs 5-11 give an overview of these applications.[6-27,32]

(11)

This type of condensation reaction of aminal esters may proceed with even weaker CH-acidic compounds (eq 12), such as esters[33-35] which have in the α-position, amino,[21,36-39] alkoxy[21,40] and heteroaryloxy,[39] thio,[21,39] phosphonyl,[41] and silyl groups.[41] Aminomethylenation reactions have also been reported for the following functionalities or compound classes: lactones,[33,42-51] α,β-unsaturated esters[38,52] and lactones,[53] thioesters,[33] imidates,[41] isocyanides[41] and nitriles,[6,21,41] amides[33] and lactams,[27,33,54-58] cyclic imides,[55,59] thioamides[33] and thiolactams,[33,60] amidines,[41] amidinium[41] and phosphonium salts,[61,62] phosphonates,[41,62] ketone hydrazones,[63,64] cyclopentadienes,[60-67] xanthene,[68] toluenes,[68-73] nitroarenes,[74] 2-methyl-1-pyrroline *N*-oxides,[75] 2-alkyl-5-nitroimidazole,[17] 4-methylpyridine,[68,73,76,77] methylpyrimidines,[68,77-79] 3-methylpyridazine,[78,80] 2-methylpyrazine,[78] 2-pyridones,[81] 1,3,4-thiadiazoles,[82] 1,4-dihydro-4-oxo-1,8-naphthyridine,[83] pyrimidine acids[84] and esters,[85] 3-arylidenebenzothiazines[86] and 3-methyl-1,2,4-triazines.[87]

(17)

Compounds containing two acidic CH_2 groups can be formylated once or twice; examples of this type of reaction have been demonstrated with dinitriles,[59,88] 1,2-bis(phenylsulfonyl)ethane,[21] 2,2-dimethyl-1,3-cyclopentanedione,[59] 5,10-dihydroindeno[2,1-*a*]indene,[67] ethyl 4-oxoglutarate,[59] diethyl succinate,[59] diethyl adipate,[59] diethyl tetrathioadipate,[59] *N*-alkylsuccinimides,[59] and *N*-alkylglutarimides.[59] NH_2-Acidic compounds react with aminal esters analogously to CH_2-acidic compounds, i.e. the nitrogen atom is aminomethylenated. A few amides have been converted to the corresponding acylamidines (eq 18).[33,89] This condensation reaction is of less importance, because the same results can be achieved with the more accessible DMF acetals.

(18)

Since the primary condensation products from amides still contain an acidic methylene group, further formylation can occur (eq 19).[33] Similar results were obtained in the formylation of diethyl aminomethylphosphonate (eq 20).[90]

(19)

(20)

If two acidic functions of the type XH_2 and XH are present in suitable positions, the condensation reaction can be used for ring closure (eq 21).[91] In some cases the desired condensation reaction is accompanied by transformations of other functional groups present in the molecule (eqs 22 and 23).[77,92]

(21)

Weakly acidic heteronucleophiles substitute for the alkoxy group in aminal esters. Thus hydrocyanic acid,[83] terminal alkynes,[93] and thiols[94] afford cyano, alkynyl, and alkylthio aminals (eq 24). With secondary amines the substitution of the alkoxy group is accompanied by a transamination to give tris(dialkylamino)methanes (eq 25).[95] The alcoholysis of aminal esters proceeds very similarly, giving rise to the formation of DMF acetals,[4,84] whereas phenols are formylated in the 4-position. *N*-Monosubstituted formamides are converted by *t*-BAE to *N*,*N*′,*N*′-trisubstituted formamidines (eq 26).[38,43]

(25)

(26)

With stronger CH-, NH-, or OH-acidic compounds such as phenols bearing electron-attracting groups,[1c] imides of dicarboxylic acids,[59] tertiary CH-acidic acids,[93] and extremely strong CH_2-acidic compounds,[96] as well as mineral acids, the aminal esters act as a base to give formamidinium salts (eq 27).

(27)

The strong basicity of *t*-BAE is exploited in the synthesis of methylenedioxybenzenes from catechols and dichloromethane.[97] Electrophilic reagents such as acyl cyanides,[98] acyl azides,[99] CS_2,[1c] isothiocyanates,[100] and *N*-chloroamides[101] undergo a variety of unusual reactions with aminal esters. Although the mechanisms of these interesting reactions have been investigated thoroughly, they are - with a few exceptions - of less importance in the preparative sense because the resulting products are often obtainable with better yields from DMF acetals. Eq 28 gives three examples.

The reaction of *t*-BAE with Schiff bases of aromatic aldehydes, heteroaromatic aldehydes, and benzalazines at temperatures of about 160 °C represents a valuable synthesis of 1,1,2-triaminoethylenes and 1,1-diaminoethylenes (eq 29).[102] The reaction of *t*-BAE with aromatic aldehydes affords mixtures which are not easy to separate (eq 30).[103] 1,2-Diaminoethylene derivatives were isolated from reactions with *p*-tolyl- and anisaldehyde.[104]

(30)

Heating selenium and *t*-BAE produces *N,N,N´,N´*-tetramethylselenourea.[105] Oxidation of MAE with peroxides affords *N,N,N´,N´*-tetramethylurea,[106,107] whereas with dibutyldiborane *N,N,N´,N´*-tetramethylformaldehydaminal is formed.[108] Formamidinium (dimethylcarbamoyltetracarbonyl)ferrate is obtained from ***Pentacarbonyliron*** and aminal esters (eq 31).[108]

(31)

Related Reagents.

N,N-Dimethylformamide; ***N,N-Dimethylformamide Diethyl Acetal***; ***Tris(dimethylamino)methane***; ***Tris(formylamino)methane***; ***Dimethylchloromethyleneammonium Chloride***.

4-*t*-Butoxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one[1]

(5*R*,6*S*)-(R = *t*-Boc)

[112741-50-1] · $C_{21}H_{23}NO_4$ · 4-*t*-Butoxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one · (MW 353.45) (5*S*,6*R*)-(R = *t*-Boc)

[112741-49-8] (5*R*,6*S*)-(R = Cbz)

[105228-46-4] · $C_{24}H_{21}NO_4$ · 4-Benzyloxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4*H*-oxazin-2-one · (MW 387.46) (5*S*,6*R*)-(R = Cbz)

[100516-54-9]

(chiral glycine enolate equivalent useful for the preparation of α-substituted α-amino acids and α,α-disubstituted α-amino acids in high enantiomeric excess[2,3])

Alternate Name: t-butyl 6-oxo-2,3-diphenyl-4-morpholinecarboxylate.

Physical Data: R = *t*-Boc: mp 206 °C. R = Cbz: mp 205 °C.

Solubility: sol THF, CH_2Cl_2.

Form Supplied in: commercially available as the individual enantiomers or as racemates.

Preparative Method: via a three-step procedure from *erythro*-2-amino-1,2-diphenylethanol.[4]

Handling, Storage, and Precautions: no special handling required.

α-Substituted α-Amino Acids.

The *N*-protected 5,6-diphenyl-2,3,5,6-tetrahydrooxazin-2-ones serve as chiral nucleophilic glycine equivalents by deprotonation at C-3 to give the corresponding enolates.[2,3] The enolates are formed using ***Lithium Hexamethyldisilazide*** or ***Sodium Hexamethyldisilazide*** in THF at low temperature.[2] Alkylation is best achieved by addition of the base to a solution of the oxazinone and electrophile in THF-HMPA (10:1) at -78 °C (eq 1)[2a] or by formation of the sodium enolate in the presence of ***15-Crown-5*** at -78 °C and subsequent addition of the electrophile (eq 2).[3] Alkylation takes place with very high stereoselectivity to afford the C-3 modified oxazinone with the new substituent oriented *anti* to the C-5 and C-6 phenyl groups.[2]

The amino acid is released by scission of the benzylic carbon-heteroatom bonds, generally via a reductive process.[2-5] Hydrogenolysis and dissolving metal reduction of the Cbz-protected oxazinone gives the amino acid zwitterion directly (eq 3). The *t*-Boc protected oxazinone undergoes dissolving metal reduction to give the *t*-Boc amino acid (eq 4). Alternatively, the *t*-Boc group can be removed from the oxazinone by treatment with ***Iodotrimethylsilane*** or ***Trifluoroacetic Acid*** and the resulting compound can then be hydrogenated to afford the amino acid zwitterion. Amino acids possessing alkyl, allyl, (ethoxycarbonyl)methyl, hydroxyalkyl, o-aminoalkyl, and methyl-β-D-ribofuranose functionality have been prepared via this enolate chemistry.[2,3,6,7]

(3)

(4)

α,α-Disubstituted α-Amino Acids.

The 3-alkyloxazinones also undergo enolization and subsequent alkylation to afford, upon deprotection, α,α-dialkyl α-amino acids.[2a,3,8,9a] Again, the newly introduced alkyl group is oriented *anti* to the phenyl groups of the oxazinone. Alkylation by addition of the base to a solution of the oxazinone and electrophile works only with allylic and benzylic halides and can require as much as 2-5 equiv of ***Potassium Hexamethyldisilazide*** (eq 5).[2a,8] Alternatively, formation of the sodium enolate in the presence of 15-crown-5 followed by addition of the electrophile permits coupling of the enolate even to simple alkyl halides (eq 6).[3,9a] The disubstituted amino acids are liberated as described above (eq 7).

(5)

Boron Enolates.

The oxazinones can be converted to their corresponding boron enolates by treatment with ***Di-n-butylboryl Trifluoromethanesulfonate*** and ***Triethylamine*** in CH_2Cl_2.[9] The boron enolates react with aldehydes at -78 °C to give β-(hydroxy)alkyl-substituted oxazinones. Condensation of the boron enolate with acetaldehyde followed by recrystallization of the major product and then deprotection affords allothreonine (eqs 8 and 9).[9c] This approach has been used in the asymmetric synthesis of diaminopimelic acid and derivatives thereof.[9a,b]

(9)

[3 + 2] Dipolar Cycloadditions.

Highly substituted proline derivatives can be prepared by removal of the *t*-Boc protecting group from the oxazinone followed by condensation of the heterocycle with an aldehyde in the presence of ***p-Toluenesulfonic Acid*** in benzene. Under these conditions, Schiff base formation and ylide generation occur. Subsequent [3 + 2] cycloaddition with a dipolarophile affords the bicyclic heterocycle, which is then deprotected to yield the desired proline derivative (eqs 10 and 11).[10]

1-(*t*-Butoxycarbonyl)imidazole

[49761-82-2] · $C_8H_{12}N_2O_2$ · 1-(*t*-Butoxycarbonyl)imidazole · (MW 168.20)

(a reagent for the introduction of the *t*-butoxycarbonyl group at nucleophilic sites[1])

Physical Data: mp 44.5-47 °C; bp 64 °C/1 mmHg.

Solubility: sol CH_2Cl_2, $CHCl_3$, THF, hexane, acetone, and DMF, among others.

Form Supplied in: not commercially available.

Preparative Method: 1-(*t*-butoxycarbonyl)imidazole (**1**) can be prepared from the reaction of imidazole and 1,2,2,2-tetrachloroethyl-*t*-butyl carbonate[1a] or the reaction of *t*-butanol and *N,N´*-carbonyldiimidazole[1b] in high yield. The reagent has been reported to be stable at rt.[2]

Handling, Storage, and Precautions: anhydrous conditions are recommended.

t-Butoxycarbonylation.

The amine functions of various amino acids have been protected with the *t*-butoxycarbonyl (Boc) group by (**1**) (eq 1).[1b,3] Polar anhydrous organic solvents have been used in general, although traces of moisture can be tolerated.

(1)

Alkylation of (**1**), or its silver perchlorate complex, produces water-soluble imidazolium salts with enhanced

electrophilic character (eq 2).[4] The perchlorate and tetrafluoroborate salts of this type are remarkably stable and they have been used to protect amino acids in aqueous media (eq 3).[4]

(2)

(3)

Selective protection of a single amine in alkyl diamines by (**1**) is reported (eq 4).[5] Furthermore, the reaction of ***Hydrazine*** with (**1**) affords *t*-butoxycarbonylhydrazide, which is a useful reagent in peptide chemistry.[1b]

(4)

Incorporation of the Boc group at the aromatic nitrogen of the pyridine ring system (eq 5)[6] and at a carbon nucleophile (eq 6)[7] by (**1**) has also been reported.

(5)

(6)

Formation of *O*-Alkylperoxycarbonic Acids.

Epoxidation of alkenes in a biphasic system could be performed by in situ generation of *O*-alkylperoxycarbonic acids (eq 7).[2] The reaction is typically carried out by the addition of 35% ***Hydrogen Peroxide*** to a solution of (**1**) and the alkene substrate in an organic solvent. The epoxide of cholesteryl acetate was prepared quantitatively in a 3:1 ratio of α- to β-epoxide by this method.

(7)

N-t-Butoxycarbonyl-*N*-methylaminomethyllithium[1]

[-] · $C_7H_{14}LiNO_2$ · *N-t*-Butoxycarbonyl-*N*-methylaminomethyllithium · (MW 151.13)

(α-amino carbanion nucleophile for displacement and addition reactions[1])

Alternate Name: N-Boc-α-lithiodimethylamine.

Preparative Methods: can be prepared by stirring *N*-Boc-dimethylamine with ***s-Butyllithium*** at -50 °C in THF for 2 h. The organolithium reagent reacts with electrophiles to provide substitution products in good yields. *N*-Boc-dimethylamine can be prepared from the reaction of ***Potassium t-Butoxide*** and ***Dimethylcarbamoyl Chloride*** in THF.

α-Amino Organolithium Reagents.

α-Amino organolithium reagents useful for the elaboration of amines via α-amino carbanion synthetic equivalents can be prepared from *N*-Boc secondary amines which bear a methyl or methylene group. The general application of this methodology for amine elaboration is shown in eq (1). Lithio derivatives of *N*-benzyloxycarbonyl (Cbz) and *N*-methoxycarbonyl amines can also be generated by tin-lithium exchange reactions.[2] The generation and use of other *N*-substituted organometallic reagents has been reviewed.[3]

(1)

Conversion to the α-lithioamine synthetic equivalents is achieved by reaction with ***s-Butyllithium*** or *s*-BuLi/***N,N,N´,N´-Tetramethylethylenediamine*** in diethyl ether or THF at low temperatures.[1] Addition of electrophiles provides the α-

substituted *N*-Boc amines in good yields. The *N*-Boc groups can be cleaved under acidic or basic conditions to provide the elaborated secondary amines. It is important that the solvent and reagents be anhydrous and the *s*-BuLi be of good quality. A specific case for the key steps of lithiation and substitution for *t*-butoxycarbonyl-*N*-methylaminomethyllithium is shown in eq (2). Selectivity for the less substituted position is usually observed as shown in eq (3).

Extensions of this methodology to heterocyclic amines have been achieved with control of stereochemistry. Lithiation of *N*-Boc-piperidine followed by electrophilic substitutions provide 2-substituted *N*-Boc-piperidines. When the electrophile is an aldehyde, the *syn* and *anti* isomers are obtained in ca. 1:1 ratio. Lithiation and substitution of 4-substituted *N*-Boc-piperidines gives diequatorial *cis*-2,4-disubstituted *N*-Boc-piperidines.[4] Lithiation and substitution of 2-substituted *N*-Boc-piperidines provides *trans*-2,6-disubstituted piperidines. The stereochemical outcome is consistent with equatorial lithiation and substitution with retention of configuration of the carbon-lithium bond (eq 4). The 2-substituted *N*-Boc-piperidine undergoes lithiation to generate a 2-axial substituent because of allylic ($A^{1,3}$) strain. This methodology has been used to prepare a 2,6-*trans*-disubstituted piperidine alkaloid, solenopsin A, from *N*-Boc-piperidine.[4] By taking advantage of the equilibration of a *trans*-2,6-disubstituted piperidine to the more stable *cis* isomer, a derivative of a *cis*-2,6-disubstituted piperidine alkaloid, the author also prepared *cis*-dihydropinidine.[5] Similar lithiation-substitution sequences have been reported with *N*-Boc-pyrrolidine and *N*-Boc-perhydroazepine.[5]

E_1 = Me, 89%; $SiMe_3$, 94%; PhCHOH, 76%; CHO, 65%; CyCHOH, 46%

E_2 = PhCHOH, 96%; CHO, 87% (4)

Solenopsin *N*-Boc-dihydropinidine

With a leaving group adjacent to the site of lithiation, elimination can occur followed by a second lithiation; for 3-methoxy-*N*-Boc-piperidine with 2 equiv of *s*-BuLi, *N*-Boc-2-substituted Δ^2-piperidines are obtained (eq 5).[5]

(5)

E = $SnBu_3$, 92%
CHO, 75%
$SiMe_3$, 92%

High enantioselectivities are observed in the lithiation-substitution sequence when *s*-BuLi/***(-)-Sparteine*** is used as the lithiating base for *N*-Boc-pyrrolidine (eq 6).[6] The sequence proceeds by an asymmetric deprotonation to provide an enantioenriched organolithium intermediate which maintains configuration and reacts with electrophiles stereoselectively to give highly enantioenriched products.[6] Repetition of this sequence for a second substitution with enantioenriched reactant gives a substantial amplification of enantioenrichment of (*S*,*S*)-2,5-dimethyl-*N*-Boc-pyrrolidine (eq 7).[7]

1-*N*-(*t*-Butoxycarbonyl)-1*H*-benzotriazole 3-*N*-Oxide

[111615-82-8] · $C_{11}H_{13}N_3O_3$ · 1-*N*-(*t*-Butoxycarbonyl)-1*H*-benzotriazole 3-*N*-Oxide · (MW 235.27)

(a reagent for protection of amines with the *t*-butoxycarbonyl group[1])

Physical Data: mp 105 °C.

Solubility: sol DMF, CH_2Cl_2, and dioxane, among others.

Form Supplied in: the reagent is a white solid; however, it is not commercially available.

Handling, Storage, and Precautions: anhydrous conditions are not necessary for reactions, and the reagent can be stored at rt.

Introduction.

The subject of this review was believed initially to be 1-*N*-(*t*-butoxycarbonyloxy)benzotriazole. However, a single-crystal X-ray analysis established the structure unequivocally as 1-*N*-(*t*-butoxycarbonyl)-1*H*-benzotriazole 3-*N*-oxide (**1**). It is likely that initially the carbonate, i.e. 1-*N*-(*t*-butoxycarbonyloxy)benzotriazole, is formed, and it then rearranges to the more stable carbamate (**1**). Two syntheses for (**1**), which actually had been originally targeted for 1-*N*-(*t*-butoxycarbonyloxy)benzotriazole, are reported. In the first synthesis, ***1-Hydroxybenzotriazole*** is converted to its chloroformate, which in turn is allowed to react with *t*-butanol to give 1-*N*-(*t*-butoxycarbonyloxy)benzotriazole (eq 1).[1] In the second synthesis, 1-hydroxybenzotriazole is deprotonated by ***Triethylamine***, and subsequent mixing with ***Di-t-butyl Dicarbonate*** affords the carbonate which rearranges to (**1**) (eq 2).[2]

t-Butoxycarbonylation.

Reagent (**1**) is exceptionally effective in N-protection of amino acids. For example, when 1 equiv of the reagent was added to a solution of L-proline and triethylamine in aqueous dioxane, an essentially quantitative conversion to the corresponding N-Boc amino acid took place in under 1 min.[1] The reaction in aqueous DMF proceeds somewhat more sluggishly; however, the reaction reaches completion within 30 min. The speed of these reactions is in sharp contrast to the more commonly used reagents for *N*-*t*-butoxycarbonylation, such as ***Di-t-butyl Dicarbonate***, ***2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile*** (Boc-ON), 1,2,2,2-tetrachloroethyl *t*-butyl carbonate, or ***t-Butyl Azidoformate***, which usually require from a few hours to overnight reaction duration. The isolated yields for the products of the reactions of several typical amino acids with (**1**) have been reported in the range of 80-99% (eq 3).

The reaction of (**1**) with simple amines, such as ***Piperidine*** or benzylamine, or even less reactive amines, such as aniline (eq 4) or ***Imidazole***, have been reported.[1] In contrast to the reactions with amino acids, simpler amines appear to require somewhat longer reaction times.

2-(*t*-Butoxycarbonyloxyimino)-2-phenylacetonitrile

[58632-95-4] · $C_{13}H_{14}N_2O_3$ · 2-(*t*-Butoxycarbonyloxyimino)-2-phenylacetonitrile · (MW 246.27)

(reagent for protection of amino acids as *t*-butyl carbamates[1-3] and for protection of alcohols as *t*-butyl carbonates[4])

Alternate Name: Boc-ON.

Physical Data: mp 87-89 °C.

Solubility: very sol ethyl acetate, ether, benzene, chloroform, dioxane and acetone; sol methanol, 2-propanol, and *t*-butanol; insol petroleum ether and water.

Form Supplied in: solid.

Handling, Storage, and Precautions: contact with the reagent may cause irritation. The toxicological properties of the reagent have not been thoroughly investigated. The reagent should be stored in a brown bottle at -20 °C to prolong shelf life. After several weeks at rt the reagent undergoes gradual decomposition with evolution of CO_2.

Amine Protection.

The reagent, informally referred to as Boc-ON, has been widely employed for the protection of amines as their *t*-butoxycarbonyl (Boc) derivatives. The original description of Boc-ON reports its utility for the N-protection of α-amino acids (eq 1),[1] and this use is still the major application.[5]

The reaction is generally carried out using 1.1 equiv of Boc-ON and 1.5 equiv of ***Triethylamine*** in either 50% aqueous dioxane or 50% aqueous acetone. Boc derivatives are obtained in high yields after 4-5 h at 20 °C or 1 h at 45 °C. The oxime byproduct (eq 1) can be easily and completely removed from the reaction mixture by extraction with ether, ethyl acetate, or benzene. To secure high purity and high yield, distillation of the dioxane or acetone prior to extraction of the oxime byproduct is recommended, though direct extraction may be feasible in most cases. Yields for various amino acids range from good to virtually quantitative (Table 1).

Table 1 Examples of Boc-Amino Acids Prepared with Boc-ON[2]

Boc-amino acid	Reaction time (h)	Oxime extraction solvent	Yield (%)
Ala-OH	4	Ether	80
Asn-OH	20	EtOAc	86
$Glu(OH)_2$	3	EtOAc	78
Gly-OH	2	EtOAc	87
Leu-OH·$0.5H_2O$	3	Ether	99
Met-OH·DCHA[a]	3	EtOAc	82
Phe-OH·DCHA[a]	5	Ether	98
Pro-OH	1.5	Benzene	88
Trp-OH	3	EtOAc	99

[a] DCHA = dicyclohexylamine.

Boc-ON offers a distinct advantage over *t*-Boc azide which can require reaction temperatures of 50-60 °C.[6] In addition, *t*-Boc azide is thermally unstable and decomposes with apparent detonation at temperatures above 80 °C. Boc-ON is comparable to ***Di-t-butyl Dicarbonate*** in terms of reaction times, yields, convenience, availability, and work-up

procedure.[7]

Boc-ON has also been employed for the protection of secondary amines (eqs 2 and 3).[8,9]

(2)

(3)

The reagent will selectively protect the amino group in the presence of alcohols and phenols as well as carboxylic acids. Examples include the Boc protection of a kanamycin A derivative (eq 4)[10] and of the glycopeptide antibiotic A41030A (eq 5).[11]

(4)

2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile

(5)

In the case of diamino acids, such as ornithine or lysine, Boc-ON has been used to effect selective protection of N^W at pH 11 (eqs 6 and 7).[12,13]

(6)

(7)

This selective protection has also been accomplished with copper-chelated diamino acids (eq 8).[14]

(8)

Alcohol Protection.

Boc-ON has also been employed to protect alcohols as their *t*-butyl carbonates.[4,15,16] For this application the alcohol must first be deprotonated to its alkoxide conjugate base (eqs 9 and 10).

(9)

(10)

Related Reagents.

N-(t-Butoxycarbonyloxy)phthalimide; ***N-(t-Butoxycarbonyloxy)succinimide***; ***t-Butyl Azidoformate***; ***Di-t-butyl Dicarbonate***.

N-(*t*-Butoxycarbonyloxy)phthalimide

[15263-20-4] · $C_{13}H_{13}NO_5$ · N-(*t*-Butoxycarbonyloxy)phthalimide · (MW 263.25)

(reagent for protection of amino acids as *t*-butyl carbamates[1])

Physical Data: mp 118 °C (dec).

Solubility: sol *t*-butanol and THF; insol water.

Form Supplied in: solid.

Handling, Storage, and Precautions: contact with the reagent may cause irritation. The toxicological properties of the reagent have not been thoroughly investigated.

Amine Protection.

N-(*t*-Butoxycarbonyloxy)phthalimide (**1**) has been utilized for the protection of amines as their *t*-butoxycarbonyl (Boc) derivatives, particularly for the N-protection of α-amino acids (eq 1).[1]

Equimolar amounts of (**1**), a base (NaOH or Na_2CO_3), and the amino acid in *t*-butanol-water (2:1) are heated to 90 °C for 2 h. Upon cooling, the byproduct sodium hydroxyphthalimide precipitates. The filtrate is then acidified to pH 3 with citric acid and extracted with chloroform. The extract is washed with water to obtain the Boc derivatives in moderate to good yield (Table 1). A related reagent where the phthalimide moiety is replaced by a succinimide can give comparable or superior yields (Table 1).[1,2] The 9-fluorenylmethyloxycarbonyl (Fmoc) succinimide has also been prepared and can give good yields of Fmoc-protected amino acids.[3]

Table 1 Examples of Boc-Amino Acids Prepared with *N*-(*t*-Butoxycarbonyloxy)phthalimide or *N*-(*t*-Butoxycarbonyloxy)-succininide[1]

Boc-amino acid	Reagent	Yield (%)
Ala-OH	Phthalimide-NOBoc	76
Ala-OH	Succinimide-NOBoc	75
Asn-OH	Phthalimide-NOBoc	81
[*S*-Bn]-Cys-OH	Succinimide-NOBoc	80
Gly-OH	Phthalimide-NOBoc	73
Gly-OH	Succinimide-NOBoc	78
Leu-OH	Succinimide-NOBoc	74
Pro-OH	Phthalimide-NOBoc	65
Pro-OH	Succinimide-NOBoc	87

These reagents offer some advantage over *t*-Boc azide, which is thermally unstable and decomposes with apparent detonation at temperatures above 80 °C. However, ***2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile***[4,5] and ***Di-t-butyl Dicarbonate***[6] are generally the reagents of choice because the reactions are complete at ambient temperature within 2-4 h and because the yields are usually higher.

The reagent will selectively protect the amino group in the presence of alcohols, and may show selectivity for less hindered amines. The antibiotic sisomicin (eq 2) reacted with (**1**) to give a clean product by TLC. However, after silica gel chromatography the sole product isolated was obtained in only 26% yield, with the remainder of the starting material recovered. The authors suggest that while the reaction was remarkably selective and went to apparent completion, the product was unstable to silica gel.[7]

Related Reagents.

2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile; ***N-(t-Butoxycarbonyloxy)succinimide***; ***Di-t-butyl Dicarbonate***; ***9-Fluorenylmethyl Chloroformate***.

N-(*t*-Butoxycarbonyloxy)succinimide

[13139-12-3] · $C_9H_{13}NO_5$ · *N*-(*t*-Butoxycarbonyloxy)succinimide · (MW 215.21)

(reagent for the protection of amino groups, including amino acids[2])

Alternate Name: Boc-OSu.

Physical Data: mp 98-100 °C.[1]

Solubility: sol ether, ethyl acetate, acetone; insol water, petroleum ether.

Form Supplied in: white solid, widely available.

Handling, Storage, and Precautions: stable under normal storage conditions. No known toxicity.

Protection of Amino Compounds.

N-(*t*-Butoxycarbonyloxy)succinimide (Boc-OSu) has been developed to supplement the unstable ***t-Butyl Chloroformate*** for the protection of amino compounds and especially of amino acids. The reagent is a stable compound easily prepared from *t*-butanol and *N*-oxysuccinimide chloroformate[1] and has been used for the protection of various compounds including amino acids, peptides,[2] proteins,[3,4] and amino saccharides.[5] *N*-Oxysuccinimide carbonates have been shown to give very pure N-protected amino acids with a particularly low content of dipeptide byproduct.[6] It is also noteworthy that both the Boc and the OSu groups can be introduced into amino acids almost simultaneously in a one-pot synthesis of Boc-protected *N*-oxysuccinimide active esters of amino acids (eq 1).[7]

Attempts to protect α-hydrazino acids regioselectively led to almost no discrimination between N-α and N-β protection, compared to the very good regioselectivity observed with benzyloxycarbonyloxysuccinimide (eq 2).[8]

N-(*t*-Butoxycarbonyl)pyrrole

[5176-27-2] · $C_9H_{13}NO_2$ · *N*-(*t*-Butoxycarbonyl)pyrrole · (MW 167.21)

(used as a synthetic equivalent of pyrrole; the *t*-butoxycarbonyl group can be cleaved under acidic or basic conditions[1])

Physical Data: bp 98-99 °C/19 mmHg.

Solubility: freely sol common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Method: see Reese and Dhanak.[1]

Purification: distillation under reduced pressure.

N-(*t*-Butoxycarbonyl)pyrrole is prepared by the deprotonation of pyrrole with ***Sodium Hydride*** followed by acylation with phenyl *t*-butyl carbonate.[1] Other preparative methods include the acylation of pyrrole with ***Di-t-butyl Dicarbonate*** in the presence of ***Triethylamine*** and catalytic ***4-Dimethylaminopyridine***,[2] and treatment of the potassium salt of pyrrole with ***t-Butyl Azidoformate***.[3]

N-(*t*-Butoxycarbonyl)pyrrole serves as a convenient synthetic equivalent of pyrrole. Many of the synthetically important transformations of pyrrole, substituted pyrroles, and indoles involve strongly basic conditions and it is often necessary to protect the nitrogen. The *t*-butoxycarbonyl group can be attached and removed under mild conditions and is also stable to a variety of conditions used for functionalization of the pyrrole ring. Thus 2-lithio-*N*-(*t*-butoxycarbonyl)pyrrole can be generated quantitatively with ***Lithium 2,2,6,6-Tetramethylpiperidide*** and trapped with ***Chlorotrimethylsilane*** or other electrophiles. The protecting group can be subsequently removed using a solution of ***Sodium Methoxide*** in methanol (eq 1).[4] Under these conditions, (1-hydroxy)alkylpyrroles (derived from the addition of the 2-lithiopyrrole to aldehydes) are converted to (1-methoxy)alkylpyrroles. The *t*-butoxycarbonyl group can also be cleaved under acidic conditions using ***Trifluoroacetic Acid*** in CH_2Cl_2.[1,2]

N-(*t*-Butoxycarbonyl)pyrrole also undergoes Diels-Alder reactions with acetylene, benzyne, and their derivatives. Thus reaction of *N*-(*t*-butoxycarbonyl)pyrrole with benzyne generated from bromofluorobenzene and magnesium gave the adduct in 41% yield (eq 2).[3]

Other alternatives to *N*-(*t*-butoxycarbonyl)pyrrole that can be used for some of the reactions described above include various *N*-trialkylsilylpyrroles[1,5] and methoxycarbonylpyrrole.[6]

N-(*t*-Butoxycarbonyl)-*p*-toluenesulfonamide

[18303-04-3] · $C_{12}H_{17}NO_4S$ · *N*-(*t*-Butoxycarbonyl)-*p*-toluenesulfonamide · (MW 271.33)

(useful component in Mitsunobu reactions for the direct preparation of protected amines from alcohols)

Physical Data: mp 121-123 °C.

Solubility: sol most common organic solvents.

Form Supplied in: white solid; commercially available.

Preparative Method: the title compound (**1**) is readily prepared in high yield by addition of *t*-butanol to tosyl isocyanate.[1]

Handling, Storage, and Precautions: the reagent can be stored for extended periods of time in an amber bottle at rt.

Mitsunobu Reactions.

Under standard Mitsunobu conditions, primary (eq 1),[1] secondary (eq 2),[1] and allylic *N*-Boc sulfonamides (eq 3)[4] have been prepared in good yields. The reagent has a pK_a of 8.5 in DMSO,[2] making it a suitably acidic component in the Mitsunobu[3] reaction.

(1)

(2)

(3)

It is possible to selectively remove either of the nitrogen protecting groups of these *N*-Boc sulfonamides.[1] For example, treatment of (**2**) with ***Trifluoroacetic Acid***, or thermolysis in ***Dimethyl Sulfoxide*** affords sulfonamide (**3**) (eq 4). Alternatively, ***Sodium Naphthalenide*** serves to deprotect (**2**) to give the *N*-Boc compound (**4**).

(4)

Compound (**1**) has been effectively used for the formation of the *N*,*N*-diprotected ethyl (*R*)-alaninate (**6**) from the corresponding (*S*)-alcohol (**5**) with clean inversion of stereochemistry (eq 5).[5]

(5) (6) (5)

N-Boc sulfonamide (**1**) has also proved useful in the synthesis of the thromboxane A_2 antagonist (**10**).[6] The Mitsunobu reaction with (**1**) was carried out on scalemic ester alcohol (**7**) to provide the desired *N*-Boc sulfonamide (**8**) along with diene (**9**) (eq 6).

(7) (9) (8)

(8):(9) = 4:1

(10) (6)

A related compound, *t*-butyl ((2-(trimethylsilyl)ethyl)sulfonyl)carbamate (**12**), prepared from methanesulfonamide (**11**) in two steps (eq 7), has also been shown to be an effective component in the Mitsunobu reaction (eq 8) (see also β-***Trimethylsilylethanesulfonyl Chloride***).[7]

(7)

1-*t*-Butoxycarbonyl-1,2,4-triazole

[41864-24-8] · $C_7H_{11}N_3O_2$ · 1-*t*-Butoxycarbonyl-1,2,4-triazole · (MW 169.18)

(a reagent for protection of amines with the *t*-butoxycarbonyl group[1])

Physical Data: mp 40 °C.

Solubility: sol DMF and DMSO.

Form Supplied in: the reagent is commercially available and is supplied as a solid.

Preparative Method: 1-*t*-butoxycarbonyl-1,2,4-triazole (**1**) is available commercially, but it can readily be prepared from the reaction of *t*-butoxycarbonyl azide with 1-trimethylsilyl-1,2,4-triazole or reaction of *t*-butanol with *N,N´*-carbonyl-di-1,2,4-triazole in high yield.[1]

Handling, Storage, and Precautions: anhydrous conditions are recommended for reactions, and the reagent is best stored at 0-4 °C.

t-Butoxycarbonylation.

(**1**) is exceedingly reactive towards amines. Simple amines react with (**1**) to give the corresponding carbamates in high yields. However, the reaction has been reported to proceed somewhat more slowly with carboxylate salts of amino acids. Nonetheless, yields for the protection of amino acids under these conditions are in the range of 80-92%.[1]

t-Butoxychlorodiphenylsilane

[17922-24-6] · $C_{16}H_{19}ClOSi$ · *t*-Butoxychlorodiphenylsilane · (MW 290.86)

(reagent for the protection of primary, secondary, and tertiary alcohols; reacts selectively with primary hydroxy groups in dichloromethane; *t*-butoxydiphenylsilyl ethers are highly reactive towards F^-, allowing for selective removal[1])

Alternate Name: *t*-butoxydiphenylsilyl chloride.

Physical Data: bp 130-145 °C/0.5 mmHg; *d* 1.075 g cm^{-3}; fp 56 °C.

Solubility: sol most organic solvents.

Form Supplied in: pale yellow oil; stabilized with calcium carbonate.

Handling, Storage, and Precautions: corrosive; the reagent is moisture sensitive and should be handled under an inert atmosphere.

Reactivity.

t-Butoxychlorodiphenylsilane reacts with primary, secondary, and tertiary alcohols in DMF, in the presence of ***Triethylamine***, to give the corresponding silyl ethers in good yield (eq 1).[1] Secondary alcohols can also be silylated in dichloromethane; however, small amounts of ***4-Dimethylaminopyridine*** (0.1 equiv) or ***N,N-Dimethylformamide*** (0.1 equiv) are required to catalyze the reaction (eq 2). Selective silylation of primary alcohols can be achieved using dichloromethane alone (eq 3).

(1)

(2)

(3)

Stability.

One of the most interesting attributes of the *t*-butoxydiphenylsilyl protecting group is its sensitivity to fluoride. A primary *t*-butoxydiphenylsilyl ether can be cleaved selectively in the presence of a primary or secondary *t*-butyldimethylsilyl ether, using 2 equiv of ***Tetra-n-butylammonium Fluoride*** (1 M solution in THF) in dry dichloromethane (eqs 4, 6, 7).[1,2] Alternatively, selective cleavage of the *t*-butyldimethylsilyl ethers can be achieved using acidic conditions (eq 5).[1]

(4)

(5)

(6)

(7)

Selective cleavage of a secondary *t*-butoxydiphenylsilyl ether in the presence of a primary *t*-butyldimethylsilyl ether could not be achieved (eq 8). This problem can be circumvented by the use of the diphenylisopropoxysilyl protecting group (eqs 9 and 10).[1,3]

(8)

(9)

(+ 14% diol) (10)

The *t*-butoxydiphenylsilyl protecting group is compatible with reactions such as ***Pyridinium Chlorochromate*** oxidation,[4] acylation, and reduction. Highly reactive nucleophiles such as ***n-Butyllithium*** should, however, be avoided.

t-Butoxymagnesium Bromide

t-BuOMgBr

[19065-60-2] · C_4H_9BrMgO · *t*-Butoxymagnesium Bromide · (MW 177.32)

(associated alkoxide base)

Preparative Method: the reagent is prepared in situ by reacting anhydrous *t*-BuOH with 1.0 equiv EtMgBr in Et_2O or THF.[1,2] The crystalline solid, which has a dimeric structure, is obtained by the reaction of MeMgBr with acetone in Et_2O.[3]

Handling, Storage, and Precautions: use the same precautions that are recommended for ***Potassium t-Butoxide***, i.e. avoid contact of solutions with eyes, skin, and clothing. Conduct all reactions under an inert atmosphere.

Oxidation of Alcohols.

Bromomagnesium alkoxides of a variety of alcohols including saturated primary alcohols (eq 1) react with ***N-Chlorosuccinimide*** in the presence of *t*-BuOMgBr to give the corresponding carbonyl compounds in good yields.[2] A very low yield of the aldehyde is produced when the unsaturated alcohol, 7-phenyl-4-hepten-1-ol, is reacted similarly (eq 2). Although the substitution of ***m-Chloroperbenzoic Acid*** or ***Diacetatobis(tri-o-tolylphosphine)palladium(II)*** for NCS leads to a significant improvement in the yield of the unsaturated aldehyde, best results are obtained if ***1,1´-(Azodicarbonyl)dipiperidine*** is used as the oxidizing agent (eq 2).[2] This method gives high yields of oxidation products when applied to a variety of other alcohols as well. The combination of *t*-BuOMgBr and 1,1´-(azodicarbonyl)dipiperidine is capable of oxidizing keto alcohols to diketones without prior formation of the halomagnesium alkoxide of the substrate (eq 3).[2]

$$Me(CH_2)_6CH_2OMgBr + NCS \xrightarrow[\text{THF, rt}]{t\text{-BuOMgBr}} Me(CH_2)_6CHO \quad (1)$$

80%

(2)

NCS	34%
m-CPBA	74%
$PhI(OAc)_2$	76%

89%

(3)

Rearrangement Reactions.

Cis- and *trans*-2,4-diphenylthietane dioxides rearrange to the corresponding *cis*- and *trans*-3,5-diphenyl-1,2-oxathiolane (2,3)-*cis*-2-oxides (eqs 4 and 5, respectively) upon reaction with *t*-BuOMgBr.[1] These reactions are

stereospecific with respect to the phenyl groups, but stereoselective with respect to the oxygen atoms on sulfur. When EtMgBr is used as the base, both of these sulfones undergo stereoselective rearrangement to the *trans*-1,2-diphenylcyclopropanesulfinate anion. The influence of *t*-BuOMgBr on the course of these reactions is attributed to its unique dimeric structure.[4]

(4)

(5)

The protected aldopyranose 2,3,4,6-tetra-*O*-benzyl-D-glycopyranose is readily converted into the protected ketopyranose 1,3,4,5-tetra-*O*-benzyl-L-sorbopyranose by an internal hydride transfer process in the presence of 5.0 equiv of *t*-BuOMgBr in CH_2Cl_2 (eq 6).[5] This rearrangement proceeds poorly in THF and not at all in PhH or MeCN. Bromomagnesium alkoxides of other alcohols, e.g. *i*-PrOH, 2,4,6-trimethylphenol, and 4-chlorophenol, in CH_2Cl_2 were also reasonably effective for the reaction.[5]

t-Butoxymethyllithium[1]

[87996-22-3] · $C_5H_{11}LiO$ · *t*-Butoxymethyllithium · (MW 94.08)

(hydroxymethyl anion equivalent[2])

Solubility: sol THF.

Preparative Methods: generated in situ by a tin-lithium exchange reaction between butyllithium and an α-stannyl ether[3] or by metalation of *t*-butyl methyl ether with an *s*-butyllithium/potassium *t*-butoxide reagent.[2]

Handling, Storage, and Precautions: stable at low temperature (-10 °C or less) in solution.

Reagent Preparation.

A general method for the preparation of *t*-butoxymethyllithium and closely related reagents, such as methoxymethyllithium [*14704-15-5*], ethoxymethyllithium [*104681-85-8*], and benzyloxymethyllithium [*71316-95-5*], involves the use of a tin-lithium exchange reaction. Several of these reagents have been made by treatment of α-chloro ethers with a complex of ***Tin(II) Chloride*** and ***Lithium Bromide*** in THF to generate α-trihalostannyl ethers. These ethers undergo tin-lithium exchange with ***n-Butyllithium*** to give the desired reagents (eq 1).[3a] This transmetalation will also proceed smoothly with butyllithium and alkoxymethyltributyltin (eq 2). In this case, the tributyltin compound is formed from benzyl alcohol/NaOH/tributylstannylmethyl iodide,[3b] benzyloxymethyl Grignard/***Tri-n-butylchlorostannane***,[3b] ***Chloromethyl Methyl Ether***/tributylstannyl Grignard,[3c] or diethoxymethyltributyltin/***Acetyl Chloride***/***Tri-n-butylstannane***.[3c]

(2)

The transmetalation strategy has also been used to form alkoxymethyllithium reagents from alkoxymethyl telluride by lithium-tellurium exchange.[4] This reaction proceeds in solvents of low polarity, such as toluene and hexane, in which tin-lithium exchange is sluggish.

For *t*-butoxymethyllithium, a more practical preparation for large-scale work is the direct metalation of *t*-butyl methyl ether (TBME) with ***s-Butyllithium*** and ***Potassium t-Butoxide*** (eq 3).[2] The metalation is done in neat TBME to form *t*-butoxymethylpotassium, which is converted to the desired reagent by addition of a solution of LiBr in THF. *t*-Butoxymethyl- and methoxymethylpotassium have also been prepared by metalation of the corresponding ethers with butylpotassium.[5]

(3)

A third option for generating methoxymethyllithium involves treatment of ***Chloromethyl Methyl Ether*** with ***Lithium*** metal (eq 4).[6] This reaction proceeds smoothly in dimethoxymethane, but does not work in ether or THF.

(4)

1,2-Addition to Carbonyls.

One of the most common uses of alkoxymethyllithium reagents is addition to ketones and aldehydes to generate monoalkylated 1,2-diols in good yields (eq 5).[2,3c,7] Subsequent reaction with ***Acetic Anhydride/Iron(III) Chloride*** cleaves the *t*-butyl group and forms a diacetate, which can be hydrolyzed to a diol.[2] A variety of carbonyl compounds can participate in the 1,2-addition reaction, including α,β-unsaturated ketones[8-10] and aldehydes,[11] amides,[12] and lactones.[13]

(5)

1,4-Addition to Carbonyls.

When converted to an organocopper reagent by reaction with 1 equiv of copper(I) bromide *N* dimethyl sulfide, *t*-butoxymethyllithium can be used for conjugate addition of *t*-butoxymethyl to α,β-unsaturated carbonyls (eq 6).[2,14] In addition, the copper reagent can be used in enantioselective conjugate additions.[15] A complexed copper reagent formed from a chiral ligand derived from (-)-ephedrine, ***Copper(I) Iodide***, and *t*-butoxymethyllithium reacts efficiently with 2-cyclohexenone to give (*R*)-3-(*t*-butoxymethyl)cyclohexanone (75% yield, 89% ee).

(6)

Other Reactions.

t-Butoxymethyllithium can be used to convert acid chlorides to *t*-butoxymethyl ketones in one step (eq 7).[2] Addition of 1 equiv of ***Copper(I) t-Butoxide*** to the lithium reagent generates an organocopper derivative which reacts cleanly with acid chlorides.

(7)

The alkoxymethyllithium reagents also provide a convenient route to alkyl α-stannyl and α-silyl ethers. Alkoxymethyllithium reacts with either ***Chlorotrimethylsilane*** or trialkyltin chloride to yield trimethylsilylmethyl methyl ether[6b] or *t*-butyl α-stannyl ether,[2] respectively (eq 8). In addition, *t*-butoxymethyllithium can be alkylated efficiently with ***Benzyl Bromide*** to give $Ph(CH_2)_2O$-*t*-Bu in 84% yield.[2]

(8)

$R^1 = Me, M = Si, R^2 = Me, 81\%$
$R^1 = t\text{-}Bu, M = Sn, R^2 = Me, 94\%$
$R^1 = t\text{-}Bu, M = Sn, R^2 = Bu, 94\%$

Related Reagents.

A number of similar hydroxymethyl anion equivalents have been developed, including (methoxymethoxy)methyllithium,[16] (ethoxyethoxy)methyllithium,[17] and (benzyloxymethoxy)methyllithium.[18] These reagents are usually formed by protection of trialkylstannylmethanol, followed by a tin-lithium exchange reaction. Seebach has generated $LiOCH_2Li$ by treating tributylstannylmethanol with 2 equiv of butyllithium.[19] Others have used alkoxymethylmagnesium halides,[6a,20] metalated esters,[21] and metalated amides[22] as hydroxymethyl anion equivalents.

Dialkoxymethyllithium reagents have been used as one-carbon nucleophiles to generate a variety of functionalized acetals.[23] These reagents are prepared by reductive lithiation of phenylthio-substituted precursors or transmetalation of tri-*n*-butylstannyl compounds.

See also ***1-(Benzyloxymethoxy)propyllithium***, ***(Diisopropoxymethylsilyl)methylmagnesium Chloride***, ***1-Lithio-1-methoxycyclopropane***, ***1-Methoxyallyllithium***, and ***Tri-n-butyl[(methoxymethoxy)methyl]stannane***.

t-Butylamine

***t*-BuNH$_2$**

[75-64-9] · $C_4H_{11}N$ · *t*-Butylamine · (MW 73.14)

(reagent for preparation of hindered imines and amides;[1] reagent for selective cleavage of methyl phosphate esters; solvent for metal reductions and couplings; solvent for selective bromination of phenols; hindered base; equivalent of ammonia)

Physical Data: bp 45 °C, *d* 0.698 g cm^{-3}.

Solubility: broadly sol organic solvents.

Form Supplied in: mobile liquid; widely available.

Purification: distillation from sodium hydroxide.

Handling, Storage, and Precautions: as a volatile amine, handling should always be done in a fume hood. Store in tightly capped bottles at rt in ventilated cabinets.

Hindered Imines.

Numerous procedures are available for the preparation of *N*-*t*-butyl imines utilizing various dehydrating methods. Aldehydes condense readily without solvent or catalyst, or with sieves as dehydrating agent.[1,3,5,6] Ketones require a catalyst such as ***Titanium(IV) Chloride***,[4] ***Potassium Carbonate***,[3a] or dry EtOH.[2] The steric hindrance provided by the *t*-butyl group typically discourages reaction at the imine carbon as in the monoalkylation of ketones and aldehydes through their magnesio-imines (eq 1),[3] and the cyclization of α-chloro ketimines to cyclopropanes (eq 2).[4] The *t*-butyl group has also been an excellent substituent for the preparation of stable oxaziridines from imines (eq 3).[5] The differences in the rate of reaction typically seen between aldehydes and ketones have been used to prepare *t*-butyl imines of the former selectively.[6] Numerous examples also exist of the use of *t*-butyl amides for the purpose of discouraging reaction at the amide carbonyl group.[7]

(1)

(2)

(3)

Phosphate Ester Cleavage.

This reagent has found a unique advantage in the selective S_N2 cleavage of *methyl* esters of phosphoric acid in the presence of *ethyl* esters allowing nucleotide chemists unusual flexibility (eq 4).[8a] Selective cleavage of a β-cyanoethyl phosphate ester has also been effected through hindered base elimination in pyridine.[8b]

(4)

Solvent for Metal-Catalyzed Couplings and Reductions.

Substitution of *t*-butylamine for ethylamine or ammonia in dissolving metal reductions is often advantageous.[9] Useful advantage has been made in Cu catalyzed couplings of acetylenes and naphthols.[10]

Hindered Base in Eliminations.

Several examples are available of the use of the hindered amine function in eliminations.[8c,11]

Selective *o*-Bromination of Phenols.

This amine has been used to successfully act as acid scavenger in the bromination of phenols, producing only *ortho* products. Effective removal of HBr by precipitation of the amine salt as it is formed is crucial to the regioselectivity.[12] See ***Bromine-t-Butylamine***.

Ammonia Equivalent.

The facile acid removal of the *t*-butyl group in *t*-butyl esters has been extended in some cases to amides and amines.[4,13] The typical acidic reagents for this transformation are harsher, limiting the utility. While sulfonamides are more typical as ammonia carriers, acid cleavage does allow selective production of the sulfonamide from an *N*-*t*-butyl benzenesulfonamide.[13]

(geminal donor-acceptor-substituted alkenes;[1] for synthesis of trialkylketenimines and -amidines,[2,3] α-functionalized imidoyl cyanides,[4] carboxylic amides,[5] and 1-aza-2-cyano-1,3-dienes[6])

Alternate Names: N-t-butyl-β,β-dimethyl-α-cyanoenamine; 2-(*t*-butylamino)-3-methylcrotononitrile.

Physical Data: bp (**1**) 97-98 °C/21 mmHg; (**2**) 89-94 °C/15 mmHg; (**3**) 95-96 °C/12 mmHg; (**4**) 112-117 °C/14 mmHg; (**5**) 135-146 °C/12 mmHg; (**6**) 94-101 °C/11 mmHg; (**8**) 98-100 °C/11 mmHg; (**9**) 110-114 °C/12 mmHg; (**10**) 146-157 °C/12 mmHg; (**11**) 83 °C/0.017 mmHg; (**13**) 115-125 °C/0.05 mmHg; mp (**3**) 30 °C; (**11**) 44 °C.

Solubility: sol most organic solvents; compatible with all solvents.

Form Supplied in: commercially available (R^1 = R^2 = Me, R^3 = *i*-Pr, *t*-Bu) as colorless liquid or low-melting solid.

Analysis of Reagent Purity: ^{1}H NMR (GC cannot be used as these reagents are subject to tautomerize into stable imidoyl cyanides).

Preparative Methods: highly reproducible synthesis from cyanation of α-chloro aldimines with potassium cyanide in methanol under reflux (eq 1).[6] This reaction is amenable to large-scale preparation (1-2 mol) and synthesis of several higher homologs.[6,7] DMSO, DMF, or water can be used as well in these cyanation reactions.[4]

Handling, Storage, and Precautions: these reagents are stable for a long period at -20 °C. Stable at rt for several weeks. As the reagents might act as a cyanide source, use in a well-ventilated fume hood is recommended.

Introduction.

α-Cyano enamines are a class of geminal donor-acceptor-substituted alkenes.[1] Upon heating, e.g. distillation in vacuo or gas chromatographic analysis, α-cyano enamines tautomerize partially into imidoyl cyanides (eq 2).[6] Both α-cyano enamines and imidoyl cyanides are stable isolable species.

(2)

Synthesis of Trialkylketenimines and Amidines.

Numerous syntheses of ketenimines, having at least one aryl substituent on carbon or nitrogen, have been reported hitherto. The rare and labile trialkylketenimines are easily accessible from α-cyano enamines by reaction with methylmagnesium iodide or ***Methyllithium*** in diethyl ether (eq 3).[2,3] Trialkylketenimines may be isolated or treated in situ with primary amines to afford amidines (eq 4).[2]

(3)

$R^1 = Me, Et; R^2 = Me, Et; R^3 = i\text{-}Pr, t\text{-}Bu, Cy$

(4)

$R^4 = Ph, i\text{-}Pr, 4\text{-}MeC_6H_4, 4\text{-}MeOC_6H_4$

Functional Group Transformation of Aldehydes into

Carboxylic Amides.

Heating of α-cyano enamines with dry hydrogen chloride in an anhydrous alcohol, e.g. methanol, ethanol, or *n*-butanol, produces carboxylic amides and the corresponding alkyl chlorides (eqs 5 and 6).[5] The intermediate enammonium chlorides are accessible by reaction of α-cyano enamines with dry ***Hydrogen Chloride*** in benzene (eq 5).[8] As α-cyano enamines are easily accessible from aldehydes, this conversion corresponds to the transformation of an aldehyde into a carboxylic amide.[9]

(5)

R^4 = Me, Et, *n*-Bu

R^4 = Me, Et, *n*-Bu

(6)

Synthesis of Functionalized Imidoyl Cyanides.

α-Cyano enamines react instantaneously in CCl_4 at rt with ***N-Bromosuccinimide*** and ***N-Chlorosuccinimide*** to give access to stable α-chloro- and α-bromoimidoyl cyanides (with practically no limitations in the substitution pattern of higher analogs) (eq 7).[4] The α-halo substituent of these trifunctional compounds is easily displaced by nucleophiles, such as thiolates, to give α-sulfenylated imidoyl cyanides (eq 8).[10] On the other hand, α-bromoimidoyl cyanides are readily converted into 1-aza-2-cyano-1,3-dienes by treatment with ***Sodium Methoxide*** in methanol under reflux (eq 9).[10]

(7)

(8)

R^4 = Et, *i*-Pr, *t*-Bu, *s*-Bu, Ph, Bn, *i*-Bu, *n*-Bu

(9)

R^1 = H, alkyl; R^2 = alkyl

Synthesis of Nontautomerizable α-Cyano Enamines.

N-Alkylation of tautomerizable α-cyano enamines is readily accomplished with a variety of alkylating agents, including alkyl fluorosulfonates, dialkyl sulfates, or ***Triethyloxonium Tetrafluoroborate*** (eq 10).[11]

(10)

Similar α-cyano enamines may also be obtained by reaction of α-chloro enamines with ***Potassium Cyanide*** (eq 11).[12] Addition of organolithium reagents to the cyano group followed by acidic hydrolysis provides α-diketones.[12]

t-Butyl Azidoformate

[1070-19-5] · $C_5H_9N_3O_2$ · *t*-Butyl Azidoformate · (MW 143.15)

(electron-deficient azide; can undergo cycloadditions with alkenes to yield triazolines;[1] used for the introduction of a *t*-Boc group on alcohols and amines)

Physical Data: bp 57-61 °C/40 mmHg; n^{24} 1.4224-1.4230.

Solubility: freely sol common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: see Insalaco and Tarbell.[10]

Handling, Storage, and Precautions: as with all azides of low molecular weight, *t*-butyl azidoformate is sensitive to both heat and shock. It is usually purified by distillation under reduced pressure and detonation under these conditions has been reported.[2] All operations involving this reagent should be carried out with great caution in a fume hood and behind a safety shield. The vapors of this reagent are toxic and inhalation is known to cause giddiness, nausea, and severe headache. It is recommended that the reagent be used immediately after preparation. The original literature should be thoroughly consulted before preparation and use of this reagent.

Introduction.

t-Butyl azidoformate is prepared by the reaction of *t*-butylcarbonic diethylphosphoric anhydride and potassium azide.[10] Other preparations involve the reaction of *t*-butyl carbazate with nitrous acid,[3] and the reaction of ***t-Butyl Chloroformate*** with tetramethylguanidinium azide.[4] *t*-Butyl azidoformate has been used in three broad classes of reactions: for the generation and reactions of the corresponding nitrenes, for the cycloaddition of the azide moiety to alkenes and other unsaturated groups, and for the *t*-butyloxycarbonylation of a wide variety of functional groups.

t-Butoxycarbonylnitrenes.

The nitrenes can be generated from *t*-butyl azidoformate both by thermolysis and photolysis. The synthetic utility of these nitrenes is limited because they often react by a variety of pathways to give a mixture of products. One of the few useful reactions involves heating *t*-butyl azidoformate in DMSO to give the corresponding sulfoximides via the nitrene (eq 1).[5]

(1)

Cycloaddition Reactions.

t-Butyl azidoformate has been used only sparingly in cycloadditions to alkenes. Azidoformates usually begin to decompose above 60 °C and only cycloadditions that proceed readily below this temperature are synthetically useful. This requirement has limited the cycloaddition partners to strained and/or electron-rich alkenes. The Δ^2-triazolines formed may be isolated or subjected to irradiation directly to give the aziridines. Cycloadditions to strained alkenes often proceed in high yields but with poor regioselectivity. However, if aziridines are the desired products, the poor regioselectivity in the cycloaddition is not a drawback since both regioisomeric triazolines lead to the same aziridine. Heating the substituted 7-oxabicyclo[2.2.1]hept-2-ene with *t*-butyl azidoformate in the dark followed by irradiation of the crude mixture of regioisomeric triazolines gives the aziridine in 63% yield (eq 2).[6]

(2)

t-Butoxycarbonylation.

t-Butyl azidoformate has been used for the *t*-butoxycarbonylation of a variety of functional groups such as alcohols, phenols, and amines.[7] Eq 3 illustrates the use of this reagent for the *t*-butoxycarbonylation of an amine.[7a] The mild conditions of the reaction coupled with the importance of the *t*-Boc functionality as a protecting group has made the reagent popular and it has found widespread use in peptide chemistry.[8] The *t*-butoxycarbonylation of pyrroles and

indoles has also been accomplished using this reagent.[9] However, in recent years, other commercially available compounds have replaced *t*-butyl azidoformate as the reagent of choice for such reactions in view of the potentially explosive properties of the latter.

Related Reagents.

1-(t-Butoxycarbonyl)imidazole; ***1-N-(t-Butoxycarbonyl)-1H-benzotriazole 3-N-Oxide***; ***2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile***; ***N-(t-Butoxycarbonyloxy)phthalimide***; ***1-t-Butoxycarbonyl-1,2,4-triazole***; ***Di-t-butyl Dicarbonate***.

t-Butyl 4-Benzoylperbenzoate

[71616-77-8] · $C_{18}H_{18}O_4$ · *t*-Butyl 4-Benzoylperbenzoate · (MW 298.34)

(reagent for low-temperature initiation of radical reactions)

Physical Data: mp 62-64 °C.

Solubility: sol benzene, methanol, cyclohexane.

Form Supplied in: not commercially available.

Preparative Method: prepared from the corresponding carboxylic acid chloride by treatment with ***t-Butyl Hydroperoxide***.[1]

Handling, Storage, and Precautions: avoid exposure of the reagent to light and heat; store protected from light in a refrigerator or freezer.

In the search for efficient photoinitiators for polymerization processes and radical C-C bond forming reactions a range of novel peresters were prepared, including *t*-butyl 4-benzoylperbenzoate (**1**).[1] On photolysis this compound undergoes efficient homolysis of the peroxide linkage, producing a carboxyl radical and a *t*-butoxy radical (eq 1). The latter is able to initiate further radical chemistry by hydrogen atom abstraction from a suitable donor. The advantages of using this system are that radical chemistry can be initiated at relatively low temperatures (contrasting with the thermal conditions often employed, such as ***Azobisisobutyronitrile*** in benzene at reflux) and the irradiation is carried out at relatively long wavelength (360 nm) which should not cause unwanted excitation in most other reactants.

The use of this initiator has been examined in some Kharasch-type additions of acyl radicals to alkene acceptors (eqs 2 and 3).[2]

4 °C	1:10.4
rt	1:6.3
78 °C	1:2.1

In competition reactions, involving addition to either 1-hexene or methyl crotonate, addition to methyl crotonate is preferred with the highest selectivity being observed when the reaction was conducted at 4 °C. This selectivity was then utilized to effect a cyclization reaction (eq 4).

Of the two possible pathways, only that resulting in the six-membered ring product is observed, due to the high regioselectivity in the initial acyl radical addition. Alternative methods of initiation of the reaction, using ***Dibenzoyl Peroxide*** or photolysis in the presence of benzophenone, were tried for comparison, but gave markedly lower yields of product.

[119838-38-9]

(chiral glycine derivatives[1] for the synthesis of amino acids)

Alternate Names: N-t-butoxycarbonyl-2-*t*-butyl-3-methylimidazolidin-4-one; Boc-BMI.

Physical Data: mp 68-70 °C; [α]rtD = 14.6° (*c* = 1.18, $CHCl_3$).

Solubility: sol all common organic solvents.

Form Supplied in: colorless crystalline solid.

Preparative Method: the commercial glycine *N*-methylamide hydrochloride is converted to the racemic imidazolidinone (**2**) by imine formation with ***Pivalaldehyde*** and cyclization under acidic conditions (eq 1).[1,2] The mandelate salt of like configuration is less soluble and is used for highly efficient resolution; subsequent treatment with Boc anhydride (***Di-t-butyl Dicarbonate***) gives the enantiomeric Boc-BMI (**1**) (eq 2).

Handling, Storage, and Precautions: stable in a bottle at rt for years.

Reactions of Boc-BMI with Electrophiles.

The enolate of Boc-BMI is generated with ***Lithium Diisopropylamide*** in THF at -75 °C; the resulting solutions of this highly nucleophilic reagent are stable up to 0 °C. All reactions occur from the face of the enolate *trans* to the *t*-Bu group at C(2). Alkylations[1,3-6] even with secondary alkyl halides are so efficient, to give (**3**), that one-pot double alkylations, which yield (**4**), are possible; the sequence in which two different alkyl halides are employed determines the absolute configuration of the α-branched α-amino acids eventually obtained.

(3)

(4)

The method has been used to prepare isotopically labelled amino acids.[3,7] While Boc-BMI enolate adds to aldehydes with only moderate diastereoselectivity, reduction of the acylation products (**5**) gives allothreonine derivatives (**6**).[8] Michael additions to α,β-unsaturated esters,[9] ketones,[10] and nitro compounds[1] lead to products of type (**7**) and (**8**) (for a general discussion see Suzuki and Seebach[9]).

(5)

(6)

(7)

(8)

Preparation of and Michael Addition to 5-Alkylidene Boc-BMI.

Radical bromination to give (**9**) (eq 3),[11] Arbuzov reaction, and alkenation lead to (*E*)-5-alkylidene-Boc-BMI, to which cuprates add highly diastereoselectively with formation of the imidazolidinones (**10**) containing two new stereogenic centers (eq 4).[12]

(9)

(3)

(10) (4)

Hydrolysis to Nonproteinogenic Amino Acids.

Numerous amino acids, including α-branched ones, have been prepared from Boc-BMI. Only a few examples can be alluded to here: (**11**) from (*S*)-(**1**), EtI, and $Br(CH_2)_4Cl$;[3] (**12**) from (*S*)-(**1**), 3-methylbutanoyl chloride, and ***Lithium Triethylborohydride***;[8] (**13**) from (*R*)-(**1**), butanal, and dibutylcuprate;[12] (**14**) from (*S*)-(**1**) and 4-phenylbut-2-enoate.[9]

(11)

(12)

(13)

(14)

The method is applicable to the synthesis of amino acids with extremely bulky substituents in the α-position.[4b]

Chiral Imidazolidinones with Other Substitution Patterns.

The intermediate imidazolidinone (**2**) can also be *N*-acylated by ***Benzoyl Chloride*** or ***Benzyl Chloroformate***, and other

substituents on the acetal center and/or on the N(3) nitrogen can be present, depending upon the aldehyde used for the imine formation and upon the glycine amide employed at the beginning of the synthesis. Chiral substituents, such as the 1-phenylethyl group may be placed on N(3), and the imidazolidinone may be derived from a dipeptide. Some examples are collected for (**15**), with references, in Table 1.[1,5,13-17] These different derivatives have advantages of their own, depending on the particular synthetic application. An access to Boc-BMI by kinetic resolution has recently been described.[18]

(15)

Table 1 Chiral Imidazolidinones (**15**) with Different Substitution Patterns

R^1	R^2	R^3
t-BuO[5]	*i*-Pr	Me
t-BuO[1]	*t*-Bu	Bn
BnO[1]	*t*-Bu	Me
BnO[1]	*t*-Bu	Bn
BnO[13]	*t*-Bu	CH_2CO_2R
BnO[13]	*t*-Bu	(*S*)-$CHMeCO_2Me$
BnO[14]	H	(*S*)-CHMePh
Ph[15,16]	*t*-Bu	Me
Ph[1]	*t*-Bu	Bn
Ph[17]	*t*-Bu	(*S*)- or (*R*)-CHMePh

Other Synthetic Building Blocks from Boc-BMI.

Deoxygenation of Boc-BMI leads to the imidazolidine (**16**) which can be lithiated on the methylene group next to N(1), and thus converted to compounds (**17**); from the corresponding ester ($R^E = CO_2Me$), 2,3-diaminopropionic acid derivatives (**18**) and (**19**) are available.[19]

t-Butyl Chloride-Aluminum Chloride[1]

t-BuCl.AlCl$_3$

(t-BuCl)

[507-20-0] · C_4H_9Cl · *t*-Butyl Chloride-Aluminum Chloride · (MW 92.57) ($AlCl_3$)

[7446-70-0] · $AlCl_3$ · *t*-Butyl Chloride-Aluminum Chloride · (MW 133.34)

(*t*-butylating agent;[1] hydrocarbon isomerization promoter;[1] sludge $AlCl_3$ catalyst[3])

Physical Data: *t*-BuCl: bp 51-52 °C; $AlCl_3$: sublimes at 178 °C.

Solubility: both *t*-BuCl and $AlCl_3$ sol organic solvents such as CH_2Cl_2 and $CHCl_3$ as well as CS_2.

Form Supplied in: *t*-BuCl: liquid; $AlCl_3$: solid. Both are commercially available.

Preparative Method: prepared by mixing equimolar amounts of *t*-BuCl and $AlCl_3$ at -78 °C.[2] This compound is a white or pale yellow needle-like crystal, which is stable and can be stored indefinitely at -78 °C. However, it decomposes at about -30 °C to yield a reddish liquid and HCl. In most reactions involving the use of *t*-BuCl.$AlCl_3$, both *t*-BuCl and $AlCl_3$ are generally added to the reaction solution independently without premixing. The ratio between *t*-BuCl and $AlCl_3$ may also vary, depending on the requirement of the specific reaction.

Handling, Storage, and Precautions: *t*-butyl chloride-aluminum chloride is corrosive and moisture sensitive. Thus it should be handled in an anhydrous atmosphere.

Introduction.

t-Butyl chloride-***Aluminum Chloride*** (1:1 molar ratio) is prepared at -78 °C, but is not stable at -30 °C and decomposes into a reddish liquid,[2] which belongs to a family of catalysts called aluminum chloride sludges.[3] The sludges are valuable catalysts for commercial-scale alkylation reactions since the liquid state of the catalysts ensures continuous flow operations.[3] Sludge catalysts have also found application in hydrocarbon isomerization.[3,27] Reagents derived from *t*-BuCl.$AlCl_3$ are not limited to the 1:1 molar ratio of the components. In many reactions, varying ratios of *t*-BuCl and $AlCl_3$ may be used, depending on the need of the specific reaction, and the addition of *t*-BuCl and $AlCl_3$ is generally performed without premixing the two components.

t-Butylation.

t-Butyl chloride-aluminum chloride is primarily used as a *t*-butylating agent in organic synthesis.[1] Efforts have been made to determine the structure and nature of this reagent. ^{1}H NMR analysis showed that the crystalline compound, isolated from the reaction of 1:1 molar equivalent of *t*-BuCl and $AlCl_3$ at -78 °C, is only a donor-acceptor complex since the complex did not contain any free *t*-butyl cation. However, *t*-BuCl was completely ionized to $Me_3C^+Al_2Cl_7^-$ in anhydrous HCl with excess $AlCl_3$ (eq 1).[4]

$$t\text{-BuCl} \xrightarrow[\text{HCl}]{\text{excess } AlCl_3} Me_3C^+\ Al_2Cl_7^- \qquad (1)$$

Friedel-Crafts alkylation with *t*-BuCl.$AlCl_3$ as a *t*-butylating agent has been well studied.[1] Early interest in this reaction was directed toward the mechanism of ionization.[1,5] The practical importance of the *t*-butylation in the perfume industry for the preparation of xylene musk also provided further impetus for examination.[1a] Recently, this reaction has been employed in organic synthesis to protect certain positions of arenes.[6] The *t*-butyl group introduced can be readily removed later.[7] Two important features have been established regarding the use of *t*-BuCl.$AlCl_3$ as an alkylating agent in aromatic substitution.[1a] It is difficult to achieve *ortho* substitution of substituted aromatic compounds, with the exception of fluorine substituted compounds. This is due to the steric bulk of the *t*-butyl group. Further, due to the strong Lewis acidic character of $AlCl_3$, *t*-butylation of aromatic compounds using *t*-BuCl.$AlCl_3$ is always accompanied by isomerization and disproportionation. These side reactions can be suppressed by employing solvents such as $MeNO_2$ and varying the reaction conditions.

Various arenes have been alkylated by *t*-BuCl.$AlCl_3$ (eq 2). The reaction occurs readily with benzene, monosubstituted benzene (alkyl and halo), *o*-xylene, and *m*-xylene as substrates.[1,8] However, abnormal reactions were encountered when arenes such as *p*-xylene and *p*-chlorotoluene are used as substrates, which only have *ortho* positions available for the intended *t*-butylation.[9] For example, the principal products from the reaction of *p*-xylene with *t*-BuCl.$AlCl_3$ are isobutane, toluene, *m*- and *p*-*t*-butyltoluenes, 3,5-di-*t*-butyltoluene, 2-(*p*-methylbenzyl)-*p*-xylene, and di-*p*-xylylmethane (eq 3).[9a,9b] With an excess of *t*-BuCl, 1,3,5-tri-*t*-butylbenzene can be prepared from di-*t*-butylbenzene in good yield (eq 4).[10] The *t*-BuCl.$AlCl_3$ system is able to alkylate phenols, but the best results with these substrates were obtained by use of alkenes and alcohols as alkylating agents.[1a] *t*-Butylation of naphthalene and its derivatives is also successfully achieved with *t*-BuCl.$AlCl_3$.[11] In the case of naphthalene, only the thermodynamic product, 2-*t*-butylnaphthalene, is observed (eq 5).[1a] When acenaphthene is used in the alkylation, both mono- and disubstitution products are obtained (eq 6).[12]

(2)

R = alkyl, halo

(3)

(4)

(5)

(6)

t-Butyl chloride-aluminum chloride has also been used for the *t*-butylation of alkenic substrates. Its reaction with alkenes was widely studied due to its obvious industrial importance.[13,14] Although oligomerization of alkenes can occur,[13e] it is possible to obtain β-*t*-butylalkyl chlorides as the major addition products of the reaction (eq 7).[14a-d] Elimination of HCl in situ led to the formation of *t*-butylated alkenes.[13a,14] Silyl enol ethers react with *t*-BuCl.$AlCl_3$ to yield α-*t*-butyl ketones or aldehydes (eq 8).[15] However, the best Lewis acid for this type of reaction is ***Titanium(IV) Chloride***. Compounds which contain very acidic C-H bonds, such as malononitrile, can be similarly *t*-butylated, presumably through enolization.[16]

(7)

(8)

Silylalkynes react with *t*-BuCl.$AlCl_3$ to form *t*-butylated alkynes (eq 9).[17]

(9)

t-Butyl chloride-aluminum chloride has been used to *t*-butylate PCl_3.[18] When PCl_3 is treated with *t*-BuCl.$AlCl_3$, *t*-butylphosphonyl dichloride is obtained upon hydrolysis (eq 10) (Clay reaction). This reaction is also applicable to a

number of organophosphorus compounds such as dichlorophenylphosphine (eq 11) and chlorodiphenylphosphine.[19] Reaction with diphosphorus pentasulfide leads to the formation of *t*-butylphosphinothioic acids after hydrolysis.[20]

(10)

(11)

Reaction between *t*-BuCl.$AlCl_3$ and chloroamines was also investigated.[21] When trichloroamine is used, 90% *t*-butylamine is obtained, along with 8% of 2,2-dimethylaziridine as a minor product (eq 12). However, the use of monochloroamine decreased the yield of *t*-butylamine to a range of only 7-20%.

(12)

Hydride Abstraction and Isomerization.

When *t*-BuCl.$AlCl_3$ reacts with crowded arenes such as *p*-xylene, abnormal reactions occur.[9] This results from initial hydride abstraction by *t*-BuCl.$AlCl_3$ from the benzylic positions. Similar reactions are observed with *p*-chlorotoluene and other crowded aromatics. When the *t*-butylation is conducted in the presence of an isoalkane, not only *t*-butylated products but also the alkylarenes derived from the isoalkane are observed (eq 13).[22] This phenomenon can also be explained by hydride abstraction by *t*-BuCl.$AlCl_3$ from the alkanes. This hydride abstraction has been elegantly utilized in the preparation of polyalkyltetralins (intermediates in the manufacture of musk aroma compounds, eq 14).[23] The polyalkyltetralins are prepared by combining *p*-cymene with alkenes under the catalysis of *t*-BuCl.$AlCl_3$. The reaction goes through initial hydride abstraction by *t*-BuCl.$AlCl_3$ from the *p*-cymene to generate the cumyl cation, which is subsequently alkylated by an alkene. A concurrent cyclization yields the final product.[23] 1,1,4,4,5,5,8,8-octamethyl-1,2,3,4,5,6,7,8-octahydroanthracene can be prepared by combining 1,3,5-tri-*t*-butylbenzene with *t*-BuCl.$AlCl_3$ (eq 15).[24]

(13)

(14)

(15)

t-Butyl chloride-aluminum chloride is exploited in the preparation of diamondoid compounds.[25] It was found that *t*-BuCl facilitates the isomerization of trimethylenenorbornane to adamantane by $AlCl_3$ (eq 16). The same reagent is also employed in the isomerization of heptacyclo[8.4.0.0^{2,12}.0^{3,8}.0^{4,6}.0^{5,9}.0^{11,13}]tetradecane (binor-S).[26] Compared to the *t*-BuBr.$AlBr_3$ system, *t*-BuCl.$AlCl_3$ is less well documented in the literature for this type of isomerization.[27]

(16)

t-Butyl chloride-aluminum chloride is also found to facilitate the methylation of methylcyclohexane with tetramethylsilane (eq 17).[28] Only 5% 1,1-dimethylcyclohexane is obtained when methylcyclohexane was treated with $Me_4Si.AlCl_3$. In contrast, 85% 1,1-dimethylcyclohexane was obtained when *t*-BuCl was added to the reaction system.

(17)

Other Reactions.

t-Butyl chloride-aluminum chloride is a good chlorinating agent for isoalkanes. It has been successfully used to selectively chlorinate 2,3-dimethylbutane (eq 18) and methylcyclohexane at the tertiary positions in excellent yields.[29] Dehydrochlorination of 2-chloro-2,3-dimethylbutane led to formation of 2,3-dimethylbutenes. When 1-chloro-1-methylcyclohexane was subjected to the same treatment, both 1-methylcyclohexene and methylenecyclohexane were obtained. The two reactions, along with recycling of HCl and isobutene, led to an industrial process for the manufacture of tertiary monoalkenes.[29]

(18)

t-Butyl chloride interacts with $AlCl_3$ to eliminate HCl to form isobutene, which can be polyacetylated by ***Acetyl Chloride***.[30] Upon treatment of the reaction mixture with aqueous ***Ammonia***, 2,4,6-trimethylpyridine, 4-acetonyl-2,6-dimethylpyridine, and 1,3,6,8-tetramethyl-2,7-naphthyridine were obtained in total 92% yield with a ratio of 36:40:24, respectively. If liquid ammonia is used, the yield of the reaction remained the same, but the proportion of 1,3,6,8-tetramethyl-2,7-naphthyridine increased to 63%, while only traces of 4-acetonyl-2,6-dimethylpyridine could be detected. The amount of 2,4,6-trimethylpyridine obtained was essentially the same (eq 19).

(19)

A: total yield 92%	36%	40%	24%
B: total yield 91%	37%	traces	63%

t-Butyl Chloroacetate

[107-59-5] · $C_6H_{11}ClO_2$ · *t*-Butyl Chloroacetate · (MW 150.60)

(reagent used in glycidic ester condensations[1] and as a two-carbon alkylating agent[2])

Physical Data: bp 48-49 °C/11 mmHg.

Form Supplied in: colorless liquid; widely available.

Preparative Method: prepared by treatment of chloroacetyl chloride with *t*-butyl alcohol.[3]

Handling, Storage, and Precautions: is a lachrymator and should be used in a well-ventilated fume hood.

t-Butyl chloroacetate has been used extensively in the formation of glycidic esters via the Darzens reaction[4] since the reagent minimizes metal enolate self-condensation.[1,5] Darzens reaction of *t*-butyl chloroacetate (**1**) and chiral η^6-$Cr(CO)_3$ complexed aromatic aldehydes (**2**) leads to a mixture of *cis* and *trans* glycidic esters of high optical purity (eq 1).[6] A related chloroacetate has been used in an asymmetric Darzens glycidic ester condensation for the synthesis of the calcium channel blocker diltiazem.[7] α-Halo ketones undergo a novel Darzens-type reaction in the presence of *N*-tri-*n*-butylstannylcarbamates.[8] Condensation of enolates of *t*-butyl chloroacetate with chiral imines leads to 3-haloazetidinones or aziridines, depending on the metal enolate.[9] The triisopropoxytitanium enolate of (**1**) gives (3*R*,4*R*)-chloroazetidinone (**4**) (eq 2), while lithium (eq 3) and zinc enolates (eq 4) give only (2*R*,3*S*) (**5**) and (2*S*,3*R*) (**6**) aziridines, respectively.

t-Butyl chloroacetate is the reagent of choice for the vicarious nucleophilic substitution of hydrogen in nitroarenes.[10] This reaction has been applied to the formal total synthesis of eupolauramine (eq 5).[11]

Although less reactive than the corresponding bromide, *t*-butyl chloroacetate has been used as a two-carbon alkylating agent. For example, *N*-formylglycine is formed by the reaction of (**1**) and sodium diformylamide.[2] The synthesis of dialkyl alkoxycarbonylmethanephosphonates,[12] rhenium enolate complexes,[13] and *t*-butyl (triphenylphosphoranylidine)acetate[14] also rely upon the electrophilic nature of (**1**).

The limitations of *t*-butyl chloroacetate as an electrophile is illustrated in the synthesis of (-)-8-azaestrone by Meyers (eq 6).[15] Reaction of the lithium anion of (**7**) with (**1**) gives a 2:1 ratio of (**8**) to (**9**). The undesired lactam (**9**) is formed by nucleophilic attack of (**10**) on the chlorine atom of (**1**), presumably due to the steric bulk of the alkylating agent (eq 7).

Related Reagents.

Methyl Bromoacetate; ***Methyl Chloroacetate***.

t-Butyl Chloroformate

[24608-52-4] · $C_5H_9ClO_2$ · *t*-Butyl Chloroformate · (MW 136.58)

(reagent for the protection of amino groups, including amino acids[2])

Alternate Name: Boc-Cl.

Physical Data: bp 3-4 °C/0.9-1.7 mmHg.[1]

Solubility: sol ether, toluene, and most organic aprotic solvents.

Form Supplied in: not commercially available; should be prepared from *t*-butanol[2] or potassium *t*-butoxide[1,3] and phosgene shortly before use.

Handling, Storage, and Precautions: unstable at rt. *t*-Butyl chloroformate should be kept as a solution in anhydrous solvent at low temperature (deep freezer) and for a period of time not exceeding a few days. Decomposition leads to high pressure in the storage vessel. May contain some residual phosgene. Reacts with DMSO or DMF.

Protection of Amino Groups.

t-Butyl chloroformate (Boc-Cl), first prepared by Choppin and Rogers in 1948,[1] has been used, despite the reagent's instability, for the *t*-butyloxycarbonyl (Boc) protection of amino compounds and especially of amino acids. Boc protection has gained considerable importance because of the resistance of the protecting group to strong base hydrolysis and catalytic hydrogenation, as well as the ease of deprotection under mildly acidic conditions. Boc protection has become a fundamental tool of modern peptide synthesis and particularly of the Merrifield strategy for solid-phase peptide synthesis. Most amino acids have been protected with Boc-Cl using slightly modified Schotten-Baumann conditions (eq 1).[2]

Reaction of pyridine compounds with Boc-Cl and ***Sodium Borohydride*** in methanol at -65 °C afforded the corresponding *N*-*t*-butyloxycarbonyldihydropyridine derivatives in good yield (eq 2).[4]

The main drawback of the reagent remains its very low stability and the difficulties encountered in its preparation. Various preparative procedures are currently available in the literature.[5] It is also necessary to determine the reagent concentration in solution accurately, which can be done by reacting an aliquot with a selected amino compound before use. These liabilities notwithstanding, *t*-butyl chloroformate can be a cheap and valuable reagent for Boc protection and in some cases it is the best reagent available. This is, for instance, the case in the synthesis of Boc-protected *N*-carboxy anhydrides, which are used as building blocks in peptide synthesis (eq 3).[6] ***Di-t-butyl Dicarbonate*** required much longer reaction times in this case. These Boc-UNCAs (urethane-protected *N*-carboxy anhydrides) are, in fact, best prepared from the reaction of Boc-Cl with Leuchs anhydride in the presence of *N*-methylmorpholine or any nonnucleophilic organic base.

Preparation of Other Reagents for Boc Protection.

Because of its low stability, *t*-butyl chloroformate has mainly been used as a source of various other reagents that are

easier to handle under ordinary conditions. ***t-Butyl Azidoformate***, the most widely employed reagent before the discovery of ***Di-t-butyl Dicarbonate***, is conveniently obtained from Boc-Cl through the formation of *t*-butyl carbazate (eq 4).[7]

t-Butyl azidoformate is also obtained more directly from Boc-Cl and hydrazoic acid (eq 5).[8]

Various active carbonates, which are primarily used for the preparation of stable reagents for the introduction of the Boc protection, have been prepared from Boc-Cl.[9]

Exchange reactions utilizing hydrogen fluoride[10] and various salts such as sodium[11] and silver fluoride do not lead to the more stable *t*-butyl fluoroformate, which has to be prepared instead from carbonyl chlorofluoride or fluorophosgene.[12]

t-Butyl Carbonates and Carbamates.

Because Boc-Cl is potentially the cheapest reagent for the synthesis of *t*-butyl carbonates, e.g. (**1**) and (**2**), or carbamates, it has been claimed in numerous patents and may have growing utility in industrial processes, such as for the production of carbonates as components in thermal recording materials.[13]

s-Butyl Chloroformate

[17462-58-7] · $C_5H_9ClO_2$ · *s*-Butyl Chloroformate · (MW 136.58)

(reagent for preparation of mixed anhydrides for peptide synthesis[1,2])

Physical Data: bp 115-117 °C; *n*24D 1.4037.

Preparative Method: prepared (50% yield) by reaction of *s*-butanol with 1.5 equiv of phosgene.[1]

Purification: purified by distillation.

Handling, Storage, and Precautions: no information available.

Mixed Anhydrides for Peptide Synthesis.

s-Butyl chloroformate (**1**) reacts with *N*-protected amino acids to give the mixed anhydride (**2**); treatment with an amino acid ester (or an alkaline aqueous solution of an unprotected amino acid) results in amide bond formation, affording (**3**) (eq 1).[1,2] The method is rapid and clean; since the only byproducts of the reaction are CO_2 and *s*-butanol, the products are obtained in a high state of purity, and sometimes crystallize directly from the reaction mixture. Other simple alkyl chloroformates may of course be used in place of (**1**), but Vaughan and Osato noted that (**1**) and *i*-butyl chloroformate provided highest yields, with a slight advantage for the former.[1]

While racemization is generally not observed in the synthesis of dipeptides, careful choice of conditions is necessary for the preparation of higher peptides. The use of THF as solvent in the anhydride formation step is recommended, along with shorter reaction times (5-10 min at -5 °C) if racemization is likely to be a problem.[3]

t-Butyl Chloromethyl Ether

[40556-01-2] · $C_5H_{11}ClO$ · *t*-Butyl Chloromethyl Ether · (MW 122.59)

(reagent for introducing an acid-labile alcohol- or an imidazole-protecting group[1])

Physical Data: decomposes upon attempted isolation.

Solubility: sol CH_2Cl_2, $CHCl_3$, CCl_4.

Form Supplied in: generated immediately prior to use.

Analysis of Reagent Purity: ^{1}H NMR (CCl_4, δ 5.6[1] or 5.4[2] (2H, s), 1.2 (9H, s)).

Preparative Methods: chlorination of *t*-butyl methyl ether using NCS,[1] treatment of *t*-butyl methylthiomethyl ether with sulfuryl chloride,[2] or cleavage of *t*-butyl methoxymethyl ether with BCl_3.[4]

Handling, Storage, and Precautions: solutions in CH_2Cl_2 appear to remain unchanged upon standing at rt for several days.[2] Concentration apparently leads to decomposition. The structurally similar ***Chloromethyl Methyl Ether*** is a putative carcinogen.

Protection of Alcohols.

This reagent was introduced in 1978 as a reagent for protecting alcohols as *t*-butoxymethyl ethers.[1] An acetal protecting group analogous to the more common methoxymethyl (MOM) group, the *t*-butoxymethyl moiety can be removed under significantly milder conditions (see below). The initial report described its preparation via treatment of methyl *t*-butyl ether (MTBE) with ***N-Chlorosuccinimide*** in CCl_4 under sunlamp irradiation. Removal of succinimide by filtration gave a crude CCl_4 solution of *t*-butyl chloromethyl ether which was stable under nitrogen at rt. A subsequent report highlighted the importance of excluding both oxygen and acid during the chlorination, recommending carrying out the reaction under dry nitrogen and advocating the addition of *N*,*N*-diisopropyl-3-pentylamine as a proton scavenger.[3] An interesting study detailing a general entry into a variety of chloromethyl ethers described the conversion of *t*-butyl methoxymethyl ether into *t*-butyl chloromethyl ether using ***Boron Trichloride*** (eq 1).[4] A related procedure has been reported, entailing preparation of *t*-butyl methylthiomethyl ether and its nearly quantitative conversion to the desired reagent by treatment with ***Sulfuryl Chloride*** in CH_2Cl_2 (eq 2).[2]

(1)

(2)

Protection of alcohols proceeds by addition of the crude solution of *t*-butyl chloromethyl ether to a THF solution of the alcohol and 4 equiv ***Triethylamine*** at -20 °C (eq 3), followed by warming to rt.[1] The product *t*-butoxymethyl ethers can be chromatographed on alumina. Deprotection is effected by treatment with aqueous ***Trifluoroacetic Acid*** in THF at rt, conditions which do not lead to deprotection of methoxymethyl ethers (eq 4). The imidazole N-H of histidine derivatives can also be protected using *t*-butyl chloromethyl ether.[3] This group is stable to nucleophilic or basic reagents and catalytic hydrogenolysis, conditions which might be encountered during peptide synthesis, but can be removed with trifluoroacetic acid or with anhydrous ***Hydrogen Chloride*** or ***Hydrogen Bromide*** in acetic acid.

t-Butyl 2-Chloro-2-trimethylsilylacetate

[66406-43-7] · $C_9H_{19}ClO_2Si$ · *t*-Butyl 2-Chloro-2-trimethylsilylacetate · (MW 222.79)

(alkenation of enolizable ketones leading to functionalized, tetrasubstituted alkenes (α,β-unsaturated esters) via a Peterson alkenation)

Physical Data: bp 55 °C/1.4 mmHg.

Solubility: sol THF.

Preparative Method: prepared from ***t-Butyl Chloroacetate*** by sequential reaction with ***Lithium Diisopropylamide*** and ***Chlorotrimethylsilane*** followed by aqueous workup and distillation.[1]

Handling, Storage, and Precautions: as this material is an activated alkyl halide, it must be considered a potential alkylating agent and lachrymator and handled with care and suitable protective clothing (e.g. gloves) in a fume hood.

The classical method for alkenation of an aldehyde utilizes Wittig reagents (phosphorus ylides) or related species such as the Wadsworth-Emmons reagent. These reagents do not generally give useful yields in the alkenation of ketones because of problems of steric hindrance between the ketone and the phosphorus reagent and because of competing enolization of the ketone. α-Silyl carbanions are generally less basic and less subject to steric encumbrance than the corresponding phosphorus ylides.[2] Therefore the Peterson alkenation[2] of ketones by α-silyl carbanions frequently provides superior results to the phosphorus reagents such as in the alkenation of cyclopentanone (eq 1).[3]

(1)

If the α-silyl carbanion is also functionalized with a leaving group such as chloride, condensation with carbonyl compounds can lead to epoxysilanes (eq 2).[4]

(2)

If the carbanion is further substituted with a *t*-butoxycarbonyl group, the epoxysilane reaction pathway is suppressed and Peterson alkenation is the normal reaction course. Thus the reaction of *t*-butyl 2-chloro-2-lithio-2-trimethylsilylacetate, derived from *t*-butyl 2-chloro-2-trimethylsilylacetate by reaction with LDA, with aldehydes (eq 3) and ketones (eq 4) leads to tri- and tetrasubstituted functionalized alkenes, α-chloro-α,β-unsaturated esters.[1]

(3)

(4)

In the case of unsymmetrical ketones, moderate (eq 5) to good (eq 6) degrees of stereoselection are observed in the alkenation process, although yields are typically low.

(5)

(6)

Chloro *t*-butoxycarbonylalkenes are of use as functional intermediates in, for example, the total synthesis of prostaglandins.[5] More general is the interest in these products as herbicides,[6] insecticides,[7] and antibiotics.[8] In the latter case, the Peterson alkenation was utilized to prepare C(2)-substituted monic acid esters (eq 7).

t-Butyldimethylchlorosilane

t-BuMe$_2$SiCl

[18162-48-6] · $C_6H_{15}ClSi$ · *t*-Butyldimethylchlorosilane · (MW 150.72)

(widely used reagent for the protection of alcohols, amines, carboxylic acids, ketones, amides, thiols, and phenols;[1] useful for regioselective silyl enol ether formation[2] and stereoselective silyl ketene acetal formation[3])

Alternate Names: *t*-butyldimethylsilyl chloride; TBDMSCl; TBSCl.

Physical Data: mp 86-89 °C; bp 125 °C.

Solubility: very sol nearly all common organic solvents such as THF, methylene chloride, and DMF.

Form Supplied in: moist white crystals, commonly available.

Handling, Storage, and Precautions: hygroscopic, store under N_2; harmful if inhaled, swallowed, or absorbed through skin; should be used and weighed out in a fume hood.

Protecting Group.

The reactions of TBDMSCl closely parallel those of ***Chlorotrimethylsilane*** (TMSCl). However, TBDMS ethers are about 10^4 more stable toward hydrolysis than the corresponding TMS ethers.[1,4] The hydrolytic stability of the TBDMS group has made it very valuable for the isolation of many silicon-containing molecules. Since its introduction in 1972, the TBDMS protecting group has undoubtedly become the most widely used silicon protecting group in organic chemistry.[1] Alcohols are most commonly protected as their TBDMS ethers by treatment of the alcohol in DMF (2 mL g^{-1}) at rt with 2.5 equiv of ***Imidazole*** (Im) and 1.2 equiv of TBDMSCl. Alcohol protection in the presence of ***4-Dimethylaminopyridine*** (DMAP) allows a greater range of solvents to be used (protection of alcohols in solvents other than DMF using TBDMSCl alone are sluggish) and distinguishes a kinetic preference for protection of primary alcohols in the presence of secondary alcohols.[5] Table 1 outlines conditions for the selective protection of primary and secondary alcohols using TBDMSCl and DMAP as catalyst.

Table 1 Use of DMAP to Catalyze the Protection of Diols With TBDMSCl

Amine(s)	Solvent	GC ratio of A:B:C
DMAP (0.04 equiv), Et_3N (1.1 equiv)	CH_2Cl_2	95:0:5
Im (2.2 equiv)	DMF	59:11:30
Im (0.04 equiv), Et_3N (1.1 equiv)	DMF	No reaction
DMAP (0.04 equiv), Et_3N (1.1 equiv)	DMF	0:0:96

Alcohol:

Products:

A

B

C

Table 2[6] compares the rate of hydrolysis of several bulky silicon ethers with acid, base, and fluoride; TBDMS ethers are less resistant to hydrolysis than the corresponding TIPS (triisopropylsilyl) and TBDPS (*t*-butyldiphenylsilyl) ethers.

Table 2 Comparison of TBDMS, TIPS, and TBDPS rates of hydrolysis by F^-, H^+, and OH^- ($t_{1/2}$).

$ROSiR'_3$	R = *n*-Bu[a]		R = Cy[a,b]		
	H^+	OH^-	H^+	OH^-	F^-
TBDMS	<1 min	1 h	<4 min	26 h	76 min
TIPS	18 min	14 h	100 min	44 h	137 min
TBDPS	244 min	<4 h	360 min	14 h	

[a] H^+ refers to 1% HCl in 95% EtOH at 22 °C; OH^- refers to 5% NaOH in 95% EtOH at 90 °C. [b] F^- refers to 2 equiv of *n*-Bu_4NF in THF at 22 °C.

The TBDMS group is also suitable for the protection of amines, including heterocycles, carboxylic acids, and phenols. Other more reactive reagents are also available for introduction of the TBDMS group including ***t-Butyldimethylsilyl Trifluoromethanesulfonate***, MTBSA, and TBDMS-imidazole.[1,7]

Anion Trap.

TBDMSCl is useful as an anion trapping reagent. For example, TBDMSCl was found to be an efficient trap of the lithio α-phenylthiocyclopropane anion.[8] When dichlorothiophene was treated with 2 equiv of ***n-Butyllithium*** followed by 2 equiv of TBDMSCl the di-TBDMS-thiophene was isolated.[9] The lithium anions of primary (eq 1) and secondary (eq 2) nitriles were trapped with TBDMSCl to give *C,N*-disilyl- and *N*-silylketenimines in excellent yields.[10]

(1)

(2)

Silyl stannanes have been prepared by trapping tin anions with TBDMSCl or other silyl chlorides. Alkynes treated with with silyl stannanes and catalytic ***Tetrakis(triphenylphosphine)palladium(0)*** give *cis*-silyl stannylalkenes in good yields.[11]

Silyl Ketene Acetals.

The lithium enolates of esters may be trapped with TBDMSCl to prepare the corresponding ketene silyl acetals.[3] The resulting TBDMS ketene acetals are more stable than the corresponding TMS ketene acetals and have a greater preference for *O*- vs. *C*-silylation products. When TMSCl was used to trap the enolate of methyl acetate, a 65:35 ratio of *O*- to *C*-silated products was obtained. In addition, *O*-(TMS) silyl ketene acetals are thermally and hydrolytically unstable. However, similar treatment of lithium enolates with TBDMSCl provided the corresponding *O*-(TBDMS) silyl ketene acetals exclusively (eq 3). The *O*-TBDMS ketene acetals generally survive extraction from cold aqueous acid. ***Lithium Diisopropylamide*** was found to be satisfactory for the preparation of the ester enolates. The lower reactivity of TBDMSCl requires that the enol silation be performed at 0 °C with added HMPA.[12]

(3)

A detailed study of the formation of (*E*)- and (*Z*)-silyl ketene acetals was recently published.[3d] It was found that the formation of silyl enolates does not correspond to simple kinetic vs. thermodynamic formation of the enolates. Formation of the ester enolates occurred under kinetic control and a kinetic resolution accounted for selective formation of (*E*)- and (*Z*)-silyl ketene acetals. Table 3 summarizes some of these results.

Table 3 Effects of Reaction Conditions on (*Z*):(*E*) Ratio of TBDMS Silyl Ketene Acetal Formation of Ethyl Propionate

Ester:base ratio	Base	Solvent	Additive	(*Z*):(*E*) Silyl ketene acetal ratio	Yield (%)
1:1	LDA	THF	-	6:94	90
1.05:1	LDA	THF	45% DMPU	≥98:2	80
1.2:1	LDA	THF	23% HMPA	93:7	65
1:1	LDA	THF	23% HMPA	85:15	80
1:1	LHMDS	THF	23% HMPA	>91:9	85
1.1:1	LHMDS	THF	23% HMPA	>95:5	60

(*E*)

Claisen Rearrangement.

The first silyl ketene acetal Claisen rearrangement was introduced in 1972 using TMS ketene acetals. Since then, the silyl Claisen rearrangement using TBDMS ketene acetals has found widespread use in organic synthesis.[13,14] One advantage of the silyl ketene acetal Claisen rearrangement is that the ketene acetal geometry may be predictably controlled (see above). Two components of the reaction contribute to stereocontrol: the geometry of the silyl ketene acetal and the contribution of boat vs. chair transition state. A useful variant of the Claisen rearrangement involves the use of an enantiomerically pure α-silyl secondary alcohol prepared by Brook rearrangement of a TBDMS-protected primary alcohol. In this reaction the stereochemistry at the silicon-bearing center is transferred to the Claisen product.[15] The (*E*)-enolate was prepared by treatment of the ester with ***Lithium Hexamethyldisilazide*** (eq 4); the (*Z*)-enolate was prepared by treatment of the ester wit h LDA (eq 5).[15b] As expected, the (*Z*)- and (*E*)-silyl ketene acetals gave the corresponding *syn* and *anti* Claisen products in good selectivity. The vinylsilane was hydrolyzed to the alkene using 50% HBF_4 in acetonitrile at 55 °C.

The silyl ketene acetals of methyl α-(allyloxy)acetates were found to undergo [3,3]-sigmatropic rearrangement, whereas the corresponding lithium enolates undergo [2,3]-sigmatropic rearrangement.[16] An interesting ring contraction based on the TBDMS silyl ketene acetal Claisen rearrangement has also been reported.[17]

TBDMS Enol Ethers.[18]

Enolates trapped with TBDMSCl to prepare the corresponding enol ethers are more stable than the corresponding TMS enol ethers.[19] The potassium enolate of 2-methylcyclohexanone, prepared by addition of ***Potassium Hydride*** to a solution of the ketone and TBDMSCl in THF at -78 °C followed by warming to rt, gave the thermodynamic enol ether in a 56:44 ratio. In the presence of HMPA, the ratio improves to 98:2 (eq 6). This method works especially well with ketones with a propensity for self-condensation.[20]

(6)

Potassium enolates derived from acylfulvalenes were trapped with TBDMSCl but not TMSCl or diphenylmethylsilyl chloride.[21] Interestingly, TBDMSCl was found to be compatible with CpK anion at -78 °C. TBDMS enol ethers have also been used as β-acyl anion equivalents.[22] The TBDMS-silyl enol ethers of diketones (eq 7) and β-keto esters (eq 8) may be prepared by mixing them with TBDMSCl in THF with imidazole.[23] Alcohols may be protected under acidic conditions as their TBDMS ethers by treatment with β-silyl enol ethers in polar sovents.

(7)

(8)

Aldol Reaction.

The catalyst system TBDMSCl/$InCl_3$ selectively activates aldehydes over acetals for aldol reactions with TBDMS enol ethers.[24] Acetals and aldehydes are activated towards aldol reactions using TMSCl/$InCl_3$ or Et_3SiCl/$InCl_3$ as catalysts (eq 9).

(9)

TBDMSCl as Cl⁻ Source.

TBDMSCl was used as a source of chloride ion in the Lewis acid-assisted opening of an epoxide.[25] The epoxide was treated with TBDMSCl and ***Triethylamine*** followed by ***Titanium Tetraisopropoxide*** and additional TBDMSCl to give the *trans* chloride as the major product in 67% yield (eq 10).

(10)

TBDMSCl-Assisted Reactions.

Nitro aldol (Henry) reactions have been reported to be promoted by TBDMSCl.[26] To a THF solution of ***Tetra-n-butylammonium Fluoride*** is added sequentially equimolar amounts of the nitro compound, aldehyde, and Et_3N, followed by an excess of TBDMSCl (eq 11). Substitution of TMSCl for TBDMSCl reduces the yield of nitro aldol product. The authors speculate that TBDMSCl is responsible for activation of the aldehyde while *n*-Bu_4NF activates the nitro compound. In a related method, primary and secondary nitro alkanes were treated with LDA in THF followed by addition of TBDMSCl to give the corresponding silyl nitronates. The silyl nitronates reacted with a variety of aliphatic and aromatic aldehydes which gave vicinal nitro TBDMS aldol products.[27]

(11)

Reaction with Nucleophiles.

TBDMSCl is the reagent of choice for the preparation of other TBDMS-containing reagents. For example, ***t-Butyldimethylsilyl Cyanide*** may be prepared by the reaction of TBDMSCl and ***Potassium Cyanide*** in acetonitrile containing a catalytic amount of ***Zinc Iodide***.[28] TBDMSCN has also been prepared by treatment of TBDMSCl with KCN and ***18-Crown-6*** in CH_2Cl_2 at reflux and by treatment of TBDMSCl with ***Lithium Cyanide*** prepared in situ.[29] ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** is prepared by treatment of TBDMSCl with ***Trifluoromethanesulfonic Acid*** at 60 °C.[30] Other nucleophiles, such as thiolates, also react with TBDMSCl.[31] ***t-Butyldimethylsilyl Iodide*** was prepared by treatment of TBDMSCl with ***Sodium Iodide*** in acetonitrile.[32] In contrast to THF cleavage reactions using TMSI, the more stable TBDMS-protected primary alcohol may be isolated from the reaction in eq 12.

(12)

Mannich Reaction.

The Mannich reaction of *N*-methyl-1,3-oxazolidine with 2-methylfuran was shown to proceed smoothly in the presence of TBDMSCl and catalytic ***1,2,4-Triazole*** in 61% yield. Interestingly, this reaction failed with TBDMSOTf due to the destruction of 2-methylfuran. The reaction proceeds with decreased yield (31%) in the absence of triazole. These reaction conditions allowed for the isolation of the TBDMS-protected alcohol (eq 13).[33]

(13)

Acid Chlorides.

TBDMS esters, when treated with DMF and ***Oxalyl Chloride*** in methylene chloride at 0 °C, give the corresponding acid chlorides in excellent yields under neutral conditions (eq 14).[34] Similarly, *N*-carboxyamino acid anhydrides were prepared via the intermediacy of an acid chloride prepared from a TBDMS ester (eq 15).[35]

(14)

(15)

Conjugate Additions.

When a mixture of TBDMSCl and a β-aryl enone (2:1) was added to $Bu_2CuCNLi_2$ at -78 °C, the TBDMS group added 1,4 to the enone to give β-silyl carbonyl compounds (eq 16).[36] *N*-TBDMS silyliminocuprates also add to α,β-unsaturated carbonyl compounds.[37]

(16)

α-Silyl Aldehydes.

Initial attempts to isolate TMS α-silyl aldehydes were unsuccessful due to the lability of the TMS group. However, the α-silyl aldehyde was prepared from the cyclohexyl imine of acetaldehyde by treatment with LDA followed by TBDMSCl (eq 17). Typical of TBDMSCl trapping reactions of imines and hydrazones, *C*-silylation was observed. The imine was hydrolyzed with HOAc in CH_2Cl_2 which gave the α-silyl aldehyde. These compounds, after treatment with organometallic reagents such as ***Ethylmagnesium Bromide*** or ***Ethyllithium***, may be eliminated in a Peterson-like manner to give either *cis* or *trans* alkenes (eq 18).[38]

(17)

(18)

α-Silyl Ketones.

When SAMP or RAMP hydrazones were treated with LDA followed by TBDMSCl, the corresponding α-silyl hydrazones were isolated. Ozonolysis of the hydrazone gave the enantiomerically enriched α-silyl ketones (eq 19).[39] Yields for the overall process are 52-79% for the preparation of α-silyl ketones and 22-42% for the preparation of α-silyl aldehydes. TBDMSOTf may also be used for quench of the SAMP/RAMP hydrazone enolate.

(19)

Acyl Silanes.

Although acyl trimethylsilanes are known, they are usually unstable and lead to poor diastereoselectivity in aldol reactions.[40] TBDMS acyl silanes, however, were prepared in 50% yield from 1-methoxy-1-lithiopropene in the presence of TMEDA at rt (eq 20). The lithium enolates of TBDMS acyl silanes were treated with aldehydes to give the corresponding aldol products in reasonable yields.

(20)

TBDMS acyl enones were prepared by treatment of an ethoxyethyl (EE)-protected alkoxyallene with *n*-BuLi at -85 °C followed by treatment of resulting anion with TBDMSCl (eq 21). Acid hydrolysis of the OEE group led to the TBDMS acyl enones in good yield.[41]

t-Butyldimethylchlorosilane

(21)

Modified Amine Base.

The regioselectivity of ketone deprotonation was improved by the use of lithium *t*-butyldimethylsilylamide as base.[42] The base was prepared by deprotonation of isopropylamine with *n*-BuLi in THF (eq 22). The resulting anion was quenched with TBDMSCl to give the amine in 70% yield after distillation. Deprotonation of various ketones using this amide base was found to be equally or more selective than LDA. For example, the TBDMS-modified base gave a 62:38 ratio of kinetic to thermodynamic enolate, whereas LDA gave a 34:66 ratio with phenyl acetone.

(22)

N-Formylation.

When secondary amines were treated with TBDMSCl, DMAP, and Et_3N in DMF the corresponding *N*-formyl derivatives were formed (eq 23).[43] It was found that the reaction proceeds through a Vilsmeier type reagent formed by the reaction of TBDMSCl and DMF. It is possible that other TBDMS alkylation reactions, such as protection of alcohols in DMF, may proceed through a similar DMF-derived Vilsmeier reagent.

N-Silyl Imines.

When aldehydes were treated first with tris(trimethylstannyl)amine followed by TBDMSCl, the corresponding *N*-TBDMS imines were isolated in good yields.[44] These silyl imines reacted with ester enolates to give β-lactams (eq 24).

N´-t-Butyl-*N,N*-dimethylformamidine[1]

[3717-82-6] · $C_7H_{16}N_2$ · *N´-t*-Butyl-*N,N*-dimethylformamidine · (MW 128.22)

(lithiation of the title reagent generates an aminomethyl carbanion equivalent which reacts with electrophiles to give, after hydrolysis, homologated *N*-methylamines; exchange with a secondary amine allows for its subsequent lithiation and alkylation)

Physical Data: bp 133-134 °C.

Preparative Method: condensation of ***t-Butylamine*** with either *N,N*-dimethylformimidate salts or with dimethylformamide dimethyl acetal cleanly affords *N´-t*-butyl-*N,N*-dimethylformamidine (eq 1).[1,2a,b]

Handling, Storage, and Precautions: store under an inert atmosphere.

Synthetic Utility.

Deprotonation of *N´-t*-butyl-*N,N*-dimethylformamidine produces a dipole-stabilized carbanion.[1,2c] Treatment of this species with electrophiles followed by hydrolysis of the formamidine affords the corresponding α-substituted amine (eq 2).[2a,d]

The related *N´-n*-butyl- and *N´*-cyclohexylformamidines (**1**) and (**2**) are also effective in the above procedure.[2a,3]

(1) **(2)**

When the title formamidine (or the *n*-butyl or cyclohexyl analog) is heated in the presence of a secondary amine, dimethylamine is displaced producing a new formamidine derivative of the secondary amine. Deprotonation and alkylation followed by formamidine hydrolysis allows entry into a host of 1-substituted amines.[1] For example, a variety of 1-substituted tetrahydroisoquinolines (eq 3) can be prepared by this method.

(3)

In addition to the exchange method with the title reagent, the *t*-butylformamidines of secondary amines can be prepared by aminolysis of *O*-ethyl formimidate salts (eq 4).[4]

(4)

This route has been used to alkylate indolines (eq 5),[4a] tetrahydroquinolines,[4a] dihydroisoindoles,[4b] and *N*-methylanilines.[4a]

(5)

Exchange of the title reagent with tetrahydro-β-carbolines followed by lithiation and alkylation gives access to a variety of indole alkaloids.[5] Piperidines,[2b,6,7] pyrrolidines,[2b,7] perhydroazepines (eq 6)[2b] and *cis*- and *trans*-decahydroquinolines,[8] as well as others,[7f] can also be alkylated via their formamidine derivatives.

(6)

α-Arylpyrrolidines and -piperidines can be accessed by bridging dialkylations of *N*-benzyl-*N*-methylamines with 1,3- or 1,4-dihalides.[9] Other amine heterocycles, such as thiazolidine and 1,3-thiazine, may be alkylated at the carbon between the nitrogen and sulfur.[2b]

Unsaturated cyclic formamidines can be prepared by the sequence of formamidine exchange, metalation, selenation, and selenoxide elimination (eq 7).[10]

(7)

These unsaturated formamidines can be alkylated by the formamidine methodology. Metalation causes deprotonation of the alkenic proton adjacent to the ring nitrogen (eq 8).[10]

(8)

Nucleophilic additions adjacent to nitrogen have also been effected by using α´-methoxyformamidines. In this case the methoxyformamidines were not prepared from the title reagent and the formamidine is serving as a protecting and stabilizing group for the α-amino ether (eq 9).[11]

(9)

Various achiral formamidines that contain a chelating group have also been successfully utilized.[12] Thus by incorporation of a methoxy group on the formamidine, spiroisoquinolines (eq 10)[12a] and fused annulated isoquinolines can be prepared efficiently using the above methodology.

(10)

Conversion of the title reagent to ***N´-t-Butyl-N-methyl-N-trimethylsilylmethylformamidine*** (eq 11) allows for the one-carbon homologation of carbonyl compounds to nitriles, amines, aldehydes, and ketones.[13]

(11)

Formamidines form higher order cyanocuprates which add in a 1,4 fashion to Michael acceptors.[14] Incorporation of a chiral auxiliary in the formamidine results in high levels of asymmetric induction (see the chiral enantiopure ***(S)-N,N-Dimethyl-N´-(1-t-butoxy-3-methyl-2-butyl)formamidine***).[1,15]

t-Butyldimethylsilyl Cyanide

***t*-BuMe$_2$SiCN**

[56522-24-8] · $C_7H_{15}NSi$ · *t*-Butyldimethylsilyl Cyanide · (MW 141.29)

(preparation of stable silylated cyanohydrins;[1] silylating agent;[2] synthesis of isocyanides via oxirane ring opening[3])

Alternate Names: t-butylcyanodimethylsilane; TBDMSCN.

Physical Data: bp 163-167 °C/760 mmHg; mp 76-78 °C.

Solubility: sol organic solvents (methylene chloride, THF, chloroform); reacts rapidly with water and protic solvents.

Preparative Methods: conveniently prepared by refluxing ***t-Butyldimethylchlorosilane*** (1 equiv), ***Potassium Cyanide*** (1.3 equiv) and ***18-Crown-6*** (0.31 equiv) in dry methylene chloride under nitrogen.[4] The reagent can also be prepared by the reaction of ***Silver(I) Cyanide*** with *t*-butyldimethylchlorosilane,[2] or stirring at 60 °C for 4 h a mixture of sodium cyanide, Amberlite XAD-4 resin, and *t*-butyldimethylchlorosilane in acetonitrile.[5]

Handling, Storage, and Precautions: must be protected from moisture and handled in a well-ventilated fume hood. Exposure to water releases highly toxic HCN gas.

Cyanosilylation.

The Lewis acid-catalyzed reaction of *t*-butyldimethylsilyl cyanide (TBDMSCN) with aldehydes and ketones affords the corresponding silylated cyanohydrins in good yield (eq 1).[1,6,7] These have a greater stability than the silylated cyanohydrins obtained by using ***Cyanotrimethylsilane***. The addition of TBDMSCN to sterically hindered ketones proceeds smoothly in the presence of a catalytic amount of ***Zinc Iodide*** or potassium cyanide/18-crown-6 (eqs 2-4).[8] A chelation-controlled stereoselective synthesis of silylated cyanohydrins has also been reported (eq 5).[9]

Silylation.

TBDMSCN silylates alcohols, phenols, and carboxylic acids efficiently and in high yield.[2]

Oxirane Ring Opening.

Oxiranes undergo ring opening when refluxed with TBDMSCN/zinc iodide in methylene chloride, yielding isocyanides (eq 6).[3] The rate of the oxirane ring opening is slower than the corresponding reactions with trimethylsilyl cyanide/zinc iodide.[10]

t-Butyldimethylsilyl Ethylnitronate

[77242-15-0] · $C_8H_{19}NO_2Si$ · *t*-Butyldimethylsilyl Ethylnitronate · (MW 189.33)

(reagent for diastereoselective nitro-aldol condensations;[1] dipole in thioaldehyde [2 + 3] cycloadditions;[2] oxygen source for thioketone to ketone conversion;[3] oxidative coupling with silyl enol ethers[4])

Physical Data: bp 30 °C/0.05 mmHg.[1b]

Solubility: sol THF.

Form Supplied in: colorless oil. *Drying:* similar trimethylsilyl derivatives are water sensitive.[5]

Preparative Method: must be synthesized from ***Nitroethane***.[5]

Handling, Storage, and Precautions: this reagent is presumed to be moisture sensitive; the hydrolysis product is nitroethane. All nitro compounds should be treated with caution. Use in a fume hood.

Nitro-Aldol Condensation.

Nitro-aldol condensations of *t*-butyldimethylsilyl ethylnitronate (**1**) with aldehydes give the *erythro* isomer almost exclusively (eq 1).[1] The silylnitronate must be distilled, the ***Tetra-n-butylammonium Fluoride*** (TBAF) must be freshly dried over molecular sieves, and the reaction time must not be too long or else the diastereoselectivity may be compromised.[1b] The nitroaldol (**2**) may also be obtained by deprotonation/reprotonation of a mixture of (**2**) and its diastereomer, but -100 °C is required to achieve high diastereoselectivity in this reaction. For the nitro-aldol reaction the *t*-butyldimethylsilyl nitronates are less labile and more selective than the trimethylsilyl derivatives.

(1)

1,3-Dipole in [3 + 2] Cycloadditions.

t-Butyldimethylsilyl ethylnitronate has been used as a highly reactive dipole to trap thiopivaldehyde (**4**) (R = *t*-Bu)[2a,b] and other reactive thioaldehydes (**4**) (eq 2),[2c] which are generated by photolysis of phenacyl sulfides (**3**), to give heterocycles (**5**) (Table 1). Use of this reagent to titrate thioaldehyde solutions has also been demonstrated.[2d]

Table 1 Ethylnitronate plus Thioaldehyde [3 + 2] Cycloadditions (eq 2)

R	Yield of (**5**) (%)	Diastereomeric mixture
t-Bu	93	No
H	73	No
$CH{=}CH_2$	92	Yes
CH_2CH_2Ph	91	Yes

Other more complex phenacyl sulfides have been photolytically cleaved to thioaldehydes and trapped with (**1**),[2e] culminating with its use as a dipole in the total synthesis of (±)-methynolide (eq 3).[3] A thiocarbonyl to carbonyl conversion is the end result of the transformation using this reagent.

Oxidative Coupling.

Oxidative coupling of *t*-butyldimethylsilyl ethylnitronate with a silyl enol ether in DMF using manganese(III) pyridinecarboxylate [$Mn(pic)_3$] as the reducing agent gives an enone after elimination of nitrous acid (eq 4).[4]

Related Reagents.

Nitromethane.

t-Butyldimethylsilyl Hydroperoxide-Mercury(II) Trifluoroacetate

t-$BuMe_2SiOOH + Hg(CF_3CO_2)_2$

(t-$BuMe_2SiOOH$)

[78957-19-4] · $C_6H_{16}O_2Si$ · *t*-Butyldimethylsilyl Hydroperoxide-Mercury(II) Trifluoroacetate · (MW 148.28) ($Hg(CF_3CO_2)_2$)

[13257-51-7] · $C_4F_6HgO_4$ · *t*-Butyldimethylsilyl Hydroperoxide-Mercury(II) Trifluoroacetate · (MW 426.62)

(peroxymercuration of alkenes[1])

Physical Data: $(CF_3CO_2)_2Hg$: mp 171-173 °C; t-$BuMe_2SiOOH$: mp -8 °C, bp 20-35 °C.

Solubility: $(CF_3CO_2)_2Hg$: sol THF, DME, dioxane; insol hexane; t-$BuMe_2SiOOH$: sol most common organic solvents.

Form Supplied in: $(CF_3CO_2)_2Hg$: white, hygroscopic crystals; t-$BuMe_2SiOOH$: colorless liquid. Widely available.

Handling, Storage, and Precautions: acute poison. $(CF_3CO_2)_2Hg$ is easily absorbed through the skin and is corrosive. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light. *t*-Butyldimethylsilyl hydroperoxide is a strong oxidant, and reacts readily with traces of metals.

The title hydroperoxide, in combination with $(CF_3CO_2)_2Hg$, effects peroxymercuration of alkenes. The corresponding intermediate is then reduced with ***Sodium Borohydride*** to furnish an epoxide (eq 1).[1] In contrast to the OH-directed epoxidation of allylic alcohols, this method appears to provide an avenue to the epoxy alcohols of opposite relative configuration (2-cyclopenten-1-ol and 2-cyclohexen-1-ol have been employed to demonstrate this stereoselectivity).[1]

Similarly, a mixture of *t*-$BuMe_2SiOOH$ and $(AcO)_2Hg$ has been reported to promote ring opening of cyclopropanes, giving the corresponding mercurated peroxides.[2]

Related Reagents.

Mercury(II) Acetate; ***Mercury(II) Trifluoroacetate***.

O-(*t*-Butyldimethylsilyl)hydroxylamine

(**1**; R^1 = Me, R^2 = *t*-Bu)

[41879-39-4] · $C_6H_{17}NOSi$ · *O*-(*t*-Butyldimethylsilyl)hydroxylamine · (MW 147.29) (**2**; R^1 = R^2 = Me)

[22737-36-6] · $C_3H_{11}NOSi$ · *O*-(Trimethylsilyl)hydroxylamine · (MW 105.21) (**3**; R^1 = Ph, R^2 = *t*-Bu)

[103587-51-5] · $C_{16}H_{21}NOSi$ · *O*-(*t*-Butyldiphenylsilyl)hydroxylamine · (MW 271.43)

(preparation of *O*-silyloximes;[1] generation of nitrosoalkenes;[1,2] generation of azadienes[3])

Physical Data: (**1**) mp 62-65 °C; bp 87-90 °C/40 mmHg. (**2**) bp 98-100 °C; *d* 0.860 g cm^{-3}. (**3**) mp 74-75 °C; bp 175 °C/0.6 mmHg.

Solubility: freely sol hexane, chloroform, and most organic solvents; insol water.

Form Supplied in: colorless solid or liquid; commercially available.

Preparative Methods: the reagents are most conveniently prepared by treatment of ***Hydroxylamine*** hydrochloride with ethylenediamine in dichloromethane, followed by the appropriate chlorosilane.[4] A two-step procedure using ammonia in place of ethylenediamine has also been reported.[1]

Purification: reagents are purified via distillation and/or recrystallization (>97% GC).

Handling, Storage, and Precautions: *O*-silylhydroxylamines should be protected from moisture and handled in a fume hood.

Preparation of *O*-Silyloximes and Oximes.

O-Silylhydroxylamines are used to prepare *O*-silyloximes via treatment of carbonyl compounds with these reagents in

$CHCl_3$ in the presence of 4 Å molecular sieves.[1] Treatment of *O*-silyloximes with fluoride ion yields the desilylated oximes, thus allowing the oximation of acid- or base-sensitive ketones and aldehydes.

A series of 3-alkyl-2-chlorocyclohexanone silyloximes (methyl, ethyl, *i*-propyl) have been prepared and their conformations extensively examined.[5] By analysis of the vicinal interproton coupling, these compounds were shown to exist predominantly in the diaxial chair conformation (**5**) while the precursor ketones prefer the diequatorial conformation (**4**). This observation was corroborated by an X-ray crystal structure of *trans*-3-methyl-2-chlorocyclohexanone *t*-butyldiphenylsilyloxime, which showed that the chair with diaxial substituents is indeed preferred in the solid state. A strong hyperconjugative stabilization of the axial conformation, termed the vinylogous anomeric effect, was proposed to be the origin of this preference.

(4)

(5)

Generation of Nitrosoalkenes.

Treatment of silyloximes of α-halocarbonyl compounds with fluoride ion generates nitrosoalkenes without extraneous nucleophilic species present.[1] Nitrosoalkenes generated from (**6**) have been used in intramolecular [4 + 2] cycloadditions (eq 1).[2] Electron-rich alkenes are required for concerted cycloadditions as this is an inverse electron-demand cycloaddition. The choice of fluoride source is critical for success in that the highest yields are obtained when the nitrosoalkene is slowly generated via use of sparingly soluble metal fluorides such as ***Cesium Fluoride*** or ***Potassium Fluoride***.

Generation of 1-Azadienes.

O-Silyloximes have also been used to generate 1-azadienes for [4 + 2] cycloadditions.[3] Thus an *O*-silyloxime of an α,β-unsaturated aldehyde can be treated with an acid chloride or chloroformate in the presence of ***Chlorotrimethylsilane*** and ***Aluminum Chloride*** to give an α-cyanohydroxamic acid derivative, which upon mild thermolysis forms an azadiene (eq 2). These azadienes undergo efficient intermolecular [4 + 2] cycloadditions or, with an tethered alkene, intramolecular cycloadditions.

Reactions at the Hydroxylamine Nitrogen.

These reagents have been used as *O*-protected forms of hydroxylamine for synthetic transformations involving the unprotected nitrogen. Thus *O*-silylhydroxylamines have been used to prepare *N*-hydroxy-β-lactams[6] and substituted dihydro-3-hydroxy-1,2,3-benzotriazines,[7] as well as *N*-alkylated hydroxylamines for use as leukotriene biosynthesis inhibitors.[8]

Related Reagents.

O-Benzylhydroxylamine Hydrochloride; ***N,O-Bis(trimethylsilyl)hydroxylamine***; ***Hydroxylamine***; ***O-(Mesitylsulfonyl)hydroxylamine***.

t-Butyldimethylsilyl Iodide

***t*-BuMe$_2$SiI**

[72726-45-5] · $C_6H_{15}ISi$ · *t*-Butyldimethylsilyl Iodide · (MW 242.17)

(reagent capable of converting oxiranes into hydrolytically stable allylic silyl ethers, which can then be converted into their corresponding allylic alcohols without rearrangement[1-3])

Alternate Name: TBDMSI.

Physical Data: mp 53-60 °C dec.[2]

Solubility: sol most organic solvents.

Handling, Storage, and Precautions: should be used as prepared.

t-Butyldimethylsilyl iodide (TBDMSI) is typically generated in situ by the treatment of (phenylseleno)-*t*-butyldimethylsilane with 0.5 equiv of ***Iodine*** in acetonitrile.[1,2] It is then used as prepared owing to the instability of the pure form.[1]

A wide variety of hydrolytically stable allylic silyl ethers can be easily prepared from oxiranes using this reagent. Oxiranes react with TBDMSI in acetonitrile at 0 °C to form silylated halohydrins. These were then isolated and reacted with ***1,5-Diazabicyclo[4.3.0]non-5-ene*** (DBN) in refluxing THF to afford the desired allylic silyl ethers.[1,2] The net change in this sequence is the conversion of oxiranes into allylic alcohols (eqs 1-4).

(1)

(2)

(3)

(4)

The protecting group can be removed by treatment of the allylic silyl ethers with ***Tetra-n-butylammonium Fluoride*** in moist DMSO or THF. Desilylation may also be accomplished by the use of ***Potassium Fluoride*** in the presence of a catalytic amount of ***18-Crown-6***.[1,2]

Related Reagents.

N-(*t*-Butyldimethylsilyl)-*N*-methyltrifluoroacetamide[1]

[77377-52-7] · $C_9H_{18}F_3NOSi$ · *N*-(*t*-Butyldimethylsilyl)-*N*-methyltrifluoroacetamide · (MW 241.33)

(excellent *t*-butyldimethylsilylating reagent for alcohols, amines, carboxylates, thiols, and inorganic oxyanions;[1,2] is often used to protect hydroxy and amino groups;[1] derivatizing reagents for GC-MS analysis[3])

Alternate Name: BSMTFA.

Physical Data: bp 168-170 °C; *d* 1.12 g cm^{-3}.[1]

Solubility: sol most aprotic organic solvents.[1]

Form Supplied in: colorless liquid;[1] neat or with 1% *t*-butyldimethylsilyl chloride commercially available.[4,5]

Preparative Method: obtained in 91% yield by reaction of *N*-methyl-2,2,2-trifluoroacetamide (1.0 equiv) in benzene and acetonitrile (1:1 v/v) with NaH (1.0 equiv) and then with *t*-$BuMe_2SiCl$ (1.2 equiv) at 4 °C.[1]

Handling, Storage, and Precautions: moisture-sensitive; is easily transferable with a gas-tight syringe.[1]

t-Butyldimethylsilylation of Functional Groups.[1]

In the presence of 1% of ***t-Butyldimethylchlorosilane*** as the catalyst, *N*-(*t*-butyldimethylsilyl)-*N*-methyltrifluoroacetamide (BSMTFA) functions as an extremely reactive *t*-butyldimethylsilylating reagent for alcohols, amines, carboxylic acids, and thiols. Silylation is generally completed within 5 min at 25 °C in acetonitrile.[1] This amide is more reactive than *N*-(*t*-butyldimethylsilyl)-*N*-methylacetamide.

In the protection of a hydroxy group, the resultant *t*-butyldimethylsilyl (TBDMS) ethers are stable under the conditions for acetate saponification and hydrogenation.[1] These silyl ethers also remain intact towards the Jones reagent and

Wittig reagents. The TBDMS ethers are approx. 10^4 times more stable against hydrolysis than the corresponding trimethylsilyl (TMS) ethers.[6] Selective removal of the TBDMS group can be accomplished by use of dilute acetic acid or ***Tetra-n-butylammonium Fluoride*** in THF at 25 °C.

Silylation of ketones by use of BSMTFA occurs in ***Triethylamine*** and DMF at 40-60 °C to give the corresponding silyl enol ethers in good to excellent yields (eq 1).[7,8] In addition, silyl ether formation takes place in ***N-Hydroxysuccinimide*** (88% yield) and *N*-hydroxypyrrole (99% yield) by use of BSMTFA in THF.[9]

(1)

TBDMS amines are approx. 100 times more stable than the labile TMS ethers towards solvolysis.[1] Reaction of dibenzyl aspartate with BSMTFA in acetonitrile and then with *t*-BuMgCl in ether affords an *N*-silylated β-lactam in 75% yield (eq 2).[10] On the other hand, *N*-silylation of the sulfoximine PhMeS(=O)=NH proceeds in 92% yield with BSMTFA at 90 °C.[11] The oxime and amide functionalities can also be silylated with BSMTFA (eq 3).[12,13]

(2)

Selective Silylation.

The bulkiness of the TBDMS group enables BSMTFA to possess greater selectivity than the corresponding TMS-containing agents in silylation. In general, *t*-butyldimethylsilylation of secondary amines, which are sterically more congested, proceeds more slowly than that of alcohols, carboxylates, thiols, and primary amines.[1,4] Reaction of alkyldiamines with BSMTFA gives disilylated derivatives, in which each of the two primary amino groups is monosilylated. Trisilylation occurs after a prolonged reaction time.[5] Selective monosilylation of a dihydroxy aromatic compound can be accomplished in 92% yield by use of 1.5 equiv of BSMTFA in a mixture of DMF and THF (eq 4).[14]

(4)

Derivatizing Reagent for GC-MS Analyses.

For organic compounds containing active protons (e.g. alcohols, amines, carboxylates, and thiols), silylation is often used to improve resolution and peak symmetry, or to decrease adsorption on the column for GC-MS analysis.[3,15-17] Use of BSMTFA as the derivatizing reagent produces a mass spectrum with a prominent peak at *M* - 57 *m*/*z*, which represents loss of a *t*-butyl group from the molecular ion of the silylated species. In comparison, the trimethylsilylated amino acids are often unstable, easily hydrolyzed, and produce varying GC results.[17]

Silylation of Inorganic Oxyanions.[2,18]

The TBDMS derivatives of some inorganic oxyanions can be prepared by reaction of the corresponding free acids or the ammonium salts with BSMTFA in DMF. Those oxyanions include arsenate, arsenite, borate, carbonate, molybdenate, phosphate, phosphite, pyrophosphate, selenate, selenite, sulfate, sulfite, and vanadate. The *t*-butyldimethylsilylated inorganic oxyanions are relatively stable in comparison with the corresponding TMS derivatives, which show significant degradation on GC. Moreover, those *t*-butyldimethylsilylated oxyanions display single, sharp, and symmetrical chromatographic peaks without tailing on GC and produce easily interpretable mass spectra dominated by a characteristic *M* - 57 ion peak.

t-Butyldimethylsilyl Perchlorate

t-BuMe$_2$Si-OClO$_3$

[67124-66-7] · $C_6H_{15}ClO_4Si$ · *t*-Butyldimethylsilyl Perchlorate · (MW 214.72)

(silylating reagent)

Form Supplied in: clear liquid.

Preparative Methods: prepared in a one-step trityl salt-silyl hydride exchange reaction between *t*-butyldimethylsilane and ***Triphenylmethyl Perchlorate*** (eq 1).[1]

Purification: distillation under reduced pressure.[1]

Handling, Storage, and Precautions: potentially explosive; moisture sensitive; safety shield recommended.

The hindered *t*-butyldimethylsilyl (TBDMS) group has synthetic utility as a very stable alcohol-protecting group. The advantage of TBDMS perchlorate over the corresponding chloride in the protection of secondary and tertiary alcohols is reflected in the relative rates of silylation (Table 1).[1]

Table 1 Reaction Rates

Alcohol	*t*-BuMe$_2$SiOClO$_3$; py-MeCN	*t*-BuMe$_2$SiCl; imidazole-DMF
t-BuOH	$t_{1/2}$ ~30 s; 100% in 5 min	30% in 3 days
	$t_{1/2}$ ~3 min; 100% in 20 min	10% in 3 days

Although stable, removal of the protecting group with 1% HCl in 95% EtOH at rt is quantitative after 15 min.[1]

t-Butyldimethylsilyl Trifluoromethanesulfonate[1]

t-BuMe$_2$SiOSO$_2$CF$_3$

[69739-34-0] · $C_7H_{15}F_3O_3SSi$ · *t*-Butyldimethylsilyl Trifluoromethanesulfonate · (MW 264.33)

(highly reactive silylating agent and Lewis acid capable of converting primary, secondary, and tertiary alcohols[1b] to the corresponding TBDMS ethers, and converting ketones[2] and lactones[2a,3] into their enol silyl ethers; promoting conjugate addition of alkynylzinc compounds[4] and triphenylphosphine[5] to α,β-enones; activation of chromones in [4 + 2] cycloaddition reactions;[6] rearrangement of allylic tributylstannyl silyl ethers;[7] activation of pyridine rings toward Grignard reagents[8] and transalkylation of tertiary amine *N*-oxides;[9] and transformation of *N*-*t*-butoxycarbonyl groups into *N*-alkoxycarbonyl groups[10])

Alternate Name: TBDMS triflate.

Physical Data: bp 60 °C/7 mmHg; colorless oil, *d* 1.151 g cm^{-3}.

Solubility: sol most organic solvents such as pentane, CH_2Cl_2, etc.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 1.00 (s, 9H, *t*-Bu), 0.45 (s, 6H, Me).

Form Supplied in: liquid; widely available.

Preparative Method: [1b] to 24 g (0.16 mol) of ***t-Butyldimethylchlorosilane*** at 23 °C under argon is added 14 mL (0.16 mol) of ***Trifluoromethanesulfonic Acid*** dropwise. The solution is heated at 60 °C for 10 h, at which time no further hydrogen chloride evolves (removed through a bubbler). The resulting product is distilled under reduced pressure: 34 g (80% yield) of TBDMS triflate; bp 60 °C/7 mmHg.

Handling, Storage, and Precautions: the material should be stored under argon at 0 °C. The compound has an unpleasant odor and reacts rapidly with water and other protic solvents.

Silylation of Alcohols.[1]

Primary, secondary, and tertiary alcohols are silylated by reaction with TBDMS triflate in excellent yields. For instance, treatment of *t*-butanol with 1.5 equiv of TBDMS triflate and 2 equiv of ***2,6-Lutidine*** in CH_2Cl_2 at 25 °C for 10 min gives a 90% yield of (*t*-butoxy)-*t*-butyldimethylsilane.[1b] The following alcohols are similarly silylated in

excellent yields (70-90%): 2-phenyl-2-propanol, *endo*-norborneol, *cis*-2,2,4,4-tetramethylcyclobutane-1,3-diol, and 9-*O*-methylmaytansinol (converted to the 3-TBDMS derivative) (eq 1).[1b]

(1)

Formation of Enol Silyl Ethers.[2,3]

Various sterically hindered ketones have been converted into enol silyl ethers by treatment with 1-2 equiv of TBDMS triflate and 1.5 equiv of ***Triethylamine*** in CH_2Cl_2 or 1,2-dichloroethane at rt. A representative example is depicted in eq 2.[2a]

(2)

Reactions of chiral β-keto sulfoxides with 1.1 equiv of ***Lithium Diisopropylamide*** in THF at -78 °C followed by 1.2 equiv of TBDMS triflate at -78 °C produce the corresponding (*Z*)-enol silyl ethers (eq 3).[2b]

(3)

$R^1 = H, R^2 = Me; R^1 = R^2 = Me; R^1 = H, R^2 = Ph$

Lactones have also been transformed into silyl ketene acetals upon treatment with TBDMS triflate and triethylamine in CH_2Cl_2 (eqs 4 and 5).[2a,3] In the case of 8a-vinyl-2-oxooctahydro-2*H*-1,4-benzoxazine, the resulting silyl ketene acetal undergoes Claisen rearrangement to provide the octahydroquinoline (eq 6).[3]

(4)

(5)

(6)

Conjugate Addition of Alkynylzinc Bromides.[4]

Alkynylzinc bromides undergo conjugate addition with α,β-unsaturated ketones in the presence of TBDMS triflate in ether-THF at -40 °C to give the corresponding 1,4-adducts (54-96% yields). A representative example is illustrated in eq 7.[4] Other trialkylsilyl triflates such as ***Triisopropylsilyl Trifluoromethanesulfonate*** or ***Trimethylsilyl Trifluoromethanesulfonate*** can effectively replace TBDMS triflate.

(7)

Phosphoniosilylation.[5]

Cyclic enones treated with TBDMS triflate and ***Triphenylphosphine*** in THF at rt provide the corresponding 1-(3-*t*-butyldimethylsilyloxy-2-cycloalkenyl)triphenylphosphonium triflates (eq 8) which, upon lithiation with ***n-Butyllithium*** followed by Wittig reaction with aldehydes, afford various conjuated dienes.[5]

(8)

Silylation of Chromones.[6]

The preparation of 4-*t*-butyldimethylsilyloxy-1-benzopyrylium triflate is carried out by heating chromone and TBDMS triflate at 80 °C for 1 h (without solvent) under nitrogen (eq 9).[6b] The silylated chromones undergo addition reaction with enol silyl ethers and 2,6-lutidine,[6b] and [4 + 2]-type cycloaddition reactions with α,β-unsaturated ketones in the presence of TBDMS triflate and 2,6-lutidine. An example of the cycloaddition reaction is shown in eq 10.[6a]

(9)

Rearrangement of Allylic Tributylstannyl Silyl Ethers.[7]

α-Silyloxy allylic stannanes are isomerized with TBDMS triflate to (*Z*)-γ-silyloxy allylic stannanes (eq 11).[7] The resulting allylic stannanes undergo addition reactions with aldehydes in the presence of ***Boron Trifluoride Etherate*** to provide the 3-(*t*-butyldimethylsilyloxy)-4-hydroxyalkenes.[7a]

Activation of Pyridine.[8]

N-(*t*-Butyldimethylsilyl)pyridinium triflate, prepared from pyridine and TBDMS triflate in CH_2Cl_2 at rt, undergoes addition reactions with alkyl and aryl Grignard reagents to give 4-substituted pyridines after oxidation with oxygen (eq 12).[8] Only about 1% of the 2-substituted pyridines were formed in the cases studied.

(12)

Transalkylation of Tertiary Amine *N*-Oxides.[9]

N-(*t*-Butyldimethylsilyloxy)-*N*-methylpiperidinium triflate is quantitatively formed from the reaction of *N*-methylpiperidine *N*-oxide (eq 13).[9b] The resulting amine salts derived from various trialkylamine *N*-oxides undergo transalkylation by treatment with ***Methyllithium*** in THF at 0 °C followed by alkyl halides and ***Tetra-n-butylammonium Fluoride*** in a sealed tube at 110 °C for 10 h, to afford trisubstituted amines (eq 14).[9a]

(13)

(14)

Interconversion of *N*-Boc Group into *N*-Alkoxycarbonyl Group.[10]

Treatment of *t*-butyl alkylcarbamates with 1.5 equiv of TBDMS triflate and 2 equiv of 2,6-lutidine in CH_2Cl_2 at rt for about 15 min furnishes the corresponding TBDMS carbamates (eq 15).[10] Desilylation of these silyl carbamates with aqueous fluoride ion gives excellent yields of the corresponding primary amines. The silyl carbamates are also converted into other *N*-alkoxycarbonyl derivatives by treatment with TBAF and alkyl halides in THF at 0 °C (82-88% yields).[10]

t-Butyldiphenylchlorosilane[1]

t-$BuPh_2SiCl$

[58479-61-1] · $C_{16}H_{19}ClSi$ · *t*-Butyldiphenylchlorosilane · (MW 274.86)

(reagent for the temporary protection of hydroxy groups as their *t*-butyldiphenylsilyl ethers; selectivity can be obtained for primary vs. secondary hydroxy groups; other protection (carbonyl, amine, etc.) is also possible;[2] deprotection is conveniently effected with fluoride ion, strong acid, or base; the TBDPS ether group is compatible with a large number of organic functional group transformations,[1-3] in nucleoside chemistry,[1] as well as in numerous examples in which polyfunctional molecules are chemically manipulated[4])

Alternate Name: TBDPS-Cl.

Physical Data: colorless liquid, bp 93-95 °C/0.015 mmHg; n_D^{20} 1.5680; *d* 1.057 g cm^{-3}.

Solubility: miscible in most organic solvents.

Form Supplied in: colorless liquid 98%.

Preparative Method: a dry 1 L, three-necked round bottomed flask is equipped with a magnetic stirring bar, a 500 mL equalizing dropping funnel fitted with a rubber septum, a reflux condenser, and nitrogen inlet tube. The flask is flushed with nitrogen, then charged with 127 g (0.5 mol) of diphenyldichlorosilane in 300 mL of redistilled pentane. A solution of ***t-Butyllithium*** in pentane (500 mL, 0.55 mol), is transferred under nitrogen pressure to the dropping funnel using a stainless steel, double-tip transfer needle. This solution is slowly added to the contents of the flask and when the addition is complete, the mixture is refluxed 30 h under nitrogen with stirring. The suspension is allowed to cool to rt, the precipitated lithium chloride is rapidly filtered through a pad of Celite, and the latter is washed with 200 mL of pentane. The solvent is removed by evaporation, and the colorless residue is distilled through a short (10 cm), Vigreux column, to give 125-132 g of the colorless title compound.

Handling, Storage, and Precautions: the reagent is stable when protected from moisture and protic solvents. A standard M solution of the reagent can be prepared in anhyd DMF and kept at 0 °C under argon in an amber bottle. Use in a fume hood.

Preparation of *t*-Butyldiphenylsilyl Ethers and Related Transformations.

A standard protocol[1] involves the addition of the reagent (1.1 equiv) to a solution of the alcohol (1 equiv) and ***Imidazole*** (2 equiv) in DMF at 0 °C or at room temperature. When silylation is complete, the solution is diluted with water and ether or dichloromethane and the organic layer is processed in the usual way. In some instances the addition of ***4-Dimethylaminopyridine*** (DMAP) can enhance the reaction rate.[5,6] Selective protection of the primary hydroxy group in carbohydrate derivatives has been achieved using this reagent and ***Poly(4-vinylpyridine)*** in CH_2Cl_2 or THF in the presence of ***Hexamethylphosphoric Triamide***.[7] Enol *t*-butyldiphenylsilyl ethers are easily formed by trapping of enolates with the chloride.[8] Amines can be selectively converted into the corresponding primary *t*-butyldiphenylsilylamines essentially under the same conditions.[9] *t*-Butyldiphenylsilyl cyanohydrins are prepared in the presence of ***Potassium Cyanide***, ***Zinc Iodide***, and a carbonyl compound.[10]

Selectivity and Compatibility of *O*- and *N*-*t*-Butyldiphenyl Silyl Derivatives.

The *O*-*t*-butyldiphenylsilyl ether protective group offers some unique advantages and synthetically useful features compared to other existing counterparts.[1,2] Silylation of a primary hydroxy group takes place in preference to a secondary, giving products that are often crystalline, and detectable on TLC plates under UV light, because of the presence of a strong chromophore. The TBDPS group is compatible with a variety of conditions[1] used in synthetic transformations such as hydrogenolysis ($Pd(OH)_2$, C/H_2, etc.), *O*-alkylation (NaH, DMF, halide), de-*O*-acylation (NaOMe, NH_4OH, K_2CO_3/MeOH), mild chemical reduction with hydride reagents, carbon-carbon bond formation with organometallic reagents, transition metal-mediated reactions, Wittig reactions, etc. These reactions were tested during the total synthesis of thromboxane B_2[11] for which the TBDPS group was originally designed. Subsequently, numerous related organic transformations have been carried out in the presence of TBDPS ethers in the context of natural product synthesis[3,4] and functional group manipulations.[2] It is distinctly more acid stable than the *O*-trityl, *O*-THP, and *O*-TBDMS groups, and is virtually unaffected under conditions that cause complete cleavage of these groups (50% HCO_2H, 2-6 h; 50% aq TFA, 15 min; HBr/AcOH, 0 °C, few min; 80% aq acetic acid, few h).[1] It is also compatible with conditions used for the acid-catalyzed formation and hydrolysis of acetal groups and in the presence of some Lewis acids (e.g. TMSBr,[12] $BCl_3.SMe_2$,[13] Me_2AlCl,[8] etc.). The mono-TBDPS derivative of a primary amine[9] is stable to base, as well as to alkylating and acylating reagents. Thus a secondary amine can be acylated in the presence of a primary *t*-butyldiphenylsilylamino group.

Deprotection.[1,2]

The *O*-TBDPS group can be cleaved under the following conditions: ***Tetra-n-butylammonium Fluoride*** in THF at rt; variations of F^--catalyzed reactions (e.g. F^-/AcOH; HF/pyridine;[14] HF/MeCN,[15] etc.); aqueous acids and bases[1] (1 N HCl, 5 N NaOH, aq methanolic NaOH or KOH); ion exchange resins;[7] ***Potassium Superoxide***, ***Dimethyl Sulfoxide***, ***18-Crown-6***.[16] Selective cleavage of a TBDPS ether in the presence of a TBDMS ether in carbohydrate derivatives involves treatment with ***Sodium Hydride***/HMPA at 0 °C.[17] Although the *O*-TBDPS group is stable to most hydride reagents, ***Lithium Aluminum Hydride*** reduction of an amide group has resulted in the cleavage[18] of an adjacent *O*-TBDPS ether, possibly via internal assistance. TBDPS-amines are cleaved by 80% AcOH or by HF/pyridine.[9]

N-t-Butylformamide

(R = *t*-Bu)

[2425-74-3] · $C_5H_{11}NO$ · *N-t*-Butylformamide · (MW 101.15) (R = H)

[75-12-7] · CH_3NO · Formamide · (MW 45.04)

(amidation of alkenes; amidation of heterocycles; synthesis of secondary amines)

Physical Data: N-t-butylformamide: mp 16 °C; bp 202 °C; *d* 0.903 g cm^{-3}. Formanide: mp 2 °C; bp 111 °C/20 mmHg; *d* 1.133 g cm^{-3}.

Solubility: N-t-butylformamide is miscible with most common organic solvents and with water.

Form Supplied in: commercially available in 98% purity.

Preparative Method: N-t-butylformamide is prepared from ***t-Butylamine*** and ethyl formate.[1]

Purification: by distillation.

Hydroamidation of Alkenes.

t-Butylformamide adds across the double bond of alkenes in a Markovnikov fashion using ***1,1-Di-t-butyl Peroxide*** as the radical initiator (eq 1).[2] Dimerization of *t*-butylformamide occurs under these conditions in the absence of an alkene. The related reagent formamide undergoes similar reactions with alkenes (eq 2) and these reactions have been initiated both photochemically and by peroxides.[3-5]

(1)

(2)

Amidation of Pyridines.

Pyridines undergo amidation when combined with *t*-butylformamide and ***t-Butyl Hydroperoxide*** and Fe^{II} but the reactions show little regioselectivity and the yields are poor. Higher yields and good regiochemical control are obtained with formamide (eq 3).[6]

(3)

Numerous heteroaromatic bases, mostly substituted quinolines and pyridines, have been amidated with formamide under radical conditions (eq 4).[7] The radicals for these amidations have been generated from formamide by a variety of means, usually from ***Hydrogen Peroxide-Iron(II) Sulfate***, but also from decomposition of ***Hydroxylamine-O-sulfonic Acid***,[8] or from ***Iodosylbenzene*** and ***Sodium Azide***.[9] These amidations and related reactions with nitrogen heterocycles have been reviewed.[10] Amidations under these conditions provide a useful method for acylating pyridines, quinolines, and related compounds that cannot ordinarily be acylated under conventional Friedel-Crafts conditions.

(4)

Synthesis of Secondary Amines.

t-Butylformamide is alkylated under phase transfer conditions to yield *N*,*N*-dialkylformamides in good yield. Hydrolysis provides secondary amines. This reaction provides an alternative to the Ritter reaction and works with a variety of tertiary amines (eq 5).[11]

t-Butyl Hydroperoxide[1-3]

***t*-Bu-O-OH**

[75-91-2] · $C_4H_{10}O_2$ · *t*-Butyl Hydroperoxide · (MW 90.12)

(oxidizing agent used for the oxidation of alcohols and alkenes to allylic oxygenated compounds and epoxides[1,2])

Alternate Name: TBHP.

Physical Data: the following data are for a 90% aqueous solution: flash point 35 °C; *d* 0.901 g cm^{-3}; *n*20D 1.3960. The density of a 70% aqueous solution is 0.937 g cm^{-3}.

Solubility: sol alcohol, ether, chloroform; slightly sol H_2O, DMSO.

Form Supplied in: clear colorless liquid; widely available as 70-90% aqueous solutions, and anhydrous in hydrocarbon solvents. Aqueous solutions may be dried by a phase separation procedure, followed by azeotropic distillation to remove the last vestiges of water if necessary.[1]

Handling, Storage, and Precautions: eye protection and rubber gloves should be worn when handling this material; avoid skin contact; this reagent should be handled only in a fume hood. Eye and skin irritant; immediately flush with water if contact is made with the eyes. Flammable liquid; oxidizer; sensitive to shocks and sparks. May react explosively with reducing agents. Store in an explosion-proof container, and keep away from reducing materials and strong acids and bases. Avoid using high strength solutions; do not distill. The use of molecular sieves for drying is not recommended.

General Considerations.

The title reagent is used in oxidations of various substrates to give epoxides, ketones, aldehydes, carboxylic acid esters, and nitro or azoxy compounds. The reagent and its metal complexes have been extensively reviewed.[1-3] This article describes representative applications to problems in organic synthesis.

Oxidations of Alkenes.

Hydroxylation.

Under basic conditions (tetraethylammonium hydroxide, Et_4NOH), in the presence of catalytic amounts of ***Osmium Tetroxide***, TBHP vicinally hydroxylates alkenes (eq 1).[4] This method is preferable over the use of osmium tetroxide stoichiometrically due to the expense and toxicity of the latter (see also ***Osmium Tetroxide-t-Butyl Hydroperoxide***). This method is also preferable to the use of osmium tetroxide catalytically with ***Hydrogen Peroxide***[5] or metal chlorates,[6] both of which give lower yields for tri- and tetrasubstituted alkenes, and can lead to over-oxidation. Et_4NOH can be replaced with Et_4NOAc, which allows this reaction to be carried out on alkenes containing base-sensitive functional groups, and often gives better yields than the use of Et_4NOH (eq 2).[7]

(1)

(2)

Chlorohydroxylation of nonfunctionalized alkenes can be accomplished (eq 3) through the reaction of TBHP with ***Titanium(IV) Chloride***.[8] Chlorohydroxylation can also be done asymmetrically to the alkenes of allylic alcohols using TBHP with ***Dichlorotitanium Diisopropoxide*** and an asymmetric tartrate catalyst, and the stereochemistry can be controlled by the ratio of titanium to tartrate (eq 4) varying (see below).

(3)

(4)

Oxidation of Allylic, Benzylic, and Propargylic Carbons.[1,2]

Alkenes with an allylic hydrogen can be selectively oxidized to the allylic alcohol by TBHP in the presence of ***Selenium(IV) Oxide*** (eq 5).[9] This is preferable to the oxidation using stoichiometric SeO_2 by itself, which leads to reduced forms of selenium and can make isolation and purification of the product difficult. Less substituted alkenes require 0.5 equivalents of SeO_2 while for more substituted alkenes it may be present in catalytic amounts. The regioselectivity of this reaction favors the more substituted site being oxidized. The addition of small amounts of carboxylic acids also aids this reaction with certain alkenes (eq 5). See also ***Selenium(IV) Oxide-t-Butyl Hydroperoxide***.

(5)

Alkenes can also be oxidized to give rearranged allylic alcohols using TBHP with phenylselenenic acid and ***Diphenyl Diselenide*** (eq 6).[10] The reaction proceeds through a β-hydroxyl phenylselenide adduct of the alkene, which then eliminates the selenide to give the allylic alcohol and a phenylselenenic acid byproduct. This method is preferable to the use of phenylselenenic acid with hydrogen peroxide, since the latter can lead to epoxidation of the alkene of the product to give the epoxy alcohol. This method also does not oxidatively remove the selenium from the phenylselenenic acid byproduct, as the H_2O_2 method does, allowing the phenylselenenic acid to be recovered and

easily reduced back to diphenyl diselenide.

(6)

Oxidations of allylic carbons to carbonyls to give enones may be effected by the reaction of the alkene with TBHP catalyzed by ***Hexacarbonylchromium*** (eq 7).[11] These reaction conditions are milder than other chromium reagents used for the same purpose, and are selective towards allylic carbons. This system has also been used for the oxidation of benzylic carbons to carbonyls, with much better yields than ***Chromic Acid*** oxidations.[12] Other chromium(VI) catalysts can also be used along with TBHP to oxidize allylic and benzylic carbons to the corresponding carbonyl.[13]

(7)

Propargylic carbons can also be oxidized, using TBHP and SeO_2 (eq 8).[14] Unlike allylic systems, propargylic systems show a great tendency towards oxygenation on both sides of the triple bond, and are generally more reactive towards α oxygenation. A mixture of the propargylic alcohol, ketone, diol, and ketol will generally result from this reaction. If there are two sites possible for oxygenation, methine and methylene groups have about the same reactivity towards these conditions, while methyl groups show a lesser preference for oxidation. In symmetrical alkynes the diol is prevalent, and in some cases where the alkyne is in conjugation with other π systems the ketone is an important product, whereas in most other cases the ketone and ketol are minor products. If the alkyne has one methine and one methylene substituent, the enynone can be an important product.

If a chromium(VI) catalyst is used in the presence of TBHP, propargylic carbons will be oxidized to the alkynic ketone (eq 9).[15] The more highly substituted alkyl substituent on the alkyne is preferentially oxidized, and symmetrical alkynes give the monoketone accompanied by the diketone.

Oxidation of π-allylpalladium complexes can also occur with TBHP using a molybdenum(IV) catalyst to give the allylic alcohol (eq 10).[16] Hydroxyl attack will occur axially, *syn* to the complexed palladium. This conversion can also be carried out with peroxy acids or singlet oxygen, but these methods are not as selective.

Epoxidation.[1,2,17]

TBHP is widely used as an epoxidizing agent, both synthetically and industrially.[18] TBHP has been used to effect regiospecific, stereospecific, and asymmetric epoxidations. In general, the rates of epoxidations using TBHP are slowed by polar solvents, and increased with higher alkyl substitution of the alkene. TBHP is considered superior to hydrogen peroxide for epoxidations, because it is soluble in hydrocarbon solvents, while hydrogen peroxide can readily transform the epoxide to the *vic*-glycol.

Epoxidations of simple alkenes can be carried out using TBHP with a vanadium or molybdenum catalyst (eq 11).[19]

(11)

Epoxidations of alkenes in compounds containing other functional groups can also be accomplished using TBHP with a molybdenum catalyst (eq 12).[19,20] For nonconjugated dienes, more highly substituted alkenes can be selectively epoxidized over less substituted alkenes. Conjugated dienes are less susceptible to epoxidation than isolated alkenes, but the regioselectivity for the different double bonds of a conjugated system follows the same pattern as that for isolated alkenes (eq 13).

(12)

(13)

Epoxidations of compounds with functional groups in the allylic position can also be effected using TBHP and a molybdenum or vanadium catalyst, but the yields are not as high as those for isolated double bonds, and longer reaction times are required.[21] TBHP epoxidizes the alkenes of allylic and homoallylic alcohols stereoselectively with either molybdenum or vanadium catalysts (eqs 14 and 15).[21] With acyclic systems, vanadium-catalyzed epoxidations give predominantly the *erythro* product, and molybdenum-catalyzed epoxidations give predominantly the *threo* product.[22]

(14)

(15)

98% isomeric purity

For cyclic systems, vanadium- and molybdenum-catalyzed reactions give predominantly the *cis* product (eq 16).[23] There are several factors that can affect the selectivity of this reaction for cyclic allylic alcohols. With increasing ring size, the selectivity decreases slightly for vanadium-catalyzed reactions, and more dramatically for molybdenum-catalyzed reactions. The selectivity was also observed to be better for cyclic allylic alcohols where the hydroxyl is in a quasi-axial position.

(16)

>95% isomeric purity

The epoxidation of α,β-unsaturated ketone and aldehyde compounds is accomplished by TBHP in the presence of catalytic amounts of Triton-B (***Benzyltrimethylammonium Hydroxide***) (eq 17).[24] This method has also been used for the synthesis of mono- and diepoxy-1,4-benzoquinones (eq 18).[25]

(17)

Cyclic allylic alcohols conjugated to a second alkene react with TBHP catalyzed by vanadium to give not the epoxy but a bicyclic ether and new allylic alcohols, with the oxygen bridging the original allylic alcohol to the terminus of the conjugated diene (eq 19).[26]

Stereoselective epoxidation of unactivated alkenes can be effected by remote chiral auxiliaries in the presence of molybdenum or vanadium catalysts. The configuration of the remote alcohol determines which face of the alkene is epoxidized (eq 20).[27]

Allylic alcohols can be asymmetrically epoxidized with TBHP and stoichiometric quantities of a titanium-diethyl tartrate complex, generated in situ.[28] Either enantiomer can be formed by using either (+)- or (-)-diethyl tartrate, or by varying the ratio of titanium catalyst to (+)-diethyl tartrate (eq 21), because the nature of the titanium catalyst changes as the molar ratio of titanium to tartrate changes. This latter method is generally preferred due to the ready availability and relatively low cost of (+)-diethyl tartrate. In the presence of 3Å or 4Å molecular sieves, the titanium/tartrate complex may be used in catalytic quantities, but with somewhat lower product enantiomeric purities.[29] These methods can also be used for the stereospecific epoxidation of homoallylic alcohols, but in lower degrees of enantiomeric purity, because the hydroxyl group is further away from the reacting center, lessening its directing effec ts.[30]

The use of TBHP and a titanium/tartrate complex in either stoichiometric or catalytic quantities is known as the

Sharpless asymmetric epoxidation.[1] This method gives better stereo- and enantioselectivity than epoxidations using peroxy acids. Asymmetric epoxidations can be carried out using other transition metal catalysts and chiral ligands, but the enantioselectivities are not as high.[31] The Sharpless asymmetric epoxidation can also be used for the kinetic resolution of allylic alcohols.[32]

Asymmetric epoxidations of simple alkenes can be accomplished by Sharpless epoxidation of alkenylsilanols.[33] The alkenylsilanols are prepared from lithium alkenes, and after the Sharpless epoxidation the silyl group is removed by fluoride ion to give the simple epoxide (eq 22). Asymmetric epoxidations can also be done on alkenes without other functional groups using optically active diols as the solvent, but the ee values are generally very low.[34]

Epoxidation of vinyl allenes by TBHP and ***Vanadyl Bis(acetylacetonate)*** catalyst leads to the formation of cyclopentenones (eq 23).[35] The intermediate in this reaction is an epoxide of the allene. The stereochemistry of the double bond can be retained. The stereoselectivity is kinetic in nature, and can be lost due to epimerization of the kinetic product if the reaction is continued for long periods of time.

Other Reactions with Alkenes.

Double bonds of silyl enol ethers can be oxidatively cleaved to the corresponding ketones or carboxylic acids using TBHP with $MoO_2(acac)_2$ as a catalyst (eq 24).[36] The ease with which enols can be generated regiospecifically makes this a very powerful method in organic synthesis. This reaction selectively cleaves the double bond of silyl enol ethers in the presence of other double bonds within the molecule.

(24)

The alkenes of allylic alcohols can also be cleaved under these conditions (eq 25).[37] In addition to cleaving the double bond of the allylic alcohol, the single bond between the alkene carbon and the allylic carbon bearing the hydroxyl group is also cleaved under these conditions. Vicinal diols are also cleaved to give the corresponding ketones or carboxylic acids (eq 26).[38]

(25)

(26)

Oxidation of α,β-unsaturated esters and ketones with palladium-catalyzed TBHP gives β-keto esters or 1,3-diketones (eq 27).[39] Hydrogen peroxide can also be used as the oxidant for this reaction.

(27)

Under basic conditions, TBHP can add in Michael fashion to a double bond that has an electron withdrawing group attached (eq 28).[40]

(28)

Reactions with Other Functional Groups.

Oxidation of Alcohols.[1,2]

In the presence of catalytic amounts of diphenyl diselenide, TBHP oxidizes benzylic and allylic alcohols to the corresponding ketones (eq 29).[41] Saturated alcohols can be oxidized to the corresponding carbonyl compounds as well if bis(2,4,6-trimethylphenyl) diselenide is used as the catalyst and a small amount of a secondary or tertiary amine is present. These conditions do not affect other double bonds present in the substrate. This system can also be used for the oxidation of α-hydroxy selenides and thiols, selectively oxidizing the hydroxy function to the carbonyl.

(29)

Saturated alcohol oxidation can also be achieved without oxidizing alkenes by the reaction of the alcohol with TBHP and benzyltrimethylammonium tetrabromooxomolybdate (BTMA-Mo) as a catalyst, and secondary alcohols will be oxidized preferentially over primary ones under these conditions (eq 30).[42] If the reaction time is lengthened, primary alcohols will be converted to the appropriate acid derivative depending upon the conditions used. Using $VO(acac)_2$ as the catalyst will oxidize secondary alcohols over primary ones selectively as well.[43]

(30)

Oxidation of alcohols can also be done using TBHP and a chromium(VI) catalyst (eq 31).[44] This system works best for allylic, benzylic, and propargylic alcohols, and will selectively oxidize these in the presence of other alcohols.

(31)

Oxidation of Sulfur-Containing Compounds.[2]

Sulfides can be oxidized with TBHP to give sulfoxides.[45] If vanadium, molybdenum, or titanium catalysts are used, the addition of one equiv of TBHP will furnish the sulfoxide, while the use of excess TBHP will oxidize the sulfide to the sulfone (eqs 32 and 33). In the absence of metal catalysts the oxidation cannot be carried beyond the sulfoxide.[46] If only one equivalent of TBHP is used, sulfides will be preferentially oxidized over any alkenes present; however, excess TBHP will also oxidize alkenes. The oxidation of thiols with TBHP and Mo^{VI} or V^{V} catalysts produces sulfonic acids (eq 34).[47]

(32)

(33)

(34)

Using Sharpless asymmetric epoxidation conditions (see above), modified by the addition of one mol equiv of water, unsymmetrical sulfides could be asymmetrically oxidized to sulfoxides (eq 35).[48] Asymmetric oxidations of sulfides to sulfoxides have also been carried out using optically active diols with TBHP and a molybdenum catalyst, but the enantioselectivities were very low (~10%).[49]

(35)

Oxidation of Phosphines.

Alkyl phosphines can be oxidized to the appropriate phosphine oxides by TBHP (eq 36).[50]

(36)

Oxidation of Selenides and Selenoxides.

Alkenes can be produced oxidatively from selenides, through the selenoxides and elimination. This is done by stirring TBHP with basic alumina and the appropriate selenide (eq 37).[51] This transformation can also be accomplished by treatment of the selenide with ***Hydrogen Peroxide***, ***Ozone*** followed by ***Triethylamine***, periodate, or peroxy acids.

(37)

Oxidation of Nitrogen-Containing Compounds.[2]

Reactions of TBHP with compounds containing nitrogen have been used to effect a variety of oxidations, both of the nitrogen atom itself and of adjacent carbon atoms. Tertiary amines react with TBHP in the presence of vanadium and molybdenum catalysts to give amine oxides (eq 38).[52] This transformation can also be done with cumene and pentene hydroperoxides.

(38)

Secondary amines are oxidized to imines by TBHP in the presence of ruthenium(II) catalysts (eq 39).[53] Tertiary amines

are oxidized by TBHP in the presence of ruthenium catalyst to give α-(*t*-butyldioxy)alkylamines, which decompose to iminium ion intermediates when treated with acid (eq 40).[54] *N*-Methyl groups are selectively oxidized when other *N*-alkyl or -alkenyl groups are present.

(39)

(40)

Amides are selectively oxidized to imides by TBHP, and other hydroperoxides, in the presence of cobalt or manganese salts as catalysts (eq 41).[55] The selectivity of this transformation is demonstrated by the oxidation of 3-ethoxycarbonyl-2-piperidone to the appropriate imide, with no other oxidation products. ***Peracetic Acid*** also effects this transformation, in many cases giving better yields and shorter reaction times, but the conditions for oxidation with TBHP are milder. Oxidation of amides with TBHP catalyzed by ruthenium gives the corresponding *t*-butylperoxy amide (eq 42).[56]

(41)

(42)

Nitronate anions, formed by deprotonation of nitro compounds, react with TBHP catalyzed by $VO(acac)_2$ or ***Hexacarbonylmolybdenum*** to give 1-hydroxy nitro compounds (eq 43). Analogous to α-hydroxyl carbonyl compounds, these collapse to give the carbonyl derivative and nitrous acid.[57]

(43)

Introduction of Peroxy Groups into Organic Molecules.[58]

Using catalytic amounts of copper, cobalt, or manganese salts, TBHP reacts with molecules that contain a slightly activated carbon-hydrogen bond, replacing the activated hydrogen with a peroxy group. This transformation can also be accomplished with other hydroperoxides. Carbon-hydrogen bonds α to an alkene (eqs 44 and 45),[59,60,61] phenyl groups,[60] carbonyls,[61] nitriles,[62] oxygen,[60,61] or nitrogen (eq 46)[63] atoms are activated towards this reaction. The primary function of the metal salts in these reactions is to initiate decomposition of the hydroperoxide.

(44)

(45)

(46)

Peroxy groups may also replace alcohols (eq 47),[64] ethers,[65] or sulfates[66] directly, or be added to an alkene (with Markovnikov regioselectivity),[9] by reacting the functionalized organic compound with TBHP and concentrated sulfuric acid in acetic acid. Epoxides are transformed into β-hydroxy dialkyl peroxides using TBHP in the presence of base (eq 48).[67]

(47)

(48)

Peroxy *t*-butyl organosilanes can be prepared by reacting TBHP with the appropriate silyl chloride and pyridine, ammonia, or triethylamine (eq 49).[68] Peroxides of a number of other heteroatoms in organic compounds, such as germanium,[69] boron,[70] cadmium,[71] tin,[72] aluminum,[73] and mercury,[74] can also be synthesized using TBHP.

(49)

2,4,6-Substituted phenols react with TBHP to give 2- or 4-(*t*-butylperoxy)-2,4,6-trisubstituted quinones if the 4-substituent is not a methyl group, and 3,5,3´,5´-tetrasubstituted stilbene-4,4´-quinones if the 4-substituent is a methyl group (eq 50).[75]

Reactions with Carbonyl Compounds.

Aldehydes react with TBHP in the presence of catalytic amounts of copper, cobalt, or manganese salts to give the *t*-butyl ester (eq 51).[76] In the absence of a metal catalyst, benzaldehyde will react with TBHP to give a mixture of the *meso* and racemic forms of benzopinacol dibenzoate.

TBHP reacts with acid chlorides under basic conditions to give the appropriate *t*-butyl peroxy ester.[77] For small acids, 30% KOH is used, but for longer-chain acids, pyridine is substituted as the base (eq 52).[78] The use of pyridine as the base in this reaction allows the synthesis of carbamate peroxy esters from isocyanates and carbamic acid chlorides (eq 53).[79]

(53)

TBHP reacts with ketones or aldehydes in the presence of a strong acid catalyst to give products with diperoxy groups in place of the carbonyl (eq 54), or in the absence of the acid catalyst to give an α-hydroxyl *t*-butyl peroxide (eq 55).[80]

(54)

(55)

Conversion of Halides to Alcohols.

Grignard reagents react with TBHP to give the appropriate alcohol or phenol (eq 56).[81] This provides an alternative method for the conversion of halides to alcohols or phenols. Because the hydrogen of the peroxide is activated, either two equiv of Grignard reagent must be used or the magnesium salt of the hydroperoxide, prepared from the hydroperoxide and ethylmagnesium bromide.

(56)

Conversion of Alcohols to Halides.

In cases where traditional methods fail, alcohols can be converted to halides by a radical chain reaction.[82] This is accomplished by transforming the alcohol into a chloroglyoxylate, reacting it with TBHP, and warming this in the presence of a halogen donor such as CCl_4 or $BrCCl_3$, to initiate a radical reaction where first a *t*-butoxyl radical is eliminated, then CO_2 is eliminated twice in succession, leaving an alkyl radical which then reacts with the halogen donor to give the halide (eq 57).

N-t-Butylhydroxylamine[1]

***t*-BuNHOH**

[16649-50-6] · $C_4H_{11}NO$ · *N-t*-Butylhydroxylamine · (MW 89.14) (.HCl)

[57497-39-9] · $C_4H_{12}ClNO$ · *N-t*-Butylhydroxylamine Hydrochloride · (MW 125.60)

(condenses with a wide variety of aldehydes to afford *N-t*-butylnitrones;[2] condenses with alkynes to afford *N-t*-butylnitrones;[3] used with phenylacetyl chloride in the synthesis of aziridinones;[4] alkene amination[5])

Physical Data: mp 64-65 °C; hydrochloride, mp 183-185 °C.

Form Supplied in: available commercially as the hydrochloride salt.

Preparative Methods: nitro reduction;[6] oxaziridine hydrolysis;[7-9] amine oxidation.[10]

Purification: recrystallization from pentane.

Handling, Storage, and Precautions: hygroscopic; oxidizes slowly to the nitroso compound.

For a discussion of this reagent, see the entry for ***N-Cyclohexylhydroxylamine***.

t-Butyl Hypobromite[1]

***t*-BuOBr**

[1611-82-1] · C_4H_9BrO · *t*-Butyl Hypobromite · (MW 153.02)

(alkoxybromination of alkenes;[2] bromination of alkanes;[3] allylic bromination[4])

Physical Data: bp 44-45 °C/85 mmHg; mp -27 to -28 °C; *d* 1.33 g cm^{-3}.

Solubility: sol ether, CCl_4, CH_2Cl_2.

Analysis of Reagent Purity: the reagent can be assayed by thiosulfate titration of iodine liberated by the addition of the reagent to a solution of KI in aq HCl.[5]

Preparative Methods: prepared in 43% yield on a 0.18 mol scale by addition of *t*-butyl alcohol to a solution of Ag_2SO_4 and bromine in water.[3] The product is isolated by distillation. Since much material is lost during the distillation, many workers have found it more convenient to prepare and use the reagent in solution. In one procedure the reagent is generated in CH_2Cl_2 solution from Hg_2O, bromine, and *t*-butyl alcohol.[6] It has also been prepared from NaBr, NaOCl, *t*-butyl alcohol, and acetic acid.[2]

Handling, Storage, and Precautions: reported[3] to be stable for weeks at 0 °C in the dark. It decomposes at 85 °C, upon irradiation or by washing with 5% aq $NaHCO_3$ solution. It also decomposes upon repeated washing with water. Should be handled in a fume hood.

Alkoxybromination of Alkenes.

t-BuOBr has been used for the alkoxybromination of alkenes,[2,7] though there appears to be little advantage over the use of the more readily available ***Bromine*** or ***N-Bromosuccinimide***. For unsymmetrical alkenes the additions follow Markovnikov's rule. For terminal alkenes, selectivities are on the order of 2:1 (eq 1).

Substituted and unsubstituted 3,4-dihydro-2*H*-pyrans have been alkoxybrominated by this reagent (eq 2).[8] Little diastereoselectivity was seen in substituted examples.

There are a few examples in the literature[9] of the preparation of β-bromo *t*-butyl ethers with this reagent. It has been proposed[10] that it would be possible to catalyze these reactions with ***Boron Trifluoride Etherate***, but no examples have been reported. The analogous chloro[10] and iodo[11] compounds have been prepared from the chloro and iodo reagents.

Bromination of Alkanes.

t-BuOBr has occasionally been used for the radical chain bromination of alkanes.[3] The radical chain carrier in these reactions is the *t*-butoxy radical. This radical is less selective than the bromine radical, and so these reactions often give a more random distribution of products than reagents such as NBS.[12]

Allylic Brominations.

t-BuOBr has occasionally been used for allylic bromination reactions. Alden and Davies reported[4] that the allylic bromination of 2-methylenebicyclo[2.2.1]heptane with *t*-BuOBr gives only the *exo* diastereomer (eq 3), whereas NBS gives *exo*/*endo* mixtures.

(3)

Other Applications.

t-BuOBr has been used to brominate nitroalkanes,[13] for aromatic bromination,[14] and for bromolactonizations.[15]

t-Butyl Hypochlorite[1]

***t*-BuOCl**

[507-40-4] · C_4H_9ClO · *t*-Butyl Hypochlorite · (MW 108.57)

(reagent for ionic[2] or radical[3] chlorination of hydrocarbons; *N*-chlorination;[4] oxidation of alcohols,[5] sulfides,[6] and selenides[7])

Physical Data: bp 79.6 °C/750 mmHg; *d* 0.9583 g cm^{-3}.

Solubility: sparingly sol H_2O; sol alcohol, CCl_4, and $CHCl_3$.

Form Supplied in: commercially available as neat liquid.

Preparative Method: usually prepared by the method of Mintz and Walling.[8]

Purification: distillation is possible but can be hazardous, and is reported not to improve purity.

Handling, Storage, and Precautions: avoid exposure of the reagent to light; store protected from light in a refrigerator or freezer.

Radical Chlorination.

Under typical radical conditions, *t*-BuOCl can effect chlorination of a range of substrates, including alkanes, alkenes, ethers, epoxides, and aldehydes.[3] Reaction occurs by hydrogen abstraction from the substrate by the *t*-BuO&bdot; radical, this process showing the expected selectivity pattern of primary < secondary < tertiary (eq 1).[3a,c] The reaction can be initiated by irradiation or by the use of chemical initiators such as ***Azobisisobutyronitrile***[3a] or trialkylboranes.[3c] Reaction with alkenes results in allylic chlorination,[3d,e] whereas ethers[3b] and epoxides[3f] give products arising from attack at the position α to oxygen (eqs 2 and 3) and aldehydes give the corresponding acid chlorides (eq 4).[3b]

(1)

(2)

(3)

(4)

Ionic Reactions with Alkenes and Arenes.

Allylic chlorination with double bond rearrangement can also be effected by *t*-BuOCl under nonradical conditions in nonprotic solvents.[2] This process appears facile with particularly electron-rich alkenes, or if a catalyst such as ***Boron Trifluoride Etherate*** is employed (eq 5). If an alcohol is used as the solvent then β-chloro ethers are obtained via electrophilic addition (eq 6).[9]

(5)

(6)

Chlorination of aromatics can also be effected by use of the *t*-BuOCl-BF_3.OEt_2 reagent combination,[9] or by the use of *t*-BuOCl in the presence of silica[10] or certain zeolites (eq 7).[11] Activated aromatics react with *t*-BuOCl alone, whereas deactivated systems do not react, even in the presence of catalysts under forcing conditions. The modified *o*/*p* selectivity in the presence of zeolite is notable. Chlorination of other types of systems, such as aminoquinones[12] and indoles,[13] has also been reported (eqs 8 and 9).

(7)

silica, CCl_4	65:35	100%
H^+, Na^+ Faujasite X, CH_2Cl_2	9:91	88%

(8)

(9)

Chlorination at Nitrogen.

Chlorination of a wide range of nitrogen-containing systems to give chloroamines and related compounds, or products derived thereof, is an important use for *t*-BuOCl.[4] Examples include the hydroxylation of penicillins (eq 10)[4a-c] and a method for the asymmetric synthesis of amines via amino ester intermediates (eq 11).[4d] Both methods involve *N*-chlorination followed by dehydrochlorination and nucleophilic addition by the solvent.

Oxidation Reactions.

The oxidation of secondary alcohols, using *t*-BuOCl in the presence of ***Pyridine***, gives high yields of the corresponding ketones (eq 12),[5] whereas in the absence of pyridine both the ketone and α-chloro ketone are usually formed (eq 13),[3b] the latter products probably arising from the initially formed ketones via chlorination by chlorine generated in situ.

The oxidation of sulfoxides using *t*-BuOCl is very well established and can be used to prepare either *cis*- or *trans*-substituted thiane oxide products (eqs 14 and 15). Oxidation of selenides and tellurides is also possible in an analogous fashion, to give selenoxides and telluroxides (or their hydrates), respectively.[7]

(14)

(15)

Other Applications.

Other types of reaction involving *t*-BuOCl which have been reported include cyclization of unsaturated peroxides to give chloroalkyl 1,2-dioxolanes (eq 16),[14] a ring expansion reaction of isopropenylcycloalkenols (eq 17),[15] and a dehydrogenation protocol for the synthesis of tetraethynylethylenes (eq 18).[16]

t-Butyl Hypoiodite

_t_-BuOI

[917-97-5] · C_4H_9IO · *t*-Butyl Hypoiodite · (MW 200.02)

(reagent for radical and ionic iodinations)

Physical Data: orange-red solution, λ_{max} 515 nm.

Solubility: sol CCl_4 and benzene.

Form Supplied in: not commercially available.

Preparative Methods: the reagent has not been isolated in pure form and its precise nature is uncertain. Reagents considered to be *t*-butyl hypoiodite have been commonly prepared by the reaction of ***t-Butyl Hypochlorite*** with either ***Iodine*** or metal iodide salts, or by the reaction of ***Potassium t-Butoxide*** with iodine. Tanner and co-workers have shown that the reagent generated by the first of these methods is quite different to that formed by the other two methods.[1] Although the reagent formed by the latter two methods can be thought of as *t*-BuOI, the actual structure of the reagent is uncertain and there may be slight differences in the composition of different batches. This situation is amply illustrated for the reaction of *t*-BuOCl with AgI (eqs 1-4) The scheme adequately explains the spectroscopic and molecular weight measurements of the product formed in this way, and also the liberation of varying amounts of iodine (eq 4).

$$ICl + AgI \longrightarrow AgCl + I_2 \qquad (4)$$

Handling, Storage, and Precautions: reported to be very sensitive to moisture and is best generated in situ as required.

Iodination Reactions.

Barton and co-workers employed *t*-BuOI reagents, made by two of the above described methods, for a range of novel photochemical applications (eqs 5-7).[2-4]

$$RCO_2H \xrightarrow[h\nu,\ \text{benzene}]{t\text{-BuOK},\ I_2} R\text{-}I + CO_2 \qquad (5)$$

(6)

(7)

Irradiation of a benzene solution of a carboxylic acid and the reagent derived from *t*-BuOK and iodine results in efficient decarboxylation to form the one-carbon shortened alkyl iodide (eq 5).[2] This photochemical Hunsdiecker-type reaction presumably involves transformation of the starting carboxylic acid into the corresponding acyl hypoiodite, which then undergoes homolytic fission. This latter process is too facile to allow hydrogen atom abstraction by the carboxyl radical to compete. However, when amides are subjected to these reaction conditions, hydrogen atom abstraction can occur, resulting in a novel synthesis of lactones (eq 6).[3] Similar remote functionalization is possible in steroid systems via alkoxyl radicals, generated using either the *t*-BuOCl-I_2 or *t*-BuOK-I_2 combinations (eq 7).[4]

Reaction of carboxylic acids with excess alkyl iodide, in the presence of iodine and *t*-BuOCl, in the dark can give good yields of esters (eq 8).[5] Evidence points to this reaction proceeding via heterolytic S_N1 or S_N2 substitution, depending on the substrate structure.

$$R^1CO_2H + R^2I \xrightarrow{t\text{-BuOCl, } I_2} R^1CO_2R^2 \qquad (8)$$

Reagents derived from *t*-BuOCl and a metal iodide can be used to effect iodination of hydrocarbons and phenols (eqs 9 and 10).[6,7] The selectivities displayed by the radical hydrocarbon iodination led Tanner and Gidley to propose a chain reaction involving an iodonyl radical as the hydrogen atom abstracting species.[6]

(9)

(10)

Addition reactions of *t*-BuOI (prepared from *t*-BuOCl and HgI_2) to alkenes can be carried out under radical or ionic conditions (eqs 11 and 12) with regiocomplementary results.[8] The additions catalyzed by BF_3 etherate were examined in detail and found to be stereospecific, probably involving *anti* addition.

t-Butyl (*E*)-4-Iodo-2-methyl-2-butenoate

[53689-87-5] · $C_9H_{15}IO_2$ · *t*-Butyl (*E*)-4-Iodo-2-methyl-2-butenoate · (MW 282.12)

(regioselective annulations;[1] methyl vinyl ketone equivalent[2])

Alternate Name: *t*-butyl γ-iodotiglate.

Physical Data: bp 80 °C/0.005 mmHg.[1]

Preparative Method: treatment of ***Chloroacetaldehyde*** with the phosphorane shown in eq 1 followed by halogen exchange with ***Sodium Iodide***/acetone affords the title reagent in 76% overall yield.[1,2]

Cyclohexenone Annulation.

The title reagent is a ***Methyl Vinyl Ketone*** equivalent and has been employed in Robinson annulation reactions. A cyclohexanone derivative (lithium enolate or enamine) is alkylated with the iodobutenoate. Subsequent hydrolysis of the alkylated intermediate with ***p-Toluenesulfonic Acid*** affords the unsaturated carboxylic acid in 80-90% combined yield (eq 2).[1,2] An oxidative decarboxylation procedure (eq 3) via a Curtius rearrangement of the derived acyl azide

affords an ene carbamate. Basic hydrolysis of the carbamate followed by an in situ base-catalyzed aldol condensation completes the cyclohexenone annulation in 75-90% overall yield from the carboxylic acid intermediate.[1-3]

t-Butyl Isocyanide[1,2]

***t*-BuNC**

[7188-38-7] · C_5H_9N · *t*-Butyl Isocyanide · (MW 83.13)

(reactive amphiphilic reagent for 1,1-additions to form various heterocyclic *N*-*t*-butylimines; asymmetric amino acid synthesis; fragment condensation of peptides; mild carboxylic acid esterifications; metal-catalyzed cyanation of acetals, α,β-enones, and 1-alkenes; other applications involving various iminyl 1,1-addition reactions[1,2])

Physical Data: bp 91 °C/38 mmHg; *d* 0.74 g cm^{-3}.

Solubility: sol most organic solvents, including methanol, ethanol, ether, toluene, dichloromethane.

Form Supplied in: pure liquid; commercially available.

Analysis of Reagent Purity: by gas chromatography.

Preparative Methods: dehydration of ***N-t-Butylformamide*** with ***Phosphorus Oxychloride***[3] and by the Hofmann carbylamine reaction.[4]

Handling, Storage, and Precautions: awful smelling liquid: should be stored and used in a fume hood; contaminated equipment should be washed with 5% methanolic sulfuric acid.

Heterocyclic Synthesis.

Silver(I) Cyanide catalyzes the formyl transfer from *t*-butyl isocyanide to 1,*n*-amino alcohols, diamines, and amino thiols.[5] An example is the conversion of γ-aminopropanol to 5,6-dihydro-4*H*-1,3-oxazine (eq 1). The reaction can be extended to *o*-aminophenol, *o*-phenylenediamine, and *o*-aminothiophenol, affording benzoxazole (54%), benzimidazole (64%), and benzothiazole (93%), respectively.

Four-membered ring formation of 2,3-bis(alkylimino)oxetanes can be performed in high yields from ketones and 2 equiv of *t*-butyl isocyanide (eq 2).[6] Iminodioxolane derivatives are available in excellent yield from *t*-butyl cyanoketene (eq 3).[7]

(2)

(3)

A spiro 1,4-dioxan-2-one is formed in a Lewis-acid catalyzed reaction in reasonable yields from cycloalkyl ethylene acetals, which are easily prepared from the ketone and ethylene glycol (eq 4).[8] [4 + 1] Cycloaddition of kinetically stabilized azetes with *t*-butyl isocyanide affords sterically hindered pyrrole imines (eq 5).[9] An intermediate ketenimine built from 3-aminoacrylamide reacts with *t*-butyl isocyanide, forming the diiminopyrroline system (eq 6).[10]

(4)

(5)

(6)

[4 + 1] Cycloaddition of 1,3-diaza-2-methylthiobutadienes with *t*-butyl isocyanide affords 4-imino-2-thioimidazolines (eq 7).[11] Isocyanides react with thiazolines, causing a ring transformation to imidazolines (eq 8).[12] In the presence of ***Boron Trifluoride Etherate***, *t*-butyl isocyanide dimerizes, forming pivalonitrile *N*-*t*-butylimine which reacts with *o*-phenylenediamine to afford 2-*t*-butylbenzimidazole (eq 9).[13]

(7)

(8)

(9)

A structurally interesting boron heterocycle, namely a borapyrrole derivative, can be made by [4 + 1] cycloaddition plus alkyl tautomerization (eq 10).[14]

(10)

Asymmetric Synthesis of α-Amino Acids and Peptide Coupling.

Enantioselective formation of α-amino acids can be performed by asymmetrically induced Ugi reaction (eqs 11 and 12).[15,16]

(11)

(*R*)

(12)

89% ee

The chiral auxiliaries in eqs 11 and 12 are aminopyranoses with protected hydroxy functions, derived from glucose and galactose respectively. Another effective auxiliary is (*R*)-α-ferrocenylisobutylamine.[17] In eq 13 chiral induction is nearly quantitative.

(13)

A method for fragment condensation of peptides involves using *t*-butyl isocyanide as coupling reagent (eq 14).[18]

(14)

Mild Esterification.

In the chemistry of β-lactam antibiotics, especially of penicillins and cephalosporins, introduction of the ester group is often difficult. This problem can be solved by using the Passerini reaction with α-geminal polyhalogenated aldehydes and *t*-butyl isocyanide (eq 15).[19] The cleavage of β-haloalkyl esters can be performed under very mild conditions and regioselectively by cobalt(I) phthalocyanine anion without attack of the penicillin moiety.

(15)

Esterification of carboxylic acids with absolute alcohols can be achieved under mild conditions using *t*-butyl isocyanide. Exceptionally high yields are achieved in forming dicarboxylic monoalkyl esters (eq 16).[20]

(16)

Cyanation Reactions.

α-Imino nitriles are accessible in excellent yield from aldehyde acetals and *t*-butyl isocyanide (eq 17).[21] *t*-Butyl

isocyanide serves as a cyanide source for cyanohydrin ether formation (eq 18).[8]

(17)

(18)

t-Butyl isocyanide undergoes formal [4 + 1] cycloaddition to α,β-enones in the presence of ***Diethylaluminum Chloride*** to give *N*-*t*-butylimines of β,γ-butenolides (~65%). Catalytic hydrogenation and hydrolysis afford γ-butyrolactones.[22a] This tertiary isocyanide donates cyanide for conjugate hydrocyanation of α,β-enones, producing β-cyano ketones (eq 19).[22b]

(19)

Regioselective hydrocyanation of terminal alkenes can be accomplished by hydrozirconation with Schwartz's reagent (***Chlorobis(cyclopentadienyl)hydridozirconium***), followed by imine insertion with *t*-butyl isocyanide and iodinolysis (eq 20).[23]

Other Applications.

Cyclohexenimines are accessible from ***Allyl Chloride***, ***Acrylonitrile***, and *t*-butyl isocyanide via *N*-*t*-butyl vinylketenimine in a [4 + 2] cycloaddition (eq 21).[24]

By a cross-coupling reaction of octyl-9-BBN, *t*-butyl isocyanide, and iodobenzene, an alkylarene ketimine is formed, which hydrolyzes by acid catalysis to the corresponding ketone (eq 22).[25] Unsymmetrical ketones may also be obtained by 1,1-addition of an alkyllithium reagent to *t*-butyl isocyanide, lithium-boron exchange with R_2BCl, thioglycolic acid-induced migration of one R group from boron to carbon, and alkaline oxidation (H_2O_2, OH^-)[26]

Arylimino esters are available by a palladium-catalyzed reaction of aryl halides with *t*-butyl isocyanide and ***Tri-n-butyl(methoxy)stannane***. The reaction conditions have been developed with great care (eq 23).[27] Cyclic imino esters are also formed by formal substitution of carbon monoxide with *t*-butyl isocyanide and 5-aryl-2,3-dihydro-1,3-furandiones via a ketene intermediate (eq 24).[28]

Radical carbon-carbon linkage of acrylonitrile and *t*-butyl isocyanide can be performed in acceptable yields by using ***Azobisisobutyronitrile*** as radical initiator and ***Tris(trimethylsilyl)silane*** (eq 25).[29]

(25)

Isocyanides can insert at a benzylic carbon between a carbon-sulfur and a methoxycarbonyl bond to form a ketene *S,N*-acetal containing the isocyanide carbon (eq 26).[30]

(26)

Polymerization of isocyanides under the action of Ni^{II} catalysis leads to helical polymethylenimines (eq 27).[31]

(27)

Oxidation of *t*-butyl isocyanide by elemental ***Sulfur*** with ***Tellurium*** as catalyst gives the corresponding isothiocyanate in reasonable yield (eq 28).[32] Direct oxidative addition to *t*-butyl isocyanide by elemental ***Selenium*** affords *t*-butyl isoselenocyanate.[33]

(28)

Related Reagents.

t-Butyl α-Lithiobis(trimethylsilyl)acetate

[62803-13-8] · $C_{12}H_{27}LiO_2Si_2$ · *t*-Butyl α-Lithiobis(trimethylsilyl)acetate · (MW 266.46)

(forms bis(trimethylsilyl)ketene at 25 °C; reacts with aldehydes to form α-silylated vinyl esters)

Preparative Method: an approximately 1 M solution in THF is prepared by addition of *t*-butyl bis(trimethylsilyl)acetate to a 1.0 M solution of ***Lithium Diisopropylamide*** maintained at -78 °C. The solution is stirred for 1 h at -78 °C following complete addition.[1] A simplified procedure utilizes ***n-Butyllithium*** in place of LDA and produces the amine-free reagent in THF/hexane.[2]

Formation of a Ketene.

Solutions of the reagent (**1**) decompose smoothly in THF at 25 °C to provide a useful synthesis of bis(trimethylsilyl)ketene (eq 1).[3]

(1) 85% GLC; 60% isolated

Reaction with Aldehydes.

The reagent reacts via a Peterson alkenation process with aldehydes to give *t*-butyl 2-trimethylsilyl-2-alkenoates (**2**) (eq 2).[1,4] Only the 1,2-addition product is obtained with 2-butenal (eq 3). The reaction fails with ketones; only a proton transfer reaction to produce the ketone enolate is observed.

(2)

(2)

(3)

The (*E*) isomer of (**2**) is normally the favored product,[2,5] but selectivity for the (*Z*) isomer, especially with bulky aldehydes such as pivaldehyde, can be obtained by reaction in the presence of ***Magnesium Bromide*** or ***Diethylaluminum Chloride*** (eq 4).[5]

(4)

(*E*) (Z)

E:*Z* = 1:9; greater than 100:1 without Et_2AlCl

The products (**2**) are desilylated with ***Tetra-n-butylammonium Fluoride*** to produce an allenolate anion (**3**) which can be trapped in situ by protonation or reaction with aldehydes (eq 5).[2]

Related Reagents.

t-Butyl Trimethylsilylacetate; ***Ethyl Lithio(trimethylsilyl)acetate***; ***Ethyl 2-(Methyldiphenylsilyl)propanoate***; ***Ethyl Trimethylsilylacetate***; ***Methyl 2-Trimethylsilylacrylate***; ***Trimethylsilylacetic Acid***.

t-Butyl α-Lithioisobutyrate

(R = *t*-Bu)

[54191-20-7] · $C_8H_{15}LiO_2$ · *t*-Butyl α-Lithioisobutyrate · (MW 150.15) (R = Me)

[35717-10-3] · $C_5H_9LiO_2$ · Methyl α-Lithioisobutyrate · (MW 108.07) (R = Et)

[53807-80-0] · $C_6H_{11}LiO_2$ · Ethyl α-Lithioisobutyrate · (MW 122.09)

(relatively stable ester enolates)

Physical Data: white solids. The X-ray crystal structure of the TMEDA complex (R = *t*-Bu) has been obtained.[1] The IR and ^1H, ^{13}C, and ^7Li NMR spectra for amine-free reagents have been reported.[2,3]

Solubility: sol THF; insol hexane and benzene (R = Me, *t*-Bu); the ethyl enolate (R = Et) is moderately sol benzene.[4]

Preparative Methods: for most transformations, a THF solution prepared by addition of the appropriate isobutyric ester to 1 equiv (or slight excess) of ***Lithium Diisopropylamide*** in THF at -78 °C is used directly. Solid reagents are prepared by addition of slightly less than 1 equiv of the ester (diluted 1:1 in toluene or benzene) to a 0.4 M solution of LDA in the same solvent at 10 °C. The precipitate is isolated by centrifugation and dried for at least 5 h at 1 mm (65% yield).[3]

Handling, Storage, and Precautions: the reagents react with air and moisture. Solutions of the amine-free reagents in THF slowly form β-keto esters with a half-life of 4200 min at 25 °C (R = Et).[4] The solid reagents are stable indefinitely at 25 °C.

Reactions.

The esters of isobutyric acid form relatively stable lithium enolates. Transformations of these enolates often occur in high yield, in part due to their greater stability and also because steric hindrance slows subsequent side reactions of the product.

Acylation with aroyl chlorides affords α,α-dimethyl β-keto esters which may be hydrolyzed and decarboxylated to isobutyrophenones.[5] Arylation of this stable enolate may be accomplished by reaction with arenechromium tricarbonyl complexes (e.g. anisole) and subsequent iodination (eq 1).[6] Vinylation may be effected by ***Nickel(II) Bromide*** catalysis.[7]

(1)

For other applications of these ester enolates, see the entry for ***Ethyl Lithioacetate***.

Related Reagents.

t-Butyl α-Lithiobis(trimethylsilyl)acetate; ***Dilithioacetate***; ***Ethyl Bromozincacetate***; ***Ethyl Lithioacetate***; ***Ethyl Lithio(trimethylsilyl)acetate***.

t-Butyl *N*-Lithio-*N*-(*p*-toluenesulfonyloxy)carbamate

[134953-60-9] · $C_{12}H_{16}LiNO_5S$ · *t*-Butyl *N*-Lithio-*N*-(*p*-toluenesulfonyloxy)carbamate · (MW 293.26)

(electrophilic aminating agent for several carbanions;[1] can react with organoboranes to produce *N*-Boc protected primary amines[2])

Solubility: sol THF and diethyl ether.

Preparative Method: prepared from *t*-butyl *N*-(*p*-toluenesulfonyloxy)carbamate and ***n-Butyllithium*** at -78 °C in anhydrous THF.

Handling, Storage, and Precautions: should be used immediately as prepared for best results.

Electrophilic Amination.

t-Butyl *N*-lithio-*N*-(*p*-toluenesulfonyloxy)carbamate (**1**) is prepared from *t*-butyl *N*-(*p*-toluenesulfonyloxy)carbamate, which is easily obtained on a large scale by tosylation of the commercially available *t*-butyl *N*-hydroxycarbamate.[3] (**1**) is an electrophilic aminating reagent and a synthetic equivalent of $^{+}$NHBoc. It reacts with alkyllithium reagents (eq 1)[1a] or arylcopper reagents (eq 2)[1b] to provide primary amines in their *N*-Boc protected form.

$$\mathrm{RLi} \xrightarrow[\text{THF, -78 to 0 °C}]{\text{TsON(Li)Boc}} \mathrm{RNHBoc} \qquad (1)$$

R = Me, 60%; Bu, 71%; *s*-Bu, 42%

(2)

Ar = Ph, 51%; 2-anisyl, 73%; 2-pyridyl, 53%; 2-thienyl , 47%; 3-furyl, 48%

Zinc ester enolates react with (**1**) to give the corresponding *N*-Boc α-amino carboxylic esters in moderate yield (eq 3).[1a] In contrast, diethyl α-cuprophosphonates give *N*-Boc α-amino phosphonic esters in acceptable yields (eq 4).[1a]

(3)

(4)

R = Me, 80%; Ph, 50%

Reaction with Organoboranes.[2]

Primary and secondary alkylboranes react rapidly at low temperature with (**1**) to give the corresponding *N*-Boc protected primary amines (eq 5). The reaction presumably proceeds via the anionotropic rearrangement of an organoborate complex (eq 6). *N*-Boc protected aniline is obtained from triphenylborane under the same conditions with a yield of 16%. This yield can be increased by using the potassium form of the aminating reagent, which is more reactive with organoboranes.

(5)

R = Bu, 81%; *s*-Bu, 30%

The reaction of alkyl derivatives of ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) with (**1**) results in migration of the *B*-cyclooctyl group, producing *N*-Boc-5-aminocyclooctanol (eq 7).

n-Butyllithium[1]

[109-72-8] · C_4H_9Li · *n*-Butyllithium · (MW 64.05)

(strong base capable of lithiating carbon acids;[1] useful for heteroatom-facilitated lithiations;[2,3] useful for lithium-halogen exchange;[1,4] reagent of choice for lithium-metal transmetalation reactions[1a,c,5])

Physical Data: colorless liquid; stable at rt; eliminates LiH on heating; d^{25} 0.765; mp -76 °C; bp 80-90 °C/0.0001 mmHg; dipole moment 0.97 D.[6] ^{13}C NMR, ^{1}H NMR, ^{6}Li NMR[8] and MS studies have been reported.[7-9]

Solubility: sol hydrocarbon and ethereal solvents, but should be used at low temperature in the latter solvent type: half-lives in diethyl ether and THF have been reported;[10] reacts violently with H_2O and other protic solvents.

Form Supplied in: commercially available as approximately 1.6 M, 2.5 M, and 10.0 M solution in hexanes and in cyclohexane, approximately 2.0 M solution in pentane, and approximately 1.7 M, and 2.7 M solution in *n*-heptane. Hexameric in hydrocarbons;[1c] tetrameric in diethyl ether;[1c] dimer-tetramer equilibrium mixture in THF;[11] when used in combination with tertiary polyamines such as TMEDA and DABCO, reactivity is usually increased.[1,12]

Analysis of Reagent Purity: since the concentration of commercial solutions may vary appreciably it is necessary to standardize solutions of the reagent prior to use. A recommended method for routine analyses involves titration of the reagent with *s*-butyl alcohol using 1,10-phenanthroline or 2,2´-biquinoline as indicator.[15] Several other methods have been described.[16]

Preparative Methods: may be prepared in high yield from *n*-butyl chloride[13] or *n*-butyl bromide[14] and ***Lithium*** metal in ether or hydrocarbon solvents.

Handling, Storage, and Precautions: solutions of the reagent are pyrophoric and the reagent may catch fire if exposed to air or moisture. Handling of the reagent should be done behind a shield in a chemical fume hood. Safety goggles, chemical resistant gloves, and other protective clothing should be worn. In case of fire, a dry-powder extinguisher should be used: in no case should an extinguisher containing water or halogenated hydrocarbons be used to fight an alkyllithium fire. Bottles and reaction flasks containing the reagent should be flushed with N_2 or preferably Ar and kept tightly sealed to preclude contact with oxygen or moisture. Standard syringe/cannula techniques for air and moisture sensitive chemicals should be applied when transferring the reagent. For detailed handling techniques see Wakefield.[1b]

Lithiations.

n-Butyllithium is a commonly used reagent for deprotonation of a variety of nitrogen (see ***Lithium Diisopropylamide***), oxygen, phosphorus (see ***Diphenylphosphine***), and carbon acids to form lithium salts. Compared to its *s*- and *t*-butyl analogs, *n*-BuLi is less basic[17] and less reactive but it is usually the reagent of choice for deprotonation of relatively strong carbon acids. These lithiations are most favorable when the conjugated bases are stabilized by resonance or when the carbanion forms at the sp hybridized carbon of a triple bond. Thus indene,[18] triphenylmethane,[19] allylbenzene,[20] and methyl heteroaromatics (e.g. ***Pyridine***, quinoline, and isoquinoline derivatives)[21] are readily lithiated with *n*-BuLi at the benzylic position. Allenes are lithiated at C-1 or C-3 depending on the number and size of the alkyl groups at these positions,[22] and terminal alkynes react with *n*-BuLi to give lithium acetylides.[4] Propargylic hydrogens can also be removed,[23] and treatment of terminal alkynes with 2 equiv of *n*-BuLi results in the lithiation of both propargylic and acetylenic positions (eq 1).[23a]

The metalating ability of *n*-BuLi (and other organolithiums) is greater in electron-donating solvents than in hydrocarbons. Electron-donating solvents such as diethyl ether or THF provide coordination sites for the electron deficient lithium and promote the formation of lower-order organolithium aggregates.[1a,c] These exhibit significantly higher levels of reactivity than do the higher-order oligomers present in hydrocarbon solvents. *n*-Butyllithium is often used in the presence of added lithium complexing ligands, such as ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) and ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO), which further enhance the reactivity of this reagent.[12] Many compounds, normally unreactive toward *n*-BuLi alone (e.g. benzene), are readily lithiated[24] and even polylithiated[25] by a combination of *n*-BuLi and one of these additives. Allylic[26,27] and benzylic sites bearing no additional activating groups at the α-position (e.g. toluene)[12c] are also lithiated in the presence of lithium complexing donors (eq 2).[26]

(2)

Metal alkoxides are often employed as additives to enhance the metalating ability of *n*-BuLi. Particular use has been made of the ***n-Butyllithium-Potassium t-Butoxide*** mixture,[28] which is capable of effecting rapid metalation of benzylic[29] and allylic[30] systems as well as aromatic rings.[28] Although the products of these metalations are not organolithium compounds they do, nevertheless, readily react with electrophiles. Alternatively, they may be converted into the corresponding organolithium derivatives by the addition of ***Lithium Bromide***.[30a,31] Using *t*-BuOK/*n*-BuLi for deprotonation, the one-pot synthesis of 2-(4-isobutylphenyl)propanoic acid (ibuprofen) from *p*-xylene, through a sequence of metalations and alkylations, has been achieved in 52% overall yield.[29] Dimetalation of arylalkynes with *n*-BuLi/*t*-BuOK followed by addition of electrophiles has been used as a route to *ortho*-substituted arylalkynes (eq 3).[31b]

(3)

Facile and regioselective α-deprotonation is often effected by treatment of heteroatom-containing (e.g. oxygen, sulfur, nitrogen, and the like) compounds with *n*-BuLi, and these reactions have been extensively reviewed.[2,3,32,33] Thus sulfones,[34] certain sulfides,[35] and sulfoxides[36] can be lithiated adjacent to sulfur under various conditions, and α-heterosubstituted vinyllithium compounds are often available from the corresponding ethers,[37] thioethers,[38] chlorides,[39] and fluorides[40] via lithiation using *n*-BuLi. Isocyanides[41] and nitro compounds[42] have been lithiated adjacent to nitrogen with *n*-BuLi in THF at low temperatures (less than -60 °C) and the formation of various α-phosphorus

alkyllithiums has been reported.[43] Simple ethers are also susceptible to lithiation at the α site by *n*-BuLi, especially at elevated temperatures.[44] The initial proton abstraction in these systems is generally followed by various cleavage reactions resulting from α,β- and α´,β´-eliminations as well as the Wittig rearrangement.[45] Tetrahydrofuran, for example, is rapidly lithiated by *n*-BuLi at 35 °C ($t_{1/2}$ = 10 min) to give ethylene and the lithium enolate of acetaldehyde.[46]

Due to the stabilizing effect of two sulfur atoms, 1,3-dithianes are easily lithiated at the α-position on treatment with *n*-BuLi (see ***2-Lithio-1,3-dithiane***).[47] The 2-lithio-1,3-dithianes constitute an important class of acyl anion equivalents, permitting electrophilic substitution to occur at the masked carbonyl carbon.[47] Hydrolysis of the 1,3-dithiane functionality into a carbonyl group is effected in the presence of mercury(II) ion (eq 4).[48]

When conducted at sufficiently low temperatures (less than -78 °C), α-deprotonation can occur faster than nucleophilic addition to an electrophilic center present in the same molecule. This strategy, which involves initial lithiation followed by intramolecular nucleophilic addition of the newly generated C-Li bond to an electrophilic moiety, is useful for the construction of carbocycles including medium and large ring systems (eqs 5 and 6).[49,50]

(5)

(6)

A large number of heteroaromatic compounds,[2] such as furans (see ***Furan***),[51] thiophenes (eq 7),[52] oxazoles,[53] and *N*-alkyl- and *N*-aryl substituted pyrroles (see ***2-Lithio-N-phenylsulfonylindole***),[54] pyrazoles,[55] imidazoles,[56] triazoles,[57] and tetrazoles,[58] are lithiated under various conditions α to the ring heteroatom using *n*-BuLi. However, pyridine and other nitrogen heteroaromatics bearing the pyridine, pyrimidine, or pyrazine nucleus are generally not lithiated. Indeed, they have a tendency to undergo nucleophilic addition reactions with this reagent[1b] (see ***2-Lithiopyridine***).

(7)

When the α-position is benzylic, propargylic, or allylic, deprotonation takes place more readily and *n*-BuLi is generally the reagent of choice for these reactions.[59,60] However, the more basic ***s-Butyllithium*** is a better reagent for deprotonation of alkyl allyl ethers[61] and certain alkyl allyl thioethers[62] which react slowly (if at all) with *n*-BuLi in THF at low temperatures (less than -65 °C).

Proton removal adjacent to a heteroatom is further facilitated if the lithium can be coordinated to proximate electron donors, such as a carbonyl oxygen, permitting the formation of dipole-stabilized carbanions.[33] Thus various 2-alkenyl *N*,*N*-dialkylcarbamates undergo rapid α-deprotonation adjacent to oxygen on treatment with *n*-BuLi/TMEDA at -78 °C.[63,64] The resulting dipole-stabilized lithium carbanions react with ketones and aldehydes in a highly regioselective fashion providing γ-hydroxyalkylated enol esters (eq 8) which, following cleavage of the carbamoyl moiety (***Titanium(IV) Chloride***/H_2O or MeOH), afford δ-hydroxy carbonyl compounds (homoaldols) as lactols or lactol ethers.[65] Similarly, aliphatic or aromatic amides[66,67] (eq 9),[67a] phosphoramides,[68] and some formamidine derivatives (e.g. 1,2,3,6-tetrahydropyridine,[69] thiazolidine,[69] 1,3-thiazine,[69] and tetrahydroisoquinolines[70]) are selectively lithiated α to the nitrogen at the activated position. Electrophilic substitution of the intermediate organolithiums followed by hydrolytic cleavage of the amide or formamidine group provides a synthetically valuable route to α-substituted (or γ-substituted[69]) secondary amines.[33] Use of the more basic *s*-BuLi (or ***t-Butyllithium***) is generally required for deprotonation of the analogous nonbenzylic or nonallylic systems.

(9)

n-Butyllithium is also used for the stereoselective α-lithiation of chiral sulfonyl compounds,[71] chiral 2-alkenyl carbamates,[64,72] various heterocyclic amine derivatives with chiral auxiliaries appended on the nitrogen (e.g. oxazoline[73] or formamidine[74,75] groups) (eq 10),[75] and chiral oxazolidinones derived from benzylamines (eq 11).[76] These elegant reactions have been applied to the asymmetric syntheses of a number of natural products.[77,78]

(10)

(11)

Ortho Lithiations.

Heteroatom-containing substituents on aromatic rings facilitate metalation by organolithium reagents and direct the metal almost exclusively to the *ortho* position. This effect, usually referred to as *ortho* lithiation, is of considerable synthetic importance and the topic has been extensively reviewed.[2,4,79] Although *n*-BuLi (typically in THF or Et_2O with added TMEDA)[80] is capable of effecting a large number of *ortho* lithiations, the use of this reagent is somewhat limited by its tendency to undergo nucleophilic carbonyl additions with some of the most potent and useful *ortho* directors, particularly tertiary amide and carbamate functionalities (e.g. $CONEt_2$ and $OCONEt_2$).[79,81] For example, *N*,*N*-dimethyl- and -diethylbenzamides afford primarily aryl butyl ketones upon treatment with *n*-BuLi (see ***2-Lithio-N,N-diethylbenzamide***).[82] The reagent of choice for these lithiations is ***s-Butyllithium***, which is less nucleophilic than *n*-BuLi and hence more tolerant of electrophilic functional groups.[79] There are, however, a variety of *ortho*-directing groups that are well suited for *n*-BuLi-promoted lithiations. These include NR_2,[80] CH_2NR_2,[80] $CH_2CH_2NR_2$,[80] OMe (see ***o-Lithioanisole***),[83] OCH_2OMe,[84] SO_2NR_2,[85] C=NR,[86] 2-oxazolinyl,[85,87] F,[88] CF_3,[80] and groups that contain acidic hydrogens and themselves undergo deprotonation prior to lithiation of the aromatic ring (thus requiring the use of 2 equiv of *n*-BuLi), e.g. CONHR,[89] CH_2OH,[80] NHCO-*t*-Bu,[90] and SO_2NHR[80] (eq 12).[91] *n*-Butyllithium is also used frequently for the *ortho* lithiation of heterocyclic aromatic rings,[2] including those that contain the pyridine nucleus (eq 13).[92]

Formation of Enolate Anions and Enolate Equivalents.

Owing to its tendency to undergo nucleophilic addition with carbonyl groups and other electrophilic carbon-heteroatom multiple bonds (C=NR, C&tbond;N, C=S),[1] *n*-BuLi is usually not the reagent of choice for the generation of enolate anions or enolate equivalents from active hydrogen compounds. This is done most conveniently using the less nucleophilic lithium dialkylamides (e.g. ***Lithium Diisopropylamide*** (LDA), ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LiTMP), and ***Lithium Hexamethyldisilazide*** (LTSA)) prepared (often in situ) from sterically hindered secondary amines, typically by treatment with *n*-BuLi.[93] However, less reactive carbonyl compounds such as amides (eq 14)[94] and carboxylic acids[95] as well as those containing carbon-nitrogen or carbon-sulfur multiple bonds, e.g. imines,[96] oxazines,[97] nitriles,[98] some hydrazones,[99] and thioamides,[100] can be lithiated α to the electrophilic carbon with *n*-BuLi under various conditions. β-Keto esters can be alkylated at the α´-carbon using ***Sodium Hydride*** for the first deprotonation and *n*-BuLi for abstraction of the less acidic α´-proton followed by addition of alkyl halides.[101] Lithiation of unsymmetrical imines using *n*-BuLi takes place regioselectively at the most substituted α-carbon (eq

15).[96] In contrast, LDA directs metalation and subsequent alkylation predominantly to the less substituted α-position in similar systems.[102] Lithium enolates of camphor imine esters, prepared by addition of *n*-BuLi, undergo highly diastereoselective Michael additions with α,β-unsaturated esters (eq 16).[103] The tightly chelated structures of the intermediate enolates permit selective *re* face approach of the Michael acceptors, giving rise to the high degree of distereoselectivity observed.

(14)

(15)

Metal-Halogen Interchange and Transmetalation Reactions.

The metal-halogen interchange reaction which involves the exchange of halogen and lithium atoms is an important method for the preparation of organolithium compounds not readily accessible through metalation. In particular, the generation of aryl-, vinyl-, and cyclopropyllithium derivatives from the corresponding bromides or iodides on treatment with *n*-BuLi (usually in ethereal solvents at or below -78 °C) is of considerable synthetic utility (eqs 17-19).[104-106] The relative rates of exchange depend on the halide and decrease in the order I > Br > Cl > F. Fluorides and chlorides, with the exception of some polychlorinated aliphatic[107] and aromatic compounds,[108] are quite resistant to lithium-halogen interchange; instead, they tend to promote *ortho* and α lithiations.[79]

(17)

(18)

(19)

gem-Dihalocyclopropanes react with *n*-BuLi in a highly stereoselective fashion (eq 19), although subsequent isomerization can take place.[109] Alkyl-substituted vinyllithiums can be prepared with retention of configuration[105,110] and even aryl-substituted vinyllithium compounds retain their configuration under controlled conditions (<-78 °C in

THF or at rt in hydrocarbon solvents).[111] Simple alkyllithiums are generally not accessible by this route because of the unfavorable interchange equilibrium that ensues when primary or secondary halides are treated with *n*-BuLi, except in cases where the initially formed organolithium is rapidly consumed in a subsequent, irreversible reaction (eq 20).[112] Primary alkyllithiums may be prepared, however, from the corresponding alkyl iodides (but not from the bromides)[113] on treatment with the more reactive ***t-Butyllithium*** which renders the exchange operationally irreversible.[114]

n-Butyllithium is the reagent of choice for effecting a number of transmetalation reactions involving the replacement of tin, selenium, tellurium, or mercury by lithium.[1a,1c,5] These reactions are typically conducted at low temperatures (less than -60 °C) in ethereal solvents, with THF being the most commonly employed reaction medium. The tin-lithium exchange is a particularly important operation, providing a convenient route to aryl- and vinyllithiums,[115] as well as functionalized lithio derivatives which are not readily accessible by other means, such as α-alkoxylithium compounds,[116] oxiranyllithiums,[117] and amino-substituted organolithiums.[118] The Sn-Li exchange in these systems and subsequent trapping of the intermediate lithio derivatives proceed stereoselectively with retention of configuration at the tin-bearing carbon (eqs 21 and 22).[116c,118c] Consequently, enantiomerically enriched functionalized products are available through this methodology from homochiral α-hetero-substituted stannanes.[119]

Appropriately substituted alkenic α-alkoxylithiums, derived from the corresponding tri-*n*-butyltin compounds on treatment with *n*-BuLi, have also been used to initiate 5-*exo*-*trig* cyclization reactions to give tetrahydrofuran derivatives (eq 23).[120] Other related ring-forming reactions have been reported.[121]

Organoselenium compounds, particularly selenoacetals or selenothioacetals, undergo facile lithium-selenium exchange reactions on treatment with *n*-BuLi, typically in THF at -78 °C.[122-124] The intermediate α-seleno organolithium derivatives formed in these reactions are readily trapped with electrophiles to afford a variety of synthetically useful α-functionalized selenide products[3,125] (eq 24).[126] Studies on cyclohexyl selenoacetals have shown that Li-Se exchange takes place almost exclusively at the axial position[123] and that equatorial α-lithio sulfides, derived from mixed Se,S-acetals by Li-Se exchange, epimerize within minutes at -78 °C to give the more stable axial lithio isomers.[124] *n*-Butyllithium may be used for the majority of Li-Se exchanges although selenoacetals derived from sterically hindered ketones react quite slowly with this reagent, and in these cases the use of the more reactive ***s-Butyllithium*** is warranted.[123]

A variety of organolithiums, including benzylic, vinylic, alkynic, and 1-alkoxylithium compounds, are also accessible through the lithium-tellurium exchange, which involves the treatment of diorganotellurides with *n*-BuLi at -78 °C in THF (eq 25);[127] vinyllithium derivatives have been prepared from the corresponding organomercurials by essentially

the same methodology.[128]

Rearrangements.

n-Butyllithium is used frequently to promote various anionic rearrangement reactions. 2,3-Wittig rearrangements are commonly effected by treatment of allylic and propargylic ethers with *n*-BuLi,[129] and 1,2-, 1,4-, as well as 3,4-rearrangements with similar systems are also known.[130] These reactions are most often initiated at low temperatures either by α-deprotonation adjacent to oxygen or via Li-Sn exchange, and the rearrangement occurs upon warming of the reaction mixture to 0 °C. Additional benzylic, propargylic, or allylic stabilization is necessary for deprotonation by *n*-BuLi; however, the Li-Sn method does not suffer from this limitation.[131] 2,3-Wittig rearrangements involving (*Z*)-allylic ethers proceed generally with high *syn* stereoselectivity (eq 26),[131] whereas the opposite tendency is observed with (*E*)-allylic ethers.[132] The regiochemistry of unsymmetrical bis-allylic ethers depends on the degree of substitution at the α- and γ-carbons, with the less substituted allylic position being the preferred site of deprotonation (eq 27).[133] The cyclic variant of the 2,3-Wittig rearrangement can be used for ring contraction reactions and it provides a useful method for the construction of macrocyclic ring systems (eq 28).[134]

(27)

(28)

Secondary 1,2-epoxy alcohols may be prepared through the Payne rearrangement in aprotic media by treatment of primary 2,3-epoxy alcohols with *n*-BuLi in THF with catalytic amounts of ***Lithium Chloride***,[135] and α,β-unsaturated ketones are obtained from trimethylsilyl substituted propargylic alcohols through the Brook rearrangement followed by alkylation of the intermediate allenyllithium products and acidic workup (eq 30).[136] Quaternary ammonium salts, such as benzyltrimethylammonium ion, react with *n*-BuLi to deliver nitrogen ylides which can undergo either the Stevens rearrangement to give tertiary amines or the Sommelet-Hauser rearrangement to afford *ortho* alkyl-substituted nitrogen-containing aromatics, depending on the reaction conditions (eq 31).[137] Dibenzyl thioether has been reported to undergo a Sommelet-Hauser type rearrangement on treatment with *n*-BuLi/TMEDA in HMPA,[138] and appropriately substituted sulfonic ylides, prepared from sulfonium salts on treatment with *n*-BuLi, undergo 2,3-sigmatropic rearrangements (eq 32).[139]

Elimination Reactions.

A number of eliminations can be effected using *n*-BuLi. The formation of phosphorus, nitrogen, and sulfur ylides[1a] and the generation of benzyne intermediates from aromatic halides[140] are well established processes, and α-eliminations resulting in the formation of carbenes have been used to prepare cyclopropanes,[141] oxiranes,[142] and other products via subsequent carbenoid rearrangements (eq 33).[143] Vinylidene dihalides undergo dehalogenation with concomitant formation of a triple bond on treatment with 2 equiv of *n*-BuLi.[144] The initial product of this reaction is a lithium acetylide which can be quenched with methanol to give a terminal alkyne or alkylated in situ by addition of alkyl halides to afford internal alkynes (eq 34).[145] The decomposition of (arylsulfonyl)hydrazones of aldehydes or ketones upon treatment with at least 2 equiv of *n*-BuLi (Shapiro reaction) is a useful method for the generation of vinyllithium compounds (eq 35).[146] In cases where two regioisomers can be produced, *n*-BuLi appears to promote the formation of the less substituted vinyllithium via deprotonation of the kinetically more acidic proton, whereas the use of *s*-BuLi

reportedly leads to the more substituted vinyllithium product.[147]

t-Butyllithium[1]

[594-19-4] · C_4H_9Li · *t*-Butyllithium · (MW 64.06)

(strong base capable of lithiating weak acids;[1] useful for heteroatom-faciliated lithiations;[2-4] reagent of choice for lithium-halogen exchange;[5] can add to π-bonds[1,6])

Physical Data: colorless solid; decomposes above 140 °C with loss of LiH; sublimes at 70 °C/0.1 mmHg. X-ray structures of the solvent-free tetramer and the ether-solvated dimer[7a] and ^{13}C NMR studies in hydrocarbon[8a] and ethereal solutions[7b] have been reported.

Solubility: sol hydrocarbon solvents, diethyl ether, and THF but should be used at low temperature; half-lives in various solvents have been reported;[9] reacts violently with H_2O and other protic solvents.

Form Supplied in: commercially available as an approximately 1.7 M solution in pentane or heptane. Tetrameric in hydrocarbons,[8] dimeric in diethyl ether,[7] monomeric in THF[10a] although earlier reported as dimeric.[1,10b] In combination with tertiary polyamines such as ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA), ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO), or ***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine*** (PMDTA), reactivity is often increased.[1,11]

Analysis of Reagent Purity: since the concentrations of commercial solutions vary appreciably, especially after the original seal is broken, it is necessary to standardize solutions of the reagent prior to use. The classical Gilman double titration method is described in detail by Wakefield.[1b] A particularly convenient method for routine analyses involves titration of the reagent with *s*-butyl alcohol using 1,10-phenanthroline or 2,2´-biquinoline as indicator.[13] A variety of other methods have been described.[14]

Preparative Method: the reaction of *t*-butyl chloride with 1-2% Na-Li alloy in dry pentane requires particular attention to detail to achieve a reasonable yield of the reagent. Detailed procedures should be consulted.[1b,12]

Handling, Storage, and Precautions: solutions of the reagent are pyrophoric and the reagent may ignite spontaneously upon exposure to air, producing a purple flame. It is prudent to conduct all operations involving *t*-BuLi behind a shield. In case of fire, a dry-powder extinguisher should be used: in no case should an extinguisher containing water or halogenated hydrocarbons be used to fight an alkyllithium fire. Bottles and reaction flasks containing the reagent should be flushed with N_2 or preferably Ar and kept tightly sealed to preclude contact with oxygen or moisture. The reagent may be cautiously transferred under an inert gas atmosphere using standard syringe/cannula techniques.[1b] Most reactions of *t*-butyllithium are exothermic

and for this reason are usually carried out at temperatures well below ambient. For detailed handling techniques see Wakefield.[1b]

Lithiations.

t-Butyllithium is less frequently used for proton abstraction than is ***n-Butyllithium*** or ***s-Butyllithium***. However, as it is more reactive and less nucleophilic than its isomers, *t*-BuLi may be the reagent of choice for the lithiation of relatively weak acids (eq 1). The addition of 1 equiv of a tertiary polyamine increases the metalating ability of the reagent.[1,11] Simple hydrocarbons, which are used as solvents, are generally inert to lithiation by *t*-BuLi. Although ethers and amines are often used as solvents in low temperature reactions involving *t*-BuLi, ethers,[15] THF,[16] and TMEDA[17] are readily lithiated by the reagent. Indeed, treatment of THF with *t*-BuLi has been reported to afford ethylene and the lithium enolate of acetaldehyde at temperatures as low as -78 °C.[16a]

Monodeprotonation of terminal alkynes is conveniently accomplished with *n*-BuLi (see ***Propynyllithium***); the use of excess *t*-BuLi in hexane may lead to polylithiation.[18] For example, treatment of 1-butyne with 3 equiv of *t*-BuLi in hexane affords a mixture of allene and alkyne upon quench with an electrophile (eq 2).[19]

Highly regioselective proton abstractions may result when substrates containing such heteroatoms as oxygen, nitrogen, sulfur, and the like are treated with an organolithium. Several reviews of the topic[2-4,6,20] and a collection of detailed experimental procedures[21] are available. Two categories of heteroatom-facilitated lithiations are recognized: α-lithiation, involving removal of a proton from the carbon bearing the heteroatom, and β- (or *ortho*-) lithiation, involving abstraction of a proton from the β-position.[2,4] Lithiation of acyclic[22] (eq 3),[22a] cyclic (eq 4),[23] and conjugated enol ethers (eq 5)[24] using *t*-BuLi provides a simple route to readily functionalized α-lithio vinyl ethers (see ***1-Ethoxyvinyllithium***). Vinyl sulfides behave analogously[25] and sulfur appears to be a stronger α-director than is oxygen (eq 6).[26] Alkyl phenyl thioethers are α-lithiated by *t*-BuLi in the presence of ***Hexamethylphosphoric Triamide*** (eq 7).[27] Furans and thiophenes are readily α-lithiated by *t*-BuLi, but use of the less reactive *n*-BuLi is more convenient.[1,2,21] At temperatures below -100 °C, *t*-BuLi in THF regioselectively deprotonates enamines derived from β-acyl aldehydes in preference to 1,2- or 1,4-addition[28] (eq 8).[28a]

Heteroatom-directed *ortho* lithiations of aromatic compounds are most often accomplished with *n*- or *s*-BuLi, either alone or in combination with TMEDA.[4] Some benefit derives from the use of the bulkier and more basic *t*-BuLi for *ortho* lithiation of substrates bearing substituents susceptible to nucleophilic attack (eq 9)[29] or resistant to deprotonation by less reactive bases (eq 10)[9,30] The key step in a highly stereoselective asymmetric synthesis of chiral ferrocenes involves *ortho* lithiation of a ferrocenyl acetal at -78 °C using *t*-BuLi in THF (eq 11).[31]

(11)

Lithium-Halogen Exchange.

t-Butyllithium is often the reagent of choice for the preparation of an organolithium by lithium-halogen exchange. The reversible metathesis (eq 12), most readily accomplished at low temperature with bromides and iodides, leads to an equilibrium mixture favoring the more stable organolithium.[1,32] The benefits of using *t*-BuLi (rather than *n*- or *s*-BuLi) for the preparation of organolithiums by lithium-halogen exchange derives from two considerations: (1) the interchange equilibrium is favorable when an aryl, vinyl, cyclopentyl, or primary-alkyl halide is treated with a tertiary organolithium,[33] and (2) the exchange may be rendered operationally irreversible by employing 2 equiv of *t*-BuLi since 1 equiv of the reagent rapidly consumes the *t*-butyl halide generated in the reaction to give isobutane, isobutene, and lithium halide (eq 13).[34]

$$R^1\text{-}X + R^2\text{-}Li \rightleftharpoons R^1\text{-}Li + R^2\text{-}X \qquad (12)$$

(13)

Aryl halides readily undergo lithium-halogen exchange with alkyllithiums in ethereal solvents at temperatures at or below -78 °C and the less expensive *n*-BuLi is often used for this purpose.[1,32] However, the presence of the *n*-butyl halide product can cause complications when the aryllithium is warmed since a coupling reaction may ensue[1,32] (for example, the reaction of ***Phenyllithium*** with *n*-butyl iodide in THF at -78 °C has a half-life of ~30 min). This potential problem is avoided when 2 equiv of *t*-BuLi are used for the generation of aryllithiums.

Vinyllithiums are readily prepared with retention of configuration from the corresponding vinyl bromides or iodides in a stereoselective exchange with 2 molar equiv of *t*-BuLi, provided that the reaction is conducted at temperatures below -110 °C.[35] The reactions are conducted most conveniently in the Trapp solvent,[36] a 4:4:1 mixture of THF, diethyl ether, and pentane (or hexane), by slow addition of 2 equiv of *t*-BuLi in pentane to a solution of the halide which is held at -110 to -120 °C. The preparation of (*E*)-1-hexenyllithium and its conversion to (*E*)-1-phenylthio-1-hexene is illustrative (eq 14)[35a] of the method, and detailed experimental procedures are available.[37] The stereoselective lithium-halogen exchange of vinyl halides is the key step in a highly diastereoselective metalla-Claisen rearrangement (eq 15)[38] and α-keto dianions may be prepared from the lithium enolates of α-bromo ketones by the exchange reaction with excess *t*-BuLi (eq 16).[39]

(14)

(15)

(16)

Cyclopropyllithiums (see ***Cyclopropyllithium***) are, in general, easily prepared from the corresponding bromides or iodides with retention of configuration by low-temperature lithium-halogen exchange using either *n*-BuLi or *t*-BuLi.[1,32] The more reactive *t*-BuLi was found to be superior for the generation of (1-ethoxycyclopropyl)lithium, a reagent useful for the preparation of cyclobutanones (eq 17).[40]

(17)

The early literature suggests that metal-halogen exchange between primary alkyl halides and alkyllithiums is not, in general, a preparatively useful reaction due to unfavorable equilibria (eq 12) and competition from coupling and elimination reactions.[1,32] However, more recent mechanistic studies of the exchange reaction[41,42] have revealed that virtually all of the difficulties historically associated with use of this method for the preparation of simple alkyllithiums can be overcome by the use of *t*-BuLi and judicious choice of experimental conditions.[5] Primary alkyllithiums are conveniently prepared at -78 °C (the exchange has been conducted at temperatures as low as -131 °C)[5a] by addition of 2.1-2.2 equiv of *t*-BuLi in pentane to a solution of primary alkyl iodide in pentane-diethyl ether (3:2 by vol).[5] Under these conditions (eq 18) the exchange is exceedingly rapid, the yield of alkyllithium is excellent,[5] and the only byproduct is a small quantity of easily removed hydrocarbon derived from formal reduction of the iodide via proton abstraction from the cogenerated *t*-BuI.[43] The alkyllithium may be used at low temperature but residual *t*-BuLi remaining in solution may complicate product isolation following addition of an electrophile to the cold reaction mixture, particularly if an excess of *t*-BuLi was employed. Any residual *t*-BuLi is easily removed by simply allowing solutions containing the primary alkyllithium and *t*-BuLi to warm to room temperature: the *t*-BuLi is rapidly consumed by proton abstraction from diethyl ether, leaving clean solutions of the less reactive primary alkyllithium.[5] The success of this route to primary alkyllithiums depends critically on the appropriate choice of both halide and solvent.[5] Alkyl iodides rather than alkyl bromides or chlorides must be used in the exchange: under the conditions of the reaction (eq 18), lithium-iodine exchange most probably involves rapid attack of *t*-BuLi on the iodine atom of the halide,[42,44] while lithium-bromine exchange occurs predominantly by a single electron transfer (SET) mechanism.[42] Alkyl chlorides are essentially inert to the action of *t*-BuLi under the conditions indicated in eq 18.[42] Moreover, it is advisable to run the reaction in a solvent system that contains diethyl or a similar ether; the use of THF or other strongly coordinating Lewis bases such as TMEDA should be avoided as elimination and coupling reactions may compete with exchange in these solvents.[5a]

$$\text{R-CH}_2\text{-I} \xrightarrow[\text{-78 °C, 5 min}]{t\text{-BuLi},\ n\text{-C}_5\text{H}_{12},\ \text{Et}_2\text{O}} \text{R-CH}_2\text{-Li} \xrightarrow{\text{E}^+} \text{R-CH}_2\text{-E} \qquad (18)$$

Low-temperature lithium-iodine exchange with *t*-BuLi has been used to prepare 5-hexenyllithiums from 6-iodo-1-hexenes.[43] When warmed, these alkenic alkyllithiums undergo highly stereoselective and totally regiospecific 5-*exo* cyclization via a cyclohexane chair-like transition state[45] to afford high yields of (cyclopentylmethyl)lithiums that may be functionalized by reaction with an electrophile[46] (eq 19).[46b] Such isomerizations have also been conducted in a tandem fashion to give polycyclic products[47] (eq 20).[47a] Alkynic alkyllithiums, which are prepared by lithium-iodine exchange with *t*-BuLi, cyclize in a stereoselectively *syn* fashion to four-, five-, and six-membered carbocyclic rings bearing an exocyclic lithiomethylene moiety[48] (eq 21).[48a] Related chemistry initiated by lithium-selenium exchange with *t*-BuLi has also been reported.[49]

(19)

(20)

(21)

Reaction of 2 equiv of *t*-BuLi with α,o-diiodoalkanes at -23 °C affords nearly quantitative yields of three- through five-membered carbocyclic rings via cyclization of an intermediate α-lithio-o-iodoalkane (eq 22).[50] When 4 equiv of *t*-BuLi are used at -78 °C, α,o-dilithioalkanes such as ***1,4-Dilithiobutane***, ***1,5-Dilithiopentane***, and 1,6-dilithiohexane result.[5b]

(22)

Low-temperature lithium-iodine exchange between *t*-BuLi and a primary alkyl iodide is more rapid than lithium-bromine exchange with aryl bromides.[51] Indeed, the iodine exchange reaction is so facile that it is sometimes possible to conduct preparatively useful lithium-iodine exchange in the presence of other reactive functional groups[1] such as ketones (eq 23).[52] Metal-halogen exchange-initiated intramolecular conjugate additions have also been reported[53] (eq 24).[53b]

(23)

(24)

Dehalogenation of vicinal diiodides initiated by exchange with *t*-BuLi has been used to access highly strained alkenes[54] such as cubene (eq 25).[55]

(25)

Addition of Carbon-Carbon Double Bonds.

In the presence of ethers or amines, *t*-BuLi adds rapidly to ethylene at -25 °C at 1 atm of pressure to give neohexyllithium (3,3-dimethylbutyllithium) in quantitative yield (eq 26).[56] It should be noted that neohexyllithium may unexpectedly result from addition of *t*-BuLi to the ethylene generated from the decomposition of diethyl ether[15] or THF[16] when these solvents are present in reaction mixtures containing *t*-BuLi.[56]

(26)

Addition of *t*-BuLi to other carbon-carbon double bonds is not a facile process unless: (1) the π-system is conjugated[1,57] (in which case anionic polymerization may result),[58] (2) the alkene is at least somewhat strained (eq 27),[59] (3) the resulting anion is stabilized as in vinylsilanes,[60] vinylphosphines,[61] and the like (eq 28),[62] (4) a good leaving group is present at the allylic position,[63] or (5) there is intramolecular assistance provided by a suitably placed heteroatom[6] (eq 29).[64]

(27)

At high temperatures, alkyllithiums have been observed to alkylate aromatic rings by addition to the π-system and subsequent loss of LiH.[1,65] Of the butyllithiums, *t*-BuLi has been found to be more reactive than either of its isomers in the alkylation of naphthalene and other condensed aromatics.[66] Addition of *t*-BuLi, as well as other organolithiums, across the azomethine linkage of pyridine and similar nitrogen heterocycles is a facile process.[1]

Addition to Carbon-Heteroatom Multiple Bonds.

The behavior of *t*-BuLi in reactions with carbon-heteroatom π-bonds is relatively unremarkable and parallels that of other organolithium reagents.[1] Even in cases where steric hindrance might be expected to lead to difficulties, product yields are reasonable. Thus, for example, tri-*t*-butylcarbinol (3-*t*-butyl-2,2,4,4-tetramethyl-3-pentanol) may be prepared by addition of *t*-BuLi to di-*t*-butyl ketone (2,2,4,4-tetramethyl-3-pentanone), although there is a significant amount of reduction in this case,[67] and *N*-lithio-di-*t*-butylimines may be generated by addition of *t*-BuLi to *t*-butyl cyanide.[68]

Related Reagents.

n-Butyllithium; ***s-Butyllithium***.

s-Butyllithium[1]

[598-30-1] · C_4H_9Li · *s*-Butyllithium · (MW 64.06)

(strong base capable of lithiating weak carbon acids;[1] useful for heteroatom-facilitated lithiations;[2-4] reagent of choice for *ortho* lithiations[5])

Physical Data: colorless to pale yellow liquid; slowly eliminates LiH; d^{25} 0.783; bp 90 °C/0.05 mmHg;[6,7] ^{13}C NMR, ^{1}H NMR, ^{6}Li NMR, and MS studies have been reported.[8-11]

Solubility: sol hydrocarbon and ethereal solvents, but should be used at low temperature in the latter solvent type: half-lives in ethereal solvents have been reported;[12] reacts violently with H_2O and other protic solvents.

Form Supplied in: commercially available as approximately 1.3 M solution in cyclohexane. Mostly tetrameric in hydrocarbons;[9,13] mostly monomeric in THF;[14] when used in combination with tertiary polyamines such as ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) and ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO), reactivity is usually increased.[1,15]

Analysis of Reagent Purity: since the concentration of commercial solutions may vary appreciably it is necessary to standardize solutions of the reagent prior to use. A recommended method for routine analyses involves titration of the reagent with *s*-butyl alcohol using 1,10-phenanthroline or 2,2´-biquinoline as indicator.[16] Several other methods have been described.[17]

Preparative Method: may be prepared in high yield from *s*-butyl chloride and ***Lithium*** metal in hydrocarbon solvents.[13]

Handling, Storage, and Precautions: solutions of the reagent are pyrophoric and the reagent may catch fire if exposed to air or moisture. Handling of the reagent should be done behind a shield in a chemical fume hood. Safety goggles, chemical resistant gloves, and other protective clothing should be worn. In case of fire, a dry-powder extinguisher should be used: in no case should an extinguisher containing water or halogenated hydrocarbons be used to fight an alkyllithium fire. Bottles and reaction flasks containing the reagent should be flushed with N_2 or preferably Ar and kept tightly sealed to preclude contact with oxygen or moisture. Standard syringe/cannula techniques for air- and moisture-sensitive chemicals should be applied when transferring the reagent.[18] For detailed handling techniques see Wakefield.[1b]

Lithiations.

s-Butyllithium is a powerful metalating agent which is used frequently to convert a variety of organic compounds into their lithio derivatives. The resulting organolithium products may be subsequently functionalized with a large number of electrophiles, hence allowing the preparation of, for example, alcohols, carboxylic acids, ketones, esters, organosilicon compounds, and other organometallic compounds.[1] The metalations of relatively strong carbon acids, such as terminal alkynes, triarylmethanes, and methyl heteroaromatics, may be regarded as simple acid-base reactions and these are done most conveniently using the less basic ***n-Butyllithium***,[19] which is also less reactive and easier to handle than *s*-BuLi. However, the use of *s*-BuLi is warranted for deprotonation of weaker carbon acids (e.g. preparation of aryl-,[15] vinyl-,[20,21] and certain allyllithiums,[15,21,22]) and those that require a less nucleophilic lithiating agent.[5,23]

Lithiations employing *s*-BuLi are most often conducted in electron-donating solvents such as Et_2O, THF, and DME which coordinate to lithium much more strongly than do the alkyl groups of hydrocarbon solvents and thus enhance the reactivity of the organolithium species. It is generally agreed that this effect is the consequence of the depolymerization of higher order organolithium aggregates (tetramers) into smaller units (dimers and monomers).[1] The increased reactivity of organolithiums in ether solvents can, in fact, lead to α-deprotonation of the solvent molecules at elevated temperatures; in diethyl ether, for example, *s*-BuLi has a maximum lifetime of about an hour at +20 °C and THF is attacked even more readily.[12] Hence, to ensure the integrity of the organolithium reagents in these solvents, the use of low-temperature conditions (typically -78 °C) is imperative.

s-Butyllithium is often used in the presence of various lithium complexing ligands such as ***Hexamethylphosphoric Triamide***, TMEDA, and DABCO, which serve to further enhance the reactivity of this reagent.[15] The *s*-BuLi/TMEDA complex is an extremely powerful lithiating agent, effecting rapid deprotonation of many compounds, e.g. benzene, tetramethylsilane, and propene (eq 1),[15] which are unreactive toward *s*-BuLi alone. Compared to the analogous *n*-BuLi/TMEDA complex, *s*-BuLi/TMEDA is considerably more potent as a metalating agent; e.g. the lithiation of Me_4Si proceeds ~1000 times faster with *s*-BuLi/TMEDA than with *n*-BuLi/TMEDA.[15a]

(1)

Metal alkoxides, such as ***Potassium t-Butoxide***, are also used in combination with *s*-BuLi to facilitate the metalation of weak carbon acids including aromatic compounds,[24] vinylic systems,[25] and others.[26,27] The products of these metalations are organopotassium derivatives, but they can be readily converted into the corresponding organolithium compounds by the addition of ***Lithium Bromide***.[26,27]

s-Butyllithium is often used to effect regiospecific and rapid deprotonation of heteroatom-containing compounds.[2-4,28,29] Heteroatoms such as oxygen, sulfur, nitrogen, phosphorus, and halogens enhance the acidity of α- or β-protons through either inductive or coordination effects and hence facilitate deprotonation. For example, the α-lithiation of vinyl thioethers,[30] vinyl chlorides,[31] and vinyl thioesters[32] is effected at low temperatures using *s*-BuLi in the presence of HMPA or TMEDA. The vinyllithium compounds derived from thioethers are important acyl anion equivalents which, after alkylation, are readily converted into substituted ketones (eq 2).[30]

Lithiation of α-disubstituted alkenes is directed to the β-site in cases where the α-substituents are capable of activating the β-position through either inductive effects or chelation (eqs 3 and 4).[20,33] Internal coordination to the lithium by the electron-donating β-substituent in eq 4 permits deprotonation and subsequent electrophilic substitution to take place stereoselectively.[20]

The preparation of a variety of α-heteroatom-substituted alkyllithiums is conveniently achieved using *s*-BuLi and in many cases this reagent exhibits highly original reactivity. ***(Methoxymethyl)trimethylsilane***, for example, undergoes facile lithiation on treatment with *s*-BuLi in THF at -78 °C to give $Me_3SiCHLiOMe$, which is readily hydroxyalkylated by the addition of aldehydes or ketones (eq 5).[34] With other butyllithium reagents, this reaction takes a completely different course: *n*-BuLi undergoes a nucleophilic attack on the Si atom with concomitant loss of the CH_2OMe group, and the use of ***t-Butyllithium*** gives $LiCH_2SiMe_2CH_2OMe$ through preferential deprotonation of one of the trimethylsilyl protons.[34] In a similar reaction, ***(Chloromethyl)trimethylsilane*** is lithiated α to the chlorine atom using *s*-BuLi to furnish synthetically useful α,β-epoxytrimethy lsilanes after treatment with aldehydes or ketones (eq 6).[23] Again, *s*-BuLi appears to be a superior reagent for this lithiation: the use of *n*-BuLi results in loss of the chloride anion, presumably through initial nucleophilic attack of this reagent upon the silicon atom and subsequent alkyl migration, and *t*-BuLi leads to the predominant formation of ***Trimethylsilylmethyllithium***, formally derived from Li-Cl exchange.[23] Selenide Bis(trimethylsilylmethyl) selenide,[35] ***Methylenetriphenylphosphorane***,[36] phosphonic acid triamides,[37] and 1,3-oxathianes[38] are also readily lithiated on treatment with *s*-BuLi. The final ketene *O*,*S*-acetal product in eq 7 is formed via the Peterson alkenation process after addition of 2-methylpropanal to the lithio intermediate.[38a]

(5)

(6)

(7)

Metalation of *N*-methylpiperidine, *N*-methylpyrrolidine, and ***Trimethylamine*** takes place exclusively at the methyl group when *s*-BuLi is used in combination with *t*-BuOK (eq 8),[26] and the same mixture can be used to metalate *t*-butyl methyl ether (eq 9).[27] The intermediate organopotassium product in eq 9 is converted into the corresponding organolithium derivative by addition of LiBr to give *t*-BuOCH$_2$Li, the synthetic equivalent of hydroxymethyllithium (LiCH$_2$OH).[27]

(8)

(9)

Many allylic or benzylic heteroatom-containing compounds are often lithiated more conveniently using the less reactive

n-BuLi rather than *s*-BuLi. However, the more basic *s*-BuLi is a better reagent for the deprotonation of alkyl allyl ethers[39] and certain allyl thioethers[21b] that react slowly (if at all) with *n*-BuLi in THF at low temperatures (<-65 °C). The allyllithium derivatives formed in these reactions may be alkylated or hydroxyalkylated either at the α- or the γ-position, depending on the electrophile and the structure of the allylic anion. With metalated allyl ethers, primary alkyl halides tend to attack the γ-position to afford alkylated enol ethers, but carbonyl compounds react to give products derived mainly from α-attack (eq 10).[39,40] The opposite tendency is generally observed with analogous lithiated allyl thioethers[21,41,42] which, upon addition of alkyl halides, give primarily α-alkylated products (eqs 11 and 12).[21b,42] Generally, soft electrophiles (e.g. RI) exhibit a higher propensity for γ-attack than do hard electrophiles (e.g. RCl).[42]

(10)

(11)

RX	α:γ	
n-BuCl	97:3	70%
n-BuBr	91:9	79%
n-BuI	70:30	100%

(12)

Proton removal adjacent to a heteroatom is further facilitated if the lithium can be internally coordinated to proximate electron donors, such as the carbonyl oxygen, permitting the formation of dipole-stabilized carbanions.[28] Thus lithiations of various amides,[43] thioamides,[44] imides,[45] esters,[46] Boc derivatives of cyclic amines (pyrrolidines, piperidines, and hexahydroazepines),[47] thioesters,[32] *N*,*N*-dialkylthiocarbamates,[32] and various formamidine derivatives[48] are achieved conveniently using *s*-BuLi (eqs 13-17).[32,43b,44,47a,48a] Subsequent addition of electrophiles followed by hydrolytic removal of the activating carbonyl, carbamoyl, or formamidine moiety provides a valuable synthetic route to a variety of α-substituted amines, alcohols, and thiols.[28,46] Successful alkylation of the dipole-stabilized carbanions may require the conversion of the initial lithio carbanions into their organocuprate derivatives, e.g. by the addition of *n*-PrC&tbond;CCu.[48a]

(17)

Lithiation takes place more readily if the dipole-stabilized anions are further activated by an adjacent aromatic ring or a double bond and, in fact, many such compounds are most conveniently deprotonated using the less reactive *n*-BuLi.[28]

Stereoselective *s*-BuLi-promoted α-lithiations have been accomplished with various piperidine and isoquinoline derivatives bearing chiral oxazoline or formamidine substituents on the nitrogen (eqs 18 and 19).[49,50] Asymmetric deprotonations α to oxygen in carbamates and α to nitrogen in Boc-protected pyrrolidines have been effected using *s*-BuLi in the presence of ***(-)-Sparteine***, which is a homochiral lithium-complexing ligand.[51,52] These deprotonations lead to the formation of chiral dipole-stabilized carbanions which react with electrophiles under strict stereocontrol to give substituted products in high enantiomeric excess, typically >95% ee. In the case of the *N*-oxazoline derivatives of piperidine and isoquinoline, enantiomerically enriched secondary amines are obtained upon hydrolytic removal of the oxazoline moiety.[49a] These reactions are of considerable synthetic value and this methodology has been successfully applied to the asymmetric synthesis of 2-piperidines[49] and 2-pyrrolidines (eq 20),[52] 2-alkanols,[51a] 2-hydroxyalkanoic acids,[51a] alkanediols,[51b,c] and lactones (e.g. (*R*)-pantolactone) (eq 21).[51b]

ortho Lithiations.

s-Butyllithium is a commonly used reagent for *ortho* lithiation of aromatic rings bearing heteroatom-containing substitutents. This methodology has been exploited extensively as a route to a wide variety of polysubstituted aromatic compounds, including natural products[53] (eq 22),[53e] and several excellent reviews have been published on the topic.[2,5,54] Included in the list of groups commonly used for *s*-BuLi-promoted *ortho* lithiations are OMe,[55] CH_2NEt_2,[55] NMe_2,[56] $CONEt_2$,[57] $OCONEt_2$,[57] SO_2NR_2,[58] 2-oxazolinyl,[57] and groups that contain acidic hydrogens and themselves

undergo deprotonation prior to ring lithiation, e.g. CONHR[57,58] and SO_2NHR.[57,58] Depending on the substituent, both inductive and coordination effects can be invoked to account for the observed regiochemistry.[2,59] Although a large number of *ortho* lithiations may be conducted with *n*-BuLi,[2] the use of *s*-BuLi is generally preferred, especially when the reactions involve aromatic tertiary amides or *O*-aryl carbamates which are susceptible toward nucleophilic additions with the latter. For example, *N*,*N*-dimethyl- and -diethylbenzamides have been shown to afford primarily aryl butyl ketones upon treatment with *n*-BuLi.[55,60] The recommended procedure for *ortho* lithiation involves slow addition of the aromatic substrate in anhydrous THF to a slight excess of 1:1 *s*-BuLi/TMEDA in THF at -78 °C.[55] Under these conditions, the lithiation is usually complete within 5 min.

(22)

When two *ortho*-directing groups are in a *meta* relationship, lithiation is generally directed to their common site. Notable exceptions to this behavior are found in cases where $CONEt_2$, CONR, or oxazoline substitutents are *meta* to a dialkylamino group.[5] These systems exhibit nearly total reversal of the general trend and, as a result, almost exclusive metalation of the 6-position is observed (eq 23).[56] Considerable amounts of 6-substituted products are also obtained in cases where $OCONEt_2$ and OMe groups are in a *meta* relationship.[57] When two *ortho*-directing substituents are *ortho* or *para* to each other, the regiochemistry of the reaction depends on the relative directing abilities of these groups (eq 24).[57]

(23)

(24)

A large number of substituted polyaromatic and heteroaromatic compounds are also accessible through *s*-BuLi-induced *ortho* lithiation reactions. These include, for example, derivatives of naphthalene,[57] furan,[61] thiophene,[62] pyridine,[63] quinoline,[64] and N-protected imidazoles.[65] The smooth *ortho* lithiation of pyridyl (eq 25)[63] and quinolinyl systems is notable given the well-known tendency of organolithium compounds to undergo nucleophilic addition reactions with the pyridine nucleus.[1]

(25)

Lithium-Halogen Interchange and Transmetalation Reactions.

The lithium-halogen interchange involves the exchange of halogen by lithium in a reversible reaction, with the most stable organolithium species being favored at equilibrium. Hence, the most synthetically useful lithium-halogen exchanges take place between alkyllithiums and aryl halides, cyclopropyl halides, and vinyl halides. These reactions are accomplished most conveniently using *n*-BuLi rather than *s*-BuLi and, as a result, the latter has been employed only in a relatively few cases. However, the formation of select α-halo- and α-dihalolithiums,[66] aryllithium compounds,[67] and vinyllithium derivatives[68] using *s*-BuLi has been reported. The preparation of simple alkyllithium compounds by lithium-halogen exchange is usually limited to the generation of primary alkyllithiums from primary alkyl iodides by treatment with the more reactive tertiary alkyllithiums (such as *t*-BuLi).[69]

The lithium-selenium exchange has been exploited extensively for the generation of a variety of organolithiums from selenides, selenoacetals, and mixed *S,Se*-acetals, with *n*-BuLi being the most commonly employed reagent for these reactions.[3,70] Although *s*-BuLi can be used for all of these conversions, the primary role of this reagent is to provide a more reactive lithiating agent for the generation of synthetically useful[3,71] α-selenoalkyllithiums from selenoacetals of sterically hindered ketones.[72] For example, 2,2-bis(methylseleno)adamantane is completely unreactive toward *n*-BuLi in THF at -78 °C, but it undergoes a facile (30 min) Li-Se exchange on treatment with *s*-BuLi under identical conditions to afford the expected α-selenoorganolithium product in high yield (eq 26).[72]

(26)

The following order of reactivity of organolithium reagents toward selenoacetals has been established: *t*-BuLi/THF-hexane &AApprox; *s*-BuLi/THF-hexane > *n*-BuLi/THF-hexane &AApprox; *s*-BuLi/ether-hexane >> MeLi/THF-ether > *t*-BuLi/hexane &AApprox; *n*-BuLi/hexane.[72] As seen from this order, the reactivity of *s*-BuLi in ether-hexane is comparable to that of *n*-BuLi in THF-hexane. The α-selenoalkyllithiums generated in ether-hexane are more stable than those prepared in THF. In this medium they also exhibit higher reactivity toward certain carbonyl compounds, especially hindered[73] or highly enolizable ketones.[74] The 1-methyl-1-phenylselenoethyllithium product in eq 27 (generated in ether-hexane) undergoes nucleophilic 1,2-addition with a cyclic α,β-unsaturated ketone to afford ring-expanded ketones after treatment with TlOEt.[75]

Organolithium compounds are also accessible through the replacement of tin and tellurium by lithium, with the various organotin compounds being particularly important precursors for otherwise inaccessible organolithium derivatives (e.g. α-amino- and α-alkoxy-substituted organolithiums). Although *s*-BuLi is well suited for these transformations,[52,76] most of the synthetic applications exploiting this methodology involve the use of *n*-BuLi.

Eliminations.

Arylsulfonylhydrazones undergo formal elimination reactions on treatment with 2 equiv of *s*-BuLi to give vinyllithium compounds.[77,78] Tosylhydrazones should be avoided with this reagent because they are susceptible to ring lithiation and benzylic deprotonation; instead, the use of hindered 2,4,6-triisopropylbenzenesulfonylhydrazones is recommended

(eq 28).[77] In cases where two regioisomers can be produced, *s*-BuLi appears to promote the formation of the more substituted vinyllithium compounds. In contrast, the use of *n*-BuLi leads to the less substituted vinyllithium product.[78] Other notable *s*-BuLi-induced elimination reactions are the α-eliminations involving bis(phenylthio)methyllithium-containing cycloalkanol derivatives, which have been exploited as a route to ring-expanded ketones (eq 29),[79] and β-eliminations of *ortho*-lithiated 2-carboxamide-substituted furan derivatives, which have been used to prepare ring-opened enyne products.[80]

(28)

(29)

Formation of Enolate Anions and Enolate Equivalents.

s-Butyllithium may be used for the generation of enolate anions or enolate equivalents from active hydrogen compounds provided that nucleophilic addition of this reagent to the electrophilic carbon center is avoided. Thus the less reactive amides and imines are often suitable substrates for these reactions. For example, the bicyclic lactam in eq 30 undergoes two consecutive enolization/alkylation reactions in a highly diastereoselective fashion to afford a dialkylated product,[81] and the *N*-*t*-butylimine of 2-heptanone is deprotonated using *s*-BuLi to afford a mixture of two isomeric ketones after alkylation and hydrolysis (eq 31).[82] The less substituted ketone was obtained as the only isomer when *s*-BuLi was used with HMPA. Similar reactions have been reported for α-nitro imines,[83] and thiolactams.[84]

no additives	53:47	41%
HMPA added	100:0	61%

Rearrangements.

Salicylamides are available from various aryl carbamates, including those derived from ***Pyridine*** and naphthalene,[63] through the *s*-BuLi-mediated O-C 1,3-carbamoyl migration reactions (Snieckus rearrangement).[57] This regiospecific rearrangement is the anionic equivalent of the Fries rearrangement and it involves low-temperature (-78 °C) *ortho* lithiation of aryl carbamates with *s*-BuLi/TMEDA/THF followed by warming of the reaction mixture to rt (eq 32).[85] Benzylic carbamates rearrange to give products derived from either 1,4- or 1,2-carbamoyl migration (eq 33) following treatment with *s*-BuLi in THF,[86] and lithiated phenolic esters rearrange to furnish acyl phenols even at low temperatures (eq 34).[67] *s*-Butyllithium is also capable of initiating various Wittig rearrangements involving allylic ethers, but these reactions are done more conveniently using the less reactive *n*-BuLi.

Related Reagents.

n-Butyllithium; ***t-Butyllithium***; ***Potassium Hydride-s-Butyllithium-N,N,N´,N´-Tetramethylethylenediamine***.

[109-72-8] · C_4H_9Li · *n*-Butyllithium-Boron Trifluoride Etherate · (MW 64.06) (BF_3.OEt_2)

[109-63-7] · $C_4H_{10}BF_3O$ · *n*-Butyllithium-Boron Trifluoride Etherate · (MW 141.93)

(Lewis acid catalyst/strong base combination used to simultaneously generate an anion and activate an electrophile at low temperature, i.e. double activation[2])

Physical Data: see ***n-Butyllithium*** and ***Boron Trifluoride Etherate***.

Form Supplied in: the reagents are mixed with reactants in situ. BF_3.OEt_2 is supplied as a purified, redistilled liquid. *n*-Butyllithium is available as a 2 M solution in cyclohexane, 1.6 M, 2.5 M, and 10 M solution in hexanes, and a 2 M solution in pentane.

Handling, Storage, and Precautions: BF_3.OEt_2 is a fuming, corrosive liquid and is immediately hydrolyzed by moisture in air; *n*-butyllithium solutions are moisture sensitive and pyrophoric. Accordingly, both reagents should be stored and handled in the absence of moisture under N_2.[3]

Alkynyllithium Reagents and BF_3.OEt_2.

The most common use of the *n*-BuLi/BF_3.OEt_2 reagent combination is in the formation of lithium acetylides from terminal alkynes and their subsequent addition to a variety of electrophiles. While boron halides (BX_3) undergo rapid displacement with organolithiums (RLi) to furnish alkylhaloboranes (RBX_2 and R_2BX) and trisubstituted boranes (R_3B) at ambient temperatures,[4] it has been determined that organolithiums and BF_3.OEt_2 are stable together at low temperature and react independently.[5] Moreover, addition of BF_3.OEt_2 to lithium acetylides at -78 °C in THF affords an intermediate, lithium alkynyltrifluoroborate complex (**1**) (eq 1), which reacts smoothly with carboxylic acid anhydrides,[6] esters,[7] and tertiary amides[8] to give α,β-alkynic ketones in high yields (eqs 2-4). The acetylide-amide coupling can also be used with a subsequent ***Lithium Aluminum Hydride*** reduction to afford azacycloalkanes (eq 5).[8d]

(1)

It has also been found that this complex cleaves epoxides to afford β-hydroxyalkynes in excellent yields (eq 6);[9] this method has been used extensively, as seen in the syntheses of FK 506,[10] okadaic acid,[11] lipoxin B,[12] *N*-acetylactinobolamine,[13] and leukotriene B_4.[14] The use of other metal acetylides for this transformation requires longer reaction times, higher temperatures and/or expensive catalysts, frequently resulting in low yields. Reaction of borate complex (**1**) (R = Ph) with (2*S*,3*S*)-3-phenylglycidol gave diol (**2**) with >99:1 diastereoselectivity, whereas the diethylaluminate complex afforded a 3:1 mixture (eq 7).[15] Borate complex (**1**) can also be used in the ring opening of

oxetanes to give γ-hydroxyalkynes (eq 8).[16]

(6)

(7)

(2) **(3)**

PhCCLi, $BF_3 \cdot OEt_2$	>99:1
PhCCLi, Et_2AlCl	3.2:1

Borate complex (**1**; R = CH_2OTr) has also been added to an α-diazo ester to give a β,γ-alkynic ester as well as to an α-hydroxyaldehyde (**1**; R = CMe_2OTHP) to afford an α,β-dihydroxyalkyne.[17,18]

Lithium Enolates and Stabilized Alkyllithiums with $BF_3.OEt_2$.

The mechanisms by which $BF_3.OEt_2$ activates most of the following reactions remain unclear; while coordination of the Lewis acid with certain electrophiles prior to nucleophilic addition has been reported,[5] the possibility of BF_3/organolithium complexes cannot be precluded in all cases. It has been shown that the lithium enolates of amides[19] will cleave epoxides in the presence of $BF_3.OEt_2$ to afford γ-hydroxyamides, while the lithium enolates of both amides and esters will open oxetanes to give δ-hydroxy esters and δ-hydroxyamides in high yield (eq 9).[20] It was found that the lithium enolate of optically active iron acyl (**4**) would cleave *trans*-(±)-2,3-epoxybutane at -78 °C to afford γ-hydroxy product (**5**) as a 10:1 mixture of diastereomers (eq 10);[21] the enantiofacial recognition of this reaction allows for the synthesis of optically active β,γ-dimethyl-γ-lactones.

It also has been shown that the lithium enolates of ketones and esters can be added to $BF_3.OEt_2$-activated 3-thiazolines to give functionalized thiazolidines[22a] and trisubstituted thiophenes;[22b] lithium enolates of ketones can also be dialkoxymethylated using orthoformates in this manner.[23] In the presence of $BF_3.OEt_2$ the sodium-lithium dianion of β-keto esters will react with disubstituted epoxides to give tetrahydrofurans after acid-promoted cyclization,[24] as well as undergo Claisen condensations with tertiary amides.[25]

Concerning other stabilized organolithiums, α-lithiated sulfones can be treated with $BF_3.OEt_2$ activated aldehydes to afford *trans*-alkenes after reduction (Julia alkenation);[26] in addition, treatment with activated epoxides gives γ-hydroxy sulfones (eq 11) and α,β-unsaturated ketones after oxidation-elimination.[27] In the absence of $BF_3.OEt_2$ these processes suffer from low yields and/or long reaction times. In a separate example, it was found that when lithiated 2-styryl-1,3-dithiane was treated with aldehydes and ketones, a mixture of alcohols (**6**) and (**7**) would result (eq 12); however, treatment of the dithiane anion with $BF_3.OEt_2$ prior to the addition of carbonyl compound resulted in exclusive α-addition to give alcohol (**7**).[28]

Other examples of reactions of stabilized organolithiums with $BF_3.OEt_2$ activation include the cleavage of a monosubstituted epoxide with an α-lithiophosphonate,[29] the addition of α-lithiated sulfoximines[30] to aldehydes and imines, and the cleavage of oxetanes with lithiomethylphosphonates (eq 13).[31]

Nonstabilized Organolithiums with $BF_3.OEt_2$.

By far the most common reaction of nonstabilized organolithiums with $BF_3.OEt_2$ activation is the cleavage of epoxides. Examples include alkyl-, alkenyl-, and aryllithiums in both intra- and intermolecular variations; the mechanism of these reactions appears to include complexation of the Lewis acid at oxygen followed by nucleophilic attack of the carbon nucleophile on the resulting alkoxyboron trifluoride salt.[5] The organolithium reagents used include commercial reagents (***Methyllithium***, ***s-Butyllithium***, ***n-Butyllithium***, ***t-Butyllithium***, ***Phenyllithium***) as well as those prepared from alkylstannanes, alkenyl halides, aryl halides, furans, and indoles.

In one example it was found that in the presence of $BF_3.OEt_2$, diepoxide (**8**) could be treated with an excess of alkyl- and aryllithiums to afford symmetric 1,3-diols; more importantly, 1 equiv of organolithium reagent could be used to give C(2) differentiated epoxy alcohols which could be further elaborated with a second organolithium species (eqs 14 and 15).[32]

While vinyllithium reagents will cleave epoxides in good yields, a threefold excess of the reagent is required; it has been reported that this shortcoming can be avoided by the conversion of the lithium reagent to the corresponding alkenylaluminum species (see ***Diethylaluminum Chloride***) which will react smoothly under stoichiometric conditions in the presence of $BF_3.OEt_2$ to afford homoallylic alcohols in good yields.[33] Oxetanes are also cleaved by organolithium-BF_3 reagents.[5]

Other reactions of organolithiums utilizing $BF_3.OEt_2$ include those with: alkyl/aryllithiums and oxime ethers to give substituted *O*-alkyl hydroxylamines;[34] alkyl/aryllithiums and 2-isoxazolines to afford substituted isoxazolidines;[35] butenolide anions and orthoesters to give acylated butenolides;[2] alkyllithiums and imines to give α-alkylated amines;[36] an allenic zirconium species and aldehydes to afford β-alkynic alcohols;[37] and alkyllithiums with aldehydes/ketones to afford alcohols.[38]

n-Butyllithium-Potassium *t*-Butoxide[1]

(*n*-BuLi)

[109-72-8] · C_4H_9Li · *n*-Butyllithium-Potassium *t*-Butoxide · (MW 64.06) (*t*-BuOK)

[865-47-4] · C_4H_9KO · *n*-Butyllithium-Potassium *t*-Butoxide · (MW 112.22)

(superbase for metal-hydrogen exchange of a carbon acid R-H;[2] can generate organopotassium compounds[3])

Physical Data: see ***n-Butyllithium*** and ***Potassium t-Butoxide***; NMR[4] and ESR[5] studies of the *n*-BuLi/*t*-BuOK mixture have been reported.

Solubility: see ***n-Butyllithium*** and ***Potassium t-Butoxide***.

Preparative Method: prepared in situ under nitrogen by addition of equimolar potassium *t*-butoxide to a solution of *n*-butyllithium at 0 °C.

Handling, Storage, and Precautions: use in a fume hood; must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture. Solutions in THF decompose above -40 °C.

Metal-Hydrogen Exchange.

Freshly prepared *n*-BuLi/*t*-BuOK is more basic than *n*-BuLi and *n*-BuK.[6] When treated with this superbase, hydrocarbons in the low acidity range of pK_a 35-50 undergo a clean metal-hydrogen exchange: benzene,[2] cyclopropane derivatives,[7,8] cumene,[7] a variety of 1- or 2-alkenes having allylic C-H bonds,[2,9-13] cyclohexene,[7,14] α-pinene,[15] conjugated dienes,[11,16-18] ene sulfides,[19] 4*H*-pyrans,[20] and 1,4-dihydropyridines.[20] *n*-BuLi/*t*-BuOK did not succeed in metalating saturated hydrocarbons such as octane and cyclohexane.

Benzene and substituted benzene, in the presence of *n*-BuLi/*t*-BuOK, undergo site selective metal-hydrogen exchange (eq 1). Best results are obtained in THF at -75 °C or -50 °C. Upon quenching with carbon dioxide, the corresponding acids are obtained in good to excellent yield.[21,22]

When alkenes are treated with *n*-BuLi/*t*-BuOK, the metalation occurs regioselectively: allylic methyl groups are much more readily attacked than methylene groups, which are less reactive than methine centers.[9,12] Furthermore, *cis*-2-alkenes generally react faster than their *trans* counterparts. This holds even for 4,4-dimethyl-2-pentene (eq 2).[23]

Above -60 °C, ethereal solvents are rapidly attacked by *n*-BuLi in the presence of *t*-BuOK.[6b] Nevertheless, acetal functions are suitable protecting groups for superbase metalations of alkenols.

The *n*-BuLi/*t*-BuOK mixture can convert 2-alkynyl ethers into allenic ethers and some α-substituted derivatives (eq 3).[24]

(3)

In the cases where metal-hydrogen exchange leads to a resonance-stabilized organometallic species, the intermediate organopotassium compounds precipitate.[3] Benzyl-, allyl-, pentadienyl-, and cyclooctadienylpotassium can be prepared in this way.[9,13,16] The accompanying lithium *t*-butoxide can be completely removed by washing with benzene or toluene. The resulting organopotassium can serve as a reagent of general applicability in preparing transition metal complexes through transmetalation (eq 4).[25]

t-Butylmagnesium Chloride[1]

***t*-BuMgX**

(X = Cl)

[672-22-5] · C_4H_9ClMg · *t*-Butylmagnesium Chloride · (MW 116.87) (X = Br)

[2259-30-5] · C_4H_9BrMg · *t*-Butylmagnesium Bromide · (MW 161.32)

(adds to many unsaturated functional groups; *t*-butyl can displace halide and like groups; can function as a strong base and a Lewis acid[1b-f])

Physical Data: NMR observations indicate that *t*-BuMgCl in Et_2O and THF and *t*-BuMgBr in THF are in fact mixtures of *t*-BuMgX, *t*-Bu_2Mg, and MgX_2.[2,3] Although essentially monomeric in THF, *t*-BuMgCl is mainly dimeric in Et_2O.[4] A solid of composition *t*-BuMgBr$(Et_2O)_2$, probably having a dimeric structure, has been isolated.[5]

Solubility: sol Et_2O and THF; insol hydrocarbons.

Form Supplied in: solutions of *t*-BuMgCl in Et_2O and THF are commercially available.

Analysis of Reagent Purity: see entry for ***Methylmagnesium Bromide***.

Preparative Methods: [1c,e,6] in spite of the commercial availability of *t*-BuMgCl solutions, *t*-BuMgCl[3,7] and *t*-BuMgBr are often prepared from reaction of a *t*-butyl halide and ***Magnesium***, usually in Et_2O or THF.

Handling, Storage, and Precautions: see entry for ***Methylmagnesium Bromide*** *t*-Butyl Grignard reagents do not significantly attack Et_2O or THF at normal reaction temperatures.

Preparation.

Side reactions in preparations of *t*-BuMgX and other tertiary alkyl Grignard reagents tend to be more significant than in preparations of less branched reagents. *t*-Butyl radicals, intermediates in the formation of the Grignard reagent, couple, disproportionate, and attack solvent molecules. Moreover, reaction of the Grignard reagent and unreacted alkyl halide is particularly significant with *t*-BuI. Because of side reactions, X generally exceeds *t*-Bu in the Grignard solutions. Yields generally seem to be improved by slow addition of the halide to the Mg and by use of activated[8] Mg (see the entry for ***Phenylmagnesium Bromide***). A considerable excess of *t*-BuX and Mg often is used to ensure that sufficient *t*-BuMgX is present for the subsequent reaction. When exact stoichiometry is important, determining the *t*-BuMg

concentration is important.

Structure.

See the entry for ***Methylmagnesium Bromide***.

Workup Procedures.

See the entry for ***Methylmagnesium Bromide***.

Representative Applications.[1b-f]

Also see the entry for ***Methylmagnesium Bromide***. A *t*-butyl Grignard reagent is used in reactions that result in attachment of its organic group to an electrophilic carbon atom of the substrate, most often of a carbonyl group, nitrile, or other unsaturated function. A generally unwanted reaction, reduction of such substrates by transfer of a β-H of the *t*-Bu or other tertiary or branched alkyl group, sometimes is more rapid. *t*-BuMgCl and di-*t*-butyl ketone, for example, normally furnish only di-*t*-butylmethanol.[9] The generation of a chiral sulfoxide (eq 1) exemplifies addition to a different unsaturated functional group.[10] Abstraction of a hydrogen α to unsaturated functions by a Grignard reagent, particularly a hindered one, may also compete with addition. Only abstraction is seen with the particularly acidic (**1**). Condensation with benzaldehyde (eq 2) does not occur when the anion is formed using an organolithium compound because equilibrium favors the anion and the aldehyde rather than their addition product.[11]

n-Butylmagnesium Bromide-Methylcopper(I)[1]

_n_-BuMgBr-MeCu

[59532-66-0] · $C_5H_{12}BrCuMg$ · *n*-Butylmagnesium Bromide-Methylcopper(I) · (MW 239.90) (*n*-BuMeCu$^-$)

[70196-77-9] · $C_5H_{12}Cu$ · *n*-Butylmagnesium Bromide-Methylcopper(I) · (MW 135.70) (MgBr$^+$)

[43245-19-8] · BrMg · *n*-Butylmagnesium Bromide-Methylcopper(I) · (MW 104.21)

(serves as a butyl transfer reagent in substitution reactions)

Alternate Names: butylmethylcopper(I)magnesium bromide; bromomagnesium butylmethylcuprate.

Solubility: sol ether, THF.

Preparative Methods: a suspension of CuI (1.5 mmol) in THF (3 mL) is stirred at -78 °C and treated with a solution of salt-free MeLi (1.5 mmol) in ether. The resultant yellow precipitate of MeCu dissolves when a THF solution of *n*-BuMgBr (1.5 mmol) is added and a purple solution is formed.[2,3] In a similar fashion, the reagent is prepared from CuI, salt-free *n*-BuLi, and MeMgI.[3]

Handling, Storage, and Precautions: the reagent must be generated and immediately used in the absence of moisture and oxygen. Use in a fume hood.

Butylmagnesium bromide-methylcopper is a mixed lower order magnesium cuprate. It shows increased thermal stability in comparison to ***Lithium Di-n-butylcuprate***. The reagent selectively transfers the *n*-butyl group in reactions with acid chlorides (eq 1)[2] or 5-acetoxy-1,3-alkadienes (eq 2).[3]

n-Butylmanganese Chloride

***n*-BuMnCl**

[88626-90-8] · C_4H_9ClMn · *n*-Butylmanganese Chloride · (MW 147.51)

(butylmanganese halides are especially interesting for their chemoselectivity; acylation,[1,2] carboxylation,[3] 1,2-addition to ketones and aldehydes,[4] 1,4-addition to conjugated unsaturated ketones,[5] aldehydes,[6] esters[7] and amides as well as alkylation of alkyl bromides[8] can be performed under mild conditions and in high yields)

Preparative Methods: [7b] BuMnCl can be prepared in THF, at 0 °C, by reaction of ***n-Butyllithium*** or BuMgX with ***Manganese(II) Chloride*** or, better, with the soluble ate complex $MnCl_4Li_2$. The latter is easily obtained by mixing $MnCl_2$ and ***Lithium Chloride*** (2 equiv) in anhydrous THF at rt until dissolution (about 1 h). BuMnBr can be obtained in ether or in THF, between -10 °C and 0 °C, from BuLi or BuMgX and $MnBr_4Li_2$ (prepared by mixing $MnBr_2$ + 2 LiBr in ether or THF at rt). BuMnI is prepared by adding BuLi or BuMgX to MnI_2 in ether or in THF between -10 °C and -20 °C. Organomanganese iodides are now of historical interest only since organomanganese chlorides in THF, or organomanganese bromides in ether, are both less expensive and more stable.

Commercial $MnCl_2$ and $MnBr_2$ must be dried by heating under vacuo before using (200 °C, 10^{-2} mmHg, 2 h). Anhydrous $MnBr_2$ can be conveniently prepared (>95%) by reaction of Br_2 with Mn (1.01 equiv, electrolytic grade) in anhydrous ethyl acetate. The reaction is exothermic and the temperature must be kept between 35 and 45 °C. Anhydrous MnI_2 is obtained by adding ***Iodine*** slowly (exothermic) to a suspension of Mn (1.01 equiv, electrolytic grade) in ether at rt. The use of manganese halides containing some impurities such as Ni, Fe, and Cu salts can strongly decrease the stability of BuMnX (and more generally of all alkylmanganese halides).

Handling, Storage, and Precautions: butylmanganese halide solutions must be handled under an inert atmosphere in the absence of moisture. In THF, BuMnX are stable at rt. In ether, BuMnI is stable at -10 °C and BuMnBr at 10 °C. These reagents are best generated in situ and used rapidly.

Acylation.[1]

BuMnI[1a,b] and BuMnBr[1f] (prepared in ether) react under mild conditions with a vast array of acylating agents (RCOCl, $(RCO)_2O$, RCO_2CO_2Et, etc.) to give the corresponding ketones in high yields (eqs 1 and 2); similarly, $ClCO_2Et$ leads to esters.[1c] BuMnCl prepared in THF is also acylated in high yield under mild conditions (eq 3).[1d]

$$\mathrm{BuMnX} + \mathrm{C_7H_{15}COCl} \xrightarrow[0\ ^\circ\mathrm{C\ to\ rt}]{\mathrm{ether}} \mathrm{BuCOC_7H_{15}} \qquad (1)$$

X = I, 91%; X = Br, 96%

$$\mathrm{BuMnI} + \mathrm{EtOCO(CH_2)_6COZ} \xrightarrow[0\ ^\circ\mathrm{C\ to\ rt}]{\mathrm{ether}} \mathrm{BuCO(CH_2)_6CO_2Et} \qquad (2)$$

Z = Cl, 96%; Z = OCO_2Et, 91%

$$\mathrm{BuMnCl} + \mathrm{PhCOCl} \xrightarrow[0\ ^\circ\mathrm{C\ to\ rt}]{\mathrm{THF}} \mathrm{BuCOPh} \qquad (3)$$

90%

In some cases the yield can be improved in the presence of copper salts (eq 4). A dramatic improvement is especially observed with *s*- or *t*-alkylmanganese chlorides (eq 5).

$$\mathrm{BuMnCl} + \mathrm{ClCO(CH_2)_5Br} \xrightarrow[0\ ^\circ\mathrm{C\ to\ rt}]{\mathrm{THF}} \mathrm{BuCO(CH_2)_5Br} \qquad (4)$$

no CuCl, 1.5 h: 85%
1% CuCl, 30 min: 92%

$$t\text{-}\mathrm{BuMnCl} + \mathrm{C_7H_{15}COCl} \xrightarrow{\mathrm{THF}} t\text{-}\mathrm{BuCOC_7H_{15}} \qquad (5)$$

no CuCl: 0%
1% CuCl: 96%

Interestingly, this acylation is highly chemoselective and numerous functional groups are tolerated;[1b,d] for example, halides, allylic halides, nitriles, esters, and even unprotected keto groups (eq 6).[1b] In addition, the reaction can be performed in the presence of various cosolvents which are not commonly used in organometallic chemistry, such as CH_2Cl_2 or EtOAc (eq 7).[1e]

$$BuMnCl + ClCO(CH_2)_3CO_2Et \xrightarrow[88\%]{THF} BuCO(CH_2)_3CO_2Et \quad (6)$$

The acylation of organomanganese reagents is a very general reaction and numerous functionalized or polyunsaturated ketones can be prepared in high yields.

Acylation: Catalytic Procedure.[2]

Butylmanganese compounds are also involved in the Mn-catalyzed acylation of BuMgCl (eq 8). This procedure is very economic and easy to carry out; in addition, the chemoselectivity is generally excellent (eq 9).

$$C_7H_{15}COCl + 3\%\ MnCl_4Li_2 \xrightarrow[\substack{30\ min \\ 87\%}]{\substack{BuMgCl,\ THF \\ 0\text{-}10\ °C}} BuCOC_7H_{15} \quad (8)$$

$$EtCO(CH_2)_5COCl + 3\%\ MnCl_4Li_2 \xrightarrow[\text{45 min, 91\%}]{\text{BuMgCl, THF, 0-10 °C}} EtCO(CH_2)_5COBu \quad (9)$$

Carboxylation.[3]

Butylmanganese halides are easily carboxylated in ether or in THF to give the expected $BuCO_2H$ in good yields. Contrary to BuLi and BuMgX, butylmanganese halides smoothly react at room temperature (the exothermic effect is very limited) without side-reaction. Thus they do not add to the resulting $BuCO_2MnX$. The related lithium or magnesium tributylmanganates can also be carboxylated under similar conditions (eq 10).

$$Bu_3MnMgCl \xrightarrow[\text{2. } H_2O,\ \text{86\%}]{\text{1. } CO_2\text{, THF, 20 °C}} 3\ BuCO_2H \quad (10)$$

1,2-Addition.[4]

In ether, butylmanganese halides readily add to aldehydes and ketones at 0 °C, affording the corresponding alcohols in high yields (eqs 11 and 12).[1g,4a] However, they do not react with various less reactive carbonyl compounds such as amides and esters (except with formates).[3] It should be noted that BuMnX can be used in the presence of various amides (NMP, DMF) or ester (EtOAc) as cosolvent.

$$BuMnBr + HexCHO \xrightarrow[\text{0-20 °C, 98\%}]{\text{ether}} BuCH(OH)Hex \quad (11)$$

$$BuMnI + Pr_2CO \xrightarrow[\text{0-20 °C, 90\%}]{\text{ether}} BuPr_2COH \quad (12)$$

In THF, butylmanganese halides are less reactive towards carbonyl compounds.[4a] Thus they also add to aldehydes at rt in high yields (eq 13) but with ketones the reaction is slower and results in lower yields than in ether (from BuCOBu,

70% instead of 92%).

$$\text{BuMnCl} + \text{HexCHO} \xrightarrow[\text{0-20 °C, 95\%}]{\text{THF}} \text{HexCH(OH)Bu} \qquad (13)$$

Butylmanganese halides prepared from BuMgX are more reactive than those prepared from BuLi (electrophilic activation by MgX_2) (eq 14). In general, organomanganese reagents are of use when performing chemoselective 1,2-additions to functionalized ketones or aldehydes (eq 15).

$$\text{BuMnX} + \text{PrCOPr} \xrightarrow[\text{20 °C}]{\text{ether}} \text{BuPr}_2\text{COH} \qquad (14)$$

X = I, Br	10 min	30 min	6h
BuMnX, LiX	34%	53%	80%
BuMnX, MgX_2	81%	99%	-

$$\text{EtCO(CH}_2\text{)}_9\text{CHO} \xrightarrow[\text{20 °C}]{\text{BuMnX}} \text{EtCO(CH}_2\text{)}_9\text{CH(OH)Bu} \qquad (15)$$

BuMnBr, ether	90%
BuMnCl, THF	89%

A recent report[4b] showed that in THF, BuMnO(CO)-*t*-Bu adds more stereoselectively than BuMnBr to 4-*t*-butylcyclohexanone (axial preference) (eq 16).

Conjugate Addition.[5-7]

BuMnCl readily adds to alkylidenemalonic esters to afford the conjugate addition products (eq 17).[7b]

With the less reactive Michael acceptors, such as α,β-ethylenic ketones, the conjugate addition reaction does not occur or gives low yields. However, in the presence of ***Copper(I) Chloride*** as catalyst, the 1,4-addition product is obtained in high yields under very mild conditions (eq 18).[5] It is interesting to note that the conjugate addition reaction also takes place easily with the less reactive β-disubstituted enones (eq 19).

Butylmanganese compounds are also involved in the Mn-Cu-catalyzed conjugate addition of BuMgCl to enones (eq

20). The reaction has been successfully extended to α,β-ethylenic aldehydes (eq 21)[6] and, in the presence of Me_3SiCl, to α,β-ethylenic esters (eq 22)[7a] and amides.

Generally, the Cu-catalyzed conjugate addition of organomanganese chloride reagents (as well as the Mn-Cu-catalyzed conjugate addition of RMgCl) gives higher yields and is easier to carry out than the classical organocopper procedures.[5]

Alkylation.[8]

Butylmanganese halides react only with a few very reactive alkylating agents such as ***Allyl Bromide***. In addition, even with this latter, the reaction is very slow and gives a moderate yield (~70%). However, BuMnCl prepared in THF can be easily alkylated at rt in the presence of both copper salt (CuCl) as catalyst and NMP as cosolvent. Under these conditions the alkylated products are generally obtained in excellent yields even from the less reactive alkyl bromides (eq 23).

This procedure is as simple to carry out as the classical Cu-catalyzed Grignard reaction but the yields are very often better and the chemoselectivity is clearly superior. For example, in the case of eq 24, BuMgCl alone gives only a 45%

yield.

$$BuMnCl + Br(CH_2)_5COBu \xrightarrow[\text{THF-NMP, 20 °C}]{\text{3\% CuCl}} Bu(CH_2)_5COBu \quad (24)$$

(*R*)-2-*t*-Butyl-6-methyl-4*H*-1,3-dioxin-4-one[1]

(*R*)

[107289-20-3] · $C_9H_{14}O_3$ · (*R*)-2-*t*-Butyl-6-methyl-4*H*-1,3-dioxin-4-one · (MW 170.21) (*S*)

[139973-88-9]

(enantiopure derivative of acetoacetic acid,[2-4] highly reactive Michael acceptor for Cu^I-doped Grignard and for Gilman reagents;[2,5] component for [2 + 2] photocycloadditions;[2] catalytic hydrogenation leads to the *cis*-disubstituted dioxanone;[2,5] the dienolate generated from the reagent can be used for chain elongations at the C(6)-Me carbon[6])

Physical Data: mp 59.8-60.2 °C; [α]rtD = -215° (*c* = 1, $CHCl_3$).

Solubility: sol most common organic solvents; poorly sol pentane at low temperature.

Preparative Methods: acid-catalyzed acetalization of ***Pivalaldehyde*** with (*R*)-3-hydroxybutanoic acid[8] gives the *cis*-1,3-dioxan-4-one (**2**) in 40% yield after recrystallization from ether/pentane. (Up to 60% yield can be obtained by using freshly loaded acidic ion-exchange resin and following the procedure of Seebach et al.[7b] Runs with up to 120 g hydroxy butanoic acid were performed in this way). Bromination with ***N-Bromosuccinimide*** leads to a mixture of brominated dioxinones which are debrominated hydrogenolytically to (**1**) (eq 1). The yield (**2**) -> (**1**) is ~45% after recrystallization from pentane/ether (50:3) at -20 °C.[4,7] The enantiomer *ent*-(**1**) is of course equally readily available from (*S*)-3-hydroxybutanoic acid.[9] Both enantiomers of 3-hydroxybutanoic acid are commercially available.

Handling, Storage, and Precautions: dioxinone (**1**) is commercially available and is indefinitely stable as a

crystalline solid stored in a dark bottle at rt.

Reactions of 4*H*-1,3-Dioxin-4-one (1).

The cuprate additions to (**1**) occur preferentially from the face *trans* to the *t*-Bu group. An example is the preparation of and correlation with mevalonolactone (**4**) in eq 2 by Michael addition of ***Lithium Diallylcuprate*** to give (**3**) and ozonolysis for degradation by one carbon.[5] Two examples of the use of the dienolate derived from dioxinone (**1**) are shown in eqs 3 and 4. The dienolate adds to aromatic aldehydes in a 1,2-fashion with reasonable diastereoselectivities at the exocyclic carbon atom. Oxidative degradation of the major diastereoisomer (**5**), obtained with benzaldehyde, leads to the β-hydroxy acid (**6**) of (*S*) configuration (eq 3).[6] With α,β-unsaturated aldehydes the exocyclic dienolate carbon reacts in a Michael addition. Thus the adduct (**7**) is isolated (53%) in a diastereomer ratio of 20:1 (eq 4).[6] Activation of the exocyclic methyl group in (**1**) is also realized by ***N-Bromosuccinimide*** bromination.[3,4,10] The resulting 6-bromomethyldioxinone has been employed in a vineomycinone B2 synthesis: see the intermediate (**8**) in eq 5.[11]

(4)

(5)

Other Enantiopure Dioxinones for Self-regeneration of the Stereogenic Center.

The principle of preparing dioxinones from enantiopure β-hydroxy acids was also applied to 3-hydroxypentanoic acid,[3,6] 4,4,4-trifluoro-3-hydroxybutanoic acid,[12] 4,4,4-trichloro-3-hydroxybutanoic acid,[13] and (*S*)-serine;[3,14] aldehydes other than pivaldehyde and ketones[15] may be used for dioxinone preparation as well. Furthermore, numerous other dioxinones have been prepared from the parent compound (**1**) (eqs 3, 4, 6 and 7). The dibromide intermediate (**9**) in the preparation of (**1**) can be converted to an aldehyde, which after undergoing Wittig alkenation, followed by catalytic hydrogenation, leads to the 3-hydroxyadipic acid derivative (**10**) shown in eq 6, in an overall yield of 55%.[10] Aldol condensations of dioxanone (**2**) with aldehydes and shift of the double bond from the exo- to the endocyclic position produce 2,5,6-trisubstituted dioxinones such as (**11**), which can be used for the preparation of 2,3-disubstituted β-hydroxycarboxylic acids: see (**12**) in eq 7.[16,17] Such compounds are not accessible by current enantioselective aldol addition methodology. An example of the preparation of a CF_3-branched 3-hydroxycarboxylic acid derivative is shown in eq 8; trifluoromethyldioxinone (**13**) and ***Lithium Di-n-butylcuprate*** give a dioxanone which is solvolyzed in methanol to the hydroxy ester (**14**).[12b]

(6)

(7)

(8)

Dioxinones Obtained by Resolution or Prepared with a Chiral Auxiliary.

2-Phenyl-4*H*-1,3-dioxin-4-ones (**15**) derived from formylacetate or acetoacetate can be readily prepared in enantiopure form by preparative resolution[14,18] on cellulose triacetate.[18] These have been used for Michael additions and hydrolysis to long-chain β-hydroxycarboxylic acids, for example the tridecanoic acid (**16**) from (*R*)-(**15a**).[18] The cuprate adducts formed with the methylphenyldioxinone (*S*)-(**15b**) can be hydrogenolytically cleaved directly to β-branched β-hydroxy acids with benzyl protection of the hydroxy functional group; see (**17**) in eq 9.[18]

(R)-2-t-Butyl-6-methyl-4H-1,3-dioxin-4-one

The chiral auxiliary approach involving dioxinones has been chosen by Demuth et al.[19] and, most extensively, by Kaneko and his collaborators.[20-22] They have used menthol esters (**18**) and (**19**) for typical diastereoselective reactions of dioxinones, with subsequent hydrolysis, for the preparation of various enantiopure products. For a review, also referring to the work of Winkler about photoreactions of *rac* or achiral dioxinones, see the articles by Kaneko.[23,24] For a table with enantiopure dioxinones as of mid-1991, see Kinkel et al.[14]

(*R*,*R*)-2-*t*-Butyl-5-methyl-1,3-dioxolan-4-one[1]

(*R*,*R*)

[104194-02-7] · $C_8H_{14}O_3$ · (*R*,*R*)-2-*t*-Butyl-5-methyl-1,3-dioxolan-4-one · (MW 158.20) (*S*,*S*)

[81037-06-1]

(cyclic acetals from (*R*)- and (*S*)-lactic acid and pivaldehyde;[1b,2-6] reagents for the preparation of enantiopure α-hydroxy-α-methyl carboxylic acids by alkylation of the corresponding lithium enolate with alkyl,[1b,2-4] allyl,[1b,2,7,8] and benzyl[1b] halides, by hydroxyalkylation with aldehydes and ketones,[1b,3,9,10] and by Michael addition to nitroalkenes;[9,11] precursor to the 5-bromo derivative used for radical reactions;[12,13] precursor to 2-*t*-butyl-5-methylene-1,3-dioxolan-4-one;[13-15] an acceptor for radical additions;[15,16] and an ene component for Diels-Alder reactions leading to cyclic, heterocyclic, and bicyclic α-hydroxy carboxylic acids[14,17-19])

Physical Data: mp ca. 5 °C; bp 80 °C/20 mmHg; $[\alpha]^{rt}_D$ = +44.8° (*c* = 1.83, $CHCl_3$) for (*S*,*S*)-(**1**) containing 4% (2*R*,5*S*) epimer after two recrystallizations from ether/pentane at -75 °C.

Solubility: good to excellent in all common organic solvents.

Preparative Method: on a 0.5 mol scale reagent (*S*,*S*)-(**1**) is prepared by condensation of ***Pivalaldehyde*** and (*S*)-lactic acid under acid catalysis in pentane, with azeotropic removal of the water formed. The crude product is distilled in vacuo to give 93% of a 4:1 *cis*/*trans* mixture. Two recrystallizations from pentane/ether at -75 °C furnish 60% (*S*,*S*)-(**1**) (*cis*/*trans* = 96:4).

Handling, Storage, and Precautions: stable for many months under an inert atmosphere in a refrigerator.

Reactions of the Enolate of (1) with Electrophiles.

Addition of the dioxolanones (**1**) to solutions of ***Lithium Diisopropylamide*** or ***Lithium Hexamethyldisilazide*** in THF at dry-ice temperature generates the corresponding enolates which react with alkyl halides,[1b,2-4,7,8] carbonyl compounds,[1b,3,9,10] and nitroalkenes[9,11] almost exclusively from the face remote from the *t*-Bu group to give products of type (**2**). These can be hydrolyzed to simple α-hydroxy-α-methyl carboxylic acids or further elaborated. Four examples are

(R,R)-2-t-Butyl-5-methyl-1,3-dioxolan-4-one

shown in (**3**)-(**6**) in which the part of the molecule originating from lactic acid is indicated in bold.

Analogous Transformations with other α-Hydroxy Carboxylic Acids.

The conversion of lactic acid to products (**2**)-(**6**) is an example of the principle of self-regeneration of the stereogenic

centers (SRSC) which is also applicable to β-hydroxy-, α- and β-amino acids (see Related Reagents). Many α-hydroxy carboxylic acids occur naturally, and most α-amino acids can be converted to hydroxy acids by diazotization, with retention of configuration,[20] producing a host of readily available starting materials for this kind of conversion, for example in the synthesis of the antitumor alkaloid (**7**).[21] Table 1 lists various dioxolanones (**8**) made from the corresponding hydroxy acids and aldehydes or ketones, together with information on reactions carried out with them. This method is also applicable to α-mercapto carboxylic acids.[1,22]

(*R*)- and (*S*)-*t*-Butyl-5-methylene-1,3-dioxolan-4-one, a Chiral α-Alkoxy Acrylate.

It is also possible to introduce an exocyclic double bond onto the dioxolanone ring, as in compounds (**9**)-(**11**), derived from lactic[13,14,17-19,26] and malic[12,27] acids. These α,β-unsaturated carbonyl derivatives are acceptors for radical additions[12,15,16] and undergo cycloadditions with dienes[14,17-19,26,27] and heterodienes.[18] The Diels-Alder adduct (**12**) of *ent*-(**9**) with cyclopentadiene is formed[14,17a,19] with *exo* selectivity (96:4) and serves as a precursor to norbornenone (**13**).[14,19] Cycloadduct (**14**), obtained from methylenedioxolanone (**9**) and an open-chain triene, is also the result of an *exo* addition and is used in tetronolide synthesis.[17b]

Menthone-Derived Dioxolanones: Chiral Glycolic Acid Derivatives.[28]

Acetalization of menthone and phenylmenthone with glycolic acid leads to chromatographically separable mixtures of diastereoisomeric dioxolanones (**15**) and (**16**); they are precursors for chiral enolate derivatives of glycolic acid. Alkylations occur highly selectively, and the products can be solvolyzed with ethanol to give ethyl α-hydroxy carboxylates of either (*R*) or (*S*) configuration. Thus spiro compound (**16b**) gives the allylation product (**17**) (84%), from which pure ethyl (*R*)-2-hydroxypent-4-enoate is obtained.

Andrea Rolf Sting & Dieter Seebach

Eidgenössische Technische Hochschule Zürich, Switzerland

N´-t-Butyl-*N*-methyl-*N*-trimethylsilylmethylformamidine

[80376-66-5] · $C_{10}H_{24}N_2Si$ · *N´-t*-Butyl-*N*-methyl-*N*-trimethylsilylmethylformamidine · (MW 200.40)

(conveniently effects the transformation of ketones and aldehydes to homologated nitriles,[1] amines,[2] aldehydes,[2] and ketones[3])

Alternate Name: TMS-Form.

Physical Data: bp 78-80 °C/7 mmHg.

Preparative Methods: easily synthesized by a two-step procedure (eq 1).[2] Initially, the condensation of ***t-Butylamine*** with either ***N,N-Dimethylformamide*** or dimethylformamide dimethyl acetal cleanly affords ***N´-t-Butyl-N,N-dimethylformamidine***. Subsequent lithiation and silylation with ***Chlorotrimethylsilane*** results in a 70% overall yield of the purified title reagent.

Handling, Storage, and Precautions: the reagent should be handled in a fume hood. Refrigeration should be used for prolonged storage.

Synthetic Utility.

The synthetic utility of TMS-Form has been demonstrated by the one-carbon homologation of a wide variety of ketones and aldehydes. The title compound is deprotonated with ***s-Butyllithium*** and then treated with a ketone to form an enamine by the Peterson alkenation (eq 2). A mixture of geometric isomers usually results; however, subsequent hydrolysis of the formamidine moiety affords a single compound. By varying the conditions under which the formamidine unit is destroyed, the corresponding homologated nitriles,[1] amines,[2] aldehydes,[2] and ketones[3] are obtained.

(2)

Homologation Processes.

The title reagent has recently been used for the homologation of ketones and aldehydes to nitriles.[1] The alkene formed from the previously described Peterson alkenation between the carbonyl compound and the anion of the title compound is treated with ***N,N-Dimethylhydrazine*** to form the corresponding hydrazone (eq 3). Quaternization with ***Iodomethane*** followed by methoxide-induced elimination affords the nitrile (65-89%).[1] Moreover, these nitriles can be prepared without purification or isolation of any intermediates. Thus 2-cyclohexen-1-one is transformed to the corresponding homologated nitrile in 66% yield (eq 4).

Alternatively, treatment of the intermediate hydrazone with ***Copper(II) Acetate*** easily affords the homologated aldehyde (55-84% from TMS-Form).[2] For example, α-tetralone is converted to the homologated aldehyde in 66% yield (eq 5).

Reduction of the *N*-vinylformamidine with ***Sodium Borohydride*** in acidic media reduces both the imine and the enamine functionalities. The resulting aminal is then hydrolyzed to give the *N*-methylamine (52-70% from TMS-Form). For example, veratraldehyde affords the corresponding homologated *N*-methylamine in 67% yield (eq 6). In addition, homologated *N*-alkylamines are prepared by reaction of the initial *N´-t*-butyl-*N,N*-dimethylformamidine anion with an electrophile and then utilizing this newly prepared compound in the outlined protocol (eq 7).

In a similar vein, the analogous *N*-butyl-*N*-(trimethylsilylmethyl)formamidine is converted to an alkene by the standard method (eq 8). Treatment with ***t-Butyllithium*** then forms the α-lithio enamine, which can be alkylated by a host of

electrophiles. Hydrazinolysis of the formamidine furnishes the homologated ketone or aldehyde. Some examples of this homologating nucleophilic acylation method are illustrated in Table 1.[4]

n-Butyl Nitrite

[544-16-1] · $C_4H_9NO_2$ · *n*-Butyl Nitrite · (MW 103.12)

(reagent for nitrosation[1-3,7] and oximation[4])

Physical Data: bp 78 °C; fp -13 °C.

Solubility: sol THF, propanol.

Form Supplied in: commercially available liquid.

Handling, Storage, and Precautions: nitrosation agents should be handled with care since products such as nitrosamines are extremely hazardous.

Ionic and Transition Metal Catalyzed Nitrosation.

n-Butyl nitrite has been widely employed as a nitrosation agent, particularly for the preparation of nitrosamines. Examples include the *N*-dealkylation-*N*-nitrosation of tertiary aromatic amines (eq 1)[1] and the deamination of aziridines (eqs 2 and 3).[2]

(1)

(2)

(3)

$R = Me, R' = C_5H_{11}$

In the first sequence (eq 1) little competing nitration of the aromatic ring was observed. The aziridine deamination occurs by a stereospecific loss of N_2O from an intermediate *N*-nitrosoaziridine. The method can be combined with an aziridine preparation to provide a means of interconverting the (*E/Z*) isomers of disubstituted alkenes.

Nitrosation of certain carbon electrophiles using butyl nitrite is also feasible, for example the conversion of sulfonamides into the corresponding α-oxime derivatives (eq 4).[3]

(4)

Transition metal catalyzed introduction of oxime (hydroxyimino) functionality into carbonyl compounds and nitriles may also be achieved starting with the corresponding α,β-unsaturated derivatives (eqs 5-7).[4] This reaction is thought to proceed via reaction of BuONO with an intermediate cobalt enolate, formed by metal catalyzed conjugate reduction of the starting material by the silane.

(5)

(6)

(7)

The same authors have described a related reaction which transforms simple alkenes into the corresponding nitrosoalkane dimers (eq 8)[5] (a radical synthesis of the nitroso alkane dimers is also possible by using *t*-BuONO).[6] This reaction is catalyzed by a number of iron complexes such as ***Tris(acetylacetonato)iron(III)***, and proceeds best when nitrogen monoxide, generated by the decomposition of BuONO, is removed from the reaction mixture by bubbling nitrogen gas.

(8)

Other uses for butyl nitrite include the nitrosation of amino acid hydrazines,[7] used in the Rudinger modification for peptide synthesis, and the substitution of BuONO for other reoxidants in certain palladium-catalyzed reactions.[8]

t-Butyl (*E*)-3-Oxo-4-hexenoate

(**1**; R = *t*-Bu)

[132117-94-3] · $C_{10}H_{16}O_3$ · *t*-Butyl (*E*)-3-Oxo-4-hexenoate · (MW 184.23) (**2**; R = Et)

[25654-09-5] · $C_8H_{12}O_3$ · Ethyl (*E*)-3-Oxo-4-hexenoate · (MW 156.18) (**3**; R = Me)

[37734-08-0] · $C_7H_{10}O_3$ · Methyl (*E*)-3-Oxo-4-hexenoate · (MW 142.15)

(for base-catalyzed cycloaddition;[1] β-keto ester with additional enone reactivity for trapping intermediates)

Alternate Name: Nazarov reagent.

Physical Data: bp (**2**) 101 °C/15 mmHg; (**3**) 95 °C/14 mmHg.

Preparative Methods: the *t*-butyl ester has been prepared by reacting the Reformatsky reagent derived from *t*-butyl bromoacetate with (*E*)-***Crotonaldehyde***, followed by oxidation with ***Manganese Dioxide*** to afford the desired *t*-butyl (*E*)-3-oxo-4-hexenoate (**1**) in 55% overall yield.[1] In a similar way, the reaction of the lithium enolate of ethyl acetate with (*E*)-crotonaldehyde followed by Jones oxidation gave, after isolation by Kügelrohr distillation, a 50% overall yield of the ethyl ester.[2] This synthesis is amenable to scale-up and has been submitted to *Organic Syntheses*.[3] The enol content for this compound is 40% when neat and 60% in a CCl_4 solution. Mention should be made of the reported quantitative yield of the ethyl ester by reaction of the lithium enolate of ethyl acetate with (*E*)-crotonyl chloride.[4]

Handling, Storage, and Precautions: use in a fume hood.

Base-Catalyzed Cycloaddition.

These γ,δ-unsaturated β-keto esters are known as Nazarov reagents since they undergo Michael addition with enolizable ketones followed by an aldol condensation, accomplishing Robinson annulation. No example using the reagent (**1**) (or other esters) for this specific six-membered ring formation has been found in the literature. A very closely related transformation by base-catalyzed cycloaddition (or double Michael addition) of (**1**) with ***Methyl 6-Oxo-1-cyclohexenecarboxylate*** gave the corresponding *cis*-decalin, the *t*-butyl ester being selectively cleaved by acid with

concomitant decarboxylation (eq 1). High stereoselectivity in favor of the *exo* adduct is achieved using a nonpolar solvent. Several substituted 6-oxo-1-cyclohexenecarboxylates react similarly.[1] This methodology was applied to the synthesis of optically active 14β-hydroxy steroids.[5]

Pyranones.

3-(1-Oxo-2-propenyl)coumarins (benzopyran-2-ones) are easily prepared in one step by cyclocondensation of (**2**) with 2-hydroxybenzaldehyde, affording a divinyl ketone (eq 2)[6] susceptible to undergo double Michael addition and to be a good substrate for the Nazarov cyclization.[6] As a potential source of 3,5-bis(alkenyl)pyrazoles, 2,3-dihydropyran-4-ones were prepared by condensation of the ethoxymagnesio enolate of (**2**) with cinnamoyl or sorbitoyl chloride (eq 3).[7] After acylation, the enolic hydroxy group originating from the acyl chloride adds exclusively to the double bond. With (*E*)-3-chloroacryloyl chloride it is the enolic hydroxy group originating from the β-keto ester which undergoes conjugate addition, giving the 4*H*-pyran-4-one (eq 4).[8]

(3)

(4)

Other Heterocyclic Compounds.

In the pyranone synthesis (eqs 3 and 4) this reagent reacts like other β-keto esters, with the added advantage of having an enone for further reaction. This aspect was exploited in the synthesis of 1,4,5,6-tetrahydropyridazin-4-ones. Thus the reaction of (**2**) with a diazonium salt affords the α-hydrazone, which cyclized on heating (eq 5).[9] Also, condensation of (**2**) with dimethylformamide dimethyl acetal affords the enamine in almost quantitative yield. When treated with ***Phenylhydrazine*** in acetic acid, the pyrazole is obtained, while using DME instead of acetic acid resulted in the formation of the 1,4,5,6-tetrahydro-3-pyridinecarboxylate (eq 6).[10]

t-Butyltetramethylguanidine

[88248-68-4] · $C_9H_{21}N_3$ · *t*-Butyltetramethylguanidine · (MW 171.29)

(strong base for formation of aziridines, alkylation, nitronation)

Physical Data: bp 80-82 °C/20 mmHg.

Form Supplied in: colorless liquid.

Preparative Method: prepared via reaction of ***t-Butylamine*** with the highly hygroscopic Vilsmeier salt obtained by reaction of *N,N,N´,N´*-tetramethylurea and ***Phosgene***.[1-3]

t-Butyltetramethylguanidine (**1**) is one of a range of hindered pentaalkylguanidines prepared by Barton for use as strong bases, and has been used in aziridine formation in a series of cholesterol derivatives (such as the conversion of (**2**) to (**3**), eq 1).[4]

(2)

(1)

(3)

The reagent is particularly useful in the preparation of esters of sterically compromised acids via the alkylation of their carboxylate salts (eqs 2 and 3). Thus the extremely hindered carboxyl group of hederagenin is converted efficiently to its methyl ester (**4**).[3] Keto acid (**5**) is esterified in similarly productive fashion.[5]

(2)

The reagent successfully effects monoalkylation of β-keto esters (eq 4). No *O*-methylation is observed in this reaction.[3]

(4)

The conjugate addition of nitronate anions to oxidized naphthalenes such as (**6**) occurs smoothly in the presence of (**1**) (eq 5);[6] use of ***Triethylamine*** led to substantial decomposition of starting materials.

(5)

The reagent also proves significantly superior to triethylamine in the conversion of hydrazones to vinyl iodides (eq 6).[7]

(6)

The above reaction was examined using a variety of bases (eq 7); use of (**1**) gave best overall yields of iodide (**7**) and also minimized formation of azine byproduct (**8**) (Table 1).[8]

(7)

Table 1 Preparation of Vinyl Iodides from Hydrazones (eq 7)

Base	Yield of vinyl iodide (**7**) (%)	Yield of azine (**8**) (%)
DBN	55	8
Piperidine	35	18
N-Methylmorpholine	30	25
Butylamine	35	20
Triethylamine	38	20
(**1**)	70	15

In the reaction of camphor-derived hydrazones, the use of (**1**) was essential to prevent rearrangement (eqs 8 and 9).[8] When triethylamine was employed in place of (**1**), rearranged allylic iodide (**9**) became the major product.

(8)

(9)

(9)

The use of (**1**) in the arylation of 2-naphthol using tetraphenylbismuth esters completely suppresses the *O*-arylation, which is otherwise a troublesome side reaction (eq 10).[9]

(10)

In the reduction of nitro compounds to oximes, the exceptional basicity of (**1**) is problematic (eq 11); for instance, the desired oxime (**10**) is obtained as the minor product (23%) and the major product is the nitrile (**11**), the product of over reaction.[10]

(11)

The reagent participates in a mild Nef reaction in the presence of ***Diphenyl Disulfide*** and a secondary nitroalkane such as (**12**) (eq 12).[11]

Nitroalkanes are again the substrates for the tetraalkylguanidine-mediated synthesis of trisubstituted pyrroles (**13**) invented by Barton et al (eq 13). The reagent gives better yields in a shorter reaction time than with ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.[12]

The salt (**14**) obtained from the reaction of (**1**) and *m*-iodoxybenzoic acid oxidizes nitronate anions at rt to give the corresponding carbonyl compounds (eq 14). Once again, DBU gives comparable results but the yields of the reaction are lower.[13] Salt (**14**) is also able to cleave glycols under extremely mild conditions.[14]

1-*t*-Butylthio-1-*t*-butyldimethylsilyloxypropene[1]

[102146-11-2] · $C_{13}H_{28}OSSi$ · 1-*t*-Butylthio-1-*t*-butyldimethylsilyloxypropene · (MW 260.51) (*E*)

[97250-84-5] (*Z*)

[97250-83-4]

(excellent reagent for Lewis acid-mediated aldol-type[2-9] and Michael additions,[17-21] under either stoichiometric or catalytic conditions)

Physical Data: colorless liquid.

Solubility: sol *n*-pentane, diethyl ether, dichloromethane, etc.

Analysis of Reagent Purity: (NMR) ^{1}H 0.15 (s, 6H), 0.95 (s, 9H), 1.30 (s, 9H), 1.65 (d, 3H, *J* = 6.7 Hz), 5.22 (q, 1H, *J* = 6.7 Hz) ppm (*Z* isomer). ^{1}H 0.18 (s, 6H), 0.95 (s, 9H), 1.30 (s, 9H), 1.60 (d, 3H, *J* = 6.8 Hz), 5.22 (q, 1H, *J* = 6.8 Hz) ppm (*E* isomer).

Preparative Methods: obtained by reaction of *t*-butyl thiopropionate with ***Lithium Diisopropylamide*** in THF and subsequent trapping with ***t-Butyldimethylsilyl Trifluoromethanesulfonate*** (95% *Z* isomer),[2] or with LDA in THF/HMPT and subsequent trapping with ***t-Butyldimethylchlorosilane*** (95% *E* isomer).[2]

Handling, Storage, and Precautions: the reagent should be stored in the absence of moisture at -15 °C.

Enantioselective Aldol Additions.[1]

The reagent undergoes Lewis acid-catalyzed Mukaiyama-type additions to aldehydes to give *syn* α-methyl-β-hydroxy thioesters with good yields and remarkable enantioselectivities (eq 1).[3a-d] Slow addition of the aldehyde (3-4.5 h) in propionitrile is necessary for high enantioselectivity.[3b-d]

A similar version of the reaction makes use of 100 mol % tin(II) oxide, 65 mol % ***Trimethylsilyl Trifluoromethanesulfonate***, and 50 mol % chiral diamine under slow addition conditions (9 h), with slightly worse results (58-82% yield; *syn*:*anti* = 91:9-98:2; 68-94% ee).[3e] These reactions are the catalytic versions of the stoichiometric reaction outlined in eq 2.[3c,3d,3f-i]

Under similar conditions to eq 2, the reagent adds to α-keto esters to give the corresponding substituted malates in good yield and high stereoselectivity (eq 3).[3j]

Under similar conditions to eq 3, silyl ketene acetals derived from α-benzyloxy thioesters[4a-c] or α-silyloxy thioesters[4d] add to various aldehydes to give either *anti* (91-99%) or *syn* (88-97%) α,β-dihydroxy thioesters, depending on the reagent used, in good yield (46-93%) and with high enantioselectivity (82-98% ee).

Another catalytic asymmetric aldol reaction is shown in eq 4. Slow addition of the aldehyde is again necessary for high selectivity.[5] Catalyst A is preferred in reactions with aromatic and unsaturated aldehydes, while catalyst B is employed in reactions with primary aldehydes.[5] In contrast to the catalysts mentioned above (eqs 1-3), both A and B give *anti* aldols as the predominant stereoisomers.[5]

catalyst A	R^2 = Et, *t*-Bu; R^3 = Me	54-94% yield; 60-89% ee *anti*:*syn* = 66:33 to 94:6
catalyst B	R^2 = Et; R^3 = Me	81-85% yield; 70-82% ee *anti*:*syn* = 88:12 to 91:9

Diastereoselective Aldol Additions.[1]

Boron Trifluoride Etherate mediates the addition of both (*E*) and (*Z*) title reagents to various aldehydes to give the aldol products with high *anti* selectivity (*anti*:*syn* = 91:9-96:4) irrespective of the silyl ketene acetal geometry (eq 5).[2,6] *Syn* selectivity is obtained using the (*E*) isomer via fluoride-mediated addition to benzaldehyde (*syn*:*anti* = 95:5),[2] or via TMSOTf-catalyzed addition to benzaldehyde dimethyl acetal (*syn*:*anti* = 78:22).[7a-d] ***Titanium(IV) Chloride*** mediates the addition of both (*E*) and (*Z*) title reagents to propynals to give the aldol products with high *anti* selectivity (*anti*:*syn* &egt; 95:5) irrespective of the silyl ketene acetal geometry, while high *syn* selectivity (*syn*:*anti* &egt; 98:2) is obtained in the $TiCl_4$-mediated addition to cobalt-complexed propynals.[7e] High *syn* selectivity is obtained in the uncatalyzed reaction of either (*E*)- or (*Z*)-*O*-silacyclobutyl analogs via a direct silicon group transfer (eq 5).[8]

Simple stereoselectivity (*syn*:*anti* ratios) can be controlled in the $Sn(OTf)_2$-mediated addition of the reagent to α-keto esters by varying the silyl ketene acetal geometry (eq 6).[3j]

The reagent undergoes Lewis acid-promoted Mukaiyama-type additions[1] to chiral aldehydes with moderate to good stereocontrol (eq 7).[2,6,9a-d] It is remarkable that high diastereoselectivity (>99%) can be obtained using $TiCl_4$ due to chelation control, and that these results are independent of the silyl ketene acetal geometry.[2,9b] These reactions have been used for establishing three consecutive stereocenters in the total synthesis of several biologically interesting compounds.[10-13]

Et	SMe	$TiCl_4$	5:95	81	9c	0:100:0:0

Addition to Other Electrophiles.

Zinc Chloride catalyzes the addition to a chiral azetinone with good yield. The stereochemical outcome depends on the sulfur substituent (eq 8).[14]

(8)

$R^2 = MeSCH_2$ 98:2
$R^2 = 2\text{-picolyl}$ 2:98

$TiCl_4$ mediates the addition of the title reagents to achiral and chiral thionium ions with good diastereoselectivity (eq 9).[15]

Tin(IV) Chloride or $BF_3.OEt_2$ mediate the addition of the title reagents to norephedrine-derived 2-methoxyoxazolidines; yields and diastereomeric ratios are independent of the silyl ketene acetal geometry (eq 10).[16]

Michael Additions.

In the presence of a catalytic amount of trityl salts (2-3 mol %), thioester silyl ketene acetals react stereoselectively with acyclic α,β-unsaturated ketones to give the Michael adducts in high yield (eq 11).[17a]

(11)

In the case of cyclic ketones, either the *syn* or the *anti* products can be obtained stereoselectively by varying catalyst and substituents (eq 12).[17a,b] For high *syn* selectivity the *t*-butyl thioester group (R^2 = *t*-Bu) is essential, while both the substituent on silicon (R^3) and silyl ketene acetal geometry have little effect on the diastereoselectivity.[17b]

R^1	R^2	R^3	X	(*E*):(*Z*)	*anti*	*syn*
H	Et	Ph	$SbCl_6$	100:0	92	8
H	*t*-Bu	Me	OTf	0:100	21	79
Me	*t*-Bu	Me	$SbCl_6$	0:100	<5	>95
SPh	*t*-Bu	*t*-Bu	$SbCl_6$	0:100	<5	>95
CO_2Me	*t*-Bu	*t*-Bu	$SbCl_6$	0:100	10	90

Catalytic amounts (5 mol %) of trityl chloride and ***Tin(II) Chloride***,[18] or ***Antimony(V) Chloride*** and tin(II) triflate,[19] have also been used to promote the Michael additions, with stereoselectivity in favor of the *anti* isomers and slightly reduced ratios in comparison with the above results. No stereoselectivity was observed with catalytic amounts (10 mol %) of ***Ytterbium(III) Trifluoromethanesulfonate***.[20]

Using the Michael-aldol protocol, several key intermediates on the way to natural products have been synthesized, e.g. dehydroiridodiol,[17a] aromatin,[17b] and fastigilin-C (eq 13).[21]

R = H	73%	Aldol ratio = 6:1 (-95 °C, CH_2Cl_2)
R = OMe	81-90%	Aldol ratio = 100:0 (-78 °C, CH_2Cl_2)

Related Reagents.

1-*t*-Butylthio-1-*t*-butyldimethylsilyloxyethylene[1]

[121534-52-9] · $C_{12}H_{26}OSSi$ · 1-*t*-Butylthio-1-*t*-butyldimethylsilyloxyethylene · (MW 246.48)

(excellent reagent for Lewis acid-mediated aldol-type reactions,[2] under either stoichiometric[3c-e] or catalytic conditions[3a,b,4-6])

Physical Data: colorless liquid; bp 145 °C/20 mmHg.

Solubility: sol *n*-pentane, diethyl ether, dichloromethane, etc.

Analysis of Reagent Purity: (NMR) ^{1}H 0.20 (s, 6H), 0.96 (s, 9H), 1.39 (s, 9H), 4.68 (m, 2H) ppm.

Preparative Method: the reagent is obtained by reaction of *t*-butyl thioacetate with ***Lithium Diisopropylamide*** in THF/HMPT and subsequent trapping with ***t-Butyldimethylchlorosilane*** (75% yield).[2]

Handling, Storage, and Precautions: the reagent should be stored in the absence of moisture at -15 °C.

Enantioselective Aldol Additions.[1]

The reagent undergoes Lewis acid-catalyzed Mukaiyama-type additions to aldehydes to give β-hydroxy thioesters with good yields and remarkable enantioselectivity (eq 1).[3a,b] Slow addition of the aldehyde (3-20 h) is necessary for high enantioselectivity.[3a]

(1)

This reaction is the catalytic version of the stoichiometric reaction outlined in eq 2.[3c,d]

(2)

Under the same conditions as eq 2, the reagent adds to α-keto esters to give the corresponding 2-substituted malates in good yield (74-81%) and excellent enantiomeric excesses (92-98%).[3e]

Other catalytic asymmetric aldol reactions are shown in eq 3. Slow addition of the aldehyde is necessary for catalyst B[5] but not for A.[4]

(3)

catalyst A	$R^2 = t$-Bu; $R^3 = t$-Bu	91-98% yield; 44-85% ee
catalyst B	$R^2 =$ Et, t-Bu; $R^3 =$ Me	75-98% yield; 81-92% ee

Under either the catalytic (eq 1) or the stoichiometric conditions (eq 2), the reagent undergoes addition to chiral aldehydes with complete reagent control, i.e. the stereochemistry of the aldol reaction is totally controlled by the chiral catalyst regardless of the inherent diastereofacial preference of the chiral aldehydes (eq 4).[6]

(4)

Titanium(IV) Chloride and ***Tin(IV) Chloride*** mediate the addition of the title reagent to chiral α-alkoxy aldehydes[2,7] and

β-alkoxy aldehydes[2] with complete chelation control (eq 5), whereas the corresponding silyl ketene acetal is unselective.[1,2]

Addition to Other Electrophiles.

Trimethylsilyl Trifluoromethanesulfonate catalyzes the addition to a chiral iminium ion with good yield and complete stereoselectivity (eq 6).[8]

Chlorotrimethylsilane-$InCl_3$ catalyzes the addition to *O*-trimethylsilyl monothioacetals to afford the corresponding sulfide derivatives in good yield.[9] Titanium tetrachloride mediates the addition of the title reagent to a chiral acetal with high diastereoselectivity (eq 7).[10]

Related Reagents.

For comparison and more details, see also those entries that deal with other silyl ketene acetals, in particular ***1-t-Butylthio-1-t-butyldimethylsilyloxypropene***, ***Ketene t-Butyldimethylsilyl Methyl Acetal***, and analogs.

n-Butyl *N*-(*p*-Toluenesulfonyl)iminoacetate[1]

(R = Bu)

[2292-87-7] · $C_{13}H_{17}NO_4S$ · *n*-Butyl *N*-(*p*-Toluenesulfonyl)iminoacetate · (MW 283.34) (R = Me)

[89366-20-1] · $C_{10}H_{11}NO_4S$ · Methyl *N*-(*p*-Toluenesulfonyl)iminoacetate · (MW 241.26) (R = Et)

[83670-53-5] · $C_{11}H_{13}NO_4S$ · Ethyl *N*-(*p*-Toluenesulfonyl)iminoacetate · (MW 255.29)

(easily prepared *N*-tosyl imines of glyoxylate esters[2] are useful as enophiles in inter-[3,4] and intramolecular[5] imino ene reactions and as dienophiles in achiral[6] and asymmetric[7,8,20-23] hetero Diels-Alder reactions)

Physical Data: bp R = Bu, 130-135 °C/0.001 mmHg; R = Et, 145-150 °C/0.02 mmHg.

Solubility: sol various organic solvents, usually used in benzene or toluene; reactions often run without solvent.

Form Supplied in: viscous yellow oil.

Handling, Storage, and Precautions: usually prepared and distilled directly before use or generated and used in situ.

Preparations.

Although a variety of alkyl glyoxylates have been utilized for the preparation of *N*-tosyliminoacetates, the most widely used compound has been the butyl derivative (**1**). Albrecht and Kresze[1] published the first preparation of (**1**) in 1965, when butyl glyoxylate was found to react with ***N-Sulfinyl-p-toluenesulfonamide***[9] under Lewis acid catalysis to produce the *N*-tosyliminoacetate (**1**) (eq 1). This reaction presumably proceeds through an initial [2 + 2] cycloaddition, followed by extrusion of sulfur dioxide.

(1)

(1)

Two groups have independently published preparations of *N*-tolyliminoacetates by reactions of glyoxylates and ***p-Toluenesulfonyl Isocyanate***. Le Goffic and Baillarge[10a] found that Lewis acid catalysis of the reaction in refluxing benzene produced (**1**) in 95% isolated yield (eq 2). A few years later, Holmes and co-workers[10b] found that the reaction could be effected without catalysis in refluxing toluene to produce the corresponding methyl ester in good yield. The mechanism of this reaction is thought to parallel the pathway in eq 1.

(1) (2)

Imino Ene Reactions.

The first report of an ene reaction of an *N*-tosylimine with an alkene appeared in 1976, when Achmatowicz and Pietraszkiewicz[3] showed that imino ene reactions could be effected thermally or under Lewis acid conditions to produce γ,δ-unsaturated amino acid derivatives (**2**) (eq 3).

(3)

(2)

Interestingly, Kresze and Braxmeier[11] have found that the same ene reactions can be effected using *N*-perfluorobutylsulfonyliminoacetate (**3**), resulting in a reaction rate increase relative to (**1**) of approximately three orders of magnitude.

(3)

More recently, Weinreb and co-workers[4,5] investigated the stereochemical features of the intermolecular ene reaction of (**1**). It was found that the reactions are stereospecific when conducted thermally, apparently proceeding through a pericyclic mechanism. When ethyl *N*-tosyliminoacetate was heated at 170 °C with cyclohexene, only sulfonamido ester (**4**), derived from the *endo* transition state **A**, was isolated (eq 4). None of the diastereomer (**5**), derived from an *exo* transition state **B**, was detected. When the reaction was run under Lewis acid catalysis, however, a mixture of (**4**) and (**5**) was isolated. It is presumed that the addition of a Lewis acid induces a change in mechanism from a pericyclic to an ionic process.

(4)

(4)

(5)

Weinreb and co-workers[5a,12] also found that ene reactions could be effected intramolecularly with unsaturated alkyl esters of *N*-tosyliminoacetates. The *N*-tosylimine derived from (*E*)-crotyl glyoxylate was prepared in situ and heated in *o*-dichlorobenzene to afford the single ene product (**7**),[13] arising from a cyclization through the intermediate *N*-tosylimine (**6**) (eq 5).

(6) (7) (5)

In an attempt to construct the framework of polyoxamic acid (**10**), Baumann and Duthaler[14] reacted ethyl *N*-tosyliminoacetate with methallene (eq 6). While only isolating minor amounts of the desired [2 + 2] adduct (**9**), a 33% yield of (**8**), derived from an imino ene reaction, was isolated.

Hetero Diels-Alder Reactions.

The first example of an *N*-tosyliminoacetate as a dienophile was reported by Kresze[1] in 1965. The reaction was found to be generally regioselective (eq 7).

Other groups have explored the addition of (**1**) to cyclic dienes in a study of the stereochemistry of the reaction.[15] Barco and co-workers[16] found that when an *N*-tosyliminoacetate (**1**) was allowed to react with ***Cyclopentadiene***, only the *exo* adduct (**11**) was formed (eq 8). This compound was further elaborated upon to produce 8-aza-9,11-etheno-PGH_1, a prostaglandin endoperoxide analog.

Holmes and co-workers[8,17] have studied the hetero [4 + 2]-reaction of *N*-tosyliminoacetates with various cyclohexadienes and have applied the adducts to natural product syntheses. Cyclohexadiene was found to afford only the expected *exo* isomer (**12**) when reacted with ethyl *N*-tosyliminoacetate (eq 9). This compound was further functionalized to provide (±)-actinobolamine.[17a]

Advances have also been made toward asymmetric hetero Diels-Alder reactions using chiral ester derivatives of (**1**). For example, Holmes and co-workers[8] have employed the *N*-tosylimine glyoxylate derivatives of ethyl (*S*)-lactate (**13a**) and (*R*)-pantolactone (**13b**) (eq 10) in Lewis acid-catalyzed reactions with cyclopentadiene to produce only the *exo* isomers (**14**) and (**15**) with the diastereomeric ratios dependent upon the particular chiral auxiliary employed.

Chiral sulfonamide	Ratio **(14)**:**(15)**
(13a) $R^* =$ 	12:88
(13b) $R^* =$ 	85:15

Hamada and co-workers[18] have recently reported a diastereoselective hetero Diels-Alder reaction between chiral diene (**16**) and (**1**) to produce the single diastereomer (**17**) in good yield (eq 11). This compound has been further elaborated to the alkaloid (-)-cannabisativine, the enantiomer of the natural product.[18b]

(11)

Recently, Whiting and co-workers[19] have achieved modest diastereoselectivity in a reaction of ethyl *N*-(1*R*)-camphorsulfonyliminoacetate (**18**) with Danishefsky's diene (***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene***) (eq 12). Inseparable mixtures of tetrahydropyridone diastereomers were isolated in varying ratios under both thermal and Lewis acid-catalyzed conditions.

(*R*)-(+)-*t*-Butyl 2-(*p*-Tolylsulfinyl)acetate

[58059-08-8] · $C_{13}H_{18}O_3S$ · (*R*)-(+)-*t*-Butyl 2-(*p*-Tolylsulfinyl)acetate · (MW 254.34)

(reagent for asymmetric aldol-type condensation;[1] used for the synthesis of sulfinyl dienophiles[13])

Physical Data: $[\alpha]_D^{20}$ = +149° (EtOH, *c* = 2.25)

Preparative Methods: conveniently prepared[2,3] by reaction of the magnesium enolate of *t*-butyl acetate (readily made with ***Bromomagnesium Diisopropylamide***) with ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate*** (eq 1). It was also made in 91% yield by reacting a solution of ***Lithium Diisopropylamide*** with (*R*)-(+)-methyl *p*-tolyl sulfoxide and *t*-butyl carbonate (eq 2).[4] It should be noted that asymmetric oxidation of *t*-butyl 2-(*p*-tolylsulfinyl)acetate with a modified Sharpless reagent gave a poor ee.[5]

Aldol-Type Condensation.

Aldol-type condensation of the magnesium enolate of (*R*)-(+)-*t*-butyl 2-(*p*-tolylsulfinyl)acetate, prepared with *t*-butylmagnesium bromide, with aldehydes and ketones afforded, after desulfurization with ***Aluminum Amalgam***, β-hydroxy esters in very high diastereoselectivity (eq 3).[3,6,7] Two chiral centers are created in the first step with very high diastereoselectivity (mainly one diastereomer is formed). A model M based on the structure of the sulfinyl ester enolate (determined by ^{13}C NMR)[8] and on electrophilic assistance of magnesium to the carbonyl approach, was proposed to explain and predict the absolute configuration of the two created chiral centers.[3]

(3)

The first application of this aldol-type asymmetric synthesis was reported by Corey during the later stages of the total synthesis of maytansine.[9] This result (eq 4) showed that the *t*-butyl ester could be replaced by a phenyl ester as long as

the same base, *t*-BuMgBr, is used for the condensation. The reaction of the α,β-unsaturated aldehyde gave, after desulfurization, the corresponding β-hydroxy ester in 80% yield and 86% de.

(4)

Optically active five- and six-membered lactones were also prepared by this aldol-type condensation (eq 5).[10]

Propargylic aldehyde was also used to prepare, by condensation with (+)-(*R*)-*t*-butyl *p*-tolylsulfinylacetate, a precursor of the C-3-C-8 fragment of leukotriene B_4 (eq 6).[11]

It should be noted that a poor ee was observed during the Michael addition of (+)-(*R*)-*t*-butyl *p*-tolylsulfinylacetate to an α,β-unsaturated ester.[12]

Preparation of Sulfinyl Dienophiles.

This sulfinyl ester was also used to prepare optically active sulfinyl dienophiles by a Knoevenagel-type condensation of ***Glyoxylic Acid*** (eq 7).[13,14]

(*R*)-(+)-*t*-Butyl 2-(*p*-Tolylsulfinyl)propionate

(*R*,*R*)

[83909-72-2] · $C_{14}H_{20}O_3S$ · (*R*)-(+)-*t*-Butyl 2-(*p*-Tolylsulfinyl)propionate · (MW 268.37) (*R*,*S*)

[83909-83-5]

(reagent for asymmetric aldol-type condensation)

Physical Data: $[\alpha]_D$ = +148° (EtOH, *c* = 0.3) for the 1:1 mixture of diastereomers.

Preparative Methods: the synthesis of this compound was first reported by methylation of ***(R)-(+)-t-Butyl 2-(p-Tolylsulfinyl)acetate*** via enolate generation with lithium bases such as ***n-Butyllithium*** or ***t-Butyllithium*** at 0 °C and with only ***Iodomethane*** as the alkylating agent (eq 1).[1] The diastereomeric ratio was shown by ^{1}H NMR to be 50:50 with BuLi and 42:58 with *t*-BuLi. The title compound was also prepared from ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate*** and the magnesium enolate of *t*-butyl propionate in 68% yield as a 1:1 ratio of the two possible diastereomers (eq 2).[1]

Aldol-Type Condensation.

The aldol-type condensation of the enolate anion of sulfinylpropionate, which was prepared as usual with the base *t*-butylmagnesium bromide, with aldehydes afforded after desulfurization with ***Aluminum Amalgam*** the corresponding β-hydroxy esters in high yield (90%) and, with aliphatic aldehydes, high diastereoselectivity (eq 3).[2,3] The amount of asymmetric induction was determined by transformation of the β-hydroxy esters to the corresponding isopropyl-substituted alcohols.

t-Butyl 2,2,2-Trichloroacetimidate

[98946-18-0] · $C_6H_{10}Cl_3NO$ · *t*-Butyl 2,2,2-Trichloroacetimidate · (MW 218.51)

(reagent for preparation of *t*-butyl esters and ethers,[1] and *t*-butylamines[5])

Physical Data: mp 21 °C;[1b] bp 65-69 °C/12 mmHg.[1a]

Solubility: sol organic solvents, preferably nonpolar ones especially cyclohexane (polar solvents promote ionization and decomposition).

Form Supplied in: white solid; commercially available in small quantities.

Preparative Methods: [1a] ***Potassium t-Butoxide*** (1.68 g, 15 mmol) was dissolved in *t*-butanol (30 mL) and this solution was added over 15 min to a stirred solution of ***Trichloroacetonitrile*** (21.6 g, 15 mL, 15 mmol) in dry diethyl ether (30 mL) cooled to 0 °C under nitrogen. The yellow mixture was allowed to warm to 20 °C over 1 h, and then heated to reflux for 1 h. After the reaction mixture had been cooled to rt, volatiles were removed on the rotary evaporator and the residual oil was dissolved in pentane (30 mL). The solution was filtered and the pentane was removed on the rotary evaporator. The residue was then distilled to yield 23 g (70%), bp 65-69 °C/12 mmHg, which solidified on storage.

Handling, Storage, and Precautions: the reagent is slowly hydrolyzed by water and thus should be stored cold under an inert atmosphere. The hydrolysis products are isobutene and trichloroacetamide. The use of polar solvents degrades the reagent more quickly due to decomposition in solvents that promote ionization.

t-Butyl Esters.

The facile preparation of (**1**) (eq 1) provides an easily handled reagent for formation of *t*-butyl esters (eq 2),[1a] extending the usefulness of trichloroacetimidates.[6] The typical previous method involved treatment of the acid with ***Isobutene*** and an inorganic acid catalyst under pressure.[2] The ***Boron Trifluoride Etherate*** catalyzed reaction in cyclohexane has the advantages of Lewis acid catalysis, easy reactions on small scales, and simple workup without water or base.[1,3] An instructive example is provided from the synthesis of dealanylalahopcin (eq 3).[3b] Yields are typically 70-90% with a simple nonaqeuous workup.

(1)

(2)

(3)

t-Butyl Ethers.

The methodology for preparing esters with reagent (**1**) has been extended to include ethers.[1a] In particular, this method has shown high selectivity for the formation of the less hindered ether (eq 4).[1a] Typical reactions are carried out in cyclohexane-dichloromethane mixtures for 16-20 h, giving 70% yields. Secondary alcohols require 2 equiv for effective reaction. These conditions compare favorably with the typical isobutene procedure.[4]

(4)

N-*t*-Butylanilines.

There is a single report of the very encouraging *t*-butylation of a nitrogen, in this case from the nonbasic hindered

aniline (**2**) (eq 5).[5]

t-Butyl 2,4,5-Trichlorophenyl Carbonate

[16965-08-5] · $C_{11}H_{11}Cl_3O_3$ · *t*-Butyl 2,4,5-Trichlorophenyl Carbonate · (MW 297.57)

(reagent for the Boc protection of amino groups;[1] preparation of active esters for peptide synthesis[1])

Physical Data: mp 67-68.5 °C.

Form Supplied in: commercially available solid.

Preparative Method: reaction between 2,4,5-trichlorophenol and ***Phosgene*** in toluene at -10 °C in the presence of dimethylaniline gives 2,4,5-trichlorophenyl chloroformate. Treatment with *t*-butanol and quinoline in CH_2Cl_2 then affords *t*-butyl 2,4,5-trichlorophenyl carbonate.[1]

Purification: recrystallization from methanol/water (charcoal).

Preparation of Active Esters for Peptide Synthesis.

t-Butyl 2,4,5-trichlorophenyl carbonate (**1**) reacts with amino acids in the presence of ***Triethylamine*** to give the *N*-Boc-protected amino acid (**2**), along with 2,4,5-trichlorophenol (eq 1).[1] High yields are obtained (often 90-95%), except for the hydroxy amino acids. Reagent (**1**) is more easily prepared than ***t-Butyl Azidoformate***, commonly used for introduction of the Boc group, but seems otherwise to offer little advantage if protection is the only aim. The utility of (**1**) arises because (**2**) and the 2,4,5-trichlorophenol may be extracted together from the reaction mixture into ethyl acetate; addition of ***1,3-Dicyclohexylcarbodiimide*** then affords the *N*-Boc-protected 2,4,5-trichlorophenyl ester (**3**) of the amino acid. These activated esters may be employed for peptide synthesis; they are generally crystalline solids, stable in alcoholic solvents and on storage, and their reactivity towards amino groups is at least as high as that of the corresponding *p*-nitrophenyl esters (see also ***p-Nitrophenol***). Following peptide formation, the 2,4,5-

trichlorophenol coproduct is readily removed.

---

n-Butyltrichlorostannane[1]

n-BuSnCl$_3$

[1118-46-3] · $C_4H_9Cl_3Sn$ · *n*-Butyltrichlorostannane · (MW 282.16)

(Lewis acid catalyst for polymerization reactions, esterifications,[2] dehydration processes, acetalizations, and transacetalizations[3])

Alternate Names: butyltrichlorotin; butyltin trichloride.

Physical Data: bp 93 °C/10 mmHg; *d* 1.7 g cm^{-3}; n_D 1.5235.

Solubility: sol cold water, common organic solvents.

Form Supplied in: colorless liquid, widely available. *Drying:* the usual procedure is vacuum distillation. It dissolves in water to give strongly acidic, clear solutions. Hydrolysis is reversible: BuSnCl$_3$ may be recovered by distillation.[4]

Handling, Storage, and Precautions: storage of anhydrous BuSnCl$_3$ in a dark desiccator is recommended. It is reputed to be of low toxicity with respect to other organotins. Use in a fume hood.

Esterifications and Transesterifications.

Monoorganotin(IV) halides have been employed as esterification and transesterification catalysts.[1e] BuSnCl$_3$ shows fairly good activity in the reactions shown in eqs 1 and 2.[1e,2] BuSnCl$_3$ is also an effective esterification catalyst for fatty acids derived from palm oil.[2]

$$EtCO_2H + BuOH \longrightarrow EtCO_2Bu + H_2O \qquad (1)$$

$$EtCO_2Bu + MeOH \longrightarrow EtCO_2Me + BuOH \qquad (2)$$

Formation of Diallyl Ethers from Allylic Alcohols.

Butyltrichlorostannane catalyzes the dehydration of the following alcohols: (*E*,*Z*)-MeCH=CHCH$_2$OH, (*E*)-

MeCH=CHCH(OH)Me, $Me_2C=CHCH_2OH$, $MeCH=CHCH(OH)CH_2CH=CH_2$, and $MeCH=CHCH(OH)CH(R)CH=CH_2$ (R = Me, *n*-Pr) to give isomeric mixtures of diallyl ethers[5a] in high yields (80-90%). Three isomeric species are formed from dehydration of (*E*)-3-penten-2-ol (eq 3).

Formation of Cyclic Ethers from Diols and Triols.

Organotin halides catalyze the conversion of 1,*n*-diols (*n* = 4-6) to cyclic ethers[5] (eq 4); cyclizations of triols have been also described.[3,5b]

The catalytic activity of tin compounds is in the order $MeSnCl_3$ &egt; $PhSnCl_3$ &egt; $SnCl_4$ > $BuSnCl_3$ >> Me_2SnCl_2 > Bu_2SnCl_2 >> $(Bu_2SnCl)_2O$. $BuSnCl_3$ is preferred over ***Tin(IV) Chloride*** and other monoorganotin halides because it is easy to handle, is inexpensive, and it can be recovered unchanged after workup. The following cyclic ethers have been synthesized from the corresponding diols: THF, 2-methyl-THF, 2,5-dimethyl-THF, 2,5-dihydrofuran, THP, 2-methyl-THP, 2,4-diallyl-THP, and 1,4-dioxane. 3-Hydroxy-THF and 3-hydroxymethyl-THP are also prepared in 92% and 70% yield from 1,3,4-trihydroxybutane and 1,5,6-trihydroxyhexane.[3] A related cyclization is that of acetonylacetone to 2,5-dimethylfuran (eq 5).[5b]

Dehydration of Cyclic Diols.

1,3-Cyclopentane-, 1,4-cyclohexane-, and 1,2-cyclooctanediol, when heated at 180-235 °C in the presence of $BuSnCl_3$ ([diol]/[Sn] in the range 20-40), give rise to mixtures of dehydrated products.[5b] 1,2-Cyclooctanediol yields a mixture of cyclooctanone, 1,4-epoxycyclooctane, and 1,3-cyclooctadiene (eq 6).[5]

Acetalizations and Transacetalizations of Diols and Triols.

$BuSnCl_3$, which is able to act both as an acid and as a dehydrating agent, promotes acetalizations using diols and triols[6] with many advantages compared to other methods. Reactions occur under mild conditions, with very short reaction times and in absence of solvent. Even aqueous solutions of aldehydes can be used (eq 7).

Transacetalizations of aldehyde dialkyl acetals, $R^1CH(OR^2)_2$, with diols and polyols can be carried out using $BuSnCl_3$ as the catalyst.[6b,c] As in acetalizations, reactions of glycerol with acetals provide mixtures of 1,3-dioxolanes and 1,3-dioxanes, the latter being the major products (eq 8).

Several examples where $BuSnCl_3$ has been used as a catalyst for transacetalizations of 1,2-diols, 1,3-diols, 1,3-propanethiol, and 1,2,3-propane- and 1,2,4-butanetriols with ***2,2-Dimethoxypropane*** have been reported.[6d] The same catalyst has been employed for acetonation of the above alcohols using the enol ether ***2-Methoxypropene***.[6d]

t-Butyl Trimethylsilylacetate

[41108-81-0] · $C_9H_{20}O_2Si$ · *t*-Butyl Trimethylsilylacetate · (MW 188.34)

(used to prepare lithium enolates which can be alkylated;[1,2] can be alkenated with aldehydes and ketones;[3] can be acylated;[4] can be reacted with Group 14 halides[5])

Physical Data: air stable, colorless liquid; bp 67 °C/13 mmHg; n^{20}_D 1.4184; ^{1}H NMR ($CDCl_3$, 90 MHz) 0.13 (s, 9H), 1.45 (s, 9H), 1.80 (s, 2H); IR 1710 cm^{-1}.

Preparative Methods: an advantage of *t*-butyl trimethylsilylacetate over its methyl and ethyl ester analogs is that it can be prepared by *C*-silylation of the lithium enolate of *t*-butyl acetate at -78 °C in THF (85-90% yield). Under the same conditions the enolates of methyl and ethyl acetate give primarily *O*-silylated products.[3] The reagent has also been prepared by a rapid ***Boron Trifluoride Etherate*** catalyzed reaction of ***Trimethylsilylketene*** with *t*-butyl alcohol.[6]

Lithium Enolate.

Most applications require initial formation of the enolate (**1**) (eq 1), which is obtained as a white solid suspended in THF, stable indefinitely at -78 °C.[1]

(1)

Alkylation Reactions.

Enolate (**1**) is readily alkylated with a variety of primary alkyl halides at -70 to 0 °C in THF,[2,7] usually in the presence of TMEDA or DMSO. The alkylation products may be desilylated (eq 2) to provide a two-carbon chain extension which is not prone to dialkylation or elimination side reactions.[7a]

The reagent is spiroalkylated in two steps with 2-methyl-1,4-diiodobutane (eq 3).[7b]

Enolate (**1**) can be vinylated with 2-bromopropene in the presence of a Ni catalyst.[7c]

Peterson Alkenation.[8]

Enolate (**1**) reacts with aldehydes or ketones to give α,β-unsaturated esters (eq 4).[1,8] In some cases (**1**) gives better yields and different *E*:*Z* ratios from the analogous Horner-Emmons reactions with phosphonoacetates.[9]

Reaction with Acyl Derivatives.

Enolate (**1**) does not react with ethyl acetate or *N*,*N*-dimethylacetamide, and gives a complicated mixture of products with acetyl chloride. However, (**1**) is acetylated with acetylimidazole to give the lithium enolate of *t*-butyl acetoacetate (eq 5).[4a]

Protonation of the reaction mixtures obtained with a variety of acylimidazoles gives β-keto esters in 50-94% yields. Enolate (**1**) reacts with a variety of lactones to give Peterson alkenation products (eq 6).[4b]

Enolate (**1**) reacts with some aromatic nitriles (but not with benzonitrile) to give *N*-silylenamines.[10]

Reaction with Group 14 Halides.

Enolate (**1**) reacts with ***Chlorotrimethylgermane*** or ***Tri-n-butylchlorostannane*** to give *t*-butyl (trimethylgermyl)(trimethylsilyl)acetate (83% yield)[5a] and *t*-butyl (trimethylsilyl)(tri-*n*-butylstannyl)acetate,[5b] respectively.

Related Reagents.

2-Butynoic Acid[1]

[590-93-2] · $C_4H_4O_2$ · 2-Butynoic Acid · (MW 84.07)

(dianion used in α- and γ-alkylation;[2] used in conjugate addition reactions and Diels-Alder reactions)

Physical Data: mp 78-80 °C.[3]

Preparative Methods: from 3-methyl-2-pyrazolin-5-one via bromination followed by basic hydrolysis;[3] via carboxylation of propynylsodium or ***Propynyllithium***.[4,5]

Purification: sublimation (60 °C/0.02 mm Hg).[3]

Handling, Storage, and Precautions: use in a fume hood.

Selective α- and γ-Alkylation.

The dianion of butynoic acid undergoes selective alkylation at the α- or γ-position depending on the reaction conditions (eq 1).[2] The original Pitzele procedure using ***Lithium Diisopropylamide*** in THF-HMPA or ***Lithium 2,2,6,6-Tetramethylpiperidide*** is not regioselective and leads to mixtures in favor of the alkynic derivative.[6] Reaction of aldehydes under the latter conditions also gives mixtures of alkynic and allenic derivatives.[7,8]

Conjugate Addition.

2-Butynoic acid undergoes conjugate addition with ***Phenylcopper*** or ***Lithium Diphenylcuprate*** to yield the (*E*) derivative with high stereoselectivity (eq 2).[9] Stereospecific *syn* addition is also observed with esters of 2-butynoic acid.[10]

Cycloaddition.[11]

2-Butynoic acid undergoes Diels-Alder reactions with ***Cyclopentadiene*** (neat, 1 h, 185 °C; 68%).[12] The intramolecular version with a sorbyl ester is also known (eq 3).[13]

Related Reagents.

3-Butyn-2-one; ***3,3-Diethoxy-1-propyne***; ***Methyl Propiolate***; ***Propargyl Aldehyde***; ***3-Tetrahydropyranyloxy-1-propyne***; ***3-Tetrahydropyranyloxy-1-trimethylsilyl-1-propyne***.

3-Butyn-2-one

[1423-60-5] · C_4H_4O · 3-Butyn-2-one · (MW 68.08)

(conjugate acceptor, dienophile)

Physical Data: bp 85 °C; *d* 0.87 g cm^{-3}.

Solubility: sol chloroform, diethyl ether, ethanol.

Form Supplied in: neat liquid; widely available.

Preparative Methods: from 3-butyn-2-ol using oxidation[1,2] or catalytic isomerization.[3]

Handling, Storage, and Precautions: is a highly toxic, flammable liquid. It is also a severe lachrymator. It may be fatal if inhaled, swallowed, or absorbed through the skin. When handling this material, appropriate protective clothing, safety goggles, and an approved respirator should be worn. The material should be refrigerated when stored. Use in a fume hood.

3-Butyn-2-one has been employed successfully in Pictet-Spengler[4] reactions, Diels-Alder and ene reactions,[5] 1,3-dipolar cycloadditions,[6] and cyclotrimerizations.[7] A regioisomeric mixture of isoxazoles is produced when 3-butyn-2-one is reacted with bromonitrile oxide (generated in situ).[7] The major product is an intermediate in the synthesis of the β-agonist broxaterol.

A variety of nucleophiles successfully add to 3-butyn-2-one (and related alkynones).[8,9] Attempts to use 3-butyn-2-one in Robinson annulations have not been very successful.[10] Nitro-stabilized carbanions add well using phase transfer catalysis (eq 1), yielding preferentially the (*E*) isomer.[11]

Trialkylboranes[12] and ***Tris(trimethylsilyl)aluminum***[13] efficiently transfer alkyl and trimethylsilyl groups, respectively, in a conjugate fashion.

Asymmetric reduction has been achieved using several different reagents.[14-17] Many other alkynones are reduced with high levels of asymmetric induction and the best result to date with 3-butyn-2-one was achieved using either Eapine- or Prapine-Borane.[14,18] For more sterically hindered alkynones, ***(+)-B-Chlorodiisopinocampheylborane*** works well.[14] Reduction of the tosylhydrazone of 3-butyn-2-one produces 1,2-butadiene in reasonable yield.[19]

Related Reagents.

4-Methoxy-3-buten-2-one; ***Methyl Vinyl Ketone***; ***Propargyl Aldehyde***.

γ-Butyrolactone[1]

[96-48-0] · $C_4H_6O_2$ · γ-Butyrolactone · (MW 86.09)

(useful source of di- and trifunctional acyclic synthons; can be converted into various types of substituted γ-lactones and tetrahydrofurans)

Alternate Names: 4-hydroxybutyric acid γ-lactone; dihydro-2(3*H*)-furanone.

Physical Data: bp 204 °C; mp -43.5 °C; *d* 1.129 g cm^{-3}.

Solubility: misc with water; sol most organic solvents (e.g. CH_2Cl_2, Et_2O, benzene, THF, and MeOH).

Form Supplied in: colorless liquid (>99%); inexpensive.

Purification: hygroscopic; water can be removed by distillation from CaH_2, $CaSO_4$, or BaO under dry Ar. When the commercial reagent is distilled twice from CaH_2, the fraction boiling at 80-81 °C/11 mmHg contains 99.8% γ-butyrolactone.[2]

Handling, Storage, and Precautions: avoid contact with skin or eyes; do not inhale or ingest; vapor is irritating to the eyes and upper respiratory tract. Anhydrous γ-butyrolactone should be used immediately after distillation for best results. Use in a fume hood.

Formation of Halo Acid Derivatives.

The proclivity of lactones to undergo halide-assisted ring opening has often been exploited for easy access to valuable synthetic intermediates.[3] Thus alcoholysis in the presence of ***Hydrogen Bromide*** provides 4-bromobutyrates (eq 1).[4,5] Related procedures involving ***Bromotrimethylsilane***,[6] ***Boron Tribromide***,[7] or ***Phosphorus(III) Bromide***[3d] as the bromide source are also effective. Similarly, 4-iodobutyrates are obtained by using ***Iodotrimethylsilane***,[6a,8] BBr_3/***Sodium Iodide***,[7] or the ***Boron Triiodide***-*N*,*N*-diethylaniline complex (eq 2).[9] Alternatively, they can be prepared on a large scale from bromo or chloro esters by halogen exchange.[3f] The latter are readily available through alcoholysis of 4-chlorobutanoyl chloride (eq 3).[10]

(2)

(3)

Reaction of γ-butyrolactone with 2.1 equiv of ***Bromine*** in the presence of red phosphorus affords α-bromo-γ-butyrolactone.[11] When 4 equiv of bromine are used, ring opening ensues to furnish 2,4-dibromobutyric acid bromide, which upon methanolysis affords methyl 2,4-dibromobutyrate in high overall yield (eq 4).[12] Dibromobutyrates are useful for preparing cyclopropanes (eq 4),[12] azetidines,[13] and β-lactams (eq 5).[14]

(4)

Aminolysis.

In the presence of an ***Aluminum Chloride-Triethylamine*** couple, lactones smoothly react with primary or secondary amines to give the corresponding o-hydroxyalkanamides (eq 6).[15]

Lewis Acid-Induced Carbon-Carbon Bond Formation.

The outcome of the Friedel-Crafts reaction of γ-butyrolactone with benzene can be manipulated by simply varying the amount of $AlCl_3$ so that either 4-phenylbutyric acid or α-tetralone can be obtained at will (eq 7).[16] In the presence of

Triethylsilane and a catalytic amount of a trityl salt, lactones undergo condensation with silyl ketene acetals and in situ reduction of the resulting unsaturated esters to give α-substituted cyclic ethers (eq 8).[17] When a carbon nucleophile is used in place of Et_3SiH, α,α-disubstituted cyclic ethers are obtained.[17]

Formation of Hydroxy Esters.

Although 4-hydroxybutyrates may be prepared by acid-catalyzed alcoholysis of γ-butyrolactone, their isolation from the resulting lactone-hydroxy ester equilibrium is tedious and yields are low.[18] The practical alternative entails lactone saponification and subsequent reaction of the carboxylate with a suitable electrophile (eq 9).[19] Silyl esters can be prepared in a similar manner.[20]

(9)

One of the most commonly used methods for converting lactones into acyclic compounds involves reduction with ***Diisobutylaluminum Hydride*** and Wittig homologation of the resulting lactol[21] (see also ***Dihydro-5-(hydroxymethyl)-2(3H)-furanone***). A related, more recent procedure[22] provides α,β-unsaturated esters in a single operation (eq 10).[23]

(10)

Reactions with Organometallics.

In general, unsubstituted lactones tend to undergo double attack by organometallics to give diols, whereas substituted lactones are more susceptible to monoaddition.[24,25] However, the outcome strongly depends on the nature of the organometallic reagent and reaction conditions.[24-26] Monoaddition can be achieved with organolithium compounds (eq 11),[24a] although yields of keto alcohols are rarely high.[27] Lithium acetylides have been widely exploited for the synthesis of natural spiroacetals,[28] such as the insect pheromone (**1**) (eq 12).[28a] The highly oxophilic organocerium reagents give superior yields of monoaddition products when compared to their lithium precursors (eq 13).[25] Organocerates are also advantageous for converting lactones into hydroxyallylsilanes (see also ***Cerium(III) Chloride***).[29]

(11)

(12)

(13)

Grignard compounds exhibit an innate preference for double addition[24,30] giving high yields of diols which can be easily transformed into γ,γ-disubstituted-γ-butyrolactones (eq 14).[31] Analogously, α,o-di-Grignard reagents provide spirolactones (see also ***1,5-Bis(bromomagnesio)pentane***).[32]

(14)

Alkylation and *C*-Silylation.

Clean α-monoalkylation of γ-butyrolactone is usually achievable by exposure to LDA and reaction of the enolate with a primary alkyl, allyl, or propargyl halide in the presence of HMPA (in the absence of HMPA, α,α-dialkylation is also observed).[33,34] An example is depicted in eq 15.[35] A highly effective but equally elaborate procedure, suitable for both

alkylation and acylation, utilizes a crown ether-potassium complex instead of LDA.[2] *C*-Silylation of γ-lactones can be realized in a highly selective fashion by using γ-***Butyrolactone*** as silylating agent. Addition of a Grignard reagent to the resulting α-silyl-γ-butyrolactone, followed by alkenation and eventual oxidation delivers 4-oxocarboxylic acids in good overall yields (eq 16).[36]

(15)

(16)

Aldol Reaction.

Generally speaking, lactone-derived enolates and silyl ketene acetals show poor simple diastereoselection.[37] Thus reaction of lithiated γ-butyrolactone with benzaldehyde provides a modest 30:70 ratio of *syn* and *anti* adducts which can be reversed by the intervention of ***Zinc Chloride*** (eq 17).[38] In the latter case a zinc enolate is involved. Higher *anti*-selectivity has been encountered with a sterically more demanding aldehyde.[39a] Useful levels of *syn* selectivity are conferred by Lewis acid-mediated aldol reaction of 2-(trimethylsilyloxy)-4,5-dihydrofuran[40] (prepared from γ-butyrolactone) with propynal-hexacarbonylcobalt complexes (eq 18).[41]

Exposure of the easily prepared α,α-bis(phenylthio)-γ-butyrolactone to ***Ethylmagnesium Bromide*** leads to a magnesium enolate which undergoes aldol reaction in excellent yields (eq 19).[42a] The resulting adducts can be transformed into 3-(1´-hydroxyalkyl)-2(5*H*)-furanones by oxidation of the phenylthio group and elimination of the resulting sulfoxide.[42] Alternatively, 3-(1´-hydroxyalkyl)-2(5*H*)-furanones are accessible in one step from butenolides (see also α,β-***Butenolide***).[43]

(19)

Alkylidenation.

Many methods exist for the α-methylenation[44,45] and α-alkylidenation[45a,46-48] of lactones. An appealing procedure for preparing α-methylene-γ-butyrolactone entails α-formylation and subsequent condensation with formaldehyde.[45a] (*E*)-α-Alkylidene-γ-butyrolactones, essentially free of their (*Z*) isomers, are available from γ-butyrolactone in high yields through the vinylogous carbamate (**2**) and α-butylthiolactone (**3**) (eq 20).[46] Usefully, α-alkylidene-lactones can be isomerized to 3-alkyl-2(5*H*)-furanones by heating with deactivated W-2 ***Raney Nickel***.[46]

Sequential treatment of γ-butyrolactone with LDA and bis(methoxy(thiocarbonyl)) disulfide provides a lithium enolate which reacts with aldehydes to give preferentially either (*E*)- or (*Z*)-α-alkylidene-γ-butyrolactones, depending on whether $ZnCl_2$ is added before the aldehyde (eq 21).[47] Apparently, these reactions involve episulfides and the double bond geometry depends on the stereochemical outcome of the initial aldol process. Methylenation or alkylidenation of the lactone carbonyl group can be effected by using the Tebbe reagent (μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***) and its variants.[49]

Cadmium Carbonate

$CdCO_3$

[513-78-0] · $CCdO_3$ · Cadmium Carbonate · (MW 172.42)

(used in the preparation of aryl glycosides[1-8] and also for cleavage of thioacetals[9])

Physical Data: mp 357 °C; *d* 4.258 g cm^{-3}.

Solubility: sol concentrated ammonia and dilute acids.

Form Supplied in: white powder and chunks.

Handling, Storage, and Precautions: should be stored in a cool dry place. It is a carcinogen and hence should be handled carefully.

Synthesis of Glycosides.

$CdCO_3$ has been used as a catalyst in the Koenigs-Knorr synthesis of aryl glycosides.[1-3] Better yields are reported with $CdCO_3$ than with the usual catalyst, silver carbonate. For example, the 3-β-D-glucuronide triacetate methyl ester of estrone was prepared in 71% yield (eq 1), compared to 7% yield using silver carbonate.[1] Similar preparations of the β-D-glucuronides of 17β-estradiol,[1] estriol,[1,4] equilin,[1] equilenin,[1] phenolphthalein,[5] cholesterol,[6] and anthracyclines[7] are documented in the literature.

This methodology has also been used to prepare 2-aminoethyl glycosides (eq 2) for the preparation of carbohydrate-protein conjugates.[8]

Cleavage of Thioacetals.

Thioacetals of aldosugars are cleaved by $CdCO_3$ in the presence of $HgCl_2$ (see ***Mercury(II) Chloride-Cadmium Carbonate***). This method has been used to prepare acyclic derivatives of monosaccharides (eq 3).[9]

Cadmium Chloride

$CdCl_2$

[10108-64-2] · $CdCl_2$ · Cadmium Chloride · (MW 183.31)

(organocadmium reagents are useful in the synthesis of keto esters,[2] in regioselective,[3] stereoselective[4] addition reactions, and in osmium-catalyzed hydroxylation;[5] $CdCl_2$ is useful in ring opening[6] and oxidation[7-11] reactions)

Physical Data: mp 568 °C; *d* 4.047 g cm^{-3}.

Solubility: insol ether; slightly sol methanol, ethanol; sol acetone; freely sol water.

Form Supplied in: white crystalline solid; widely available. *Drying:* for some applications the cadmium chloride must be anhydrous. The recommended procedure involves drying to a constant weight at 110 °C in an oven, grinding throughly, and storing in a desiccator.

Handling, Storage, and Precautions: should be stored in a dry place. It is a highly toxic cancer suspect agent and should be handled carefully.

Organocadmium Reagents.

Cadmium chloride is most often used to prepare organocadmium compounds. Use of organocadmium derivatives for the preparation of simple ketones was introduced as early as 1936.[1] Alkyl organocadmium derivatives, prepared by reaction of the corresponding RMgBr compounds with anhydrous $CdCl_2$ in ether, react with a variety of ester acid chlorides to give keto esters (eq 1).[2]

$$Me_2CHCH_2CH_2MgBr \xrightarrow[\text{2. } ClCOCH_2CH_2CO_2Me,\ C_6H_6]{\text{1. } CdCl_2,\ Et_2O} \underset{73\%}{} Me_2CHCH_2CH_2COCH_2CH_2CO_2Me \quad (1)$$

Lithium enolates of α,β-unsaturated esters condense cleanly with aldehydes, affording the α product exclusively. This

is in accordance with the normal regiochemical behavior of vinylogous anions. Use of organocadmium reagents prepared in situ from their lithium derivatives reverses the regioselectivity (eq 2).[3]

Cadmium chloride mediated addition of organometallics to chiral α-keto amides influences the stereochemistry of the reaction (eq 3).[4]

N-Chloro-*N*-cadmium carbamates can be generated in situ by reaction of the corresponding *N*-chloro sodiocarbamates with cadmium chloride in acetonitile. These organocadmium reagents are useful in an osmium-catalyzed procedure which effects *cis* addition of hydroxyl and carbamate moieties across an alkenic linkage (eq 4).[5]

(4)

Synthetically useful cadmium homoenolates have been prepared by the heterometalation-type ring cleavage of electron-rich cyclopropanes by cadmium chloride under ultrasonic irradiation at room temperature (eq 5).[6]

(5)

Oxidations.

In the synthesis of polycyclic aromatics, dehydrogenations are effectively carried out using cadmium chloride as an oxidizing agent (eqs 6 and 7).[7,8]

(6)

Cadmium chloride has been employed as an oxidizing agent in the conversion of 1,5-cyclooctadiene to cyclooctatetraene through the intermediacy of cyclooctatetraenyl dianion (eq 8).[9-11]

Calcium-Ammonia[1]

Ca/NH_3

[7440-70-2] · Ca · Calcium · (MW 40.08)

[7664-41-7] · H_3N · Calcium · (MW 17.03)

(mild reducing agent capable of reducing double and triple bonds; moderately strong base)

Physical Data: Ca: mp 842-848 °C; bp 1240 °C; *d* 1.55 g cm^{-3}; NH_3: mp -77.7 °C; bp -33.35 °C; d_{-79} 0.817 g cm^{-3}.

Form Supplied in: Ca: silver, white, soft metal; NH_3: anhydrous gas or liquid in sealed ampules.
Drying: ammonia can be dried by passing the gas through a KOH drying tube prior to condensation.

Handling, Storage, and Precautions: calcium metal is a water reactive, flammable solid. In case of contact with water, the heat of the reaction may be sufficient to ignite the product hydrogen as well as the metal. Anhydrous liquid ammonia is corrosive, especially in contact with water. Although classified as a nonflammable gas, it will burn within certain concentration limits. The liquid may cause frostbite in contact with the skin. Use in a fume hood.

Reduction of Aromatic Hydrocarbons.

Although calcium in liquid ammonia, apparently in the form of $Ca(NH_3)_6$,[2] has long been known to convert aromatic hydrocarbons to unconjugated dienes and even monoalkenes,[3] alkali metals in ammonia or in ammonia/alcohol have generally been the reagents of choice, even though calcium is safer to handle. Thus benzene, toluene, and *o*- and *p*-xylene afford the corresponding monoalkenes in high yield after treatment with calcium hexamine after 24 hours (eq 1).[3] Similar reductions of bi- and terphenyl yield dihydro derivatives, while naphthalene gives 1,4-dihydronaphthalene at -75 °C and a mixture of the 1,4-derivative and 1,2,3,4-tetrahydronaphthalene at -33 °C (eq 2).[4]

(1)

(2)

The reductions of aromatic hydrocarbons by calcium in liquid ammonia can be effected under two different conditions.[5] In the first case, the calcium is dissolved in ammonia and the latter is removed eventually with the aid of high vacuum to give solid calcium hexamine. In the second procedure, ammonia is added to a mixture of the calcium and the hydrocarbon. While the first method produced substantially higher yields of cyclohexene from benzene, nearly the same results were realized by both methods in the reduction of toluene.

Improved yields and cleaner products were realized by the use of calcium shot in ammonia with ether and HMPA.[6] For example, the reduction of *t*-butylbenzene by this method afforded 1-, 3-, and 4-*t*-butylcyclohexenes in yields of 56%, 34%, and 10%, respectively, results which are comparable to the better known lithium-amine system.[7] Calcium in methylamine/ethylenediamine was found to be an even better system, since substantially higher quantities of the more thermodynamically stable alkenes were formed from reduction of a large number of aromatic hydrocarbons.[8] Thus the yield of 1-*t*-butylcyclohexene in the reduction of the parent hydrocarbon was increased to 87% (eq 3).

(3)

Birch-type products were obtained by effecting calcium reductions in butylamine/ethylenediamine in the presence of *t*-butyl alcohol.[9] The authors recommend that all such calcium reductions be run in the presence of white sand using a Hershberg stirrer to remove the insoluble coatings on the surface of the calcium metal. Use of this technique for the reduction of anisole provided the 2,5-dihydro derivative in 86% yield (eq 4).

(4)

Reduction of Alkynes and Alkenes.

Dialkylalkynes have been reduced to *trans*-alkenes by calcium in ammonia[5] and by calcium in methylamine/ethylenediamine.[10] Thus, 2-nonyne, 3-nonyne, 4-nonyne, and 4-octyne gave the corresponding *trans*-alkenes in yields of 70-88% and purities of 72-91% (eq 5).[10] Similar reduction of 1-heptyne apparently gave substantial metalation unless a large excess of the metal was employed. In the latter case, the major product was heptane.

(5)

Arylated alkenes such as 1,1-diphenylethylene and 1,1,2-triphenylethylene have been reduced to the corresponding ethanes by calcium in ammonia.[11]

Reduction of Other Functional Groups.

Few functional groups other than those above have been reduced by calcium in liquid ammonia. The carbon-carbon double bond of several α,β-unsaturated ketones has been reduced by this reagent to give saturated ketones (eq 6).[12] In several cases, though, both the alkene and the ketone have been reduced to saturated alcohols (eq 7).[13]

(6)

(7)

Calcium/ammonia solutions have been found to be useful when low basicity is desired, as in the conversion of both stereoisomers of the diacetoxy ketone (**1**) ($R^1 = R^2 = OAc$) to the corresponding ketone ($R^1 = OAc$, $R^2 = H$).[14] In this case, calcium was shown to be a better reagent than lithium for this reduction.

(1)

Calcium in ammonia offers better selectivity than lithium in the debenzylation of a variety of benzyl ethers containing other functional groups.[15] For example, in eq 8 the benzyl group of the alkynic ether is removed without concomitant reduction of the triple bond.

(8)

Epoxides have also been reduced to alcohols by calcium in ammonia (eq 9).[16] The results are similar to those realized by the use of lithium metal.

(9)

Calcium/Ammonia as a Base.

Although little used for many years, solutions of calcium in ammonia have been employed to convert certain active hydrogen compounds to their calcium salts. For example, calcium salts have been prepared from terminal alkynes,[17] alcohols,[18] nitrogenous heterocycles such as 1,2,4-triazole,[19] and other organonitrogen compounds, illustrated by dicyanodiamide.[20]

Calcium Carbonate

$CaCO_3$

[471-34-1] · $CCaO_3$ · Calcium Carbonate · (MW 100.09)

(relatively insoluble white solid; a useful acid scavenger and stabilizing agent for acid sensitive compounds,[1] and a coreactant in reactions producing acidic byproducts.)

Physical Data: widely available as powder (reagent grade) or ppt powder (USP). Occurs naturally as limestone, marble, and chalk. Three crystal forms are known: (1) aragonite *[14791-73-2]*; mp 825 °C (dec); *d* 2.93 g cm^{-3}; water sol 0.0015 g/100 mL (at 25 °C); (2) calcite *[13397-26-7]*; mp 1339 °C (103 atm); *d* 2.71 g cm^{-3}; water sol 0.0014 g/100 mL (at 25 °C); (3) vaterite [*13701-58-1]*; found in N. Ireland and Israel.

Handling, Storage, and Precautions: none; nontoxic; generates calcium oxide and releases carbon dioxide on heating.

Elimination.

Halides (eq 1)[2] and sulfoxides (eq 2)[3] are converted to alkenes (or their tautomers) on heating with $CaCO_3$ in appropriate solvents. In the case of halo ketone eliminations (eq 3)[4] the methods of Holysz[5a] and Joly,[5b] employing lithium carbonate/lithium halide mixtures, appear to be more commonly used, and in some instances more effective (see ***Lithium Carbonate-Lithium Bromide***).[6]

(3)

Halogenation.

Calcium carbonate is often used with reagents such as ***N-Bromosuccinimide*** (eq 4),[7] phosphorus halides,[8] and ***Benzyltrimethylammonium Dichloroiodate*** (BTMA) (eq 5).[9]

(4)

(5)

Substitutions.

Silver(I) Perchlorate promoted substitutions of reactive halides may be effected under mild conditions, as shown in eq 6[10] and eq 7.[11] This provides a useful alternative[12] to classical Friedel-Craft conditions.

(7)

Pinacol Rearrangement.

Rearrangement of glycol monotosylates (eq 8)[13] is effected by the procedure of Corey.[14] Solvolysis of an analogous bicyclic epoxy tosylate in an aqueous suspension of $CaCO_3$ gave a 1,5-diketone in good yield (eq 9).[15]

(8)

(9)

Thioether and Acetal Deprotection.

Mercury(II) Chloride induced cleavage of thioethers[16] and acetals (eq 10),[17] and their selenium analogs,[18] employs added $CaCO_3$.

Cycloadditions.

Cycloaddition (eq 11)[19] and related reactions (eq 12)[20] have sometimes used $CaCO_3$ as a coreactant.

Other Divalent-Metal Carbonates.

Other divalent-metal carbonates related to calcium carbonate include $MgCO_3$ *[546-93-0]*, ***Zinc Carbonate*** *[3486-35-9]*, $SrCO_3$ *[1633-05-2]*, and $BaCO_3$ *[513-77-9]*. In general, these carbonates have not been widely used. Barium carbonate has served a similar role in halogenation and dehydrohalogenation reactions as the calcium salt. Since barium is more toxic than calcium, its equivalent use is not recommended. Calcium, strontium, and barium carbonates have all been used as supports for noble metal catalysts in hydrogenation reactions, and in some cases appear to give better selectivity than analogous carbon- or alumina-supported catalysts.[21]

A novel coumarin synthesis (eq 13), employing zinc or magnesium carbonate,[22] avoids the acidic conditions of the Pschorr synthesis.

Calcium Hydride[1]

CaH_2

[7789-78-8] · CaH_2 · Calcium Hydride · (MW 42.10)

(used as a drying agent for reagents and solvents, as a desiccant in reactions, as a base, and as a catalyst and cocatalyst)

Physical Data: mp 816 °C, *d* 1.902 g cm^{-3}.

Form Supplied in: gray orthorhombic crystals, fine ground powder, coarse ground powder, and granules/lumps.

Handling, Storage, and Precautions: moisture sensitive and pyrophoric. It reacts vigorously with water, and should be stored and handled under dry conditions (argon or nitrogen).

Calcium hydride reacts with water to form calcium hydroxide and hydrogen gas (eq 1). It reacts much more slowly than the other metal hydrides as a base (toward organic acids), and has therefore found its most widespread use as a drying agent. Thus it has been used to dry hydrocarbons, ethers, amines (including pyridine), esters, phosphites, and alcohols. A typical procedure is to stir the liquid containing approximately 5% w/v calcium hydride for a period of time (1-2 h at least; preferably 24 h), and decanting, filtering, or distilling the liquid away from the calcium salts.[2] Traces of water and cyanide may be removed from ***N,N-Dimethylformamide*** in this manner.[3]

$$CaH_2\,(s) + H_2O \longrightarrow Ca(OH)_2\,(aq) + H_2\,(g) \qquad (1)$$

Specific compounds dried with calcium hydride and analyzed for residual water content include benzene,[2] dioxane,[2] acetonitrile,[2,4] methanol,[5] ethanol,[5] 2-butanol[5] and *t*-butyl alcohol.[5] Benzene is dried to <=0.2 ppm and dioxane to <=50 ppm residual water.[5] Simply stirring acetonitrile over calcium hydride for seven days and distilling leaves 1900 ppm water.[5] A more rigorous drying protocol for acetonitrile has also been reported for electrochemical use.[4] Methanol and ethanol are dried to ~100 ppm residual water content,[5] in conflict with an early recommendation against using this drying agent.[6] Apparently, calcium hydride reacts with water considerably faster than with alcohols, making it an excellent drying agent for these compounds. On the other hand, perhaps the most convenient drying agent for the lower alcohols is 3°A molecular sieves (powdered sieves are best for all but methanol, where beads are best).[5] ***Molecular Sieves*** are as good as calcium hydride for methanol and ethanol, and superior for 2-butanol and *t*-butyl alcohol.[5]

Calcium hydride has also been used as a desiccant, removing water as it is formed in a reaction. For example, the condensation of methylboronic acid to trimethylboroxin (eq 2) proceeds in 58% yield in the presence of calcium

hydride. Note that the reverse reaction is exothermic and quantitative. Other desiccants are not as efficacious.[7] Similarly, calcium hydride removes the water formed in the condensation of methylboronic acid with pinacol (eq 3).[8]

(2)

(3)

Two instances have been reported where calcium hydride has apparently been used as a desiccant for residual water in reagents such as tetrabutylammonium halides. For example, benzylation of an alcohol with ***Potassium Hydroxide***, ***Benzyl Bromide***, calcium hydride, and ***Tetra-n-butylammonium Iodide*** (eq 4) was used in a ganglioside synthesis.[9] Another such example is the S_N2 ring opening of an allylic ether, which required calcium hydride, probably as a desiccant (eq 5).[10]

(4)

(5)

An early report describes calcium hydride as a basic catalyst for the 1,4-addition of 2-nitropropane to benzalacetophenone (eq 6).[11] In this reaction the methanol is essential (no reaction without it), and the order of addition is important (the calcium hydride must be added last).

(6)

Calcium hydride assists in the acylation of alcohols (acting as a base), including tertiary ones, by anhydrides and acid chlorides (eq 7).[12,13]

(7)

The site of methylation of 2-aminoethanol is influenced by the gegenion of the hydride used: ***Sodium Hydride*** affords 96% *O*-methylation while calcium hydride yields exclusive *N*-methylation (eq 8).[14]

(8)

The Sharpless asymmetric epoxidation (SAE) is an extremely valuable technique for the synthesis of epoxy alcohols from allylic alcohols.[15] Although the asymmetric epoxidation gives good yields (76-80%) and high selectivities (&egt;90% ee), it may require a long reaction time. Wang and co-workers studied the effect of additives on the Sharpless epoxidation of (*Z*)-2-tridecen-1-ol.[16] Addition of silica gel alone did not affect the selectivity, the yield, or the reaction time. Addition of calcium hydride shortened the reaction time but decreased the selectivity. Addition of both, however, resulted in a reaction time shortened from 96 h to 8 h, with no loss of selectivity (eq 9). The calcium hydride/silica gel-modified Sharpless reagent has since been studied on a variety of allylic alcohols,[17] and has been used by other groups as well.[18]

Calcium Hypochlorite[1]

$Ca(OCl)_2$

[7778-54-3] · $CaCl_2O_2$ · Calcium Hypochlorite · (MW 142.99)

(oxidizing agent for the conversion of alcohols to aldehydes,[2] ketones,[3] carboxylic acids,[4] esters,[3] and methyl esters;[5] aldehydes to acids[6] and *t*-butyl esters;[5] ethers to esters,[3] and thioethers to sulfoxides;[7] for the C-C bond cleavage of 1,2-dioxygenated compounds;[8] for the chlorination of benzenoid compounds;[1] for the conversion of alkenes to chlorohydrins[9])

Alternate Names: calcium oxychloride; hypochlorous acid, calcium salt; B-K powder.

Physical Data: mp 100 °C; specific gravity 2.35.

Solubility: insol organic solvents; slightly sol H_2O (with decomposition); very sol H_2O with a few drops of HOAc; aqueous solutions of acetic acid, acetonitrile, acetone, MeOH, and *t*-butanol, and biphasic solutions of H_2O with EtOAc, CH_2Cl_2, ether, benzene, and CCl_4 are used for oxidations.

Form Supplied in: white or light yellow granular solid with strong chlorine odor; widely available.

Purification: composition is generally 60-70% $Ca(OCl)_2$ [$Ca(OCl)_2$, 65%; NaCl, 15%; H_2O, 10%; $Ca(OH)_2$, 4%; $CaCO_3$, 3%; $CaClO_3$, 1.5%; $CaCl_2$, 1%].[10]

Handling, Storage, and Precautions: commercially available $Ca(OCl)_2$ (65%) is easy to handle and may be stored in a desiccator without substantial decomposition.[11] Anhydrous $Ca(OCl)_2$ must be stored in a brown bottle kept away from sunlight and moisture. *It explodes when in direct contact with organic material, especially lubrication oils.* This reagent should be handled in a fume hood.

General Conditions of Use.

$Ca(OCl)_2$ is an inexpensive and broad-based reagent for the oxidation of a variety of functional groups.[1-9] Its advantage over ***Sodium Hypochlorite*** (NaOCl) is its relative stability at ambient temperature[11] and its ease of handling as a solid. NaOCl is commercially available in dilute aqueous solutions (usually about 3-5%) that deteriorate rather rapidly. Thus the solution must be frequently titrated to define the quantity of oxidant present. In addition, because of the low concentration of NaOCl in solution an excessive volume of solvent is usually present.[12] The major difficulty encountered with the use of $Ca(OCl)_2$ is that of solubility. It is insoluble in most common organic solvents and forms a

cloudy solution in water. However, complete solubility in water is attained by the addition of a few drops of acetic acid, giving a final oxidizing solution that is clear and light yellow. Aqueous organic biphasic solutions are also useful media in which to carry out the oxidations.

Oxidation of Alcohols, Ethers, Thioethers, and Aldehydes.

$Ca(OCl)_2$ efficiently oxidizes primary alcohols to esters[3] (eq 1), where both the acid and alcohol portion of the ester are derived from the alcohol. In the presence of ***Molecular Sieves*** and with excess MeOH, methyl esters[5] are obtained (eq 2), while with *t*-butanol, carboxylic acids[4] are generated (eq 3). A variety of substituted methyl benzoates are thus easily prepared from the corresponding benzyl alcohols by the former method, and *t*-butyl esters are available from aldehydes.[5] Aldehydes, which are easily oxidized to carboxylic acids[6] with $Ca(OCl)_2$ (eq 4), are themselves available in remarkably high yield from primary alcohols, in less than 15 min, when a catalytic amount of 4-(benzoyloxy)-2,2,6,6-tetramethylpiperidin-1-oxyl is added (eq 5).[2] (***Ruthenium(III) Chloride*** has also been used to catalyze this reaction.[13])

$$\text{RCHO} \xrightarrow[\text{MeCN, } H_2O\text{, AcOH}]{Ca(OCl)_2\text{, 0 °C, 1 h}} \text{RCO}_2\text{H} \qquad (4)$$

R = 3-pentyl	75%
R = *p*-ClC_6H_4	92%
R = *m*-$NO_2C_6H_4$	84%

$$\text{Me}(CH_2)_{10}\text{—}\equiv\text{—}CH_2OH \xrightarrow[\substack{CH_2Cl_2,\ H_2O,\ HCO_3^-,\ \text{cat.} \\ 96\%}]{Ca(OCl)_2\text{, 5 °C, 5 min}} \text{Me}(CH_2)_{10}\text{—}\equiv\text{—CHO} \qquad (5)$$

Secondary alcohols afford ketones[3] in high yield in aqueous media (eq 6), or in organic media (CH_2Cl_2, CCl_4, Et_2O, EtOAc) with a catalytic amount of hypochlorite resin (IRA 900)[14] using a triphasic system (liquid-solid-solid) (eq 7). Acyclic and cyclic ethers give esters (eq 8)[3] and lactones (eq 9),[3] respectively, although the yields are lower than for the oxidation of the other groups. A variety of alkyl and aryl-alkyl thioethers can be selectively oxidized to sulfoxides (eq 10)[7] in yields exceeding 70% however, dibenzyl sulfide is inefficiently converted to dibenzyl sulfoxide (25%).

$$\text{Borneol} \xrightarrow[\substack{\text{MeCN, } H_2O\text{, AcOH} \\ 98\%}]{Ca(OCl)_2\text{, 0 °C, 1 h}} \text{Camphor} \qquad (6)$$

$$\text{Cyclopentanol} \xrightarrow[\substack{CCl_4\text{, IRA 900} \\ 90\%}]{Ca(OCl)_2\text{, rt, 3 h}} \text{Cyclopentanone} \qquad (7)$$

$$(n\text{-Bu})_2\text{O} \xrightarrow[\substack{\text{MeCN, } H_2O\text{, AcOH} \\ 40\%}]{Ca(OCl)_2\text{, rt, 1 h}} \text{Butyl butanoate} \qquad (8)$$

Carbon-Carbon Bond Cleavage Reactions.

α-Diols, α-diones, α-hydroxy ketones, and α-hydroxy and α-keto acids[8] are oxidatively cleaved with $Ca(OCl)_2$ (eqs 11 and 12). The yields are good to excellent and the products obtained (aldehydes, ketones, acids) depend on the oxidation state of the carbon atoms bearing the original oxygen groups. In an interesting two-step high-yield preparation of piperonal, the glycol obtained from electrochemical oxidation of isosafrole is converted to piperonal in near quantitive yield by glycol cleavage[15] when treated with $Ca(OCl)_2$ in benzene/H_2O (eq 13).

Chlorination of Benzenoid Compounds.

As depicted in eq 14, if the glycol of isosafrole is oxidized in $MeCN/CH_2Cl_2/H_2O$ at ambient temperature, ring chlorination[15] takes place instead of C-C bond cleavage to afford 1-[2-chloro-4,5-(methylenedioxy)phenyl]propane-1,2-diol (85%). $Ca(OCl)_2$ can thus be used for chlorination of aromatics (benzene, naphthalene).[1] While chlorobenzene, nitrobenzene, and 4-nitrotoluene do not react, good results are obtained when the substrate has strong electron-donating substituents (eqs 15-17).[1] Activated rings having oxidizable substituents will undergo chlorination and oxidation, depending on the reactivities of the groups and the number of equivalents of $Ca(OCl)_2$ used (eqs 18 and 19).

Conversion of Alkenes to Chlorohydrins.

$Ca(OCl)_2$ converts mono-, di-, tri-, and tetrasubstituted, cyclic, and acyclic alkenes to the corresponding chlorohydrins[9] in good yield (eqs 20-23). The reactions are carried out under mild conditions and the expected regiochemistry is obtained.

[13429-83-9] · $C_{10}H_{14}O_4$ · (-)-(1*S*,4*R*)-Camphanic Acid · (MW 198.22) (1*R*)

[67111-66-4] (±)

[465-48-5]

(enantiomeric purity determination;[2] chemical resolution;[3] chiral auxiliaries[4])

Physical Data: mp 201-204 °C; (1*S*): $[\alpha]_D$ -20.4° (*c* 1.71, dioxane); $[\alpha]_D$ -18° (*c* 1, dioxane).

Solubility: sol EtOH, ether, boiling H_2O, and AcOH.

Form Supplied in: white solid.

Preparative Methods: commercially available. Alternatively, the acid can be prepared in two steps from camphoric acid (1. PCl_5; 2. H_2SO_4; 65% overall yield). The acid can be converted to the corresponding acid chloride upon treatment with ***Thionyl Chloride*** (99% yield).[1,5]

Purification: crystallized from hot toluene.

Handling, Storage, and Precautions: stable; no special precautions.

Analysis of the Enantiomeric Purity of Alcohols and Amines.

It has been shown that camphanic acid is an efficient chiral derivatizing agent for the determination of the enantiomeric purity of alcohols and amines.[2] A typical procedure involves mixing a solution of the amine or the alcohol (in CH_2Cl_2, py, or benzene) with camphanoyl chloride in the presence of a base (Et_3N, py, DMAP, or $NaHCO_3$). Alternatively, the substrate can be coupled directly with camphanic acid in the presence of DCC/DMAP. These conditions, however, can potentially lead to significant kinetic resolution.[6] Camphanic acid was initially developed for the analysis of the enantiomeric purity of α-deuterated primary alcohols[7] and amines.[8] Distinct signals by ^1H NMR for the two diastereomers can usually be observed upon addition of a chiral shift reagent or when using C_6D_6 as the solvent.[9] Since then, this chiral derivatizing agent has been widely used for measuring the enantiomeric excess of several classes of compounds such as α-monodeuterated glycine derivatives (**1**),[10] α-and β-amino acids (**2, 3**),[11,12] α,α-disubstituted α-amino acids (**4**),[13] secondary alcohols (**5**),[14] 1,2-amino alcohols (**6**),[15] and sulfoximines.[16]

[35963-20-3] (±)

[5872-08-2]

(acid catalyst,[1-8] resolving agent,[9,10] chiral auxiliary[11-20])

Physical Data: mp 203-206 °C (dec).

Solubility: sol dichloromethane, methanol, benzene; insol ether.

Form Supplied in: white crystals, racemic (±).

Analysis of Reagent Purity: melting point, NMR.

Preparative Methods: commercially available from several sources; can be prepared by sulfonation of camphor with acetic-sulfuric anhydride.[21]

Purification: recrystallize from ethyl acetate.

Handling, Storage, and Precautions: hygroscopic; corrosive.

Acid Catalyst.

Camphorsulfonic acid (CSA) has been used extensively in synthetic organic chemistry as an acid catalyst. It has particularly been used in protecting group chemistry. For example, hydroxyl groups can also be protected as tetrahydropyranyl (THP) ethers using dihydropyran and a catalytic amount of CSA (eq 1).[1] Both 1,2- and 1,3-diols can be selectively protected by reaction with orthoesters in the presence of camphorsulfonic acid to form the corresponding cyclic orthoester (eq 2).[2] This method of protection is particularly useful in that reduction of the orthoester with ***Diisobutylaluminum Hydride*** forms the monoacetal, which allows for preferential protection of a secondary alcohol in the presence of a primary alcohol. Ketones have also been protected using catalytic CSA (eq 3).[3]

(1)

(2)

(3)

Overman has shown that camphorsulfonic acid can also be used in nucleophile-promoted alkyne-iminium cyclizations.[22] Alkylamines can react with formaldehyde and sodium iodide to yield piperidines in good yield. This methodology has been applied in the total synthesis of pumiliotoxin A (eq 4).[4]

(4)

The most efficient catalyst for intramolecular opening of epoxides is CSA.[5,6] The formation of tetrahydrofurans or tetrahydropyrans is highly dependent on the structure of the hydroxy epoxide. The presence of a saturated chain at the secondary epoxide position leads to formation of tetrahydrofurans (eq 5)[5] via 5-*exo* ring closure, whereas an electron-rich double bond at this position gives tetrahydropyrans (eq 6)[6] via 6-*endo* ring closure. This methodology has also been extended to the synthesis of oxepanes (eq 7).[6]

(5)

(6)

(7)

CSA is also the acid of choice for use in phenylselenation reactions.[7] It has been used as an acid catalyst in hydroxyselenation reactions of alkenes (eq 8)[7] and organoselenium-induced cyclizations (eq 9) using ***N-Phenylselenophthalimide*** (NPSP).[7]

(8)

(9)

CSA has also been used to catalyze spiroacetalizations.[8,22] In Schreiber's approach to the talaromycins he utilized a CSA-catalyzed spiroacetalization (eq 10) and found that the use of different solvents led to varying percentages of isomeric products.[8] Other approaches to the talaromycins also utilize CSA for the required spiroacetalization.[23]

Resolving Agent.

Scalemic CSA has been used to resolve amines by forming diastereomeric salts which can be separated by fractional crystallization (eq 11).[9] In this instance, after obtaining the desired crystalline diastereomeric salt, the undesired diastereomer was completely transformed into the desired one by a resolution-racemization procedure (eq 12).[9] Additionally, racemic ketones can be resolved by forming enantiomeric iminium salts (eq 13).[10] Two different procedures have been devised depending on the ease of enamine formation.

(12)

Chiral Auxiliaries.

Asymmetric Diels-Alder Reactions.

The commercial availability of either enantiomer of camphorsulfonic acid has made it quite useful in asymmetric Diels-Alder reactions. Reaction of the sultone (generated from CSA) with ***Lithium Diisopropylamide*** followed by esterification and β-elimination yields the crystalline acrylate (eq 14).[11] The Lewis acid-catalyzed [4 + 2] cycloaddition of 1,3-dienes with this acrylate affords the corresponding scalemic adduct which can be reduced with ***Lithium Aluminum Hydride*** to yield an enantiomerically pure alcohol (eq 15).[12]

A different approach to the asymmetric Diels-Alder reaction involves the use of the sultam derived from CSA. Lewis acid-promoted reaction with dienes followed by reductive removal of the chiral auxiliary is analogous to that previously discussed for the sultone. Smith has successfully utilized this approach to synthesize the chiral acid used in the synthesis of the immunosuppressant FK-506 (eq 16).[13]

Oxaziridines.

Davis has developed the use of chiral 2-sulfonyloxaziridines derived from camphorsulfonic acid as chiral auxiliaries in the asymmetric oxidation reactions.[24] Although other oxaziridines may be preferable, the camphor-derived oxaziridines can be used for the oxidation of sulfides and disulfides to sulfoxides and thiosulfinates as well as for the epoxidation of alkenes.[24] On the other hand, the camphoryloxaziridines are the preferred reagents for hydroxylation of lithium enolates of esters, amides, and ketones, as utilized in the synthesis of kjellmanianone (eq 17).[14]

Chiral Sulfides.

Optically active sulfides prepared from (+)-CSA can be used to prepare optically active 1,2-diaryloxiranes (eq 18).[15]

Grignard Addition to Enones.

The sultam generated from camphorsulfonic acid can also be used as a chiral auxiliary in the conjugate addition of Grignard reagents to enones. Simple alkylmagnesium chlorides add in a 1,4-fashion to afford imides (eq 19).[16]

Asymmetric Hydrogenation of Camphor-Derived Sultamides.

The sultamide of CSA can be used as a chiral auxiliary for synthesis of β-substituted carboxylic acids (eq 20).[17]

Asymmetric Acetoxylation of Esters.

The silyl enol ether derived from CSA reacts with ***Lead(IV) Acetate*** to yield the α-acetoxy ester with good diastereoselectivity. Hydrolysis of the chiral auxiliary gives the α-hydroxy acid, whereas reduction affords the terminal α-glycol (eq 21).[18]

(21)

Allylation of Aldehydes.

Synthesis of enantiomerically pure allyl alcohols can be accomplished by catalytic asymmetric addition of divinylzinc to aldehydes using a camphorsulfonic acid-derived catalyst (eq 22).[19]

(22)

Synthesis of Epoxides from Chiral Chlorohydrins.

Asymmetric halogenation of CSA-derived esters allows for the formation of enantiomerically pure halohydrins and terminal epoxides (eq 23).[20]

(enantiomeric excess determination;[2] chemical resolution;[3] synthesis of chiral auxiliaries;[4] chiral precursor for natural product synthesis;[1] synthesis of chiral reagents[5])

Physical Data: mp 65-67 °C; (1*S*)-(+): $[\alpha]_D$ + 32.1° (*c* 1, $CHCl_3$).

Solubility: sol CH_2Cl_2; slightly sol ether; insol H_2O.

Form Supplied in: both enantiomers and the racemic sulfonyl chloride are commercially available.

Preparative Methods: can be prepared from ***10-Camphorsulfonic Acid*** upon treatment with ***Phosphorus(V) Chloride*** or ***Thionyl Chloride***.[6]

Purification: crystallized from hexane or from MeOH.

Handling, Storage, and Precautions: corrosive and moisture-sensitive. This reagent should be handled in a fume hood.

Reagent for Determination of Enantiomeric Excesses and for Chemical Resolution of Alcohols and Amines.

10-Camphorsulfonyl chloride has been widely used as a chiral derivatizing agent for the assay of enantiomeric purity of alcohols and amines by NMR techniques.[2] A typical procedure for the preparation of the sulfonate ester or sulfonamide involves mixing a solution of the alcohol or amine in CH_2Cl_2 with camphorsulfonyl chloride in the presence of an amine base (Et_3N, py, or DMAP). This reagent has been particularly valuable for determining the enantiomeric purity of secondary alcohols (**1, 2**) and β-hydroxy esters (**3**).[7]

(1)

(2)

(3)

In some cases (**3**), the addition of a chiral shift reagent ($Eu(hfc)_3$) is necessary to obtain baseline separation of the signals corresponding to the β-proton of both diastereomers by ^1H NMR. Diastereomeric mixtures derived from secondary alcohols have also been analyzed by HPLC.[8] The resolution of a secondary alcohol (**4**) could be achieved by a selective crystallization of one of the two diastereomeric camphorsulfonate esters.[3]

(4)

The enantiomeric purities of primary and secondary amines have also been established by ^{1}H NMR spectroscopy by their conversion into the corresponding sulfonamide. These derivatives often produce crystalline compounds that are suitable for X-ray crystallographic studies. For example, the enantiomeric purities of amines (**5**),[9] (**6**),[10] and (**7**)[11] were determined by ^{1}H NMR spectroscopy and the absolute stereochemistry of (**7**) was unequivocally established by X-ray crystallography.

(5)

(7)

(6) Ar = 3,4-$(OMe)_2C_6H_3$

A general protocol for the HPLC separation of diastereomeric camphorsulfonamides[12] derived from racemic α-amino acids has been developed (eq 1).[13] More complex amino acids, such as (**8**), were successfully analyzed by this procedure.[14]

(8)

Synthesis of Chiral Auxiliaries.

Their availability and crystalline nature has made camphor derivatives the precursors of choice for the design and synthesis of chiral auxiliaries.[4] 10-Camphorsulfonyl chloride is the starting material for the synthesis of chiral auxiliaries (**9**)-(**12**) (eq 2). Sulfonamides (**9**) and (**10**)[15] have been used as chiral auxiliaries in a number of reactions, e.g. the Lewis acid-catalyzed Diels-Alder reaction, the [3 + 2] cycloaddition of a nitrile oxide to an acrylate, and the stereoselective conjugate addition reaction of organocopper reagents to α,β-unsaturated esters.[4]

In addition to being an efficient chiral controller in a number of stereoselective transformations of chiral acrylates, (i.e. the Diels-Alder reaction,[4] the conjugate reduction,[16] the asymmetric dihydroxylation,[17] and the nitrile oxide cycloaddition[18]) the bornanesultam (**11**)[19] has been shown to be an exceptionally efficient chiral auxiliary for stereoselective aldol condensations (eqs 3 and 4). Depending upon the reaction conditions, *N*-propionylsultam can produce either the *syn* or *anti* aldol product with an excellent diastereoselectivity.[20] Furthermore, good diastereoselectivities are also observed for the corresponding acetate aldol reaction (eq 5).[21]

Oxathiane (**12**) has been shown to be an efficient chiral auxiliary in the nucleophilic addition to carbonyl compounds.[22]

10-Camphorsulfonyl chloride has also been widely used as a useful precursor to chiral dienophiles in hetero-Diels-Alder reactions.[23]

An elegant use of the chirality and the leaving group ability of the camphorsulfonate ester has been reported in the synthesis of a chiral C_2 symmetric cyclopentadienyl ligand (eq 6).[24]

(6)

Synthesis of Chiral Reagents.

An efficient chiral α-chloro-α-nitroso reagent derived from 10-camphorsulfonyl chloride (1. Cy_2NH; 2. NH_2OH; 3. *t*-BuOCl; 70-78%) has been developed for the asymmetric α-amination of ketone enolates (eq 7).[25] The resulting β-keto *N*-hydroxylamine can be converted to the *anti*-1,2-hydroxyamine under reducing conditions ($NaBH_4$; Zn, HCl, AcOH).

(7)

Several oxaziridines related to (**14**)[5] (eq 8) have been used, most notably in the enantioselective oxidation of sulfides to sulfoxides,[26] of selenides to selenoxides,[27] and of alkenes to oxiranes.[28] It is also the reagent of choice for the hydroxylation of lithium and Grignard reagents[29] and for the asymmetric oxidation of enolates to give α-hydroxy carbonyl compounds.[5,30] A similar chiral fluorinating reagent has also been developed.[31]

(8)

(14)

Chiral Precursor for Natural Product Synthesis.

10-Camphorsulfonyl chloride has been used as a chiral starting material for the synthesis of a number of products[1] such as ketopinic acid[32] (eq 9), which has been used to resolve alcohols[33] and hemiacetals.[34]

(Camphorylsulfonyl)oxaziridine[1]

(+)-(**1**)

[104322-63-6] · $C_{10}H_{15}NO_3S$ · (Camphorylsulfonyl)oxaziridine · (MW 229.30) (-)-(**1**)

[104372-31-8]

(neutral, aprotic, electrophilic, and asymmetric oxidizing agents for the chemoselective oxidation of many nucleophilic substrates such as sulfides, enamines, enol esters, carbanions, and enolates[1])

Physical Data: (+)-(**1**): mp 165-167 °C, $[\alpha]_D$ +44.6° ($CHCl_3$, *c* 2.2); (-)-(**1**): mp 166-167 °C, $[\alpha]_D$ -43.6° ($CHCl_3$, *c* 2.2).

Solubility: sol THF, CH_2Cl_2, $CHCl_3$; slightly sol isopropanol, ethanol; insol hexane, pentane, water.

Form Supplied in: commercially available as a white solid.

Analysis of Reagent Purity: by mp and specific rotation determination.

Preparative Methods: the enantiopure (+)- and (-)-(camphorylsulfonyl)oxaziridines (**1**) and [(8,8-dichlorocamphor)sulfonyl]oxaziridines (**2**) are commercially available. They can also be prepared on a large scale via the oxidation of corresponding camphorsulfonimines with buffered ***Potassium Monoperoxysulfate*** (Oxone)[2] or buffered peracetic acid.[3] Since oxidation takes place from the *endo* face of the C=N double bond, only a single oxaziridine isomer is obtained. The precursor camphorsulfonimines can be prepared in 3 steps (>80% yield) from inexpensive (+)- and (-)-***10-Camphorsulfonic Acid***s. A variety of (camphorylsulfonyl)oxaziridine derivatives such as (**2**)-(**4**) are also readily available via the functionalization of the camphorsulfonimines followed by oxidation.[1,2-6]

Purification: by recrystallization.

Handling, Storage, and Precautions: indefinitely stable to storage at room temperature and to exposure to air.

Asymmetric Oxidation of Sulfides.

Prochiral sulfides are oxidized by (camphorylsulfonyl)oxaziridine (**1**) to optically active sulfoxides. Over-oxidation to sulfones is not observed (eq 1).[7] However, the best chiral *N*-sulfonyloxaziridines for the asymmetric oxidation of sulfides to sulfoxides are the (+)- and (-)-***N-(Phenylsulfonyl)(3,3-dichlorocamphoryl)oxaziridine***s.[8]

(1)

Oxidation of Enamines.

Enamines are rapidly oxidized by (+)-(camphorylsulfonyl)oxaziridine (**1**). Disubstituted enamines give rise to racemic α-amino ketones, while trisubstituted enamines afford, after hydrolysis, α-hydroxy ketones (eq 2).[9] A mechanism involving initial oxidation of the enamine to an α-amino epoxide is suggested to account for these products.

Oxidation of Oxaphospholenes.

Reaction of oxaphospholene (**5**) with (+)-[(8,8-dichlorocamphoryl)sulfonyl]oxaziridine (**2**) affords β-hydroxy-γ-keto-phosphonate in 49% ee with undetermined absolute configuration (eq 3).[10] Higher temperatures accelerate the reaction but lower the stereoselectivity.

Oxidation of Organolithium and Organomagnesium Compounds.

Oxidation of phenylmagnesium bromide and phenyllithium with ***(±)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine*** or (camphorylsulfonyl)oxaziridine (**1**) gives phenol (eq 4).[11] Products are cleaner with the latter reagent because addition of the organometallic reagent to the C=N double bond of the imine is not observed. Oxidation of (*E*)- and (*Z*)-vinyllithium reagents with (+)-(**1**) affords enolates. The reaction is fast and represents useful methodology for the stereo- and regioselective formation of enolates.[12] While the enolates can be trapped with ***Chlorotrimethylsilane*** to give silyl enol ethers, better yields and higher stereoselectivity are obtained with ***Bis(trimethylsilyl) Peroxide*** (eq 5).[12]

Oxidation of Phosphoranes.

Monosubstituted phosphoranes (ylides) are rapidly oxidized to *trans*-alkenes by (+)-(**1**), while disubstituted phosphoranes give ketones (eq 6). A mechanism involving initial attack of the carbanion of phosphorane to the electrophilic oxaziridine oxygen atom of (+)-(**1**) is proposed.[13]

Asymmetric α-Hydroxylation of Enolates.

α-Hydroxylation of enolates represents one of the simplest and most direct methods for the synthesis of α-hydroxy carbonyl compounds, a key structural unit found in many natural products.[1b] Enolate oxidations using (+)- and (-)-(**1**) and their derivatives generally effect this transformation in good to excellent yields with a minimum of side reactions (e.g. over-oxidation). Furthermore, these reagents are the only aprotic oxidants developed to date for the direct asymmetric hydroxylation of prochiral enolates to optically active α-hydroxy carbonyl compounds.

By choice of the appropriate reaction conditions and (camphorylsulfonyl)oxaziridine derivative, acyclic α-hydroxy ketones of high enantiomeric purity have been prepared.[1] An example is the oxidation of the sodium enolate of deoxybenzoin with (+)-(**1**). The reaction proceeds very fast at -78 °C, affording (+)-(*S*)-benzoin in 95% ee. Both benzoin enantiomers are readily available by choice of (+)- or (-)-(**1**), because the configuration of the oxaziridine controls the absolute stereochemistry of the product (eq 7).[14] Detailed studies have indicated that the generation of a single enolate regioisomer is a pre-condition for high enantioselectivity, although this does not necessarily always translate into high ee's. Hydroxylation of tertiary substituted acyclic ketone enolates usually gives lower stereoselectivities due to the formation of (*E*/*Z*) enolate mixtures (eq 8).[14] In addition to enolate geometry, the molecular recognition depends on the structure of the oxidant, the type of enolate, and the reaction conditions.[1b] Generally the stereoselectivity can be predicted by assuming that the oxaziridine approaches the enolate from the least sterically hindered direction.

(7)

(8)

The asymmetric hydroxylation of cyclic ketone enolates, particularly the tetralone and 4-chromanone systems, has been studied in detail because the corresponding α-hydroxy carbonyl compounds are found in many natural products.[1b] Some general trends have been observed. 2-Substituted 1-tetralones having a variety of groups at C-2 (Me, Et, Bn) are best oxidized by chlorooxaziridine (**2**) in >90% ee (eq 9).[2c,15,16] However, substitution of a methoxy group into the 8-position lowers the stereoselectivity. For the 8-methoxytetralones, (8,8-dimethoxycamphorylsulfonyl)oxaziridine (**3**) is the reagent of choice. Similar trends have also been observed in 4-chromanones.[1b] Oxidation of the lithium enolate of (**6**) with (8,8-methoxycamphorsulfonyl)oxaziridine (**3**) affords 5,7-dimethyleucomol (**7**) in &egt;96% ee (eq 10).[17] Hydroxylation of the enolate of 1-methyl-2-tetralone (**8**) to (**9**) gives poor to moderate stereoselectivities. The optimum result, 76% ee, is obtained using the sodium enolate and oxaziridine (+)-(**1**) (eq 11).[15]

(9)

It should be pointed out that enolates are oxidized by the (camphorylsulfonyl)oxaziridine at a much faster rate than sulfides. An example is the preparation of α-hydroxy ketone sulfide (**9**), an intermediate for the total synthesis of (±)-breynolide (eq 12).[18]

The asymmetric hydroxylation of ester enolates with *N*-sulfonyloxaziridines has been less fully studied.[1b] Stereoselectivities are generally modest and less is known about the factors influencing the molecular recognition. For example, (*R*)-methyl 2-hydroxy-3-phenylpropionate (**10**) is prepared in 85.5% ee by oxidizing the lithium enolate of methyl 3-phenylpropionate with (+)-(**1**) in the presence of HMPA (eq 13).[19] Like esters, the hydroxylation of prochiral amide enolates with *N*-sulfonyloxaziridines affords the corresponding enantiomerically enriched α-hydroxy amides. Thus treatment of amide (**11**) with LDA followed by addition of (+)-(**1**) produces α-hydroxy amide (**12**) in 60% ee (eq 14).[19] Improved stereoselectivities were achieved using double stereodifferentiation, e.g. the asymmetric oxidation of a chiral enolate. For example, oxidation of the lithium enolate of (**13**) with (-)-(**1**) (the matched pair) affords the α-hydroxy amide in 88-91% de (eq 15).[20] (+)-(Camphorsulfonyl)oxaziridine (**1**) mediated hydroxylation of the enolate dianion of (*R*)-(**14**) at -100 to -78 °C in the presence of 1.6 equiv of LiCl gave an 86:14 mixture of *syn*/*anti*-(**15**) (eq 16).[21] The *syn* product is an intermediate for the C-13 side chain of taxol.

(14)

(11) (12)

(15)

(13)

(*R*)-(**14**)

(16)

syn-(**15**) 85:15 *anti*-(**15**)

Hydroxylation of the sodium enolate of lactone (**16**) with (+)-(**1**) gives α-hydroxy lactone in 77% ee (eq 17).[15] Kinetic resolution and asymmetric hydroxylation with (camphorsulfonyl)oxaziridines has been applied to the synthesis of enantiomerically enriched α-hydroxy carbonyl compounds having multiple stereocenters, which may otherwise be difficult to prepare.[22] Thus hydroxylation of the enolate of racemic 3-methylvalerolactone with substoichiometric amounts of (-)-(**1**) affords (2*S*,3*R*)-verrucarinolactone in 60% ee (eq 18) which on recrystallization is obtained enantiomerically pure.[22]

(17)

(18)

Oxidation of the dienolate of (**17**) with (+)-(**1**) affords α-hydroxy ester (**18**), a key intermediate in the enantioselective synthesis of the antibiotic echinosporin (eq 19),[23] whereas oxidation of enolates derived from 1,3-dioxin vinylogous ester (**19**) gives rise to both α´- and γ-hydroxylation depending on the reaction conditions (eq 20).[24] With (+)-(**1**) the lithium enolate of (**19**) gives primarily the α´-hydroxylation product (**20**), while the sodium enolate gives γ-hydroxylation product (**21**). Only low levels of asymmetric induction (ca. 16% ee) are found in these oxidations. Birch reduction products are also asymmetrically hydroxylated in situ by (+)-(**1**) (eq 21).[25]

(19)

Few reagents are available for the hydroxylation of stabilized enolates such as β-keto esters, e.g. Vedejs' MoOPH reagent (***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)***) fails.[26] On the other hand, oxaziridines hydroxylate such enolates in good yield with good to excellent stereoselectivities.[1b] For example, enantioselective hydroxylation of the potassium enolate of the β-keto ester (**22**) with methoxyoxaziridine (-)-(**3**) affords (*R*)-(+)-2-acetyl-5,8-dimethoxy-1,2,3,4-tetrahydro-2-naphthol (**23**), a key intermediate in the asymmetric synthesis of the anthracycline antitumor agents demethoxyadriamycin and 4-demethoxydaunomycin (eq 22).[27] Hydroxylation of the sodium enolate of enone ester (**24**) furnishes kjellmanianone (**25**), an antibacterial agent isolated from marine algae (eq 23).[5] With (+)-(**1**) the ee's are modest (ca 40%), but improved to 69% ee with benzyloxaziridine (**4**).

10,2-Camphorsultam[1]

(-)-D-(2*R*)

[94594-90-8] · $C_{10}H_{17}NO_2S$ · 10,2-Camphorsultam · (MW 215.31) (+)-L-(2*S*)

[108448-77-7]

(versatile chiral auxiliary: *N*-enoyl derivatives undergo highly stereoselective [2 + 4] Diels-Alder[2] and [2 + 3][3] cycloadditions, cyclopropanations,[4] aziridinations,[5] dihydroxylations,[6] hydrogenations,[7] azido-iodinations[8] and conjugate hydride,[9] Grignard,[10] cuprate,[11] allylsilane[12] and thiolate[13] additions; radical additions[14] and S_N2' reactions[15] at the α-position also occur stereoselectively; enolates of *N*-acyl derivatives participate in highly stereoselective aldolizations,[16] alkylations,[17] halogenations, and aminations, the latter three types of reactivity being useful for α-amino acid preparation;[18] free radicals generated at the α-position of *N*-acyl derivatives participate in stereoselective intra- and intermolecular addition reactions;[19] the *N*-fluoro derivative functions as an enantioselective, electrophilic fluorinating reagent[20])

Alternate Name: bornane-10,2-sultam.

Physical Data: mp 183-185 °C (EtOH). (-)-D-(2*R*) enantiomer: $[\alpha]_D^{20}$ -31±1° ($CHCl_3$, *c* 2.3). (+)-L-(2*S*) enantiomer: $[\alpha]_D^{20}$ +34±1° (EtOH, *c* 1.00).

Form Supplied in: white crystalline solid; both enantiomers are commercially available (~same price) or may be readily prepared (3 steps, >70% overall yield) from ***10-Camphorsulfonic Acid***.[21]

Handling, Storage, and Precautions: stable indefinitely at ambient temperature in a sealed container; mild irritant.

Introduction.

Exploitation of chiral auxiliary controlled face discrimination in the reaction of a reactant with a prochiral molecule or functional group is a powerful strategy in asymmetric synthesis.[22] Clearly the choice of auxiliary for a desired chemical transformation is crucial for optimal synthetic efficiency. Hence, the ease with which the auxiliary can be introduced, the extent of stereoselection it imparts to the desired transformation, and the ease of its nondestructive removal are of critical importance. The 10,2-camphorsultam not only meets these criteria for a range of transformations, but also generally imparts crystallinity to all derived intermediates, thereby facilitating purification and isolation of enantiomerically pure products. Indeed, 10,2-camphorsultam derivatization alone allows for facile crystallographic determination of absolute configuration.[23]

Preparation of Derivatives.

N-Acyl- and *N*-enoylsultam derivatives are routinely prepared in good yields using either sodium hydride-acid chloride[16a] or trimethylaluminum-methyl ester[18g] single-step protocols. A variant of the former method employing in situ stabilization of labile enoyl chlorides with CuCl/Cu has also been reported.[3k] A two-step procedure via the *N*-TMS derivative (**1**) is useful when a nonaqueous work-up is desirable and for synthesis of the *N*-acryloyl derivative.[24] *N*-Enoyl derivatives may also be prepared via the phosphonate derivative (**2**) by means of an Horner-Wadsworth-Emmons reaction (eq 1).[2c,2d]

An *N*-acyl-β-keto derivative has been prepared by reaction with a diketene equivalent[17b] and the *trans*-N-cinnamoyl derivative by a Heck type coupling reaction.[4] The *N*-fluoro derivative (**3**) is prepared by direct fluorination (eq 2).[20]

Reactions of *N*-Enoyl Derivatives.

[4 + 2] Diels-Alder Cycloadditions (Alkene -> Six-Membered Cycloadduct).[2]

N-Enoylsultam derivatives were originally devised as activated chiral dienophiles for stereoselective Diels-Alder reactions.[1,2a]

Thermal reactions of *N*-enoylsultams generally show only moderate *endo* and π-face selectivity, e.g. *N*-acryloyl- and *N*-crotonoyl-10,2-camphorsultams (**4**) and (**6**) with cyclopentadiene (eq 3, Table 1).[2g] The thermal hetero-Diels-Alder reaction of *N*-glyoxaloyl-10,2-camphorsultam with 1-methoxybuta-1,3-diene also proceeds with moderate *exo* and π-face selectivity (57% *exo*, 46% de).[2h] Thermal hetero-Diels-Alder reactions of *N*-acylnitroso-10,2-camphorsultam with cyclopentadiene and 1,3-cyclohexadiene, however, proceed with excellent selectivity (>98% ee, π-face selectivity not established).[2i]

Table 1 Intermolecular Diels Alder Reactions of *N*-Enoylsultams (**4**)/(**5**) ® (**6**) and (**4**) ® (**7**)

Dienophile	Diene	Lewis acid[a]	Temp (°C)/time (h)	Adduct	Yield crude (cryst)[b] (%)	de crude (cryst) (%)
(**4**)	Cyclopentadiene	None	21 (72)	(**6**) R^1 = H	80[c]	66
(**5**)	Cyclopentadiene	None	21 (96)	(**6**) R^1 = Me	51[d]	52
(**4**)	Cyclopentadiene	$EtAlCl_2$	- 130 (6)[e]	(**6**) R^1 = H	96 (83)	95 (99)
(**5**)	Cyclopentadiene	$TiCl_4$	- 78 (1)	(**6**) R^1 = Me	98 (83)	93 (99)
(**4**)	1,3-Butadiene	$EtAlCl_2$	- 78 (18)	(**7**) R^2 = H	93 (81)	94 (99)
(**4**)	Isoprene	$EtAlCl_2$	- 94 (18)	(**7**) R^2 = Me	88 (68)	94 (99)

[a] $EtAlCl_2$ (1.5 equiv), $TiCl_4$ (0.5 equiv). [b] >98% *endo*. [c] 89% *endo*. [d] 79% *endo*. [e] EtCl as solvent.

Lewis acid-mediated reactions of *N*-enoylsultams, on the other hand, occur under very mild conditions and with high levels of *endo* and π-face selectivity (eq 3, Table 1).[2b,2g] Dicoordinate $TiCl_4$, $EtAlCl_2$, and Me_2AlCl are particularly effective and their role in the stereodifferentiating process, which results in almost exclusive C(α)-*re* face dienophile attack, has been rationalized.[2g] Both inter- and intramolecular reactions proceed well even on a preparative scale (e.g. >100 g), often requiring just a single recrystallization to furnish isomerically pure products, valuable as synthetic intermediates (eq 4, the key step in a synthesis of (-)-pulo'upone).[2d] The hetero-Diels-Alder reaction of *N*-glyoxaloyl-10,2-camphorsultam with 1-methoxybuta-1,3-diene also proceeds efficiently and with high *endo* and π-face selectivity in the presence of 2% $Eu(fod)_3$ (90% *endo*, 88% de).[2h] These levels of asymmetric induction compare very favorably with those obtained using alternative auxiliaries (see Related Reagents below) for most substrates.

[3 + 2] Cycloadditions (Alkene -> Five-Membered Cycloadduct).[3]

The levels of selectivity found for 1,3-dipolar cycloaddition reactions are not as high as those obtained for Lewis acid-catalyzed Diels-Alder reactions. However, the 10,2-camphorsultam auxiliary can achieve synthetically useful levels of induction in these reactions, and this has been attributed to efficient enoyl conformational control by the sultam moiety leading to preferred C(α)-*re* face attack even in the absence of metal complexation.[1d]

The reactions of *N*-enoyl-10,2-camphorsultams with various nitrile oxides to give isoxazolines have been well studied.[3a-c] Indeed, the high regioselectivity and high π-face selectivity (62-90% de)[3a] observed in reactions with the *N*-acryloyl compound (**4**) have been exploited in synthesis (eq 5, the key step in a synthesis of (+)-hepialone[3b]), although related toluene-2,α-sultam auxiliaries provide still higher selectivity (see α-***Methyltoluene-2,α-sultam***). Isoxazolines may also be obtained by regioselective and similarly π-face selective cycloadditions of silyl nitronates followed by acid catalyzed elimination of TMS alcohol[3d-f] (eq 6, the key step in a synthesis of (+)-methylnonactate).[3f] A cyclic, photochemically generated azomethine ylide also participates in *exo* and π-face selective 1,3-dipolar cycloaddition with (*ent*-**4**), a reaction for which alternative auxiliaries were significantly less effective (eq 7, the key step in a synthesis of (-)-quinocarcin).[3g-i]

Nickel catalyzed [3 + 2] cycloadditions of methylenecyclopropane and 2,2-dimethylmethylenecyclopropane with (**4**) afford 3-methylenecyclopentane derivatives with extremely high π-face selectivities (91% and 98% de respectively); five alternative auxiliaries were found to be less effective.[3j,3k] Palladium catalyzed [3 + 2] cycloaddition of 2-(TMS-methyl)-3-acetoxy-1-propene with an *N*-enoylsultam, however, proceeds with disappointing selectivity (4-26% de).[3l] A norephedrine derived auxiliary ((4*R*,5*S*)-4-methyl-5-phenyl-2-oxazolidinone) was similarly ineffective in this instance.[3l]

Cyclopropanation and Aziridination (Alkene -> Three-Membered Cycloadduct).[4,5]

Cyclopropanation of various *trans*-*N*-enoyl derivatives using diazomethane with $Pd(OAc)_2$ as catalyst affords cyclopropyl products with good C(α)-*re* π-facial control (eq 8).[4] Similarly, aziridination with *N*-aminophthalimide-lead tetraacetate affords *N*-phthalimidoaziridines with variable but generally good π-face selectivity (33-95% de).[5]

Dihydroxylation, Azido-Iodination and Hydrogenation (Alkene -> α,β-Addition Product).[6-8]

syn-Dihydroxylation of β-substituted *N*-enoylsultams using *N*-methylmorpholine with a catalytic amount of OsO_4 affords vicinal diol products with good C(α)-*re* π-facial selectivity (80-90% de) (eq 9, the key step in a synthesis of (+)-LLP 880β).[6a] Similar levels of selectivity but lower chemical yields are obtained using $KMnO_4$ and *N*-dienoylsultams.[6b] Regioselective but poorly stereoselective *trans* addition of iodine azide to *N*-crotonoyl- and *N*-cinnamoyl-10,2-camphorsultams has also been reported (34% and 47% de, respectively). The sense of addition corresponds to iodonium ion formation from the C(α)-*re* face followed by S_N2 attack of azide at the β-position.[8] Heterogeneous *syn* hydrogenation of β,β-disubstituted enoylsultams over Pd/C using gaseous hydrogen (100 psi) affords reduced products, again with excellent C(α)-*re* topicity (90-96% de).[7]

1,4-Hydride, Grignard, Cuprate, Allylsilane, and Thiolate Addition (Alkene -> β- or α,β-Functionalized Product).[9-13]

β,β-Disubstituted enoylsultams undergo efficient reduction with L-Selectride®.[9a] The *syn* hydrogenated products obtained result from conjugate hydride delivery (and protonation) on the opposite π-face [i.e. C(α)-*si*] to that from hydrogenation (90-94% de) (eq 10).[9b] Similarly, simple alkylmagnesium chlorides also undergo 1,4-addition-protonation with *trans*-β-substituted enoylsultams from this face (72-89% de).[10] Use of α-substituted *N*-enoyl substrates,[9a] or trapping of the intermediate aluminum or magnesium enolates with other electrophiles, allows creation of two asymmetric centers in one synthetic operation.[9a,10] The observed topicity is that of *syn* addition from the C(α)-*si* face. As PBu_3 stabilized alkylcopper reagents,[11a,11b] Grignard reagents (in the presence of copper salts),[11c] and cuprates (Gilman reagents)[11d] participate in analogous reactions but show reversed π-face selectivity, an appropriate 1,4-addition-trapping protocol can be devised to generate products with any desired configuration at both the α- and β-positions (eq 11).[11c] This complementarity has been rationalized.[11] Phosphine stabilized alkyl- and alkenylcopper reagents also add to *N*-(β-silylenoyl)sultams (giving aldols after C-Si oxidative bond cleavage). In this case, either π-face selectivity can be achieved, depending on the promoting Lewis acid employed.[11b] Similar Lewis acid dependent selectivity is observed for addition of allyltrimethylsilane to *N*-enoylsultams.[12]

Stereoselective *anti* addition of thiophenol to *N*-[β-(*n*-butyl)methacryloyl]-10,2-camphorsultam [the key step in a synthesis of (+)-*trans* whiskey lactone] has been explained by a sulfur-induced, stereoelectronically directed protonation following C(β)-*re* face conjugate addition.[13]

Radical Addition and S_N2' Displacement (Alkene -> α-Functionalized Product).[14,15]

Stereoselective radical additions to *N*-enoylsultams occur at the α-position, while additions to the β-position are essentially nonselective.[1d,14] The S_N2' displacement of γ-bromo-*N*-enoylsultams with higher order cyanocuprates occurs with good π-face selectivity (90-96% de).[15]

Reactions of *N*-Acyl Derivatives.

Aldolization (Acyl Species -> β-Hydroxyacyl Product).[16]

Chiral oxazolidin-2-ones and 10,2-camphorsultams presently represent state of the art aldol reaction mediators. Both auxiliaries have similarly high π-facial preferences (totally overwhelming any modest facial preference of most chiral aldehydes), allowing the predictable formation of essentially one (of four possible) diastereomeric aldol type products by judicious choice of auxiliary antipode and reaction conditions.[16a] Although sultam mediated aldolizations generally require a 2-3 fold excess of aldehyde to go to completion (cf. 1-2 equiv when oxazolidin-2-one mediated), which is clearly wasteful when employing a valuable aldehyde, the superior crystallinity and cleavage properties of the sultam adducts makes the choice of auxiliary for a given aldolization dependent on the specific substrate.

syn-Aldols with (*R*) configuration at the α-position are obtained from boryl enolates of (-)-10,2-camphorsultam derivatives (**8**) on condensation with aldehydes.[16b] The observed topicity is consistent with C(α)-*si*/C=O-*re* interaction of the nonchelated (*Z*)-enolate and the aldehyde.[16b] *syn*-Aldols with (*S*) configuration at the α-position are obtained from lithium (BuLi-THF) or better tin(IV) enolates of the same derivatives (**8**), and this outcome is consistent with C(α)-*re*/C=O-*si* interaction of the chelated (*Z*)-enolate and the aldehyde.[16b] *anti*-Aldols with (*S*) configuration at the α-position are obtained from in situ prepared *O*-silyl-*N*,*O*-ketene acetals of sultams (**8**) on condensation with aldehydes in the presence of $TiCl_4$[16c] (Mukaiyama aldolization). This topicity arises from C(α)-*re*/C=O-*re* interaction of the *(Z)-N,O*-ketene acetal and the Lewis acid coordinated aldehyde (eq 12).[16c] These same *anti*-aldols can also be obtained from sultams (**8**) with similarly excellent stereocontrol using boryl enolates in the presence of $TiCl_4$, and this unique procedure is the method of choice when using crotonaldehyde or methacrolein.[16d] *anti*-Aldols with (*R*) configuration at the α-position should be obtained from sultams (*ent*-**8**) using the above Mukaiyama conditions. Enantiocontrolled synthesis of α-unsubstituted β-hydroxy carbonyl compounds from the *N*-acetyl derivative is best accomplished using the Mukaiyama conditions (58-93% de).[16e] The synthesis of beetle sex pheromone (-)-serricorole serves to highlight the power of the above methods.[16f,16g]

Alkylation (Acyl Species -> α-Alkylated Acyl Product).[17]

An efficient procedure for the C(α)-*re* alkylation of lithium and sodium enolates of *N*-acylsultams with various (even nonactivated) primary halides in the presence of HMPA has been developed (88.7-99% de).[17a] Alkylation with $ClCH_2NMeCO_2Bn$ enables a two-step β-lactam synthesis.[1c,17a] Michael-type alkylation of a β-keto derivative with arylidenemalononitriles in toluene containing piperidine has been reported to give 4*H*-pyrans (60-70% de).[17b]

α-Amino Acid Preparation.[18]

Three distinct strategies for the asymmetric preparation of α-amino acids using the 10,2-camphorsultam auxiliary have been developed. The first is a glycine anion strategy[18a] centered on alkylation, with excellent C(α)-*si* π-face stereocontrol, of lithium enolates of sultam derivative (**9a**) [mp 107-109 °C (EtOH)][18b,18c] to give adducts (**10**) (eq 13). α-Amino acids are obtained simply by Schiff base hydrolysis (0.5N HCl, rt) and auxiliary cleavage (LiOH, aq THF). Compound (**9b**) has also been reported to participate in analogous chemistry,[18d] but it is not crystalline and its derivatives require more vigorous hydrolysis. Commercially available (**9a**) is thus the preferred reagent, comparing favorably with other glycine anion synthetic equivalents (see ***4-t-Butoxycarbonyl-5,6-diphenyl-2,3,5,6-tetrahydro-4H-oxazin-2-one***). Promising preliminary results of deprotonation-alkylation of (**9a**) under phase transfer catalysis have also been disclosed.[1c,18c,18j]

The second strategy involves a bromination-azide displacement-hydrogenolysis protocol. Treatment of boryl enolates of *N*-acylsultams (**8**) with NBS provides the key α-bromo derivatives (**11**) with good C(α)-*re* topicity (eq 14).[1c,18b] Stereospecific substitution with tetramethylguanidinium azide [$(Me_2N)_2C{=}NH_2^+N_3^-$], hydrogenolysis (H_2-Pd/C), and auxiliary cleavage provides α-amino acids in good overall yield.[1c,18b] As with the previous strategy, given that an appropriate derivative is crystallized to enantiomeric homogeneity, the enantiomeric purity of the product will reflect the extent of racemization during auxiliary hydrolysis (e.g. phenylglycine: 90.3% ee, isoleucine: >99% ee).[1c] This problem can be circumvented by the use of nonbasic Ti(O-*i*-Pr)$_4$ assisted transesterification with allyl alcohol then rhodium-catalyzed deprotection. This allows for the preparation of either free or *N*-Fmoc α-amino acids of excellent enantiomeric purity.[18e]

The third strategy involves electrophilic amination of sodium enolates of *N*-acylsultams (**8**) using ***1-Chloro-1-nitrosocyclohexane*** as an [NH_2^+] equivalent.[18f-i] The reaction proceeds via nitrone intermediates which are routinely hydrolyzed without isolation to give the key α-*N*-hydroxyamino derivatives (**13**) with outstanding C(α)-*re* π-facial control (eq 15). Nitrogen-oxygen bond hydrogenolysis (Zn, aq HCl, AcOH), then auxiliary cleavage, affords α-amino acids.[18f,18g] Omission of the hydrogenolysis step allows access to *N*-hydroxy-α-amino acids, which are extremely difficult to prepare by alternative means.[18f] The scope of the reaction has been extended to encompass the use of 1-chloro-1-nitrosocyclohexane as an electrophilic partner in conjugate addition-trapping reactions [allowing an expedient preparation of (2*S*,3*S*)-isoleucine],[18f,18g] *N*-alkyl-α-amino acid preparation,[18h] and homochiral α-substituted cyclic nitrone formation [giving a concise preparation of the piperidine alkaloid (-)-pinidine].[18i]

α-Radical Addition (Acyl Species -> α-Functionalized Acyl Product).[19]

Radicals derived from α-iodo-*N*-acylsultams give high levels of asymmetric induction in intramolecular addition reactions with allyltributylstannanes (85->94% de)[19a] and 5-*exo*-dig type cyclizations and annulations (eq 16).[19a] In addition, zipper type manganese(III) promoted oxidative radical cyclization of *N*-(*trans*-4-methyl-4,9-nonadienoyl)-10,2-camphorsultam gives a *cis*-fused hydrindane derivative with modest (50% de) selectivity at the α-center.[19b] All these reactions proceed at or above room temperature, making the levels of induction remarkable. Furthermore, effective alternative auxiliaries are scarce.[1d,14]

Nondestructive Auxiliary Cleavage.

One feature which makes the sultam chiral auxiliary, and to an even greater extent the related toluene-2,α-sultam auxiliaries (see ***α-Methyltoluene-2,α-sultam***), so versatile is the ease with which *N*-acyl bond fission occurs in derivatives. A great variety of extremely mild, bimolecular and intramolecular nondestructive cleavage protocols have been developed which tolerate a wide array of molecular functionality, simple extraction and crystallization usually providing almost quantitative auxiliary recovery without loss of enantiomeric purity.

Saponification with LiOH[6a] or H_2O_2-LiOH[16b] in aqueous THF is routinely employed for conversion of *N*-acylsultams to enantiomerically pure carboxylic acids. A variant conducted in aprotic media with phase transfer catalysis has also been reported.[18d] If base sensitive functionality is present, then the corresponding esters can be prepared by nonbasic titanium mediated alcoholysis. This can be accomplished with ethyl,[11b] benzyl,[4] or allyl[18e] alcohols, and in the latter two instances the carboxylic acids can be subsequently liberated by neutral hydrogenolysis or $RhCl(PPh_3)_3$ catalyzed hydrolysis,[18e] respectively. Lactones and esters can also be formed by intra-[18j] and intermolecular[2d] sultam cleavage with lithium alkoxides and bromomagnesium alkoxides.[11d] β-Lactams can be prepared by intramolecular ring closure of metallated β-aminomethyl derivatives[1b,17a] and an aluminum thiobenzyloxy ate complex has been used to obtain thioester derivatives.[13] Reductive cleavage of *N*-acylsultams using lithium aluminum hydride[2f] or L-Selectride®[3b,3f] in THF gives rise to the corresponding primary alcohols.

Auxiliary cleavage with concomitant carbon-carbon bond formation is a particularly attractive option, which has been demonstrated in a bimolecular sense using the dianion of methyl sulfone (giving a methyl ketone),[16f] and in an intramolecular sense using a Claisen-type condensation of a β-acetoxy enolate (giving a δ-lactone).[25] An interesting halolactonization procedure has also been devised; for certain α-aryl-bis-(γ-unsaturated)-*N*-acyl derivatives this allows for highly efficient auxiliary cleavage and asymmetric formation of two stereocenters, one of which is quaternary (eq 17), the key step in a synthesis of (-)-mesembrine).[26]

Enantioselective, Electrophilic Fluorination.

(-)-*N*-Fluoro-10,2-camphorsultam (**3**) [mp 112-114 °C (CH_2Cl_2-pentane)] is an enantioselective, electrophilic fluorinating agent.[20] Fluorination of stabilized enolates occurs with highly variable yield (5-63%) and stereoselectivity (10-70% de).

Carbon Dioxide[1]

O=C=O

[124-38-9] · CO_2 · Carbon Dioxide · (MW 44.01)

(agent for the carboxylation of phenols,[2] organometallic reagents[3] and various carbanions, and for the preparation of dialkyl carbonates, urethanes, and ureas[1])

Physical Data: bp -78.5 °C (sub); critical temp 31.06 °C; vapor pressure 6300 kPa at 25 °C; mp -56.6 °C (at 5.2 atm); density: solid: 1.56 g cm^{-3} (at -79 °C); liquid: 1.101 g cm^{-3} (at -37 °C); gas: 1.977 g L^{-1} (at 0 °C).

Solubility: 75.9 mL/100 mL in H_2O at 20 °C and 101.3 kPa; 31 mL/100 mL in EtOH at 15 °C.

Form Supplied in: solid pellets (dry ice); compressed gas or liquid. *Drying:* pass gas through conc H_2SO_4 or a column of anhydrous calcium sulfate.

Handling, Storage, and Precautions: colorless, odorless gas which is dangerous to respiration at high concentrations; TLV = 5000 ppm.

Carboxylation of Phenoxides.

The reactions of sodium or potassium phenoxides with carbon dioxide under pressure (the Kolbe-Schmitt reaction) or of phenols with anhydrous ***Potassium Carbonate*** (Marasse modification) are a very important source of hydroxy aromatic acids.[2] Carboxylation is favored at the *ortho* position, but *para* isomers may also be obtained at higher temperatures (eq 1). Depending on the reaction conditions, 2-naphthol may be converted into either the 1-carboxylic acid (<150 °C) or the 3-isomer (>200 °C) (eq 2). Carboxylation is retarded by electron withdrawing groups, but enhanced by electron releasing substituents. Resorcinol, for example, is carboxylated simply by bubbling CO_2 through an alkaline solution (eq 3).[4]

(1)

Na salt (150 °C, 80% yield) 97: 2
K salt (210 °C, 48% yield) 4:96

(2)

(3)

Carboxylation of Organometallic Derivatives.

Carbon dioxide inserts readily into metal-carbon bonds with two possible outcomes (eq 4).[5] By far the most familiar and common pathway is the formation of a new carbon-carbon bond leading to a carboxylic acid, as in the very familiar reactions[6] of Grignard reagents and organolithium compounds (eqs 5 and 6),[7,8] although care must be taken to use low temperatures and an excess of CO_2 in order to avoid further reaction of the product with additional reagent.

(4a)

(4b)

(5)

(6)

In a few special cases, however, carbon-oxygen bond formation may take place (eq 4b), as in the reaction of the cobalt complex (**1**) to form (**3**) in addition to the expected (**2**) (eq 7).[9] Treatment of (**3**) with ***Hydrogen Chloride*** afforded ethyl formate, while reaction with ***Iodomethane*** afforded ethyl acetate in high yield. Another example of carbon-oxygen bond formation was observed during the reaction of a methallyl palladium π-complex with CO_2 (eq 8), although this could be suppressed by the addition of ***1,2-Bis(diphenylphosphino)ethane*** (diphos).[10]

(7)

(8)

The reaction of diethylzinc with CO_2 is very slow, but it may be accelerated by ligands such as ***N,N,N´,N´-Tetramethylethylenediamine*** or ***N-Methylimidazole***.[11] Vinyl and aryl copper reagents are similarly unreactive, but again they may be activated by the addition of suitable ligands, as in the stereoselective synthesis of β-substituted acrylic acids from alkynes (eq 9).[12]

(9)

The heteroatom facilitated lithiation of sp^2 carbon, including the lithiation of heterocycles and the directed lithiation of aromatic compounds, is a powerful and flexible synthetic strategy.[13] The intermediates react with CO_2 in good to excellent yields to form carboxylic acids which, in many cases, could otherwise be obtained only with considerable difficulty. Carboxylation is strongly favored at C-2 in the common heterocycles: furan, pyrrole, thiophene, imidazole, oxazole, thiazole, pyridine, pyrimidine, benzofuran, indole, benzothiophene, and their derivatives.[14] For benzenoid aromatic derivatives, reaction occurs at *ortho* (eqs 10 and 11)[15,16] or benzylic sites (eq 12),[17] but neighboring positions in a second aromatic ring may also participate (eqs 13 and 14).[18]

(13)

(14)

Carboxylation of Ketone Enolates and Other Carbanions.

Ketones may be converted into β-keto acids by treatment with CO_2 in the presence of a variety of bases, e.g. potassium phenoxide,[19] lithium 2,6-di-*t*-butyl-4-methylphenoxide,[20] ***Triethylamine-Magnesium Iodide***,[21] and ***1,8-Diazabicyclo[5.4.0]undec-7-ene***,[22] and with ***Methyl Magnesium Carbonate***.[23] Several urea-based magnesium complexes, inspired by the biotin carboxylases, have also been utilized.[24] There has been considerable interest in the trapping of preformed enolates with CO_2 (eqs 15 and 16),[25] especially under conditions of kinetic control.[26]

(15)

(16)

Yields are only poor to fair in most cases, probably because of the competing formation of enol carbonates[27] which decompose to the parent ketone on workup and/or the instability of the β-keto acid products. The successful trapping of enolates from Li/NH_3 reduction of enones (eq 17)[26,28] and *n*-butylthiomethylene ketones (eq 18)[29] has been reported.

(17)

(18)

Carboxylation of Miscellaneous Carbanions.

In addition to ketones, various other carbanions have been carboxylated, including those from esters,[30] dithianes,[31] and aldimines,[32] as have phosphoranes.[33]

Preparation of Dialkyl Carbonates, Urethanes, and Ureas.

Alcohols may be converted into symmetrical dialkyl carbonates by reaction with a combination of CO_2, ***Triphenylphosphine***, and ***Diethyl Azodicarboxylate***,[34] while cyclic carbonates may be obtained from the reaction of epoxides with CO_2 with catalysis by a range of Lewis acids.[35] Allylic epoxides react with CO_2 and ***Palladium(II) Acetate*** plus ***Triisopropyl Phosphite*** to form cyclic carbonates with retention of configuration.[36]

Allylic and homoallylic alcohols may also be transformed into cyclic carbonates by conversion of the derived lithium alkoxides into hemicarbonates followed by in situ cyclization with iodine (eq 19).[37] Amines have been converted into urethanes by a mixture of ***Copper(I) t-Butoxide***, ***t-Butyl Isocyanide***, and CO_2[38] and into symmetrical ureas by treatment with Et_3N, ***1,3-Dicyclohexylcarbodiimide***, and CO_2.[39]

(19)

Related Reagents.

N,N´-Carbonyldiimidazole; ***Diethyl Carbonate***; ***Methyl Magnesium Carbonate***; ***Methyl Chloroformate***; ***Methyl Cyanoformate***.

Carbon Disulfide[1]

CS_2

[75-15-0] · CS_2 · Carbon Disulfide · (MW 76.14)

(starting material for the synthesis of various sulfur and heterocyclic compounds;[1] protecting group for secondary amines[2])

Physical Data: mp -111.6 °C; bp 46.3 °C; *d* 1.26 g cm^{-3}; flashpoint -30 °C; fire point 102 °C.

Solubility: sol alcohol, ether, THF, benzene, CCl_4, $CHCl_3$; insol cold H_2O.

Form Supplied in: colorless liquid; discolors to yellow under influence of light.

Handling, Storage, and Precautions: should be stored in brown bottles in absence of light. CS_2 forms explosive mixtures with air (explosion limit 1-60 vol %). CS_2 is teratogenic. Constant inhalation or constant resorption through the skin cause chronic symptoms of poisoning, e.g. sight defects and headache. Inhalation of concentrated CS_2 vapor can be lethal. Use in a fume hood.

Reactions with Organometallic Compounds.

Grignard Reagents.

Treatment of CS_2 with Grignard reagents RMgX (**1**) leads to dithioesters (**2**) (eq 1).

If THF is used as solvent, dithioesters can be obtained in 60-85% yield.[3] This method fails when *t*-alkyl- or cyclohexylmagnesium halides are used. With diethyl ether as solvent, the dithioesters are obtained in poor yields.[4] The reaction of CS_2 with an allylic Grignard reagent followed by methylation affords the dithioesters (**3**), bearing an

inverted allylic chain as expected.[5] Treatment of (**3**) with first ***Lithium Diisopropylamide***, then with ***Iodomethane***, leads to an isoprenic ketene dithioacetal (**4**) (eq 2).

It is also possible to prepare various ketene dithioacetals in a one-pot synthesis with Grignard reagents and CS_2 as starting materials.[6]

Organocopper Reagents.

When catalytic amounts of ***Copper(I) Bromide*** are used, the reaction of CS_2 with Grignard reagents leads to dithioesters in 80-100% yield (eq 3).[7]

The organocopper(I) compound (**5**) is the reacting species.[7a] With this method, halides containing bulky groups can also be converted to dithioesters.

Reactions with Alcohols.

Treatment of alcohols with sodium hydroxide and CS_2 and subsequent reaction with an alkyl halide, usually methyl iodide, leads to *O*-alkyl *S*-methyl dithiocarbonates which can be pyrolyzed to alkenes (Tschugaeff reaction) (eq 4).[8]

Formation of the metal salt of the alcohol can be difficult.[9] If ***Sodium Methylsulfinylmethylide*** in DMSO is used as base, the dithiocarbonates can be prepared in good yields.[10] The decomposition temperature is lowered when pyrolysis is also carried out in DMSO.[11]

Vicinal diols react with CS_2 under basic conditions, to give the corresponding bis-dithiocarbonates. Reduction with ***Tri-n-butylstannane*** in toluene[12] gives high yields of the alkenes.

Recently, a variety of reducing agents has been developed to convert dithiocarbonates derived from alcohols, especially secondary ones, to alkanes. The hydroxy function can be selectively replaced by hydrogen under mild conditions, with tri-*n*-butylstannane,[13a] tri-*n*-butylstannane/***Triethylborane***,[13b] or ***Tris(trimethylsilyl)silane***/***Azobisisobutyronitrile***[13c] as radical-based reducing agents.

Reaction with Amines.

Primary Amines.

Treatment of primary amines with base and CS_2 leads to isothiocyanates via the dithiocarbamate derivatives.[14] Alkyl or aryl amines which do not contain groups that react with butyllithium, can be converted in 55-99% yield to the corresponding isothiocyanates. The amines are treated with an equimolar amount of ***n-Butyllithium*** and CS_2 to give the lithium dithiocarbamate (**6**). Subsequent reaction with *n*-butyllithium and CS_2 forms the complex (**7**). Loss of Li_2CS_3 leads to an isocyanate (eq 5).[15]

Diamines.

Aliphatic diamines react with CS_2 to give betaines (**8**). After pyrolysis of (**8**), cyclic thiourea derivatives are obtained (eq 6).[16]

In the same way, 1,2-diarylamines and their hetero analogs can be converted to heterocyclic compounds.[17]

Secondary Amines.

Treatment of secondary amines with base and CS_2 leads to the corresponding dithiocarbamates.[18] Dithiocarbamates of functionalized secondary amines form heterocyclic compounds.[19] For example, monoalkylaminobutynes (**9**) react readily with CS_2 to give 4-methyl-3-alkyl-5-methylenethiazolidine-2-thiones (**10**) (eq 7).[20]

(9)
R = alkyl, benzyl

(10)
58-87%

Protecting Group.

As mentioned above, under basic conditions, secondary amines form with CS_2 dithiocarbamates. Subsequent reaction with an organometallic base and one equivalent of electrophile gives, in good yields, the secondary amines substituted in the α-position (eq 8).[2,21]

Electrophile (El) = alkyl halogenides, carbonyl compounds

68-87%

The natural reactivity at α-position is umpoled.[22] This is a simple and versatile method for nucleophilic aminoalkylation[23] in a one-pot procedure. The reaction can be applied to numerous aliphatic and aromatic secondary amines.

Reactions with Enolizable Hydrogen Compounds.

Enamines.

Reactions of enamines with CS_2 afford several heterocycles.[24] Treatment of cyclic enamines with CS_2 leads to 1,4-dipoles (**11**) (eq 9).

(9)

$n = 1, 2, 3$ **(11)**

In the absence of moisture the 1,4-dipoles (**11**) can be stored for several days at 0 °C. Further reactions with electrophiles lead to various heterocycles.[25]

Carbonyl Compounds.

In the case of aldehydes, only self-condensation products are obtained, whereas aliphatic ketones usually form the corresponding dithiocarboxylates or α-ketoketene dithioacetals.[26] If cyclic ketones are used, occurrence of carbon-carbon cleavage or formation of α-ketoketene acetals depend on the steric demands of the base. Treatment of cyclohexanone with lithium 4-methyl-2,6-di-*t*-butylphenoxide (**12**) (readily obtained by treatment of the phenol with *n*-butyllithium) and CS_2, followed by methylation, leads via the dithiocarboxylate ion (**13**) to the α-ketoketene dithioacetal (**14**) (eq 10).[27]

(12) **(13)**

(10)

(14) 86%

If the reaction is carried out with lithium methoxide as base, 1,1-dithiodicarboxylic acid ester (**15**) is formed (eq 11).[28]

This carbon-carbon cleavage in cyclic ketones corresponds to an inverse Dieckmann-type reaction. Bulkier alkoxides like ethoxide or isopropoxide afford only α-ketoketene dithioacetals.[27]

Carbon Monoxide[1]

CO

[630-08-0] · CO · Carbon Monoxide · (MW 28.01)

(carbonylation of various organic compounds[1])

Physical Data: mp -205.0 °C; bp -191.5 °C; *d* 1.250 g L^{-1} (*d*04 at 760 mmHg).

Solubility: appreciably sol some organic solvents, such as EtOAc, $CHCl_3$, acetic acid.

Form Supplied in: cylinder types, valves, and pressure regulators.

Preparative Methods: may be generated by the dehydration of formic acid.

Purification: major impurities are CH_4 (~0.2%), N_2 (~0.5%), H_2, and O_2. O_2 can be removed from CO by passing the gas through a short bed of reduced Cu or MgO_2.

Handling, Storage, and Precautions: highly poisonous, odorless, colorless, and tasteless gas. All operations should be carried out in a fume hood.

Reactions with Carbocations.

The reaction of carbocations with CO leading to acylium cations is a key step in the Koch reaction. The Koch reaction produces tertiary carboxylic acids by treating alcohols with CO in a strong acid. It can be applied to alkanes, alkenes, and other compounds equivalent to alcohols under acidic conditions. A variety of acid systems, including Brønsted acids such as H_2SO_4, HF, and H_3PO_4, as well as in combination with Lewis acids such as BF_3, $AlCl_3$, $SbCl_5$, and SbF_5, are effective. The use of HCO_2H as a CO source is a practical method for laboratory scale reactions and this method is often used as an in situ preparation of CO. The treatment of alcohols, including secondary ones, with HCO_2H in 96% H_2SO_4 gives tertiary carboxylic acids (eq 1).[2] Adamantane is also carbonylated to 1-adamantanecarboxylic acid (eq 2).[3] Besides the HCO_2H method, the Koch synthesis can also be conducted at normal pressure of CO in the presence of copper or silver salts. Cyclohexene, for example, yields only 1-methylcyclopentanecarboxylic acid via ring contraction of the first-formed carbocation under 1 atm of CO (eq 3).[4] The Gatterman-Koch reaction[5] is the formylation of aromatic hydrocarbons with CO and HCl in the presence of $AlCl_3$ (eq 4).[6] Other catalytic systems such as HF/BF_3, HF/SbF_5, $HF/CF_3SO_3H/BF_3$, and CF_3SO_3H have been investigated and found to be effective for this reaction. Formylation and sulfonation take place when aromatic compounds are exposed to an atmosphere of CO at 0 °C in a

HSO_3F/SbF_5 system (eq 5).[7]

Reactions with Carbanions.

The reaction of organolithium reagents with CO gives carbonyl lithium reagents (acyllithium or aroyllithium), which

have not been utilized in practical synthetic reactions until recently. Difficulties in controlling the reaction of carbonyl lithium reagents are attributed to their extremely high reactivity. Acyllithium can be trapped by ***Chlorotrimethylsilane*** under extremely careful reaction conditions (eq 6).[8] A controlled, slow-rate addition of alkyllithium to a solution of Me_3SiCl saturated with CO at -110 °C is recommended. Direct nucleophilic acylation of ketones by in situ generated acyllithium reagents leading to α-hydroxy ketones has been described (eq 7).[9] The use of aldehydes,[10] lactones,[11] CS_2,[12] isocyanate[13] disulfide,[14] and carbodiimide[15] as trapping electrophiles has also been reported. Acylcuprate reagents successfully undergo nucleophilic 1,4-addition to α,β-unsaturated ketones and aldehydes (eq 8).[16]

(6)

(7)

(8)

The reaction of an α-silylalkyllithium with CO is a convenient access to acylsilane enolates, which can be trapped by electrophiles such as H^+, Me_3SiCl, and benzaldehyde (eq 9).[17] The formation of the enolates takes place in a highly stereoselective manner to give (*E*) enolates.

(9)

Reactions with Radicals.

The reaction of alkyl halides with ***Tri-n-butylstannane*** in the presence of ***Azobisisobutyronitrile*** (0.1-0.2 equiv) under CO pressure (65-80 atm) leading to aldehydes proceeds via the reaction of alkyl radicals with CO to give acyl radicals followed by abstraction of a hydrogen atom from $HSnBu_3$ (eq 10).[18] Aromatic halides can also be converted to aromatic aldehydes.[19] The use of ***Tris(trimethylsilyl)silane*** (TTMSS) in place of $HSnBu_3$ as a radical mediator permits the carbonylation under a lower pressure of CO (20 atm).[20] The radical carbonylation is applied to carbonylative cyclization of 4-alkenyl halides to cyclopentenes (eq 11).[21] The intramolecular trapping of acyl radicals by alkenes is utilized for the synthesis of functionalized unsymmetrical ketones.[22] The carbonylation of alkynes in the presence of thiols initiated by AIBN gives β-alkylthio-α,β-unsaturated aldehydes (eq 12).[23]

(10)

(11)

(12)

Transition Metal-Catalyzed Reactions.

Ring-opening siloxymethylation to 1,3-diol derivatives takes place in the reaction of cyclopentene oxide with $HSiEt_2Me$ and CO in the presence of $Co_2(CO)_8$ (eq 13).[24] The reagents $ML_n/HSiR_3/CO$ provide several important synthetic methods, which are covered under the reagent headings of ***Octacarbonyldicobalt-Diethyl(methyl)silane-Carbon Monoxide***, ***Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide***, and ***Tricarbonylchloroiridium-Diethyl(methyl)silane-Carbon Monoxide***.

(13)

Hydroformylation has been an extremely important industrial process, and consequently has been the most extensively studied of all carbonylation reactions.[25] A wide variety of metals such as Pt, Co, Rh, Ir, and Ru exhibit catalytic activity for hydroformylation of alkenes. Among them, Rh has been preferred for laboratory use because of its higher activity (eq 14).[26] Various phosphine-modified catalysts such as $Co_2(CO)_8$/phosphine, (phosphine)$PtCl_2/SnCl_2$, and phosphine-modified Rh have been examined extensively to obtain high selectivity for the more desirable linear aldehydes. Practical, regioselective hydroformylation of functionalized terminal alkenes can be achieved by using a bis-organophosphite ligand (**1**).[27] Catalytic systems using diphosphines with natural bite angles near 120° increase regioselectivity for straight-chain aldehydes.[28] Highly selective formation of branched-chain aldehydes is attained by use of a zwitterionic Rh complex (eq 15).[29] Hydroformylation using $PtCl_2/SnCl_2$ in the presence of chiral ligands such as (-)-DIPHOS, (-)-DIOP, and chiraphos is reported to produce moderate enantioselectivity.[30] The highest level of enantioselective discrimination is realized with $PtCl_2/SnCl_2$ and (2*S*,4*S*)-4-(diphenylphosphino)-2-[(diphenylphosphino)methyl]pyrrolidine ((-)-BPPM) in the presence of ***Triethyl Orthoformate***, which converts the product aldehyde to its diethyl acetal, although the branched/linear ratios are low.[31]

(14)

(1)

(15)

Hydrocarboxylation or hydroesterification is also an important process of CO. The asymmetric synthesis of (+)-ibuprofen and (+)-naproxen is attained based on asymmetric hydrocarboxylation of vinylarenes using (*S*)-(+)-1,1´-binaphtyl-2,2´-diyl hydrogen phosphate ((*S*)-BNPPA) (eq 16).[32]

(16)

Terminal alkynes may be carbonylated to acetylenecarboxylic esters in the presence of $PdCl_2$ as catalyst and $CuCl_2$ as reoxidant in the presence of NaOAc (eq 17).[33] Hydroesterification of alkynes to α,β-unsaturated esters is catalyzed by $[P(p\text{-Tol})_3]_2PdCl_2/SnCl_2$,[34] $PdCl_2/CuCl/HCl/O_2$,[35] and $(PPh_3)_2PtCl_2/SnCl_2$.[36] Pd-catalyzed intramolecular carbonylation of alkynyl alcohols is an attractive route to α-methylene-γ-lactones (eq 18).[37]

(17)

(18)

Ketones and aldehydes are formed using CO. Pd-catalyzed carbonylation of aryl or vinyl halides (or triflates) is an attractive method for a wide variety of carbonyl compounds. Carbonylation of aryl halides in the presence of hydrogen and a tertiary amine leads to the formation of aldehydes (eq 19).[38] Use of hydrogen donor such as HCO_2Na,[39] poly(methylhydrosiloxane) (PHMS),[40] $HSiEt_3$,[41] and $HSnBu_3$[42] also gives aldehydes. The Pd-catalyzed carbonylative coupling of aryl triflates with organostannanes is a potentially valuable route to unsymmetrical ketones (eq 20).[43] Organozinc reagents may be used in ketone syntheses.[44] Esters are obtained from aryl, vinyl, and heteroaryl halides (triflates) via the Pd-catalyzed carbonylation in the presence of alcohols.[45] The intramolecular version has been utilized for the preparation of α-methylene-γ-lactones from vinyl halides (eq 21).[46] The synthesis of lactams is also achieved in the presence of $Pd(OAc)_2/PPh_3$.[47] Aryl halides may be doubly carbonylated to α-keto amides in the Pd-catalyzed carbonylation of aryl halides with amines (eq 22).[48]

(19)

(20)

(21)

(22)

The catalytic carbonylation of benzyl chloride to arylacetic acid derivatives is shown to occur with Pd complexes as catalysts in the presence of a base under mild reaction conditions (eq 23).[49] $Co_2(CO)_8$-catalyzed carbonylation under phase transfer conditions (organic solvent/aq NaOH system containing catalytic amounts of quaternary ammonium salt) is also effective for the transformation of benzyl chlorides to arylacetic acids.[50]

(23)

Pd-catalyzed cyclocarbonylation of aryl- or heteroaryl-substituted allyl acetates with Ac_2O gives bicyclic aromatic systems (eq 24).[51] Allylic phosphonates are cleanly carbonylated to β,γ-unsaturated amides in the presence of a catalytic amount of $Rh_6(CO)_{16}/NBu_4Cl$ (eq 25).[52] Use of NH_4Cl/Et_3N in place of $PhCH_2NH_2$ is found to be effective for the preparation of primary amides. Under more harsh reaction conditions (50 atm, 110 °C), allylamines may be carbonylated directly to β,γ-unsaturated amides in the presence of $Pd(OAc)_2$/dppp.[53] The Pd-catalyzed carbonylation of propargyl carbonates in MeOH affords allenic esters (eq 26).[54]

(24)

(25)

(26)

Exposure of an azirine to CO in the presence of $Pd(PPh_3)_4$ affords bicyclic β-lactams (eq 27).[55] 2-Arylaziridines are

carbonylated with retention of configuration in the presence of $[RhCl(CO)_2]_2$ to give monocyclic β-lactams (eq 28).[56] Similar carbonylative ring-expansion reactions are observed in the Rh-catalyzed reaction of azetidine-2,4-diones,[57] Co-catalyzed reaction of azetidines,[58] and Co/Ru-catalyzed reaction of oxetanes.[59]

(27)

(28)

Cyclic ethers, including oxiranes, oxetane, and tetrahydrofuran, react with CO and *N*-(trimethylsilyl)amine in the presence of $Co_2(CO)_8$ to form siloxy amides (eq 29).[60]

(29)

N-acyl-α-amino acids can be synthesized by amidocarbonylation of aldehydes with acetamide and synthesis gas (eq 30).[61] It is possible to achieve a direct, one-step synthesis of *N*-acyl-α-amino acids from precursors other than aldehydes themselves. For example, allyl alcohols can be converted to *N*-acyl-α-amino acids via isomerization of allyl alcohols to aldehydes followed by amidocarbonylation (eq 31).[62]

(30)

(31)

Heterocyclic rings can be constructed by oxidative carbonylation under mild reaction conditions. The formation of a pyran ring is achieved by oxidative carbonylation of hydroxy alkenes (eq 32).[63] Transformation of allenic amines to α-heterocyclic acrylic acid derivatives is also carried out under ambient conditions (eq 33).[64]

(32)

(33)

CO acts as reducing agent in the water gas shift reaction (WGSR).[65] Application of WGSR in organic synthesis includes hydrogenation, related reductions, and carbonylation. Ru-catalyzed reduction of aromatic nitro compounds to aromatic amines under mild reaction conditions (at rt under 1 atm of CO) has been achieved (eq 34).[66] Montmorillonite-bipyridine-$Pd(OAc)_2/Ru_3(CO)_{12}$ is an active catalyst for the reductive carbonylation of aromatic nitro compounds to urethanes (eq 35).[67] The reaction is highly selective and no side products such as azo, azoxytoluene, or *N*-methylanilines are detected.

Miscellaneous.

Selenium effectively catalyzes the carbonylation of various amines with CO and O_2 to give urea derivatives quantitatively (eq 36).[68] Turnover numbers of Se reach 10^4 by using 0.8 mg of Se (0.01 mmol) for the carbonylation of benzylamine (200 mmol). The reaction can be applied to the synthesis of cyclic ureas.[69]

CO forms Lewis acid-base complexes with organoboranes. When the organoborane is heated with CO to 100-125 °C, a tertiary alcohol is obtained after workup by oxidation (eq 37).[70]

O=C=S

[463-58-1] · COS · Carbon Oxysulfide · (MW 60.07)

(agent for the thiocarboxylation of Grignard reagents,[2] enolates,[3] and other carbanions, and for the preparation of thiocarbonates,[1,4] ureas,[1] and various heterocycles[1])

Alternate Names: carbon oxide sulfide; carbonyl sulfide.

Physical Data: bp -50.2 °C; mp -138.2 °C; critical temp 105 °C; density (liquid) 1.25 g cm^{-3} at -87 °C; density (gas) 1.073 g L^{-1} at 0 °C.

Solubility: 54 mL/100 mL in H_2O at 20 °C; sol EtOH, CS_2.

Form Supplied in: compressed gas. *Drying:* pass gas through conc H_2SO_4.

Handling, Storage, and Precautions: carbon oxysulfide is a colorless, odorless, toxic gas. Use in a fume hood.

Reactions of Carbon Oxysulfide with Grignard Reagents, Enolates, and Other Carbanions.

Carbon oxysulfide reacts in a similar manner to carbon dioxide with a range of anionic substrates to form carbothioic acids [RC(=O)SH], with the option of in situ alkylation to carbothioic esters [RC(=O)SR´]. While overreaction of COS with Grignard reagents (eq 1) to afford trialkyl carbinols[2] appears to be more of a problem than with CO_2, the trapping of enolates with COS followed by methylation proceeds in high yield (eq 2)[3] and allows improved access (after Hg^{II} catalyzed transesterification) to β-keto esters,[5] compared with the more direct CO_2 based approach.[6]

$$\mathrm{PhMgBr} \xrightarrow{\mathrm{COS},\ H_3O^+} \underset{40\%}{\mathrm{PhCOSH}} + \underset{52\%}{\mathrm{Ph_3COH}} \qquad (1)$$

Acylation of thioenolate derivatives varies according to the substrate, occurring either on carbon (with *t*-butyl methyl thioketone) or sulfur (with diisopropyl thioketone).[7] Carbon oxysulfide has also been used to acylate phosphorus ylides[8] and acyllithium intermediates [RC(=O)Li].[9]

Reactions of Carbon Oxysulfide with Alkoxides, Phenolates, and Amines.

Carbon oxysulfide reacts extremely slowly with dry ethanol to form ethanethiol, but in the presence of KOH, potassium ethanethiocarbonate [KSC(=O)OEt] is formed.[1] Phenolate salts react similarly to give *O*-acylated products,[4] in contrast to the Kolbe-Schmitt reaction with CO_2.[10] Amines are converted by COS into thiocarbamates [$RNHC(=O)S^-$ RNH_3^+] which, on heating, decompose to ureas and H_2S.[1]

Heterocycle Formation.

Aminonitriles have been condensed with COS to afford thiazoles (eq 3),[11] and a thioxopyrimidine (eq 4). The latter process allowed access to a pyrrolopyrimidinone after a more direct approach based on ***Ethyl Chloroformate*** failed.[12]

Related Reagents.

Carbon Dioxide; ***Carbon Disulfide***; ***Methyl Magnesium Carbonate***; ***Methyl Chloroformate***.

Carbon Suboxide

O=C=C=C=O

[504-64-3] · C_3O_2 · Carbon Suboxide · (MW 68.03)

(1,3-dielectrophile used mainly for the synthesis of five- and six-membered heterocycles functionalized with oxo and hydroxy groups in the 1,3-position[1])

Alternate Name: 1,3-dioxo-1,2-propadiene.

Physical Data: mp -112.5 °C; bp 6.8 °C; *d* 1.114 g cm^{-3} (at 0 °C); 1.135 g cm^{-3} (at -12 °C); η_D 1.45384.

Solubility: sol ether, THF, benzene, etc.; reacts with H_2O and protic solvents.

Preparative Methods: for synthetic use, C_3O_2 can be prepared conveniently by three routes. (a) Pyrolysis of diacetyl tartaric anhydride at 770 °C under normal pressure.[1c] (b) Dehydration of malonic acid with P_4O_{10} at 150 °C.[1c,2] (c) Thermolysis of bis(trimethylsilyl) malonate in the presence of P_4O_{10} at 160 °C.[3] Good results[4] are also obtained by using method (b) and the apparatus as depicted in Birkofer and Sommer[3] (but also including a calcium oxide tube[1c] to absorb the acetic acid which is also formed by this most simple procedure). All three procedures can be adjusted to yield at least 7 g (>0.1 mol) of C_3O_2.

Handling, Storage, and Precautions: pure C_3O_2 is rather stable;[1b] nevertheless, it is advisable to use it within a few days after its preparation. Usually solutions of C_3O_2 in ether or THF are used in synthesis. An assay of the content of such solutions can be performed by adding an excess of aniline to an aliquot, and weighing the amount of malonic acid dianilide formed. *Caution*: Small amounts of C_3O_2 act as a lachrymator; in high concentrations it attacks eyes, nose, and respiratory organs, producing a feeling of suffocation. Use in a fume hood.

Reactions.

As an internal dianhydride, C_3O_2 represents the most electrophilic malonic acid derivative, but due to its value it is only used if other reagents fail. One typical example is the reaction of pyrazoles to yield cross-conjugated mesomeric pyrazolo[1,2-*a*]pyrazole betaines (eq 1).[5]

(1)

In a similar way amidine derivatives react with C_3O_2 to yield six-membered pyrimidine betaines (eq 2),[2,6] and *N*-substituted 2-aminopyridines[7,8] and pyrimidines[9] lead to bicyclic cross-conjugated betaines. 1,3-Dinucleophiles bearing only one hydrogen atom add C_3O_2 inevitably to zwitterionic compounds.[8]

(2)

Another example is the synthesis of 4-hydroxy-2-pyrones (**1**), structural units found in many natural products. Silyl enol ether derivatives of aldehydes and ketones react smoothly with C_3O_2 to afford the trimethylsilyl ether of the target compounds, which are easily hydrolyzed to (**1**) (eq 3).[10] Ketones themselves react very sluggishly with C_3O_2 even if catalyzed by Lewis acids, and then they afford the pyronopyrones (**2**) in low yield by reaction of a second equivalent of C_3O_2 with (**1**) (eq 4).[11] The reason is that ketones are less nucleophilic than 4-hydroxy-2-pyrones. Thus acetone yields (**2**) (R^1 = H, R^2 = Me) in only 8% yield,[12] whereas triacetic acid lactone (**1**) (R^1 = H, R^2 = Me) affords the same compound (**2**) in 20% yield. The addition of 2 equiv of C_3O_2 to a substrate, leading to pyrono derivatives of the expected compound, is frequently observed in carbon suboxide reactions.[1]

$R^1 = H$, Alk; $R^2 = H$, Alk, Ar; R^1-R^2 = -$(CH_2)_3$-

Alternatives.

Malonyl Chloride, ***Bis(2,4,6-trichlorophenyl) Malonate***, and even ***Diethyl Malonate*** may be used as substitutes. The reaction of trimethylsilyl enol ethers with malonyl dichloride (eq 3) may serve as an example since 4-hydroxy-2-pyrones are also formed with this reagent;[13] however, the yield is much lower and side products are formed. It has been shown that *N*-substituted 2-amino heterocycles form zwitterionic bicyclic pyrimido derivatives (eq 2) in good yields if heated with bis(2,4,6-trichlorophenyl) malonate (AME) to 160 °C for 3 minutes.[14] Heating of 2-phenylaminopyridine with diethyl malonate in tetralin forms the expected pyridopyrimidine betaine (eq 2) in 25% yield.[15]

Related Reagents.

Bis(2,4,6-trichlorophenyl) Malonate; ***Bis(trimethylsilyl) Malonate***; ***(Chlorocarbonyl)ethylketene***; ***Diethyl Malonate***; ***Malonic Acid***; ***Malonyl Chloride***.

Carbon Tetrabromide

[558-13-4] · CBr_4 · Carbon Tetrabromide · (MW 331.65)

(brominating agent used in synthesis of α-acetoxycarboxylic acids[4] and allenes;[5-8] radical additions to alkenes[12-28]).

Alternate Name: tetrabromomethane.

Physical Data: shining plates, mp 88-90 °C; bp 190 °C (dec).

Solubility: insol in water, sol in organic solvents.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: FT-IR data.[1]

Preparative Method: carbon tetrabromide is most conveniently prepared by the exhaustive bromination of acetone in the presence of alkali.[2]

Purification: can be sublimed in vacuo; bromide removal via reflux with dil aq Na_2CO_3, followed by steam-distillation and EtOH recrystallization.[29]

Handling, Storage, and Precautions: safety data are available.[3]

Carbon Tetrabromide-Tin(II) Fluoride.

The reaction of aldehydes with CBr_4 and SnF_2 in DMSO at 25 °C gives 1-substituted 2,2,2-tribromoethanols in moderate to good yields. The acetate of the product can be hydrolyzed to an α-acetoxycarboxylic acid by $AgNO_3$ (eq 1).[4]

2,3-Diacetyl-D-erythronolactone[4] has been prepared in a similar fashion (eq 2).

Allene Synthesis.

The system of carbon tetrabromide (1 equiv) with methyllithium (2 equiv) converts C_n alkenes into C_{n+1} allenes.[5-8] The synthesis of 1,2,6-cyclodecatriene from *cis,cis*-1,5-cyclononadiene[7] serves as an example (eq 3).

When 1 equiv of MeLi is used, the intermediate dibromocyclopropane can be isolated (eqs 4 and 5). Bicyclobutanes are the sole products when the resulting allene would be highly strained (eq 4),[9] or they are significant byproducts (eq 5) when the allene possesses two bulky geminal groups.[10]

Dehalogenation of dibromocyclopropanes with an alkyllithium in the presence of (-)-sparteine gives optically active allenes of low optical purity.[11]

Radical Reactions.

The addition of CBr_4, or other halogenocarbons, to alkenes is known as the Kharasch reaction. The reactions of terminal alkenes furnish the addition products in the highest yields (eq 6).

The reaction can be initiated by photoirradiation,[12] radical initiators,[13] inorganic salts,[14,15] ruthenium complexes,[16-19] other transition metal complexes,[20-24] samarium diiodide,[25] or by a manganic salt generated electrochemically in situ.[26] The scope and limitations of this reaction have been reviewed in two monographs.[27,28]

For related chemistry using CBr_4, see the entries ***Triphenylphosphine-Carbon Tetrabromide***, ***Triphenylphosphine-Carbon Tetrabromide-Lithium Azide***, ***Tribromomethyllithium*** and ***1,2-Bis(diphenylphosphino)ethane***.

1,1´-Carbonylbis(3-imidazolium) Bis(methanesulfonate)

[82257-34-9] · $C_9H_{14}N_4O_7S$ · 1,1´-Carbonylbis(3-imidazolium) Bis(methanesulfonate) · (MW 354.33)

(dehydrating agent capable of preparing isocyanides under acidic conditions[2])

Preparative Method: freshly prepared by adding ***Methanesulfonic Acid*** to a solution of ***N,N´-Carbonyldiimidazole*** in acetonitrile.

The preparation of isocyanides from *N*-alkylformamides is typically accomplished with a dehydrating agent under basic conditions.[1,3] The preparation of isocyanides using ***Trichloromethyl Chloroformate*** (diphosgene)[4] and chlorodimethylforminium chloride[5] (Vilsmeier reagent) has been reported. The title reagent was developed to prepare chiral isocyanides from chiral *N*-formyl amino acids, with minimal racemization (eq 1). The other, more basic, reaction conditions had proven unacceptable.

(1)

The reaction was carried out with freshly prepared carbonylbis(3-imidazolium) bis(methanesulfonate) in acetonitrile, at ambient temperature, over 4 h. Carbonyldiimidazole, without methanesulfonic acid, did

not effect the transformation. Cyclohexyl isocyanide (85%), *t*-butyl isocyanide (85%), and methyl-L-2-isocyanoisovalerate (90%) were prepared to further demonstrate the reagent. Carbonylbis-(3-imidazolium) bis(methanesulfonate) failed to prepare 2-nitro-5-methoxyphenyl isocyanide from the corresponding *N*-formylanilide. Carbonylbis-(3-imidazolium) bis(methanesulfonate) is conveniently prepared from readily available starting materials and avoids the problems associated with handling ***Phosgene*** or phosgene equivalents.

1,1´-Carbonylbis(3-methylimidazolium) Bis(trifluoromethanesulfonate)[1]

[120418-31-7] · $C_{11}H_{12}F_6N_4O_7S_2$ · 1,1´-Carbonylbis(3-methylimidazolium) Bis(trifluoromethanesulfonate) · (MW 490.36)

(versatile coupling reagent for aminoacylations[2])

Alternate Name: 1,1-carbonylbis(3-methylimidazolium) bistriflate.

Physical Data: pale white solid mp 78-80 °C; ^{1}H δ ($CDCl_3$) 8.86 (s, 2H), 7.44 (m, 2H), 7.16 (m, 2H), 4.00 (s, 6H).

Solubility: sol nitromethane, chloroform; insol ether; reacts with water.

Analysis of Reagent Purity: freshly prepared sample is treated with water: 200 mol % of *N*-methylimidazolium triflate is produced along with CO_2.

Preparative Methods: fresh methyl triflate is added to 1,1-carbonylbisimidazole in nitromethane at 10 °C. Solvent is then removed in vacuo, or the reagent used in situ.[2]

Handling, Storage, and Precautions: usually prepared under anhydrous conditions and used immediately. Can be stored in dry nitromethane solution or in solid state in absence of moisture. Preparation using aged methyl triflate should be avoided, owing to possible contamination of the coupling reagent with triflic acid.[2]

Coupling Reactions.

When *N*-Cbz derived amino acids are exposed to a freshly prepared solution of carbonylbis(3-methylimidazolium) triflate in nitromethane, coupling ensues with loss of CO_2 to give the derived amide and one equivalent of methylimidazolium triflate (eq 1).[2]

(1)

The acylated species so prepared can be coupled with alcohols to yield esters or with amines to form amides. The yields of coupled product are typically high and formation of the coupled products takes place within 15 min in the case of amides (eq 2) and within 3 h for esters.[2]

(2)

Of particular note is the fact that sterically hindered alcohols (e.g. menthol) couple in nearly quantitative yield (eq 3).

Racemization is not prevalent under these neutral conditions: routine analysis of the diastereomeric excess of coupled products revealed a >99.75:0.25 ratio, confirming both the mildness of the system and the near neutral conditions that persist during the coupling. The system compares most favorably against conventional coupling agents such as ***N,N´-Carbonyldiimidazole***,[3,4] where sluggish *O*-acylations are common[5] and racemization of the acyl component in the couplings has been observed.[6]

trans-Carbonyl(chloro)bis(triphenylphosphine)iridium(I)[1]

[14871-41-1] · $C_{37}H_{30}ClIrOP_2$ · *trans*-Carbonyl(chloro)bis(triphenylphosphine)iridium(I) · (MW 780.264)

(catalyst precursor for homogeneous hydrogenations,[2,3] decarbonylation of acyl halides,[10] and the hydrosilation[12] and hydroboration[13] of alkenes)

Alternate Name: Vaska's compound.

Physical Data: mp 327-8 °C (dec); ^{1}H NMR δ (C_6D_6) 6.6 (m);[15] IR νCO = 1953 cm^{-1} (nujol).

Solubility: sol toluene and chloroform; insol diethyl ether and alcohols.

Form Supplied in: yellow crystals, widely available.

Preparative Method: in a round-bottomed flask a mixture containing 3.52 g (10 mmol) of $IrCl_3.3H_2O$, 13.1 g (50 mmol) of PPh_3, 4 mL of aniline, and 150 mL of DMF is heated under nitrogen at reflux for 12 h. After filtering the resulting red-brown solution hot, 300 mL of warm methanol is added rapidly and the mixture stirred. Upon cooling in an ice bath, yellow crystals of *trans*-$IrCl(CO)(PPh_3)_2$ are collected on a filter and washed with 250 mL of methanol and then with 25 mL of diethyl ether (87-90%).

Handling, Storage, and Precautions: the compound is stable in air but readily takes up oxygen in solution.

Hydrogenation.

Although *trans*-$IrCl(CO)(PPh_3)_2$ was initially prepared by Angoletta[2] it was correctly formulated by Vaska[3] and henceforth has commonly been referred to as Vaska's compound. While a number of alkenes and activated alkynes can be hydrogenated in the presence of a catalytic amount of Vaska's compound, isomerization is frequently a faster pathway and during the course of the reaction a number of isomers can accumulate.[4] The catalyst precursor can be activated by weak UV radiation. Indeed, under these conditions 1,3-cyclohexadiene can be hydrogenated selectively (98%) to cyclohexene (eq 1), a reaction that does not take place thermally.[5] In a related study, butynediol is selectively hydrogenated during photolysis using Vaska's compound in toluene/trifluoroethanol (1:1).[7]

(1)

Hydrogen Transfer.

Selective hydrogen transfer from ***Formic Acid*** to α,β-enones can be accomplished with a catalytic amount of *trans*-IrCl(CO)$(PPh_3)_2$ (eq 2).[8] The polystyrene-supported reagent is an even more efficient catalyst for this transfer hydrogenation (with 70% conversion).[9]

$$RCH{=}CHCOR' + HCO_2H \longrightarrow RCH_2CH_2COR' + CO_2 \quad (2)$$

Decarbonylation.

Vaska's compound can also be used to catalyze the decarbonylation and dehydrohalogenation of aliphatic acid halides into mixtures of alkenes selectively and under mild conditions (yields ca. 75%).[10] Aromatic acid halides are not affected, making it possible to eliminate selectively one carbonyl functionality from the dichloride of 4-(*p*-carboxyphenyl)butyric acid, *p*-$ClOCC_6H_4(CH_2)_3COCl$. The resulting *p*-allylbenzoyl chloride is unstable, however, leading to extensive polymerization. Vaska's compound also catalyzes the decarbonylation of formate esters to alcohols and carbon monoxide.[11]

H-X Addition.

Vaska's compound catalyzes the regioselective hydrosilation of alkynes and styrenes with a number of silane reagents at high temperatures.[12] For example, addition of ***Triethylsilane*** to phenylacetylene using Vaska's compound in catalytic amounts affords the β_{trans} adduct in 88% yield. Photolysis of *trans*-IrCl(CO)$(PPh_3)_2$ leads to a moderately active catalyst for the hydroboration of 1-octene with ***Catecholborane*** (eq 3).[13] Unfortunately, no reaction is observed with styrenes under identical conditions. More active and selective rhodium catalysts for the hydroboration of alkenes are well established.[14]

(3)

Related Reagents.

Carbonyl(chloro)bis(triphenylphosphine)rhodium(I); ***Chlorotris(triphenylphosphine)rhodium(I)***.

Carbonyl(chloro)bis(triphenylphosphine)rhodium(I)[1]

(*trans*/*cis*)

[13938-94-8] · $C_{37}H_{30}ClOP_2Rh$ · Carbonyl(chloro)bis(triphenylphosphine)rhodium(I) · (MW 690.96) (*trans*)

[15318-33-9] (*cis*)

[16353-77-8]

(catalyst for carbonylation,[2] decarbonylation,[3] carbonyl exchange,[4] reduction,[5] hydrometalation,[6] and C-H activation reactions;[7] reagent for alkylation of acid chlorides[8])

Physical Data: mp 209-210 °C (*trans* isomer), 204-205 °C (*cis* isomer), 195-197 °C (*trans*/*cis* mixture); IR carbonyl stretching 1970 cm^{-1} (nujol mull), 1977 cm^{-1} ($CHCl_3$).

Solubility: sol chloroform and dichloromethane; moderately sol aromatic hydrocarbons and CCl_4; insol ether, alcohols, and aliphatic hydrocarbons.

Form Supplied in: bright yellow crystalline solid, widely available.

Preparative Methods: to a solution of $RhCl_3.3H_2O$ (2 g, 7.6 mmol) in 70 mL of absolute ethanol is slowly added triphenylphosphine (7.2 g, 2.75 mmol) in 300 mL of boiling absolute ethanol. The solution becomes clear within 5 min, at which point sufficient (10-20 mL) 37% formaldehyde solution is added, causing the red solution to become pale yellow. After several minutes, yellow microcrystals precipitate. Upon cooling, the resulting crystals are washed with ethanol and diethyl ether, dried (4.5 g, 85%) and recrystallized from hot toluene.[1c]

Handling, Storage, and Precautions: the complex is air-stable as a crystalline solid and can be stored without special precautions. In solution it readily reacts with oxygen, which therefore must be excluded during preparation and use of this reagent.

Carbonylation Reactions.

Rhodium is the most widely used catalyst for the carbonylation of alkenes with CO and H_2.[1,2] Although $RhH(CO)_2L_2$ (L = PPh_3, PBu_3, etc.) is recognized as the actual species that reacts with alkenes in the ligand modified rhodium catalyst system, many other rhodium complexes can be utilized as precursors in the presence of suitable ligands (L), CO, and H_2. $RhCl(CO)(PPh_3)_2$ has been used as a catalyst precursor in the hydroformylation of alkenes and formaldehyde.[1b,2b]

Hydroformylation of terminal alkenes produces a mixture of regioisomeric linear and branched aldehydes. Triphenylphosphine-stabilized rhodium catalysts can be used to form linear, unbranched aldehydes from simple alkenes such as propene. The presence of

triphenylphosphine, however, gives poor results in the hydroformylation of $R_fCH{=}CH_2$ (R_f = perfluoroalkyl group), which with ***Dodecacarbonyltetrarhodium*** or ***Hexadecacarbonylhexarhodium*** produces the branched aldehydes $R_fCH(CHO)Me$ regioselectively and in good yields.[9]

Heterocyclic compounds have been obtained through rhodium-catalyzed hydroformylation of functionalized alkenes such as allylamines (eq 1),[10] 3-butenamides (eq 2)[11] and allyl alcohols.[12]

(1)

$[Rh] = RhCl(CO)(PPh_3)_2$ or $Rh(acac)CO(PPh_3)_2$

(2)

[Rh]	
$RhCl(CO)(PPh_3)_2$	53:47: 0
$RhH(CO)PPh_3)_3$-dppb	98: 2: 0
$RhCl(PPh_3)_3$	53:41: 6
$RhCl(PPh_3)_3$-10 $P(OPh)_3$	3: 3:94

Hydroformylation of formaldehyde has been extensively investigated because of its importance to the commercial production of ethylene glycol (eq 3).[1b,13] The $RhCl(CO)(PPh_3)_2$-***Triethylamine*** catalyst system produced a mixture of straight chain carbohydrates, from trioses to hexoses.[14] The hydroformylation in the presence of 3-ethylbenzothiazolinium bromide gives trioses selectively.

(3)

$RhCl(CO)(PPh_3)_2$ catalyzes the reaction of CO with epoxides (eq 4),[15] amines (eqs 5 and 6),[16,17] and azides (eq 7).[17]

(4)

$$RNH_2 \xrightarrow{CO,\ [Rh]} RNHCHO + (RNH)_2CO \qquad (5)$$

$$ArNH_2 \xrightarrow[{[Rh]}]{CO,\ EtOH} ArNHCO_2Et \qquad (6)$$

$$ArN_3 \xrightarrow[{[Rh]}]{CO} ArNCO + N_2 \qquad (7)$$

$$[Rh] = RhCl(CO)(PPh_3)_2,\ [RhCl(CO)(dppe)]_2,\ [Rh(dppp)_2Cl]_2$$

Decarbonylation Reactions.

$RhCl(CO)(PPh_3)_2$ is a product of the stoichiometric decarbonylation of aldehydes with ***Chlorotris(triphenylphosphine)rhodium(I)*** (eq 8).[3b,18] However, at elevated temperatures $RhCl(CO)(PPh_3)_2$ is an effective catalyst for the decarbonylation of aroyl chlorides and aroyl cyanides (eq 9).[3a,19]

$$RCHO \xrightarrow{RhCl(PPh_3)_3} RH + RhCl(CO)(PPh_3)_2 \qquad (8)$$

$$ArCOX \xrightarrow[{50\text{-}95\%}]{RhCl(CO)(PPh_3)_2,\ 200\ ^\circ C} ArX + CO \qquad (9)$$

$$X = Cl,\ CN$$

Carbonyl Exchange (Isotope Labelling).

The carbonyl carbon of aroyl chlorides can be ^{13}C or ^{14}C labelled through acyl carbonyl exchange reactions with CO catalyzed by $RhCl(CO)(PPh_3)_2$ without formation of aryl chloride (ArCl) decarbonylation products (eqs 10 and 11).[4] Statistical distribution of ^{13}C is easily attained. The carbonyl group of aliphatic acid chlorides is also easily exchanged, but small amounts of decarbonylated products are formed.[4] Alkene migration or isomerization does not occur in the carbonyl exchange reactions of 3-butenoyl chlorides, although 1,3-scrambling of chlorine has been observed in the $RhCl(PPh_3)_3$-catalyzed decarbonylation of 3-butenoyl chlorides to allyl chlorides.[20]

$$\mathrm{ArCOCl} + {}^{13}\mathrm{CO} \xrightleftharpoons{\mathrm{RhCl(PPh_3)_3}} \mathrm{Ar}^{13}\mathrm{COCl} + \mathrm{CO} \quad (10)$$

$$\mathrm{PhCOCl} + \mathrm{Me}^{14}\mathrm{COCl} \xrightleftharpoons{\mathrm{RhCl(CO)(PPh_3)_2}} \mathrm{Ph}^{14}\mathrm{COCl} + \mathrm{MeCOCl} \quad (11)$$

Reduction Reactions.

The most widely studied homogeneous hydrogenation catalysts are all rhodium complexes. $RhCl(CO)(PPh_3)_2$ has been rarely used because of its low reactivity as a hydrogenation catalyst. The low reactivity, however, allows it to be a potentially useful catalyst for selective hydrogenation of terminal alkenes.[21] $RhCl(CO)(PPh_3)_2$-catalyzed reduction of diphenylacetylene with ***Sodium Borohydride*** gives (*Z*)-stilbene, whereas (*E*)-stilbene is formed with $RhCl(PPh_3)_3$ as the catalyst.[22]

Aromatic nitro compounds are reduced in good yields to aromatic amines with secondary alcohols as the reducing agent using the $RhCl(CO)(PPh_3)_2$-KOAc catalyst system (eq 12).[23]

$$\mathrm{ArNO_2} \xrightarrow[\text{120-150 °C}]{\mathrm{RhCl(CO)(PPh_3)_2},\ \mathrm{R_2CHOH}} \mathrm{ArNH_2} \quad (12)$$

Hydrometalation Reactions.

For the catalytic hydrometalation of alkenes, $RhCl(CO)(PPh_3)_2$ has no advantages over $RhCl(PPh_3)_3$ and its congeners, chloroplatinic acid (***Hydrogen Hexachloroplatinate(IV)***),[24] or radical catalysts.[25] The regioselectivity of hydrometalation of terminal alkynes depends on the ligands. For example, the hydrosilation and hydrogermylation of phenylacetylene in the presence of $RhCl(CO)(PPh_3)_2$ gives (*E*)-1-silyl- or 1-germyl-substituted 2-phenylethylene, whereas with $Rh[(CF_3CO)_2CH](C_2H_4)_2$ the isomeric 2-metalated 2-phenylethylenes are produced (eq 13).[26] In the hydrostannation of terminal alkynes, $RhCl(CO)(PPh_3)_2$ gives 2-stannyl-1-alkenes as the major product.[6]

M	R'	R	[Cat]	Yield (%)	Isomer ratio

Sn	$SiMe_3$	Bu	$RhCl(CO)(PPh_3)_2$	91	76:24:0

[a] RI = radical inhibitor, galvinoxyl

Hydrosilanes easily react with acylmetal complexes (metal = Fe, Mo, Mn) to form silyloxyalkyl metal complexes by using $RhCl(CO)(PPh_3)_2$ or $Rh(CO)(PPh_3)_3$ as catalysts.[27]

Hydrocarbon C-H Activation.

Under photochemical conditions, $RhCl(CO)(PPh_3)_2$ activates C-H bonds of aromatic and aliphatic hydrocarbons, leading to carbonylated products (eq 14)[7,28] and/or dehydrogenated products (eq 15).[29] UV irradiation of a solution of $RhCl(CO)(PPh_3)_2$ leads to the extrusion of CO to form a coordinatively unsaturated complex, $RhCl(PPh_3)_2$ (eq 16), which then inserts into the C-H bond of the hydrocarbon.[30] This photochemical reaction can be used for isotope labelling of aldehydes with ^{13}CO (eq 17).[28]

Alkylation of Acid Chlorides.

A number of rhodium complexes, including *trans*-RhCl(CO)$(PPh_3)_2$, facilitate the alkylation of acid chlorides, affording ketones in moderate to high yields.[8] This reaction proceeds by initial pretreatment of the catalyst precursor with an appropriate Grignard, organolithium, or organoytterbium[31] reagent to give an active alkylrhodium(I) species (eq 18). This reaction is specific for acid chlorides. Alkylation of ketones[32] and amines[33] can also be effected by *trans*-RhCl(CO)$(PPh_3)_2$ in a carbon monoxide-water system. In a more recent study,[34] nucleophilic addition of allylic stannanes to aromatic aldehydes has been accomplished by using derivatives of *trans*-RhCl(CO)$(PPh_3)_2$ in high yields (eq 19).

Oxidation Reactions.

The liquid phase oxidation of benzaldehyde to benzoic acid proceeds readily in the presence of a catalytic amount of *trans*-RhCl(CO)$(PPh_3)_2$ in benzene and under an atmosphere of oxygen (conversion is 78%).[35] Oxidation of terminal alkenes to methyl ketones also employs the use of a rhodium catalyst.[36]

Miscellaneous.

trans-RhCl(CO)$(PPh_3)_2$ is a moderately active catalyst precursor for the hydrosilation[37] and transfer hydrogenation[38] of imines. This rhodium complex is also used in the photochemical dehydrogenation of hydrocarbons,[39] and the thermal carbonylation of alkyl halides.[40]

The reaction of 1,5-dienes with hydrosilanes using *trans*-RhCl(CO)$(PPh_3)_2$ gives dehydrogenative silylation products, 1-silyl-1,5-dienes, in high yields (eq 20).[41]

Carbonyl(cyclopentadienyl)(phthaloyl)cobalt[1]

[99807-97-3] · $C_{14}H_9CoO_3$ · Carbonyl(cyclopentadienyl)(phthaloyl)cobalt · (MW 284.16)

(precursor to other cyclopentadienyl(phthaloyl)cobalt complexes which react with alkynes readily to give quinones or cyclopentadienylcobalt complexed quinones[1])

Physical Data: orange-yellow solid; mp 132-133 °C.

Solubility: very sol most organic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: ^{1}H NMR, IR, microanalysis.

Preparative Method: prepared in 98% yield by reaction of benzocyclobutenedione with commercially available dicarbonyl cyclopentadienylcobalt in xylene for 3.25 h at 160 °C.

Purification: flash chromatography on silica gel with petroleum ether.

Preparation of Phthaloyl- or Maleoyl(carbonyl)(cyclopentadienyl)cobalt Complexes.

Benzocyclobutenedione and 3,4-dimethylcyclobutenedione each react with ***Dicarbonyl(cyclopentadienyl)cobalt(I)*** in xylene to give carbonyl(cyclopentadienyl)cobalt complexes (**1**) and (**2**).[1] Analogously, they react with a mixture of ***Octacarbonyldicobalt*** and pentamethylcyclopentadiene to give carbonyl(pentamethylcyclopentadienyl)cobalt complexes (**3**) and (**4**) (eqs 1-4).[2-4]

(1)

(1)
orange-yellow
mp 132-133 °C

(2)

(2)
yellow
mp 80-81 °C

(3)

(3)
yellow-orange
mp 142-143 °C

(4)

Synthesis of Quinones.

In general, phthaloyl and maleoyl transition metal complexes can be used in the synthesis of quinones[5,6] according to the following scheme: 1) an alkyne must coordinate to a free site on a coordinatively unsaturated metal center; 2) the alkyne must insert into the metal-carbonyl bond; and 3) the metal must reductively eliminate to give the quinone (eq 5).

(5)

Complexes (**1**-**4**) do not react under thermal conditions (xylene, 120 °C) with alkynes. However, photolysis leads to dissociation of carbon monoxide, so when phthaloyl complex (**1**) is photolyzed in the presence of 3-hexyne it gives 2,3-diethyl-1,4-naphthoquinone (eq 6). However, when maleoyl complex (**2**) is treated under identical conditions, the cyclopentadienylcobalt complex of the corresponding benzoquinone is obtained (eq 7).[1] The 1,4-benzoquinones form more stable complexes with cyclopentadienylcobalt than the 1,4-naphthoquinones.

(1) (6)

(2) (7)

Activation of complex (**1**) with ***Trimethylamine N-Oxide***, with acetonitrile as solvent, allows the isolation of the acetonitrile complex (**5**). This reacts with 3-hexyne to give the cyclopentadienyl(2,3-diethylnaphthoquinone)cobalt complex (**7**). Complex (**7**) can be formed in better yield under milder conditions by using the more labile benzonitrile complex (**6**) (eq 8).[1]

Naphthoquinone complexes such as (**7**) are very unstable. The analogous complex formed by reaction with the terminal alkyne, 1-hexyne, is not isolated under the conditions which give (**7**).[1] However, 1,4-naphthoquinone complexes are formed generally by reaction of the pentamethylcyclopentadienyl complex (**3**) with alkynes upon activation of the CO ligand with ***N-Methylmorpholine N-Oxide*** (NMMO) (Table 1).[3] The extra steric bulk of the pentamethylcyclopentadienyl ligand protects the 1,4-naphthoquinone complexes from decomplexation relative to the corresponding cyclopentadienyl complexes.

The cyclopentadienylcobalt complexes of 1,4-benzoquinones are quite easy to form from reactions of cyclopentadienyl(maleoyl)cobalt complexes.[1] Photolysis of cyclopentadienyl(maleoyl)cobalt complex (**2**) in the presence of diethyl sulfide gives complex (**8**). This reacts with a wide variety of alkynes to give cyclopentadienyl(1,4-benzoquinone)cobalt complexes (Table 2).

Table 2 Reaction of Complex **(8)** with Alkynes to give CpCo(benzoquinone) Complexes

General Considerations.

The phthaloyl- and maleoyl(cyclopentadienyl)cobalt complexes should be compared to other phthaloyl- and maleoylcobalt complexes when being considered for use in the synthesis of quinones.[5,6] The main advantage of the cyclopentadienylcobalt complexes is the fact that quinone complexes can be obtained. This is currently the best method for making cyclopentadienyl(quinone)cobalt complexes.[3] Very limited work has been done on the application of these complexes in synthesis. Preliminary deprotonation/alkylation studies of maleoyl complexes (**2**) and (**4**) have been carried out but are only reported in dissertation form at this time.[4] This dissertation also contains some very preliminary work on the use of cyclopentadienyl(quinone)cobalt complexes in synthesis and the results are promising. The cyclopentadienyl ligand in these complexes makes them amenable to standard chromatographic purification, thus making the process of developing synthetic modifications of these complexes very feasible.

Related Reagents.

Phthaloylbis(triphenylphosphine)cobalt Chloride.

N,N´-Carbonyldiimidazole[1]

[530-62-1] · $C_7H_6N_4O$ · *N,N´*-Carbonyldiimidazole · (MW 162.15)

(reagent for activation of carboxylic acids;[1] synthesis of esters,[2] amides,[3] peptides,[4] aldehydes,[5] ketones,[6] β-keto thioesters,[7] tetronic acids;[8] ureas,[9] isocyanates,[10] carbonates;[9] halides from alcohols;[11] glycosidation;[12] dehydration[13-16])

Physical Data: mp 116-118 °C.

Solubility: no quantitative data available. Inert solvents such as THF, benzene, $CHCl_3$, DMF are commonly used for reactions.

Form Supplied in: commercially available white solid.

Analysis of Reagent Purity: purity can be determined by measuring the amount of CO_2 evolved on hydrolysis.

Preparative Methods: prepared by mixing phosgene with four equivalents of imidazole in benzene/THF.[17]

Purification: may be purified by recrystallization from hot, anhydrous THF with careful exclusion of moisture.[17]

Handling, Storage, and Precautions: moisture sensitive; reacts readily with water with evolution of carbon dioxide. May be kept for long periods either in a sealed tube or in a desiccator over P_2O_5.

Activation of Carboxylic Acids: Synthesis of Acyl Imidazoles.

N,N´-Carbonyldiimidazole (**1**) converts carboxylic acids into the corresponding acylimidazoles (**2**) (eq 1).[1] The method can be applied to a wide range of aliphatic, aromatic, and heterocyclic carboxylic acids, including some examples (such as formic acid and vitamin A acid) where acid chloride formation is difficult. The reactivity of (**2**) is similar to that of acid chlorides, but the former have the advantage that they are generally crystalline and easily handled. Isolation of (**2**)

is simple, but often unnecessary; further reaction with nucleophiles is usually performed in the same reaction vessel. Conversion of (**2**) into acid chlorides (via reaction with HCl),[18] hydrazides,[3] hydroxamic acids,[3] and peroxy esters[19] have all been described. Preparation of the more important carboxylic acid d erivatives is described below.

Esters from Carboxylic Acids.

Reaction of equimolar amounts of carboxylic acid, alcohol, and (**1**) in an inert solvent (e.g. THF, benzene, or chloroform) results in ester formation (eq 2). Since alcoholysis of the intermediate acylimidazole is relatively slow, the reaction mixture must be heated at 60-70 °C for some time. However, addition of a catalytic amount of a base such as ***Sodium Amide*** to convert the alcohol to the alkoxide, or a catalytic amount of the alkoxide itself, allows rapid and complete formation of the ester at room temperature.[2] The base catalyst must of course be added after formation of (**2**) from the acid is complete, as indicated by cessation of evolution of carbon dioxide.

Esters of tertiary alcohols may not be prepared from carboxylic acids containing acidic α-protons using this modified procedure, since deprotonation and subsequent condensation, competes. However, the use of stoichiometric ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** as base has been shown to provide good yields of *t*-butyl esters even for acids with acidic α-protons (eq 3).[20] This procedure was unsuccessful for pivalic acid or for *N*-acyl-α-amino acids.

An alternative approach to increasing the rate of esterification is to activate further the intermediate (**2**). ***N-Bromosuccinimide*** has been used for this purpose,[21] but unsaturation in the carboxylic acid or alcohol is not tolerated. More generally useful is the addition of an activated halide, usually ***Allyl Bromide***, to a chloroform solution of (**1**) and a carboxylic acid, resulting in formation of the acylimidazolium salt (**3**) (eq 4).[22] Addition of the alcohol and stirring for 1-10 h at room temperature or at reflux affords good yields of ester in a one-pot procedure. These conditions work well for the formation of methyl, ethyl, and *t*-butyl esters of aliphatic, aromatic, and α,β-unsaturated acids. Hindered esters such as *t*-butyl pivalate can be prepared cleanly (90% yield). The only limitation is that substrates must not contain functionality that can be alkylated by the excess of the reactive halide.

Since the purity of commercial (**1**) may be variable due to its water sensitivity, it is common to employ an excess in order to ensure complete conversion of the carboxylic acid to the acylimidazole. It has been suggested that alcohols react faster with residual (**1**) than with the acylimidazole (**2**), thus reducing the yield of ester. A procedure has been developed for removal of excess (**1**) before addition of the alcohol.[23]

Macrolactonization has been accomplished using (**1**).[24] Thiol and selenol esters can also be prepared in one pot from carboxylic acids using (**1**);[25] reaction of the intermediate (**2**) with aromatic thiols or selenols is complete within a few minutes in DMF, while aliphatic thiols require a few hours. Formation of the phenylthiol ester of *N*-Cbz-L-phenylalanine was accompanied by only slight racemization. ***N,N´-Carbonyldi-sym-triazine*** can be used in place of (**1**), with similar results.

Amides from Carboxylic Acids: Peptide Synthesis.

Analogous to ester formation, reaction of equimolar amounts of a carboxylic acid and (**1**) in THF, DMF, or chloroform, followed by addition of an amine, allows amide bond formation.[3] The method has been applied to peptide synthesis (eq 5).[4] One equivalent of (**1**) is added to a 1 M solution of an acylamino acid in THF, followed after 1 h by the desired amino acid or peptide ester. The amino acid ester hydrochloride may be used directly instead of the free amino acid ester. An aqueous solution of the amino acid salt can even be used, but yields are lower.

As is the case in esterification reactions, the presence of unreacted (**1**) can cause problems since the amine reacts with this as quickly as it does with the acylimidazole, forming urea byproducts that can be difficult to separate. Use of exactly one equivalent of (**1**) is difficult due to its moisture sensitivity, and also because of the tendency of some peptides or amino acids to form hydrates. Paul and Anderson solved this problem by use of an excess of (**1**) to form the acylimidazole, then cooling to -5 °C and adding a small amount of water to destroy the unreacted (**1**) before addition of the amine.[26]

For the sensitive coupling of Cbz-glycyl-L-phenylalanine and ethyl glycinate (the Anderson test), Paul and Anderson reported the level of racemization as 5% using THF as solvent at -10 °C, but as <0.5% in DMF.[4] Performing the same coupling reaction at room temperature, Beyerman and van den Brink later claimed that the degree of racemization in DMF was in fact as high as 17%, and reported better results (no detectable racemization) using the related reagent *N*,*N*´-carbonyl di-*sym*-triazine in place of (**1**).[27] In a comparative study of several reagents, Weygand and co-workers also observed extensive racemization using (**1**).[28] In the formation of tyrosine esters, Paul reported that the mixed anhydride method is to be preferred to use of (**1**), since *O*-acylation is a major side reaction with the latter.[29]

Aldehydes and Ketones from Carboxylic Acids.

Reduction of the derived acylimidazole (**2**) with ***Lithium Aluminum Hydride*** achieves conversion of an aliphatic or aromatic carboxylic acid to an aldehyde (eq 6).[5] ***Diisobutylaluminum Hydride*** has also been used, allowing preparation of α-acylamino aldehydes from *N*-protected amino acids.[30] Similarly, reaction of (**2**) with Grignard reagents affords ketones,[6] with little evidence for formation of tertiary alcohol.

Reaction of acylimidazoles with the appropriate carbon nucleophile has also been used for the preparation of α-nitro ketones[31] and β-keto sulfoxides.[32]

C-Acylation of Active Methylene Compounds.

Treatment of an acylimidazole, derived from a carboxylic acid and (**1**), with the magnesium salt of a malonic or methylmalonic half thiol ester results in *C*-acylation under neutral conditions (eq 7).[7] The presence of secondary hydroxyl functionality in the carboxylic acid is tolerated, but primary alcohols require protection. Magnesium salts of malonic esters may be used equally effectively. Intramolecular *C*-acylation of ketones has also been reported.[33]

Tetronic Acids.

A synthesis of tetronic acids reported by Smith and co-workers relies on the reaction between (**1**) and the dianion derived from an α-hydroxy ketone (eq 8).[8] The reaction proceeds in moderate yield (31-57%).

Ureas and Carbonates.

Reagent (**1**) may be used as a direct replacement for the highly toxic ***Phosgene*** in reactions with alcohols and amines. Reaction of (**1**) with two equivalents of a primary aliphatic or aromatic amine at room temperature rapidly yields a symmetrical urea (eq 9).[9] If only one equivalent of a primary amine is added to (**1**), then the imidazole-*N*-carboxamide (**4**) is formed (eq 10). These compounds can dissociate into isocyanates and imidazole, even at room temperature, and distillation from the reaction mixture provides a useful synthesis of isocyanates (eq 10).[10] Secondary amines react only at one side of (**1**) at room temperature, again giving the imidazole-*N*-carboxamide of type (**4**).

Reaction of (**1**) with one equivalent of an alcohol provides the imidazole-*N*-carboxylic ester (**5**) (eq 11).[34] Further treatment with another alcohol or phenol yields an unsymmetrical carbonate; alternatively, reaction with an amine affords a carbamate (eq 12).[34]

Heating (**1**) with an excess of an alcohol or phenol gives the symmetrical carbonate.[9] This reaction can be accelerated dramatically by the presence of catalytic base (e.g. ***Sodium Ethoxide***). Reaction under these conditions is so exothermic even at room temperature that only *t*-butanol stops at the imidazole-*N*-carboxylic ester stage.

1,2-Diamines, 1,2-diols, or 1,2-amino alcohols react with (**1**) to form cyclic ureas,[35] carbonates,[36] or oxazolidinones,[35] respectively. In the case of cyclohexane-1,2-diols, the *cis*-diol reacts much more rapidly than the *trans*, as would be expected.[36] Thiazolidinones can also be prepared using (**1**).[37]

Halides from Alcohols.

Treatment of an alcohol with (**1**) and an excess (at least three equivalents) of an activated halide results in its conversion to the corresponding halide (eq 13).[11] Any halide more reactive than the product halide may be used, but in practice ***Allyl Bromide*** or ***Iodomethane*** give best results as they are effective and readily removed after the reaction. Acetonitrile is the best solvent and yields are generally high (>80%). Bromide or iodide formation work well, but not chlorination. Optically active alcohols are racemized.

Glycosidation.

A mild glycosidation procedure involving (**1**) has been reported by Ford and Ley.[12] A carbohydrate derivative in ether or dichloromethane reacts with (**1**) through the anomeric C-1-hydroxyl to give the (1-imidazolylcarbonyl) glycoside (IMG) (**6**) (eq 14). Isolation of (**6**) is not usually necessary; treatment with one equivalent of an alcohol and two equivalents of ***Zinc Bromide*** in ether at reflux gives the glycoside. Generally, higher α:β ratios are obtained for more hindered alcohols and when ether is used as solvent rather than the less polar dichloromethane. Along with the fact that the α:β ratio is independent of the configuration of (**6**), this suggests an S_N1-type mechanism. In contrast, treatment of (**6**) with ***Acetyl Chloride*** provides the anomeric chloride with essentially exclusive inversion.

Dehydration.

Reagent (**1**) has been used for the dehydration of various substrates, including aldoximes (to give nitriles),[13] β-hydroxy amino acids,[14] and β-hydroxy sulfones.[15] 3-Aryl-2-hydroxyiminopropionic acids undergo dehydration and decarboxylation, to give 2-aryl acetonitriles, upon reaction with (**1**).[16]

N,N´-Carbonyldi-*sym*-triazine

[41864-22-6] · $C_5H_4N_6O$ · *N,N´*-Carbonyldi-*sym*-triazine · (MW 164.13)

(reagent for peptide synthesis[1]; preparation of thiol or selenol esters[2])

Physical Data: mp 134-136 °C.

Solubility: no information available. Reactions are usually performed in DMF.

Analysis of Reagent Purity: purity has been determined by measuring the amount of CO_2 evolved on hydrolysis.

Preparative Methods: from triazole and phosgene in THF, in the presence of one equivalent of pyridine (80% yield).[1]

Purification: material prepared as above is 95% pure, and is generally used directly.

Handling, Storage, and Precautions: may be stored in a desiccator over P_2O_5 at room temperature for many months without apparent decomposition.

Peptide Synthesis.

N,N´-Carbonyldi-*sym*-triazine (**1**) may be used to effect activation of an *N*-protected amino acid towards amide bond formation, presumably via the acyltriazole intermediate (**2**) (eq 1).[1] Unlike the related reagent ***N,N´-Carbonyldiimidazole***, (**1**) may be used without problems in DMF, a suitable solvent for small and large peptides. Racemization is apparently lower when (**1**) is used rather than *N,N´*-carbonyldiimidazole; coupling of CbzGly-Phe-OH to glycine ethyl ester (the Anderson test) showed 17% racemization using *N,N´*-carbonyldiimidazole, whereas none was observed using (**1**) under strictly analogous conditions. This is presumably related to the fact that (**2**) reacts more rapidly with amines than does the corresponding acylimidazole, as expected based on consideration of the relative acidities of imidazole and triazole.

Thiol and Selenol Esters.

The acyltriazole resulting from activation of a carboxylic acid by (**1**) can be reacted without isolation with a thiol or selenol, affording a thiol or selenol ester, respectively.[2] Racemization is slight when the method is applied to *N*-protected amino acids (eq 2). *N*,*N*´-Carbonyldiimidazole can be used in place of (**1**), with similar results. Reaction with aromatic thiols or selenols is complete within minutes; alkyl thiols require a few hours. The 1,2,4-triazole formed is easily removed by extraction with water.

Carbonylhydridotris(triphenylphosphine)rhodium(I)[1]

$RhH(CO)(PPh_3)_3$

[17185-29-4] · $C_{55}H_{46}OP_3Rh$ · Carbonylhydridotris(triphenylphosphine)rhodium(I) · (MW 918.79)

(catalyst for hydroformylation, hydrogenation, isomerization, and hydrosilylation of alkenes. It has also been used as a carbonylation catalyst and as a catalyst for the conjugate addition of activated Michael donors)

Alternate Names: hydridocarbonyltris(triphenylphosphine)rhodium(I); carbonyltris(triphenylphosphine)rhodium(I) hydride.

Physical Data: mp 172-174 °C (under N_2), 120-122 °C (in air).[2]

Solubility: moderately sol $CHCl_3$, CH_2Cl_2, and C_6H_6; sparingly sol cyclohexane; insol light petroleum and EtOH.[1,3]

Form Supplied in: yellow solid, widely available.

Preparative Methods: can be prepared from $RhCl_3.3H_2O$, PPh_3, and formaldehyde (see cautionary note below).[2,4] It can also be prepared from other rhodium complexes,[1] for example by the reaction of hydrazine with *trans*-carbonylchlorobis(triphenylphosphine)rhodium(I) in ethanolic solution.

Handling, Storage, and Precautions: is moisture sensitive and decomposes in many solvents above 80 °C. The preparation of the complex from $RhCl_3.3H_2O$, PPh_3, and formaldehyde (see above) results in the liberation of HCl which can react with formaldehyde to form the potent carcinogen bis(chloromethyl) ether.

Hydroformylation (Oxo Reaction).[1,5]

$RhH(CO)(PPh_3)_3$ has largely displaced cobalt-based catalysts in industrial hydroformylations. The aldehyde products are reduced to the corresponding alcohols for use in the plastics industry.[1] Whereas the earlier process involved operating at high temperatures and pressures, the use of $RhH(CO)(PPh_3)_3$ allows the reaction to occur at or below atmospheric pressure and at room temperature.[6,7] The catalyst is often added to reactions as a solid. However, it can also be generated in situ from other rhodium complexes under typical hydroformylation conditions. In all these cases $RhH(CO)(PPh_3)_3$ is the actual precursor to the active catalysts, $RhH(CO)(PPh_3)_2$ and $RhH(CO)_2PPh_3$ (eq 1).[8]

$$RhH(CO)(PPh_3)_3 \xrightleftharpoons{-PPh_3} RhH(CO)(PPh_3)_2 \xrightleftharpoons{+CO,\ -PPh_3} RhH(CO)_2(PPh_3) \quad (1)$$

For aliphatic alkenes, much emphasis has been placed on optimization of hydroformylation in favor of the linear product (eq 2) (R = alkyl). The best results are obtained by employing low gas pressures and a 1:1 ratio of H_2 to CO, in the presence of added ***Triphenylphosphine***.[1,9] Added diphosphines with bite angles near 120° also increase selectivity for the linear product.[10] Excess triphenylphosphine retards the rate of reaction and lower pressures of CO lead to competing hydrogenation and isomerization.[11]

Steric hindrance in the alkene can lead to excellent regioselectivity as well as selectivity for a terminal alkene in preference to a trisubstituted alkene (eq 3).[12] A bulky silyl substituent also controls hydroformylation regioselectivity.[13] The use of a polymer-supported catalyst also leads to a high ratio of linear to branched product.[14]

Hydroformylation of styrene is quite selective for the branched isomer. Reaction of the corresponding tricarbonylchromium complex, tricarbonyl(η^6-styrene)chromium, improves this selectivity dramatically (from 87:13 to >98:2, in favor of the branched isomer),[15] as does reaction with 1,2,3,4,5-pentafluorostyrene.[16] Addition of diphenylpyridinylphosphine also results in improved regioselectivity (as high as 94:6 in favor of the branched isomer) if the reaction is carried out under high pressure.[17]

The influence of chelation control on regioselectivity has been examined using phosphorus,[18,19] nitrogen,[20,21] and sulfur[22] substituents. In the case of nitrogen this has led to the synthesis of a variety of heterocycles, although often as isomeric mixtures (eq 4).[21]

Carbonylation is sometimes a competing process. In reactions with alkenylamines, carbonylation is generally favored where the amine is unhindered and nucleophilic.[23,24] Double hydroformylations are also possible.[25,26] Alkynes are usually less reactive than alkenes under typical hydroformylation conditions.[23,27]

Many studies of asymmetric hydroformylations have been carried out using chiral rhodium-based catalysts. Rather than preparing pure, chiral catalysts it is often simpler to generate such catalysts in situ by adding chiral diphosphine ligands to $RhH(CO)(PPh_3)_3$ in solution.[28-32] Naturally, $RhH(CO)(PPh_3)_3$ is no longer the active catalyst in these reactions. Asymmetric hydroformylation of methyl 2-(acetylamino)acrylate using (-)-DIOP as the added chiral ligand provided the branched product with excellent regioselectivity and reasonable enantioselectivity (eq 5).[33]

If an alkene such as ethylene is treated with $RhH(CO)(PPh_3)_3$ and CO only (i.e. no H_2) then co-oligomerization can occur, leading to polymers of the type H-$(CH_2CH_2CO)_n$-Et or H-$(CH_2CH_2CO)_n$-OR.[34] $RhH(CO)(PPh_3)_3$ also catalyzes hydroacylation[35] and silylformylation[36] of alkenes.

Hydrogenation.[37]

$RhH(CO)(PPh_3)_3$ is a hydrogenation catalyst selective for terminal alkenes. Under standard conditions, $RhH(CO)(PPh_3)_3$ is less efficient than the widely used Wilkinson's catalyst, ***Chlorotris(triphenylphosphine)rhodium(I)***. However, the selectivity of Wilkinson's catalyst derives from differences in double bond stereochemistry, with little difference in rate of hydrogenation of terminal, internal, or cyclic alkenes.[38] $RhH(CO)(PPh_3)_3$, on the other hand, can catalyze the hydrogenation of terminal alkenes at ambient temperature and pressure in the presence of internal, conjugated, or cyclic double bonds (eq 6).[38,39] At higher temperatures and pressures, internal[40] and cyclic alkenes[41] can also be hydrogenated.

Functional groups such as keto, aldehyde, hydroxy, cyano, chloro, and carboxy are not reduced by the complex. $RhH(CO)(PPh_3)_3$ will not catalyze the hydrogenation of alkynes. However, it will react stoichiometrically with alkynes to give stable complexes.[42,43] Complexes generated from $RhH(CO)(PPh_3)_3$ (or $Rh_6(CO)_{16}$ or $Rh_4(CO)_{12}$) and diphosphines will catalyze the hydrogenation of α,β-unsaturated aldehydes.[44] In the presence of chiral diphosphines this reaction is enantioselective, as in the hydrogenation of neral to produce (+)-citronellal (eq 7).[44]

(7)

Isomerization.

$RhH(CO)(PPh_3)_3$ is a homogeneous catalyst for the isomerization of terminal alkenes to give the more stable internal alkene. Initially, the (*Z*)-2-alkene is formed and this is then slowly isomerized to the (*E*)-2-alkene.[45,46] The isomerization of 3-phenoxyprop-1-ene has been achieved with $RhH(CO)(PPh_3)_3$; however, the yields and selectivity are not as good as those obtained using ***Dichlorotris(triphenylphosphine)ruthenium(II)***.[47] The *exo*-methylene of a fused five-membered lactone has been isomerized in the presence of $RhH(CO)(PPh_3)_3$ to internalize the double bond.[48] Double bond migration has also been observed in nitrogen heterocycles, such that cyclic *N*-allylamides are isomerized to the cyclic enamide.[49] Allylic alcohols are isomerized to aldehydes in the presence of $RhH(CO)(PPh_3)_3$[50] and when chiral diphosphines are added a modest degree of enantioselectivity is observed.[51] β-Trimethylsilyl allylic alcohols have been isomerized to provide a stereoselective synthesis of trimethylsilyl enol ethers.[52] This reaction is believed to proceed via the α-trimethylsilyl ketone as the direct transformation of α-trimethylsilyl ketones into trimethylsilyl enol ethers has been demonstrated.[53] The stereoselective synthesis of α,β-unsaturated ketones has been achieved by the $RhH(CO)(PPh_3)_3$-catalyzed isomerization of vinyl epoxides.[54] Other Rh^I catalysts were also shown to catalyze this isomerization and the best yields and selectivities were obtained with ***Hydridotetrakis(triphenylphosphine)rhodium*** (eq 8).

(8)

Rh^I	Yield (%)	(*E*):(*Z*)
$RhH(CO)(PPh_3)_3$	86	79:21
$RhH(PPh_3)_4$	91	100:1

An example of a catalytic isomerization in the presence of $RhH(CO)(PPh_3)_3$ that does not involve a double bond isomerization is the conversion of *cis*-2,3-epoxycyclohexan-1-ol to the *trans* isomer.[55]

Hydrosilylation.

As with many hydrogenation catalysts, the efficacy of $RhH(CO)(PPh_3)_3$ as a hydrosilylation catalyst has been investigated. $RhH(CO)(PPh_3)_3$ has been used in the hydrosilylation of a number of alkenic substrates, including 1-hexene,[56] styrene,[56,57] 1,3-butadiene,[58] and acrylonitrile.[59] In the first two examples, $RhCl(PPh_3)_3$ and $RhCl(CO)(PPh_3)_3$, respectively, were found to be superior catalysts. In the last two examples, under certain conditions, $RhH(CO)(PPh_3)_3$ proved to be the most effective of the catalysts that were investigated. Alkynes have also been hydrosilylated to produce both (*Z*)- and (*E*)-alkenes.[60]

Conjugate Addition.

In the presence of $RhH(CO)(PPh_3)_3$, activated Michael donors such as ethyl cyanoacetate, malononitrile, and benzyl cyanide undergo conjugate addition to α,β-unsaturated carbonyl compounds in high yield.[61] In the presence of the chiral *trans* chelating diphosphine ligand 2,2´´-bis(1-diphenylphosphinoethyl)-1,1´´-biferrocene (TRAP), and using α-substituted α-cyanocarboxylate as donor, this reaction proceeded with high enantioselectivity (eq 9).[62]

Miscellaneous.

$RhH(CO)(PPh_3)_3$ has been used in carbonylation reactions of amines[63] and alkenes[64] and in cross-carbonylation of alkynes and alkenes.[65] The complex has also been used as a decarbonylation catalyst,[66] although it does not perform as well as Wilkinson's catalyst in such reactions. $RhH(CO)(PPh_3)_3$ has been used, albeit less efficiently than Pd/Al_2O_3, to effect the rearrangement of tetrahydrofurylhydrosilane to give the corresponding oxasilacyclohexane in which the silicon had migrated into the ring.[67] The reduction of nitrobenzene by cyclohexanol in the presence of $RhH(CO)(PPh_3)_3$ has been reported,[68] although $Rh(CO)_2Cl_2$ was found to be a superior catalyst for this reaction. $RhH(CO)(PPh_3)_3$ also undergoes many inorganic ligand exchange reactions,[1] which are not detailed here as they are presently of little value to the synthetic chemist.

2-Carboxyethyltriphenylphosphonium Perbromide

[55985-85-8] · $C_{21}H_{20}Br_3O_2P$ · 2-Carboxyethyltriphenylphosphonium Perbromide · (MW 574.93)

(bromine transfer agent for selective α-bromination of ketones[1] and ketone acetals[2] in the presence of double bonds,[1-3] activated aromatic rings,[2] esters[1] or another free enolic position[1,4])

Alternate Name: 2-carboxyethyltriphenylphosphonium tribromide.

Physical Data: mp 139-41 °C.

Solubility: sol THF (25 g/100 mL), dichloromethane; insol alcohol.

Form Supplied in: orange solid; not widely available; purity &egt;98%.

Analysis of Reagent Purity: identification in phosphonium salt mixtures by TLC/SIMS.[5]

Preparative Methods: Ph_3P (26.2 g, 0.1 mol), acrylic acid (7.2 g, 0.1 mol) and 49% HBr (50 mL) were stirred at rt until a homogeneous solution was obtained, then heated at 95-100 °C for 10 min, whereupon the mixture was cooled and glacial HOAc (240 mL) was added; bromine (9.8 mL) was added slowly with stirring to this mixture at 0 °C; after 0.5 h, the product was filtered and recrystallized from MeCN to give the perbromide (52.5 g, 91%);[1] a two step procedure involving bromination of the isolated intermediate monobromide can also be used.

Handling, Storage, and Precautions: irritant and moisture sensitive solid; store in a dry place. This reagent should be handled in a fume hood.

Saturated Ketones.

With this reagent, saturated ketones undergo α-bromination to give mainly the thermodynamically more stable

bromo ketone (eq 1).[1,4] No reaction was observed in the case of bicyclic ketones or camphor, or with esters under the above conditions.[1]

(1)

Unsaturated Ketones.

These are brominated without affecting the double bond to afford the desired α-bromo ketone (eq 2).[1,3]

(2)

Aryl Alkyl Ketones.

Variable results are obtained with these compounds, depending on the activation level of the aromatic ring.[1,2] Either the nature of the solvent (dichloromethane, THF with or without H_2O) (eq 3) and/or the use of the one-pot acetalization-bromination procedure[2] also play a critical role in determining the distribution of the brominated products; these effects have not yet been optimized.

Note that recovery and reuse of the monobromide byproduct (after treatment with bromine) is possible.

For α-bromination of ketones this reagent often compares favorably with other ammonium or phosphonium salts.[2] Reagents for similar transformations include ***Pyridinium Hydrobromide Perbromide***,[6] ***Phenyltrimethylammonium Perbromide***,[7,8] ***2-Pyrrolidone Hydrotribromide***[9] and the phosphonium reagents described by Cristau et al.[2]

(*E*)-(Carboxyvinyl)trimethylammonium Betaine

[54299-83-1] · $C_6H_{11}NO_2$ · (*E*)-(Carboxyvinyl)trimethylammonium Betaine · (MW 129.16)

(reaction of allylic alcohols with (*E*)-(carboxyvinyl)trimethylammonium betaine affords (*E*)-3-(allyloxy)acrylic acids, which on heating are transformed to γ,δ-unsaturated aldehydes via Claisen rearrangement/decarboxylation[8,9])

Physical Data: mp 176-177 °C (dec);[9] 240-245 °C (dec).[7]

Analysis of Reagent Purity: IR (KBr) cm^{-1}: 1665, 1600, 1360; ^1H NMR (D_2O, DSS ref) δ: 3.3 (br s, 9 H, Me_3N), 6.3 (br d, 1 H, *J* = 13, vinyl CH), 6.8 (br d, 1 H, *J* = 13, vinyl CH); elemental analysis.

Preparative Methods: A mixture of 25.0 g of ethyl propiolate, 14 mL of dichloromethane, and 440 mL of water is cooled to 5 °C and 90 mL of an aqueous 25% solution of trimethylamine is added with vigorous stirring over a period of 30 min. The mixture is then warmed to 25 °C for 3 h. The aqueous layer is separated and washed three times with 100 mL of dichloromethane. The aqueous solution is concentrated in vacuo at 45 °C. When the residue gives the appearance of a wet solid, it is treated with 150 mL of dioxane and concentrated as described above. The dioxane treatment-concentration procedure is repeated three times. The resulting yellow solid is triturated with acetonitrile until a white solid is obtained (25 g, 76% yield).

Purification: yellow impurities can be removed by trituration with acetonitrile to obtain a white solid. This is dried at 25 °C in vacuo (0.1 mmHg) for 14 h.

Handling, Storage, and Precautions: the reagent will slowly decompose at room temperature over a period of several months. Storage in a closed container at low temperatures is recommended. This reagent should be handled in a fume hood.

Synthesis of γ,δ-Unsaturated Aldehydes.

The Claisen rearrangement of allyl vinyl ethers[1] is a useful synthetic transformation. However, this synthetic method is limited due to the lack of efficient general methods for the preparation of allyl vinyl ethers. These intermediates are normally prepared by vinyl ether exchange with simple alkyl vinyl ethers and an allylic alcohol in the presence of a Lewis acid (usually mercury(II) acetate) or mineral acid.[2] Often yields in these reactions are low, and the use of mercury is

becoming unacceptable environmentally.

Useful modifications of the Claisen rearrangement have been reported (e.g. those of Johnson,[3] Ireland,[4] and Eschenmoser[5]); however, these methods give products at the carboxylic acid oxidation level, and additional steps are required if an aldehyde is the desired product.

The betaine (**1**)[6,7] can be used to convert primary and secondary allylic alcohols (**2**) to the corresponding γ,δ-unsaturated aldehydes (**3**) via allyloxyacrylic acids (**4a**).[8,9] The γ,δ-unsaturated aldehydes (**3**) obtained from the Claisen rearrangement-decarboxylation of (**4a**) are the same products that would be obtained from Claisen rearrangement of the corresponding allyl vinyl ethers. The basic conditions required for the addition of allyic alcohols to the betaine (**1**) complement the previous methods of allyl vinyl ether formation.

(2) (3) (1)

(4a) R = H
(4b) R = Na

Thus heating the sodium alkoxides of allylic alcohols with betaine (**1**) affords moderate to good yields of the corresponding *trans*-3-(allyloxy)acrylic acid sodium salts (**4b**). Aqueous solutions of the adducts (**4b**) are first washed with ether and then acidified to give the corresponding carboxylic acids (**4a**). These crude products are heated with a trace of hydroquinone at temperatures of 150-200 °C to give products (**3**) from Claisen rearrangement-decarboxylation of (**4a**).[10] Sealed tubes or other high-pressure vessels are not necessary since the acrylic acids (**4a**) have a much higher boiling point than the aldehydes (**3**). The acids are heated under the appropriate reduced pressure such that the product is removed rapidly from the reaction mixture. The aldehydes (**3**) are isolated in good to excellent yields often in analytically pure form (Table 1).

Table 1 Yields of Allyloxy Acrylic Acids (**4a**) and γ,δ-Unsaturated Aldehydes (**3**) from Allylic Alcohols Using Betaine (**1**)

Catechol[1]

[120-80-9] · $C_6H_6O_2$ · Catechol · (MW 110.11)

(reagent for heterocycle synthesis; allylation catalyst; carbonyl protecting group; transition metal ligand)

Alternate Name: pyrocatechol.

Physical Data: mp 104-105 °C; bp 119-121 °C/10 mmHg; *d* 1.344 g cm^{-3}; sublimable (vp 1.0 mmHg, 75 °C); steam volatile.

Solubility: sol benzene, acetone, ether, ethanol, 2.3 parts water, pyridine, aqueous alkali; slightly sol chlorinated solvents.

Form Supplied in: colorless needles (or plates).

Purification: recrystallization from toluene; distillation.

Handling, Storage, and Precautions: toxic (readily absorbed through skin); irritant; causes burns. Light and air sensitive. Explodes on contact with conc. HNO_3.

Alkylation and Heterocycle Synthesis.

Catechol undergoes many of the reactions characteristic of phenols, and as such is used to prepare *o*-alkoxyphenols, *o*-dialkoxybenzenes, and heterocycles.[1] The high yield preparation of five-membered *o*-phenylene heterocyclic systems from catechol is particularly common, and includes 1,3,2-benzodioxaborole from diborane (eq 1) (see ***Catecholborane***),[2] methylenedioxybenzene from

diiodomethane,[3] *o*-phenylene carbonate from phosgene,[4] 1,3-benzodioxoles from allenic derivatives,[5] *o*-phenylene chloro- and bromoboronates from the respective boron trihalides,[6,7] and *o*-phenylene phosphorochloridite from phosphorus trichloride.[8] Larger heterocyclic ring systems, such as 1,4-benzodioxanes (eq 2)[9] and dibenzo- and dicyclohexyl-18-crown-6 polyethers[10] are prepared in good yields using alkylations of catechol.

(1)

(2)

Allylation Catalyst.

Bis(catecholato)allylsiliconates, prepared in situ from catechol, triethylamine, and allyl(trialkoxy)silanes, are effective allylating agents for aldehydes (eq 3).[11] Good yields of homoallylic alcohols are obtained in a regiospecific manner.

(3)

Carbonyl Protecting Group.

Ketones and aldehydes react with catechol under acidic conditions to form cyclic acetals (eq 4).[12] The acetals formed are more stable to acid than ethylene acetals.[13] Cleavage of the *o*-phenylene acetals of α-

unbranched and aromatic ketones with BBr_3 gives geminal dibromides and vinyl bromides, respectively (eq 5).[14]

(4)

(5)

Transition Metal Ligand.

Catechol binds readily to virtually all transition metals, giving catecholato metal complexes.[15] The σ- and π-donating properties of catecholato ligands,[16] as well as other hydroxo ligands,[17] are postulated to stabilize unsaturated organometallic derivatives.

Catecholborane[1]

[274-07-7] · $C_6H_5BO_2$ · Catecholborane · (MW 119.92)

(reducing agent for several functional groups;[2] used to prepare alkyl- and alkenylboronic acids and esters via hydroboration of alkenes and alkynes;[3] can be used for synthesis of amides and macrocyclic lactams from carboxylic acids[4])

Physical Data: mp 12 °C; bp 50 °C/50 mmHg; *d* 1.125 g cm^{-3}.

Solubility: sol diethyl ether, THF, CH_2Cl_2, $CHCl_3$, CCl_4, toluene, and benzene; reacts readily with water and other protic solvents.

Form Supplied in: available as a colorless liquid; 1.0 M solution in THF.

Analysis of Reagent Purity: the technical bulletin *Quantitative Analysis of Active Boron Hydrides*, available upon request from the Aldrich Chemical Company, Milwaukee, WI, USA, describes methodology to determine reagent purity by hydrogen gas evolution.

Purification: the neat reagent may be purified by distillation at reduced pressure.

Handling, Storage, and Precautions: should be stored in a cold room or refrigerator, without exposure to atmospheric moisture; cold storage has been found to minimize loss of hydrogen activity as well as pressure build-up; the neat reagent may be stored as a solid at 0 °C; a sample stored over one year at 0-5 °C showed no detectable loss in hydride activity;[1a] syringe and double-tipped needle techniques are recommended for reagent transfer. Use in a fume hood.

Functional Group Reductions.

Catecholborane (CB) is one of the most versatile boron hydride reducing agents. This reagent possesses enhanced thermal stability and solubility characteristics as compared with other boron hydride reagents. Reductions can be carried out in several organic solvents including CCl_4, $CHCl_3$, benzene, toluene, diethyl ether, and THF, as well as in the absence of solvent.[1a]

Several functional groups do not react with catecholborane. Alkyl and aryl halides, nitro groups, sulfones, disulfides, thiols, primary amides, ethers, sulfides and alcohols are all inert toward the reagent. Nitriles, esters, and acid chlorides react slowly, while aldehydes, ketones, imines, and sulfoxides are readily reduced in a few hours at room temperature.[1a]

Catecholborane readily reduces tosylhydrazones[2] to the corresponding methylene derivatives (eqs 1 and 2). This mild method may be used to advantage with substrates possessing sensitive functional groups which preclude the use of the more conventional Wolff-Kishner and Clemmensen reductions.[5]

Evans[6a] has demonstrated that catecholborane will undergo conjugate reduction of α,β-unsaturated ketones at room temperature (eqs 3 and 4).[6,7] This reaction is limited to α,β-unsaturated ketones that can adopt an *s-cis* conformation, while α,β-unsaturated imides, esters, and amides are unreactive under these conditions. It was also determined that catalytic quantities of ***Chlorotris(triphenylphosphine)rhodium(I)*** greatly accelerate the 1,4-addition process such that reduction occurs readily at -20 °C.

Cyclic enones bearing an endocyclic alkene, e.g. (**1**) and (**2**), do not undergo 1,4-addition but are instead reduced exclusively at the carbonyl group. It is also possible to selectively reduce *trans*-1,2-disubstituted enones in the presence of 1,1-disubstituted systems. The trapping of the intermediate boron enolate by aldehyde electrophiles has also been demonstrated.[6]

(1)

(2)

Several diastereoselective and enantioselective reductions of ketones mediated by catecholborane have also been reported. Acyclic β-hydroxy ketones are stereoselectively reduced to *syn* 1,3-diols by catecholborane (eq 5).[8] In several instances it was found that stereoselectivity could be enhanced by performing the reaction with Rh^{I} catalysis. The high levels of diastereoselectivity are believed to be due to the ability of catecholborane to preorganize the substrate prior to intermolecular delivery of hydride by a second molecule of catecholborane. The incorporation of a methyl group between the hydroxyl and carbonyl groups can affect the *syn* diastereoselectivity, the extent depending upon the stereochemical relationship between the two substituents (eqs 6 and 7).

(5)

Conditions	Yield (*syn*:*anti*)
-10 °C	82% (10:1)
-10 °C, Rh^{I}	76% (12:1)
-35 °C	87% (6:1)
-35 °C, Rh^{I}	86% (20:1)

(6)

35:1

(7)

6:1

Chiral oxazaborolidines, initially reported by Itsuno[9] and later developed by Corey,[10] have been used for the enantioselective reduction of ketones. Corey has demonstrated that oxazaborolidine (**3**), prepared from ***α,α-Diphenyl-2-pyrrolidinemethanol*** and butylboronic acid, is a highly effective catalyst for the asymmetric reduction of ketones using catecholborane as a stoichiometric reductant. This system was also shown to be superior for the asymmetric 1,2-reduction of enones.

	*R*	93%

Hydroboration of Alkenes.

Hydroborations of alkenes by catecholborane[3] are generally much slower than those employing dialkylboranes.[11] Elevated temperatures are usually required; however, the reaction rates may be enhanced by the use of Wilkinson's catalyst,[12] *N*,*N*-dimethylaniline-borane,[13] and ***Lithium Borohydride***.[14] The alkylboronic esters obtained are easily hydrolyzed to the corresponding alkylboronic acids or converted to aldehydes,[15] ketones,[16] carboxylic acids,[17] and alcohols.[3e,8] The esters may also be homologated, thus making possible the synthesis of substituted boronic esters, which have become increasingly useful as reagents for stereodirected synthesis.[18]

Catecholborane has been widely used for the transition metal catalyzed hydroborations of alkenes.[12,19] Both Rh^{I} and Ir^{I} have been used as the metal catalyst. Catalysis not only has a beneficial effect on rate, but has also been found to alter the chemo-, regio- and stereochemical course of the hydroboration when compared to the uncatalyzed reaction.[19]

Evans has established that the rate of the transition metal catalyzed hydroboration is very sensitive to the alkene substitution pattern.[20,21] Terminal alkenes undergo complete hydroboration within minutes at room temperature, while 1,1- and 1,2-disubstituted alkenes require several hours. Trisubstituted alkenes are unreactive. The sensitivity of the catalyzed reaction to steric effects affords the possibility for selective hydroboration of the less hindered of two alkenyl groups in a given substrate (eq 8).[20]

(8)

Good to excellent levels of 1,2-asymmetric induction are obtained in the catalyzed hydroboration of chiral 1,1-disubstituted alkenes with catecholborane (eq 9). The extent of asymmetric induction has been found to depend on the size of X and, to a lesser extent, the size of R´. The catalyzed and uncatalyzed reactions are stereocomplementary, with the former favoring the formation of products with *syn* stereochemistry while the latter favors products with *anti* stereochemistry.[20,22] Allylic and homoallylic diphenyl phosphinite and amide functional groups have also been used to direct the regiochemistry of the catalyzed hydroboration reaction. Examples of this methodology with both cyclic and acyclic substrates have been reported.[20,23]

(9)

Several groups have reported catalyst systems for the asymmetric hydroboration of prochiral alkenes using the catalyzed hydroboration reaction with a chirally modified metal catalyst.[24] Most of the reactions employ a Rh^I catalyst modified with chirally modified bidentate phosphine ligands. Enantiomeric excesses obtained with several alkene substrates are in the good to excellent range.[24b,f]

Hydroboration of Alkynes.

The hydroboration of alkynes with catecholborane is an efficient route to alkenylboronic esters and acids. The regioselectivity of the addition to unsymmetrical alkenes is very similar to that displayed by ***Disiamylborane***.[3c-e] The rate of reaction can be enhanced through use of *N*,*N*-dimethylaniline-borane complex.[13]

The alkenylboronic esters and acids obtained have proven to be valuable synthetic intermediates. Perhaps the most widespread use of these intermediates has been in the Pd^0 catalyzed cross-coupling reaction with alkenyl, alkynyl, and aryl halides to give the corresponding alkenes (eq 10).[25]

Protonolysis of alkenylboronic esters deriving from internal alkynes provides a route for the stereospecific synthesis of *cis*-disubstituted alkenes, while an oxidative workup will afford the corresponding ketone.[3d,e] Iodo- and bromoalkenes can also be prepared stereospecifically from alkenylboronic ester intermediates.[26] These compounds are useful in alkene cross-coupling reactions as well as in the preparation of alkenylmagnesium and alkenyllithium compounds. Haloalkenes may also be prepared from alkenylboronic acids via organomercurial intermediates (eq 11).[27]

Reagent for Amide and Lactam Synthesis.

Carboxylic acids react rapidly with catecholborane to produce 2-acyloxy-1,3,2-benzodioxaborolanes, e.g. (**4**). This reaction has been used as the carboxyl activation step for the synthesis of amides and macrocyclic lactams (eq 12).[4]

Related Reagents.

Bis(benzoyloxy)borane; ***Disiamylborane***.

Catechylphosphorus Trichloride[1]

(trichloride)

[2007-97-8] · $C_6H_4Cl_3O_2P$ · Catechylphosphorus Trichloride · (MW 245.43) (tribromide)

[3712-44-5] · $C_6H_4Br_3O_2P$ · Catechylphosphorus Tribromide · (MW 378.81)

(chlorinating reagent; exchange of oxygen and sulfur to chlorine)

Alternate Names: CPT; 2,2,2-trichloro-2,2-dihydro-1,3,2-benzodioxaphosphole.

Physical Data: mp 61-62 °C; bp 132-135 °C/12 mmHg; ^{31}P NMR: δ -26 ppm.

Solubility: sol CH_2Cl_2, $CHCl_3$, CCl_4, Et_2O, benzene, hexane; reacts violently with H_2O and other protonic solvents, also with alcohols, acetone, DMF, THF.

Form Supplied in: pale yellow solid; commercially available.

Handling, Storage, and Precautions: the solid must be stored in absence of moisture; the dissolved solid is easy to handle; the substance is corrosive and toxic on contact. This reagent should be handled in a fume hood.

Reactions with catechylphosphorus trichloride (CPT) are normally carried out by heating (30 min, water bath) without solvents (other conditions are described, see equations). The products must be separated by distillation from the catechylphosphoryl (bp 120-122 °C/13 mmHg) or thiophosphoryl chloride (bp 114 °C/13 mmHg) also formed. Normally the boiling points of the products are lower than those of the byproducts.

Displacement of Double-Bonded Oxygen or Sulfur by Chlorine.

CPT converts carboxylic acids and dithiocarboxylic acids to acid chlorides (eqs 1 and 2).[1-3] Also sulfonic, phosphinic, and phosphonic acids react in the same way to give the corresponding acid chlorides (eqs 3-5; R´ = H).[1,4,5]

$$RCO_2H \xrightarrow{CPT} RCOCl \qquad (1)$$

$$RCSSH \xrightarrow{CPT} RCSCl \qquad (2)$$

$$RSO_3H \xrightarrow{CPT} RSO_2Cl \qquad (3)$$

$$R_2PO_2R' \xrightarrow{CPT} R_2POCl + R'Cl \qquad (4)$$

$$RPO_3R'_2 \xrightarrow{CPT} RPOCl_2 + 2\,R'Cl \qquad (5)$$

$$R' = H,\ Alk$$

Esters of phosphinic, phosphonic, and carboxylic acids were cleaved by CPT to alkyl chlorides and acid monochlorides or dichlorides (eqs 4-6; R´ = Alk).[1,5] Anhydrides of carboxylic acids also react with CPT to give acid chlorides (eq 7).[1,2]

$$RCO_2R' \xrightarrow{CPT} RCOCl + R'Cl \qquad (6)$$

$$(RCO)_2O \xrightarrow{CPT} 2\,RCOCl \qquad (7)$$

In all cases the yield of acid chlorides is higher than the yield of the reactions with PCl_5.

CPT converts alkyl formates to α,α-dichloromethyl alkyl ethers[1,2,6] and *N*,*N*-disubstituted formamides to the corresponding amide dichlorides (eqs 8 and 9);[1] in particular, dimethylformamide dichloride (Vilsmeier reagent) was obtained in high yield and very good purity.

$$\mathrm{OCHOR} \xrightarrow{\mathrm{CPT}} \mathrm{Cl_2CHOR} \qquad (8)$$

$$\mathrm{OCHNR_2} \xrightarrow[\mathrm{Et_2O,\ 0\ ^\circ C}]{\mathrm{CPT}} \mathrm{ClCHNR_2^+\ Cl^-} \qquad (9)$$

Both types of dichlorides are good chlorinating reagents. The reactions of unsubstituted amides, urethanes, and dithiocarbamides with CPT give nitriles,[1,2] isocyanates,[1,2,7] and isothiocyanates,[8] respectively, in good yields (eqs 10-12).

$$\mathrm{RCONH_2} \xrightarrow{\mathrm{CPT}} \mathrm{RCN} \qquad (10)$$

$$\mathrm{RNHCO_2R'} \xrightarrow{\mathrm{CPT}} \mathrm{RNCO} \qquad (11)$$

$$\mathrm{RNHCSS^-\ RNH_3^+} \xrightarrow{\mathrm{CPT}} \mathrm{RNCS} \qquad (12)$$

Displacement of Single-Bonded Oxygen or Sulfur by Chlorine.

CPT converts alcohols to alkyl chlorides[1,9] and cyclic ethers (e.g. THF or ethylene oxide) to α,o-dichloroalkanes (eqs 13 and 14).[1,2] Acetals and hemiacetals were cleaved by CPT to α-chloro ethers and alkyl chlorides and HCl, respectively (eq 15).[1,10] Trialkyl trithioorthoformate reacts with CPT to give the stable dialkyl chlorodithioorthoformate (eq 16).[11]

$$\mathrm{ROH} \xrightarrow{\mathrm{CPT}} \mathrm{RCl} \qquad (13)$$

(14)

$$RCH(OR')OR'' \xrightarrow{CPT} RCH(OR')Cl + R''Cl \qquad (15)$$

$R'' = H, Alk$

$$CH(SR')_3 \xrightarrow{CPT} ClCH(SR')_2 + R'Cl \qquad (16)$$

CPT converts phosphites to chlorophosphites (eq 17);[1,12] it is the best method for the synthesis of pure diethyl chlorophosphite.[12] Silyl ethers or disiloxanes react with CPT to give silyl chlorides (eq 18).[1]

$$P(OR)_3 \xrightarrow{CPT} ClP(OR)_2 + RCl \qquad (17)$$

$$Me_3SiOR' \xrightarrow{CPT} Me_3SiCl + R'Cl \qquad (18)$$

$R' = Alk, Me_3Si$

Catechylphosphorus Tribromide.

This reagent reacts in the same way. It is particularly suitable for the synthesis of acid bromides from acids,[13] α,α-dibromomethyl alkyl ethers from alkyl formates,[14] and trimethylsilyl bromide from hexamethyldisiloxane.[15]

Catechol Sulfate

[4074-55-9] · $C_6H_4O_4S$ · Catechol Sulfate · (MW 172.16)

(selective reagent for the conversion of amines to sulfamate salts[4] and sulfamides;[9] mild reagent for sulfonation of carbon acids[16])

Alternate Name: pyrocatechol cyclic sulfate; 1,3,2-benzodioxathiole 2,2-dioxide.

Physical Data: mp 35.5-36 °C; bp 76-78 °C/1.25 mmHg.[4]

Solubility: Sparingly sol water and hexane; sol most organic solvents.

Form Supplied in: white solid or colorless needles.

Preparative Method: reaction of catechol with SO_2Cl_2.[4]

Purification: distillation and recrystallization (hexane).

Handling, Storage, and Precautions: stable indefinitely at ambient temp; no information available on toxicity.

The reactivity of catechol sulfate (CS) with hydroxide ion is anomalous relative to other sulfuric acid diesters. Surprising is the very high rate of cleavage[1] and that only S-O fission is observed.[2] X-ray crystal data suggest this unusual reactivity to be due to ring-strain effects and a distorted nonplanar conformation.[3]

Conversion of Amines to Sulfamate Salts.

Amines may be cleanly converted to catecholyl esters of sulfamic acids on reaction with CS.[4] These readily isolable esters may be efficiently hydrolyzed on mild alkaline treatment. This two-step process affords greater selectivity than possible with other reagents such as $ClSO_3H$ and SO_3 complexes,[5] fuming H_2SO_4,[6,7] and $SO_2Cl_2/SbCl_5$.[8] As example of the selectivity observed with CS, amine (**1**) is quantitatively converted to ester (**2**) which is then cleanly hydrolyzed to sulfamate salt (**3**) (eq 1). In contrast, while reaction of (**1**) with Me_3N/SO_3 gives (**3**) directly, it is formed as a minor

component (15-20%) of a complex mixture. Ester (**2**) is then cleanly converted to (**3**) by reaction with alkali.

The CS sulfamation procedure is limited to primary aliphatic amines. Aromatic amines react only slowly with CS and secondary amine/CS condensation products are not cleaved by alkali.

Conversion of Amines to Sulfamides.

Catecholyl sulfamate esters, which are available as described above, may be combined with a second amine to provide sulfamides.[9] Other known procedures for sulfamide preparation employ strongly electrophilic agents such as SO_2Cl_2.[10-13] The two-step CS procedure is advantaged in its selectivity and in that either symmetrical or unsymmetrical sulfamides may be obtained. It is limited in that the amine which reacts with CS must be primary and thus tetrasubstituted products cannot be obtained directly. Sulfamides of the type $R^1R^2NSO_2NH_2$ have been prepared by using a primary amine in which the alkyl substituent is acid labile (e.g. 4-MeOPhCH_2).[14] Exemplary of the two-step CS sulfamide methodology is the preparation of (**4**) (eq 2).

Conversion of Carbon Acids to Sulfonate Salts.

Reaction of a carbanion with CS yields the catecholyl ester of a sulfonic acid. The ester is easily hydrolyzed with alkali to give the desired sulfonic acid salt.[15] This procedure is selective and the intermediate esters may easily be isolated in pure form. Carbon acids may also be sulfonated by SO_3 and various of its complexes.[16] However, the yields are generally low and the desired products difficult to obtain in pure form. Exemplary of CS sulfonation is the preparation of substituted methionic acid (**5**) (eq 3).[15]

Celite

[61790-53-2]

(diatomaceous, siliceous, or infusorial earth; filter aid; clarifying agent; adsorbent for reagents; chromatography[1])

Physical Data: inorganic solid, mainly SiO_2.

Solubility: insol H_2O, acid, or dilute base.

Form Supplied in: Celite® is a well known trademark of Manville, Filtration and Minerals; an off-white to white solid; widely available.

General Considerations.

Celite is composed of mostly SiO_2, and is known as diatomaceous earth or infusorial earth.[1] Celite is used in a wide variety of applications including, but not limited to, a filter aid, heat insulating material, clarifying agent, filler, adsorbent for dynamite, chromatography, and as a mild abrasive. It is useful for removal of finely divided particulate matter like decolorizing carbon, and adsorbance of colloidal substances. Future and current uses for Celite include immobilization of enzymes, spores, or cells for chemical transformations as well as reagent support in columns for microscale chemistry. The focus of this entry is the use of Celite as a surface for reagents or reactants in heterogenous reactions including oxidation, alkylation, and dehydration of organic compounds.

Chromium Oxidations.

Oxidations employing ***Chromium(VI) Oxide*** on Celite or ***Pyridinium Chlorochromate*** on Celite have been useful for oxidation of β-hydroxynitrosamines, β-hydroxynitrosoureas,[2] secondary alcohols (eq 1),[3] propargyl alcohols,[4] and primary alcohols to aldehydes (eq 2).[5]

(1)

(2)

Potassium Fluoride.

Potassium Fluoride-Celite is a heterogenous catalyst that promotes an efficient cyclization that is useful in the synthesis of prenylated flavanones (eq 3).[6] Other studies include arylation reactions of 1,3-dicarbonyl compounds using fluoride ion by activation with iron,[7] *C*-, *N*-, *O*-, and *S*-alkylations with alkyl halides,[8] and KF/Celite alkylation reactions compared with other inorganic solid supports.[9]

(3)

Silver Carbonate.

Perhaps the best known reagent employing Celite is Fetizon's reagent. ***Silver(I) Carbonate*** promotes reactions with phenols, amines, hydrazines, hydroxylamines, oximes, and fragmentations. An extensive review[10] describes selective oxidation of sensitive alcohols to aldehydes or ketones under neutral conditions, and includes a mechanistic discussion. Other studies include a series of papers on the oxidation of carbohydrates,[11] oxidative coupling of phenols (eq 4),[12] a mechanistic study,[13] and oxidation of allylic alcohols (eq 5).[14]

Phosphorus Pentoxide.

Phosphorus(V) Oxide/Celite has been used to mediate Bischler-Napieralski reactions (eq 6),[15] and has been used to dehydrate triflic acid to triflic anhydride in 70-90% yield (eq 7).[16]

Cerium

Ce

[7440-45-1] · Ce · Cerium · (MW 140.12)

(reagent for the Barbier and the Reformatsky reactions and pinacol coupling)

Physical Data: mp 804 °C; bp ca. 3470 °C; *d* 6.77 g cm^{-3}.

Form Supplied in: powder, chip, foil, and ingot are commercially available in 99.9% purity.

Handling, Storage, and Precautions: metallic cerium is sensitive to air and is stored in mineral oil or under argon. It readily burns in air from friction, and the preparation of cerium powder by scraping cerium ingots with a rasp should therefore be carried out in a glove bag or a dry box. Cerium is reputed to be of low toxicity.

Preparation of Organocerium Compounds.

Cerium powder or chips can be used for the Barbier reaction between alkyl halides and carbonyl compounds. Allylic and benzylic halides react most easily under mild conditions.[1,2] The reactions are chemoselective and additions to carbonyl compounds containing functional groups such as nitriles, nitro compounds, esters, and vinylic iodides are possible (eq 1).

α-Halo esters undergo cerium-promoted Reformatsky reactions with carbonyl compounds. The reaction occurs even at -40 °C, and chemoselectivity is observed under these conditions (eq 2).[1] β-Halo esters also react with ketones in the presence of cerium to give γ-lactones together with pinacol coupling products (eq 3).[3]

Cerium in combination with ***Iodine*** is used for reductive coupling of carbonyl compounds (eq 4).[4] Aromatic aldehydes and ketones (except benzophenone) are most easily dimerized to pinacols. On the other hand, the reactions of cyclic ketones depend on the ring size: 4-7 membered ketones undergo smooth dimerization, while cyclododecanone is subjected to reduction to give the corresponding secondary alcohol in 70% yield. Ester, nitrile, and vinyl halide moieties are not affected under these conditions, and over-reduction of the carbonyl substrate to generate alkenes is not observed with the cerium reagent. It is not clear whether this system has any advantages compared to the more widely used low-valent titanium reagents.

Cerium(III) Acetate-Boron Trifluoride Etherate

$Ce(OAc)_3$-$BF_3.OEt_2$

($Ce(OAc)_3$)

[537-00-8] · $C_6H_9CeO_6$ · Cerium(III) Acetate-Boron Trifluoride Etherate · (MW 317.27) ($BF_3.OEt_2$)

[109-63-7] · $C_4H_{10}BF_3O$ · Cerium(III) Acetate-Boron Trifluoride Etherate · (MW 141.95)

(two-component Lewis acid catalyst system[1,2] for the cyclocondensation of aldehydes with siloxydienes[3])

Physical Data: complex generated in situ.

Solubility: slightly sol toluene.

Form Supplied in: generated in situ from anhydrous cerium(III) acetate and ***Boron Trifluoride Etherate***.

Preparative Methods: anhydrous $Ce(OAc)_3$ is required for the preparation of this Lewis acid system and is obtained by drying cerium(III) acetate hydrate at 100 °C under high vacuum for at least 3 h. This material is then slurried into toluene under an argon atmosphere for 30 min, cooled to -78 °C, and treated with freshly distilled $BF_3.OEt_2$ to give the title reagent.

Handling, Storage, and Precautions: this binary Lewis acid system is best used as prepared. Strictly anhydrous conditions are required. Cerium reagents are generally of low toxicity. $BF_3.OEt_2$ is extremely moisture sensitive. This reagent should be handled in a fume hood.

Cyclocondensation of Aldehydes with Siloxydienes.

Thus far, reported applications of $Ce(OAc)_3$-$BF_3.OEt_2$ have been limited to the area of Lewis acid-catalyzed cyclocondensation reactions of activated dienes with aldehydes.[1-3] In the context of efforts aimed at developing a fully synthetic route to tunicaminyl uracil, a subunit of the tunicamycins, Danishefsky and co-workers examined a number of Lewis acid promoters for the cyclocondensation of aldehyde (**1**) with the oxygenated diene (**2**).[1,4] They found that the binary Lewis acid $Ce(OAc)_3$-$BF_3.OEt_2$ (toluene, -78 °C, 2 h) afforded a 45% yield of a single diastereomeric product, dihydropyrone (**3**), along with ca. 20% of recovered aldehyde (**1**) (eq 1). The facial sense of the reaction can be rationalized by invoking chelation of the β-alkoxy aldehyde by the highly oxophilic[5] $Ce(OAc)_3$-$BF_3.OEt_2$, followed by α-face attack of the diene (**2**) on the chelated ensemble.[6] Apparently both oxygen atoms of the (benzyloxy)methoxy C-

5´ appendage play a role in the observed extraordinary diastereofacial selectivity.[2] The use of alternative Lewis acids, including those known to favor chelation control (e.g. $SnCl_4$), afforded (**3**) along with significant and varying amounts of two of the other three possible diastereomeric dihydropyrones.[1]

One limitation of the $Ce(OAc)_3$-$BF_3.OEt_2$ mediated cyclocondensation chemistry was found during attempts to extend the scope of the process to include aldehyde substrates incorporating a nucleoside subunit. For example, the aldehydes (**4**) failed to react with diene (**2**) to give the targeted dihydropyrones (**5**) (eq 2).[2] Evidently the two-component catalyst system is modified or destroyed by the uracil ring.

Cerium(IV) Ammonium Nitrate[1]

$(NH_4)_2Ce(NO_3)_6$

[16774-21-3] · $CeH_8N_8O_{18}$ · Cerium(IV) Ammonium Nitrate · (MW 548.26)

(volumetric standard oxidant;[2] oxidant for many functional groups;[1] can promote oxidative halogenation[3])

Alternate Name: ammonium cerium(IV) nitrate; ceric ammonium nitrate; CAN.

Solubility: sol water (1.41 g mL^{-1} at 25 °C, 2.27 g mL^{-1} at 80 °C); sol nitric acid.

Form Supplied in: orange crystals; widely available.

Handling, Storage, and Precautions: solid used as supplied. No toxicity data available, but cerium is reputed to be of low toxicity.

Functional Group Oxidation.

Ce^{IV} in acidic media is a stronger oxidant than elemental chlorine and is exceeded in oxidizing power only by a few reagents (F_2, XeO_3, Ag^{2+}, O_3, HN_3). The thermodynamically unstable solutions can be kept for days because of kinetic stability. CAN is a one-electron oxidant soluble in water and to a smaller extent in polar solvents such as acetic acid. Its consumption can be judged by the fading of an orange color to pale yellow, if the substrate or product is not strongly colored. Because of its extremely limited solubility in common organic solvents, oxidations are often carried out in mixed solvents such as aqueous acetonitrile. There are advantages in using dual oxidant systems in which Ce^{IV} is present in catalytic amounts. Cooxidants such as ***Sodium Bromate***,[4] ***t-Butyl Hydroperoxide***,[5] and ***Oxygen***[6] have been employed. Electrolytic recycling[7] of Ce^{IV} species is also possible.

Cerium(IV) sulfate and a few other ligand-modified CAN reagents have been used for the oxidation. The differences in their oxidation patterns are small, and consequently it is quite safe to replace one particular oxidizing system with another. More rarely employed is cerium(IV) perchlorate.

Oxidation of Alkenes and Arenes.

The outcome of the oxidation of alkenes is solvent dependent, but dinitroxylation (eq 1)[8] has been achieved. Certain arylcyclopropanes are converted into the 1,3-diol dinitrates.[9]

CAN promotes benzylic oxidation of arenes,[10] e.g. methyl groups are converted into formyl groups but less efficiently when an electron-withdrawing group is present in the aromatic ring. A very interesting molecule, hexaoxo[1_6]orthocyclophane in an internal acetal form (eq 2),[11] has been generated via CAN oxidation. Regioselective oxidation is observed with certain substrates, e.g. 2,4-dimethylanisole gives 3-methyl-*p*-anisaldehyde. Oxidation may be diverted into formation of non-aldehyde products by using different media: benzylic acetates[12] are formed in glacial acetic acid, ethers[13] in alcohol solvents, and nitrates[14] in acetonitrile under photolytic conditions.

Polynuclear aromatic systems can be oxidized to quinones,[15] but unsymmetrical substrates will often give a mixture of products. It has been reported that mononitro derivatives were formed by the oxidation of polynuclear arenes with CAN adsorbed in silica,[16] whereas dinitro compounds and quinones were obtained from oxidation in solution.

Oxidation of Alcohols, Phenols, and Ethers.

A primary alcohol can be retained when a secondary alcohol is oxidized to ketone.[17] Tetrahydrofuran formation (eq 3)[18] predominates in molecules with rigid frameworks, which are favorable to δ-hydrogen abstraction by an alkoxyl radical.

(3)

Tertiary alcohols are prone to fragmentation;[19] this process is facilitated by a β-trimethylsilyl group (eq 4)[20]. Other alcohols prone to fragmentation are cyclobutanols,[21] strained bicyclo[*x.y.z*]alkan-2-ols,[22] and homoallylic alcohols.[18d]

(4)

CAN converts benzylic alcohols into carbonyl compounds.[23] Even *p*-nitrobenzyl alcohol gives *p*-nitrobenzaldehyde in the catalytic oxidation system.[23c] Oxygen can be used[6] as the stoichiometric oxidant.

Catechols, hydroquinones, and their methyl ethers readily afford quinones on Ce^{IV} oxidation.[4,24] Partial demethylative oxidation is feasible, as shown in the preparation of several intramolecular quinhydrones (eq 5)[25] and a precursor of daunomycinone.[26] Sometimes the dual oxidant system of CAN-$NaBrO_3$ is useful. In a synthesis of methoxatin (eq 6)[27] the *o*-quinone moiety was generated from an aryl methyl ether.

Oxidative regeneration of the carboxylic acid from its 2,6-di-*t*-butyl-4-methoxyphenyl ester[28] is the basis for the use of this auxiliary in a stereoselective α-hydroxyalkylation of carboxylic acids. The smooth removal of *p*-anisyl (eq 7)[29] and *p*-anisylmethyl[30] groups from an amidic nitrogen atom by Ce^{IV} oxidation makes these protective groups valuable in synthesis.

Simple ethers are oxidized[31] to carbonyl products and the intermediate from tetrahydrofuran oxidation can be trapped by alcohols.[32]

Vicinal diols undergo oxidative cleavage.[33] There is no apparent steric limitation as both *cis*- and *trans*-cycloalkane-1,2-diols are susceptible to cleavage. However, under certain conditions α-hydroxy ketones may be oxidized without breaking the C-C bond.[6]

Oxidation of Carbonyl Compounds.

The Ce^{IV} oxidation of aldehydes and ketones is of much less synthetic significance than methods using other reagents. However, cage ketones often provide lactones (eq 8)[34,35] in good yield. Tetracyclones furnish α-pyrones.[36]

Concerning carboxylic acids and their derivatives, transformations of practical value are restricted to oxidative hydrolysis such as the conversion of hydrazides[37] back to carboxylic acids, transamidation of *N*-acyl-5,6-dihydrophenanthridines,[38] and decarboxylative processes, especially the degradation of α-hydroxymalonic acids (eq 9).[39] In some cases the Ce^{IV} oxidation is much superior to periodate cleavage. A related reaction is involved in a route to lactones.[40]

Nitrogenous derivatives of carbonyl compounds such as oximes and semicarbazones are oxidatively cleaved by Ce^{IV},[41] but only a few synthetic applications have been reported.[42]

Oxidation of Nitroalkanes.

Ce^{IV} oxidation provides an alternative to the Nef reaction.[43] At least in the case of a ketomacrolide synthesis (eq 10),[44] complications arising from side reactions caused by other reagents are avoided.

(10)

Oxidation of Organosulfur Compounds.

Thiols are converted into disulfides using reagents such as ***Bis[trinitratocerium(IV)] Chromate***.[45] Chemoselective oxidation of sulfides by Ce^{IV} reagents to sulfoxides[4,46] is easily accomplished. Stoichiometric oxidation under phase transfer conditions[46b] and the dual oxidant[4] protocols permit oxidation of a variety of sulfides.

The reaction of dithioacetals including 1,3-dithiolanes and 1,3-dithianes with CAN provides a convenient procedure for the generation of the corresponding carbonyl group.[47] The rapid reaction is serviceable in many systems and superior to other methods, e.g. in the synthesis of acylsilanes.[48] In a series of compounds in which the dithiolane group is sterically hindered, the reaction led to enones, i.e. dehydrogenation accompanied the deprotection (eq 11).[49]

(11)

R = H, Me

Oxidative Cleavage of Organometallic Compounds.

Oxidative deligation of both σ- and π-complexes by treatment with CAN is common practice. Ligands including cyclobutadiene and derivatives (eq 12)[50] and α-methylene-γ-butyrolactone (eq 13)[51] have been liberated successfully and applied to achieving the intended research goals. In the recovery of organic products from a Dötz reaction, CAN is often employed to cleave off the metallic species.[52]

Generation of α-Acyl Radicals.

As a one-electron oxidant, Ce^{IV} can promote the formation of radicals from carbonyl compounds. In the presence of interceptors such as butadiene and alkenyl acetates, the α-acyl radicals undergo addition.[53] The carbonyl compounds may be introduced as enol silyl ethers, and the oxidative coupling of two such ethers may be accomplished.[54] Some differences in the efficiency for oxidative cyclization of δ,ε-, and ε,ζ-unsaturated enol silyl ethers using CAN and other oxidants have been noted (eq 14).[55]

Oxidative Halogenation.

Benzylic bromination[56] and α-iodination of ketones[3a] and uracil derivatives[3b] can be achieved with CAN as in situ oxidant.

Related Reagents.

Cerium(IV) Ammonium Nitrate-Sodium Bromate

$(NH_4)_2Ce(NO_3)_6$-$NaBrO_3$

($(NH_4)_2Ce(NO_3)_6$)

[16774-21-3] · $CeH_8N_8O_{18}$ · Cerium(IV) Ammonium Nitrate-Sodium Bromate · (MW 548.26) ($NaBrO_3$)

[7789-38-0] · $BrNaO_3$ · Cerium(IV) Ammonium Nitrate-Sodium Bromate · (MW 150.91)

(capable of selective oxidation of secondary alcohols, oxidative cleavage of alkyl and silyl ethers)
Cerium(IV) ammonium nitrate.

Solubility: very sol water.

Form Supplied in: small, orange-red, monoclinic crystals. Sodium bromate.

Physical Data: mp 381 °C (dec); *d* 3.34 g cm^{-3}.

Solubility: sol water (27.5 g/100 g at 0 °C; 90.9 g/100 g at 100 °C).

Form Supplied in: white granules or cryst. powder.

Handling, Storage, and Precautions: ingestion may cause vomiting, diarrhea, methemoglobinemia, renal injury. These reagents should be handled in a fume hood.

Oxidation of Alcohols.

Sodium Bromate oxidizes benzylic alcohols to the corresponding aldehydes or ketones under ***Cerium(IV) Ammonium Nitrate*** (CAN) catalysis (eq 1).[1] The reagent has been utilized for the oxidation of secondary alcohols to ketones. Primary/secondary diols can be oxidized selectively to afford hydroxy ketones in the presence of CAN or $Ce(SO_4)_2$ (eq 2).[2] Oxidation of a primary/primary 1,4-diol gives a γ-lactone (eq 3).[2] CAN catalyzes the oxidative cleavage of alkyl and silyl ethers to carbonyl compounds with $NaBrO_3$ (eq 4).[3]

R^1 = alkyl, aryl; R^2 = H, alkyl, aryl;

Cerium(IV) Ammonium Sulfate[1]

$Ce(NH_4)_4(SO_4)_4.2H_2O$

[7637-03-8] · $CeH_{16}N_4O_{16}S_4$ · Cerium(IV) Ammonium Sulfate · (MW 596.52) (.$2H_2O$)

[10378-47-9] · $H_{20}CeN_4O_{18}S_4$ · Cerium(IV) Ammonium Sulfate · (MW 632.55)

(convenient reagent for oxidation of aromatic rings,[2] and halophenols to quinones,[6] for regioselective Baeyer-Villiger oxidation,[11] and oxidative aromatization[12])

Alternate Name: ceric ammonium sulfate; CAS.

Physical Data: mp 140 °C (dec).

Solubility: sol water, dil. H_2SO_4, dil. H_2SO_4-MeCN.

Form Supplied in: orange solid, widely available.

Handling, Storage, and Precautions: cerium(IV) ammonium sulfate is a stable reagent and precautions required for handling strong oxidizing agents such as ***Potassium Permanganate*** will be sufficient. Cerium is reputed to be of low toxicity.

Cerium(IV) ion is a potent one-electron oxidant.[1] ***Cerium(IV) Ammonium Nitrate*** (CAN), is the most widely utilized cerium(IV) oxidizing agent, but cerium(IV) ammonium sulfate (CAS) is a good substitute when complications due to the involvement of nitrate ligands occur, resulting in side products such as nitrate esters.[1]

Synthesis of Quinones by Oxidation of Aromatic Rings.

The most important application of CAS is in the oxidation of aromatic rings. CAN oxidizes polycyclic aromatic hydrocarbons only in moderate yields (20-60%),[1] and these reactions are often complicated by the formation of nitrate esters.[2] In contrast, CAS generally oxidizes aromatic hydrocarbons to quinones in good yields. For example, naphthalene is oxidized to 1,4-naphthoquinone in excellent yield by CAS in a dilute mixture of H_2SO_4 and MeCN (eq 1).[3]

(1)

Other polycyclic aromatic hydrocarbons such as phenanthrene, anthracene, and fluoranthene are converted to the corresponding quinones on oxidation with CAS. Whereas 1-methylnaphthalene gives 1-naphthaldehyde under the conditions,[3] 1-phenyl- and 1-bromonaphthalene react to form some 2-substituted naphthoquinones through an interesting rearrangement (eq 2).[4]

(2)

Oxidation of 1,4-diphenylnaphthalene gives 2,3-diphenyl-1,4-naphthoquinone or 4-hydroxy-2,4-diphenyl-1(4*H*)-naphthalenone, depending upon the reaction conditions (eq 3).[5]

(3)

A process utilizing catalytic amounts of Ce^{IV} and Ag^{II} has also been reported (eq 4).[6]

(4)

Unfortunately, this reagent system is not suitable for the oxidation of substrates of higher ionization potential nor for oxygen-substituted compounds.

The major product isolated from the reaction of CAS with benzo[*b*]fluoranthene is a lactone (eq 5).[7]

Oxidation of Phenols to Quinones.

Halophenols are conveniently oxidized by CAS to haloquinones in good yields (eq 6).[8] On oxidation with CAS, halonaphthols furnish 1,2-diones as minor products in addition to 1,4-quinones.

A direct and convenient route for the conversion of gentisic acid to the corresponding quinone has been developed through the use of CAS in $CHCl_3$ (10% within 15 min) (eq 7).[9]

Baeyer-Villiger Oxidation.

Oxidation of 1,3-bishomocubanone with a slurry of CAS gives rise to the corresponding lactone (eq 8),[10] which is obtained only as a minor product in the peroxy acid Baeyer-Villiger oxidation conditions.

(8)

Oxidative Halogenation.

The reaction of RPh (R = H, Cl, Br, I, Me) with ***Potassium Iodide*** in CF_3CO_2H containing CAS gives a mixture of 2- and 4-RC_6H_4I. Oxidation of methyl 4-methylbenzoate with CAS under the reaction conditions gives exclusively methyl 3-iodo-4-methylbenzoate.[11]

Oxidative Aromatization.

A new type of oxidative aromatization of cyclohexenone with the CAS-***Iodine*** system has been developed (eq 9).[12]

Cerium(III) Chloride[1]

$CeCl_3.7H_2O$

[7790-86-5] · $CeCl_3$ · Cerium(III) Chloride · (MW 246.47) (.$7H_2O$)

[18618-55-8] · $H_{14}CeCl_3O_7$ · Cerium(III) Chloride · (MW 372.59)

(mild Lewis acid capable of selective acetalization;[2] organocerium reagents have increased oxo-[3] and azaphilicity[4] and greatly reduced basicity;[5] in combination with $NaBH_4$ is a selective 1,2-reducing agent[6])

Alternate Name: cerous chloride; cerium trichloride.

Physical Data: mp 848 °C; bp 1727 °C; *d* 3.92 g cm^{-3}.

Solubility: insol cold H_2O; sol alcohol and acetone; slightly sol THF.

Form Supplied in: white solid; widely available. *Drying:* for some applications the cerium trichloride must be strictly anhydrous. The following procedure has proven most efficacious: a one-necked base-washed flask containing the heptahydrate and a magnetic stirring bar was evacuated to 0.1 Torr and heated *slowly* to 140 °C over a 2 h period. At 70 and 100 °C, considerable amounts of water are given off, and these critical temperature zones should not be passed through too quickly. The magnetically stirred white solid is heated overnight at 140 °C, cooled, blanketed with nitrogen, treated with dry THF (10 mL g^{-1}), and agitated at rt for 3 h. To guarantee the complete removal of water, *t*-butyllithium is added dropwise until an orange color persists.

Handling, Storage, and Precautions: anhydrous $CeCl_3$ should be used as prepared for best results. Cerium is reputed to be of low toxicity.

Organocerium Reagents.

Organocerates, most conveniently prepared by the reaction of lithium compounds with anhydrous $CeCl_3$ in THF, are highly oxophilic and significantly less basic than their RLi and RMgBr counterparts. As a consequence, 1,2-addition reactions involving readily enolizable ketones are not adversely affected by competing enolization.[3] Well-studied examples of this phenomenon abound.[7] Although alkyl and vinyl cerates have most often been used,[3,5,7] Cl_2CeCH_2CN,[8] Cl_2CeCH_2COOR,[9] Cl_2CeC&tbond;$CSiMe_3$,[10] and $Cl_2CeCH_2SiMe_3$[11] are known to be equally effective. The last reagent has been utilized for the methylenation of highly enolizable ketones (eq 1)[11a] and for the

conversion of carboxylic acid halides, esters, and lactones into allylsilanes (eq 2).[11b-d] Amides and nitriles also condense with organocerates with equal suppression of enolization.[3,4] In general, high levels of steric hindrance in either reaction partner can be tolerated (eq 3). In select examples, the level of double stereodifferentiation can be impressively high.[5,7,12]

The discovery has been made that allyl anions produced by the reductive metalation of allyl phenyl sulfides condense cleanly with α,β-unsaturated aldehydes in 1,2-fashion at the more substituted allyl terminus in the presence of ***Titanium Tetraisopropoxide***.[13] Use of the allylcerium reagent instead reverses the regioselectivity. Further, the stereochemical preference is *cis* at -78 °C (kinetic control) and *trans* when warmed to -40 °C (eq 4).[14] Grignard addition reactions to vinylogous esters are improved if promoted by $CeCl_3$ (eq 5).[15]

(4)

(5)

Stereodivergent pathways relative to other organometallics have surfaced in the addition of organocerium(III) reagents to chiral α-keto amides (eq 6)[16] and 2-acyloxazolidines (eq 7).[17] Applications of this type hold considerable synthetic potential not only in additions to carbonyl compounds,[18] but also to oxime ethers,[19] oxiranes,[20] and oxazolidines.[21]

MeMgBr, Et_2O, -78 °C	76:24
MeMgBr, $CeCl_3$, THF, -78 °C	25:75

MeMgBr, Et_2O, -90 °C → -78 °C	94: 6
MeLi, $CeCl_3$, THF, -85 °C	16:84

The uniquely high reactivity of cerium reagents toward the often poorly electrophilic azomethine or C=N double bond of hydrazones has been extensively investigated. Smooth 1,2-addition occurs in good yield (67-81%) provided the air-sensitive hydrazones are acylated; when a chiral auxiliary is present, excellent diastereofacial control operates and enantiomerically enriched α-branched amines result (eq 8).[22] There appears to be a fundamental difference between warmed reagents (-78 °C -> 0 °C -> -78 °C) and those generated and used at -78 °C. Sonication appears to facilitate conversion to the organocerate.[23] For SAMP hydrazones and related compounds the condensation is accommodating of a wide range of substitution both in the hydrazone and in the nucleophile. Subsequent reductive cleavage of the N-N bond with preservation of configuration can be performed by hydrogenolysis over W-2 ***Raney Nickel*** at 60 °C (free hydrazones; less preferred because of competing saturation of aromatic substituents if present) or by treatment with ***Lithium*** in liquid ammonia (acylated hydrazines).[22c]

The preparation of (±)-1,3-diphenyl-1,3-propanediamine illustrates an alternative way in which this chemistry can be utilized (eq 9).[24] In all of the 1,2-addition reactions, the preferred reagent stoichiometry appears to be RLi:$CeCl_3$:hydrazone = 2:2:1. A detailed study of the consequences of varying the relative proportions of these constituents has indicated the optimal ratios of RLi:$CeCl_3$ to be 1:1, notwithstanding the fact that not all of the $CeCl_3$ is consumed in the transmetalation step.[25] The proposal has been made that the empirical formula of the cerate best approximates $R_3CeCl_3Li_3$.

Cerium enolates, available by transmetalation of the lithium salts with $CeCl_3$ at -78 °C[26] or by reduction of α-bromo ketones with ***Cerium(III) Chloride-Tin(II) Chloride***,[27] give higher yields of crossed aldol products without altering the stereoselectivity. The $CeCl_3$-$SnCl_2$ reagent combination also acts on α,α´-dibromo ketones to give oxylallyl cations that can be captured in the usual way.[28]

Selective Reductions.

Equimolar amounts of ***Sodium Borohydride***$_4$ and $CeCl_3.7H_2O$ in methanol act on α,β-unsaturated ketones at rt or below to deliver allylic alcohols cleanly by 1,2-addition.[29] This widely used reducing agent[30] is not renowned for its diastereoselectivity[31] and asymmetric induction capabilities,[32] although exceptions are known.[33] Sometimes a stereofacial preference opposite that realized with other hydrides is encountered (eqs 10 and 11).[34]

Allylic alcohol products that are especially sensitive are known to undergo ionization and solvent capture under these mildly acidic conditions (eq 12).[35] The Lewis acidic character of $CeCl_3$ has also been used to advantage in the selective acetalization[6] of saturated aldehydes under the Luche conditions, thereby preventing their reduction.[2] Since ketones and conjugated aldehydes are less responsive, these functionalities are not transiently protected and suffer reduction (eq 13).[36] $NaBH_4$-$CeCl_3$ in MeCN transforms cinnamoyl chlorides into cinnamyl alcohols,[37] while ***Lithium Aluminum Hydride-Cerium(III) Chloride*** in hot DME or THF can effectively reduce alkyl halides and phosphine oxides.[5]

Cerium(III) Chloride-Tin(II) Chloride

$CeCl_3$-$SnCl_2$

· $CeCl_3$ · Cerium(III) Chloride-Tin(II) Chloride · Cl_2Sn · Cerium(III) Chloride-Tin(II) Chloride

(combined reagent; reduces α-bromo ketones to yield cerium enolates which undergo cross-aldol reaction; reduces α,α´-dibromo ketones to yield oxyallyl cations which undergo [3 + 4] cycloaddition with 1,3-dienes)

Physical Data: see ***Cerium(III) Chloride*** and ***Tin(II) Chloride***.

Aldol Reactions with α-Bromo Ketones.[1]

The combination of cerium(III) trichloride-tin(II) chloride in conjunction with α-bromo ketones and carbonyl compounds in THF affords β-hydroxy ketones in good to excellent yields after aqueous workup (eq 1).

Carbon-carbon bond formation takes place regioselectively at the site of the bromine atom. Thus the reaction of 2-bromo-2-methylcyclohexanone or 2-bromo-6-methylcyclohexanone with benzaldehyde affords the corresponding β-hydroxy ketone without any contamination of the regioisomer (eq 2). This result indicates that no retro-aldol or cross-enolization processes occur in the reaction.

(2)

Reactions with ketones provide low yields (30-40%) of the desired aldol products compared with aldehydes. The difference in reactivity between aldehydes and ketones was successfully exploited in the chemoselective aldol condensation to 6-oxoheptanal (eq 3).

(3)

The success of this strategy for cross-aldol reaction is attributed to activation of carbonyl group by Lewis acidic $CeCl_3$ which promotes the reduction of bromine by $SnCl_2$ (eq 4). Neither $CeCl_3$ nor $SnCl_2$ alone gives the coupled products. A cerium enolate intermediate is implicated in the reaction since the tin enolate generated from 2-bromocyclohexanone and low-valent tin ($SnCl_2/LiAlH_4$) reacts with benzaldehyde to afford the *erythro* isomer predominantly,[2] while $CeCl_3$-$SnCl_2$ gives high *threo* selectivity in the same reaction (*erythro:threo* = 15:85-11:89) (eq 5).

(4)

Reformatsky-type reactions cannot be carried out utilizing this combination of reagents,[3] and α-chloro ketones are also unreactive as cerium enolate precursors. Examples of related reagents include the organoaluminum system Et_2AlCl-$SnCl_2$.[4] This combination sometimes requires a Pd^0 complex, whereas the $CeCl_3$-$SnCl_2$ system functions effectively without palladium and is less sensitive to air and moisture contamination.

[3 + 4] Cycloadditions.[5]

The combined reagent $CeCl_3$-$SnCl_2$ promotes the [3 + 4] cycloaddition reaction of α,α´-dibromo ketones with 1,3-dienes in THF effectively under mild conditions (0 °C-rt, 2 h) (eq 6). Furan and cyclopentadiene provide very good yields of the expected cycloadducts. With acyclic 1,3-dienes, 4-cyclohepten-1-ones are produced in modest yields. It is noteworthy that the reaction of 2,4-dibromo-3-pentanone with isoprene gives both [3 + 4] and [3 + 2] cycloadducts. [3 + 2] Cycloaddition proceeds similarly with enamines to afford 2-cyclopenten-1-ones after treatment with 3% ethanolic NaOH solution.

The $CeCl_3$-$SnCl_2$ reagent is a more convenient system for these cycloadditions compared to other procedures.[6] This reaction procedure is quite simple and is carried out at room temperature in air. The reaction involves reduction of an α,α´-dibromo ketone to afford an oxyallyl cation that can be captured by 1,3-dienes in the usual way.

Cerium(III) Iodide

CeI_3

[7790-87-6] · CeI_3 · Cerium(III) Iodide · (MW 520.83)

(organocerium reagents prepared from cerium triiodide and organolithiums have reduced basicity and possess enhanced nucleophilicity toward the carbonyl group; promotes aldol reaction between α-halo ketones and aldehydes; in combination with $LiAlH_4$ is a selective 1,2-reducing agent)

Alternate Name: cerium triiodide

Physical Data: mp 752 °C.

Solubility: sol water, acetone.

Form Supplied in: bright yellow solid.

Preparative Methods: pure CeI_3 is prepared by the reaction of metallic cerium with iodine or mercury(II) iodide at high temperature.[1,2] Another method is to dissolve CeO_2 in aqueous HI solution, adding 12 moles of NH_4I per mole of CeO_2, and evaporating the mixture to dryness. The mixture is heated in vacuo at 300-350 °C to leave pure CeI_3.[3] CeI_3 is prepared in situ by the reaction of powdered cerium with iodine in THF.[4]

Handling, Storage, and Precautions: extremely hygroscopic and turns brown when exposed to air owing to the liberation of iodine. This reagent should be stored under nitrogen and handled in a glove bag.

Organocerium Reagents.

Organocerium reagents are prepared by the reaction of CeI_3 with organolithium compounds in THF.[4] The reagents possess reduced basicity and react with various carbonyl compounds to give the corresponding addition products, even though the substrates are susceptible to enolization, metal-halogen exchange, or 1,4-addition (eqs 1-3) (see also ***Cerium(III) Chloride***).[4,5]

$$Bn_2CO \xrightarrow[\text{THF, -78 °C}]{\text{BuLi, CeI}_3} Bn_2C(OH)Bu \qquad (1)$$

98%

(2)

(3)

Aldol Reaction.

Cerium triiodide is used for cross-aldol reaction between α-halo ketones and aldehydes including α,β-unsaturated aldehydes.[6] The reaction proceeds in THF at room temperature to afford α,β-unsaturated ketones (eq 4); β-hydroxy ketones are not produced. Ketones, however, do not react under these conditions.

PhCOCH=CHCH=CHCH=CHMe (4)

Selective Reductions.

α,β-Unsaturated carbonyl compounds are subject to selective 1,2-reduction by ***Lithium Aluminum Hydride*** in combination with CeI_3 to give allylic alcohols.[7] This method is applicable to α,β-unsaturated aldehydes (eq 5), esters, and lactones that do not undergo selective 1,2-reduction with $NaBH_4$-$CeCl_3$ (see also ***Cerium(III) Chloride***).

Cerium(III) Methanesulfonate[1]

$Ce(OSO_2Me)_3$

[77998-20-0] · $C_3H_9CeO_9S_3$ · Cerium(III) Methanesulfonate · (MW 425.42) (.2H_2O)

[73640-09-2] · $C_3H_{13}CeO_{11}S_3$ · Cerium(III) Methanesulfonate · (MW 461.46)

(stable, soluble cerium(III) salt used as a mediator for organic oxidation)

Alternate Name: cerous methanesulfonate.

Physical Data: white crystalline solid.

Solubility: very sol water, aqueous methanesulfonic acid, and aqueous acetonitrile; sol methanol; insol acetone.

Preparative Methods: prepared by the reaction of methanesulfonic acid with an aqueous suspension of cerium(III) carbonate. Solids can be precipitated with acetone or a large excess of methanesulfonic acid.

Handling, Storage, and Precautions: best used in aqueous solution as prepared. Cerium(III) salts are generally believed to be of low toxicity.

Electrochemical Oxidation.

The methanesulfonate salt of cerium is a convenient mediator for these oxidations because of its high solubility, the stability of the mesylate anion to electrochemical and cerium(IV) oxidation, and the very limited reactivity of the anion with oxidized products or intermediates.[2] ***Cerium(IV) Trifluoromethanesulfonate*** also works well but is more expensive. A solution of cerium(III) methanesulfonate in aqueous methanesulfonic acid is oxidized to cerium(IV) at a platinum, RuO_2/Ti, IrO_2/Ti, or PbO_2/Ti anode.[3] Generally, protons are reduced to hydrogen at the cathode, which is isolated by a perfluorinated ion exchange membrane. Useful reductions can also be performed at the cathode,

such as the reductive coupling of formaldehyde to ethylene glycol.[4]

Oxidations which have been performed with cerium(IV) methanesulfonate in aqueous methanesulfonic acid include the oxidation of alkylaromatics to ketones or aldehydes,[2] polycyclic aromatics to quinones,[2,5] and alkenes to carboxylic acids.[6] The organic substrate is generally employed as a second phase, either as a pure liquid or dissolved in an inert solvent such as 1,2-dichloroethane.[2] This improves selectivity and aids in product separation. The aqueous Ce^{IV} solution can then be regenerated electrochemically. The oxidation of 4-fluorotoluene to 4-fluorobenzaldehyde was performed directly at the anode with cerium trifluoromethanesulfonate as the mediator.[7]

It is sometimes beneficial to modify the oxidizing solution so as to contain an organic cosolvent and/or comediators (catalysts). Thus the oxidation of highly reactive substrates such as 4-methoxytoluene to 4-methoxybenzaldehyde was best accomplished with acetonitrile as a cosolvent.[2] Also, the cerium(IV) oxidation of cyclododecene to dodecanedioic acid was performed with ***Ruthenium(VIII) Oxide***[6] and the oxidation of 2-methylnaphthalene to 2-methyl-1,4-naphthoquinone was performed with Cr^{VI} as comediator.[2]

A solid cerium(IV) material, $Ce(MeSO_3)_2(OH)_2$, can be conveniently prepared by electrochemical oxidation of Ce^{III} in dilute aq. $MeSO_3H$. This solid can be used directly or redissolved in water for organic oxidations.[2]

Cerium(IV)-Nafion 511

(selective oxidation of secondary alcohols)

Physical Data: see ***Cerium(IV) Ammonium Nitrate***.

Form Supplied in: Nafion 511 is supplied as white granules 1 mm in diameter; Nafion® is a registered trademark of E. I. du Pont de Nemours & Co.

Preparative Methods: Nafion 511 (1.1 g) is stirred with a solution of $(NH_4)_2Ce(NO_3)_6$ (1.75 g) in 30 mL of deionized water for 36 h at 25 °C. The catalyst (cerium(IV)-Nafion 511, Ce/NAFK) is filtered, washed with water (10 mL × 5) and dried to constant weight. Titration of the polymer indicates capacity of 0.54 mmol of Ce^{IV} per gram, which corresponds to 71% of the theoretical capacity of a fully loaded resin (**1**).

(1)

Oxidation of Alcohols.

t-Butyl Hydroperoxide can oxidize alcohols to carbonyl compounds in the presence of a polymer supported catalyst (Ce/NAKF).[1] In contrast to the ***Cerium(IV) Ammonium Nitrate-Sodium Bromate*** system, this method is not affected by the presence of carbon-carbon double bonds in the substrates. Thus 2-cyclododecen-1-ol and 11-dodecen-2-ol give the corresponding ketones in good yields (eq 1). Selective oxidation of secondary hydroxyls in the presence of primary ones has also been achieved (eqs 2 and 3). These reactions are performed with ***Sodium Bromate*** as a co-oxidant in AcOH at 55 °C. The catalyst is easily recovered and reused without loss of Ce^{IV} ion.

Cerium(IV) Pyridinium Chloride

[40888-83-3] · $C_{10}H_{12}CeCl_6N_2$ · Cerium(IV) Pyridinium Chloride · (MW 513.06)

(oxidizing reagent for the direct preparation of amides from protected carboxylic acids;[1] for the functionalization of methyl-substituted aromatic compounds[2])

Alternate Name: dipyridinium hexachlorocerate(IV).

Solubility: sol acetonitrile, methanol, ethanol, and water.

Form Supplied in: yellow powder.

Analysis of Reagent Purity: elemental analysis.

Preparative Methods: by reaction of cerium(IV) hydroxide with anhydrous hydrogen chloride and pyridine.[3]

Purification: dry at 120 °C under reduced pressure (0.1 mmHg) for 3 h.[3]

Handling, Storage, and Precautions: hygroscopic, store under nitrogen and protect from exposure to moisture.

Preparation of Amides.[1]

Various amides are directly prepared from 5-acyl-5,6-dihydrophenanthridine carboxylic acid derivatives by reaction with primary amines in the presence of cerium(IV) pyridinium chloride and copper(II) oxide (eq 1). This reagent is far superior to ***Cerium(IV) Ammonium Nitrate*** (CAN) for this purpose. Employment of secondary amines did not give satisfactory results. 5-Acyl-5,6-dihydrophenanthridines with functional groups such as esters, carbonyls, or halogens in the same molecule are also converted to the corresponding amides. The benzoylation of α-amino ester proceeds without racemization.

R = Ph, Ph(CH$_2$)$_3$-, MeCH$_2$CH(Ph)-, etc.
R' = Ph(CH$_2$)$_2$-, MeCH(Ph)-, etc.

Oxidation of Aryl Methyl Groups.[2]

Methyl-substituted aromatic compounds are oxidized to alkoxymethylbenzene derivatives by treatment with cerium pyridinium chloride in alcohol. Oxidation of hexamethylbenzene in ethanol proceeds at reflux temperature to afford the ethyl ether in good yield, while the reaction in methanol gives a 1:1 mixture of methyl ether and chloride (eq 2).

in MeOH	38%	36%
in EtOH	75%	-

Cerium(IV) Trifluoromethanesulfonate

$Ce(OSO_2CF_3)_4$

[107792-63-2] · $C_4CeF_{12}O_{12}S_4$ · Cerium(IV) Trifluoromethanesulfonate · (MW 736.34)

(oxidizing agent for benzyl alcohols and toluenes)

Alternate Name: ceric triflate.

Solubility: sol water, THF, DME, dioxane; insol dichloromethane, hexane, benzene.

Form Supplied in: yellow solid.

Preparative Methods: by the reaction of trifluoromethanesulfonic acid with freshly prepared cerium(IV) carbonate.[1] The reagent can be prepared in situ by the electrochemical oxidation of $Ce(OTf)_3$ in aqueous trifluoromethanesulfonic acid.[2]

Purification: thus far the reagent has only been used in crude form as prepared above.

Handling, Storage, and Precautions: the reagent is extremely hygroscopic and should be stored under strict absence of moisture. This reagent should be handled in a fume hood.

Oxidation of Benzyl Alcohols and Aryl Methyl Groups.

Benzyl alcohols are readily oxidized by $Ce(OTf)_4$ in MeCN-H_2O at room temperature to the corresponding benzaldehydes (eq 1).[1] Under similar conditions, aryl methyl groups are converted to aldehydes in good yields (eq 2) (see also ***Cerium(IV) Ammonium Nitrate*** and ***Cerium(IV) Ammonium Sulfate***).[1] $Ce(OTf)_4$ appears to be more reactive as an oxidizing agent than CAN or CAS.

Cerium(IV) Trifluoroacetate

$$Ce(O_2CCF_3)_4$$

[52118-96-4] · $C_8CeF_{12}O_8$ · Cerium(IV) Trifluoroacetate · (MW 592.17)

(oxidizing agent for aromatic hydrocarbons)

Solubility: sol acetone, DME, DMSO, acetonitrile, TFA containing lithium trifluoroacetate; insol chloroform, dichloromethane, benzene.

Form Supplied in: yellow solid.

Preparative Methods: by the reaction of cerium(IV) hydroxide with TFA to give the basic salt $Ce(OH)_2(O_2CCF_3)_2$, which on further treatment with TFA and its anhydride affords the desired reagent.[1] Thus far the reagent has only been used in the crude state without purification.

Handling, Storage, and Precautions: is sensitive to moisture and light and should therefore be stored under nitrogen and protected from light.

Oxidations of Arenes.

Cerium(IV) trifluoroacetate reacts instantaneously at room temperature with methylbenzenes to give coupling products.[1] For example, durene is oxidized rapidly in TFA containing cerium trifluoroacetate to give a diphenylmethane derivative (eq 1).

Reaction of anthracene with cerium(IV) trifluoroacetate in alcohols provides 9-alkoxyanthracenes (eq 2).[2] Use of lower alcohols affords the corresponding 9-alkoxyanthracenes in good yields, while reaction of higher alcohols results in poor yields of the products, a significant amount of anthraquinone being formed.

Cerium(IV) Trihydroxide Hydroperoxide[1]

$Ce(OH)_3O_2H$

[93131-81-8] · CeH_4O_5 · Cerium(IV) Trihydroxide Hydroperoxide · (MW 224.12)

(mild oxidizing reagent for a variety of functional groups[2,3]

Solubility: insol H_2O, MeCN, EtOH, DMSO, THF.

Form Supplied in: orange-red solid, readily available.

Preparative Method: by the addition of 30% hydrogen peroxide solution (20 mL) to a solution of $CeCl_3.7H_2O$ (0.03 mol) in water (100 mol). Upon addition of conc NH_4OH (15 mL), precipitation of the reagent occurs, which is then washed with water, acetone, and dried in the air (95%).[2]

Handling, Storage, and Precautions: stable at high temperatures >180 °C and for months at rt. Cerium is reputed to have low toxicity.

Heterogeneous oxidations with this reagent (CTH) proceed in dry benzene under reflux. The oxidant is separated by filtration. Evaporation of the solvent and chromatography of the residue affords the oxidation product. Several drawbacks observed with Ce^{IV} oxidations[1a,4] are not encountered with CTH. Change of color from red-orange to pale yellow indicates the deactivation of the reagent, which can be regenerated by two consecutive washings with sodium hydroxide (54-10%) followed by hydrogen peroxide (30%) solutions.

Oxidations.

Allylic, propargylic, and saturated alcohols are not easily oxidized with this reagent, although benzylic alcohols are transformed to their aldehydes (eq 1).

(1)

Benzoins are converted to the benzils (eq 2) and hydroquinones to quinones (eq 3) in high yields.

(2)

(3)

α-Hydroxycarboxylic acids are converted to carbonyl compounds with degradation (eq 4), and thiols are oxidized to disulfides (eq 5) in excellent yields.

(4)

(5)

Aromatic amines are transformed to azo compounds (eq 6).

(6)

A comparison of CTH with ***Cerium(IV) Ammonium Nitrate*** (CAN),[4,5] ***Nickel(II) Peroxide*** (NP),[6] and 2,2´-bipyridylchromium peroxide (BPCP)[7] is shown in Table 1.

Table 1 Comparison of Oxidation Agents[a]

Substrate	Product	CTH	CAN	NP	BPCP
Benzyl alcohol	Benzaldehyde	95	94	91	95
Cinnamyl alcohol	Cinnamaldehyde	15		86	100
Furoin	Furil	95	5		90
2-Mercapto-benzothiazole	2-Benzothiazolyl disulfide	95			100
p-Toluidine	4,4¢Dimethyl-azobenzene	65		25

Cesium Carbonate

Cs_2CO_3

[534-17-8] · CCs_2O_3 · Cesium Carbonate · (MW 325.82)

(used in the synthesis of crown ethers and macrocycles;[1] catalyzes the Horner-Emmons cyclization;[2] used as base for alkylations[3])

Physical Data: mp 610 °C (dec).

Solubility: sol water, alcohol, ether.

Form Supplied in: white powder; widely available.

Purification: crystallized from ethanol (10 mL g^{-1}) by slow evaporation.

Handling, Storage, and Precautions: irritant; handle with gloves; hygroscopic; keep away from moisture; flush eyes or skin with copious amounts of water in case of contact; possible mutagen; avoid inhalation.

Macrocyclization Reagent.

Crown ethers, generally used as ionophores for various applications, can be prepared by using Cs_2CO_3. This reagent serves as both a base and a cation template in the macrocylization of dicarboxylic acids and α,o-alkyl dihalides to generate crown ethers.[1,5] For example, a crown ether is produced in 85% yield when dicesium pyridine-3,5-dicarboxylate, generated from the acid and Cs_2CO_3, reacts with 1,11-dibromo-3,6,9-trioxoundecane in DMF upon heating the reaction mixture between 60-70 °C for 48 h (eq 1). Under similar conditions, aromatic dicarboxylic acids afford related crown ethers. This procedure also works well for crown ethers prepared from salicylic acid and bromopolyethylene glycols.[1]

(1)

Thia crown ethers can also be prepared with Cs_2CO_3. Yields for these reactions are consistently good (45-95%) when the cesium salts of α,o-dithiols are treated with α,o-dihalides in DMF (eq 2).[5] Much lower yields (1-20%) are obtained if other methods, such as high dilution techniques, are used in the absence of a cesium counterion. Similar chemistry has been used to prepare functionalized cyclophane derivatives by replacing the α,o-dihalide with 1,3-dichloroacetone and using *o*-xylylenedithiol as the α,o-dithol.[6]

(2)

Chiral crown ethers have also been prepared by using Cs_2CO_3. A chiral diol and chiral ditosylate, both prepared from (*R*,*R*)-(+)-hydrobenzoin, have been coupled using NaH as a base and Cs_2CO_3 as a template in DMF (eq 3).[7]

Tosylamides have been used to prepare aza macrocycles with Cs_2CO_3. The bicarbonate salt ($CsHCO_3$) is not basic enough to deprotonate ditosylamides.[8] Also, carboxamides and urethanes do not react as efficiently with Cs_2CO_3 as do tosylamides. Among the alkali bases, Cs_2CO_3 provided consistently higher yields than ***Lithium Carbonate***, ***Sodium Carbonate***, ***Potassium Carbonate*** and Rb_2CO_3. A typical example involved treating 1,10-bis[(*p*-tolylsulfonyl)amino]decane with two equivalents of Cs_2CO_3 in dry DMF followed by the addition of 1,6-dibromohexane and stirring the mixture at room temperature for 24 h to give the aza macrocycle in 72% yield. Reduction with sodium amalgam in buffered methanol gave the cyclic diamine (eq 4).

Cs_2CO_3 has been used to prepare derivatized calix[4]arenes for use as lipophilic, water-soluble, and ionophoric receptors.[9] The calix[4]arene cone structure depends on the type of base used for alkylation of the phenolic hydroxyl groups. For example, a cone is generated when NaH is the base during alkylation of the calix[4]arene with ethyl bromoacetate in acetone. When Cs_2CO_3 is used, a 1,3-alternate cone is obtained, whereas a partial cone is formed when K_2CO_3 is used.[9]

Carcerands and carceplexes have been prepared by using Cs_2CO_3. For example, mixing a tetrathiol, a tetrachloride, and pulverized Cs_2CO_3 in DMF/THF under high dilution conditions afforded the carcerand.[10] FAB-MS of the product indicated that the cesium ion served as a template.

Lactonizations can be accomplished using Cs_2CO_3 and o-bromocarboxylic acids at 40 °C in DMF.[4b,11] These conditions afford mixtures of lactones and diolides with their product distribution depending on the ring size. Cs_2CO_3 has been used in a macrocyclization reaction to generate steroids under anionic conditions.[12]

Horner-Emmons Base.

The Horner-Wadsworth-Emmons reaction is sensitive when the carbonyl component contains acidic hydrogens, such as hydroxyl groups. This problem can be circumvented by using Cs_2CO_3 as the base. The method is somewhat dependent on the type of solvent used and the degree of hydration of Cs_2CO_3 (eq 5).[2] NaH has also been replaced with Cs_2CO_3 in a synthesis of D-*erytho*-C_{18}-sphingosine using a Wittig-Horner reaction.[13] A tandem Wittig-Michael reaction in which a lactol is treated with dimethyl phosphonoacetate in the presence of Cs_2CO_3 has been reported (eq 6).[14] An intermolecular Michael addition of a cyclic β-keto ester to an α,β-ynone has been accomplished with Cs_2CO_3 in 89% yield.[15] An intramolecular Diels-Alder reaction using Cs_2CO_3 and paraformaldehyde in THF has been used to produce the neurotoxic toxin slaframine from an amide.[16]

Alykylation Base.

Esterification under mild conditions can be accomplished with Cs_2CO_3 or $CsHCO_3$.[3] For example, amino acid and peptide esters can be made by generating the cesium salt of the corresponding carboxylic acid followed by treating the salt with an alkyl halide in DMF (eq 7).

Mono-*C*-alkylation of β-dicarbonyl compounds is complicated by competitive *O*-alkylation and dialkylation reactions.[17] *C*-Alkylation of 2,4-pentanedione has been achieved with ***Iodomethane*** in 75% yield using K_2CO_3 as a base. The use of Cs_2CO_3 by itself, or in combination with K_2CO_3, allows for improved monoalkylation reactions using higher molecular weight alkyl halides (eq 8).[18] Phenolates generated with Cs_2CO_3 are alkylated with ***Dimethyl Sulfate*** in 94% yield.[19]

$$BrCH_2CO_2Et + (MeCO)_2CH_2 \xrightarrow[CH_2Cl_2]{Cs_2CO_3} \underset{92\%}{(MeCO)_2CHCH_2CO_2Et} + \underset{8\%}{MeCOCH{=}CMeOCH_2CO_2Et} + \underset{<1\%}{MeCOC(CH_2CO_2Et){=}CMeOCH_2CO_2Et} \quad (8)$$

Dibenzyl carbonate is prepared in 63-70% yield when Cs_2CO_3 is treated with ***Benzyl Chloride*** at 100-110 °C for 12 h.[20] Cs_2CO_3 has also been used to mediate Michael additions of glycine esters. Treating a Schiff base of glycine and an enone with 10 mol % Cs_2CO_3 gives substituted prolines in 60-78% yield after hydrogenation (eq 9).[21] Replacement of NaH with 5-10 mol% Cs_2CO_3 under standard Schmidt conditions in the preparation of trichloroacetimidates allows for large scale preparation of *O*-α-cellobiosyl trichloroacetimidate heptacetate in good yield.[22]

Cleavage of aryl esters has been accomplished using either Cs_2CO_3 or $CsHCO_3$. For example, refluxing resorcinol dibenzoate in DME for 24 h with 1.5 equiv Cs_2CO_3 produces the monobenzoate in greater than 95% yield.[23] Cs_2CO_3 and ***Di-t-butyl Dicarbonate*** cleave 2-oxazolidinones at 25 °C in MeOH to give Boc-amino alcohols in 70% yield (eq 10).[24]

Cesium Fluoride

CsF

[13400-13-0] · CsF · Cesium Fluoride · (MW 151.90)

(fluoride ion source for removal of silyl protecting groups; reagent for mild desilylative anion and ylide formation; base catalyst; reagent for hydrogen bond-assisted alkylation; reagent for halide exchange)

Physical Data: mp 682 °C; bp 1251 °C; *d* 4.115 g cm^{-3}; refractive index 1.478 (18 °C).

Solubility: sol H_2O and MeOH; insol dioxane, pyridine.

Form Supplied in: white deliquescent crystalline powder.

Purification: dry by heating at 100 °C for 2 h in vacuo.[1]

Handling, Storage, and Precautions: hygroscopic. Keep container tightly closed. Harmful if inhaled or swallowed. Causes irritation of skin, eyes, and mucous membranes and may cause allergic reaction. Incompatible with acids: store away from acids. Use in a fume hood with safety goggles and chemically resistant gloves and clothing.

Catalysis of Condensations of Carbonyl Compounds.

Knoevenagel condensations of cyclohexanone and benzaldehyde with three active-methylene partners have been studied using various fluoride catalysts. Cesium and rubidium counterions lead to higher yields than the less soluble potassium, sodium, and lithium salts.[2] Silyl enol ethers react with aldehydes and ketones with CsF catalysis to form α,β-unsaturated ketones, or with unsaturated ketones by conjugate addition.[3] Trimerization of isocyanates occurs at 130 °C with CsF catalysis, forming aromatic isocyanurates in high yields.[4]

Desilylative Elimination and Carbanion Formation.

Fluoride ion desilylates compounds of the type C-Si, leading to useful carbanion-like reactivity, particularly when appropriate stabilizing substituents are present. When β-substituents are reasonable leaving groups, the expected eliminations occur. These types of reactions, with which water interferes, are particularly amenable to the use of CsF, since CsF can be made anhydrous much easier than the more commonly encountered ***Tetra-n-butylammonium Fluoride***.

Cyclopropenes have been prepared by desilylation of 1,1-dichloro-2-trimethylsilylcyclopropane with CsF in diglyme at 80 °C (eq 1).[5] A similar example of an advantage of CsF (and fluoride ion sources in general) - mild elimination conditions allowing isolation of unstable species - is seen in a synthesis of allene oxides. 1-(*t*-Butyl)allene oxide can be obtained in 55% yield by treating the precursor trimethylsilyloxirane with CsF (eq 2) and trapping the volatile products in a cold trap.[6] Desilylative 1,2-elimination from cyclohexadienes has been used to obtain the interesting benzene isomers 1,2,3-cyclohexatriene and cyclohexen-3-yne, which were trapped in situ by Diel-Alder reactions.[7] Sulfine, sulfene, and alkylsulfenes can be trapped as Diels-Alder adducts after their generation by desilylative 1,2-elimination from trimethylsilylmethanesulfinyl chloride, trimethylsilylmethanesulfonyl chloride, and trimethylsilylalkanesulfonic anhydrides, respectively.[8]

(1)

(2)

CsF-induced 1,4-elimination produces xylylene intermediates which undergo intramolecular cycloaddition with an alkene (eq 3).[9] Similar 1,4-elimination/Diels-Alder strategies have been used in the synthesis of other targets,[10] and in a cyclodimerization to give the bisthioacetal of [2,3:6,7]dibenzo-1,5-cyclooctanedione.[11]

(3)

Stereoselective synthesis of 1,4-dienamine derivatives is achieved by CsF-induced desilylative ring-opening of tetrahydropyridinium salts. The diene is produced selectively as the (*Z*,*E*) diastereomer (eq 4). The authors contrast this behavior with that of an analogous tetrahydropyridine *N*-oxide, which undergoes spontaneous sila-Cope rearrangement to give the (*Z*,*Z*) diastereomer (eq 5).[12]

Numerous desilylative reactions of trimethyl(α-bromobenzyl)silanes with electrophiles are induced by CsF (eq 6).[13]

Acyl-, alkynyl-, benzyl-, allyl-, oxiranyl-,[14] heteroaryl-,[15] trichloromethyl-,[16] aryl-,[17] β-keto-,[18] β-sulfonyl-,[19] and cyclopropylsilanes[20] are useful carbanion precursors. When treated with CsF or other fluoride salts, they undergo desilylative addition to carbonyl compounds, including CO_2, aldehydes, ketones, and lactones; *C*-alkylation with ***Benzyl Bromide*** also can occur (eqs 7-11). Conjugate addition is also observed; nitroalkenes give 1,4-addition products, and reaction of allylsilane with cyclohexenone in the presence of CsF gives the 1,4-addition product selectively, whereas the presence of tetrabutylammonium fluoride leads to diallylated product.[21]

(10)

(11)

Cyclization of a carbanion produced by desilylation with CsF leads to 1,3-thiazolidines (eq 12).[22]

(12)

Anionic reactivity remote from the silyl bond cleavage site is observed when ketene bis(trimethylsilyl) acetals or α,β-unsaturated ketene bis(trimethylsilyl) acetals are treated with CsF and an aldehyde.[23] Complementary regioselectivity occurs with ***Titanium(IV) Chloride*** (eq 13).[24]

(13)

A novel method for the production of thiiranes from carbonyl compounds involves desilylation with CsF (eq 14).[25]

(14)

Stannyl Anion Generation.

By treatment of (trimethylsilyl)tributylstannane with CsF, a stannyl anion is formed. This method was used to achieve intramolecular reaction of a vinyl iodide with an ester, forming a spirocyclopentenone, which reacted further with the tributylstannyl anion under the reaction conditions (eq 15). Four subsequent steps completed a formal total synthesis of acorone.[26]

Ylide Formation.

Wittig reaction of a phosphonium salt with benzaldehyde is observed with CsF in DMF.[27] Similarly, CsF can be used to carry out Horner-Wadsworth-Emmons reactions.[28] Sulfonium, ammonium, and phosphonium ylides can be obtained by desilylation.[29] This ylide formation strategy has been used in a synthesis of the retronecine skeleton.[30]

Acylation and Transesterification.

Esters, amides, and thioesters are obtained in high yields under neutral conditions when the carboxylic acid is treated with the appropriate protic nucleophile, 1-ethyl-2-fluoropyridinium tetrafluoroborate, and CsF in methylene chloride (eq 16). *p*-Nitrophenyl esters of optically pure *N*-phthaloylamino acids are converted to methyl esters in MeOH/CsF without the racemization observed when triethylamine is employed.[31]

Acylations of 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose in quantitative yields are achieved with acyl fluorides and CsF

(eq 17). High ratios of either anomeric product can be obtained by changing the order of addition of the reagents.[32]

.

Phosphate esters can be transesterified in alcohols containing excess CsF.[33] This method has been used to advantage in the regioselective protection of hydroquinones by phosphorylation in the presence of CsF.[34] Ribooligonucleotides have also been synthesized by this approach.[35]

Acylation of alcohols is very efficient with acylthiazolidine-2-thiones and CsF in warm DMF. Benzyl 3-phenylpropionate was obtained in 99% yield by this method (eq 18).[36]

Hydrogen Bond-Assisted Halide Displacements.

Treatment of catechols with CH_2Cl_2 in the presence of CsF results in high yields of methylenated products (eq 19) with little competition from intermolecular condensations.[37] Hydrogen bonding of the catechol with fluoride has been demonstrated, and is thought to be responsible for the facilitation of the reaction. Numerous other H-bonding substrates are also alkylated more readily under the influence of fluoride (eq 20).[38] This alkylation promotion by CsF obviates prior conversion of phthalimide to its alkali metal derivative for use in the Gabriel synthesis (eq 21).[39] CsF leads to an order of magnitude in rate enhancement relative to ***Potassium Fluoride*** in some cases, although the higher expense of CsF may negate this advantage.

M	Time (h)	Yield (%)
K	4	73
Rb	1	82
Cs	0.2	82

1,2-Cycloalkanediols can also be methylenated under analogous conditions.[40] Glycols can be monoalkylated by treatment of their stannylene acetals with alkyl halides. CsF considerably improves the yields of these reactions.[41] Thus the dibutylstannylene acetal of dimethyl L-tartrate was monoalkylated with benzyl iodide and CsF in DMF at room temperature in 99% yield (eq 22), whereas the reaction without CsF required elevated temperatures and gave only a 13% yield. This method has recently been applied in syntheses of lepidimoide[42] and *myo*-inositol phosphates.[43] In a related reaction, glycol xanthates react with alcohols in the presence of CsF to provide monoalkylated glycols as a key step in syntheses of xylofuranosides.[44] Phosphoric acid alkylation by alkyl halides is catalyzed by CsF.[45] Several macrocyclic crown ethers have been prepared by reaction of ditosylated half-crowns with diol half-crowns in the presence of CsF.[46]

Synthesis of Acid Fluorides.

Organic halides can be converted to acid fluorides by metal-catalyzed (M = Pd, Pt, Co, Rh) carbonylation in the presence of fluoride salts (eq 23). CsF is superior to fluorides with other counterions.[47]

(23)

Preparation of Alumina-Supported Fluoride Reagents.

Mixing of aqueous CsF or KF with alumina followed by drying gave an effective base catalyst.[48] Its preparation was optimized by testing the activity in promoting Michael addition of nitroethane to buten-2-one and methylation of phenols with MeI.

Activation of Si-X Bonds.

Silicon-hydrogen, -oxygen, and -nitrogen bonds are activated by fluoride ions under heterogeneous conditions. ***Triethoxysilane*** is a mild, efficient and highly selective reducing agent in the presence of CsF, leading to quantitative yields of 1,2-reduction products from enones (eq 24). Other bifunctional compounds also can be reduced with quantitative regioselectivity.[49]

(24)

A system of CsF and $Si(OR)_4$ effects selective 1,4-addition in condensation of ketones with activated alkenes in good yield (eq 25). A silyl enol ether is formed in situ via reaction of CsF-activated $Si(OR)_4$ with the ketone.[49] This system has also been used to effect 1,4-addition to unsaturated amides.[50] Although bis(silyl)enamines undergo sluggish reaction, if any, with various electrophiles, the presence of CsF or tributylammonium fluoride allows high-yielding reactions with carbonyl compounds to afford 2-aza-1,3-dienes (eq 26).[51]

(25)

Benzostabase Protecting Group.

Aromatic and aliphatic primary amines have been protected as their benzostabase derivatives in high yield by heating with 1,2-bis(dimethylsilyl)benzene and CsF in polar aprotic solvents (eq 27).[52]

Desilylation of *O*-Silyl and *N*-Silyl Compounds.

O-Silyl compounds serve frequently as protecting functionalities in organic synthesis. CsF is sometimes used for cleavage of these Si-O bonds, but usually has no advantage over the more commonly used tetrabutylammonium fluoride. Cleavage of O-Si bonds with CsF has been used in the preparation of cesium selenocarboxylates.[53] CsF can be used to cleave *N*-trimethylsilyl groups from amides[54] and carbodiimides.[55]

Fluorodemetalation of Organogermanium, -tin, -lead, and -boron Compounds.

Cesium fluoride can be used to cleave C-M bonds; evidence for an associative mechanism in this process has been obtained.[56] Similar reactivity is observed in the reaction of organotin carboxylates and stannyl ethers with CsF and alkyl halides; the O-Sn bond is converted to O-C.[57] A borane-amine complex has been decomposed to the free amine by refluxing with CsF in Na_2CO_3/EtOH.[58]

CsF-Mediated Claisen Rearrangement.

Aryl propargyl ether Claisen rearrangement leads to an intermediate allene which undergoes intramolecular capture by the concurrently formed phenol to give a pyran or a furan. A comparison of the effects of various salts on the regioselectivity revealed that CsF promotes the furan formation, despite the fact that *both* CsCl and KF promote pyran formation. The reaction also was applied in a synthesis of chelerythrine (eq 28).[59]

Alkyl Fluoride Synthesis.

n-Octyl fluoride has been made in 77% yield (along with 15% of *n*-octane) by treatment of *n*-octyl bromide with CsF and catalytic NBu_4Br at 85 °C.[60]

Related Reagents.

Diphenylsilane-Cesium Fluoride; ***Phenylsilane-Cesium Fluoride***; ***(Trimethylsilyl)methanesulfonyl Chloride-Cesium Fluoride***.

Cesium Fluoroxysulfate

$CsOSO_2OF$

[70806-67-6] · $CsFO_4S$ · Cesium Fluoroxysulfate · (MW 247.96)

(mild fluorinating agent capable of electrophilic addition to C=C bonds[1-3] and fluorofunctionalization of saturated hydrocarbons,[4,5] aromatics,[6-10] ketones and β-diketones,[11,12] enol acetates,[2,3,11,12] organosilicon[11] and organotin[13,14] derivatives, etc.)

Solubility: insol cold water; gives 0.07 M soln in acetonitrile.

Analysis of Reagent Purity: iodometric titration.[15]

Preparative Method: the reagent can be readily prepared from dilute fluorine and Cs_2SO_4: fluorine (20% mixture with nitrogen) was passed into Cs_2SO_4 in a polyethylene vessel with cooling to -4 °C. The yellowish-white precipitate is centrifuged, washed with a little water, and dried in vacuo.[8,15]

Handling, Storage, and Precautions: the synthesis of up to 200 g of $CsOSO_2OF$ has been described.[8] The reagent is easily handled, provided due care is taken not to cause detonation: avoid mechanical pressure (sharp strikes), any contact with a metallic spatula,[15] and do not heat. A protective shield should always be used. The reagent has been stored in a polyethylene vessel at 0 °C for 14 days without significant loss of activity.[8]

Fluorination.

The main result of $CsOSO_2OF$ reactions with various organic substrates is electrophilic fluorination, the hypofluorite moiety in the anionic fragment $FOSO_2O^-$ serving as the F^+ synthon.

Unsaturated compounds react readily with $CsOSO_2OF$ (**1**) to yield products of addition, of addition with incorporation of solvent or external nucleophile, and of addition-elimination, depending on the reaction conditions. The reactions of (**1**) with alkenes gives 1,2-addition products (**2**), which can be conveniently transformed into ethyl sulfates (**3**) by treatment with $Et_3O^+BF_4^-$ (eq 1).[1] The same reaction in the presence of methanol (rt, CH_2Cl_2) gives β-methoxyalkyl fluorides (**4**). Analogously, reactions in AcOH and HF give vicinal fluoroacetates (**5**) and difluorides (**6**), respectively (eq 2).[2,3] In some cases the reaction proceeds to give vinyl fluorides (**7**) (eq 3). For example, interaction of 1,1-diphenylethylene with (**1**) gives 2-fluoro-1,1-diphenylethylene.[2] Fluorination of norbornene gives a 1:1 mixture of 2-fluoronortricyclene and 7-*syn*-fluoronorbornene.[2]

(1)

(2)

(3)

Reaction of the reagent (**1**) with 1,2-diphenylacetylene in methanol gives a mixture of 1,1-difluoro-2,2-dimethoxy-1,2-diphenylethane and 2,2-difluoro-1,2-diphenylethanone.[16]

Aromatic and aliphatic aldehydes react with $CsOSO_2OF$, giving acid fluorides in good yields, presumably via radical pathways (eq 4).[4]

(4)

Room temperature fluorination of cyclic enol acetates by (**1**) gives α-fluorocycloalkanones in high yield (70-90%).[2] β-Diketones and barbituric acid give the corresponding *gem*-difluorinated derivatives.[11,12] Room temperature fluorination of uridine in methanol followed by treatment with Et_3N gives 5-fluorouridine (79%).[11] Similarly, 1,3-dimethyluracil gives the 5-fluoro derivative (89%).[11]

Cesium fluoroxysulfate is a mild fluorinating agent for activated aromatics,[6-10] such as phenols (eq 5), alkoxy-substituted benzenes, and naphthalenes. The reaction is catalyzed by HF, H_2SO_4, CF_3SO_3H, FSO_3H,[6] and BF_3.[9]

(5)

The reaction of toluene with $CsOSO_2OF$ in acetonitrile gives benzyl fluoride as the principal product,[7] but in the presence of catalysts, *o*- and *p*-fluorotoluenes (6:1) are produced.[6] In some cases of aromatic substitution the formation of fluorinated cyclohexadienones is observed (eq 6).[9]

(6)

Trimethylchlorosilane reacts smoothly with $CsOSO_2OF$ to give trimethylfluorosilane.[11] Trimethyltin-substituted alkenes give fluoroalkenes (eq 7).[13]

(7)

Oxidation.

The reagent (**1**) easily oxidizes secondary alcohols to ketones, and 1,2-dihydroxy-4-butylbenzene to the quinone derivative.[17] Ph_3P and dibenzothiophene are oxidized in room temperature reactions with $CsOSO_2OF$.[5,11]

Related Reagents.

Chlorine Fluoroxysulfate; ***(2-Chloro-1,1,2-trifluoroethyl)diethylamine***; ***Fluorine***; ***N-Fluoro-N-t-butyl-p-toluenesulfonamide***; ***Dibromomethane***.

Chloral[1]

[75-87-6] · C_2HCl_3O · Chloral · (MW 147.39)

(electrophile which can react with a variety of nucleophiles,[1] insert into metal-C, -N, and -O bonds,[2] undergo ene and Diels-Alder reactions,[3] add to ketenes,[4] and function as a hydride acceptor[5])

Alternate Name: 2,2,2-trichloroacetaldehyde.

Physical Data: anhydrous: bp 98 °C; mp -57.5 °C; *d* 1.512 g cm^{-3}; refractive index 1.4557 (20 °C); hydrate [$Cl_3CCH(OH)_2$]: mp 57 °C; bp 96 °C; *d* 1.908 g cm^{-3}.

Solubility: anhydrous: sol CH_2Cl_2, $CHCl_3$, CCl_4, C_6H_6, Et_2O, THF, EtOAc, *n*-C_6H_{14}; sol and reacts with H_2O and alcohols; hydrate: sol H_2O, EtOH, Et_2O, C_6H_6.

Form Supplied in: anhydrous: colorless oily liquid, fairly widely available; hydrate: colourless crystals, widely available.

Analysis of Reagent Purity: various iodometric and colorimetric methods are available, but analysis by GLC offers the best discrimination.[1]

Purification: fresh commercial ~99% material is suitable for most purposes; chloral hydrate and polychloral are removed by distillation from P_2O_5.

Handling, Storage, and Precautions: toxic by inhalation, ingestion, and skin absorption. Irritating to the eyes, nose, throat, and skin; liquid and vapors are especially damaging to the eyes. Handle in an efficient fume hood and wear safety glasses, rubber or plastic gloves, and a laboratory coat. Bottles should be tightly sealed and refrigerated. Limited shelf life; hence may require redistillation from P_2O_5 before use. The hydrate, which is a powerful soporific, is much more stable but the same handling precautions apply. For small accidental spillages, (<~5 mL), flood with water and wash down the drain. Treat larger spillages with about 2-3 volumes of water and then adsorb onto proprietary spillage granules for disposal. Small quantities of unwanted reagent may be destroyed by hydrolysis to chloroform and sodium formate: add the chloral (*x* mol) slowly to a cooled (0 °C) and stirred solution of sodium hydroxide (1.5*x* mol) in water (100*x* mL). After 2 h, extract the chloroform layer with water and add to the departmental waste chlorinated solvent; the aqueous residues may be washed down the fume hood drain with plenty of water.

Introduction.

Chloral is an important source of dichloroacetic acid and its derivatives,[1] and the relative ease with which the Cl_3C-, $Cl_3CCH(OH)$- and Cl_2C= groups, derived from chloral by reaction, can be transformed into other types of functionality[1,3a] makes chloral a versatile synthetic reagent.

Formation of Hemiacetals and Acetals.

Anhydrous chloral reacts vigorously with a wide variety of alcohols to form hemiacetals.[1,6] Acetals are formed with acid catalysts and azeotropic distillation of water. Similarly, diols, hydroxy acids, and hydroxy ketones react to give cyclic acetals.[1,7] Chloral hydrate is usually used in combination with concentrated H_2SO_4.[1] Useful *erythro-threo* equilibration of lithium ketolates has been achieved through the formation of the chloral hemiacetal (eq 1).[8] Chloral adds ***Sodium Methoxide*** to form first the sodium salt of the hemiacetal which decomposes into dichlorocarbene, methyl formate and sodium chloride.[9a] ***Potassium t-Butoxide***, however, is usually preferred for generating **:**CCl_2 from chloral.[9b]

(1)

The hemiacetals formed from 2-alken-1-ols and chloral are cyclized in the presence of ***Mercury(II) Trifluoroacetate*** to the acetals. Demercuration and reductive cleavage gives *cis*-diols (eq 2).[10] The Hg^{II}-assisted addition of chloral to 1-penten-3-ol, followed by the electrophilic displacement of the mercury atom with iodine, gave a mixture of the stereoisomers of (**1**), which were used in a synthesis of the insect pheromone *exo*-brevicomin (**2**) (eq 3).[11] The transposition of the double bond and the hydroxyl group in 5-alkyl-4-hydroxycyclopentenones (in connection with a prostaglandin synthesis) has been achieved through a similar cyclic acetal formation (eq 4).[12]

(1) **(2)**

As an Alkylating and Acylating Agent for Amines and Amides.

Formylation (with simultaneous production of chloroform) of strongly basic primary and secondary amines and the esters of amino acids occurs in good yield on treatment with chloral.[1] Aromatic amines usually require the presence of Et_3N, otherwise hemiaminals or aminals may form.[1,13] Amides are formylated by chloral under alkaline conditions.[14] The hemiaminals formed from moderately nucleophilic amines may be dehydrated to afford chloral imines, or suffer elimination of chloroform to give the formyl derivative.[15] If the H-atom on the center adjacent to the N-atom of the chloral imine is acidic, then 1,4-elimination of HCl may be observed.[16] This chemistry has been used to convert the 7α-amino-1-oxacephem (**3**) into its 7β-epimer (57.5% overall) by the reduction (KBH_4, 0 °C) and hydrolysis (HCl, MeCN) of the intermediate (**4**) (eq 5).[17] Chloral catalyses the *N*-nitrosation of various secondary amines in the pH range 6.4-11.0 since the first-formed iminium ion is readily attacked by nitrite anion; the presumed adduct [R_2N-$CH(CCl_3)$-ONO] collapses to R_2NNO and chloral.[18]

Aromatic amines condense with chloral hydrate and hydroxylamine to afford *N*-(hydroxy-iminoacetyl) derivatives which are readily cyclized in the presence of concentrated H_2SO_4 to provide a good route to isatin and its analogs (eq 6).[19] Acid hydrazides when refluxed with chloral in the presence of an alcohol are converted (70-80%) directly into the corresponding ester (eq 7).[20] The hydrazide to amide conversion can be made similarly.

Aldol and Related Reactions.[1]

With aldehydes the best method for the directed cross-aldol condensation involves reaction of chloral with the TMS enolate of the aldehyde in the presence of ***Titanium(IV) Chloride*** (eq 8).[21] The TMS enolates of ketones react similarly to give the 1,1,1-trichloroethan-2-ols in excellent yields.[22] With simple methyl ketones, the condensation occurs at the methyl group.[23] Mesityl oxide affords (**5**) under buffered conditions (AcOH-NaOAc) (eq 9), whereas in the absence of the NaOAc the tetrahydro-1,4-pyranone (**6**) is formed.[23b]

(8)

(9)

(5) **(6)**

The rather more stable enolate anions derived from β-diketones, α-cyanoacetates, α-nitroacetates, etc., are *C*-alkylated by chloral.[24-26] The 1,1,1-trichloro-2-hydroxyethyl derivative thus formed may be dehydrated under suitable conditions.[24d] When the condensation is performed with solid ***Potassium Carbonate*** in THF solution, β-diketones are deacylated. Thus acetylacetone is transformed into $Cl_3CCH{=}CHCOMe$ (74%)[25] and 2-acetylcyclopentanone is converted into (**8**) through a Favorskii rearrangement of the intermediate deacetylated product (**7**) (eq 10).[26] A 1,1,1-trichloro-2-hydroxyethyl derivative is also formed when chloral is allowed to react with various other anions (e.g. those derived from sulfones,[27] amides,[28] or 2-methylquinoline[29]). In this last case, chloral has been used as a convenient masked equivalent of glyoxylic acid (eq 11).[29]

(10)

(7) **(8)**

(11)

Electrophilic Aromatic Substitution.

Much research on chloral has been devoted to its use in electrophilic aromatic substitution reactions (promoted by acids or Lewis acids), not least because of the former importance of DDT.[1] Alkylation produces aryltrichloromethylcarbinols which may be transformed into aldehydes, α-hydroxy acids, and α-alkoxy acids.[30] The aryltrichloromethylcarbinols are oxidatively cleaved by alkaline ***Hydrogen Peroxide*** to afford carboxylic acids after acidification; yields are 85-98%.[31] Mild conditions (i.e. ***Zinc Chloride***) are necessary for furans, or a photochemical procedure can be employed.[32] The alkylation of dichloroaluminum phenolates with chloral is *ortho* selective. The products (**9**) are transformed by basic ***Alumina*** (decalin, reflux) into isoxindigos (**10**) (eq 12).[33] Asymmetric *o*-selective hydroxyalkyl ation of phenols occurs when chiral alkoxyaluminum chlorides are used as catalysts; the % ee's, however, are only poor to moderate.[34] Acrylate esters undergo formal electrophilic substitution at the α-position when treated with chloral in the presence of ***1,4-Diazabicyclo[2.2.2]octane*** as catalyst.[35]

(12)

(9) **(10)**

Additions to Alkenes, Dienes, and Ketenes.

Anhydrous chloral affords formal ene adducts on reaction with suitable alkenes. Although chloral is a relatively reactive enophile, the thermal addition is really only successful with the more reactive (i.e. Type 1)[36] enes. The addition is strongly catalyzed by Lewis acids (e.g. $AlCl_3$, $SnCl_4$, $TiCl_4$, $FeCl_3$, etc.), such that a solvent (e.g. CH_2Cl_2, CCl_4) is necessary to moderate the room temperature reactions, and the useful reactivity range spans Type 1-Type 4 enes.[3a,b] The Lewis acid improves the yield and also has a profound effect upon the diastereoselectivity of the addition (eqs 13 and 14). Although the reactions with Type 1 enes appear to be concerted, the formation of significant byproducts with the less nucleophilic Type 2-4 enes points to an electrophilic addition pathway (eq 15).[3b,37,38] Chiral

alkoxyaluminum Lewis acid catalysts promote the asymmetric ene addition of chloral to 2-methylpropene with enantioselectivities of about 70-80% ee.[39] ***Aluminum Chloride***-promoted electrophilic additions of chloral to alkenes are also well documented.[1] For example, addition to 1,5-cyclooctadiene and to norbornadiene affords, respectively, the oxatricyclic compounds (**11**; 47%) and (**12**; 36%).[40] The cyclohexene-chloral ene adduct is rearranged by $AlCl_3$ into the oxabicyclo[3.2.1]octane (**13**)[3c] and not into an oxabicyclo[2.2.2]octane as thought previously.[41]

(13)

T (°C)	h	Solvent	Catalyst	R	S
95	18	-	-	83	17
20	0.5	CCl_4	$AlCl_3$ (2%)	24	76
20	0.5	CCl_4	$SnCl_4$ (2%)	10	90
20	0.5	CCl_4	$TiCl_4$ (2%)	0	100

(14)

20	3	CH_2Cl_2	$FeCl_3$ (2%)	60	40

(11)

(12)

(13)

(14)

Thermal addition of chloral to isoprene yields the expected Diels-Alder adduct predominantly, whereas in the $AlCl_3$ catalyzed addition the ene adduct predominates.[3a,d] Thermal addition to 1,3-cyclohexadiene affords the oxabicyclo[2.2.2]octane only with pure reagents, otherwise rearrangement occurs to the oxabicyclo[3.2.1]octane (**14**).[3c] Chloral undergoes an exothermic formal [4 + 2] cycloaddition to the strained double bonds of *t*-butyl 2,3,4-tri-*t*-butylcyclobutadienecarboxylate,[42] successfully traps α-oxo-*o*-quinomethanes to give isocoumarins,[3e] but otherwise is not an especially versatile and reactive dienophile. It is, however, one of the few carbonyl acceptors for the carbon-carbon double bond of ketenes.[1,4a-d] Addition to ketene in the presence of quinidine as a chiral catalyst is highly enantioselective (98% ee) and affords (*R*)-3-trichloromethyl-2-oxetanone (**15**; 89% yield).[4c] Ketene acetals readily add chloral to give 2,2-dialkoxy-4-trichloromethyloxetanes under Lewis acid catalysis ($ZnCl_2$ or $EtAlCl_2$).[43]

(15)

As a Hydride Acceptor.

Chloral on dehydrated chromatographic alumina transforms structurally diverse secondary alcohols (CCl_4 solution, 25 °C, 24 h) into ketones in good yields and some diols into the corresponding keto alcohols.[5a,44] The readily available β-hydroxy sulfides and selenides are chemoselectively oxidized to β-keto sulfides and selenides.[45] The method generally seems to be tolerant of a number of potentially sensitive functional groups, and product isolation simply involves filtration and evaporation. Aldehydes and ketones are also prepared in an Oppenauer oxidation of halomagnesium alkoxides using chloral as the hydride acceptor.[5b]

Insertion into Metal-C, -N, and -O Bonds.

Although chloral adds simple organometallic compounds (e.g. HC&tbond;C^-K^+, ArMgX) to form, after hydrolysis, the substituted trichloroethanol,[1,2a-e] it can be reduced by alkyl Grignard reagents (i.e. hydride transfer) or react at the Cl_3C- group with methyl- or phenyllithium.[1] The product distribution is often sensitive to reaction conditions and the order of addition of reagents. In the presence of a Lewis acid catalyst ($GaCl_3$, $InCl_3$ or $AlCl_3$) activated $RSiMe_3$ compounds (i.e. R = allyl, aryl, vinyl, ethynyl, or propargyl) add to chloral to give, after hydrolysis, the corresponding α-trichloromethylated carbinols [$RCH(OH)CCl_3$].[46] ***Crotyltributylstannane*** reacts with chloral at room temperature without the need for Lewis acid catalysis; the stereoselective substitution reaction occurs with an allylic shift (eq 16).[2f,47] Chloral also inserts readily into the metal-O bond of alkoxysilanes, -germanes, and -plumbanes,[2g,48] into the Si-N bond of trimethylsilyldimethylamine,[49] into the metal-C bond of silyl- and germylketene dimethyl acetals,[50] and into the Hg-C and Hg-Si bonds.[51]

Chloramine[1]

NH_2Cl

[10559-90-3] · ClH_2N · Chloramine · (MW 51.48)

(aminating agent; oxidizing agent)

Alternate Names: chloramide; monochloramine.

Physical Data: mp -66 °C.[2]

Solubility: sol H_2O, ether, methylene chloride, alcohol; slightly sol benzene, carbon tetrachloride.

Preparative Methods: prepared in situ by the reaction of aqueous NH_3 and NaOCl;[3] this aqueous solution [chloramine (aq)] can frequently be used for subsequent reactions; however, in many cases it is advisable to use an anhydrous ethereal solution of chloramine [chloramine (anhyd)];[4] chloramine (g) has been prepared by the gas phase reaction of Cl_2 with excess NH_3,[5] but this appears to be synthetically less useful.

Handling, Storage, and Precautions: although chloramine (aq or anhyd) is generally prepared immediately before use, storage at 0 °C for short periods of time (<=1 h) does not appear to be detrimental; only dilute solutions[4] should be prepared, as more concentrated solutions decompose readily to N_2, Cl_2, and NCl_3; use in a fume hood.

Amination of Organometallic Reagents.

Organoboranes react with chloramine (aq) under alkaline conditions to afford fair to good yields of primary amines, thus providing a convenient route to amines from alkenes (eq 1).[6] However, ***Hydroxylamine-O-sulfonic Acid*** (especially in DME) was found to be a more effective aminating agent, in terms of both yield and convenience.[7] ***Hydroxylamine*** and ***Hydrazine*** were ineffective, and *N*-chlorodimethylamine gave either chloroalkanes[8] or alkyldimethylamines,[9] depending on the reaction conditions (radical vs. polar mechanism).

(1)

Chloramine (anhyd) reacts with Grignard reagents to furnish amines in poor to good yield.[10] Chloromagnesium Grignard reagents gave better yields than the bromo or iodo compounds, while the dialkylmagnesium reagents gave excellent yields.[11] Phenyl Grignard reagents gave poor yields of amines, the aromatic chlorides being obtained instead.[10b] Organolithium and organozinc reagents also react with chloramine (anhyd) to give amines.[12]

Reaction with Alcohol Anions.

Chloramine (anhyd) reacts with the sodium salts of aliphatic alcohols to give fair yields of the *O*-alkylhydroxylamines.[1a,13,14] The reaction with phenoxide anions, however, takes several different paths. While *ortho*-unsubstituted phenoxide ions give *o*-aminophenols (in poor yield) by simple *C*-amination, treatment of 2,6-disubstituted phenolic salts in molten phenols with <1 equiv of chloramine (anhyd) proceeds further with subsequent ring expansion to give 1,3-dihydro-2*H*-azepinones (eq 2).[15] Unsymmetrical 2,6-disubstituted phenols gave mixtures of the two possible ring expanded products, the ratios being governed primarily by steric control.[15d] Use of excess chloramine (anhyd) gave products due to oxidative coupling of the phenol.[16] Placement of a carbonyl group in the *ortho* position gave rise to 2-hydroxyanilides (eq 3).[17]

(2)

(3)

Reaction with Nitrogen-Containing Compounds.

Chloramine (aq) and substituted chloramines react with aliphatic amines to give hydrazines.[1a,1b,18] ***Hydroxylamine-O-***

sulfonic Acid, however, is often superior to chloramine (aq).[19]

α-Oximino ketones react with chloramine (aq) to give α-diazo ketones (Forster reaction).[20] When combined with a photolytic Wolff rearrangement, this provides a convenient, generally useful method of ring contraction.[21] This sequence of reactions has demonstrated great promise in the synthesis of nor-steroids (eq 4).[22]

(4)

The reaction of chloramine (anhyd) with toluenesulfonamides provides a method for either hydrodeamination or halodeamination of primary amines (eq 5).[23] This method has demonstrated superiority to the related hydrodeamination using hydroxylamine-*O*-sulfonic acid in aqueous base.[24]

(5)

Oxidations.

Chloramine (anhyd) has been reported to oxidize anilines to mixtures of *cis*- and *trans*-azobenzenes.[4b] Although the yields were modest (20-50%), this method does provide access to the relatively rare *cis* isomers. Other oxidants (***Manganese Dioxide***, ***Lead(IV) Acetate*** or ***(Diacetoxyiodo)benzene***) give only the *trans* isomers.

Benzyl alcohols were also oxidized to carbonyl compounds in good to excellent yield, but this method has not been extended to aliphatic (nonbenzylic) alcohols.

Related Reagents.

Ammonia; ***Chloramine-Aluminum(III) Chloride***; ***Chloramine-T***; ***Hydrazine***; ***Hydroxylamine-O-sulfonic Acid***; ***Trichloramine***.

Chloramine-Aluminum(III) Chloride

NH_2Cl-$AlCl_3$

(NH_2Cl)

[10599-90-3] · ClH_2N · Chloramine-Aluminum(III) Chloride · (MW 51.48) ($AlCl_3$)

[7446-70-0] · $AlCl_3$ · Chloramine-Aluminum(III) Chloride · (MW 133.34)

(reagent for aminating arenes, alkanes, and alkyl chlorides[1])

Physical Data: bp -66 °C.

Solubility: sol cold H_2O, ether, and methylene chloride; v sl sol CCl_4 and benzene.

Analysis of Reagent Purity: chlorine in chloramine is determined by iodometric titration.[8]

Preparative Methods: ***Chloramine*** can be prepared either by a gas phase or a liquid phase technique. In the gas phase technique, ammonia and chlorine are allowed to react and chloramine is collected in methylene chloride.[1-4] Since the gas phase technique is relatively cumbersome and provides only small amounts of the desired material, liquid phase techniques in which chloramine is extracted into an organic solvent from an aqueous phase are used. Sodium hypochlorite solution is added to aqueous ammonia at 0 °C; chloramine is distilled with water into cold ether[5-7] or extracted with methylene chloride.[1]

Handling, Storage, and Precautions: this reagent should be handled in a fume hood.

Amination.

Mono-, di-, and trichloramines in the presence of ***Aluminum Chloride*** have been reported to aminate various organic substrates, e.g. arenes, alkanes, and alkyl halides. Amination is carried out with an excess of the aromatic compound, a 1.7-2 molar ratio of $AlCl_3$/*N*-haloamine, and an aryl halide additive in the case of dichloramine at temperatures in the range -35 to -15 °C. Under these conditions the reaction of toluene with chloramine/$AlCl_3$ gives primarily *o*- and *p*-chlorotoluene, and only 13% of *m*-toluidine (eq 1).

The reactions with trichloramine-aluminum(III) chloride and dichloramine/$AlCl_3$ give *m*-toluidine in 43%[1,9] and 25%[10] yields, respectively. Based on literature analogy involving the trichloramine/$AlCl_3$ system, a mechanistic scheme entailing addition-elimination is proposed for the *meta* substitution (eq 2).

Amination of adamantane with chloramine/$AlCl_3$ gives 1-aminoadamantane (eq 3) in 40% yield, again in lower yield than that obtained with trichloramine/$AlCl_3$ (85% yield).[1,11,12]

Amination of *t*-butyl chloride produces *t*-butylamine (eq 4) in 7-20% yield, which is much lower than that obtained with trichloramine/$AlCl_3$ (56% yield).[1,13]

A possible rationalization for the lower yields with chloramine as compared to trichloramine in amination of the three organic substrates has been given.[1]

Chloramine-T[1]

[127-65-1] · $C_7H_{13}ClNNaO_5S$ · Chloramine-T · (MW 281.69)

(source of chloronium cations and/or nitrogen anions; oxidizing agent; in conjunction with OsO_4 can hydroxyaminate alkenes)

Alternate Names: *N*-chloro-*N*-sodio-*p*-toluenesulfonamide.

Physical Data: mp 167-170 °C (dec).

Solubility: insol ether, benzene and chloroform; sol cold H_2O; v sol hot H_2O; dec in EtOH.

Form Supplied in: white or pale yellow solid; widely available. While other *N*-halo-*N*-sodiosulfonamides and -carbamates have been reported in the literature and used in organic synthesis, only chloramine-T and its demethyl analog, chloramine-B, are commercially available. *Drying:* in some reactions, anhydrous chloramine-T [chloramine-T (anhyd)] is required; the drying of the trihydrate at 80 °C under vacuum has been described,[2] although precautions should be taken (see below).

Analysis of Reagent Purity: by iodometric titration.[3]

Handling, Storage, and Precautions: irritant; keep containers tightly sealed and protect from light; although the trihydrate is stable, there have been reports of chloramine-T (anhyd) decomposing with explosive force;[2,4] to minimize potential risks it is advised that chloramine-T (anhyd) be prepared in minimal amounts and all manipulations be performed behind safety shields (full-face and free-standing); use in a fume hood.

Reaction with Chalcogens and their Derivatives.

Chloramine-T reacts with a variety of sulfur-containing compounds to form sulfur-nitrogen bonds.[1] A partial listing includes thiols, sulfides, sulfoxides, disulfides, sulfimides, xanthates, thioketones, sulfenyl chlorides, and sulfinyl chlorides. The reaction of chloramine-T with sulfides forms the basis for a deprotection of thioacetal groups. Thus 1,3-oxathiolanes,[5] 1,3-dithiolanes,[6] and 1,3-dithianes[7] are all cleaved by chloramine-T to regenerate the carbonyl compounds. However, with chloramine-T (anhyd), 1,3-dithianes yield ketene thioacetals (eq 1).[8]

(1)

Selenides react with chloramine-T (anhyd) to give selenimides (eq 2).[9] In the case of primary alkyl phenyl selenides, the selenimide further undergoes β-elimination to give the terminal alkene (eq 3).[10] Tellurides behave similarly.[11] Allyl phenyl selenides can be converted to protected allylic amines via [2,3]-sigmatropic rearrangement of the selenimides (eq 4).[12]

(2)

(3)

(4)

Diphenyl disulfide and diphenyl diselenide react with chloramine-T (anhyd) to give reagents that convert alkenes to *trans*-vicinal phenylthio(seleno)-*N*-tosylamines (eq 5).[13] Extension of this to the synthesis of α-phenylthio(seleno) ketones from silyl enol ethers has been reported.[14]

(5)

Chloramine-T (anhyd) converts selenium and tellurium metal to the diimide species (**1**) and (**2**), respectively. The selenium analog (**1**) has been used for the allylic amination of alkenes and alkynes (eq 6),[2,15] while its tellurium counterpart (**2**) has found utility in the synthesis of *N*-tosylimines from aldehydes.[16] Compound (**1**) has also been used in the 1,2-diamination of 1,3-dienes, but the yields were poor.[17]

(1)

(2)

(6)

Other Reactions with Alkenes.

Chloramine-T, either alone or in conjunction with other agents, reacts with a variety of carbon-carbon double bonds to generate useful products. Under acidic conditions in aqueous acetone, alkenes give chlorohydrins,[18] while in an acetic acid medium the acetylated products are produced.[19] An intramolecular version allows for the synthesis of chlorolactones (eq 7).[20] Electron-rich alkenes, such as enamines, react to give α-aminated aldehydes (eq 8).[21] Vinyl ethers give the α-(*N*-tosylamino)aldehydes.

(7)

(8)

The reaction of alkenes with chloramine-T in the presence of catalytic amounts of ***Osmium Tetroxide*** provides a convenient and general method for the vicinal oxyamination of alkenes (eq 9).[22] Phase transfer conditions have also been employed.[23]

(9)

Other Oxidations.

Chloramine-T reacts with NaBr and NaI to provide a convenient method of generating BrCl and ICl, respectively, in situ (see ***Bromine Chloride***).[24,25] Chloramine-T has also been used to oxidize aldoximes to nitrile oxides as part of a synthesis of isoxazolines (eq 10).[26] A similar oxidation of aldehyde hydrazones to nitrilimines has also been reported.[27]

Chloranil[1]

[118-75-2] · $C_6Cl_4O_2$ · Chloranil · (MW 245.89)

(oxidant, particularly useful for dehydrogenation to aromatic[1,2] and α,β-unsaturated carbonyl[2] compounds)

Alternate Names: 2,3,5,6-tetrachloro-2,5-cyclohexadiene-1,4-dione; 2,3,5,6-tetrachloro-*p*-benzoquinone.

Physical Data: mp 290 °C; sublimes: E_0 742 mV (benzene).

Solubility: insol H_2O; sol ether; slightly sol alcohol, chloroform, CS_2, and light petroleum.

Form Supplied in: yellow solid.

Analysis of Reagent Purity: UV (λ_{max} 290 [log ε 4.34, cyclohexane]).

Purification: sublimation or recrystallization from benzene or acetic acid.

Handling, Storage, and Precautions: potential skin irritant; this reagent should be handled in a fume hood.

Dehydrogenation Reactions.

Chloranil and other quinones of high oxidation potential (see ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone***) are powerful oxidants which have found extensive application in dehydrogenation reactions.[1,2] Chloranil is particularly suitable for the aromatization of hydroaromatic substrates and has been used successfully in the synthesis of aromatic carbocycles[3] and nitrogen[4] and sulfur[5] heterocycles. The sequential aromatization of Diels-Alder adducts is an important application (eq 1).[6] Chloranil has also been used to facilitate the formation of α,*p*-dimethylstyrene from citral (eq 2), where its cheapness and efficacy makes it a preferred dehydrogenating reagent.[7]

Dehydrogenation reactions have been shown to proceed faster in polar solvents such as alcohols and DMF and are enhanced by electron donating substituents in the ring system to be oxidized.[1]

Although skeletal rearrangements rarely occur during dehydrogenation reactions with quinones, Wagner-Meerwein rearrangements leading to alkyl group migration have been reported in the aromatization of cycloalkanes possessing *gem*-dialkyl substituents.[8] A somewhat more unusual oxidation of *gem*-dialkylpyrazolidines, which is markedly accelerated by the addition of chloranil, gives pyrazoles without rearrangement by C-C bond cleavage (eq 3).[9] Chloranil is also an effective reagent for the dehydrogenation of *N*-substituted dihydroquinolines[10] and -isoquinolines,[11] where high yields of quinolinium and isoquinolinium salts are formed (eq 4).

(4)

While quinones do not usually react directly with furans, oxidation of the intermediate hydroquinone by the addition of a high potential quinone such as chloranil results in the formation of 2-furylquinones in reasonable yield (eq 5).[12]

(5)

Chloranil and other high potential quinones have been extensively used in the dehydrogenation of cyclic carbonyl compounds,[2] particularly steroidal ketones.[2,13] One reaction of importance is the formation of 4,6-dien-3-ones from 4-en-3-ones (eq 6).[14] In certain instances, steroids may be fully aromatized using this procedure.[15]

(6)

Other Oxidation Reactions.

In addition to dehydrogenation, quinones with high E_0 values effect various oxidation reactions.[1] Chloranil in particular is an effective electron acceptor photosensitizer for the oxidation of toluenes to benzaldehydes, where other classical photosensitizers have been shown to fail.[16]

Miscellaneous Reactions.

Chloranil undergoes facile nucleophilic displacement reactions with primary and secondary amines, leading to 2,5-bis-amino derivatives (eq 7).[17] Spectroscopic studies have demonstrated that with aliphatic amines at least, the reaction

proceeds via a one-electron oxidation of the amine.[18,19] Chloranil has also been shown to induce the dimerization of diaryldiazomethanes through a reaction believed to involve prior addition across the quinone carbonyl group.[20]

Chlorine[1]

[7782-50-5] · Cl_2 · Chlorine · (MW 70.91)

(powerful oxidizing and chlorinating agent)

Physical Data: yellowish-green gas, mp -101 °C, bp -34 °C; *d* 3.21 g cm^{-3} (gas, rt), 1.56 g cm^{-3} (liq, -35 °C).

Solubility: sl sol water (0.7 g in 100 mL at 20 °C); sol acetic acid, benzene, aliphatic hydrocarbons, chlorinated solvents, DMF.

Form Supplied in: packaged in cylinders with stainless steel or monel regulators.

Preparative Methods: chlorine is commercially available, but small quantities can be generated in the laboratory. The most common procedure involves the treatment of solid $KMnO_4$ with conc HCl (0.89 g of $KMnO_4$ and 5.6 mL of conc HCl per g of chlorine required).[2] It is recommended that chlorine so generated be dried by passing in succession through gas-washing bottles containing H_2O (to remove HCl), concd H_2SO_4 (to remove H_2O), and glass wool (to remove spray).[3] Preparations using conc HCl/MnO_2[4] or by heating $CuCl_2$ (anhyd)[5] have also been reported.

Analysis of Reagent Purity: iodometric titration; the chlorine can be volatilized and the moisture and residue determined gravimetrically.[1a]

Purification: commercial chlorine should be purified with H_2SO_4, CaO, and P_2O_5 and subsequently condensed in a dry ice-acetone bath and vaporized, repeatedly, while the noncondensable gases are removed with a pump.[4]

Handling, Storage, and Precautions: [5] highly toxic, nonflammable gas. Forms explosive mixtures with hydrogen, acetylene, or anhydrous ammonia. It is corrosive when moist. Chlorine is a strong oxidant and reacts violently with combustible substances, reducing agents, organic compounds, phosphorus, and metal powders. Avoid skin contact. Use protective clothing and a full-face respirator equipped with a NIOSH-approved organic vapor-acid gas canister. Cylinders should be stored away from sources of heat. All reactions should be conducted in a well-ventilated fume hood. The amount of chlorine added to a reaction mixture can be determined by weighing the cylinder before and after addition, or by condensing the required volume into a calibrated vessel and subsequently allowing it to volatilize while connected to the reaction vessel, or by generation from a known quantity of $KMnO_4$.

Substitution Chlorination.

Chlorine atoms, obtained from the dissociation of chlorine molecules by thermal or photochemical energy, react with saturated hydrocarbons by a radical chain mechanism. Chlorine reacts with methane to form methyl chloride, methylene chloride, chloroform, and carbon tetrachloride.[1a] Trialkylboranes have also been used to induce the radical chlorination of alkanes, e.g. chloro-2,3-dimethylbutanes are produced from 2,3-dimethylbutane.[6] Ethers are also chlorinated by photoinduced radical substitution reactions (eq 1).[7a]

(1)

The chlorination of carboxylic acids with molecular chlorine is catalyzed by phosphorus and its trihalides.[7b] Chlorine has been used to chlorinate methyl esters of carboxylic acids to form monochloro esters.[8] Chlorinations with chlorine favor the (o - 1)-position rather than the (o - 2)-position obtained with ***Sulfuryl Chloride***.[8] Thus the chlorination of methyl heptanoate with chlorine results mainly in methyl 6-chloroheptanoate, whereas chlorination with sulfuryl chloride results mainly in methyl 5-chloroheptanoate.[8] Low temperatures are required for the chlorination of long-chain carboxylic acid methyl chlorides, as unsaturated compounds are formed at higher temperatures due to the elimination of HCl.

The main products of the chlorination of carbamates are the *N*-dichloro derivatives (eq 2).[7c]

(2)

Aromatic amines react readily with chlorine, e.g. aniline is chlorinated to give 2,4,6-trichloroaniline in high yield (eq 3).[7d]

(3)

Primary and secondary amides react with chlorine to give *N*-chloroamides and HCl.[7e] The reaction is reversible, and the products are favored by highly polar solvents.

α-Chlorination of aliphatic acids has been achieved with chlorine using enolizing agents like chlorosulfonic acid, H_2SO_4, HCl, or $FeCl_3$ with a radical trapper like *m*-dinitrobenzene, oxygen, or chloranil.[9] The imidyl hydrogen atoms of aldazines can be substituted with chlorine (eq 4).[7f]

(4)

Addition Chlorination.

Saturated chlorides are formed when chlorine reacts with alkenes, e.g. chlorination of ethylene results in ethylene dichloride and chlorination of vinyl chloride gives 1,1,2-trichloroethane.[1a] These alkyl chlorides are important synthetic intermediates, e.g. 1,1,2-trichloroethane can be converted into vinylidene chloride in an alkaline medium.[1a] The addition of chlorine to 1-trimethylsilyl-1-alkenes in CH_2Cl_2 at low temperatures, followed by the elimination of Me_3SiX with methanolic sodium methoxide at 25 °C, produces vinyl chlorides in good yields (eq 5).[10]

(5)

The radical chain addition reactions of chlorine are initiated by light or the walls of the reaction vessel and inhibited by oxygen. Some ionic addition reactions are accelerated by ***Iron(III) Chloride***, ***Aluminum Chloride***, ***Antimony(V) Chloride***, or ***Copper(II) Chloride***.[11]

Chlorination of Aromatics.

Aromatic compounds may be chlorinated in the presence of Lewis acids like iron and iron(III) chloride. Low temperatures favor monochlorination, while high temperatures (150-190 °C) favor dichlorinated products.[11] The chlorination of alkylbenzenes in alcoholic media can result in higher yields of monochloro derivatives than when $FeCl_3$ is used.[12] Chlorine diluted in water converts tyrosine into 3-chloro-4-hydroxybenzyl cyanide (eq 6);[13] larger amounts of chlorine give 3,5-dichloro-4-hydroxybenzyl cyanide and 1,3-dichloro-2,5-dihydroxybenzene. The latter product can be converted into 2,6-dichloro-*p*-benzoquinone with additional aqueous chlorine.

(6)

Toluene is chlorinated by the radical mechanism to give benzyl chloride, benzal chloride, and benzotrichloride.[11] Sulfuryl chloride, ***t-Butyl Hypochlorite***, ***Hydrogen Chloride*** (in the presence of a copper-salt catalyst), and ***N-Chlorosuccinimide*** have also been used to chlorinate aromatics.[11]

Chlorination of phenol yields 2-chlorophenol and 4-chlorophenol in a ratio of 0.45:0.49, which is higher than the *ortho*/*para* ratio obtained with *t*-butyl hypochlorite.[14] 4-Alkylphenols react with chlorine in various solvents to form mainly 4-alkyl-4-chlorocyclohexa-2,5-dienones (in yields of 19-100%) and substitution products.[15] Other chlorinating agents (alkyl hypochlorites, sulfuryl chloride, hypochlorous acid, and antimony pentachloride) have also been used, but they result in polychlorinated cyclohexadienones and cyclohexenones.[15] The chlorination of dimethylphenols with chlorine in acetic acid containing HCl results in polychlorinated cyclohexenones (eq 7).[16]

The α-monochlorination of alkyl aryl ketones by chlorine gas occurs readily in a variety of solvents (e.g. CH_2Cl_2, $CHCl_3$, CCl_4, HOAc).[17] α,α-Dichlorination of alkyl aryl ketones occurs with sodium acetate in refluxing acetic acid (5 h, 80-90% yield). Alternatively, DMF can be used as the catalyst (80-100 °C, 35-45 min) (eq 8).[18]

R = Me, Et, Pr, *t*-Bu, Ph; R^1 = H, Cl, Br, Me

Chlorination of phenylenedibenzenesulfonamides by chlorine in nitrobenzene results in the formation of a mixture of dichloro derivatives.[19] The more useful tetrachloro derivative can be prepared by successive oxidations and additions of HCl, or in one step using Cl_2 in DMF (eq 9).[19] The temperature must be kept below 60 °C when Cl_2/DMF is used, or a runaway thermal reaction can result.[20]

(9)

Chlorine has been used for the chlorination of heterocycles,[7i -k] but the varied reactivity of substrates makes discussion of these reactions too lengthy for this review.

Oxidation of Alcohols.

Alcohols have been oxidized with complexes of chlorine with dimethyl sulfide,[21] DMSO,[22] iodobenzene,[21] pyridine,[23] and HMPA.[21] Secondary hydroxyl groups are more readily oxidized than primary hydroxyl groups when the ***Chlorine-Pyridine*** (eq 10)[23] and chlorine-HMPA complexes[21] are used. The same results are obtained with 3-iodopyridine dichloride.[23]

(10)

Hydroxythiols undergo chlorination reactions with Cl_2 in dichloromethane to form sultines and sulfinic esters after hydrolysis (eq 11).[24]

(11)

The oxidation of glycols usually results in C-C bond cleavage, but oxidation of the *s*-carbinol can be effected with a complex of a methyl sulfide (RSMe) and chlorine or NCS, or of DMSO and chlorine.[25] The tricyclic α-ketol (**2**) (eq 12) can be prepared from the glycol (**1**) using these reagents.[25]

(12)

(1) (2)

Chlorinolysis.

The C-C bond of short-chain hydrocarbons (<C_3 and any partially chlorinated derivatives) can be cleaved by chlorine at high temperatures to give chlorinated products. 1,2-Dichloroethane and 1,2-dichloropropane are cleaved by chlorine to give carbon tetrachloride and tetrachloroethylene with HCl as a byproduct.[11]

C-S Bond Cleavage.

The benzylic group of alkyl benzyl sulfides can be selectively cleaved by chlorine in aqueous acetic acid to give alkanesulfonyl chlorides (eq 13).[26]

(13)

Excess chlorine has been used to cleave the secondary C-S bond in lactam (**3**) (eq 14) to give the azetidin-2-one (**4**) in nearly quantitative yield.[27] When *N*-acyl groups are present, as in eq 15, the nitrogen lone pair electrons are inhibited, so cleavage of the tertiary C-S bond is favored over the azetidine C-S bond.[27]

(14)

(3) (4)

Phth = phthalimido

(15)

Other Reactions.

Chlorine and ***Sodium Bromide*** are used to produce ***Bromine Chloride***, which can be used in bromination reactions which are faster than those with elemental ***Bromine***, and which take place in aqueous solution rather than acidic solvents; the bromination of 4-nitrophenol to 2,6-dibromo-4-nitrophenol is one example.[28]

Thiocyanogen, prepared in anhydrous conditions from silver or lead thiocyanate and bromine, cannot be used for addition reactions with halogenated alkenes and is too expensive for most commercial processes.[29] Thiocyanogen can be prepared in a two-solvent system from ***Sodium Thiocyanate*** and chlorine.[29] The thiocyanogen is extracted into the toluene layer and can be used for addition reactions to vinyl halides in the synthesis of haloalkylene bisthiocyanates.

Several methods for the preparation of ***Phosgene*** are known, e.g. the gas-phase reaction of chlorine with carbon monoxide on activated carbon, the decomposition of trichloromethyl chloroformate, and the reaction of carbon tetrachloride with oleum.[30] Phosgene can be synthesized conveniently just before use by the reaction of chlorine with carbon monoxide in the presence of catalytic amounts of *t*-phosphine oxides, using carbon tetrachloride as the solvent.[30]

Chlorodimethylsulfonium chloride, generated in situ from ***Dimethyl Sulfide-Chlorine***, is a useful reagent for the conversion of epoxides to α-chloro ketones (eq 16)[31] and of aldoximes to nitriles,[32] in the presence of tertiary amines. Bromodimethylsulfonium bromide, generated in the same way, can be used to form α-bromo ketones, but the yields are lower than those obtained for α-chloro ketones.[31]

(16)

Chlorine and ***Triphenylphosphine*** are used in the synthesis of lactams from cycloalkanone oximes in high yields (eq 17).[33]

(17)

Alkanesulfonyl chlorides, which are useful reagents and intermediates in organic synthesis, can be conveniently produced from dithiocarbonic acid esters (eq 18).[34]

(18)

The indirect oxidation of trialkyl phosphites to trialkyl phosphates can be achieved in high yield and purity with chlorine in the corresponding alcohol (eq 19).[35] The indirect oxidation can also be effected by carbon tetrachloride, bromotrichloromethane, ***Carbon Tetrabromide***, ***Chloroform***, and hexachlorocyclopentadiene in alcohol.[35] Cyclic phosphites may undergo ring opening during reactions with chlorine, depending on the size of the ring and its degree of substitution.[7g]

(19)

Cyclooctanone oxime can be synthesized from cyclooctane by a photochemical reaction with chlorine and nitrous oxide (eq 20).[36] The oxime hydrochloride intermediate is converted into the oxime by aqueous sodium hydroxide.

(20)

Chlorine can be used for the synthesis of hydrazines from ureas, via diaziridinone intermediates (eq 21).[7h]

(21)

Related Reagents.

Chlorine-Chlorosulfuric Acid

Cl_2 + $ClSO_3H$

(Cl_2)

[7782-50-5] · Cl_2 · Chlorine-Chlorosulfuric Acid · (MW 70.91) ($ClSO_3H$)

[7790-94-5] · $ClHO_3S$ · Chlorine-Chlorosulfuric Acid · (MW 116.53)

(effective agent for α-halogenation of aliphatic acids; $ClSO_3H$ + Br_2 or $ClSO_3H$ + I_2 are similar)

Alternate Name: chlorine-chlorosulfonic acid.

Physical Data: $ClSO_3H$: mp -80 °C, bp 152 °C; *n*20D 1.433; *d* at 18 °C, 1.766 g cm^{-3}; for Cl_2 see ***Chlorine***.

Form Supplied in: transparent liquid; widely available.

Purification: commercial chlorosulfuric acid is usually contaminated with sulfuric acid and hydrogen chloride, and should be distilled before use (bp 86-88 °C at 33 mmHg).

Handling, Storage, and Precautions: chlorosulfuric acid is poisonous, and a strong oxidant and skin irritant: handle very carefully with gloves and a protective face shield; store in isolation from water, as it reacts to form H_2SO_4 and HCl; prolonged heating causes decomposition to H_2SO_4, SO_2, and Cl_2.

Chlorination of Carboxylic Acids.

Chlorine (or bromine or iodine) mixed with ***Chlorosulfonic Acid*** is conveniently used for the corresponding α-halogenation of aliphatic acids. The radical chlorination of aliphatic acids, e.g. photochlorination, occurs at random positions, while acid-catalyzed chlorination (e.g. the present reaction, as well as Hell-Volhard-Zelinsky procedures using PCl_3) gives exclusively α-chloro acids.[1,2] Molecular oxygen and ***Chloranil***,[3] as well as 7,7,8,8-tetracyanoquinodimethane,[4] are effective radical trappers. Chlorosulfuric acid is much more effective than sulfuric acid, as it forms homogeneous mixtures and has a stronger acidity.

The mechanism for the chlorosulfuric acid-mediated halogenation of an aliphatic acid involves the initial conversion of the aliphatic acid into an enolized monoacyl sulfate, followed by the addition of molecular halogen to give an α-haloacyl halide (eq 1).[5]

Examples of chlorination of aliphatic acids with 4:1 molar ratios of aliphatic acid:$ClSO_3H$ and with 2:1 molar ratios of Cl_2:O_2 are given in Table 1.[3,4,6,8,9]

Table 1 Chlorination of Aliphatic Acids with Cl_2-$ClSO_3H$

Acid	Conditions	Products, yield (%)	
	120 °C[3,6]	 75	 0.3
	120 °C[3]	 82	 1.6
	120 °C[3]	 81	
		$Me(CH_2)_{14}$	

Bromine- or Iodine-Chlorosulfuric Acid Reagents.

Similarly, bromination or iodination of aliphatic acids is possible by using the reagents chlorosulfuric acid-halogen in dichloroethane without any radical trapper. Examples of brominations with 1:1:1 molar ratios of aliphatic acid:$ClSO_3H$:Br_2 are given in eqs 2 and 3.[10]

$$EtCO_2H \xrightarrow[78\%]{Br_2,\ ClSO_3H,\ ClCH_2CH_2Cl,\ 85\ °C} MeCHBrCO_2H \qquad (2)$$

$$i\text{-}PrCO_2H \xrightarrow[95\%]{Br_2,\ ClSO_3H,\ ClCH_2CH_2Cl,\ 85\ °C} Me_2CBrCO_2H \qquad (3)$$

Examples of iodination with molar ratios of 65:32:6.5 of aliphatic acid:$ClSO_3H$:I_2 are shown in eqs 4 and 5.[11] Here, excess $ClSO_3H$ converts the HI evolved to I_2, leading to the stoichiometry as shown in eq 6.[12]

$$EtCO_2H \xrightarrow[79\%]{I_2,\ ClSO_3H,\ ClCH_2CH_2Cl,\ 80\ °C} MeCHICO_2H \qquad (4)$$

(5)

$$EtCO_2H + 0.5\ I_2 + ClSO_3H \longrightarrow MeCHICO_2H + HCl + 0.5\ H_2SO_4 + 0.5\ SO_2 \quad (6)$$

The similar oxidation of HBr to Br_2 is observed, but not that of HCl.[13] The yields for iodination of acetic acid (12%) and α,α-disubstituted acids (e.g. isobutyric acid, 14%) are poor, but in general acids give 93-98% yields.[11]

The effect of substituents on the relative rate constant k_{rel} of bromination and iodination fits the Taft equation (eq 7),[14] where ρ* is the polar reaction constant, &SSigma;σ* is the sum of polar substituent constants, δ is the steric reaction constant, and &SSigma;E_σ is the sum of steric substituent constants. The observed ρ* values are negative for both bromination and iodination, suggesting an electrophilic attack of the positively polarized halogen molecule on the double bond of the enol.

$$\log k_{rel} = \rho^*\Sigma\sigma^* + \delta\Sigma E_\sigma \quad (7)$$

Related Reagents.

Chlorine Fluoroxysulfate[1]

$ClOSO_2F$

[13637-84-8] · $ClFO_3S$ · Chlorine Fluoroxysulfate · (MW 134.51)

(strong electrophilic chlorinating agent, capable of halogen abstraction reactions to give esters of fluorosulfuric acid,[1-7] of electrophilic additions[8-11] and substitutions[12-14])

Physical Data: colorless liquid; mp -84.3 °C; bp 45.1 °C.[1]

Preparative Methods: can be obtained either by the reaction of peroxydisulfuryl difluoride ($F_2S_2O_6$) with Cl_2[3,15] or by insertion of SO_3 into ClF.[16,17]

Handling, Storage, and Precautions: stable and is not explosive.[1] However, it can ignite organic materials upon contact (including nonperfluorinated grease).[4] It is hydrolyzed by water to give HCl and fluorosulfuric acid. This reagent should be handled in a fume hood.

Synthesis of Fluorosulfates.

The chemical behavior of $ClOSO_2F$ (**1**) is determined by its ability to serve as a Cl^+ synthon.[1] It smoothly substitutes halogen atoms (Cl, Br, I) for fluorosulfate groups (eq 1).[1-7]

$$\underset{\textbf{(1)}}{RX + ClOSO_2F} \longrightarrow ROSO_2F + XCl \qquad (1)$$

For example, 1,2-dichloroethane or alkylchloroacetates react with (**1**) at -40 °C to 0 °C to give the corresponding fluorosulfates (eq 2).[5]

$$ClCH_2CH_2Cl \xrightarrow{ClOSO_2F} ClCH_2CH_2OSO_2F$$

$$ClCH_2CO_2R \xrightarrow{ClOSO_2F} FSO_2OCH_2CO_2R \qquad (2)$$

Geminal chlorine atoms can be substituted to give *gem*-difluorosulfates, for example eq 3.[3]

$$CF_2ClCFCl_2 \xrightarrow{ClOSO_2F} CF_2ClCF(OSO_2F)_2 \qquad (3)$$

The addition of fluorosulfuric acid[2,3] or bromine[7] catalyzes the reactions. In the case of mustard gas and its analogs, $S[(CH_2)_nCl]_2$, the reaction with (**1**) gives the corresponding bis-fluorosulfates, while the sulfur atom undergoes chlorination to give $Cl_4S[(CH_2)_nOSO_2F]_2$.[6] Perfluoroalkyl bromides are also readily transformed into the corresponding fluorosulfates, R_fOSO_2F.[2,7] In the case of perfluoroalkyl iodides the relatively stable derivatives of type $R_fI(OSO_2F)_2$ can be isolated.[1,7]

Perfluoroalkenes, fluorochloroalkenes, and chloroalkenes react with (**1**) to give β-chlorofluorosulfates (eq 4).[8-11]

(4)

Hexafluorobenzene, C_6F_6, also gives a 1,4-addition product and then the 1,2,3,4,5,6-addition product.[9] Addition to the C&tbond;C bond gives mono- and diadducts.[11]

Nitrile groups can add 1 mol of (**1**) in accordance with eq 5.[4,18]

(5)

Reaction of (**1**) with *N*-chlorodifluoromethanimine gives the corresponding diazene (eq 6).[19]

$$F_2C{=}NCl \xrightarrow{ClOSO_2F} FSO_2OCF_2N{=}NCF_2OSO_2F \qquad (6)$$

Chlorination.

The electrophilic chlorination of various organic substrates is a typical reaction of (**1**), the reagent serving as the source of Cl^+. Alcohols and carboxylic acids react with (**1**) to give the corresponding hypochlorites (eq 7).[1] The reaction yields are variable and are determined by the stability of the final products.[1]

$$ROH + ClOSO_2F \longrightarrow ROCl \qquad (7)$$

$$R = \text{alkyl, acyl}$$

This process was applied to the synthesis of inorganic hypochlorites, for example TeF_5OH -> TeF_5OCl.[20]

Reagent (**1**) is also a powerful chlorinating agent for aromatic substitutions.[12,13] For example, benzene gives hexachlorobenzene even at -100 °C.[12] In the presence of SbF_5 the reagent (**1**) chlorinates the pentafluorobenzene, C_6HF_5, into chloropentafluorobenzene, C_6ClF_5.[14]

Perfluoronitroso compounds undergo substitution of the nitroso group by chlorine (eq 8).[21]

$$R_fNO + \underset{\textbf{(1)}}{ClOSO_2F} \longrightarrow R_fCl \qquad (8)$$

Chlorine-Pyridine

$Cl_2.C_5H_5N$

[40007-00-9] · $C_5H_5Cl_2N$ · Chlorine-Pyridine · (MW 150.01)

(mild oxidizing agent)

Physical Data: [1] white crystals that decomposed rapidly when the solvent (CCl_4) was removed; mp <=47 °C.

Solubility: sol chloroform; insol carbon tetrachloride.

Form Supplied in: not commercially available.

Preparative Methods: although the chlorine-pyridine complex has been isolated,[1] the reagent is more conveniently prepared in situ.[2]

Handling, Storage, and Precautions: the same precautions associated with the use of ***Chlorine*** (protective clothing, respirator) should be followed; use in a fume hood.

The chlorine-pyridine complex has been used for the oxidation of alcohols.[2] Secondary alcohols are oxidized to ketones, while primary alcohols stop at the aldehyde stage. The faster rate observed for secondary alcohols (~20 min) vs. primary alcohols (~60 min) suggested that chlorine-pyridine might be useful in selective oxidations. In the oxidation of steroid diols and triols, chlorine-pyridine showed moderate to good selectivity (eqs 1-3).[2] Other reagents have been shown to be superior in effecting similar transformations.[3] However, these results may be misleading due to the problems that attend the oxidation of steroidal alcohols (axial vs. equatorial, adjacent to an angular methyl group, etc.). Thus chlorine-pyridine may be more selective than eqs 1 and 3 suggest. The usefulness of this reagent needs to be investigated further.

Chloroacetaldehyde

$ClCH_2CHO$

[107-20-0] · C_2H_3ClO · Chloroacetaldehyde · (MW 78.50)

(bifunctional electrophile; heterocycle building block;[4-10] α-chloro nitrone precursor[15])

Alternate Name: 2-chloroethanal.

Physical Data: bp 85-86 °C.

Solubility: sol water and most organic solvents.

Form Supplied in: aqueous solution (45-55%).

Analysis of Reagent Purity: oxime titration.

Preparative Methods: Water-free chloroacetaldehyde can be prepared by periodate oxidation of α-chlorhydrin[1] or through pyrolysis (200 °C) of 4-chloro-1,3-dioxolan-2-one.[2] Extraction of aqueous solutions of chloroacetaldehyde with organic solvents provides the hemiacetal.[3]

Handling, Storage, and Precautions: intensely irritating. Highly prone to polymerization, should be used immediately after preparation. This reagent should be used in a fume hood.

Heterocycles.

Chloroacetaldehyde is a building block for many types of heterocycles such as pyrroles,[4] furans,[5] thiophenes,[6] imidazoles,[7] thiazolines,[8] thiazoles,[9] or indoles.[10]

Wittig Reaction.

Alkoxycarbonylalkylidenephosphoranes react with chloroacetaldehyde in high yield to give γ-chlorotiglates. The *trans/cis* ratio is greater than 0.94 (eq 1).[11]

α-Cyanoenamines.

α-Cyanoenamines,[12] easily prepared from α-chloroacetaldehyde (eq 2), can be used for the synthesis of higher ketones,[13] 1,2-diketones,[13] 1,4-diketones,[14] and 1,5-diketones.[12]

α-Chloro Nitrones.

α-Chloroaldehydes are easily converted into the corresponding α-chloro nitrones with various hydroxylamines. (eq 3).[15] The lower representatives (R = H, Me) are unstable and should be stored at -20 °C.

The Ag^+ mediated reaction of α-chloro nitrones with unactivated alkenes results either in a [4 + 2] cycloaddition (eq 4)[15 -19] or, especially in solvents like SO_2 or $MeNO_2$, in a substitution (eq 5).[16,17] Mono-, 1,2-di-, or tetrasubstituted alkenes predominantly react via cycloaddition, whereas with 1,1-di- or trisubstituted alkenes, substitution becomes the main reaction, thereby giving access to β,γ-unsaturated aldehydes. The configuration of the alkene is retained in both cases.

(4)

(5)

With strong bases, the cycloadducts are converted with potassium *t*-butoxide into iminolactones which upon hydrolysis furnish γ-lactones (eq 6).[16,17,19]

(6)

Treatment of the cyano 1,2-oxazine cycloadducts with Ag^+ followed by sodium tetraphenylborate results in the formation of easily crystallizable iminium salts.[15] Deprotonation of these salts with weak bases furnish tetrahydro-1,2-oxazines which undergo cycloreversion at slightly elevated temperature to give mono-α,β-unsaturated dialdehydes after hydrolysis (eq 7).[20]

The cycloaddition-cycloreversion sequence has been used to synthesize indoles from 1,4-dihydro-5-nitronaphthalene.[21]

Slightly activated benzene derivatives furnish β-arylaldehydes upon treatment with α-chloro nitrones and $AgBF_4$ (eq 8).[18] Following the same procedure, *p*-cresol furnishes benzofurans (eq 9).[18] Electrophilic aromatic substitution reactions of chloro nitrones have also been described for furans[22] and indoles.[23]

The Ag^+-induced cycloaddition of α-chloro nitrones to alkynes followed by chromatography through deactivated alumina furnishes α,β-unsaturated ketones (eq 10).[24]

α-Chloro nitrones are alkylated by anions of dialkyl malonates, providing easy access to α-alkoxycarbonyl-β-formyl-carboxylic acid esters (eq 11).[25]

Related Reagents.

2,3-Dichloropropionaldehyde.

Chloroacetonitrile

$ClCH_2CN$

[107-14-2] · C_2H_2ClN · Chloroacetonitrile · (MW 75.50)

(reagent for two-carbon homologation of alkenes via organoboranes;[1] useful in Wittig alkenation of ketones[2] and Darzens condensations[3])

Physical Data: bp 124-126 °C; *d* 1.193 g cm^{-3}.

Form Supplied in: colorless liquid, widely available.

Handling, Storage, and Precautions: highly toxic and a lachrymator; use in a fume hood.

Homologation of Alkenes via Organoboranes.

Organoboranes undergo a base-induced reaction with a variety of α-halo esters, ketones, and nitriles.[4] The reaction substitutes the α-halogen with an alkyl group from boron (eq 1).

$$R_3B + ClCH_2CN \xrightarrow{\text{base}} RCH_2CN \qquad (1)$$

The use of ***9-Borabicyclo[3.3.1]nonane*** provides for efficient use of the alkyl group on boron.[1] The two chlorines of dichloroacetonitrile may be successively replaced (eq 2).

The reaction proceeds with retention of configuration of the original boron-carbon bond. This feature has been used

for the stereoselective construction of steroid side chains (eq 3).[5,6]

Either the natural or unnatural C-20 stereochemistry may be obtained (eq 4), depending on the configuration of the ethylidene unit.

Wittig Alkenation of Ketones.

Ketones may be converted into α,β-unsaturated nitriles through a modified Wittig-Horner-Emmons reaction (eq 5).[2] The (*E*) isomer predominates.

Darzens Condensations.

Glycidonitriles may be obtained by treating ketones with chloroacetonitrile and base (eq 6).[3] These glycidonitriles may be rearranged to carboxylic acids (eq 7).

Related Reagents.

Dichloroacetonitrile; ***Iodoacetonitrile***; ***Methyl Bromoacetate***; ***Methyl Chloroacetate***.

Chloroacetyl Chloride

[79-04-9] · $C_2H_2Cl_2O$ · Chloroacetyl Chloride · (MW 112.94)

(acylating agent;[1-34] chlorinating agent;[39] a two-carbon building block for cyclization;[6,13,25-27,33] a precursor to monochloroketene[35-38])

Physical Data: mp -22 °C; bp 105-106 °C; *d* 1.418 g cm^{-3}.

Solubility: sol ether, acetone, and methylene chloride.

Form Supplied in: liquid; commercially available.

Handling, Storage, and Precautions: is corrosive and moisture sensitive. It should be used in an anhydrous atmosphere. Pure $ClCH_2COCl$ can be obtained by simple distillation of the commercial product. This reagent should be used in a fume hood.

Introduction.

Chloroacetyl chloride is a versatile reagent and has been extensively used in organic synthesis. It is primarily used as an acylating agent. The multi-functional nature of $ClCH_2COCl$ has made it a suitable two-carbon building block for cyclization. Numerous cyclic compounds, especially heterocycles, have been prepared through the use of the reagent. Chloroacetyl chloride is also a valuable precursor for monochloroketene and occasionally serves as a chlorinating agent.

C-Acylation.

Acylation of carbon functionalities using $ClCH_2COCl$ as an acylating reagent generally falls into two categories: acylation under Friedel-Crafts conditions and under anionic conditions. Friedel-Crafts acylation of arenes using $ClCH_2COCl$ as an acylating agent is usually carried out in CS_2, nitromethane, sulfolane, etc. solution with ***Aluminum Chloride*** as a promoter, although other Lewis acids have also been employed. Benzene, toluene, naphthalene, *s*-hydrindacene, fluorene, and fluorenone react readily with $ClCH_2COCl$ under the reaction conditions.[1] Heterocyclic arenes, phenols, and derivatives of phenols are also similarly acylated.[2,3] In the case of phenols, the major acylation

products are the *para* isomers (eq 1). However, excellent *ortho* regioselectivity can be achieved by combining $ClCH_2COCl$ with phenoxides of aluminum and magnesium (eq 2),[4] a condition similar to that used in the Kolbe-Schmitt reaction.[5]

(1)

(2)

In the Friedel-Crafts reaction, both the acyl and the alkyl chloride functionalities of $ClCH_2COCl$ can react with an arene, resulting in the formation of a cyclic compound. For example, treatment of 1,2,3,4-tetrahydronaphthacene with $ClCH_2COCl/AlCl_3$ led to formation of 6-oxo-1,2,3,4,5,6-hexahydrobenz[*d*]aceanthrylene in 22% yield (eq 3).[6a] When 3,5-dimethoxytoluene is used as the substrate, a 2,3-dihydrobenzofuran-3-one is obtained almost quantitatively (eq 4).[6b,c] The carbonyl group of $ClCH_2COCl$ may also participate in cyclization under appropriate conditions.[6d,e] This behavior is illustrated by the formation of 2,7-difluoro-9-chloromethylenexanthene in the reaction of 4,4´-difluorophenyl ether with $ClCH_2COCl$ under $AlCl_3$ activation (eq 5).

(3)

(4)

The Friedel-Crafts acylation reaction of $ClCH_2COCl$ has been extended to alkenes and alkynes.[7,8] When alkenes serve as substrates, addition or addition-elimination products can be obtained selectively depending on the reaction conditions. The addition-elimination reactions led to formation of α,β-unsaturated ketones (eq 6). In the case of 1,8-bis(trimethylsilyl)-2,6-octadiene acylation, using the $ClCH_2COCl$/***Titanium(IV) Chloride*** system at low temperature yielded chloromethylcyclopentanols (eq 7).[7e] When acetylene is treated with $ClCH_2COCl$ in the presence of $AlCl_3$, 1,4-dichlorobut-3-en-2-one was obtained in 75% yield (eq 8).[8a] In the presence of ***Sodium Tetracarbonylcobaltate***, alkynes were cyclized by $ClCH_2COCl$ (eq 9).[8b]

(8)

(9)

R = Et, *t*-Bu, CH_2SCN, TMS, CH_2OCH_2OMe

Organocadmium and organozinc compounds are generally the reagents of choice in the preparation of chloromethyl ketones from $ClCH_2COCl$,[9] even though Grignard reagents are sometimes also used for the preparation.[10] Strong bases such as ***Lithium Diisopropylamide*** (LDA) and ***Lithium Hexamethyldisilazide*** (LHMDS) have been introduced as deprotonation agents for the *C*-acylation reaction of a number of enolizable carbonyl compounds.[11] For the strongly acidic C-H bond of 1,3-cyclohexanedione, a weak base such as pyridine is sufficient to achieve this purpose.[12] An interesting reaction involving enolate *C*-acylation is the synthesis of 3-furanones by organocopper conjugate addition to α,β-unsaturated ketones. Trapping of the enolate with $ClCH_2COCl$ and subsequent base-promoted ring closure offers a very simple route to the construction of a furan ring (eq 10).[13]

(10)

N-Acylation.

Acylation of nitrogen groups in organic compounds is the most frequently used reaction of $ClCH_2COCl$ in organic synthesis.[14-28] Primary and secondary amines react readily with $ClCH_2COCl$ to form amides.[14-17] In the case of diamines, both nitrogen atoms can be acylated. In fact, the diacylation has been utilized in the synthesis of cyclams[17a,b] and enantiomerically pure *trans*-2,3-diphenyl-DABCO.[17] Other nitrogen containing compounds such as *O*,*N*-dimethylhydroxylamine hydrochloride,[18a] benzyloxyguanidine,[18b] hydrazines,[18c] and amides[19] can also be acylated by $ClCH_2COCl$, under appropriate conditions. A one-pot procedure has been developed for reductive acylation of nitro compounds to chloroacetamides.[18d] If both amino and hydroxyl functionalities exist in the same

molecular, *N*-acylation generally proceeds preferentially.[20]

Chloroacetyl chloride is able to add across the C=N double bonds of imines to form *N*-chloroalkylchloroacetamide.[21] These addition products generally are unstable and are used for further reaction without isolation. The C=N double bonds of imines can be reductively acylated in the presence of ***Trichlorosilane***.[21f,g] The addition reaction is also applicable to carbodiimides[22] and other multiply bonded heteroatom functions such as P=N and S=N.[23]

1,3,5-Triisopropylhexahydrotriazine can undergo ring opening with $ClCH_2COCl$ in the presence of KSCN to form *N*-isopropyl-*N*-isothiocyanatomethylchloroacetamide in 67% yield (eq 11).[24]

(11)

Similar to *C*-acylation, cyclocondensation can also proceed in *N*-acylation to form cyclic compounds.[25] The α-chlorine atom of $ClCH_2COCl$ is also reactive in this case.

The cyclization is not limited to the formation of only C-N and C-C bonds, but can also occur through forming C-N and C-N bonds.[26] This transformation was exemplified by the preparation of 3-hydroxy-1-phenylpyrido[1,2-*a*]pyrazinium chloride in the reaction of $ClCH_2COCl$ with phenyl(2-pyridyl)ketimine (eq 12).[26b] Besides the α-chlorine, the carbonyl group of $ClCH_2COCl$ can also be utilized for the cyclization.

(12)

The chlorine atom at the α position of $ClCH_2COCl$ may also be displaced by an oxygen to form a ring containing both O and N atoms.[27] Cyclization of 4-amino-1-phenylisoquinolin-3-ol hydrochloride with $ClCH_2COCl$ generated 6-phenyl-2,3-dihydro-1*H*-[1,4]oxazino[2,3-*c*]isoquinolin-2-one in 40% yield (eq 13).[27b]

(13)

If a substrate has both N and S atoms, a heterocycle containing both atoms can be obtained upon treatment with $ClCH_2COCl$.[28] Preparation of thiazoles from thiobenzamide and $ClCH_2COCl$ has been accomplished through this process.[28c]

O-Acylation.

Like *N*-acylation, *O*-acylation using $ClCH_2COCl$ can be achieved either with or without a base.[29-33] Acylation has been successfully carried out with various hydroxy group-containing compounds such as alcohols,[29] phenols,[31] and saccharides[30] as substrates. Acylation of an enolate by $ClCH_2COCl$ has also been documented.[32] It is reported that treatment of salicylic hydrazide with $ClCH_2COCl$ in the presence of $MeSO_3H$ yielded 4,5-dihydro-5*H*-1,3,4-benzoxadiazepin-5-one in 59% yield (eq 14).[33]

(14)

S-Acylation.

S-Acylation is a less well-studied reaction of $ClCH_2COCl$.[34] However, it has found use in the preparation of 2-oxo-1,4-dithiane and its derivatives, which can be further transformed to the analogs of tetrathiafulvalene for the study of conducting molecular solids.[34b,c]

Precursor to Monochloroketene.

By treatment with Et_3N, $ClCH_2COCl$ loses HCl to yield monochloroketene.[35-38] The ketene generated by this method has been extensively used to perform [2 + 2] cycloadditions. The most widely studied reaction is the addition of the

ketene to imines for the construction of the valuable β-lactam ring (eq 15).[35] This reaction proceeds readily with a wide range of imines with varying structures. Even diimines can be doubly cyclized. The in situ generated ketene was also trapped by allenes.[36a] An interesting method regarding the preparation of squaric acid is based the use of the monochloroketene.[36b]

(15)

Beside [2 + 2] cycloadditions, [4 + 2] and [8 + 2] cycloadditions involving the in situ generated chloroketene have also been studied.[35a,37,38]

Chlorination.

Chloroacetyl chloride occasionally serves as a chlorinating agent.[39] 2,4-Pentanedione was chlorinated at the 1- and 5-positions upon treatment with $ClCH_2COCl/AlCl_3$ in the presence of $Cu(OAc)_2$.[39a,b] Chloroacetyl chloride has also been used to transform 2-picoline *N*-oxide and 2-oxo-2-dimethylamino-5-methyl-1,2-oxophospholane to 2-chloromethylpyridine and 2-oxo-2-chloro-5-methyl-1,2-oxophospholane, respectively.[39c,d]

Related Reagents.

Chloroacetyl Fluoride; ***Dichloroketene***.

Chloroacetyl Fluoride

[359-14-8] · C_2H_2ClFO · Chloroacetyl Fluoride · (MW 96.49)

(acylating agent; a precursor to chloroacetylium ion)

Physical Data: bp 73-75 °C; d^{20} 1.379 g cm^{-3}.[1]

Preparative Methods: generally prepared by fluorination of $ClCH_2COCl$.[1] A variety of reagents has been employed for this transformation, including benzoyl fluoride/KH_2F,[2a] KHF_2,[2b] KF,[2c] KF/tetraalkylammonium chloride,[2d] and dialkylaminosulfur trifluoride.[2e] Preparation of $ClCH_2COF$ may also be accomplished from $ClCH_2CO_2H$ through the use of 2-chloro-1,1,2-trifluoroethyldiethylamine as the fluoride source.[3] Treatment of $ClCH_2CF_2CF_2OCH_3$ with SO_3 leads to the formation of $ClCH_2COF$ in 94% yield, which is the highest yield reported for the preparation of the reagent.[4]

Handling, Storage, and Precautions: is corrosive, moisture sensitive, and should be stored under anhydrous conditions. This reagent should be handled in a fume hood.

Chloroacetyl fluoride is less well studied compared to its analog ***Chloroacetyl Chloride***. The majority of the publications concerning $ClCH_2COF$ are centered on its structure and spectroscopic properties.[5] Regarding synthetic chemistry aspects, $ClCH_2COCl$ has mainly been used as an acylating agent. When $ClCH_2COF$ was treated with SbF_5 in SO_2 solution at low temperature, chloroacetylium ion was observed.[6a] Its stable hexafluoroantimonate salt has been isolated (eq 1) and used as chloroacylating agent for aromatic compounds (eq 2).[6b] Chloroacetylium hexafluoroantimonate reacts with benzene, toluene, *p*-xylene, and mesitylene to generate the corresponding chloroacylated products in high yields. In the case of toluene, a 7.7:3.4:88.9 isomer distribution ratio was obtained for the *ortho*, *meta*, and *para* isomers.

(1)

(2)

Reaction between $ClCH_2COF$ and diazomethane led to formation of $ClCH_2COCHN_2$, which was in situ converted to α-chloro-α´-fluoroacetone in 32% yield by the addition of HF (eq 3).[7]

(3)

It was also reported that $ClCH_2COF$ can be electrochemically transformed into chlorofluoroacetic acids.[8]

Related Reagents.

Chloroacetyl Chloride.

Chloroacetyl Isocyanate

[4461-30-7] · $C_3H_2ClNO_2$ · Chloroacetyl Isocyanate · (MW 119.51)

(preparation of primary amides from Grignard reagents,[11] monosubstituted ureas from primary amines[12] and from β-lactams[13])

Physical Data: fp 61 °C; bp 50-55 °C/20 mmHg, 68-79 °C/70 mmHg; *d* 1.403 g cm^{-3}.

Solubility: sol benzene, THF, etc.

Form Supplied in: colorless-yellow oil, commercially available; can also be prepared in the laboratory.[1]

Handling, Storage, and Precautions: toxic, lachrymator, corrosive, reacts with moisture; refrigerate and store under nitrogen; should be handled in a fume hood.

Addition Reactions.

Chloroacetyl isocyanate (**1**) undergoes a variety of reactions, typical of the isocyanate class, including addition reactions with alcohols,[2] amines,[3] organic peroxides,[4] ketene silyl acetals,[5] hydrazines,[6] 2-pyrazolines,[7] and triazoline-3,5-diones.[8] In addition, the bifunctionality of this reagent endows it with specialized uses including the synthesis of heterocyclic rings[9,10] and polymers.[3,4]

Addition-Cleavage Reactions: *N*-Unsubstituted Amides and Ureas.

Grignard reagents add to reagent (**1**) to afford mixed imides.[11] These compounds may then be cleaved either reductively or hydrolytically at the chloromethyl-substituted carbonyl to give primary amides (eq 1).

(1)

Likewise, chloroacetyl ureas derived from (**1**) and primary amines are subject to regioselective cleavage by nucleophiles to give *N*-monosubstituted ureas.[12]

Condensation of (**1**) with photopyridones (β-lactams, eq 2)[13] gave *N*-chloracetylcarbamoyl derivatives. Treatment of these compounds with ***Triethylamine*** in methanol gave the all-*cis*-1,2,3-trisubstituted cyclobutanes, whereas treatment with sodium methoxide in methanol afforded the *trans*,*trans*-cyclobutanes. The latter class of compounds provides an intermediate for the synthesis of oxetanosyl *N*-glycosides.

Related Reagents.

Chlorosulfonyl Isocyanate; ***Trichloroacetyl Isocyanate***.

2-Chloroacrylonitrile

[920-37-6] · C_3H_2ClN · 2-Chloroacrylonitrile · (MW 87.51)

(ketene equivalent for use in the Diels-Alder reaction[1] and other cycloaddition reactions; undergoes Michael additions and radical additions)

Physical Data: mp -65 °C; bp 88-89 °C; *d* 1.096 g cm^{-3}.

Solubility: sol most organic solvents other than pure hydrocarbons.

Form Supplied in: neat colorless liquid.

Analysis of Reagent Purity: ^1H NMR, ^{13}C NMR.

Handling, Storage, and Precautions: highly toxic; use only in a fume hood. Reagent can be absorbed through the skin. Always wear gloves when handling this reagent.

[4 + 2] Cycloaddition Reactions.

2-Chloroacrylonitrile is a reasonably good dienophile for the Diels-Alder reaction. It reacts thermally with a variety of cyclic dienes such as cyclopentadiene[2] and cyclohexadiene.[2,3] Most often the initial cycloadducts are hydrolyzed immediately to produce the corresponding ketones (eq 1). In this fashion, 2-chloroacrylonitrile, along with ***2-Acetoxyacrylonitrile***, is one of the most popular ketene equivalents for use in the Diels-Alder reaction.[1] In the case of substituted cyclohexadienes the starting diene is often an unconjugated 1,4-diene which under the reaction conditions isomerizes to the reactive 1,3-diene and produces the desired Diels-Alder adduct (eq 2).[4]

Once again the product α-chloro nitrile is hydrolyzed to produce the bicyclo[2.2.2]octanone. The hydrolysis reaction is usually carried out with either ***Potassium Hydroxide*** in DMSO[2,5] or with ***Sodium Sulfide*** in refluxing ethanol.[6]

Copper salts have been used to catalyze the Diels-Alder reaction of 2-chloroacrylonitrile.[6] Most notable is the successful cycloaddition of the thermally sensitive substituted cyclopentadiene (**1**) (eq 3).[6a,b] Use of copper(II) fluoroborate allowed the reaction to take place at 0 °C. This ultimately produced ketone (**2**), an important intermediate in the early syntheses of prostaglandins. Diels-Alder reactions between furans and 2-chloroacrylonitrile have also been achieved via copper catalysis (eq 4).[6d] Interestingly, the base-catalyzed hydrolysis of adduct (**3**) produced the amide (**4**) instead of the expected ketone. There have been other instances in which the intermediate α-chloronitrile yields products other than the hydrolyzed ketone.[7]

As seen from the above examples, cyclic dienes are usually used in conjunction with 2-chloroacrylonitrile.[8] Such dienes include substituted cyclohexadienes,[4,7a-d,9] substituted cyclopentadienes,[6a-c,7e] hydroxypyrones,[10] fulvenes,[11] furans,[6d,12] and isobenzofurans.[13] Other dienes which give [4 + 2] cycloadducts with 2-chloroacrylonitrile include vinyl heterocycles[14] and a few acyclic dienes.[15] It has been stated that thermal cycloadditions are limited to 140 °C due to polymerization of the chloroacrylonitrile above this temperature.[3] In addition to the aforementioned Cu^{2+} catalysis, ***Zinc Iodide***,[12b] triorganotin cations,[12e] and high pressure[12a,f] have been used to accelerate the cycloaddition reactions of 2-chloroacrylonitrile and furans.

In addition to 2-chloroacrylonitrile and ***2-Acetoxyacrylonitrile***, other ketene equivalents have been developed.[1] These include acrylonitrile,[2] 2-aminoacrylonitrile,[16a] 2-methylthioacrylonitrile,[16b] 2-chloroacryloyl chloride,[17a,b] 2-bromoacrolein,[17c] vinyl boronates,[4,18a] vinylboranes,[18b] nitroethylene,[19] and vinyl sulfoxides.[20] One comparative study found that 2-chloroacrylonitrile was both more reactive and more regioselective than either 2-acetoxyacrylonitrile or dibutyl vinyl boronate.[4] Chiral vinyl sulfoxides have been explored as possible chiral ketene equivalents.[17c,20]

Other Cycloaddition Reactions.

In addition to [4 + 2] cycloadditions, 2-chloroacrylonitrile also undergoes [2 + 3][21,22] and [2 + 2][23] cycloaddition reactions. In particular, 2-chloroacrylonitrile is a good dipolarophile and has produced cycloadducts with nitrones[21] and a number of different azomethine ylides.[22] In the case of nitrones the cycloadducts have been hydrolyzed to isoxazolidinones; thus 2-chloroacrylonitrile once again functions as a ketene equivalent in these reactions (eq 5).[21c] Chiral nitrones have been found to undergo stereoselective cycloaddition reactions and have been used in the synthesis of chiral amino acids[21c] and carbapenem derivatives.[21a]

Michael Additions and Radical Additions.

As with other acrylonitriles, 2-chloroacrylonitrile is an excellent acceptor of nucleophiles[23e,24] and nucleophilic radicals.[25] In a number of instances[24a,b,25b,e] the initial addition product can undergo a further cyclization, in which case 2-chloroacrylonitrile functions as a convenient two-carbon annulating agent. Such an annulation is illustrated for both a polar addition (eq 6)[24b] and a radical addition (eq 7).[25b] 2-Chloroacrylonitrile has been used extensively in the homologation of nucleophilic radicals[25a,c,f] and, in keeping with the captodative effect,[25d] has been shown to react 10-15 times faster than acrylonitrile.[25a,d]

2-Chloroacrylonitrile

1-Chloroallyllithium

[80411-43-4] · C_3H_4ClLi · 1-Chloroallyllithium · (MW 82.46)

(reacts with substituted epoxides,[4] thiiranes,[5] esters,[1] alkyl bromides,[6] imines,[10] and azirines[10] in the α-mode; with carbonyl compounds[2] and alkyl halides[3] gives a mixture of α- and γ-adducts; 1-chloroallylzinc gives highly diastereoselective α-addition with aldehydes and ketones[7])

Solubility: sol diethyl ether, THF.

Handling, Storage, and Precautions: highly unstable; generated at -78 °C in the presence of electrophiles in an inert atmosphere.

Chloroallyllithium was first prepared[1] by treating γ-chloroallyltriphenyllead (**1**) with ***n-Butyllithium*** at -90 °C (eq 1). Reaction with various electrophiles gives products arising from both α- and γ-attack.[1-4] However, (**2**) displays exclusive α-selectivity in its reaction with epoxides to give either the corresponding β-chloro-γ-ethylenic alcohols (**3**) or a mixture of (**3**) and the cyclized products (oxetanes) (**4**) (eq 2).

$R^1 = H, Me, Et, Ph, CH_2OH, CH_2OEt; R^2 = H$

$R^1 = R^2 = Pr, H_2C{=}CHCH_2CH_2$

Similarly, the reaction with thiiranes gave 2-vinylthietanes (**7**) by intramolecular cyclization of the initially formed β-chloro-γ-ethylenic thiolithium (**6**) (eq 3).[5] The α-regioselectivity was also observed in the acylation of (**2**) with esters (except with t-butyl carboxylate). α-Chloro-α,β-unsaturated ketones (**9**)[1] were formed by base-catalyzed isomerization of initially formed α-chloroacyl adducts (**8**) (eq 4).

$R^1 = R^3 = H$; $R^2 = Et$, CH_2OEt, 
$R^1 = R^2 = Me$, Pr, CH_2-CH=CH_2; $R^3 = H$
$R^1 = R^2 = R^3 = H$
$R^1 = H$; $R^2 = R^3 = -(CH_2)_4-$

$R^1 = Et$, Pr, Bu, *i*-Pr, Ph, $MeOCH_2CH_2$

Alkylation of α-chloroallylithium gave mixtures of α- and γ-alkylated products (**10**) and (**11**) (eq 5).[3] However, with

a few alkylating agents, a high degree of α- (*n*-butoxymethylene chloride) or γ- (dimethylmethyleneammonium iodide) regioselectivity was observed. The γ-alkylated products are formed exclusively in the (*Z*) configuration, which is explained on the basis of transition state (**12**) (eq 5).

R = Bu; X = Br, Cl
R = C_6H_{13}, cyclo-C_6H_{11}, $PhCH_2$, $H_2C{=}CHCH_2CH_2$
$MeCH{=}CHCH_2$, $Me(CH{=}CH)_2CH_2$, $BuC{\equiv}CCH_2$

Subsequently, 1-chloroallyllithium was directly generated in situ by treating ***Allyl Chloride*** with ***Lithium Diisopropylamide*** at -78 °C and was shown to undergo alkylation with high α-regioselectivity with a variety of primary alkyl bromides.[6] The secondary allyl chloride intermediates (**13a**) and (**13b**) have been used as building blocks for the synthesis of disubstituted alkenic insect sex pheromones of *A. leucotreta* (**14a**) and *S. littoralis* (**14b**), respectively (eq 6). The α-alkylation/cuprate displacement sequence is also applicable to anions of methallyl and crotyl chloride and is a promising route for the synthesis of more complex systems (eq 7).[6]

(13a) $n = 4$
(13b) $n = 8$

(14a) R = Pr, $n = 4$
(14b) R = Me, $n = 8$

(7)

The chloroallyllithium (**2**) derived from (**1**) and butyllithium adds to carbonyl compounds to form products of both α- and γ-addition in varying proportions (eq 8).[2] The epoxides (**19**) thus obtained were a mixture of (*E*) and (*Z*) isomers, while the *cis* configuration was maintained in the γ-adducts (**20**), as observed earlier (eq 8).

(8)

Interestingly, the anion (**21**) with a Zn^{2+} counterion reacts with aldehydes and ketones with exclusive α-addition and with high diastereoselectivity in the product chlorohydrins (eq 9).[7] No epoxides were formed with Zn^{2+} as counter cation. Treatment of the chlorohydrins (**22**) with potassium ethoxide gave *cis*-vinyloxiranes (**19**) in quantitative yields (eq 9). Chloroallyllithium (**2**) generated by direct deprotonation of allyl chloride with LDA, however, gave only γ-adducts (**20**) with aromatic aldehydes and ketones (eq 10),[7] in contrast to the ambident behavior of (**2**) generated from

1-Chloroallyllithium

(**1**).[2]

The anion (**2**) underwent regioselective α-addition with imines[8,9] and azirines,[10] followed by intramolecular cyclization to afford the corresponding vinylaziridines (**24**) (eq 11) and 2-vinylazabicyclobutanes (**26**), respectively (eq 12).

1-Chlorobenzotriazole[1]

[21050-95-3] · $C_6H_4ClN_3$ · 1-Chlorobenzotriazole · (MW 153.57)

(positive halogen reagent for mild oxidations[2,3] and selective chlorinations[4])

Alternate Names: 1-chloro-1*H*-benzotriazole; *N*-chlorobenzotriazole; 1-CBT.

Physical Data: colorless needles; mp 104-106 °C; λ_{max} 252 nm.

Solubility: sol CH_2Cl_2, CCl_4, C_6H_6, MeCN, MeOH.

Analysis of Reagent Purity: solutions can be standardized by iodometric or potentiometric titration.[1]

Preparative Methods: treat benzotriazole with sodium hypochlorite in 50% aq acetic acid. The reagent quickly precipitates and is obtained in nearly quantitative yield after recrystallization from CH_2Cl_2/petroleum ether.[2a]

Handling, Storage, and Precautions: may ignite spontaneously;[5] *reacts explosively with DMSO;*[2b] light sensitive; stable to air and moisture in brown bottles; storage recommended at 0 °C; discard or repurify if discoloration occurs. This reagent should be handled in a fume hood.

Oxidation of Alcohols and Nitrogen Compounds.

1-Chlorobenzotriazole (1-CBT) behaves similarly to positive halogen compounds such as ***N-Bromosuccinimide***, ***N-Chlorosuccinimide***, and ***Chloramine-T***, acting as a source of halonium ion (Cl^+) or halogen radical (Cl&bdot;). The reagent is convenient to use and prepare, and in some applications gives higher yields than ***t-Butyl Hypochlorite***. Alcohols, hydrazones, 1,1- and 1,2-disubstituted hydrazines and aminobenzotriazoles are efficiently oxidized under extremely mild conditions by 1-CBT (Table 1).[2] Reactions are typically carried out by warming equimolar amounts of substrate and 1-CBT in CH_2Cl_2, CCl_4, or C_6H_6; reaction with hydrazines occurs readily in the cold. After a brief induction period a rapid exothermic reaction occurs, typical of a radical chain process, affording the oxidized product and benzotriazole hydrochloride which precipitates. Secondary alcohols are oxidized faster than primary alcohols, as is generally observed with *N*-halide oxidizing agents. Trace amounts of benzotriazole are easily removed from the product by washing with dilute aqueous sodium hydroxide.

Table 1 Oxidation of Alcohols and Nitrogen Compounds by 1-Chlorobenzotriazole

Starting material	Solvent	Product	Yield (%)
Benzyl alcohol	CH_2Cl_2	Benzaldehyde[a]	70
1-Phenylethanol	CCl_4	Acetophenone[a]	65
Cyclohexanol	CH_2Cl_2	Cyclohexanone[a]	70
Hydrazobenzene	CH_2Cl_2	Azobenzene	90
4,5-Diphenyl-pyrazolidin-3-one	CH_2Cl_2	*trans*-Stilbene	75
1-Aminobenzotriazole	CH_2Cl_2	Benzyne[b]	80

[a] Isolated as the 2,4-dinitrophenylhydrazone. [b] Isolated as tetraphenylnaphthalene after reaction with tetraphenylcyclopentadienone; two mols of oxidant required.

Reaction with Sulfides.

Sulfides are efficiently oxidized to sulfoxides by 1-CBT in methanol or methylene chloride at -78 °C.[3a] The reaction is very fast and clean, giving no overoxidation to sulfones as is often observed with peroxy acids (e.g. ***m-Chloroperbenzoic Acid***). The performance of the reagent is comparable to *t*-butyl hypochlorite. This transformation has been used in the conversion of steroidal thioacetals to ketones.[3b] The intermediate formed between 1-CBT and sulfides may also react with alcohols or primary and secondary amines. Treatment of the ensuing adduct with ***Silver(I) Tetrafluoroborate*** gives the corresponding amino- or alkoxysulfonium fluoroborate.[3c]

Chlorination of Heteroaromatics.

Indoles and other nitrogen heterocycles are selectively chlorinated by 1-CBT in high yield. This procedure often succeeds where the standard reagent *t*-butyl hypochlorite fails.[4] Multiple equivalents of chlorine may be selectively incorporated simply by adjusting the initial amount of 1-CBT used (eq 1).[4b] The chlorination of some indoles is better effected by using 1-chloroisatin.[4c]

(1)

1-CBT (mol equiv)	Product	Yield (%)
1	$R^1 = Cl$; $R^2, R^3, R^4 = H$	79
2	$R^1, R^2 = Cl$; $R^3, R^4 = H$	64
4	$R^1, R^2, R^3, R^4 = Cl$	61

Other Applications.

The title reagent has been shown to undergo ready addition to alkenes, giving 1,2- and 2,2-chloroethylbenzotriazoles,[6] as well as to effect α-chlorination of ketones.[1] 1-CBT has also been used in the preparation of other benzotriazole derivatives (1-nitro-, 1-bromo-, and 1-iodobenzotriazoles),[7,8] as well as the selenium transfer reagent bis(1-benzotriazolyl) selenide.[9]

μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium[1]

[67719-69-1] · $C_{13}H_{18}AlClTi$ · μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium · (MW 284.60)

(methylenating agent for alkenation of carbonyl compounds,[2-4] particularly esters, ketones, and aldehydes; of low basicity and functions without epimerization at α-chiral centers)

Alternate Name: Tebbe reagent.

Physical Data: red solid.

Solubility: highly sol toluene, benzene, or dichloromethane; will dissolve in THF at low temperature (but not stable for prolonged periods in ethereal solvents). Nearly insol saturated hydrocarbons.

Form Supplied in: may be purchased as the pure solid or prepared from titanocene dichloride and trimethylaluminum.

Handling, Storage, and Precautions: the dry solid is air-sensitive and may be pyrophoric in air, especially when impure; it must be handled under an atmosphere of nitrogen or argon. The reagent is most conveniently stored and handled as a toluene solution; in this form the reagent is somewhat pyrophoric in air and must be handled using syringe and cannula techniques as practiced when using Grignard or alkyllithium solutions.

Tebbe Reagent as a Source of $Cp_2Ti{=}CH_2$.

The complex $Cp_2TiCH_2.AlMe_2Cl$, commonly referred to as the Tebbe reagent,[5] is a source of the reactive titanium methylene species $Cp_2Ti{=}CH_2$ as shown in eq 1. The methylene intermediate, formation of which is greatly accelerated by bases such as THF or pyridine, is useful for the methylenation of carbonyl compounds in a process similar to Wittig alkenation; the driving force is the high oxophilicity of titanium. The scope of reactivity is greater than with the corresponding phosphoranes;[6] thus esters and amides are converted to vinyl ethers and enamines by the Tebbe reagent.[2,7] The lower basicity of the Tebbe reagent offers further advantages over the Wittig procedure (see below). Although many examples of methylenation of unsaturated

substrates are known, and carbon-carbon double bonds usually do not interfere, it should be noted that the Tebbe reagent will react with certain alkenes to form titanacyclobutanes.[8] These titanacycles, of importance as intermediates in degenerate metathesis of terminal alkenes and ring-opening metathesis polymerization of strained cyclic alkenes,[9] and as synthetic reagents themselves,[1b] have been studied in some detail. The most stable titanacyclobutanes are those derived from monosubstituted alkenes; even these will revert to free alkene and active methylene when heated to about 60 °C.[10] Therefore mild heating may be used to improve yields of irreversibly formed methylenation products for certain substrates.[3] Furthermore, use of excess Tebbe reagent will in certain cases lower the yield of alkene product.[3,11]

(1)

The reagent may be purchased as a pure solid, or synthesized as such using Schlenk line and glovebox techniques.[5a,12] Since isolation of the Tebbe reagent is time-consuming, in situ preparations of the complex have been developed.[3,13] It should be noted that in situ preparation produces a solution with one equiv of excess $AlMe_2Cl$ and often affords somewhat lower yields than the isolated reagent.[1a,13a] Typical conditions[2,13a] for use involve combining the reagent in toluene solution at low temperature with the substrate and a Lewis base such as THF and/or pyridine. After warming to room temperature, the solution is chilled and quenched with aqueous sodium hydroxide, diluted with ether, dried, filtered through Celite, and the product further purified, often by chromatography on neutral or basic alumina.

Tebbe methodology is specific for methylene transfer. However, approaches to analogous Group 4 metal reagents having substituted alkylidene units have been developed and show considerable promise.[1a,14] Several other titanium-based reagents for methylene transfer have been developed.[1a,15,16] A widely used system for methylenation of ketones[15a] is the still undefined mixture formed from $Zn/CH_2X_2/TiCl_4$. Also, thermolysis of Cp_2TiMe_2 provides a clean aluminum-free source of $Cp_2Ti{=}CH_2$ and shows considerable synthetic promise.[16] These various methylenation and alkylidenation processes have been comprehensively reviewed.[1a]

Methylenation of Aldehydes and Ketones.

The Tebbe reagent accomplishes methylenation of aldehydes and ketones.[4,5a,11,17-23] Table 1 shows some representative conversions with yields for the Wittig reagent included where available; the titanium reagent affords consistently higher yields and is less sensitive to steric crowding than ***Methylenetriphenylphosphorane***.[4] It is particularly useful in preparation of exocyclic alkenes (e.g. entries 2, 4, 5 and 8); only in extremely hindered substrates such as fenchone (entry 3) is the reagent ineffective. Also, the titanium complex efficiently methylenates such readily enolizable ketones as β-tetralone (entry 4).

8[21]	63	
The Tebbe reagent will methylenate aldehydes and ketones without epimerization at α-chiral centers, as illustrated in eq (2).[22] The relatively low basicity of this reagent also permits conversions such as eq (3), which gives almost exclusively β-elimination across the C(1´)-C(2´) bond when attempted by the Wittig method.[11] When a large excess of Tebbe reagent is used in eq (3), *gem*-dimethylation occurs via a titanacyclobutane. Ketones with α,α-disubstitution (e.g. eq 4) will enolize rather than methylenate;[23] these titanium enolates are not active in the aldol reaction. The Tebbe reagent shows synthetically useful selectivity for ketones in preference to esters, as in the conversion of entry 8 (where 15% methyl ketone byproduct was observed), which was unsuccessful using $Zn/CH_2X_2/TiCl_4$ due to cyclopropanation. However, the $Zn/CH_2X_2/TiCl_4$ mixture is much more widely used for ketone methylenation since in certain preparations it will not react with esters.[1a]

(2)

(3)

(4)

Methylenation of Esters and Lactones.

The greatest advantage of the Tebbe reagent is that, unlike phosphorous ylides, it may be used to convert esters and lactones to versatile enol ethers.[2] The reaction is quite general and typically proceeds in good to excellent yield.[3,7,24-50] Several representative conversions are presented in Table 2.

The procedure is tolerant of the acetal (entries 2 and 5) and cyano (entry 9) groups. Double bonds typically retain their stereochemistry (entry 8) and position. In a few instances, double bond migration has been reported upon workup;[30,47] precautions to minimize such rearrangement are described.[13a] Other compatible functionalities include various siloxy groups,[36,46] halide,[44,48] and thioacetal.[24] Ketone and ester groups may be simultaneously methylenated (entry 3), or a keto group may be preferentially methylenated with 1 equiv of reagent.[7,21] Literature estimates of ketone versus ester selectivity are given as 4:1 in general[2] and 25-30:1 for acetophenone against methyl benzoate.[23] It has been observed that yields may differ depending on whether isolated Tebbe reagent is used or if the complex is generated in situ; for example, 94% in entry 1 compared with 68-70% by in situ methods.[13a] Nonetheless, yields are often excellent using the in situ reagent (e.g. entry 11 and others[3,35]), which is considerably less expensive than the isolated complex. Since enol ethers are not known to form titanacyclobutanes on reaction with the Tebbe complex, *gem*-dimethylation does not occur when excess reagent is employed.[3]

Methylenation of allyl esters (Table 2, entries 4, 9, 12, and 13) affords allyl vinyl ethers[2,24,25,27,32,42-45,49] which are useful substrates for the Claisen rearrangement (e.g. eq 5[25] and eq 6[24a]). Although the methylene group of the Ti complex is mildly basic, solutions of the reagent are Lewis acidic, particularly when an extra equivalent of $AlMe_2Cl$ is present from in situ reagent preparation. The acidic character of the reagent has been used to advantage in a mild one-pot synthesis of 1,5-dienes from allyl esters in which a Claisen rearrangement occurs under Lewis acid catalysis (eq 6 and entry 12).[24a]

(6)

The Tebbe complex has found frequent application in carbohydrate chemistry.[26,31b,33,35,36]

The titanium reagent allows transformations of esters without epimerization at α-chiral centers, as is illustrated in the methyl ketone preparation of eq 7.[28b] Cyclic carbonates may be methylenated as well (eq 8).[1b]

In at least one case where the Tebbe procedure is ineffective, presumably for steric reasons, an ester has been efficiently methylenated with $Zn/CH_2X_2/TiCl_4$.[38] However, hindered esters may be methylenated with the Tebbe reagent (e.g. entry 7).

Methylenation of Amides.

Amides have been converted to enamines of methyl ketones by the Tebbe reagent (eq 9).[1a,b,7,51] No added base is required. Isolation of enamines is possible, or in situ alkylation may be performed.[7] The reaction has been little developed.

(9)

Titanium Enolates from Acid Chlorides.

Acid chlorides have been reported to react with the Tebbe reagent to afford titanium enolate complexes (eq 10),[52] although yields are much lower than those obtained using titanacyclobutane precursors.[53] These enolate complexes of methyl ketones are known to participate in aldol reactions.[53]

(10)

Other Reactions of the Tebbe Reagent.

Silyl esters and thioesters are methylenated by the Tebbe reagent.[1a] The complex is known to react with alkynes to give stable titanacyclobutenes.[54] Reaction with anhydrides gives enolate complexes which are not active in the aldol reaction.[55] By contrast, unhindered imides may be methylenated in good yield with excellent selectivity in unsymmetrical cases.[55] Nitriles react to afford vinylimidotitanium complexes, which have been studied in some detail.[56] The reagent has found application in the preparation of various organometallic complexes.[57]

Chlorobis(cyclopentadienyl)hydridozirconium[1]

[37342-97-5] · $C_{10}H_{11}ClZr$ · Chlorobis(cyclopentadienyl)hydridozirconium · (MW 257.87)

(hydrozirconation reagent; reducing reagent of unsaturated compounds; starting material for organozirconium complexes)

Alternate Name: Schwartz's reagent.

Solubility: insol; hydrolyzed in water; very slowly converted by CH_2Cl_2 to Cp_2ZrCl_2.

Form Supplied in: commercially available as white powder (95%).

Analysis of Reagent Purity: IR (nujol) 1390 cm^{-1} (metal-hydrogen bond). The purity of $Cp_2Zr(H)Cl$ is measured by reaction with acetone. A small sample is assayed in a 5 mm NMR tube in C_6D_6 by treatment with a known amount of excess acetone, and the relative areas of the signal for the mono- and diisopropoxides are determined by ^1H NMR.[2,3]

Preparative Methods: $Cp_2Zr(H)Cl$ is prepared by the reaction of ***Dichlorobis(cyclopentadienyl)zirconium*** with ***Lithium Tri-t-butoxyaluminum Hydride***,[4,5] ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Vitride or Red-Al),[3] or ***Lithium Aluminum Hydride***.[2] Zirconocene dichloride (100 g, 0.342 mol) is dissolved in dry THF (650 mL, heating required) in a 1 L Schlenk flask under argon. To this solution (at or slightly above rt) is added dropwise, over a 45 min period, a filtered solution of $LiAlH_4$ in diethyl ether (prepared from 3.6 g, 94.9 mmol of 95% $LiAlH_4$ and 100 mL dry ether, followed by filtration using a cannula fitted with a piece of glass fiber filter; a Schlenk filtered or commercial clear solution would work as well). The resulting suspension is allowed to stir at room temperature for 90 min. It is then Schlenk filtered under argon using a D frit. The white solid is washed on the frit with THF (4 × 75 mL), CH_2Cl_2 (2 × 100 mL) with stirring or agitation of a stirbar immersed in the slurry and ether (4 × 50 mL). The resulting white solid is dried in vacuo to give a white powder: 65.5-81 g, 77-92% yield.[2]

Purification: over-reduction product Cp_2ZrH_2 reacts rapidly with methylene chloride to form $Cp_2Zr(H)Cl$.[2]

Handling, Storage, and Precautions: slowly develops a pink color when exposed to light and appears to be

photosensitive. This compound should be handled in a fume hood.

Hydrozirconation of Unsaturated Compounds.

Alkenes[6] react with $Cp_2Zr(H)Cl$ to give alkylzirconium complexes. Hydrozirconation of alkenes proceeds to place the zirconium moiety at the sterically least hindered position of the alkene as a whole. Formation of this product involves either the regiospecific addition of Zr-H to a terminal alkene or addition to an internal alkene followed by rapid rearrangement via Zr-H elimination and readdition to place the metal in the less hindered position of the alkyl chain (eq 1).[6,7] This is in sharp contrast to hydroboration or hydroalumination reactions. However, the tendency of zirconium to migrate towards the terminal position in the case of 1-arylalkenes is lower than simple alkenes.[8] Alkenes containing a heteroatom such as oxygen undergo C-heteroatom bond cleavage during the hydrozirconation reactions under some conditions (eq 2).[9] Alkylzirconium complexes obtained here are easily converted into alkanes,[10] alkyl halides (eq 3),[6] alcohols (eqs 4 and 5),[7] nitriles (eq 6),[11] aldehydes, carboxylic acids or esters (eq 7)[12] by hydrogenation (or hydrolysis), halogenation, oxidation, successive treatment with isocyanide and iodine, or carbonylation.

Hydrozirconation of alkynes gives alkenylzirconium complexes (eq 8).[13] Zr-H addition to the alkyne proceeds with *cis* stereochemistry. Hydrozirconation of various unsymmetrically disubstituted alkynes occurs readily to give a mixture of alkenylzirconium compounds. Over a period of several hours, this initial mixture of alkenyl species can be converted to one with higher regioselectivity, at room temperature, through catalysis with $Cp_2Zr(H)Cl$.[13] It is interesting to note that, whereas alkylzirconium complexes positionally rearrange rapidly, no such process occurs for purified alkenyl analogs. Alkenylzirconium complexes are also easily converted into alkenyl halides[13] and aldehydes (eq 9)[14] when they are treated with ***N-Bromosuccinimide*** and isocyanide/H^+, respectively.

In situ generation of $Cp_2Zr(H)Cl$ or in situ hydrozirconation is practically useful. There are several in situ procedures which consist of ***Dichlorobis(cyclopentadienyl)zirconium***/***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al), Cp_2ZrCl_2/***t-Butylmagnesium Chloride***[15] or Cp_2ZrCl_2/***Lithium Triethylborohydride***.[16] Comparison of hydrozirconation using $Cp_2Zr(H)Cl$ and these in situ procedures is shown in Table 1.[15,16]

Table 1 Comparison of Hydrozirconation using Schwartz's Reagent and Various in situ Procedures[15,16]

1-Decyne[a]	80	100	88	80	95

[a] Isolated yield (%) of H^+ quenched materials. [b] Isolated yields.

$(MeC_5H_4)_2Zr(H)Cl$ reacts about seven times faster with 1-hexene or acetophenone than $Cp_2Zr(H)Cl$.[17] Hydrozirconation of other various unsaturated bonds such as Schiff bases,[18] ketones,[3,4,19] diazoalkanes,[20] nitriles,[21] carbon dioxide (eq 10),[22] 1-ene-3-ynes,[23] dienes,[24] phosphaimines,[25] thioketones,[26] carbon oxide,[27] and isocyanide[28] has been investigated.

(10)

Hydrozirconation of unsaturated bonds attached to metals also proceeds. Alkenylzinc or alkynylzinc compounds react with $Cp_2Zr(H)Cl$ to give unstable 1,1-bimetallic reagents which can be used for highly stereoselective alkenation of aldehydes (eq 11).[29] Similarly, addition of $Cp_2Zr(H)Cl$ to a solution of (neohexenyl)diisobutylaluminum gives a 1,1-bimetallic complex.[30] Its structural analysis by X-ray clearly shows the 1,1-bimetallic system.[31] Reaction of stannylacetylenes with $Cp_2Zr(H)Cl$ seems to give 1,1-bimetallic compounds, since the iodination product is 1-iodo-1-stannylalkenes.[32] The regioselectivity of hydrozirconation of unsaturated bonds attached to metals is noteworthy. Hydrozirconation of an alkynyl ligand attached to Ru[33] or Zr,[34] and an alkenyl ligand attached to Zr,[35] shows the opposite regioselectivity to those described above, which give 1,1-bimetallic compounds (eq 12). However, the reaction of $Cp_2Zr(H)Cl$ with $Cp(CO)_2Re{=}CHR$[36] gives a 1,1-bimetallic intermediate with Zr and Re. An acyl ligand on zirconium also reacts with $Cp_2Zr(H)Cl$.[37] When $Cp_2Zr(H)Cl$ is treated with potassium allyl alkoxide or homoallyl alkoxide, intramolecular hydrozirconation seems to give oxazirconacycles.[38]

(11)

Carbon-Carbon Bond Forming Reactions of Hydrozirconation Products.

Hydrozirconation products of unsaturated compounds can be used for further C-C bond forming reactions. Since alkyl or alkenyl carbon attached to zirconium is not nucleophilic like Grignard, lithium, or aluminum reagents, the direct C-C bond formation is very limited. Only carbonylation (eq 7) and acylation with ***Acetyl Chloride*** can be used. However, transmetalation of the alkyl or alkenyl moiety from zirconium to other metals changes the situation. It provides a variety of C-C bond formation reactions of hydrozirconation products.

The alkyl or alkenyl moiety of hydrozirconation products are transferred from zirconium to aluminum when they are treated with ***Aluminum Chloride***. These organoaluminum dichlorides obtained here are converted into ketones or α,β-unsaturated ketones in high yields (eq 13).[39] Interestingly, since hydrozirconation of alkenes gives the terminal alkylzirconium exclusively, this method can provide a single ketonic product from a mixture of isomeric alkenes. For alkenylzirconium,

through this sequential use of two reactive organometallic species, the ketone is formed by overall *cis* addition of acyl-H to an alkyne.[39] Similar treatment of 1-(trimethylsilyl)-4-bromo-1-butyne with $Cp_2Zr(H)Cl$ followed by $AlCl_3$ affords 1-(trimethylsilyl)cyclobutene (eq 14).[40]

(13)

(14)

Transmetalation from Zr to Cu produces the corresponding organocopper compounds which can be used for addition to α,β-unsaturated ketones (eq 15).[41] It is noteworthy that functionalized lithiocuprates, which contain -CN, $-CO_2Si(i\text{-}Pr)_3$, -OCOPh, or Cl groups, are easily prepared by this method.[42]

(15)

Migration of an alkenyl group from zirconium to boron (eq 16),[43] tin,[44] or selenium (eq 17)[44] also proceeds. Alkyltin compounds can be prepared from alkylzirconium and ***Tin(IV) Chloride***.[45] Imine transfer from zirconium to phosphorus or boron is also possible.[46]

(16)

Catalytic reactions using transition metals have been investigated. Cross-coupling reaction of alkenylzirconium with aryl halides or alkenyl halides is catalyzed by Ni or Pd complexes (eq 18).[47] The effect of addition of metal salts such as ***Zinc Chloride*** and ***Cadmium Chloride*** is remarkable in this reaction.[48] Addition of alkenylzirconium to α,β-unsaturated ketones is also catalyzed by Ni (eqs 19 and 20).[49]

Alkylzirconium compounds react with α,β-unsaturated ketones (eq 21)[50] or ***Allyl Chloride***[51] in the presence of a catalytic amount of copper compound.

Formation of cationic species from alkyl- or alkenylzirconium compounds with a catalytic amount of ***Silver(I) Perchlorate*** is one method to make direct C-C bonds with aldehydes (eq 22).[52] Both alkyl and alkenyl groups attack aldehydes to give desired products in high yields. When 3-trimethylsilyl-1-propyne is used as a starting alkyne, (*E*)-selective terminal 1,3-dienes are formed.[53] Alkynes, 1-ethoxyethyne, and (*Z*)-1-methoxy-1-buten-3-yne give two- and four-carbon homologation of aldehydes, respectively, after treatment with an acid (eq 23).[54] A direct C-C bond formation of alkenylzirconium compounds with epoxides also proceeds in the presence a catalytic amount of $AgClO_4$.[55]

(23)

Organozirconium complexes, prepared by either hydrozirconation or the reaction of organolithium reagents with $Cp_2Zr(H)Cl$, can be converted into diene (eq 24),[56] alkyne (eq 25),[57] silanimine (eq 26),[58] and diazobenzene (or hydrazido(1-)) (eq 27)[59] Zr^{II} complexes which react with unsaturated compounds to afford various zirconacycles.

Chlorobis(cyclopentadienyl)methylzirconium[1]

[1291-48-8] · $C_{11}H_{13}ClZr$ · Chlorobis(cyclopentadienyl)methylzirconium · (MW 271.90)

(used to generate zirconocene complexes with stable and unstable organic molecules;[2] catalyzes the carboalumination of R_3Al to terminal alkynes[3])

Physical Data: pale yellow crystals.

Solubility: sol aromatic solvents.

Analysis of Reagent Purity: ^1H NMR (benzene-d_6) δ 5.73 (s, C_5H_5), 0.32 (s, CH_3) in a ratio of 10:3.

Preparative Methods: can be prepared by the reaction of Cp_2ZrMe_2 with ***Dichlorobis(cyclopentadienyl)zirconium***. A 0.5 M solution of each reagent in toluene is heated to 130 °C for 35 h. $Cp_2ZrMeCl$ is isolated in >90% yield by recrystallization from toluene/hexanes.[4] Alternatively, it can be prepared in pure form by the treatment of $(Cp_2ZrCl)_2O$ with ***Trimethylaluminum***.[5] Although $Cp_2ZrMeCl$ is available in a reasonable quantity as mentioned, it is often convenient to generate an analog of $Cp_2ZrMeCl$ in the reaction media and use it in situ. Thus treatment of Cp_2ZrCl_2 with ***t-Butyllithium*** generates $Cp_2Zr(i\text{-Bu})Cl$ through β-hydride elimination and insertion. $Cp_2Zr(i\text{-Bu})Cl$ shows a comparable reactivity to $Cp_2ZrMeCl$.[6]

Handling, Storage, and Precautions: the dry solid is highly sensitive to moisture, forming $(Cp_2ZrCl)_2O$, and should be kept tightly sealed to preclude moisture. Use of this reagent immediately following preparation is recommended.

Formation of Cp_2Zr Complex.

$Cp_2ZrMeCl$ is a convenient reagent to produce mixed dialkylzirconocenes in the reaction with RLi (eq 1).[7] By the application of this method, zirconocene complexes of either unstable or stable organic molecules can be generated from $Cp_2ZrMeCl$.[8] The formation of zirconocene complexes is achieved by substituting the halogen atom of $Cp_2ZrMeCl$ with an alkyl or a vinyl organometallic reagent which possesses at least one β-hydrogen atom. Thermolysis then results in the

concomitant generation of methane. This procedure is complementary to Cp_2Zr-butene (zirconocene equivalent) promoted zirconocene complex formation of unsaturated molecules,[9] since the zirconocene equivalent does not allow the isolation of Cp_2Zr complexes from very unstable or very reactive organic molecules. This β-hydrogen abstraction process is reported to involve an interaction of a β-C-H bond with the empty orbital of the zirconium valence shell.[10] The general scheme for the formation of complexes of unstable organic molecules and the organic precursor required for their syntheses is shown in eqs 2-8.
