(8)

In each case, a metal-halogen exchange with an organolithium reagent followed by the addition of $Cp_2ZrMeCl$ produces the precursor for the zirconocene complex. Thermolysis of these precursors at temperatures ranging between 20-100 °C causes the evolution of methane to give the desired zirconocene complexes, which can be isolated as their trimethylphosphine adducts or trapped with an unsaturated compound. Through this procedure, Cp_2Zr complexes of arynes with a variety of substitution patterns (eq 3),[8a,11] cyclic alkynes containing five to eight membered rings (eq 4), cyclic alkenes (eq 5),[8b,c] benzdiynes (multiply unsaturated aromatic species) (eq 6),[12] imines (eq 7),[13] and thioaldehydes (eq 8)[14] have all been reported. Interestingly, methyl(2-norbornenyl)zirconocene is known to exist as a thermally stable complex (eq 9).[15] This stability is attributed to the strain and the bulkiness of the 2-norbornenyl ligand. Thermolysis of methyl(2-furyl)zirconocene, derived from $Cp_2ZrMeCl$ and 2-furyllithium, yields a ring-enlarged and methyl-migrated compound instead of a Cp_2Zr-heteroaryne complex (eq 10).[16]

(9)

The reactions of Cp_2Zr complexes toward unsaturated molecules reveal their usefulness for preparing many functionalized compounds (eq 11). Thus the Cp_2Zr-benzyne complexes react with many unsaturated compounds to give benzo-fused compounds (eq 12).[8,17] A cyclopentyne-zirconocene complex has been used for the preparation of an optically active cyclopentenone derivative.[18] In this reaction the addition of an optically active allylic ether to the cyclopentyne complex proceeds with ~100% asymmetric induction (eq 13).

Reaction of $Cp_2ZrMeCl$ with lithium amide derivatives and the subsequent extrusion of methane through β-hydrogen elimination is a very efficient way of generating imine-zirconocene complexes, zirconaaziridines.[13] Zirconaaziridines, which can be isolated as trimethylphosphine adducts or THF adducts, have proven to be valuable intermediates in organic synthesis. These complexes react with carbonyl compounds or alkynes to give amino alcohols or allylic amines. When the azazirconacyclopentene prepared from zirconaaziridine and alkyne is treated with ***Carbon Monoxide*** under high pressure, di- and trisubstituted pyrroles are obtained in synthetically viable yields (eq 14).[13b] In a similar manner, reaction

of the lithium amide of an allylic amine with $Cp_2ZrMeCl$ when heated to 60 °C gives an azazirconacyclopentene, which is converted to a pyrrole when treated with an isocyanide.[13d] Notable and efficient application of the benzyne complex chemistry derived from $Cp_2ZrMeCl$ has been seen in the effective synthesis of the pharmacophore of potent antitumor antibiotics.[19]

(14)

Hydroamination.

Imidozirconocene complexes[20] can be generated in situ by treating $Cp_2ZrMeCl$ with a lithium amide (which does not have β-hydrogen) followed by elimination of methane upon heating. This transient species reacts with an alkyne derivative to give an azazirconacyclobutene derivative which can be converted to a carbonyl compound via an enamine. Carbonyl compounds also react with imidozirconocene complexes giving imine compounds (eq 15).

Carbometalation.

In the chemistry of carbometalation of alkylaluminum compounds mediated by zirconocene derivatives,[21] reaction of a stoichiometric amount of $Cp_2ZrMeCl$ with 1-pentynyldimethylalane is known to give an alkenylmetal species, which is converted to diiodo or 2-methyl-1-pentene in good yields upon treatment with excess iodine or water. This process is an Al-assisted direct addition of the Zr-carbon bond to the alkyne (eq 16). It is interesting to note that the $Cp_2ZrMeCl$-catalyzed R_3Al addition to alkyne is a Zr-assisted Al-carbon bond addition (eq 17).

Chlorobis(dimethylglyoximato)(pyridine)cobalt(III)[1]

[23295-32-1] · $C_{13}H_{19}ClCoN_5O_4$ · Chlorobis(dimethylglyoximato)(pyridine)cobalt(III) · (MW 403.75)

(starting material for alkyl(pyridine)cobaloxime(III) complexes,[1] precursor for cobaloximes(II) and cobaloximes(I),[2] which have found widespread applications as catalysts for carbon-carbon,[3] carbon-oxygen,[4] carbon-nitrogen,[5] and carbon-hydrogen[6] bond formations)

Alternate Name: chloro(pyridine)cobaloxime(III).

Physical Data: mp 235 °C; polarographic half-wave potentials (acetonitrile solution, vs. $Ag/AgNO_3$ electrode): -0.65, -1.45, -2.42, -2.91 V.

Solubility: sol CH_2Cl_2; limited sol ethyl acetate, hot ethanol; sparingly sol most other organic solvents and water. Chloro(pyridine)cobaloxime(III) can be replaced without any change in reactivity by its 4-*t*-butylpyridine[7] derivative which has good solubility in toluene, carbon tetrachloride, alcohols and ethyl acetate.

Handling, Storage, and Precautions: forms brown, air stable crystals. The axial pyridine ligand can be removed by dilute acid extraction from ethyl acetate solutions of chloro(pyridine)cobaloxime(III). Due to their low solubility in common organic solvents, chloro(pyridine)cobaloxime(III) and -cobaloxime(II) (often the cobalt remainder in cobaloxime mediated transformations) are easily removed by adsorptive filtration of the reaction mixture on a short silica gel column. Acidic aqueous ethanol solutions of chloro(pyridine)cobaloxime(III) are photodecomposed when irradiated at wavelengths below 500 nm, yielding cobalt(II) salts, dimethylglyoxime, and pyridinium salts. For some applications the use of either iodo- or bromocobaloxime(III)[7] is advantageous, as activation of the halogen-carbon bond is essential for chlorocobaloxime(III) to be employed in organic synthesis. However, reduction potentials, bond strengths, and photostabilities increase on moving from the iodo to the chloro ligand,[8] so iodo(pyridine)cobaloxime(III) must be stored in tinted bottles.[9]

Inhalation of chlorocobaloxime(III) dust and contact with eyes should be avoided; wearing of protecting gloves for handling this compound is recommended. This compound should be handled in a fume hood.

Ligand Exchange Reactions.

Chlorocobaloxime(III) is a convenient source of the cobaloxime residue. It reacts with organomagnesium or -lithium compounds to yield the corresponding alkylcobaloximes(III).[1] This reaction is an efficient approach to arylcobaloximes which are otherwise difficult to obtain (eq 1).

The chloro ligand can be substituted in the presence of metal ions (Ag^+, Hg^{2+}, Tl^{3+}) which form precipitating metal chlorides.[10] The entering ligand can be a solvent molecule that binds reversibly in a dynamic equilibrium, such as DMF, or an alkyl ligand that binds irreversibly. An example of the latter reaction is the formation of nitromethylcobaloxime which is formed from nitromethane, presumably via the nitronic acid (eq 2).

Upon reduction of chlorocobaloxime(III) by iron(II) salts,[11] ***Zinc*** in protic solvents,[12] ***Sodium Borohydride*** in alcohols,[1] ***Sodium Amalgam*** in THF, or on the surface of a cathode,[3a] the chloro ligand is removed from the complex and versatile catalytic properties of the cobaloxime moiety are unmasked. Hence immobilized derivatives of chlorocobaloxime(III) have been prepared by reaction of chloroaquacobaloxime with the copolymers of 4-vinylpyridine/styrene and 4-vinylpyridine/acrylamide (eq 3).[13]

Carbon-Carbon Bond Formation.

In situ electrochemical reduction of chloro(pyridine)cobaloxime(III) to nucleophilic cobaloxime(I) allows carbon-carbon bond

formation. The example given in eq 4 illustrates this catalytic transformation for the conversion of a bromoacetal to hexahydrobenzofuran.[3] The key step of the reaction is a stereoselective cyclization of the intermediate alkoxyalkyl radical which is generated from an intermediate alkylcobaloxime. The alkene function which was present in the starting material is regenerated in the product via hydridocobaloxime elimination.

(4)

A combination of intramolecular 7-*endo* cyclization and intermolecular, cobaloxime-mediated, stereoselective alkyl-alkenyl cross coupling allows formation of the 5,7-fused bicyclic lactone from the linalool derivative in eq 5.

(5)

Alkyl-alkenyl cross coupling is a major area in alkylcobaloxime research.[3a,b] In contrast to the alternative carbon-carbon bond forming reactions via alkyl radicals under reductive conditions, application of the cobaloxime methodology allows the regeneration of the carbon-carbon double bond in the adduct. In particular photochemical alkyl-alkenyl cross couplings have been investigated under either stoichiometric or catalytic conditions. The stoichiometric reaction starts from an alkylcobaloxime(III) which is photolyzed in the presence of an alkene such as acrylonitrile or styrene. However, it should be noted that the solvent and the alkene used have a marked influence upon the yields and the product distribution of the reaction. The catalytic version requires in situ regeneration of cobaloxime(I). The adduct radical which is formed in the first step of the reaction can also be reduced to yield a carbanion which is then protonated. Aryl substituted alkenes are best suited for this transformation. Several usefully functionalized alkenes are simply reduced under these reaction conditions (eq 6).[3b] Application of this methodology to perfluoroiodides is straightforward and allows selective introduction of the perfluoroalkyl substituent, but bromocobaloxime(III) has been proven to be more efficient in this process than chlorocobaloxime (eq 7).[3c]

Chlorobis(dimethylglyoximato)(pyridine)cobalt(III)

Carbon-Heteroatom Bond Formation.

Photolysis of solutions of alkylcobaloxime(III) in the presence of O_2 or NO yields alkylperoxycobaloximes(III) or oximes.[15,16] The former can then be transformed into products such as alcohols or substituted tetrahydrofurans, the latter then into amino sugars.[17] Catalytic versions of these processes require ***Sodium Borohydride*** as reducing agent. The scope of these reactions is still limited to aryl substituted alkenes (eqs 8-10).[4,5]

Carbon-Hydrogen Bond Formation.

Sodium borohydride reduction of chlorocobaloxime(III) under a hydrogen atmosphere leads to an efficient homogeneous hydrogenation catalyst which selectively reduces carbon-carbon bonds of substituted pyridines or acrylates.[6] Reduction of pyridinium salts to dihydropyridines requires the presence of a base such as ***Sodium Carbonate***, whereas sodium bicarbonate leads to significant amounts of tetrahydropyridines (eq 11).

4-Chloro-2-butanone

[6322-49-2] · C_4H_7ClO · 4-Chloro-2-butanone · (MW 106.55)

(reagent for Robinson annulation; often interchangeable with methyl vinyl ketone and the corresponding Mannich base 4-dialkylamino-2-butanone)

Alternate Names: 2-chloroethyl methyl ketone; 1-chloro-3-butanone.

Physical Data: bp 105-110 °C.

Solubility: sol most organic solvents.

Analysis of Reagent Purity: ^{1}H NMR data are available.[1]

Form Supplied in: liquid; commercially available.

Purification: by distillation.

Handling, Storage, and Precautions: use in a fume hood.

Annulation.

4-Chloro-2-butanone is one of three reagents commonly used for unsubstituted ring formation in the Robinson annulation. The other reagents are 3-buten-2-one (***Methyl Vinyl Ketone***, MVK) and the quarternary salt of the Mannich base 4-dimethylamino-2-butanone (or 4-diethylamino-2-butanone). The choice of reagent for the best yield from a specific substrate has to be determined empirically. MVK is the most difficult to handle because it can polymerize during preparation or annulation. Nevertheless, MVK has been widely used.[2]

One of the first annulations[3] with 4-chloro-2-butanone gave the product in a 70% yield, whereas only 12% was obtained from the corresponding Mannich base (eq 1). The acid-catalyzed annulation, first developed with 1-chloro-3-pentanone,[4,5] has been used with 4-chloro-2-butanone[6] to afford a much better yield (eq 2) than was obtained with MVK (12-34%).

(1)

(2)

Annulation by Dialkylation.

The dimethylhydrazone of a cyclic 1,3-dione reacts regioselectively to give the dialkylated hydrazone, which can then be cyclized sequentially to the bicyclic and the tricyclic ketones (eq 3).[7] The reaction works equally well for 1,3-cyclohexanedione and 1,3-cyclopentanedione.

Stannylation.

The reagent reacts with ***Tin(II) Chloride*** to form the β-trichlorostannyl ketone, which can also be prepared (slightly faster) from $HSnCl_3$ and MVK as well as other vinyl ketones. The intermediate trichloro compounds can be converted to the tributylstannyl ketones (eq 4).[8]

Alkynylsilane Functionalization.

Organometallic derivatives of propargylic silanes react with the reagent, as well as other α- or o-chlorocarbonyl compounds, to form homopropargylic alcohols (with the Zn reagent, eq 5)[9] or allenic alcohols (with the Al reagent, eq 6).[10] The products are used to form oxygenated heterocycles.[11]

3-Chloro-1-butene

[563-52-0] · C_4H_7Cl · 3-Chloro-1-butene · (MW 90.55)

(alkylating agent[15,22] and organometallic precursor useful for introduction of 2-buten-1-yl (crotyl) and 1-buten-3-yl moieties)

Physical Data: bp 63.9-64.2 °C; *d* 0.900 g cm^{-3}; n_D^{20} 1.4155.

Solubility: insol water; sol all organic solvents.

Form Supplied in: colorless liquid.

Preparative Methods: from 1-buten-3-ol using PCl_3/py,[1] $SOCl_2$/HMPA,[2] Ph_3P/CCl_4,[3] Ph_3P/CCl_3COCCl_3,[4] $Me_2CC(Cl)NMe_2$,[5] or $PO(OPh)_2Cl$/LiCl;[6] from 2-buten-1-ol using $SOCl_2/FeCl_3$.[7]

Purification: by distillation.

Handling, Storage, and Precautions: stable at 0 °C in quartz;[8] flammable liquid and lachrymator.[9] Use in a fume hood.

Introduction.

This summary of 3-chloro-1-butene (**1**) chemistry focuses on the racemic reagent, although the (+)[1] and (-)[10] forms are known. 3-Chloro-1-butene is relatively stable at ambient temperature. However, it exists in equilibrium (eq 1)[11] with 1-chloro-2-butene (K_{eq} = 2.32; PhMe, 80 °C);[8] catalysis by UV light,[12] glass surfaces,[8] and by Ir, Rh, and Co coordination complexes[13] has been observed. Care must be taken that reactions with (**1**) are not complicated by the isomerization product. The thermolysis chemistry of (**1**) has been studied.[14]

(1) (1)

The reactions of (**1**) in protic, dipolar aprotic, and nonpolar solvents in the presence and absence of nucleophiles (S_N1, S_N2, S_N2', E1, E2, and S_Ni) have been studied extensively and reviewed.[15] Friedel-Crafts alkylation of alkenes has also been studied.[16] Primarily, (**1**) has been used for electrophilic and nucleophilic introduction of 2-buten-1-yl (crotyl) and 1-buten-3-yl groups in organic synthesis. These reactions for (**1**) and other allylic compounds have been reviewed.[17]

Electrophilic Reactions.

3-Chloro-1-butene acts as an ambident electrophile at both α (S_N2) and γ (S_N2') positions in chloride displacement reactions. In early work, exclusive S_N2 reaction was reported with various nucleophiles (NaOEt/EtOH, KOAryl/Me_2CO, NaS-*n*-Bu/EtOH, $Me_4N^+OAc^-/Me_2CO$, and Kphthalimide/MeOH).[15] In later studies of the regioselectivity effects of counterion and solvent (EtO^-, PhS^-, and $(CO_2Et)_2CH^-$),[18] only modest changes were observed, all reactions strongly favoring the S_N2 pathway (83-95%). In contrast, the S_N2' reaction is a significant or dominant pathway with Et_2NH (100%),[19] Me_3N (70%),[20] and fluorenyl anions (30-100%).[21] In addition, the S_N2' reaction is strongly favored with many organometallic reagents, as is illustrated by the examples given in Table 1.

Table 1 Effects of Nucleophile and Solvent on the a:g Regioselectivity of Alkylations with 3-Chloro-1-butene

Reagent	Solvent	a:g Ratio
$4\text{-}MeOC_6H_4MgBr$[22]	Et_2O	14:86
n-BuMgCl[23]	THF	21:79
PhLi[24]	Et_2O	1:99
n-BuLi[23]	Et_2O	2:98
$LiCH_2C(NNMe_2)CO_2Li$[25]	THF HMPA	20:80
$Zn(CH_2CO_2\text{-}t\text{-}Bu)_2$[26]	THF	0:100

n-BuCu[23]	Et_2O	10:90
Ph_2CuLi[23]	Et_2O	19:81
$n\text{-}Bu_2CuLi$[23]	Et_2O	22:78
$n\text{-}BuCuBF_3$[23]	THF	0:100
$NC(CH_2)_3CuCNZnI$[27]	THF	4:96

Other chloride substitution reactions of (**1**) include the π-allyl complex reactions of Pd, Ni, and other transition metals. The $PdCl_2$ promoted reaction of (**1**) with NaOAc to give a 35:65 α:γ ratio of butenyl acetates is representative.[28] Additional

examples of palladium π-allyl complex reactions of (**1**) are 2,5-enyne (eq 2)[29] and 1,4-diene (eq 3)[30] syntheses. Both proceed with exclusive γ-substitution. Interestingly, it has been found in amination studies of the palladium π-allyl complex of (**1**) with Me_2NH that regioselectivity can be controlled by the charge on the complex.[31] Thus while γ-substitution is the normal product (α:γ = 10:90; 100%), α-substitution is dominant (α:γ = 71:22; 93%) if the reaction proceeds via a cationic complex generated by $AgBF_4$ precipitation of chloride.

(2)

(3)

π-Allyl complex reactions of (**1**) with other metals are known. The nickel π-allyl complex-mediated carbonylative cycloaddition with alkynes is representative (eq 4).[32]

Nucleophilic Reactions.

A variety of organometallic reagents have been prepared from (**1**). These reagents undergo nucleophilic reactions with electrophiles at both α- and γ-positions. The chemistry of allylic organometallic reagents, including those derived from (**1**), has recently been reviewed.[33] The α:γ regioselectivity can be controlled during electrolytic coupling of (**1**) with acetone by choice of cathode (α:γ = 90:10 to 29:71).[34]

The reaction of 1-buten-3-ylmagnesium chloride with nitro compounds is representative of a general synthesis of secondary hydroxylamines.[35] Exclusive reaction at the secondary center of (**1**) is observed. On the other hand, reaction of the same reagent with $(ClCH_2)Me_2SiCl$ yields nearly equal amounts of α- and γ-products (eq 5).[36] Methoxide-induced rearrangement provides the homologation products in the same ratio.

A mixed butenyl/butyl cuprate reagent is obtained on reaction of ***Lithium Di-n-butylcuprate*** with (**1**). This reagent

undergoes exclusive γ-butenyl transfer to a vinyl phosphate (eq 6).[37] In contrast, an organocopper reagent derived from (**1**) and Cu^0 gives exclusive α-coupling with PhCHO and PhCOCl (eq 7).[38] Similarly, organozinc compounds generated from (**1**) undergo exclusive α-coupling with aldehydes[39] and aldimines.[40] Interestingly, the aldehyde reaction was conducted in a two-phase aqueous/C-18 silica system, avoiding the need for an organic solvent.

Related Reagents.

Allyl Chloride; ***Crotyl Chloride***; ***Methallyl Chloride***.

(*E*)-4-Chloro-3-buten-2-one[1]

(**1**; $R^1 = R^2 = H$)

[7119-27-9] · C_4H_5ClO · (*E*)-4-Chloro-3-buten-2-one · (MW 104.52) (**2**; R^1 = Me, R^2 = H)

[57982-323-8] · C_5H_7ClO · (*E*)-1-Chloro-1-penten-3-one · (MW 118.56) (**3**; R^1 = H, R^2 = Me)

[105-32-8] · C_5H_7ClO · (*E*)-4-Chloro-3-penten-2-one · (MW 118.56)

(ketovinylation reagent which reacts with a variety of nucleophiles; used as a methyl vinyl ketone equivalent under aprotic conditions; precursor to dienol borinates)

Alternate Name: 2-chlorovinyl methyl ketone.

Physical Data: (**1**) bp 21 °C/21 mmHg; *d* 1.130 g cm^{-3};[2a] (**2**) bp 38-40 °C/11 mmHg; (**3**) bp 43-45 °C/14 mmHg; *d* 1.076 g cm^{-3}.

Solubility: insol water; sol most organic solvents.

Preparative Method: from acetylene and acetyl chloride catalyzed by aluminum chloride.[2]

Purification: distillation in vacuo.

Handling, Storage, and Precautions: the chloro enone is lachrymatory and corrosive to the skin. Therefore handling with gloves in a fume hood is essential. The compound has limited stability at room temperature and should be stored under nitrogen at 4 °C or lower; it solidifies at ca. 5 °C. Under these conditions, darkening and HCl loss is minimized, enabling the chloro enone to be stored for several weeks.

Ketovinylation of Carbonyl Compounds.

(*E*)-4-Chloro-3-buten-2-one (**1**) is a vinylogous acyl chloride and as such is highly reactive towards nucleophiles. Reaction with the enolates of substituted malonic esters, β-keto esters, and 1,3-diketones leads to highly functionalized products which may be utilized in a variety of synthetic schemes.[1a] For example, the enolates of substituted β-keto esters undergo conjugate addition to the chloro enone followed by loss of chloride ion to give ketovinyl substituted keto esters. Treatment of these products with ***Hydrochloric Acid*** in acetic acid with heating affords substituted α-pyrones (eq 1).[1a,3]

The ketovinylation of enolates derived from cyclic ketones[4] provides an alternative to the use of methyl vinyl ketone as an entry to 1,4-diketones required for the Robinson annulation.[5] For example, (**1**) efficiently traps the enolate derived from the conjugate addition of lithiated (*E*)-butenyl(*t*-butyl)phenyl phosphine oxide to 2-methylcyclopentenone. Hydrogenation of the double bonds followed by aldol cyclization affords hydrindenone precursors to vitamin D in 56% overall yield and with high diastereoselectivity (eq 2).[5b]

Substitution with Hetero Nucleophiles.

Chloride may be replaced by SR,[1c] NR_2, OR, $C_5H_5N^+Cl^-$,[4] and RNH in a conjugate addition-elimination.[6] In particular, (**1**) has been utilized extensively in synthetic approaches to the indole alkaloids in which the key step is vinylic substitution by tryptamine (eq 3).[6] The coupling of substituted homoallylic amines to 4-chlorobutenone followed by intramolecular photocycloaddition affords fused cyclobutanes, which undergo retro-Mannich fragmentation to ketoimines followed by Mannich ring closure to give perhydroindoles in good yields.[6b] By using this methodology, synthetic routes to mesembrine[6b] and vindorosine[6d] have been achieved.

(E)-4-Chloro-3-buten-2-one

Substitution with Organometallic Reagents.

Lithium dialkylcuprates and organocopper reagents readily undergo conjugate addition to (**1**) with predominant retention of the double bond geometry.[7] For example, the conjugate addition of bis(trimethylsilylmethyl)copperlithium to (*E*)-4-chloropent-3-en-2-one (**2**) affords the silylmethyl derivative in 51% yield (*E*:*Z* = 74:26). Irradiation at -76 °C isomerizes the product to the (*Z*) isomer which upon heating at 38 °C undergoes a 1,5-shift of the silyl group to give a trimethylsilyloxy-substituted butadiene, a compound of general use in Diels-Alder chemistry (eq 4).[7a] Normally alkenylcopper reagents are too unreactive to add to β-chloro enones. However, in the presence of 3% ***Tetrakis(triphenylphosphine)palladium(0)*** coupling with (**1**) proceeds with high stereoselectivity and in high yield. For example, the formation of (*E*,*Z*)-dienones is readily achieved (eq 5).[7b]

4-Chlorobut-3-en-2-one as a Bifunctional Reagent.

The ability to form dienol borinates while retaining the chloro functionality enables the reagent to react as a dipolar synthon. Thus treatment of the β-chloro enone (**3**) with ***Di-n-butylboryl Trifluoromethanesulfonate*** in the presence of ***Diisopropylethylamine*** generates the dienol borinate, which undergoes addition to aldehydes with high *syn* diastereoselectivity to give substituted hydroxy-β-chloro enones. These can then undergo an intramolecular conjugate addition in the presence of ***Trimethylsilyl Trifluoromethanesulfonate*** to afford dihydropyrones in good yields (eq 6).[8]

(E)-4-Chloro-3-buten-2-one

A route to α,β-unsaturated aldehydes has been reported in which the vinyl chloride moiety is converted into a dimethyl acetal and the carbonyl group can then react with Grignard reagents to form γ-hydroxy acetals. These are then hydrolyzed and dehydrated to the unsaturated aldehydes (eq 7).[2a]

1-Chlorocarbonylbenzotriazole

[65095-13-8] · $C_7H_4ClN_3O$ · 1-Chlorocarbonylbenzotriazole · (MW 181.58)

(formation of carbamates from alcohols;[1,2] peptide synthesis[3,4])

Physical Data: mp 54-55 °C.

Preparative Methods: by bubbling phosgene through a suspension of benzotriazole in toluene at 60 °C until a clear solution is obtained. Evaporation at reduced pressure gives (**1**) (99% yield); this crude material has mp 52-54 °C. Alternatively, an ethereal solution of benzotriazole may be added dropwise over 20 min to a 20% solution of phosgene in toluene (4 equiv); stirring until a clear solution is obtained followed by evaporation at reduced pressure gives 98% yield of (**1**) with mp 52 °C.[1]

Purification: recrystallization from light petroleum.

Preparation of Carbamates from Alcohols.

Reaction of 1-chlorocarbonylbenzotriazole (**1**) with an alcohol results in formation of the 1-alkoxycarbonylbenzotriazole (**2**). These compounds are stable to water or alcohols, but react with amines (or hydrazines) to give the carbamates (**3**) (eq 1).[1,2] Similarly, unsymmetrical ureas can be prepared if an amine is used rather than an alcohol in the first step.[5]

Peptide Synthesis.

(**1**) reacts with two equivalents of an amino acid in dioxane to give the *N*-(1-benzotriazolylcarbonyl) (Btc) amino acid (**4**) (eq 2), which separates almost quantitatively from the hydrochloride salt of the second equivalent of amino acid employed.[6]

These Btc-amino acids can be used for peptide synthesis in two ways. Reaction of (**4**) with an amine or amino acid in acetonitrile or in aqueous acetone effects amide bond formation without racemization (eq 3).[3] Benzotriazole and CO_2 are the coproducts.

N-Activation can also be achieved. Treatment of the ester (**5**), derived from (**4**), with a Cbz-protected amino acid again results in loss of CO_2 and benzotriazole to form an amide bond (eq 4).[4] This procedure seems to offer little advantage over other methods of peptide synthesis, however.

(1,3-dielectrophiles used mainly for the synthesis of five- and six-membered heterocycles functionalized with oxo and hydroxy groups in 1,3-positions)

Alternate Names: chlorocarbonylketenes; α-carbonyl acetyl chlorides; CCKs.

Physical Data: R = Et, bp 75-78 °C/22 mmHg;[1] R = Ph, bp 84-85 °C/0.2 mmHg;[2] R = 2-ClC_6H_4, bp 93-95 °C/0.12 mmHg;[3] R = 3-$CF_3C_6H_4$, bp 65-69 °C/0.04 mmHg;[3] R = 2,4,6-$Me_3C_6H_2$, bp

96 °C/0.35 mmHg;[3] R = 4-*t*-BuC_6H_4, bp 105-110 °C/0.40 mmHg;[3] R = Bn, bp 110-112 °C/1.5 mmHg;[2] R = $PhCH_2CH_2$, bp 94-95 °C/0.7 mmHg.[2]

Preparative Method: substituted malonyl dichlorides lose HCl above 80 °C to form CCKs.[6] In order to avoid mixtures[7] of malonic acid dichlorides and CCKs, the crude product obtained from the reaction of malonic acid with $SOCl_2$ is heated at reflux in toluene at atmospheric pressure under a slow stream of nitrogen, prior to distillation at reduced pressure (Nakanishi-Butler procedure).[2]

The unsubstituted CCK (R = H) is unknown (and has so far not even been prepared by FVP). This compound, which is formed from the parent malonyl dichloride under very weakly basic conditions[4a] at rt, dimerizes rapidly in a [4 + 2] cycloaddition to yield 6-chloro-3-chlorocarbonyl-4-hydroxy-2-pyrone.[4,5]

Handling, Storage, and Precautions: use in a fume hood.

Reactions.

Reactions of CCKs with nucleophiles are performed in aprotic solvents either at reflux temperature, with evolution of HCl gas, or (usually at lower temperatures) with a base (in most cases ***Triethylamine***) as HCl scavenger. Thus a recent patent describes the reaction of several cyclic hydrazines with various CCKs in the presence of bases (eq 1).[3]

(1)

N-Substituted imidazoles (and benzimidazoles) undergo cycloaddition with CCKs, in the presence of Et_3N, to form zwitterionic pseudo-cross-conjugated mesomeric pyrrolo[1,2-*a*]imidazoles (eq 2).[8] Cross-conjugated mesomeric pyrazolopyrazole betaines of type (**1**) are readily prepared starting with pyrazoles;[8,9] for derivatives of (**1**) with R = H,[8] see ***Carbon Suboxide***.

(2)

$R^1 = Me, Ph$ $R = Ph, PhCH_2$

(1)

$R^1, R^2 = H, Me, Ph$

$R = Et, Ph$

Thioamides, and even amides, react as 1,3-dinucleophiles with CCKs to afford cross-conjugated mesomeric thiazine[10,11] or oxazine[1,11c,12,13] betaines (eq 3). Thiolactams[10,11] and lactams[1] lead to bicyclic thiazine and oxazine derivatives. Both zwitterionic thiazines and oxazines are good candidates for 1,4-dipolar cycloadditions with alkynic and alkenic bonds.[10b,11c,d] The intramolecular version,[11c] especially with bicyclic thiazines, has been introduced as a very valuable route to a variety of complex azapolycyclic ring systems found in Nature.[11d]

(3)

$X = S, O$

The cycloaddition of CCKs with cyanamides occurs at the C&tbond;N bond, leading to chlorooxazinones (eq 4).[13] Similar reactions with other nitriles[5b,14] (and other C=N bonds such as those in carbodiimides[15] and isocyanates[5b]) were reported earlier with substituted malonyl dichlorides, at a time when it was not yet recognized that redistilled dichlorides[2,7] are actually CCKs, and CCKs were postulated as intermediates only.

(4)

Alternatives.

CCKs represent a very valuable class of reactive malonic acid derivatives. Their advantages over ***Bis(2,4,6-trichlorophenyl) Malonate*** are (a) their much lower MW and (b) their reactivity at lower temperature. Thus the reaction of amidines (eq 3; X = NR^3, yielding zwitterionic pyrimidines, cf. AMEs) can be performed with both reagents. However, mesomeric thiazine and oxazine betaines rearrange or decompose at higher temperatures (>60-80 °C).[16] If the products (such as pyrazolopyrazoles, e.g. **1**) are stable at very high temperatures (>250 °C), they can be prepared simply by heating the substrates with the appropriate substituted diethyl malonate.[17]

Related Reagents.

Bis(2,4,6-trichlorophenyl) Malonate; ***Bis(trimethylsilyl) Malonate***; ***Carbon Suboxide***; ***Malonic Acid***; ***Malonyl Chloride***.

6-Chloro-1-(*p*-chlorobenzenesulfonyloxy)benzotriazole

[57320-65-7] · $C_{12}H_7Cl_2N_3O_3S$ · 6-Chloro-1-(*p*-chlorobenzenesulfonyloxy)benzotriazole · (MW 344.17)

(reagent for active ester formation;[1] synthesis of amides,[1] esters,[2] thiol esters[3] from carboxylic acids; peptide synthesis[1])

Physical Data: mp 125-127 °C.

Preparative Method: prepared by reaction of 6-chloro-1-hydroxybenzotriazole with *p*-chlorobenzenesulfonyl chloride in 1M aqueous NaOH/ether.

Purification: recrystallization from benzene/petroleum ether.

Handling, Storage, and Precautions: stable for long periods in the absence of moisture and light.

Active Ester Formation.

6-Chloro-1-(*p*-chlorobenzenesulfonyloxy)benzotriazole (**1**) converts carboxylic acids to the 1-acyloxybenzotriazole derivatives (**2**) in good yield (eq 1).[1] A study of several related reagents found (**1**) to be most suitable based on overall considerations of reactivity, stability, and accessibility. The reaction occurs rapidly (usually less than 1 h) in the presence of one equivalent of ***Triethylamine*** in $CHCl_3$ or EtOAc; the more polar solvent MeCN is required if ***Pyridine*** is used as base. The active esters (**2**) can generally be isolated as stable, crystalline solids.

The active esters (**2**) react readily in the presence of base with amines,[1] alcohols,[2] and certain thiols[3] to provide amides, esters, and thioesters, respectively (eq 2). Aminolysis is generally rapid, as is reaction with primary alcohols; use of secondary alcohols such as *i*-propanol requires higher temperature (boiling $CHCl_3$), while no reaction is observed between (**2**) and *t*-butanol.

Ester formation may also be achieved without isolation of (**2**) by mixing a carboxylic acid and an alcohol with (**1**) in

the presence of two equivalents of base (eq 3).[2] Formation of the 1-alkoxy-6-chlorobenzotriazole as byproduct is suppressed by the use of ether as solvent rather than $CHCl_3$; use of pyridine in MeCN is also suitable.

Similarly, one-pot amide synthesis is possible;[1] formation of sulfonamide by direct reaction of (**1**) with amine is avoided by using *N*-methylmorpholine or pyridine as base instead of Et_3N.[1a]

Peptide Synthesis.

This method of amide bond formation has been used for peptide synthesis; the active ester is usually reacted with the amino component in situ (eq 4).[1]

These reaction conditions have advantages over the popular ***1,3-Dicyclohexylcarbodiimide*** (DCC) method, not least that the sulfonic acid and hydroxybenzotriazole co-products can be washed out with aqueous sodium bicarbonate. In the coupling of *N*-protected L-asparagine or L-glutamine with amino components, no dehydration of the side-chain amide (to the nitrile) was observed. Free hydroxy or imino groups do not cause problems, as shown by the successful preparation of serine-, tyrosine- and histidine-containing peptides.

Using the coupling of Cbz-Phe-Ile-OH with H-Pro-OBn in DMF as a test, the degree of racemization using (**1**) with various bases was compared with other methods; less racemization occurred using (**1**) than with DCC.[1b] A more extensive comparison of degree of racemization has also been reported.[4]

Chlorocyanoketene[1]

[60010-89-1] · C_3ClNO · Chlorocyanoketene · (MW 101.49)

(functions as a potent electrophile in reactions with a wide variety of ketenophiles including alkenes,[3] alkynes,[4] arylaldehydes,[5] and imines[6-8])

Alternate Name: CCK.

Preparative Methods: chlorocyanoketene readily undergoes self-condensation and must be generated in situ prior to usage. By generating the ketene in the presence of a ketenophile, concentration-related difficulties are circumvented and yields are greatly improved.[2] A most convenient route to the title compound is afforded by the thermal decomposition of pseudo esters of azidofuranones. Starting with commercially available mucochloric acid the desired furanone is synthesized in a two-step process: etherification and azidation (eq 1). Alcohols with at least three carbons, such as isopropanol, are desirable for the etherification in order to minimize the detonation capability of the subsequent azide.[2]

Cycloadditions to Alkenes.

Cycloadditions of chlorocyanoketene (CCK) to alkenes give good yields of the corresponding cyclobutanone and include additions to di-, tri-, and tetrasubstituted alkenes. The addition process is in complete accord with a concerted $_{\pi}2_s + {}_{\pi}2_a$ mechanism. Cyclobutanones (**1**), (**2**), and (**3**) are obtained by a highly stereoselective route as evidenced by the formation of their respective single diastereomers (eqs 2-7).

(4)

(2) (5)

(3) (6)

(7)

Alkenic ketenophiles with higher nucleophilic character react with CCK in a dipolar fashion. For example, treatment of cyclopentadiene with CCK gives a 55:45 mixture of diastereomers (eq 8). Further exemplifying this dipolar mode is the reaction of the ketene with dihydropyran (eq 9), whose product likely arises from a proton transfer process involving a zwitterionic intermediate.[3]

(8)

(9)

Cycloadditions to Alkynes.

CCK cycloadds to alkynes to give cyclobutenones. Reactions using terminal alkynes give complex mixtures, while employment of internal alkynes affords the corresponding cyclobutenones in good yields (eqs 10-13).[4]

(10)

(11)

(12)

(13)

4-Chloro-4-cyanobutenones, by virtue of the initial cycloadditions, are in equilibrium with their respective vinylketenes at room temperature, and these reactive intermediates can be intercepted by other ketenophiles, as

exemplified in eq 14.[4]

Cyclohexadienones are the result of trapping the vinylketenes with an alkyne. Reductive elimination of these products gives highly functionalized phenols.

Cycloadditions to Arylaldehydes.

Chlorocyanoketene cycloadds to arylaldehydes to form β-lactones which consequently decarboxylate under the reaction conditions to give exclusively the (*E*) isomer of 1-halo-1-cyano-2-phenylethylenes. The initial cycloaddition is a nonconcerted dipolar process in which the cyanoketene uniquely functions as an electrophile and the aldehyde as the nucleophile (eq 15).[5]

Cycloadditions to Imines.

CCK cycloadds to a variety of imines to form both β- and δ-lactams depending on the particular imine used.[6-8] Among the most studied imines are cinnamylideneamines and benzylideneamines. In the former series of cycloadditions, it is generally found that 2-azetinone formation is enhanced when the *N*-substituent of the imine is small. Stereochemical control is realized through the bulk of this substituent as well as the substitution pattern of the imine (eq 16). Within the benzylidene series, cycloadditions are stereospecific where the *N*-substituent is an aryl group resulting in a *trans* relationship between the 3-cyano group and the proton at the 4 position. The yield of corresponding *cis* diastereomer is progressively increased by increasing steric bulk (eq 17). As in the case with arylaldehydes, stereochemical outcomes in the cycloadditions of imines to CCK are best rationalized by invoking a dipolar intermediate.

N-Chloro-*N*-cyclohexylbenzenesulfonamide[1]

[15963-66-3] · $C_{12}H_{16}ClNO_2S$ · *N*-Chloro-*N*-cyclohexylbenzenesulfonamide · (MW 273.78)

(used for radical chlorination at allylic[1,4] or benzylic carbon[1])

Physical Data: mp 42 °C.

Solubility: sol benzene, CCl_4, $CHCl_3$, CH_2Cl_2; insol H_2O, petroleum ether.

Analysis of Reagent Purity: mp, NMR, combustion analysis.

Preparative Methods: *N*-cyclohexylbenzenesulfonamide can be prepared by addition of benzenesulfonyl chloride to a solution of cyclohexylamine in pyridine and purified by recrystallization from ethanol. *N*-Chlorination is accomplished by treating a solution of *N*-cyclohexylbenzenesulfonamide in dichloromethane with NaOCl solution at 0 °C followed by dropwise addition of glacial acetic acid.[1] Alternatively, a suspension of *N*-cyclohexylbenzenesulfonamide in acetic acid can be treated with NaOCl solution or powdered *N*-cyclohexylbenzenesulfonamide can be added to a solution containing $NaHCO_3$ and NaOCl.[2]

Purification: precipitation from $CHCl_3$ solution by addition of petroleum ether or trituration with petroleum ether.

Handling, Storage, and Precautions: to avoid decomposition, this reagent should be protected from prolonged exposure to light and moisture. Store under nitrogen in the dark. This toxic reagent should be handled in a fume hood.

Allylic Chlorination.

This reagent (**1**) has been used as a chlorine source in radical chlorination of allylic and benzylic positions. Treatment of alkenes bearing allylic carbon-hydrogen bonds with (**1**) in refluxing benzene in the presence of a radical initiator such as ***Dibenzoyl Peroxide*** results in the formation of allyl chlorides in good to moderate yields (eq 1).[1]

(1)

As with the more commonly used chlorinating agent ***N-Chlorosuccinimide***, this chlorination proceeds via a radical chain reaction in which Cl_2 is liberated and reacts with a carbon radical.[3] Consequently, isomeric mixtures are often obtained (eqs 2-4).[1,4]

(2)

(3)

(4)

Separation of the resulting isomeric products is often difficult. For example, the isomeric chlorinated products in eq 4

were separated from one another using preparative gas chromatography.[4] *N*-Cyclohexylbenzenesulfonamide precipitates upon cooling of the reaction mixture and can be recovered by filtration.[1]

Chlorination at benzylic positions proceeds in good yields (eq 5).[1]

(5)

Related Reagents.

t-Butyl Hypochlorite; ***N-Chlorosuccinimide***; ***Hypochlorous Acid***; ***Phenylselenium Trichloride***.

Chloro(η^5-cyclopentadienyl)[(4*R,trans*)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-*O*$^{\alpha}$,*O*$^{\alpha´}$]titanium

(4*R*,*trans*)

[132068-98-5] · $C_{36}H_{33}ClO_4Ti$ · Chloro(η^5-cyclopentadienyl)[(4*R*,*trans*)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-*O*$^{\alpha}$,*O*$^{\alpha´}$]titanium · (MW 613.0)

(highly enantio- and diastereoselective addition of allyl and terminally monosubstituted allyl groups to achiral and chiral aldehydes;[1] can also be used for enantioselective aldol reactions,[2] especially of glycine ester enolates[2a])

Physical Data: mp 214 °C (Mettler DSC); $[\alpha]_D$ = -243.4° (*c* = 1, $CHCl_3$); X-ray, ^1H, ^{13}C NMR.[1a]

Solubility: sol toluene (ca. 370 mg mL^{-1}), THF (ca. 470 mg mL^{-1}), diethyl ether (ca. 150 mg mL^{-1}).

Form Supplied in: pale yellow powder or crystals.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$);[1] may contain 1-5% of (4*R*,*trans*)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanol (but does not affect its efficiency).

Preparative Method: see ***Trichloro(cyclopentadienyl)titanium***.

Handling, Storage, and Precautions: the dry solid must be stored under exclusion of moisture and UV at rt (brown, tightly sealed bottle). It can, however, be handled quickly in the open, e.g. for weighing. Reactions should be carried out in dry equipment and with absolute solvents under argon or N_2.

Allyltitanation of Aldehydes.

The two-stage, one-pot procedure involves first the generation of the allyltitanium reagents (*R*)-(**2a-f**) (eq 1) by transmetalation of allyl-Grignard or allyl-Li compounds with a slight excess (1.2 equiv) of (*R*,*R*)-(**1**). It is advisable to analyze the content of the allylmetal precursor solution. Optimal conditions (time and temperature) of these transmetalations are preferably determined by test reactions with a simple aldehyde, assessing for maximal diastereo- and enantioselectivity. For stable allylmetal compounds, 1-3 h at 0 °C is usually sufficient. The allyltitanates (**2**) can be analyzed by ^{1}H and ^{13}C NMR.[1a] Fast allylic rearrangements are responsible for the formation of the thermodynamically most stable allyltitanium isomer with terminal substitution and *trans* double bond, irrespective of the nature of the organometallic precursor.

(*R*,*R*)-(**1**)

M =	MgCl	(*R*)-(**2a**), $R^1 = H$
	MgCl	(*R*)-(**2b**), $R^1 = Me$
	Li	(*R*)-(**2c**), $R^1 = CH{=}CH_2$
	Li	(*R*)-(**2d**), $R^1 = Ph$
	Li	(*R*)-(**2e**), $R^1 = SiMe_3$
	Li	(*R*)-(**2f**), $R^1 = 4\text{-}MeOC_6H_4O$

The second step, performed in situ, is the addition of ca. 0.75 equiv (based on **1**) of an aldehyde at -78 °C (eq 2). Most reactions are completed within 3 h and the resulting cyclopentadienyltitanium trialkoxides are hydrolyzed by stirring overnight with aqueous NH_4F (45%) at rt. The precipitated cyclopentadienyltitanium oxide (**3**) is removed by filtration and can be recycled to $CpTiCl_3$. The chiral ligand (**4**) and the product (**5**) are separated by crystallization or precipitation of (**4**) followed by distillation and/or chromatography.

The homoallylic alcohols (**5**) are isolated in fair to good yields. Their optical purity often exceeds 95% and the *anti* diastereomers are produced almost exclusively (&egt;98% ds). Exceptions with up to 33% *syn* epimer have, however, been obtained for (**2f**).[1b] The reagent controlled stereoselectivity of (*R*)-(**2**) and the enantiomers (*S*)-(**2**) is best documented by conversions with chiral aldehydes, examples being (**6**),[1a] (**7**),[1a] and (**8**).[1b]

The allylation of (2*S*)-2-phenylbutyraldehyde to give (**6**) allows a comparison with other similar reagents. Whereas the transformation to (**6**) with (*S*)-(**2a**) (mismatched pair) proceeds with 95% ds, lower selectivity is observed for the allyltitanium reagent prepared analogously from ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium*** (79% ds) or from ***B-Allyldiisopinocampheylborane*** (74% ds).[3a] Due to the fast *E*/*Z* isomerization of (**2**), the *syn* isomers of (**5**) cannot be obtained as the major product by using allyltitanium compounds, e.g. (*R*)-(**2b**), derived from chloride (**1**). *Syn*-crotyl adducts are efficiently obtained with chiral allylboron reagents,[3] e.g. diisopinocampheyl-(*Z*)-crotylborane[3a,b] or diisopropyl tartrate (*Z*)-crotylboronate.[3c] Inferior stereoselectivity is also exhibited by 2-substituted and 1,3-disubstituted allyltitanium reagents derived from (**1**).[1,2b] The use of similar chiral titanium reagents[4] and stereoselective additions with other allylmetal compounds[5] have recently been reviewed. While all these methods rely on stoichiometric amounts of a chiral reagent, catalytic amounts of a chiral acyloxyborane complex mediate the enantioselective addition of allylsilanes[6a] and allylstannanes[6b] to aldehydes. Very recently, the addition of allyltributyltin was also found to be catalyzed by a complex formed from 1,1´-bi-2-naphthol and $TiCl_4$ (see ***(R)-1,1´-Bi-2,2´-naphthotitanium Dichloride***).[7]

Aldol Reaction.

In addition to the allyl derivatives (**2**) (eq 1), titanium ester enolates derived from chloride (**1**) react with aldehydes, affording aldol products after hydrolysis. Compared to the analogous reagents prepared from ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium*** the enantioselectivity of these enolates is only moderate, 78% ee for the enolate of *t*-butyl acetate[2] and 26-78% ee in the case of 2,6-dimethylphenyl propionate.[4] Better selectivity (81-94% ee) was, however, obtained for Ti enolates (**9**) derived from stabase-protected glycine esters (**10**) (eq 3).[2a] The primary *N*-bis-silyl-protected adduct (**11**) can easily be transformed to other *N*-derivatives, e.g. the *t*-butyl carbamate (**12**). This method thus gives access to L-*threo*-α-amino-β-hydroxy acids. Further details and references to other methods are provided in the entry for ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium***, an analogous reagent affording the enantiomer of (**12**).

1-Chloro-3-diazo-2-propanone

[20485-53-4] · $C_3H_3ClN_2O$ · 1-Chloro-3-diazo-2-propanone · (MW 118.53)

(undergoes Darzens condensation with aldehydes;[1,2] efficiently alkylates benzene;[3] forms a quaternary ammonium salt with trimethylamine;[4] undergoes P-H carbene insertion[5] with dimethyl phosphite; displaceable diazo moiety[6])

Alternate Name: chloromethyl diazomethyl ketone.

Physical Data: mp 3 °C; bp 75 °C/13 mmHg.

Preparative Method: prepared by reaction of chloroacetyl chloride with excess diazomethane. In most recent reports,[1] the crude material is purified by fractional vacuum distillation to furnish product as a yellow oil in 52% yield. In earlier references, isolation of pure material is accomplished by three-fold distillation under reduced pressure[8] or crystallization from diethyl ether at -80 °C.[7]

Handling, Storage, and Precautions: no difficulties have been reported. However, alkyl diazo compounds in general are considered explosive and appropriate precautions should be taken during handling and distillation of these materials. Use in a fume hood.

Darzens Condensation.

Darzens condensation[1,2] of 1-chloro-3-diazo-2-propanone (**1**) with aldehydes (**2a-e**) affords epoxy diazo ketones (**3a-e**) (eq 1). Treatment (stoichiometric quantities) of (**1**) and benzaldehyde (**2a**) in ice-cold methanol with an aqueous ***Sodium Hydroxide*** solution provides 1-diazo-3,4-epoxy-4-phenyl-2-butanone (**3a**) in 69% yield. In all cases the reaction is reported to proceed stereoselectively and affords epoxides which are exclusively of the *trans* configuration. Diadduct (**4**) is obtained on treatment of the diazo ketone with two molar equivalents of sodium hydroxide and a large excess of benzaldehyde.

(**a**) R = Ph; (**b**) R = *p*-$NO_2C_6H_4$; (**c**) R = *p*-$MeOC_6H_4$; (**d**) R = *trans*-PhCH=CH; (**e**) R = 2-thienyl

(4)

Alkylation of Benzene.

In a process reported to involve a cycloheptatrienyl intermediate, 1-chloro-3-diazo-2-propanone has been shown to alkylate benzene providing benzyl ketone (**6**).[3] The method employs sequential catalysis by rhodium(II) trifluoroacetate and ***Trifluoroacetic Acid***. Diazo ketone (**1**) is added to excess benzene containing a catalytic amount of rhodium(II) trifluoroacetate. Subsequent removal of excess benzene and treatment with trifluoroacetic acid in dichloromethane affords (**6**) in an 84% yield. Several α-diazo ketones were utilized to provide a variety of benzyl ketones, illustrating the scope and efficiency of this means of electrophilic aromatic alkylation.

Quaternary Ammonium Salts.

1-Chloro-3-diazo-2-propanone reacts with ***Trimethylamine*** to form quaternary ammonium salt (**7**).[4]

(7)

Phosphorus-Hydrogen Carbene Insertion.

In a ***Copper(I) Acetylacetonate*** catalyzed reaction, (**1**) and dimethyl phosphite form 3-chloro-2-oxopropylphosphonate (**8**) via P-H carbene insertion (eq 3).[5]

(1) (8)

Diazo Displacement.

Displacement of the diazo moiety in (**1**) with ***Phosphoric Acid*** furnishes 3-chloro-2-oxopropyl hydrogen phosphate

(**9**).[6]

2-Chloro-1,1-diethoxyethane

[621-62-5] · $C_6H_{13}ClO_2$ · 2-Chloro-1,1-diethoxyethane · (MW 152.62)

(versatile two-carbon synthon; forms carbocycles,[4] heterocycles;[14-18] used in the synthesis of alkynes[1,2] and alkenes[3,5,6])

Alternate Names: 1-chloro-2,2-diethoxyethane; chloroacetaldehyde diethyl acetal.

Physical Data: colorless liquid, bp 151 °C; *d* 1.018 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: neat liquid of high purity; readily available.

Handling, Storage, and Precautions: flammable, moisture sensitive. Use in a fume hood.

Alkoxyalkynes[1] and Alkynols.[2]

Sodium ethoxyacetylide is formed on treatment with ***Sodium Amide***/liq. NH_3, from which ethoxyacetylene, 1-ethoxyalkynes, or 1-ethoxyalkynols can be obtained by quenching the acetylide anion with the appropriate electrophile (eq 1).

The alkoxyalkynols formed can easily be converted to α,β-unsaturated esters on acid treatment.[3]

Hydroxycyclopentenones.[4]

Biologically important 4-hydroxycyclopentenones are readily available in a high yielding route by reaction of 2-chloro-1,1-diethoxyethane with a dithiane (eq 2). It is noteworthy that yields are much lower with the corresponding bromoacetal.

Functionalized Allylsilanes.[5]

With 1-ethoxy-3-trimethylsilyl-1-propyne, the reagent under ***Titanium(IV) Chloride*** catalysis affords 2-carbonylethoxyallyltrimethylsilane regio- and stereoselectively (eq 3).

Vinylation of Enolates.[6]

An electrophilic species equivalent to a vinyl cation can be generated by treating the reagent with ***Sodium Dicarbonylcyclopentadienylferrate*** (eq 4).

Isocytosine can be vinylated with 2-chloro-1,1-diethoxyethane to give the corresponding imidazolo[1,2-*a*]pyrimidine-5(1*H*)-one and -7(8*H*)-one (eq 5).[7] The process is reversable upon treatment with ***Lead(IV) Acetate*** and mild basic hydrolysis. Annulations to give six-membered ring systems containing a bridgehead nitrogen are also common.[8]

Miscellaneous applications include the synthesis of vinyl ethers[9] under acid catalysis and ketene acetals[10] under base catalysis; synthesis of sulfonic esters or sulfonyl ethers in reactions with a sulfinic acid in the presence of ***Boron Trifluoride Etherate***;[11] as a precursor to glycol aldehyde;[12] and use in the synthesis of *N*-nitrosamino aldehydes.[13] Among the heterocycles synthesized are imidazopyrazines,[14] imidazopyrazoles,[15] phenoxypyrimidinones,[16] 3-

substituted 1,5-dihydrobenzodithiepines,[17] *P*-functionalized phospholene oxides,[18] etc.

Related Reagents.

Chloroacetaldehyde; ***Ethoxyacetylene***.

Chlorodiethylborane

[5314-83-0] · $C_4H_{10}BCl$ · Chlorodiethylborane · (MW 104.39)

(reagent for the synthesis of organoboranes;[1] protection of sugars;[2] cleavage of strained ethers;[3] component of polymerization catalysts[4])

Physical Data: bp 81 °C.

Solubility: sol diethyl ether, THF, pentane, benzene.

Preparative Methods: chlorodiethylborane is conveniently prepared by the redistribution reaction of triethylborane and boron trichloride in the presence of a catalytic amount of tetraethyldiborane.[5] The product is isolated by distillation in 98% yield. Other methods are also known,[6-8] e.g. ^{10}B-labelled chlorodiethylborane is obtained by the reaction of ^{10}B-labelled triethylborane with antimony pentachloride.[6]

Handling, Storage, and Precautions: chlorodiethylborane is a colorless, mobile, thermally stable liquid. It is spontaneously flammable in air and should be handled and stored under nitrogen or argon. It reacts with alcohols and water.

Organoboranes.

Various diethylorganoboranes containing alkyl,[9] alkenyl,[10] alkynyl,[11] allylic,[12-16] aryl,[17,18] amino,[19-24] and other groups[25-30] are prepared by the transmetalation reaction of chlorodiethylborane with the corresponding alkali metal, tin, silver, or silicon derivatives. Allylic diethylboranes generated from alkenes via metalation are useful intermediates in the contrathermodynamic isomerization and allylic monodeuteration of alkenes (eq 1),[12,14] and the hydroxyalkylation, hydroxymethylation, acylation, and formylation of alkenes (eqs 2 and 3).[13,15,16]

(2)

(3)

Bis(dialkylboryl)alkenes derived from l-alkynes are readily hydrolyzed to stereochemically pure (*Z*)-alkenes (eq 4).[10]

(4)

R = alkyl; R' = alkyl, Ph

The reduction of chlorodiethylborane with ***Lithium Aluminum Hydride*** affords tetraethyldiborane, a useful hydroborating agent, also available by other methods.[31-33] This method, however, initially generates a pure reagent. Deuterium labelled tetraethyldiborane is readily prepared (eq 5).[31]

(5)

Tetraethyldiborane and other primary alkylboranes exist in equilibrium with alkyldiboranes and trialkylboranes. The mixtures have a mean composition corresponding to tetraalkyldiborane.[33]

The hydroxyl and carboxyl groups of sugars can be protected as diethylboryl derivatives with a mixture of chlorodiethylborane and triethylborane (eq 6).[2]

Cleavage of Ethers.[34]

Chlorodiethylborane cleaves strained cyclic ethers, e.g. oxetanes.[3] Dialkylbromoboranes, particularly *B*-bromo-9-borabicyclo[3.3.1]nonane, are more effective reagents.[35]

Polymerization Catalysis.

Chlorodiethylborane is applied in polymerization catalysis, e.g. regulating the alternation of copolymerization of methacrylate and styrene,[4,36,37] or as a component in Ziegler-Natta-type catalysts for polymerization of alkenes.

Related Reagents.

9-Bromo-9-borabicyclo[3.3.1]nonane; ***Bromodimethylborane***.

Chlorodifluoromethane

$CHClF_2$

[75-45-6] · $CHClF_2$ · Chlorodifluoromethane · (MW 86.45)

(difluoromethylating reagent, can function as a precursor to difluorocarbene)

Physical Data: bp -40.8 °C.[1]

Solubility: sol ether, acetone, chloroform.

Form Supplied in: gas.

Preparative Method: prepared by the chlorination of CH_2F_2 with Cl_2;[2] by the hydrogenation of CCl_2F_2 in a Pt-lined tube at high temperature;[3] by the halogen-exchange reaction of $CHCl_3$ with HF and $SbCl_5$;[4] and by the reaction of HCF_2CO_2Ag with Cl_2.[5]

Handling, Storage, and Precautions: should be handled in a fume hood.

Reaction with Oxygen Nucleophiles.

Treatment of $CHClF_2$ with alkoxides in the corresponding alcohols gives alkyl difluoromethyl ethers.[6] Reaction of $CHClF_2$ with phenols in an aqueous dioxane solution and in the presence of an excess of ***Sodium Hydroxide*** produces aryl difluoromethyl ethers (eq 1).[7]

$$CHClF_2 + NaOR \longrightarrow ROCF_2H \qquad (1)$$

$$R = \text{alkyl, aryl}$$

Reaction with Phosphorus Nucleophiles.

Treatment of the anion of diethyl phosphite with $CHClF_2$ in hexane gives diethyl difluoromethylphosphonate (49%) (eq 2).[8] A modification of this route which employed THF as the solvent afforded the difluoromethylphosphonate in higher yield (77%).[9]

$$CHClF_2 + (RO)_2PONa \longrightarrow (RO)_2P(O)CF_2H \qquad (2)$$

Reaction with Sulfur Nucleophiles.

Reaction of $CHClF_2$ with sulfite in aqueous solution yields the difluoromethanesulfonate (eq 3).[10] Treatment of $CHClF_2$ with RSNa gives the difluoromethyl sulfide (eq 4).[6,11]

$$CHClF_2 + SO_3^{2-} \longrightarrow CF_2HSO_3^- \qquad (3)$$

$$CHClF_2 + RSNa \longrightarrow RSCHF_2 \qquad (4)$$

R = alkyl, aryl

Reaction with Carbon Nucleophiles.

Treatment of $CHClF_2$ with phosphonium ylides affords the corresponding 1,1-difluoroalkenes (eq 5).[12] Reaction of $CHClF_2$ with the carbanions of an alanine derivative or malonate affords the α-difluoromethylated alanine derivative[13] and the α-difluoromethylated malonate,[14,15] respectively (eq 6).

$$Ph_3P{=}CHR + CHClF_2 \longrightarrow F_2C{=}CHR \qquad (5)$$

(6)

Reaction with Nitrogen Nucleophiles.

Treatment of $CHClF_2$ with 2-ethoxycarbonylindole gives the corresponding *N*-difluoromethyl-2-ethoxycarbonylindole in excellent yield (eq 7).[15] When the sodium derivative of carbostyril is treated with $CHClF_2$, however, a mixture of 2-difluoromethoxyquinoline (18-35%), *N*-difluoromethyl-α-quinolone (10-18%), and two other compounds is obtained (eq 8).[15]

(7)

+ two others (8)

Difluorocarbene Formation and Reactions.

Difluorocarbene has been generated from $CHClF_2$ and base; it undergoes cycloaddition with alkenes to give the corresponding *gem*-difluorocyclopropane derivatives (eq 9).[16] Tetrafluoroethylene (TFE) is obtained by pyrolysis of $CHClF_2$ at high temperature (eq 10).[17]

Chlorodiiodomethane[1]

$CHClI_2$

[638-73-3] · $CHClI_2$ · Chlorodiiodomethane · (MW 302.27)

(carbenoid precursor used for formation of halo substituted cyclopropanes[2])

Physical Data: clear liquid, bp 200 °C (88 °C/30 mmHg);[3] *d* 3.17 g cm^{-3} at 0 °C.[4]

Solubility: sol CH_2Cl_2, benzene, hexane, dioxane, chloroform; insol water.

Preparative Methods: reaction of ***Iodoform*** with ***Mercury(II) Chloride***;[5] reaction of ***Chloroform*** with ***Ethyl Iodide*** in the presence of ***Aluminum Chloride***;[2] reaction of chloroform with ***Sodium Iodide*** and ***Sodium Hydroxide*** under phase transfer catalysis.[6] *Drying:* material is redistilled before use.

Analysis of Reagent Purity: bp and NMR (δ ^1H 6.18 ppm;[6] δ ^{13}C (calc. 60.6 ppm)).[7]

Handling, Storage, and Precautions: best kept in the dark for extended periods.

Halosubstituted Cyclopropanes.

Reaction of chlorodiiodomethane with alkenes under a variety of conditions gives rise to substituted cyclopropanes in reasonable yield. The additions, which have been proven to be electrophilic in nature, give product mixtures which are dependent on the conditions used. If hydroxide is used, under phase transfer conditions, chloroiodocyclopropanes result (eq 1). A wide range of alkene substituents has been studied.[8]

(1)

Reaction with alkenes in the presence of ***Diethylzinc***, however, gives rise to chloro-substituted cyclopropanes almost exclusively (eq 2).[9,10] The high *endo*:*exo* ratio is of note here (the analogous reaction with bromodiiodomethane gives the bromocyclopropane with a 2.8:1 *endo:exo* ratio).

(2)

The most widely studied additions to alkenes are those using copper metal to generate the carbenoid species. Exclusive formation of chlorocyclopropanes ensues and the yields are often good. Addition to cyclohexene in the presence of ***Copper*** powder gives a 48% yield of product, but with a diminished *endo:exo* ratio (eq 2).[10] A similar addition to *cis*-cyclooctene gives a 50% yield of product with a 6.2:1 *endo:exo* ratio.[2] Application of this protocol to other alkenes was reported (eq 3).[2] The high *cis,cis:trans,trans* ratio for addition to (*Z*)-4-octene is complemented by the exclusive formation of the *cis,trans* adduct with (*E*)-4-octene. Addition to substituted styrenes has been studied in order to probe the electrophilic nature of the addition reaction (eq 4).[2] While the *cis:trans* ratios of the product cyclopropanes remained comparable, the rates of formation varied widely, allowing a Hammet ρ value of -1.13 for this reaction to be assigned. The relative stability of chlorodiiodomethane and related halomethanes to hydrolysis has been studied.[11]

(3)

(4)

R = H, 41%, R = *p*-Br, 53%; R = *p*-Me, 56%, R = *m*-CF_3, 36%; R = *p*-Cl, 50%; R = *m*-Cl, 47%

Experiments conducted in the presence of *radical inhibitors* gave the most reproducible results for base hydrolysis in aqueous (dioxane/water) solution, exposing this potential source of side reaction.[11]

Related Reagents.

Bis(trichloromethyl)mercury; ***Bromoform***; ***Chlorodifluoromethane***; ***Chloroform***; ***Chloroiodomethane***; ***Phenyl(tribromomethyl)mercury***; ***Phenyl(trichloromethyl)mercury***.

(+)-*B*-Chlorodiisopinocampheylborane

(+)

[112246-73-8] · $C_{20}H_{34}BCl$ · (+)-*B*-Chlorodiisopinocampheylborane · (MW 320.80) (-)

[85116-37-6]

(chiral reducing agent for various prochiral ketones;[1] reagent for asymmetric aldol condensation of methyl alkyl ketones;[2] reacts with *meso*-epoxides to give nonracemic chlorohydrins[3])

Alternate Name: (+)- and (-)-DIP-Chloride™.

Physical Data: mp 52-56 °C; (-)-DIP-Chloride $[\alpha]_D$ -67.07° (*c* = 13.5, CH_2Cl_2); ^{11}B NMR (diethyl ether) singlet at δ = 74 ppm (with reference to $BF_3.OEt_2$).

Solubility: sol in both polar and nonpolar aprotic solvents like diethyl ether, THF, methylene chloride, pentane, hexane, etc.

Form Supplied in: white crystalline solid, available commercially.

Handling, Storage, and Precautions: the dry solid and its solutions are moisture and air sensitive. The reagent reacts instantaneously with water and protic solvents to liberate HCl. Containers of DIP-Chloride should be stored in the absence of moisture. Cans or bottles of DIP-Chloride should be flushed with N_2 and kept tightly sealed to avoid contact of oxygen and moisture. The solid reagent should be crushed, transferred, or weighed only in glove bag or dry box under N_2 atmosphere. The reagent can be stored for several years under N_2 atmosphere below 25 °C. Use

in a fume hood.

Asymmetric Reduction of Ketones.

The reagent, developed by Brown and co-workers, is used primarily for the asymmetric reduction of a variety of prochiral ketones to form secondary alcohols with high enantiomeric purity.[1] It has been demonstrated that reduction of aryl alkyl ketones with DIP-Chloride proceeds with extraordinary consistency and predictable stereochemistry (eq 1).[4,5] Reduction of a variety of substituted aryl alkyl ketones demonstrates that representative aromatic substituents do not affect the stereochemical outcome.[1a] The reagent shows poor enantioselectivity with unhindered aliphatic ketones; however, hindered aliphatic ketones like 3,3-dimethyl-2-butanone provide the corresponding alcohol in 95% ee.[5,6] Bicyclic ketones like α-tetralone, 1-indanone, and 2´-acetonaphthone are reduced by the reagent in 87%, 97%, and 98% ee, respectively.[5] Substrates with heteroaromatic groups show some decrease in the enantioselectivity (e.g. 2´-acetylthiophene and 3-acetylpyridine are reduced in 91% and 92% ee, respectively).[5] The reagent has been recently applied to the reduction of fluoro ketones.[7] It has been shown that good enantioselectivity can be obtained if the reduction of fluoro ketones are carried out neat (without solvent) (eq 2). The reagent shows poor selectivity in the reduction of unhindered alkynic ketones. However, hindered alkynic ketones are reduced in relatively good optical purity (eq 3).[8] A variety of hindered alkynic ketones have been recently synthesized and converted by the reagent to the corresponding propargylic alcohol in high yields and in essentially optically pure form.[8] It has also been demonstrated that DIP-Chloride is a remarkably effective reagent for the asymmetric reduction of acylsilanes to form corresponding α-silyl alcohols in 96-98% ee (eq 4).[9]

(1)

R = Me, Et, *n*-Pr, *n*-nonyl

(2)

(3)

(4)

Chiral secondary alcohols are potentially of great importance in biological and medicinal science. For example, 3-chloro-1-phenyl-1-propanol, which is obtained in >99% ee via DIP-Chloride reduction of the corresponding ketone, provides access to a highly enantioselective synthesis of antidepressant agents such as Tomoxetine, Fluoxetine, and Nisoxetine.[10] Another representative application of DIP-Chloride is found in the synthesis of (1*R*,3*S*)-1-aminomethyl-3,4-dihydro-5,6-dihydroxy-3-phenyl-1*H*-2-benzopyran, a potent and selective D1 agonist.[11] The reagent has also been applied to the synthesis of a prostaglandin intermediate[1a] and for the synthesis of a dolaphenine intermediate which is the C-terminal unit of dolastatin (a promising anticancer agent).[12]

Enolboration of Ketones and Opening of *meso*-

Epoxides.

Methyl alkyl ketones have been successfully enolized by Ipc_2BX (X = OTf or Cl) in the presence of a tertiary amine. The corresponding enolborinates have been used in asymmetric aldol condensations (eq 5).[2] The reagent has also been applied to the enantioselective opening of *meso*-epoxides to form the corresponding nonracemic chlorohydrins (eq 6).[3]

Chlorodiisopropylsilane

[2227-29-4] · $C_6H_{15}ClSi$ · Chlorodiisopropylsilane · (MW 150.73)

(reagent for the synthesis of *O*-diisopropylsilyl derivatives for intramolecular hydrosilylation reactions; used in a 1,3-*anti*-selective reduction of β-hydroxy ketones,[1-3] and in a mild method for reducing β-hydroxy esters[4])

Physical Data: bp 150-153 °C,[5] bp 54-55 °C/45 mmHg;[6] *d* 0.872 g cm^{-3}.[6]

Solubility: generally sol organic solvents; reacts with alcohols, ammonia,[6] and water.

Form Supplied in: neat liquid, commercially available.

Analysis of Reagent Purity: ^1H NMR δ($CDCl_3$) 4.35 (Si-H).[5] The most likely impurity is tetraisopropyldisiloxane, $(i\text{-}Pr_2SiH)_2O$, for which the corresponding signal is slightly upfield at 4.28.[7]

Preparative Method: obtained by reaction of trichlorosilane with isopropylmagnesium chloride;[6] the original yield of 45% may be raised to 70-80% by employing conc hydrochloric acid to quench the reaction.[2]

Purification: distillation at atmospheric or reduced pressure.

Handling, Storage, and Precautions: shelf-stable provided moisture is excluded. Corrosive; yields HCl on reaction with water. Use in a fume hood.

1,3-*Anti*-Selective Reduction of β-Hydroxy Ketones.

Treatment of β-hydroxy ketones (**1**) with chlorodiisopropylsilane in the presence of ***Pyridine***, or (more generally) ***Triethylamine*** with catalytic ***4-Dimethylaminopyridine***, gives β-diisopropylsilyloxy ketones (**2**) (eq 1).[1,2] These derivatives may be purified by chromatography on silica gel, and are obtained in yields of ca. 70-80%. Under the influence of Lewis acidic catalysts, most usefully ***Tin(IV) Chloride***, they undergo intramolecular hydrosilylation to give *trans*-siladioxanes (**3**), along with minor amounts of *cis* stereoisomers (**4**) (e.g. R^1, R^2 = *i*-Pr, diastereomer ratio (dr) = 120:1; R^1, R^2 = Bu, dr = 40:1).[1,2] After desilylation, *anti*-diols (**5**) may be isolated. The overall yields of (**5**)

from hydroxy ketones (**1**) are in the region 60-70%.[2]

The hydrosilylation step is presumed to occur via six-membered cyclic transition state (**6**). The stereoselectivity results from (a) the equatorial disposition of R^1, and (b) steric and stereoelectronic effects (including possibly a C=O&dotbond;Si interaction) which promote the axial orientation for the carbonyl group. The dimethylsilyl derivative (**7**) has been used in similar sequences,[2] but selectivities were found to be lower and optimization was complicated by the hydrolytic instability of Me_2Si-O bonds.

(6)

(7)

The 1,3-*anti* selectivity is maintained in the presence of an α-substituent, i.e. in substrates such as (**8**). Thus diisopropylsilylation/hydrosilylation of both diastereomers of (**8**) gave the 1,3-*trans*-siladioxane (**9**), with dr &egt; 250:1 (eq 2).[3] However, with the more challenging substrates (**10**) the α-position was found to have more influence. Both diastereomers gave principally the 1,2-*trans* product (**11**) (eq 3) but, while *anti*-(**10**) resulted in dr = 97:1, *syn*-(**10**) gave only dr = 5:1.

(2)

(8)
either diastereomer

(9)

(3)

(10)
either diastereomer

(11)

As part of the above work it was found that the superacid $TfOH_2^+B(OTf)_4^-$ may also be used as the hydrosilylation catalyst.[3] In one case it gave superior results to those obtained with $SnCl_4$.

The 1,3-*anti*-selective reduction of β-hydroxy ketones may also be accomplished using ***Tetramethylammonium Triacetoxyborohydride***,[8] and the samarium-catalyzed intramolecular Tishchenko reduction.[9] The former gives the *anti*-diols directly, although with slightly lower stereoselectivity than the intramolecular hydrosilylation. The latter results in monoacylated products, and gives excellent yields and selectivities.

Intramolecular Reduction of β-Hydroxy Esters.

Intramolecular hydrosilylation is also possible within β-diisopropylsilyloxy esters (**13**), constituting an exceptionally mild method for reducing ester groups to the aldehyde oxidation level (eq 4).[4] The derivatives (**13**) may be synthesized from β-hydroxy esters (**12**) as described above for the analogous ketones. Treatment with fluoride ions

(but not Lewis acids) induces hydride transfer to give alkoxysiladioxanes (**14**) in excellent yields (&egt;95%). Although usually performed in dichloromethane, the hydrosilylation may also be accomplished with ethyl acetate as solvent, providing strong evidence for intramolecularity.

While the reduction in eq 4 is not stereoselective, the stereocontrolled elaboration of (**14**) may be achieved in principle via conformationally biased carbocations (**15**). This has been demonstrated for the allylation of (**14**) with ***Allyltrimethylsilane*** (eq 5).[4] The major products (**16**) appear to derive from axial attack on (**15**). The most effective catalyst was $TfOH_2^+B(OTf)_4^-$, which could be used at levels of 1-2 mol % and gave yields of 78-85% with dr &egt; 20:1. While it is possible that the superacid acts by protonation of the alkoxy oxygen in (**14**), it is probably more likely that the active species is the supersilylating agent $Me_3Si\ B(OTf)_4$,[10] derived from superacid and allylsilane.

Intramolecular Hydrosilylation/Oxidation of Alkenols.

Since the advent of methods for the oxidative degradation of organosilicon compounds, it has been possible to develop controlled hydration methodology based on the hydrosilylation of C=C bonds. A useful variant involves the *O*-silylation of an alkenol with a dialkylsilylating agent R_2SiHX, followed by intramolecular hydrosilylation/oxidation to give a diol product.[11,12] Because of the intramolecular delivery of the Si-H moiety, these reactions often take place with excellent stereoselectivity. While most of this work has employed Me_2SiH as the internal reagent, the use of *i*-Pr_2SiH has been explored occasionally.[13,14] An example where it proved advantageous is the conversion of allylic alcohol (**17**) to *syn*-diol (**18**) (eq 6) in dr 30:1.[14] A related method involving dimethylsilyl groups gave dr of only 2.4:1 with this substrate.[12]

Synthesis of Other Organosilicon Reagents.

Aside from the direct applications referred to above, *i*-Pr_2SiHCl serves as an intermediate for the synthesis of certain other reagents. Examples are (a) *i*-$Pr_2Si(OTf)_2$, used for the protection of diols as diisopropylsilylene derivatives,[15] (b) dialkylarysilanes (**19**) for the introduction of a fluorescent *O*-protecting group,[16] and (c) the disiloxane (**20**), which may be converted to (**21**) (for diol protection)[7] or (**22**) (used in intramolecular ionic hydrogenation).[17]

Chlorodimethoxyborane[1]

[868-81-5] · $C_2H_6BClO_2$ · Chlorodimethoxyborane · (MW 108.34)

(borylating reagent;[3,4] preparation of substituted allyl boronates;[5,6] preparation of enol borates[10,11])

Physical Data: mp -87.5 °C; bp 74 °C; *d* 1.079 g cm^{-3}.

Solubility: sol aprotic solvents (ether, THF, CH_2Cl_2, hydrocarbons); reacts with water and protic solvents.

Preparative Method: prepared from a 2:1 mole mixture of $B(OMe)_3$ and BCl_3.[2]

Handling, Storage, and Precautions: air and moisture sensitive; store and handle under an inert atmosphere.

Preparation of Organoboronates.

Chlorodimethoxyborane has been extensively used in organic synthesis for the preparation of boronic ester derivatives. Typically, $ClB(OMe)_2$ is allowed to react with an organolithium reagent at low temperatures in THF or ether to afford the corresponding organoboronates. The boronates obtained are then usually elaborated without isolation. Alkyl and allyl sulfones have been converted into ketones and aldehydes via the corresponding α-sulfonylboronic esters. The α-sulfonylboronic esters were synthesized via lithiation of the sulfone and subsequent reaction with $ClB(OMe)_2$ in THF (eq 1).[3] Use of $ClB(OMe)_2$ was critical for the borylation reaction, as both $FB(OMe)_2$ and trimethoxyborane gave unsatisfactory results. The efficiency of the chlorodimethoxyborane reagent has been attributed to the low solubility of LiCl in THF.[3] Similarly, 2-aryl- and 2-alkylfurans have been converted into 2(3*H*)-butenolides via the oxidation of boronic ester derivatives (eq 2).[4] The 5-furylboronate derivatives were prepared in a very efficient manner by reacting the corresponding lithiofurans with 1 equiv of $ClB(OMe)_2$ in trimethoxyborane (prepared in situ by reacting BCl_3 with an excess of $B(OMe)_3$). Yields for the corresponding reactions were poor when trimethoxyborane or fluorodimesitylborane were used.

Preparation of Substituted Allylboronates.

The preparations of substituted allylboronic acid ester derivatives using halodialkoxyboranes,[5,6] trialkoxyboranes,[7] and halobis(dialkylamino)boranes[8] have been extensively studied in recent years. For example, a variety of γ-alkoxyallylboronates have been efficiently prepared via lithiation of allyl ethers and subsequent reaction with halodialkoxyboranes (eq 3).[5] Most notably, the preparation of (*E*)- and (*Z*)-crotylboronates has been thoroughly investigated. Reaction of (*E*)- or (*Z*)-crotylpotassium (see also Schlosser's base) with either $ClB(OMe)_2$[8b] or $F(BOMe)_2$[7a] affords the corresponding crotyldimethoxyborane. The crude boronate can be hydrolyzed to the boronic acid, which upon esterification can then be converted into a variety of crotylboronates, including the chiral diisopropyl tartrate (DIPT) modified crotylboronate reagents (eq 4).[6,7] However, the borylation reaction (especially when carried out on a large scale) is accompanied by the formation of methyl dicrotylborinate and tricrotylborane, resulting in lower yield and erosion of the isomeric purity (92-95%) of the crotylboronate. Use of $ClB(NMe2)_2$[8b] gave the crotylboronate in high isomeric purity; however, the yield was low. These problems can be overcome by using ***Triisopropyl Borate***, which gives the crotylboronate in high yield and >98% isomeric purity.[7a] Superior results were also obtained in the synthesis of alkyl boronic esters when $B(O\text{-}i\text{-}Pr)_3$ was used in place of $ClB(OMe)_2$.[9] For example, reaction of MeLi with $ClB(OMe)_2$ gave methyldimethoxyborane in 43% yield, whereas the corresponding reaction with $B(O\text{-}i\text{-}Pr)_3$ proceeded in 98% yield.[9]

(3)

(4)

Preparation of Enol Borates.

Reaction of $ClB(OMe)_2$ with either lithium enolates[10] or trimethylsilyl enol ethers[11] affords the corresponding dimethyl enol borates. The enol borate (used without isolation) reacts with aldehydes to afford the dioxaborinane (**1**) (eq 5). The dioxaborinane (**1**) represents an internally protected aldol, which can be elaborated without the need for isolation and protection of the alcohol. Thus addition of an allyl metal such as allylmagnesium bromide affords the allylic diol (**2**) in good yield, albeit with low diastereoselectivity (eq 5).[10] Alternatively, the dioxaborinane can be reduced with ***Sodium Borohydride*** to the corresponding diol.[11]

Related Reagents.

Triisopropyl Borate; ***Trimethyl Borate***.

Chlorodimethylphenylsilane

[768-33-2] · $C_8H_{11}ClSi$ · Chlorodimethylphenylsilane · (MW 170.72)

(nucleophilic silylation;[1] alcohol derivatization;[2] antenna chromophore;[3] enolate trapping;[4] Kumada-Fleming-Tamao oxidation[5])

Alternate Names: dimethylphenylsilyl chloride; DMPSCl.

Physical Data: bp 194-198 °C (63 °C/2 mmHg), d_4^{20} 1.026 g cm^{-3}; n_D^{20} 1.508.

Solubility: sol THF, ether, hexane.

Form Supplied in: liquid. Typical low-level impurities are metathesis products including dichloromethylphenylsilane (bp 205 °C).

Analysis of Reagent Purity: generally used as received. The methyl group appears at δ 2.4 and the silicon atom at δ 19.9 in the ^{1}H and ^{29}Si NMR spectra, respectively.[6]

Preparative Methods: widely available.

Handling, Storage, and Precautions: like other chlorosilanes, this compound can be destructive to tissue of the mucous membranes, upper respiratory tract, eyes and skin. Store in a cool dry place; the compound is moisture sensitive.

Chlorodimethylphenylsilane (DMPSCl) may be used in many of the same applications as chlorotrialkylsilanes, but in some cases the presence of the phenyl group on silicon offers advantages. For example, $Me_2PhSiLi$ is easier to prepare than Me_3SiLi.[7]

Nucleophilic Silation using Dimethylphenylsilylmetallics.

Several dimethylphenylsilylmetallics have been prepared (see Table 1). The most useful reaction in the class is conjugate addition of the silylcuprates to α,β-unsaturated esters and enones (eq 1).[1]

$(Me_2PhSi)_2Cu(CN)Li$[1a,1b,11]	$Me_2PhSiCCl_2Li$[13]

Hydroxyl Derivatization.

Chlorodimethylphenylsilane is a useful derivatizing agent for alcohols.[2] DMPSCl derivatized monosaccharides may be analyzed chromatographically with UV detection.[14] A novel application of the UV-absorbing ability of the dimethylphenylsilyloxy chromophore uses 266 nm light absorbed by the DPS `antenna' in 3α-dimethylphenylsilyloxy-5α-androstane-11,17-dione for photolytic reduction of the C-17 keto group.[3] Photolysis with 308 nm light absorbed by the ketone moieties produces predominately D-ring epimerization.

Other Nucleophilic Reactions at Silicon.

DMPSCl may be used to trap ester enolates[4] (however, lactam enolates silylate at carbon).[15] Numerous *C*-silylations of organolithium compounds with DMPSCl have been reported (eq 2).[5,16] Other compounds derived from DMPSCl include the azide,[17] tributylstannane,[18] cyanide,[19] isocyanate,[20] and isoselenocyanate.[21]

Protodesilation/Oxidation (Kumada-Fleming-Tamao

Oxidation).

Another advantage of the dimethylphenylsilyl group over trialkylsilyl is that the phenyl substituent may be readily removed by protodesilation.[7] Kumada-Fleming-Tamao oxidation converts *C*-silyl compounds into alcohols. Allylic dimethylphenylsilanes are preferred substrates for conversion to the corresponding allylic alcohols,[5] which is the basis for use of the β-silylethyl vinyl ketone (from **1**) as a β-hydroxyethyl vinyl ketone synthon in the Robinson annulation reaction.

Chlorodimethylsilane

$ClMe_2SiH$

[1066-35-9] · C_2H_7ClSi · Chlorodimethylsilane · (MW 94.62)

(intramolecular hydrosilation of allyl alcohols, homoallyl alcohols, allyl amines, and α-hydroxy ketones for the regio- and stereoselective synthesis of polyols and amino alcohols)

Physical Data: bp 35-36 °C; mp -111 °C; *n*20D 1.3830; *d* 0.852 g cm^{-3}.

Solubility: sol common aprotic organic solvents.

Form Supplied in: neat liquid.

Handling, Storage, and Precautions: moisture sensitive and corrosive. Must be stored under nitrogen in a tightly capped bottle in a freezer and transferred or weighed quickly via syringe. This reagent should be handled in a fume hood.

Intramolecular Hydrosilation of Allyl and Homoallyl Alcohols.

For a detailed description of the intramolecular hydrosilation-oxidation sequence, see ***1,1,3,3-Tetramethyldisilazane***. 1,1,3,3-Tetramethyldisilazane and ***N,N-Diethylaminodimethylsilane*** are frequently employed for preparation of hydrodimethylsilyl ethers for the intramolecular hydrosilation of allyl and homoallyl alcohols. Chlorodimethylsilane in combination with a tertiary amine such as ***Triethylamine*** is another useful reagent for the synthesis of hydrodimethylsilyl ethers, especially for large scale preparations.[1]

Other chlorodiorganosilanes (ClR_2SiH) such as ***Chlorodiisopropylsilane*** ($Cl(i\text{-}Pr)_2SiH$),[2] ***Chlorodiphenylsilane*** ($ClPh_2SiH$),[3] and 1-chloro-1-silacyclohexane ($(CH_2)_5SiClH$),[4] are also useful reagents for intramolecular hydrosilation, including catalytic asymmetric intramolecular hydrosilation.[3,4] These bulky hydrosilanes have some advantages over $ClMe_2SiH$ in these reactions, since the silylated intermediates are less moisture sensitive, are more easily handled, and can lead to higher stereoselectivity in the alkene hydrosilation step.

Intramolecular Hydrosilation of Allyl Amines.

The amino group of an allyl amine is silylated with chlorodimethylsilane, and then the resulting silazane is subjected to standard platinum-catalyzed cyclization and oxidation steps to form a *syn*-2-amino alcohol (eq 1). Exclusive formation of the four-membered cyclic product and the high stereoselectivity should be noted.[5]

Intramolecular Hydrosilation of Carbonyl Groups.

Catalytic asymmetric intramolecular hydrosilation of the carbonyl group of an α-hydroxy ketone has been attained by using chlorodimethylsilane as the silylating agent and a rhodium catalyst containing an optically active bidentate ligand (eq 2).[6]

In addition, chlorodiisopropylsilane is a useful reagent for Lewis acid catalyzed intramolecular hydrosilation of β-hydroxy ketones[7] and for fluoride ion induced reduction of esters.[8] It may also be mentioned that chlorodi-*t*-butylsilane is used in highly stereoselective intramolecular ionic hydrogenations of hydroxy alkenes.[9]

Chlorodiphenylphosphine

[1079-66-9] · $C_{12}H_{10}ClP$ · Chlorodiphenylphosphine · (MW 220.64)

(mild reagent for the halogenation of alcohols,[1] conversion of vicinal diols to alkenes,[2] transformation of sulfoxides to thioesters,[3] and formation of phosphines[4])

Physical Data: bp 320 °C; *d* 1.229 g cm^{-3}.

Form Supplied in: light-yellow liquid; widely available.

Handling, Storage, and Precautions: handle only in a chemical fume hood, wear respirator, chemical-resistant gloves, and safety goggles; do not breathe vapor, and avoid contact with eyes or skin. The compound is a corrosive lachrymator. It reacts violently with water to generate hydrogen chloride gas. It may be fatal if inhaled. See the material safety data sheet for first aid procedures.

Halogenation Reagent.

Primary and secondary alcohols can be converted to iodides and bromides in excellent yields employing chlorodiphenylphosphine, ***Imidazole***, and the appropriate halogen.[1] This reagent system is superior to most phosphorus-based reagents, which require the removal of triphenylphosphine and its oxide, because the phosphorus byproducts can be removed by basic aqueous extraction. Imidazole serves to neutralize the liberated halogen acids, enhances the reactivity, and can be washed away from the toluene phase during the extraction. Primary alcohols react at room temperature in less than 10 min (eq 1). Secondary alcohols require elevated temperatures and longer reaction times (eq 2). Competitive chlorination does not arise from the chloride anion generated during the reaction.

(1)

(2)

Alkenes from Vicinal Diols.

The same reagent system can be employed to convert vicinal diols to alkenes (eqs 3 and 4).[2] This single step procedure is more efficient than methods that require transformation of the diols to activated groups, such as disulfonates or cyclic thiocarbonates, which are subsequently converted into alkenes. The reaction proceeds through a vicinal iododiphenylphosphinate which can sometimes be isolated.

(3)

(4)

Thioesters from Sulfoxides.

Chlorodiphenylphosphine has been utilized to convert sulfoxides into thioesters (eq 5).[3] α-Lithio sulfoxides react with chlorodiphenylphosphine to provide α-sulfinylphosphines, which are rearranged by iodine to α-sulfenylphosphine oxides. Horner-Bestmann oxygenation gives the thioesters in good yields. This transformation has also been applied to cyclic sulfoxides to provide thiolactones (eq 6).[5]

Phosphine and Phosphine Oxide Formation.

Chlorodiphenylphosphine has been electrochemically coupled with organic halides to generate phosphines.[4] It also reacts with anions to give alkyl- or arylphosphines which can be oxidized to phosphine oxides. This method has been used to form a bifunctional molecule capable of serving as a phase transfer catalyst and transition metal ligand (eq 7).[6]

(7)

1,3-Dienylphosphines, bifunctional transition metal ligands, have been generated employing chlorodiphenylphosphine by two different routes. The first one involves hydrozirconation of conjugated enynes, followed by reaction with chlorodiphenylphosphine, to provide the dienylphosphines (eq 8).[7] In the other process, an in situ generated methylenephosphine phosphonate anion is alkylated with an α,β-enal to give the dienylphosphine (eq 9).[8] The second procedure is more versatile, because α,β-unsaturated aldehydes are more readily available than the corresponding enynes.

(8)

(9)

Ketones have been converted to vinylphosphine oxides (eq 10).[9] This process requires the conversion of the ketone to the trisylhydrazone. Subsequent formation of the vinyl carbanion, trapping with chlorodiphenylphosphine, and oxidation yields the vinylphosphine oxides.

(10)

β-Ketophosphine oxides can be prepared from enolates by trapping with chlorodiphenylphosphine, followed by oxidation.[10] This sequence has also been applied to enolates generated from a Michael addition (eq 11).

α-Functionalized phosphine oxides are versatile reagents for the formation of enol ethers, enamines, and vinyl sulfides via Horner-Wittig reactions.[11] α-Alkoxyphosphine oxides can be prepared by reaction of acetals with chlorodiphenylphosphine (eq 12). Ketene acetals can be generated from carbonyl compounds via the Horner-Wittig reaction with α,α-dialkoxyphosphine oxides made in a similar fashion to that of the previous equation from orthoesters and chlorodiphenylphosphine.[12] α-Aminophosphine oxides can be formed by reaction between chlorodiphenylphosphine and aminals in an analogous fashion.[13]

Propargylic alcohols react with chlorodiphenylphosphine to form phosphinite esters which subsequently undergo [2,3]-sigmatropic shifts to give allenylphosphine oxides.[14] This transformation has been coupled with an intramolecular Diels-Alder reaction to give vinylphosphine oxides (eq 13).

Other Applications.

Aldoximes and ketoximes react with chlorodiphenylphosphine to produce phosphinyloximes which undergo rearrangement to phosphinylimines.[15] This class of compounds can be reduced to provide protected amines, combined with organometallic reagents to give new amine derivatives, treated with hydrogen cyanide to yield α-aminonitriles, or reacted with diethyl phosphite to produce α-aminophosphonates (eq 14)

(14)

Lithium diphenylphosphide (Ph_2PLi) can be prepared from chlorodiphenylphosphine and lithium metal.[16] This is a versatile reagent for the dehydroxylation of α-hydroxy ketones and inversion of alkenes via epoxides.[17]

Chlorodiphenylphosphine can be oxidized with oxygen to form chlorodiphenylphosphine oxide.[18] This reagent can be utilized for the activation of carboxylic acids and protection of amines (see ***RC098-***).

Chlorodiphenylphosphine has been utilized as a reducing agent for diselenides and pyridine *N*-oxides.[19]

Chlorodiphenylsilane[1]

[1631-83-0] · $C_{12}H_{11}ClSi$ · Chlorodiphenylsilane · (MW 218.76)

(hydrosilylation;[1] precursor to alkyldiphenyl- and aryldiphenylsilanes[2])

Physical Data: bp 140-145 °C/7 mmHg (99-101 °C/1 mmHg; 83-85 °C/0.4 mmHg); *d* 1.137 g cm^{-3}; *n* 1.5845.

Solubility: sol benzene, chloroform, carbon tetrachloride, and ether.

Form Supplied in: liquid. Commercially available.

Preparative Methods: chlorodiphenylsilane may be prepared in high yield by treatment of diphenylsilane with triphenylmethyl chloride in refluxing benzene[3] or with PCl_5 at rt in CCl_4.[4]

Handling, Storage, and Precautions: moisture sensitive. Reactions are typically conducted under an inert atmosphere. The compound is corrosive and liberates HCl upon contact with moisture; may burn exposed skin and can be destructive to eyes, mucous membranes, and upper respiratory tract. Chemically incompatible with water, alcohols, and amines.

Hydrosilylation of Alkenes and Alkynes.

In the presence of a catalyst (typically chloroplatinic acid, H_2PtCl_2), chlorodiphenylsilane hydrosilylates double and triple bonds. As a difunctional reagent, chlorodiphenylsilane may be used in a reaction with an organometallic reagent (see the following section) to displace chlorine prior to the hydrosilylation reaction as in eq 1[5] or hydrosilylation may be conducted first with subsequent reaction at silicon as illustrated in eq 2.[6] The regiochemistry of the reaction has been reviewed.[7]

An enantioselective synthesis of chiral diols via intramolecular hydrosilylation using a chiral catalyst followed by oxidative cleavage of the Si-C bond (with retention of configuration) has been reported.[8] Intramolecular hydrosilylation/oxidation of allylamines provides a highly regio- and stereoselective synthesis of 2-amino alcohols (eq 3).[9]

Chloride Displacement by Organometallic Reagents.

Organolithium and Grignard reagents react with chlorodiphenylsilane to produce substituted alkyl- or aryldiphenylsilanes (eqs 4 and 5).[2]

Related Reagents.

Triethylsilane.

2-Chloro-1,3-dithiane

[57529-04-1] · $C_4H_7ClS_2$ · 2-Chloro-1,3-dithiane · (MW 154.69)

(readily accessible electrophilic 1,3-dithiane reagent; formyl cation equivalent; reacts with alkyl- and arylmagnesium halides,[1] enamines,[2] 1,3-dicarbonyl compounds,[1,2] electron-rich aromatics,[1,3] and with P,[4,5] N,[3] S,[3] and Se[6] nucleophiles)

Physical Data: mp 50 °C (dec).

Solubility: sol benzene, chloroform, THF, and ether.

Preparative Methods: the reagent can be easily obtained by chlorination of ***1,3-Dithiane***, either with ***N-Chlorosuccinimide*** (NCS) in benzene[3] or with ***Sulfuryl Chloride*** in chloroform.[5] The latter procedure generally gives a cleaner product[7] and is described here.

Sulfuryl chloride (11 mmol) in 5 mL of chloroform is slowly added to 1,3-dithiane (10 mmol) in 25 mL of chloroform at -40 °C in a nitrogen atmosphere. A white precipitate (chlorosulfonium salt) forms instantly. This precipitate gradually dissolves when the reaction mixture is allowed to warm to rt in 30 min. After stirring for an additional 30 min the solvent is evaporated at 0 °C and 1.55 g of 2-chloro-1,3-dithiane (**1**) of better than 95% purity (^{1}H NMR: C(2)-H δ 6.20) is obtained as a white or pale-yellow solid. A (minor) impurity is the sulfenyl chloride $ClCH_2S(CH_2)_3SCl$ (δ 4.80), formed by attack of chloride at the central carbon atom of the chlorosufonium salt.[5]

Handling, Storage, and Precautions: the reagent should be prepared shortly before use and rigidly protected against moisture, both in the solid form and in solution. Handle in a fume hood.

Reaction with Carbon Nucleophiles.

Organomagnesium (Aluminum) Reagents.

2-Chloro-1,3-dithiane (**1**) reacts readily with secondary and aromatic Grignard reagents,[1] thereby providing products such as (**2**), (**3**), and (**4**) that are not readily available by classical 2-lithio-1,3-dithiane chemistry.[8]

(2) 53%

(3) 60%

(4) 75%

Reaction with 3-substituted allylic aluminum reagents[9] affords dithianes (**5**), which arise from an allylic rearrangement, free of any other isomer (eq 1). Alkylation of 2-lithio-1,3-dithiane with allylic halides would give the isomeric, nonrearranged products.[8] The related reagent 1,3-dithienium tetrafluoroborate gives similar results in this reaction and affords better yields.[9]

(1)

(5)

The aluminum derivative of 1-bromo-2-propyne affords (**6**) upon combination with (**1**).[9] The phenylacetylene derivative (**7**) had earlier been obtained by a Grignard reaction with (**1**).[10]

(6)

(7)

Reaction with Electron-Rich Arenes.

Reaction of (**1**), prepared with NCS, with phenol or dimethylaniline affords the crystalline 4-substituted 2-(1,3-dithianyl) derivatives (**8**) and (**9**), respectively.[3]

(8) 75%

(9) 30%

Excellent yields of products (**10**), (**11**), and (**12**) are obtained by combining the corresponding phenols with (**1**), prepared with sulfuryl chloride.[1] In the reaction mixture obtained from phenol, 20% of the 2-substituted isomer was present (NMR).

(10) 99%

(11) 96%

(12) R = OMe, 86%
R = Me, 85%
R = Cl, 81%

In a study of 1,3-benzodioxole derivatives, the 6-substituted 2-(1,3-dithianyl) compound (**13**), obtained from reaction of the diol with (**1**) in 79% yield, served as starting material for the corresponding 6-methyl compound (reduction with ***Raney Nickel***) as well as for the interesting 4,5-quinone (**14**) (eq 2).[11]

(13)

(2)

(14)

Reaction of the anion of *N*-(phenylsulfonyl)indole with (**1**) gives the 2-[2-(1,3-dithianyl)]indole (**15**) (65%) which, after deprotection, can be functionalized at C-2´ to give (**16**) (eq 3).[7]

1,3-Dicarbonyl Compounds.

Reaction of (**1**) with the Na salts of malonic acid esters affords the 2-[2-(1,3-dithianyl)] derivatives (**17**) in excellent yields.[1] Danishefsky and co-workers have applied this procedure for the introduction of a critical C-1 unit in their approach towards the synthesis of naphthyridinomycin alkaloids.[12] Reaction of Na acetoacetic ester likewise affords (**18**).[2] These compounds can be deethoxycarbonylated by treatment with NaCl in DMSO.[2,13]

Enamines.

Taylor and LaMattina have reported the synthesis of 2-[2-(1,3-dithianyl)]aldehydes (**19**) (R = H) and ketones by reaction of (**1**) with morpholino enamines (eq 4).[2] This method has the advantage over classical methods for α-formylation of carbonyl compounds in that it directly introduces a base-stable protected formyl substituent.

(4)

(19)

Reaction with Phosphorus Nucleophiles.

Reagent (**1**) reacts with ***Triphenylphosphine*** to give phosphonium salt (**20**) (78%)[5] and with ***Triethyl Phosphite*** to give diethyl phosphonate (**21**) (85%).[4,5] Both compounds are excellent reagents for the synthesis of ketene dithioacetals by the Horner-Wittig reaction. The reactions of (**20**) are restricted to aldehydes (eq 5);[5] however, (**21**) reacts well with both aldehydes and ketones (eq 6).[5,14,15]

(5)

(20)

(6)

(21)

Reaction with S, Se, and N Nucleophiles.

Reaction of (**1**) with thiophenol affords 2-phenylthio-1,3-dithiane in 90% yield.[3] Reaction with ***Imidazole*** and with ***Succinimide*** affords the corresponding *N*-[2-(1,3-dithianyl)] compounds, also in excellent yields.[3a] Reaction of (**1**) with areneselenolate anions affords 2-arylseleno-1,3-dithianes (**22**) (eq 7).[6] These compounds, like the earlier studied (**7**)[10] and (**1**) itself,[3] show a strong anomeric effect in solution.[6]

(22)

R = NMe_2, OMe, Me, H, I, Cl, CF_3, NO_2

Other Applications.

Reagent (**1**) has found use in the preparation of 2-(1,3-dithianyl)-substituted polycarbonyl-metal complexes of Cr,[16] W,[16] and Mn.[17]

2-Chloro-3-ethylbenzoxazolium Tetrafluoroborate[1]

[63212-53-3] · $C_9H_9BClF_4NO$ · 2-Chloro-3-ethylbenzoxazolium Tetrafluoroborate · (MW 269.44)

(reagent for the conversion of alcohols to alkyl chlorides,[2,3] and preparation of isocyanides from formamides,[4] ketones from α-hydroxy carboxylic acids,[5] alkynes from aryl ketones,[6] and 1,2-*trans*-nucleosides from 1-hydroxy sugars[7])

Physical Data: mp 152 °C (dec).

Solubility: sol DMSO; slightly sol CH_2Cl_2, $CHCl_3$; insol Et_2O.

Form Supplied in: white solid.

Preparative Method: from *o*-aminophenol in three steps.[2] Commercially available.

Handling, Storage, and Precautions: hygroscopic and should be handled and stored under an argon atmosphere.

Synthesis of Alkyl Chlorides.

2-Chloro-3-ethylbenzoxazolium tetrafluoroborate (**1**) reacts with a variety of alcohols in the presence of tetraethylammonium chloride and triethylamine to afford the corresponding alkyl chlorides in high yields and generally with inversion of configuration.[2] 1-Hydroxy sugars are converted to the corresponding 1-chloro sugars with retention of configuration at the anomeric centers (eq 1). In reactions with alcohols, (**1**) is more reactive than the related reagents, 2-halopyridinium salts (**2**)[8] and 2-fluorobenzothiazolium tetrafluoroborate (**3**).[9]

(1)

(2)

(3)

1,2-Dichloroalkanes are prepared from epoxides under similar reaction conditions (eq 2).[3]

(2)

Synthesis of Isocyanides.

Isocyanides are useful intermediates in organic synthesis, and are frequently prepared via the dehydration of formamides.[10] Although several methods for achieving this transformation have been reported, rather drastic conditions, such as reflux in the presence of base, are often required.[11] As a useful alternative, dehydration of formamides proceeds smoothly in the presence of (**1**) and two equiv of triethylamine at room temperature; a variety of isocyanides can be prepared using this mild and simple procedure (eq 3).[4]

(3)

Synthesis of Ketones from α-Hydroxy Carboxylic Acids.

Treatment of α-hydroxy carboxylic acids, readily prepared from the corresponding carboxylic acids, with (**1**) and two equiv of triethylamine at room temperature affords ketones in good yields (eq 4).[5]

One-Step Formation of Arylalkynes from Aryl Ketones.

Aryl ketones are converted to the corresponding alkynes by treatment with (**1**) in the presence of a large excess of triethylamine at room temperature.

Synthesis of 1,2-*trans*-Nucleosides.

1,2-*trans*-Nucleosides are prepared from 1-hydroxy sugars and heterocycles by using (**1**) as a condensing reagent.[7]

1-Chloroethyl Chloroformate[1]

[50893-53-3] · $C_3H_4Cl_2O_2$ · 1-Chloroethyl Chloroformate · (MW 142.97)

(reagent for the *N*-dealkylation of tertiary amines[1,2])

Alternate Names: α-chloroethyl chloroformate; ACE-Cl.

Physical Data: bp 118-119 °C; *d* 1.325 g cm^{-3}; n_D^{20} 1.4230.

Form Supplied in: commercially available liquid.

Preparative Method: by stirring phosgene and acetaldehyde in the presence of benzyltributylammonium chloride, followed by distillation (96% yield).[2]

Purification: purified by vacuum distillation.

N-Dealkylation of Tertiary Amines.

1-Chloroethyl chloroformate (**1**) introduced by Olofson and co-workers, effects the selective, high yielding dealkylation of tertiary amines (eq 1).[2] Heating the amine (**2**) at reflux in 1,2-dichloroethane with 1 equiv of (**1**) for one hour results in formation of the ACE-piperidine (**3**). Evaporation of the solvent followed by heating the residue in methanol gives the hydrochloride salt of the secondary amine (**4**). Reagent (**1**) is preferred over the related reagent ***Vinyl Chloroformate*** for this application as the overall reaction conditions are milder and yields are higher.

(1)

Ease of cleavage of *N*-substituents is observed to occur in the order $ArCH_2$ > allyl, *t*-alkyl >> *s*-alkyl > methyl > primary alkyl >> piperidine ring opening.[3] Dealkylation of aromatic amines can be achieved, but this requires higher temperatures. Acetoxy and alkoxycarbonyl groups are stable to the reaction conditions.

2-Chloroethyl Chloromethyl Ether

[1462-33-5] · $C_3H_6Cl_2O$ · 2-Chloroethyl Chloromethyl Ether · (MW 128.98)

(reagent for cyclopropanol synthesis;[1,2] formaldehyde equivalent in hydroxymethylation of Grignard reagents;[3] used for protection of indoles[4])

Alternate Name: 1-chloro-2-(chloromethoxy)ethane.

Physical Data: bp 145-147 °C (66-68 °C/22 mmHg);[3] *d* 1.28 g cm^{-3}.[5]

Solubility: sol most commonly used organic solvents including ethereal (THF, diethyl ether), halogenated (CH_2Cl_2, $CHCl_3$, CCl_4), and hydrocarbon solvents; incompatible with alcohol solvents.

Analysis of Reagent Purity: best ascertained by ^1H NMR [(300 MHz, $CDCl_3$/TMS) δ 3.96 (t, *J* = 5.7 Hz, 2 H), 3.96 (t, *J* = 5.7 Hz, 2 H), 5.53 (s, 2 H)].[3]

Preparative Method: most conveniently prepared by reaction of 2-chloroethanol and 1,3,5-trioxane with HCl(g) at 0 °C (1.0 mol scale, 66% yield).[3,6]

Purification: by distillation.

Handling, Storage, and Precautions: chloromethyl ethers are recognized carcinogens.[7] Preparation and handling of the reagent should be carried out in an efficient fume hood, and skin contact should be avoided. Chloromethyl ethers are also moisture-sensitive and should be stored and transferred under inert atmosphere. Excess reagent should be hydrolyzed in water before removing from the fume hood.[3]

Synthesis of Cyclopropanol Derivatives.

2-Chloroethyl chloromethyl ether serves as a precursor to (2-chloroethoxy)carbene[8] via deprotonation of the chloromethylene group with ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LiTMP) followed by α-elimination.[1] Trapping of the carbene intermediate with an alkene (excess) affords a 2-chloroethyl cyclopropyl ether. The corresponding cyclopropanol is obtained by cleavage of the 2-chloroethyl moiety upon treatment with ***n-Butyllithium***.[1,8] This methodology offers an efficient means for preparation of secondary cyclopropanols (eq 1),[8] but is not suitable for the synthesis of tertiary derivatives.

This reaction sequence has been applied by Danheiser and co-workers in the synthesis of cyclopentenols via an oxyanion-accelerated vinylcyclopropane rearrangement (eq 2).[2] In these cases the alkene is used as the limiting reagent in the cyclopropanation reaction. Upon treatment with *n*-BuLi the intermediate 2-vinylcyclopropanol alkoxides undergo an accelerated [1,3]-sigmatropic shift to afford the corresponding 3-cyclopentenols in a one-pot synthesis from the (2-chloroethyl) cyclopropyl ethers. The overall transformation is highly stereoselective and can be viewed as a [4 + 1] annulation proceeding via suprafacial *exo* addition of hydroxycarbene to a diene.

Hydroxymethylation of Grignard Reagents.

Hydroxymethylation of Grignard reagents via reaction with formaldehyde generally proceeds in only moderate yields and is complicated by difficulties in handling formaldehyde. Ogle and co-workers have developed a two-step, one-pot alternative procedure which involves reaction of Grignard reagents with 2-chloroethyl chloromethyl ether, followed by removal of the 2-chloroethyl group by treatment with ***Sodium-Potassium Alloy*** (eq 3).[3] Use of diethyl ether as solvent gives optimum yields. This two-step protocol can also be applied to alkynyllithium reagents to provide propargyl alcohol derivatives.

Protection of Indoles.

An example of protection of an indole with the 2-chloroethoxymethylene group was reported in the synthesis of (±)-austamide (indole derivative, $ClCH_2CH_2OCH_2Cl$, KH, DMF-THF, 50% yield).[4] Cleavage of this protecting group was effected by treatment with KCN in acetonitrile in the presence of ***18-Crown-6*** (84% yield).

C-(1-Chloroethyl) *N*-Cyclohexyl Nitrone[1]

[37898-42-3] · $C_9H_{16}ClNO$ · *C*-(1-Chloroethyl) *N*-Cyclohexyl Nitrone · (MW 189.69)

(nitrone precursor of *N*-cyclohexyl-*N*-1-propenylnitrosonium cation, i.e. *N*-alkyl-*N*-vinylnitrosonium cations[1])

Alternate Names: α-(1-chloroethyl) *N*-cyclohexyl nitrone; α-chloro-*N*-cyclohexylpropanaldonitrone; *N*-(2-chloropropylidene-*N*-cyclohexylamine *N*-oxide.

Physical Data: mp 73-75 °C.

Solubility: sol ether, ethanol, dichloromethane, 1,2-dichloroethane, liquid sulfur dioxide.

Form Supplied in: not commercially available.

Preparative Methods: by condensation of freshly distilled 2-chloropropanal and *N*-cyclohexylhydroxylamine in anhydrous ether and dichloromethane in the presence of magnesium sulfate at 0 °C.[2a] Recrystallization is from a mixture of ether and pentane. *N*-Cyclohexylhydroxylamine hydrochloride is commercially available and the free base is easily liberated. The simpler aldonitrones, *C*-chloromethyl *N*-cyclohexyl and *N*-*t*-butyl nitrones, are made by chlorination of the appropriate *C*-methyl *N*-alkyl nitrone with *N*-chlorosuccinimide in carbon tetrachloride at 0 °C.[2a]

Handling, Storage, and Precautions: may be stored in a freezer under argon, but it slowly becomes yellow on standing at room temperature. For best results it should be used shortly after preparation.

[4 + 2] Cycloadditions.

Eschenmoser and co-workers introduced *N*-vinyl-*N*-alkyl-nitrosonium cations as heterodienes in reverse electron demand, Diels-Alder-type [4 + 2] cycloadditions in 1972.[2] *C*-α-Chloroalkyl *N*-cyclohexyl aldonitrones are the precursors which are treated with ***Silver(I) Tetrafluoroborate*** in 1,2-dichloroethane in the presence of a suitable alkene to produce 5,6-dihydro-4*H*-1,2-oxazin-2-ium tetrafluoroborate cycloadducts (eq 1).[2a] This salt may be used directly, but the usual workup is with aqueous ***Potassium Cyanide*** to give 3-cyanotetrahydro-2*H*-1,2-oxazines. Exchange to the

more stable tetraphenylborates is facile.[2a] The cycloaddition is regioselective with the oxygen of the *N*-vinylnitrosonium cation becoming attached to the carbon of the alkene which can best stabilize a positive charge (i.e. Markovnikov's r ule).

(1)

These cycloadducts, which may be derived from cyclic and acyclic di-, tri-, and tetrasubstituted alkenes, are useful synthetic intermediates. The preparation of γ-lactones is illustrative (eq 2[2b] and eq 3[3a]). The mechanism probably involves base-catalyzed rearrangement of the 3-cyano adduct to an iminolactone by elimination-addition with expulsion of hydrogen cyanide. Acid-catalyzed hydrolysis leads to the products. Propellane lactones have been prepared by this method.[4]

(2)

When *C*-α,β-dichloroethyl nitrones are used as starting materials, the identical sequence of reactions leads to α-methylene-γ-lactones via a 3-cyano-4-chloromethyl adduct (eq 4).[3a] Other contributions from the ETH laboratories have demonstrated that *C*-α,β-epoxy nitrones can be used for the same purpose. The reagent used to generate the vinylnitrosonium ion is a trialkylsilyl trifluoromethansulfonate, and the initially formed cyano-protected cycloadduct must be desilylated and converted to a mesylate before further reaction with base (eq 5).[5] The nitrone precursors for the reactions outlined in eqs 4 and 5 are easily prepared by condensation of 2,3-dichloropropanal and epoxypropanal, respectively, with *N*-cyclohexylhydroxylamine.

Intramolecular examples of the epoxy nitrone-alkene reaction are known (eq 6), but further conversion into useful products was not efficient.[6] Enol acetates also undergo the cycloaddition.[7]

When the dihydro-4*H*-1,2-oxazin-2-ium tetraphenylborate is allowed to react with ***Potassium Carbonate*** in dichloromethane (or with ***Diisopropylethylamine***, Hunig's base), proton abstraction occurs to give a 5,6-dihydro-2*H*-1,2-oxazine which upon heating undergoes electrocyclic ring opening. The imine thus formed can be hydrolyzed, and an important synthesis of unsaturated dicarbonyl compounds is achieved (eq 7). The key feature of this sequence is that a cyclic alkene starting material is oxidatively cleaved (as in ozonolysis) to a product with carbonyl group and an extended alkylidene chain at the original alkenic carbon atoms (carboxolytic cleavage).[2a] A creative application of this method is the synthesis of a 4-prenylindole from 8-nitro-1,4-dihydronaphthalene.[8]

Enol ethers have proved somewhat problematic and unwanted side products often appear.[9] A bicyclic and several benzobicyclic enol ethers gave low yields of propellane-type nitrile adducts. The major products were keto alcohols thought to be formed from fragmentation of oxonium compounds. Nevertheless, the cycloadduct nitriles underwent further conversions in good yield to form macrocyclic lactones with a formylmethylene appendage.

There are reports of ketone carbonyl groups functioning as heteroenes in [4 + 2] cycloadditions with *N*-vinylnitrosonium salts.[10]

The *N*-vinylnitrosonium salts also undergo facile [4 + 2] cycloadditions with alkynes.[3c] The first-formed adducts are *N*-cyclohexyl-4*H*-1,2-oxazin-2-ium tetrafluoroborates and subsequent hydrolysis affords α,β-unsaturated ketones, a viable alternate route route to these common products (eq 8).

Electrophilic Substitution Reactions.

The *N*-vinylnitrosonium ions are strongly electrophilic and their interaction with alkenes often leads to substitution in competition with cycloaddition. For example, when the reaction is conducted with trisubstituted alkenes in a highly polar solvent, such as liquid sulfur dioxide, unsaturated nitrones are formed in addition to the dihydro-4*H*-1,2-oxazinium salts (eq 9).[3b] The stereochemistry of the alkene is retained. Mild acid hydrolysis of the nitrones affords β,γ-unsaturated aldehydes. Similarly, electron-rich aromatic compounds are alkylated and hydrolytic workup affords α-arylaldehydes (eq 10).[3b] The *N*-vinyl-*N*-cyclohexylnitrosonium ion is an α-acyl carbocation equivalent in these reactions. Analogous substitutions were successful with indole and *N*-methylindole, and they represent abbreviated pathways to *C*-(3-indolyl-1-ethyl) and *C*-(3-indolylmethyl) nitrones.[11]

2-Chloroethyl Dichloromethyl Ether

[13930-34-7] · $C_3H_5Cl_3O$ · 2-Chloroethyl Dichloromethyl Ether · (MW 163.44)

(reagent for forming cyclopropanols from alkenes[1])

Alternate Name: dichloromethyl 2-chloroethyl ether.

Physical Data: bp 106-110.5 °C/10 mmHg.

Solubility: sol most organic solvents.

Preparative Method: not commercially available. It can be prepared by the action of ***Phosphorus(V) Chloride*** on β-chloroethyl formate (eqs 1 and 2).[2,3]

This is the reagent of choice for the preparation of cyclopropanols from alkenes. The method is very versatile and general in scope. It involves carbene insertion into an alkene to form the β-chloroethyl cyclopropyl ether (eq 3) which is then converted to the cyclopropanol (eq 4).[1]

(3)

(4)

The alkenes employed ranged from monosubstituted to tetrasubstituted to give the cyclopropyl ethers in 23-86% yield (eqs 5-9).[1]

(5)

(6)

(7)

(8)

(9)

A more recent example yields an interesting spiro compound (eq 10).[4]

(10)

Cyclopropyl ethers have been prepared by a similar carbene insertion using 2-chloroethyl dichloromethyl ether as shown in eq 11.[5]

1-Chloroethyltrimethylsilane

[7787-87-3] · $C_5H_{13}ClSi$ · 1-Chloroethyltrimethylsilane · (MW 136.72)

(nucleophilic addition of α-lithio derivative to aldehydes and ketones affords epoxysilanes, leading to methyl ketones)

Physical Data: bp 115-116 °C; *d* 0.862 g cm^{-3}.

Analysis of Reagent Purity: ^1H NMR.

Preparative Method: α-lithio derivative prepared from 1-chloroethyltrimethylsilane in THF and *s*-butyllithium (1.5 M in *n*-hexane or cyclohexane) at -78 °C, followed by warming to -55 °C.[1]

Form Supplied in: liquid; commercially available.

Handling, Storage, and Precautions: use in a fume hood.

Treatment of aldehydes and ketones with the α-lithio derivative of 1-chloroethyltrimethylsilane, prepared in situ, gives α,β-epoxytrimethylsilanes in moderate to high yields (35-96%) (eqs 1 and 2.[1,2]

This bulky carbanion also reacts with sterically hindered ketones in moderate yields (eq 3).[1] It is speculated that this carbanion adds to hindered ketones via a single electron transfer mechanism.

Acidic hydrolysis of the resulting α,β-epoxytrimethylsilanes yields homologated methyl ketones (eq 4).[3] The carbanion thus acts as a nucleophilic acylating species with reduction taking place at the original carbonyl group. This two-step sequence is more convenient than other methods for this type of homologation and proceeds under milder conditions.[4] The intermediate α,β-epoxytrimethylsilane can also be converted into an enol ether, enol acetate, alkenyl bromide, or enamide.[5]

Chloroform

$CHCl_3$

[67-66-3] · $CHCl_3$ · Chloroform · (MW 119.38)

(commonly a solvent in organic synthesis; also used in the preparation of dichlorocarbenes and α-trichloromethyl carbinols; and as a trichlorolithiocarbenoid precursor)

Physical Data: mp -63.5 °C; bp 61.7 °C; *d* 1.483 g cm^{-3}.

Solubility: very slightly sol water; sol ether, acetone, benzene, and ligroins.

Form Supplied in: colorless liquid with a sweet pleasant odor; available in high purity (99-99.9%).

Handling, Storage, and Precautions: oxidized by air and sunlight to phosgene. The addition of a small amount of alcohol or pentylenes prevents this. The solution should be handled with the usual precautions related to highly toxic substances; cancer suspect agent.

Formation of Dichlorocarbenes.

Chloroform reacts more rapidly with aqueous base than does dichloromethane or carbon tetrachloride (eq 1). The reaction proceeds by an S_N1cB mechanism[1] that involves the loss of a proton, followed by loss of Cl^-.[2] The dichlorocarbene is then hydrolyzed to formic acid or carbon monoxide.[3] Most reactions involving chloroform are based on its ability to form a dichlorocarbene in alkali media. The dichlorocarbenes are obtained by reacting $CHCl_3$ and OH^-, often under phase-transfer catalysis conditions,[4] and the dichlorocarbenes react with alkenes and nonalkene substrates.[5]

$$HCCl_3 \underset{}{\overset{OH^-}{\rightleftharpoons}} CCl_3^- \xrightarrow{-Cl^-} :CCl_2 \qquad (1)$$

Addition to Alkenes via Dihalocarbenes.

Dichlorocarbenes add to double bonds to give 1,1-dichlorocyclopropanes[6] that are versatile substrates for subsequent ring opening.[7] Dihalocyclopropanes are very useful compounds[8] that can be reduced to cyclopropanes, treated with ***Magnesium*** to give allenes, or converted to many other products. As an example, dichlorocarbene can be used as a

high yield two-step alternative to the Simmons-Smith reaction (eq 2).[9] It is also useful for the preparation of 2-chloronaphthalene derivatives (eq 3).[10]

(2)

(3)

When more than one isolated double bond is present in a substrate, products of both mono and multiple cyclopropanation are isolated, unless a selective phase-transfer catalysis method is used. Dichlorocyclopropanation can be followed by rearrangement if the dichlorocarbene adduct is either strained or otherwise unstable (eq 4).[11] Another useful rearrangement involves the expansion of pyrroles and indoles to pyridines and quinolines derivatives, respectively (eq 5).[12]

(4)

(5)

A similar rearrangement has been reported for the addition to furans, thiophenes, and polycyclic aromatics which, by loss of a proton, form expanded trienes with an exocyclic double bond (eq 6).[13] A second equivalent of dichlorocarbene can add to the exocyclic double bond, but in poor yield (eq 7).

(6)

(7)

The formation of 1,1-dichlorocyclopropanes from allylic alcohols is of particular synthetic value because the initial

adducts can undergo rearrangement under acidic conditions to give good yields of cyclopentenones (eq 8).[14] If an electron-withdrawing group is present on the double bond, a Michael addition with trichloromethyl anion might occur (eq 9).[15]

The most studied reaction of chloroform involving the formation of a dichlorocarbene is the Reimer-Tiemann reaction.[16] This reaction is commonly divided into normal and abnormal transformations, depending on the reaction products. A normal Reimer-Tiemann reaction is one in which a phenol (or electron-rich aromatic such as pyrrole) yields one or more aldehydes on treatment with chloroform and alkali (eq 10).[17]

The abnormal Reimer-Tiemann reaction product can be subdivided further into cyclohexadienones and ring-expansion products. When *ortho*- or *para*-substituted phenols are subjected to the reaction, 2,2- or 4,4-disubstituted cyclohexadienones may be obtained, in addition to the normal product (eq 11).[18] With certain five-membered ring substrates, a ring expansion can also occur (eq 12).[19]

(11)

(12)

Several other methods for the direct introduction of an aldehyde group into an aromatic ring exist under acidic and/or anhydrous conditions.[20] The Reimer-Tiemann reaction is mainly useful for phenols[21] and certain heterocyclic compounds, such as pyrroles and indoles. Attempts to improve the procedure have focused on the nature of the base, the effect of the solvent, the use of phase-transfer catalysts,[22] the use of ultrasound,[23] cyclodextrins, and alternative precursors to dichlorocarbene.[24] No modification has led to a significant improvement in yield. However, alterations in *ortho/para* ratios and increased yields of abnormal products have been accomplished.[25]

Addition to Nonalkenic Substrates via Dihalocarbenes.

Halocarbenes insert much less readily than carbenes to C-H single bonds, though a number of instances have been reported (eq 13).[26]

(13)

The reaction of dichlorocarbene with substrates other than hydrocarbons appears to be initiated by coordination of the electrophilic carbene with a Lewis basic site. Subsequent reactions that are attributable to differences in the basic functions or involvement with other reactive sites lead to differences in the chemistry of each substrate. The reactions of phase-transfer-generated dichlorocarbene with organic molecules possessing such heteroatoms as oxygen, nitrogen, and sulfur and no other more reactive functionality have led to a number of useful transformations. Alcohols react to give chlorides (eq 14).[27] Allylic alcohols that contain particularly reactive double bonds react preferentially at the alkenic sites.[28] In the absence of such complications, alcohols larger than about seven carbons react to yield chlorides, whereas small water-soluble alcohols generally yield the corresponding orthoformate in poor yield (eq 15).[29]

$$ROH + :CCl_2 \longrightarrow RCl + CO \qquad (14)$$

$$HCCl_3 + 3\,RO^- \longrightarrow HC(OR)_3 + 3\,Cl^- \qquad (15)$$

The facile addition of dichlorocarbenes under phase-transfer conditions has also been observed with imines[30] and can be a convenient pathway for the synthesis of some nitrogen-containing ring systems.[31] The hydrolysis of the *C,N*-diarylaziridines to the corresponding α-chloroacetanilides was also reported (eq 16).[32]

(16)

The reaction of chloroform under basic conditions is a common test for both primary aliphatic and aromatic amines (eq 17). The so-called Hofmann carbylamine reaction can also be used synthetically for the preparation of isocyanides, though yields are generally not high.[33] However, some improved procedures have been reported.[34] When secondary amines are involved, the adduct cannot lose two molecules of HCl; instead it is hydrolyzed to an *N,N*-disubstituted formamide (eq 18).[35] The reaction also yields imidazopyridines when α-(aminomethyl)pyridines are reacted with chloroform under phase-transfer catalysis conditions (eq 19).[36]

(17)

(18)

(19)

Dichlorocarbene can also be used as a dehydrating agent with primary amides, amidines, thioamides, and aldoximes, giving the corresponding nitriles (eq 20).[37]

(20)

Friedel-Crafts Reaction.

Chloroform reacts with aromatics rings[38] to form di- and triarylmethanes (eq 21).[39] The coupling of the two phenyl rings to the methyl group can be followed by a Scholl condensation (eq 22).[40] The reaction can also be used for the high-yield synthesis of highly chlorinated mono-, di-, and triarylmethanes.[41]

$$C_6H_6 + CHCl_3 \xrightarrow{Al,\ CuCl} Ph_2CH_2 + Ph_3CH \qquad (21)$$

Addition to Aldehydes.

Chloroform can condense with aromatic aldehydes under basic conditions (or by cathodic reduction)[42] to produce aryl trihalomethyl-substituted methanols (eq 23).[43]

In the case of aliphatic aldehydes the reaction is not efficient due to the aldol condensation. However, a convenient general synthesis of α-trichloromethyl carbinols can now be used.[44] Condensation of chloroform with aliphatic ketones to form dialkyl(trichloromethyl) carbinols[45] can also be accomplished in lower yields, except in the case of cyclohexanone where the product was obtained in 92% yield.[46]

Trichloromethyl carbinols can be oxidized to ketones,[47] hydrolyzed to hydroxy acids,[48] condensed to diaryltrichloroethanes and related products,[49] or can be used for the preparation of ordinary derivatives of the hydroxy group, such as the chloride[50] or the acetate.[51] They can also be reduced to give (*Z*)-vinyl chlorides.[52] Secondary trichloromethyl carbinols are reduced by chromium(II) to form (*Z*)-monochlorovinyl compounds in one step; in the presence of a carboxy function in the α-position, an (*E*) double bond is formed. Tertiary carbinols favor the formation of dichlorovinyl compounds and rearranged carbonyl products (eq 24).

A variety of α-chloromethyl, α,α-dichloromethyl, and α,α,α-trichloromethyl ketones can also be synthesized from trichloromethyl carbinols utilizing cathodic reduction (eq 25).[53]

(25)

Another use of the reaction of the aryl trihalomethyl-substituted methanols involves their reaction with nucleophiles[54] under basic conditions, by forming first a dichloro epoxide, which in turn reacts with the nucleophile to form an acid chloride that gives rise to the final product (eq 26). This reaction is used for the preparation of α-substituted arylacetic acids, where the α-substituent is methoxy[55] (or alkoxy[56] in general), hydroxy,[57] amino,[58] and even chloro.[59] A method for the preparation of α-methoxy aliphatic acids has also been reported.[60]

(26)

Reactions via Trichlorolithiocarbenoids.

Chloroform can be lithiated to form Cl_3CLi, a species that has proven to be a versatile synthon,[61] although other polyhalomethanes are sometimes preferred. Of particular interest is the reaction of Cl_3CLi with carbonyl functions (eq 27).[62]

(27)

Polyhalomethyllithium carbonyl adducts may be easily converted to a variety of important structural classes, such as α-chloro ketones,[63] α,β-unsaturated aldehydes,[64] α-chloroaldehydes,[65] α-hydroxyaldehydes,[66] and dichloroalkenes.[67] Chloroform can readily give (trichloromethyl)alkenes by deprotonation with butyllithium and alkylation by iodoalkenes. The chloroalkenes generated can then undergo interesting transition metal catalyzed intramolecular cyclizations,[68] affording five- or six-membered rings (eq 28). Trichlorolithiomethane can also generate *gem*-dichloroalkenes by reacting with α-sulfonyl carbanions,[69] although their bromo analogs give better results (eq

29).

Chloroform in the presence of lithium triethylmethoxide can be used to convert organoboranes to the corresponding trialkyl carbinols (eq 30).[70] The reaction proceeds in good yield for tri-*n*-butylborane, but gives poor results when extended to tri-*s*-butylborane and other secondary, hindered organoboranes. ***Dichloromethyl Methyl Ether*** is a much more effective participant in this reaction.[71]

Related Reagents.

Bromoform; ***Phenyl(tribromomethyl)mercury***; ***Phenyl(trichloromethyl)mercury***.

trans-Chlorohydridobis(triethylphosphine)platinum(II)

[20436-52-6] · $C_{12}H_{31}ClP_2Pt$ · *trans*-Chlorohydridobis(triethylphosphine)platinum(II) · (MW 467.87) (*trans*)

[16842-17-4]

(catalyst for nitrile hydration[1])

Physical Data: mp 81-82 °C; bp 130 °C/0.01 mmHg; sublimes at 75 °C/0.01 mmHg.

Solubility: sol organic solvents, incl. pentane (avoid chlorinated solvents).

Form Supplied in: white solid; commercially available.

Analysis of Reagent Purity: mp, NMR, IR.

Preparative Method: prepared in three steps from $PtCl_2$.[2]

Handling, Storage, and Precautions: air stable as the solid.

Nitrile Hydration.

The hydration of nitriles to amides is catalyzed by $(Et_3P)_2PtHCl$ (**1**) and the PMe_3 analog under mild conditions (80 °C) in the presence of one equivalent of ***Sodium Hydroxide*** per Pt (eq 1).[1] The maximum rate with acetonitrile occurs at about a 1:1 mixture of water to nitrile (70 and 178 moles amide per mol Pt per hour for Et_3P and Me_3P complexes, respectively). Phase transfer catalysts can be added to increase the rate with water-immiscible nitriles. Further addition of triethylphosphine also increases the reaction rate. In general, the trimethylphosphine analog appears to give higher rates than the triethylphosphine complex.

(1)

The title reagent might have particular value with hydrolysis-sensitive compounds, since the reaction conditions are much milder than those used with acid or base catalysts. The catalyst is particularly selective for hydrolysis of a nitrile in the presence of a conjugated double bond. For instance, conjugate addition of water to the alkenic double bond of acrylonitrile can be minimized, especially at lower temperatures. In addition, compounds which contain esters undergo selective nitrile hydrolysis (eq 2).

Methacrylate Polymerization.

Various *trans*-PtHX(PEt_3)$_2$ species catalyze the polymerization of methyl methacrylate in CCl_4.[3] The rate follows NO_3 > Cl > Br > NO_2 > CN. Co-polymerizations of methyl methacrylate with styrene have also been reported.[4] The monomer reactivity ratios were 0.50 and 0.65, respectively, and were suggested to proceed via a radical mechanism.

Alkene Hydrogenation.

Catalytic hydrogenation of simple alkenes, both terminal and internal, linear and cyclic, have been accomplished with (**1**) under ambient conditions in the presence of mineral acid.[5]

Alkene Hydroformylation.

In the presence of ***Tin(II) Chloride***, (**1**) catalyzes the hydroformylation of 1-hexene with moderate performance.[6]

Alkene Hydrosilation.

Complex (**1**) can function as an alkene hydrosilylation catalyst, but the activity is not as good as other catalysts.[7]

Chlorohydridotris(triphenylphosphine)rhodium(III) Chloride

[12124-48-0] · $C_{54}H_{46}Cl_2P_3Rh$ · Chlorohydridotris(triphenylphosphine)rhodium(III) Chloride · (MW 961.72)

(catalyst for carboxamide decomposition,[2] chloroacetate carbonylation,[3] hydrogen transfer,[4] and hydrogenation[5])

Physical Data: α-form mp (dec) 160 °C; β-form mp (dec) 100 °C.

Analysis of Reagent Purity: elemental analysis.

Preparative Method: prepared from ***Rhodium(III) Chloride*** and ***Triphenylphosphine***.[1]

Carboxamide Decomposition.

The distillation of secondary carboxamides over this catalyst results in generation of nitriles (eq 1).[2] Higher yields are reported when ***Chlorotris(triphenylphosphine)rhodium(I)*** is employed for production of nitriles from carboxamides. Use of various iridium complexes, palladium complexes, and ruthenium complexes results in a less efficient process.

(1)

The title reagent also catalyzes the transformation of malonamides into acetamides (eq 2).[2] In this case, the activities of $RhCl(PPh_3)_3$ and $HRhCl_2(PPh_3)_3$ do not mirror one another with respect to substrate selectivity and rate. This disparate reactivity is probably a reflection of the different mechanistic pathways followed by these two catalysts: $RhCl(PPh_3)_3$ requires oxygen to be catalytically active while $HRhCl_2(PPh_3)_3$ does not.

(2)

Carbonylation.

The carbonylation of chloroacetates has been effected using $HRhCl_2(PPh_3)_3$ adsorbed onto active carbon as a catalyst (eq 3).[3] When carbon monoxide pressures were less than 20 bars, lower product selectivities were observed. ***Rhodium(III) Chloride*** and $RhCl(PPh_3)_3$ can also function as catalysts for the carbonylation of chloroacetates.

(3)

Alkene Isomerization.

Exposure of 1-pentene to $HRhCl_2(PPh_3)_3$ results in isomerization of the alkene to an internal position (eq 4).[4] Presumably this reaction occurs through the addition-elimination of a rhodium hydride species. Other catalysts that exhibit comparable activity in this type of isomerization are $RhCl_3(PPh_3)_3$ and $HRuCl(PPh_3)_3$.

(4)

Hydrogenation.

$HRhCl_2(PPh_3)_3$ supported on silica can be used as a hydrogenation catalyst (eq 5).[5] In a comparison with other rhodium-based catalysts the following reactivity order emerges: $RhCl(PPh_3)_3 > H_2RhCl(PPh_3)_3 > HRhCl_2(PPh_3)_3$.

3-Chloro-1-hydroxytetrabutyldistannoxane[1]

[95970-99-3] · $C_{16}H_{37}ClO_2Sn_2$ · 3-Chloro-1-hydroxytetrabutyldistannoxane · (MW 534.40)

(mild Lewis acid catalyst for urethane formation,[3] transesterification,[4c] esterification,[4c] acetalization,[6] deacetalization,[7] and deprotection of silyl ethers[7])

Alternate Name: CHTD.

Physical Data: mp 107-115 °C.

Solubility: insol H_2O, cold MeOH; sol most organic solvents.

Preparative Methods: a mixture of dibutyltin oxide (14.9 g, 60 mmol) and dibutyltin dichloride (6.07 g, 20 mmol) in 95% ethanol (200 mL) is heated under reflux. After 6 h the transparent solution is concentrated to give a white powder. This is pulverized, then exposed to ambient atmosphere overnight. The exposure to air converts partially formed ethoxydistannoxane to the corresponding hydroxydistannoxane. Recrystallization of the crude product from hot hexane affords pure 3-chloro-1-hydroxytetrabutyldistannoxane (15.1 g, 72%).

Handling, Storage, and Precautions: is extremely stable in air and to moisture and thus can be handled and stored in the open air. Because this compound is not volatile, it is virtually nontoxic under the usual conditions.

Urethane Formation.

CHTD catalyzes the reaction between isocyanates and alcohols much more efficiently than conventional organotin catalysts, and polyurethane formation from tolylene diisocyanate and poly(oxypropylene triol) is effected by 5×10^{-4} mol of CHTD per mol of -NCO.[2] The mechanism of the catalysis has been disclosed.[3]

Transesterification.[4]

Transesterification is catalyzed by CHTD (eq 1). The reaction is quite simple: a mixture of an ester and an alcohol is heated under reflux in toluene in the presence of the catalyst. The catalyst is surprisingly active; even 0.05 mol % catalyst is effective. The reaction proceeds under almost neutral conditions, and thus various functional groups remain intact during the reaction. Notably, β-keto esters are transesterified smoothly (eq 2), and transesterification of one of the acetoxy groups in 1,*n*-diol diacetates is realized in a highly selective manner (eq 3). The unique reactivities are ascribed to the template effects of the dimeric formulation shown in (**1**).

$$RCO_2R' + R''OH \longrightarrow RCO_2R'' + R'OH \qquad (1)$$

(1)

Esterification of Carboxylic Acids.[4c,5]

The CHTD catalyst is effective not only for intermolecular esterification of carboxylic acids (eq 4) but also macrolactonization of o-hydroxy acids (eq 5). Most significantly, the distannoxane-catalyzed esterification is free from the reverse reaction (hydrolysis). Simply heating the two reactants completes the reaction without the use of a Dean-Stark apparatus. The absence of hydrolysis is a consequence of the double-layered structure of CHTD, whose hydrophobic surface butyl groups prevent the water from approaching the catalytically important core sites, i.e. the tin atoms.

$$RCO_2H + R'OH \longrightarrow RCO_2R' + H_2O \qquad (4)$$

(5)

Acetalization of Carbonyls.[6]

Exposure of carbonyls to ethylene glycol in refluxing benzene, toluene, or methanol in the presence of a catalytic amount of CHTD affords the corresponding acetals in high yields. Mild reaction conditions allow facile preparation of products that are otherwise difficult to obtain. Ketones are acetalized more slowly than aldehydes. However, addition of an equivalent amount of aldehyde accelerates the reaction dramatically. A unique transcarbonylation mechanism is responsible for this acceleration.

Deprotection of Acetals and Silyl Ethers.[7]

Acetals are converted to parent carbonyls by treating with 1 mol % of CHTD in diethylene glycol dimethyl ether or dioxane-water at 100 °C. THP ethers are deprotected when heated in methanol or THF-H_2O under catalysis by CHTD. Silyl ethers are also converted to alcohols under analogous conditions.

1-Chloro-2-iodoethane[1]

[624-70-4] · C_2H_4ClI · 1-Chloro-2-iodoethane · (MW 190.42)

(iodinating reagent for organometallic compounds[1,2] and carbanions;[3] alkylating agent[4])

Alternate Names: ethylene iodochloride; ethylene chloroiodide.

Physical Data: bp 38-40 °C/18 mmHg, 55-57 °C/37 mmHg, 140 °C/760 mmHg;[5] n_D^{25} 1.5636; *d* 2.12 g cm^{-3}.

Solubility: sol all common organic solvents; insol H_2O.

Analysis of Reagent Purity: VPC R_t 5.1 min (relative to air) on a 2 m × 6 mm 20% diethylene glycol succinate column at 125 °C;[6] NMR δ 3.7-3.4 (m, A_2B_2, CH_2I), δ 3.6-3.2 (m, A_2B_2, CH_2Cl).[6]

Preparative Methods: prepared in 76% yield by bubbling ***Ethylene*** gas into a CH_2Cl_2 solution of freshly redistilled ***Iodine Monochloride*** maintained at 30 °C by ice-cooling until the temperature begins to fall.[7] Other methods of preparation include reaction of ethylene, ***Copper(II) Chloride***, and ***Iodine*** at 75-85 °C in a pressure reactor;[6] reaction of excess 1,2-dichloroethane with ***Sodium Iodide*** in acetone[8] or with ***Aluminum Iodide*** in CS_2;[9] and by reaction of 2-iodoethanol with ***Thionyl Chloride***.[10]

Purification: material that is exposed to light and air develops a slight rose-colored tint due to the formation of I_2. It is usually suitable for use unless the color is very pronounced. The compound is purified by washing with aq thiosulfate and redistillation at reduced pressure.[7]

Handling, Storage, and Precautions: 1-chloro-2-iodoethane is a dialkylating agent and should be used only in an effective fume hood. Avoid inhalation of the vapor and contact of the liquid with the skin. The compound is light sensitive and should be stored refrigerated in the dark.

Iodinating Reagent.

1-Chloro-2-iodoethane is a selective reagent for the introduction of iodine atoms into organic molecules via carbanions or other organometallic species. It is only mildly electrophilic and can be used in the presence of many sensitive functional groups. The byproducts of the iodination reaction are ethylene and a metal chloride. In the syntheses of the

hydroquinoid fungal antibiotics Frustulosin[2] and Aurocitrin[1] the dimethoxyiodo vinyl ether was a crucial intermediate. It was readily prepared from an aryllithium which was available by direct metallation (eq 1).

(1)

In their study of planar cyclooctatetraene analogs, Cracknell and co-workers[8] investigated a number of reagents to effect iodination of the metalated biphenylene and found that ethylene iodochloride was superior to both ***Iodine*** and ***Diiodomethane*** for preparation of the iodobiphenylene (eq 2). Similarly, it was shown to be an effective reagent for synthesis of iodobenzylic chlorides (eq 3).[11]

(2)

One of the principal uses of the reagent is to trap organometallic species as the iodides which can then subsequently be used to regenerate the carbanionic intermediates by halogen-metal exchange. This was shown to be especially effective by Fuchs and co-workers in their cytochalasin model studies where halogen-metal exchange on α-iodo sulfones in the presence of acid anhydrides effected acylation with <1% formation of butyl ketones (eq 4).[3]

Alkylation Reactions.

1-Chloro-2-iodoethane tends to react by electron transfer mechanisms, which makes it an inefficient alkylating agent even with good nucleophiles. For example, even with Na_2S little or no alkylation was observed, and the products were ethylene and halide salts.[12] Similarly, treatment of anionic metal carbonyl complexes[13] resulted in dimerization (eq 5). With ***Chloroiodomethane*** these complexes alkylate normally (eq 6). This is probably a consequence of the weak C-I bond for which the activation energy for homolytic cleavage has been estimated to be as little as 30 kcal mol^{-1}.[14]

(6)

However, with extremely powerful nucleophiles, or nucleophilic atoms which are not easily oxidized, the reagent will function as a normal alkylating agent. Carboxylate salts react to form chloroethyl esters, and cyanamino-s-triazine salts are alkylated.[15] Collman has used the reagent with highly nucleophilic rhodium complexes to produce organometallic dimers linked by $-CH_2-CH_2-$ bridges (eq 7).

1-Chloro-2-iodoethylene

(*E*)

[28540-81-0] · C_2H_2ClI · 1-Chloro-2-iodoethylene · (MW 188.40) (*Z*)

[31952-74-6]

(cross-coupling reagent used as a precursor of chloroenynes, terminal, and unsymmetrical internal diynes)

Alternate Name: 1-chloro-2-iodoethene.

Physical Data: [1] (*E*), bp 113-114 °C; mp -41.0 °C, *d* 2.10 g cm^{-3}, bp of *n*-propanol azeotrope 87.5-88.5 °C. (*Z*), bp 116-117 °C; mp -36.4 °C, *d* 2.21 g cm^{-3}, bp of *n*-propanol azeotrope 93.6-94.0 °C.

Preparative Methods: 1-chloro-2-iodoethylene can be prepared by either chloromercuration of ***Acetylene***[2] followed by iodinolysis[3] or electrophilic addition of ***Iodine Monochloride*** to acetylene (eq 1).[1] The chloromercuration reaction is highly stereoselective and gives exclusively the (*E*) isomer, while the electrophilic addition of ICl has been reported to give a diastereomeric mixture (however, this reaction has also been reported to be stereoselective[4]). The (*E*)-alkenyl mercury intermediate can be isomerized[5] to an (*E*)/(*Z*) mixture by treatment with a catalytic amount of ***Dibenzoyl Peroxide*** at 100 °C in *p*-xylene. Its iodinolysis gives an (*E*) and (*Z*) mixture of 1-chloro-2-iodoethylenes.

Purification: stereoisomerically pure (*Z*)-1-chloro-2-iodoethylene can be obtained by azeotropic fractional distillation of stereoisomeric mixtures with *n*-propanol. Stereoisomerically pure samples can be isomerized to give a mixture of (*Z*) and (*E*) isomers upon long exposure to sunlight and should be stored accordingly.

Handling, Storage, and Precautions: use in a fume hood.

Cross-Coupling Reactions.

1-Chloro-2-iodoethylene can readily participate in selective mono-cross-coupling reactions because of the difference in reactivity between the two carbon-halogen bonds. Cross-coupling with alkylmercurials[6] is nonstereospecific because of its radical nature, and leads to a mixture of diastereomers in most cases. On the other hand, Pd-catalyzed cross-coupling[7] with alkynylzincs yields stereospecifically the corresponding (*E*)-chloroenynes (**1**) in good yields (eq 2).[4]

It is worth noting that the (*Z*)- or (*E*)-chloroenynes, e.g. (**1**) or (**2**), can also be stereospecifically prepared by Pd/Cu-catalyzed cross-coupling of alkynes with (*Z*)- or (*E*)-***1,2-Dichloroethylene*** (eq 3).[8] On the other hand, the corresponding reaction with 1,2-dibromoethylene gives a mixture of mono- and dialkynylated products.[9]

The chloroenynes (**1**) and (**2**) can readily participate in further cross-coupling reactions, and this methodology has been applied to the synthesis of a variety of natural products[10] and oligomeric unsaturated compounds.[11] Dehydrohalogenation

of the chloroenynes (**1**) with ***Sodium Amide*** in liquid ammonia can lead to 1-sodio-1,3-diynes which, in turn, can be further transformed into terminal and symmetrical or unsymmetrical internal diynes (eq 4).[4]

Related Reagents.

(E)-1-Bromo-2-phenylthioethylene; ***1,2-Dichloroethylene***.

Chloroiodomethane[1]

$ClCH_2I$

[593-71-5] · CH_2ClI · Chloroiodomethane · (MW 176.38)

(chloromethylating agent for organozinc,[2] -lithium,[3] -phosphorus,[4] and -transition metal compounds,[5] and alkenes;[6] can generate *N*,*N*-dimethylmethyleneiminium iodide (Eschenmoser's salt) by reaction with *N*,*N*,*N´*,*N´*-tetramethylmethylenediamine[7])

Alternate Name: CIM.

Physical Data: bp 108-109 °C; *d*204 2.42 g cm^{-3}; *n*20D 1.582.

Solubility: sol ethers, acetone, polyhalomethanes, and benzene.

Form Supplied in: pale yellow oil; commercially available or readily preparable via halogen exchange of dichloromethane with iodide sources.[1,8]

Analysis of Reagent Purity: NMR (CCl_4/TMS), δ (ppm) 5.00.

Handling, Storage, and Precautions: should be stored over tin or silver wire in the dark.

Cyclopropanation of Alkenes.

The ***Diethylzinc***/chloroiodomethane (CIM) reagent system is a valuable alternative to Furukawa's version of the Simmons-Smith cyclopropanation reaction (eq 1).[2,9] The formation of the (chloromethyl)zinc species seems to proceed via a radical chain mechanism, considering the accelerating effect of oxygen and the retarding effect of radically polymerizable alkenes.[2] The samarium carbenoid generated from Sm(Hg) and CIM cyclopropanates allylic alcohols with high regio- and stereoselectivity via the directing effect of the hydroxyl function (eq 2).[10] Generally, CIM affords better results in these carbenoid reactions than ***Diiodomethane***.

Generation and in situ Trapping of Chloromethyllithium.

The extreme thermal instability of ***Chloromethyllithium***[11] severely limits its synthetic applicability. A method has been devised to generate and trap (chloromethyl)lithium by reacting CIM with an alkyllithium in the presence of a substrate.[3a,12] Addition of ***n-Butyllithium*** to a mixture of a boronic ester and CIM in THF at low temperature yields the methylene insertion product with retention of the configuration of the alkyl moiety (eq 3).[3] Aldehydes and ketones can also capture the in situ generated carbanion species in THF at -78 °C.[12] The initial chloromethyl adducts are amenable to further reactions depending on the substrates and reaction conditions applied,[12,13] e.g. delayed hydrolytic workup yields the epoxides (eq 4).[12] The chlorohydrin products can be lithiated in situ to the β-oxidoalkyllithiums for further transformations (e.g. eq 5).[14]

(4)

(5)

Wittig Chloromethylenation.

Treatment of ***Triphenylphosphine*** with CIM in THF at reflux forms the phosphonium iodide (**1**) in good yield, which in turn is transformed to the corresponding ylide by treatment with ***Potassium t-Butoxide*** and hence can chloromethylenate aldehydes and ketones (eq 6).[4,15]

(6)

The Mannich Reaction.

The dimethylaminomethylation of carbonyl compounds is conveniently carried out via the enol trimethylsilyl ethers by a combination of CIM and *N,N,N´,N´*-tetramethylmethylenediamine (TMMD; ***Bis(dimethylamino)methane***) in

DMSO at ambient temperature (eq 7).[7] The reagent system CIM/TMMD also provides a convenient route to Eschenmoser's salt (**2**) (***Dimethyl(methylene)ammonium Iodide***) (eq 8).[7]

(7)

Chloroiodomethane-Zinc/Copper Couple

$ClCH_2I$-Zn(Cu)

($ClCH_2I$)

[593-71-5] · CH_2ClI · Chloroiodomethane-Zinc/Copper Couple · (MW 176.38) (Zn(Cu))

[12019-27-1] · Zn · Chloroiodomethane-Zinc/Copper Couple · (MW 65.39)

(used in the preparation of cyclopropanes[1], and alkenes from aldehydes[2])

Physical Data: $ClCH_2I$: bp 108-109 °C; *d* 2.422 g cm^{-3}. Zn(Cu): mp >400 °C; *d* ca. 7.14 g cm^{-3}.

Solubility: $ClCH_2I$: sol organic solvents; insol H_2O. Zn(Cu): insol organic solvents and H_2O.

Form Supplied in: $ClCH_2I$: colorless to brown liquid. Zn(Cu): reddish-brown or dark gray powder; often prepared directly before use.

Preparative Method: see ***Zinc/Copper Couple***.

Purification: chloroiodomethane can be purified by distillation.

Handling, Storage, and Precautions: chloroiodomethane is light sensitive and should be stored in the dark. It can be stabilized with copper wire. Zinc-copper couple deteriorates in moist air and should be stored under nitrogen. Very active zinc-copper couple is oxygen sensitive. It evolves hydrogen on contact with strong aqueous acids.

Chloroiodomethane reacts with zinc-copper couple to give chloromethylzinc iodide that will rearrange to iodomethylzinc chloride in ethereal solvents (eq 1).[3] The Schlenk equilibria favors the bis(halomethyl)zinc-ZnX_2, so the active species in solution are bis(chloromethyl)zinc-ZnI_2 (**1**), or bis(iodomethyl)zinc-$ZnCl_2$ (**2**). Except for the identity of the zinc salt, (**2**) is the same product formed from zinc-copper couple and diiodomethane, and its reactions parallel those of the Simmons-Smith reagent.[4]

Chloroiodomethane and zinc-copper couple cyclopropanate alkenes and convert aldehydes to terminal alkenes (eq 2).[2] Chloroiodomethane works better than the other dihalomethanes, giving styrene in 80% yield compared to 72% with ***Diiodomethane***

Chloroiodomethane and zinc-copper couple have not been used widely for cyclopropanation, but chloroiodomethane and diethylzinc have been used to generate $ClCH_2ZnEt$. This reagent was first prepared by Miyano[1] for cyclopropanations, and was reported to be superior to the Furukawa[5] reagent generated from diiodomethane and diethylzinc. Denmark found that *cis*-cyclodecene cyclopropanated in 94% (GC yield) using chloroiodomethane compared to 12% (GC yield) using diiodomethane under the same conditions (eq 3).[6] Miyano found that oxygen accelerated these reactions and proposed a radical mechanism for the formation of the chloromethylzinc intermediate, but Denmark found that the reagent prepared in 1,2-dichloroethane gave comparable results without oxygen.

Related Reagents.

Chloromagnesium Dimethylcuprate[1]

$Me_2CuMgCl$

[67234-12-2] · $C_2H_6ClCuMg$ · Chloromagnesium Dimethylcuprate · (MW 153.39) (Me_2Cu^-)

[47942-29-0] · C_2H_6Cu · Chloromagnesium Dimethylcuprate · (MW 93.63) ($MgCl^+$)

[32195-53-2] · ClMg · Chloromagnesium Dimethylcuprate · (MW 59.76)

(methyl transfer reagent in conjugate additions)

Alternate Name: dimethylcoppermagnesium chloride.

Physical Data: prepared in situ.

Preparative Methods: methylmagnesium chloride (1 equiv) in THF is added dropwise to a rapidly stirred slurry of ***Copper(I) Iodide*** iodide (0.5 equiv) in anhydrous THF at -78 °C, and the resultant mixture is stirred at -78 °C for 15 min.[2] In a similar way, the reagent is generated using 0.5 equiv $LiCuBr_2$[3] (15 min, -60 °C) or ***Copper(I) Bromide***.[4]

Handling, Storage, and Precautions: the reagent must be generated and used immediately in the absence of moisture and oxygen. Handle in a fume hood.

Chloromagnesium dimethylcuprate seems to be a forgotten brother of its bromo analog. A few studies show some superior qualities in conjugate additions. In reaction with α,β-unsaturated aldehydes the reagent gives 1,4-adducts almost exclusively (eq 1);[4] it reacts readily at low temperature in a stereoselective manner with 2-alkyne nitriles without the need for a large excess of the reagent (eq 2).[5]

Chloromethane[1]

CH_3Cl

[74-87-3] · CH_3Cl · Chloromethane · (MW 94.95)

(methylating agent attacking C-, O-, N-, P-, S-, Se-, and Te-based nucleophiles; organometallic derivatives provide source of $Me^{\delta-}$ in reactions with >C=O, M-X, halogen, etc., and also as a base towards C-H; radical substitution of Me by C&bdot;, halogen, etc.)

Alternate Name: methyl chloride.

Physical Data: mp -97.7 °C; bp -24.22 °C; *d* 0.991 g cm^{-3} (-25 °C).

Solubility: miscible with most organic solvents, sparingly with aqueous media.

Form Supplied in: colorless gas.

Purification: gas passed through conc. H_2SO_4 then water, and dried with P_2O_5 and fractionally distilled.

Handling, Storage, and Precautions: usually available in cylinders. Potent alkylating agent; high toxicity. Use in a fume hood.

Methylating Agent.[2]

Nucleophilic displacement occurs readily at carbon (eq 1), often via anions as in the methylation of lithio-rhenocene ($LiReCp_2$)[3a] and the more classical methylation of acetoacetic, malonic, and cyanoacetic esters,[3] or in the alkylation of cyclopentadiene, or the α-attack of aliphatic ketones.[4] The Friedel-Crafts reaction with benzene may be modified to provide any or all of the possible polymethylbenzenes, as in the preparation of 1,2,4,5-tetramethylbenzene.[5] A range of Lewis acid catalysts have been applied[6a,6b] and the use of boron triflate exemplifies the introduction of more novel catalysts.[6c,6d] Methyl cyanate may be obtained from metal cyanates (MeCl, xylene-*N*,*N*-dialkylamide mixtures)[7] and dimethyl carbonate similarly from K_2CO_3 (phase-transfer catalysts; dipolar aprotic solvent).[8]

$$MeCl + X^- \longrightarrow MeX + Cl^- \qquad (1)$$

The carbonylation of MeCl leading to ***Acetyl Chloride*** is achieved in the presence of superacids or metal catalysts (eq 2).[9] Correspondingly, metal sulfites are advocated[10] as routes to ***Methanesulfonic Acid*** (eq 3). *N*-Methylation, either to

give more fully alkylated amines or to give quaternary ammonium salts, has been widely reported (eq 4).

$$MeCl + CO \longrightarrow MeCOCl \quad (2)$$

$$MeCl + SO_3^{2-} \longrightarrow MeSO_3^- + Cl^- \quad (3)$$

$$RNH_2 \longrightarrow RNHMe \longrightarrow RNMe_2 \longrightarrow RNMe_3^+ \quad (4)$$

In cases where the substrate is very susceptible to electrophilic attack, both methylation and formylation are observed when such reactions are carried out in DMF. The analogous reaction with phosphorus (R_3P, $(RO)_3P$) provides phosphonium salts, the deprotonation of which leads to synthetically useful phosphonium ylides (eq 5).

$$(RCH_2)_3P + MeCl \longrightarrow [(RCH_2)_3PMe]^+ Cl^- \longrightarrow [(RCH_2)_2PMe]^+ [CHR]^- \quad (5)$$

Reductive methylation is observed when Cl or another displaced group is removed by single-electron transfer to give Cl^- and, effectively, Me&bdot;. An example is the formation of Me_2SO_2 by the electrochemical reduction of MeCl in dipolar aprotic solvents containing SO_2.[11] Nucleophilic oxygen (e.g. OH^-, OR^-, RCO_2^-) and sulfur (e.g. S^{2-}, HS^-, RS^-, SCN^-, $S_2O_3^{2-}$, RSO_2^-, thiourea) are similarly methylated, while Te and Se show analogous chemistry. Halide ion exchange reactions (including N_3^-) are valuable routes between the various methyl halides and also allow the synthesis of labelled RCl (e.g. $Me^{36}Cl$).

Asymmetric methylation is achieved using chiral phase-transfer catalysts (e.g. *N*-benzylcinchoninium salts), as in the attack at C-2 of 2-phenyl-5-methoxy-6,7-dichloroindanone.[12]

Organometallics.

Methylmagnesium chloride (MeCl, Mg, Et_2O under dry, O_2-free conditions) provides a nucleophile capable of reacting with (i) metal halides in a transmetalation reaction, (ii) proton sources, including alcohols, phenols, amines, imines, and amides, (iii) electrophilic carbon, as in aldehydes, ketones, carboxylic acid derivatives, nitriles, and epoxides, and (iv) elements such as O_2, S_8, I_2, interhalogens such as CNCl, and species such as CO_2 and SO_2. While Grignard reactions give alcohols with many carboxylic acid derivatives, the reaction with RCOCl (eq 6) may be used to form methyl ketones in good yield (63-92%) by the presence of ***Tris(acetylacetonato)iron(III)*** (THF, rt).[13] Such a process replaces the older techniques which used $FeCl_3$, or the formation of organozinc or -cadmium intermediates.

$$MeCl + Mg \longrightarrow MeMgCl \xrightarrow{RCOCl} MeCOR + MgCl_2 \quad (6)$$

Substitution in the Alkyl Group.

Hydrogen abstraction provides a carbon-based radical which leads to substituted derivatives. Thus further chlorination of MeCl leads to CH_2Cl_2, $CHCl_3$, and CCl_4 (eq 7); fluorination of MeCl proceeds similarly.[14] Hydrogen isotope exchange may also be achieved in this way.

$$\mathrm{MeCl} + \mathrm{X_2} \longrightarrow \mathrm{H_2CXCl} + \mathrm{HX} \longrightarrow \mathrm{CHX_2Cl} \longrightarrow \mathrm{CX_3Cl} \qquad (7)$$

$$\mathrm{X = Cl, F}$$

4-(Chloromethyl)-3,5-dimethylisoxazole[1]

[19788-37-5] · C_6H_8ClNO · 4-(Chloromethyl)-3,5-dimethylisoxazole · (MW 145.59)

(annulation reagent used for the construction of cyclohexenones in the syntheses of steroids, terpenes, and alkaloids[2])

Physical Data: bp 87-88 °C/8 mmHg; *d* 1.173 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: liquid (97-98 + % pure).

Handling, Storage, and Precautions: light-sensitive lachrymator; refrigerate; handle and store under nitrogen.

The primary use for this reagent is in the isoxazole annulation.[2a,b] This procedure is related to the Robinson annulation.[1b] The method involves alkylation of a ketone, an α,β-unsaturated ketone, or an enamine with a latent 3-ketoalkyl synthon (eq 1).[2b]

(1)

In Stork's original procedure, catalytic hydrogenation of the isoxazole unmasks the appended β-amino enone, which then cyclizes to a vinylogous carbinolamide. Subsequent methanolysis and hydrolysis furnishes a 1,5-diketone which cyclizes to a cyclohexenone (eq 2).

A limitation of the original Stork procedure involves the instability of the intermediate vinylogous carbinolamides. These intermediates may undergo dehydration to the corresponding dihydropyridines. These are sensitive intermediates which readily air-oxidize to β-acylpyridines. Based on this potential side-reaction, Stork reported a method for the synthesis of β-acylpyridines from intermediate carbinolamides (eq 3).[3]

Scott, Banner, and Saucy have reported a modification of the original Stork procedure that moderately improves the overall yield of enone.[2f] The modification involves acetalization of the ketone prior to hydrogenation of the isoxazole, thus suppressing formation of the delicate vinylogous carbinolamides. Subsequent hydrogenation of the isoxazole provides a stable enamide which is directly converted to the corresponding 3-keto alkyl intermediate and cyclized to the desired enone in overall yields of about 65%.

An asymmetric isoxazole annulation for the formation of a chiral quaternary carbon has been reported.[2e] Alkylation of a diastereomeric pair of imines with 4-(chloromethyl)-3,5-dimethylisoxazole under appropriate conditions proceeded with diastereoselectivity, providing the corresponding isoxazolyl aldehyde in 70% ee. Unmasking of the keto functionality and subsequent cyclization provided the corresponding optically active cyclohexenone (eq 4).

An alternative method for the reductive cleavage of isoxazoles using ***Samarium(II) Iodide*** has been reported and applied to the Stork isoxazole annulation.[4] Importantly, even delicate acetals survive the reduction, and subsequent cyclization efficiently furnishes the cyclohexenone in 78% overall yield (eq 5). The SmI_2 modification significantly enhances the yields of the enone obtained.

The Stork isoxazole annulation has been applied to the synthesis of steroids such as (±)-D-homotestosterone, (±)-progesterone, and $\Delta^{9(11)}$-dehydrotestosterone.[5,6] It has also been applied to the synthesis of substituted hydroazulenes, a ring system characteristic of the pseudoguaianolide family of sesquiterpenes.[7]

Recently, 4-(chloromethyl)-3,5-dimethylisoxazole has been transformed into a nucleophilic mercaptomethylisoxazole (eq 6). The mercaptomethylisoxazole has been used to open epoxides.[8]

Chloromethyldiphenylphosphine Oxide

[89302-51-2] · $C_{13}H_{12}ClOP$ · Chloromethyldiphenylphosphine Oxide · (MW 250.66)

(useful reagent in the synthesis of phosphinylacetaldehydes which are stereoselectively transformed into 3,3-disubstituted allylic alcohols[5])

Solubility: sol THF.

Preparative Methods: chlorination of $Ph_2P(O)CH_2OH$[1] with ***Phosphorus(V) Chloride/Calcium Carbonate***[2] or reaction of ***Diphenylphosphinic Chloride/Aluminum Chloride*** with 1-1.1 mol % ***Paraformaldehyde*** and ***Hydrogen Chloride*** at 120-150 °C.[3] Reaction of $Ph_2P(O)SiMe_3$ with R^1CH_2Cl gives yields of 50-95%[4]

3,3-Disubstituted Allylic Alcohols via Phosphinoylacetaldehydes.

Condensation of chloromethyldiphenylphosphine oxide with ketones and subsequent treatment of the resultant epoxides (**1**) with ***Boron Trifluoride Etherate*** provides α,α-disubstituted (diphenylphosphinyl)acetaldehydes (**2**) (eq 1).

3,3-Disubstituted allylic alcohols are obtained from (**2**) via a vanadium(II)-mediated intermolecular pinacol cross-coupling[5] followed by Horner-Wittig elimination,[6] as shown in eq 2. The diols (**3**) are obtained stereoselectively through the chelation controlled pinacol coupling with *threo*/*erythro* ratios of 7.5-99:1.

This methodology provides a general stereoselective route to allylic alcohols which are important synthetic intermediates[7] as well as constituents in many natural products.[8] Alternative phosphorus-based methods involving alkenation of ketones generally lack stereospecificity, especially when the two substituents are similar in size.[9]

Alternatives to phosphorus methods are the stereospecific carbometalation of terminal alkynes,[10] and the reaction of alkynic esters with cuprates and subsequent reduction or addition to the ester.[11] Both methods are limited by the organometallic reagents.

1-(Chloromethyl)-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane Bis(tetrafluoroborate)

[140681-55-6] · $C_7H_{14}B_2ClF_9N_2$ · 1-(Chloromethyl)-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane Bis(tetrafluoroborate) · (MW 354.26)

(easily handled, cost-effective, site-selective electrophilic fluorinating agent applicable to a wide variety of organic substrates possessing overt or masked carbanionic character[1-4])

Alternate Names: F-TEDA-BF_4; Selectfluor™.

Physical Data: apparent mp 190 °C (thermal behavior is complicated; exothermic decomposition can occur at temperatures >80 °C); *d* 1.731 g cm^{-3}.

Solubility: v sol cold H_2O (176 g L^{-1} at 20 °C), dil HCl (decomposed by dil NaOH); sol MeCN; sl sol MeOH, EtOH, Me_2CO; sol DMF (reacts slowly on heating), pyridine (reacts), and DMSO (reacts rapidly and exothermically).

Form Supplied in: free-flowing, virtually nonhygroscopic, white solid. Available commercially.

Analysis of Reagent Purity: NMR (^1H, ^{19}F; soln. in D_2O);[1] iodimetric titration [acidified (HCl) soln. in H_2O-Me_2CO (1:1) + excess KI; I_2 determined with thiosulfate/starch (1 I_2 &ident; 1 ^+NF)]. Note that the reagent (known as F-TEDA-BF_4;[3] TEDA = triethylenediamine) oxidizes aqueous bromide ion to bromine at rt but not chloride to chlorine.[5]

Handling, Storage, and Precautions: store below 38 °C (lower temperatures are advisable for bulk storage); use in solution or suspension; do not heat the solid reagent above 80 °C. Take standard precautions to avoid breathing dust or vapors (evolved during reaction), contact with eyes or skin (dust or its solutions), and contamination of clothing. F-TEDA-BF_4 is moderately toxic (male rat oral LD_{50} 640 mg kg^{-1}; female rat 350-500 mg kg^{-1}), and is an irritant to the eye and respiratory system. Always use approved dust mask (or respirator), gloves, and safety glasses when handling the solid. Carry out solubility tests on a sensible scale when seeking alternative solvents (note the problem with DMSO referred to above). An MSDS (Material Safety Data Sheet) and further information is available from Air Products and Chemicals, Inc., Speciality

Gases Dept., 7201 Hamilton Boulevard, Allentown, PA 18195-1501, USA.

Fluorination of Stabilized Carbanions.

Highly stabilized carbanions [e.g. alkali metal salts of substituted malonates (eq 1), phosphonates (eq 2)] react rapidly and efficiently with this reagent.[2-4] Only low yields (<20%) of α-fluoro ketones can be obtained from highly reactive ketone-derived metal enolates; this drawback can be overcome by using enol acetate or silyl enol ether derivatives of ketones as substrates (see below).[3]

(1)

(2)

Fluorination of Enols, Enol Acetates, Silyl Enol Ethers, and Enamines.

Numerous enolizable substrates of the 1,3-dicarbonyl class ($RCOCH_2COR'$) have been monofluorinated efficiently under mild conditions with an equimolar proportion of F-TEDA-BF_4 (e.g. eqs 3-6); difluorination can be achieved (e.g. eq 6; yields here estimated by NMR), but efficient introduction of the second fluorine may require a two-step procedure (depending on the equilibrium enol content of the monofluoride) (eq 7).[4]

(3)

F-TEDA-BF4
MeCN, rt, 5 h
84%

(4)

F-TEDA-BF4
MeCN, rt, 3 h
87%

(5)

F-TEDA-BF4
MeCN, rt, 54 h

87%
4%

(6)

F-TEDA-BF_4 is highly effective for introducing fluorine selectively at positions 6 or 16 in steroids via attack on enol acetate or silyl enol ether derivatives.[2,3] High yields of 16-fluoro targets can be achieved with excellent stereoselectivity (e.g. eq 8). Fluorination at position 6 (e.g. eq 9) proceeds cleanly and more rapidly (typically, reactions are complete within 15 min at rt in MeCN).

(8)

(9)

Fluorination of the prototypical enamine 1-morpholinocyclohex-1-ene with a suspension of the 1,1,1-trifluoroethyl analog of F-TEDA-BF_4, $CF_3CH_2{+}N(CH_2CH_2)_3{+}NF\ (CF_3SO_3^-)_2$,[1] in CH_2Cl_2 at 20 °C gives 2-fluorocyclohexanone in 81% yield.[2] [Note that within the *Selectfluor* range of 1-alkyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane salts, ease of F^+ transfer increases as the electronegativity of the 1-alkyl group increases (CF_3CH_2 > CH_2Cl > CH_3).[1]] Fluorination of enamines of Δ^4- or $\Delta^{1,4}$-3-keto steroids with F-TEDA-BF_4 is said to produce a mixture of 4-fluoro and 6-fluoro products.[3]

Fluorination of Alkenes.

Alkenes capable of producing highly stabilized carbocations through notional addition of F^+ (e.g. styrene, α-methylstyrene, *trans*-stilbene, 1-phenylcyclohexene) react smoothly with F-TEDA-BF_4 at room temperature in the presence of weak nucleophiles (e.g. H_2O, MeOH, AcOH, HF-pyridine) (e.g. eq 10).[3]

(10)

Nu = F, OMe, OAc, OH *erythro*:*threo* = 60-72:40-28

Fluorination of Aromatic Compounds.

Benzene resists attack by F-TEDA-BF_4 under normal conditions. The introduction of electron-releasing (+*I*, +*M*) ring substituents facilitates fluorination (e.g. eqs 11-13).[1,2,3,6]

(11)

(12)

(13)

Organosulfur Compounds.

The first step in the sequence $RSCH_2R^1$ -> $R+S(F)CH_2R^1$ -> $RSCHFR^1$ -> $RS(O)_xCHFR'$ (x = 1, 2) can be effected smoothly with F-TEDA-BF_4, the Pummerer-like rearrangement of the fluorosulfonium salt (not isolated) being effected with a nitrogenous base (***Triethylamine*** or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***) (e.g. eqs 14-16).[3]

(14)

(15)

(16)

Fluorination of Carbon-Metal Bonds.

Grignard reagents react slowly with suspensions of F-TEDA-BF_4 in dry diethyl ether or THF at rt to provide the corresponding monofluorides (eqs 17 and 18).[3]

$$n\text{-}C_{12}H_{25}MgBr \xrightarrow[\text{Et}_2\text{O, rt}]{\text{F-TEDA-BF}_4} n\text{-}C_{12}H_{25}F \qquad (17)$$

58%

$$\text{PhMgBr} \xrightarrow[\text{Et}_2\text{O, rt}]{\text{F-TEDA-BF}_4} \text{PhF} \qquad (18)$$

61%

The availability of F-TEDA-BF_4 has at last made possible the synthesis of 5-fluorocyclopentadiene, the fugitive nature of which requires it to be trapped in situ (eq 19).[7] Treatment of ***Thallium(I) Cyclopentadienide*** with positive halogen sources such as NBS and NCS is a known route to other 5-halogenocyclopentadienes.

(19)

Electrophilic fluorination of vinylstannanes with F-TEDA-BF_4 provides easy access to fluoroalkenes carrying a variety of functional groups (e.g. eqs 20 and 21).[8]

(20)

(21)

Fluorination of Quinuclidine.

Quantitative transfer of F^+ occurs from F-TEDA-BF_4 to quinuclidine at rt in acetonitrile (eq 22).[9] This method provides easy access to *N*-fluoroquinuclidinium tetrafluoroborate (NFQNBF_4), one of a family of *N*-fluoroammonium salts (fluoride,[10] triflate,[11] tetrafluoroborate,[11] perfluoroalkanecarboxylate[11]) originally developed in response to worldwide demand for more generally acceptable (less aggressive, nonexplosive, less toxic, inexpensive) site-selective electrophilic fluorinating agents than ***Perchloryl Fluoride***, O-F reagents (e.g. ***Trifluoromethyl Hypofluorite***, ***Cesium Fluoroxysulfate***), ***Xenon(II) Fluoride***, and ***Fluorine*** itself.[12]

(22)

F-TEDA salts arose out of research aimed at the development of a similar yet more powerful family of *N*-fluoroammonium salts than NFQN salts; tunable fluorinating ability and considerably greater commercial prospects were also targets. [Fluorinating power can be adjusted via the electronegativity of the quaternizing alkyl group (see earlier).[2]] In-house synthesis of both NFQN and F-TEDA salts is an unwelcome prospect in many laboratories since fluorine is required;[1,10,11] the commercial availability of F-TEDA-BF_4 has resolved this major problem, making possible renewed interest in NFQN salts.

At present, not enough information is available to provide a proper appraisal of advantages to be gained by using an NFQN salt rather than its F-TEDA analog; given the current relative costs and availability of quinuclidine and TEDA, F-TEDA-BF_4 will normally be preferred. Limited data indicate that highly basic carbanions give better yields of C-F products with NFQN salts than with F-TEDA salts.

Some Comparisons.

Electrochemical measurements (reduction potentials),[5] supported by practical experience, indicate the following order of fluorinating power for *N*-fluoro reagents: $(CF_3SO_2)_2NF$, $ClCH_2{+}N(CH_2CH_2)_3{+}NF$ $(BF_4^-)_2$ (*F-TEDA-BF$_4$*; A), $Me{+}N(CH_2CH_2)_3{+}NF$ $(TfO^-)_2$, $HC(CH_2CH_2)_3{+}NF$ TfO^-, pyF^+ TfO^- (A), $(PhSO_2)_2NF$ (A), *p*-$MeC_6H_4SO_2NFMe$ (A) ($TfO^- = CF_3SO_3^-$; A = available commercially). The electrophilic fluorination power of F-TEDA-BF_4 falls not far short of that of the powerful so-called DesMarteau N-F reagent,[13] *N*-fluoro[bis(trifluoromethyl)sulfonyl]imide, $(CF_3SO_2)_2NF$, the only liquid in this group (bp 90-91 °C). This reagent is not available commercially, and its preparation entails a costly multistep synthesis terminating in a direct fluorination procedure [$(CF_3SO_2)_2NH + F_2$ -> $(CF_3SO_2)_2NF + HF$] requiring considerable expertise and special equipment.[14] Not all power-variable Meinert-Umemoto[15] *N*-fluoropyridinium salts (e.g. ***N-Fluoropyridinium Triflate***) are available commercially, and sensitivity to attack by moisture or bases can be a drawback.[16] *N*-Fluorobenzenesulfonimide, $(PhSO_2)_2NF$ (Differding's reagent),[17] and *N*-fluoro-*N*-alkylarenesulfonamides (Barnette reagents),[18] developed for the fluorination of carbanions, seem too unreactive to be viewed as general-purpose reagents.

Overall, F-TEDA-BF_4 is probably the best general-purpose electrophilic fluorinating agent available at the time of writing: it fluorinates a wide variety of electron-rich carbon centers rapidly under mild conditions with high efficiency and selectivity, and no special apparatus or handling techniques are required. Soluble in a number of useful reaction solvents (including aqueous systems), F-TEDA-BF_4 is compatible with common reactor materials and offers the additional advantage of being degradable into manageable waste products.[19] A most welcome alternative to the use of highly toxic and potentially explosive electrophilic fluorinating agents such as F_2, $FClO_3$, and CF_3OF, F-TEDA-BF_4 was already in commercial use just four years after its design and synthesis by Banks and Sharif.[2,19]

(Chloromethyl)isopropoxydimethylsilane

[18171-11-4] · $C_6H_{15}ClOSi$ · (Chloromethyl)isopropoxydimethylsilane · (MW 166.73)

(the Grignard reagent is a nucleophilic hydroxymethylating agent for aldehydes, ketones, epoxides, organic halides, and sulfoximines)

Physical Data: bp 64-66 °C/54 mmHg; *n*20D 1.4160; *d* 0.926 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: neat liquid.

Handling, Storage, and Precautions: moisture sensitive, but no special precautions are necessary for handling in the air for a short period of time. May be stored under nitrogen in a tightly capped bottle in a refrigerator.

The Grignard Reagent.[1,2]

The Grignard reagent, (*i*-PrO)Me_2SiCH_2MgCl, is readily prepared from (*i*-PrO)Me_2SiCH_2Cl by the reaction with ***Magnesium*** activated with ***1,2-Dibromoethane*** in THF in greater than 90% yield. It is sufficiently stable to be stored at room temperature for at least two days with little decrease in activity. The reagent is a versatile nucleophilic hydroxymethyl anion equivalent, in combination with ***Hydrogen Peroxide*** oxidation of the silicon-carbon bond (see also the diisopropoxy counterpart, ***(Diisopropoxymethylsilyl)methylmagnesium Chloride***) (eq 1).[3] The primary products, (*i*-PrO)Me_2SiCH_2E, are stable to weakly basic and acidic aqueous workup and silica gel chromatography. **Caution**: transition metal catalysts such as copper, nickel, and palladium, if used for any reactions with this reagent, should be removed prior to the subsequent oxidation, otherwise vigorous decomposition of hydrogen peroxide may occur.

$$(i\text{-PrO})Me_2SiCH_2MgCl + E^+ \longrightarrow (i\text{-PrO})Me_2SiCH_2E \xrightarrow{H_2O_2,\ F^-,\ \text{base}} HOCH_2E \quad (1)$$

The nucleophilic hydroxymethylation is applicable to aldehydes, including α,β-unsaturated aldehydes (eq 2)[4] and protected sugar derivatives (eq 3),[5] and ketones (eqs 4 and 5).[1,6] Following H_2O_2 oxidation, the corresponding 1,2-diols are obtained in high overall yields. It should be noted that the β-hydroxysilanes do not undergo β-elimination (Peterson alkenation) even under oxidation conditions which contain fluoride ion (eq 4).[1] A highly stereoselective hydroxymethylation of α-hydroxy ketones is also noted (eq 5).[6]

(2)

(3)

Epoxides are converted into 1,3-diols by a sequence involving copper-catalyzed Grignard addition, followed by oxidation of the five-membered cyclic alkoxysilane intermediates (eq 6).[7] Similarly, primary alcohols are homologated via the tosylates (eq 7).[7] Allylic halides are hydroxymethylated without isomerization or migration of the double bond (eq 8).[8] Alkenyl sulfoximines are also hydroxymethylated with retention of the alkene geometry, via nickel-catalyzed cross-coupling with the corresponding diorganozinc reagent in the presence of ***Magnesium Bromide*** as a co-catalyst, followed by oxidation (eq 9).[9]

Chloromethyllithium[1]

$ClCH_2Li$

[18645-12-0] · CH_2ClLi · Chloromethyllithium · (MW 56.42)

(converts aldehydes or ketones to chlorohydrins or oxiranes;[2-6] $R^1CO_2R^2$ to $RCOCH_2Cl$;[2] $B(OR)_3$ to $ClCH_2B(OR)_2$;[1,7] RBY_2 to RCH_2BY_2;[7-9] $ClSiR_3$ to $ClCH_2SiR_3$[10])

Physical Data: stable at -108 °C in the presence of LiBr; unstable at higher temperatures; unstable even at -130 °C in the absence of LiBr.[11]

Preparative Methods: preferably by addition of ***Methyllithium/Lithium Bromide*** or ***n-Butyllithium*** solution dropwise to a vigorously stirred solution of ***Chloroiodomethane*** and the substrate in THF cooled with a dry ice-acetone bath;[3,4] inexpensive $ClCH_2Br$ in place of $ClCH_2I$ is almost as efficient;[6,8] an alternative is ***Lithium*** wire, $ClCH_2Br$, and substrate in THF with sonication.[5]

Handling, Storage, and Precautions: see ***n-Butyllithium***; ***Chloroiodomethane***. The reagent must be generated under an inert atmosphere of nitrogen or argon.

Chlorohydrins.

O-Lithio chlorohydrins are the initial products of the reaction of $ClCH_2Li$ with carbonyl compounds.[2-6] If the reaction mixture is acidified promptly, before oxirane formation occurs, chlorohydrins can be isolated. The small body of literature data suggests that the most efficient and convenient procedure is the addition of an ether solution of methyllithium/lithium bromide to an equimolar mixture of chloroiodomethane and the carbonyl compound in THF at -78 °C (eq 1).[4] Although BuI can be less convenient than the more volatile MeI to separate, BuLi is otherwise a satisfactory alternative to MeLi and yielded 97% of isolated chlorohydrin from cinnamaldehyde.[4] Phenylacetaldehyde with its strongly acidic α-protons provided a severe test of generality and yielded 65% of chlorohydrin (eq 2).[4]

Sonication of benzaldehyde with lithium metal wire and $ClCH_2Br$ in THF at -50 °C has yielded 90% of the chlorohydrin (same transformation as eq 1).[5]

Although there is ordinarily no need to prepare the $ClCH_2Li$ in advance of adding the carbonyl reagent,[4] older chlorohydrin preparations were done with preformed $ClCH_2Li$ (eq 3).[2,3]

Preformed $ClCH_2Li$ has converted ethyl benzoate, $PhCO_2Et$, to chloroacetophenone, $PhCOCH_2Cl$ (61%).[2]

The reaction of BuLi with $ClCH_2Br$, as well as that of MeLi with $ClCH_2I$, in the presence of ketones has been used to produce *O*-lithio chlorohydrins, which were then lithiated and further transformed as described in the subsection β-

lithio lithium alkoxides below.[6]

Oxiranes.

If a solution of *O*-lithio chlorohydrin initially formed from $ClCH_2Li$ and a carbonyl compound is allowed to stand at rt for a sufficient time, generally a few hours, ring closure to the oxirane results.[2-6] These reactions are especially clean and nearly quantitative when $ClCH_2Li$ is generated from $ClCH_2I$ and MeLi/LiBr or BuLi in the presence of the carbonyl substrate in THF cooled with a dry ice-acetone bath (eqs 4-6).[4]

Sonication of acetophenone, $ClCH_2Br$, and lithium metal wire in THF has yielded 82% of the oxirane (same net transformation as eq 4).[6] Several other aldehydes and ketones were similarly converted to oxiranes in 72-91% yields. Reactions of ketones were carried out at -15 °C, aldehydes at -50 °C.

For an alternative reagent which costs less and converts carbonyl compounds to oxiranes faster and equally efficiently, see ***Bromomethyllithium***.

Boronic Esters.

Addition of butyllithium to ***Triisopropyl Borate*** and $ClCH_2I$ in THF at -78 °C followed by treatment with anhydrous HCl yields diisopropyl (chloromethyl)boronate (eq 7), a useful synthetic intermediate (see ***Pinacol (Chloromethyl)boronate***).[7]

With boronic esters, $ClCH_2Li$ adds to the boron atom to form a borate complex, which on warming to rt rearranges to form the homologous boronic ester (eqs 8 and 9).[7] A chiral group was shown to migrate with retention of configuration (eq 10).[7]

R = Me_2CH, 94%; R = Ph, 96%
R = $PhCH_2OCH_2$, 90%

The conditions for in situ generation of $ClCH_2Li$ have been explored with boronic esters as substrates. Less expensive $ClCH_2Br$ was found to work almost as well as $ClCH_2I$ (eq 11).[8] It was also found that with $ClCH_2Br$ and R = 1-hexyl, addition of the BuLi at 0 °C resulted in a 47% yield, but temperatures between 0 °C and -78 °C were not tested.[8]

R = 1-hexyl: X = I, 97%; X = Br, 91%
R = 3-hexyl: X = I, 96%; X = Br, 89%

The reaction of eq 11 with $ClCH_2Br$ also yielded 89-91% with R = cyclopentyl, cyclohexyl, *trans*-2-methylcyclopentyl, *trans*-2-methylcyclohexyl, and *exo*-norbornyl.[8] However, in view of the possible problems in separating starting material and product that differ by only one methylene unit, the nearly quantitative conversions achieved with $ClCH_2I$ may justify the extra cost.

Boracyclane Ring Expansion.

Boracyclanes of ring sizes 5-11 undergo efficient ring expansion when treated with $ClCH_2Li$ generated in situ (eq 12).[9] Since these compounds are easily converted to carbocycles via the reaction with $LiCCl_2OMe$, which inserts a carbonyl group in place of BOMe, and since the 7-membered borepane can be prepared fairly directly from 1,5-hexadiene via a hydroboration route, this chemistry affords an efficient route to medium-sized rings.[9]

(12)

(Chloromethyl)silanes.

Addition of butyllithium to mixtures of $ClCH_2Br$ and various chlorosilanes in THF at -60 to -70 °C (-78 °C cooling bath) yields (chloromethyl)silanes.[10] A typical example is illustrated in eq 13. Similar conditions were used to prepare Ph_3GeCH_2Cl, Ph_3SnCH_2Cl, and Ph_3PbCH_2Cl.[10]

(13)

β-Lithio Lithium Alkoxides.

These are indirect derivatives of $ClCH_2Li$ and ketones which can be produced via lithiation of *O*-lithio chlorohydrins with ***Lithium Naphthalenide*** and related reagents (eq 14).[6] If warmed to rt, β-lithio lithium alkoxides eliminate Li_2O to form alkenes. At -78 °C, β-lithio lithium alkoxides react with variety of electrophiles EX to form *C*-substituted derivatives. Examples of EX and E included D_2O, D; MeSSMe, SMe; CO_2, CO_2H; $BrCH_2CH{=}CH_2$, $CH_2CH{=}CH_2$; and cyclohexanone, 1-hydroxycyclohexyl. Overall yields were generally in the useful range, 50-95%, for any of the processes described.[6]

Related Reagents.

1-Chloroethyllithium has been prepared at -115 °C from MeCHClBr and *s*-BuLi and reacted with benzaldehyde to form the corresponding oxirane (60%, *cis/trans* ratio 2:1).[3] Similarly prepared $MeCH_2CHClLi$ with cyclohexanone yielded the chlorohydrin (70%), and Me_2CClLi with benzaldehyde yielded the oxirane (42%).[3] See also ***Bromomethyllithium***; ***Dimethylsulfonium Methylide***; ***Dibromomethyllithium***; ***Dichloromethyllithium***; ***Tribromomethyllithium***; ***Trichloromethyllithium***.

Donald S. Matteson

Chloromethyl Methyl Ether[1]

$MeOCH_2Cl$

[107-30-2] · C_2H_5ClO · Chloromethyl Methyl Ether · (MW 80.51)

(used for the protection of alcohols, phenols, acids, amines, β-keto esters and thiols. A one-carbon synthon for alkylation of aromatics and active methylene derivatives)

Alternate Name: methoxymethyl chloride; MOMCl.

Physical Data: bp 55-57 °C; *d* 1.060 g cm^{-3}.

Solubility: sol nearly all organic solvents.

Form Supplied in: available as a technical grade liquid.

Preparative Methods: besides the original method[2] which uses HCl, formalin, and methanol, MOMCl can be prepared from methoxyacetic acid[3] or methylal (***Dimethoxymethane***).[4]

Handling, Storage, and Precautions: MOMCl is an OSHA-regulated carcinogen and depending on the method of preparation may contain bis(chloromethyl) ether, which is a more potent carcinogen. This reagent should be handled in a fume hood.

Protection of Alcohols.

Treatment of an alcohol with MOMCl and *i*-Pr_2NEt (0 °C, 1 h -> 25 °C, 8 h, 86% yield)[5] is the most commonly employed procedure for introduction of the MOM group. Formation of the sodium alkoxide and reaction with MOMCl is also very effective.[6] This method is particularly useful for the protection of the enol of β-keto esters.[7] Because of the carcinogenicity of MOMCl, a number of methods for the introduction of the MOM group have been developed which do not rely on the chloride. The methods are all based on the use of $CH_2(OMe)_2$ with various catalysts such as P_2O_5,[8] Me_3SiI,[9] Nafion H,[10] $CH_2{=}CHCH_2SiMe_3$/TMSOTf/P_2O_5,[11] $FeCl_3$,[12] Montmorillonite clay (H^+),[13] or TsOH/LiBr.[14] In the last case, 1,3-diols give methylene acetals. It is often difficult to achieve monoprotection of 1,3-diols but some success has been recorded, as illustrated in eqs 1-3.[15-17]

(1)

(2)

In the orthoester route when unsymmetrical diols are used, the most hindered alcohol is protected, in contrast to the normal methods which are expected to protect the least hindered alcohol. Diols capable of forming a stannylene derivative are efficiently monoprotected (eq 3).[17]

(3)

Cleavage of MOM Ethers.

Since the MOM group is an acetal, it can be cleaved using acid hydrolysis. In general, aqueous acid in an organic cosolvent has proven to be effective.[18-21] Use of the weak acid ***Pyridinium p-Toluenesulfonate*** in refluxing *t*-BuOH or 2-butanone is particularly effective for cleavage of MOM ethers of allylic alcohols.[22] MEM ethers are also cleaved under these conditions. Eq 4 shows that a MOM group can be cleaved with anhydrous ***Trifluoroacetic Acid*** in the presence of an acetonide which is normally cleaved with aqueous acid.[23]

Catecholborane halides, particularly the bromide (***B-Bromocatecholborane***), are effective reagents for the cleavage of MOM ethers. The bromide cleaves the following groups in the order: MOMOR &AApprox; MEMOR > *t*-Boc > Cbz &AApprox; *t*-BuOR > BnOR > allylOR > *t*-BuO_2CR &AApprox; secondary alkylOR > BnO_2CR > primary alkylOR >> alkylO_2CR. The *t*-butyldimethylsilyl (TBDMS) group is stable to this reagent. The chloride is less reactive and thus may be more useful for achieving selectivity in multifunctional substrates. Yields are generally >83%.[24] A variety of other boron based reagents have been developed which are useful for MOM ether cleavage. The use of ***Bromobis(isopropylthio)borane*** (eq 5)[25] has the advantage that 1,2- and 1,3-diols do not give formyl acetals as is sometimes the case in cleaving MOM groups with neighboring hydroxyl groups.[26] The reagent also cleaves MEM groups and under basic conditions affords the *i*-$PrSCH_2OR$ derivatives. With ***Bromodimethylborane***, MEM and MTM ethers are also cleaved, but esters are not affected.[27]

Bromotrimethylsilane, a reagent similar to but not as powerful as ***Iodotrimethylsilane***, will cleave MOM ethers as well as acetonide, THP, trityl, and *t*-$BuMe_2Si$ groups, but the reagent will not cleave esters, methyl and benzyl ethers, *t*-butyldiphenylsilyl ethers, and amides. One example is shown in eq 6.[28]

Boron Trifluoride Etherate in the presence of ***Thioanisole***,[29] ***Magnesium Bromide*** in the presence of butanethiol,[30] ***Triphenylcarbenium Tetrafluoroborate***,[31] and ***Lithium Tetrafluoroborate***[32] are also useful for cleavage of the MOM group. The action of lithium tetrafluoroborate is unique (eq 7) and the mechanism for cleavage is not well understood.

Protection of Phenols.

The reaction of MOMCl with a phenol under phase-transfer conditions works well to give phenolic MOM ethers[33] and will selectivity protect a phenol in the presence of an alcohol.[34] The more classical Williamson ether synthesis[35] also provides excellent results, but may require the addition of a crown ether to enhance the nucleophilicity of the

phenolate anion.[36] As in the case of alcohol protection, alternatives using methylal have been developed for phenol protection which do not rely on the carcinogenic MOMCl.[37] Phenolic silyl ethers can be converted directly to MOM ethers by reaction with TASF (***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate***) and MOMCl.[38]

Cleavage of Phenolic MOM Ethers.

Again, mild acid[37,39] is used for cleavage, but other alternatives such as ***Sodium Iodide***/acetone/cat. HCl/50 °C,[40] ***Diphosphorus Tetraiodide***/CH_2Cl_2/0 °C -> rt,[41] or TMSBr/CH_2Cl_2[42] are also effective.

Protection of Thiols.

Lithium[43] and potassium[44] thiolates react with MOMCl to form the thioethers. The use of MOMCl can be avoided by the reaction of the zinc thiolate with methylal.[45]

Protection of Acids.

The reaction of MOMCl with an acid in the presence of a base affords the MOM ester.[46-48] As with the thiols, the zinc carboxylate reacts with methylal to afford the MOM ester.[49] MOM esters are quite acid sensitive and are unstable to silica gel chromatography.[50] The MOM ester is easily cleaved with acid, $MgBr_2$,[51] or Me_3SiBr containing a trace of MeOH.[52]

Protection of Amine Derivatives.

Heterocyclic amines and amides are protected as their MOM derivatives by reaction of the amine or amide with MOMCl in the presence of a base such as ***Diisopropylethylamine***,[53] ***Sodium Hydride***,[54] LiH, ***Potassium t-Butoxide***,[55] or ***Sodium Hydroxide***.[56] These derivatives are cleaved with ***Hydrogen Chloride***/EtOH[53] or ***Boron Tribromide***.[55] To hydrolyze scopolamine without formation of the rearranged product (**1**) it was necessary to protect the amine nitrogen as the methoxy-methochloride as illustrated in eq 8.[57]

Use in C-C Bond-Forming Reactions.

Since MOMCl is an excellent electrophile it readily reacts with enolates[58] and other carbanions[59] and thus serves as an easily handled one-carbon synthon. Friedel-Crafts alkylation with MOMCl and a Lewis acid such as ***Tin(IV) Chloride***,[60] ***Titanium(IV) Chloride***,[61] ***Zinc Chloride***,[62] and ***Aluminum Chloride***[63] or ***Acetic Acid***[64] is a common method for introduction of a chloromethyl group onto an aromatic nucleus (eqs 9 and 10).[60,64] The reaction is quite general and tolerates a broad range of functionality.

(9)

(10)

Alkenes react in a similar fashion giving methoxymethyl derivatives, but in this case the intermediate carbenium ion is trapped with methoxide or another nucleophile such as a nitrile to afford the methyl ether or amide in a Ritter-like reaction (eq 11).[65] In similar fashion, silyl enol ethers give ketones (eq 12),[66,67] allylsilanes afford homologated alkenes (eq 13),[68] and stannylalkynes are converted to propargyl ethers.[69]

(11)

$\gamma:\alpha = 55:45$

MOMCl can be converted to the Grignard reagent or the lithium reagent and used to introduce one carbon by nucleophilic attack on ketones and esters.[70] These reagents are best prepared in methylal.[71]

Chloromethyl Methyl Sulfide

$MeSCH_2Cl$

[2375-51-5] · C_2H_5ClS · Chloromethyl Methyl Sulfide · (MW 96.58)

(protection of carboxylic acids and alcohols;[1] introduces a methyl[2] or methylene[3] unit on carbon or nitrogen;[4] preparation of vinyl sulfides;[5] corresponding Grignard reagent reacts with various electrophiles;[6] oxidative additions with various metals[7])

Alternate Name: methylthiomethyl chloride; MTMCl.

Physical Data: bp 38 °C/55 mmHg, 52 °C/100 mmHg, 107 °C/750 mmHg; d^{20} 1.1773 g cm^{-3}.

Solubility: sol acetonitrile, ether, dichloromethane.

Form Supplied in: colorless liquid; commercially available.

Handling, Storage, and Precautions: hydrolyzes easily; flammable; exhibits obnoxious odor. Use in a fume hood.

Protective Group.

Carboxylic acids react with chloromethyl methyl sulfide (MTMCl) to give MTM esters (eq 1).[1,8-11] This protective group is stable for 1 h in contact with an aqueous solution of pH 0-15.[9] It is also stable to sodium borohydride and Zn-MeOH.[8] Primary and secondary alcohols[12,13] and phenols[14] react with MTMCl to yield the corresponding MTM ethers (eq 2). The MTM ether function is stable to basic, nucleophilic, and mild acidic conditions (aq AcOH).[12,14] Various mild conditions can be used for selective deprotection.[1]

$$RCO_2H \xrightarrow[\text{NEt}_3\ (1\ \text{equiv}),\ \text{MeCN}\ \text{reflux, 24 h}]{\text{MTMCl (1 equiv)}} RCO_2\text{-MTM} \qquad (1)$$

Electrophilic Reagent.

Silyl enol ethers react with MTMCl in the presence of ***Iodotrimethylsilane***[15] or ***Zinc Bromide***[3] to give methylthiomethylated products (eq 3).[3] The methylthio group can be removed reductively to accomplish an overall methylation. Oxidative removal of the methylthio group provides a way for α-methylenation of carbonyl compounds (eq 3).[3] Other carbon nucleophiles that react with MTMCl include aromatic compounds,[2] stabilized carbanions,[16,17] and organotin acetylides.[18] Similarly, introduction of the MTM group on nitrogen with MTMCl provides a way for eventual methylation[19] or methylenation.[4,20,21] Phosphonates (eq 4),[5,22] phosphine oxides,[23] or phosphorus ylides[24] derived from MTMCl have been used in the preparation of vinyl sulfides, which lead to the corresponding ketones after hydrolysis.[5]

Reaction with Metals.

The Grignard reagent prepared from MTMCl reacts with various electrophiles (eq 5).[6] Oxidative additions of

transition metals (Pt, Pd, Ni, Fe) with MTMCl give organometallic compounds containing the methylthiomethyl ligand.[7,25-29] These compounds have been prepared because of interest in their structures and reactions.

$$\text{MTMCl} \xrightarrow[\text{10-20 °C}]{\text{Mg}} \text{MeSCH}_2\text{MgCl} \xrightarrow{\text{C}_{12}\text{H}_{25}\text{Br}} \underset{\text{76\%}}{\text{MeSC}_{13}\text{H}_{27}} \qquad (5)$$

Related Reagents.

Chloromethyl Phenyl Sulfide.

2-Chloromethyl-4-nitrophenyl Phosphorodichloridate

[23561-36-6] · $C_7H_5Cl_3NO_4P$ · 2-Chloromethyl-4-nitrophenyl Phosphorodichloridate · (MW 304.45)

(phosphorylation of alcohols[1,2])

Physical Data: bp 165-167 °C/0.2 mmHg; solidifies when chilled, mp 43-44 °C.

Preparative Method: by heating at reflux a mixture of 2-chloromethyl-4-nitrophenol and ***Phosphorus Oxychloride*** in the presence of a catalytic amount of KCl.[1]

Purification: by distillation.

Phosphorylation of Alcohols.[3]

Reaction of 2-chloromethyl-4-nitrophenyl phosphorodichloridate (**1**) with one equivalent of an alkyl alcohol or phenol gives the alkyl or phenyl 2-chloromethyl-4-nitrophenyl phosphate (**2**) (eq 1).[1] Hydrolysis of (**2**) in aqueous pyridine affords the alkyl (phenyl) dihydrogen phosphates (**3**) (eq 2);[1] this is a useful method for the phosphorylation of valuable alcohols since only one equivalent of alcohol is required. Alternatively, (**2**) may be treated with a second alcohol in the presence of pyridine to provide a mixed diester (**4**) of phosphoric acid.[2]

These transformations rely on the conversion of (**2**) to the inner salt (**5**), an active phosphorylating agent, upon reaction with pyridine. The 2-chloromethyl-4-nitrophenyl group therefore acts as an activatable protecting group. The reaction byproduct, the salt (**6**), is precipitated from the reaction mixture on addition of ethanol, and is readily removed by filtration.

Chloromethyl 4-Pentenyl Ether

[98486-13-6] · $C_6H_{11}ClO$ · Chloromethyl 4-Pentenyl Ether · (MW 134.61)

(protection of alcohols[1])

Alternate Name: 4-pentenyloxymethyl chloride; POMCl.

Physical Data: bp 158-160 °C/760 mmHg, 34-38 °C/3.1 mmHg.

Solubility: sol dichloromethane.

Preparative Method: chloromethyl 4-pentenyl ether is prepared in 90-98% yield by treatment of a mixture of 4-pentenol and ***Paraformaldehyde*** (1.25 equiv) with ***Hydrogen Chloride*** gas at 0 °C. The crude product can be used directly or purified by distillation.[2,3]

Purification: by distillation.

Handling, Storage, and Precautions: potent alkylating agent; moisture sensitive. Use in a fume hood.

Protection of Alcohols.

Primary or secondary alcohols can be protected with the POM group upon treatment with POMCl (2 equiv) in the presence of Hünig's base (***Diisopropylethylamine***) (4 equiv) in dichloromethane (eq 1).[2] This protective group survives in 75% aqueous acetic acid but not in 5% aqueous hydrochloric acid.[4] Deprotection is performed with ***N-Bromosuccinimide*** (2.5 equiv) in 1% aqueous acetonitrile or a 1:1 mixture of 2% aqueous acetonitrile and dichloromethane.[4] The mild deprotection processes can tolerate many other protecting groups such as *t*-butyldimethylsilyl, benzyl, *p*-methoxybenzyl, acyl, allyl, and ethoxyethyl groups.[5]

Chloromethyl Phenyl Sulfide[1]

[7205-91-6] · C_7H_7ClS · Chloromethyl Phenyl Sulfide · (MW 158.65)

(reactive electrophile for many nucleophiles;[2] α-methylenating agent;[3] acyl carbanion equivalent;[4] phenylthiocarbene,[5a,b] phenylthiomethyl carbanion,[5c] and halomethyl phenyl sulfoxide precursors[6])

Physical Data: bp 66 °C/0.2 mmHg.

Solubility: sol most organic solvents; insol H_2O.

Form Supplied in: liquid; commercially available.

Preparative Methods: there are several preparative methods available.[1a,b] The two most convenient methods are the reaction of ***Thioanisole*** with ***Sulfuryl Chloride***[7] and the reaction of ***Thiophenol*** with bromochloromethane using ***1,8-Diazabicyclo[5.4.0]undec-7-ene***[8] or an alkali metal hydroxide as the base.[9]

Handling, Storage, and Precautions: stench; the material should be handled in a well-ventilated fume hood and kept cooled. Freshly prepared material can be stored at 0-5 °C without any appreciable decomposition. It is advisable to use freshly prepared or distilled material for reactions.

Alkylation Reactions.

The reagent reacts readily with silyl enol ethers of ketones, lactones, and esters in the presence of ***Zinc Bromide*** or ***Titanium(IV) Chloride*** as the Lewis acid. α-Methylated ketones,[10] α-methylenated ketones (eq 1),[3b,c] γ-lactones (eq 2),[3a] and esters (eq 3)[3a] can be synthesized by this method. The regioselectivity of the introduced substituents is controlled by the structures of the silyl enol ethers.

The α:γ ratios in phenylthiomethylation of silyl dienol ethers are controlled by the size of the substituents on the silyl atom and the substituents on the α- and γ-positions of the *O*-silylated dienolate (eq 4).[11,12]

1. $R^1 = Ph$, $R^2 = Me$, $R^3 = R^4 = H$	45:55
2. $R^1 = Ph$, $R^2 = Ph$, $R^3 = R^4 = H$	85:15
3. $R^1 = Ph$, $R^2 = Me$, $R^3 = Me$, $R^4 = H$	31:69
4. $R^1 = Ph$, $R^2 = Me$, $R^3 = H$, $R^4 = Me$	74:26

Phenylthiomethylation-desulfurization of phenols yields *C*-methylated phenols in moderate yields. The *ortho*:*para* ratio is 3:1. A major useful byproduct in some cases, especially when only the *para* position is free, is a diphenylmethane. The Lewis acid of choice is ***Tin(IV) Chloride*** (eq 5).[2a] Phenylthiomethylation of aromatic hydrocarbons gives a low yield of the *C*-alkylated product.[13,14] Cationic polar [4 + 2] cycloaddition of the reagent with styrene using $SnCl_4$ as a Lewis acid gives a thiochroman (eq 6).[15] Allylic silanes can be alkylated by using $TiCl_4$ as a Lewis acid (eq 7).[16]

(6)

(7)

Phenylthiomethylation of metal enolates gives moderate yields of the *C*-alkylated products (eq 8).[17]

(8)

N-Alkylation.

Substituted methylene radicals can be generated from the substituted phenylthiomethylene group.[18] *N*-Alkylation of secondary amines,[18] sulfonamides,[18] imides,[19] and nitriles[20] gives the alkylated products. The *N*-phenylthiomethylated products can be transformed into pyrrolidine derivatives by radical cyclization with ***Tri-n-butylstannane-Azobisisobutyronitrile*** (eq 9).[18] Phenylthiomethylation of benzimidazole[2b] and benzotriazole[21] occurs at the *N*-1 position. The *N*-phenylthiomethylated benzotriazole can be readily alkylated and the product is a versatile 1,1-dipole synthon equivalent (eq 10).[21]

(9)

O-Alkylation.

The *O*-phenylthiomethylated products of phenols are utilized for the synthesis of aryl arylsulfonylmethyl ethers[22] and for protection of the phenol group; the protecting group is more resistant to hydrolysis by ***Mercury(II) Chloride*** in 4:1 acetonitrile-water than the methylthiomethyl group.[2g]

S-Alkylation.

A sulfonium salt is formed by the phenylthiomethylation of the reagent with sulfides. The appropriately substituted sulfonium salt can undergo [2,3]-sigmatropic rearrangement to a dithioacetal derivative,[23] which is a potentially useful isoprenoid synthon (eq 11).[24] The bis(phenylthio) acetal is a very useful acyl carbanion equivalent precursor.[2f,24,25]

P-Alkylation.

Phenylthiomethylphosphonate and -phosphine oxide ylides, derived by deprotonation of the corresponding phosphorus derivatives obtained by phenylthiomethylation of the respective phosphorus compounds, undergo the

Horner-Wittig reaction with carbonyl compounds to give good yields of vinyl sulfides.[2c,4,26] Hydrolysis of the vinyl sulfides yields aldehydes and ketones.[4,24] The ylides are acyl anion equivalents (eq 12). Various carbonyl and ylide components are used for the synthesis of ketones and enones.[4]

(12)

(Phenylthiomethylene)triphenylarsorane, derived by deprotonation (*n*-BuLi/THF) of the corresponding arsonium salt obtained from the reaction of chloromethyl phenyl sulfide and ***Triphenylarsine*** in the presence of ***Sodium Iodide*** in acetonitrile, reacts with aldehydes giving α-phenylthio epoxides in THF and vinyl sulfides in THF-HMPA. The α-phenylthio epoxides are rearranged with silica gel to α-phenylthio carbonyl compounds which upon desulfurization[10] yield methyl ketones. Hydrolysis of the vinyl sulfides gives aldehydes with one-carbon homologation (eq 13).[27]

(13)

Thiocarbene Generation.

Phenylthiocarbene, generated by the reaction of chloromethyl phenyl sulfide with ***Potassium t-Butoxide*** in hexane[28] or with a phase transfer catalyst[5a,b] (***Benzyltriethylammonium Chloride*** and 50% ***Sodium Hydroxide***), adds to alkenes[5a,b] and 1,1-dimethylallene[28b] yielding phenylthiocyclopropanes and 2-(phenylthio)-1-methylenecyclopropane, respectively, in good yields (eqs 14 and 15). An alternative method for the generation of the phenylthiocarbene is by reaction of bis(phenylthio) acetals with organolithium reagents.[29] Phenylthiocyclopropane can also be prepared by the reaction of thiophenol with 1-bromo-3-chloropropane in aqueous potassium hydroxide followed by cyclization of the resulting 3-chloropropyl phenyl sulfide with ***Potassium Amide*** in liquid ammonia.[30] 1-Lithio-1-phenylthiocyclopropane, prepared by deprotonation of phenylthiocyclopropane, has numerous interesting applications in synthesis.[31-33]

(14)

(15)

Reaction with Organometallic and Transition Metal Salts.

(η^5-Cyclopentadienyl)dicarbonyl(phenylthiomethyl)iron, $Cp(CO)_2FeCH_2SPh$, prepared from the reaction of ***Bis(dicarbonylcyclopentadienyliron)*** and chloromethyl phenyl sulfide, is used as a methylene transfer agent. Its reaction with *cis*-cyclooctene gives bicyclo[6.1.0]nonane.[34] Phenylthiomethyl carbanion[5c] is prepared by the reaction of chloromethyl phenyl sulfide with ***Chromium(II) Chloride*** and ***Lithium Iodide***[35] or with ***Samarium(II) Iodide*** (eq 16).[36] In the case of the [α-phenylthioalkyl)chromium compound], $PhSCHRCr^{III}$, *threo* selectivity is observed in the addition with aldehydes.

The coupling of organocuprates[37] and organotin compounds catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)***[38] with chloromethyl phenyl sulfide leads to carbon-carbon bond formation in good yields (eqs 17 and 18).

Oxidation Reactions.

Chloromethyl Phenyl Sulfoxide is prepared in good yield by the oxidation of chloromethyl phenyl sulfide with ***Sulfuryl Chloride*** and wet silica gel in methylene chloride (eq 19).[6a] ***Fluoromethyl Phenyl Sulfoxide*** is prepared by the oxidation of ***Fluoromethyl Phenyl Sulfide*** with NBS in aqueous MeOH; fluoromethyl phenyl sulfide is prepared from the reaction of chloromethyl phenyl sulfide using ***Potassium Fluoride*** and ***18-Crown-6*** in refluxing acetonitrile (eq 19).[6b]

(19)

Related Reagents.

Benzyl Bromomethyl Sulfide; ***Benzyl Chloromethyl Sulfide***; ***Chloromethyl Methyl Sulfide***; ***Chloromethyl Phenyl Sulfone***; ***Chloromethyl Phenyl Sulfoxide***; ***Chloromethyl p-Tolyl Sulfide***.

Chloromethyl Phenyl Sulfone[1]

[7205-98-3] · $C_7H_7ClO_2S$ · Chloromethyl Phenyl Sulfone · (MW 190.65)

(synthesis of α,β-epoxy sulfones[1] and aziridines;[2] reacts with electrophilic arenes, heterocyclic arenes, and alkenes;[3] source of the α-phenylsulfonylmethyl radical[1a])

Physical Data: mp 52 °C.

Solubility: sol THF, $CHCl_3$, CH_2Cl_2, and most organic solvents.

Preparative Methods: several methods are available.[4] The most convenient is the reaction of ***Sodium Benzenesulfinate*** dihydrate with bromochloromethane in dimethyl sulfoxide.[4c]

Handling, Storage, and Precautions: use in a fume hood.

α,β-Epoxy Sulfones.

Epoxy sulfones are prepared by the reaction of the chloromethyl phenyl sulfone carbanion ($PhSO_2CHClM$) with carbonyl compounds. The one-step Darzens-type condensation can be effected by using a phase transfer catalyst, benzyltriethylammonium chloride in 50% sodium hydroxide (eq 1).[5] A less satisfactory two-step method involves the addition of α-lithiochloromethyl phenyl sulfone to carbonyl compounds at low temperature to give isolable β-hydroxy-α-chloro sulfones which are cyclized by ***Potassium Hydroxide*** in methanol (eq 2).[5c,6] The phase-transfer catalyst method gives *trans*-epoxy sulfones from aldehydes and mixtures of isomers from unsymmetrical ketones. In the two-step method the stereochemistry of the epoxy sulfones is not always determined by the stereochemistry of the β-hydroxy-α-chloro sulfones.[7] α,β-Epoxy sulfones can also be prepared by the epoxidation of α,β-unsaturated sulfones with alkaline ***Hydrogen Peroxide*** (giving *trans*-α,β-epoxy sulfones),[8] potassium chlorite (producing *cis*-α,β-epoxy sulfones),[9] ***1,1-Di-t-butyl Peroxide*** and alkyllithium (stereospecific),[10] ***t-Butyl Hydroperoxide*** (nonstereospecific),[10] and ***m-Chloroperbenzoic Acid***.[11]

(1)

(2)

α,β-Epoxy sulfones undergo rearrangement-elimination either with ***Boron Trifluoride Etherate*** or thermally in a similar manner to α,β-epoxy sulfoxides. Normally, α-phenylsulfonyl carbonyl compounds or their mixture with the corresponding α,β-unsaturated carbonyl compounds are the final products (eq 3).[5c,6]

(3)

Reaction with a Lewis acid (i.e. ***Magnesium Bromide***) gives good yields of the α-bromo carbonyl compounds (eq 4).[5c,12]

(4)

Ring opening of α,β-epoxy sulfones with ***Sodium Azide*** in DMF gives α-azido aldehydes which can be converted to α-azido nitriles by the Beckmann elimination (eq 5).[13] One-carbon homologation of ketones to α-hydroxy aldehydes is effected by the reaction of the α,β-epoxy sulfones with hydroxide ion generated by adding water to ***Potassium t-Butoxide*** (eq 6).[14] β-Keto phosphonates, valuable synthetic intermediates, are prepared by the reaction of α-substituted-α,β-epoxy sulfones with ***Diethyl Phosphonite*** (eq 7).[15]

(7)

The acidic α-hydrogen of α,β-epoxy sulfones can be removed with ***n-Butyllithium*** at -102 °C to give the α-lithio-α,β-epoxy sulfone carbanion which reacts with ***Chlorotrimethylsilane***, aldehydes, ketones, and alkyl halides to give the corresponding adducts which can undergo further chemical transformations. This process demonstrates the equivalency of the α,β-epoxy sulfones to the acyl anion (eq 8).[16]

(8)

Addition to Imines.

N-Aryl(phenylsulfonyl)aziridines are prepared by the reactions of the α-lithiochloromethyl phenyl sulfone with diaryl imines. The aziridines and alkylated aziridines, formed by the alkylation of the α-lithio-*N*-aryl(phenylsulfonyl)aziridines, undergo [1,3]-dipolar cycloaddition with ***Dimethyl Acetylenedicarboxylate*** to give substituted pyrroles (eq 9).[2b] Bis(phenylsulfonyl)aziridine is formed by the reaction of the chloromethyl phenyl sulfone carbanion with quinazoline (eq 10);[2a] 1,5-, 1,6-, 1,7-, and 1,8-naphthyridines react similarly to give the corresponding phenylsulfonylaziridines.[2a]

Vicarious Nucleophilic Substitution of Hydrogen (VNS).

The chloromethyl phenyl sulfone carbanion undergoes vicarious nucleophilic substitution of hydrogen (VNS) in electrophilic arenes, heterocyclic arenes, and alkenes[3] to give phenylsulfonylmethyl functionalized compounds. The most common starting aromatic compounds for this reaction are nitroarenes (eq 11).[17] The reaction can be applied to *ortho*-, *meta*-, *para*- and polysubstituted nitroarenes. The VNS reaction with electrophilic arenes is complementary to the Friedel-Crafts reaction.[3a]

(11)

Electrophilic heterocyclic arenes (nitrothiophenes, 2-nitrofuran, *N*-protected nitropyrroles, *N*-protected nitroimidazoles, nitropyrazoles, nitropyridines, nitroquinolines, *N*-protected nitroindole, and 1,2,4-triazine)[18] undergo the VNS reaction with the chloromethyl phenyl sulfone carbanion (e.g. eqs 12 and 13).[3b,18] These reactions provide a convenient way to introduce the phenylsulfonylmethyl group into these compounds. Electrophilic alkenes with electron-withdrawing groups which can provide high stabilization of negative charge and β-substituents facilitating the abstraction of a geminal proton, can undergo the VNS reaction (eq 14).[19] The principle of the VNS reaction has been applied in the synthesis of a precursor of aklavinone, an anthracycline antibiotic (eq 15).[20]

(12)

(13)

(14)

(15)

Radical Reaction.

The phenylsulfonylmethyl radical, generated by the reaction of chloromethyl phenyl sulfone with ***Tri-n-butylstannane*** and ***Azobisisobutyronitrile*** in refluxing benzene, adds diastereoselectively to enamines to give the *syn* adduct as the major product. The origin of the diastereoselectivity is explained on the basis of an allylic 1,3-strain model (eq 16).[1d,21]

(16)

α-Alkyl phenylsulfonylmethyl radicals, generated from the corresponding α-bromo- or α-chloroalkyl phenyl sulfones, undergo tandem radical cyclization to cyclopentane derivatives (eqs 17 and 18).[22,23] The method provides a quick entry to these molecules.

Chloromethyl Phenyl Sulfoxide[1]

[7205-94-9] · C_7H_7ClOS · Chloromethyl Phenyl Sulfoxide · (MW 174.65)

(synthesis of α,β-epoxy sulfoxides;[2a-c] one-carbon homologating agent[3])

Physical Data: bp 120-121 °C/4 mmHg.

Solubility: sol $CHCl_3$ and THF.

Preparative Methods: chlorination of methyl phenyl sulfoxide with either ***Sulfuryl Chloride***[4] in methylene chloride or ***N-Chlorosuccinimide***[5] in chloroform gives a good yield of the product. A one-pot procedure starting with ***Thioanisole*** consists of chlorination with sulfuryl chloride in methylene chloride[6] followed by oxidation with the same reagent in the presence of wet silica gel.[7] Another alternative is to employ ***Silver(I) Nitrate*** and sulfuryl chloride in acetonitrile.[8]

Handling, Storage, and Precautions: use in a fume hood.

α,β-Epoxy Sulfoxides.

Epoxy sulfoxides are prepared by the reaction of the chloromethyl phenyl sulfoxide carbanion (PhSOCHClM) with carbonyl compounds. When ketones are used as electrophiles, either a one-step Darzens-type condensation using ***Potassium t-Butoxide*** in *t*-BuOH[2b,c] or a two-step route involving the addition of α-lithiochloromethyl phenyl sulfoxide (best generated by the reaction of $PhSOCH_2Cl$ with ***Lithium Diisopropylamide***; ***n-Butyllithium*** has been used, but caution should be taken due to the possible desulfinylation reaction) to ketones to give α-chloro-β-hydroxy sulfoxides (chlorohydrins), followed by treatment with ***Potassium Hydroxide*** in aqueous methanol (eq 1; R^1, R^2 = alkyl, aryl).[2a,3c]

With aldehydes (eq 1; R^1 = H, R^2 = alkyl), only the two-step route can be used satisfactorily.[2b] A high degree of diastereoselectivity is observed in the formation of the chlorohydrins.[2a] Thermal[2b] or Lewis acid-catalyzed[3c] reactions of the epoxy sulfoxides (R^1 and/or R^2 = alkyl) give α,β-unsaturated aldehydes with one-carbon homologation. This process has been applied to the synthesis of (±)-suaveolin (eq 2).[9]

Thermal elimination of the chlorohydrins derived from aldehydes (R^1 or R^2 = H) provides chloromethyl ketones[10] in good yields (eq 3). One-carbon ring expansion[11] of the chlorohydrins derived from cyclic ketones can be induced by ***Lithium Diisopropylamide*** through an α-sulfinyl carbenoid intermediate (eq 3). Eliminative deoxygenation[3b] of the chlorohydrins with low-valent titanium gives vinyl sulfides (eq 3). 1-Chlorovinyl sulfoxides derived from the chlorohydrins undergo the Fritsch-Wiechell rearrangement with ***t-Butyllithium*** to give terminal alkynes (eq 4).[12]

Lithiochloromethyl phenyl sulfoxide gives 1,2-addition products with enones.[13] The transformation of a chlorohydrin [R^1-R^2 = -$(CH_2)_3$-] to an α,β-unsaturated γ-hydroxycyclohexanecarbaldehyde[14] has been demonstrated (eq 5).

(5)

Addition to Imines.

The addition of lithiochloromethyl phenyl sulfoxide to aryl imines provides sulfinylaziridines as a mixture of *cis* and *trans* isomers which undergo 1,3-dipolar cycloaddition with ***Dimethyl Acetylenedicarboxylate*** (DMAD), giving *N*-aryl-2,3,4-trisubstituted pyrroles (eq 6).[15]

(6)

Alkylation with Alkyl Halides.

Chloroalkyl phenyl sulfoxides, available from alkylation of lithiochloromethyl phenyl sulfoxide with alkyl bromides or iodides, give high yields of terminal vinyl chlorides upon pyrolysis[16] and undergo the sila-Pummerer rearrangement with LDA and ***Chlorotrimethylsilane*** to yield thiol esters (eq 7).[17]

Direct chlorination of alkyl phenyl sulfoxides with NCS is a useful alternative method for the preparation of chloroalkyl phenyl sulfoxides.[18] Addition of lithiochloroalkyl phenyl sulfoxide to carbonyl compounds gives the chlorohydrins which can be transformed via α,β-epoxy sulfoxides into carbonyl compounds with one-carbon homologation,[19] α-sulfenylated ketones and aldehydes,[20] α-amino ketones and aldehydes,[21] α-acetoxy ketones,[22] alkyl vinyl ketones and divinyl ketones,[23] epoxides and allylic alcohols,[24] 2-acyl cyclic ethers and 3-keto cyclic ethers,[25] α-chloro and α-alkoxy ketones,[26] α,β-unsaturated ketones,[26] (*E*)-1-acylbutadienes,[27] 1,3-dihydroxy ketones,[28] functionalized cyclohexane derivatives,[29] spiro-methylenecyclopropanes,[30] and α-fluoro ketones.[31]

Eliminative deoxygenation of chloroalkyl phenyl sulfoxides using ***Trimethylsilyl Trifluoromethanesulfonate*** with ***Triethylamine*** as a base gives α-chlorovinyl phenyl sulfides.[32]

Bromomethyl and Iodomethyl Phenyl Sulfoxides.

α-Lithio anions derived from bromomethyl phenyl sulfoxide[33a-c] and iodomethyl phenyl sulfoxide[34a,b] react with carbonyl compounds and alkyl iodides in an analogous manner to the chloromethyl phenyl sulfoxide.[35a,b] α-Phenylsulfinyl radicals generated from either chloroalkenyl or bromoalkenyl phenyl sulfoxide undergo radical cyclization to cyclopentane derivatives together with the reduction products (eq 8).[36] Debromination of bromomethyl phenyl sulfoxide also occurs with ***Octacarbonyldicobalt*** on alumina.[37]

Pyrolysis of bromohydrins gives bromomethyl ketones.[35a] Solvolysis of iodohydrins of cyclic ketones with ***Silver(I) Nitrate*** in 95% ethanol provides vinyl sulfones, α-hydroxy sulfones, and/or one-carbon ring expansion products depending on the ring size, presumably through a common phenylsulfinyl carbenium ion.[35b,38]

(synthesis of 1-aza-1,3-dienes,[2] α-amino acetals,[2,3] allylic amines,[4] α,β-unsaturated aldehydes,[5] α-alkoxy aldimines,[6,7] α-*t*-butyl aldimines,[7] α-sulfenylated aldimines,[8] 1,4-diimines,[9] α-cyano enamines,[10] β-chloro amines,[11] aromatic ketones,[12] aziridines,[13] 2-imidazolidinethiones,[14] 2-imidazolidinones,[15] α-aryl aldehydes,[16] 2-aza-1,3-dienes;[17,18] reductive dechlorination of α-halo aldehydes[18])

Alternate Name: *N*-isopropyl-α-chloroisobutyraldimine.

Physical Data: 2-chloro-2-methylpropanal *N*-isopropylimine (R = *i*-Pr, R^1 = R^2 = Me, X = Cl): bp 47-49 °C/24 mmHg; 2-bromo-2-methylpropanal *N*-isopropylimine (R = *i*-Pr, R^1 = R^2 = Me, X = Br): bp 58-61 °C/14 mmHg; 2-chloro-2-methylpropanal *N*-*t*-butylimine (R = *t*-Bu, R^1 = R^2 = Me, X = Cl): bp 50-52°/30 mmHg.

Solubility: sol most organic solvents; not compatible with aqueous acidic solutions; basic aqueous solutions cause a slow hydrolysis.

Form Supplied in: 2-chloro-2-methylpropanal *N*-isopropyl- and *N*-*t*-butylimines are commercially available as colorless liquids.

Analysis of Reagent Purity: GC, ^{1}H NMR.

Preparative Methods: aldimines, which are easily accessible from aldehydes and primary amines and which may be prepared in situ, react smoothly with ***N-Chlorosuccinimide*** in CCl_4 at room temperature to give α-chloro aldimines (eq 1).[2] Similarly, α-bromo[7] and the labile α-iodo aldimines[19] are accessible by reaction of aldimines with ***N-Bromosuccinimide*** and ***N-Iodosuccinimide***, respectively (eq 2). Alternatively, the condensation of α-chloro and α-bromo aldehydes with primary amines in the presence of magnesium sulfate,[18] ***Titanium(IV) Chloride***,[20] or ***Molecular Sieves***[28] as dehydrating agent affords the corresponding α-halo aldimines (eq 3).

(1)

Handling, Storage, and Precautions: α-chloro aldimines are relatively stable bifunctional reagents which are preferably kept in the refrigerator, well-protected from moisture. α-Bromo aldimines are more labile and only readily accessible with *N*-*t*-butyl substituents. α-Iodo aldimines are best freshly prepared and used immediately. The use of α-halo imines in the presence of water is incompatible (except for a fast cyanation reaction; see below). Use in a fume hood.

α-Halo aldimines are protected or modified α-halo aldehydes, but their chemistry is quite different from that of α-halo aldehydes.[1,21,22] They are suitable building blocks for a variety of heterocycles and have a high synthetic potential for functional group transformations. Comparable reagents are β-haloenamines.[23]

Synthesis of 1-Aza-1,3-dienes, α-Amino Acetals, Allylic Amines, and α,β-Unsaturated Aldehydes.

α-Chloroisobutyraldimines react with ***Sodium Methoxide*** in methanol to give 1-aza-1,3-dienes and rearranged α-amino acetals (via a 2-methoxyaziridine intermediate) (eq 4).[2] Selective formation of 1-aza-1,3-dienes is obtained with ***Potassium t-Butoxide*** (eq 5),[4] while complete rearrangement into α-amino acetals is achieved by reaction with alcohols without added base (eq 6).[2,3] The α-amino acetals serve as precursors for α-(*N*-alkylamino) aldehydes (eq 6).[3] Higher analogs, having at least one α-methyl replaced by ethyl or higher alkyl, do not rearrange but are dehydrochlorinated on treatment with sodium methoxide or potassium *t*-butoxide (eq 7).[2,4] The resulting 1-aza-1,3-dienes are easily converted into allylic amines (eq 8)[4] and α,β-unsaturated aldehydes (eq 9).[5]

$R^1 = CH_2R^3$, $R^3 \neq H$, $R^2 = \text{alkyl}$

(8)

(9)

Synthesis of α-Alkoxy Aldimines, α-*t*-Butylaldimines, α-Sulfenylated Aldimines, and 1,4-Diimines.

While the reaction of α-bromo aldimines with alcohols produces rearranged α-amino acetals, the silver-induced alcoholysis affords α-alkoxy aldimines (eq 10).[6] In addition to oxygen nucleophiles, the α-halogen in α-chloro aldimines can be displaced by sulfur or carbon nucleophiles, e.g. thiolates (eq 12)[7,8] or ***t-Butyllithium*** (eq 11).[7] Coupling of α-bromo aldimines to give 1,4-diimines via captodative stabilized radical intermediates is accomplished with ***Lithium Diisopropylamide*** (eq 13).[9] A similar coupling of α-chloro aldimines by ***Methylcopper*** to give 1,4-diimines has been reported.[12]

(13)

R^1, R^2 = $(CH_2)_5$; R^1 = R^2 = Me; R = *i*-Pr, *t*-Bu

Synthesis of α-Cyano Enamines,[11] Acylation of Arenes under Non-Friedel-Crafts Conditions, and Synthesis of β-Chloro Amines.

Cyanation of α-chloro aldimines leads to α-cyano enamines, which are potential building blocks (eq 14).[10] The conversion of α-chloro aldimines with ***Phenyllithium*** into alkyl phenyl ketimines and, after hydrolysis, into alkyl phenyl ketones constitutes a mild acylation of arenes under non-Friedel-Crafts conditions (eq 15).[12] Electrophilic reduction of α-chloro aldimines by the ***Borane-Dimethyl Sulfide*** complex is a route to sterically hindered β-chloro amines (eq 16).[11]

(14)

(15)

(16)

Synthesis of Aziridines, 2-Imidazolidinethiones, and 2-Imidazolidinones.

Nucleophilic reduction of α-chloro aldimines with ***Lithium Aluminum Hydride*** in ether gives ready access to aziridines (eq 17).[13] Ambident nucleophiles, such as ***Potassium Thiocyanate*** and potassium cyanate, react with α-chloro aldimines in methanol to produce 4-methoxy-2-imidazolidinethiones and 4-methoxy-2-imidazolidinones, respectively (eqs 18 and 19).[14,15] The latter heterocycles can be cleanly converted into the corresponding demethoxylated five-membered aza heterocycles,[14,15] 4-imidazolin-2-ones (eq 19),[24] or triimidazohexahydro[1,3,5]triazines (eq 18).[25]

(17)

α-Arylation of Aldehydes, Synthesis of 2-Aza-1,3-dienes, Reductive Dehalogenation of α-Halo Aldehydes, and Synthesis of 3-(1-Chloroalkyl)oxaziridines.

The Friedel-Crafts-type arylation of α-chloro aldimines in the presence of ***Aluminum Chloride*** gives rise to α-aryl aldimines, which are hydrolyzed to α-aryl aldehydes (eq 20).[16] α-Substituents which stabilize the intermediate α-imidoylcarbenium ions, e.g. phenyl substituents, greatly enhance the yields of this reaction.[16,26] Higher alkyl analogs give lower yields of α-arylation products due to competing 1,2-dehydrochlorination to give α,β-unsaturated aldimines. When toluene is used as the arene, the *ortho*:*para* regiochemistry is about 7:93.[26] This reaction proceeds also with heteroaromatic compounds such as furan (eq 21).[26] The reductive conversion of α-halo aldehydes to aldehydes is not easy to accomplish due to the sensitivity of the carbonyl function for reductive processes. However, this conversion can be performed via *N*-benzyl α-halo aldimines, which undergo 1,4-dehydrohalogenation to give 2-aza-1,3-dienes

(eq 22).[17,18] The latter heterodienes are easily hydrolyzed to aliphatic and aromatic aldehydes (eq 22).[18]

$R^1 = Me, Et; R^2 = Ph, Me, Et; Ar = Ph, 4\text{-}MeC_6H_4, 2,5\text{-}Me_2C_6H_3$

(21)

(22)

Oxidation of α-halo aldimines with ***m-Chloroperbenzoic Acid*** produces stable 3-(1-chloroalkyl)oxaziridines (eq 23), which undergo rearrangement with ***Methyllithium*** to α-(*N*-alkylamino) aldehydes (eq 24) and which oxygenate phenyllithium to phenol (eq 24).[27]

(23)

X = Cl, Br; $R^1 = R^2 = Me$; $R^1 = R^2 = (CH_2)_5$; R = *i*-Pr, *t*-Bu, Cy

(*E*)-(3-Chloro-1-methyl-1-propenyl)trimethylsilane

[116399-78-1] · $C_7H_{15}ClSi$ · (*E*)-(3-Chloro-1-methyl-1-propenyl)trimethylsilane · (MW 162.76)

(annulation reagent; alkylative equivalent of 3-buten-2-one; 3-oxobutyl synthon)

Alternate Name: (*E*)-1-chloro-3-trimethylsilyl-2-butene.

Physical Data: bp 92-94 °C/74 mmHg.

Solubility: freely sol organic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: $\delta_H(CCl_4)$ 0.0 (9H, s), 1.67 (3H, d, *J* 1.5 Hz), 3.93 (2H, d, *J* 7 Hz), 5.8 (1H, t of q, *J* 7 and 1.5 Hz).

Preparative Method: see ***1-Iodo-3-trimethylsilyl-2-butene***.

Basis and Example of Use.

This reagent acts as the alkylative equivalent of 3-buten-2-one (***Methyl Vinyl Ketone***), permitting regiospecific enolate alkylation under nonequilibrating conditions. As a vinylsilane it can be converted,[1] via the corresponding α,β-epoxy silane, into a 3-oxobutyl moiety, and hence used in an alkylative equivalent of Robinson annulation.[2] Application of such methodology can be seen (eq 1) in the preparation of bicyclodecenones via the alkylation of dihydrocarvone with this reagent.[3] Apart from this application, and its use in combination with potassium iodide[4] (see ***1-Iodo-3-trimethylsilyl-2-butene***), it has seen little use so far.

2-Chloro-1-methylpyridinium Iodide[1]

[14338-32-0] · C_6H_7ClIN · 2-Chloro-1-methylpyridinium Iodide · (MW 255.49)

(activation of carboxylic acids;[1] formation of esters[2] and amides;[3] lactonization;[4] ketene formation;[5] β-lactam synthesis;[6,7] carbodiimide synthesis[8])

Alternate Name: Mukaiyama's reagent.

Physical Data: mp 204-206 °C.

Form Supplied in: commercially available yellow solid.

Preparative Method: by reaction between 2-chloropyridine and ***Iodomethane*** in acetone at reflux.[9]

Purification: recrystallization from acetone.

Handling, Storage, and Precautions: hygroscopic.

Activation of Carboxylic Acids: Ester Formation.

2-Chloro-1-methylpyridinium iodide (**1**) reacts with a mixture of a carboxylic acid and an alcohol, in the presence of two equivalents of base, to form an ester (eq 1).[2] The pyridinium salt (**2**) is formed rapidly by displacement of chloride from (**1**) by the carboxylate; subsequent reaction with the alcohol results in formation of the ester, along with 1-methyl-2-pyridone (**3**). A variety of solvents may be employed, but yields are highest in dichloromethane or pyridine. ***Tri-n-butylamine*** or ***Triethylamine*** are often used as base. The co-product (**3**) is insoluble in dichloromethane and so precipitates from this solvent. Good results are obtained even for hindered carboxylic acids and alcohols.

Amide Synthesis.

In a similar way, amides can be prepared efficiently by treatment of an equimolar amount of a carboxylic acid and an amine with (**1**) in the presence of base (eq 2).[3]

Lactone Formation.

The ester formation method has found widespread use in the synthesis of lactones by cyclization of hydroxy acids (eq 3).[4] The cyclization process is believed to be entropically favored because of the close proximity of all reactants to a central pyridinium salt (**4**). Optimum conditions for the process involve addition over 8 h of a solution of the hydroxy acid (0.0125 M) and triethylamine (8 equiv) in dichloromethane or acetonitrile to a solution of (**1**) (4 equiv; 0.04 M) in the same solvent at reflux. After a further 30 min at reflux, evaporation of the solvent and chromatography affords the lactone. Results of a study of the formation of lactones of various ring sizes are shown in Table 1. Good results are obtained for ring sizes 7 and &egt;12, but attempts to form 8- or 9-membered lactones result in substantial dimerization.

Table 1 Lactone Formation by Cyclization of Hydroxy Acids with Reagent (**1**)

Ring size	% Yield lactone	% Yield dimer
7	89	0
8	0	93
9	13	34
12	61	24
13	69	14
16	84	3

Cyclization of sensitive *trans*-γ-hydroxy acids to give strained *trans*-bicyclic γ-lactones of the type (**5**) is often problematic due to dehydration of the tertiary alcohol. A study showed (**1**) to be the reagent of choice for this transformation (eq 4).[10] Other reagents, such as ***1,3-Dicyclohexylcarbodiimide*/*Pyridine*** or ***2,2´-Dipyridyl Disulfide*/*Triphenylphosphine***, give far lower yields.

(4)

(5)

Ketene Formation.

There is evidence that the above esterification procedure may occur at least partly via formation of the ketene from the carboxylic acid.[5] If a carboxylic acid contains a suitably placed alkene, the resulting ketene can undergo intramolecular [2 + 2] cycloaddition (eq 5).[5] Benzene is the best solvent for this reaction, giving yields comparable to those obtained by ketene formation from the corresponding acid chloride.

β-Lactam Synthesis.

Dehydration of β-amino acids to give β-lactams can be effected in high yield using (**1**) in CH_2Cl_2 or MeCN (eq 6).[6]

β-Lactams can also be prepared by the reaction of carboxylic acids, activated by (**1**), with imines; best results are obtained with ***Tripropylamine*** as base in CH_2Cl_2 at reflux (eq 7).[7]

(7)

Carbodiimides from Thioureas.

Conversion of *N,N´*-disubstituted thioureas into carbodiimides can be effected by treatment with (**1**) and 2 equiv of base (eq 8).[8]

Chloromethyl *p*-Tolyl Sulfide[1]

[34125-84-3] · C_8H_9ClS · Chloromethyl *p*-Tolyl Sulfide · (MW 172.68)

(source of the *p*-tolylthio carbanion[2] and reactive electrophiles;[1] starting material for the synthesis of 1-halomethyl *p*-tolyl sulfoxide[3])

Physical Data: bp 125-126 °C/15 mmHg.

Solubility: sol most organic solvents; insol H_2O.

Preparative Methods: several methods are available.[4] The most commonly used and convenient method is the chlorination of methyl *p*-tolyl sulfide with ***Sulfuryl Chloride*** in methylene chloride.[4a,b]

Handling, Storage, and Precautions: use in a fume hood.

Chloromethyl *p*-Tolyl Sulfide Carbanion.

The reaction of *p*-tolylthiochloromethylpotassium, generated by the reaction of chloromethyl *p*-tolyl sulfide with ***Potassium t-Butoxide*** in *t*-butanol in the presence of ***1,4-Diazabicyclo[2.2.2]octane*** (DABCO), with benzaldehyde gives the corresponding α,β-epoxy sulfide as a mixture of isomers, the *cis* isomer being the predominant product. When ***Pivalaldehyde*** is used as the carbonyl component, only the *cis* isomer of the corresponding α,β-epoxy sulfide is formed. The *cis* isomers upon treatment with ***Boron Trifluoride Etherate*** rearrange to α-tolylthio aldehydes with the exclusive migration of the *p*-tolylthio group (eq 1).[2a] This type of rearrangement is analogous to the reaction of α,β-epoxy sulfoxides[5] (see also ***Chloromethyl Phenyl Sulfoxide***).

Attempts to generate *p*-tolylthiochloromethylpotassium with *t*-butoxide in *t*-butanol without DABCO in the presence of the carbonyl compounds gave only *trans*-1,2-bis(*p*-tolylthio)ethylene as a byproduct, presumably by a displacement-elimination reaction involving the *p*-tolylthiochloromethyl carbanion (eq 2).[2a]

A low yield of β-hydroxy-α-chloro sulfide is obtained from the reaction of *p*-tolylthiochloromethyllithium with benzaldehyde, presumably due to the inefficient generation of the carbanion with *n*-butyllithium. The phenylthio analog of the α,β-epoxy sulfide is prepared by the reaction of bis(phenylthio)methyllithium with carbonyl compounds. The adducts, α-hydroxybis(phenylthio) acetals, on reaction with ***Copper(I) Trifluoromethanesulfonate*** (6 equiv) in benzene containing ***Diisopropylethylamine*** (4 equiv), give α,β-epoxy sulfides which are thermally labile and undergo thermal rearrangement to α-phenylthio ketones (eq 3).[6]

A high yield of a Grignard reagent, *p*-tolylthiomethylmagnesium chloride, is obtained by the reaction of chloromethyl *p*-tolyl sulfide with ***Magnesium*** in THF at 10-20 °C. The temperature is the crucial factor, and small amounts of ***Iodine*** and ***1,2-Dibromoethane*** are used to initiate the Grignard reaction. (+)-(*S*)-*p*-Tolyl *p*-tolylthiomethyl sulfoxide is formed in 81% yield with 88% optical purity upon reacting an equimolar amount of the Grignard reagent with (-)-(*S*)-menthyl *p*-toluenesulfinate (see ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***) (eq 4).[2b] This method is used for preparation of the chiral thioacetal monosulfoxide with a higher chemical yield but lower optical purity than the method reported earlier, which utilizes *p*-tolylthiomethyllithium as the carbanion partner.[7] The chiral thioacetal monosulfoxide is useful as a chiral synthon for the synthesis of chiral α-substituted aldehyde s (eq 5).[8]

N-Alkylation.

2*H*-1,3-Benzothiazine derivatives, a group of compounds with significant pharmacological activities, are synthesized by *N*-alkylation followed by cyclization of aryl and alkyl nitriles using ***Antimony(V) Chloride*** as a Lewis acid (eq 6).[9]

P-Alkylation.

The Michael-Arbuzov reaction of chloromethyl *p*-tolyl sulfide with ***Trimethyl Phosphite***[10] or ***Triethyl Phosphite***[11] yields dimethyl- or diethylphosphonylmethyl *p*-tolyl sulfides, which are important intermediates for the synthesis of vinyl sulfides and sulfoxides,[12] as well as for optically active derivatives of dimethylphosphonylmethyl *p*-tolyl sulfoxide (eq 7). This method of preparation of the chiral *p*-tolylthio monosulfoxide is complementary to the reaction using dimethylphosphonylmethyllithium and (-)-(*S*)-menthyl *p*-toluenesulfinate in which the (+)-(*R*) isomer is obtained in high yield and high optical purity (eq 8). The lithio dimethylphosphonylmethyl *p*-tolyl sulfoxide reacts with aldehydes and ketones to give the corresponding vinyl sulfoxides, which can be converted into optically active allylic alcohols (eq 9).[10,13]

Self-Condensation.

Bis(*p*-tolylthio)methane, an important dithioacetal for nucleophilic alkylation,[14] is formed by self-alkylation of chloromethyl *p*-tolyl sulfide using neutral ***Alumina*** as a catalyst (eq 10).[15]

Oxidation.

Fluoromethyl *p*-tolyl sulfide, which can be oxidized to fluoromethyl *p*-tolyl sulfoxide with ***N-Bromosuccinimide*** in methanol, is synthesized by the reaction of chloromethyl *p*-tolyl sulfide with ***Potassium Fluoride*** in the presence of ***18-Crown-6*** (eq 11).[3b] Chloromethyl *p*-tolyl sulfoxide can be synthesized by a one-pot operation from methyl *p*-tolyl sulfide with ***Silver(I) Nitrate*** and ***Sulfuryl Chloride*** via the intermediacy of chloromethyl *p*-tolyl sulfide (eq 12).[3b,c]

Chloromethyl *p*-Tolyl Sulfone

[7569-26-8] · $C_8H_9ClO_2S$ · Chloromethyl *p*-Tolyl Sulfone · (MW 204.68)

(synthesis of α,β-epoxy sulfones and alkylated sulfones;[1] reacts with electrophilic arenes and heterocyclic arenes;[2] source of α-*p*-tolylsulfonyl radicals[1a])

Physical Data: mp 81-82 °C.

Solubility: sol THF, $CHCl_3$, CH_2Cl_2, and most organic solvents.

Preparative Methods: by oxidation of the corresponding sulfoxide[3] or by reaction of sodium *p*-toluenesulfinate with bromochloromethane.[4]

Handling, Storage, and Precautions: use in a fume hood.

α,β-Epoxy Sulfones.

The chemistry of chloromethyl *p*-tolyl sulfone resembles that of chloromethyl phenyl sulfone (see ***Chloromethyl Phenyl Sulfone***). α,β-Epoxy *p*-tolyl sulfones derived from carbonyl compounds are conveniently prepared by a one-step Darzens-type condensation using ***Benzyltriethylammonium Chloride*** (TEBA) as phase-transfer catalyst, and 50% ***Sodium Hydroxide*** as a base (eq 1).[4a,5] *trans*-α,β-Epoxy *p*-tolyl sulfones, and a mixture of *cis* and *trans* isomers, are obtained from aldehydes and unsymmetrical ketones, respectively.

(1)

α,β-Epoxy *p*-tolyl sulfones can also be prepared by the epoxidation of α,β-unsaturated *p*-tolyl sulfones with alkaline ***Hydrogen Peroxide*** (giving *trans*-α,β-epoxy *p*-tolyl sulfones)[6] and potassium chlorite (producing *cis*-α,β-epoxy *p*-

tolyl sulfones).[7]

α,β-Epoxy *p*-tolyl sulfones undergo reactions similar to those of α,β-epoxy phenyl sulfones. Rearrangement with ***Boron Trifluoride Etherate*** gives the expected α-tolylsulfonyl substituted carbonyl products (eq 2).[5b] The reaction with sodium diethyl phosphite gives synthetically useful α-keto phosphonates (eq 3).[8]

(2)

(3)

Alkylation Reactions.

Alkylation of chloromethyl *p*-tolyl sulfone with alkyl halides can be effected either by using a phase-transfer catalyst or ***n-Butyllithium*** as a base (eqs 4 and 5).[5a,9] *p*-Tolylsulfonylchloromethylmagnesium, prepared by the reaction with ***Ethylmagnesium Bromide***, is stable and undergoes normal Grignard reactions, e.g., carbonylation and carbonyl addition reactions.[10]

(4)

(5)

Reaction of α-Alkylated Sulfones.

Racemic and optically active α-chloro-β-keto *p*-tolyl sulfones, prepared by oxidation of the corresponding sulfoxides, undergo Favorskii rearrangement to give α-alkyl amides. This process can be used to synthesize optically active α-alkyl amides by the asymmetric Favorskii rearrangement (eq 6).[11] α-Chloro-α-alkyl-β-keto *p*-tolyl sulfones undergo metal-halogen exchange with *n*-butyllithium to give the corresponding enolates which can be protonated to give substituted α-*p*-tolylsulfonyl derivatives (eq 7).[12]

(6)

(7)

Vicarious Nucleophilic Aromatic Substitution of Hydrogen (VNS).

The chloromethyl *p*-tolyl sulfone carbanion behaves similarly to the corresponding phenyl analog in the vicarious nucleophilic substitution of hydrogen (VNS) with electrophilic arenes and heterocyclic arenes.[2] The reaction with 1,4-dicyanonaphthalene gives both the VNS product and the corresponding bis(cyclopropane) derivative (eq 8).[13] The reaction with 6-nitroquinoxaline gives the normal VNS product (eq 9),[13] whereas the reaction with 6-azaquinoxaline gives either VNS and/or the corresponding bis(cyclopropane) products depending on temperature, the base used and its concentration (eq 10).[14]

(8)

20 °C	0%	84%
-10 °C	25%	23%
-30 °C	44%	0%

Radical Reactions.

The α-*p*-tolylsulfonylmethyl radical, generated using either ***Tri-n-butylstannane***, ***Azobisisobutyronitrile***,[15] or ***Hexabutyldistannane*** with UV irradiation,[16] adds to enol ethers, enamines, and silyl enol ethers. The addition to enamines shows considerable *syn* diastereoselectivity which can be explained on the basis of an allylic 1,3-strain model (eq 11). When an alkenic or alkynic moiety is present in the α-substituent of the α-*p*-tolylsulfonylmethyl radical, cyclization can occur to give five-membered ring compounds (eqs 12 and 13).[15b,17]

(Chloromethyl)trimethylsilane[1]

Me_3SiCH_2Cl

[2344-80-1] · $C_4H_{11}ClSi$ · (Chloromethyl)trimethylsilane · (MW 122.67)

(reagent for direct alkene synthesis;[2] electrophile for the formation of a variety of functionalized synthetic intermediates for alkene synthesis;[3] alkylation adducts are frequently a source of fluoride-induced reactive intermediates;[4] readily undergoes metal-halogen exchange to generate a reagent for Peterson methylenation[5])

Alternate Name: trimethylsilylmethyl chloride.

Physical Data: bp 97-98 °C; *d* 0.886 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: highly flammable liquid; corrosive; irritant; use in a fume hood.

Reactions with Carbonyl Compounds.

Terminal alkenes are efficiently generated upon treatment of an aldehyde or ketone with Me_3SiCH_2Cl in the presence of ***Triphenylphosphine*** in a sealed tube (eq 1).[2] Reaction times are generally not more than 60 min, and the method is operationally simple, although use of this protocol for methylenation is limited to substrates which lack enolizable α-hydrogens, since in such cases studied, silyl enol ether formation is a competitive pathway.

(1)

Conversion of aldehydes and ketones to α,β-epoxy trimethylsilanes is readily achieved by treatment of Me_3SiCH_2Cl with the appropriate alkyllithium reagent at low temperature, and subsequent quenching with the desired carbonyl compound.[6] It is critical that ***s-Butyllithium*** be used as the lithiating reagent, as use of ***n-Butyllithium*** results in attack at silicon and use of ***t-Butyllithium*** results in metal-halogen exchange. The resultant α,β-epoxy trimethylsilanes undergo facile hydrolysis under relatively mild conditions to provide the corresponding aldehydes in

good yields (eq 2). A variety of substrates have been successfully subjected to this sequence, including α,β-unsaturated carbonyl compounds and sterically congested aldehydes and ketones.

(2)

In the presence of ***Cesium Fluoride*** in DMF, Me_3SiCH_2Cl reacts with benzaldehyde to form phenyloxirane in 60% yield (eq 3);[7] this method has not yet proven to be a generally applicable route to epoxides.

(3)

Electrophile for *O*-, *N*-, and *S*-Alkylations.

A novel method for phenol homologation utilizes Me_3SiCH_2Cl to trap phenoxides, forming trimethylsilylmethyl phenyl ethers which, upon treatment with *s*-butyllithium, undergo 1,2-Wittig rearrangement of the intermediate lithiated trimethylsilylmethyl species to produce trimethylsilyl-substituted benzyl alcohols in good yields. Subjecting these phenylsilylmethanols to basic hydrolysis with methanolic potassium hydroxide produces the homologated phenols (eq 4).[8]

Much of the utility of Me_3SiCH_2Cl is derived from the lability of the methylene carbon-silicon bond in its alkylation products from nitrogen-containing nucleophiles. The subsequent, relatively mild conditions of fluoride treatment effect 1,3-dipole formation. This fluoride-promoted azomethine ylide generation methodology constitutes a highly stereoselective means for the synthesis of pyrroles by the trapping of the reactive intermediate with ***Dimethyl Fumarate*** or ***Dimethyl Maleate*** (eq 5).[4]

(Chloromethyl)trimethylsilane

Other dipolarophiles, including aldehydes, nitroalkenes, styrenes, and functionalized alkynes (eq 6), have also proven to be effective cycloaddition substrates for ylides generated in this fashion.[9]

(6)

Intramolecular trapping of ylides derived from the Me_3SiCH_2Cl alkylation adducts of a variety of 3- and 4-substituted benzylamines proceeds through a Sommelet-Hauser pathway, providing the rearranged products in good yields (eq 7).[10]

Azolylmethyl anions, generated by the fluoride-induced desilylation of Me_3SiCH_2Cl adducts of pyrroles, imidazoles, pyrazoles, triazoles, and tetrazoles, and azinonylmethyl anions similarly derived from (trimethylsilylmethyl)azinones, have demonstrated efficacy in the addition reactions to carbonyl compounds.[11]

Sulfur alkylation products of Me_3SiCH_2Cl have also been used as a convenient source of reactive intermediates. Lithiated (2-benzothiazolylthio)(trimethylsilyl)methane (eq 8) functions as a synthetic equivalent for the mercaptomethyl anion by (a) reaction with an electrophile, (b) fluoride-promoted desilylation/reaction with a carbonyl compound, and (c) alkyllithium addition to the benzothiazole 2-position.[12]

Thiiranes have been prepared by the reaction of aldehydes with *S*-methyl *S*´-trimethylsilylmethyl *N*-(*p*-tolylsulfonyl)dithioiminocarbonate in the presence of cesium fluoride (eq 9).[13] This novel route to thiiranes utilizes the 1,3-dipolar cycloaddition of the iminothiocarbonyl ylide derived from a Me_3SiCH_2Cl alkylated thiol to aldehydes.

(9)

Preparation of Other Reagents.

One of the principal uses of this reagent has been for the formation of ***Trimethylsilylmethylmagnesium Chloride***, most often used for the methylenation of carbonyl compounds;[5] however, since both this reagent and the corresponding lithio reagent are now widely available commercially, its use in this capacity has diminished considerably. Similarly, chloromethyltrimethylsilane has been used to prepare many other now commercially available reagents, including trimethylsilylmethyl acetate, trimethylsilylmethyl isocyanide, ***Trimethylsilyldiazomethane*** and trimethylsilylmethyl trifluoromethanesulfonate, each useful for a variety of synthetic transformations.

Related Reagents.

(Iodomethyl)trimethylsilane; ***Trimethylsilylmethyllithium***; ***Trimethylsilylmethylmagnesium Chloride***; ***Trimethylsilylmethylpotassium***; ***Trimethylsilylmethyl Trifluoromethanesulfonate***.

Chloromethyl Trimethylsilyl Ether

$ClCH_2OSiMe_3$

[23586-77-8] · $C_4H_{11}ClOSi$ · Chloromethyl Trimethylsilyl Ether · (MW 138.67)

(hydroxymethyl cation equivalent[1])

Physical Data: only characterized by ^1H and ^{13}C NMR at -50 °C.

Solubility: sol dichloromethane.

Preparative Method: prepared in situ under nitrogen by addition of a cooled (-78 °C) solution of ***Sulfuryl Chloride*** (1 equiv) in dry dichloromethane (2 M) to a solution of ethyl (trimethylsilyloxy)methyl sulfide in dichloromethane (1 M).[1]

Handling, Storage, and Precautions: low stability; best prepared in situ at low temperature.

Hydroxymethyl Cation Equivalent.

Chloromethyl trimethylsilyl ether, prepared in situ at -78 °C in dichloromethane, reacts with 1-(trimethylsilyloxy)cyclopentene (3 equiv) and a catalytic amount of ***Zinc Bromide*** (10 mol %) to give 2-hydroxymethylcyclopentanone in 71% yield (eq 1).[1] Since the preparation of chloromethyl trimethylsilyl ether generates an equivalent amount of ethylsulfenyl chloride, 2-ethylthiocyclopentanone is also obtained. Overall, this reagent provides a method for α-hydroxymethylation of carbonyl compounds.

Chloromethyl Trimethylsilylmethyl Sulfide

$ClCH_2SCH_2SiMe_3$

[105850-89-3] · $C_5H_{13}ClSSi$ · Chloromethyl Trimethylsilylmethyl Sulfide · (MW 168.76)

(thiocarbonyl ylide synthon[1])

Physical Data: bp 75 °C/20 mmHg.

Solubility: sol acetonitrile, THF.

Preparative Method: prepared in 69% yield by introducing dry ***Hydrogen Chloride*** into a mixture of trimethylsilylmethanethiol[2] and 1,3,5-trioxane (see ***Formaldehyde***) at temperature below 0 °C.[3]

Purification: by distillation.

Handling, Storage, and Precautions: potent alkylating agent; moisture sensitive; stench; use in a fume hood.

Stereospecific [3 + 2] annulation of chloromethyl trimethylsilylmethyl sulfide (**1**) with electron-deficient alkenes in the presence of ***Cesium Fluoride*** in acetonitrile at room temperature gives tetrahydrothiophenes in good yields (eq 1).[3] This reaction presumably goes through thiocarbonyl ylide intermediate (**2**).

Sulfide (**1**) also reacts with acetylenedicarboxylate to give the corresponding dihydrothiophenes.[3] However, (**1**) is not reactive towards cyclic alkenes such as maleic anhydride.

The title reagent also reacts with aromatic aldehydes to yield the corresponding [3 + 2] cycloadduct 1,3-oxathiolanes (eq 2).[4] Simple ketones and oxoesters do not undergo this reaction.

When sulfide (**1**) is heated with nitrogen-containing aromatic heterocycles followed by treatment with cesium fluoride in acetonitrile, various 1,3-thiazolidines are obtained (eq 3).[1] This is formally a [3 + 2] cycloaddition between the thiocarbonyl ylide (**2**) and the carbon-nitrogen double bond.

3-Chloro-3-methyl-2-trimethylsilyloxy-1-butene

[69875-71-4] · $C_8H_{17}ClOSi$ · 3-Chloro-3-methyl-2-trimethylsilyloxy-1-butene · (MW 192.76)

(allyl halide, precursor of 2-oxyallyl cation with the aid of $AgClO_4$; precursor of silyl vinyl ether)

Physical Data: bp 74-75 °C/90 mmHg.

Solubility: sol common organic solvents; insol and slowly decomposed in H_2O.

Form Supplied in: oil.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$-Me_4Si) δ 0.18 (s, 9H), 1.95 (br s, 3H), 4.23 (br s, 1H), 4.40 (s, 1H), 4.87 (br s, 1H), 5.30 (m, 1H).

Preparative Method: [1] a mixture of 3-chloro-3-methyl-2-butanone (**1**),[2] ***Chlorotrimethylsilane***, and ***Triethylamine*** in DMF is heated at 85-90 °C for 18 h. The mixture is diluted with petroleum ether, washed with cold water, and dried over Na_2SO_4. Solvent is evaporated, and the remaining oil is fractionated under reduced pressure to give 3-chloro-3-methyl-2-trimethylsilyloxy-1-butene (**2**) in 52% yield (eq 1). A byproduct, 2-methyl-3-(trimethylsilyloxy)-1,3-butadiene, is isolated in foreruns (54-55 °C/95 mmHg, 9%).[1]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; use only in a chemical fume hood; recommended to distill just prior to use.

2-Trimethylsilyloxyallyl Cation.[1,3-5]

Reaction of 3-chloro-3-methyl-2-trimethylsilyloxy-1-butene (**2**) with ***Silver(I) Perchlorate*** produces 3,3-dimethyl-2-trimethylsilyloxyallyl cation (**3**), which reacts with cyclopentadiene, furan, or alkenes to give 2,2-dimethylbicyclo[3.2.1]oct-6-en-3-one (**4**), 2,2-dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (**5**), or 2,2-dimethylcyclopentanone derivatives (**6**), respectively (eqs 2 and 3). The reaction with furan in nitromethane is assumed to be a concerted reaction which gives the tricyclic ketone as the sole product. The one in THF/Et_2O results in a stepwise reaction to give 2-(1,1-dimethyl-2-trimethylsilyloxy-3-chloro-2-butenyl)furan.

In general, the reaction of 2-oxyallyl cation with furans is either concerted or stepwise (Scheme 1). Concerted reaction of the 2-oxyallyl cation species (**3**) with the furan follows the [3 + 4] manner to give 8-oxabicyclo[3.2.1]oct-6-en-3-ones (**9**). Stepwise reaction of the allyl cation first produces a 2-substituted furyl cation intermediate (**8**) which then cyclizes to give the same products (**9**) or undergoes intermolecular reaction with a nucleophile to give a mixture of dihydrofurans (**10**) and (**11**). Alternatively, deprotonation of the intermediate cationic species affords 2-substituted furans (**12**).

Scheme 1

Similar 2-oxyallyl cation species are generated from α-halo ketones with ***Triethylamine*** or from α,α´-dihalo ketones with ***Zinc/Copper Couple*** or ***Pentacarbonyliron***. Cycloaddition reactions of 2-oxyallyl cation species have been reviewed.[3]

The electrophilicity of the oxyallyl intermediates decreases in the order of M = FeX > SiR_3 > ZnX > Li > Na. The allyl cation of high electrophilicity favors stepwise reaction pathways, while less electrophilic 2-oxyallyl cations needs more nucleophilic furans to afford [3 + 4] cycloaddition products.

Regioselective Synthesis of Silyl Vinyl Ethers.[6]

Reaction of (**2**) and its derivatives with lithium dialkyl- or diarylcuprate proceeds in an S_N2' fashion to give 4-substituted 2-methyl-3-trimethylsilyloxy-2-butenes (**13**) (eq 4). This method can be applied to the synthesis of the silyl vinyl ethers that are inaccessible by other methods.

2-Chloromethyl-3-trimethylsilyl-1-propene

[18388-03-9] · $C_7H_{15}ClSi$ · 2-Chloromethyl-3-trimethylsilyl-1-propene · (MW 162.73)

(bifunctional electrophilic and nucleophilic reagent displaying reactions characteristic of both allylsilanes and allyl halides; useful for exomethylene annulation reactions)

Physical Data: bp 162-163 °C/768 mmHg; *d* 0.899 g cm^{-3}; *n* 1.4540.

Solubility: insol water; miscible with organic solvents.

Form Supplied in: colorless liquid; commercially available.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$) δ 4.99 (s, 1H), 4.75 (s, 1H), 3.96 (s, 2H), 1.68 (s, 2H), 0.04 (s, 9H); ^{13}C NMR ($CDCl_3$) δ 143.0, 112.3, 49.9, 23.6, -1.5.[1]

Preparative Methods: from 3-chloro-2-methyl-1-propene,[2] from ***(Iodomethyl)trimethylsilane***,[3] from 2-(hydroxymethyl)-3-trimethylsilyl-1-propene,[4] from 3-chloro-2-(chloromethyl)-1-propene and ***Trichlorosilane***,[5] and from ***Methyl Chloroacetate***.[1,6]

Handling, Storage, and Precautions: flammable liquid (flash point 43 °C). Storage at 4 °C under N_2 advised. Handle under N_2. May be harmful by inhalation, ingestion, or skin absorption. Vapor or mist is irritating to the eyes, mucous membranes, and upper respiratory tract. Causes skin irritation. Toxicological properties not thoroughly investigated. Use in a fume hood.

Characterization of Reagent.

This reagent, 2-chloromethyl-3-trimethylsilyl-1-propene (**1**), at once an allyl chloride and allylsilane, is best considered as a synthetic equivalent of the zwitterion (**2**).

Methylenecyclopentane 3,4-Annulation with Enones.

By virtue of the fact that the electrophilic and nucleophilic reactivities of (**1**) are triggered under well differentiated conditions, this reagent has found some utility for cyclopentane annulation in which the ring is invariably constructed by a two-step process. This was first demonstrated by Knapp et al. with the methylenecyclopentane annulation of cyclic enones (**3**) (eqs 1 and 2).[3,7]

(1)

(2)

(4) **(5)**

	n	X	Lewis acid		Yield (%)		Yield (%)
(3a)	1	H	$TiCl_4$	**(4a)**	8	**(5a)**	-
(3b)	1	SPh	Et_2AlCl	**(4b)**	63	**(5b)**	73
(3c)	2	H	$TiCl_4$	**(4c)**	80	**(5c)**	60
(3d)	2	SPh	Et_2AlCl	**(4d)**	80	**(5d)**	79

This sequence makes use of the ability of allylsilanes to undergo the Michael reaction with α,β-unsaturated ketones under Lewis acidic conditions (eq 1) (see ***Allyltrimethylsilane***). Best results are achieved with α-phenylthio substitution; the sensitive cyclopentenone (**3a**) suffers extensive polymerization during this step. Cyclization is then achieved by base treatment (eq 2). In the case of (**4c**) a 3:1 mixture of isomers results, but the predominant diastereoisomer of (**5c**) is not characterized. These results contrast with those obtained by Trost and Chan with the trimethylenemethane complex (**6**) (eq 3).[8] This reagent generated in situ from ***3-Acetoxy-2-trimethylsilylmethyl-1-propene*** in the presence of a palladium catalyst accomplishes the methylenecyclopentane annulation with a variety of activated alkenes in one step under mild conditions (eqs 3 and 4).[9] A good yield (60%) is obtained in this concerted reaction with cyclopentenone, although poor yields are observed with cyclohex-2-enone and cyclohept-2-enone, in contrast to Knapp's two-step sequence.[7,9-11]

(3)

(6)

(4)

(6)

1,2-Aldehyde Addition Reactions.

The allylsilane reactivity of (**1**) with aldehydes under Lewis acid conditions (eq 5) forms the basis of another mode of annulation, furnishing either 3-methylenetetrahydrofurans (**8**) (eq 6) or α-methylenebutyrolactones (**9**) (eq 7).[12]

(5)

(10)

(6)

(8)

(7)

(9)

The first step proceeds under catalysis by ***Boron Trifluoride Etherate*** in the preferred solvent chloroform to give homoallyl alcohols (**10**) in good yield (eq 5). Cyclization to the ether (**8**) is accomplished by treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) in the presence of ***Lithium Perchlorate*** (eq 6). The equivalent transformation has been more commonly achieved in one step in generally high yields by use of 3-acetoxy-2-trimethylsilylmethyl-1-

propene (eq 8)[13,14] or 2-trialkylstannylmethyl-3-trimethylsilyl-1-propene in the presence of a palladium catalyst.[15,16]

(8)

Alternatively, (**10**) may be oxidized to a carboxylic acid; cycloesterification with ***Trifluoromethanesulfonic Anhydride*** then yields α-methylenebutyrolactones (**9**) (eq 7).[12] This same transformation has also been demonstrated in one step using 2-(bromomethyl)acrylic acid[17b] or its ethyl ester under reducing conditions (eq 9).[17]

(9)

The same authors have described the addition of (**1**) to protected α-aminoaldehydes to give amino alcohols with high levels of diastereoselectivity in moderate to good yields (eq 10).[18,19] They report isolation of a single diastereoisomer following chromatographic purification.

(10)

Alkylations.

An interesting example of the use of (**1**) for the construction of a six-membered ring has been demonstrated by Guiles and Meyers (eq 11).[20] Tetrahydroisoquinoline alkylation with (**1**) occurred with high enantioselectivity. Following deprotection, cyclization was initiated in the presence of fluoride ion with formaldehyde. A racemic product was obtained due to the reversible aza-[3,3]-sigmatropic rearrangement of the iminium ion intermediate.

A few examples have appeared in the literature in which solely the electrophilic character of (**1**) has been utilized;[21-23] in this respect, 2-mesyloxymethyl-3-trimethylsilyl-1-propene has found more general usage.[11]

Chloromethyltriphenylphosphonium Chloride[1]

[5293-84-5] · $C_{19}H_{17}Cl_2P$ · Chloromethyltriphenylphosphonium Chloride · (MW 347.22)

(precursor to the chloro-substituted ylide for Wittig reactions with aldehydes and ketones to form 1-chloroalkenes and, after elimination of HCl, terminal alkynes)

Physical Data: mp 260 °C.

Solubility: suspensions in most organic solvents can be treated with base to form the soluble phosphorus ylide.

Form Supplied in: white powder, available commercially (chloride or iodide salt) or synthetically from ***Triphenylphosphine*** and ***Chloroiodomethane***.[2]

Handling, Storage, and Precautions: for best results the anhydrous salt should be used. The ylide, formed from the salt and strong base, will react with air, water, or other acidic protons.

Preparation of the Ylide and Stereoselectivity.

The Wittig reaction of chloromethylenetriphenylphosphorane forms chloroalkenes from carbonyl compounds with complete regioselectivity. The ylide is prepared by treating a suspension of dry phosphonium salt under N_2 with a strong base. ***n-Butyllithium*** has often been used, but the chloroalkene products are usually obtained as (*E*)/(*Z*) mixtures,[3,4] and side reactions have occasionally been reported.[2,3] Better results are obtained with bases such as ***Potassium Hexamethyldisilazide***,[5] ***Potassium t-Butoxide***,[2] or ***Sodium Amide***.[6] Although stereoselectivity for this ylide is often low (even in the absence of Li cation),[2] several (*E*)- or (*Z*)-selective reactions have been reported. Reaction of the chloro-substituted ylide, prepared from KHMDS in toluene, with an α-keto amino acid derivative (eq 1) gave an 85:15 (*Z*)/(*E*) ratio of chloroalkenes in 85% yield.[5]

High (*E*) selectivity was obtained in the reaction of this ylide (generated from the salt and *t*-BuOK in *t*-butanol) with benzaldehyde. A 1:1 mixture of chlorostyrenes was formed at rt, but 100% (*E*)-alkene was produced after refluxing the reaction for 4 h (eq 2).[2]

Synthesis of Alkynes.

Synthetically, the most common use for the chloroalkene products is the preparation of alkynes. Dehydrohalogenation of the vinyl chlorides with an excess of strong base (***n-Butyllithium*** or ***Lithium Diisopropylamide***) gives terminal alkynes in good yield. This methodology has been used in the synthesis of alkynyl steroids (eq 3)[7] and carbohydrate derivatives (eq 4).[8] The transformation of RCHO to RC&tbond;CH has also been performed in the synthesis of lycopene isomers,[9] and derivatives of vitamin D[10] and retinal.[11]

(3)

A useful alternative to the Wittig reaction for vinyl halide synthesis is the ***Chromium(II) Chloride*** mediated reaction of an aldehyde and chloroform.[12] The organochromium intermediate forms 1-chloroalkenes from aliphatic and aromatic aldehydes with high (*E*) selectivity in yields of 55-75%. The procedure, however, requires 6 equiv of the expensive chromium reagent. Other alkene-forming reactions, such as the Peterson alkenation[13] and the Tebbe reaction,[14] are not useful for the preparation of vinyl chlorides.

N-Chloromorpholine

[23328-69-0] · C_4H_8ClNO · *N*-Chloromorpholine · (MW 121.57)

(useful reagent for selective and efficient chlorination of activated aromatics[1])

Alternate Name: NCM.

Physical Data: bp 63-64 °C/36-38 mmHg.[1]

Solubility: sol diethyl ether, trifluoroacetic acid, carbon tetrachloride.

Preparative Methods: not commercially available; prepared from ***Morpholine*** and aqueous ***Sodium Hypochlorite*** at <10 °C, followed by ether extraction, concentration below 30 °C, and vacuum distillation.[1,2]

Analysis of Reagent Purity: can be determined iodometrically.[3]

Handling, Storage, and Precautions: lachrymatory liquid; begins to decompose at ambient temperature within hours, or on distillation at atmospheric pressure.[4] Preferably used immediately after distillation; however, can be stored at -18 °C for several weeks with limited decomposition. Solid which forms on standing (morpholine hydrochloride) can be removed by filtration just before use.[1] Store under inert atmosphere. This reagent should be handled in a fume hood.

Chlorination of Activated Aromatics.

Phenol, anisole, and related activated aromatic compounds are selectively chlorinated by *N*-chloromorpholine (NCM) in the *para* position in high yield, with formation of only small amounts of the corresponding *ortho* isomers. For example, 2-chloroanisole and NCM afford 2,4-dichloroanisole in 80% yield (eq 1). Less than 1% each of 2,6-dichloroanisole and 2,4,6-trichloroanisole are obtained under these conditions.[1]

(1)

Salicylic acid and NCM also give chlorination mainly *para* to the phenolic hydroxyl group (eq 2).[5]

(2)

These chlorinations are usually carried out in either trifluoroacetic acid or 80% aqueous sulfuric acid. In the latter solvent, highly activated substrates such as phenols can undergo ring sulfonation. Such side reactions can generally be minimized by keeping the reaction mixtures cold and employing short reaction times.[1,5]

Other structurally similar chlorinating agents, such as *N*-chloropiperidine (NCP), have also been used for selective *para* chlorination of activated aromatics. There appears to be no strong preference for use of NCM over NCP or related compounds, as overall yields and isomer ratios are generally excellent with each of these reagents.[1] Mechanistic details of these transformations have been published.[6]

Unfortunately, NCM as well as other reagents in this family chlorinate less activated aromatics such as alkylbenzenes relatively unselectively, to afford mixtures of 2- and 4-substituted products.[7] The isomer ratio can be affected by changing the acid strength of the solvent,[7a] or by use of added silica gel;[3] however, only limited specificity for one isomer can be obtained in this fashion.

Chlorodealkylation of Alkyl Phenols.

t-Butyl substituted phenols react with NCM to substitute chlorine for the *t*-butyl group (eq 3).[5]

Other Reactions.

NCM can be used to prepare morpholino-substituted sulfenamides[8] and selenamides[9] upon reaction with alkyl sulfides and selenides, respectively. Such amides have been used as vulcanization accelerators in the rubber industry.

1-Chloro-1-nitrosocyclohexane

[695-64-7] · $C_6H_{10}ClNO$ · 1-Chloro-1-nitrosocyclohexane · (MW 147.5)

(electrophilic [NH_2^+] for alkenes and can function as a dienophile for [4 + 2] reactions)

Physical Data: bp 52 °C/12 mmHg.

Solubility: sol in wide range of organic solvents.

Form Supplied in: solid; widely available.

Preparative Methods: the most commonly used method is the reaction of cyclohexanone oxime with a chlorinating agent such as ***t-Butyl Hypochlorite*** in trichlorofluoromethane (eq 1).[1]

1-Chloro-1-nitrosocyclohexane shows a wide range of reactivity towards different functional groups. Deboer first demonstrated the reactivity of this reagent by reacting it with allylic alkenes such as phenylpropene to give cyclohexylidene-*N*-(2-phenyl)-prop-1-en-3-yl nitrone hydrochloride in 76% yield (eq 2).[2]

(2)

Other authors have shown that this reagent can be used effectively in the synthesis of polyhydroxylated cyclohexyl derivatives, alkaloids, and amino acids. 1-Chloro-1-nitrosocyclohexane reacts with 1,3-butadiene in ethanol to give 3,6-dihydro-1,2-dioxine (eq 3).[3] Kresze in 1981 reported a synthesis of polyhydroxy amino compounds by utilizing the reactivity of 1-chloro-1-nitroso compounds towards dienes such as *trans*-1,3-cyclohexadien-5,6-diyl diacetate (eq 4).[4] In 1984, Kibayashi reported a facile route to naturally occurring tropane alkaloids.[5] The approach employs a Diels-Alder cycloaddition of cyclohepta-1,3-dienes with nitroso compounds followed by an intramolecular C-N bond formation (eq 5).

(3)

(4)

(5)

Recently, Oppolzer demonstrated the use of 1-chloro-1-nitrosocyclohexane as a convenient electrophilic nitrogen source in the asymmetric synthesis of amino acids and α-hydroxyamino acids.[6] Treatment of an *N*-alkylsultam with ***Sodium Hexamethyldisilazide*** followed by 1-chloro-1-nitrosocyclohexane gave diastereomerically pure crystalline *N*-hydroxy amino acids (eqs 6 and 7).

2-Chloro-2-oxo-1,3,2-benzodioxaphosphole

[1499-17-8] · $C_6H_4ClO_3P$ · 2-Chloro-2-oxo-1,3,2-benzodioxaphosphole · (MW 190.52)

(phosphorylation of alcohols;[1] peptide synthesis,[2] β-lactam synthesis[3])

Alternate Name: *o*-phenylene phosphorochloridate.

Physical Data: mp 59-61 °C; bp 80-81 °C/1.2 mmHg.

Form Supplied in: commercially available as a white to off-white solid.

Preparative Method: prepared by heating 2,2,2-trichloro-1,3,2-benzodioxaphosphole with a slight excess of acetic anhydride.[1]

Purification: purified by distillation.

Handling, Storage, and Precautions: moisture sensitive, but may be kept indefinitely in a sealed vessel.

Preparation of Monophosphate Esters from Alcohols.[1,4]

2-Chloro-2-oxo-1,3,2-benzodioxaphosphole (**1**) is an extremely active phosphorylating agent for alcohols, reacting rapidly and quantitatively even with hindered alcohols such as *t*-butanol.[1] The resulting phosphotriesters (**2**) (eq 1) need not be isolated, and are hydrolyzed in the presence of base to the stable, often crystalline, *o*-hydroxyphenyl phosphates (**3**). Oxidation to the monoalkyl phosphates (**4**) may conveniently be accomplished using buffered bromine water or with aqueous periodic acid. Where the original alcohol contained unsaturation, however, these conditions are unsatisfactory and the transformation may be achieved with ***Lead(IV) Acetate*** in dioxane.[1] Reductive conditions (H_2/Adams catalyst) have also been employed.[5]

The overall procedure is of great utility for the phosphorylation of alcohols, including tertiary alcohols, and has been applied to the phosphorylation of nucleosides.[6] The phosphates (**4**) are generally isolated as their barium salts, free of inorganic phosphate, and indeed are often analytically pure before recrystallization.

Peptide Synthesis.

Treatment of (**1**) with an amine and a carboxylate salt results in amide bond formation, via the phosphoramidate intermediate (**5**) (eq 2).[2] No racemization was observed for the example shown (the Anderson test).

β-Lactam Synthesis.

Reagent (**1**) has been used for the condensation of carboxylic acids with amines to give β-lactams (eq 3).[3] The *trans* isomer predominated in this example.

1-Chloro-3-pentanone

[32830-97-0] · C_5H_9ClO · 1-Chloro-3-pentanone · (MW 120.58)

(reagent for Robinson annulation; often interchangeable with 1-penten-3-one and the corresponding Mannich base 1-dialkylamino-3-butanone)

Alternate Name: 2-chloroethyl ethyl ketone

Physical Data: bp 62-65 °C/15 mmHg; *d* 1.042 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: liquid; commercially available.

Purification: by distillation.

Annulation.

The reagent is the synthetic equivalent of 1-penten-3-one (ethyl vinyl ketone) and the quaternary salt of the Mannich base 1-dimethylamino-3-butanone in the Robinson annulation. The use of the reagent in this annulation has been briefly reviewed.[1,2] The reagent is believed to generate the vinyl ketone.[3] Although most annulations are done with base in organic solvents, the reagent can also be used with acid in organic[4] and in aqueous solution. In water, it reacts as expected with 2-methylcyclopentane-1,3-dione (eq 1).[5]

(1)

However, the corresponding cyclohexane derivative gives an acid as the major product, which presumably results from opening of a bridged aldol intermediate (eq 2).[5]

Careful examination of products shows that often both mono- and bis-annulation products are formed (eq 3).[6] The bis-annulation can give two intermediate products, which converge to one (eq 4).[6] The bis-annulation can also be done without isolation of the intermediates (eq 5).[7]

(3)

(4)

While most of the annulations have been done with a strong base, the reactions with 1,3-dicarbonyl compounds are efficient with ***Triethylamine*** in boiling EtOAc (eq 6).[8] This method has been applied to synthesis of spiroenediones (eq 7).[9]

(7)

Quinoline Synthesis.[10]

The reagent was used to prepare a quinoline by a Skraup-type reaction (eq 8). Although the yield is low, it is comparable to the yields from the α,β-unsaturated aldehydes or ketones, which usually are in the 20-30% range.[11]

5-Chloro-1-penten-3-one

[20757-87-3] · C_5H_7ClO · 5-Chloro-1-penten-3-one · (MW 118.56)

(reagent for the construction of fused ring systems and polyketones with 1,4- and 1,5-carbonyl relationships)

Physical Data: bp 25 °C/0.08 mmHg.

Solubility: sol most organic solvents.

Analysis of Reagent Purity: ^{1}H NMR data are available.[1]

Preparative Method: not commercially available; prepared in a two-step sequence from β-chloropropionyl chloride and ethylene to give 1,5-dichloro-3-pentanone in 95% yield,[2] which is then monodehydrochlorinated in 83% yield;[3] earlier preparations[4,5,6] of 1,5-dichloro-3-pentanone gave much lower yields.

Handling, Storage, and Precautions: use in a fume hood.

Condensations.

The reagent is used to generate a 2,6,10-triketone, which can be condensed to a tricyclic system[1] by multiple intramolecular aldol condensations (eq 1). It is the synthetic equivalent of ***Divinyl Ketone***; however, it allows sequential Michael addition of two different carbonyl compounds to produce an unsymmetrical 2,6,10-triketone, a procedure which is unsuccessful if used with divinyl ketone.

5-Chloro-1-penten-3-one

Diels-Alder Reaction.

The reagent undergoes a Diels-Alder reaction to yield β-chloro ketones, which can be dehydrohalogenated to the vinyl ketones. Thiazolium salt catalyzed additions of aldehydes to the vinyl ketones lead to 1,4-diketones, which can be further elaborated by repeated sequences of the same type to 1,4,7-triketones and 1,4,7,10-tetraketones (eq 2).[3]

m-Chloroperbenzoic Acid[1]

[937-14-4] · $C_7H_5ClO_3$ · *m*-Chloroperbenzoic Acid · (MW 172.57)

(electrophilic reagent capable of reacting with many functional groups; delivers oxygen to alkenes, sulfides, selenides, and amines)

Alternate Name: m-CPBA; MCPBA.

Physical Data: mp 92-94 °C.

Solubility: sol CH_2Cl_2, $CHCl_3$, 1,2-dichloroethane, ethyl acetate, benzene, and ether; slightly sol hexane; insol H_2O.

Form Supplied in: white powder, available with purity of 50%, 85%, and 98% (the rest is 3-chlorobenzoic acid and water).

Analysis of Reagent Purity: iodometry.[2]

Purification: commercial material (purity 85%) is washed with a phosphate buffer of pH 7.5 and dried under reduced pressure to furnish reagent with purity >99%.[3]

Handling, Storage, and Precautions: pure *m*-CPBA is shock sensitive and can deflagrate;[4] potentially explosive, and care is required while carrying out the reactions and during workup.[5] Store in polyethylene containers under refrigeration.

Functional Group Oxidations.

The weak O-O bond of *m*-CPBA undergoes attack by electron-rich substrates such as simple alkenes, alkenes carrying a variety of functional groups (such as ethers, alcohols, esters, ketones, and amides which are inert to this reagent), some aromatic compounds,[6] sulfides, selenides, amines, and N-heterocycles; the result is that an oxygen atom is transferred to the substrate. Ketones and aldehydes undergo oxygen insertion reactions (Baeyer-Villiger

oxidation).

Organic peroxy acids (**1**) readily epoxidize alkenes (eq 1).[1b] This reaction is *syn* stereospecific;[7] the groups (R^1 and R^3) which are *cis* related in the alkene (**2**) are *cis* in the epoxidation product (**3**). The reaction is believed to take place via the transition state (**4**).[8] The reaction rate is high if the group R in (**1**) is electron withdrawing, and the groups R^1, R^2, R^3, and R^4 in (**2**) are electron releasing.

(1)

(4)

Epoxidations of alkenes with *m*-CPBA are usually carried out by mixing the reactants in CH_2Cl_2 or $CHCl_3$ at 0-25 °C.[9] After the reaction is complete the reaction mixture is cooled in an ice bath and the precipitated *m*-chlorobenzoic acid is removed by filtration. The organic layer is washed with sodium bisulfite solution, $NaHCO_3$ solution, and brine.[10] The organic layer is dried and concentrated under reduced pressure. Many epoxides have been purified chromatographically; however, some epoxides decompose during chromatography.[11] If distillation (*caution*: check for peroxides[12]) is employed to isolate volatile epoxides, a trace of alkali should be added to avoid acid-catalyzed rearrangement.

Alkenes having low reactivity (due to steric or electronic factors) can be epoxidized at high temperatures and by increasing the reaction time.[13] The weakly nucleophilic α,β-unsaturated ester (**5**) thus furnishes the epoxide (**6**) (eq 2).[13b] When alkenes are epoxidized at 90 °C, best results are obtained if radical inhibitor is added.[13a] For preparing acid-sensitive epoxides (benzyloxiranes, allyloxiranes) the pH of the reaction medium has to be controlled using $NaHCO_3$ (as solid or as aqueous solution),[14] Na_2HPO_4, or by using the *m*-CPBA-KF[9a] reagent.

(2)

Regioselective Epoxidations.

In the epoxidation of simple alkenes (**2**) (eq 1), due to the electron-releasing effect of alkyl groups the reactivity rates are tetra- and trisubstituted alkenes > disubstituted alkenes > monosubstituted alkenes.[1a] High regioselectivity is observed in the epoxidation of diene hydrocarbons (e.g. **7**) having double bonds differing in degree of substitution (eq 3).[15] Epoxidation takes place selectively at the more electron-rich C-3-C-4 double bond in the dienes (**8**)[16] and (**9**).[17]

(3)

(8)

(9)

Diastereoselective Epoxidation of Cyclic Alkenes.

π-Facial stereoselectivity (75% *anti*) is observed in the epoxidation of the allyl ether (**10a**) since reagent approach from the α-face is blocked by the allylic substituent; a higher diastereoselectivity (90% *anti* epoxidation) is observed when the bulkier O-*t*-Bu is located on the allylic carbon (eq 4).[18] Due to steric and other factors, the norbornene (**11**) undergoes selective (99%) epoxidation from the *exo* face.[19] In 7,7-dimethylnorbornene (**12**), approach to the *exo* face is effectively blocked by the methyl substituent at C-7, and (**12**) is epoxidized from the unfavored *endo* face, although much more slowly (1% of the rate of epoxidation of **11**).[19] The geminal methyl group at C-7 is able to block the approach of the peroxy acid even when the double bond is exocyclic to the norbornane ring system (for example, epoxidation of (**13**) proceeds with 86% *exo* attack, while (**14**) is oxidized with 84% *endo* attack). Folded molecules are epoxidized selectively from the less hindered convex side; *m*-CPBA epoxidation of the triene lactone (**15**) takes place from the α-face with 97% stereoselectivity.[20] The triepoxide (**16**) has been obtained in 74% yield by epoxidizing the corresponding triene;[21] in the epoxidation step, six new chiral centers are introduced stereoselectively as a result of steric effects.

(a) R = Me 1:3
(b) R = *t*-Bu 1:9

(11)

(12)

(13)

(14)

(15)

(16)

Unhindered methylenecyclohexanes and related compounds show a moderate preference for axial epoxidation. In the epoxidation of (**17**) the ratio of axial:equatorial attack is 86:14;[22] for the alkene (**18**) the ratio is 75:25.[23]

(17)

(18)

Epoxidation of Cyclic Alkenes having Directing Groups.

Henbest showed that in the absence of severe steric interference, allylic cyclohexenols are epoxidized stereoselectively by organic peroxy acids to furnish *cis*-epoxy alcohols;[24a] a large number of *cis*-epoxy alcohols have been prepared by epoxidizing allylic cyclohexenols.[7] A mixture (5:1) of labile bisallylic alcohols (**19**) and (**20**) was reacted with *m*-CPBA (eq 5); from the reaction mixture diepoxide (**21**) was isolated as a single isomer.[25] Epoxidation of (*Z*)-cyclooct-2-en-1-ol (**22**) furnishes exclusively (99.8%) the *trans*-epoxide (**23**) (eq 6).[24b] Similar observations have been made subsequently.[26] This result, as well as the stereoselectivity observed during the epoxidation of other allylic alcohols, both cyclic and acylic, has been rationalized on the basis of transition state models.[24,27]

(19) (20) (21)

(6)

Stereoselectivity has been observed during the peroxy acid epoxidation of some homoallylic and bishomoallylic alcohols,[28] and the epoxidation of the allylic carbamate (**24**) is *syn* stereoselective (eq 7).[28]

(7)

cis:*trans* = 10:1

Epoxidations of Acyclic Alkenes.

Since acyclic systems normally are not rigid, high stereoselectivity has been observed only when special structural features are present. The presence of functional groups (OH, NH, CO, and ether) which form hydrogen bonds with the peroxy acid can facilitate stereoselective epoxidations by imparting rigidity to the system. High *anti* selectivity (>95%) has been observed in the epoxidation of both (**25**) and (**26**) each of which has a branched substituent adjacent to the carbon carrying the silicon group.[29] High *anti* selectivities have been noted during the epoxidation of (**27**)

(95%),[30] (**28**) (96%),[31] (**29**) (95%),[32] and (**30**) (96%).[33] High *syn* selectivity has been observed in the reactions of (**31**) (98%)[33] and (**32**) (93%).[34] When the allyl alcohol (**28**) reacts with *m*-CPBA, in the transition state the reagent is hydrogen-bonded to the ether oxygen as well as to allylic hydroxyl. The high selectivity is due to the cooperative effect of the hydroxyl group and the ether oxygen.[31]

(30)

(31)

(32) $R^1 = (CH_2)_6CO_2Me$
$R^2 = (CH_2)_5Me$

High stereoselectivity has also been observed in the epoxidation of some acyclic homoallylic alcohols.[35]

Oxidation of Enol Silyl Ethers and Furans.

Epoxides of enol silyl ethers undergo facile ring opening and only in rare cases have stable epoxides been isolated.[36] α-Hydroxy enones have been prepared in two steps from α,β-unsaturated ketones; the enol silyl ether (**33**) prepared from the corresponding enone is treated with *m*-CPBA and the resulting product reacts with triethylammonium fluoride to furnish an α-hydroxy enone (**34**) (eq 8).[37] This method has also been used for the preparation of α-hydroxy ketones,[38] α-hydroxy acids,[39] and α-hydroxy esters. As illustrated in (eq 9), aldehydes have been converted to protected α-hydroxy aldehydes in a similar fashion.[40] Epoxidation of enol silyl ethers according to eq 10 has been used in synthesizing α,α´-dihydroxy ketones from methyl secondary alkyl ketones; the silyl ether (**36**) furnishes the corresponding dihydroxy ketone quantitatively upon brief acidic treatment.[41] Peroxy acid oxidation of furfuryl alcohols yields pyranones according to eq 11.[42,43] Furfurylamides also react similarly.[44]

(35) **(36)**

Baeyer-Villiger Rearrangement.

Reaction of a ketone (**37**) with peroxy acid results in oxygen insertion to furnish the esters (**38**) and (**39**). This reaction, known as the Baeyer-Villiger rearrangement, has been reviewed recently.[45] Cyclobutanones undergo very facile rearrangement with peroxy acids, as well as with ***Hydrogen Peroxide*** in presence of base. The cyclobutanone (**40**) reacted readily with *m*-CPBA to furnish regio-, stereo-, and chemoselectively the lactone (**41**) (eq 12),[38b] which was elaborated to gingkolide. Baeyer-Villiger reaction of (**40**) with H_2O_2/base furnished a γ-lactone which was the regioisomer of (**41**). When 1,2,3,8,9,9a-hexahydro-1-methyl-3a,8-methano-3a*H*-cyclopentacycloocten-10-one, which has double bonds as well as a keto group, was treated with *m*-CPBA, exclusive alkene epoxidation was observed.[46] Ketones having stannyl groups on the β-carbon undergo a tin-directed Baeyer-Villiger reaction.[47]

(37)

(38)

(39)

Oxidation of Nitrogen-Containing Compounds.

Primary amines are oxidized by *m*-CPBA to the corresponding nitro compounds. One of the intermediates formed in this reaction is the corresponding nitroso compound, which reacts sluggishly with the reagent. High yields are obtained by carrying out the reaction at a high temperature (~83 °C) and increasing the reaction time (3 hours). For example, *n*-hexylamine is oxidized to 1-nitrohexane in 66% yield.[48] When a substrate having the amino group at a chiral center was oxidized, the nitro compound was formed with substantial (~95%) retention of configuration.[49]

m-CPBA oxidation of the sulfilimine (**42**) prepared from 2-aminopyridine, furnished 2-nitrosopyridine (**43**) (eq 13).[50]

Secondary amines have been oxidized to hydroxylamines with *m*-CPBA.[26b] In this reaction, substantial amounts of nitrone as byproduct are expected. (The best method for the preparation of hydroxylamines is to oxidize the secondary amine with 2-(phenylsulfonyl)-3-aryloxaziridine (see e.g. ***(±)-trans-2-(Phenylsulfonyl)-3-phenyloxaziridine***) to the nitrone, and then to reduce the nitrone with ***Sodium Cyanoborohydride***).[51]

m-CPBA oxidation of N-heterocycles furnishes in high yields the corresponding *N*-oxides.[52] Several tertiary *N*-oxides have been prepared by the reaction of tertiary amines with *m*-CPBA in $CHCl_3$ at 0-25 °C and employing chromatography on alkaline alumina; for example, trimethylamine *N*-oxide was obtained in 96% yield.[53] When the optically pure tertiary amine (**44**) is oxidized with *m*-CPBA, the initially formed amine oxide rearranges to the hydroxylamine (**45**) with complete 1,3-transfer of chirality (eq 14).[54]

(14)

Reaction of *m*-CPBA with the isoxazole (**46**) furnishes the nitrone (**47**) (eq 15).[55] *m*-CPBA oxidation of (-)-isoxazole (**48**) and subsequent workup results in the formation of the (-)-cyclopentanone (**49**) (eq 16);[56] the initially formed nitrone is hydrolyzed during workup. The oxaziridine (**51**) has been prepared by epoxidizing the sulfonimine (**50**) (eq 17).[57]

(15)

(-)-(**48**) 86% ee

(16)

(-)-(**49**) 86% ee

(17)

The cleavage of the *N*,*N*-dimethylhydrazone (**52**) proceeds rapidly in the presence of *m*-CPBA, even at low temperatures, to furnish the ketone (**53**), without isomerization to the more stable *cis* isomer (eq 18).[58]

(18)

Oxidation of Phosphorus-Containing Compounds.

m-CPBA oxidation of the phosphite (**54**) is stereospecific; it furnishes the phosphate (**55**) (eq 19).[59a] However, aqueous ***Iodine*** is the reagent of choice for the oxidation of nucleotidic phosphite triesters.[59b] *m*-CPBA oxidation of thiophosphate triesters furnishes the corresponding phosphate esters with retention of configuration.[60]

(19)

Oxidation of Sulfur-Containing Compounds.

n-Butanethiol is oxidized by *m*-CPBA in CH_2Cl_2 at -30 °C to furnish in 82% yield *n*-butanesulfinic acid (*n*-$BuSO_2H$); other thiols react similarly.[61] Sulfides are oxidized chemoselectively to sulfoxides by *m*-CPBA; the reaction is fast even at -70 °C, and the product is free from sulfone.[62] Three reagents (*m*-CPBA, ***Sodium Periodate***, and

Iodosylbenzene) are regarded as ideal for the oxidation of sulfides to sulfoxides.[63] Good diastereoselectivity has been observed in the oxidation of the sulfide (**56**) (eq 20).[64] Sulfides carrying suitably located hydroxyl groups are oxidized diastereoselectively, due to the directing influence of the hydroxyl group.[65] A phenyl sulfide carrying a variety of functional groups (epoxide, hydroxyl, ether, carbamate, and enediyne) has been chemoselectively oxidized in 99% yield to the corresponding sulfone.[52]

(20)

(56) R = Ph

Allenyl chloromethyl sulfoxide (**57**) reacts with *m*-CPBA to furnish allenyl chloromethyl sulfone (**58**) (eq 21).[66] The enethiolizable thioketone (**59**) has been oxidized to the (*E*)-sulfine (**60**) (eq 22).[67] The 2´-deoxy-4-pyrimidinone (**62**) has been prepared by reacting the 2-thiopyrimidine nucleoside (**61**) with *m*-CPBA (eq 23).[68] Thioamides have been transformed to the amides in high yields.[69]

(21)

(57) **(58)**

(22)

(59) **(60)**

Oxidation of Selenides.

Phenyl selenides react rapidly with *m*-CPBA at -10 °C to form phenyl selenoxides,[70a] which on warming to 0 °C or at rt undergo facile *cis* elimination. This procedure for introducing unsaturation under mild conditions has been used in the synthesis of thermally sensitive compounds; for an example see eq 24.[70b] The selenonyl moiety is a good leaving group, and its generation in the substrate can lead to the formation of cyclic compounds. The oxazoline (**64**) has been synthesized through oxidation of the selenide (**63**) and treatment of the oxidized material with base (eq 25).[71]

Oxidation of Allylic Iodides.

m-CPBA oxidation of the primary allylic iodide (**65**) furnishes the secondary allylic alcohol (**66**) (eq 26);[72] this

involves rearrangement of the iodoxy compound formed initially.

Comparison with Other Reagents.

To effect epoxidation, the most commonly used reagents are *m*-CPBA, ***Peracetic Acid*** (PAA), and ***Trifluoroperacetic Acid*** (TFPAA). TFPAA is not commercially available. *m*-CPBA is more reactive than PAA and is the reagent of choice for laboratory-scale reactions. For large-scale epoxidations the cheaper PAA is preferred. The highly reactive TFPAA is used for unreactive and heat-sensitive substrates; its reactivity permits the use of low reaction temperatures. The recently introduced reagent magnesium monoperphthalate (MMPP) (see ***Monoperoxyphthalic Acid***) is more stable than *m*-CPBA and has many applications.[4]

Epoxidations of hydroxyalkenes have been carried out with ***t-Butyl Hydroperoxide***/vanadium (TBHP/V). *m*-CPBA epoxidation of (*Z*)-cyclooct-2-en-1-ol is *anti* selective; with TBHP/V it is *cis* selective.[24b] Similar differences have been noticed in some acyclic systems.[27c] Since the directing effect of the hydroxyl group is larger in the TBHP/V system it is a better reagent for hydroxyl-directed regioselective epoxidations of polyunsaturated alcohols;[73] the TBHP/V system also exhibits higher hydroxyl-directed selectivity in highly hindered allylic alcohols.[74]

m-CPBA epoxidation of hindered alkenes takes place selectively from the less hindered side; the epoxide of opposite stereochemistry can be prepared by a two-step procedure involving initial preparation of bromohydrin, followed by base treatment.[28]

For the epoxidation of extremely unreactive alkenes[38b] and for the preparation of epoxides which are highly susceptible to nucleophilic attack, ***Dimethyldioxirane*** is the reagent of choice.[75] Electron-deficient alkenes such as α,β-unsaturated ketones are usually oxidized with ***Hydrogen Peroxide***/base.

m-Chloroperbenzoic Acid-2,2,6,6-Tetramethylpiperidine Hydrochloride

[937-14-4] · $C_7H_5ClO_3$ · *m*-Chloroperbenzoic Acid-2,2,6,6-Tetramethylpiperidine Hydrochloride · (MW 172.57)

[935-22-8] · $C_9H_{20}ClN$ · *m*-Chloroperbenzoic Acid-2,2,6,6-Tetramethylpiperidine Hydrochloride · (MW 177.75)

(reagent for the oxidation of alcohols at rt;[1] when used in combination with other oxidizing properties of *m*-CPBA this reagent can effect conversion of alkenic alcohols to epoxy ketones or secondary alcohols to esters or lactones[2])

Solubility: sol CH_2Cl_2, $CHCl_3$, diethyl ether, THF.

Form Supplied in: for *m*-CPBA, see ***m-Chloroperbenzoic Acid***; 2,2,6,6-tetramethylpiperidin-1-oxyl is a red solid, mp 36-38 °C and is available commercially.

Preparative Method: 2,2,6,6-tetramethylpiperidine hydrochloride is prepared by passing dry HCl into a cold solution of ***2,2,6,6-Tetramethylpiperidine*** in ether.

Oxidation of Alcohols.

Secondary alcohols are oxidized to ketones at room temperature by *m*-CPBA in the presence of catalytic (1-2%) quantities of 2,2,6,6-tetramethylpiperidine-1-oxyl, and HCl.[1] The nitroxide can be conveniently generated in situ from 2,2,6,6-tetramethylpiperidine hydrochloride (**1**), which also provides the requisite HCl (eq 1). The reaction can be conducted in CH_2Cl_2, $CHCl_3$, or ether solvents. In practice a slight excess of *m*-CPBA is used to offset its slow decomposition catalyzed by the nitroxide. Workup simply involves removal of the *m*-CPBA by filtration and/or extraction with base followed by removal of solvent. Yields of ketones are generally quite high (75-95%).

Primary alcohols are oxidized to aldehydes by this reagent, but further oxidation of the aldehydes to carboxylic acids by *m*-CPBA is sometimes observed. The oxidation is tolerant of any functional groups stable to *m*-CPBA and dilute mineral acid. Combining this oxidation procedure with other oxidizing properties of *m*-CPBA enables a range of unique transformations to be effected in a simple manner.

Preparation of Epoxy Ketones.

Epoxy ketones are conveniently prepared from alkenic alcohols in a one-pot procedure by epoxidation of the alkene using slightly more than 2 equiv of *m*-CPBA followed by addition of TMP.HCl to the reaction mixture to effect oxidation of the alcohol.[2] The procedure is particularly advantageous for the preparation of sensitive epoxy ketones. For example, (**2**) is prepared in 86% yield from norbornenol by this procedure (eq 2), compared to a 31% yield obtained by the ***Dipyridine Chromium(VI) Oxide*** oxidation of the same substrate.[3]

Combining this procedure for preparing epoxy ketones from allylic alcohols with the hydrazine-induced Wharton rearrangement[4] provides a convenient sequence for the transposition of allylic alcohols, as exemplified by the conversion of (**3**) to (**4**) (eq 3).

Preparation of Esters and Lactones from Secondary Alcohols.

Although under ordinary conditions the Baeyer-Villiger oxidation does not interfere with the peracid-mediated alcohol oxidation, under more forcing conditions the reactions can be coupled to afford esters and lactones directly from secondary alcohols.[2] Phenyl-2-propanol was converted to benzyl acetate in 90% yield by this process (eq 4). To accomplish this two-step sequence, a large excess of *m*-CPBA (3.5-4.0 equiv) is required; even under these conditions yields vary, depending on the reactivity of the ketone product to the Baeyer-Villiger reaction. Use of more reactive peracids (such as trifluoroperacetic acid or permaleic acid) was ineffective as these were rapidly degraded by the nitroxide catalyst.

Related Oxidants.

The oxoammonium ion (**5**) is believed to be the species responsible for alcohol oxidation in this system, and several related methods for oxidizing alcohols involving generation of this intermediate from the nitroxide using chlorine,[5] bromine,[5] copper(II) salts,[6] sodium hypochlorite,[7] or electrochemically[8] have been reported. Acid-catalyzed oxidation of alcohols by *m*-CPBA alone has also been reported.[9]

1-Chloro-2-phenylacetylene

(X = Cl)

[1483-82-5] · C_8H_5Cl · 1-Chloro-2-phenylacetylene · (MW 136.57) (X = Br)

[932-87-6] · C_8H_5Br · 1-Bromo-2-phenylacetylene · (MW 181.03) (X = I)

[932-88-7] · C_8H_5I · 1-Iodo-2-phenylacetylene · (MW 228.03)

(reacts with tertiary enolates to form phenylethynyl adducts; starting material for the preparation of ynamines, ynehydrazines, alkynylphosphonates, and alkynyl ethers)

Alternate Name: (chloroethynyl)benzene; phenylchloroethyne.

Physical Data: X = Cl: bp 78 °C/20 mmHg;[3] X = Br: bp 40-41 °C/0.1 mmHg, *d* 1.456 g cm^{-3}; X = I: bp 115-117 °C/16 mmHg, *d* 1.75 g cm^{-3}.

Preparative Methods: the method of choice is by reaction of phenylacetylene with sodium hypochlorite;[1] it can also be prepared by reaction of sodium phenylacetylide with *p*-toluenesulfonyl chloride[2] or lithium phenylacetylide and *N*-chlorosuccinimide.[3]

Handling, Storage, and Precautions: use in a fume hood.

Phenylethynylation.

1-Chloro-2-phenylacetylene reacts with tertiary ketone or ester enolates to give phenylethynyl adducts (**1**) and (**2**) in 70-95% yields. Hydration of the ethynyl group leads to dicarbonyl systems (**3**).[4] Additional enolate addition/elimination reactions with chloroacetylenes to yield alkynyl derivatives (**4**) and (**5**) have been reported for dichloroacetylene (see ***Trichloroethylene*** and 1-chloro-2-phenylthioacetylene.[4] This method is limited to tertiary enolates. Similar alkynylations have been reported for tertiary β-dicarbonyl enolates using alkynyl lead triacetates[5] or alkynyl iodonium tetrafluoroborates.[6]

(1)

(2)

(3)

(4)

(5)

Preparation of Ynamines and Ynehydrazines.

1-Chloro-2-phenylacetylene reacts with lithium dimethylamide to yield the ynamine (**6**) in 87% yield. Ynamines can also be prepared from the reaction with tertiary amines.[7,8] Similarly, the trimethyl ynehydrazine derivative (**7**) can be prepared from the reaction with lithium trimethylhydrazide.[9]

(6)

(7)

Reaction with Other Nucleophiles.

1-Chloro-2-phenylacetylene reacts with ***Triethyl Phosphite***, undergoing an Arbuzov reaction to yield the phosphonate (**8**).[10] Similarly, reaction with alkoxides leads to alkoxyacetylenes (**9**).[11]

(8)

(9)

Related Reagents.

4-Chlorophenyl Chlorothionoformate

[937-64-4] · $C_7H_4Cl_2OS$ · 4-Chlorophenyl Chlorothionoformate · (MW 207.08) · $C_7H_5BrN_2$ · 3-Bromo-3-phenyldiazirine · $C_7H_5ClN_2$ · 3-Chloro-3-phenyldiazirine

(dehydrating agent;[1] has been used in radical deoxygenation;[2] serves as a building block in the synthesis of penems[3] and heterocycles;[4] used for introduction of the thiocarbonyl group[5])

Alternate Name: O-(4-chlorophenyl) carbonochloridothioate.

Physical Data: bp 82 °C/0.8 mmHg;[6] 114-116 °C/0.8 mmHg.[7]

Form Supplied in: distillable liquid; commercially available.

Preparative Method: from thiophosgene and *p*-chlorophenol in the presence of sodium hydroxide.[2,6]

Handling, Storage, and Precautions: protect from moisture.

Use as Dehydrating Agent.

The reagent converts oximes to nitriles under mild conditions (rt, 1.5 h) (eq 1).[1]

(1)

Use in the Chugaev Reaction.

The closely related reagent, *p*-tolyl chlorothionoformate, has been used for Chugaev eliminations (eq 2);[8] presumably, *p*-chlorophenyl chlorothionoformate could serve the same function.

Use in Radical Deoxygenation.

The reagent has been used in radical deoxygenation (eq 3).[2]

Use as a Building Block.

The reagent has been incorporated into the structure of a thiopenem antibiotic (eq 4).[3]

(4)

The reagent is also useful for introducing the thiocarbonyl function, since the chlorine atom and chlorophenol residues can be replaced successively by nucleophiles (eq 5).[4,5]

3-Chloro-3-phenyldiazirine[1]

(X = Cl)

[4460-46-2] · $C_7H_5ClN_2$ · 3-Chloro-3-phenyldiazirine · (MW 152.58) (X = Br)

[4222-25-7] · $C_7H_5BrN_2$ · 3-Chloro-3-phenyldiazirine · (MW 191.99)

(stable cyclic isomer of chlorodiazomethane; excellent source of chlorocarbene following thermolysis or photolysis[2])

Physical Data: colorless liquid; bp 33-35 °C/0.5 mmHg; IR N=N stretch 1560 cm^{-1}; UV λ = 388 nm.

Solubility: sol hydrocarbons, diethyl ether, ethyl acetate, and acetonitrile

Preparative Methods: by treatment of benzamidine hydrochloride with NaOCl (eq 1).

Handling, Storage, and Precautions: can be stored in the dark at 0-10 °C for several weeks under Ar without decomposition; solutions of the reagent have not been known to detonate, although more volatile chlorodiazirines, e.g. methylchlorodiazirine, are prone to explosion[3] and are shock sensitive; explosions have occurred on warming to rt after storage at 77 K. Extreme care is required during cold trap procedures when solid diazirine is present; in GC, diazirine must never be injected neat (the high temperature at the injector block will lead to an explosion). Always take precautions (e.g. safety shields) when working with diazirines.

Diazirines are cyclic isomers of diazoalkanes. The chemistry of diazirines has a relatively short history, dating from the discovery of these compounds in 1960 by Paulsen,[4] and Schmitz and Ohme.[5] The increasing interest and the progress in this field have encouraged continuous reviews.[6] In 1965, Graham's pioneering paper described the synthesis of 3-chloro-3-phenyldiazirine.[1b] The mechanism for hypochlorite oxidation of amidines (with diazirine formation) has been reviewed.[7,8]

Reactions of Diazirines.

The reaction of phenylchlorodiazirine with ***Phenyllithium*** (eq 2) yields diphenylbenzamidine, whereas the reaction with ***Methyllithium*** gives acetophenone.[1d]

(2)

Another facet of halodiazirine chemistry is the reaction with nucleophiles[7,8] and this is illustrated by the reaction of phenylbromodiazirine with the nucleophiles methoxide, fluoride, and cyanide ions (eq 3).

(3)

Synthetically, the exchange reaction has been used to prepare methoxy-substituted methylenecyclopropanes (eq 4).[8]

(4)

An exchange reaction of phenylbromodiazirine with *N*-methylethanolamine affords diazirine, which yields the carbene upon loss of nitrogen. The oxazolidine product is formed by the intramolecular O-H insertion of the carbene (eq 5).[9]

(5)

Reactions of Carbenes.

Chlorodiazirine compounds are remarkably stable in the presence of organic and inorganic reagents, in sharp contrast to the behavior of their linear isomers, which can only be detected by isolation matrix techniques.[10] Because of their stability, chlorodiazirines have been investigated as a source of chlorocarbenes following thermolysis, photolysis,[2] or ultrasound.[11] Thermal decomposition of phenylchlorodiazirine in cyclohexene gives a mixture of *exo*- and *endo*-7-chloronorcaranes.[1b,12] Thus chlorodiazirines have played an essential role in the development of singlet chlorocarbene reactivities toward alkenes. Arylchlorocarbenes can be classified as electrophilic carbenes.[7b,13] Accordingly, selectivity for addition to alkenes is greatest when the alkene possesses electron-donating substituents. Phenylchlorocarbene reacts readily with α,β-unsaturated esters to produce cyclopropane products in high yields (eq 6).[14,15]

(6)

Phenylchlorocarbene may be trapped with ***Tri-n-butylstannane***,[1d] substituted alkynes,[1d] triethylsilane,[16] or cumene (eq 7).[16]

(7)

Transformation of phenylchlorodiazirine to 1,3-dioxolane and 1,3-dithiolane has been demonstrated (eq 8).[17]

(8)

The carbonyl ylide generated from arylchlorodiazirine and acetone undergoes 1,3-dipolar cycloaddition to either benzaldehyde[18] or diethyl fumarate (eq 9).[19]

(9)

Photolysis of phenylchlorodiazirine in the presence of pyridine yields a pyridinium ylide (λ = 480 nm). Cycloaddition of the pyridinium ylide to ***2-Chloroacrylonitrile*** yields 1-cyano-3-phenylindolizine regioselectively (eq 10).[20]

(10)

In the reaction of arylchlorodiazirine with ***Allylamine***, the insertion of the carbene into an N-H bond is followed by HCl elimination to give a Schiff base in good yield (eq 11).[21]

(11)

Related Reagents.

Diazomethane; ***Di-t-butyl Dicarbonate***.

3-Chloro-1-propynyllithium[1]

[67811-22-7] · C_3H_2ClLi · 3-Chloro-1-propynyllithium · (MW 80.44)

(undergoes addition/substitution reactions[3-5] with electrophiles; adducts with organoboranes are good sources of allenes,[2] enynes,[7,8] alkenes,[9] and alkynes[2,6])

Alternate Name: lithium chloropropargylide.

Solubility: sol ether, THF.

Form Supplied in: not commercially available; used as a solution prepared prior to reaction.

Preparative Methods: to freshly distilled ***Propargyl Chloride*** (20 mmol) in THF (10 mL) at -70 °C is added 1.6 M ***Methyllithium*** (20 mmol) in ether. The resulting clear solution is ready for use.[2] Use of ***n-Butyllithium*** in place of MeLi is reported to result in lower yields in the subsequent reactions.[3]

Handling, Storage, and Precautions: highly moisture sensitive; use soon after preparation, in a fume hood.

Reaction with Electrophiles.

The carbenoid is used for C-C/C-X bond formation with a number of electrophiles, as shown in eqs 1-5.[3-5]

(1)

(2)

chlorotetrolic esters

(3)

(4)

(5)

Synthesis of Alkylallenes.[2]

Trialkylboranes add to 3-chloro-1-propynyllithium in THF at -70 °C to form the adduct (**1**) (eq 6), which after being warmed to 25 °C can be protonated with acetic acid to give terminal alkylallenes (**2**) (eq 7). Where chiral, the migrating alkyl group retains its configuration.

(6)

(1)

(7)

Synthesis of α-Allenic and Homopropargylic Alcohols.[6]

The intermediate organoborane (**1**) can be treated with an aldehyde to form a C-C bond, resulting in an allenic or alkynic alcohol, depending on the temperature at which the organoborane precursor is maintained. Warming the adduct (**1**) to 25 °C and cooling back to -78 °C before reacting with aldehyde affords α-allenic alcohol (**3**) after oxidative workup (eq 8). On the other hand, if the organoborane is maintained at -78 °C or below throughout and treated with aldehyde, the resulting product, after an oxidative workup, is homopropargylic alcohol (**4**) (eq 9). The reaction conditions permit a wide variety of structural features in both the organoborane and aldehyde.

(8)

(9)

Synthesis of 1,5-Enynes.[7]

The organoborane (**1**) is converted to a 1,5-enyne by treating it with an allylic bromide in the presence of ***Copper(I) Iodide*** and LiOMe (eq 10).

Synthesis of Alkylallenes and 1,3-Enynes.[8]

As a γ-halo organolithium compound, 3-chloro-1-propynyllithium has been used for C-C bond formation with organotransition metals via migratory insertion to give terminal alkylallenes or 1,3-enynes (eqs 11 and 12).

Synthesis of α,β-Unsaturated Aldehydes or Ketones.[9]

1,2-Dienols can be obtained by treating the title reagent with an aldehyde, followed by reduction with ***Lithium Aluminum Hydride***. These allenols can be coupled to aryl or alkenyl halides under palladium catalysis in the presence of a tertiary amine, resulting in a facile synthesis of β-methyl-α,β-unsaturated carbonyls (eq 13).

Enones containing other carbonyl groups in the same molecule that are not accessible by the conventional aldol condensation can be synthesized using this approach.

Related Reagents.

Propargyl bromide, 3-chloro-1-butyne, and 3-chloro-3-methyl-1-butyne can also be metalated, and the derived lithium reagents, 3-bromo-1-propynyllithium, 3-chloro-1-butynyllithium, and 3-chloro-3-methyl-1-butynyllithium, can be trapped with electrophiles.[10]

See also ***Lithium Acetylide***; ***Propynyllithium***; and ***3,3-Diethoxy-1-propyne***.

N-Chlorosuccinimide

[128-09-6] · $C_4H_4ClNO_2$ · *N*-Chlorosuccinimide · (MW 133.53)

(electrophilic α-chlorination of sulfides, sulfoxides, and ketones; preparation of *N*-chloroamines)

Alternate Name: 1-chloro-2,5-pyrrolidinedione; NCS.

Physical Data: mp 144-146 °C.

Solubility: sol H_2O; sl sol CCl_4, benzene, toluene, AcOH; insol ether.

Form Supplied in: white powder or crystals having a weak odor of chlorine when pure; widely available.

Purification: the commercial reagent acquires a light yellow color and a rather strong odor of chlorine after long storage but is easily recrystallized from acetic acid: rapidly dissolve 200 g of impure sample in 1 L preheated glacial AcOH at 65-70 °C (3-5 min); cool to 15-20 °C to effect crystallization; filter through a Buchner funnel and wash the white crystals once with glacial AcOH and twice with hexane; dry in vacuo (>85% recovery).

Analysis of Reagent Purity: the standard iodide-thiosulfate titration method is suitable.

Handling, Storage, and Precautions: store under refrigeration and protect from moisture; acutely irritating solid, with toxic effects similar to those of the free halogens; avoid inhalation; use an efficient fume hood; perform all operations as rapidly as possible to avoid extensive decomposition of the reagent.

N-Chlorosuccinimide is a convenient reagent for the electrophilic substitution and addition of chlorine to organic compounds. Other chlorinating agents of use include ***Chlorine***, ***Sulfuryl Chloride***, ***Chloramine-T***, ***t-Butyl Hypochlorite***, and ***Trichloroisocyanuric Acid***. The primary advantages of using NCS include the ease in handling, the mild conditions under which chlorination proceeds, and the ease of removal of the inoffensive byproduct succinimide.

α-Chlorination of Carbonyl Derivatives.

Carbonyl compounds can be chlorinated in the α-position by addition of NCS directly to the lithium enolates, enoxyborinates, or more commonly to the silyl enol ether derivatives.[1] In combination with methods for the regiospecific generation of enolates and silyl enol ethers, α-chloroketones of desired structure can be produced. For example, β-ionone can be chlorinated selectively in the α´-position by addition of NCS to the kinetic enolate (eq 1).[2] With the appropriate chiral auxiliary, NCS chlorinates silyl ketene acetals with high levels of diastereoselectivity (eq 2).[3] α-Chloro ketones, α-chloro esters, and α-chloro sulfones may also be prepared by reaction of NCS with the β-keto derivatives and in situ deacylation in the presence of base (eq 3).[4] NCS is also an effective reagent for the α-chlorination of acid chlorides.[5]

(1)

(2)

(3)

Chlorination of Sulfides and Sulfoxides.[6]

The reaction of alkyl sulfides with NCS has been used extensively for the preparation of α-chloro sulfides, and NCS is generally regarded as the reagent of choice for the preparation of these useful synthetic intermediates (see also ***Trichloroisocyanuric Acid***). Since the mechanism of chlorination involves initial formation of an *S*-chlorosulfonium salt followed by a Pummerer-like rearrangement, monochlorination proceeds smoothly in CCl_4 or benzene in the absence of added acid or base.[7] The most straightforward procedure involves the addition of NCS to a solution of the sulfide in CCl_4 at rt or reflux, followed by removal of insoluble succinimide by filtration. The resulting α-chloro

sulfides are easily hydrolyzed and, as this is usually undesirable, α-chloro sulfides must be prepared under strictly anhydrous conditions and are often used without further purification. A method has been developed for the conversion of benzylic halides to aromatic aldehydes (eq 4);[8] however, this transformation is more conveniently effected in one operation with other reagents (see ***Hexamethylenetetramine***). Many advantages have led to the preferred use of NCS in the Ramberg-Bäcklund rearrangement sequence (eq 5), which has been recently reviewed.[9]

(4)

(5)

The chlorination of trimethylsilylmethyl sulfides with NCS and trifluoroacetic acid affords the product of chlorodesilation in high yield.[10] The degradation of carboxylic acids to ketones can be achieved by α-sulfenation followed by reaction with NCS in the presence of $NaHCO_3$ (eq 6).[11] The *S*-chlorosulfonium ion intermediate undergoes a decarboxylative Pummerer-like rearrangement to afford the ketone upon hydrolysis. α-Phenylthio esters and amides can be successfully α-chlorinated using NCS in CCl_4 at 0 °C (eq 7).[12] 1,3-Dithianes are deprotected to afford ketones by reaction with NCS alone or in combination with ***Silver(I) Nitrate*** in aqueous acetonitrile (see also ***N-Bromosuccinimide***, ***Mercury(II) Chloride***, ***1,3-Diiodo-5,5-dimethylhydantoin***).[13]

Sulfides can be oxidized to sulfoxides by reaction with NCS in methanol (0 °C, 1 h).[14] Similarly, selenides couple with amines when activated by NCS to form selenimide species. These have been generated from allylic selenides in order to prepare allylic amines and chiral secondary allylic carbamates by [2,3]-sigmatropic rearrangement (eq 8).[15]

The α-chlorination of sulfoxides is generally performed in dichloromethane in the presence of a base (either K_2CO_3 or pyridine) and proceeds more slowly than the reactions with sulfides.[16] α-Chloro sulfoxides bearing high optical purity at sulfur are especially useful in asymmetric synthesis, but unfortunately the chlorination of optically active sulfoxides is generally accompanied by significant racemization at sulfur. Alternate procedures are available for achieving chlorination with predominant retention or inversion.[17] Using NCS and ***Potassium Carbonate*** the degree of racemization is minimized and chloromethyl *p*-tolyl sulfoxide can be prepared in 87% ee and 91% chemical yield (eq 9).[18]

(9)

Reaction with Vinylic and Acetylenic Derivatives.

NCS is a suitable source of chlorine for the conversion of vinylcopper and other organometallic derivatives to the corresponding vinyl chlorides.[19] (*E*)-(1-Chloro-1-alkenyl)silanes are available from the appropriate 1-trimethylsilylalkynes by hydroalumination with ***Diisobutylaluminum Hydride*** followed by direct treatment of the vinylaluminum intermediate with NCS in ether at -20 °C (eq 10) (the corresponding (*Z*)-isomer is obtained by NBS-catalyzed isomerization of the (*E*)-isomer).[20] 1-Chloroalkynes can be prepared by reaction of the corresponding lithium acetylides with NCS in THF.[21]

(10)

Chlorination of Aromatic Compounds.

NCS has also been used for the chlorination of pyrroles and indoles; however, the reaction is less straightforward than when NBS and ***N-Iodosuccinimide*** are used.[22] In the chlorination of 1-methylpyrrole, it has been demonstrated that basic conditions ($NaHCO_3$, $CHCl_3$) lead to the formation of 1-methyl-2-succinimidylpyrrole (eq 11).[23] In the presence of catalytic amounts of perchloric acid, thiophenes and other electron-rich aromatic compounds have been chlorinated with NCS.[24] (***N-Chlorosuccinimide-Dimethyl Sulfide*** is used for the selective *o*-substitution of phenols.)

(11)

THF	89%	3%
$CHCl_3$, $NaHCO_3$	-	76%

Synthesis of *N*-Chloroamines.

The conversion of secondary amines to *N*-chloroamines by reaction with NCS in ether or dichloromethane has many advantages over the use of aqueous hypochlorite, including ease of isolation. This method has been used repeatedly in the preparation of *N*-chloroamines for alkene amination (eqs 12 and 13)[25] and other reactions.[26]

(12)

(13)

Other Oxidation and Chlorination Reactions.[27]

gem-Chloronitro compounds are prepared by treating nitronate anions with NCS in aqueous dioxane, or alternatively by reaction of ketoximes with NCS (eq 14).[28] Oxidative decarboxylation of carboxylic acids with ***Lead(IV) Acetate*** and NCS has been used effectively for the synthesis of tertiary alkyl chlorides (eq 15).[29]

(14)

(15)

NCS is also regularly used for the direct oxidation of alcohols to ketones. The presence of ***Triethylamine*** serves to activate the reagent for rapid quantitative oxidation of catechols and hydroquinones to *o*- and *p*-quinones, respectively, and for the oxidation of benzophenone hydrazone to diphenyldiazomethane.[30] ***N-Chlorosuccinimide-Dimethyl Sulfide*** is also used in the mild oxidation of alcohols, as well as in the conversion of allylic alcohols to allylic chlorides.

(oxidizing agent for alcohols to aldehydes and ketones,[1] catechols and hydroquinones to quinones,[2] aromatic amines to sulfilimines,[3] hydroxamic acids to acylnitroso compounds;[4] chlorination of allylic and benzylic alcohols,[5] *ortho* alkylation and formylation of phenols,[6] preparation of chloromethyl thioethers,[7] thioalkylation of pyrroles, indoles, and enamines;[8] preparation of sulfur ylides of active methylene compounds,[9] preparation of sulfonium salts from enamines and cyclopentadienyl anions,[10] dehydration to form keto enamines from β-diketones and nitriles from aldoximes[11])

Alternate Names: Corey-Kim reagent; dimethyl(succinimido)sulfonuim chloride.

Physical Data: $R^1 = R^2$ = Me: mp 70-72 °C.

Solubility: the reagents are slightly more sol in CH_2Cl_2, toluene, and THF than the NCS from which they are derived.

Form Supplied in: prepared in situ from NCS and dialkyl sulfides.

Handling, Storage, and Precautions: see ***N-Chlorosuccinimide***, ***Dimethyl Sulfide***, and other articles on alkyl sulfides.

N-Chlorosuccinimide-Dialkyl Sulfides.

These reagents are generally prepared in situ in solvents such as toluene, CH_2Cl_2, or THF. The reagents themselves are generally more soluble than the NCS from which they are derived and are often prepared at a temperature of about 0 °C to facilitate reaction with the limitedly soluble NCS, but because of their thermal instability are not prepared at higher temperature. They are often used at temperatures as low as -78 °C.

Oxidations.

N-Chlorosuccinimide-dimethyl sulfide (NCS-DMS) is one of several reagents for converting alcohols to alkoxydimethylsulfonium salts, which in the presence of base convert to the corresponding carbonyl compounds via intramolecular proton transfer and loss of dimethyl sulfoxide.[1,12] These oxidations are among the mildest and most selective for conversions of alcohols to aldehydes and ketones. This reaction does not suffer the overoxidation to acids

or the carbon-carbon bond cleavages which are often encountered in chromium(VI) or manganese(VII) oxidations (eq 1).[1,13]

(1)

Several higher members of this class, including the NCS-diisopropyl sulfide reagent, are reported to show unusual selectivity for primary and secondary alcohols. Thus at 0 °C the reagent selectively oxidizes primary alcohols rather than secondary, whereas at -78 °C it selectively oxidizes secondary alcohols rather than primary (eq 2).[14]

(2)

These reagents are also effective in the oxidation of *s,t*-1,2-diols to α-ketols (eq 3).[13] Metal-based reagents give carbon-carbon bond cleavage with such diols.

(3)

Oxidation of 1,3-keto alcohols or 1,3-diketones gives 1,3-diketo sulfonium ylides, which may be reduced to the 1,3-diketones (eq 4).[9]

(4)

Catechols and hydroquinones are oxidized to quinones (eq 5),[3] and *N*-hydroxyureas are oxidized to nitroso compounds (eq 6).[4]

(5)

Halogenations.

Allylic, benzylic, and cyclopropyl carbinyl alcohols are reported to undergo chlorination with or without allyl rearrangement, depending upon structure.[15] Thus primary and secondary allylic carbinols generally give the chlorides without rearrangement (eqs 7 and 8), whereas 2-formyl secondary allylic alcohols give the rearranged product (eq 9).[5]

(9)

The NCS-dialkyl sulfide reagents are thermally labile, and depending on structure undergo a variety of transformations leading ultimately to α-chlorination of the sulfide (eq 10).[7]

(10)

O-Alkylation of Anilines and Phenols.

Treatment of anilines with NCS-DMS leads to sulfilimines, which may be converted to 2-alkylanilines (eq 11).[3] Similarly, phenols give directly the 2-substituted product (eq 12).[6]

(11)

(12)

Other Alkylations.

NCS and allylic sulfides react with 3-unsubstituted indoles at -20 °C to give initially 3-sulfonium salts which on warming to 20 °C rearrange to 2-allyl-3-thiomethylindoles (eq 13). These are readily desulfurized, either with or without concomitant reduction of the allylic double bond, to give 3-allyl or 3-alkyl substituted indoles.[8b,8c]

(13)

On the other hand, 3-alkyl-1*H*-indoles react with NCS-dialkyl sulfides in the presence of base to give 3-alkyl-3-alkylthioalkyl-3*H*-indoles (indolinenes, eq 14).[16]

(14)

NCS-DMS reacts with cyanoacetate anions nearly exclusively at nitrogen to give *N*-alkylthiomethylketenimines (eq 15).[17]

(15)

Thioalkylation.

Treatment of pyrroles with NCS-DMS leads to 2-thiomethylpyrroles (eq 16). Indoles give 3-thioalkylindoles (eq 17).[8a-c]

(16)

(17)

NCS-DMS reacts with enamines to give sulfonium salts (eq 18),[10a,10b] and with cyclopentadienyl anions to give bis- and tris-substituted sulfonium salts (eq 19).[10c]

(18)

(19)

Dehydrations.

While certain 1,3-diketones produce the sulfonium ylide, the treatment of *N*-acetylpiperidine-3,5-dione first with NCS-DMS and then with an amine in the presence of TFA resulted in the formation of the enaminone. The yields for this conversion were report to be significantly better than in the traditional method of azeotropic water removal (eq 20).[11a]

(20)

It was found during an attempt to produce *N*-methylthiomethyl nitrones that treatment of aldoximes with NCS-DMS resulted in high yields of nitriles (eq 21).[11b]

Chlorosulfonic Acid[1]

[7790-94-5] · $ClHO_3S$ · Chlorosulfonic Acid · (MW 116.53)

(strong acid with weak sulfur-chlorine bond; a strong sulfating, sulfonating, and dehydrating agent; also a chlorinating agent)

Alternate Name: chlorosulfuric acid.

Physical Data: mp -81 to -80 °C; bp 151-152 °C/755 mmHg; *d* 1.753 g cm^{-3}.

Solubility: sol 1,1,2,2-tetrachloroethylene, chloroform, dichloromethane, nitrobenzene, acetic acid, and acetic anhydride; slightly sol carbon disulfide and carbon tetrachloride; reacts with alcoholic solvents.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: strong acid, causing severe chemical burns if in contact with skin; use in a fume hood, since fumes are hazardous and extremely irritating to eyes, nose, and respiratory tract; reacts violently with moisture, releasing HCl and H_2SO_4; store under nitrogen in a cool dry place.

Aromatic Sulfonation/Chlorosulfonation.

Aromatic compounds react with chlorosulfonic acid to produce the corresponding sulfonated products.[2] The resulting sulfonic acids react with excess chlorosulfonic acid to produce sulfonyl chlorides (eqs 1 and 2).

(2)

This method has been used to prepare the sulfonated derivatives of benzene,[2] benzoic acid,[3] acetanilide,[4] naphthalene,[2] and anthracene.[5] Additional examples include chlorosulfonation of biphenyl (eq 3),[6] chlorophenols,[6,7] benzophenone,[8] diphenyl sulfone,[8] and ferrocene.[9]

(3)

Arylsulfonamides are obtained by the reaction of aromatic compounds with $ClSO_3H$ followed by ammonia (eqs 4 and 5).[10]

(4)

(5)

Treatment of aromatic amino acids such as tyrosine and tryptophan with $ClSO_3H$ leads to the formation of the

corresponding arylsulfonic acids (eq 6). This technique has been used to modify peptides.[11]

Some abnormal products are obtained when aromatic halides react with $ClSO_3H$. For example, *p*-dichlorobenzene and *p*-dibromobenzene undergo chlorination on reaction with $ClSO_3H$ in the presence of iodine (eq 7).[2a,12] Fluorobenzene, iodobenzene, *o*-dichlorobenzene, and *o*-dibromobenzene yield the corresponding sulfones.[2a,12]

α-Sulfonation of Carboxylic Acids.

Chlorosulfonic acid has been used to prepare α-sulfonated derivatives of carboxylic acids (eqs 8 and 9).[13]

Sulfation.

Treatment of alcohols with $ClSO_3H$ produces the corresponding sulfate esters. By this method the carotenoid alcohols lycoxanthin and zeaxanthin were converted to their sulfate esters (eqs 10 and 11).[14] The hydroxy amino acids serine and threonine are converted to their corresponding sulfate esters by $ClSO_3H$.[11] Carbohydrates[15] and chitin[16] are also sulfated by treatment with $ClSO_3H$.

(11)

Sulfamation.

Reaction of amines with $ClSO_3H$ produces sulfamates (eq 12).[17]

(12)

Chlorination.

$ClSO_3H$ has been used to chlorinate polycyclic alkanes such as adamantane (eq 13).[18,19]

(13)

Aliphatic acids react with $ClSO_3H$ in the presence of chlorine to give corresponding α-chloro acids (eqs 14 and 15).[20]

(14)

(15)

Rearrangement of Ozonides.

Chlorosulfonic acid catalyzes the rearrangement of 1,2,4-trioxalans (ozonides) to 1,2,4,5-tetraoxans (eq 16).[21]

(16)

Decarbonylation.

Cyclopropenyl carboxylic acids and esters have been efficiently decarbonylated using $ClSO_3H$ and this method has been used for the generation of cyclopropenyl carbocations (eqs 17 and 18).[22]

(17)

(18)

Cyclization of Benzils.

Treatment of benzils with excess of $ClSO_3H$ leads to the formation of chlorosulfonated phenylbenzofurans (eq 19).[23]

(19)

Related Reagents.

Chlorosulfonyl Isocyanate[1]

$ClSO_2NCO$

[1189-71-5] · $CClNO_3S$ · Chlorosulfonyl Isocyanate · (MW 141.53)

(most chemically reactive isocyanate;[1] CSI can undergo two types of nucleophilic addition, namely to the carbonyl carbon and to the sulfur of the sulfonyl chloride; the isocyanate portion can undergo formal cycloaddition)

Alternate Name: CSI.

Physical Data: mp -44 to -43 °C; bp 107-108 °C/760 mmHg, 38 °C/50 mmHg; *d*204 = 1.626 g cm^{-3}; *n*27D = 1.4435.

Solubility: sol most organic solvents; reacts violently with water.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: reacts explosively with water to form sulfamic acid, hydrogen chloride, and carbon dioxide; fumes slightly in air, has a choking smell, and undergoes thermal decomposition only above about 300 °C. Glass stoppers of bottles used for storage of CSI stick fast after a short time, even when covered with silicone grease, so that polyethylene bottles with screw caps are best for longer storage times (a few weeks); can be kept indefinitely in sealed glass ampules. Suitable solvents include saturated aliphatic hydrocarbons (more or less limited solubility below 0 °C), aromatic hydrocarbons such as benzene and toluene, chlorinated hydrocarbons such as CH_2Cl_2, $CHCl_3$, CCl_4, and chlorobenzene, diethyl ether, diisopropyl ether, and acetonitrile. Liquid sulfur dioxide is particularly favorable, since it increases the reactivity of CSI still further. Solvents such as acetone and ethyl acetate can be used to a limited extent, but only at low temperatures.

Classification of Reactions.

CSI is probably the most chemically reactive isocyanate known, and has been the subject of several reviews.[1] It can be synthesized by reaction of sulfur trioxide with cyanogen chloride.[2]

Reactions with CSI are classified according to the probable site of reaction. The CSI molecule has two electrophilic sites for attack by nucleophilic reagents, namely the carbonyl carbon (Class I) and the sulfur of the sulfonyl chloride group (Class III). The isocyanate portion can also undergo formal cycloaddition reactions (Class II), which makes CSI a very versatile reagent (eq 1).

(1)

Class I: Addition Involving Initial Attack on the Isocyanate Carbon.

CSI undergoes nucleophilic additions by alcohols (thiols/phenols) and amines to yield *N*-chlorosulfonyl carbamates and urea derivatives, respectively, which can undergo further transformations with water/alcohol/amine (eq 2; X = OR, SH, or NR_2).[1] Primary alcohols can be selectively derivatized with CSI in the presence of other groups without affecting, in general, other sterocenters in complex molecules (eqs 3 and 4).[3a,3b]

(2)

The reagent obtained by reaction of CSI with methanol followed by treatment of the intermediate with ***Triethylamine*** (eq 5) has been used to synthesize carbamates from primary alcohols and to dehydrate secondary alcohols.[4] The above intermediate itself has been used for the synthesis of various heterocycles.[5] Similar intermediates obtained from reaction of CSI and 2,4,6-trichlorophenol are found to be useful bactericides and fungicides,[6] and can be further transformed to the isocyanates by treatment with alcohols followed by pyrolysis of the resultant carbamates (eq 6).[7]

$$ClSO_2NHCO_2Ar \xrightarrow[-\,HCl]{ROH} ROSO_2NHCO_2Ar \xrightarrow[-\,ArOH]{\Delta} ROSO_2NCO \quad (6)$$

$$R = Me,\ Pr,\ MeOCH_2CH_2$$

The reaction of CSI with hydroxy groups of α-hydroxy ketones, followed by thermal ring closure of the intermediate carbamate, results in the formation of oxazolones (eq 7).[8]

$$R^1 = Ph,\ t\text{-}Bu;\ R^2,\ R^3 = Me,\ Ph$$

Thiocarbamates are obtained from the reaction of CSI with thiols (eq 8), and have been used for the synthesis of potential herbicides.[9]

$$RSH \xrightarrow[PhH]{CSI} ClSO_2NHCOSR \xrightarrow{PhNH_2} PhNHSO_2NHCOSR \quad (8)$$

90%

$$R = C_{12}H_{25}$$

CSI also undergoes reaction with amides, sulfonamides (eq 9), and certain phosphoramides.[10,1b] The addition products can be readily converted to the corresponding isocyanates by pyrolytic elimination of the sulfamoyl chloride. However, the dipolar intermediate postulated for the reaction of *N*,*N*-dialkylamides produces amidines through loss of carbon dioxide (eq 10).[11] The amidines were further derivatized to prepare insecticidal and acaricidal compounds.[12]

$$RSO_2NH_2 \xrightarrow{CSI} RSO_2NHCONHSO_2Cl \xrightarrow[-\,ClSO_2NH_2]{\Delta} RSO_2NCO \quad (9)$$

75-92%

The generality of the reaction of CSI with acetals of aliphatic aldehydes,[13] and similar reactivity of orthoesters,[1b] has been reviewed. The reaction of acetals has been used for the conversion of isopropylidine-protected sugars to the corresponding carbonates (eq 11).[14] A similar reaction sequence with carboxylic acids[15] sometimes provides intermediate *N*-chlorosulfonylcarboxamides which are stable enough to be isolated, or which can be treated with ***N,N-Dimethylformamide*** to provide a one-pot synthesis of nitriles (eq 12). The reported[16] anhydropenicillin rearrangement (eq 13) is believed to proceed by an intermediate similar to that described above. Interestingly, such an intermediate also has been used as a mild reagent for displacement of an *N*-trimethylsilyl group.[17]

R = *t*-Bu, Cy, $ClCH_2CH_2$, Bn, PhCH=CH, 1-naphthyl

R = Ph_3C

Aromatic compounds undergo facile reaction with CSI. Treatment of the resultant *N*-chlorosulfonylcarboxamides with DMF in situ afforded the corresponding nitriles (eq 14).[18]

Nucleophilic attack by aldehydic carbonyl groups on the isocyanate carbon atom gives products as shown in eq 15, by way of 1,4-dipolar intermediates.[13] Reaction of arylmethylene malonaldehydes with CSI has provided bicyclic 1,3-oxazin-2-one derivatives (eq 16).[19]

Enolizable ketones upon treatment with CSI produce *N*-chlorosulfonyl-β-ketocarboxamides, which have been used for the synthesis of β-ketonitriles by in situ treatment with DMF (eq 17).[20] However, in the presence of excess CSI, ketones with two α-hydrogens have been observed to undergo further transformations (eq 18).[21] The final product distribution depends on solvent, substituents, and concentration. Nonenolizable ketones, such as benzophenone and γ-pyrones,[22] produce azomethines (eq 19). The azomethine intermediate of benzophenone further cyclizes to provide benzoisothiazole (eq 20).[13] α,β-Unsaturated ketones are converted into 3,4-dihydro-1,3-oxazin-2-ones (eq 21).[13]

β-Diketones and β-keto esters react with CSI to produce amides (eqs 22 and 23).[13] Heterocycles have been obtained from the reaction of CSI with amino compounds having ester or carbonyl functions.[23] The reaction of CSI with ethyl 3-oxo-2-(arylhydrazono)butanoates gives thiazolotriazinediones (eq 24).[24]

CSI has been used as a dipolar synthon of the type shown in eq 25 in its reaction with cyanohydrins. The final products of this one-pot reaction are 5,5-disubstituted 2,4-oxazolidinediones.[25]

The reagent has been used to introduce the nitrile functionality in cyclic enamides (eq 26)[26] and in some other electron-rich alkenes (eqs 27 and 28).[27,28]

(27)

(28)

An attempt to use CSI as a dienophile in its reaction with 2-vinylindole was not successful (eq 29).[29] The product obtained was the indole-3-carboxamide, as reported earlier.[30] Similar electrophilic substitution on pyrroles[31] and thiophene[32] using CSI in the presence of DMF has furnished the respective cyanation products.

(29)

Brief treatment of CSI with epoxides at low temperature has provided the corresponding 1,3-dioxolan-2-ones (major products) and oxazolidine-2-one derivatives (eq 30).[33] This reaction is both regio- and stereospecific. Aziridines have also provided analogous products from their reaction with CSI.[33a] 1,2-Diols having substituents with good migratory aptitudes gave the rearrangement products, but unsubstituted or alkyl substituted 1,2-diols gave the corresponding carbamates as the major product (eq 31).[34]

CSI also has been used as a mild chlorinating agent in its reaction with 6-aryl-3(2*H*)-pyridazinones to produce 6-aryl-3-chloropyridazines (eq 32).[35] 1-Trimethylsilylalkynes react with CSI to produce primary 2-alkynamides after hydrolysis (eq 33).[36] CSI reacts with nitrones derived from cyclic conjugated ketones to produce enamides (eq 34),[37] and with substituted nitrones to produce amides (eq 35).[38] Similar reactions with substituted 3,4-dihydro-2*H*-pyrrole 1-oxide produce 2*H*-pyrroles (eq 36).[39]

(36)

Recently, a facile denitrosation of *N*-nitrosoamines has been demonstrated by Dhar et al. (eq 37).[40] The reactivity of CSI towards sulfoxides[41] has been used for the reduction of sulfoxides to sulfides in the presence of ***Sodium Iodide*** (eq 38).[41c]

(37)

(38)

The new reagent *N*-carbo(trimethylsilyloxy)sulfamoyl chloride, obtained from CSI as a substitute for sulfamoyl chloride, has been used for the synthesis of 3-amino-4-*N*-alkyl-5-aryloxy-1,2,4,6-thiatriazine-1,1-dioxides.[42]

Class II: Cycloaddition to Isocyanate C=N.

The formal [2 + 2] cycloaddition of CSI to a variety of alkenes to produce β-lactams has been the most thoroughly studied reaction (eq 39).[43] A competing elimination reaction (path b) forms an alkene byproduct. The ratio of β-lactam to alkene is determined by the pattern and type of substitution on the alkene. Both concerted and nonconcerted 1,4-dipolar mechanisms have been proposed for these reactions. Regiochemistry is dictated by the formation of the most stable carbocation, and the *cis* adduct is generally formed. Several examples are given in review articles,[1] which show the diversity of β-lactams available from this route. An improved procedure for β-lactam formation from volatile alkenes and CSI has been published.[44]

Reaction of CSI with conjugated or nonconjugated dienes also leads to 2-azetidinones after hydrolysis of the *N*-chlorosulfonyl group (eqs 40 and 41).[45]

The reaction of CSI with vinyl acetates leads to 4-acetoxy-2-azetidinones upon hydrolysis (eq 42).[46] These β-lactams are ideal building blocks for synthesis of a wide variety of classes of antibiotics. The resulting β-lactams are also convenient precursors to *erythro*- and *threo*-amino acids.[47]

(42)

CSI reacts with functionalized allenes to provide α-alkylidene β-lactams (eq 43).[48]

(43)

X	Y	R	Yield (%)
Me	SAr	Me	55[48d]
Me	SAr	TMS	87[48d]
Me	SAr	$(CH_2)OTBDMS$	66[48f]
Me	OAc	H	22[48e]
$Cl_2P(O)$	Me	Me	93[48g]

Alternative acyl and sulfonyl isocyanates that are preparatively useful for β-lactam synthesis include $Cl_3CH_2OSO_2NCO$, $Cl_3CH_2SO_2NCO$, and CF_3CONCO.[49] Methods for deprotection to the core β-lactam are described.

CSI has been useful as a mechanistic probe to study uniparticulate electrophilic addition to a number of fluxional molecules such as bullvalene, barrelene, and homobarrelene.[50]

CSI yields 2:1 adducts with Schiff's bases to form *s*-triazinediones (eq 44).[51]

(44)

As a result of their large degree of p character, highly strained carbon-carbon single bonds can undergo formal cycloaddition with CSI (eq 45).[52]

(45)

CSI reacts with most alkynes to give six-membered heterocyclic ring structures. Hydrolysis affords ketones (eq 46), while methanolysis affords β-keto esters. Interestingly, only the alkynic portion of 1-octene-4-yne reacts with CSI.[53]

(46)

Azirines react with CSI to give three products derived from [2 + 2 + 2] cycloadducts (eq 47).[54]

(47)

Amidines react with CSI to form mesionic compounds with an interesting structure (eq 48).[55]

(48)

Regioselective 1,3 dipolar cycloaddition of nitrile oxides with CSI gives 3-aryl-substituted 1,2,4-oxadiazolin-5-ones after hydrolysis (eq 49).[56]

(49)

Transition metal 2-alkenyl and 2-alkynyl complexes undergo [3 + 2] cycloadditions with CSI, which lead to pyrrolidones and pyrrolinones respectively with migration of the metal atom (eqs 50 and 51).[57]

(50)

(51)

[M] = $CpFe(CO)_2$, $CpMo(CO)_3$, $Mn(CO)_5$, $Pt(PR_3)_2Cl$

Type III Reactions.

Type III reactions involve compounds which react with the chlorosulfonyl portion of CSI. These include compounds which are unreactive towards the isocyanate group (eqs 52 and 53)[58,59] or which react with the chlorosulfonyl portion under special experimental conditions such as high temperature (eq 54)[60] or radical conditions (eq 55).[61]

(52)

(53)

(54)

R = H, 3-Cl, 4-Cl, 4-Me, 4-MeO, 4-CN

(55)

R = H, Me, Et, Bu, $ClCH_2$, Cl_2CHCH_2

By changing the reaction conditions in eq 55, a dramatically different product is obtained (eq 56).[1a]

Chloro(thexyl)borane

[75030-54-5] · $C_6H_{14}BCl$ · Chloro(thexyl)borane · (MW 132.43)

(hydroboration agent)

Alternate Name: chloro(1,1,2-trimethylpropyl)borane.

This reagent, which was first used in hydroboration reactions by Zweifel and Pearson,[1] has been replaced by ***Chloro(thexyl)borane-Dimethyl Sulfide***. In fact, Zweifel and Pearson prepared their reagent from borane-dimethyl sulfide in THF, so there is reason to believe that they were actually working with the dimethyl sulfide complex of the chloro(thexyl)borane that they prepared. Brown and Sikorski[2] have prepared chloro(thexyl)borane free of dimethyl sulfide in both THF and Et_2O and examined the reactions of the reagents obtained with alkenes in the same solvents. The THF complex of chloro(thexyl)borane could be obtained cleanly by treating BH_2Cl with 2,3-dimethyl-2-butene in THF, but the same reaction in Et_2O gave a complex, equilibrating mixture containing thexylborane, chloro(thexyl)borane, and dichloro(thexyl)borane. Hydroboration of terminal alkenes with the chloro(thexyl)borane reagent in THF (or with the complex mixture obtained in Et_2O) led to mixtures containing trialkylborane, dialkylchloroborane, and alkyldichloroborane species. However, these workers showed that the chloro(thexyl)borane-dimethyl sulfide reagent in CH_2Cl_2 reacts cleanly with alkenes to give the desired alkylchlorothexylborane product.[2]

Chloro(thexyl)borane-Dimethyl Sulfide

[75067-06-0] · $C_8H_{20}BClS$ · Chloro(thexyl)borane-Dimethyl Sulfide · (MW 194.57)

(highly regioselective, monohydroborating agent for alkenes and alkynes, producing thexylalkylchloroboranes or thexylalkenylchloroboranes, respectively, which are synthetically useful intermediates;[1] reduces carboxylic acids to aldehydes;[2] reduces aldehydes and ketones to alcohols[2b])

Solubility: sol CH_2Cl_2, ether, and THF, but CH_2Cl_2 is the solvent of choice;[3] reacts rapidly with protic solvents.[2b]

Form Supplied in: prepared in situ.

Preparative Method: most conveniently prepared from commercially available monochloroborane-dimethyl sulfide complex and 2,3-dimethyl-2-butene in CH_2Cl_2 (eq 1).[1a,3]

Analysis of Reagent Purity: analyzed by ^{11}B NMR and IR spectroscopy and by hydrogen evolution upon reaction with methanol.[3]

Handling, Storage, and Precautions: very reactive with oxygen and moisture and must be handled using standard techniques for handling air-sensitive materials.[4] Reported to be stable for at least two months when stored at 0 °C in CH_2Cl_2 solution under N_2.[2b]

Hydroboration of Alkenes and Alkynes.

Chloro(thexyl)borane-dimethyl sulfide (ThxBHCl.SMe_2) in CH_2Cl_2 is a monohydroborating agent with exceptionally high regioselectivity.[1] This reagent has also been prepared in THF/Et_2O by the reaction of ***Thexylborane-Dimethyl Sulfide*** with one equivalent of HCl.[5] However, CH_2Cl_2 is superior to Et_2O or THF as a solvent for hydroborations with

this reagent.[3] Like ***Disiamylborane*** (Sia_2BH) and ***9-Borabicyclo[3.3.1]nonane*** (9-BBN), $ThxBHCl.SMe_2$ has large steric requirements and reacts preferentially to add boron at the least hindered carbon atom of the carbon-carbon double or triple bond (eq 2).

However, $ThxBHCl.SMe_2$ is more sensitive to electronic factors that either Sia_2BH or 9-BBN due to its higher Lewis acidity. Upon reaction with styrene followed by oxidation, $ThxBHCl.SMe_2$ gives a greater than 99:1 ratio of 2-phenylethanol to 1-phenylethanol, which is higher than any of the other common hydroborating agents.[1b] Internal alkenes are much less reactive than terminal alkenes toward hydroboration with $ThxBHCl.SMe_2$, and this reagent shows a much higher rate of reaction with *cis* disubstituted alkenes than with the *trans* isomers.[1c] Cyclohexenes and trisubstituted alkenes react more slowly with $ThxBHCl.SMe_2$ than do terminal or *cis* alkenes, and some redistribution of the reagent to $ThxBH_2.SMe_2$ and $ThxBCl_2.SMe_2$ can be observed with the long reaction times (>10 h) required for the reaction with relatively unreactive alkenes.[1b] $ThxBHCl.SMe_2$ reacts more rapidly with 1-hexyne or 3-hexyne than with 1-hexene.[6] Hydroborations of terminal alkynes with this reagent result in regioselective *syn* addition, affording the alkenylchloro(thexyl)borane in high yield.

Alkylchloro(thexyl)boranes (**1**) are useful intermediates in a variety of organic transformations. Reduction of these intermediates with ***Potassium Triisopropoxyborohydride*** (KPBH) in the presence of another alkene produces the mixed dialkylthexylborane (**2**), which can be converted to the corresponding unsymmetrical ketones (eq 3).[1b,7] Dialkylthexylboranes (**2**) are also produced by reaction of alkylchloro(thexyl)boranes (**1**) with equimolar amounts of organolithium or Grignard reagents.[5] Reduction of alkylchloro(thexyl)boranes at -78 °C with KPBH followed by addition of a 1-halo-1-alkyne and warming to room temperature affords *B*-(*cis*-1-halo-1-alkenyl)alkyl(thexyl)boranes (**3**) (eq 4). Treatment with ***Sodium Methoxide*** induces a selective migration of the alkyl group, resulting in the formation of *B*-(*trans*-1-alkyl-1-alkenyl)thexylborinate (**4**), which can be converted to the (*E*)-alkene (**5**) by protonolysis with isobutyric acid or to the ketone (**6**) by alkaline hydrogen peroxide oxidation.[8] The low migratory aptitude of the thexyl group results in only 2-7% of product where the thexyl group has migrated.

Hydroboration of 1-bromo-1-alkynes with chloro(thexyl)borane leads to the synthesis of alkynyl ketones in 61-63% yields by the sequence of reactions[9] shown in eq 5. Sequential treatment of alkenylchloro(thexyl)boranes, which are formed by the reaction of chloro(thexyl)borane with alkynes, with lithium chloropropargylide and aldehydes affords 1,3-enynols or 1,2,4-trienols depending on the reaction conditions.[10]

Alkylchloro(thexyl)boranes prepared from terminal alkenes can be hydrolyzed with one equivalent of water and then oxidized with ***Pyridinium Chlorochromate*** (PCC) to the corresponding aldehyde in moderate yields (eq 6).[11]

Reduction of Carboxylic Acids to Aldehydes.

Aliphatic carboxylic acids are reduced rapidly (15 min) and aromatic carboxylic acids are reduced slowly (24 h) by chloro(thexyl)borane-dimethyl sulfide to the corresponding aldehydes.[2] Sodium bisulfite adducts were prepared to

purify the aldehydes. Aliphatic aldehydes are isolated in 80-93% yields, and aromatic aldehydes are isolated in 46-78% yields.[2a] Alkoxy, nitro, cyano, halo, and ester functional groups are not reduced under these conditions.

Reductive Cyclization of o-Azidoalkenes.

Hydroboration of o-azidoalkenes with chloro(thexyl)borane followed by hydrolysis affords, via an intramolecular reductive cyclization, the corresponding pyrrolidine (78%) or the piperidine (53%) (eq 7).[12]

Chlorotitanium Triisopropoxide[1]

$ClTi(O\text{-}i\text{-}Pr)_3$

[20717-86-6] · $C_9H_{24}ClO_3Ti$ · Chlorotitanium Triisopropoxide · (MW 260.62)

(mild Lewis acid used for the preparation of organotitanium derivatives[1] and titanium enolates;[1,2] alkyl, [3-5] allyl,[3,4,6] aryl,[3-5] alkenyl,[7] allenyl,[8] and alkynyl[9,10] titanium triisopropoxides exhibit reduced basicity and add to carbonyl compounds with enhanced chemo-, regio-, and stereoselectivity;[1b-f] titanium enolates[2] react with aldehydes and imines[11] with high levels of *syn* selectivity[12] and greatly enhanced diastereofacial selectivity;[13] titanium isopropoxides mediate the regioselective opening of epoxides[14,15] and serve as a titanium source for the preparation of chiral titanium complexes[16])

Alternate Names: chlorotitanium tris(isopropoxide); chlorotriisopropoxytitanium; chlorotris(2-propanolato)titanium.

Physical Data: mp 45-50 °C; bp 61-65 °C/0.1 mmHg; *d* 1.091 g cm^{-3}.

Solubility: sol most nonprotic organic solvents, e.g. Et_2O, THF, CH_2Cl_2, toluene, hexanes.

Form Supplied in: syrupy liquid; 1.0 M solution in CH_2Cl_2 or hexanes.

Preparative Method: available commercially, but can be easily made from a 3:1 mixture of ***Titanium Tetraisopropoxide*** and ***Titanium(IV) Chloride***,[3] which can be distilled to give the pure reagent or used in situ.[17]

Handling, Storage, and Precautions: corrosive; moisture sensitive; flammable liquid; can be stored under nitrogen, in pure form or in solution, for months.

Organotitanium Reagents.

The conversion of a variety of readily available organomagnesium (RMgX, Grignard) or organolithium reagents (RLi) to organotitanium derivatives of the general type $RTiX_3$ (X = Cl, OR´, or NR_2´´) often results in significant improvements in chemo-, regio-, diastereo-, and enantioselectivity.[1] Similar effects are also possible with the titanation of enolates. The synthetic advantages of the organotitanium species are derived not only from the modulation of their nucleophilicity and Lewis basicity, but also through their improved solubility in organic solvents and their increased steric and electronic requirements.

Among the various titanium alkoxides, the isopropoxy derivatives are most synthetically useful because they exist in a monomeric form while retaining adequate titanium reactivity. Although less bulky alkoxide ligands (e.g. MeO, EtO) are expected to form more reactive titanium species, these derivatives are, overall, less reactive because they exist as oligomers.

Titanation of Organomagnesium and Organolithium Reagents.

The widely used 1,2-additions of organometallic reagents to aldehydes and ketones often take place with low stereoselectivity and without significant discrimination among different carbonyl groups. Treatment of these carbon nucleophiles with $ClTi(O\text{-}i\text{-}Pr)_3$ (**1**) can have a dramatic effect in their chemo- and stereoselectivity. The resulting alkyltitanium triisopropoxide reagents are usually employed in carbonyl additions in situ, although some, such as ***Methyltitanium Triisopropoxide***, can also be isolated in a pure form. An important advantage of these reagents is that they generally react much faster with aldehydes than with ketones (eq 1).[1b-f,3,5,9,18] They also tolerate a variety of other electrophilic functional groups, such as halides, esters, cyano, and nitro groups.

(1)

MeLi	42:58

R	
Me	75:25
n-Bu	90:10
$CH_2{=}CHCH_2$	71:29
Ph	9:91

Titanation of functionalized organozinc nucleophiles[21] results in highly stereocontrolled additions to aldehydes (eq 4).[22]

(4)

Titanation of lithiated allyl or crotyl carbamates allows a highly stereoselective homoaldol[6] addition to aldehydes in an S_N2' fashion. Titanation with ***Titanium Tetraisopropoxide*** or ***Chlorotris(diethylamino)titanium***, however, is often a more stereocontrolled process than titanation with (**1**) (eq 5).[23]

HC≡CLi	4:1
HC≡CMgBr	1:1

Titanation of phosphonate- or phosphinoxide-stabilized carbanions improves their aldehyde selectivity[26] and can affect the stereoselectivity of their additions to aldehydes.[27] With phosphonate acetate, titanation results in a stereoselective Knoevenagel condensation (eq 9).[28]

E:*Z* = 90:10

(9)

Titanation of Enolates.[2]

The conversion of lithium enolates to the corresponding titanium derivatives often results in enhanced chemo-, regio-, and stereoselectivities during the aldol reactions with aldehydes. Due to their suppressed Lewis acidity, the titanium enolates add selectively to aldehydes in the presence of ketones, while the reverse selectivity can be achieved via the in situ protection of the aldehyde moiety with ***Titanium Tetrakis(diethylamide)*** (eq 10).[29]

(10)

$ClTi(O\text{-}i\text{-}Pr)_3$	86:14
$ClTi(OPh)_3$	90:10
$ClTi(NEt_2)_3$	93: 7

Addition of titanium enolates to chiral aldehydes, including α-alkoxy derivatives, takes place with no chelation[19] and with high diastereoselectivity (eq 12).[31]

(12)

A complete reversal of diastereoselectivity upon titanation is possible during addition of ester enolates to chiral imines (eq 13).[11]

(13)

additive	
none	93: 7
$ClTi(O\text{-}i\text{-}Pr)_3$	8:92

Titanation of chiral enolates often has a dramatic effect on their diastereofacial selectivity; examples include the enolates of chiral amides,[32] chiral imides,[33] chiral α´-silyloxy ketones,[34] and chiral α´-benzoyloxy ketones (eq 14).[13]

(14)

365:1

A complete reversal of regioselectivity is observed in the reactions of enedithiolates with α,β-unsaturated ketones in the presence of (**1**). Although the lithium enedithiolates react by 1,4-addition, the titanium derivatives afford only 1,2-addition products, while the corresponding aluminum species give 1,4-addition through the sulfur atom (eq 15).[35]

(15)

Enolization of the imines of α-amino esters generates *N*-metalated azomethine ylides, which react with α,β-unsaturated carbonyl compounds to form pyrrolidine derivatives. The use of titanium intermediates,[36,37] formed with a base and (**1**) or ***Dichlorotitanium Diisopropoxide***, results in an increase of the regio- and stereoselectivity of this process (eq 16).[37]

(16)

Regioselective Epoxide Opening.

Titanium alkoxides promote the regioselective opening of asymmetric epoxides and epoxy alcohols with a variety of nucleophiles. Although ***Titanium Tetraisopropoxide*** is used more often for this purpose,[14,15] (**1**) is used in the formation of titanium acetylide nucleophiles,[9] or as a source of the Cl^- nucleophile (eq 17).[15]

Preparation of Chiral Titanium Complexes.[16]

Chiral ligands on titanium can lead to significant enantioselectivities in various titanium-mediated reactions. For this purpose, numerous chiral alkoxytitanium complexes have been investigated.[16] A common titanium source for many of these derivatives is (**1**), although dichlorotitanium diisopropoxide and titanium(IV) isopropoxide are also often used. One successful application is the enantioselective addition of alkyl groups to aldehydes (eq 18).[38]

Chlorotris(diethylamino)titanium[1]

$ClTi(NEt_2)_3$

[6607-37-0] · $C_{12}H_{30}ClN_3Ti$ · Chlorotris(diethylamino)titanium · (MW 299.72)

(efficient transmetalating agent useful in the conversion of reactive and nonselective organolithium or -magnesium compounds into organotitanium reagents for chemo- and stereoselective Grignard-type,[2,3] aldol,[4-6] homoaldol,[7,8] and Michael additions[9])

Alternate Name: chlorotitanium tris(diethylamide).

Physical Data: bp 94-96 °C/0.02 mmHg.

Solubility: sol ether, THF, CH_2Cl_2, toluene.

Form Supplied in: liquid.

Preparative Methods: the reaction of ***Lithium Diethylamide***, prepared by the reaction of $HNEt_2$ with BuLi[10a] or Li/styrene,[10b] with a stoichiometric amount of ***Titanium(IV) Chloride*** affords $ClTi(NEt_2)_3$ (eq 1). The reaction of $TiCl_4$ with ***Titanium Tetrakis(diethylamide)*** also leads to $ClTi(NEt_2)_3$.[10c] $ClTi(NMe_2)_3$ is accessible via similar routes.[10a]

$$LiNEt_2 + TiCl_4 \longrightarrow ClTi(NEt_2)_3 \qquad (1)$$

Handling, Storage, and Precautions: moisture-sensitive; should be handled and stored under an inert gas atmosphere (e.g. N_2). Syringe techniques are adequate.

Traditional carbanions such as alkyllithium reagents, lithium enolates, and other deprotonated CH-acidic compounds, as well as some organomagnesium reagents, are so basic and reactive that carbonyl addition and substitution reactions often show low degrees of chemo- and stereoselectivity. In many of these cases, titanation using $ClTiX_3$ (X = Cl, OR, NR_2) increases carbanion selectivity dramatically.[1,11] Control of chemoselectivity is best achieved by titanating with ***Titanium(IV) Chloride*** or ***Chlorotitanium Triisopropoxide***, the alternative and less readily available $ClTi(NEt_2)_3$ not being necessary. However, in stereoselective reactions the nature of the ligands on titanium play a pivotal role. The transmetalating agents $ClTi(NMe_2)_3$ and $ClTi(NEt_2)_3$ (or their Br analogs) have been used in a number of such cases.[1] All of them involve resonance stabilized ambident carbanions, e.g. enolates, allylic, and heteroallylic species. In contrast, saturated titanium compounds of the type $RTi(NEt_2)_3$ (R = alkyl), although readily available from RLi and

$ClTi(NEt_2)_3$, do not undergo Grignard-type reactions, aminoalkylation being the preferred reaction mode.[1,11]

The aldol addition of titanium enolates generally affords the *syn* configured aldols, irrespective of the geometry of the enolate.[1,4] This property is of particular synthetic interest in the case of cyclic ketones (eq 2),[4] because the boron analogs afford the *anti*-aldols in a complementary manner.[12]

X =	O-*i*-Pr	86:14
	NMe_2	92:8
	NEt_2	97:3

Cram selectivity in the reaction of chiral aldehydes with the very reactive allylmagnesium chloride can also be increased dramatically by prior titanation, $CH_2{=}CHCH_2Ti(NEt_2)_3$ being most selective.[2] This reagent is also useful in axially selective allyl additions to cyclohexanone derivatives.[3]

The tris(diethylamino)titanium enolate of ethyl acetate reacts with chiral α-siloxy ketones to afford the aldol adducts with >99% nonchelation control.[5] Simple diastereoselectivity in the addition of crotyltitanium reagents to ketones is of particular synthetic interest because other metal reagents fail. $MeCH{=}CHCH_2Ti(NEt_2)_3$ is best suited for prochiral aliphatic ketones (ds > 90%),[3] whereas aromatic ketones require reagents with alkoxy ligands at titanium.[3,11]

Racemic aminotitanium homoenolate equivalents react stereoselectively with achiral[7] and chiral aldehydes.[13] For example, of eight possible diastereomers from γ-attack on 2-phenylpropanal, only two are formed in a ratio of 93:7 (eq 3).[13] The results obtained by employing $ClTi(NEt_2)_3$ in related cases are similar or better, as in the synthesis of D- and L-3,6-dideoxy-3-*C*-methylhexofuranosides.[13] Enantiomerically pure analogs react with achiral aldehydes enantio- and diastereoselectively.[14]

(3)

Several other chiral titanium compounds having amino ligands have been reported,[1] including one of the most stereoselective reagents for homoaldol additions currently available.[8]

Lithiated bis-lactim ethers do not react stereoselectively with aldehydes, but can be titanated with $ClTi(NR_3)_3$ (R = Me, Et) to form highly selective reagents for the synthesis of enantio- and diastereomerically pure α-amino-β-hydroxy acids (eq 4).[6] These reagents also undergo enantioselective Michael additions to nitro alkenes and α,β-unsaturated esters.[9]

Chlorotriethylsilane

Et_3SiCl

[994-30-9] · $C_6H_{15}ClSi$ · Chlorotriethylsilane · (MW 150.75)

(silylating agent, Lewis acid catalyst)

Alternate Name: triethylsilyl chloride.

Physical Data: bp 145-147 °C; *d* 0.898 g cm^{-3}.

Solubility: readily sol most aprotic organic solvents, although CH_2Cl_2 is most commonly used; reacts with H_2O and other protic solvents.

Form Supplied in: colorless liquid, or as a 1.0 M solution in THF.

Handling, Storage, and Precautions: should be handled and stored under an anhydrous, inert atmosphere.

General Considerations.

The triethylsilyl moiety is often used as a protecting group for alcohols because of its greater stability towards hydrolysis than the smaller trimethylsilyl group. Alcohols can normally be silylated with Et_3SiCl using either ***Imidazole*** in DMF or ***Triethylamine/4-Dimethylaminopyridine*** in CH_2Cl_2 (eqs 1 and 2).[1,2] For substrates which are more difficult to derivatize, it may be advantageous to carry out the reaction in neat ***Pyridine*** (eq 3)[3] or to generate the alkoxide salt prior to the addition of Et_3SiCl (eq 4).[4-6]

(1)

(2)

(3)

(4)

Silyl ethers have also been obtained by in situ trapping of an intermediate alkoxide that results from a nucleophilic addition onto an ester[7] or epoxide[8] (eqs 5 and 6).

Silyl enol ethers can be prepared from ketones by trapping the kinetically formed lithium enolate with Et_3SiCl (eqs 7 and 8),[9,10] or by the conjugate addition of a dialkylcuprate to an α,β-unsaturated ketone with silylation of the enolate intermediate (eq 9).[11-13] Surprisingly, the addition of ***Lithium Di-n-butylcuprate*** to an α,β-unsaturated lactone in the presence of Et_3SiCl resulted in the 1,4-addition of the triethylsilyl moiety, apparently via the in situ formation of an

intermediate silylcuprate species (eq 10).[14]

(5)

(6)

(7)

(8)

(9)

(10)

Organolithium salts generally react with Et_3SiCl to afford organosilanes. Schlessinger used a deprotonation-silylation procedure to introduce a triethylsilyl group at the α-position of an alkylimine (eq 11).[15] A variety of other stabilized carbanions have been reported to react cleanly with Et_3SiCl (eqs 12-15).[16 -19]

(11)

(12)

(13)

(14)

(15)

In a similar manner, aryl, vinyl-, and alkynylsilanes can be prepared by the reaction of the appropriate carbanion with Et_3SiCl (eqs 16-21).[20-25]

(16)

(17)

(18)

(19)

(20)

(21)

Related Reagents.

t-Butyldimethylchlorosilane; ***Chlorotrimethylsilane***; ***Chlorotriphenylsilane***.

(2-Chloro-1,1,2-trifluoroethyl)diethylamine[1]

Et_2NCF_2CHFCl

[357-83-5] · $C_6H_{11}ClF_3N$ · (2-Chloro-1,1,2-trifluoroethyl)diethylamine · (MW 189.61)

(mild electrophilic fluorinating agent capable of nucleophilic substitution of hydroxyl group[1-7] by fluorine)

Alternate Name: Yarovenko reagent.

Physical Data: bp 32-33 °C/6 mmHg;[2] bp 33-34 °C/6 mmHg.[1]

Solubility: sol most aprotic organic solvents.

Preparative Method: from diethylamine and chlorotrifluoroethylene at -5 to -10 °C without solvent.

Purification: by distillation.

Handling, Storage, and Precautions: highly sensitive toward moisture (elimination of HF) and should be stored in tightly closed polyethylene vessels; reactions should be performed in thoroughly predried glass or quartz vessels; use in a fume hood.

Fluorination.

The main application of the reagent (**1**) is in the preparation of alkyl or acyl flourides by the substitution reaction of hydroxyl groups (alcohols, carboxylic acids, and their salts) by fluorine (eqs 1 and 2).[2]

$$\underset{}{ROH} + \underset{\textbf{(1)}}{Et_2NCF_2CHFCl} \longrightarrow RF \qquad (1)$$

(2)

The fluorination of some cyclic secondary and especially tertiary alcohols may lead to the elimination of HF and alkene formation.[3,4] Thioacids give acyl fluorides, rather than thioacyl fluorides.[2]

The fluorination can be performed using equimolar amounts or a slight excess of the reagent, either without solvent or in a solvent such as CH_2Cl_2, MeCN, Et_2O, or THF. As a rule, the reactions are slightly exothermic or performed at rt. Neither *t*-amino groups nor alkoxycarbonyl groups prevent fluorination (eq 3).[5]

(3)

The reagent has been used extensively for the fluorination of steroids (eq 4).[6-8]

(4)

One paper[9] describes the application of (**1**) to the fluorination of aromatic aldehydes to give difluoromethylene compounds (eq 5).

$$\mathrm{ArCHO} \xrightarrow{(1)} \mathrm{ArCHF_2} \qquad (5)$$

$$\mathrm{Ar} = \mathrm{Ph},\ p\text{-}\mathrm{NO_2C_6H_4},\ m\text{-}\mathrm{NO_2C_6H_4}$$

The mechanism of the fluorination includes nucleophilic substitution of the highly labile fluorine atom in the α-position to nitrogen to give the alkoxyamino intermediate which, in turn, undergoes S_N2 reaction to give the corresponding fluoride and diethylamide of fluorochloroacetic acid (eq 6).

(6)

An analogous reagent ($Et_2NCF_2CHFCF_3$ + $Et_2NCF{=}CFCF_3$; Ishikawa reagent) has been described.[10]

Chlorotrifluoroethylene

[79-38-9] · C_2ClF_3 · Chlorotrifluoroethylene · (MW 116.47)

(addition reactions; cycloadditions; trifluorovinylations)

Physical Data: mp -158 °C; bp -28.4 °C.

Solubility: sol organic solvents (ether, THF).

Form Supplied in: flammable gas, inhibited with 1% Bu_3N.

Handling, Storage, and Precautions: inhalation toxicity LC_{50}: 1000 ppm; flammable; use in a fume hood.

Addition Reactions.

Chlorotrifluoroethylene is a starting material for the preparation of fluorinated molecules, via addition or addition-elimination reactions, the regioselectivity of which is not always, but can be, excellent. Halogenation according to eq 1 is a good example.[1] Hydrobromination under UV irradiation also gives a unique pentahaloethane (eq 2).[2]

$$CF_2{=}CFCl + ICl \xrightarrow[62\%]{-5\ °C} \underset{98:2}{CF_2Cl\text{-}CFClI + CF_2I\text{-}CFCl_2} \qquad (1)$$

$$CF_2{=}CFCl + HBr \xrightarrow[\substack{20\ °C \\ 92.5\%}]{h\nu} CF_2Br\text{-}CHFCl \qquad (2)$$

Lewis acid catalyzed addition of CCl_4 proceeds via addition-substitution (eq 3).[3]

$$CF_2{=}CFCl + CCl_4 \xrightarrow[\text{75 °C, 70\%}]{AlCl_3} CCl_3\text{-}CF_2\text{-}CCl_3 + \ldots \quad (3)$$

The nucleophilic addition of alcohols,[4] thiols,[5] and primary and secondary amines[6] in the presence of base occurs readily; the regioselectivity corresponds to a better stabilization of the negative charge by -CFCl, than by $-CF_2$ (eqs 4 and 5). With diethanolamine,[7] further substitution occurs (eq 6).

$$CF_2{=}CFCl + PrSH \xrightarrow[\text{50\%}]{B^-} PrSCF_2\text{-}CHFCl \quad (4)$$

$$CF_2{=}CFCl + ROH \xrightarrow{B^-} ROCF_2\text{-}CHFCl \quad (5)$$

$$CF_2{=}CFCl + HN(CH_2\text{-}CH_2OH)_2 \xrightarrow[\text{92\%}]{B^-}$$

(6)

Various organometallic reagents[8-11] follow the addition-elimination pattern (eqs 7-9), as do lithium amides (eq 10).

$$CF_2{=}CFCl + PhMgBr \xrightarrow[\text{82\%}]{} Ph\text{-}CF{=}CFCl \quad (7)$$

$$CF_2{=}CFCl + PhLi \xrightarrow[\text{55\%}]{} Ph\text{-}CF{=}CFCl \quad (8)$$

$$CF_2{=}CFCl + MeC{\equiv}CLi \xrightarrow[\text{73\%}]{} MeC{\equiv}C\text{-}CF{=}CFCl \quad (9)$$

$$CF_2{=}CFCl + Ph\text{-}N(Me)Li \xrightarrow[\text{71\%}]{} Ph\text{-}N(Me)\text{-}CF{=}CFCl \quad (10)$$

Thiolates and alcoholates follow the same scheme. Allylates represent an interesting case since the initially formed allyl fluorovinyl ether undergoes a fluorine accelerated Claisen rearrangement, even at -35 °C (eq 11).[12]

Cycloadditions.

Insertion of difluorocarbene generates chloropentafluorocyclopropane (eq 12).[13]

Various cycloadditions are observed at high temperatures (pressure vessel) with alkenes, alkynes, and conjugated dienes ([2 + 2] addition prevails largely over [4 + 2]) (eqs 13-15).[14-16]

Trifluorovinylations.

A useful synthon for the nucleophilic introduction of the trifluorovinyl moiety is obtained by chlorine/lithium exchange (eq 16).[17]

(16)

The vinyllithium species must be handled at low temperatures. It reacts with aldehydes or ketones to give trifluorovinylcarbinols, which are a source of α-fluoro-α-ethylenic acids (by acidic treatment). They are also a source of α,β-difluoro-α-ethylenic alcohols if a lithium reagent is added, in a second step, to the reaction mixture (eq 17).[18]

(17)

The analogous zinc derivative[19] is much more thermally stable, and can be vinylated, arylated, or acylated by a palladium catalyzed reaction with vinyl or aryl halides, or with acyl chlorides (eq 18).[18]

(18)

The analogs CF_2=CFBr and CF_2=CFI have been used in several similar reactions, but they are more expensive. However, when treated with ***Zinc*** powder, they deliver the corresponding zinc derivative.[20]

1-Chloro-*N*,*N*,2-trimethylpropenylamine[1]

(X = Cl)

[26189-59-3] · $C_6H_{12}ClN$ · 1-Chloro-*N*,*N*,2-trimethylpropenylamine · (MW 133.62) (X = F)

[65560-29-4] · $C_6H_{12}FN$ · 1-Fluoro-*N*,*N*,2-trimethylpropenylamine · (MW 117.17) (X = Br)

[73630-93-0] · $C_6H_{12}BrN$ · 1-Bromo-*N*,*N*,2-trimethylpropenylamine · (MW 178.07) (X = I)

[65560-41-0] · $C_6H_{12}IN$ · 1-Iodo-*N*,*N*,2-trimethylpropenylamine · (MW 225.07)

(mild halogenation of alcohols and acids under neutral conditions;[2] conversion of *N*-protected amino acids into peptides without racemization;[3] coupling of acids and allylic alcohols with organometallics;[9] [2 + 2] cycloaddition synthons, more reactive than dimethylketene[1b,4,5])

Alternate Name: tetramethyl-α-chloroenamine; TMCE

Physical Data: X = Cl: bp 129-130 °C (760 mmHg), *d* 1.01 g cm^{-3}; X = F: bp 89-92 °C (760 mmHg); X = Br: bp 42-45 °C (15 mmHg); X = I: bp 61-63 °C (9 mmHg), *d* 1.55 g cm^{-3}.

Solubility: very sol most organic solvents; reacts instantaneously with H_2O, alcohols, and protic solvents.

Preparative Methods: 1-chloro-*N*,*N*,2-trimethylpropenylamine is conveniently prepared by the reaction of *N*,*N*,2-trimethylpropanamide with ***Phosgene*** followed by dehydrochlorination of the intermediate α-chloroiminium chloride (eq 1).[1a,6] Recent unpublished results of our laboratory have shown that ***Phosphorus Oxychloride*** or di- or triphosgene can also be used for the preparation of TMCE.

The corresponding 1-fluoro-, 1-bromo- and 1-iodo-*N*,*N*,2-trimethylpropenylamines (tetramethyl-α-fluoro-, -bromo-, and -iodoenamines; TMFE, TMBE, and TMIE) are readily prepared from TMCE by halogen exchange (eq 2).[1a,7]

Analysis of Reagent Purity: IR, ^{1}H NMR, elemental analysis.[6]

Handling, Storage, and Precautions: 1-chloro-, 1-fluoro-, and 1-bromo-*N*,*N*,2-propenylamines are thermally stable. They must be transferred in the absence of moisture and stored under nitrogen in sealed tubes. In spite of these precautions, light precipitates sometimes may form. 1-Iodo-*N*,*N*,2-trimethylpropenylamine is less stable and should be used when freshly prepared.

Halogenation Reactions.

1-Chloro-, 1-bromo- and 1-iodo-*N*,*N*,2-trimethylpropenylamines are mild reagents which transform alcohols into the corresponding halides (eqs 3-6).[2b] The reaction proceeds under neutral conditions, thus allowing the presence of acid-sensitive functional groups. The reaction occurs with inversion of configuration (eq 4). Secondary allylic and propargylic alcohols give some rearranged halides (eqs 5 and 6), but their formation seems to occur after the halogenation step.

(3)

(4)

100% inversion

(5)

71% 29%

The halogenation reaction has been applied to the modification of various furanose and pyranose hemiacetals (eqs 7 and 8).[8]

The reaction of 1-fluoro-*N*,*N*,2-trimethylpropenylamine with alcohols usually gives a mixture of products.[2b] In some cases a bulkier derivative has been successfully used to transform alcohols into fluorides (eqs 9 and 10).[2b,8]

(10)

All the 1-halo-*N*,*N*,2-trimethylpropenylamines rapidly convert acids into acid halides (eqs 11 and 12).[2a] Since the only byproduct is the relatively inert *N*,*N*,2-trimethylpropanamide, the isolation of the acid halide will often be unnecessary. This method has been applied in peptide synthesis; no racemization was observed (eq 13).[3]

(11)

(12)

(13)

Coupling Reactions.

1-Chloro-*N*,*N*,2-trimethylpropenylamine is an excellent reagent for the coupling of carboxylic acids (eq 14) or allylic alcohols (eq 15) with organometallic compounds.[9]

(14)

(15)

[2 + 2] Cycloadditions.

TMCE is a source of tetramethylketeniminium chloride.[1a] This highly electrophilic intermediate can be trapped by Schiff bases to generate azetidiniminium salts which readily hydrolyze to β-lactams (eq 16).[1b,5a] This has been developed into a general method to produce β-lactams from tertiary amides (eqs 17 and 18).[5c,5d]

(16)

(17)

(18)

With the less nucleophilic carbon-carbon multiple bonds, cycloaddition will only occur in the presence of a Lewis acid which displaces the equilibrium toward the cumulene form (eq 19).[1a,4] $AgBF_4$, $ZnCl_2$, $AlCl_3$, and $SnCl_4$ have been successfully used, but the combination of TMCE with ***Zinc Chloride*** is the most convenient in many cases.[4b] Thus tetramethylketeniminium salts, which are most often generated in situ, behave as highly reactive equivalents of dimethylketene for the preparation of cyclobutanones and cyclobutenones. Indeed, the cyclobutane- and cyclobuteneiminium salts intermediates are readily hydrolyzed (eqs 20-23).

(19)

The reaction has been extended to other 2-substituted 1-chloro-*N*,*N*-dialkylvinylamines.[10] An asymmetric version of the cycloaddition has been described (eq 24).[11]

Miscellaneous Reactions.

Reaction of 1-chloro-*N*,*N*,2-trialkylpropenylamines with azide ion gives 2-amino-1-azirines; these three-membered ring amidines are useful intermediates for the synthesis of pyridines.[12] 1-Chloro-*N*,*N*,2-trialkylpropenylamines react readily with electron-rich aromatics in electrophilic substitutions, without the need of an acid catalyst.[13] The corresponding α-metalated vinylamines give nucleophilic aminoalkenylation reactions.[14] TMCE reacts with potassium cyanide to yield 1-cyano-*N*,*N*,2-trimethylpropenylamine, a synthetic intermediate for the preparation of α-diketones.[15] TMCE is smoothly converted to *N*,*N*-dimethylmethacrylamide in the presence of ***Pyridine N-Oxide*** and ***Triethylamine***; this reaction has been applied successfully to the preparation of various α,β-unsaturated amides.[16] 1-Phosphonato enamines have been obtained by treatment of TMCE with trialkyl phosphites.[17] The reaction of metal carbonyl anions with TMCE has been described; this leads to the formation of new transition metal organometallic compounds with novel structural features.[18]

Chlorotrimethylgermane

Me_3GeCl

[1529-47-1] · C_3H_9ClGe · Chlorotrimethylgermane · (MW 153.16)

(precursor of germanium masked dienolate for regioselective C-C bond formation;[1] germanium enolates and α-germyl ester for aldol,[10] Peterson-type reaction,[8] and Claisen rearrangement[11])

Alternate Name: trimethylgermanium chloride.

Physical Data: mp -13 °C; bp 102 °C; *d* 1.240 g cm^{-3}.

Solubility: sol ether, THF, hexane, benzene, CH_2Cl_2, $CHCl_3$.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: is air-stable, but moisture sensitive. Germanium compounds are reputed to be of lower toxicity than stannanes. Use in a fume hood.

Allylgermanes.

The reaction of certain lithium dienolates with trimethylgermanium halides (Me_3GeCl and Me_3GeBr) produces the α-trimethylgermylated β,γ-unsaturated esters (**1**) (eq 1).[1] On the other hand, the reaction of lithium dienolate (**2a**) with tin chlorides Bu_xSnCl_{4-x} (x = 0-3) produces the γ-stannylated α,β-unsaturated esters, and the same reaction with ***Chlorotrimethylsilane*** gives the *O*-silylated dienol ethers (eq 2). The α-germylation of (**2**) is a reflection of kinetic control, as is observed in the alkylation of (**2**) with alkyl halides. The γ-stannylation is due to the thermodynamic stability of the product, and the *O*-silylation is ascribed to the strong affinity of Si for oxygen. In fact, the α-germylated (**1a**) undergoes rearrangement to the γ-isomer upon heating. Further, treatment of (**2a**) with chlorotriphenylgermane gives the γ-germylated product, owing to the steric bulkiness of the triphenylgermyl group.

(1a) $R^1 = Me$, $R^2 = H$, $R = Et$
(1b) $R^1 = H$, $R^2 = H$, $R = Me$
(1c) R^1-$R^2 = (CH_2)_3$, $R = Et$
(1d) R^1-$R^2 = (CH_2)_4$, $R = Me$

In general, lithium dienolates (for example **2**) react with carbon electrophiles at the α-position and thus the carbon chain elongation at the γ-position is not easy. However, C-C bond formation at the γ-position takes place via the α-germylated compounds (**1**), which are α-alkoxycarbonylallylgermane derivatives. The Lewis acid mediated reactions of (**1**) with acetals, aldehydes, and reactive halides afford the γ-alkylated α,β-unsaturated esters having predominant (*E*) geometry (eq 3). The reaction of allylic halides with (**1a**) in the presence of TMSCl at 10 kbar is highly regioselective and gives the head-to-tail coupling product in high yields (e.g. eq 4). The use of high pressures and TMSCl is essential to this regioselective allylic-allylic coupling. The amination reaction of lithium dienolates often produces a mixture of α- and γ-amino acid derivatives. However, the Lewis acid mediated reaction of α-germyl (Ge-masked dienolates) derivatives (**1**) with DEAD (***Diethyl Azodicarboxylate***) regioselectively provides the γ-adduct (see eq 5).[1,2] On the other hand, the ***Zinc Chloride*** mediated reaction of the γ-stannylated dienolates (shown in eq 2) with DEAD gives the α-adduct.

(3)

(4)

(5)

The reaction of Ge-masked dienolates (**1**) with Michael acceptors in the presence of Lewis acids produces the 1,4-γ-adduct regioselectively, whereas the reaction in the presence of ***Tetra-n-butylammonium Fluoride*** gives the 1,4-α-adduct exclusively (eq 6).[3] The coupling between cyclopentenone and the crotonate lithium dienolate gives a 1,4-α-adduct,[4] and the reaction of some enones with the vinylogous Reformatsky reagent derived from ethyl 4-bromocrotonate to some enones affords a 1,4-α-adduct under the controlled reaction conditions.[5] The 1,2-γ-selectivity is obtained in the reaction of lithium dienolates with certain enones[6] and enols.[7]

(6)

Germanium Enolates and α-Germyl Esters.

Peterson-type reaction of *t*-butyl (trimethylgermyl)acetate, derived from lithium *t*-butylacetate and Me_3GeCl, with aldehydes and ketones gives stereoselectively (*E*)-2-alkenoic acid esters (eq 7).[8] Normally, high (*E*)-selectivity is obtained: (*E*)/(*Z*) = 93:7 for $R^1 = Me(CH_2)_6$, R^2 = H; (*E*)/(*Z*) = >99:1 for R^1 = Ph, R^2 = Me. The (*E*) selectivity via trimethylgermylacetate is higher than that via trimethylsilylacetates.[9]

(7)

The germanium enolate of propiophenone, prepared in situ by the reaction with ***Lithium Diisopropylamide*** in ether followed by treatment with Me_3GeCl, reacts with benzaldehyde to give mainly the *syn*-aldol, while the same enolate produces the *anti*-aldol predominantly if the coexisting lithium halides are removed before condensation (eq 8).[10] The chemical yield is low in the absence of LiX, but is increased in the presence of ***Boron Trifluoride Etherate***. The salt effect on the diastereoselectivity is not observed with the germanium enolate prepared with chlorotriphenylgermane.

(8)

The asymmetric Claisen rearrangement of allyl vinyl ethers is effected with a chiral organoaluminum reagent, (*R*)-(**3**) or (*S*)-(**3**).[11] This method provides a facile asymmetric synthesis of various acylgermanes (and acylsilanes) with high enantiomeric purity (eq 9). The reactions of the trimethylgermyl derivative proceeds with higher enantioselectivity (91% ee) than that of the trimethylsilyl analog (80% ee).

(9)

Other Trimethylgermyl Derivatives.

Reactions of α-stannylvinyllithiums RR´C=C(Li)$SnMe_3$ with Me_3MCl (M = Si, Ge, Pb) give the corresponding mixed bis(trimethylmetal)alkenes, RR´C=C($SnMe_3$)MMe_3.[12] Irradiation of acyltriphenylgermanes in THF gives five- and six-membered cyclic ketones bearing an α-(triphenylgermyl)methyl group (eq 10).[12] Cyanotrimethylgermane, prepared from Me_3GeCl and ***Silver(I) Cyanide***, reacts with terminal alkynes in the presence of ***Palladium(II) Chloride*** catalyst in toluene to produce (*Z*)-3-trimethylgermyl-2-alkenenitriles in good yields.[13] Similar addition reactions take place with ***Cyanotrimethylsilane***, but the reaction is slower than that of Me_3GeCN.

Chlorotrimethylsilane[1,2]

$ClSiMe_3$

[75-77-4] · C_3H_9ClSi · Chlorotrimethylsilane · (MW 108.64)

(protection of silyl ethers,[3] transients,[5-7] and silylalkynes;[8] synthesis of silyl esters,[4] silyl enol ethers,[9,10] vinylsilanes,[13] and silylvinylallenes;[15] Boc deprotection;[11] TMSI generation;[12] epoxide cleavage;[14] conjugate addition reactions catalyst[16-18])

Alternate Names: trimethylsilyl chloride; TMSCl.

Physical Data: bp 57 °C; *d* 0.856 g cm^{-3}.

Solubility: sol THF, DMF, CH_2Cl_2, HMPA.

Form Supplied in: clear, colorless liquid; 98% purity; commercially available.

Analysis of Reagent Purity: bp, NMR.

Purification: distillation over calcium hydride with exclusion of moisture.

Handling, Storage, and Precautions: moisture sensitive and corrosive; store under an inert atmosphere; use in a fume hood.

Protection of Alcohols as TMS Ethers.

The most common method of forming a silyl ether involves the use of TMSCl and a base (eqs 1-3).[3,19-22] Mixtures of TMSCl and ***Hexamethyldisilazane*** (HMDS) have also been used to form TMS ethers. Primary, secondary, and tertiary alcohols can be silylated in this manner, depending on the relative amounts of TMS and HMDS (eqs 4-6).[23]

(6)

Trimethysilyl ethers can be easily removed under a variety of conditions,[19] including the use of ***Tetra-n-butylammonium Fluoride*** (TBAF) (eq 7),[20] citric acid (eq 8),[24] or ***Potassium Carbonate*** in methanol (eq 9).[25] Recently, resins ($OH^-$and H^+ form) have been used to remove phenolic or alcoholic TMS ethers selectively (eq 10).[26]

(7)

(8)

(9)

(10)

Transient Protection.

Silyl ethers can be used for the transient protection of alcohols (eq 11).[27] In this example the hydroxyl groups were silylated to allow tritylation with concomitant desilylation during aqueous workup. The ease of introduction and removal of TMS groups make them well suited for temporary protection.

(11)

Trimethylsilyl derivatives of amino acids and peptides have been used to improve solubility, protect carboxyl groups, and improve acylation reactions. TMSCl has been used to prepare protected amino acids by forming the *O*,*N*-bis-trimethylsilylated amino acid, formed in situ, followed by addition of the acylating agent (eq 12).[5] This is a general method which obviates the production of oligomers normally formed using Schotten-Baumann conditions, and which can be applied to a variety of protecting groups.[5]

(12)

Transient hydroxylamine oxygen protection has been successfully used for the synthesis of *N*-hydroxamides.[6] Hydroxylamines can be silylated with TMSCl in pyridine to yield the *N*-substituted *O*-TMS derivative. Acylation with a mixed anhydride of a protected amino acid followed by workup affords the *N*-substituted hydroxamide (eq 13).[6]

(13)

Formation of Silyl Esters.

TMS esters can be prepared in good yields by reacting the carboxylic acid with TMSCl in 1,2-dichloroethane (eq 14).[4] This method of carboxyl group protection has been used during hydroboration reactions. The organoborane can be transformed into a variety of different carboxylic acid derivatives (eqs 15 and 16).[7] TMS esters can also be reduced with metal hydrides to form alcohols and aldehydes or hydrolyzed to the starting acid, depending on the reducing agent and reaction conditions.[28]

(14)

(15)

(16)

Protection of Terminal Alkynes.

Terminal alkynes can be protected as TMS alkynes by reaction with ***n-Butyllithium*** in THF followed by TMSCl (eq 17).[8] A one-pot β-elimination-silylation process (eq 18) can also yield the protected alkyne.

(17)

(18)

Silyl Enol Ethers.

TMS enol ethers of aldehydes and symmetrical ketones are usually formed by reaction of the carbonyl compound with ***Triethylamine*** and TMSCl in DMF (eq 19), but other bases have been used, including ***Sodium Hydride***[29] and ***Potassium Hydride***.[30]

(19)

Under the conditions used for the generation of silyl enol ethers of symmetrical ketones, unsymmetrical ketones give mixtures of structurally isomeric enol ethers, with the predominant product being the more substituted enol ether (eq 20).[10] Highly hindered bases, such as ***Lithium Diisopropylamide*** (LDA),[31] favor formation of the kinetic, less substituted silyl enol ether, whereas ***Bromomagnesium Diisopropylamide*** (BMDA)[10] generates the more substituted, thermodynamic silyl enol ether. A combination of TMSCl/***Sodium Iodide*** has also been used to form silyl enol ethers of simple aldehydes and ketones[32] as well as from α,β-unsaturated aldehydes and ketones.[33] Additionally, treatment of α-halo ketones with ***Zinc***, TMSCl, and TMEDA in ether provides a regiospecific method for the preparation of the more substituted enol ether (eq 21).[34]

(20)

Reagents	Ratio (A):(B)
LDA, DME; TMSCl	1:99
NaH, DME; TMSCl	73:27
Et_3N, TMSCl, DMF	78:22
KH, THF; TMSCl	67:33
TMSCl, NaI, MeCN, Et_3N	90:10
BMDA, TMSCl, Et_3N	97:3

(21)

Mild Deprotection of Boc Protecting Group.

The Boc protecting group is used throughout peptide chemistry. Common ways of removing it include the use of 50% ***Trifluoroacetic Acid*** in CH_2Cl_2, ***Trimethylsilyl Perchlorate***, or ***Iodotrimethylsilane*** (TMSI).[19] A new method has been developed, using TMSCl-phenol, which enables removal of the Boc group in less than one hour (eq 22).[11] The selectivity between Boc and benzyl groups is high enough to allow for selective deprotection.

(22)

In Situ Generation of Iodotrimethylsilane.

Of the published methods used to form TMSI in situ, the most convenient involves the use of TMSCl with NaI in acetonitrile.[12] This method has been used for a variety of synthetic transformations, including cleavage of phosphonate esters (eq 23),[35] conversion of vicinal diols to alkenes (eq 24),[36] and reductive removal of epoxides (eq 25).[37]

(23)

(24)

(25)

Conversion of Ketones to Vinylsilanes.

Ketones can be transformed into vinylsilanes via intermediate trapping of the vinyl anion from a Shapiro reaction with TMSCl. Formation of either the tosylhydrazone[38] or benzenesulfonylhydrazone (eq 26)[13,39] followed by reaction with *n*-butyllithium in TMEDA and TMSCl gives the desired product.

(26)

Epoxide Cleavage.

Epoxides open by reaction with TMSCl in the presence of ***Triphenylphosphine*** or tetra-*n*-butylammonium chloride to afford *O*-protected vicinal chlorohydrins (eq 27).[14]

(27)

Formation of Silylvinylallenes.

Enynes couple with TMSCl in the presence of Li/ether or Mg/***Hexamethylphosphoric Triamide*** to afford silyl-substituted vinylallenes. The vinylallene can be subsequently oxidized to give the silylated cyclopentanone (eq 28).[15]

Conjugate Addition Reactions.

In the presence of TMSCl, cuprates undergo 1,2-addition to aldehydes and ketones to afford silyl enol ethers (eq 29).[16] In the case of a chiral aldehyde, addition of TMSCl follows typical Cram diastereofacial selectivity (eq 30).[16,40]

Conjugate addition of organocuprates to α,β-unsaturated carbonyl compounds, including ketones, esters, and amides, are accelerated by addition of TMSCl to provide good yields of the 1,4-addition products (eq 31).[17,41,42] The effect of additives such as HMPA, DMAP, and TMEDA have also been examined.[18,43] The role of the TMSCl on 1,2- and 1,4-addition has been explored by several groups, and a recent report has been published by Lipshutz.[40] His results appear to provide evidence that there is an interaction between the cuprate and TMSCl which influences the stereochemical outcome of these reactions.

(31)

The addition of TMSCl has made 1,4-conjugate addition reactions to α-(nitroalkyl)enones possible despite the presence of the acidic α-nitro protons (eq 32).[44] Copper-catalyzed conjugate addition of Grignard reagents proceeds in high yield in the presence of TMSCl and HMPA (eq 33).[45] In some instances the reaction gives dramatically improved ratios of 1,4-addition to 1,2-addition.

Chloro(trimethylsilylmethyl)ketene

[89121-60-8] · $C_6H_{11}ClOSi$ · Chloro(trimethylsilylmethyl)ketene · (MW 162.67)

(intermediate capable of cycloadding to activated alkenes[1] for direct conversion to α-methylenecyclobutanones and -cyclopentanones[2])

Solubility: sol nonpolar organic solvents usually employed for [2 + 2] cycloadditions.

Form Supplied in: generated in situ by dehydrochlorination of the acid chloride precursor.

Chloro(trimethylsilylmethyl)ketene[2] presently stands as the preferred synthetic equivalent to the very unstable methyleneketene (CH_2=C=C=O)[3] in [2 + 2] cycloaddition reactions. Generation of the title ketene is achieved by conversion of β-(trimethylsilyl)propionic acid[4] to its acyl chloride, subsequent α-chlorination with ***N-Chlorosuccinimide*** in thionyl chloride as solvent at 70 °C,[5] and ultimate dehydrochlorination with ***Triethylamine*** (eq 1).[2] If an adequately reactive acceptor alkene is not present, the ketene is captured by the acid chloride to produce the ester shown.

With cyclopentadiene, vinyl ethers, and silyl enol ethers, smooth [2 + 2] cycloaddition takes place in both a regio- and stereocontrolled fashion. In a manner paralleling that observed with alkyl-substituted ketenes,[6] chloro(trimethylsilylmethyl)ketene is captured with the Me_3SiCH_2 group projected into the more sterically crowded

endo environment; the chlorine atom finds itself *exo* oriented (eq 2).[2] Although the silicon atom is sterically congested, elimination in the presence of fluoride ion from ***Tetra-n-butylammonium Fluoride*** proceeds rapidly in DMSO solution at 20 °C to give the annelated 2-methylenecyclobutanone derivative. Treatment of the initial adduct with ethereal ***Diazomethane*** results in ring expansion via 1,2-shift of the nonhalogenated carbon atom.[7] Comparable treatment of this product with F^- leads to the methylenecyclopentanone.

The same chemical behavior is exhibited by vinyl ethers, as illustrated for the dihydropyran adduct in (eq 3).[2] As seen before, the high level of α-substitution does not deter attack by diazomethane. Attempts to accomplish analogous Baeyer-Villiger ring expansions have failed.

(3)

When silyl ethers are the co-reactants, more highly functionalized, angularly hydroxylated products are obtained following mild acidic hydrolysis (eq 4).

(4)

Although methyl(phenylthiomethyl)ketene enters satisfactorily into analogous [2 + 2] cycloaddition, the conditions required for reductive elimination appear too vigorous for implementation with polyfunctional molecules.[8,9]

Related Reagents.

Dichloroketene; ***Diphenylketene***.

3-Chloro-2-trimethylsilyloxy-1-propene[1]

[76634-95-2] · $C_6H_{13}ClOSi$ · 3-Chloro-2-trimethylsilyloxy-1-propene · (MW 164.71)

(used for silyl enol ether synthesis;[2] electrophilic acetonylation reagent[3])

Physical Data: 61-63 °C/35-37 mmHg.

Solubility: sol common organic solvents but avoid hydroxylic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: a mixture of 16.5 g (0.10 mol) of 3-chloro-1-(trimethylsilyl)propan-2-one and 454 mg (1.0 mmol) of mercury(II) iodide was heated at 75-85 °C for 72 h. The mixture was distilled to give 13 g of 3-chloro-2-trimethylsilyloxy-1-propene.[2] Alternatively, isomerization of 3-chloro-1-(trimethylsilyl)propan-2-one with ***Tetrakis(triphenylphosphine)nickel(0)*** gave the product in 90% yield.[3]

Purification: by distillation.

Handling, Storage, and Precautions: can be stored in a glass bottle under nitrogen. The reagent must be protected from moisture. The reagent should be handled in a well-ventilated hood and contact with the skin and eyes should be avoided.

Synthesis of Silyl Enol Ethers via Alkylation Reactions.

Alkylation and arylation of 3-chloro-2-trimethylsilyloxy-1-propene with lithium dialkyl- and diarylcuprate, respectively, gives silyl enol ethers in a regiospecific manner (eq 1).[2]

(1)

R = Me, 96%; Bu, 74%; Ph, 79%

Electrophilic Acetonyl Equivalent.[4]

α-Metalated imines, hydrazones, and activated methylene compounds are acetonylated with 3-chloro-2-trimethylsilyloxy-1-propene in high yield (eq 2).

(2)

Highly regioselective acetonylation at either the tertiary or secondary α-carbon of 2-methylcyclohexanone can be achieved by selecting the optimal nitrogen substituent (eqs 3-5).

(3)

(4)

(5)

Formation of Imino Ketones.

Reaction of the title reagent with *N*-acetoxyaminoquinazolone gave the corresponding chloro ketone, which was converted to an imino ketone (eq 6).[5]

Reaction with Transition Metal Complexes.

3-Chloro-2-trimethylsilyloxy-1-propene can be a precursor of oxyallyl cations or a formal analog of trimethylenemethane. The reaction with ***Nonacarbonyldiiron*** gives the (oxodimethylidenemethane)iron dimer $[(MeCOMe)(CO)_3Fe]_2$.[6] A similar (η^3-2-trimethylsiloxyallyl)$Fe(CO)_2NO$ complex was also prepared.[7] Os, Ir, and Pt carbonyls gave the corresponding metallacyclobutan-3-ones.[2a]

Cycloaddition.

The reaction of an analog, 3-bromo-3-methyl-2-trimethylsiloxy-1-butene, with 1,3-dienes in dichloromethane in the presence of ***Zinc Chloride*** gave cycloheptenones as [3 + 4] cycloaddition products in good to excellent yields (eqs 7 and 8).[8] Styrene derivatives give [3 + 2] cycloadducts as major products. For example, 2-(*p*-methylphenyl)-1-propene affords an aromatic sesquiterpene, α-cupranone, and its regiosomer (eq 9).

Chlorotrimethylstannane

Me_3SnCl

[1066-45-1] · C_3H_9ClSn · Chlorotrimethylstannane · (MW 199.25)

(starting material for the synthesis of alkyl-, allyl-, alkenyl-, and alkynyltrimethylstannanes and trimethyltin enolates; palladium-catalyzed coupling reactions[14])

Alternate Name: trimethyltin chloride.

Physical Data: mp 37-39 °C; bp 153-156 °C.

Solubility: sol ether, THF, hexane, CH_2Cl_2.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: is air stable, but is decomposed by moisture. Commercially available trimethyltin chloride may be used as received. The reagent is very toxic and corrosive, and should be handed with gloves in a fume hood.

Introduction.

Trimethyltin hydride, cyanide, methoxide, azide, and lithium are prepared from trimethyltin chloride by the procedures similar to those given in ***Tri-n-butylchlorostannane***. Similarly, hexamethylditin, bis(trimethyltin) oxide, and diethylaminotrimethyltin are prepared from trimethyltin chloride.

Organotrimethyltins via Transmetalation.

Lithiated 1,3-dithianes react with trialkyltin or triphenyltin chlorides to form the corresponding 1,3-dithian-2-yltin compounds.[1] The organocopper compound, derived from (α-(dialkoxyboryl)alkyl)zinc iodide and CuCN.2LiCl, reacts with trimethyltin chloride to afford the α-boron substituted organotin in 87% yield (eq 1).[2] Accordingly, sulfur- and boron-stabilized anions are readily converted to the corresponding trimethyltin derivatives.

(1)

Allyl anions are also transformed to the corresponding allyltrimethyltin derivatives in high yields. Allyl anions substituted by 9-BBN, generated from ***B-Allyl-9-borabicyclo[3.3.1]nonane*** by treatment with ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LTMP) react with trimethyltin chloride to afford the α-trimethyltin-substituted allyl-9-BBN in good yields (eq 2).[3] Trimethyltin bromide may also be used in this procedure. The resulting allylic borane reacts with aldehydes in the presence of pyridine to produce the *anti*-homoallyl alcohols with a (*Z*)-alkenyltrimethylstannyl group (eq 3)[4] (see also ***9-[1-(Trimethylsilyl)-2(E)-butenyl]-9-borabicyclo[3.3.1]nonane***). γ-Chloro-substituted allyltrimethyltins are prepared by the reaction of trimethyltin chloride with chloro-substituted allyllithiums, which are generated from allyl chlorides and LTMP.[5] 2,4-Pentadienyltrimethylstannane, prepared by the reaction of pentadienyllithium with trimethyltin chloride, reacts with *p*-quinones in the presence of $BF_3.OEt_2$ to afford the corresponding pentadienylated conjugate adducts in fair to good yields without formation of the Diels-Alder adduct (eq 4).[6] On the other hand, the use of 2,4-pentadienyltrimethylsilane produces the Diels-Alder adduct exclusively. The tin reagent produces the conjugate adducts with *p*-quinones, regardless of the substituents and their substitution pattern. With α,β-unsaturated aldehydes, the pentadienyl tin reagent gives the 1,2-adducts (pentadienyl carbinols), whereas the 1,4-adduct is obtained with chalcone.[6] Here also, the reaction of pentadienyltrimethylsilane with crotonaldehyde affords the corresponding Diels-Alder adduct.[7]

R = Bu, 70%; Me, 72%

M = Sn	86%	0%
M = Si	0%	91%

The intramolecular transfer reaction of lithium 1-alkynyltrialkylborates, prepared in situ from lithium acetylides and trialkylboranes, induced by trimethyltin chloride is highly stereoselective, with the resultant dialkylboryl-substituted alkenylstannanes having the migrating alkyl group *trans* to the trialkyltin group (eq 5).[8] Conversion of the resulting dialkylboryl group (R = Et) to the alkenylcopper followed by treatment with methanol or alkyl halides produces di- or trisubstituted alkenyltrimethylstannanes, respectively (eq 6).[9] By starting from conjugated terminal enynes, 2-(trimethylstannyl)-1,3-butadienes are similarly synthesized.

Alkenylstannanes have been utilized for a variety of synthetic applications. The palladium-catalyzed coupling reaction of vinyl triflates and vinyl halides with alkenylstannanes affords 1,3-dienes.[10] The facile transmetalation reaction between alkenylstannanes and alkyllithiums remains as one of the most direct routes to certain alkenyllithium reagents. Treatment of alkenylstannanes with iodine affords the corresponding vinyl iodides with retention of configuration of the vinyl group.

Although the hydrostannylation reaction of alkynes provides a simple route to alkenylstannanes, it is generally not stereoselective. The addition reaction of (trialkylstannyl)copper and related reagents to 1-alkynes and α,β-alkynic esters and amides exhibits high regio- and stereoselectivity.[11] Vinyl triflates and vinyl iodides have also been converted to alkenylstannanes by the reaction with $Me_3SnMgMe$ in the presence of ***Copper(I) Cyanide*** catalyst.[11b] The hydroalumination of alkynes with ***Diisobutylaluminum Hydride*** followed by treatment with ***Methyllithium*** yields alanates, which are converted to alkenyltrimethylstannanes by addition of trimethyltin chloride (see also ***Tri-n-butylchlorostannane***).[12] Generally, conversion of vinylalanes to alanates (ate complexes) is needed to enhance the reactivity toward electrophiles such as Me_3SnCl. The direct transmetalation of vinylalanes to vinylstannanes is accomplished by carrying out the reaction with Me_3SnCl in the presence of LiX (X = Cl, Br, I) in DME.[13]

Palladium-Catalyzed Reactions.

Benzylchlorobis(triphenylphosphine)palladium(II) catalyzes the reaction of acid chlorides with tetraorganotin compounds (Me_4Sn, Ph_4Sn, Ph_3SnMe, Me_3SnCH_2Ph, $(PhCH_2)_4Sn$, Bu_4Sn, $Bu_3SnCH{=}CH_2$, Me_3SnCl) to give ketones in quantitative yields (eq 7).[14] Trimethyltin chloride (1 equiv) also reacts with benzoyl chloride to give acetophenone in quantitative yield, although the reaction takes five times longer to reach completion than the reaction using ***Tetramethylstannane***. By using a trimethyl- or tributylorganotin reagent, the group other than the methyl or butyl groups transfers exclusively in the following order:
RC&tbond;C > RCH=CH > aryl > $RCH{=}CHCH_2$ &AApprox; $arylCH_2$ > $MeOCH_2$.

The palladium-catalyzed coupling of alkenyl iodides with alkynyltrimethylstannanes takes place under mild conditions, stereospecifically and chemoselectively, to give high yields of conjugated enynes (eq 8).[15] Organic groups on tin undergo selective transmetalation with palladium, as shown above, and the alkynic group has the fastest transfer rate of all the organic substituents.

Trimethyltin Enolates.

Trimethyltin enolates, prepared in situ from lithium enolates and trimethyltin chloride, undergo a rapid aldol condensation with aldehydes to give nearly a 1:1 mixture of the *syn* and *anti* aldols in high yields.[16] However, the trimethyltin enolate generated in situ from the lithium enolate of 4-thianone gives the *anti* aldol with very high diastereoselectivity upon treatment with 2-methylpropanal (eq 9).[17] The lithium enolate itself also provides high *anti* diastereoselectivity (95:5) in this case.

4-Chloro-2-trimethylstannyl-1-butene

[85370-32-7] · $C_7H_{15}ClSn$ · 4-Chloro-2-trimethylstannyl-1-butene · (MW 253.34)

(precursor of a number of bifunctional reagents,[1,2] which have been employed for effecting synthetically useful methylenecyclopentane annulation sequences[1-4])

Physical Data: colorless liquid, distillation temperature (bulb-to-bulb) 55-60 °C/12 mmHg.

Solubility: insol H_2O; sol THF, Et_2O, $CHCl_3$, and other common organic solvents.

Preparative Methods: 4-chloro-2-trimethylstannyl-1-butene (**3**) is readily prepared from the commercially available butynol (**1**). Regioselective addition of $Me_3SnCu.Me_2S$[5] (see ***Trimethylstannylcopper-Dimethyl Sulfide***) to (**1**) provides[6] 3-trimethylstannyl-3-buten-1-ol (**2**), which upon reaction with Ph_3P-CCl_4 in the presence of Et_3N affords (**3**) (eq 1). This preparative sequence can be carried out on a reasonably large scale (0.2 mol) and produces overall yields of about 50%.

Handling, Storage, and Precautions: when stored in a freezer under an atmosphere of argon the reagent is stable for extended periods of time (years). It should be distilled prior to use and handled only in a well-ventilated fume hood.

Conversion into Bifunctional Reagents.

Reagent (**3**) is an effective precursor to a number of synthetically useful bifunctional reagents. Transmetalation[7] of (**3**) with MeLi in THF at low temperature provides the novel reagent (**4**) (eq 2).[1] The latter species is stable in THF if the temperature of the solution is kept below -50 °C. At higher temperatures, (**4**) self-destructs,[2] presumably[8b] to produce LiCl and methylenecyclopropane. Treatment of (**4**) with $MgBr_2$,[1c] $CuBr.Me_2S$ (0.5 equiv),[2] CuCN,[1b,c] or PhSCu[1b,c] produces, respectively, the Grignard reagent (**5**), the homocuprate (**6**), and the heterocuprates (**7**) and (**8**).

(2)

Methylenecyclopentane Annulations.

Reagents (**4**)-(**8**) serve as useful bifunctional species in a variety of contexts. The lithio reagent (**4**) has been employed for the direct conversion of aldehydes and ketones into substituted 3-methylenetetrahydrofurans (eq 3)[1a,c] and of α,β-unsaturated *N,N′,N′*-trimethylhydrazides into functionalized methylenecyclopentanes (eq 4).[1a,c]

(3)

(4)

More importantly, reagents (**5**)-(**8**) have been employed effectively in the development of a synthetically useful methylenecyclopentane annulation method involving α,β-unsaturated ketones as substrates.[9] The two required steps, involving conjugate addition of the 2-(4-chloro-1-butenyl) group to the enone and subsequent intramolecular alkylation, may be carried out separately (eqs 5, 6 and 8)[1-3] or via a one-pot protocol (eq 7).[4] The importance of the one-pot process is particularly illustrated by the conversion of (**11**) into (**12**) (eq 7), since attempted intramolecular alkylation of (**13**) gives very poor yields of (**12**).[4] Although, normally, reagents (**5**)-(**8**) may be successfully interchanged for the conjugate addition step, it has been reported[2] that attempted additions of reagents (**7**) and (**8**) to the enone (**14**) are singularly unsuccessful. It is worth noting that substances (**9**), (**10**), (**12**), and (**15**) have played central roles in the total synthesis of a number of terpenoid natural products: (±)-$\Delta^{9(12)}$-capnellene,[1c,3a] (±)-pentalenene,[3b,c] (±)-methyl cantabrenonate,[4] (±)-methyl epoxycantabronate,[4] and (+)-ceroplastol I.[2]

(5)

(9)

(6)

(7)

(8)

Related Reagents.

By use of chemistry similar to that outlined above, ***5-Chloro-2-trimethylstannyl-1-pentene*** (**16**)[6] and (*Z*)-5-chloro-3-trimethylstannyl-2-pentene (**20**)[8] have also been employed as precursors of useful bifunctional reagents. The Grignard reagent (**18**) and the cuprate (**19**), both obtained from (**16**) via the lithio species (**17**), can be used to carry out efficient methylenecyclohexane annulation sequences (eq 9).[10,11] Similarly, (*Z*)-ethylidenecyclopentane annulations (eq 10)[8b] can be accomplished by utilizing reagent (**22**), which is derived from (**20**) via (**21**). These annulation methods have found appreciable use in natural product synthesis.[8b,10c,12]

5-Chloro-2-trimethylstannyl-1-pentene[1]

[89045-21-6] · $C_8H_{17}ClSn$ · 5-Chloro-2-trimethylstannyl-1-pentene · (MW 267.38)

(cyclohexane annulation; bifunctional reagent;[2-4] intramolecular Stille coupling[5])

Alternate Name: (4-chloro-1-methylenebutyl)trimethylstannane.

Physical Data: bp 55-60 °C/12 mmHg.[6]

Analysis of Reagent Purity: GLC, ^{1}H NMR.[6]

Preparative Methods: treatment of commercially available 5-chloro-1-pentyne with $Me_3SnCu.Me_2S$ (see ***Trimethylstannylcopper-Dimethyl Sulfide***) in THF at -68 °C in the presence of excess MeOH provides a 9:1 mixture of 5-chloro-2-trimethylstannyl-1-pentene and 5-chloro-1-trimethylstannyl-1-pentene.[6-8] Slow column chromatography removes the minor product.[6]

Purification: silica gel chromatography (pet. ether) followed by distillation.[6]

Handling, Storage, and Precautions: organostannanes should be considered as toxic compounds.[9] This reagent should be handled in a well-ventilated fume hood and gloves should be worn to prevent contact with the skin.

1,2-Additions.

See also ***(Z)-5-Chloro-3-trimethylstannyl-2-pentene*** and ***4-Chloro-2-trimethylstannyl-1-butene***. Addition of 5-chloro-2-lithio-1-pentene, prepared from the title reagent and MeLi at -78 °C, to cyclohexanone affords the chloro alcohol in 84% yield (eq 1). At higher temperatures (-50 °C), decomposition of this product occurs.[10]

(1)

Methylenecyclohexane Annulations.

Alkylation of the *N,N*-dimethylhydrazone of a cyclohexanone with 5-iodo-2-trimethylstannyl-1-pentene (prepared from the title reagent by treatment with NaI, acetone, 84%) and immediate cleavage of the hydrazone provides a ketovinylstannane. Conversion of the stannane to the iodide and metal-halogen exchange completes the annulation, affording the allylic, angular alcohol (eq 2).[11]

(2)

Methylenecyclohexanes have been prepared from enones in a two-step sequence by means of a cuprate addition followed by an intramolecular alkylation. The cuprate is prepared from 5-chloro-2-lithio-1-pentene (see above) either by treatment with ***Tri-n-butylphosphine*** and copper(I) bromide-dimethyl sulfide in THF or with ***Magnesium Bromide*** (to make the Grignard) followed by $CuBr.Me_2S$.[10] Addition of the cuprate to an enone occurs to give a mixture of diastereomers (R &neq; H). Intramolecular alkylation is effected by ***Potassium Hydride*** in THF to give the kinetic products, which possess a *cis* ring fusion. These may be equilibrated (MeONa, MeOH) to provide the thermodynamically favored product when R = H (Table 1) (eq 3).[10]

Table 1 Cyclohexane Annulations

n	R^1	R^2	Yield (conjugate addition) (%)	Yield [cyclization (*cis*:*trans*)] (%)
1	H	H	65	84 (4.9:1)
1	H	Me	38	88 (100:0)
1	Me	H	67	90 (100:0)
2	H	H	61	86 (1:2)
2	H	Me	55	82 (3.5:1)
2	Me	H	58	78 (100:0)

This methodology has been used to synthesize the sesquiterpenoids (±)-axamide-1 and (±)-axisonitrile-1,[12,13] and the sesterterpenoid (±)-palauolide (eqs 4 and 5).[14]

A trimethylstannyl group has been used as a removable anchoring group in an annulation sequence directed towards enantiomerically pure clerodane diterpenoids (eq 6).[15]

5-Chloro-2-trimethylstannyl-1-pentene

Intramolecular Stille Couplings.

Bicyclic dienes have been prepared from the alkylated keto acetal (see eq 2) by formation of the enol triflate, followed by palladium-catalyzed Stille coupling (eq 7).[7,16]

Related Reagents.

4-Chloro-2-trimethylstannyl-1-butene; ***(Z)-5-Chloro-3-trimethylstannyl-2-pentene***.

Chlorotriphenylsilane

Ph_3SiCl

[76-86-8] · $C_{18}H_{15}ClSi$ · Chlorotriphenylsilane · (MW 294.87)

(bulky silylating agent[1-3])

Alternate Name: triphenylsilyl chloride.

Physical Data: mp 92-94 °C; bp 240-243 °C/35 mmHg.

Solubility: readily sol most aprotic organic solvents, although CH_2Cl_2 is most commonly used; reacts with H_2O and other protic solvents.

Form Supplied in: colorless solid.

Handling, Storage, and Precautions: somewhat prone to hydrolysis, and should be handled and stored under an anhydrous, inert atmosphere.

General Considerations.

Like other bulky trialkylsilyl groups, the triphenylsilyl group was introduced to serve as a hydrolytically stable protecting group for alcohols. The hydroxyl functionality can be easily derivatized using Ph_3SiCl in the presence of a tertiary amine or ***Imidazole*** as a base (eqs 1 and 2).[1-3]

(1)

(2)

A wide variety of Grignard reagents and organolithium complexes participate in reactions with Ph_3SiCl to afford organosilanes. Thus the reaction of allylmagnesium chloride with Ph_3SiCl gives the allylsilane in high yield (eq 3).[4] However, when hydrosilyl Grignard reagents are employed, reduction to the silane occurs (eq 4).[5] Azaallyl anion[6] and diazolithium salts[7] can each be silylated to give the anticipated silane adducts (eqs 5 and 6). Similarly, arylsilanes[8] and alkynylsilanes[9-12] are produced upon silylation of the appropriate metalated[13] carbanions with Ph_3SiCl (eqs 7-11).

(11)

Other types of heteroatomic nucleophiles are capable of reacting with Ph_3SiCl to produce the silyl derivative. For example, ***Sodium Dicarbonylcyclopentadienylferrate*** combines with Ph_3SiCl to give the iron silane (eq 12).[14] Silylcuprates can be prepared by lithiation of Ph_3SiCl followed by treatment with copper(I) ion.[15] Addition of the lithium disilylcuprate to aroyl chlorides produces the acyl silane (eq 13),[16] while conjugate addition of the higher order silyl cyanocuprate to an alkynic morpholinium species was utilized for the synthesis of a heterosubstituted allenylsilane (eq 14).[17]

Chlorotriphenylstannane

Ph_3SnCl

[639-58-7] · $C_{18}H_{15}ClSn$ · Chlorotriphenylstannane · (MW 385.49)

(precursor of alkyl-, allyl-, and allenyltriphenylstannanes for stereo- and regioselective C-C bond formation;[1,4] triphenyltin enolates for diastereoselective aldol condensation[5,6] and for avoiding polyalkylation[11])

Alternate Name: triphenyltin chloride.

Physical Data: mp 108 °C (dec); bp 240 °C/13.5 mmHg.

Solubility: sol THF, CH_2Cl_2; slightly sol ether.

Form Supplied in: white solid; widely available.

Handling, Storage, and Precautions: normally, commercially available chlorotriphenylstannane may be used as received. The reagent is air stable, but is decomposed by moisture. The reagent is toxic and should be handled with gloves. Use in a fume hood.

Introduction.

As mentioned in the entry for ***Tri-n-butylchlorostannane***, Ph_3SnCl is a useful starting material for the synthesis of other triphenyltin reagents such as ***Triphenylstannane***, cyanotriphenylstannane, triphenyltin methoxide, triphenyltin azide, and triphenylstannyllithium, etc.

Organotriphenyltins via Transmetalation.

The reaction of Ph_3SnCl with allylic anions substituted with heteroatoms such as sulfur and oxygen affords allylic triphenylstannanes having heteroatoms at the γ-position. The subsequent reaction of the allylic tin derivatives with aldehydes in the presence of ***Boron Trifluoride Etherate*** give the *syn*-γ-adduct predominantly (eq 1).[1] In general, the reaction with aldehydes is carried out without isolating the intermediate allylic stannanes; thus treatment of the allylic anion with Ph_3SnCl, followed by addition of aldehydes/$BF_3.OEt_2$, produces the homoallyl alcohols. The γ-regioselectivity is perfect, but the *syn* diastereoselectivity is between 90 and 70% de.

Chlorotributylstannane may be used instead of Ph_3SnCl, and similar levels of diastereoselectivity are obtained. However, the use of triphenylstannane derivatives is recommended due to their lower toxicity and easier separation of the triphenylstannyl residue. Lithiated 1,3-dithianes react with chlorotrialkyl- or chlorotriphenylstannanes to form the corresponding 1,3-dithian-2-ylstannyl compounds.[2] Cyclohexyl- and cyclohexenyltriphenylstannanes are prepared from the corresponding Grignard reagents with Ph_3SnCl.[3] The reaction of allenylmagnesium bromides with Ph_3SnCl and ***Sodium Iodide*** gives allenyltriphenylstannanes, which react regioselectively with α,β-enones in the presence of ***Titanium(IV) Chloride*** to afford the conjugate propargylation products in good yields (eq 2).[4] Propargylation of nitroalkenes takes place with allenyltriphenylstannanes in the presence of $TiCl_4$.[4]

Triphenylstannyl Enolates.

Triphenylstannyl enolates, prepared in situ by reaction of lithium enolates with Ph_3SnCl, react with aldehydes at -78 °C to afford mainly *syn* products, irrespective of the geometry of the enolate (eq 3). Assistance with a Lewis acid is not necessary.[5] The corresponding tributylstannyl and trimethylstannyl enolates, prepared in a similar manner, react with benzaldehyde to give a ca. 1:1 mixture of *syn* and *anti* adducts. On the other hand, the reaction of the enol stannanes of cyclohexanone or propiophenone, prepared from enol acetates and trimethyl- or tributyltin methoxide and isolated by

distillation, with aldehydes under kinetic conditions (-78 °C) give predominantly the *anti* aldols, with diastereoselectivity as high as 95:5 being achieved (eq 4).[6]

At higher temperatures (45 °C), mainly *syn* selectivity is observed. ***Lithium Chloride***, present in the in situ generated tin enolate, plays an important role in producing the *syn* diastereoselectivity in these reactions, as has been established for the reactions of germanium enolates.[7] However, the triphenylstannyl or trimethylstannyl enolate of 4-thianone, prepared in situ from the corresponding lithium enolate and Ph_3SnCl or Me_3SnCl, reacts with 2-methylpropanal to form the *anti* aldol predominantly.[8]

α-Lithiostannylalkylphosphonates react with aldehydes with the complete elimination of the organotin moiety (eq 5).[9] The stereoselective formation of the (*E*)- or (*Z*)-α-alkenylphosphonates is dependent on the tin substituent; Ph_3Sn derivatives produce the (*Z*)-alkene predominantly (with 60-97% stereoselectivity), whereas Bu_3Sn analogs afford the (*E*)-alkene with 80-97% selectivity.

Although the alkylation of lithium enolates is often accompanied by undesired polyalkylation, it is avoided by using tin enolates.[10] The polyalkylation is a major drawback in the alkylation of enolates formed by cuprate conjugate addition to enones, but the use of trialkylstannyl and triphenylstannyl enolates prevents polyalkylation and enhances the yield of the desired monoalkylation product.[11]

Chlorotris(triphenylphosphine)cobalt

$CoCl(Ph_3P)_3$

[26305-75-9] · $C_{54}H_{45}ClCoP_3$ · Chlorotris(triphenylphosphine)cobalt · (MW 881.28)

(monovalent cobalt complex; homogeneous catalyst for hydrogenation and hydrodimerization of alkenes; strong nucleophile, reacting with alkyl acyl halides to afford coupling products; useful for the preparation of organocobalt complexes)

Physical Data: mp 177 °C (N_2, sealed tube).

Solubility: sol benzene and CH_2Cl_2; insol EtOH.

Preparative Methods: a solution of ***Cobalt(II) Chloride*** hexahydrate (0.6 g, 2.5 mmol) and ***Triphenylphosphine*** (2.0 g, 7.6 mmol) in EtOH (70 mL) was treated under N_2 and stirring with a solution of ***Sodium Borohydride*** (0.08 g, 2.1 mmol) in EtOH at 30-40 °C; the resulting brown-green precipitate was washed several times with EtOH and water and dried (yield 92%);[1] reductions with powdered Zn, and electrolysis, are equally effective methods; corresponding Br and I complexes are prepared similarly from $CoBr_2$ and CoI_2.

Handling, Storage, and Precautions: the solid reagent is fairly stable in air; it has been stored under N_2 atmosphere over several months at rt.

Hydrogenation Catalyst.

Like ***Chlorotris(triphenylphosphine)rhodium(I)***, $CoCl(Ph_3P)_3$ is a homogeneous hydrogenation catalyst that effects the reduction of alkenes and dienes to saturated alkanes; details are available in the patent literature. The Co complex is a less effective hydrogenation catalyst than the corresponding Rh complex, and vigorous reaction conditions are required. However, under mild reaction conditions the complex is a suitable catalyst for the selective reduction of dienes to alkenes, because of its low catalytic activity (eq 1).

(1)

Dimerization and Hydrodimerization of Alkenes.

$CoCl(Ph_3P)_3$ selectively catalyzes the dimerization of ethylene to butenes in the presence of ***Boron Trifluoride Etherate*** via formation of one-to-one complexes (eq 2).[2]

(2)

Terminal alkenes (1-butene, 1-pentene) neither dimerize nor isomerize under these conditions, demonstrating the highly selective behavior of the catalyst. At a higher temperature (60 °C), $CoCl(Ph_3P)_3$ acts as an effective catalyst for the cyclic dimerization of butadiene and mainly affords 1,5-cyclooctadiene (eq 3).[3] A hydridocobalt species is presumed to be an active catalyst in these reactions.

(3)

Hydrodimerization of methyl acrylate is effectively catalyzed by this complex, giving mainly β-to-β coupled dimethyl adipate (eq 4),[4] in contrast to $HCo(dmg)_2P(n\text{-}Bu)_3$, which affords the α-substituted cobaloxime derivative (eq 5).[5]

(4)

(5)

Reaction with Alkyl Halides.

$CoCl(Ph_3P)_3$ is highly nucleophilic and reacts with alkyl halides to give trivalent alkyl cobalt complexes, followed by cleavage of the resulting Co-C bond which leads to the formation of a new C-C bond. The reaction of benzylic mono-, di-, and trihalides with $CoCl(Ph_3P)_3$ gives coupling products with a single, double, and triple bond, respectively (eq 6).[6]

(6)

The coupling of allylic halides affords regioselectively a 1,5-diene with retention of the geometry of the double bond; squalene was synthesized by this method in moderate yields (eq 7).[7]

(7)

Biomimetic conversion of bromohydrins to ketones is achieved by $CoCl(Ph_3P)_3$ in good yield (eq 8).[8] This process is analogous to the biological transformation of 1,2-diols to ketones catalyzed by diol dehydrogenase and vitamin B_{12}.

(8)

Organocobalt Reagent.

Air-stable, crystalline phthaloylcobalt and malonylcobalt complexes are conveniently synthesized in high yield by the reaction of cyclobutenediones with $CoCl(Ph_3P)_3$ (eq 9).[9]

(9)

The addition-elimination reaction of the complex with alkynes provides an efficient and regioselective synthetic method for the preparation of substituted benzoquinones (eq 10).[10]

(10)

Related Reagents.

Phthaloylbis(triphenylphosphine)cobalt Chloride; ***Chlorotris(triphenylphosphine)rhodium(I)***.

Chlorotris(triphenylphosphine)rhodium(I)[1,2]

$RhCl(PPh_3)_3$

[14694-95-2] · $C_{54}H_{45}ClRh$ · Chlorotris(triphenylphosphine)rhodium(I) · (MW 925.24)

(catalyst precursor for many reactions involving alkenes, alkynes, halogenated organics, and organometallic reagents; notably hydrogenations, hydrosilylations, hydroformylations, hydroborations, isomerizations, oxidations, and cross-coupling processes)

Alternate Name: Wilkinson's catalyst.

Physical Data: mp 157 °C. It exists in burgundy-red and orange polymeric forms, which have identical chemical properties (as far as is known).

Solubility: about 20 g L^{-1} in $CHCl_3$ or CH_2Cl_2, about 2 g L^{-1} in benzene or toluene; much less in acetic acid, acetone, methanol, and other aliphatic alcohols. Virtually insol in alkanes and cyclohexane. Reacts with donor solvents like DMSO, pyridine, and acetonitrile.

Form Supplied in: burgundy-red powder, possibly containing excess triphenylphosphine, triphenylphosphine oxide, and traces of rhodium(II) and -(III) complexes.

Analysis of Reagent Purity: ^{31}P NMR displays resonances for the complex in equilibrium with dissociated triphenylphosphine (CH_2Cl_2, approximate δ ppm: 31.5 and 48.0 {*J* values: Rh-P^1 -142 Hz; Rh-P^2 -189 Hz; P^1-P^2 -38 Hz} shifted in the presence of excess PPh_3).[3] Triphenylphosphine oxide contaminant can also be observed (CH_2Cl_2, δ ppm: 29.2) but paramagnetic impurities are generally not evident. In rhodium NMR a signal is observed at -1291 ppm.

Preparative Method: good quality material can be obtained using the latest *Inorganic Syntheses* procedure,[4] with careful exclusion of air. Recrystallization is *not* recommended.

Handling, Storage, and Precautions: the complex should be stored at reduced temperature under dinitrogen or argon. It oxidizes slowly when exposed to air in the solid state, and faster in solution. Such partial oxidation can influence the catalytic efficacy. Consequently, the necessary precautions are governed by the reaction in question. For mechanistic and kinetic studies, reproducible results may only be obtained if the catalyst is freshly prepared and manipulated in an inert atmosphere; even the substrate should be treated to remove peroxides. For hydrogenations of alkenes on a preparative scale, complex that has been handled in the air for very brief periods should be active, but competing isomerization processes may be enhanced as a result of partial oxidation of the catalyst. At the other extreme, exposure to air just before use is clearly acceptable for oxidations in the presence of O_2 and *t*-BuOOH.

Background.[1]

In solution, Wilkinson's catalyst is in equilibrium with the 14e species $RhCl(PPh_3)_2$ (**1**) and triphenylphosphine. The 14e complex is far more reactive than the parent material; consequently it is the reactive entity most likely to coordinate with the substrate and/or the reagents. Generally, the catalytic cycles involving this material then proceed via a cascade of oxidative addition, migratory insertion, and reductive elimination reactions. The postulated mechanism for the hydrogenation of alkenes illustrates these features (Scheme 1), and is typical of the rationales frequently applied to comprehend the reactivity of $RhCl(PPh_3)_3$. Other types of transformations may be important (e.g. transmetalations), and the actual mechanisms are certainly more complicated in many cases; nevertheless, the underlying concepts are similar.

Scheme 1 Simplified mechanism for alkene hydrogenations mediated by $RhCl(PPh_3)_3$

Two important conclusions emerge from these mechanistic considerations. First, $RhCl(PPh_3)_3$ is not a catalyst in the most rigorous sense, but a catalyst precursor. This distinction is critical to the experimentalist because it implies that there are other ways to generate catalytically active rhodium(I) phosphine complexes in solution. Wilkinson's catalyst is a convenient source of homogeneous rhodium(I); it has been extensively investigated because it is easily obtained, and because it was discovered early in the development of homogeneous transition metal catalysts. However, for any transformation there always may be better catalyst precursors than $RhCl(PPh_3)_3$. Secondly, reactions involving a catalytic cycle such as the one shown in Scheme 1 are inherently more complicated than most in organic chemistry. Equilibria and rates for each of the steps involved can be influenced by solvent, temperature, additives, and functional groups on the substrate. Competing reactions are likely to be involved and, if they are, the performance of the catalytic systems therefore is likely to be sensitive to these parameters. Consequently, the purity of the Wilkinson's catalyst used is an important factor. Indeed, less pure catalyst occasionally gives superior results because removal of a fraction of the triphenylphosphine in solution by oxidation to triphenylphosphine oxide gives more of the dissociation product (**1**).

In summary, practitioners of organometallic catalysis should consider the possible mechanistic pathways for the desired transformation, then screen likely catalyst systems and conditions until satisfactory results are obtained. Wilkinson's catalyst is one of the many possible sources of homogeneous rhodium(I).

Hydrogenations.

Wilkinson's catalyst is highly active for hydrogenations of unconjugated alkenes at ambient temperatures and pressures. Steric effects are important insofar as less hindered alkenes react relatively quickly, whereas highly encumbered ones are not reduced (eq 1).[5] Hydrogen in the presence of $RhCl(PPh_3)_3$ under mild conditions does not reduce aromatic compounds, ketones, carboxylic acids, amides, or esters, nitriles, or nitro (eq 2) functionalities. Moreover, hydrogenations mediated by Wilkinson's catalyst are stereospecifically *cis* (eq 1). These characteristics have been successfully exploited to effect chemo-, regio-, and stereoselective alkene reductions in many organic syntheses (eqs 1-3). For instance, steric effects force delivery of dihydrogen to the least hindered face of the alkene in (eq 3).[6] Eq 4 illustrates that 1,4-cyclohexadienes can be reduced with little competing isomerization/aromatization,[7] unlike many other common hydrogenation catalysts.[5]

(3)

Strongly coordinating ligands can suppress or completely inhibit hydrogenations mediated by Wilkinson's catalyst; examples include 1,3-butadiene, many phosphorus(III) compounds, sulfides, pyridine, and acetonitrile. Similarly, strongly coordinating substrates are not hydrogenated in the presence of Wilkinson's catalyst, presumably because they bind too well. Compounds in this category include maleic anhydride, ethylene, some 1,3-dienes, and some alkynes. Conversely, transient coordination of functional groups on the substrate can be useful with respect to directing $RhCl(PPh_3)_3$ to particular regions of the molecule for stereoselective reactions. However, in directed hydrogenations Wilkinson's catalyst is generally inferior to more Lewis acidic cationic rhodium(I) and iridium(I) complexes.[8] The activity of Wilkinson's catalyst towards hydrogenation of alkenes has been reported to be enhanced by trace quantities of oxygen.[9]

Hydrogenations of alkynes mediated by Wilkinson's catalyst generally give alkanes. *Cis*-alkene intermediates formed in such reactions tend to be more reactive than the alkyne substrate, so this is usually not a viable route to alkenes. Some alkynes suppress the catalytic reactions of $RhCl(PPh_3)_3$ by coordination. Nevertheless, hydrogenation of alkynes mediated by $RhCl(PPh_3)_3$ can be useful in some cases, as in eq 5 in which the catalyst tolerates sulfoxide functionalities and gives significantly higher yields than the corresponding reduction catalyzed by ***Palladium on Barium Sulfate***.[10]

Wilkinson's catalyst can mediate the hydrogenation of allenes to isolated alkenes via reduction of the least hindered bond.[11] Di-*t*-butyl hydroperoxide is hydrogenated to *t*-BuOH in the presence of $RhCl(PPh_3)_3$, though this transformation could occur via a radical process.[12]

Hydrogen Transfer Reactions.

Wilkinson's catalyst should lower the energy barrier for dehydrogenations of alkanes to alkenes since it catalyzes the

reverse process, but no useful transformation of this kind have been discovered. Presumably, the activation energy for this reaction is too great since alkanes have no coordinating groups. Alcohols and amines, however, do have ligating centers, and can dehydrogenate in the presence of Wilkinson's catalyst. These reactions have been used quite often, mostly from the perspective of hydrogen transfer from an alcohol or amine to an alkene substrate, although occasionally to dehydrogenate alcohols or amines.

2-Propanol solvent under basic conditions has been extensively used to transfer hydrogen to alkenes and other substrates. Elevated temperatures are usually required and under these conditions $RhCl(PPh_3)_3$ may be extensively modified prior to the catalysis. Ketones, alkenes (eq 6), aldimines (eq 7),[13] nitrobenzene, and some quinones are reduced in this way.

(6)

(7)

Wilkinson's catalyst mediates a Cannizzaro-like process with benzaldehyde in ethanol; the aldehyde serves as a dihydrogen source to reduce itself, and the benzoic acid formed is esterified by the solvent (eq 8).[14] Pyrrolidine is *N*-methylated by methanol in the presence of $RhCl(PPh_3)_3$, a reaction that presumably occurs via hydrogen transfer from methanol, condensation of the formaldehyde formed with pyrrolidine, then hydrogen transfer to the iminium intermediate (eq 9).[15]

(8)

(9)

Hydrosilylations.[16]

Wilkinson's catalyst is one of several complexes which promote hydrosilylation reactions, and it often seems to be among the best identified.[17] However, hydrosilylations with $RhCl(PPh_3)_3$ tend to be slower than those mediated by H_2PtCl_6. Good turnover numbers are observed, the catalyst eventually being inactivated by P-C bond cleavage reactions at the phosphine,[18] and other unidentified processes. Catalysts without phosphine ligands may be even more robust than $RhCl(PPh_3)_3$ because they are unable to decompose via P-C bond cleavage.[19] Wilkinson's catalyst is relatively efficient with respect to converting silanes to disilanes.[20] The latter reaction could be useful in its own right but in the context of hydrosilylation processes it means that the product yields based on the silane are less than quantitative.

For hydrosilylation of alkenes, the reaction rate increases with temperature and hence many of these reactions have been performed at 100 °C. Higher reaction rates are obtained for silanes with very electronegative substituents and low steric requirements (e.g. $HSi(OEt)_3$ > $HSi(i\text{-}Pr)_3$). Terminal alkenes usually are hydrosilylated in an anti-Markovnikov sense to give terminal silanes. Internal alkenes tend not to react (e.g. cyclohexene), or isomerize to the terminal alkene which is then hydrosilylated (eq 10). Conversely, terminal alkenes may be partially isomerized to unreactive internal alkenes before the addition of silane can occur. 1,4-Additions to dienes are frequently observed, and the product distributions are extremely sensitive to the silane used (eq 11).

(10)

(11)

α,β-Unsaturated nitriles are hydrosilylated, even γ-substituted ones, to give 2-silyl nitriles with good regioselectivity (eq 12).[21] Secondary alkyl silanes are also formed in the hydrosilylation of phenylethylene. In fact, the latter reaction has been studied in some detail, and primary alkyl silanes, hydrogenation product (i.e. ethylbenzene), and *E*-2-silylphenylethylenes are also formed (eq 13).[22] Equimolar amounts of ethylbenzene (**2**) and *E*-2-silylphenylethylene (**4**) are produced, implying these products arise from the same reaction pathway. It has been suggested that this involves dimeric rhodium species because the relative amounts of these products increase with the rhodium:silane ratio; however, competing radical pathways cannot be ruled out. Certainly, product distributions are governed by the proportions of all the components in the reaction (i.e. catalyst, silane, and alkene), and the reaction temperature. Side products in the hydrosilylation of 1-octene include vinylsilanes and allylsilanes (eq 14).[23,24]

(12)

mol % catalyst	(2):(3):(4):(5)
3.1	39: 34: 43: 3
0.12	3: 25: 2: 47

Hydrosilylation of alkynes gives both *trans* products (i.e. formally from *cis* addition), and *cis* products (from either isomerization or *trans* addition); H_2PtCl_6, however, gives almost completely *cis* addition to *trans* products.[25] Moreover, CC-H to CC-SiR_3 exchange processes can occur for terminal alkynes giving (**6**) (eq 15).[25-27] The product distribution in these reactions is temperature dependent, and other factors may be equally important. Nonstereospecific transition metal catalyzed hydrosilylations of alkynes are not confined to Wilkinson's catalyst, and the origin of the *trans* addition product has been investigated in detail for other homogeneous rhodium and iridium complexes.[19]

temperature	(6):(7):(8):(9)
65 °C	4: 31: 57: 8
80 °C	3: 55: 35: 7

Hydrosilylation of terminal alkenes has been used in a polymerization process to form new polymeric organic materials.[28]

Hydrosilylation of α,β-unsaturated aldehydes and ketones gives silylenol ethers via 1,4-addition, even when the 4-position is relatively hindered.[29] Hydrolysis of the silyl enol ethers so formed gives saturated aldehydes. Combination of these reduction and hydrolysis steps gives overall reduction of alkenes conjugated to aldehydes, in selectivities which are generally superior to those obtained using hydridic reducing agents (eqs 16 and 17). Dihydrosilanes tend to reduce α,β-unsaturated carbonyl compounds to the corresponding alcohols, also with good regioselectivity (eq 18).

(18)

Similar hydrosilylations of α,β-unsaturated esters are useful for obtaining silyl ketene acetals with over 98:2 (*Z*) selectivity (eq 19);[30] this transformation is complementary to the reaction of α-bromo esters with zinc and chlorotrialkylsilanes, which favors the formation of the corresponding (*E*) products.[30] In cases where (*E*):(*Z*) stereoselectivity is not an issue, ***Rhodium(III) Chloride*** ($RhCl_3.6H_2O$) may be superior to Wilkinson's catalyst.[31] Unconjugated aldehydes and ketones are reduced by silanes in the presence of $RhCl(PPh_3)_3$; trihydrosilanes react quicker than di- than monohydrosilanes.[32,33]

(19)

Alcohols (eq 20)[34] and amines (eq 21)[35] react with silanes in the presence of Wilkinson's catalyst to give the silylated compounds and, presumably, hydrogen. These reactions are useful in protecting group strategies.

(20)

(21)

N,*N*-Dimethylacrylamide and triethylsilane combine in the presence of Wilkinson's catalyst (50 °C) to give a *O*,*N*-silylketene acetal as the pure (*Z*) isomer after distillation; this reaction can be conveniently performed on a gram scale (eq 22). The products have been used in new aldol methodology.[36]

(22)

Hydrostannylations.

Hydrostannanes add to alkynes in uncatalyzed reactions at 60 °C. Phenylacetylene, for instance gives a mixture of (*E*)- and (*Z*)-vinylstannanes, wherein the tin atom has added to the terminal carbons. In the presence of Wilkinson's catalyst, however, the hydrostannylation proceeds at 0 °C to give mostly the regioisomeric vinylstannanes (eq 23).[37] Terminal stannanes in the latter process seem to result from competing free radical additions. This may not be a complication with some other catalysts; the complexes $PdCl_2(PPh_3)_2$ and $Mo(\eta^3\text{-allyl})(CO)_2(NCMe)_2$ also mediate hydrostannylations of alkynes, and they are reported to be 100% *cis* selective.[38] Hydrostannanes and thiols react in a similar way to silanes and alcohols (eq 24).[39]

(23)

(24)

Hydroacylations.

Alkenes with aldehyde functionality in the same molecule, but displaced by two carbon atoms, can cyclize via intramolecular hydroacylation reactions. Substituent effects can have a profound influence on these transformations. For instance, 3,4-disubstituted 4-pentenals cyclize to cyclopentanones without serious complications,[40] but 2,3-disubstituted 4-pentenals give a cyclopropane as a competing product (eqs 25 and 26).[41] Formation of the latter material illustrates two features which restrict the applicability of this type of reaction. First decarbonylation of the aldehyde can occur, in this case presumably giving a rhodium alkyl complex which then inserts the pendant alkene functionality. Secondly, decarbonylation reactions convert the catalyst into $RhCl(CO)(PPh_3)_2$, which tends to be inactive. Moreover, the reaction is only generally applicable to the formation of five-membered rings, and it is apparently necessary to use quite large amounts of Wilkinson's catalyst to ensure good yields (eq 27).[42] Rhodium(I)

complexes other than $RhCl(PPh_3)_3$ can give better results in some cases.[43]

(25)

(26)

$R = (CH_2)_7Me$ 1:1

(27)

Lactols can be cyclized under the typical hydroacylation conditions (eq 28), presumably via equilibrium amounts of the corresponding aldehyde.[40] Finally, intermolecular hydroacylation has been formally achieved in the reaction of a pyridyl aldimine with ethylene under pressure at 160 °C; here the pyridine functionality anchors the aldimine to the rhodium, and decarbonylation is impossible (eq 29).

(28)

(29)

Decarbonylations.

Wilkinson's catalyst has been known for some time to decarbonylate aldehydes, even heavily functionalized ones, to the corresponding hydrocarbons.[44] Some examples are shown in eqs 30-33, illustrating high stereochemical retention in the decarbonylation of chiral, cyclopropyl, and unsaturated aldehydes.[45,46] Acid chlorides are also decarbonylated by $RhCl(PPh_3)_3$.

(30)

(31)

93% retention

(32)

94% retention

(33)

100% retention

The problem with all these reactions is that stoichiometric amounts of the catalyst are required, and the process is inordinately expensive. Consequently, it has only been used by those wishing to illustrate a decarbonylation occurs for some special reason, or in the closing stages of small scale syntheses of complex organic molecules. Very recently, however, it has been shown that the reaction can be made catalytic by adding ***Diphenyl Phosphorazidate***.[47] The role of the latter is to decarbonylate the catalytically inactive $RhCl(CO)(PPh_3)_2$, regenerating rhodium(I) without carbonyl ligands. Examples of this catalytic process are shown in eqs 34 and 35. The path is now clear for extensive use of $RhCl(PPh_3)_3$ for catalytic decarbonylation reactions in organic synthesis.

(34)

(35)

Catalytic decarbonylations of a few substrates other than aldehydes have been known for some time, e.g. conversion of benzoic anhydrides to fluorenones at high temperatures (ca. 225 °C).[48]

Hydroformylations.[49]

Carbon monoxide reacts rapidly with $RhCl(PPh_3)_3$ to give $RhCl(CO)(PPh_3)_2$. With hydrogen, in the presence of triphenylphosphine, the latter carbonyl complex affords some ***Carbonylhydridotris(triphenylphosphine)rhodium(I)***, and this very actively mediates hydroformylations.[50] Reactions wherein $RhCl(PPh_3)_3$ is used as a hydroformylation catalyst probably proceed via this route. A more direct means of hydroformylation is to use $RhH(CO)(PPh_3)_3$. Nevertheless, Wilkinson's catalyst (an unfortunate term here because Wilkinson also pioneered hydroformylations using $RhH(CO)(PPh_3)_3$) has been used to effect hydroformylations of some substrates. Eq 36 is one example and illustrates that transient coordination of the acyl group with rhodium apparently leads to predominant formation of a branched chain aldehyde, whereas straight chain aldehydes are usually formed in these reactions.[51] Other hydroformylation catalysts that have been studied include cobalt and iridium based systems.[49]

(36)

Hydroborations.[52]

Addition of ***Catecholborane*** to alkenes is accelerated by Wilkinson's catalyst, and other sources of rhodium(I) complexes.[53] Unfortunately, the reaction of Wilkinson's catalyst with catecholborane is complex; hence if the conditions for these reactions are not carefully controlled, competing processes result. In the hydroboration of styrene, for instance, the secondary alcohol is formed almost exclusively (after oxidation of the intermediate boronate ester, eq 37); however, the primary alcohol also is formed if the catalyst is partially oxidized and this can be the major product in extreme cases.[54,55] Conversely, hydroboration of the allylic ether (**12**) catalyzed by pure Wilkinson's catalyst gives the expected alcohol (**13**), hydrogenation product (**14**), and aldehyde (**15**), but alcohol (**13**) is the exclusive (>95%) product if the $RhCl(PPh_3)_3$ is briefly exposed to air before use.[54] The *syn*-alcohol is generally the favored diastereomer in these and related reactions (eq 38), and the catalyzed reaction is therefore stereocomplementary to uncatalyzed hydroborations of allylic ether derivatives.[56-58]

(37)

(12)

(38)

(13) **(14)** **(15)**

syn product favored

Other sources of rhodium(I) are equally viable catalysts for hydroborations, notably Rh(η^3-CH_2CMeCH_2)(*i*-$Pr_2PCH_2CH_2P$-*i*-Pr_2) which gives a much cleaner reaction with catecholborane than Wilkinson's catalyst.[59] Other catalysts for hydroborations are also emerging.[60-62]

Catecholborane hydroborations of carbonyl and related functionalities are also accelerated by $RhCl(PPh_3)_3$ (eqs 39-41); however, several related reactions proceed with similar selectivities in the absence of rhodium.[63-65]

(39)

(40)

(41

de 10:1

Cyclization, Isomerization, and Coupling Reactions.

Inter- (eq 42)[66] and intramolecular (eq 43)[67] cyclotrimerizations of alkynes are mediated by Wilkinson's catalyst. This is an extremely efficient route to ring fused systems. Similarly, Diels-Alder-like [4 + 2] cyclization processes are promoted by $RhCl(PPh_3)_3$;[68] dienophile components in these reactions need not be electron deficient, and they can be an alkene or alkyne (eqs 44 and 45). Allenes oligomerize in pathways determined by their substituents. For instance, four molecules of allene combine to give a spirocyclic system (eq 46), but tetraphenylallene isomerizes to give an indene (eq 47).[69]

(46)

(47)

Wilkinson's catalyst is also capable of mediating the formation of C-C bonds in reactions which apparently proceed via oxidative addition of an unsaturated organohalide across the metal (eq 48),[70] or via transmetalation from an organometallic (eq 49).[71] These two transformation types are very similar to couplings developed by Heck so, predictably, some palladium complexes also mediate these reactions (see ***Tetrakis(triphenylphosphine)palladium(0)*** and ***Palladium(II) Acetate***).

(48)

(49)

Intermolecular reactions of dienes, allenes, and methylenecyclopropanes with alkenes are mediated by $RhCl(PPh_3)_3$, although mixtures of products are usually formed (eqs 50, 51).[72-75]

(50)

(51)

Wilkinson's catalyst mediates hydrogenation of 1,4-cyclohexadienes without double bond isomerization (see above), but at elevated temperatures in the absence of hydrogen it promotes isomerization to conjugated dienes (eq 52).[76] Isomerization of allylamines to imines followed by hydrolysis has also been performed using $RhCl(PPh_3)_3$ (eq 53),[77] although $RhH(PPh_3)_4$ and other catalysts are more frequently used for this reaction type.[78]

(52)

(53)

Oxidations.

Cleavage of alkenes to aldehydes and ketones is promoted by Wilkinson's catalyst under pressures of air or oxygen,[79] but these reactions are inferior to ozonolysis because they tend to form a mixture of products. More useful are the oxidations of anthracene derivatives to anthraquinones in the presence of oxygen/***t-Butyl Hydroperoxide*** and catalytic $RhCl(PPh_3)_3$ (eq 54).[80,81] Wilkinson's catalyst reacts with oxygen to form an adduct so $RhCl(PPh_3)_3$ is clearly quite different from the true catalyst in all the reactions mentioned in this section.

(54)

Other Transformations.

At high temperatures (>200 °C) aromatic sulfonyl chlorides are desulfonated to the corresponding aryl halides in the presence of Wilkinson's catalyst (eq 55).[82] Benzamides and malonamide also decompose under similar conditions, giving benzonitrile and acetamide, respectively.[83]

(55)

Diazonium fluoroborates are reduced to the corresponding unsubstituted aryl compounds by Wilkinson's catalyst in DMF; the solvent is apparently the hydride source in this reaction (eq 56).[84]

(56)

Finally, aryl group interchange between triarylphosphines is mediated by Wilkinson's catalyst at 120 °C, but a near

statistical mixture of the exchanged materials is formed along with some byproducts.[85]

(*Z*)-5-Chloro-3-trimethylstannyl-2-pentene[1]

[101849-67-6] · $C_8H_{17}ClSn$ · (*Z*)-5-Chloro-3-trimethylstannyl-2-pentene · (MW 267.36)

(cyclopentane annulations;[2,3] bifunctional reagent;[4-6] spirotetrahydrofuran synthesis[7])

Alternate Name: [1-(2-chloroethyl)-1-propenyl]trimethylstannane.

Physical Data: bp 40-50 °C/0.3 mmHg.[8]

Analysis of Reagent Purity: ^{1}H NMR.[8]

Preparative Methods: by the addition of ***Lithium Phenylthio(trimethylstannyl)cuprate*** to ethyl 2-pentynoate,[9] followed by stereospecific deconjugation (eq 1)[10,11] to afford ethyl (*Z*)-3-trimethylstannyl-3-pentynoate as a single isomer.[10] Reduction and conversion to the chloride provides the title reagent (eq 2).[8]

Purification: by distillation.[8]

Handling, Storage, and Precautions: organostannanes should be considered as toxic compounds.[12] This reagent should be handled in a well-ventilated fume hood and gloves should be worn to prevent contact with the skin.

Spirotetrahydrofuran Synthesis.

See also ***4-Chloro-2-trimethylstannyl-1-butene***. Treatment of the title reagent with ***Methyllithium*** results in complete formation of the (*Z*)-vinyllithium reagent. Addition to cyclohexanone affords a mixture of the chloro alcohol (31%) and the spirotetrahydrofuran (40%) (eq 3).[8]

(3)

It is interesting to note that treatment of (*E*)-5-chloro-3-trimethylstannyl-2-pentene under these conditions (MeLi, THF, -78 °C, cyclohexanone or benzaldehyde) provided only the ethylidenecyclopropane (isolated as a chloro sulfide by treatment with ***2,4-Dinitrobenzenesulfenyl Chloride***).[8] A 1,2-addition product was not isolated.

[3 + 2] Annulations.

See also ***4-Chloro-2-trimethylstannyl-1-butene***. (*Z*)-5-Chloro-3-trimethylstannyl-2-pentene has been used in a two-step process as a cyclopentane annulation reagent.[8,13] (*Z*)-5-Chloro-3-lithio-2-pentene (see above) is treated with ***Magnesium Bromide*** in THF to provide the vinyl Grignard. The cuprate derived from this adds in a 1,4-fashion to cycloalkenones to afford the chloro ketone (as a mixture of diastereomers when R &neq; H). Closure to the *cis*-fused bicyclic ketone is accomplished by an intramolecular alkylation (Table 1; eq 4).[8]

(Z)-5-Chloro-3-trimethylstannyl-2-pentene

Table 1 (Z)-Ethylidenecyclopentane Annulations

n	R^1	R^2	Yield (conjugate addition)(%)	Yield (annulation product) (%)

Chromic Acid[1]

[7738-94-5] · CrH_2O_4 · Chromic Acid · (MW 118)

(reagent for oxidizing secondary alcohols to ketones, primary alcohols to carboxylic acids, and α-hydroxy ketones to α-diketones; for converting tertiary cyclobutanols to 1,4-ketols and 1,4-diketones; for cleaving 1,2-glycols to keto acids)

Alternate Name: Jones reagent.

Solubility: sol acetone and water.

Preparative Methods: the Jones reagent is a solution of chromium(VI) oxide and sulfuric acid in water,[2-4] in a typical procedure,[4a] 67g of CrO_3 is dissolved in 125 mL of H_2O and 58 mL of conc H_2SO_4 is then carefully added; the precipitated salts are dissolved by adding an additional (minimal) quantity of water (the total volume of the resultant solution should not exceed 225 mL); alternatively, 23.5 g of CrO_3 is dissolved in 21 mL of conc H_2sO_4 with cooling and then diluted with distilled water to give a total volume of 175 mL.[2,4b]

Handling, Storage, and Precautions: the mutagenicity of chromium(VI) compounds is well documented;[1f] handle with great care; use in a fume hood.

Oxidation of Secondary Alcohols to Ketones.

The Jones reagent oxidizes cyclooctanol to cyclooctanone (92-96%) on a fairly large scale.[4] Nortricyclanol (**1**) is oxidized to the highly strained and reactive ketone nortricyclanone (**2**) (eq 1).[5] An epimeric mixture of 3,3-dimethyl-*cis*-bicyclo[3.2.0]heptan-2-ols is oxidized by Jones reagent to 3,3-dimethyl-*cis*-bicyclo[3.2.0]heptan-2-one (83-93%).[6] Jones reagent oxidizes alcohols (**3**) and (**5**) to the acid labile ketones (**4**) and (**6**), respectively (eqs 2 and 3).[7] A 90% yield of Δ^5-pregnene-3,20-dione is obtained from the Jones oxidation of pregnenolone.[8] The Jones reagent, in the presence of oxalic acid, oxidizes 1,2-diphenylethanol and *t*-butylphenylmethanol to benzyl phenyl ketone and *t*-butyl phenyl ketone, respectively, in quantitative yield.[9] This procedure is also effective for the oxidation of 7-norbornanol to 7-norbornone. Chromic acid in aqueous acetic acid oxidizes *t*-butylphenylmethanol to *t*-butyl phenyl ketone, with formation of significant amounts of the cleavage products benzaldehyde and *t*-butanol.

(1)

(2)

(3)

1,4-Ketols and 1,4-Diketones from tertiary Cyclobutanols.

Jones reagent cleaves tertiary cyclobutanols to 1,4-ketols (eq 4) and 1,4-diketones (eqs 5 and 6).[10]

(4)

(5)

(6)

Oxidation of α,β-Unsaturated Alcohols.

In general, allylic alcohols are easily converted to the corresponding α,β-unsaturated ketones. Ethyl 3-hydroxy-4-pentenoate (**7**) is oxidized to the volatile ketone ethyl 3-oxo-4-pentenoate (**8**) (eq 7),[11] which is an intermediate in the preparation of the Nazarov annulation reagent.[12] The Jones reagent was superior to ***Pyridinium Chlorochromate***, ***Pyridinium Dichromate***, and ***Dimethyl Sulfoxide-Oxalyl Chloride*** (Swern reagent) for the oxidation of this alcohol.

(7) (7) (8)

The steroidal lactone (**9**) and its isomeric allylic alcohol (**10**) are stereospecifically oxidized to the epoxy ketone (**11**) by the Jones reagent (eq 8).[13] Epoxidation occurs only when the hydroxyl group is axial and epoxidation is faster than oxidation of the hydroxyl group.

Oxidation of 6-hydroxy-2-(4-methoxyphenyl)-2-methyl-2*H*-pyran-3(6*H*)-ones (**12**) (eq 9) with Jones reagent affords diones (**13**), which are intermediates in the synthesis of 5-substituted 2-pyrrolidinones[14] and 1-oxaspiro[5.5]undecane derivatives.[15] The pyrrolidinone (γ-lactam) skeleton is found in molecules with great value in medicinal chemistry, and spiroacetals are subunits in numerous important natural products.

Jones oxidation of phosphorus-containing tertiary allylic alcohols such as (**14**) led to formation of the 1,3-carbonyl transposed β-substituted α,β-unsaturated ketones (**15**) (eq 10), which are useful intermediates for a variety of

phosphorus-substituted and nonphosphorus-bearing heterocyclic systems.[16]

(10)

(14) **(15)**

Alkynic ketones are prepared in 40-80% yield via the Jones oxidation of the corresponding secondary alcohols.[2] Alkynic glycols are oxidized to the diketones with Jones reagent.[2]

Cleavage of *s*,*t*-1,2-Glycols to Keto Acids.

Jones reagent oxidatively cleaves *s*,*t*-1,2-glycol (**16**) to keto acid (**17**) (eq 11), and (**18**) or (**19**) to (**21**) (eq 12).[17]

(11)

(16) **(17)**

Oxidation of Benzoins to Benzils.

Benzoins are oxidized to benzils (90-95%) with Jones reagent in acetone.[18]

Oxidation of Primary Alcohols.

Primary alcohols are rapidly oxidized by the Jones reagent to carboxylic acids. Double bonds and triple bonds are not oxidized.[19,20] Jones oxidation of alcohol (**22**) affords carboxylic acid (**23**), which is used in the synthesis of the antitumor agent (±)-sarkomycin (eq 13).[21]

(13)

Other Applications.

Although ethers are generally inert toward chromic acid oxidation, the Jones reagent oxidizes benzyl ethers to the benzoic acid, esters, and ketones (eq 14).[22] The bicyclic acetoxy ether (**24**) is oxidized to the acetoxylactone (**25**) with Jones reagent at room temperature (eq 15).[23]

(14)

(15)

Oxidation of the alcohol (**26**) with Jones reagent gives the δ-lactone (**27**) instead of the ketone (eq 16).[24] The *p*-

methoxy group is necessary for this oxidation of a methyl group.

(16)

Phenols substituted by at least one alkyl group in the *ortho* position are oxidized to *p*-quinones by a two-phase (ether/aqueous CrO_3) Jones reagent.[25] Chromic acid in 50% aqueous acetic acid, Collins reagent, and Jones reagent oxidatively deoximate ketoximes to the corresponding carbonyl compounds.[26] Jones reagent oxidizes 3-trimethylsilyl-3-buten-2-ol to the Michael acceptor 3-methylsilyl-3-buten-2-one.[27] A combination of a catalytic amount of ***Osmium Tetroxide*** and stoichiometric Jones reagent in acetone at room temperature oxidizes various types of alkenes into acids and/or ketones.[28]

Chromium(II) Acetate

$Cr(OAc)_2.H_2O$

[14976-80-8] · $C_4H_8CrO_5$ · Chromium(II) Acetate · (MW 188.12)

(capable of reducing reactive carbon-halogen bonds (e.g. allylic, benzylic, α-halo carbonyl);[1] bromohydrins[2] and epoxides;[3] used in the conversion of ketoximes to ketones[4] in the presence of acid- and base-sensitive functional groups)

Physical Data: d 1.79 g cm^{-3}.

Solubility: slightly sol cold water; readily sol hot water; sol in and reacts with most acids; slightly sol alcohol; practically insol ether.

Form Supplied in: deep red powder or monoclinic crystals; composed of dimeric units. *Drying:* loses water when dried over P_2O_5 at 100 °C, changing color to brown.

Handling, Storage, and Precautions: easily oxidized, especially when moist, to chromium(III) acetate. It can be stored for several months in a stoppered vial under carbon dioxide.

Reduction of Carbon-Halogen Bonds.

2α,4α-Dibromocholestan-3-one (**1**) has been reduced to 4α-bromocholestan-3-one (**2**) in 97% yield[5] (recrystallization afforded 78% yield) when treated with a large excess of freshly prepared chromium(II) acetate in acetic acid for 10 min (eq 1). On the other hand, with the theoretical amount of reagent the yield was only 20%.[6]

(1)

(1) **(2)**

Reduction of 4-bromoisophorone (**3**) with chromium(II) acetate gives β-phorone (**4**) as the major product;[7] isophorone (**5**) is obtained as a minor product (eq 2). The reagent is freshly prepared by treatment of $CrCl_3.6H_2O$ with amalgamated zinc and then with sodium acetate.

In the construction of the ring A system of some of the giberellins,[8] iodolactone (**6**) has been reduced following the method developed by Barton and co-workers (eq 3).[2,9] Chromium(II) ion in DMSO is used in the presence of ethanethiol. The reaction occurs with inversion to give the *cis*-fused decalin system (**7**) (presumably through a radical mechanism).[8] A variety of conditions (irradiation, catalytic hydrogenation) are useless for the deiodination.

1,2,3,4,7,7-Hexachloro-5-*endo*-acetoxybicyclo[2.2.1]-2-heptene (**8**) is reduced by refluxing with chromium(II) acetate in acetic acid for 16 h to furnish (**9**) in 78% yield in which the chlorine atom *anti* to the double bond is mainly replaced (eq 4).[10] With zinc-acetic acid the reduction is not so clean since four products are formed. Reaction with ***Palladium on Carbon*** leads to reduction and dechlorination of the vinyl system.

Reduction of Bromohydrins.[2,9]

Treatment of 9α-bromo-11β-hydroxyprogesterone (**11**) with chromium(II) acetate (5 equiv) in DMSO containing butane-1-thiol (7.5 equiv) gives 11β-hydroxyprogesterone (**12**) in 80% yield (eq 5).[11] Similarly, 9α-bromocortisol-21-acetate,[12] 9α-bromoprednisolone-21-acetate,[13] and 17,20:20,21-bismethylenedioxy-9α-bromocortisol[14] afford cortisol-21-acetate (78%), prednisolone-21-acetate (74%) and 17,20:20,21-bismethylenedioxycortisol (80%), respectively. In the absence of butane-1-thiol the reduction proceeds in a different manner. The bromohydrin gives 5,9-cyclo-11β-hydroxypregnane-3,20-dione (**13**) (58%).

According to Barton et al.[2,9] the chromium(II) ion reduction of a bromohydrin (**14**) would proceed in two stages as shown in (eq 6). Thus a radical intermediate (**15**) would be the first product of reduction. Further reduction of this radical would furnish the anion (**16**), which by elimination would give the normal product (**17**) of bromohydrin reduction. The radical (**15**) could, in principle, be captured by a ready transfer donor of radical hydrogens such as butanethiol with the formation of (**18**). The BuS&bdot; radical will dimerize to $(BuS)_2$ (**19**).

Reductive Cleavage of an Epoxide.

The 16α,17α-epoxy steroid (**20**) is converted by chromium(II) acetate into the β-hydroxy ketone (**21**) and the unsaturated ketone (**22**) (eq 7).[15]

In a study of potential routes to the A/B ring system of cardiac active steroids (periplogenin, strophanthidin) Robinson and Henderson[3] studied the reduction of 4β,5β-oxidocholestan-3-one (**23**) with chromium(II) acetate. The best results were obtained by reduction of (**23**) with a large excess of freshly prepared chromium(II) acetate in aqueous acetone. In this case the desired product (**24**) could be obtained in about 50% yield (eq 8). The minor product (**25**) can be recycled.

Conversion of Ketoximes to Ketones.

The method involves the conversion of an oxime to the *O*-acetate derivative, followed by reaction with >2 mol equiv of chromium(II) acetate in 9:1 THF-water (by weight) at a temperature between 25 °C and 65 °C. Chromium(II) acetate causes reductive fission of the oxime N-O linkage to give an imine which will rapidly hydrolyze to a ketone. This method is highly effective even in the presence of acid- and base-sensitive functional groups, such as acetals, hemithioacetals, esters, and epoxides. It is noteworthy that the reaction occurs more readily with acetoximes of conjugated ketones than with those of nonconjugated ketones, and that the reaction ocurs readily with acetoximes of hindered ketones such as camphor. The reaction has been used in a three-step conversion of alkenes into ketones. For example, ***Nitrosyl Chloride*** is added to cyclooctene (**26**) and the resulting 2-chlorocyclooctanone oxime (**27**)[16] is then acetylated and treated with chromium(II) acetate at 65 °C for 16 h. Cyclooctanone (**28**) is obtained in 88% yield (eq 9).

The reaction also has been used for transposition of a carbonyl group. Oxidation of propiophenone (**29**), followed by

reduction with ***Sodium Borohydride*** and acetylation, gives the α-acetoxy acetoxime (**30**) which on treatment with excess chromium(II) acetate affords phenyl acetone (**31**) (eq 10).

(10)

(11)

X = morpholino; Y = Me, *i*-Pr, *t*-Bu

In an asymmetric synthesis of 19-norsteroids, Pappo et al.[17] cleaved (**32**) and (**33**) to (**34**) and (**35**), respectively (eq 11), in high yield using chromium(II) acetate in aqueous THF (16 h, 30-40 °C). The methyl esters of (**32**) and (**33**) were not cleaved. Hence the presence of a carbonyl group in close proximity to the N-O bond is essential for this reaction.

Chromium(II) Chloride

$CrCl_2$

[10049-05-5] · Cl_2Cr · Chromium(II) Chloride · (MW 122.92)

(reducing agent for dehalogenation of organic halides, especially allylic and benzylic halides, and for transformation of carbon-carbon triple bonds leading to (*E*)-alkenes; conversion of dibromocyclopropanes to allenes; preparation and reaction of allylic chromium reagents; reduction of sulfur- or nitrogen-substituted alkyl halides to give hetero-substituted alkylchromium reagents)

Physical Data: mp 824 °C; d_4^{14} 2.751 g cm^{-3}.

Form Supplied in: off-white solid; commercially available.

Solubility: sol water, giving a blue solution; insol alcohol or ether.

Handling, Storage, and Precautions: very hygroscopic; oxidizes rapidly, especially under moist conditions; should be handled in a fume hood under an inert atmosphere (argon or nitrogen).

Reduction of Alkyl Halides.[1,2]

Typically, the chromium(II) ion is prepared by reduction of chromium(III) salts with zinc and hydrochloric acid. Organochromium compounds produced in this way can subsequently be hydrolyzed to yield dehalogenated compounds (eq 1[3] and eq 2[4]). Anhydrous chromium(II) chloride is commercially available and can be used without further purification. The relative reactivities of various types of halide toward chromium(II) salts are shown in Scheme 1.

$$ClCH_2CO_2H \xrightarrow[HCl,\ H_2O]{CrCl_3,\ Zn} MeCO_2H \qquad (1)$$

$$X = I > Br > Cl$$

Scheme 1

Conversion of Dihalocyclopropanes to Allenes.

Reduction of geminal dihalides proceeds smoothly to give chromium carbenoids.[5] In the case of 1,1-dibromocyclopropanes, the intermediate carbenoids decompose instantaneously to give allenes (eq 3).[6,7]

(3)

Reductive Coupling of Allylic and Benzylic Halides.

Active halides, such as allyl and benzyl halides, are reduced with $CrCl_2$ smoothly to furnish homocoupling products. Allylic halides undergo coupling, forming mainly the head-to-head dimer (eq 4).[6,8]

Formation of *o*-Quinodimethanes.

α,α´-Dibromo-*o*-xylenes are reduced with $CrCl_2$ in a mixed solvent of THF and HMPA to an *o*-quinodimethane, which can be trapped by a dienophile. The method has been applied to some anthracycline precursors (eq 5).[9]

Reduction of Carbon-Carbon Unsaturated Bonds.

The reduction of alkynes with chromium(II) salts in DMF leads to (*E*)-substituted alkenes.[10] The ease of reduction depends on the presence of an accessible coordination site in the molecule (eq 6). Chromium(II) chloride in THF/H_2O (2:1) (or ***Chromium(II) Sulfate*** in DMF/H_2O) is effective at reducing α-alkynic ketones to (*E*)-enones. Less than 2%

of (*Z*)-enones are produced except in the case of highly substituted substrates, which also require longer reaction times.[11]

(6)

Reduction of Other Functional Groups.

Deoxygenation of α,β-epoxy ketones proceeds with acidic solutions of $CrCl_2$ to form α,β-unsaturated ketones.[12] Chromium(II) chloride has been regularly used in the deoxygenation of the limonoid group of triterpenes, in which ring D bears an α,β-epoxy-δ-lactone.[13] Treatment of nitrobenzene derivatives with $CrCl_2$ in methanol under reflux gives anilines (eq 7), while aliphatic nitro compounds afford aldehydes under the same reaction conditions.[14] Reduction of a nitroalkene with acidic solutions of $CrCl_2$ resulted in the formation of an α-hydroxy oxime.[15]

(7)

Preparation of Allylic Chromium Reagents.[16]

Allylic halides are reduced with low-valent chromium ($CrCl_3$-$LiAlH_4$) or $CrCl_2$ to give the corresponding allylic chromium reagents, which add to aldehydes and ketones in good to excellent yields.[17] The electronegativity of chromium is 1.6, almost the same as that of titanium (1.5). Therefore the nucleophilicity of organochromium reagents is not strong compared to the corresponding organolithium or -magnesium compounds. Chemoselective addition of allylic chromium reagents can be accomplished without affecting coexisting ketone and cyano groups (eq 8).[17] The reaction between crotylchromium reagents and aldehydes in THF proceeds with high diastereoselectivity (eq 9).[18,19] The *anti* (or *threo*) selectivity in the addition of acyclic allylic chromium reagents with aldehydes is explained by a chair-form six-membered transition state in which both R^1 and R^2 possess equatorial positions (**1** > **2**).

(8)

(9)

(1)

(2)

Addition of crotylchromium reagents to aldehydes bearing a stereogenic center α to the carbonyl provides three of the four diastereomers (eq 10).[19] Excellent *anti* selectivity is observed with respect to the 1,2-positions, but the stereoselectivity with respect to the 2,3-positions (Cram/anti-Cram ratio) is poor.[20-22] High 1,2- and 2,3-diastereoselectivity is obtained with aldehydes having large substituents, especially a cyclic acetal group, on the α-carbon of the aldehyde (eq 11).[20,23] Reaction between chirally substituted acyclic allylic bromides and aldehydes proceeds with high stereocontrol (eq 12).[24]

$CrCl_2$ 90%, 62:31:7
$CrCl_3$, $LiAlH_4$ 78%, 64:29:7

>20:1

As with allylic halides, allylic diethylphosphates[25] and mesylates[26,27] are reduced with chromium(II) salts to give allylic chromium reagents which add to aldehydes regio- and stereoselectively. This transformation reveals conversion of the electronic nature of allylic phosphates (or mesylates) from electrophilic to nucleophilic by reduction with low-

valent chromium.

The reaction of γ-disubstituted allylic phosphates with aldehydes mediated by $CrCl_2$ and a catalytic amount of LiI in DMPU is not stereoconvergent and proceeds with high stereoselectivity (eqs 13 and 14).[27] The presence of the two substituents at the γ-position slows down the process of equilibration between the intermediate allylic chromium reagents.

(13)

(14)

Because the coupling reaction between allylic halides and aldehydes proceeds under mild conditions, the reaction has been employed, in particular, in intramolecular cyclizations.[28-32] The intramolecular version also proceeds with high *anti* selectivity (eqs 15 and 16).

Functionalized and Hetero-Substituted Allylic Chromium Reagents.

When functionalized allylic halides are employed as precursors of allylic chromium reagents, an acyclic skeleton bearing a foothold for further construction is produced. Reaction of α-bromomethyl-α,β-unsaturated esters with aldehydes mediated by $CrCl_2$ (or $CrCl_3$-$LiAlH_4$) affords homoallylic alcohols, which cyclize to yield α-methylene-γ-

lactones in a stereoselective manner (eq 17).[33] Reaction between α-bromomethyl-α,β-unsaturated sulfonates and aldehydes also proceeds with high stereocontrol.[34]

The reaction of 3-alkyl-1,1-dichloro-2-propene with $CrCl_2$ results in α-chloroalkylchromium reagents, which react with aldehydes to produce a 2-substituted *anti*-(*Z*)-4-chloro-3-buten-1-ol in a regio- and stereoselective manner (eq 18).[35] Vinyl-substituted β-hydroxy carbanion synthons are produced by reduction of 1,3-diene monoepoxides with $CrCl_2$ in the presence of LiI, which react stereoselectively with aldehydes to give (*R**,*R**)-1,3-diols having a quaternary center at C-2.[36] Reduction in situ of acrolein dialkyl acetals with $CrCl_2$ in THF provides γ-alkoxy-substituted allylic chromium reagents which add to aldehydes at the same position of the alkoxy group to afford 3,4-butene-1,2-diol derivatives. The reaction rate and stereoselectivity are increased by addition of ***Iodotrimethylsilane*** (eq 19).[37]

Preparation of Propargylic Chromium Reagents.

Propargyl halides react with aldehydes or ketones in the presence of $CrCl_2$ with HMPA as cosolvent to give allenes stereoselectively (eq 20).[38] The reaction was modified to include polyfunctional propargylic halides by using $CrCl_2$ and ***Lithium Iodide*** in DMA, and allenic alcohols accompanied only by small amounts of homopropargylic alcohols are produced.[39]

(20)

Sulfur- and Nitrogen-Stabilized Alkylchromium Reagents.

In combination with LiI, $CrCl_2$ reduces α-halo sulfides to (α-alkylthio)chromium compounds, which undergo selective 1,2-addition to aldehydes. Acetophenone is recovered unchanged under the reaction conditions. The (1-phenylthio)ethenylchromium reagents prepared in this way add to aldehydes under high stereocontrol in the presence of suitable ligands like 1,2-diphenylphosphinoethane (dppe) (eq 21).[40] The reaction of *N*-(chloromethyl)succinimide and -phthalimide with $CrCl_2$ provides the corresponding α-nitrogen-substituted organochromium reagents in the presence of LiI. These organochromium reagents react in situ with aldehydes, affording protected amino alcohols (eq 22).[41]

(21)

(22)

Preparation of Alkylchromium Reagents.[42]

With the assistance of catalytic amounts of ***Vitamin B_{12}*** or cobalt phthalocyanine (CoPc), $CrCl_2$ reduces alkyl halides, especially 1-iodoalkanes, to form alkylchromium reagents which add to aldehydes without affecting ketone or ester groups. The chemoselective preparation of organochromium reagents can be done by changing either the catalyst or the solvent. Alkenyl and alkyl halides remain unchanged under the conditions of the preparation of allylchromium reagents; on the other hand, alkenyl- and alkylchromium reagents are produced selectively under nickel and cobalt catalysis, respectively (eqs 23 and 24).

Related Reagents.

Chromium(II) Chloride-Haloform; ***Chromium(II) Chloride-Nickel(II) Chloride***.

Chromium(II) Chloride-Haloform

$CrCl_2$-CHX_3

($CrCl_2$)

[10049-05-5] · Cl_2Cr · Chromium(II) Chloride-Haloform · (MW 122.92) (CHI_3)

[75-47-8] · CHI_3 · Chromium(II) Chloride-Iodoform · (MW 393.78) ($CHBr_3$)

[75-25-2] · $CHBr_3$ · Chromium(II) Chloride-Bromoform · (MW 252.77) ($CHCl_3$)

[67-66-3] · $CHCl_3$ · Chromium(II) Chloride-Chloroform · (MW 119.39) ($Me_3SiCHBr_2$)

[2612-42-2] · $C_4H_{10}Br_2Si$ · Chromium(II) Chloride-(Dibromomethyl)trimethylsilane · (MW 246.02)

(conversion of aldehydes to (*E*)-alkenyl halides or (*E*)-alkenylsilanes with one-carbon homologation; (*E*)-selective alkylidenation of aldehydes)

Physical Data: see entries for ***Chromium(II) Chloride***, ***Iodoform***, ***Bromoform***, ***Chloroform***, and ***(Dibromomethyl)trimethylsilane***.

Preparative Method: prepared in presence of reactant aldehyde: to a suspension of anhyd $CrCl_2$ (0.74 g, 6.0 mmol) in THF (10 mL) under Ar, add a solution of aldehyde (1.0 mmol) and iodoform (0.79 g, 2.0 mmol) in THF (5 mL) dropwise at 0 °C, at 0 °C for 3 h, pour the reaction mixture into water (25 mL) and extract with ether; dry the combined extracts over Na_2SO_4 and concentrate; purification by column chromatography gives an alkenyl halide. Low-valent chromium derived by reduction of $CrCl_3$ (6.0 mmol) with ***Lithium Aluminum Hydride*** (3.0 mmol) can be used instead of $CrCl_2$.

Handling, Storage, and Precautions: use in a fume hood; chromium(II) chloride should be used under an inert atmosphere (argon or nitrogen).

Preparation of (*E*)-Alkenyl Halides.[1]

The reagent prepared by treatment of CHI_3 or $CHCl_3$ with $CrCl_2$ gives iodo- and chloroalkenes, respectively (eq 1). When bromoform is employed, a mixture of bromo- and chloroalkenes is produced. This side-reaction is overcome by using a combination of $CrBr_3$ and $LiAlH_4$ instead of $CrCl_2$.[1] The rates of reaction of the haloforms are in the sequence I > Br > Cl. Reflux of a mixture of $CHCl_3$ and $CrCl_2$ in THF before addition of an aldehyde and sonication are reported

to accelerate the reaction. An iodoalkene having a terminal ^{13}C can be prepared by using $^{13}CHI_3$ (eq 2).[2] An ene-reaction product is obtained as a byproduct in the case of an aldehyde having a suitable alkenic bond.[1,3]

(1)

X = I, 0 °C, 82%, (*E*):(*Z*) = 83:17
X = Cl, 65 °C, 76%, (*E*):(*Z*) = 94:6

(2)

(*E*)-Isomers of alkenyl halides are produced selectively. The (*E*):(*Z*) ratios of the alkenyl halides increase in the order I < Br < Cl. A mixed solvent of dioxane and THF is employed to improve the (*E*):(*Z*) ratios in certain cases.[4] Isomerization using NaOH in *t*-BuOH is also effective to obtain high (*E*):(*Z*) ratios (eq 3).[5]

(3)

(*E*):(*Z*) = >40:1

Although ketones are also converted into the corresponding alkenyl halides, they are less reactive than aldehydes. Selective conversion of an aldehyde into an (*E*)-iodoalkene can thus be accomplished without affecting the coexisting ketone group.[1] The following functional groups are also tolerated during the reaction: ester, lactone, amide, nitrile, 1,3-diene, alkyne, alkene, bromide, chloride, and acetal of ethylene glycol. A hydroxyl group can be protected by using the following groups: OMe, OCH_2Ph, $OSiMe_3$(*t*-Bu), OAc, OCOPh, OTHP, and OMPM. Because the basicity of the reagent is not strong, epimerization at the α-position of aldehydes does not generally take place. The alkenyl iodides (RCH=CHI) (**1**),[6] (**2**),[7] (**3**),[8] and (**4**)[9] are prepared from the corresponding aldehydes (RCHO).

THF, 0 °C, 75%, (*E*):(*Z*) = 4:1

(1)

THF, 25 °C, 70%

(2)

THF, 0 °C, 80%, (*E*):(*Z*) = 98:2

(3)

THF, 23 °C, 66%

(4)

Preparation of (*E*)-Alkenylsilanes.[10]

When $Me_3SiCHBr_2$ is used instead of a haloform, (*E*)-alkenylsilanes are produced from aldehydes stereoselectively (eq 4). Because the reaction proceeds under mild conditions, selective transformation of an aldehyde to an (*E*)-alkenylsilane can be performed in the presence of ketone, cyano, ether, acetal, and ester groups (eq 5).[10-12]

(4)

(*E*)-Selective Wittig-Type Alkylidenation of Aldehydes.[13]

Treatment of aldehydes in THF with the reagent derived by reduction of 1,1-diiodoalkane with $CrCl_2$-DMF produces (*E*)-alkenes with high stereocontrol (eq 6).

Related Reagents.

Bromoform; ***Chloroform***; ***Chromium(II) Chloride***; ***1,1-Diiodoethane***; ***Diiodomethane***; ***Iodoform***.

Chromium(II) Chloride-Nickel(II) Chloride

$CrCl_2$-$NiCl_2$

($CrCl_2$)

[10049-05-5] · Cl_2Cr · Chromium(II) Chloride-Nickel(II) Chloride · (MW 122.92) ($NiCl_2$)

[7718-54-9] · Cl_2Ni · Chromium(II) Chloride-Nickel(II) Chloride · (MW 129.61)

(catalyst for coupling reactions between haloalkenes (or alkenyl triflates) and aldehydes; active low-valent nickel catalyst)

Physical Data: see entries for ***Chromium(II) Chloride*** and ***Nickel(II) Chloride***.

Preparative Method: a mixture of anhyd $CrCl_2$ (0.47 g, 4.0 mmol) and a catalytic amount of $NiCl_2$ (2.6 mg, 0.020 mmol) in dry, oxygen-free DMF (10 mL) is stirred at 25 °C for 10 min under Ar; add successively a solution of an aldehyde (1.0 mmol) in DMF (5 mL) and a solution of a haloalkene (or an alkenyl triflate; 2.0 mmol) in DMF (5 mL) and stir at 25 °C for 1 h, dilute the reaction mixture with ether (20 mL), pour into water (20 mL), and extract with ether repeatedly; dry the combined extracts over Na_2SO_4 and concentrate; purification by column chromatography gives an allylic alcohol; DMSO or a DMF/THF mixture may be used as solvent (ether and THF are unsuitable).

Handling, Storage, and Precautions: chromium(II) chloride should be used in a fume hood under an inert atmosphere (argon or nitrogen).

Grignard-Type Carbonyl Addition of Haloalkenes to Aldehydes.[1-3]

The carbonyl addition reaction mediated by $CrCl_2$ was first reported without any catalyst.[4] Later, a catalytic amount of nickel proved to be indispensable to promote the Grignard-type carbonyl addition of haloalkenes to aldehydes with good reproducibility (eq 1).[1,2] It is important to keep the content of $NiCl_2$ in $CrCl_2$ low (about 0.01-1% w/w) to avoid formation of dienes by homocoupling of the haloalkenes.[5] The Grignard-type reaction between alkenyl triflates and aldehydes proceeds under the same conditions.[1] In the case of α,β-unsaturated aldehydes, 1,2-addition products are the major products.

The process has many advantages. The basicity of the formed alkenylchromium reagent is not high, and epimerization at the α-position of aldehydes therefore generally does not take place. The regiochemistry of double bonds is maintained during the coupling reaction (eq 2).[6] Mild nucleophilicity of the alkenylchromium reagents permits addition to aldehydes in good to excellent yields without affecting coexisting ketone, ester, amide, acetal, silyl ether, cyano, and sulfinyl groups.[1-4,6-9] The system is especially effective for coupling reactions of highly oxygenated multifunctional substrates.[2,3,7] The stereochemistry of *trans*- and *cis*-haloalkenes is retained, at least in the case of disubstituted haloalkenes and trisubstituted trans-haloalkenes (eqs 3 and 4).[1,2] Treatment of a trisubstituted *cis*-haloalkene (or an alkenyl triflate) with the $CrCl_2$-$NiCl_2$ system often results in a *cis-trans* isomerization-coupling reaction sequence or in recovery of the starting alkenyl halide. With respect to the newly introduced stereogenic center, the process produces a mixture of two possible diastereomers with a moderate to good preference for one stereoisomer. The major products produced from α-alkoxy- and α,β-bisalkoxyaldehydes have the stereochemistry opposite to cuprate or Grignard products.[2]

(3)

(4)

Intramolecular cyclization using the reagent proceeds under mild conditions (eqs 5 and 6).[8,9]

(5)

(6)

Grignard-Type Carbonyl Addition of Haloalkynes to

Aldehydes.

Although reactions between simple haloalkynes and aldehydes proceed in the absence of $NiCl_2$, the $CrCl_2$-$NiCl_2$ system is employed in the case of highly-oxygenated substrates (eq 7)[10,11] and for intramolecular cyclizations (eq 8).[12,13] The process is exceptionally well suited for cases where the aldehyde is labile.

Active Low-Valent Nickel Catalyst.

Intramolecular cyclization of enynes[14] and enallenes[15] proceeds with a catalytic amount of low-valent nickel derived by reduction of $NiCl_2$ with $CrCl_2$ in the presence of triphenylphosphine (eq 9). Decrease of catalytic activity of the nickel is suppressed by using a polymer-supported nickel catalyst.

Chromium(VI) Oxide[1]

CrO_3

[1333-82-0] · CrO_3 · Chromium(VI) Oxide · (MW 99.99)

(reagent for oxidizing carbon-hydrogen bonds to alcohols, oxidizing alkylaromatics to ketones and carboxylic acids, converting alkenes to α,β-unsaturated ketones, oxidizing carbon-carbon double bonds, oxidizing arenes to quinones, oxidizing alcohols to aldehydes, ketones, acids, and keto acids)

Alternate Names: chromic anhydride; ***Chromic Acid*** in aqueous media.

Physical Data: mp 196 °C; *d* 2.70 g cm^{-3}.

Solubility: sol ether, H_2O, HNO_3, H_2SO_4, DMF, HMPA.

Form Supplied in: red crystals.

Handling, Storage, and Precautions: **caution**: chromium(VI) oxide is a highly toxic cancer suspect agent. All chromium(VI) reagents must be handled with care. The mutagenicity of Cr^{VI} compounds is well documented.[7] HMPA is also a highly toxic cancer suspect agent. Special care must always be exercised in adding CrO_3 to organic solvents. Add CrO_3 in small portions to HMPA in order to avoid a violent decomposition. This reagent must be handled in a fume hood.

Each mol of chromium(VI) oxide has 1.5 equivalents of oxygen. The oxidizing power of the reagent increases with decreasing water content of the solvent medium. The oxidizing medium may be aqueous acetic acid,[2,3] anhydrous acetic acid (Fieser reagent),[4] or concentrated[5] or aqueous[6] sulfuric acid.

Oxidation of Carbon-Hydrogen Bonds to Alcohols.

Chromium(VI) oxide in 91% acetic acid oxidizes the methine hydrogen of (+)-3-methylheptane to (+)-3-methyl-3-heptanol with 70-85% retention of configuration.[8] 3β-Acetoxy-14α-hydroxyandrost-5-en-17-one is obtained by direct introduction of an α-hydroxyl group at C-14 in the dibromide of 3β-acetoxyandrost-5-en-17-one (eq 1).[9]

Oxidation of Alkylaromatics to Ketones and Carboxylic Acids.

Chromium(VI) oxide in concentrated sulfuric acid oxidizes 3,4-dinitrotoluene to 3,4-dinitrobenzoic acid (89%).[5] Under milder conditions, with longer alkyl chains, the benzylic position is converted to carbonyl. Chromium(VI) oxide in acetic acid oxidizes ethylbenzene to acetophenone and benzoic acid. More rigorous oxidizing experimental conditions convert longer chain alkyl groups to carboxyl, thus yielding benzoic acid or its derivatives. Methylene groups between two benzene rings are oxidized to carbonyl derivatives in preference to reaction at alkyl side chains.[10] Indans are oxidized to 1-indanones by use of a dilute (10%) solution of chromium(VI) oxide in acetic acid at room temperature (eq 2).[11]

Allylic Oxidations.

Allylic oxidations may be complicated by carbonyl formation at either one or both allylic positions. Although chromium(VI) oxide appears to be useful for allylic oxidation in steroid chemistry, better results may be obtained in other systems with ***Di-t-butyl Chromate*** or ***Dipyridine Chromium(VI) Oxide*** (Collins reagent). However, the ***Chromium(VI) Oxide-3,5-Dimethylpyrazole*** complex (CrO_3.DMP) is useful for allylic oxidations. The complex oxidized the allylic methylene group in (**1**) to the α,β-unsaturated ketone (**2**) which was used in the synthesis of the antibacterial helenanolide (+)-carpesiolin (eq 3).[12] Chromium(VI) oxide in glacial acetic acid oxidizes 3,21-diacetoxy-4,4,14-trimethyl-Δ^8-5-pregnene to the enetrione (eq 4).[13] Complex product mixtures are formed when epoxidation competes with the allylic oxidation.[14]

(3)

(1) (2)

(4)

Oxidation of Carbon-Carbon Double Bonds.

Chromium(VI) oxide in aqueous sulfuric acid generally cleaves carbon-carbon double bonds. Rearrangements may further complicate the oxidation. In anhydrous acetic acid, chromium(VI) oxide oxidizes tetraphenylethylene to the oxirane (70% yield) and benzophenone (11%).[15] The yield is lower and more double bond cleavage occurs in aqueous acetic acid. However, use of acetic anhydride as solvent (see ***Chromyl Acetate***) affords the oxiranes from tri- and tetrasubstituted alkenes in 50-88% yields, along with benzopinacols.[16,17] Many steroidal and terpenic cyclic alkenes react with chromium(VI) oxide in acetic acid to give oxiranes, and saturated, α,β-unsaturated, α-hydroxy, and α,β-epoxy ketones which arise from the initially formed oxirane.[18,19] A synthetically useful cleavage of double bonds involving chromium(VI) oxide is the Meystre-Miescher-Wettstein degradation[20] which shortens the side chain of a carboxylic acid by three atoms at one time. This procedure is a modification of the Barbier-Wieland degradation.[21,22]

Oxidation of Arenes to Quinones.

In contrast to alkylaromatics, which undergo oxidation at the side chain with some chromium(VI) oxidants, polynuclear aromatic arenes undergo ring oxidation to quinones with chromium(VI) oxide. This chemoselectivity is shown in the chromium(VI) oxide in anhydrous acetic acid (Fieser reagent) oxidation of 2,3-dimethylnaphthalene to

2,3-dimethylnaphthoquinone in quantitative yield (eq 5).[23] In some cases, depending on experimental conditions, both benzylic and ring oxidations occur[24] or the alkyl groups may be eliminated (eq 6).[25] The oxidation of anthracene derivatives is important in the total synthesis of anthracycline antibiotics.[26,27]

(5)

(6)

Oxidation of Alcohols to Aldehydes, Ketones, Acids, and Keto Acids.

Chromium(VI) oxide in acetic acid oxidizes primary alcohols to aldehydes and acids, and secondary alcohols to ketones and keto acids (Fieser reagent) (eq 7).[28] Chromium(VI) oxide in water or aqueous acetic acid oxidizes primary alcohols to carboxylic acids.[29,30] Chromium(VI) oxide-***Hexamethylphosphoric Triamide*** (CrO_3.HMPA) selectively oxidized the primary hydroxyl group of strophanthidol (**3**) to an aldehyde group in the final step in the synthesis of strophanthidin (**4**) (eq 8).[31] The CrO_3.HMPA complex oxidizes saturated primary alcohols to aldehydes in about 80% yield.[32,33] The yields are lower with secondary alcohols and highest with α,β-unsaturated primary and secondary alcohols. It is possible to selectively oxidize certain allylic and benzylic hydroxyl groups in the presence of other unprotected saturated groups (eq 9; cf eq 8). Chromium(VI) oxide in DMF in the presence of catalytic amounts of sulfuric acid oxidizes steroidal alcohols to ketones.[34] Chromium(VI) oxide on graphite selectively oxidizes primary alcohols in the presence of secondary and tertiary alcohols.[35]

(7)

Other Applications.

Chromium(VI) oxide in aqueous acetic acid converts α-chlorohydrindene to α-hydrindanone (50-60%).[36] Suitably protected methylene or benzylidene acetals of alditols are cleaved by chromium(VI) oxide in glacial acetic acid to derivatives of ketoses.[37] Chromium(VI) oxide in anhydrous acetic acid converts methyl ethers into the corresponding formates, which can be hydrolyzed by base to alcohols (demethylation).[38]

Related Reagents.

Chromium(VI) Oxide-3,5-Dimethylpyrazole; ***Chromium(VI) Oxide-Quinoline***; ***Chromium(VI) Oxide-Silica Gel***.

Chromium(VI) Oxide-3,5-Dimethylpyrazole

(CrO_3)

[1333-82-0] · CrO_3 · Chromium(VI) Oxide-3,5-Dimethylpyrazole · (MW 99.99) ($C_5H_8N_2$)

[67-51-6] · $C_5H_8N_2$ · Chromium(VI) Oxide-3,5-Dimethylpyrazole · (MW 96.13)

(oxidizing agent for alcohols;[1] oxidant for saturated carbons α to unsaturation[2-5])

Physical Data: see ***Chromium(VI) Oxide***.

Solubility: sol dichloromethane; slightly sol ether and pentane.

Form Supplied in: formed in situ from widely available reagents.

Preparative Method: drying of the CrO_3 over P_2O_5 is recommended; rapid addition of DMP (1 equiv) to a suspension of chromium(VI) oxide (1 equiv) in dry CH_2Cl_2 (-20 °C) results in a dark red homogeneous solution after 10 min; the solution is then treated with the organic substrate (0.05-0.5 equiv).[1,2]

Handling, Storage, and Precautions: chromium salts are carcinogenic; this reagent should be used in a fume hood.

Oxidation of Alcohols.

The oxidation of primary and secondary alcohols is typically effected by treating the alcohol (1 equiv) with CrO_3.DMP (1-10 equiv) at rt (eqs 1-3).[1] Notably similar to ***Pyridinium Chlorochromate*** (PCC), the title reagent system has been shown to oxidize primary alcohols to aldehydes efficiently (eq 2). The ease of oxidation of both equatorial and axial alcohols using this complex has been demonstrated (eq 3); the reactions of both are complete within 40 min when stirred at room temperature. The authors suggest the intermediacy of a cyclic chromate ester species through which rapid intramolecular oxidation may occur.[1]

(1)

(2)

(3)

Oxidation of Unsaturated Alcohols.[1]

Allylic, benzylic, and propargyl alcohols readily interact with CrO_3.DMP to provide the expected carbonyl compounds in good to excellent yield. Allylic alcohols can be oxidized with little or no competing oxidation of allylic methylene positions within the same molecule (eqs 4 and 5).

(4)

(5)

Benzylic alcohols are oxidized with comparable efficiency and the reaction is not sensitive to the electronic nature of the aromatic ring (eqs 6 and 7). Propargyl alcohols with both internal and terminal triple bonds are oxidized in good yield using CrO_3.DMP (eq 8).

(6)

(7)

(8)

Oxidation of Saturated Allylic and Benzylic Carbons.

The CrO_3.DMP complex appears to offer two unique advantages over PCC: an empty Lewis acidic coordination site on chromium, and an internal basic nitrogen that may aid in cleavage of a carbon-hydrogen bond.[2] As a result, for allylic and benzylic oxidations, CrO_3.DMP is superior to more conventional chromium oxidants which often suffer from low yields, practical complications, and/or inconvenient and

extended reaction times. In the total synthesis of (±)-carpesiolin, CrO_3.DMP was used to install an enone from an alkene precursor (eq 9).[3] It was used once more for a similar transformation in the total synthesis of (-)-retigeranic A and several of its derivatives, where it was found to be the most efficient reagent for the purpose (eq 10).[4]

(9)

Observations made in the course of studies toward the synthesis of Δ^5-7-keto steroids provide some insight into the mechanism of CrO_3.DMP-mediated allylic oxidation.[2] Here, axial hydrogens were found to be predisposed to more facile cleavage by this reagent, a common observation with chromium oxidants. The allylic oxidation of cholesteryl benzoate was complete within 30 min when CrO_3.DMP was used in 20-fold excess. Alternatively, use of only a 12-fold excess of CrO_3.DMP provided 74% conversion following stirring for 4 h at 0 °C. Benzylic methylenes are also susceptible to oxidation by this reagent.[5]

Chromium(VI) Oxide-Quinoline

(CrO_3)

[1333-82-0] · CrO_3 · Chromium(VI) Oxide-Quinoline · (MW 99.99) (quinoline)

[91-22-5] · C_9H_7N · Chromium(VI) Oxide-Quinoline · (MW 129.16)

(mild selective reagent for the oxidation of primary and secondary alcohols to the corresponding carbonyl compounds under basic conditions)

Preparative Methods: the reagent is prepared either in solid solid form prior to use or in situ in excess base in the presence of the alcohol.[1]

Handling, Storage, and Precautions: caution all chromium(VI) reagents must be handled with care. The mutagenicity of chromium(VI) compounds is well documented.[2] This reagent should be handled in a fume hood.

General Considerations.

Chromium(VI) oxide reacts with organic bases such as isoquinoline, lutidines, picolines, pyridine, and quinoline to give 1:2 (oxide:base) complexes which are useful for oxidizing primary and secondary alcohols to the corresponding carbonyl compounds.[1,3-5] Other chromium reagents for oxidizing primary and secondary alcohols to carbonyl compounds under basic conditions include ***Dipyridine Chromium(VI) Oxide***,[1,3] chromium(VI) oxide-triethylamine,[1] ***Chromium(VI) Oxide-3,5-Dimethylpyrazole***, Collins' and Ratcliffe's reagents (see ***Dipyridine Chromium(VI) Oxide***), and ***Pyridinium Chlorochromate***.[6,7]

Oxidation of Hydrocortisone Acetate to Cortisone Acetate.

Hydrocortisone acetate (21-acetoxy-11β,17α-dihydroxy-4-pregnene-3,20-dione) reacts with chromium(VI) oxide-quinoline to yield cortisone acetate (eq 1).[1]

Chromium(VI) Oxide-Silica Gel

CrO_3/SiO_2

(CrO_3)

[1333-82-0] · CrO_3 · Chromium(VI) Oxide-Silica Gel · (MW 99.99) (SiO_2)

[60676-86-0] · O_2Si · Chromium(VI) Oxide-Silica Gel · (MW 60.09)

(reagent for oxidizing alcohols to carbonyl compounds)

Physical Data: CrO_3 mp 196 °C; *d* 2.70 g cm^{-3}.

Preparative Methods: the reagent is prepared by addition of silica gel to an aqueous solution of chromium(VI) anhydride.[1]

Handling, Storage, and Precautions: can be stored under vacuum in the dark and must be used within one week. Chromium(VI) anhydride is a highly toxic cancer suspect agent. All chromium(VI) reagents must be handled in a fume hood. The mutagenicity of Cr^{VI} compounds is well documented.[2]

Oxidation of Alcohols to Carbonyl Compounds.

Chromium(VI) anhydride-silica gel oxidizes alcohols to carbonyl compounds in good yields (eqs 1-3).[1] The (*S*)-alcohol (**1**) is oxidized to the aldehyde (**2**) by chromium(VI) anhydride-silica gel with 22% racemization (eq 2).[3] The Collins reagent (***Dipyridine Chromium(VI) Oxide***) gives only 5% racemization. Variations of this reagent include ***Sodium Dichromate*** containing ***Sulfuric Acid*** on silica gel, and pyridinium chromate on silica gel.[4] The former reagent is active after one year's storage under ordinary conditions.

Related Reagents.

In addition to sodium dichromate containing sulfuric acid on silica gel and pyridinium chromate on silica gel,[4] ***Chromyl Chloride*** on silica-alumina,[5] ***Pyridinium Chlorochromate-Alumina***,[6] ***Chromic Acid*** on graphite,[7] chromic acid adsorbed on Kieselguhr,[8] and chromic acid attached to an anion exchange resin[9] are also valuable for oxidizing alcohols to carbonyl compounds. Chromic acid on graphite selectively oxidizes primary alcohols in the presence of secondary and tertiary alcohols.[7]

Chromium(II) Perchlorate[1]

$Cr(ClO_4)_2$

[13931-95-8] · Cl_2CrO_8 · Chromium(II) Perchlorate · (MW 250.91)

(used to reduce aliphatic halides;[2,5,6] reductive dimerization of carbonyl compounds;[8] reduction of cations and peroxides[9,10])

Physical Data: no data available due to instability in pure solid form.

Form Supplied in: not available commercially; must be prepared before use as an aqueous solution.

Preparative Methods: by the reaction of high purity grade chromium powder with dilute $HClO_4$ or by reducing chromium(III) perchlorate with amalgamated Zn in dilute $HClO_4$ under an inert atmosphere.[2] Solutions can be standardized[3a] by quenching an aliquot in standard dilute $FeCl_3$ solution and titrating the Fe^{II} produced to Fe^{III} (1,10-phenanthroline end point) with 0.01 M Ce^{IV}. In kinetic measurements the disappearance of Cr^{II} can be followed spectrometrically at 750 nm.[3b]

Handling, Storage, and Precautions: greater than 1 M solutions of $Cr(ClO_4)_2$ must be prepared at ice-bath temperature, since the reaction mixture decomposes exothermically at room temperature. Dilute solutions may be safely stored at room temperature. Chromium salts are carcinogenic and should be handled with care. Perchlorates are explosive and thus should be handled appropriately behind a safety shield.

Chromium(II) as a Reducing Agent.

Chromium(II) complexes between $Cr(ClO_4)_2$ and ***1,2-Diaminoethane*** react with alkyl halides to give alkanes by the mechanism shown in eqs 1-3.[4]

$$\text{R-X} + \text{Cr}^{\text{II}} \longrightarrow \text{R}\cdot + \text{X-Cr}^{\text{III}} \quad (1)$$

$$\text{R}\cdot + \text{Cr}^{\text{II}} \longrightarrow \text{R-Cr}^{\text{III}} \quad (2)$$

$$\text{R-Cr}^{\text{III}} + \text{H}_2\text{O} \longrightarrow \text{R-H} + \text{Cr}^{\text{III}} \quad (3)$$

If the intermediate radical has an isomerization pathway available, structurally rearranged products can be obtained.[4c] For example, reduction of halides of the types RC&tbond;C$(CH_2)_n$X (n = 4 or 5) with Cr^{II} in aqueous DMF containing ethylenediamine afforded substituted methylenecycloalkanes (eq 4).[5] Geminal, vicinal, and 1,3-dihalides can be reduced by Cr^{II} to generate carbenes, alkenes, and cyclopropanes, respectively.[6]

(4)

Reduction of α-haloacetonitriles,[7a] α-haloacetamides,[7b] and α-haloacetic acids[7c,7d] with Cr^{II} gives products derived from intermediate radicals.

Carbonyl Reductions.

Aromatic aldehydes, α,β-unsaturated aldehydes, and some α,β-unsaturated ketones undergo a one-electron reductive coupling to give bimolecular products, whereas aliphatic aldehydes and ketones, aromatic ketones, and esters are unreactive.[8]

Reduction of Organic Cations.

In aqueous or in acidic ethanolic media, organic cations such as tropylium,[9a] cyclopropenium,[9b] *N*-methylacridinium,[9c] 2,4,6-triphenylpyrylium,[9c] and flavylium[9c] are reduced with $Cr(ClO_4)_2$ to the corresponding radicals or dimers.

Reduction of Organic Peroxides.

Organic peroxides, hydroperoxides, peroxy esters, and peroxy acids undergo reduction with Cr^{2+} to generate alkoxy radicals and organochromium(III) species.[6e,10]

Miscellaneous Reduction.

The addition of $Cr(ClO_4)_2$ to aqueous or methanolic solutions of mitomycin C led to efficient reductive activation of the C-1 and C-10 positions, generating nucleophilic substitution products.[11]

Chromium(II) Sulfate[1]

$CrSO_4$

[13825-86-0] · CrO_4S · Chromium(II) Sulfate · (MW 148.05)

(reducing agent for alkynes, alkenes, organohalides;[1] reductions via amine or ammonia complexes[2])

Alternate Names: chromium sulfate; chromous sulfate.

Solubility: sol water and aqueous DMF; slightly sol ethanol; insol acetone.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: an aqueous solution of $CrSO_4$ can be standardized by a titration against $(CuCl_4)^{2-}$ or $K_2Cr_2O_7$[3] as well as $FeCl_3$.[4]

Preparative Methods: the most common procedure for preparing an aqueous $CrSO_4$ solution employs a reduction of $Cr_2(SO_4)_3$ with mossy Zn and Hg in water and is used as is.[4] Alternate syntheses start with very pure Cr metal[5] or $K_2Cr_2O_7$.[3] A method for preparing crystalline blue $CrSO_4.5H_2O$ has been published.[5,6]

Handling, Storage, and Precautions: aqueous $CrSO_4$ solutions are stable at temperatures between 20 and 60 °C for several days if stored in an oxygen-free environment.[7] The aqueous solution should be stored in a vented container as the powerful reducing agent will reduce water and, over time, liberate hydrogen gas which may lead to an explosion.[8] Rigorously dried $CrSO_4.5H_2O$ can be stored in the presence of air for at least eight months.[5] However, it degrades quickly in the presence of oxygen if it is finely ground.[5]

Comments on Reaction Conditions and Workups.

Most of the described reactions are carried out in deoxygenated solvents and under an oxygen-free nitrogen atmosphere because of the sensitivity of $CrSO_4$ to oxygen. Two common workups for $CrSO_4$ reductions are described in the literature. The aqueous reaction mixture can be saturated with $(NH_4)_2SO_4$ and extracted with

an organic solvent such as ether.[9] A DMF/water reaction mixture can be directly extracted with ether/pentane.[10] Alternate approaches include oxidation of excess reducing agent by aeration[11] and removal of chromium hydroxide by filtration after making the reaction mixture basic.[9]

Alkynes to (*E*)-alkenes.

The homogeneous reduction of alkynes in water or aqueous DMF at room temperature selectively yields (*E*)-alkenes. Substitution by polar functional groups in the propargylic position accelerates the reduction.[9] Bulky substituents on the alkyne impede the reaction and terminal alkynes are more reactive than internal ones.[9] A study of reductions of α-alkynic ketones provides additional examples for the specific formation of (*E*)-alkenes (here (*E*)-alkenones) and for the steric bias of the reaction (increased steric bulk on the alkynes causes longer reaction times and lower yields).[10] An advantage of $CrSO_4$ in this type of reduction is its specificity for alkynes in the presence of other functional groups. Epoxides (eq 1), esters, and α,β-unsaturated esters are unreactive under these reaction conditions.[10] $CrCl_2$ causes the same transformation to take place but is usually less reactive with the mentioned substrates.[10] Certain alkenes can be reduced to alkanes under these conditions as discussed in the next section.

(1)

Alkenes to Alkanes.

Alkenes are reduced to alkanes by $CrSO_4$ in water and in aqueous DMF. In general, (*Z*)-alkenes react more rapidly than the (*E*)-isomers.[12] Conjugated coordination sites (such as hydroxyl groups) and conjugated electron-withdrawing substituents (esters and nitriles, for example) accelerate the rate of reduction.[12] Tetrasubstituted alkenes usually yield an even mixture of *meso*- and (±)-alkanes (eq 2).[12]

(2)

Reduction of Organic Monohalides.

The reduction of organohalides can yield two different products depending on the substrate and the reaction conditions. Benzylic (arylalkyl) and allylic halides produce the reduced alkane or a coupled product.[13] The amount of coupled product can be increased by slow addition of the $CrSO_4$ to the halide (eq 3) and by use of anhydrous solvents.[13] Aliphatic halides are usually converted to the reduced alkane independent of the reaction conditions (eq 4).[13]

(3)

$CrSO_4$ add'n rate:	1.2 h	82.0%	12.4%
	3.8 h	44.8%	42.6%

(4)

The nature of the halide affects the rate of this reaction (I > Br > Cl).[13] The presence of a hydrogen donor such as mercaptoacetic acid enhances the yield of reduced alkane.[14] For both sets of halides their reactivity with $CrSO_4$ can be generalized as follows: benzylic, α-halocarbonyl > allylic > tertiary > secondary > primary > vinylic, aromatic.[15]

Reduction of Vicinal Dihalides.

Alkenes which are stable to $CrSO_4$ can be obtained from vicinal dihalides in high yields.[16] Rapid homogeneous reaction takes place in water or aqueous DMF, consuming most of the reducing agent.[16] The stereochemical outcome of the reaction varies as some compounds lead to clean *trans* elimination (eq 5) while others give isomeric mixtures.[16] The reduction of 2,3-dihalopropenes can be influenced by the amount of reducing agent. Excess $CrSO_4$ transforms the initially formed allene into a propene (eq 6).[16] In special instances, alkynes have been prepared from the corresponding vinyl dibromides under these conditions if the alkyne is unreactive toward $CrSO_4$.[16]

(5)

(6)

equiv $CrSO_4$:	5.4	26:74	81%
	2.0	98: 2	65%

Reduction of Geminal Dihalides.

The room temperature reduction of *gem*-dihalides with $CrSO_4$ leads to mixtures of alkanes, alkenes, and alkanols when carried out in aqueous DMF. Alkanes are the predominant product (eq 7).[17] The rate of reaction varies with the halide (I > Br > Cl).[17]

(7)

One report describes the utility of $CrSO_4$ in the reduction of *gem*-dibromocyclopropanes.[11] These cyclopropanes produce mixtures of cyclic allenes, monobromocyclopropanes, cyclopropanes, and allylic alcohols.[11] High yields of cyclic allenes can be obtained with certain substrates (eq 8).[11]

(8)

Miscellaneous Reductions.

$CrSO_4$ is capable of reducing aldehydes.[18] In a special case it has been utilized selectively to hydrogenolize one of the hydroxyl groups in a 3-hexyne-2,5-diol.[19]

Reductions with Chromium(II) Complexes.

Complexation of Cr^{II} with ammonia or amines enhances its reactivity. Ammoniacal Cr^{II} prepared from an aqueous $CrSO_4$ solution readily reduces aldehydes and alkenes.[2a] Complexation with ethylenediamine enables reduction of alkyl halides which are unreactive or only slowly reactive toward $CrSO_4$ itself.[2b]

Related Reagents.

Chromyl Acetate[1]

[4112-22-5] · $C_4H_6CrO_6$ · Chromyl Acetate · (MW 202.10)

(oxidizing agent for carbon-hydrogen bonds, carbon-carbon double bonds, macrocyclic lactones, and alcohols)

Physical Data: mp 30.5 °C.

Solubility: sol CCl_4, Ac_2O, HOAc; slowly oxidizes many solvents.

Purification: spectrophotometrically or titrimetrically.[2-5]

Preparative Methods: prepared in situ from CrO_3 and Ac_2O or Ac_2O/HOAc. Slow addition of CrO_3 to a cooled solution of Ac_2O is recommended in order to avoid a highly exothermic reaction.

Handling, Storage, and Precautions: best results are obtained from the freshly prepared oxidant. Chromium compounds are toxic and should be handled with care and disposed of in conformance with established procedures. This reagent should be handled in a fume hood.

This powerful oxidant, which is sometimes called chromium(VI) oxide-acetic anyhdride or chromium(VI)-acetic anhydride-acetic acid, oxidizes carbon-hydrogen bonds in bicycloalkanes and polycycloalkanes to form alcohols and ketones.[6-12] The initially formed alcohol may also be acetylated or oxidized to the ketone in the reaction mixture. Methylbenzenes are oxidized to the corresponding benzoic acids[12] and, in the presence of sulfuric acid (Thiele reagent), benzylidene diacetates (aldehyde precursors) are obtained.[13-15] Alkenes are oxidized to oxiranes[16-18] and diol carbonates.[19] Diarylmethanes and secondary alcohols are oxidized to ketones.[12,20]

Oxidation of Carbon-Hydrogen Bonds to Form Alcohols and Ketones.

Chromyl acetate oxidizes bicyclo[2.2.1]heptane (**1**) to (**2**) and (**3**) (eq 1),[6] bicyclo[2.2.2]octane (**4**) to (**5**) and (**6**) (eq 2),[6] and adamantane (**7**) to (**8**) and (**9**) (eq 3).[6] Tricyclo[3.3.0.0.^{2,6}]octane (**10**) is oxidized to (**11**) and (**12**) in a 9:1

ratio (eq 4).[7] (-)-Isobornyl acetate (**13**) is regioselectively oxidized to (**14**) and (**15**) (4:1; eq 5), which is useful in the synthesis of nojigku acid.[8] Similarly, (-)-bornyl acetate (**16**) is oxidized to (**17**) and (**18**) (eq 6).[9] 3β-Acetoxy-5α,6β-dichloroandrostan-17-one (**19**) is oxidized by chromyl acetate to the corresponding 14α-hydroxy compound (**20**) (eq 7)[10] and 3,5α-cycloandrostane is oxidized to a mixture of three ketones.[11] The latter reaction involves oxidation and carbonyl formation α to a cyclopropane ring.

(1) (2) 23% (3) 6% (1)

(4) (5) 40% (6) 4% (2)

(7) (8) 71% (9) 9% (3)

(10) (11) (12) (4)

Oxidation of Benzylic Carbon-Hydrogen Bonds to Alcohols, Aldehydes, Carboxylic Acids, and Ketones.

Chromyl acetate in the presence of sulfuric acid converts methyl-substituted aromatic and heteroaromatic compounds to the corresponding benzylidene diacetates in fair to excellent yields (eq 8).[13-15] The benzylidene diacetates are easily hydrolyzed to aldehydes. Diphenylmethane and triphenylmethane are oxidized to benzophenone and triphenylcarbinol, respectively, in near quantitative yields.[12]

(8)

Oxidation of Carbon-Carbon Double Bonds to Oxiranes.

Chromyl acetate[16-18] and chromyl nitrate[19] stereospecifically oxidize carbon-carbon double bonds to oxiranes (eq 9). Tetraphenylethylene is converted to the oxirane, benzophenone, and benzopinacol (eq 10).[20]

(9)

(10)

Other Applications.

Unlike the ***Dipyridine Chromium(VI) Oxide*** complex and ***Pyridinium Chlorochromate*** which gave nearly exclusive α-oxidation of alkynes, chromyl acetate oxidized the α-position and the triple bond.[21] Macrocyclic lactones are oxidized to monoketo lactones with some regioselectivity. The preferred conformation of the lactone probably influences the site of oxidation.[22] New oxygenated derivatives of 1,8-epoxy-*p*-menthane were obtained by the chromyl acetate oxidation of 1,8-cineole.[23]

Chromyl Chloride[1]

[14977-61-8] · Cl_2CrO_2 · Chromyl Chloride · (MW 154.92)

(reagent for converting alkenes to aldehydes, oxiranes, ketones, chlorohydrins, α-chloro ketones, vicinal chloroacetates, and α-hydroxy ketones, and for oxidizing alkylaromatics to alcohols, aldehydes, and ketones)

Alternate Names: dichlorodioxochromium; Etard reagent.

Physical Data: mp -96.5 °C; bp 117 °C; *d* 1.911 g cm^{-3}.

Solubility: sol CCl_4, CH_2Cl_2, ether.

Form Supplied in: dark red liquid.

Preparative Methods: prepared from ***Chromium(VI) Oxide*** and ***Titanium(IV) Chloride***.[2-4]

Handling, Storage, and Precautions: cancer suspect agent; all chromium(VI) reagents must be handled with care; the mutagenicity of Cr^{VI} compounds is well documented.[5] This reagent should be handled in a fume hood.

Oxidation of Alkenes to Aldehydes, Oxiranes, Ketones, Chlorohydrins, α-Chloro Ketones, Vicinal Chloroacetates, and α-Hydroxy Ketones.

The products from the chromyl chloride oxidation of alkenes depend on the structure of the alkene and the experimental conditions. Oxidation of terminal aliphatic alkenes and alkenylaromatics with chromyl chloride in dichloromethane, followed by reductive workup with ***Zinc*** dust or ***Sulfur Dioxide***, affords the corresponding aldehydes (eqs 1 and 2).[6-9] α-Chloro Ketones are the only products if propanone replaces dichloromethane as the

solvent (eq 3).[10,11] Reductive zinc dust workup affords the corresponding ketones. The initially formed chlorohydrin and oxirane products may also be isolated.[10,12,13] Epoxidation is stereospecific, yielding an oxirane with the same geometry as the starting alkene. Oxiranes are also the intermediates leading to vicinal chloroacetates when the oxidation is performed in 2:1 dichloromethane-acetyl chloride (eq 4).[14] Chromyl chloride reacts regiospecifically with O-silylated enolates in dichloromethane at -78 °C to afford α-hydroxy ketones (eq 5).[15]

(1) (2) (1)

(3) (4) (2)

(5) (6) (3)

(7) (8) 51% (9) 20% (4)

(5)

Oxidation of Alkylaromatics to Aldehydes, Ketones, and Alcohols.

Chromyl chloride oxidizes methylbenzenes to the corresponding aldehydes (Etard reaction).[16,17] The ultrasonic-mediated chromyl chloride oxidation of diphenylmethane, indan, and triphenylmethane affords diphenyl ketone (99%), 1-indanone (80%), and triphenylmethanol (99%), respectively.[2] These yields are higher than those obtained by previous procedures.

Other Applications.

Chromyl chloride oxidizes phenols to quinones and coupling products.[18] Chromyl chloride is used to prepare ***Di-t-butyl Chromate***,[2] *t*-butyl chromate-tripyridine,[19] and 2,4-(2,4-dimethylpentyl) chromate,[2,20] which are useful oxidants.

trans-Cinnamyltributylstannane[1]

[19752-27-3] · $C_{21}H_{36}Sn$ · *trans*-Cinnamyltributylstannane · (MW 398.15)

(phenylallylating agent as an anion equivalent;[1,2] 3-carbon component in a [3 + 2] cycloaddition reaction with α,β-unsaturated acylirons[3])

Alternate Names: trans-cinnamyltributyltin; *trans*-(3-phenyl-2-propenyl)tributyltin.

Physical Data: bp 163-166 °C/0.4 mmHg;[2] bp 138-142 °C/0.5 mmHg;[4] *n*20D 1.5185.[4]

Solubility: sol THF, methylene chloride, chloroform.

Preparative Methods: by the coupling reaction of *trans*-cinnamylmagnesium bromide with ***Tri-n-butylchlorostannane*** (10-20%)[2,4,5] or trapping of the lithiated derivative of allylbenzene (*s*-BuLi in cyclohexane/TMEDA/THF) with tributylchlorostannane at -78 °C (90%).[6,7]

Analysis of Reagent Purity: CH microanalysis; IR (neat)[2] 2925 (vs), 1637 (s), 1598 (s), 1495 (s), 1463 (s), 1672 (s), 958 (s) cm^{-1};IR (1% CCl_4)[4] 1635, 956 cm^{-1}; UV (MeOH) λ_{max} 267 nm (log ε$_{max}$ 4.036);[4] ^1H NMR (100 MHz, CCl_4) δ 0.89 and 1.5 (m, 27H), 1.93 (d, 2H, *J* = 8 Hz), 5.6-6.4 (m, 2H), 7.09 (m, 5H);[2] ^1H NMR (360 MHz, $CDCl_3$) δ 0.80-0.98 (m, 15H), 1.21-1.31 (m, 6H), 1.39-1.57 (m, 6H), 1.95 (dd, 2H, *J* = 8.7, 1.0 Hz), 6.18 (d, 1H, *J* = 15.6 Hz), 6.40 (dtd, 1H, *J* = 15.6, 8.7, 1.0 Hz), 7.0-7.3 (br s, 5H);[7,8] ^{13}C NMR spectroscopy.

Handling, Storage, and Precautions: although toxicological properties have been virtually unexplored, they may be extrapolated from those observed for ***Allyltributylstannane***.[8] Use in a fume hood.

Lewis Acid-Mediated Phenyallylation Reactions.

Phenylallylation reactions can be realized under Lewis-acid catalysis in a similar manner as those observed using allyltributyl- or ***Allyltriphenylstannane***.[1] However, the regiochemistry of phenylallyl addition depends upon the nature of the reaction and the structure of the electrophile substrate used. For example, treatment of *trans*-cinnamyltributyltin with 2,3-dimethylbenzoquinone in the presence of ***Boron Trifluoride Etherate*** results in the exclusive allylation at the α-carbon (eq 1).[2] In contrast, a similar reaction with 2,6-dimethylbenzoquinone provides a mixture of α- (49%) and γ-adducts (32%) at C-3 of the starting benzoquinone.[2]

(1)

trans-Cinnamyltributyltin undergoes a $BF_3.OEt_2$-mediated addition reaction with aldehydes (eq 2)[7] as other allyltins (see ***Allyltributylstannane***).[1] Interestingly, however, the stereochemical outcome of this reaction is opposite to the *syn* selectivity encountered for the reactions involving ***Crotyltributylstannane***, where the reactions are postulated to proceed through extended transition states.[1,9] The observed *anti* selectivity of the reaction of *trans*-cinnamyltributyltin has been speculated to proceed through a cyclic transition state, presumably owing to a greater ionic contribution from the C-Sn bond compared with other allyl- or γ-alkylallyltins.[7]

(2)

A novel, highly stereoselective [3 + 2] cycloaddition has been developed between allyltins such as *trans*-cinnamyltributyltin and α,β-unsaturated acyliron complexes (eq 3).[3]

Cobalt Boride[1,2]

Co_2B

[12045-01-1] · BCo_2 · Cobalt Boride · (MW 127.8)

(a selective hydrogenation catalyst;[3] reduces nitriles to amines,[4,5] nitroarenes to azobenzenes,[6] sulfoxides to sulfides,[7,8] and, in the presence of CO, carbonylates aryl[9] and benzyl[10] halides)

Physical Data: mp 1265 °C.[11]

Solubility: insol aqueous base and most organic solvents; reacts with aqueous acid.

Form Supplied in: black granules (a mixture of Co_2B and Co_3B).

Preparative Method: a solution of $CoCl_2$ in methanol is treated with five mol equiv of $NaBH_4$ at 0 °C; the black solid which is produced can be isolated after 15 min and is air stable. Drying in vacuo (6 h) produces a pyrophoric solid.

Handling, Storage, and Precautions: while the solid can be easily handled when wet with solvent, most preparations use Co_2B generated in situ. Care must be exercised when handling Co^{II} salts as they are known to be toxic in man (e.g. large amounts of $CoCl_2$ depress erythrocyte production).

Catalyst Composition and Structure.

The composition of the catalyst produced by the reaction of ***Cobalt(II) Chloride*** and ***Sodium Borohydride*** is dependent on the reaction conditions (temperature, solvent, presence of a ligand, etc.). The amount of salts which precipitates onto the surface of the boride during preparation greatly affect their selectivity. Therefore the solubility of the byproduct salt (e.g. NaCl), in the medium in which the boride is prepared is important.[1] Early studies of the action of $NaBH_4$ on transition metal salts[12] (Fe^{II}, Cu^{II}, Pd^{II}, Ni^{II}, Co^{II}, etc.) showed that either the metal is produced (as in the case of $PdCl_2$) or a granular black solid results (as in the case of $CoCl_2$); in either case, hydrogen gas is evolved. Analysis of the black solid formed from $CoCl_2$ suggested, … {the catalyst} to be a cobalt boride….[12,13]

When Co^{II} salts react with $NaBH_4$ in a CO saturated solution, no boride forms (the solution remains green); instead, a cobalt carbonyl complex forms which carbonylates aryl[9] and benzylic[10] halides. Similarly, $CoCl_2/NaBH_4/Ph_3P$ acts as a hydroboration or bond isomerization catalyst.[14]

Hydrogenation of Alkenes and Alkynes.

From early reports[12,15] it was clear that the Co^{II} salt/borohydride catalyst was both a selective reagent for the reduction of alkenes, as well as a convenient source of hydrogen gas. Rhodium, ruthenium, and platinum salts were the most effective in the decomposition of $NaBH_4$ to generate H_2;[16] however, Ni^{II} provided the most active and selective hydrogenation catalyst for simple hydrocarbons. Co^{II} salts/$NaBH_4$ selectively reduces mono- and disubstituted alkenes (trisubstituted alkenes are unaffected) as well as alkynes, as shown in Tables 1 and 2.[3,17]

Table 1 Reduction of Alkenes and Alkynes by Co^{II} Salts and $NaBH_4$ in Ethanol

Substrate	Product (% yield)	Ratio sub:Co^{II}:$NaBH_4$	Reaction time (h)
Styrene	Ethylbenzene (>98)	1:1:2	3.5
cis-Stilbene	1,2-Diphenylethane (98)	1:1:2.5	16
trans-Stilbene	1,2-Diphenylethane (45)	1:1:2.5	16
Octene[a]	Octane (>98)	1:1:2	3
Norbornene	Norbornane (>98)	1:1:2	3
Norbornadiene	Norbornane (>98)	1:1:2	2.5
Cyclohexene	Cyclohexane (>98)	1:1:2	20
1-Methylcyclohexane	No reaction	1:1:3	19
	 (75)	1:0.5:1	12.5
β-Pinene	Pinane (44)	1:0.5:1	20
α-Pinene	No reaction	1:1:2	24
Cholesterol	No reaction	1:1:2	23
1-Octyne	*n*-Octane (98)	1:0.1:1	3
1-Octyne	*n*-Octene (95) 1-Octyne (trace) *n*-Octane (trace)	1:0.1:0.5	3
1,2-Diphenylacetylene	*cis*-Stilbene (30) *trans*-Stilbene (10) 1,2-Diphenylathane (10) Starting material (50)	1.0:0.1:0.5	11

[a] $CoCl_2 \cdot 6H_2O$ and anhydrous $CoBr_2$ could be used interchangeably.

Table 2 Hydrogenation of Alkenes using $CoCl_2/NaBH_4/MeOH$ in THF[a]

Substrate	Product (% yield)	Reaction time (h)
Styrene	Ethylbenzene (65)	3
trans-Octene	Octane (70)	8
α-Pinene	No reaction	12
Cholesterol	No reaction	12
	 (75)	8

[a] All reactions were carried out with 10 mmol $CoCl_2$, 20 mmol $NaBH_4$, 60 mmol MeOH, and 20 mmol substrate in 40 mL THF.

While there has been a tremendous amount of speculation as to the species responsible for these reactions, it has been shown that use of hydrogen gas over preformed Co_2B works as well as the $Co^{II}/NaBH_4$ reagent and that under conditions which disfavor hydrogen gas evolution (THF-MeOH, 12:1) limonene is not reduced with the $Co^{II}/NaBH_4$ reagent.[5]

Other Co^{II}/boron hydride mixtures which are effective selective reducing agents include *t*-butylamine borane (TAB)/Co_2B (in refluxing methanol)[18] and dimethoxyborane/Co_2B (or Ni_2B)[19] (4-6 equiv hydride, 0.1 equiv boride, 1 equiv alkene).

Several Co^{II}/boron hydride mixtures are effective catalysts for the reduction of α,β-unsaturated systems as shown in Table 3.[18,20-25]

Table 3 Reduction of α,β-Unsaturated Systems using Co^{II}/Boron Hydride Reagents

Substrate	Product	Yield (%)	Reagent	Ref.
		78	$NaBH_4/CoCl_2 \cdot 6H_2O$	20
Methyl cinnamate	Methyl dihydrocinnamate	85	$NaBH_4/Co_2B$ (5:0.1), MeOH, rt, 2 h	18
Methyl cinnamate	Methyl dihydrocinnamate	75	TAB/Co_2B (2:1), MeOH, rt, 3 h	18
Methyl cinnamate	Methyl dihydrocinnamate	85	$NaBH_4/CoCl_2$ (2:0.1), MeOH, rt, 1 h	21
		60	$NaBH_4/Co_2B$ (5-10:1), MeOH, 0 °C, 8 h	18

		56, 9	$NaBH_4/CoCl_2 \cdot 6H_2O$ (4:0.5)	22
		50-90	$NaB(R^1)_4/CoCl_2$ (2:1), MeOH; $R^1 = H, D, T$	23
		63	$NaBH_4/CoCl_2 \cdot 6H_2O$	24
				
$R^1 = Ph, R^2 = Me, R^3 = Et$		71	$NaBH_4/CoCl_2$ (2:0.1)	25
$R^1 = Ph, R^2 = Me, R^3 = Ph$		44	$NaBH_4/CoCl_2$ (2:0.1)	25
$R^1 = Ph, R^2 = Ph, R^3 = Et$		84	$NaBH_4/CoCl_2$ (2:0.1)	25
		78	$NaBH_4/CeCl_3 \cdot 7H_2O$ (2.0:0.1)	25

The β-thioenone example is noteworthy for several reasons:

- 1)The ketone survives in the presence of an excess of $NaBH_4$; in the absence of $CoCl_2$, an allylic alcohol is formed.
- 2)In general, reactions which use catalytic amounts of $CoCl_2$ are more effective than those which use stochiometric amounts of the chloride.

- 3)$NiCl_2$ is somewhat less effective (10% lower yield). $CeCl_3.7H_2O$ gives the inverted enone as shown in the last entry of Table 3. $FeCl_3$, CuI and $CuCl_2$ had no activity in this system.

Chiral C_2-symmetric semicorrin/Co^{II} complexes (such as **1**), in combination with $NaBH_4$, reduce β-substituted acrylates enantioselectively (eq 1).[26]

(1)

(a) R = $Ph(CH_2)_2$
(b) R = Ph
(c) R = $Me_2C{=}CH(CH_2)_2$

Substrate	Product	Yield (%)	ee (%)	Configuration
(2a)	**(3a)**	97	94	*(R)*
(4a)	**(5a)**	95	94	*(S)*
(2b)	**(3b)**	95	81	*(S)*
(4b)	**(5b)**	97	73	*(R)*
(2c)	**(3c)**	95	94	*(R)*
(4c)	**(5c)**	95	94	*(S)*

These results are comparable to those obtained with Noyori's Ru^{II}-BINAP[27] but does not require a free alcohol, carboxylate, or amide in the substrate.

Reduction of Nitrogenous Functional Groups.

Nitriles.

One of the most widely used reactions of the $CoCl_2/NaBH_4$ system is the reduction of nitriles to primary amines.[4] This method has been used in the synthesis of ^{11}C[28] and ^{3}H[23] labelled radiodiagnostics. Dimethoxyborane has been substituted for $NaBH_4$ in the reduction of nitriles and aldehydes[19,29] in the presence of transition metals (Ni^{II}, Pd^{II}, and Pt^{II} have also been used).[4]

Studies of the nitrile reduction[5,18] with the $Co^{II}/NaBH_4$ reagent has provided some insight into the mechanism of the reaction:

- 1)Co_2B acts as a heterogenous catalyst (Co_2B/H_2 works as well).
- 2)Co_2B activates the nitrile towards reaction with uncomplexed $NaBH_4$.
- 3)The reaction is pH sensitive (the optimal pH range is 8-9).

This last observation led to the development of the Co_2B/*t*-butylamine/borane system for the reduction of nitriles.[18] Example of the reduction of nitriles to amines are shown in Table 4.[4,28,30-34]

Table 4 Reduction of Nitriles to Amines

Substrate	Product	Yield (%)	Reagent	Ref.
Benzonitrile	Benzylamine	72	$NaBH_4/CoCl_2/MeOH$ (0.5:0.1)	4

Octanenitrile	Octylamine	80	$NaBH_4/CoCl_2/MeOH$ (05:0.1)	4
β-Cyanomethylpyridine	β-Aminoethylpyridine	35	$NaBH_4/CoCl_2/MeOH$ (0.5:0.1)	4
Acrylonitrile	Allylamine	70	$NaBH_4/CoCl_2/MeOH$ (0.5:0.1)	4
4-Chlorophenylacetonitrile	4-Chlorophenylethylamine	85	$BH(MeO)_2/CoCl_2$ (16:5)	28
	Bis(4-chlorophenylethyl)amine	5		
		82	$NaBH_4/CoCl_2$	30
		60	$NaNH_4/CoCl_2$ (10:1.2)	31
		65	Co_2B/H_2	32
		62	$CoCl_2/NaBH_4$ (2:5)	33
		77	$CoCl_2/NaBH_4$	34

Nitro Groups.

While nitroarenes are reduced to anilines in modest yields (30-50%) using the $Co^{II}/NaBH_4$ system,[4] nitroalkanes are reduced slowly in good yields to amines (Ni^{II} [1] and Cu^{II} [35] are preferred reagents for this reduction). Some examples of this reduction are

given in Table 5.[32,34,36,37]

Table 5 Reduction of Nitro Groups with Transition Metal/$NaBH_4$

Substrate	Product	Yield (%)	Reagent	Ref.
		80	$CoCl_2/NaBH_4$ (5:2)	32
		73	$CoCl_2/NaBH_4$	36
		80	$CuCl_2/NaBH_4$	34
Nitrobenzene	Aniline	82.5	$Ni_2B/NaBH_4$ (0.5:4)	37
Nitrobenzene	Azobenzene	41	$Co_2B/NaBH_4$ (0.5:4)	36
	Aniline	33		

Other Nitrogenous Functional Groups.

Satoh[4] has reported the use of $CoCl_2/NaBH_4$ in methanol for the reduction of primary amides to amines: however, others[1,18,38] have reported problems with reproducibility in this reaction. Azobenzenes are reduced to hydrazobenzenes and hydrazobenzenes to anilines by the action of $CoCl_2/NaBH_4$.[39] Similarly, imines (and enamines) can be reduced to secondary amines[40] by $CoCl_2/NaBH_4$. By contrast, oximes are converted into secondary alcohols by $CoCl_2/NaBH_4$.[41]

Miscellaneous Reactions.

As noted above, the course of reaction involving Co^{II} and various borohydrides is sensitive to reaction conditions. When $NaBH_4$ is added to a solution of $CoCl_2$ saturated with CO, no precipitate of Co_2B is observed; in the presence of a base, this mixture carbonylates benzylic halides (eq 2).[10]

(2)

When an aryl bromide or iodide[9] is used, a mixture of α-keto acid, glycolic acid, and benzoic acid results (the α-keto acid predominates). These reactions are thought to proceed via a $Co(CO)_4$ anion generated in situ (***Sodium Sulfide*** and NaSMe have also been used in the place of the $NaBH_4$).[10] Under phase transfer conditions this reaction has been used to prepare malonates from chloroacetates in high yield.[42]

The $Co^{II}/NaBH_4$ reduction system deoxygenates aromatic and aliphatic sulfoxides in good to excellent yields.[7] This mixture also desulfurizes sulfides, sulfoxides, and disulfides[8] in good to excellent yields (however, ***Nickel Boride*** is a generally superior desulfurizing agent). $NaBH_4$, ***Lithium Triethylborohydride***, and $NaBHEt_3$ have been used in combination with $CoCl_2$ or ***Iron(II) Chloride*** to desulfurize thiols and thioketones[43] ($FeCl_2$ is the preferred reagent for this reaction).

Adams[44] reported the reduction of an aldehyde in the presence of a ketone using the $Co^{II}/NaBH_4$ reagent in DMSO solution (***Cerium(III) Chloride*** also works in this system, a reversal of the Luche reduction protocol).[45] Satyanarayana found $CoCl_2/NaBH_4$ to be an effective hydroboration[17] and alkene isomerization catalyst[14] (in the presence of ***Triphenylphosphine*** as a ligand). The same group also found that the $CoCl_2/Ph_3P/NaBH_4$ system is an effective catalyst for the synthesis of *trans* dienes via reductive dimerization of alkynes.[46]

2. It should be noted that Co_2B represents a nominal stoichiometry of the reagent prepared by the action of $NaBH_4$ on a cobalt(II) salt as described above. Several Co_xB_y species have been described in the literature. Chemical Abstracts uses the registry number *12619-68-0* to designate cobalt boride of unspecified stochiometry. Furthermore, the reagent prepared from a cobalt(II) salt in the presence of a ligand (such as CO, Ph_3P, and glyoximate) does not always involve a boride species.

Cobalt(II) Acetate

$Co(OAc)_2.4H_2O$

[6147-53-1] · $C_4H_{14}CoO_8$ · Cobalt(II) Acetate · (MW 249.08)

(mediator of C-C bond formations,[1-5] functional group transformations,[6,7] oxidations,[8-14] reductions and carbonylations[15-17])

Physical Data: loses $4H_2O$ at 140 °C; *d* 1.705 g cm^{-3}.

Solubility: sol acid, alcohol, cold and hot water.

Form Supplied in: red-violet monoclinic crystals; widely available.

Analysis of Reagent Purity: red $Co(OAc)_2.4H_2O$ can be crystallized from solutions of cobalt bases in acetic acid. It can be dehydrated by heating at 100-120 °C for 12-15 h under vacuum.

Handling, Storage, and Precautions: anhydrous $Co(OAc)_2$ can be handled under a N_2 atmosphere for strict anhydrous conditions and must be stored in the absence of moisture; i.e. bottles flushed with N_2 in a desiccator. It is hygroscopic and an irritant. This reagent should be handled in a fume hood.

Introduction.

Cobalt diacetate has been proven to be a useful reagent for several synthetic transformations. It is generally employed with another reagent for applications.

Carbon-Carbon Bond Forming Reactions.

Cobalt(II) acetate-promoted addition of methyl acetoacetate to terminal alkenes gives substituted tetrahydrofurans (eq 1) in a highly stereoselective manner in the presence of atmospheric oxygen in acetic acid.[1] Michael addition reactions have been found to proceed in the presence of a $Co(OAc)_2$-2,2´-bipyridine complex in DMF at room temperature without any dimerization products.[2] α,β-Unsaturated ketones, methyl acrylate, and acrylonitrile react with nitromethane, malononitrile, and aniline at room temperature under neutral

conditions to afford addition products.

(1)

Cobalt(II) acetate also catalyzes the conversion of methyl formate into acetic acid (eq 2)[3] and aldol condensation of aldehydes and ketones in combination with 4-vinylpyridine-styrene-divinylbenzene copolymer (eq 3).[4]

(2)

(3)

The reagent generated from $Co(OAc)_2$-***Sodium Hydride***-sodium *t*-pentoxide is useful for the synthesis of biaryls from aryl bromides.[5]

Functional Group Transformations.

Cobalt(II) acetate catalyzes dehydration of carboxamides and aldoximes to nitriles.[6] Under phase transfer conditions, cobalt(II) acetate is a useful catalyst for the preparation of diacetate from dibromo compounds (eq 4).[7]

(4)

Oxidations.

Cobalt(II) acetate, in the presence of ***Nickel(II) Acetate***, in MeOH and EtOH oxidizes benzoin to benzil.[8] Under aerobic conditions, cobalt(II) acetate gives dihydrofurans with methyl acetoacetate and terminal alkenes.[9] Cobalt(II) acetate is one among the various metal catalysts useful for the metal catalyzed oxidation of tetralenes to α-tetralones in the presence of *N*,*N*-dialkylamides.[10] In the presence of the $Co(OAc)_2$-$Mn(OAc)_2$-NaBr system and molecular oxygen, dimethylpyrazoles can be oxidized to corresponding acids (eq 5).[11] Cobalt(II) acetate, along with ***t-Butyl Hydroperoxide*** and ***Iodosylbenzene*** as prototypical terminal oxidants, in the presence of certain ligands oxidizes alkenes to epoxides (eq 6).[12]

(5)

(6)

Cobalt(II) acetate oxidizes alkyltoluenes in the presence of oxygen (eq 7).[13] The reaction involves continuous conversion of Co^{II} to Co^{III} promoted by methyl ethyl ketone. The relative ease of oxidation of alkyl groups is methyl > ethyl > isopropyl > *s*-butyl.

(7)

The oxidation of primary and secondary aromatic alcohols to aldehydes and ketones, respectively, can be achieved with ***Peracetic Acid*** catalyzed by $Co(OAc)_2$ and ***Sodium Bromide***.[14]

Reductions and Carbonylations.

Complex reducing agents prepared from $Co(OAc)_2$/NaH/*t*-$C_5H_{11}ONa$ reduce organic halides,[15] and *gem*-dihalogenocyclopropyl compounds to monohalogeno derivatives.[16] The reagent system is also useful for carbonylations of organic halides (eq 8).[17]

Cobalt(II) Chloride

$CoCl_2$

[7646-79-9] · Cl_2Co · Cobalt(II) Chloride · (MW 129.84)

(catalyst for functional group transformations,[1-13] C-C bond formations,[8,12,14-17] oxidations and reductions,[18-27] carbonylations[28,29])

Physical Data: mp 86 °C; loses $6H_2O$ at 110 °C; *d* 3.356 g cm^{-3}.

Solubility: sol alcohol, acetone, ether, cold and hot water.

Form Supplied in: hexahydrate as orange-pink crystals; widely available.

Analysis of Reagent Purity: with alkali, the pink hexaaquacobalt(II) chloride gives a pale blue precipitate of the hydroxide. With excess ammonia this precipitate dissolves and slowly gives a brown solution through oxidation. At room temperature, the orange-pink hexahydrate crystallizes from aq solutions. Anhydrous cobalt chloride is blue in color. It can be prepared by dehydration of the hexahydrate either at 150-160 °C in vacuo or by treatment with thionyl chloride followed by evaporation of the solution and further drying under vacuum at 150 °C for 1 h.

Handling, Storage, and Precautions: anhydrous cobalt chloride should be handled under a N_2 atmosphere for strict anhydrous conditions. It should be stored in the absence of moisture, in bottles flushed with N_2 in a desiccator for a reasonable period of time. It is toxic and is an irritant. This reagent should be handled in a fume hood.

Introduction.

Cobalt chloride is a useful reagent on its own or in combination with other reagents. Several interesting transformations utilizing cobalt chloride have been reported in recent years.

Functional Group Transformations.

Anhydrous $CoCl_2$ in dry acetonitrile catalyzes several interesting transformations such as cleavage of ethers by acyl chlorides to give esters,[1] acylation of alcohols and amines by anhydrides,[2] regioselective cleavage of oxiranes with ***Chlorotrimethylsilane***,[3] acyl chlorides (eq 1),[4] anilines,[5] and benzenethiols.[6] It also catalyzes addition reactions of

alcohols with vinyl ethers to give mixed acetals,[7] and the reaction of trimethylsilyl cyanides and acetals or orthoesters to give α-cyano derivatives.[8]

(1)

$CoCl_2$ is also useful for dealkylation of tertiary amines,[9] in the synthesis of acid anhydrides from acid chlorides,[10] and for thionation of carbonyl compounds in the presence of ***Bis(trimethylsilyl) Sulfide***, providing a simple access to thioketones and thioaldehydes.[11]

Cobalt hydrides, generated from $CoCl_2$-***Sodium Borohydride-Triphenylphosphine*** in a 1:1:4 ratio, hydrodimerize terminal alkynes to the corresponding *trans,trans*-1,3-dienes (eq 2).[12] This reagent system is also useful for selective isomerization of certain alkenes.[13]

(2)

Carbon-Carbon Bond Forming Reactions.

A catalytic amount of anhydrous $CoCl_2$ in dry acetonitrile is a very useful reagent for condensation reactions involving active methylene compounds (eqs 3 and 4).[14-16]

(3)

Anhydrous $CoCl_2$ also catalyzes the asymmetric cyclopropanation of fumarates with ***Dibromomethane***.[17]

Oxidations.

Anhydrous $CoCl_2$ catalyzes the oxidation of a variety of aromatic and aliphatic aldehydes to carboxylic acids in the presence of molecular ***Oxygen*** and ***Acetic Anhydride*** at room temperature.[18] The $CoCl_2/O_2$ system in 1,2-dimethoxyethane gives lactones from ethers,[19] and in diglyme it is an effective system for benzylic group oxidation.[20]

Reductions.

The combination of anhydrous $CoCl_2$ and complex metal hydrides gives useful reagent systems for deoxygenation of allylic alcohols to alkenes,[21] hydroboration or hydrogenation of alkenes,[22] and reduction of imines to amines[23] and organic halides.[24] Reduction of β-sulfenylated unsaturated ketones with $NaBH_4$ in the presence of $CoCl_2$ gives saturated ketones.[25] Both aliphatic and aromatic sulfoxides are readily deoxygenated with $CoCl_2.6H_2O/NaBH_4/EtOH$ under a nitrogen atmosphere.[26] The same recipe is also useful for the selective reduction of certain disubstituted alkenes (eq 5).[27]

Carbonylations.

Reduction of anhydrous $CoCl_2$ by $NaBH_4$ in THF under a ***Carbon Monoxide*** atmosphere followed by aqueous NaOH treatment gives ***Sodium Tetracarbonylcobaltate***, which is useful for in situ carbonylations of benzyl halides.[22b] Reduction of anhydrous $CoCl_2$ with ***Zinc*** in THF in the presence of alkynes while bubbling CO gives alkyne-$Co_2(CO)_6$ complexes (eq 6) which are useful synthetic intermediates[28] (e.g. Pauson-Khand cyclopentenone synthesis).

(6)

The $CoCl_2.6H_2O$ reagent, under phase transfer conditions, gives reductive hydroxycarbonylations of *gem*-dibromocyclopropanes.[29]

(7)

Related Reagents.

Lithium Aluminum Hydride-Cobalt(II) Chloride; ***Octacarbonyldicobalt***; ***Sodium Tetracarbonylcobaltate***.

Cobalt(III) Fluoride[1]

CoF_3

[10026-18-3] · CoF_3 · Cobalt(III) Fluoride · (MW 115.94)

(powerful Lewis acid, used almost exclusively for fluorination of organic compounds in a solid-vapour phase reaction)

Physical Data: mp unknown; *d* 3.88 g cm^{-3}.

Solubility: reacts violently with water and hydroxylic solvents; insol almost all solvents at room temperature.

Form Supplied in: buff/brown powder when freshly prepared; rapidly darkens in moist air. Not commercially available.

Preparative Methods: cobalt(III) fluoride is normally prepared by reaction of cobalt(II) fluoride with elemental ***Fluorine*** at 200-300 °C in a stirred reactor usually constructed of copper or nickel and is then reacted with organic substrates at 100-500 °C.[1]

Handling, Storage, and Precautions: normally prepared and used in situ immediately after preparation. Can be stored in sealed vessels under dry nitrogen. Must be handled with caution since it readily releases hydrogen fluoride in contact with air. This reagent should be handled in a fume hood.

General Considerations.

The use of cobalt(III) fluoride as a fluorinating agent was suggested in 1929 by Ruff,[2] but it was not until the work on the so-called Manhattan project concerned with the development of atomic weapons in the 1940s by Fowler[3] that it came to prominence as a powerful reagent for the preparation of highly fluorinated compounds.

Much of the further development of this reagent was carried out at the University of Birmingham by Tatlow and his group over the period between 1950 and 1980 and subsequently on an industrial scale by the RTZ group at Avonmouth, Bristol.

The degree of fluorination obtained with this reagent depends very largely on the reaction temperature and to a lesser extent on the substrate structure. Thus at temperatures in excess of 400 °C, most of the hydrogen is replaced by fluorine, all double bonds including aromatic unsaturation are saturated, and functional groups are destroyed. At lower temperatures, hydrogen atoms are retained and some functional groups remain in the molecules. These general principles are exemplified in the specific reactions discussed below.

Fluorination of Hydrocarbons.

Synthesis of Perfluorocarbons.

Much of the earlier work, particularly that associated with the atomic energy project, was concerned with the preparation of perfluorocarbons used as oils and greases in the diffusion process for the separation of uranium isotopes. A wide range of open chain aliphatic compounds ranging from butane to dodecane have thus been perfluorinated.[4,5] Much of this work was carried out before the advent of modern analytical techniques and it was assumed that there was no isomerization of the hydrocarbon chain. Recent results[6] indicate that this is not so and the degree of isomerization increases with increasing chain length. After a period of inactivity, there was a resurgence of interest in this area with the identification of perfluoro compounds as blood substitutes, evaporative coolants, and as potential chlorofluorocarbon replacements. This work was largely pioneered by the RTZ (now Rhône-Poulenc) group. Two kinds of reactors have been used: for small scale work, horizontal stirred reactors of the type described by Tatlow[7] are employed, but the industrial scale reactors are largely of a fluidized-bed type. By this kind of fluorination a large number of alicyclic perfluorocarbons have been produced and have been marketed for the range of uses indicated above. The types of material produced are exemplified in Scheme 1.

Scheme 1 Examples of the fluorination of hydrocarbons with CoF_3 between 150 and 300 °C

Synthesis of Fluorohydrocarbons.

An important aspect of cobalt trifluoride chemistry has been the partial fluorination of a considerable number of substrates of varying structure, ranging from hydrocarbons through to heterocycles and ethers. In all of these fluorinations, mixtures of different levels of complexity, depending on the substrate, are obtained. As well as regioisomers, the products may also be stereoisomers. This pattern is exemplified in Scheme 2 for the fluorination of benzene at temperatures between 150 and 200 °C, much lower than those used for complete fluorination.

Scheme 2 Major (>1%) compounds formed in the cobalt trifluoride fluorination of benzene; unmarked bonds are joined to fluorine

Scheme 2 Major (> 1%) compounds formed in the cobalt trifluoride fluorination of benzene; unmarked bonds are joined to fluorine

This kind of pattern is repeated for other cyclic systems including cyclopentane,[8] cycloheptane,[9] norbornane,[10] and decalin[11]. Attempts at fluorination of cyclooctane and higher homologs result in very complex mixtures, including rearrangement products containing bicyclic systems.[12] The fluorination of bicyclo[2.2.2]octane or adamantane[13] result, somewhat surprisingly, in largely rearranged products. These rearrangements can readily be diminished or even prevented by the fluorination of analogs containing relatively small amounts of fluorine.[12]

Fluorination of Heterocycles.

A large range of heterocycles have been fluorinated including tetrahydrofuran and its alkyl and fluoroalkyl derivatives,[14] thiophene,[15] pyrrole and *N*-methylpyrrole,[16] and a number of quinoline and isoquinoline derivatives.[17] Attempts to fluorinate pyridine (unless there is already fluorine present) result in substantial degradation of the molecule.[18] These reactions lead to products which may be further elaborated to the corresponding aromatic compounds in some cases. The kinds of products which may be obtained are shown in Scheme 3.

Scheme 3 Examples of the fluorination of heterocycles with cobalt trifluoride; all unmarked bonds in products are joined to fluorine

Fluorination of Ethers.

The fluorination of ethers has been of considerable interest in the anesthetic field and a number of ethers have been fluorinated to obtain products which have shown interesting activity as well as some interesting chemistry.[19] More recently, fluorination of partly fluorinated ethers has been studied as a potential route to CFC alternatives (Scheme 4).[20]

Scheme 4 Fluorination of ethers with cobalt trifluoride

Mechanistic Features.

An unusual feature of cobalt trifluoride fluorinations which produce partially fluorinated materials is that the fluorinations are not random and for any given substrate there is a distinct pattern as to the position of the residual hydrogen atoms; this can be seen from the benzene fluorination products and also from the ether fluorinations. These results have been elegantly explained by Burdon and Parsons in terms of oxidative processes[20] and so far their postulates have stood the test of time.

Conclusions.

It must be concluded that cobalt trifluoride, although being a very useful reagent for producing highly fluorinated

substances, is rather specialized and needs nonstandard equipment for its use. In particular it needs a source of elemental fluorine and to work efficiently needs to be run on a moderately large scale (5-25 kg of fluorinating agent).

Cobalt Salen Complexes[1]

(X = Br, R = PPh_3)

[15603-80-2] · $C_{34}H_{29}BrCoN_2O_2P$ · Cobalt Salen Complexes · (MW 587.53)

(reagents for the generation of carbon centered radicals and vitamin B_{12} mimics)

Physical Data: dark brown-black solids; usually stable up to 200 °C.

Solubility: sol most organic solvents, e.g. benzene, THF, dichloromethane; also partially sol H_2O.

Preparative Methods: RCo^{III}(salen) complexes have been prepared in the same manner as the corresponding RCo^{III}(salophen) and $RCo^{III}(dmgH)_2$ complexes, and they undergo similar reactions (see also ***Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III)*** and ***Cobalt Salophen Complexes***). The formation of RCo^{III}(salen) complexes can be accomplished by reacting Co^{I}(salen) complexes, Co^{II}(salen) complexes, or Co^{III}(salen) complexes with electrophiles, radicals, and nucleophiles, respectively.[1] $NaCo^{I}$(salen) can be prepared by reduction of the $BrCo^{III}$(salen)PPh_3 complex[2] using sodium, metal amalgams,[3] $NaBH_4$/cat $Pd^{II}Cl_2$,[4] or electrochemically.[5] The supernucleophilic $NaCo^{I}$(salen) complex reacts with a variety of alkyl halides, vinyl halides, acyl halides,[3,5] and alkyl tosylates to form RCo^{III}(salen) species. Alkyl and vinyl RCo^{III}(salen) complexes can be prepared by the addition of $NaCo^{I}$(salen) to alkenes and alkynes, respectively.[1,3]

Handling, Storage, and Precautions: often light- and air-sensitive and should be stored in tinted bottles.

Reactions of $NaCo^{I}$(salen) with Aryl Halides.

$NaCo^{I}$(salen) complex has the advantage that it is more nucleophilic than $NaCo^{I}(dmgH)_2$, particularly in reactions with aryl iodides. Reactions of $NaCo^{I}$(salen) with aryl halides initially give the corresponding aryl radical via a single-

electron transfer process (see ***Cobalt Salophen Complexes***). These radicals can add either intramolecularly or intermolecularly to alkenes and alkynes (eq 1).[5b,6] The new carbon radical formed from these additions is then trapped by the Co^{II}(salen) formed in situ to form either alkyl or vinyl RCo^{III}(salen) complexes, respectively.

Reactions of RCo^{III}(salen) Complexes.

Owing to the weak nature of the Co^{III}-carbon bond (18-25 kcal mol^{-1}),[7] photolysis or thermolysis leads to homolytic cleavage and the formation of carbon-centered radicals. In practice, RCo^{III}(salen) complexes often undergo β-elimination to give alkenes unless the initially formed radical is allowed to react with an added radical trap (eq 1) (see also ***Cobalt Salophen Complexes***).[5b,6] In the presence of oxygen, alkylperoxy Co^{III}(salen) complexes ($ROOCo^{III}$(salen)) result, which can then be reduced with ***Sodium Borohydride*** to give alcohols (eq 2),[5b] while thermolysis in the presence of $(PhS)_2$, SO_2, $(PhSe)_2$, NO, $MeSO_2Cl$, $BrCCl_3$, or I_2 gives the corresponding sulfur, selenium, nitrogen, or halogen functionalized products, respectively (eq 2).[1f] The combination of the reaction of $NaCo^{I}$(salen) with an aryl halide followed by radical cyclization and β-elimination of the resulting intermediate Co^{III}(salen) complex has been used in an approach to physovenine (eq 3).[8]

The oxidative radical cyclization process has the advantage over conventional reductive cyclization processes (see also ***Tri-n-butylstannane*** and ***Tris(trimethylsilyl)silane***) in that functionality is retained in the products.

Reactions of Co^{II}(salen).

Co^{II}(salen) catalyzes the oxidation of phenols to the corresponding *p*-benzoquinones or *p*-diphenoquinones in high yield (eq 4).[9] Oxidation in the presence of ***t-Butyl Hydroperoxide*** leads to *t*-butylhydroperoxyquinol ethers, and the reagent catalyzes the oxidation of 2,4,6-trisubstituted anilines to give either 4-*t*-butylperoxy-2,5-cyclohexadiene-1-imine or nitrobenzene derivatives, depending upon the nature of the substituents in the substrate.[10] Co^{II}(salen) also catalyzes the oxidation of alcohols and amines.[11]

Cobalt Salophen Complexes[1]

(R, X absent)

[17457-14-6] · $C_{20}H_{14}CoN_2O_2$ · Cobalt Salophen Complexes · (MW 373.29)

(reagents for the generation of carbon-centered radicals; vitamin B_{12} mimics[2])

Physical Data: dark brown-black solids; usually stable up to 200 °C.

Solubility: sol most organic solvents, e.g. benzene, methanol, THF, dichloromethane.

Preparative Methods: RCo^{III}(salophen) complexes have been prepared in the same manner as for the corresponding Co^{III}(salen) and $Co^{III}(dmgH)_2$ complexes, and they undergo similar reactions (see ***Bis(dimethylglyoximato)(methyl)(pyridine)cobalt(III)*** and ***Cobalt Salen Complexes***). The formation of organoCo^{III}(salophen) complexes can be accomplished by reacting Co^{I}(salophen) or Co^{II}(salophen) with electrophiles or radicals, respectively.[1] The supernucleophilic $NaCo^{I}$(salophen) complex reacts with a variety of alkyl halides[2] and acyl halides[3] to form RCo^{III}(salophen) species.

Handling, Storage, and Precautions: often light- and air-sensitive and should be stored in tinted bottles.

Reactions of Co^{I}(salophen) Complexes with Aryl Halides.

$NaCo^{I}$(salophen) has the advantage that it is generally more nucleophilic than $Co^{I}(dmgH)_2$ and Co^{I}(salen) complexes, particularly in reactions with aryl iodides. Reactions of Co^{I}(salophen) complexes with aryl halides do not lead to isolable $ArCo^{III}$(salophen) complexes. Instead, $NaCo^{I}$(salophen) initially gives the corresponding aryl radical via a

single-electron transfer process. For example, (**1**) reacts with Co^{I}(salophen) to give the corresponding aryl radical which then undergoes a smooth 5-*exo*-trig radical cyclization, followed by trapping with Co^{II}(salophen), to give the RCo^{III}(salophen) complex (**2**); photolysis of (**2**) in C_6H_6 leads to β-elimination of HCo^{III}(salophen) (eq 1).[4] Photolytic homolysis of (**2**) in the presence of styrene leads to a new alkene product resulting from radical addition to the C-C double bond in styrene, followed by β-elimination of HCo^{III}(salophen) (eq 2).[5] Radicals produced from photolysis of (**2**) have also been trapped with O_2, TEMPO, NO, SO_2, $(PhS)_2$, $(PhSe)_2$, $MeSO_2Cl$, $BrCl_3C$, and I_2, to give oxygen, nitrogen, sulfur, selenium, and halogen functionalized products, respectively (eq 2).[6]

Reactions of AcylCo^{III}(salophen) Complexes.

AcylCo^{III}(salophen) species are conveniently prepared from acid chlorides, or the mixed acid anhydrides with 2,6-

dichlorobenzoic acid, following treatment with $NaCo^{I}$(salophen).[3] In this manner a range of primary, secondary, tertiary, vinyl, aryl, arylmethyl, oxy, and aminylacyl salophens, all of which are brightly colored, stable crystalline solids, have been prepared. Irradiation of deaerated, refluxing solutions of acylCo^{III}(salophen) complexes in methylene dichloride results in acyl carbon-cobalt bond homolysis to produce acyl radicals. These acyl radicals may add to activated alkenes intermolecularly in a Michael fashion (eq 3), or in an intramolecular manner leading to ring synthesis (eq 4).[7] The resulting product radicals are trapped by Co^{II}(salophen) to give RCo^{III}(salophen) complexes which undergo dehydrocobaltation leading to conjugated enones.[8] This method of generating acyl radicals has the advantage over conventional reductive methods for their preparation in that functionality is retained in the products (see ***Tri-n-butylstannane***). ArylmethylCo^{III}(salophen) and allylacylCo^{III}(salophen) complexes undergo carbon-cobalt bond homolysis and in situ decarbonylation, producing new alkyl radical centers which can be intercepted with oxygen, nitrogen, halogen, sulfur, and selenium containing radical trapping agents, leading to functionalized nor-alkanes (eq 5).[3] The sequence constitutes a useful, and in some cases more flexible, variant of the classical Hundsdiecker reaction, and amounts to the cobalt equivalent of the Barton radical decarboxylation reaction of carboxylic acids via their corresponding thiohydroxamic acids.[9] *N*-AllylcarbamoylCo^{III}(salophen) complexes undergo efficient 4-*exo*-trig oxidative cyclization giving rise to β-lactams; this procedure has provided a new approach to the antibiotic substance thienamycin.[10] A range of γ- and δ-lactams is available by this chemistry (eq 6).[11]

Cobalt(III) Acetate[1]

$Co(OAc)_3$

[917-69-1] · $C_6H_9CoO_6$ · Cobalt(III) Acetate · (MW 236.07)

(one-electron oxidizing agent for aromatic[4] and aliphatic hydrocarbons,[10] for oxidative halogenation,[15] oxidation of alcohols[23] and acids[26])

Physical Data: dec 100 °C.

Solubility: hydrolyzed in water; sol acetic acid, ethanol, DMSO, DMF, and MeCN; slightly sol THF, diethyl ether, $CHCl_3$, and acetone.

Form Supplied in: dark green solid, widely available.

Analysis of Reagent Purity: cobalt(III) can be determined by treating it with excess iron(II) ammonium sulfate and titration with cerium(IV) sulfate or dichromate.[2]

Preparative Methods: involves oxidation of ***Cobalt(II) Acetate*** in acetic acid solution. The various oxidants used for this purpose are ozone,[2] peracid,[3a] peroxide,[3b] and oxygen.[4] An electrochemical procedure for the generation of $Co(OAc)_3$ in solution is also available.[3c]

Handling, Storage, and Precautions: the dark green solid or solution in acetic acid is reputed to be stable at rt for three months.

Introduction.

Cobalt triacetate is a powerful one-electron oxidant in acidic media. This reagent has been successfully used in the oxidation of a variety of organic substrates.

Oxidation of Hydrocarbons.

The cobalt(III) acetate oxidation of 2-methylnaphthalene at 70 °C in acetic acid gives mainly 2-acetoxynaphthalene (eq 1).[4]

(1)

The reaction of toluene,[4] 2-methylindan,[6] isodurene,[7] hemimellitene,[8] *p*-cymene,[9] heptane,[10] adamantane,[11] and cyclohexane[12] proceeds analogously under a N_2 atmosphere to give the corresponding acetates as the main products; in the presence of ***Oxygen***, oxidation furnishes aldehydes,[5] ketones,[10] and acids.[5,12] The rate of oxidation of alkylarenes[5] and alkanes[10] is enhanced in the presence of strong acids.

Halogenation.

Treatment of representative substrates of alkylbenzene with $Co(OAc)_3$ in the presence of ***Hydrogen Fluoride***,[13] ***Lithium Chloride***,[4] ***Sodium Bromide***,[15] or ***Potassium Iodide***[14] results in corresponding halogenated derivatives.

Oxidation of Alkenes and Dienes.

Treatment of styrene,[16] 1-phenylbutadiene,[17] phenylcyclohexene,[18] α-methylstyrene,[19] or β-methylstyrene substituted with an electron donating group[20] with $Co(OAc)_3$ gives the corresponding 1,2-diol monoacetates as major products. However, oxidation of *cis*- and *trans*-β-methylstyrene at higher temperature affords the corresponding allylic acetate.[19] Reaction of 1,5-hexadienes with $Co(OAc)_3$ in the presence of 3-oxobutanoate under reflux conditions gives bis(dihydrofuran) and mono(dihydrofuran) (eq 2).[21]

(2)

Oxidation of Functionalized Substrates.

The *o*-, *m*-, and *p*-substituted benzyl alcohols[22] and aromatic secondary alcohols[23,24] are readily oxidized by $Co(OAc)_3/Br^-$ to aldehydes and ketones, respectively. The reaction of 2,6-dimethylphenol with $Co(OAc)_3$ results in the formation of 3,3´,5,5´-tetramethyl-4,4´-diphenoquinone.[25]

In the presence of $Co(OAc)_3$ along with ***Copper(II) Acetate***, phenylacetic acids are decarboxylated to benzyl acetates.[26] Aryl substituted aliphatic acids are oxidized by $Co(OAc)_3$ to γ-phenylbutyrolactone (eq 3).[26,27]

(3)

$Co(OAc)_3$ can be used in an interesting dealkylation of arylalkylamines in a mixture of chloroform and acetic anhydride.[28] Dihydroanisoin (DHA) and 1,2-bis(4-methoxyphenyl)propane-1,3-diol can be cleaved cleanly to *p*-anisaldehyde by $Co(OAc)_3$.[29]

2,4,6-Collidine

[108-75-8] · $C_8H_{11}N$ · 2,4,6-Collidine · (MW 121.18)

(most useful in dehydrohalogenation reactions;[1] used for basic properties as reaction solvent or additive)

Alternate Name: 2,4,6-trimethylpyridine.

Physical Data: bp 170 °C; mp -44.5 °C; *d* 0.913 g cm^{-3} at 20 °C. Isomers of the title reagent include 2,3,4-collidine (*[2233-29-6]*; bp 192-193 °C), 2,3,5-collidine (*[695-98-7]*; bp 182-183 °C/739 mmHg), 2,3,6-collidine (*[1462-84-6]*; bp 176-178 °C), 2,4,5-collidine (*[1122-39-0]*; bp 165-168 °C), and 3,4,5-collidine (*[20579-43-5]*; bp 205-207 °C).[2-4]

Solubility: sol 3.5 g/100 mL H_2O (20 °C) and 20.8 g/100 mL H_2O (6 °C); miscible with ether; sol methanol, ethanol, chloroform, benzene, toluene, dilute acids.[3]

Form Supplied in: liquid.

Analysis of Reagent Purity: GLC.

Purification: by distillation.

Handling, Storage, and Precautions: protect from light; moisture sensitive; incompatible with strong oxidizing agents.[5]

Dehydrohalogenation Reactions.

Numerous examples in the literature describe the utility of collidines to aid in dehydrohalogenation reactions. One example (eq 1) is the synthesis of 2-methyl-2-cyclohexenone (**2**) from 2-chloro-2-methylcyclohexanone (**1**).[6] Another example involves the dehydrobromination of tetrahydrofuran (**3**) to diene (**4**) en route from linalool to karahanaenone (62%, overall, eq 2).[7] Similarly, dehydrobromination of stigmasteryl acetate (**5**) affords 7-dehydrostigmasteryl acetate

(**6**) in a refluxing mixture of collidine and mesitylene (eq 3).[1]

(1)

(1) **(2)**
(45-49% from
2-methylcyclohexanone)

(2)

(3) **(4)**

(5)

(6) (3)

A key step in a synthesis of pyridocarbazoles used collidine in THF for a dehydrochlorination. A hindered base such as collidine was required to avoid cleavage of the lactone ring, the preferred reaction using a base such as *N*,*N*-dimethylaniline (eq 4).[8]

(4)

2,4,6-Collidine is used as solvent in the preparation of 2-benzylcyclopentanone (**8**) from 2-benzyl-2-methoxycarbonylcyclopentane (**7**) (eq 5).[9]

(5)

Cleavage of alkyl aryl ethers (72-76%) occurs in high yield with ***Lithium Iodide*** with 2,4,6-collidine as solvent.[10] In the absence of a solvent, high reaction temperatures are required.

Collidine as a Base Catalyst.

Collidine is useful as a base in a variety of reactions. Sometimes it doubles as reaction base and solvent. A mixture of monobromo isomers is obtained in very high yield when 1-methylcyclopropyl-3-methyl-3-butenylcarbinol (**9**) is treated with ***Phosphorus(III) Bromide*** and collidine (eq 6).[11] The bromo compounds shown underwent further reaction with ***Zinc Bromide*** to form *trans*-1-bromo-3,7-dimethylocta-3,7-diene in 85-90% yield.

(6)

Collidine is effective as a proton scavenger in the Koenigs-Knorr synthesis of disaccharide glycosides. ***Silver(I) Trifluoromethanesulfonate*** and collidine are paired as a useful promoter of glycosylation reactions of alcohols with glycosyl halides. For example, the reaction of hepta-*O*-acetyl-α-D-cellobiosyl bromide (**10**) with 8-ethoxycarbonyloctanol (**11**) in the presence of silver triflate and collidine afforded a 78% yield of the corresponding 1,2-orthoacetate derivative (**12**) (eq 7).[12] When a similar reaction was carried out with *N*,*N*,*N*´,*N*´-tetramethylurea in place of collidine, a different reaction path was followed to give isomeric 1,2-*trans*-glycosides.

Collidine is also used as the base for glycosidation reactions promoted by ***Tin(II) Trifluoromethanesulfonate***. Starting with glucose derivative (**13**) and protected sugar derivatives, 1,2-*trans*-β-D-disaccharides have been prepared by this method (eq 8)[13]

Collidine behaves as a nucleophilic catalyst in reactions such as the hydrolysis of picryl chloride. The reaction proceeds by formation of intermediate *N*-picryl-2,4,6-trimethylpyridinium ion (**14**) (eq 9).[14]

Collidine acts as a sterically hindered base in tritylation reactions of very weakly acidic compounds. The tritylation reaction proceeds in high yield for both acetone and acetonitrile, which serve as both reactant and solvent in the syntheses of 1,1,1-triphenyl-3-butanone (**15**) and 1,1,1-triphenylpropionitrile (**16**), respectively (eqs 10 and 11).[15] This tritylation is a general reaction, applicable to more strongly acidic compounds such as diethyl malonate and nitromethane. In the nitromethane reaction, a low yield of the desired product is obtained due to side reactions.

2,4,6-Collidinium *p*-Toluenesulfonate

[59229-09-3] · $C_{15}H_{19}NO_3S$ · 2,4,6-Collidinium *p*-Toluenesulfonate · (MW 293.39)

(acid catalyst in acetalization,[1,2] transacetalization,[7] macrolactonization,[8] and conversion of enynones to phenols[9])

Physical Data: mp 130-132 °C.

Solubility: sol benzene, toluene, dichloromethane, chloroform, ethanol, acetone.

Form Supplied in: white, moisture-sensitive, crystalline solid. Commercially available.

Preparative Method: can be prepared by the slow addition of ***p-Toluenesulfonic Acid*** in methanol to a rapidly stirred solution of ***2,4,6-Collidine*** in diethyl ether, at 20 °C. Cooling to 0 °C results in crystallization of the title reagent.

Purification: recrystallization from acetone.

Handling, Storage, and Precautions: store in desiccator under nitrogen. Very good shelf life at room temperature when kept dry. Irritant; handle with gloves.

Acid-Catalyzed Selective Acetalization.

Collidinium *p*-toluenesulfonate (**1**) is a weakly acidic salt that catalyzes selective acetalization of α,β-unsaturated ketones in the presence of saturated ketones (eq 1). Using ***Ethylene Glycol*** in the presence of (**1**) results in the isomerization of the enone double bond and acetalization of the carbonyl.[1]

A recent improvement uses (**1**) to form a mixture of acetal isomers (eq 2) which undergo isomerization in the presence of (**1**) to give the thermodynamically more stable acetal (eq 3).[2]

The title reagent has been used in the acetalization of a steroidal ketone with ethylene glycol in the presence of an acid sensitive epoxide functionality (eq 4).[3]

(4)

Acetalization of ketones (e.g. cyclohexanone) with the optically active diols (**2**) (eq 5)[4] and (**3**) (eq 6)[5] has been achieved using (**1**) in refluxing benzene, accompanied by the azeotropic removal of water. Use of toluene reduces the reaction time with no loss of yield.[6]

(2) **(3)**

(5)

(6)

Transacetalization of Dioxolane Protecting Groups.

A stoichiometric amount of (**1**) in refluxing acetone-water (120 h) leads to the deprotection of an acetal (eq 7), maintaining the integrity of an acid-sensitive TBS ether and the oxetane ring (84% yield).[7]

(7)

Acid-Catalyzed Macrolactonization.

The title reagent effects the intramolecular macrolactonization of hydroxy triamides, resulting in 8- and 10-membered lactones (eq 8).[8] The reaction is achieved by the syringe pump addition of a triamide solution in benzene to a refluxing solution of (**1**) under high dilution.

(8)

Acid-Catalyzed Cyclization of Enynones to Phenols.

The title reagent catalyzes the cyclization of enynones to phenols (eq 9).[9] The reaction is carried out at 250 °C to give yields of 30-89%.

Copper[1]

Cu

[7440-50-8] · Cu · Copper · (MW 63.54)

(reagent for the cyclization and/or coupling of various functional groups;[1] decarboxylation;[10] preparation of α-alkynic alcohols;[12] cyclopropanes,[13] nitriles,[15] ketones by benzylic oxidation[10])

Physical Data: mp 1083 °C; *d* 8.94 g cm^{-3}.

Solubility: slowly sol aq NH_3.

Form Supplied in: reddish, lustrous solid; ingots, sheets, wire, or powder (most synthetic reactions require the use of the powder form); widely available.

Analysis of Reagent Purity: by electrolytic assay,[21] or EDTA/iodometric titration.[1d]

Handling, Storage, and Precautions: should be stored in the absence of moisture; in moist air it gradually becomes coated with copper carbonate. The powder may be flammable when exposed to excessive heat or flame.

Ullmann Reaction.

Alkyl halides containing electron-attracting substituents may be coupled in the presence of copper in good yields.[1] The reaction is believed to proceed through organocopper intermediates, in an oxidant addition, rather than radicals.[2] Details for the activation of the copper catalyst by iodine in acetone are described along with the Ullmann coupling of 2-chloronitrobenzene to yield 2,2´-dinitrobiphenyl.[3]

Procedures for the preparation of unsymmetrical biaryls from a mixture of halides have been described.[4] Similarly, the coupling of vinyl bromides by copper in a stereospecific synthesis of conjugated dienes has also been reported.[5] A highly reactive copper powder has been developed that is particularly effective for Ullmann reactions.[6]

Other Ullmann-type coupling reactions include the reaction of phenols with aryl halides to yield diaryl ethers,[7] the synthesis of triarylamines through the coupling of diarylamines with aryl halides,[8] the cross coupling of allylic and benzylic bromides with acid chlorides,[6b] and the cyclization of epoxyalkyl halides.[9]

Decarboxylation.

Commercial copper powder in quinoline solution is a standard reagent for decarboxylation reactions.[10] In some instances, decarboxylation and dehydration occur to produce an exocyclic alkene.[11]

α-Acetylenic Alcohols.

Heating 1,4-diformyloxy-2-butyne with copper and adipic acid followed by treatment with acid and methanol gives 2-butyn-1-ol.[12]

Cyclopropanes.

In the presence of copper, α-diazo ketones decompose and react with alkenes to yield cyclopropyl ketones by intermolecular or intramolecular cyclization.[13] Also, copper assists the reaction of alkenes with *gem*-dihalides to produce cyclopropanes.[14]

Nitriles.

Nitriles may be prepared from aromatic aldehydes by reaction with copper powder and ammonium chloride (in situ preparation of $CuCl_2$ and NH_3).[15]

Ketones.

The formation of ketones has been reported to result from benzylic oxidation using a copper powder catalyst (eq 1).[16] The initial oxidized product (**2**) may further cyclize to (**3**) by continued use of the same reagent. The latter reaction is similar to tetramethoxydibenzofuran formation resulting from heating 4-bromo-5-iodoveratrole with copper in nitrobenzene.[17]

Other minor reactions of copper include its use as a catalyst in the synthesis of azo compounds from diazonium tetrafluoroborates,[18] rearrangements of bicyclic hydrocarbons,[19] and in the classic Gattermann version of the Sandmeyer reaction for the conversion of arenediazonium salts to halides.[20]

Related Reagents.

Copper(I) Acetate[1]

CuOAc

[598-54-9] · $C_2H_3CuO_2$ · Copper(I) Acetate · (MW 122.58)

(acetoxylation;[4] oxidation of phenols;[6] hydrogenation[3])

Alternate Name: cuprous acetate.

Physical Data: dec 285 °C.

Solubility: sol water (hydrolyzes to form Cu_2O), pyridine, HOAc; dissolves slowly in ether.

Form Supplied in: tan or white powder; commercially available.

Preparative Methods: obtained as a sublimate by heating copper(II) acetate in vacuo to temperatures above 220 °C.[2] Prepared from ***Copper(I) Oxide*** and ***Acetic Acid-Acetic Anhydride***;[3] also, from a reaction involving ***Copper(II) Acetate*** and ***Copper*** foil in anhydrous acetonitrile with acetic acid-acetic anhydride. The mixture is stirred under nitrogen for 48 h after excess copper is removed, and precipitation of copper(I) acetate in ether occurs.[4,5] Obtained by slow addition of a solution of hydroxylamine hydrogen sulfate to a hot mixture of ammoniacal copper(II) acetate solution buffered with a large amount of ammonium acetate; addition of excess acetic acid precipitates the copper(I) acetate.[1]

Handling, Storage, and Precautions: stable when dry, but decomposes with moisture or strong heating.

Acetoxylation.

Vinyl acetates are often very hard to prepare from vinyl halides. They can be synthesized either by reacting cyclic vinylic bromides with excess copper(I) acetate in acetonitrile at 80-110 °C for 2-10 h (eq 1),[4,6] or by reacting acyclic vinyl iodides with copper(I) acetate in refluxing pyridine. However, the latter

method produces poor yields of vinyl acetates (eq 2). When copper(II) acetate in refluxing *N*-methylpyrrolidone (NMP) is utilized instead, vinyl acetates are obtained in higher yields (eq 2).[7]

(1)

(2)

CuOAc, py	26%
$Cu(OAc)_2$, NMP	70%

Oxidation of Phenols.

Copper(I) acetate functions as a catalyst in the oxidation of phenols to the corresponding poly(phenylene) ethers and diphenoquinones in the presence of tertiary amines.[8]

Hydrogenation.

A dimer of the copper(I) acetate-***Quinoline*** complex activates molecular hydrogen in the homogeneous catalytic hydrogenation of quinone in solution.[3]

Related Reagents.

Copper(II) Acetate, ***Sodium Tetracarbonylcobaltate***.

Copper(II) Acetate[1]

$Cu(OAc)_2$

[142-71-2] · $C_4H_6CuO_4$ · Copper(II) Acetate · (MW 181.64)

(oxidizes carbanions,[2] radicals[3] and hydrocarbons;[4] for oxidative coupling and solvolytic cleavage of Si-C,[5] Bi-C, Pb-C, and Sb-C bonds; rapid radical scavenger; catalyst for cyclopropanation of alkenes with diazo esters;[6] Lewis acid catalyst)

Alternate Name: cupric acetate.

Physical Data: blue crystals, mp 130-140 °C (dec); *d* 1.92-1.94 g cm^{-3}.[7]

Solubility: sol H_2O (6.79 g/100 mL, 25 °C); sol AcOH, pyridine; insol ether.

Form Supplied in: widely available; the anhydrous salt can be prepared from the usually available monohydrate $Cu(OAc)_2.H_2O$ *[6046-93-1]* by heating to 90 °C until constant weight[7,8] or by refluxing $Cu(OAc)_2.H_2O$ in acetic anhydride and washing the insoluble product with Et_2O.[9]

Analysis of Reagent Purity: iodometric titration;[10] atomic absorption spectroscopy.[11]

Purification: recrystallize (as monohydrate) from warm dil HOAc.[57]

Handling, Storage, and Precautions: must be stored in the absence of moisture; is decomposed on heating to hydrogen and $Cu^{I}OAc$.[7] Irritating to skin, eyes, and respiratory system. May be dissolved in a combustible solvent for incineration.

Oxidation of Carbanions.

Oxidative coupling of terminal alkynes to diynes (eq 1) with $Cu(OAc)_2$ and ***Pyridine*** can be carried out in MeOH or in benzene/ether.[2] The reaction requires the presence of copper(I) salt; the rate-determining step corresponds to the formation of the Cu^{I} acetylide.[12]

While α-sulfonyl lithiated carbanions are oxidatively coupled with ***Copper(II) Trifluoromethanesulfonate*** (eq 2), $Cu(OAc)_2$ oxidizes them to the corresponding (*E*)-α,β-unsaturated sulfones (eq 3).[13]

Other carbanions can be coupled oxidatively by $Cu(OAc)_2$, as shown in the synthesis of β-lactams (eq 4).[14]

In the presence of ***1,4-Diazabicyclo[2.2.2]octane*** in DMF, the complex of $Cu(OAc)_2$ and 2,2´-bipyridyl catalyzes the oxygenation of α-branched aldehydes with O_2 to ketones.[15]

Carbon-Hydrogen Bond Oxidations.

Ortho hydroxylation of phenols with O_2 is catalyzed by a complex of $Cu(OAc)_2$ and ***Morpholine*** (soluble in EtOH).[16] In the absence of O_2, *ortho* acetoxylation of phenols can be induced with equimolar amounts of $Cu(OAc)_2$ in AcOH (eq 5).[17]

Allylic hydrogens are replaced by acyloxy groups by reaction of peroxy esters in the presence of catalytic amounts of copper salts, including $Cu(OAc)_2$.[18] The reaction probably proceeds via the formation of an allylic radical, which reacts quickly with Cu^{II} to form a Cu^{III} intermediate that generates the most substituted alkene, probably via a pericyclic transition state (eq 6).[19] Allylic oxidation can be enantioselective when performed in AcOH and ***Pivalic Acid*** in the presence of $Cu(OAc)_2$ and an L-amino acid.[20]

Allylic oxidation of cyclohexene and related alkenes can be achieved with catalytic amounts of ***Palladium(II) Acetate***, $Cu(OAc)_2$, hydroquinone, and O_2 as oxidant in AcOH, leading to allylic acetates.[21] Methyl glyoxylate adducts of *N*-Boc-protected allylic amines cyclize, in the presence of catalytic $Pd(OAc)_2$ and an excess of $Cu(OAc)_2$ in DMSO at 70 °C, to 5-(1-alkenyl)-2-(methoxycarbonyl)oxazolidines (eq 7).[22]

Methyl substituted benzene derivatives are oxidized in boiling AcOH to the corresponding benzyl acetates (eq 8) with sodium, potassium, or ***Ammonium Peroxydisulfate***, $Cu(OAc)_2.H_2O$, and NaOAc.[4] The peroxydisulfate radical is responsible for the primary oxidation, whereas $Cu(OAc)_2$ prevents dimerization of the intermediate benzylic radical by oxidizing it to benzyl acetate. The benzylic acetoxylation of alkyl aromatics can also be carried out with O_2 using $Pd(OAc)_2$ and $Cu(OAc)_2$ as catalysts.[23]

Cycloalkanes are transformed into the corresponding cycloalkenes by treatment with ***t-Butyl Hydroperoxide*** in pyridine/AcOH solution containing $Cu(OAc)_2.H_2O$. When Fe^{III} salts are used instead of $Cu(OAc)_2.H_2O$, the major product is the corresponding cycloalkanone.[24] Cyclohexanone is the main product of cyclohexane oxidation with H_2O_2, $Cu(OAc)_2.H_2O$ in pyridine, and AcOH (GoCHAgg system).[25] $Cu(OAc)_2$ also catalyzes the oxidation of secondary alcohols by ***Lead(IV) Acetate***.[26]

Carbon-Metal Bond Oxidations.

In MeOH and under O_2 atmosphere, a catalytic amount of $Cu(OAc)_2$ promotes the cleavage of the Si-C bond of (*E*)-alkenylpentafluorosilicates to give alkenyl ethers (eq 9). The reaction is highly stereoselective and leads to the (*E*)-enol ethers. In the presence of H_2O the corresponding aldehydes are obtained.[5]

In the presence of $Cu(OAc)_2$, 1,4-additions of alkylpentafluorosilicates to α,β-unsaturated ketones take place on heating (eq 10).[5] This reaction proceeds probably by initial one-electron oxidation with formation of an alkyl radical (eq 11), which then adds to the enone.

$$RSiF_5^{2-} + CuX_2 \longrightarrow R\cdot + [XSiF_5]^{2-} + CuX \quad (11)$$

The monophenylation of 1,*n*-diols with ***Triphenylbismuth Diacetate***[27] is greatly accelerated by catalytic amounts of $Cu(OAc)_2$.[28] This reaction can be enantioselective in the presence of optically active pyridinyloxazoline ligands as cocatalysts (eq 12).[29] Reaction of alcohols (ROH) with ***Triphenylbismuthine*** and $Cu(OAc)_2$ gives the corresponding phenyl ethers (PhOR) and benzene.[30] The treatment of Ph_5Sb with a catalytic amount of $Cu(OAc)_2$ in toluene at 20 °C gave 100% yields of Ph_3Sb, Ph-Ph, and PhH.[31] $Cu(OAc)_2$ catalyzes the arylation of amines by diaryliodonium salts,[32] aryl halides,[33] $Ph_3Bi(OCOCF_3)_2$,[34] and aryllead triacetates.[35]

Fast Radical Scavenging and Oxidation.

Rates of oxidative decarboxylation by $Pb(OAc)_4$ of primary and secondary carboxylic acids to alkenes[36] are enhanced in the presence of catalytic amounts of $Cu(OAc)_2$ or $Cu(OAc)_2.H_2O$. This effect is attributed to the fact that the rate of one-electron-transfer oxidation of alkyl radicals by Cu^{II} salts (eq 13) approaches a diffusion-controlled rate.[3] Oxidative decarboxylation of carboxylic acids can also be carried out with ***(Diacetoxyiodo)benzene*** in the presence of a catalytic amount of anhydrous $Cu(OAc)_2$.[37]

$$RCO_2Pb(OAc)_3 \longrightarrow R\cdot + CO_2 + Pb(OAc)_3$$

$$R\cdot + Cu(OAc)_2 \longrightarrow \text{alkene} + CuOAc + AcOH$$

$$CuOAc + RCO_2Pb(OAc)_3 \longrightarrow Cu(OAc)_2 + RCO_2Pb(OAc)_2$$

$$RCO_2Pb(OAc)_2 \longrightarrow R\cdot + CO_2 + Pb(OAc)_2 \quad (13)$$

The case of radical oxidation with $Cu(OAc)_2$ has been exploited by Schreiber[38] in the fragmentation of α-alkoxyhydroperoxides, as in eq 14.[38b]

(14)

In an electrochemical system containing ***Manganese(III) Acetate***, acetic acid is added to butadiene to generate an allylic radical intermediate that is oxidized with $Cu(OAc)_2.H_2O$ to the corresponding allylic cation, leading to γ-vinyl-γ-butyrolactone (eq 15),[39] a precursor in the industrial synthesis of sorbic acid.

(15)

β-Oxoesters are oxidized with $Mn(OAc)_3$ to the corresponding radicals that can add intermolecularly[40] or intramolecularly (eq 16)[41] to generate alkyl radicals. In the presence of $Cu(OAc)_2$ the latter are rapidly quenched and oxidized to give alkenes. Radical arylation with alkyl iodides can be induced with ***Dibenzoyl Peroxide***; the yield of the reaction can be improved using a catalytic amount of $Cu(OAc)_2.H_2O$,[42] which minimizes hydrogen abstraction by the intermediate radical but introduces a competitive electron-transfer oxidation of the intermediate radical. The oxidative addition of disulfides to alkenes (Trost hydroxysulfenylation[43]) can be promoted by catalytic amounts of $Cu(OAc)_2$.[44]

(16)

Reoxidant in Palladium-Catalyzed Reactions.

$Cu(OAc)_2$ has been used as a reoxidant in the Wacker oxidation ($CH_2{=}CH_2 + O_2 \rightarrow CH_3CHO$)[45] and in the $Pd(OAc)_2$-catalyzed alkenylation of aromatic compounds with alkenes[46] (eq 17).[47] $Pd(OAc)_2$ and $Cu(OAc)_2$ are effective catalysts for the reactions of nitrosobenzenes with carbon monoxide, dioxygen, and alcohols that give the corresponding *N*-alkylcarbamates.[48]

(17)

Enantioselective Cyclopropanation.

$Cu(OAc)_2$ has been used as procatalyst in the asymmetric cyclopropanation[49] of alkenes with alkyl diazoacetates with optically pure imines as cocatalyst (eq 18).[6]

$Cu(OAc)_2$ as Lewis Acid.

Decarboxylation of L-tryptophan into L-tryptamine proved most effective in HMPA in the presence of $Cu(OAc)_2$.[50] In boiling MeCN and under $Cu(OAc)_2.H_2O$ catalysis, aldoximes are converted smoothly into nitriles.[51] In the presence of various Lewis acids including $Cu(OAc)_2$, cyclodeca-1,2,5,8-tetraene is rearranged to *cis,syn*-tricyclo[4.4.0.$0^{2,4}$]deca-5,8-diene (eq 19).[52]

(19)

The Michael reaction of $O_2NCH_2CO_2R$ (R = Me, Bn) with $R^1COCH{=}CHR^2$ (R^1 = Me, Et, R^2 = H; R^1 = R^2 = Me) is catalyzed by $Cu(OAc)_2$ and gives $R^1COCH_2CHR^2CH(NO_2)CO_2R$ in dioxane at 100 °C.[53] Knoevenagel condensation of *t*-butyl malonate with ***Paraformaldehyde*** to give di-*t*-butyl methylidenemalonate can be achieved in the presence of KOH and $Cu(OAc)_2$.[54] Lithium imine anions of α-amino esters undergo $Cu(OAc)_2$-catalyzed reactions with α,o-dihalogenoalkanes to give the corresponding o-halogenoalkylimines.[55] $Cu(OAc)_2$ catalyzes the coupling of PhYbI with *n*-BuI, giving *n*-BuPh and Ph-Ph.[56]

Acyl hydrazides are converted to the corresponding carboxylic acids by bubbling oxygen through a THF or MeOH solution containing the hydrazide and a catalytic amount of $Cu(OAc)_2$ (eq 20).[58]

(20)

Synthesis of Ynamines.

Phenylacetylene reacts with dimethylamine under $Cu(OAc)_2$ catalysis to produce *N*,*N*-dimethyl-2-phenylethynylamine (eq 21).[59] The reaction is effected by bubbling oxygen through a benzene solution of the reagents and $Cu(OAc)_2$; in the absence of oxygen, 1,4-diphenylbutadiyne is the sole product. This may be suppressed by adding a reducing agent, such as hydrazine, to the reaction mixture.

Related Reagents.

Copper(I) Acetate; ***Copper(II) Acetate-Iron(II) Sulfate***; ***Iodine-Copper(II) Acetate***; ***Lead(IV) Acetate-Copper(II) Acetate***; ***Manganese(III) Acetate-Copper(II) Acetate***; ***Sodium Hydride-Copper(II) Acetate-Sodium t-Pentoxide***; ***Zinc-Copper(II) Acetate-Silver Nitrate***.

Copper(II) Acetate-Iron(II) Sulfate

$Cu(OAc)_2$-$FeSO_4$

($Cu(OAc)_2$)

[142-71-2] · $C_4H_6CuO_4$ · Copper(II) Acetate-Iron(II) Sulfate · (MW 181.64) ($Cu(OAc)_2.H_2O$)

[6046-93-1] · $C_4H_8CuO_5$ · Copper(II) Acetate-Iron(II) Sulfate · (MW 199.65) ($FeSO_4.7H_2O$)

[7782-63-0] · FeO_4S · Copper(II) Acetate-Iron(II) Sulfate · (MW 278.02)

(hydroperoxide reduction; alkoxy radical formation and β-fragmentation; carbon radical oxidation and alkene formation; stereocontrolled macrolide synthesis)

Alternate Name: cupric acetate-ferrous sulfate.

Physical Data: $Cu(OAc)_2.H_2O$: mp 115 °C (dec 240 °C); *d* 1.882 g cm^{-3}. $FeSO_4.7H_2O$: forms tetrahydrate at 56.6 °C, monohydrate at 65 °C, loses last H_2O at about 300 °C and dec at higher temperatures; *d* 1.897 g cm^{-3}.

Solubility: $Cu(OAc)_2.H_2O$: sol H_2O and alcohol; slightly sol ether and glycerol. $FeSO_4.7H_2O$: sol H_2O; very slightly sol alcohol.

Form Supplied in: $Cu(OAc)_2.H_2O$: dark green solid; widely available. $FeSO_4.7H_2O$: blue-green solid; widely available.

Preparative Methods: the reagents are prepared individually as saturated solutions in methanol and used directly. Generally, the substrate is mixed with methanolic copper acetate and to this is added a methanolic solution of iron sulfate.

Handling, Storage, and Precautions: aqueous solutions of $FeSO_4$ are oxidized by air. Use in a fume hood.

Alkoxy Radical Generation by Iron(II) Sulfate.

One-electron reduction of peroxide bonds by $FeSO_4$ generates alkoxy radicals[1-4] which are valuable intermediates in organic synthesis.[5] Alkoxy radicals rearrange to more stable alkyl radicals via δ-hydrogen abstraction,[6-8] β-fragmentation[9-17] or, in the presence of a suitably disposed pendant alkene, cyclization[18] pathways. In most cases the

generated alkyl radical is oxidatively trapped giving, for example, alkene or alkyl halide products; copper(II) acetate plays the role of alkyl radical oxidant in the reagent pair.

Alkyl Radical Oxidation by Copper(II) Acetate.

One-electron oxidation of secondary carbon radicals by $Cu(OAc)_2$ efficiently generates alkene products. Oxidation of simple alkyl radicals, such as 3-pentyl and 2-butyl, gives a mixture of alkene isomers.[2,19] In more complex systems, however, alkene formation often proceeds regio- and stereoselectively.[1,20-23] In some cases, heteroatom coordination to a Cu^{III} alkyl intermediate has been invoked to explain product selectivity.[1,22,24]

Macrolide Synthesis from α-Alkoxy Hydroperoxides.

Schreiber has used the fragmentation of α-alkoxy hydroperoxides with copper(II) acetate-iron(II) sulfate to prepare macrolides (eqs 1-3).[20-22] Requisite α-alkoxy hydroperoxides can be prepared by direct peroxyacetalization of carbonyl precursors or by trapping carbonyl oxide intermediates generated by ozonolysis. In eq 1 an alkoxy radical is produced from the hydroperoxide by the transfer of an electron from Fe^{2+}; the alkoxy radical then spontaneously transforms into a carbon-centered radical which is then oxidized by the Cu^{2+} ion to give an alkylcopper intermediate which undergoes a β-elimination to furnish the product recifeiolide.[2] The exclusive *trans* geometry observed in the product is explained by means of internal coordination of the intermediate alkylcopper with transannular oxygen lone pairs.[22]

(1)

This method has been used to prepare substrates for use in studies directed towards preparation of ionophore subunits (eq 2)[27] and for the preparation of 14-membered macrocycles from octalins (eq 3).[21] Ozonolysis of (**1**) (eq 3) selectively gives hydroperoxide (**2**) with the allylic methoxy group of (**1**) directing breakdown of the primary ozonide.[25] The sequence of hydroperoxide reduction, followed by β-fragmentation and alkene oxidation, results in overall dehydration of the molecule. Similar fragmentations have been achieved by treatment of α-alkoxy hydroperoxides with ***Methanesulfonyl Chloride/Sulfur Dioxide***.[26]

(2)

(1) (2)

(3)

(3)

The redox reagents were also used in a new synthesis of racemic *syn*-4,8-dimethyldecanal, the aggregation pheromone of the confused and red flour beetles, respectively.[32]

Other β-Fragmentation Reactions.

The isopropenyl group of carvone derivatives can be removed by ozonolysis in methanol, followed by treatment of the intermediate α-methoxy hydroperoxide with the reagents (eqs 5 and 6).[13,22] The (+)-6-methylcyclohex-2-enone produced in eq 5 is a useful synthetic intermediate.[22] A similar reaction occurs with ozonolysis products from cycloalkenes (eqs 4 and 7).[28,32]

Copper(II) acetate-iron(II) sulfate was used to convert allyl hydroperoxide (**4**) to cyclic ether (**5**) (eq 8), which is an important fragrance chemical.[12] Here the oxidized alkyl radical is trapped by an internal nucleophile before it can form the normal alkene product. Other methods to reduce the hydroperoxide (**4**) were ineffective.

(8)

(4) (5)

Iron(II) will promote homolysis of the O-O bond in cyclic peroxides.[29,30] Treatment of tetracyclic secondary ozonide (**6**) with the reagents gives cyclopentene derivative (**7**) (eq 9).[31]

Copper(I) Acetylacetonate

[14220-26-9] · $C_5H_7CuO_2$ · Copper(I) Acetylacetonate · (MW 162.65)

(catalyst for the decomposition of diazo compounds[2] and for Michael addition[3,4])

Alternate Names: cuprous acetylacetonate; (2,4-pentanedionato)copper.

Physical Data: prepared in situ.[1]

Solubility: sol dioxane, $MeNO_2$, MeCN, acetic acid.[3]

Preparative Method: can be prepared by reacting acetylacetone (***2,4-Pentanedione***) with an ammoniacal solution of CuOH (copper(I) hydroxide).[1]

Handling, Storage, and Precautions: air-sensitive; irritant.

Catalysis of the Decomposition of Diazo Compounds.

Copper(I) acetylacetonate is an effective catalyst for the decomposition of α-diazo ketones to copper carbenoids, which can undergo carbene insertion reactions (eq 1). This strategy was used in a synthesis of *cis*-jasmone (eqs 2 and 3).[2] However, the catalyst more commonly used in the decomposition of diazo compounds is ***Copper(II) Acetylacetonate***, which is commercially available.[2]

(2)

Hou reported an intramolecular carbene insertion reaction catalyzed by this reagent and also by ***Palladium(II) Acetate***.[5] The reaction of α-*O*-allyl- or α-*N*-allyl-α´-diazopropanone derivatives, such as $CH_2{=}CHCH_2OCH(Ph)COCHN_2$, give high yields of the corresponding pyranones in CH_2Cl_2 at room temperature under the catalysis of copper(I) acetylacetonate.[5]

Catalysis of Michael Additions.[3]

Cu(acac) catalyzes the Michael addition of β-dicarbonyls to 2-cyclohexenones and 2-cyclopentenones in the presence of ***Boron Trifluoride Etherate*** (eqs 4-6).[3,4]

(6)

It is believed that the catalyzed Michael addition has the mechanism shown in eq 7. Because the metal chelate is very stable, this catalytic method is irreversible, which explains the high yield of the method compared to the base-catalyzed Michael addition.[3,4]

(7)

Under a variety of conditions with this catalyst, the substituted α,β-unsaturated ketones and esters (**3-6**) are inert to Michael addition.

Copper(II) Acetylacetonate

[13395-16-9; 46369-53-3] · $C_{10}H_{14}CuO_4$ · Copper(II) Acetylacetonate · (MW 261.76)

(catalyst for decomposition of diazo compounds[1-4] and for coupling reactions of organometallics with organic halides and sulfones[9-11,13])

Alternate Names: cupric acetylacetonate; bis(2,4-pentanedionato-*O,O´*)copper.

Physical Data: crystalline solid, mp 284-288 °C (dec); structural studies have been reported.[14]

Solubility: sol $CHCl_3$; sl sol alcohols.

Form Supplied in: commercially available solid.

Preparative Methods: several available, e.g. addition of acetylacetone (***2,4-Pentanedione***) to an aq soln of $Cu(NH_3)_4^{2+}$ prepared from copper(II) nitrate trihydrate and conc aq NH_3.[15]

Purification: recrystallization from $CHCl_3$.[15a]

Handling, Storage, and Precautions: irritant.

Decomposition of Diazo Compounds.

Copper(II) acetylacetonate has been used to catalyze the decomposition of diazo compounds in preparations of carbenoids. The influence of copper chelates on carbene reactions is due to coordination with the diazoalkane as a fifth ligand to give a complex which decomposes to a copper-carbene complex. ***Copper(I) Acetylacetonate*** was also reported to have similar functionality. The reaction mechanism has been studied, based on the decomposition of ***Diphenyldiazomethane*** (eqs 1 and 2).[1]

(1)

(2)

A variety of thermal cyclizations utilize copper(II) acetylacetonate-catalyzed carbene reactions (eqs 3-5).[2-6]

(4)

(5)

Copper(II) acetylacetonate catalyzes the reaction of 2-azido-1,4-quinones with conjugated alkadienyl side chains, giving dihydropyrroloindoloquinones or dihydropyrroloquinolinoquinones, which are not produced by uncatalyzed pyrolysis or photochemical reactions (eq 6).[7] In this example, $Cu(acac)_2$ showed greater activity then many other acetylacetonate complexes or copper powder.

(6)

Copper(II) acetylacetonate has been used as a catalyst for the coupling of bis-diazo ketones to enediones (eq 7).[8]

(7)

Coupling Reactions.

The reactions of allylic sulfones and Grignard reagents take place readily under $Cu(acac)_2$ catalysis (eq 8).[9,10] The carbon-carbon bond-forming method is useful for introducing medium-length alkyl groups, e.g. butyl, hexyl, and octyl, and also succeeds with allylic chloride and acetate substrates at or below 20 °C.

(8)

The reagent also catalyzes the stereospecific cross coupling of alkenyldicyclohexylboranes with allylic or alkynic halides (eq 9).[11] (*E*)-Enynes and 1,4-dienes are produced in good yields and high isomeric purity; ***Tetrakis(triphenylphosphine)palladium(0)*** gives comparative results in similar or better yields.[11]

(9)

The coupling reaction of Reformatsky reagents with allylic halides can also be accomplished in high yield under the catalysis of copper(II) acetylacetonate.[13]

Reductive Reactions.

It was reported that aromatic nitro compounds can be reduced to the corresponding amines by ***Sodium Borohydride***-$Cu(acac)_2$ in high yield.[12]

Related Reagents.

Copper(I) Bis(trimethylsilyl)amide

$(Me_3Si)_2NCu$

[65225-97-0] · $C_6H_{18}CuNSi_2$ · Copper(I) Bis(trimethylsilyl)amide · (MW 223.93)

(reagent for the conversion of aryl and vinyl iodides into the corresponding amines)

Alternate Name: copper(I) hexamethyldisilazide.

Physical Data: colorless crystals, subl. 180 °C/0.2 mmHg.[1]

Preparative Methods: prepared in situ from ***Lithium Hexamethyldisilazide*** and ***Copper(I) Iodide***.

Handling, Storage, and Precautions: moisture and oxygen sensitive.

Aminating Agent.

The title reagent couples with aryl iodides in boiling pyridine (18 h) to give the corresponding silyl-protected primary aromatic amine, $ArN(SiMe_3)_2$ (**1**), in approximately 50% yield.[2] Methanolysis of (**1**) quantitatively liberates the free amine, $ArNH_2$. Aryl bromides also couple with $(Me_3Si)_2NLi$ to give (**1**), but higher temperatures (160 °C in quinoline, 18 h) are necessary. 1-Iodo-6-alkylcycloheptatrienes can be converted into their 1-amino counterparts using this reagent.[3] Finally, this reagent deoxygenates carbon dioxide in the presence of added ligand to produce a copper(I) isocyanate complex which can be further transformed into an alkyl isocyanate by treatment with an alkyl iodide.[4]

Copper(II) Bromide

$CuBr_2$

[7789-45-9] · Br_2Cu · Copper(II) Bromide · (MW 223.36)

(brominating agent; oxidizing agent; Lewis acid)

Alternate Name: cupric bromide.

Physical Data: mp 498 °C; *d* 4.770 g cm^{-3}.

Solubility: very sol water; sol acetone, ammonia, alcohol; practically insol benzene, Et_2O, conc H_2SO_4.

Form Supplied in: almost black solid crystals or crystalline powder; also supplied as reagent adsorbed on alumina (approx. 30 wt % $CuBr_2$ on alumina).

Purification: recryst from H_2O and dried in vacuo.[35]

Handling, Storage, and Precautions: anhydrous reagent is hygroscopic and should therefore be stored in the absence of moisture.

α-Bromination of Carbonyls.

Copper(II) bromide is an efficient reagent for the selective bromination of methylenes adjacent to carbonyl functional groups.[1] Thus 2´-hydroxyacetophenone treated with a heterogeneous mixture of $CuBr_2$ in $CHCl_3$-EtOAc gives complete conversion to 2-bromo-2´-hydroxyacetophenone with no aromatic ring bromination (eq 1).[2]

(1)

Similar selectivity is obtained with a homogeneous solution of the reagent in dioxane.[3] A limitation of the reaction is observed with 2´-hydroxy-4´,6´-dimethoxyacetophenone, which undergoes aromatic nuclear bromination with $CuBr_2$.[4]

Steroidal ketones have been selectively α-brominated with $CuBr_2$ in the presence of a double bond without bromination of the alkene (eq 2),[5] while γ-bromination occurs in other steroidal enones.[1]

(2)

Copper(II) bromide has been used to α-brominate diketotetraquinanes[6] and to introduce a double bond into a prostanoid nucleus in a one-pot bromination-elimination procedure (eq 3).[7] 3,7-Dibromo-2*H*,6*H*-benzodithiophene-2,6-diones (eq 4)[8] and 5-bromo-4-oxo-4,5,6,7-tetrahydroindoles (eq 5)[9] are prepared by the selective α-bromination of their respective ketone starting materials without bromination of the aromatic or heterocyclic rings. 4-Carboxyoxazolines are converted to the corresponding oxazoles using a mixture of $CuBr_2$ and ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (eq 6).[10]

(3)

(4)

(5)

(6)

Bromination of Alkenes and Alkynes.

Heating copper(II) bromide in methanol with compounds containing nonaromatic carbon-carbon multiple bonds leads to di- or tribromination.[11] For example, under these conditions allyl alcohol is converted to 1,2-dibromo-3-hydroxypropane in 99% yield (eq 7), while propargyl alcohol produces a mixture of *trans* di- and tribromoallyl alcohols (eq 8). 2´-Hydroxy-5´-methyl-4-methoxychalcone undergoes a bromination-ring-closure reaction, affording 3-bromo-6-methyl-5´-methoxyflavanone when heated with $CuBr_2$ in refluxing dioxane (eq 9).[12] The mechanism of the bromination of cyclohexene to 1,2-dibromocyclohexane with $CuBr_2$ has been studied.[13]

(7)

(8)

(9)

Bromination of Aromatics.

Aromatic systems are brominated by copper(II) bromide. For example, 9-bromoanthracene is prepared in high yield by heating anthracene and the reagent in carbon tetrachloride (eq 10).[14] When the 9-position is blocked by a halogen, alkyl, or aryl group, the corresponding 10-bromoanthracene is formed.[15] Under similar conditions, 9-acylanthracenes give 9-acyl-10-bromoanthracenes as the predominant products.[16] The aromatic nuclear bromination of monoalkylbenzenes has been shown to proceed cleanly under strictly anhydrous conditions (eq 11).[17a] Polymethylbenzenes are efficiently and selectively converted to the nuclear brominated derivatives by $CuBr_2$/***Alumina***.[17b] In the absence of alumina, a mixture of products resulting from benzylic halogenation is isolated. 3-Acetylpyrroles are nuclear monobrominated at the 4-position in high yield by $CuBr_2$ in acetonitrile at ambient temperature (eq 12).[18] The reaction also proceeds with ethyl 3-pyrrolecarboxylates to give 4-bromopyrrole derivatives,[19] while an excess of brominating agent at 60 °C affords 4,5-dibromopyrroles.[20]

(12)

R^1 = H, Me, Ph, Bn; R^2 = Me, Ph; X = Me, OH, OEt

Bromination of Allylic Alcohols.

Silica gel-supported copper(II) bromide has been used for the regioselective bromination of methyl 3-hydroxy-2-methylenepropanoates and 3-hydroxy-2-methylenepropanenitriles (eq 13).[21a] In the absence of silica gel, no reaction occurs between $CuBr_2$ and these substrates, while adsorption onto Al_2O_3, MgO, or TiO_2 leads to side reactions rather than the clean allylic bromination observed with $CuBr_2/SiO_2$. The reaction is stereoselective with respect to formation of the (*Z*) isomer.

(13)

Benzylic Bromination.

Toluene and substituted methylbenzenes undergo benzylic bromination using $CuBr_2$ and ***t-Butyl Hydroperoxide*** in acetic acid or anhydride (eq 14).[21b] While the yields (43-95%) are not quite as high as those obtained using ***N-Bromosuccinimide***, the copper(II) bromide procedure allows the benzylic bromination of compounds which are insoluble in nonpolar solvents.

(14)

Esterification Catalyst.

Highly sterically hindered esters are prepared by the reaction of *S*-2-pyridyl thioates and alcohols in acetonitrile with copper(II) bromide as the catalyst.[22] The reaction proceeds at ambient temperature under mild conditions and affords high yields of a range of sterically crowded esters such as *t*-butyl 1-adamantanecarboxylate (eq 15).

(15)

Conjugate Addition Catalyst.

The 1,4-addition of Grignard reagents to α,β-unsaturated esters is promoted by catalytic $CuBr_2$ (1-5 mol%) with ***Chlorotrimethylsilane***/HMPA (eq 16).[23] Under these conditions the copper(II) species is not reduced by the Grignard reagent, resulting in high yields of the conjugate addition products.

(16)

Oxidation of Stannanes and Alcohols.

Allylstannanes have been oxidized with copper(II) bromide in the presence of various nucleophilic reagents (H_2O, ROH, AcONa, RNH_2) to afford the corresponding allylic alcohols, ethers, acetates, and amines.[24] This chemistry has been extended to trimethylsilyl enol ethers, which undergo a $CuBr_2$-induced carbon-carbon bond forming process with allylstannanes (eq 17).[25] Alkoxytributylstannanes may be converted to the corresponding aldehyde or ketone with two equivalents of $CuBr_2$/***Lithium Bromide*** in THF at ambient temperature (path a, eq 18).[26] A combination of copper(II) bromide/***Lithium t-Butoxide*** oxidizes alcohols to carbonyl compounds quite rapidly and in high yield (path b, eq 18).[27]

Desilylbromination.

β-Silyl ketones are desilylbrominated to α,β-unsaturated ketones with $CuBr_2$ in DMF.[28] This occurs spontaneously in cyclic ketones, while with open-chain ketones sodium bicarbonate is required to eliminate HBr from the β-bromo ketone thus formed. The carbon-silicon bond in organopentafluorosilicates prepared from alkenes and alkynes is cleaved with copper(II) bromide to give the corresponding alkyl and alkenyl bromides (eq 19).[29] The reaction is stereoselective; thus (*E*)-alkenyl bromides are obtained from (*E*)-alkenylsilicates.

Reagent in the Sandmeyer and Meerwein Reactions.

Diazonium salts of arylamines are converted to aryl halides (Sandmeyer reaction)[30] in the presence of copper(II) halides. Recent procedures have utilized *t*-butyl nitrite/$CuBr_2$[31] or *t*-butyl thionitrite/$CuBr_2$[32] combinations to afford aryl bromides from the corresponding arylamines in high yields (eq 20). The copper salt-catalyzed haloarylation of alkenes with arenediazonium salts (Meerwein reaction) also proceeds with copper(II) halides. For example, treatment of *p*-aminoacetophenone with *t*-butyl nitrite/$CuBr_2$ in the presence of excess acrylic acid gives *p*-acetyl-α-bromohydrocinnamic acid (59% yield, eq 21).[33] The intramolecular version of this reaction, which affords halogenated dihydrobenzofurans, has been accomplished by reacting arenediazonium tetrafluoroborates with $CuBr_2$ in DMSO (eq 22).[34]

Copper(I) Bromide[1]

CuBr

[7787-70-4] · BrCu · Copper(I) Bromide · (MW 143.45) ($CuBr.SMe_2$)

[54678-23-8] · C_2H_6BrCuS · Copper(I) Bromide-Dimethyl Sulfide · (MW 205.59)

(precursor for organocopper(I) reagents and organocuprates;[1a-f] catalyst for diazo chemistry)

Alternate Name: cuprous bromide.

Physical Data: mp 504 °C; the complex with dimethyl sulfide (DMS) decomposes at ca. 130 °C; *d* 4.720 g cm^{-3}.

Solubility: insol H_2O and most organic solvents; partially sol dimethyl sulfide.

Form Supplied in: light green or blue-tinged white solid. 99.999% grade available. The DMS complex is a white solid.

Handling, Storage, and Precautions: maintenance of a dry N_2 or Ar atmosphere is recommended. The DMS complex must be tightly sealed to prevent loss of DMS. Storage of this complex in a cold place is recommended.

Precursor for Organocopper(I) Reagents and Organocuprates.

Although ***Phenylcopper*** was prepared from ***Copper(I) Iodide*** by Reich in 1923[2] and Gilman in 1936,[3] the material used for the modern characterization of this archetypal arylcopper(I) is prepared from CuBr,[4] which continues to be a favored precursor for new organocopper(I) compounds.[5-9] For example, Bertz discovered that halide-free organocopper compounds can be prepared from CuBr in ***Dimethyl Sulfide*** (DMS), owing to the precipitation of LiBr from this solvent.[5] Thus it was possible to prepare and structurally characterize the first bona fide higher order cuprate.[5a,6] Weiss recently reported the second example, a higher order alkynyl cuprate,[9] prepared from CuBr.DMS. The chemistry of organocopper reagents in DMS has now become a flourishing subfield of organometallic chemistry.[5-9]

For the first decade of the modern era of organocopper reagents, CuI was used almost exclusively as the precursor to

organocopper(I) and organocuprate reagents.[1f] In 1975, House introduced the DMS complex of CuBr, symbolized $CuBr.SMe_2$ or CuBr.DMS, as a convenient precursor for the generation of lithium organocuprates.[10] Unlike the commercial CuBr, which is invariably contaminated with traces of colored Cu^{II} impurities, CuBr.DMS is a microcrystalline white solid. This material should be stored under a dry, inert atmosphere in a refrigerator in order to minimize the loss of DMS, which is quite volatile (bp 38 °C). It is not surprising that Lipshutz found that low quality material gave poor results.[11] This author has found that for ultraprecision work, where stoichiometry is of paramount importance, the ultrapure (99.999%) grade of CuBr is preferable.[5]

Nevertheless, in a side-by-side comparison of seven Cu^{I} salts (CuCN, CuI, CuBr, CuBr.DMS, CuCl, CuOTf, and CuSCN) as precursors of a typical alkyl and a typical aryl cuprate (***Lithium Di-n-butylcuprate*** and ***Lithium Diphenylcuprate***, respectively), CuBr.DMS and ***Copper(I) Cyanide*** were found to give the best results.[12] The comparison between ultrapure CuBr and CuBr.DMS is especially interesting, as it demonstrates a dramatic effect for just 1 equiv of DMS in THF and especially in ether. Another example of a significant difference between CuBr and CuBr.DMS is provided by Davis's study of 1,6 vs. 1,4 and 1,2-addition (eq 1).[13]

No Cu	4	1	3
CuBr	4	1	15
CuBr · DMS	3	1	30

Some of the most fundamental studies in organocopper chemistry have been carried out using CuBr or CuBr.DMS as starting materials. House showed that the chemoselectivity of ***Lithium Dimethylcuprate-Lithium Bromide*** could be completely controlled by the choice of solvent.[14] Thus a molecule with remote bromoalkane and α-enone functional groups gave only conjugate addition in ether-DMS and only displacement of the Br when HMPA (***Hexamethylphosphoric Triamide***) was present (eq 2). In a recent ^{13}C NMR study it was shown that phenylcuprates are dimeric in nonpolar solvents and monomeric in polar solvents.[15] It was further conjectured that the dimer is responsible for the conjugate addition reaction, and the monomer is responsible for the (much slower) S_N2-like displacement reaction.

(2)

The preparation of the first higher order cuprate, $Ph_5Cu_2Li_3$ = $[Ph_3CuLi_3][Ph_2Cu]$ or Ph_3CuLi_2 + Ph_2CuLi, from CuBr/DMS was mentioned above.[5] House first proposed higher order Ph_3CuLi_2 in solutions prepared from 3 equiv of PhLi and CuBr in ether to account for the higher reactivity observed for this mixture in certain coupling reactions.[16] However, ^{13}C NMR and ^{6}Li NMR studies did not detect any higher order phenylcuprate in ether or THF, only in DMS.[5] While the presence of a small amount of higher order cuprate acting as a catalytic intermediate cannot be ruled out, a more plausible explanation involves the attack of PhLi on a cuprate-complexed intermediate.

The first thermally stable phosphido- and amidocuprates were prepared from $CuBr.SMe_2$.[17] (It was also shown that LiBr has a beneficial effect on the reactions of organocuprates with typical substrates.[17c]) Chiral amidocuprates have been extensively studied because of their potential for asymmetric induction.[18-20] The chiral auxiliary has also been put on the substrate, e.g. cuprates have been added to chiral unsaturated imides.[21] A good recent review provides many more examples.[1b]

Whereas Grignard reagents and lithium reagents generally give thiophilic addition to dithioesters, the corresponding organocopper reagents give carbophilic addition.[22] The best yields were obtained with CuBr.DMS and ***Copper(I) Trifluoromethanesulfonate***; good results were also obtained with CuCN and CuI. This carbophilic addition has been applied to 1,3-thiazole-5(4*H*)-thiones.[23] It is interesting to note that CuBr has also been used in the preparation of the dithioesters (eq 3).[24]

(3)

Nakamura and Kuwajima have reported the CuBr.DMS catalyzed acylation and conjugate addition reactions of the Zn homoenolate from 1-alkoxy-1-siloxycyclopropanes and ***Zinc Chloride***.[25a] They have also reported the ***Chlorotrimethylsilane***/HMPA accelerated conjugate addition of stoichiometric organocopper reagents prepared from CuBr.DMS,[25b] and of catalytic copper reagents,[25c] to α,β-unsaturated ketones and aldehydes. This procedure appears to be more general than that based on putative cuprates of intermediate stoichiometry (see ***Copper(I) Iodide***). In a very significant observation, they report that reagents derived from cuprous iodide consistently gave lower yields.[25b]

Wipf has used CuBr.DMS to catalyze the addition of alkyl and alkenylzirconocenes to acid chlorides to yield ketones,[26a] and also the 1,4-addition of alkylzirconocenes to α-enones.[26b] The hydrozirconation of alkynes followed by transmetalation to Cu^I was devised by Schwartz et al.,[27] who used CuI and ***Copper(I) Chloride***. Transmetalation from Al, B, Pb, Mn, Hg, Sm, Sn, Te, Ti, Zn, and Zr to Cu has been reviewed recently.[1h]

Carbocupration of alkynes by organocopper reagents is a very important area, as judged by the number of citations.[1a,i] An interesting example involves the use of organocopper reagents bearing protected α-hydroxy or α-thio functions.[28a] The preparation of γ-silylvinylcopper reagents via the addition of α-silylated organocopper reagents to alkynes has also been described.[28b] The carbocupration of alkynes is the key step in the synthesis of γ,γ-disubstituted allylboronates.[29] The stannylalumination of 1-alkynes is catalyzed by Cu^I and involves stannylcupration by an intermediate stannylcopper(I) reagent.[30]

The use of Grignard reagents in conjunction with Cu^I salts has been thoroughly reviewed.[1a,d] A very edifying example of the difference between organocopper reagents prepared from lithium reagents vs. Grignard reagents has been provided by Curran (eq 4).[31]

$Me_2CuLi \cdot LiBr$, THF	62	38
$Me_2CuLi \cdot LiBr$, ether	54	46
$MeCu \cdot MgBr_2$	98	2
$MeCu \cdot LiBr$	86	14
$MeCu \cdot LiI$	76	24
$MeCu(CN)Li$	75	25

Yields were 90-97%, except for the cuprate from CuCN: 60%

In chemistry that is clearly related to that of organocopper reagents, aryl bromides and aryl iodides undergo a Gabriel reaction with potassium phthalimide in the presence of CuBr (or CuI).[32] They also undergo coupling reactions with the sodium salts of active methylene compounds catalyzed by CuBr.[33] Copper-assisted nucleophilic substitution of aryl halogen has been reviewed.[1g] In a potentially far-reaching development, thermally stable, yet reactive formulations of

organocuprates suitable for commercialization have been patented.[34]

Catalysts for Diazo Chemistry.

CuBr has been used in other reactions besides those involving organocuprates. It is a popular catalyst for the activation of ***Diazomethane***, e.g. tropylium perchlorate is isolated in 85% yield starting from benzene.[35] CuBr has been used for the activation of diazoacetic esters,[1j] but not as often as CuCN, and especially CuCl. CuBr is the preferred catalyst for the Sandmeyer reaction of arenediazonium salts to afford bromoarenes,[36] and for the Meerwein reaction, the arylation of alkenes by diazonium salts.[37]

Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride[1,2]

$LiCuHBr.Al(OMe)_3$

(CuBr)

[7787-70-4] · BrCu · Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride · (MW 143.45) ($LiAlH(OMe)_3$)

[12076-93-6] · $C_3H_{10}AlLiO_3$ · Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride · (MW 128.05)

(in situ prepared hydridocopper reagent; reduces 1-alkynyl sulfides to *cis*-1-alkenyl sulfides;[3] 1,4-reduction of enones[2,4])

Preparative Methods: [4] an anhydrous THF solution of lithium trimethoxyaluminum hydride (1.9 mmol) is added dropwise to a suspension of dry[5] ***Copper(I) Bromide*** (1 mmol) in THF maintained at -5 to 0 °C under an inert atmosphere. After 30 min, the resulting dark brown suspension is cooled to -78 °C and treated with the substrate (1.1 mmol) via syringe. After a 50 min stirring time at -20 °C, methanol is added and the mixture is poured into a saturated aqueous ammonium chloride solution. The organic layer is removed from the blue (copper) layer and dried. A modification of this procedure has been reported where $CuBr.Me_2S$ was used as the copper source and HMPA was used as a cosolvent.[6] In another procedure, $CuBr.Me_2S$-lithium dimethoxyaluminum hydride-boron tribromide was used to prepare 2,6-dialkyl-2,3-dihydro-4-pyridones.[7] ***Lithium Tri-t-butoxyaluminum Hydride***-copper(I) bromide was used to regiospecifically reduce 1-acylpyridinium salts to the desired 1-acyl-1,4-dihydropyridines.[8]

Alkynes.

The use of this reagent was first reported for the reduction of 1-alkynyl sulfides to *cis*-1-alkenyl sulfides (eq 1).[3] Reduction of these compounds with ***Lithium Aluminum Hydride*** in THF produced the

corresponding *trans*-1-alkenyl sulfides (eq 2). The reduction of 1-alkynyl phenyl sulfones also proceeds to give the *cis*-alkene.[9] However, the reduction of alkynic esters showed a great tendency to oligomerize.[4]

(1)

(2)

Enones.

This reagent reduces acyclic[2,4,10] and bicyclic[11,12] α,β-unsaturated ketones to ketones and 2-cyclohexenones to cyclohexanones.[2,4] This reagent reduces cyclohexenones better than ***Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride***.[4] The deuterated copper reagent (copper(I) bromide-lithium trimethoxyaluminum deuteride) reacts with (**1**) to afford the deuterium label at the β-position (eq 3). The reduction of α,β-unsaturated esters tends to give high molecular weight materials.[4]

(3)

(**1**)

Limitations.

Although the exact structure of this reagent has not been determined, it is clearly different from other hydridocopper reagents[4] and has been shown to be superior to the ***Lithium Aluminum Hydride-Copper(I) Iodide*** reagent[13] for the preparation of (**2**) (eq 4).[10] Substitution of ***Copper(I) Iodide*** for copper(I) bromide affords a much less selective reagent (***Copper(I) Iodide-Lithium Trimethoxyaluminum Hydride***).[4] Additional limitations are discussed for the ***Copper(I) Bromide-***

Sodium Bis(2-methoxyethoxy)aluminum Hydride reagent.

(4)

(2)

Alternative Methods.

Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride[1,2]

$NaCuHBr.AlH(OCH_2CH_2OMe)_2$

(CuBr)

[7787-70-4] · BrCu · Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride · (MW 143.45) ($NaAlH_2(OCH_2CH_2OMe)_2$)

[22722-98-1] · $C_6H_{16}AlNaO_4$ · Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride · (MW 202.19)

(in situ prepared hydridocopper reagent; 1,4-reduction of α,β-unsaturated ketones,[2] esters,[2] lactones,[3] nitriles[4] and selected alkynes[5])

Preparative Method: [2] a benzene (toluene) solution of ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (16 mmol of hydride) is added dropwise to a suspension of dry[6] ***Copper(I) Bromide*** (8 mmol) in anhydrous THF at 0 °C under an inert atmosphere. After 30 min, the black mixture is cooled to -78 °C and anhydrous 2-butanol (18 mmol) is added, followed by a THF solution of substrate (1 mmol). The mixture is stirred at -20 °C for 2 h, quenched with water and poured into saturated aqueous ammonium chloride solution. After ether addition, the organic layer is washed with water and aqueous ammonium chloride solution and dried.

Handling, Storage, and Precautions: use in a fume hood.

Modifications.

Copper(I) Iodide has been used as the copper source for the reduction of α,β-unsaturated esters[7] and butenolides.[8]

α,β-Unsaturated Ketones.

The reagent is used for the 1,4-reduction of α,β-unsaturated ketones (eq 1).[2,9-12] This reagent is reported to reduce acyclic enones and enoates (in the presence of 2-butanol) better than the ***Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride*** reagent.[9] The reagent has been used to reduce 2-cyclopentenone,[13] cyclohexenones,[9,14,15] and macrocyclic enones.[16]

(1)

R = *t*-Bu, 98%; Ph, 54%

Other Enones.

The reagent reduces α,β-unsaturated esters (eq 2),[9,17-22] lactones (eqs 3 and 4),[3,23-25] and nitriles (eq 5).[4]

(2)

R = H, R^2 = Me, 84%; R = R^2 = Me, 92%; R = R^2 = Ph, 82%

(3)

(4)

(5)

R = Ph, R^1 = H, 99%; R = cyclopropyl, R^1 = Me, 70%; R = 2-furyl, R^1 = H, 51%; R = R^1 = Pr, 83%

Alkynes.

The reduction of alkynic esters affords unsaturated esters, albeit in poor yield and as a *cis*/*trans* mixture (eq 6).[9] In contrast to this, the reduction of 1-alkyl-3-(trifluoromethyl)propargyl alcohols affords only the *cis* alkene (eq 7).[5] Deuterium trapping experiments (AcOD) resulted in deuterium incorporation at the CF_3 sp^2 carbon.

(6)

(7)

Limitations.

Although the exact structure of this reagent has not been determined, it is clearly different from other hydridocopper reagents.[9] The title reagent fails to reduce sterically hindered enones (e.g. **1** and **2**).[26-29] This reagent also lacks chemoselectivity, such that it will reduce saturated ketones to alcohols and alkyl (aryl) bromides to their corresponding hydrocarbons.[30] The reagent $[(Ph_3P)CuH]_6$ is reported to reduce α,β-unsaturated carbonyl compounds in the presence of alkyl halides or sulfonates.[31]

(1)

(2)

Alternative Methods.

The 1,4-reduction of enones can be accomplished by many other methods, such as catalytic hydrogenation,[32,33] dissolving metal reduction,[34,35] benzylamine/potassium *t*-butoxide,[36] ***Pentacarbonyliron***/base,[37,38] lithium or potassium trialkyl(aryl)borohydrides,[39,40] $NaHFe_2(CO)_8$,[41] ***Tri-n-butylstannane***,[42] ***Diphenylsilane-Tetrakis(triphenylphosphine)palladium(0)-Zinc Chloride***,[30,43] ***Selenium***/CO/H_2O,[44] and ***Sodium Borohydride***/CuCl.[45] See ***Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride***, ***Lithium Aluminum Hydride-Copper(I) Iodide***, ***Lithium n-Butyl(hydrido)cuprate***. For a discussion on alternative methods of alkyne reduction to *cis*-alkenes, see ***Magnesium Hydride-Copper(I) Iodide***.

Copper Bronze[1]

Cu

[7440-50-8] · Cu · Copper Bronze · (MW 63.54)

(Ullmann coupling;[6] thermal decomposition of diazo compounds;[9] vinyl ether synthesis;[10] Guerbet reaction[3])

Physical Data: mp 1083 °C; bp 2595 °C; *d* 8.95 g cm^{-3}.

Solubility: slowly sol in ammonia water.

Form Supplied in: copper-colored, finely ground powder; commercially available.

Preparative Methods: copper bronze can be activated either by the method of Vogel[1a] or by addition of a 2% solution of iodine in acetone.[2]

Handling, Storage, and Precautions: may lose its activity due to aging. Flammable when exposed to heat, sparks, and open flame. Irritant. May discolor on exposure to air and moisture. Incompatible with strong acids, strong oxidizing agents, acid chlorides, and halogens. Use of safety goggles and chemical-resistant gloves is strongly recommended. Avoid breathing the dust. Avoid contact in eyes, on skin, on clothing.

Guerbet Reaction.

Preparation of ethylhexanol from butanol occurs within an autoclave at autogenous pressures of 50-60 atm and temperatures of about 300 °C in the presence of the hydrogenation-dehydrogenation catalyst, copper bronze. Butanol is first dehydrogenated to an aldehyde in the presence of sodium and copper bronze before undergoing aldol condensation and subsequent dehydration. The resulting α,β-unsaturated aldehyde is then hydrogenated, yielding 2-ethylhexanol.[3]

Ullmann Coupling.

Under Ullmann conditions,[6] halogen-substituted aromatic compounds react with organic halides in the presence of activated copper bronze[1b,2,4] to give the corresponding coupled products in moderate yields. A recent example is the synthesis of perfluoroalkyl-substituted aromatic aldehydes via the coupling of two different substrates (i.e. perfluorooctyl iodide and *p*-iodobenzaldehyde) (eq 1).[5]

Thermal Decomposition of Diazo Compounds.

Copper bronze can promote the intramolecular cyclization of diazo ketones in boiling cyclohexane (eq 2); anhydrous ***Copper(II) Sulfate*** in boiling THF can also be used.[7] Other diazo compounds that have been shown to undergo copper-catalyzed thermal decomposition include ethyl diazopyruvates in the presence of enol ethers or alkynes[8] and diazoacetates (eq 3).[9]

Vinyl Ether Synthesis.

Rearrangement of β-alkoxycyclopropanecarboxylates in the presence of copper bronze catalyst produces vinyl ethers (eq 4). Vicinal alkoxy and ethoxycarbonyl groups activate the substrate as the reaction proceeds.[10]

Copper(I) *t*-Butoxide

***t*-BuOCu**

[35342-67-7] · C_4H_9CuO · Copper(I) *t*-Butoxide · (MW 136.66)

(metalation agent for active hydrogen compounds;[1] cross-coupling agent of 1,3-dinitrobenzenes and aryl iodides;[2] nontransferable group of mixed organocuprates;[3] volatile copper precursor for MOCVD[4])

Physical Data: sublimation temp 160 °C (0.1 mmHg), 110 °C (10^{-4} mmHg); mp 260 °C (dec).

Solubility: slightly sol THF, benzene, cyclohexane, and hexane.

Preparative Methods: Cu^I *t*-butoxide prepared in situ by the metathesis reaction between ***Copper(I) Chloride*** and alkali metal *t*-butoxide in appropriate organic solvents can be used for synthetic purposes. Cu^I *t*-butoxide can be isolated by sublimation under vacuum.

Handling, Storage, and Precautions: extremely oxygen- and moisture-sensitive. Preparation and reaction should be conducted under rigorously oxygen-free and anhydrous conditions.

Metalation.

Cu^I *t*-butoxide metalates a variety of active hydrogen compounds under mild conditions, with concomitant quantitative liberation of *t*-butyl alcohol, in the presence or absence of added ligands to generate corresponding organic Cu^I compounds, which generally can be easily isolated by evaporation or filtration of *t*-butyl alcohol and the solvent (eqs 1 - 11).[1,5 -11] This preparative method is characterized by the absence of alkali metal salts that usually accompany Cu^I compounds prepared by the metathesis reaction between Cu^I halides and organoalkali metal compounds. Acylation of ***(Trimethylsilyl)ethynylcopper(I)*** (eq 2) with acid chlorides gives trimethylsilylethynyl ketones.[5] The Cu^I bicarbonate complex (eq 6) acts as a reversible CO_2 carrier to transfer its CO_2 moiety to cyclohexanone.[8] Cu^I carbamate (eq 7) reacts with MeI in the presence of a *t*-butyl isocyanide ligand to produce methyl carbamate.[9] Cu^I cyclohexanone-2-carboxylate (eq 8) undergoes a specific two-step decarboxylation in DMF to afford Cu^I enolate.[10] Hydrogenolysis of Cu^I *t*-butoxide occurs in the presence of ***Triphenylphosphine*** to afford hexameric $HCuPPh_3$ (eq 11), which is a useful reducing agent.[11] For the synthetic use of Cu^I acetylides, ***Copper(I) Phenoxide***, and ***Copper(I) Cyanoacetate***, see the corresponding entries.

(11)

Cross-Coupling of 1,3-Dinitrobenzenes and Aryl Iodides to 2,6-Dinitrobiphenyls.

Cu^I *t*-butoxide with ***Pyridine*** mediates cross-coupling of 1,3-dinitrobenzenes with aryl iodides to give 2,6-dinitrobiphenyls under mild conditions (eq 12).[2] This 2,6-dinitrobiphenyl synthesis is superior to the Ullmann condensation of aryl iodides with 2,6-dinitrochlorobenzene or ***Copper(I) Oxide***-promoted reaction of 1,3-dinitrobenzenes with aryl iodides in quinoline. Aryl iodides with Me, MeO, Cl, Br, CO_2Me, and NO_2 substituents and with at least one free *ortho* position can be used to give substituted 2,6-dinitrobiphenyls in 30-95% yield. Aryl iodides substituted in both *ortho* positions react sluggishly and without positional preference. Aryl bromides react less effectively. (*E*)-β-Iodostyrene reacts but alkyl iodides and allyl bromide fail to give arylated products. The incorporation of extra substituents such as Me, CO_2Bu-*t*, and CN in the dinitrobenzene unit is successful. The presence of two nitro groups is an essential requirement, the alternative use of electron-withdrawing substituents such as CO_2Me and CN instead of one nitro group of 1,3-dinitrobenzene proving ineffective.

(12)

1,3-Dinitrobenzene reacts with 4- and 2-iodophenols in the presence of Cu^I *t*-butoxide, ***Potassium t-Butoxide***, and pyridine to give 2´,6´-dinitrobiphenyl-4-ol (eq 13) and 1-nitrodibenzofuran (eq 14), respectively.[12] A similar reaction occurs by using iodomethyl phenyl sulfone and sulfoxide (eq 15). The reaction mechanism of copper-mediated vicarious nucleophilic substitution has been proposed.

(13)

(14)

(15)

$n = 1$, 68%; $n = 2$, 76%

In a similar fashion, Cu^{I} *t*-butoxide effects one-pot formation of isocoumestans in the presence of pyridine by cross-coupling of 2-iodophenols with ethyl acetylenecarboxylate via alkenylcopper intermediates (eq 16).[13]

Nontransferable Group of Mixed Organocuprates.

A nontransferable group of mixed organocuprates has been developed for stabilizing organocuprate reagents and for saving one organic group of diorganocuprates. Cu^I *t*-butoxide can be used for a nontransferable group of mixed organocuprates (eq 17).[3] The nontransferable thiophenoxy group from Cu^I thiophenoxide has been reported to be the most useful compared to *t*-BuO, PhO, *t*-BuS, and Et_2N in the reaction of lithium mixed organocuprates, but Cu^I *t*-butoxide has the advantage of easier handling. A variety of reactions of lithium and magnesium organocuprates utilizing Cu^I *t*-butoxide for the nontransferable group have been reported: *syn* carbocupration ((*t*-BuOCuR)Li/HC&tbond;CH, HC&tbond;CCH$(OEt)_2$, and MeC&tbond;CCH$(OEt)_2$);[14,15] acylation with acid chlorides ((*t*-BuOCuCH_2OBu-*t*)Li);[16] and asymmetric conjugate addition of (*t*-BuOCuBu-*n*)MgCl to 3-alkyl- and aryl-substituted cyclopentenone 2-sulfoxide enantiomers.[17]

t-BuOCuL (L = CO, *t*-BuNC, and PEt_3) Complexes.

Cu^I *t*-butoxide forms sublimable copper complexes *t*-BuOCuL (L = CO,[18] *t*-BuNC,[18] and PEt_3[1]). These complexes metalate cyclopentadiene to afford η^5-C_5H_5CuL complexes.[1,18] *t*-BuOCu(*t*-BuNC) effects metalation of, and subsequent ligand insertion with, fluorene (eq 18).[18] Cu^I *t*-butoxide-trialkylphosphine complexes effect hydride transfer to a carbonyl group (Tishchenko reaction and Meerwein-Ponndorf reduction)[19] and cyclopropane formation from methyl α-chloropropionate and methacrylonitrile.[20] *t*-BuOCu(*t*-BuNC) absorbs CO_2 reversibly (eq 19).[21] At an elevated reaction temperature, *t*-BuOCu(*t*-BuNC) effects deoxygenation of CO_2 to produce CO and *t*-butyl isocyanate, which is converted to carbamate by addition of alcohol (eq 20).[22]

$$t\text{-BuOCu}(t\text{-BuNC}) + 2\ t\text{-BuNC} + CO_2 \underset{C_6H_6,\ \text{reflux}}{\overset{C_6H_6,\ \text{rt}}{\rightleftharpoons}} t\text{-BuOCO}_2\text{Cu}(t\text{-BuNC})_3 \quad (19)$$

$$CO_2 + t\text{-BuNC} \xrightarrow[\text{tetralin, 120 °C}]{t\text{-BuOCu}} CO + t\text{-BuNCO} \xrightarrow[\text{rt}]{n\text{-BuOH}} \underset{119\%}{CO} + \underset{116\%}{t\text{-BuNHCO}_2\text{-}n\text{-Bu}} \quad (20)$$

(based on Cu)

Volatile Copper Precursor for Metallic Copper and Cu^{I} Oxide Films by MOCVD.

Metal-organic chemical vapor deposition with Cu^{I} *t*-butoxide results in the deposition of pure Cu^{I} oxide whiskers at 237 °C and of metallic copper films at 397 °C (eq 21).[4a] An elimination mechanism has been proposed for the formation of Cu^{I} oxide: elimination of isobutene from *t*-butoxide groups yields Cu^{I} hydroxide intermediates, which subsequently engage in proton transfer processes to produce Cu^{I} oxide, *t*-butyl alcohol, and water. η^5-$C_5H_5CuPEt_3$[1] and *t*-BuOCuCO[18] also act as the volatile copper precursor for MOCVD.[4b]

$$[CuOCMe_3]_4 \longrightarrow 2\ Cu_2O + xH_2O + (2\text{-}x)HOCMe_3 + (2+x)CH_2{=}CMe_2 \quad (21)$$

$$2\ Cu_2O \longrightarrow 4\ Cu + O_2$$

Copper(II) Chloride

$CuCl_2$

[7447-39-4] · Cl_2Cu · Copper(II) Chloride · (MW 134.45) (.$2H_2O$)

[10125-13-0] · $Cl_2CuH_4O_2$ · Copper(II) Chloride · (MW 170.48)

(chlorinating agent; oxidizing agent; Lewis acid)

Physical Data: anhydrous: *d* 3.386 g cm^{-3}; mp 620 °C (reported mp of 498 °C actually describes a mixture of $CuCl_2$ and CuCl); partially decomposes above 300 °C to CuCl and Cl_2; dihydrate *d* 2.51 g cm^{-3}; mp 100 °C.

Solubility: anhydrous: sol water, alcohol, and acetone; dihydrate: sol water, methanol, ethanol; mod sol acetone, ethyl acetate; sl sol Et_2O.

Form Supplied in: anhydrous: hygroscopic yellow to brown microcrystalline powder; dihydrate: green to blue powder or crystals; also supplied as reagent adsorbed on alumina (approx. 30 wt % $CuCl_2$ on alumina).

Analysis of Reagent Purity: by iodometric titration.[70]

Purification: cryst from hot dil aq HCl (0.6 mL g^{-1}) by cooling in a $CaCl_2$-ice bath.[71]

Handling, Storage, and Precautions: the anhydrous solid should be stored in the absence of moisture, since the dihydrate is formed in moist air. Irritating to skin and mucous membranes.

Chlorination of Carbonyls.

Copper(II) chloride effects the α-chlorination of various carbonyl functional groups.[1] The reaction is usually performed in hot, polar solvents containing ***Lithium Chloride***, which enhances the reaction rate. For example, butyraldehyde is α-chlorinated in DMF (97% conversion, eq 1) while the same reaction in methanol leads to an 80% yield of the corresponding α-chloro dimethyl acetal (eq 2).[2]

(1)

(2)

The process has been extended to carboxylic acids, anhydrides, and acid chlorides by using an inert solvent such as sulfolane.[3] 4-Oxo-4,5,6,7-tetrahydroindoles are selectively α-chlorinated, allowing facile transformation to 4-hydroxyindoles (eq 3).[4] The ability of the reaction to form α-chloro ketones selectively has been further improved by the use of trimethylsilyl enol ethers as substrates.[5] Recently, phase-transfer conditions have been employed in a particularly difficult synthesis of RCH(Cl)C(O)Me selectively from the parent ketones (eq 4).[6]

(3)

(4)

$R = Me(CH_2)_n$, $n = 2\text{-}5, 8$

Chlorination of Aromatics.

Aromatic systems may be chlorinated by the reagent. For example, 9-chloroanthracene is prepared in high yield by heating anthracene and $CuCl_2$ in carbon tetrachloride (eq 5).[7] When the 9-position is blocked by a halogen, alkyl, or aryl group, the corresponding 10-chloroanthracenes are formed by heating the reactants in chlorobenzene.[8,9] Under similar conditions, 9-acylanthracenes give 9-acyl-10-chloroanthracenes as the predominant products.[10]

Polymethylbenzenes are efficiently and selectively converted to the nuclear chlorinated derivatives by $CuCl_2$/***Alumina*** (eq 6).[11]

(5)

(6)

Reactions with Alkoxy and Hydroxy Aromatics.

Hydroxy aromatics such as phenols and flavanones undergo aromatic nuclear chlorination with copper(II) chloride.[12] Thus heating 3,5-xylenol with a slight excess of the reagent in toluene at 90 °C gave a 93% yield of 4-chloro-3,5-xylenol (eq 7).[13] 2-Alkoxynaphthalenes are similarly halogenated at the 1-position.[14] Attempted reaction of $CuCl_2$ with anisole at 100 °C for 5 h gave no products; in contrast, it was found that alkoxybenzenes were almost exclusively *para*-chlorinated (92-95% *para*:0.5-3% *ortho*) using $CuCl_2/Al_2O_3$ (eq 8).[15] Anisole reacts with benzyl sulfides in the presence of equimolar $CuCl_2$ and ***Zinc Chloride*** to give anisyl(phenyl)methanes (*para:ortho* = 2:1, eq 9).[16,17]

(7)

(8)

(9)

Reactions with Active Methylene-Containing Compounds.

9-Alkoxy(or acyloxy)-10-methylanthracenes react with $CuCl_2$ to give coupled products (eq 10), while the analogous 9-alkoxy(or acyloxy)-10-benzyl(or ethyl)anthracenes react at the alkoxy or acyloxy group to afford 10-benzylidene(or ethylidene)anthrones (eq 11).[18] The reactions are believed to proceed via a radical mechanism.

(10)

(11)

Under similar conditions, 9-alkyl(and aryl)-10-halogenoanthracenes give products resulting from replacement of the halogen, alkyl, or aryl groups with halogen from the $CuCl_2$.[19] Boiling toluene reacts with $CuCl_2$ to yield a mixture of phenyltolylmethanes.[20]

Lithium enolates of ketones[21] and esters[22] undergo a coupling reaction with copper(II) halides to afford the corresponding 1,4-dicarbonyl compounds. Thus treating a 3:1 mixture of *t*-butyl methyl ketone and acetophenone with ***Lithium Diisopropylamide*** and $CuCl_2$ gives a 60% yield of the cross-coupled product (eq 12).

(12)

The intramolecular variant of this reaction producing carbocyclic derivatives has been reported.[23] Copper(II) chloride catalyzes the Knoevenagel condensation of 2,4-pentanedione with aldehydes and tosylhydrazones (eq 13).[24] The reagent also catalyzes the reaction of various 1,3-dicarbonyls with dithianes such as benzaldehyde diethyl dithioacetal to give the corresponding condensation products (eq 14).[25]

(13)

Catalyst for Conjugate Additions.

The catalytic effect of copper(II) chloride on the 1,4-addition of β-dicarbonyl compounds to (arylazo)alkenes[26,27] and aminocarbonylazoalkenes[28,29] has been studied in some detail. The reactions proceed at ambient temperature in THF and afford the corresponding pyrrole derivatives (eq 15). This mild method requires no other catalyst and succeeds with β-diketones, β-ketoesters, and β-ketoamides. Copper(II) chloride also catalyzes the addition of water, alcohols, phenol, and aromatic amines to arylazoalkenes (eq 16).[30]

Oxidation and Coupling of Phenolic Derivatives.

In the presence of oxygen, copper(II) chloride converts phenol derivatives to various oxidation products. Depending on the reaction conditions, quinones and/or coupled compounds are formed.[31] Several groups have examined different sets of conditions employing $CuCl_2$ to favor either of these products. Thus 2,3,6-trimethylphenol was selectively oxidized to trimethyl-*p*-benzoquinone with $CuCl_2$/amine/O_2 as the catalyst (eq 17),[32] while 2,4,6-trimethylphenol was converted to 3,5-dimethyl-4-hydroxybenzaldehyde using a catalytic system employing either acetone oxime or amine

(eq 18).[33,34]

(17)

(18)

The oxidation of alkoxyphenols to the corresponding quinones has been studied,[35] and even benzoxazole derivatives are oxidized by a mixture of copper(II) chloride and ***Iron(III) Chloride*** (eq 19).[36] A $CuCl_2/O_2$/alcohol catalytic system has been used for the oxidative coupling of monophenols.[37]

(19)

Copper(II) amine complexes are very effective catalysts for the oxidative coupling of 2-naphthols to give symmetrical 1,1´-binaphthalene-2,2´-diols.[38] Recent work has extended this methodology to the cross-coupling of various substituted 2-naphthols.[39,40] For example, 2-naphthol and 3-methoxycarbonyl-2-naphthol are coupled under strictly anaerobic conditions using $CuCl_2$/***t-Butylamine*** in methanol to give the unsymmetrical binaphthol in 86% yield (eq 20).

(20)

Other ligands such as methoxide are also effective; a mechanistic study indicates that the selectivity for cross- rather than homo-coupling is dependent upon the copper:ligand ratio.[41] A 1:1 mixture of 2-naphthol and 2-naphthylamine is cross-coupled with $CuCl_2$/benzylamine to give 2-amino-2´-hydroxy-1,1´-binaphthyl (68% yield, eq 21).[42] The cross-coupled products from these reactions are important in view of their use as chiral ligands for asymmetric synthesis.

(21)

Dioxygenation of 1,2-Diones.

1,2-Cyclohexanedione derivatives have been converted to the corresponding 1,5-dicarbonyl compounds by oxidation with O_2 employing copper(II) chloride as the catalyst.[43] More recently, $CuCl_2$-***Hydrogen Peroxide*** has been used to prepare terminal dicarboxylic acids in high yield.[44] While 1,2-cyclohexanedione afforded α-chloroadipic acid in 85% yield, 1,2-cyclododecanedione was converted to 1,12-dodecanedioic acid in 47% yield under identical conditions (eq 22).

(22)

Addition of Sulfonyl Chlorides to Unsaturated Bonds.

The addition of alkyl and aryl sulfonyl chlorides across double and triple bonds is catalyzed by copper(II) chloride.[45-51] The reaction appears to be quite general and proceeds via a radical chain mechanism. The 2-chloroethyl sulfones produced in the reaction with alkenes undergo base-induced elimination to give vinyl sulfones (eq 23).[45-48] 1,3-Dienes similarly react, yielding 1,4-addition products (eq 24) which may be dehydrohalogenated to 1,3-unsaturated sulfones.[45,49]

(23)

(24)

The stereoselectivity of the addition to alkynes can be controlled by varying the solvent or additive, and thus favoring either the *cis* or *trans* β-chlorovinyl sulfone.[50,51] For example (eq 25), when benzenesulfonyl chloride is reacted with phenylacetylene in acetonitrile with added triethylamine hydrochloride, the *trans*:*cis* ratio is 92:8, while the same reaction performed in CS_2 without additive favors the *cis* isomer (16:84).

Acylation Catalyst.

N-Trimethylsilyl derivatives of (+)-bornane-2,10-sultam (Oppolzer's chiral sultam) and chiral 2-oxazolidinones (the Evans chiral auxiliaries) are *N*-acylated with a number of acyl chlorides including acryloyl chloride in refluxing benzene in the presence of $CuCl_2$.[52] The *N*-acylated products were prepared in high yields; the method does not require an aqueous workup, making it advantageous for large-scale preparations.

Racemization Suppression in Peptide Couplings.

A mixture of copper(II) chloride and ***Triethylamine*** catalyzes the formation of peptide bonds.[53] Furthermore, when used as an additive, $CuCl_2$ suppresses racemization in both the carbodiimide[54] and mixed anhydride[55] peptide coupling methods. Recently it was shown that a combination of ***1-Hydroxybenzotriazole*** and $CuCl_2$ gives improved yields of peptides while eliminating racemization.[56,57]

Reaction with Palladium Complexes.

π-Allylpalladium complexes undergo oxidative cleavage with copper(II) chloride to form allyl chlorides with the concomitant release of $PdCl_2$ (eq 26).[58]

This methodology has been used in the dimerization of allenes to 2,3-bis(chloromethyl)butadienes.[59] 1,5-Bismethylenecyclooctane was transformed into the bridgehead-substituted bicyclo[3.3.1]nonane system using $CuCl_2$/HOAc/NaOAc, while the same substrate produced bicyclo[4.3.1]decane derivatives (eq 27) with a ***Palladium(II) Chloride***/$CuCl_2$ catalytic system.[60]

(27)

While reaction of a steroidal π-allylpalladium complex with AcOK yields the allyl acetate arising from *trans* attack, treatment of a steroidal alkene with $PdCl_2/CuCl_2$/AcOK/AcOH gave the allyl acetate arising from *cis* attack.[61]

Reoxidant in Catalytic Palladium Reactions.

Copper(II) chloride has been used extensively in catalytic palladium chemistry for the regeneration of Pd^{II} in the catalytic cycle. In particular, the reagent has found widespread use in the carbonylation of alkenes,[62-64] alkynes,[65] and allenes[66,67] to give carboxylic acids and esters using $PdCl_2/CuCl_2$/CO/HCl/ROH, and in the oxidation of alkenes to ketones with a catalytic $PdCl_2/CuCl_2/O_2$ system (the Wacker reaction).[68] The $PdCl_2/CuCl_2$/CO/NaOAc catalytic system has been used in a mild method for the carbonylation of β-aminoethanols, diols, and diol amines (eq 28).[69]

(28)

Cyclopropanation with $CuCl_2$-$Cu(OAc)_2$ Catalyst.

Ethyl Cyanoacetate reacts with alkenes under $CuCl_2$-***Copper(II) Acetate*** catalysis to give cyclopropanes.[72] Thus heating cyclohexene in DMF (110 °C, 5 h) with this reagent combination gives a 53% yield of the isomeric cyclopropanes. The reaction also proceeds with styrene, 1-decene, and isobutene. Byproducts formed from the addition to the alkene are removed with ***Potassium Permanganate***.

Copper(I) Chloride[1]

CuCl

[7758-89-6] · ClCu · Copper(I) Chloride · (MW 99.00)

(catalyst for diazo and diazonium chemistry; for use with Grignard reagents[1])

Alternate Name: cuprous chloride.

Physical Data: mp 430 °C; *d* 4.140 g cm^{-3}.

Solubility: insol H_2O and most organic solvents; partially sol dimethyl sulfide (DMS).

Form Supplied in: light green-tinged white solid; 99.99% grade available commercially.

Handling, Storage, and Precautions: maintenance of a dry N_2 or Ar atmosphere is recommended.

General Discussion.

Copper(I) chloride is the most popular Cu^I salt for use in many of the classic name reactions of organic chemistry.[1a] Examples include the Sandmeyer reaction,[1b] the CuCl induced decomposition of arenediazonium salts to afford aryl chlorides,[2] and the related Bart reaction[1c] of arenediazonium salts with sodium metaarsenite to yield arylarsonic acids,[3] which is also catalyzed by CuCl. Kochi has elucidated the mechanisms of the Sandmeyer reaction and the Meerwein reaction[1d] of arenediazonium salts with alkenes and established that they proceed via a common radical intermediate which could be generated from other precursors.[4] Nagashima et al. took advantage of this fact when they cyclized an *N*-allyltrichloroacetamide derivative with CuCl,[5] in what is a significant extension and generalization of the Meerwein reaction (eq 1).

(1)

α-Diazo ketones with aryl substituents in the β´- or γ´-positions are decomposed by CuCl to give cyclized products. For example, Scott has reported an azulene synthesis starting from 3-phenylpropanoic acid,[6] and Iwata et al. have developed a spiroannulation method for phenolic α-diazo ketones,[7,8] as illustrated in eq 2 by the synthesis of α-chamigrene.[7] Many other examples[1e] of intramolecular reactions of diazo carbonyl compounds are known in an area that was pioneered by Stork,[9] who used ***Copper Bronze***. CuCl has also been used to catalyze cyclopropanations with ***Diazomethane***,[10] and with diazoacetic esters.[1f] It should be noted that CuI, CuBr, and CuCN have also been used to catalyze the reactions of diazo compounds, as have Cu^0 and Cu^{II}.[1e,f,9]

(2)

The Gattermann-Koch synthesis of aromatic aldehydes involves a Friedel-Crafts formylation by ClCHO in the presence of ***Aluminum Chloride*** and CuCl catalysts.[1g,11] The reaction proceeds without Cu, but at much higher pressures.[1g]

The Glazer reaction couples terminal alkynes by using dioxygen and CuCl, usually in the presence of ammonia or another amine (pyridine, $EtNH_2$).[1h] Many examples are known; eq 3 shows an example in the overlapping areas of medium-sized ring formation and annulene chemistry.[12] A related reaction mixture which uses pyridine instead of ammonia oxidatively cleaves 1,2-diaminobenzene to *cis,cis*-muconononitrile,[13a] and phenanthrenequinone to 2,2´-biphenyldicarboxylic acid.[14a] It also oxidizes the bishydrazones of α-diketones to alkynes and the monohydrazones to α-diazo ketones.[13b] 1,10-Phenanthroline has been used in conjunction with CuCl and dioxygen to oxidize alcohols to ketones or aldehydes.[14b]

(3)

Marino has reported that cyclic α,β-unsaturated epoxides react with Cu carboxylates, generated in situ from Na carboxylates and CuCl, to give *syn*-1,4-diol derivatives.[15a] Goering has shown that allyl pivalates give α-alkylation with inversion of configuration with Grignard reagents catalyzed by CuCl, but (*anti*) γ-alkylation with ***Copper(I) Cyanide*** as catalyst.[15b]

Kharasch discovered that CuCl catalyzes the coupling of aryl Grignard reagents with aryl halides,[16a] and also the 1,4-addition of Grignard reagents to α,β-unsaturated ketones.[16b] While the former has been called the Kharasch reaction,[1i] today the latter is much more important synthetically,[1i-k] and it should be named for its inventor, who was one of the true pioneers in the synthetic applications of transition metals. One way to avoid confusion would be to call the reagent prepared from a Grignard reagent and a Cu^I salt a (catalytic or stoichiometric) Kharasch Reagent by analogy with the commonly used Gilman Reagent, which is synonymous with cuprate prepared from 2 equiv of lithium reagent and a Cu^I salt.

While ***Copper(I) Iodide***, CuBr.DMS (see ***Copper(I) Bromide***), and CuCN are now used more commonly than CuCl in the preparation of organocopper reagents, there are still interesting examples which utilize CuCl. For example, the addition of BuMgBr to sorbate esters gives a mixture of 1,2- and 1,4-addition products; however, upon the addition of CuCl, 1,6-addition predominates.[17] This example also illustrates one of the problems commonly encountered when trying to interpret the results of experiments using the Kharasch reagent. Experimenters frequently mix a Grignard reagent containing one halide with a Cu^I salt containing another. CuBr.DMS has also been shown to dramatically favor 1,6-addition of Grignard reagents (see ***Copper(I) Bromide***).

Tandem organocuprate β-addition to α,β-unsaturated carbonyl compounds followed by α-alkylation, acylation or other functionalization of the regiospecifically generated α-enolate has become an important methodology.[1j,k] In what has been described as the first one-pot, three-component tandem vicinal difunctionalization reaction,[1j] Stork used CuCl to catalyze the 1,4-addition of *m*-methoxyphenylmagnesium bromide to 5,5-dimethylcyclohex-2-en-1-one, followed by α-alkylation with allyl bromide,[18] which was the seminal step in the synthesis of lycopodine. Bunce and Harris have recently combined β-addition with *intramolecular* α-acylation in a tandem conjugate addition-Dieckmann condensation reaction, which was used to prepare six-membered rings (eq 4).[19] It is interesting to note that the Stork

conditions (RMgBr/CuCl) gave better results than the Gilman reagents prepared from 2 equiv of the corresponding Li reagent and either CuI or CuCN.[19]

(4)

CuCl has been directly compared with CuBr, CuBr.DMS, CuI, CuCN, and ***Copper(I) Trifluoromethanesulfonate*** as a precursor for Gilman reagents,[20] and it appears to be inferior to the usual Cu^{I} salts for this important class of compounds. It was found early on that Cu^{II} salts catalyze many of the same organic reactions as the corresponding Cu^{I} salts,[1] e.g. a popular catalyst for coupling reactions with Grignard reagents is ***Dilithium Tetrachlorocuprate(II)*** = $CuCl_2$ + 2LiCl.[1i-l] It is generally assumed that the Cu^{II} salt is reduced to Cu^{I} under the reaction conditions; however, in most cases this has not been proven.

Along with CuBr and CuBr.DMS, CuCl continues to be a favored precursor for structural work and the preparation of new organocopper derivatives. For example, π-complexes between nonconjugated dienes and CuCl or CuBr have been characterized by X-ray crystallography.[21] Chaudret et al. have shown that $(C_5Me_5)Ru(PCy_3)H_3$ reacts smoothly with CuCl to give $(C_5Me_5)Ru(PCy_3)H_3CuCl$,[22] which was of interest in relation to the proposal that trihydrogen ligands might exist. In these two cases the product still contains the Cl atom. Many interesting examples exist where it does not (see below). A study illustrating both Cl-containing and Cl-free products is provided by Zybill and Müller, who reacted hexaphenylcarbodiphosphorane with CuCl to form a 1:1 adduct, which they reacted further with $[C_5Me_5]^-$ to yield $(C_5Me_5)CuC(PPh_3)_2$.[23]

Both dinuclear and tetranuclear Cu alkyl complexes have been prepared from CuCl and 2-substituted pyridines containing bis(trimethylsilyl)methyl and trimethylsilylmethyl substituents, respectively.[24] $MeCu(PPh_3)_3$ has been prepared and studied by NMR and X-ray crystallography;[25] such phosphine-complexed organocopper reagents have proven useful for organic synthesis. Several copper(I) cupracarboranes have been synthesized, including an interesting trimer.[26] (Trimers are much less common than tetramers in Cu^{I} chemistry.[27]) In a most incredible communication, Fenske et al. characterize the brobdingnagian product of the reaction 146 CuCl + 73 $Se(SiMe_3)_2$ + 30 PPh_3 -> $Cu_{146}Se_{73}(PPh_3)_{30}$ + 146 $ClSiMe_3$.[28]

One of the most interesting arylcopper(I) compounds is mesitylcopper(I),[29] which is a pentamer in the solid state and a tetramer in the presence of S-ligands.[30] It has recently been shown to split dioxygen,[31] and is highlighted here because it is prepared from CuCl. Hexafluoroacetylacetonatocopper(I)-alkyne complexes (prepared from CuCl) have been shown to be useful in the chemical vapor deposition of Cu metal.[32] (*E*)-1-Trimethylsilyl-1-alkenes have been prepared in high yields by the CuCl-catalyzed decomposition of α-trimethylsilyldiazoalkanes.[33] Finally, Indian chemists have shown that 1,2-diketones are produced in good yield when $Na(RCO)Fe(CO)_4$ is treated with CuCl.[34]

(carbonyl deprotection reagent; allows transformation of thioacetals, α-heterosubstituted sulfides, and selenoacetals to aldehydes or ketones)

Solubility: sol aq acetone, alcohols, THF, MeCN.

Form Supplied in: both components are commercially available solids.

Introduction.

The combination reagent $CuCl_2$-CuO, originally introduced by Mukaiyama for the hydrolysis of 1,3-dithiane derivatives to carbonyl compounds,[3] also proved to be valuable for the hydrolysis of α-heterosubstituted sulfides and vinyl sulfides to carbonyl compounds.[1] It provides an interesting alternative to other methods.[1,2,4] The reaction occurs under mild conditions; the presence of copper oxide prevents the medium from becoming too acidic.[1] It delivers disulfides[5,6] as byproducts besides the desired carbonyl compounds.

The reactions are usually carried out in wet acetone (1%) or in aqueous or anhydrous alcohols (usually MeOH or EtOH)[3] at 20 °C or at reflux temperature. In the latter case, the alcohol can be involved in the transformation[6,7] (see eq 10). A higher percentage (10%) of water proved, in one specific case, important in order to avoid side reactions (eq 2).[8] Acetonitrile, as well as THF, can be used as solvent but proved, at least in one case, less efficient.[3]

Transformation of Thioacetals and Selenoacetals to Aldehydes or Ketones.

The reaction has been successfully achieved with cyclic thioacetals such as 1,3-dithiolanes,[9] 1,3-dithianes (eq 1),[3,10-12] α,α-bis(alkylthio)alkanes,[13] α,α-bis(phenylthio)alkanes,[14] and 1,5-dihydro-2,4-benzodithiepins (eq 2).[8] The nature of the protecting group does not seem to affect the rate of the reaction, which is usually fast (20 °C or reflux, 0.5-2 h). It has been performed on several functionalized thioacetals including β,γ-unsaturated,[13] γ-keto,[15] and α-hydroxy derivatives.[15]

(1)

This reaction, coupled with the transformation of cyclic *O,O*-acetals to the corresponding 1,3-dithianes (***1,3-Propanedithiol***, ***Boron Trifluoride Etherate***, CH_2Cl_2, 0 °C), has been used to deprotect cleanly δ-keto acetals to δ-keto aldehydes without affecting the chiral center α to the aldehyde group (eq 3).[12]

(3)

Selenoacetals derived from both the methylseleno and phenylseleno series,[16] including functionalized examples,[15,17,18] have been readily transformed to the corresponding aldehydes or ketones with $CuCl_2$-CuO (eq 4). These conditions proved as effective as those involving seleninic acid.[16]

(4)

Transformation of Other α-Heterosubstituted Sulfides to Carbonyl Compounds.

α-Chloro sulfides are efficiently transformed to aldehydes[19-21] and ketones[22-24] on reaction with $CuCl_2$-CuO (eq 5). This includes the synthesis of polyfunctionalized carbonyl compounds such as α-diketones,[23,25] α-keto aldehydes,[20] and β-keto esters.[26] Particularly interesting is the one-pot transformation of ketones to α-diketones (eq 5),[23,25] which takes advantage of the in situ oxidation of intermediate α-thioketones to α-thio-α-chloro ketones by $CuCl_2$.[25]

(5)

2-Phenylthiotetrahydropyrans and 2,2-bis(alkylthio)tetrahydropyrans have been transformed, on reaction with $CuCl_2$-CuO, to 2-hydroxytetrahydropyrans[27] and to the corresponding six-membered lactones,[28] respectively (eqs 6 and 7). The latter strategy proved better by far in producing the six-membered lactones than the one implying oxidation of initially formed 2-hydroxytetrahydropyrans with Jones' reagent.

(6)

(7)

Transformation of Vinyl Sulfides and Related Derivatives.

$CuCl_2$-CuO also promotes the transformation of vinyl sulfides and related derivatives to aldehydes or ketones.[1] The reaction takes another course with 3-methylthio-[29] and 3-hydroxy-1-thio-1-alkenes,[5,30] which lead instead to α,β-unsaturated aldehydes and ketones (eq 8). The intermediate formation of a β-hydroxycarbonyl compound is not observed, and the entire conjugated system is involved in the transformation.

(8)

1-Alkoxy-3-thioalkyl-1-alkenes, which bear the thio substituent at the allylic position, have also been successfully transformed to α,β-unsaturated aldehydes and ketones using the same reagent (eq 9).[31] The reaction is easier with those derivatives that produce aldehydes rather than ketones, as in these cases the reaction mixture does not require heating.[31]

(9)

Ketene thioacetals are usually transformed into esters, provided that the reaction is performed in alcohols, and 1,1-bis(methylthio)allenes are converted to α,β-unsaturated esters (eq 10).[6]

(10)

Finally, $CuCl_2$-CuO in alcohol promotes the transformation of thioisoxazoles to aldehydes[32] and of alkyl dithioesters to methyl or ethyl esters.[7,14,33] The former reaction requires an additional reduction step (1. Al/Hg; 2. $CuCl_2$-CuO). Remarkably, this reagent allows the synthesis of β-hydroxy esters bearing a chiral α-carbon without affecting the α-chiral center and without the loss of water, which would have produced the corresponding α,β-unsaturated ester.[7]

Synthetic Uses.

The transformation of thioacetals to their corresponding carbonyl compounds is valuable in synthesis. It allows the formation of carbonyl compounds via acyl anion equivalents using 1-metallo-1,1-dithioalkanes (eqs 1 and 2).[1] Other important examples include the aldol condensation involving metallo-dithioesters,[7] which exhibits very high facial stereoselectivity (>99:1) and high simple diastereoselectivity (95:5), and the version of the thio-Claisen rearrangement which allows the very stereoselective synthesis of (*E*)-trisubstituted double bonds (eq 11).[14] It is therefore important that the conditions involved for the transformation of the thio moiety to the carbonyl compound do not interfere with the other functional groups present in the molecule.

Chemoselectivity.

Even under the mild conditions used in carbonyl group generation, $CuCl_2$-CuO deprotects THP (eq 1)[11] and ethoxyethyl (eq 2)[34] ether-protected alcohols and leads to diols from benzylidenedioxy compounds (eq 2).[34] This feature has been successfully applied to the direct synthesis of the dioxaspiro[5.5]undecanes shown in eq 2. It allows, under suitable conditions, the concomitant acetalization of ketones.[33] However, this reagent does not promote (a) cyclization of 1,4-diketones to α-enones from γ-keto-α,α-bis(thio)alkanes;[14] (b) the retro-aldol reaction of the intermediate β-hydroxy ketone shown in eq 2 (provided that 10% water is used instead of 1%), which would have produced the (4*S*,6*R*) rather than the expected (4*S*,6*S*) stereoisomer;[8,34] (c) epimerization at the α-position of an aldehyde,[12] a ketone,[12] an ester,[7] or a dithio ester;[7] (d) the (*Z*) to (*E*) or (*E*) to (*Z*) isomerization of C=C double bonds (eq 11);[14] or (e) conjugation of the C=C double bond in β,γ-unsaturated aldehydes[21] and ketones.[35]

[7782-44-7] · O_2 · Copper(I) Chloride-Oxygen · (MW 32.00)

(oxidation of alcohols,[2] amines,[6] alkenes;[7] oxidative coupling;[1] allylic oxidation;[9] oxidative cleavage;[1] oxidative dealkylation;[22] Ullmann reaction[23])

Physical Data: see ***Copper(I) Chloride***.

Solubility: sol ether, HCl, TMEDA, and NH_4OH; sl sol cold water; insol alcohol and nonpolar solvents.

Form Supplied in: O_2 is widely available as cylinders of compressed gas. CuCl is also commercially available.

Handling, Storage, and Precautions: strong oxidant. Appropriate precautions for handling of combustible compressed gases should be taken. Use in a fume hood.

Oxidation of Alcohols.

Various oxidation systems have been used to synthesize aldehydes from alcohols. In the presence of ***Copper(I) Chloride*** in pyridine, alcohols can be oxidized by molecular ***Oxygen*** to give aldehydes or ketones.[2] High yields of aldehydes or ketones are obtained when 1,10-phenanthroline is used instead of pyridine (eq 1). Under this CuCl/amine/O_2 system, 1,10-phenanthroline is more effective and allows benzylic and allylic alcohols to be oxidized much faster than aliphatic alcohols.[3]

(1)

CuCl, pyridine	36%
CuCl, 1,10-phenanthroline	86%

In the presence of a catalytic mixture of copper(I) chloride and the radical reagent ***2,2,6,6-Tetramethylpiperidin-1-oxyl*** (TEMPO), secondary alcohols are preferred over primary alcohols in their oxidation by oxygen to yield the corresponding ketones. Overoxidation is not observed, as benzylic and allylic alcohols yield aldehydes (eqs 2 and 3). However, electron-withdrawing groups attached to the aryl ring in benzylic alcohols tend to retard the reaction.[4]

An oxidation system composed of a transition metal ($M^0 = Fe^0$ or Cu^0), a transition metal ion ($M^{n+}Cl_n = FeCl_2$ or CuCl) in catalytic amounts, and molecular oxygen oxidizes (hydroxymethyl)phenols to give the corresponding salicylaldehydes (eq 4).[5]

Oxidation of Phenols.

Selectivity in copper-amine catalyzed phenol oxidations is controlled by a number of factors: substituent effects, solvent effects, and stability of phenoxy radicals. Oxidative coupling of 2,6-disubstituted phenols occurs in two ways, depending on the size of the substituent group on the benzene ring. When the substituent groups are small, carbon-oxygen coupling occurs and poly-2,6-disubstituted 1,4-phenylene ethers (**2**) are obtained. However, the presence of bulky groups allows the synthesis of 3,3,5,5-tetrasubstituted diphenoquinones (**3**) to occur through carbon-carbon coupling (eq 5).[6]

(5)

Selective phenol oxidation by oxygen may occur, depending on the type of solvent used. Synthesis of *t*-butyl-*p*-benzoquinone from *t*-butyl hydroquinones (eq 6) occurs in the presence of copper(I) chloride in pyridine, whereas 2-*t*-butyl-6-hydroxy-*p*-benzoquinone is synthesized in the presence of copper(I) chloride in a secondary amine such as piperidine, morpholine, dipropylamine, or 2,6-dimethylpiperidine (eq 7).[7]

(6)

(7)

Regarding stability of the phenoxy radical, selectivity can be achieved in the oxidation of 2,6-diphenyl-4-methoxyphenol by oxygen in the presence of copper(I) chloride (eq 8). The resulting product would be a dimeric quinone acetal (or 4-methoxy-2,6-diphenylphenoxyl) in high yield, obtained through an oxygen-stable radical.[8]

Oxidation of Amines.

Under an oxygen atmosphere, copper(I) chloride in pyridine converts amines to the corresponding nitriles (eq 9) or aldehydes (eq 10).[9] However, low yields prompted the modification of this reaction system by (a) increasing the reaction temperature (from rt to 60 °C), (b) adding molecular sieves, and (c) changing the order of addition of the reactants. This improved, extended method gives high yields of aliphatic or aromatic nitriles (eq 11).[10]

(9)

(10)

(11)

R = aliphatic or aromatic

Oxidation of Alkenes.

In the presence of a catalyst, copper(I) chloride, and ***Palladium(II) Chloride*** in aqueous DMF, terminal alkenes are oxidized by oxygen to methyl ketones (eq 12).[11]

(12)

Allylic Oxidation.

Synthesis of α,β-unsaturated ketones via copper-catalyzed allylic oxidation is possible. In the presence of copper(I) chloride, valencene was oxidized by molecular oxygen in the dark to nootkatone (eq 13). ***Iron(II) Sulfate***, $NiSO_4$, $ZnSO_4$, ***Copper(II) Sulfate*** and $MnSO_4$ are among other catalysts that have been used in allylic oxidation under an oxygen atmosphere.[12]

(13)

Oxidative Cleavage of Diols.

A copper-catalyzed oxidation system involving oxygen/copper(I) chloride in a mixture of pyridine and alcohol is able to cleave catechols to monoesters of *cis,cis*-muconic acid (eq 14).[13]

(14)

Oxidative Cleavage of Hydrazones.

Alkynes can be synthesized in high yields from dihydrazones of α-diketones via oxidation under an oxygen atmosphere in the presence of copper(I) chloride in pyridine at room temperature (eq 15). The monohydrazone of benzil can be dehydrogenated to produce azibenzil in high yield (eq 16).[14]

(15)

(16)

Oxidative Cleavage of Diamines and Diketones.

Various oxidizing reagents, for example ***Nickel(II) Peroxide***, ***Lead(IV) Acetate***, and ***Silver(I) Oxide*** in stoichiometric quantities, have limited effectiveness in the oxidation of these substrates, producing less than 50% yields of the projected oxygenation products. However, under an oxygen atmosphere, *o*-phenylenediamine undergoes oxidative cleavage in the presence of copper(I) chloride in pyridine to yield *cis,cis*-muconononitrile (eq 17).[15]

(17)

Diketones can also be oxidatively cleaved to dicarboxylic acids, as in the oxidation of phenanthrenequinone to 2,2´-biphenyldicarboxylic acid in high yield (eq 18).[16]

(18)

Oxidative Coupling of Ethynyl Compounds.

Under Glaser conditions, ethynyl compounds dissolved in polar, protic solvents are oxidatively coupled by oxygen (or air) in the presence of a catalytic mixture of copper(I) chloride and ammonium chloride in water (eq 19).[17a] This coupling reaction has been applied to ethynyl-bearing carbinols,[18] aliphatic[17b] and aromatic hydrocarbons,[17c] thiophenes,[17d] esters,[17e] acids,[17f] ethers,[17g] nitriles,[17h] enynes,[17i] alleneynes,[17j] α-diynes,[17k] triynes,[17l] and tetraynes.[17m]

(19)

Under Hay conditions, tertiary amines complexed with copper(I) chloride are effective catalysts in the oxidative polymerization of 2,6-disubstituted phenols with molecular oxygen to produce high molecular weight polyarylene ethers (eq 20). Tertiary amines such as ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) are preferred due to their ability to solubilize copper salts in nonpolar solvents such as benzene.[18]

(20)

Even though Glaser conditions are applicable to a wide range of substrates, limitations exist when comparisons to Hay conditions are made. For example, unsymmetrical coupling[19b] and oxidative cleavage of heterocyclic alkynes[20] will work under Hay conditions, but not under Glaser conditions. Yet, symmetrical coupling[19a] is possible under both conditions.[1]

Oxidative Coupling of Activated Methine Compounds.

In the presence of copper(I) chloride in TMEDA, there occurs oxidative carbon-carbon coupling of compounds containing activated CH, CH_2, or CH_3 groups that can complex with the copper catalyst. An example is the oxidation of methyl *p*-tolylcyanoacetate to 1,2-bis(methoxycarbonyl)-1,2-dicyano-1,2-di-*p*-tolylethane (eq 21).[21]

(21)

Oxidative Dealkylation.

4-Substituted *N*,*N*-dimethylanilines undergo oxidative dealkylation in the presence of the catalyst copper(I) chloride and acetic anhydride under an oxygen atmosphere to give the corresponding *N*-methylacetanilides and *N*-methylformanilides (eq 22).[22]

(22)

Ullmann Reaction.

Haloanthraquinones undergo Ullmann condensation reactions in the presence of amines in aprotic solvents under an oxygen atmosphere to form other derivatives (eq 23). In this particular reaction, chloromethoxycopper(II) (prepared in situ from the partial oxidation of copper(I) chloride with oxygen in methanol (eq 24)) increases the rate of reaction by increasing the catalytic activity of copper(I) chloride.[23]

$$4\ CuCl + O_2 \xrightarrow{MeOH} 4\ CuCl(OMe) + 2H_2O \qquad (24)$$

Copper(I) Chloride-Sulfur Dioxide

$CuCl.SO_2$

(CuCl)

[7758-89-6] · ClCu · Copper(I) Chloride-Sulfur Dioxide · (MW 99.00) (SO_2)

[7446-09-5] · O_2S · Copper(I) Chloride-Sulfur Dioxide · (MW 64.06)

(reagent for the preparation of arenesulfonyl chlorides from arenediazonium ions[1])

Physical Data: see entries for ***Copper(I) Chloride*** and ***Sulfur Dioxide***.

Form Supplied in: individual reagents commercially available; mixture is normally prepared in glacial acetic acid.

Preparative Methods: for a reaction of typical scale, glacial acetic acid (600 mL) is placed in a 4000 mL beaker and stirred magnetically. Sulfur dioxide is delivered from a cylinder through a bubbler tube with a fritted glass end immersed beneath the surface of the acetic acid. Introduction is continued for 15-30 min until saturation is evidenced by the fact that most of the SO_2 bubbles reach the surface of the acetic acid. Copper(I) chloride (15 g) is added to the solution, and the introduction of sulfur dioxide is continued until the yellow-green suspension becomes blue-green and most of the solids dissolve (20-30 min). The mixture is placed in an ice bath until use.

Handling, Storage, and Precautions: mixtures of copper(I) chloride and sulfur dioxide should be prepared immediately before use. The saturated SO_2 solution is noxious and must be prepared and used in a fume hood. Sulfur dioxide is intensely irritating to the eyes and respiratory tract.

Arenesulfonyl Chlorides.

A mixture of copper(I) chloride and sulfur dioxide is very effective in converting arenediazonium ions to arenesulfonyl chlorides (eq 1).[1] The diazonium solution is added slowly to the cooled copper(I) chloride-sulfur dioxide mixture and a normally vigorous evolution of nitrogen occurs with formation of the sulfonyl chloride. The original literature[2] recommends copper(II) chloride as the copper source which is reduced in situ to copper(I) chloride, the active catalyst. More recently, it has been found that the use of copper(I) chloride in the above procedure is superior in reproducibly providing active catalytic mixtures.[1,3]

$$ArN_2^+Cl^- \xrightarrow[MeCO_2H]{CuCl,\ SO_2} ArSO_2Cl + N_2 \qquad (1)$$

A wide variety of aromatic amines can be converted to aromatic sulfonyl chlorides via their diazonium salts by this method. Some examples are collected in Table 1. In addition, a group of fluorinated arenesulfonyl chlorides have been prepared by the same method.[4] In general, aromatic amines with electron-withdrawing substituents give the best results. For aromatic amines with electron-donating substituents, yields can be improved by the addition of magnesium chloride, which serves to raise the chloride concentration.[2] This method for the preparation of arenesulfonyl chlorides is simple and straightforward compared to alternate methods such as aromatic substitution by ***Chlorosulfonic Acid*** or oxidation of aromatic thiols with ***Chlorine*** water.

Table 1 The Conversion of Aromatic Amines to Arenesulfonyl Chlorides

Copper Chromite[1]

$$2CuO \cdot Cr_2O_3$$

[12053-18-8] · $Cr_2Cu_2O_5$ · Copper Chromite · (MW 311.10)

(hydrogenation catalyst for many functional groups;[3] decarboxylation;[4] dehydrogenation[5])

Alternate Name: Adkins or Lazier catalyst.[2]

Solubility: insol organic solvents; practically insol water and dilute acids; reactions are typically carried out in ethanol, dioxane, ether, methylcyclohexane or without solvent.

Form Supplied in: fine black powder; the best catalysts contain ca. 10% barium oxide.

Preparative Methods: although commercially available, the original preparations are often referenced in the literature.[6]

Handling, Storage, and Precautions: stable to air and moisture; care should be taken to avoid skin contact and inhalation since chromium and barium compounds are highly toxic.

Hydrogenation.[1]

The main use of copper chromite is as a hydrogenation catalyst, especially in the reduction of oxygen-containing functionality. The reactions are generally carried out at high temperatures (100-300 °C) and high pressures (40-375 atm compressed at rt), limiting the catalyst's use to robust and/or lightly functionalized molecules. Many of the possible functional group reductions may be easier to carry out using metal hydrides such as ***Lithium Aluminum Hydride*** or ***Sodium Borohydride*** under milder conditions. However, the yields of copper chromite-catalyzed hydrogenations are often high and may be well suited to large scale preparations of simple intermediates.

At the high temperatures involved in the hydrogenations, side reactions with solvent need to be considered; ethanol, for example, can behave as an alkylating agent of amines, amides may undergo alcoholysis, and esters transesterification. Consequently it may be advantageous to perform some reactions neat.

Carbonyl Compounds.

Aldehydes and ketones are amongst the easiest functional groups to hydrogenate, giving primary and secondary alcohols, respectively. However, at higher temperatures further reduction to the hydrocarbons may occur if the

alcoholic product is activated in some way (eq 1).[7] Alkenes in the molecule may also be reduced under the reaction conditions.[8] A study of the competitive hydrogenation of aldehydes, ketones, and alkenes has been published[9] and alkene reduction in the presence of cyclopropyl rings has also been reported.[10] The *cis* and *trans* stereoisomers from the reduction of 2-hydroxycyclodecanone have been separated by fractional crystallization (eq 2).[11]

(1)

(2)

The hydrogenation of esters yields the expected primary alcohols and this reaction has been reviewed.[12] Lactones give the corresponding diols (eq 3).[13] Alkenes in the molecule will also be reduced[14] but amides may be left intact since they generally require much higher temperatures before reduction takes place (eq 4).[15]

(3)

(4)

Amides[16] will react at high temperature (usually above 200 °C) and pressure to give amines (eq 5).[17] Nitro groups also give amines.[3] Glutaramides have been shown to cyclize to piperidines upon reduction[18] and indolizidines have been prepared in a similar way (eq 6).[19] Nitriles react when carbonyl groups are present in the same molecule to give cyclic amines[20] and lactams (eq 7).[21]

(5)

(6)

(7)

Aromatic Compounds.

In some cases, selective hydrogenation of aromatic nuclei can be achieved. Saturation of the 9,10-double bond of phenanthrene is possible with careful monitoring of the hydrogen uptake to prevent over-reduction.[22] Heteroaromatics are also partially reduced over copper chromite, where ***Raney Nickel*** is unselective (eq 8).[23] At 300 °C, total reduction of 2-methyl-2,3-dihydrobenzofuran to propylcyclohexane was observed in 96% yield.[24]

(8)

Hydrogenolysis.

Amines can be hydrogenolyzed to the corresponding methyl compounds (eq 9),[25] as can the benzyl alcohols.[26] Some cyclic ethers also show carbon-oxygen bond cleavage (eq 10).[27]

(9)

(10)

Decarboxylation of Aromatic Compounds.

Copper chromite has been used, usually in the presence of ***Quinoline***, as a decarboxylating reagent for aromatic compounds. Yields can be high for simple substrates[4] and a decarboxylation-aromatization has been reported (eq 11).[28] Some fairly sensitive molecules can survive the reaction conditions, including nitrile pyrroles[29] and isothiazoles (eq 12).[30] Copper chromite-catalyzed hydrogenation of *o*-acylbenzoic acid to *o*-ethylbenzoic acid was accomplished by first forming the sodium salt.[31] See also ***Copper Chromite-Quinoline***.

Dehydrogenation of Alcohols.

A few examples of copper chromite acting as a dehydrogenating agent are known.[32] Alcohols can be oxidized to ketones (eq 13)[5] and diols to lactones, presumably via the lactols (eq 14).[33] Dehydration following dehydrogenation has also been observed (eq 15).[34] Copper chromite can be activated prior to use in hydrogenation reactions by heating at reflux in cyclohexanol for 4 h, during which time cyclohexanone is formed.[5]

(14)

(15)

Other Reactions.

More unusual reactions mediated by copper chromite include carbon-carbon bond hydrogenolysis (eq 16);[35] oxidation of a carbon-hydrogen bond α to a ketone;[36] a ring contraction to give thiophenes (eq 17);[37] and a one pot conversion of β-amino alcohols to α-methyl ketones (eq 18),[38] a reaction which proceeds mechanistically via alcohol dehydrogenation, amine elimination, and resultant double bond hydrogenation.

Copper Chromite-Quinoline

[12053-18-8] · $Cr_2Cu_2O_5$ · Copper Chromite-Quinoline · (MW 311.07)

[91-22-5] · C_9H_7N · Copper Chromite-Quinoline · (MW 129.16)

(decarboxylation catalyst)

Physical Data: see the entries for ***Copper Chromite*** and ***Quinoline***.

Form Supplied in: both components are widely available. The frequently-used barium-promoted copper chromite contains varying amounts (ca. 10%) of BaO.

Preparative Methods: see the entries for the individual components.

Handling, Storage, and Precautions: the copper chromite catalyst is air- and moisture-stable; however, it should be kept as dry as possible to avoid spattering at elevated temperatures. Both reagents are toxic irritants and should be handled in a well-ventilated fume hood.

Copper Chromite (chromium copper oxide) has long been used, both industrially and in the academic laboratory, as a catalyst for hydrogenation and other reductions, but has been supplanted in recent years by the development of hydrides and other reducing agents.

Decarboxylation.

Quinoline is a favorable solvent for the decarboxylation of unsaturated carboxylic acids with ***Copper*** powder, $Cu_2Cr_2O_5$, and similar catalysts, as it forms the requisite carboxylate anion while providing a relatively low-boiling reaction medium;[1a-b] most reactions are performed at reflux between 170-200 °C. Both anhydrous $Cu_2Cr_2O_5$ and its barium-promoted forms effect decarboxylations, although metal oxide (e.g. BaO) content tends to increase reaction rates. Thus (*E*)-α-phenylcinnamic acid is decarboxylated in high yield to *cis*-stilbene in 10 min (eq 1).[1b]

(1)

Decarboxylation of 4-acyl-2-pyrrolecarboxylic acids, which gives low yields of 3-acylpyrrole products when ethanolamine and 2,6-lutidine are employed as solvents, is effected at 180-200 °C in much improved (76-85%) yields, with minimal tarring, when quinoline is used (eq 2).[2]

(2)

In a synthesis of benzo[*a*]cycl[3.2.2]azine, decarboxylation of the intermediate diacid (eq 3) gave the desired product in 49% yield.[3] Similar reactions with benzoic acid (eq 4) and acylfuran (eq 5) derivatives have been reported.[4,5]

(useful precursor for organocopper(I) and organocuprate(I) reagents[1])

Alternate Name: cuprous cyanide.

Physical Data: mp 474 °C; *d* 2.920 g cm^{-3}.

Solubility: insol H_2O and most organic solvents. The lithium halide complexes are sol THF.

Form Supplied in: off-white solid.

Handling, Storage, and Precautions: highly toxic; must be handled with care.

General Discussion.

The first investigation of organocopper chemistry was carried out by Kondyreva and Fomin,[2] who in 1915 studied the effect of heavy metal salts on organomagnesium compounds. They found that organocopper compounds, prepared from CuCl, CuBr, CuI, CuSCN, and CuCN, decomposed to give equimolar amounts of alkane and alkene when the organic group was *n*-alkyl, and biaryl when it was aryl. These observations were confirmed by Whitesides et al. a half century later.[3] The Russian authors also noted that the solutions prepared from Grignard reagents and copper salts no longer reacted with acetone to give *t*-butanol. While they did not find a synthetic application for their solutions, it should be noted that Gilman did not investigate the reaction chemistry of the solutions he prepared from 2 equiv of MeLi and copper(I) salts, either.[4] Nevertheless, organocuprates are now commonly called Gilman reagents.

The pioneering work on synthetic applications of organocopper reagents was done almost exclusively with ***Copper(I)***

Iodide. Unfortunately, nearly two decades were to pass before it was found that Gilman reagents prepared from CuCN and 2 equiv of RLi were purer, more thermally stable,[5] and often gave higher yields of the desired product than Gilman reagents prepared from CuI.[1,7] Gilman reagents such as $Bu_2CuLi.LiI$ appear to be more prone to electron transfer and radical reactions than the corresponding reagents prepared from CuCN.[6]

Based upon their apparent higher reactivity, it was originally claimed that the reagents prepared from 2 equiv of RLi and CuCN were higher order cyanocuprates, $R_2Cu(CN)Li_2$;[1a-c,7] however, NMR studies,[9-11] EXAFS investigations,[12] and theoretical calculations[13] have recently converged on the conclusion that the CN is not bonded to Cu. Lipshutz has recently conceded that the CN is not σ-bonded to Cu.[8] Thus these reagents should be represented as $R_2CuLi.LiCN$ by analogy with $R_2CuLi.LiI$ and $R_2CuLi.LiBr$ for the cuprates prepared from CuI and ***Copper(I) Bromide***, respectively. It has been demonstrated by ^{13}C NMR and ^{6}Li NMR that LiI is not free in the Gilman reagent prepared from CuI and 2PhLi in DMS,[14] and that LiI and LiCN are not part of the cuprate bonding in THF.[9-11] It has recently been shown how the aggregation states of organocopper reagents in solution may be assigned by using ^{13}C NMR spectroscopy.[11]

In contrast, both NMR and EXAFS studies confirm that CN is bonded to Cu in the so-called lower order cyanocuprates, RCu(CN)Li,[10,12] prepared from 1 equiv of RLi and CuCN. While they are relatively unreactive towards α-enones and alkyl halides,[15] they have been used successfully with more reactive substrates such as allylic carboxylates[16] and vinyloxiranes.[17] The introduction of additives such as ***Boron Trifluoride***[18,19] should give these reagents broader applicability. Trost used lower order cyanocuprates when he introduced the concept of chirality transfer in acyclic systems,[20] which has been applied brilliantly by Ibuka and Yamamoto.[18]

Recently, several novel lower order cyanocuprates have found application. For example, Piers has converted 2-alkynoates into either (*Z*)- or (*E*)-3-trimethylstannyl-2-alkenoates by treatment with $Me_3SnCu(CN)Li$ under the appropriate conditions (eq 1).[21a] He also compared lower order phenyl cyano- and thiocuprates in developing an efficient methylenecyclopentane annulation (eq 2).[21b]

(1)

In a most exciting development from the viewpoint of molecular complexity, Knochel has prepared highly functionalized cyanocuprates RCu(CN)ZnX, where X = I, Br, Cl, OMs, OTs, or $OP(O)(OR)_2$, from the corresponding alkylzinc reagents.[22] In a related development, Rieke has reported the direct formation of highly functionalized allylic organocopper reagents via the reduction of CuCN.2LiBr, CuCN.LiCl, or CuCN.2LiCl with ***Lithium Naphthalenide*** to give a highly reactive form of Cu metal.[23] Linderman has prepared α-alkoxyorganocuprate reagents from the corresponding organotin compounds and reacted them with α,β-unsaturated carbonyl compounds (eq 3).[24]

Corey has used $Bu_4NCu(CN)_2$ as a precursor to a new class of cuprate reagents, which he symbolizes as $RCu(CN)_2(NBu_4)Li$,[25] implying that they are higher order cuprates with two CN ligands bonded to Cu, although this remains to be proven. The ^{13}C NMR spectroscopy of organocopper reagents has now been developed to the point where conjectures concerning the structures of new organocopper species should not be made without making sure that they are consistent with the NMR data.[11] At the time of this writing there is still a backlog of structures that need to be checked. Theory is also being developed to the point where it can shed considerable light on whether structures are feasible or not.[13]

As discussed above, when the Gilman reagents prepared from CuI were introduced, side-by-side comparisons were not

made with the corresponding cuprates prepared from other Cu^I salts. (Or, if comparisons were made, they were not reported.) In other words, a depth-first search was done, rather than a breadth-first one.[26] Unfortunately, the same pattern was repeated when the cuprates prepared from CuCN were introduced: papers with tables of yields for typical substrates were published, but very few direct comparisons with other cuprates were made.[1b,c,7a] Thus the best advice we can give the synthetic chemist is to try several of the most successful versions of the Gilman reagent, viz, those prepared from CuI, $CuBr.SMe_2$ (see ***Copper(I) Bromide***), and CuCN.[1a-c] It is also useful to compare organocopper reagents prepared from lithium reagents with those prepared from the corresponding Grignard reagents (See ***Copper(I) Chloride***).

In one of the few direct comparisons, Fleming has shown that the silylcupration of alkynes with $(Me_2PhSi)_2CuLi.LiCN$ gives the opposite regiochemistry to $(Me_2PhSi)_2CuLi.LiBr$, prepared from CuBr.DMS.[27] It is interesting to note that Fleming's work predates Lipshutz's, and that he uses the correct (lower order) formulation. Bertz has compared CuCN with CuI, CuBr, CuBr.DMS, CuCl, CuSCN and CuOTf as far as the formation of alkyl and aryl Gilman reagents is concerned,[28a] and also reacted a number of them, including those made from CuCN, with dithioesters, where they give carbophilic addition.[28b] For the preparation of stoichiometric cuprates from Grignard reagents, ***Copper(I) Trifluoromethanesulfonate*** (copper(I) triflate) was demonstrated to be superior to the other Cu^I salts, including CuCN.[28b]

While CuCN has been used in catalytic amounts with Grignard reagents (where the ate complex may be presumed to be the active species),[16b,29,30] CuCN has not been shown to be superior to the other Cu^I salts, and even some Cu^{II} salts appear to be equally effective.[1a] For example, in the addition of Grignard reagents to nitriles, CuCN, CuI, CuBr, CuBr.DMS, and CuCl all gave the same yield of product to within ±3%. Thus the yields of ketimine product from *t*-BuMgCl and 4-methoxybenzonitrile were 87-93% (i.e. 90 ± 3%) after 2 h in refluxing THF in the presence of 2 mol % of the Cu^I salt.[30] This is a very useful extension and generalization of Bertz's work on the activation of the carbon-nitrogen double bond by Cu^I.[31]

Lipshutz has described stoichiometric higher order, mixed lithio magnesio organocuprates prepared from CuCN, 2-lithiothiophene, and Grignard reagent (1:1:1), although no evidence that a higher order species is present in such solutions has been adduced.[32a] In fact, the authors admit that these reagents are not discrete.[32a] The corresponding organocuprates prepared from CuCN, 2-lithiothiophene, and a lithium reagent (or lithium 2-thienyl(cyano)cuprate(I) and a lithium reagent) have been assigned a higher order structure,[1b] but are probably lower order R(2-thienyl)CuLi.LiCN reagents.[9-11] The 2-thienyl group was introduced as a nontransferred ligand for mixed cuprates by the Swedish group of Malmberg, Nilsson, and Ullenius.[32b] Whatever their structure may be, they have been applied to some interesting synthetic problems, such as the prostaglandin synthesis shown in eq 4.[33]

As mentioned above, $Bu_4NCu(CN)_2$ has been used as a cuprate precursor. The related alkali metal dicyanocuprates, especially $NaCu(CN)_2$, have been used in typical cuprate coupling reactions with aryl and vinyl halides.[34,35] In other typical organocopper reactions, CuCN itself reacts with acid chlorides to yield α-ketonitriles,[36] and with aryl iodides to afford aryl cyanides.[37]

It is noteworthy that the first sodium organocuprate, $Bu_2CuNa.NaCN$, was prepared from BuNa and CuCN,[38] and Seyferth prepared the first acyl cuprates from $R_2CuLi.LiCN$ and CO.[39] The latter development enables the synthesis of 1,4-diketones directly from α-enones via conjugate addition.

Whitesides et al. introduced the oxidative coupling of Cu^I ate complexes, which they prepared from CuI.[40] Bertz and Gibson demonstrated that the oxidation of organocuprates from CuCN gave significantly different results,[41] which Lipshutz et al. developed into a synthesis of unsymmetrical biaryls.[42] Oxidative couplings of heterocuprates usually proceed in poor yields;[1e,43] however, Snieckus et al. have developed useful synthetic methodology for the *N*-arylation

of amines based upon the oxidation of aryl amidocuprates.[44]

In one of his many pioneering studies, House showed that the enolates formed upon the addition of $Me_2CuLi.LiBr$ to α-enones were basically lithium enolates.[45] Nevertheless, Posner showed that the addition of 1 equiv of CuCN to a lithium enolate could dramatically decrease polyalkylation in cyclopentanone derivatives.[46]

Finally, CuCN has been used to catalyze the reactions of diazoacetic esters;[1f] however, ***Copper(I) Chloride*** is the Cu^I salt most frequently used for this purpose.

Related Reagents.

Copper(I) Cyanoacetate

$NCCH_2CO_2Cu$

[51249-59-3] · $C_3H_2CuNO_2$ · Copper(I) Cyanoacetate · (MW 147.60)

(agent generating cyanomethylcopper(I);[1] transcarboxylating agent for epoxides[2] and ketones[5])

Solubility: insol ordinary organic solvents; sol organic solvents in the presence of tertiary phosphine ligands.

Preparative Methods: acidolysis of ***Copper(I) t-Butoxide***;[1] carboxylate exchange reaction between Cu^I *n*-butyrate and ***Cyanoacetic Acid***.[3]

Handling, Storage, and Precautions: oxygen- and moisture-sensitive; preparation and reaction should be conducted under rigorously oxygen-free and anhydrous conditions.

Generation of Cyanomethylcopper(I).

Cu^I cyanoacetate decarboxylates in DMF at 50 °C to generate cyanomethylcopper(I) (eq 1).[1] Preparation of cyanomethylcopper(I) using decarboxylation of Cu^I cyanoacetate is characterized by the absence of lithium halide, in contrast to its preparation using the metathesis reaction between Cu^I halide and ***Isocyanomethyllithium***. Cyanomethylcopper(I) acts as a cyanomethylating agent of organic halides (eq 1). Cu^{II} cyanoacetate decarboxylates similarly to produce cyanomethylcopper(I) with concomitant formation of succinonitrile (eq 2).[1] Synthetic use of ***Cyanomethylcopper*** is described in the corresponding entry.

Transcarboxylation of Epoxides and Ketones.

Cu^I cyanoacetate acts as a CO_2 carrier, transferring its CO_2 moiety to propene oxide to afford propene carbonate in high yield (eq 3).[2] Cu^I cyanoacetate and cyanomethylcopper(I) catalyze the reaction of propene oxide with CO_2 to give propene carbonate.

(3)

Cu^I cyanoacetate-catalyzed carboxylation of *trans*-1,2-dideuteroethylene oxide proceeds stereospecifically with retention of configuration, while the nickel(0) catalyst effects nonstereospecific reaction (eq 4).[4]

(4)

In the presence of ***Tri-n-butylphosphine*** ligand, the decarboxylation of Cu^I cyanoacetate in DMF is highly suppressed, resulting in reversible decarboxylation (eq 5).[5] The Cu^I cyanoacetate-tri-*n*-butylphosphine complex acts as a reversible CO_2 carrier to transfer its CO_2 component to cyclohexanone in good yield (eq 6).[5]

$$NCCH_2CO_2Cu(Bu_3P)_3 \overset{DMF}{\rightleftharpoons} NCCH_2Cu(Bu_3P)_3 + CO_2 \quad (5)$$

Copper(II) Hexafluoroacetylacetonate

[14781-45-4] · $C_{10}H_{12}CuF_{12}O_4$ · Copper(II) Hexafluoroacetylacetonate · (MW 477.66)

(catalyzes diazo compound decomposition and ylide formation;[3] carbene additions[4])

Alternate Names: cupric hexafluoroacetylacetonate; bis(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato-*O,O´*)copper.

Physical Data: green solid, mp 130-135 °C (hydrated forms),[2] 114-116 °C (anhyd).[1]

Solubility: sol EtOH, dioxane, CCl_4, polar solvents; insol H_2O.[2]

Form Supplied in: commercially available as a hydrated solid.

Preparative Methods: the dihydrate can be prepared from reaction of ***Copper(II) Acetate*** and hexafluoroacetylacetone dihydrate in aq NaOH, or by directly heating $Cu(OAc)_2.H_2O$ and anhydrous hexafluoroacetylacetone.[2]

Purification: recryst from 50% EtOH or CCl_4.[2]

Handling, Storage, and Precautions: irritant.

Unusual Heteroatomic Ylides.

Copper(II) hexafluoroacetylacetonate is an effective catalyst for the preparation of ylides from diazo compounds under mild conditions. This reagent is more effective than ***Copper(I) Acetylacetonate*** and ***Copper(II) Acetylacetonate***, two examples of many transition metal chelates available for decomposition of diazo compounds. Lower reaction temperatures result in a purer product, but reaction times are greatly increased. The heat-sensitive arsonium, stibonium, bismuthonium, sulfonium, telluronium, and thiouronium ylides have been prepared in 20-78%

yield under the catalysis of this reagent (eqs 1-3).[3] ***Copper Bronze*** and other copper salts are effective, but give lower yields.

Carbene Additions to Vinyl Ethers.

The addition of ***Dimethyl Diazomalonate*** to the cyclic vinyl ether (**1**) was studied using several transition metal catalysts (eq 4).[4] The intermediate zwitterionic species (**2**) was rationalized from the formation of rearrangement products (**4a**) and (**4b**). Although $Cu(hfa)_2$ significantly reduces reaction times, as does the widely used catalyst $Rh_2(OAc)_4$, both result in significant skeletal fragmentation of the carbenium ion. However, ***Copper(II) Trifluoromethanesulfonate***, $Cu(acac)_2$, and other copper(II) acetonato chelates give little or no rearranged product while providing (**3**) in 74-80% yield.

Copper(II) Hydroxide

$Cu(OH)_2$

[20427-59-2] · CuH_2O_2 · Copper(II) Hydroxide · (MW 97.56)

(catalyst for the Ullmann condensation;[1] mediates conversion of acid hydrazides to carboxylic acids[2])

Physical Data: d 3.37 g cm^{-3}.

Solubility: sol acids, conc alkali, NH_4OH, and ethylenediamine; insol water.

Form Supplied in: blue to blue-green gel or light blue crystalline powder.

Handling, Storage, and Precautions: may decompose to Cu^{II} oxide at 60-80 °C, although the stability is dependent on the method of preparation. Hygroscopic.

Aryl Amine Synthesis.

Cu^{II} hydroxide catalyzes the Ullmann condensation reaction of 1-bromoanthraquinone or 1-amino-4-bromoanthraquinone with a large excess of ethylenediamine (eq 1).[1] The hydroxo-bridged Cu^{I}-Cu^{II} mixed valence complex formed by the reduction of Cu^{II} hydroxide has been proposed as an active species. ***Copper(II) Chloride*** and ***Copper(II) Bromide*** are ineffective. The combination catalyst of ***Copper(I) Chloride***/$Cu(OH)_2$ (2:1) shows a higher activity in the reaction of 1-amino-4-bromoanthraquinone than with $CuCl_2$ alone, but still lower than with $Cu(OH)_2$ alone.

(1)

R = H, 62%; R = NH_2, 53%

Conversion of Acid Hydrazides to Carboxylic Acids.

A stoichiometric amount of Cu^{II} hydroxide, prepared in situ from $CuCl_2$ and ***Potassium Hydroxide***, effects conversion of acid hydrazides to carboxylic acids at room temperature (eq 2).[2] Under similar reaction conditions, $Cu(OAc)_2.H_2O$ and $CuCO_3$ react slowly and $CuCl_2$, $Cu(NO_3)_2$, $CuSO_4$, and CuO are ineffective. $Cu(OAc)_2.H_2O$ and $CuCO_3$ are effective at 70 °C. In the presence of oxygen, ***Copper(II) Acetate*** acts as a catalyst at room temperature to afford carboxylic acids in excellent yields. An acyl cation intermediate generated by the oxidation of acid hydrazides with Cu^{II} hydroxide has been proposed. The copper-promoted conversion of acid hydrazides to carboxylic acids may provide a convenient method of protecting carboxylic acids bearing labile functional groups.

$$RCONHNH_2 + 4\,Cu(OH)_2 \xrightarrow{\text{THF, rt}} RCO_2H + N_2 + 3\,H_2O + 4\,CuOH \quad (2)$$

R = C_7H_{15}, 90%; R = Ph, 92%

Copper(I) Iodide[1]

CuI

[7681-65-4] · CuI · Copper(I) Iodide · (MW 190.45) (.PBu_3)

[21591-31-1] · $C_{12}H_{27}CuIP$ · Copper(I) Iodide-Tributylphosphine · (MW 392.81) (.$(SBu_2)_2$)

[35907-81-4] · $C_{16}H_{36}CuIS_2$ · Copper(I) Iodide-Bis(dibutyl sulfide) · (MW 483.11)

(the classical precursor for organocopper(I) and organocuprate reagents[1])

Alternate Name: cuprous iodide.

Physical Data: mp 605 °C; *d* 5.620 g cm^{-3}.

Solubility: insol H_2O and most organic solvents; partially sol dimethyl sulfide (DMS).

Form Supplied in: off-white to grayish solid; 99.999% grade available.

Handling, Storage, and Precautions: maintenance of a dry N_2 or Ar atmosphere is recommended.

General Discussion.

The first organocopper compound to be isolated, ***Phenylcopper***, was prepared in 1923 by Rene Reich from ***Phenylmagnesium Bromide*** and CuI.[2] In 1936, Gilman repeated the preparation of PhCu from CuI,[3a] and in 1952 he prepared ***Methylcopper*** and ***Lithium Dimethylcuprate*** from CuI and 1 and 2 equiv of ***Methyllithium***, respectively.[3b] An improved preparation of halide-free MeCu and Me_2CuLi from CuI has recently been reported,[4] and an appreciation of the role of the lithium salt from the preparation in the structure and reactivity of the reagent has developed in recent years.[5-10] Therefore it has been proposed that any salt from the metathesis reaction used to prepare the organocopper reagent should be explicitly shown in the formula, e.g. $Ph_2CuLi.LiI$,[5] PhCu/LiI,[6] $Bu_2CuLi.LiBr$,[7] $Bu_2CuNa.NaCN$,[8a] etc. Unfortunately, many of the tables in the latest *Organic Reactions* chapter on organocopper reagents do not list the Cu^I salt from which the reagents were prepared.[1a]

Interest in organocopper reagents was rekindled in 1966 when House and Whitesides[9] showed that organocuprates were intermediates in what we propose to call the Kharasch reaction, the Cu-catalyzed 1,4-addition of Grignard reagents to enones.[11] They also reported the development of two organocopper reagents which have the stoichiometry

$Li^+Me_2Cu^-$ and $MeCuP(n\text{-}Bu)_3$.[9] Both of these classes of reagents are important today (see below). Corey and Posner also used CuI to prepare $Me_2CuLi.LiI$[12] and $Bu_2CuLi.LiI$,[13] which were coupled with alkyl halides and iodobenzene. These initial reports of the synthetic value of organocopper reagents for selective C-C bond formation led to an explosion of applications,[1a-g] which like the big bang is still expanding today. The principal applications of organocopper reagents to C-C bond formation in the areas of conjugate addition to α,β-unsaturated carbonyl compounds, carbocupration of alkynes, and coupling reactions with oxiranes and alkyl, alkenyl, and aryl halides have been well reviewed.[1a -h] While CuI has been supplanted by CuBr.DMS (see ***Copper(I) Bromide***) and ***Copper(I) Cyanide*** for many purposes, it is still one of the main precursors that should be tried when optimizing an organocopper synthesis.[7]

In addition to the ate complexes prepared from 2 equiv of RLi, the organocopper(I) compounds RCu, prepared from 1 equiv of RLi and CuI, have found synthetic application in the presence of additives, which enhance the reactivity of these otherwise relatively unreactive compounds. Both Lewis bases and Lewis acids[1d] have been used for this purpose, and their utility has been extended to the organocuprates as well. Examples of the former are phosphines, such as ***Tri-n-butylphosphine***,[14] and sulfides, such as dibutyl sulfide[15] and ***Dimethyl Sulfide***;[6,16a] examples of the latter are ***Boron Trifluoride***[17,18] and ***Aluminum Chloride***.[17a,19] ***Chlorotrimethylsilane*** (TMSCl) is a useful additive,[20,21] especially in conjunction with HMPA.[6,22] In analogy with these major additives, triethylphosphine,[23a] triphenylphosphine,[23b,24] tricyclohexylphosphine,[24] dppe,[24,25] triethyl phosphite,[26] diisopropyl sulfide,[16b] triethylboron,[27] trimethylaluminum,[28] titanium tetrachloride,[17b,18a] TMSCl-DMAP,[22] TMSCl-TMEDA,[29] TMSI,[30,31] and TMSCN[31] have been used. One unique phosphine is polymer-supported $RPPh_2$,[32] where R is the polymer backbone.

The addition of BF_3 improves some of the usual organocopper reactions,[17] and it enables some unprecedented ones, e.g. the direct alkylation of allylic alcohols.[17c] It also favors 1,4- over 1,6-addition to methyl sorbate: 1,6-addition predominates with $Bu_2CuLi.LiI$,[17b] and also with BuMgBr/CuCl,[11a] but 1,4-addition is observed for $BuCu.BF_3$.[17b] One particularly interesting application of the BF_3 procedure is the conjugate addition of Cu^I aldimines to α,β-unsaturated carbonyl compounds (eq 1), which after hydrolysis gives 1,4-diketones.[18b]

In some cases the additives improve solubility; in other cases, entirely new reagents result. For example, PhCu is insoluble in ether, but it is soluble in DMS, where it has been shown to be an equilibrium mixture of $(PhCu)_4$ and $(PhCu)_3$.[25] When prepared from CuBr or CuCN in DMS, the product is Li-free, due to the precipitation of LiBr or LiCN from DMS.[6] This Li-free PhCu is relatively unreactive compared to the reagent prepared from CuI, PhCu/LiI, which still contains the LiI.[6] This LiI may be considered an activating additive. The LiI present in $Me_2CuLi.LiI$ also has an important effect in conjugate addition reactions, as the percentage of 1,2-addition can be significant for halide-free organocuprates.[4]

The LiI in PhCu/LiI is not incorporated into the organocopper(I) clusters;[6] however, in the case of $Ph_2CuLi.LiI$, ^{13}C NMR shows that both I-containing (major) and I-free (minor) clusters are present.[5] House found that although the conjugate addition of lithium dimethylcuprate to α,β-unsaturated ketones appears to require no other species in the reaction solution, ***Trimethyl Phosphite*** and ***Tri-n-butylphosphine*** complexes of methylcopper will undergo conjugate addition only if various salts such as ***Lithium Iodide***, ***Lithium Bromide***, ***Magnesium Bromide***, or ***Lithium Cyanide*** are present in the reaction medium.[10]

Organocopper reagents are assuming an increasing role in asymmetric synthesis and many of the procedures involve complex mixtures containing one or more of the additives discussed above.[15,17a,18a,c] This area has been reviewed recently,[1b] so we highlight one especially interesting example here, the enantiocontrolled synthesis of quaternary carbon centers via the asymmetric conjugate addition of organometallic reagents to enantiomerically pure 2-(arylsulfinyl)cycloalkenones.[33] Posner has noted that although $Me_2CuLi.LiI$ and $Me_5Cu_3Li_2$ work well, $Me_2CuLi.LiCN$ and $MeCu.BF_3$ do not. He concludes that no one type of organocopper reagent will be universally preferred over others for all different kinds of carbon-carbon bond-forming reactions.[33]

Tandem β-addition-α-functionalization reactions are an important strategy for rapidly building molecular complexity.[1c] A particularly impressive example (eq 2) is the three component coupling used by Suzuki and Noyori to prepare

prostaglandins,[14c,d] which owes its success to the use of derivatives of House's $RCu(PBu_3)$.[9,10,14a,b] An interesting intramolecular version involving conjugate addition-cycloacylation of alkynic diesters to give highly functionalized cyclopentenones has been developed by Crimmins.[34] Tandem organocopper addition-electrophilic functionalization of alkynes is well established,[1a,f] and Meyers has even performed such a sequence on a benzyne.[35]

Useful applications of organocopper reagents to carbohydrate chemistry have been made by the Kocienski and Fraser-Reid groups. In the former case, an oxirane ring was opened regio- and stereoselectively.[36] In a contraintuitive finding, the latter group reported that the homogeneous system using the soluble $CuI.PBu_3$ complex was less satisfactory than the heterogeneous system based upon CuI for the conjugate addition-alkylation of hex-2-enopyrano-4-ulosides.[37]

Some exciting recent developments extending the scope of organocopper chemistry involve CuI. Rieke has reported the preparation of $RCu.PBu_3$ from a highly reactive copper intermediate prepared via the reduction of $CuI.PBu_3$.[23,38] Ebert has used a similar procedure to prepare remote ester and ketone functionalized organocopper reagents.[39]

Alkenes with perfluoroalkyl substituents have been prepared by the reaction of perfluoroalkyl iodides with terminal alkynes in the presence of ultrasonically dispersed ***Zinc*** and CuI.[40a] A general procedure for the formation of organocopper reagents from alkyl and aryl halides and ***Lithium*** metal in the presence of CuI or ***1-Pentynylcopper(I)*** under ultrasonic irradiation has also been described.[40b]

One of the extraordinary things about displacement reactions mediated by Cu^I is the fact that they occur with both facility at sp^3 and sp^2 centers, as eqs 3 and 4 illustrate. Eq 3 involves a classic S_N2-like reaction, but is noteworthy

because of the complexity of the other functionality in the substrate, an α-amino acid derivative.[15a] Eq 4, the alkylation of alkenyl triflates,[41] adds a versatile alternative to the alkylation of alkenyl halides.[1a,g]

(4)

Good reviews are available of stoichiometric cuprates prepared from lithium reagents,[1a] stoichiometric cuprates prepared from Grignard reagents,[1a] and the use of Grignard reagents with catalytic amounts of Cu^I salts.[1a,e] Sadly, direct comparisons have not been made among all the variations. When one adds further variables such as which Cu^I salt is used, what halide is present in the Grignard reagent, and whether the stoichiometry is 2:1 or 1:1, it is easy to see that the choice of conditions is a complex problem, even before all the possible additives are considered. The best advice we can give the synthetic chemist is to try several sets of conditions based upon similar examples in the literature. Fortunately, an exhaustive compilation has been published recently.[1a]

A species of intermediate stoichiometry between organocopper(I) and organocuprate(I) (RCu and R_2CuLi, respectively) has been described as $Me_5Cu_3Li_2$ = MeCu + $(Me_2CuLi)_2$. While the structure of the reagent has yet to be determined, it has proved to be useful for the conjugate addition of Me to α,β-unsaturated aldehydes.[42]

In recent work that is related to the organocuprate chemistry discussed above, Miura et al. have reported the CuI-catalyzed reaction of aryl and vinyl iodides with terminal alkynes,[43a] and of aryl iodides with active methylene compounds.[43b]

Finally, not all applications of CuI involve organocuprates or related reagents. For example, Corey used CuI to catalyze intramolecular diazoalkene cyclization reactions,[44] and Yates used CuI to catalyze the Wolff rearrangement of diazo ketones.[45] House recommended $CuI.(SBu_2)_2$ for the intermolecular cyclopropanation of alkenes with α-diazo ketones. The intermediates are undoubtedly organocopper species of some kind, perhaps Cu-carbene complexes; however, it should be noted that Cu^0 and Cu^{II} are more commonly used as catalysts in conjunction with diazo compounds.[1i]

Related Reagents.

See the copper(I) iodide combination reagents following this entry; also ***Copper(I) Bromide*** and ***Copper(I) Chloride*** (and their combination reagents), ***Copper(I) Cyanide***, and ***Copper(I) Trifluoromethanesulfonate***.

Copper(I) Iodide-Lithium Trimethoxyaluminum Hydride[1]

$LiCuHI.Al(OCH_3)_3$

[7681-65-4] · CuI · Copper(I) Iodide-Lithium Trimethoxyaluminum Hydride · (MW 190.45)

[12076-93-6] · $C_3H_{10}AlLiO_3$ · Copper(I) Iodide-Lithium Trimethoxyaluminum Hydride · (MW 128.05)

(in situ prepared hydridocopper reagent; reductive removal of halogen or mesyloxy groups; reduction of epoxides to alcohols[2])

Preparative Method: [2] an anhydrous THF solution of lithium trimethoxyaluminum hydride (2.0 mmol) is added dropwise to an ice-cold suspension of ***Copper(I) Iodide*** (dried at 100 °C in vacuo prior to use; 1 mmol) in THF under an inert atmosphere. After 30 min, the resulting brown mixture is treated with substrate (1 mmol). The cooling bath is removed after 15 min and the mixture is stirred vigorously for 2 h at room temperature. Additional THF may be added to effect efficient stirring. The reaction mixture is quenched with methanol, diluted with ether, and filtered through Celite. This filtrate is washed with saturated aqueous ammonium chloride and dried.

Handling, Storage, and Precautions: use in a fume hood.

General Discussion.

This reagent was first reported for the reductive removal of primary, secondary, tertiary, allyl, vinyl, aryl, and neopentyl bromides. In all cases the halide was removed in excellent yield (85-100%) (Table 1). Simple primary and secondary mesylates and cyclohexene oxide were reductively cleaved by the conditions stated. However, the use of additional reagent and a longer reaction time (15 h) was required for the reduction of 1-chlorooctane to *n*-octane (96% yield).[2] This reagent was used to prepare allocyathin B_3 methyl acetal from a vinyl bromide (eq 1)[4] and (+)-cyclohex-2-en-1-ol from its corresponding vinyl iodide (**1**).[5] The reduction of either *exo*- or *endo*-2-bromonorbornane with CuD (prepared from $LiAlD(OMe)_3$ and CuI) proceeds with 100% retention, whereas the corresponding mesylates are reduced with complete inversion of stereochemistry.[2] This retention of stereochemistry is also observed for an adamantane ring system.[6]

Table 1 Reductions Using Copper(I) Iodide Lithium Trimethoxyaluminum Hydride

Substrate	Product	Yield (%)
1-Bromooctane	*n*-Octane	98
2-Bromononane	*n*-Nonane	100
1-Bromocyclooctene	Cyclooctene	99
1-Bromonaphthalene	Naphthalene	100
1-Octanol mesylate	*n*-Octane	95
Cyclohexene oxide	Cyclohexanol	100

(1)

Limitations.

There are examples where mesylate reductions have produced only recovered starting material (e.g. **2** and **3**),[7,8] a mixture of reduced product and the corresponding alkene,[9] or alcohols from O-S cleavage (e.g. **4**).[10]

(2)

(3)

(4)

Alternative Methods.

Potassium Tri-s-butylborohydride has been used as the hydride source.[3] The reductive removal of halogen, hydroxy, or mesyloxy groups can be accomplished by a number of different methods, such as hydrogenolysis,[11] $TiCl_3$.3THF-Mg,[12] Bu_3SnH-thiocarbonate,[13,14] NaI-Zn,[15] trialkylSiH-$AlCl_3$,[16] $LiAlH_4$-transition metal,[17-19] $LiEt_3BH$,[20,21] $NaBH_4$,[22] $NaBH_4$-Ni^0, [23] and *i*-PrMgBr-titanocene dichloride.[24] See also ***Lithium n-Butyl(hydrido)cuprate*** and ***Lithium Tri-t-butoxyaluminum Hydride***. Other hydridocopper reagents include ***Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride*** and ***Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride***.

Copper(I) Iodide-Potassium Naphthalenide[1]

$CuI.K(C_{10}H_8)$

[7681-65-4] · CuI · Copper(I) Iodide-Potassium Naphthalenide · (MW 190.45)

[4216-48-2] · $C_{10}H_8K$ · Copper(I) Iodide-Potassium Naphthalenide · (MW 167.27)

(used to prepare a zerovalent copper species which is particularly effective in promoting the Ullmann condensation, in the production of organocopper compounds, and in cross-coupling of aryl and allylic halides)

Solubility: copper species generated in dimethoxyethane under Ar.

Preparative Methods: by the reduction of ***Copper(I) Iodide*** with a stoichiometric concentration of ***Potassium*** and ca. 10% naphthalene in DME under Ar, resulting in a gray-black granular solid.

Handling, Storage, and Precautions: the reagent is generated in situ in an inert atmosphere as needed; reactions are usually carried out under argon; use in a fume hood.

Reactions of Organocopper Reagents.

The reagent reacts with pentafluorophenyl iodide in DME to yield a solid, presumed to be pentafluorophenylcopper, which subsequently produces decafluorobiphenyl either thermally or by oxidation (eq 1).[1] Alternatively, aryl-alkyl coupling (eq 2) can also be effected.[1]

(1)

(2)

Aside from this early report, the number of instances in which this method has been used successfully for the purposes intended is limited. Thus, while the substituted biaryl was formed in over 50% yield in the presence of CuI.K($C_{10}H_8$) (eq 3),[2] the corresponding reaction at nitrogen (eq 4) failed.[3] Coupling at nitrogen has, however, been reported to be successful in a different system (eq 5).[4]

(3)

(4)

Finally, there are suggestions that the procedure described to produce active copper from CuI.K($C_{10}H_8$) may prove useful in the preparation of cluster compounds[5] and in coupling reactions in metallocenes.[6]

Copper(I) Iodide-Tributylphosphine[1]

$[CuI\{(n\text{-}Bu)_3P\}]_4$

[28132-72-1] · $C_{48}H_{108}Cu_4I_4P_4$ · Copper(I) Iodide-Tributylphosphine · (MW 1571.08)

(promoter for conjugate addition of alkyl (vinyl, etc.) lithium reagents to α,β-unsaturated ketones and related compounds; preformed copper-phosphorus compound (occasionally generated in situ) to stabilize and solubilize organocoppers whose conjugate addition is facilitated by the use of a phosphorus auxiliary;[1] also used to effect oxidative coupling[2])

Alternate Name: tetrakis[iodo(tri-*n*-butylphosphine)copper(I)].

Physical Data: mp 75 °C; *d* (at 78 °C) 1.390 g cm^{-3}; decomposition to CuI and tributylphosphine at 200-210 °C/0.01 mmHg.

Solubility: sol chloroform, benzene, toluene, and ethyl ether; moderately sol ethanol, 2-propanol, and water.

Preparative Methods: generated in situ or prepared either via the reaction of ***Copper(I) Iodide*** with freshly distilled ***Tri-n-butylphosphine***[3a] or with copper(I) iodide dissolved in saturated aqueous ***Potassium Iodide*** and stirred with tri-*n*-butylphosphine.[3b]

Purification: may be recrystallized from ethanol-2-propanol and air dried.[3]

Analysis of Reagent Purity: decomposed by heating with Na_2CO_3 and residue treated with HNO_3; dissolved in water, sulfuric acid added, and Cu determined by electrolytic reduction;[3] ^1H NMR spectra[4] and electronic absorption and emission spectra have been studied.[5]

Handling, Storage, and Precautions: toxicity data unavailable. Unless refrigerated it decomposes in several days at rt to a viscous syrup;[3] use in a fume hood.

Conjugate Addition.

Early in the study of the reactions of organometallic reagents with α,β-unsaturated ketones it became clear that the reaction of organomagnesium compounds could be diverted from the normal path of 1,2-addition to favor the abnormal path of 1,4-addition by the presence of a small amount of a copper compound.[6,7] Thus *trans*-3-penten-2-one

in ether (in a flowing stream reactor) gave, in >99% conversion, <1% conjugate addition on reaction with ***Methyllithium*** to yield 2-methyl-3-hexen-2-ol. However, under the same conditions, when an organocopper reagent was preformed by adding 1 mole of *n*-Bu_3PCuI to 1 mole of MeLi, again in >99% conversion, there was >99% conjugate addition in the product to form 4-methyl-2-pentanone (eq 1).[7]

(1)

In a continuation of this work[8] the tri-*n*-butylphosphine complex of copper(I) iodide and ***Lithium Dimethylcuprate*** were compared to the corresponding trimethyl phosphite complex (see ***Copper(I) Iodide-Trimethyl Phosphite***) in the addition reactions to 5-methyl-2-cyclohexenone (eq 2), 3-methyl-2-cyclohexenone (eq 3), and 5,5-dimethyl-2-cyclohexenone (eq 4).

(2)

(3)

(4)

For the first case (eq 2), both reagents gave predominately *trans* product (*trans*:*cis* = 98:2), but the reaction with the tri-*n*-butylphosphine complex produced a 34% yield of products while the trimethyl phosphite complex yielded product in 73-87% yield (as a function of the amount of ***Lithium Iodide*** added or of tertiary phosphine ligand present).[9] In both the second and third cases (eqs 3 and 4) the two complexes gave approximately the same yields.[8] Shortly thereafter, conjugate addition of the corresponding vinyl reagent to yield γ,δ-unsaturated ketones was reported.[10]

Conjugate addition reactions of both lithium[11-15] and magnesium[16] alkyls to substituted[11-14] and unsubstituted[15,16] cyclopentenones followed by aldol type condensations[11,14] or alkylations[15,16] (if α-substitution was not present initially) have served as entries into prostaglandin synthesis. Additionally, the same process has served as a key step

in the syntheses of terpenes,[17] carbohydrates,[18] pyridine derivatives,[19] *N*-enoylsultams (producing β-silylcarboxyl derivatives[20] or alkyl substituted derivatives with good stereoface differentiation),[21] macrolides,[22] acetals,[23] and silyl enol ethers.[24]

Oxidative Coupling.

It was early reported[2] that the dialkylcuprate (e.g. ***Lithium Di-n-butylcuprate***) prepared by reaction of one equivalent of tetrakis[iodo(tri-*n*-butylphosphine)copper] in THF at -78 °C with ***n-Butyllithium*** on oxygenation produced ca. 84% octane. Subsequently, vinyl,[25-28] aryl,[29,30] and other alkyl[31,32] couplings have been effected, some with polymer supported cuprate[33] and one to a thioester to facilitate an otherwise difficult Grignard reaction.[34] Alkyl coupling to phosphorus in cyclophosphazines $(NPX_2)_{3\&b;or\&b;4}$ (X = Cl, F) can also be brought about in the presence of the title reagent.[35]

Rearrangements and Unusual Reactions.

Regioselective ring opening of β-propiolactones to yield β-substituted propanoic acids has been observed,[36] as has an unusually gentle cyclization of an azetidinone derivative to a penem (eq 5).[37] In the presence of a strained carbocycle the reagent has been found to behave much like a Lewis acid, yielding rearranged alkene (eq 6).[38]

(5)

Other Transformations and Limitations.

Organosamarium species have been generated by in situ transmetalation with the reagent.[39] It is claimed that solutions of highly reactive zerovalent copper, useful for oxidative addition to alkyl, vinyl, and aryl halides, are easily prepared by ***Lithium Naphthalenide*** reduction of the title reagent and similar species.[40] Superior results in prostaglandin synthesis have recently been obtained by substituting higher order cuprates.[41] Unlike other organometallic reagents, tetrakis[iodo(tri-*n*-butylphosphine)copper(I)] fails to react with arenesulfonyl fluorides to produce sulfones.[42]

Related Reagents.

Copper(I) Iodide-Tributyl Phosphite; ***Copper(I) Iodide-Triethylphosphine-Lithium Naphthalenide***; ***Copper(I) Iodide-Triethyl Phosphite***; ***Copper(I) Iodide-Trimethyl Phosphite***; ***Lithium Diethylcuprate-Tributylphosphine***.

Copper(I) Iodide-Tributyl Phosphite

$CuI[(n\text{-}BuO)_3P]$

(CuI)

[7681-65-4] · CuI · Copper(I) Iodide-Tributyl Phosphite · (MW 190.45) ($P(OBu)_3$)

[102-85-2] · $C_{12}H_{27}O_3P$ · Copper(I) Iodide-Tributyl Phosphite · (MW 250.36)

(seldom used promoter of conjugate addition of alkyllithium reagents to α,β-unsaturated ketones)

Solubility: sol ether and THF.

Form Supplied in: reported to be generated in situ; not isolated in either case where use is reported; not commercially available.

Conjugate Addition.

A comparison of the ***Lithium Dimethylcuprate*** addition reaction to 5-methyl-2-cyclohexenone in the presence of copper(I) iodide-tributyl phosphite, ***Copper(I) Iodide-Trimethyl Phosphite***, and ***Copper(I) Iodide-Tributylphosphine*** complexes, respectively, has been reported (eq 1).[1] For the particular case in which the copper(I) iodide-tributyl phosphite was used, the reagent was generated in situ, the ratio of products in the mixture was not determined (although the overall yield was reported as 88%), and the authors point out that the trimethyl phosphite ester has proved to be a more satisfactory complexing agent … because of its volatility and partial water solubility.[1] In the only other report,[2] an *n*-butylcopper complex was added to 2-cyclopentenone, again in the presence of a variety of phosphine and phosphite complexing agents; in this case, miniscule yields of adduct were obtained when copper(I) iodide-tributyl phosphite was used.

Copper(I) Iodide-Triethylphosphine-Lithium Naphthalenide[1]

$CuI.Et_3P.Li(C_{10}H_8)$

(LiNaph)

[7308-67-0] · $C_{10}H_8Li$ · Copper(I) Iodide-Triethylphosphine-Lithium Naphthalenide · (MW 135.12) ($CuI.PEt_3$)

[56667-47-1] · $C_6H_{15}CuIP$ · Copper(I) Iodide-Triethylphosphine-Lithium Naphthalenide · (MW 308.63)

(a zerovalent copper species which adds to organic halides to produce organocopper compounds; used to cross-couple aryl, alkynyl, and vinyl halides with acid chlorides and reactive alkyl halides; to effect conjugate additions to α,β-unsaturated ketones; to promote intramolecular cyclization with epoxide cleavage or of α,o-dihaloalkanes; to remotely functionalize esters)

Solubility: copper species generated in THF, dioxane, glyme, etc.

Form Supplied in: not commercially available; generated in situ.[2]

Analysis of Reagent Purity: not reported; reactions usually carried out under argon or dry nitrogen.

Handling, Storage, and Precautions: the reagent is generated in an inert atmosphere as needed.

Reactions of Organocopper Reagents.

It is suggested that treatment of ***Lithium Naphthalenide*** in THF or glyme under an argon atmosphere with the copper(I) iodide-triethylphosphine complex in THF (or glyme) produces a highly reactive form of zerovalent copper which is subsequently allowed to react with allyl, aryl, and alkyl halides (in the same solvent) to yield homocoupled products (eq 1).[2] Alternatively, if two alkyl, aryl, etc. halides are mixed prior to addition to the active copper species, cross-coupling occurs (eq 2).[2] A variety of functional groups (e.g. cyano, nitro) is tolerated during the coupling.[2]

(1)

(2)

The conjugate addition to 2-cyclohexenone of a variety of alkyl halides, some bearing additional functionality, has also been effected in the presence of $CuI.Et_3P.Li(C_{10}H_8)$ (eq 3).[1]

(3)

n	X	Yield (%)
6	Me	94
2	CO_2Et	90
2	CN	71
5	Cl	51

Additionally, a number of epoxides (terminal and otherwise) have been opened both intermolecularly and intramolecularly in the presence of $CuI.Et_3P.Li(C_{10}H_8)$ (eq 4). The solvent has been shown to play an important role in determining whether an *exo-tet* or *endo-tet* process occurs.[1,3] Thus for the products shown in eq (4), the ratio of cyclopentylmethanol to cyclohexanol is 1:6 in THF but 1:0 in toluene![1]

(4)

In the presence of $CuI.Et_3P.Li(C_{10}H_8)$, dihalides have been induced to undergo intramolecular cyclization (eq 5)[4] and

esters have been functionalized at remote positions (eq 6).[5]

Copper(I) Iodide-Triethyl Phosphite

$CuI[(OEt)_3P]$

[51717-23-8] · $C_6H_{15}CuIO_3P$ · Copper(I) Iodide-Triethyl Phosphite · (MW 356.60)

(promoter for the conjugate addition of alkyllithium and other reagents to α,β-unsaturated ketones and related compounds, regiospecific Ullmann reactions, alkylation of aluminates, and stereoselective synthesis of vinylsilanes)

Physical Data: mp 107-109 °C.[1,2]

Solubility: sol benzene, cyclohexane, bromoform, acetone, ether, and THF; also sol warm petroleum ether.

Form Supplied in: white crystals (97%).

Preparative Method: the complex is obtained in 88.6% yield by addition of ***Copper(I) Iodide*** to a solution of ***Triethyl Phosphite*** in benzene; the mixture is stirred and heated until the CuI dissolves; the complex is obtained upon evaporation of the solvent under reduced pressure.[2]

Purification: recrystallized from petroleum ether.[2]

Analysis of Reagent Purity: recrystallization and elemental analysis; IR spectrum provided.[2]

Handling, Storage, and Precautions: irritant; use in a fume hood; mechanical exhaust required; harmful by inhalation, ingestion, or skin absorption; incompatible with strong oxidizing agents; sensitive to air, moisture, and light; store under N_2 in a cool dry place.

Copper(I) iodide-triethyl phosphite reacts with acid chlorides in an Arbuzov-type process.[2] This complex also promotes alkylation of 1-trimethylsilylvinylaluminates with primary alkyl iodides to produce trisubstituted alkenes (eq 1),[3] as well as with 1-trimethylsilylvinylboranes and other alkyl halides.[4]

(1)

Organosamarium species have been generated by in situ transmetalation with copper(I) iodide-triethyl phosphite.[5] Although primary alkyl halides are reported to be relatively inert to copper solutions prepared from CuI and triethyl phosphite,[6] the complex was found to be effective for the transmetalation of an aryl organolithium which was subsequently utilized in an Ullmann type condensation (eq 2).[7]

(2)

Related Reagents.

Copper(I) Iodide-Trimethyl Phosphite

$CuI[(OMe)_3P]$

[34836-53-8] · $C_3H_9CuIO_3P$ · Copper(I) Iodide-Trimethyl Phosphite · (MW 314.52)

(promoter for the decomposition of diazo ketones and esters and for conjugate addition of alkyl (vinyl, etc.) lithium reagents to α,β-unsaturated ketones and related compounds)

Physical Data: mp 192-193 °C.[1]

Solubility: sol warm methanol, ethyl acetate, acetone, aniline, and dimethylaniline; also sol aq ammonia.

Form Supplied in: white crystalline powder (98%). *Drying:* dried at 60 °C (1 mmHg) for 12 h.

Purification: recrystallized from acetone or chloroform.

Analysis of Reagent Purity: recrystallization to constant mp and elemental analysis.

Handling, Storage, and Precautions: irritant; use in a fume hood; mechanical exhaust required; harmful by inhalation, ingestion or skin absorption; incompatible with strong oxidizing agents; sensitive to air, moisture, and light; store under N_2 in a cool dry place.

Decomposition of Diazo Ketones and Diazo Esters.

Along with other copper(I) salts, copper(I) iodide-trimethyl phosphite has been utilized to promote the decomposition of α-diazoacetophenone in cyclohexene to the mixture of insertion products shown in eq 1, with overall yields less than 50% and with the cyclopropane derivative produced in amounts at least six times that of the others.[1]

Indeed, decomposition of diazoacetic and diazomalonic esters in the presence of copper(I) iodide-trimethyl phosphite appears to be the method of choice.[2] The decomposition of diazomalonates in the presence of 1,2-ethylenedithiolato metallocene complexes is reported to be accelerated by CuI-P(OMe)$_3$.[3,4] It has also been reported that the intramolecular cyclization of the presumed carbonyl ylides derived from diazoacetates produces furanones directly (eq 2),[5,6] or the corresponding reaction products with alkenes.[7,8] Diethyl diazomalonate, in ethanol and in the presence of the copper(I) iodide-trimethyl phosphite reagent, permitted insertion into the hydroxyl group of the solvent to produce diethyl ethoxymalonate (82%) and a small amount (12%) of tetraethyl ethylenetetracarboxylate.[9]

Conjugate Addition.

The copper(I) iodide-trimethyl phosphite/lithium dimethylcuprate complex has been compared with the corresponding ***Tri-n-butylphosphine*** complex of ***Copper(I) Iodide*** and ***Lithium Dimethylcuprate*** in the addition reactions to 5-methyl-2-cyclohexenone (eq 3), 3-methyl-2-cyclohexenone (eq 4), and 5,5-dimethyl-2-cyclohexenone (eq 5).[10]

(4)

(5)

For the first case (eq 3), both reagents gave predominately *trans* product (*trans*:*cis* = 98:2), but the reaction with the tri-*n*-butylphosphine complex produced a 34% yield of products while the trimethyl phosphite complex yielded product in 73-87% (as a function of the amount of ***Lithium Iodide*** added or of tertiary phosphine ligand present). In both the second and third cases (eqs 4 and 5) the two complexes gave approximately the same yields.[10] Under other circumstances (where the complexes were not isolated but rather generated and used in situ), the relative yields for conjugate addition reactions have been reported to be much diminished for the copper(I) iodide-trimethyl phosphite reagent.[11] The same observation was also made with regard to the ring opening reaction of β-propiolactones with various copper reagents.[12] Additionally, an early investigation of the attempted preparation of dialkenylcuprates [$(CH_2{=}CH)_2CuLi$] suggested that the use of copper(I) iodide-trimethyl phosphite as the source of copper was only partially successful (as were many others) in avoiding decomposition of the vinyl cuprate.[13] Nonetheless, in the presence of ***Boron Trifluoride Etherate***, copper(I) iodide-trimethyl phosphite clearly has a salutary effect on the conjugate addition of the copper reagent derived from lithium *N*-*t*-butylvaleraldimine to 2-cyclohexenone.[14]

Related Reagents.

Copper(II) Nitrate-K10 Bentonite Clay[1]

$Cu(NO_3)_2$-K10

($Cu(NO_3)_2$)

[3251-23-8] · CuN_2O_6 · Copper(II) Nitrate-K10 Bentonite Clay · (MW 187.55)

(mild dethioacetalization agent;[2] oxidizing agent for 1,4-dihydropyridines;[3] highly selective nitrating reagent of halobenzenes[4] and aromatic hydrocarbons[5])

Alternate Name: claycop.

Solubility: insol water and organic solvents.

Form Supplied in: light blue, free-flowing powder prepared from K10 clay (30 g) and $Cu(NO_3)_2.3H_2O$ (20 g) in acetone (375 mL). After elimination of the solvent it retains about 10% H_2O.[1a,b]

Handling, Storage, and Precautions: no loss of activity is observed on standing for several weeks.[1a] Nitrates are potentially dangerous compounds. Scaling-up should be attempted only after appropriate safety tests. Avoid breathing dust; use in a fume hood. Store below 50 °C.

Oxidative Coupling of Thiols.

Claycop as a source of NO^+ ion effects the coupling of thiophenol into diphenyl disulfide (eq 1).[1a] This quantitative reaction serves as a reactivity test (see also ***Iron(III) Nitrate-K10 Montmorillonite Clay*** (clayfen)).[6]

(1)

Carbonyl Group Deprotections.

Thioacetals are used in organic syntheses for protection or umpolung of the reactivity of a carbonyl group.[7] *S,S*-Diethyl acetals, 1,3-dithianes, and 1,3-dithiolanes (eq 2) are cleaved into aldehydes and ketones by claycop under very mild conditions.[2] No external source of water is needed; it is provided by the internal structure of the clay. Although a wide

variety of reagents (e.g. *t*-BuSNO, Ph_3+PPMe Br_3^-, $Ph_2Se_2O_3$, $Fe(bipy)_3(ClO_4)_3.3H_2O$)[8a-d] are known to be equally effective for dethioacetalization, use of claycop shows advantages over existing methods. The reaction product is isolated simply by filtration of the spent reagent and evaporation of the filtrate.

(2)

Claycop has been utilized for the cleavage of selenoacetals (eq 3),[9] but higher yields can be obtained by the use of clayfen (97%)[9] or ***Copper(II) Chloride-Copper(II) Oxide*** (99%).[10]

(3)

Thiocarbonyl to carbonyl transformation is promoted by NO^+ ion (see also ***Nitrosonium Tetrafluoroborate***).[11] Clayfen gives excellent results with aromatic substrates while claycop is less reactive and is limited in use to aliphatics (eq 4).[12]

(4)

Aromatization of 1,4-Dihydropyridines.

1,4-Dihydropyridinedicarboxylates are aromatized smoothly at ambient temperature by claycop (eq 5).[3] 4-Arylpyridines are formed in 80-93% yields. Sonication greatly reduces the reaction time (from hours to 5-10 min).[13a] ***Pyridinium Chlorochromate*** adsorbed on ***Montmorillonite K10*** exhibits similar activity.[13b]

(5)

Nitration by Claycop Under Menke Conditions.

Halobenzenes, deactivated for electrophilic aromatic substitution, are mononitrated by means of claycop in the presence of Ac_2O.[4] The proportion of *para* product is the largest for fluorobenzene (eq 6) and the smallest for iodobenzene. The *para* preference can be further improved: lowering the temperature to 0 °C increases the *para*:*ortho* ratio to 35:1. The *para* preference is modest under classical nitration procedures (e.g. 10.8:1 by ***Nitronium Tetrafluoroborate***/sulfolane).[14]

(6)

25:1

Quantitative mononitration of toluene can be performed by claycop under Menke conditions with high *para* selectivity (eq 7).[5] Acetyl nitrate is the likely nitrating species. The process is catalytic using ***Nitric Acid*** as reagent.[5c] Similar results are achieved by ***Benzoyl Nitrate***-zeolite catalyst.[15] Highly selective nitrating agents are obtained by complexation of NO_2BF_4 or Bu_4NNO_3 with crown ethers.[16a,b]

(7)

Copper(II) Nitrate-(±)-1-Phenylethylamine[1]

($Cu(NO_3)_2.3H_2O$)

[10031-43-3] · CuN_2O_6 · Copper(II) Nitrate-(±)-1-Phenylethylamine · (MW 241.60) ((±)-PhCH(Me)NH_2)

[618-36-0] · $C_8H_{11}N$ · Copper(II) Nitrate-(±)-1-Phenylethylamine · (MW 121.18)

(reagent for the oxidative coupling of phenols[2])

Physical Data: $Cu(NO_3)_2.3H_2O$: mp 114 °C. (±)-1-Phenylethylamine: bp 185 °C/756 mmHg; *d* 0.95 g cm^{-3}. The exact structure of the copper(II) complex is unknown; the number of phenylethylamine ligands is preferentially 4 (*n* = 4).

Form Supplied in: the reagent is prepared in situ; both compounds are commercially available. (±)-1-Phenylethylamine is a colorless oil; copper(II) nitrate trihydrate is a blue crystalline deliquescent material.

Analysis of Reagent Purity: $Cu(NO_3)_2.3H_2O$: > 99%. (±)-1-Phenylethylamine: ^1H NMR ($CDCl_3$, 200 MHz) δ 1.37 (d, *J* = 6.4 Hz, 3H), 4.07 (q, *J* = 6.7 Hz, 1H), 7.19-7.33 (m, 5H); ^{13}C NMR ($CDCl_3$, 50.29 MHz) δ 25.2 (q), 50.8 (d), 125.2 (d), 126.3 (d), 127.9 (d), 147.3 (s).

Preparative Methods: prepared in situ by complexation of copper(II) nitrate with 4 equiv of (±)-1-phenylethylamine in methanol under inert atmosphere.[1,2]

Handling, Storage, and Precautions: (±)-1-phenylethylamine is stable when stored in a sealed container under nitrogen.

General Considerations.

The copper(II) nitrate-(±)-1-phenylethylamine reagent (**1**) is a typical example of a number of copper(II) amine oxidizing agents.[1-3] Reagent (**1**) can effect the oxidative coupling of phenols under anaerobic conditions. Both C-C and C-O coupled products can be obtained. Characteristic examples are given.

Synthesis of Dehydrogriseofulvin.

Reaction of (**1**) with bisphenols leads to intramolecular C-O coupled products (eq 1).[1]

Synthesis of 1,1´-binaphthalene-2,2´-diols.

The oxidative dimerization of 2-naphthols with (**1**) provides 1,1´-binaphthols (eq 2).[2]

Unsymmetrical 1,1´-binaphthalene-2,2´-diols are formed in 80-97% yield by oxidative cross-coupling of differently substituted 2-naphthols mediated by related Cu^{II}-primary amine complexes.[3b] (*S*)-(-)-1,1´-Binaphthalene-2,2´-diol and (*S*)-(-)-10,10´-dihydroxy-9,9´-biphenanthryl have been prepared with optical purities up to 98% by a similar oxidative coupling using chiral nonracemic primary amines.[1,3a,3d]

Copper(I) Oxide

Cu_2O

[1317-39-1] · Cu_2O · Copper(I) Oxide · (MW 143.08)

(weak base; activates halides towards nucleophilic substitution;[1] forms carbenoid intermediates from diazo compounds[2] and radicals from arenediazonium salts;[3] activates isocyanides towards 1,1-addition[4])

Physical Data: mp 1235 °C; *d* ~6 g cm^{-3}.

Solubility: insol most organic solvents; slightly sol quinoline and benzonitrile;[1a] variously sol acids (salt formation, in some cases disproportionation to Cu^0 and Cu^{II}).

Form Supplied in: red to brown powder; widely available. Typical impurities: Cu, CuO,[5] NaCl,[5] stabilizers (e.g. gelatine,[5] oil, zinc stearate), moisture.[5] For reactions in anhydrous media the reagent is vacuum-dried before use.

Preparative Methods: since reactions involving Cu_2O are heterogeneous, they may critically depend on the particle size.[6b] An active preparation is obtained by reduction of Cu^{II} solutions[7] but may suffer deactivation at high reaction temperatures.[1a]

Handling, Storage, and Precautions: Cu_2O is incompatible with alkynes, diazonium salts, and diazo compounds. Copper compounds are moderately toxic.

Activation of Halides Towards Nucleophilic Substitution.

Aryl halides react in the presence of Cu_2O with a variety of nucleophiles such as thiols and thiolates (eq 1),[6] phenols and phenoxides (eq 1),[1a,8,9] ammonia and amines,[9,10] lactams (eq 2),[11] cyclic imides,[11,12] ***Sodium Borohydride***,[5] and alkynes (eq 3).[13] Copper thiolates have been prepared from Cu_2O and subsequently used in a separate step.[6a,b] ***Lithium Bromide*** or ***Tetra-n-butylammonium Bromide*** transforms iodides into bromides.[1a] Typical solvents include pyridine, 2,4,6-collidine, quinoline, DMF, and DMA; elevated temperatures are required. DMSO has been used but methylthiolation occurs as a side reaction.[1a] The order of reactivity is chlorides < bromides < iodides. Besides aryl halides, vinyl halides and also 1-bromododecane react with CuSPh in good yields.[6a] An allylic iodide has been hydrolyzed by warming with Cu_2O in DMSO/water.[14] Fluorides are obtained from secondary and tertiary aliphatic chlorides or bromides with ***Hydrogen Fluoride*** and Cu_2O in ether or THF.[15]

(1)

X = O, 84%; S, 99%

(2)

(3)

Reduction is a common side reaction for aryl halides,[1,5,9,10e] especially with alkoxides and with phenols bearing electron-withdrawing substituents. With ***Sodium Ethoxide*** in refluxing 2,4,6-collidine, reduction can be the main pathway.[5] The same reagent system reduces α-bromo ketones to ketones.[5,10e] Replacement of Cu_2O by ***Copper(I) Iodide*** gives largely substitution for sodium derivatives of *n*-alkanols and cyclohexanol.[16] Reduction of 1-bromonaphthalene also predominates with carboxylic acids,[17] whereas haloferrocenes give acyloxyferrocenes.[18] Ullmann coupling to form biaryls is occasionally observed.[1,19]

Thiophenes,[20] benzothiazole,[21] pentafluorobenzene (eq 4),[20] and di- and trinitrobenzenes[22] are arylated by aryl iodides/Cu_2O. Carboxylic acids may also serve as starting materials, the reaction then proceeding with concomitant decarboxylation (see below).[23]

Decarboxylations.

Aromatic and vinylic carboxylic acids are decarboxylated by heating with Cu_2O (alone or with addition of 2,2´-bipyridyl)[24] in high-boiling solvents such as DMF, NMP, or quinoline. The Cu_2O-bipyridyl protocol has been applied to a homocubanecarboxylic acid which decarboxylates with skeletal rearrangement.[25] On dry heating with Cu_2O, α-cyanoacrylic acids furnish predominantly *cis*-α,β-unsaturated nitriles (eq 5).[26] Malonic acids (eq 6)[27] as well as some arylacetic acids capable of forming stabilized benzylic anions[28] decarboxylate with Cu_2O in acetonitrile.

Vicinal dicarboxylic acids undergo oxidative bisdecarboxylation to form alkenes when treated with Cu_2O and 2,2´-bipyridyl (eq 7).[29] Yields are usually higher than those obtained by electrolysis or with ***Lead(IV) Acetate*** but aromatization may interfere. Under 1 bar of oxygen at 50 °C, diphenylacetic acid and α-hydroxy carboxylic acids are oxidatively decarboxylated to ketones by Cu_2O in acetonitrile.[30]

(7)

Reactions of Diazo Compounds.

Cu_2O acts as a catalyst for the decomposition of α-diazo carbonyl compounds (more often used are ***Copper*** powder or ***Copper(II) Sulfate***) to give rise, via carbenoid intermediates, to cyclopropanation (eq 8) and C-H insertion (eq 9) products.[2] Most examples are intramolecular, but the reaction of *N*-methylpyrrole with ethyl diazoacetate giving predominantly insertion into the α-C-H bond has been described.[31] The performance of Cu_2O vs. other catalysts is variable.[2] In the intramolecular cyclopropanation of a 4-diazoindol-7-one derivative, a copper(I) triflate carbonyl complex prepared in situ from Cu_2O gave best results.[32]

(8)

(9)

Reactions of Diazonium Salts.

Copper(I) oxide forms radicals from arenediazonium salts which may undergo subsequent transformations like reduction (eq 10),[33] coupling to form biaryls,[34] oxidation to phenols by copper(II) nitrate (eq 11),[3] Meerwein arylation of acrylic acid derivatives,[35] homolytic aromatic substitution (eq 12),[3,36] or substitution by nitrite.[37] The oxidation reaction offers the advantage to uncatalyzed thermolysis in that it proceeds without heating or a large excess of strong

acid and usually gives phenols, even in cases where cyclization onto an *ortho* substituent normally predominates.

(10)

(11)

(12)

1,1-Addition to Isocyanides.

Substituted formimidates are obtained from isocyanides and alcohols, thiols, amines (eq 13), or amides in the presence of Cu_2O.[4] The intramolecular version of this reaction, combined in one pot with the hydroxyalkylation of an activated (allyl, benzyl, α-alkoxycarbonyl) isocyanide by an aldehyde or ketone, results in Δ^2-oxazolines.[38] Selenol esters as electrophiles yield oxazoles (eq 14),[39] and α,β-unsaturated esters or nitriles produce Δ^1-pyrrolines.[38] Analogous

schemes involving aromatic side chain metalation have been utilized in the synthesis of indoles (eq 15),[40] 3,1-benzoxazepines,[41] 3,1-benzoxazocines,[41] and 1,3-benzodiazepin-4-ones.[40a]

(13)

(14)

(15)

Miscellaneous Reactions.

Cu_2O catalyzes a variety of other transformations such as the Koch carboxylation of alkenes and alcohols by CO in strong acids. The reaction proceeds via carbenium ions, and skeletal rearrangements are the rule.[42] Polyhalomethanes and di- and trichloroacetic acid esters add to 1,3-butadiene and styrene.[43] Terminal alkynes form dimeric vinyl alkynes in boiling AcOH (eq 16).[44] Michael additions are catalyzed by Cu_2O in the presence of isocyanides,[45] as is the esterification of carboxylic acids with alkyl halides[46] and the cyclopropanation of electron-poor alkenes with α-halo carbonyl and trichloromethyl compounds.[38c,47] Exclusive β-hydrosilylation of acrylonitrile occurs with Cu_2O and TMEDA under sonication.[48] Cyclohexene is acetoxylated in up to 30% enantiomeric excess by ***t-Butyl Hydroperoxide***

and AcOH in acetonitrile with Cu_2O/proline as catalyst.[49] Autoxidation of furfural to furoic acid takes place in the presence of a Cu_2O-Ag_2O catalyst.[50] Allylic alcohols are transformed into acetates with oxygen attached to the less substituted terminus by Cu_2O in AcOH/Ac_2O (eq 17).[51] ***Copper(II) Trifluoromethanesulfonate*** in the presence of Cu_2O in nitrile solvents oxidatively couples enol silyl ethers to 1,4-diketones[52] and oxidatively cyclizes δ,ε- and ε,ζ-unsaturated enol silyl ethers (eq 18).[53]

$Cu_2O.[t\text{-}BuNC]_m$

(Cu_2O)

[1317-39-1] · Cu_2O · Copper(I) Oxide-*t*-Butyl Isocyanide · (MW 143.08) (*t*-BuNC)

[7188-38-7] · C_5H_9N · Copper(I) Oxide-*t*-Butyl Isocyanide · (MW 83.13)

(precursor to organocopper compounds reacting in aldol- and Michael-type fashion; cyclopropanation reagent; used in heterocycle synthesis)

Physical Data: reagent prepared in situ; see entries for ***Copper(I) Oxide*** and ***t-Butyl Isocyanide***.

Solubility: sl sol H_2O; sol common organic solvents.

Form Supplied in: *t*-BuNC: liquid; purified by distillation.

Preparative Methods: *t*-butyl isocyanide may be prepared by dehydration of the corresponding *N*-*t*-butylformamide.[1] The reagent is generated in situ by mixing *t*-butyl isocyanide with copper(I) oxide (or copper powder) under nitrogen prior to use. Reactions with copper(0) are described below.

Handling, Storage, and Precautions: *t*-BuNC is flammable and highly toxic. All reactions should be conducted in a well-ventilated fume hood.

Aldol and Michael Reactions: Heterocycle Synthesis.

Copper(I) oxide-*t*-butyl isocyanide and copper(0)-*t*-butyl isocyanide react with active methylene compounds to form the corresponding organocopper(I) complexes with the accompanying formation of H_2O and H_2, respectively.[2] The reaction mixture thus obtained reacts with ketones and aldehydes in the manner of the aldol condensation[2] and with α,β-unsaturated carbonyl and nitrile compounds in the manner of the Michael addition.[2]

Alkyl isocyanides having an active α-hydrogen react, in the presence of a catalytic amount of copper(I) oxide, with α,β-unsaturated carbonyl or nitrile compounds and with ketones or aldehydes, producing 1-pyrroline and 2-oxazoline derivatives, respectively (eqs 1 and 2).[3]

Copper(I) oxide-*t*-butyl isocyanide induces dimerization of α,β-unsaturated carbonyl and nitrile compounds (eq 3).[4]

Cyclopropanations: Use of Copper(0).

Copper(I) carbenoid intermediates, which may be generated in situ by the reactions of α-halo carboxylic acid esters and nitriles with copper(I) oxide-*t*-butyl isocyanide complexes, are used for cyclopropanation of electron-deficient alkenes (eq 4).[5]

When ***Copper*** powder is substituted for Cu_2O, the resulting mixed reagent reacts with active halogen compounds, probably through an oxidative addition of the carbon-halogen bond, to generate organocopper compounds. Copper(0)-*t*-

butyl isocyanide promotes cyclopropanation of α,β-unsaturated esters and nitriles with trichloromethyl compounds such as trichloroacetonitrile and trichloroacetate (eq 5).[6]

Similarly, as shown in eq 6, vinylcyclopropanes can be prepared in moderate yields by the reaction of 1,3- or 3,3-dichloropropenes with α,β-unsaturated esters.[7]

Allenes.

The reagent employing copper powder reductively transforms *gem*-dibromocyclopropanes to allenes (eqs 7 and 8).[8]

Copper(II) Permanganate

$$Cu(MnO_4)_2.7H_2O$$

[82002-29-5] · $CuMn_2O_8$ · Copper(II) Permanganate · (MW 427.52)

(oxidant capable of converting saturated and α,β-unsaturated secondary alcohols into the corresponding ketones, primary alcohols and aldehydes into carboxylic acids, and sulfides into sulfones)

Physical Data: high-melting solid.

Solubility: sol water; insol methylene chloride.

Form Supplied in: red solid, commercially available.

Handling, Storage, and Precautions: oxidant, store in glass vessel at rt.

Oxidation.

Hydrated copper permanganate is an excellent oxidant for alcohols and sulfides when used heterogeneously in methylene chloride.[1,2] For secondary alcohols, the reaction is complete in a few minutes when alcohol (2.5 mmol in 2 mL of methylene chloride) is added to the oxidant (1.2 g, 2.7 mmol). For primary alcohols, aldehydes, and sulfides the reaction time is on the order of 24 h.[2,3] In all cases the products are easily isolated in good yields by filtration followed by flash evaporation of the solvent. The anhydrous reagent is much less effective. Examples of typical reactions are given in eqs 1-7.

(1)

(2)

(3)

(4)

(5)

(6)

(7)

The presence of alkenes inhibits the oxidation of alcohols[4] and sulfides,[3] presumably by formation of π-complexes at the active site of the homogeneous reagent, thereby preventing direct contact between the alcohol and the oxidant. Interestingly, although alkenes inhibit the oxidation of other reductants, their presence does not result in reduction of the reagent to an observable extent. It has been suggested that the failure of the reagent to oxidize non-allylic unsaturated alcohols, such as cholesterol, may also be due to formation of a π-complex with the remote double bond.[4]

A reagent prepared from a finely ground mixture of $KMnO_4$ and $CuSO_4.5H_2O$ has properties similar to copper(II) permanganate heptahydrate; however, its reactions are in general less vigorous and require longer times to reach completion (see ***Potassium Permanganate-Copper(II) Sulfate***).

Copper(I) Phenoxide

PhOCu

[34046-55-4] · C_6H_5CuO · Copper(I) Phenoxide · (MW 156.65)

(phenoxylating agent for organic halides,[1] organosulfur compounds,[2] and carbon tetrachloride;[3] undergoes carbon-carbon bond cleavage by oxygen[4])

Solubility: sol DMF, diglyme; insol ether and benzene.

Preparative Methods: metathesis reaction between ***Copper(I) Chloride*** and alkali metal phenoxide in MeCN or THF produces a solution of Cu^I phenoxide complexed with alkali metal chloride,[1,2] which can be used for synthetic purposes. Cu^I phenoxide without alkali metal chloride can be prepared by phenolysis of ***Methylcopper***,[1] ***Phenylcopper***,[5] and ***Copper(I) t-Butoxide***[4] or by metathesis between $[Cu(MeCN)_4]PF_6$ and sodium phenoxide.[6]

Handling, Storage, and Precautions: oxygen- and moisture-sensitive; preparation and reaction should be conducted under rigorously oxygen-free and anhydrous conditions.

Aryl Ether Synthesis.

Alkyl phenyl ethers (eq 1) and diphenyl ether (eq 2) are prepared in good yield using Cu^I phenoxide.[1] Phenyl ether synthesis proceeds under milder reaction conditions than the Williamson ether synthesis. Cu^I phenoxide has been proposed to be an intermediate of the Ullmann ether synthesis.

(1)

$$\text{PhOCu} \xrightarrow[\text{94\%}]{\text{PhI, py, 115 °C}} \text{PhOPh} \qquad (2)$$

Sulfur Substitution.

Cu^I phenoxide reacts with carbon disulfide at room temperature to afford phenyl orthocarbonate (eq 3).[2] Substituted Cu^I phenoxides can also be used. This reaction has been called the thiophilic reaction of Cu^I and provides a synthetic method for phenyl orthocarbonate without using phosgene. Nucleophilic addition and substitution in a tetrameric Cu^I phenoxide cluster has been proposed. The reaction in the presence of a tri-*n*-butylphosphine ligand produces thiocarbonate $(PhO)_2C{=}S$ in excellent yield. At the elevated reaction temperature of 65 °C, the reaction of Cu^I phenoxide with thiocarbonates takes place to give mixed orthocarbonates $(ArO)_2(PhO)_2C$. Substitution of the sulfur atom of sodium xanthates ROCSSNa, dithioesters RCSSR, and trithiocarbonates $(RS)_2CS$ by the phenoxide anion occurs to afford mixed thiocarbonates (PhO)(RO)C=S, phenyl thioesters R(PhO)C=S, and phenyl thiocarbonate $(PhO)_2C{=}S$, respectively.

$$4\ \text{PhOCu} + CS_2 \xrightarrow[\text{92\%}]{\text{MeCN, rt}} C(OPh)_4 + 2\ Cu_2S \qquad (3)$$

Chlorine Substitution of CCl_4.

Cu^I phenoxide reacts with CCl_4 via a radical mechanism to afford phenyl orthocarbonate (eq 4),[3] while nucleophilic reaction of sodium phenoxide with CCl_4 does not give phenyl orthocarbonate. The reaction depends upon the substitution pattern at the *ortho* positions of the phenyl group. Two examples are shown in eqs 5 and 6.

$$\text{PhOCu} \xrightarrow[\text{50\%}]{CCl_4,\ \text{MeCN, rt}} C(OPh)_4 \qquad (4)$$

(5)

(6)

Oxygenolysis.

Cleavage of the carbon-carbon bond of Cu^I phenoxide takes place upon exposure to oxygen to afford *cis,cis*-muconic acid monophenyl ester (eq 7).[4] Cu^I phenoxide has been proposed to be an active reaction intermediate in the copper-promoted oxygenolysis of phenol.

Copper(II) Sulfate

$CuSO_4.5H_2O$

[7758-99-8] · CuO_4S · Copper(II) Sulfate · (MW 249.68)

(Lewis acid catalyst for alcohol dehydration,[1] acetonide formation,[6] acetal exchange;[9] reagent for formation of copper carbenoids,[15] intramolecular cyclopropanations;[21] redox catalyst with potassium permanganate for oxidation of alcohols[25] and alkenes[28])

Physical Data: 110 °C, -4H_2O; 150 °C, -5H_2O; heating above 560 °C causes decomposition to CuO; *d* 2.28 g cm^{-3}.

Solubility: sol H_2O and methanol; slightly sol ethanol; insol acetone and ether; anhyd form sol H_2O, practically insol methanol and ethanol.

Form Supplied in: blue solid, widely available. *Drying:* for certain applications, copper(II) sulfate must be used as an anhyd reagent; dehydration of $CuSO_4.5H_2O$ can be accomplished by heating in an open porcelain dish at 275 °C for two days in a drying oven, stirring the sample several times during the drying period to break up any lumps; during this time the deep blue crystals are converted to an off-white powder.

Handling, Storage, and Precautions: $CuSO_4.5H_2O$ can be stored and handled in the laboratory using normal laboratory methods; anhyd $CuSO_4$ is a powerful desiccant and must be stored out of contact with moisture, but can be weighed and transferred in the laboratory if atmospheric exposure is minimized; copper(II) sulfate is a strong irritant to the skin and mucous membranes.

Introduction.

The principal uses of $CuSO_4$ in organic synthesis stem from the chemical properties of Cu^{2+}. Firstly Cu^{2+} functions as a Lewis acid towards electron donor functions and can thus promote a variety of acid-catalyzed processes. Secondly Cu^{2+} reacts readily with diazo compounds to give carbenoid intermediates useful in subsequent addition reactions. Thirdly Cu^{2+} functions as an effective redox catalyst in several mixed oxidizing systems.

Lewis Acid Catalysis.

Complexation of oxygen by Cu^{2+} makes an oxygen-containing functional group a much better leaving group. As

such, the Cu^{2+} functions as a typical Lewis acid; however, anhyd $CuSO_4$ can be used effectively to promote a variety of reactions that would be adversely affected by significant amounts of water. The dehydration of alcohols by anhyd $CuSO_4$ is an excellent general method for the preparation of alkenes.[1] The alcohol (neat or in an inert solvent) is heated with 0.75-1.0 equiv of $CuSO_4$.[1-3] The copper sulfate can be used alone or supported on silica gel.[4] The method works well for benzylic, allylic, tertiary, and secondary alcohols, but is unsuitable for primary alcohols, which give the bis-ether rather than the alkene. The product mixtures are similar to those obtained in proton-catalyzed eliminations and suggest that carbocation intermediates are involved in the reaction. The method is mild and suitable for the formation of sensitive alkenes (eq 1).[5] See also ***Copper(II) Trifluoromethanesulfonate***, ***Phosphoric Acid***, ***Potassium Hydrogen Sulfate***, and ***Sulfuric Acid***.

Anhyd copper sulfate is also an excellent catalyst for the formation of acetonides from glycols and acetone (eq 2).[6,7] Either ***2,2-Dimethoxypropane*** or ***2-Methoxypropene*** can sometimes improve the efficiency. The regiochemistry of the copper-catalyzed process is different from that found in the proton-catalyzed reaction.

Acetonides can also be produced directly from epoxides and acetone using anhyd $CuSO_4$,[8] and acetal exchange can be used to deprotect ethylene glycol acetals under very mild conditions (eq 3).[9] Anhyd $CuSO_4$ has also been used as a Lewis acid catalyst for the removal of trityl protecting groups[10] and for Friedel-Crafts acylation of alkenes.[11]

Complexation of nitrogen by Cu^{2+} has been used to advantage in several cases. The selective hydrolysis of α-

aminodiesters is guided by chelation to nitrogen and activation of the vicinal ester group (eq 4).[12] Cycloreversions of 2-azanorbornenes to give primary amines are catalyzed efficiently by copper sulfate (eq 5).[13] Copper sulfate (or other Cu^{2+} sources) facilitates the preparation of ***Diimide*** from ***Hydrazine*** by complexation with nitrogen.[14] See also ***Copper(II) Acetate***.

Copper Carbenoids.

Copper(II) catalysts (as well as other copper species) promote the decomposition of diazo compounds and produce copper carbenoids as reactive intermediates. This is particularly useful for α-diazo carbonyl compounds, which then can add to unsaturated systems to give cyclopropanes.[15] In addition, chiral ligands can be attached to the copper, yielding cyclopropanes in high optical purities.[16,17]

Because intramolecular alkene additions are particularly favored with copper catalysts,[18] and because the low coordinating ability of the sulfate counterion is thought to contribute to an increased electrophilicity of the copper carbenoid when copper sulfate is used as the catalyst,[19] anhyd $CuSO_4$ has been used in a variety of intramolecular cyclopropanations (eqs 6 and 7, for example).[20,21]

(7)

In the absence of double bonds, intramolecular insertion reactions into C-H bonds are observed (eq 8).[22] Recently, intramolecular insertion into the B-H bond of a carborane has been found to occur readily.[23] Anhyd $CuSO_4$ has also been used effectively to promote the formation of sulfur ylides in the reactions of diazo compounds and sulfides.[24] See also ***Copper(I) Acetylacetonate***.

(8)

Redox Catalyst.

Solid mixtures of $CuSO_4$ and oxidizing agents are useful for the oxidation of alcohols. For example, it was found that a solid mixture of ***Potassium Permanganate*** and copper sulfate pentahydrate oxidized secondary alcohols to ketones in high yields; however, primary alcohols were not oxidized under the same conditions.[25] This selectivity is quite unusual since under homogeneous conditions potassium permanganate vigorously oxidizes both primary and secondary alcohols. This selectivity is reversed by admixture of a solid base (either $CuCO_3$, ***Copper(II) Hydroxide***, or ***Potassium Hydroxide***) to the $KMnO_4$-$CuSO_4.5H_2O$ oxidant (eq 9).[26]

(9)

These results are rationalized on the basis of the heterogeneous oxidation which takes place on the surface of the solid oxidant. In the absence of an admixed base, secondary alcohols produce ketones which diffuse away from the oxidant surface. Primary alcohols produce carboxylic acids which are bound to the oxidizing surface, effectively blocking further reaction. Inclusion of the heterogeneous base results in neutralization of the acid product and reexposure of the oxidant surface; thus the normal selectivity is restored.

In these oxidations the use of hydrated $CuSO_4$ is mandatory. In fact, it was found that addition of catalytic amounts of water to the solid oxidant creates a more reactive oxidant for the synthesis of lactones from hydroxyaldehydes (eq 10).[27] Small quantities of aqueous *t*-butanol added to the solid oxidant permit the direct conversion of alkenes to α-hydroxy ketones and α-diketones (eq 11).[28] Normally, alkenes are inert to the solid oxidant. These differences are attributed to the formation of a thin aqueous phase on the surface of the oxidant (&OOmega; phase) which facilitates phase transfer between the bulk liquid and the surface.

(10)

(11)

Copper sulfate in combination with ascorbic acid and oxygen has been used as a source of hydroxyl radicals to study the oxidation of dopamine.[29] Furthermore, copper sulfate has been used as a catalyst in the Ullmann reaction.[30] In both these cases, however, the copper sulfate merely serves as a source of Cu^{2+} which is reduced to a copper(I) species that is thought to be the key player in the process.

Related Reagents.

Copper(II) Sulfate-Pyridine

($CuSO_4.5H_2O$)

[7758-99-8] · CuO_4S · Copper(II) Sulfate-Pyridine · (MW 249.68) (py)

[110-86-1] · C_5H_5N · Copper(II) Sulfate-Pyridine · (MW 79.10)

(hydration of aryl-substituted oxiranes;[1] oxidation of hydroxy ketones[2])

Physical Data: see ***Copper(II) Sulfate*** and ***Pyridine***.

Hydration of Aryl-Substituted Epoxides.

Aryl-substituted oxiranes undergo stereospecific *cis* ring opening in the presence of copper(II) sulfate and pyridine in an aqueous phosphate buffer (pH 7), producing *cis*-diols. Hydration occurs at the benzylic position of the aryl-substituted epoxide. *Trans* cleavage products are also obtained in less than 15% yield (eq 1).[1]

It was also shown that *cis*-chlorohydrins could be prepared from aryl-substituted epoxides in a reaction involving copper sulfate, pyridine, and ***Lithium Chloride*** in THF (eq 2). Lithium chloride increases the catalytic activity of copper(II) sulfate in this reaction. However, when methanol is used as a solvent, *cis*-glycol monomethyl ethers are obtained (eq 3). Under such conditions, a reaction with alkyl-substituted epoxides does not take place. Substitution occurs at the benzylic position.[1]

(2)

(3)

Oxidation of Hydroxy Ketones.

Oxidation of benzoin by oxygen (or air) in the presence of stoichiometric amounts of copper(II) sulfate in aqueous pyridine gives benzil in 80% yield (eq 4).[2] Similarly, furil was obtained from furoin in 63% yield (eq 5)[3] and α-hydroxybenzyl 2-pyrrolyl ketone was oxidized to phenyl-2-pyrrolylglyoxal in 95% yield (eq 6).[4]

Copper(II) Tetrafluoroborate

$Cu(BF_4)_2$

[38465-60-0] · B_2CuF_8 · Copper(II) Tetrafluoroborate · (MW 237.15)

(Lewis acid capable of promoting Diels-Alder reactions;[1] promotes decomposition of diazo compounds;[2] functions as an oxidizing agent;[3] reacts with siloxycyclopropanes to generate β-acylalkylcopper(II) species;[4] in combination with hydrosilanes is a *syn*-selective reducing agent of alkynic sulfones[5])

Physical Data: d 2.175 g cm^{-3} for the hexahydrate.[6]

Solubility: sol water, THF, MeOH, EtOH; insol ether.

Form Supplied in: blue powder. *Drying:* copper(II) tetrafluoroborate ($Cu(BF_4)_2.xH_2O$), irrespective of the number of crystalline water, has a highly hygroscopic nature. Therefore, prior to use, it should be dried and stored in a dry nitrogen atmosphere (e.g. over KOH at 25 °C for 5 d;[1] P_2O_5 at 50 °C/1 mmHg overnight;[4,5] at 100 °C, under high vacuum for 5 h[7]). Previous work has suggested that dehydration of the hexahydrate to give a tetrahydrate[8] takes place easily at reduced pressure at rt, while the anhydrous salt appears to be unknown. Accordingly, note that the procedures so far examined for drying are unlikely to give a pure anhydrous salt.

Handling, Storage, and Precautions: because of its highly hygroscopic nature, copper(II) tetrafluoroborate should be stored so as to preclude contact with moisture. Lumps should be crushed only in a glove bag or dry box filled with N_2. Use in a fume hood.

Catalyst of Diels-Alder Reactions.

Copper(II) tetrafluoroborate has been found to promote Diels-Alder reaction of 5-methoxymethyl-1,3-cyclopentadiene and α-chloroacrylonitrile (eq 1).[1] This dienophile serves as a ketene synthon; thus, when subjected to alkaline hydrolysis, the product gives the bicyclic ketone. A similar acceleration of Diels-Alder reactions by copper tetrafluoroborate is recognized in the reaction of α-methylthioacrylonitrile and cyclopentadiene (eq 2).[9] The thermal process requires heating to 140 °C without solvent, whereas the copper-catalyzed reaction can be conducted at 20 °C in benzene solution. With furan as a dienophile, copper tetrafluoroborate in combination with hydroquinone catalyzes the [4 + 2] cycloaddition (eqs 3 and 4).[10,11] In this reaction system, a copper(I) tetrafluoroborate complex, formed through the reduction of copper(II) by hydroquinone, is believed to play a key role.[10]

Decomposition of Diazo Compounds.

Like other copper salts, copper(II) tetrafluoroborate can serve as the catalyst for the decomposition of diazo compounds to generate copper carbenoids.[2] The preference of cyclopropanation by ***Ethyl Diazoacetate*** (EDA) for less-substituted alkenes has been observed specifically with copper(II) tetrafluoroborate (also with ***Copper(II) Trifluoromethanesulfonate***), showing different selectivity with other copper catalysts (***Copper(II) Acetylacetonate***, ***Copper(I) Iodide-Trimethyl Phosphite***, $(MeO)_3P.CuCl$, ***Copper(II) Sulfate***, etc.) (eq 5). The active catalyst may be alkene coordinated copper(I) tetrafluoroborate,[12] which might be generated by the reduction of copper(II) tetrafluoroborate by diazo compounds.

$Cu(OTf)_2$	96% (21:79)
$Cu(acac)_2$	96% (64:36)

The copper(II) tetrafluoroborate-catalyzed reaction of EDA with *N*-methylpyrrole gives a mixture of 2- and 3-acetate adducts (eq 6).[13] Thermal decomposition of a pyrazoline to give a cyclopropane ring can be performed efficiently with a catalytic amount of copper tetrafluoroborate in refluxing benzene (eq 7).[14]

Oxidations.

Irradiation of a solution of benzyltrimethylsilane and 2 equiv of copper tetrafluoroborate in acetonitrile-methanol (3:1) with a 300 W high-pressure mercury lamp through a quartz filter gives benzyl methyl ether in 70% yield. Tetrakis(acetonitrile)copper(I) tetrafluoroborate is formed as a byproduct (eq 8).[3] The oxidation sequence can be applied to benzylgermanes and benzylstannanes. The reaction mechanism may involve (i) one-electron transfer from photoexcited singlet organometallic compounds to Cu^{II} to form the cation radical and Cu^{I}, (ii) dissociation of the cation radical to an arylmethyl radical, and (iii) the second oxidation of the radical by Cu^{II} to give the benzyl cation and Cu^{I}. It has also been reported that copper(II) tetrafluoroborate can be used for the effective oxidation of 5-*exo*-alkyl-5*H*-phlorin derivatives to give the corresponding 5-alkylporphyrins.[15] The oxidation ability of copper tetrafluoroborate has been utilized for the iodofunctionalization of alkenes, where Cu^{2+} ion oxidizes iodine to form iodonium cation.[16] In this reaction, water, alcohol, carboxylic acid, lithium chloride, sodium iodide, etc. can be used as the nucleophile.

Reaction with Siloxycyclopropanes.

Copper tetrafluoroborate causes ring-opening of siloxycyclopropanes to provide useful synthetic reactions.[4] Treatment of a siloxycyclopropane with $Cu(BF_4)_2$ results in desilylative dimerization to give a 1,6-diketone in good yield (eq 9).[17] The ring-opening takes place regioselectively across the bond between the methylene and siloxy carbons. The reaction is reasonably interpreted by assuming electrophilic ring-opening by Cu^{2+} ion to form the β-copper(II) ketone, followed by dimerization.

(9)

With ***Dimethyl Acetylenedicarboxylate*** and water, β-(acyl)alkyls can be trapped to give dimethyl 2-(3-oxoalkyl)maleates with a high degree of stereoselectivity (eq 10).[17] The selectivity arises from *syn* addition of β-copper(II) ketone across the triple bond followed by in situ protonation of the resulting vinylcopper species with retention of configuration. The stereoselective transfer of β-(acyl)alkyls to alkynic sulfones, which gives β-(acyl)alkylated vinylic sulfones, is also successful (eq 11). Intramolecular cyclization with 1-phenyl-2-trimethylsilyloxy-2-(3-hexenyl)cyclopropane results in modest amounts of the 5-*exo* cyclization product.[18]

(10)

Reaction with Hydrosilanes.

Copper(II) tetrafluoroborate reacts readily with hydrosilanes to give hydrogen and trialkylfluorosilanes (eq 12). When an alkynic sulfone is present in this system, highly stereoselective *syn* reduction takes place to give a vinylic sulfone (eq 13).[5] The mechanism involving the *syn* addition of HCu^{II} seems likely.

Related Reagents.

Copper(II) Trifluoromethanesulfonate

$Cu(OSO_2CF_3)_2$

[34946-82-2] · $C_2CuF_6O_6S_2$ · Copper(II) Trifluoromethanesulfonate · (MW 361.68)

(dimerization of ketone enolates and TMS enol ethers;[2a,2b] cyclization of dienolates[2c] and unsaturated silyl enol ethers;[4] allylation of ketones;[3] reactions of diazo compounds;[5-10] dehydration of alcohols[11])

Alternate Name: copper(II) triflate.

Physical Data: dec at 530 °C (no definite mp).

Solubility: sol MeOH, EtOH, DMF, MeCN, and formamide; also sol *i*-PrCN and acetone.

Form Supplied in: white powder, commercially available. Blue powder when freshly prepared (see below).

Preparative Methods: most conveniently prepared from copper(II) carbonate and triflic acid (***Trifluoromethanesulfonic Acid***) in MeCN.[1] The freshly prepared salt precipitated from Et_2O is pale blue.

Handling, Storage, and Precautions: moisture sensitive; can be handled in air for quick transfers; pure samples are only mildly corrosive. Appears to be indefinitely stable in the absence of air, moisture, and light.

Oxidative Coupling.

Both intermolecular and intramolecular oxidative coupling reactions can be effected using $Cu(OTf)_2$. Examples of dimerization include one-pot syntheses of 1,4-diketones from ketone enolates or from silyl enol ethers (eqs 1 and 2),[2a,2b] and coupling of allylstannanes with TMS-enol ethers to give γ,δ-unsaturated ketones in good to moderate yields (eq 3). Other copper(II) or tin(IV) catalysts can also be used with allylstannanes. The regiochemistry depends on both the substrate and the catalyst.

$R^1 = Ph,\ R^2 = H$ 55%
$R^1 = Ph,\ R^2 = Me$ 27%

Examples of intramolecular oxidative cyclizations promoted by $Cu(OTf)_2$ include cyclization of enolates of diketones and diesters (eq 4)[2c] and oxidative cyclization of hydrolytically resistant δ,ε- and ε,ζ-unsaturated silyl enol ethers.[4] For instance, (**1**) reacts with excess $Cu_2O/Cu(OTf)_2$ in MeCN to give a 90% yield of a 20:1 mixture of the *trans*-fused and *cis*-fused tricyclic ketones (**2**) and (**3**) (eq 5).[4]

(4)

(1)

(2) (3)

(5)

Reactions of Diazo Compounds.

These include various cyclopropanations where the metal carbenoid generated from the diazoacetic acid esters/$Cu(OTf)_2$ system reacts with alkenes (eq 6) or carbodiimides (eq 7).[5,6]

(6)

$Cu(OTf)_2$ is the reagent of choice for intramolecular cyclization of β,γ-unsaturated diazo ketones to cyclopentenones (eq 8) and for intramolecular cyclopropanation of γ,δ-unsaturated diazo ketones (eq 9).[7]

It is a useful reagent for orthoester homologation via dialkoxycarbenium ions and for oxazole formation by reaction of ketocarbenes (via diazo esters/$Cu(OTf)_2$) with nitriles (eq 10).[8] With unsaturated nitriles, the nitrile group is selectively attacked. Kinetic and ESR evidence shows that Cu^{II} -> Cu^{I} reduction is the key step.[9]

The regiochemistry of the monoacetate adducts formed from *N*-methylpyrrole with the carbenoid derived from $N_2CHCO_2Et/Cu(OTf)_2$ is indicative of a reactive and less discriminating intermediate compared to carbenoids generated from N_2CHCO_2Et with other Cu^{II} reagents (eq 11).[10]

(11)

Angularly functionalized polycyclic systems may be prepared from β,γ-unsaturated diazo ketones by a vinylogous Wolff rearrangement in the presence of copper(II) triflate. Dry ***Copper(II) Acetylacetonate*** is equally suitable.[10]

Dehydration of Alcohols.

Various tertiary, secondary, and primary alcohols are dehydrated with $Cu(OTf)_2$ to alkenes.[11] Preferred formation of Zaitsev orientation products and (*E*)-alkenes are indicative of a carbocationic mechanism. $Zn(OTf)_2$ and $Mg(OTf)_2$ are ineffective. In selected examples, yields are superior to those of H_2SO_4 and $POCl_3$/pyridine dehydrations.[11] See also ***Copper(II) Sulfate***.

Elimination Reactions.

A $Cu(OTf)_2$/Hünig base combination provides a useful method for converting 1,1-bis(phenylthio)cyclobutanes to 1-(phenylthio)cyclobutenes (eq 12).[12]

(12)

Reduction of Alkynyl Sulfones.

The $HSiEt_2Me/Cu(OTf)_2$ system reduces alkynyl sulfones to *cis* vinylic sulfones (eq 13).[13] The yields with ***Copper(II) Tetrafluoroborate*** are higher than those with $Cu(OTf)_2$. Dimeric side products are formed in some cases.

(13)

Oxazoles from Ketones.

Aliphatic ketones react with nitriles in the presence of $Cu(OTf)_2$ and catalytic amounts of ***p-Toluenesulfonic Acid*** in refluxing MeCN to give oxazoles.[14] The oxazole produced in this way is isomeric with that formed from a ketone and an amide (eq 14).

(14)

Oxidation of Alkyl Radicals.

Various alkyl radicals are oxidized with Cu^{II} triflate or perchlorate to carbenium ions whose reactivities are similar to solvolytically formed cations (eq 15).[1] The synthetic utility of such $Cu(OTf)_2$-catalyzed oxidations remains to be explored.

(15)

Related Reagents.

Copper(II) Sulfate; ***Copper(I) Trifluoromethanesulfonate***.

Copper(I) Trifluoromethanesulfonate

$CuOSO_2CF_3$

[42152-44-3] · $CCuF_3O_3S$ · Copper(I) Trifluoromethanesulfonate · (MW 212.62) (2:1 benzene complex)

[37234-97-2; 42152-46-5] · $C_8H_6Cu_2F_6O_6S_2$ · Copper(I) Trifluoromethanesulfonate · (MW 503.34)

(efficient catalyst for 2π + 2π photocycloadditions and other photoreactions of alkenes,[1] and for alkene cyclopropanation and other reactions of diazo compounds; also a selenophilic and thiophilic Lewis acid that enhances the nucleofugacity of selenide and sulfide leaving groups)

Alternate Name: copper(I) triflate.

Physical Data: moisture-sensitive white crystalline solid.

Solubility: sol MeCN, $MeCO_2H$, 2-butanone, alkenes; slightly sol benzene.

Form Supplied in: must be freshly prepared.

Preparative Methods: copper(I) trifluoromethanesulfonate (CuOTf) was first prepared as a solution in acetonitrile by synproportionation of ***Copper(II) Trifluoromethanesulfonate*** with copper(0).[2] The Cu^I in these solutions is strongly coordinated with acetonitrile, forming complexes analogous to ***Tetrakis(acetonitrile)copper(I) Perchlorate***.[3] A white crystalline solid benzene complex, $(CuOTf)_2.C_6H_6$, is prepared by the reaction of a suspension of ***Copper(I) Oxide*** in benzene with ***Trifluoromethanesulfonic Anhydride***.[4] Traces of ***Trifluoromethanesulfonic Acid*** apparently catalyze the reaction.[5] CuOTf is generated in situ by the reduction of $Cu(OTf)_2$ with diazo compounds.[6]

Handling, Storage, and Precautions: moisture sensitive.

Cyclopropanation with Diazo Compounds.

Copper(I) triflate is a highly active catalyst for the cyclopropanation of alkenes with diazo compounds.[6] In contrast to other more extensively ligated copper catalysts, e.g. ***Copper(II) Acetylacetonate***, that favor cyclopropanation of the most highly substituted C=C bond, cyclopropanations catalyzed by CuOTf show a unique selectivity for cyclopropanation of the least alkylated C=C bond in both intermolecular (eq 1) and intramolecular (eq 2) competitions. The same selectivity is found with $Cu(OTf)_2$ as *nominal* catalyst. This is because $Cu(OTf)_2$ is reduced by the diazo compound to CuOTf, and CuOTf is the *actual* cyclopropanation catalyst in both cases.[6] Selective cyclopropanation of

the least substituted C=C bond is a consequence of the alkene coordinating with the catalyst prior to interaction with the diazo compound, and the increase in stability of Cu^I-alkene complexes with decreasing alkyl substitution on the C=C bond. For catalysts with more strongly ligated Cu^I, an electrophilic carbene or carbenoid intermediate reacts with the free alkene, and the preference for cyclopropanation of the more highly substituted C=C bond arises from the enhancement of alkene nucleophilicity with increasing alkyl substitution (see ***Copper(II) Trifluoromethanesulfonate***).

(1)

CuX_n	Ratio		
CuOTf	17%	0.25:1	67%
$Cu(OTf)_2$	21%	0.27:1	77%
$Cu(acac)_2$	61%	1.78:1	35%

(2)

X = acetylacetonate	86%	14%
X = triflate	33%	66%

Cyclopropanecarboxylic esters are conveniently available, even from volatile alkenes, because CuOTf promotes cyclopropanations in good yields at low temperatures. Thus *trans*- and *cis*-2-butenes, boiling under reflux, react stereospecifically with ***Ethyl Diazoacetate*** to produce the corresponding ethyl 2,3-dimethylcyclopropanecarboxylates (eqs 3 and 4),[6] and cyclobutene reacts with ethyl diazoacetate at 0 °C to deliver a mixture of *exo*- and *endo*-5-ethoxycarbonylbicyclo[2.1.0]pentanes (eq 5).[7]

(3)

(4)

(5)

CuOTf is an outstandingly effective catalyst for the synthesis of cyclopropyl phosphonates by the reaction of ***Diethyl Diazomethylphosphonate*** with alkenes (eq 6).[8] The resulting cyclopropylphosphonates are useful intermediates for the synthesis of alkylidenecyclopropanes by Wadsworth-Emmons alkenation with aromatic carbonyl compounds (eq 7).[8]

(6)

(7)

A complex of a chiral, nonracemic bis(oxazoline) with CuOTf is a highly effective catalyst for asymmetric cyclopropanation of alkenes.[9] Copper(II) triflate complexes do not catalyze the reaction unless they are first converted to Cu^{I} by reduction with a diazo compound or with phenylhydrazine. CuOTf complexes are uniquely effective. Thus the observed enantioselectivity and catalytic activity, if any, are much lower with other Cu^{I} or Cu^{II} salts including halide, cyanide, acetate, and even perchlorate. Both enantiomers of the bis(oxazoline) ligand are readily available. Spectacularly high levels of asymmetric induction are achieved with both mono- (eq 8) and 1,1-disubstituted alkenes (eq

9).

(8)

(9)

Asymmetric Aziridination.

A chiral, nonracemic bis(oxazoline) complex of copper(I) triflate catalyzes asymmetric aziridination of styrene in good yield (eq 10).[9] However, enantioselectivity is not as high as the corresponding cyclopropanation (eq 8).

(10)

Photocycloadditions.

CuOTf is an exceptionally effective catalyst for 2π + 2π photocycloadditions of alkenes.[1] Thus while CuBr promotes photodimerization of norbornene in only 38% yield,[10] the same reaction affords dimer in 88% yield with CuOTf as catalyst (eq 11).[11] A mechanistic study of this reaction revealed that although both 1:1 and 2:1 alkene Cu^I complexes are in equilibrium with free alkene and both the 1:1 and 2:1 complexes absorb UV light, only light absorbed by the 2:1 complex results in photodimerization. In other words, photodimerization requires precoordination of both C=C bonds with the Cu^I catalyst. Thus the exceptional ability of CuOTf, with its weakly coordinating triflate counter anion, to form π-complexes with as many as four C=C bonds[12] is of paramount importance for its effectiveness as a photodimerization catalyst.

The importance of precoordination is also evident in the CuOTf-promoted 2π + 2π photocycloaddition of *endo*-dicyclopentadiene. This diene forms an isolable 2:1 complex with CuOTf involving *exo*-monodentate coordination with the 8,9-C=C bond of two molecules of diene. Consequently, intermolecular 2π + 2π photocycloaddition involving *exo* addition to the 8,9-C=C bond is strongly favored over intramolecular reaction between the 8,9- and 3,4-C=C bonds (eq 11).[11] This contrasts with the intramolecular photocycloaddition that is promoted by high energy triplet sensitizers.[12]

(11)

Especially interesting is the *trans,anti,trans* stereochemistry of the major cyclobutane product generated in the photodimerization of cyclohexene (eq 12).[13] It was noted that the formation of this product may be the result of a preliminary CuOTf promoted *cis-trans* photoisomerization that generates a *trans*-cyclohexene intermediate (eq 13).[13] Since one face of the *trans* C=C bond is shielded by a polymethylene chain, the *trans*-cyclohexene is restricted to suprafacial additions. Although a highly strained *trans*-cyclohexene intermediate could be stabilized by coordination with Cu^I, such a complex has not been isolated.

(12)

(13)

An isolable CuOTf complex of a highly strained alkene, *trans*-cycloheptene, is produced by UV irradiation of a hexane solution of *cis*-cycloheptene in the presence of CuOTf (eq 14).[14] Photocycloaddition of cycloheptene is also catalyzed by CuOTf. Surprisingly, the major product is not a *trans,anti,trans* dimer analogous to that formed from cyclohexene (eq 12) but rather a *trans,anti,trans,anti,trans* trimer (eq 15).[15]

(14)

(15)

Dissolution of the *trans*-cycloheptene-CuOTf complex in cycloheptene and evaporation of the solvent delivers a tris alkene complex of CuOTf containing one *trans*-cycloheptene and two *cis*-cycloheptene ligands. Heating *trans*-cycloheptene-CuOTf in neat *cis*-cycloheptene delivers the *trans,anti,trans,anti,trans* trimer (eq 16). Experiments with

cis-cycloheptene-d_4 show that the cyclotrimerization involves only *trans*-cycloheptene molecules, although the reaction is accelerated by the presence of *cis*-cycloheptene.[16] A likely explanation for these observations is concerted "template" cyclotrimerization of a tris-*trans*-cycloheptene-CuOTf complex formed by ligand redistribution (eq 16).[16]

(16)

The involvement of a transient photogenerated *trans*-cyclohexene-CuOTf intermediate was also adduced to explain CuOTf catalysis of photoinduced 2π + 4π cycloaddition between *cis*-cyclohexene and 1,3-butadiene (eq 17).[17] In contrast to thermal Diels-Alder reactions, this reaction generates *trans*-Δ^2-octalin rather than the *cis* cycloadduct expected for a $2\pi_s + 4\pi_s$ cycloaddition. A mechanism was proposed that involves the $2\pi_s + 4\pi_s$ cycloaddition of a *trans*-cyclohexene with 1,3-butadiene in the coordination sphere of Cu^I (eq 18).[17]

(17)

(18)

That CuOTf-catalyzed 2π + 2π photocycloadditions are not restricted to cyclic alkenes was first demonstrated in mixed cycloadditions involving allyl alcohol. To suppress homodimerization of *endo*-dicyclopentadiene (i.e. eq 11) the diene to Cu^{I} ratio is maintained at <=1:1 and allyl alcohol is used as solvent. Under these conditions, a high yield of mixed cycloadduct is generated (eq 19).[18]

(19)

That both C=C bonds participating in 2π + 2π photocycloadditions can be acyclic is evident from the photobicyclization reactions of simple diallyl ethers that deliver bicyclic tetrahydrofurans (eq 20).[19,20] In conjunction with ***Ruthenium(VIII) Oxide***-catalyzed oxidation by ***Sodium Periodate***, these CuOTf-catalyzed photobicyclizations provide a synthetic route to butyrolactones from diallyl ethers (eq 20).[20] The synthetic method is applicable to the construction of multicyclic tetrahydrofurans and butyrolactones from diallyl ethers (eqs 21 and 22) as well as from homoallyl vinyl ethers (eq 23).[20]

(20)

3-Oxabicyclo[3.2.0]heptanes are also produced in the CuOTf-catalyzed photocycloadditions of allyl 2,4-hexadienyl ethers (eq 24).[21] The CuOTf-catalyzed photocycloadditions of bis-2,4-hexadienyl ethers are more complex. Thus UV irradiation of 5,5´-oxybis[(*E*)-1,3-pentadiene] in THF for 120 h produces vinylcyclohexene and tricyclo[3.3.0.0^{2,6}]octane derivatives (eq 25).[22] However, shorter irradiations reveal that these products arise by secondary CuOTf-catalyzed rearrangements of 6,7-divinyl-3-oxabicyclo[3.2.0]heptanes that are the primary photoproducts (eq 26). UV irradiation of the divinylcyclobutane intermediates in the presence of CuOTf promotes formal [1,3]- and [3,3]-sigmatropic rearrangements to produce a vinylcyclohexene and a 1,5-cyclooctadiene that is the immediate precursor of the tricyclo[3.3.0.0^{2,6}]octane.

(24)

CuOTf-catalyzed photobicyclization of 1,6-heptadien-3-ols produces bicyclo[3.2.0]heptan-2-ols (eq 27).[23] In conjunction with pyrolytic fragmentation of the derived ketones, these CuOTf-catalyzed photobicyclizations provide a synthetic route to 2-cyclopenten-1-ones from 1,6-heptadien-3-ols (eq 28).[23] The derived ketones can also be converted into lactones by Baeyer-Villiger oxidation and, in conjunction with pyrolytic fragmentation, CuOTf-catalyzed photobicyclizations provide a synthetic route to enol lactones of glutaraldehydic acid from 1,6-heptadien-3-ols (eq 28).[23]

(28)

Copper(I) triflate-catalyzed photobicyclization of β- and γ-(4-pentenyl)allyl alcohols provides a synthetic route to various multicyclic carbon networks in excellent yields (eqs 29-31).[24] The reaction was exploited in a total synthesis of the panasinsene sesquiterpenes (eq 32).[25] It is especially noteworthy in this regard that attempted synthesis of a key tricyclic ketone intermediate for the panasinsenes by the well-known photocycloaddition of ***Isobutene*** to an enone failed to provide any of the requisite cyclobutyl ketone (eq 33).[25]

In conjunction with carbocationic skeletal rearrangement, photobicyclization of 1,6-heptadien-3-ols provides a synthetic route to 7-hydroxynorbornanes (eq 34).[26] Noteworthy is the stereoselective generation of *exo*-1,2-polymethylenenorbornanes from either the *exo* or *endo* epimer of 2,3-polymethylenebicyclo[3.2.0]heptan-3-ol.

N,*N*-Diallylamides are recovered unchanged when irradiated in the presence of CuOTf.[27] This is because the amide chromophore interferes with photoactivation of the Cu^{I}-alkene complex. Thus CuOTf-alkene complexes containing one, two, three, or even four coordinated C=C bonds exhibit UV absorption at 235 ± 5 nm (ε$_{max}$ 2950 ± 450).[12] The CuOTf complex of ethyl *N*,*N*-diallylcarbamate exhibits λ_{max} = 233.4 nm (ε$_{max}$ 2676) but the free ligand is virtually transparent at this wavelength. Consequently, UV irradiation of ethyl *N*,*N*-diallylcarbamates in the presence of CuOTf delivers bicyclic (eq 35) or tricyclic (eq 36) pyrrolidines incorporating the 3-azabicyclo[3.2.0]heptane ring system.[27]

R^1	R^2	R^3	$\varepsilon_{233\ nm}$	Yield (%)

(36)

Catalyzed Diels-Alder Reactions.

The uncatalyzed thermal intramolecular Diels-Alder reaction of 5,5´-oxybis[(*E*)-1,3-pentadiene] nonstereoselectively generates four isomeric 4-vinylcyclohexenes (eq 37). The major product has a *trans* ring fusion, in contrast to the single *cis* ring-fused isomer generated in the copper(I) triflate-catalyzed photoreaction of the same tetraene (eq 25). Copper(I) triflate also catalyzes a thermal Diels-Alder reaction of 5,5´-oxybis[(*E*)-1,3-pentadiene] that proceeds under milder conditions than the uncatalyzed reaction. The stereoselectivity is remarkably enhanced, generating mainly the major isomer of the uncatalyzed thermal reaction and a single *cis*-fused isomer (eq 37) that is different than the one favored in the photochemical reaction (eq 25).

(b)	76%	<1%	<1%	11%

C_{sp}-H Bond Activation.

Hydrogen-deuterium exchange between terminal alkynes and CD_3CO_2D is catalyzed by CuOTf (eq 38).[28] Proton NMR studies revealed that CuOTf and alkynes form π-complexes that rapidly exchange coordinated with free alkyne. A complex of CuOTf with 1,7-octadiene was isolated (eq 39). The complex rapidly exchanges terminal alkynic hydrogen

with deuterium from CD_3CO_2D and undergoes a much slower conversion to a copper alkynide (eq 39).[28] Exchange of alkynic hydrogen and deuterium is also catalyzed by CuOTf (eq 40).[28]

(38)

(39)

(40)

Activation of Aryl Halides.

Ullmann coupling of *o*-bromonitrobenzene is accomplished under exceptionally mild conditions and in homogeneous solution by reaction with copper(I) triflate in the presence of aqueous NH_3 (eq 41).[29] Yields are enhanced by the presence of a small quantity of copper(II) triflate. That the reaction is diverted to reductive dehalogenation by ***Ammonium Tetrafluoroborate*** is presumptive evidence for an organocopper intermediate that can be captured by protonation.

(41)

Biaryl is only a minor product from the reaction of methyl *o*-bromobenzoate with CuOTf (eq 42). The major product can result from replacement of the halide by NH_2, H, or OH, depending on reaction conditions. In the presence of 5% aqueous NH_3, methyl anthranilate is the major product.[30] More concentrated aqueous NH_3 (20%) favors the generation of methyl salicylate, and the yield of this product is enhanced by the presence of a substantial quantity of Cu^{II} ion.[29] Reductive dehalogenation is favored by the presence of ammonium ions, presumably owing to protonolysis of an arylcopper(III) intermediate.[29]

(42)

Activation of Vinyl Halides.

Under the optimum conditions for reductive coupling of *o*-bromonitrobenzene (eq 41), diethyl iodofumarate gives very little coupling product; the overwhelming product was diethyl fumarate generated by hydrodehalogenation (eq 43).[29]

Reductive coupling delivers *trans,trans*-1,2,3,4-tetraethoxycarbonyl-1,3-butadiene in 95% yield (GLC, or 80% of pure crystalline product) in 2 h if aqueous NH_3 is replaced by anhydrous NH_3.[29] Under the same conditions, diethyl iodomaleate undergoes 45% conversion in 20 h to deliver diethyl maleate, as well as minor amounts of *cis,cis*- and *trans,trans*-tetraethoxycarbonyl-1,3-butadiene (eq 44).[29] The stereospecificity of the reductive dehalogenations in eqs 43 and 44 is presumptive evidence for the noninvolvement of radicals in these reactions.

(43)

(44)

Elimination of Thiophenol from Thioacetals.

Conversion of thioacetals to vinyl sulfides is accomplished under exceptionally mild conditions by treatment with $(CuOTf)_2.C_6H_6$ (eq 45).[31] The reaction involves an α-phenylthio carbocation intermediate. Three factors contribute to the effectiveness of this synthetic method: the Lewis acidity of a copper(I) cation that is unencumbered by a strongly coordinated counter anion, the solubility of the copper(I) triflate-benzene complex, and the insolubility of CuSPh in the

reaction mixture. An analogous elimination reaction provides an effective route to phenylthio enol ethers from ketones (eq 46).[31]

This conversion of thioacetals into vinyl sulfides was applied to a C-C connective synthesis of 2-phenylthio-1,3-butadienes from aldehydes (eq 47).[32] The key elimination step converts cyclobutanone thioacetal intermediates into 1-phenylthiocyclobutenes that undergo electrocyclic ring opening to deliver dienes.

A different synthesis generates 2-phenylthio-1,3-butadienes directly by elimination of two molecules of thiophenol from β-phenylthio thioacetals that are readily available from the corresponding α,β-unsaturated ketones (eq 48).[33]

CuOTf-promoted elimination of thiophenol was exploited in two syntheses of 1-phenylthio-1,3-butadiene, one a C-C connective route from allyl bromide[31] and bis(phenylthio)methyllithium,[34] and another from ***Crotonaldehyde*** (eq 49).[33] A topologically analogous C-C connective strategy provides 2-methoxy-1-phenylthio-1,3-butadiene from acrolein (eq

50).[5,33] That the phenylthio rather than the methoxy substituent in 2-methoxy-1-phenylthio-1,3-butadiene controls the orientation of its Diels-Alder cycloadditions is noteworthy (eq 50).

(50)

A synthesis of 4-alkyl-2-methoxy-1-phenylthio-1,3-butadienes by a simple β-elimination of thiophenol from a thioacetal is not possible owing to skeletal rearrangement that is fostered by stabilization of a cyclopropylcarbinyl carbocation intermediate by the alkyl substituent (eq 51).[35] Interconversion of an initial α-phenylthio carbocation to a more stable α-methoxy carbocation intermediate leads to the generation of a 4-alkyl-1-methoxy-2-phenylthio-1,3-butadiene instead.

(51)

Syntheses of 1-phenylthio-1,3-butadienes from carboxylic esters (eq 52) and carboxylic acids (eq 53) are achieved by CuOTf-promoted elimination of thiophenol from intermediate thioacetals.[36]

(52)

Heterocyclization of γ-Keto Dithioacetals.

A C-C connective synthesis of furans is completed by a CuOTf-promoted heterocyclization of γ-keto thioacetals (eq 54).[31] Rather than simple β-elimination to generate a vinyl sulfide (eq 46), a presumed γ-keto carbocation intermediate is captured intramolecularly by an intimately juxtaposed carbonyl oxygen nucleophile.

Friedel-Crafts Alkylation of Arenes with Thioacetals.

$(CuOTf)_2.C_6H_6$ promotes α-thioalkylation of anisole by a dithioacetal under mild conditions (eq 55).[37]

Elimination of Benzylic Phenyl Thioethers.

That C-S bond activation by CuOTf is not limited to substrates that can generate sulfur-stabilized carbocation intermediates is illustrated by a C-C connective synthesis of *trans*-stilbene (eq 56).[31] The elimination of thiophenol under mild conditions is favored by benzylic stabilization of a carbocation intermediate or an E2 transition state with substantial carbocationic character.

Hydrolysis of Vinylogous Thioacetals.

Carbanions prepared by lithiation of γ-phenylthioallyl phenyl thioethers can serve as synthetic equivalents of β-acyl vinyl anions.[38] Umpölung of the usual electrophilic reactivity of 2-cyclohexenone is achieved by a sequence exploiting electrophilic capture of a lithiated vinylogous thioacetal and subsequent CuOTf-assisted hydrolysis (eq 57).[39] Otherwise unfunctionalized vinylogous thioacetals can be hydrolyzed to enones by ***Mercury(II) Chloride*** in wet acetonitrile.[38] However, the keto-substituted derivative in eq 57 gave only a 25% yield of enone by this method. A superior yield was obtained by CuOTf-assisted hydrolysis.[39]

Grob Fragmentation of β-[Bis(phenylthio)methyl]alkoxides.

A method for achieving Grob-type fragmentation of five- and six-membered rings depends upon the ability of a thiophenyl group to both stabilize a carbanion and serve as an anionic leaving group. For example, reaction of cyclohexene oxide with lithium bis(phenylthio)methide[34] produces a β-[bis(phenylthio)methyl]alkanol that undergoes fragmentation in excellent yield upon treatment with ***n-Butyllithium*** followed by CuOTf (eq 58).[40] Copper(I) trifluoroacetate is equally effective but salts of other thiophilic metals, e.g. mercury or silver, were ineffective. Treatment of the intermediate β-[bis(phenylthio)methyl]alkanol with CuOTf in the absence of added strong base leads primarily to elimination of thiophenol as expected (see eq 45). Fragmentation does not occur with only one equivalent of CuOTf. This suggests a key intermediate with at least one Cu^{I} ion to coordinate with the alkoxide and another to activate the phenylthio leaving group (eq 58).

Ring-Expanding Rearrangements of α-[Bis(phenylthio)methyl]alkanols.

A one-carbon ring-expanding synthesis of α-phenylsulfenyl ketones from homologous ketones depends upon the ability of a thiophenyl group to both stabilize a carbanion and serve as an anionic leaving group. For example, reaction of cyclopentanone with lithium bis(phenylthio)methide[34] produces an α-[bis(phenylthio)methyl]alkanol that rearranges to a ring-expanded α-phenylsulfenyl ketone in good yield upon treatment with CuOTf in the presence of ***Diisopropylethylamine*** (eq 59).[41] Epoxy thioether intermediates are generated from the α-[bis(phenylthio)methyl]alkanols by intramolecular nucleophilic displacement of thiophenoxide.

(59)

An analogous synthesis of α,α-bis(methylsulfenyl) ketones from homologous ketones by one-carbon ring expansion depends on copper(I)-promoted rearrangement of an α-tris(methylthio)methyl alkoxide intermediate (eq 60). Both ***Tetrakis(acetonitrile)copper(I) Perchlorate***[42] and ***Tetrakis(acetonitrile)copper(I) Tetrafluoroborate***[43] are effective in promoting the rearrangement but $(CuOTf)_2.C_6H_6$, $HgCl_2$, or $Hg(TFA)_2$ are not. Apparently, the MeCN ligand is crucial. Furthermore, treatment of the intermediate α-[tris(methylthio)methyl] alcohol with CuOTf and $EtN(i\text{-}Pr)_2$ in toluene followed by aqueous workup delivers an α-hydroxy methylthio ester (eq 61),[43] in contrast to the ring-expanding rearrangement of the analogous α-[bis(phenylthio)methyl]alkanol (eq 59).[41]

(60)

(61)

The α-[bis(phenylthio)methyl]alkanol derived from cycloheptanone does not undergo ring expansion upon treatment with CuOTf and EtN(*i*-Pr)$_2$ in benzene. Instead, 1,3-elimination of thiophenol delivers an epoxy thioether intermediate that undergoes a rearrangement involving 1,2-shift of a phenylsulfenyl group to produce an α-phenylsulfenyl aldehyde (eq 62).[41]

(62)

The α-[bis(phenylthio)methyl]alkanol derived from cyclohexanone, upon treatment with CuOTf and EtN(*i*-Pr)$_2$ in benzene, undergoes both ring-expanding rearrangement to deliver α-phenylsulfenylcycloheptanone as the major product, as well as rearrangement involving 1,2-shift of a phenylsulfenyl group to produce an α-phenylsulfenylcyclohexanecarbaldehyde (eq 63).[41] In contrast, neither ring expansion nor 1,2-shift of a methylsulfenyl group occurs upon treatment of α-[tris(methylthio)methyl]cyclohexanol with *n*-butyllithium followed by (MeCN)$_4$CuBF$_4$. Rather, after aqueous workup, an α-hydroxy methylthio ester is obtained (eq 64).[43]

(63)

(64)

Chain-Extending Syntheses of α-Phenylsulfenyl Ketones.

A C-C connective, chain-extending synthesis of α-phenylsulfenyl ketones from aldehydes (eq 65) or acyclic ketones (eq 66)[41] can be accomplished by a CuOTf-promoted activation of the α-[bis(phenylthio)methyl]alkanols generated by addition of lithium bis(phenylthio)methide.[34] Preferential migration of hydride generates phenylsulfenylmethyl ketones from aldehydes (eq 65). Regioselective insertion of a phenylsulfenylmethylene unit occurs owing to a preference for migration of the more highly substituted alkyl group of dialkyl ketones (eq 66).

(65)

(66)

Cyclopropanation of Enones.

Conjugate addition of lithium tris(phenylthio)methide[44] to α,β-unsaturated ketones produces enolates that cyclize to bis(phenylthio)cyclopropyl ketones at -78 °C upon treatment with nearly one equivalent of $(CuOTf)_2.C_6H_6$, i.e. 1.9 equivalents of Cu^I (eq 67).[45] The mild conditions that suffice to bring about nucleophilic displacement of thiophenoxide in the presence of CuOTf are especially noteworthy. In view of the requirement for more than one equivalent of Cu^I to achieve Grob-type fragmentation of β-[bis(phenylthio)methyl]alkoxides (see eq 58), it seems likely, although as yet unproven, that one equivalent of Cu^I coordinates strongly with the enolate oxygen and that a second equivalent of Cu^I is required to activate the thiophenoxide leaving group.

(67)

Vinylcyclopropanation of Enones.

Conjugate addition of sulfur-stabilized allyl carbanions to α,β-unsaturated ketones produces enolates that cyclize to vinylcyclopropyl ketones upon treatment with nearly one equivalent of $(CuOTf)_2.C_6H_6$, i.e. 1.9 equivalents of Cu^I (eq 68).[45]

Friedel-Crafts Acylation with Thio- or Selenoesters.

Methylseleno esters are readily available in excellent yields by the reaction of ***Dimethylaluminum Methylselenolate*** with *O*-alkyl esters.[37] These selenoesters will acylate reactive arenes (eq 69) and heterocyclic compounds (eq 70) when activated by CuOTf, a selenophilic Lewis acid.[37] Of the potential activating metal salts tested, $(CuOTf)_2.C_6H_6$ is uniquely effective. Mercury(II) or copper(I) trifluoroacetates that are partially organic-soluble, as well as the corresponding chlorides, silver nitrate, and copper(I) oxide that are not organic-soluble, all failed to promote any acylation. The highly reactive CuOTf-benzene complex, in dramatic contrast, was found to readily promote the acylations in benzene solution within minutes at room temperature. The presence of vinyl and keto groups is tolerated by the reaction, and while the alkyl- and vinyl-substituted derivatives afford *para* substitution only, a 2:1 mixture of *para* and *ortho* substitution occurs with the methylseleno ester of levulinic acid. Acylation of toluene is sluggish. Excellent yields of 2-acylfurans, -thiophenes, and -pyrroles are generated by this new variant of the Friedel-Crafts acylation reaction (eq 70). An intramolecular version of this reaction was shown to generate 1-tetralone from the methylseleno ester of γ-phenylbutyric acid (eq 71).[37]

Notwithstanding a prior claim that methylthio esters react only sluggishly under these conditions,[37] such a variant proved effective for a short synthesis of the 4-demethoxy-11-deoxyanthracycline skeleton (eq 72).[46] This is especially significant because methylthio esters are available by an efficient C-C connective process involving *C*-acylation of ketone lithium enolates with ***Carbon Oxysulfide*** (COS) followed by *S*-methylation with ***Iodomethane***.[46] For the deoxyanthracycline synthesis, the requisite enolate was generated by 1,4-addition of a silyl-stabilized benzyllithium derivative to 2-cyclohexenone. Treatment of the methylseleno ester with $(CuOTf)_2.C_6H_6$ in benzene, according to the method employed with analogous seleno esters,[37] results in efficient cyclization to deliver a tetracyclic diketone in good yield.

O-Acylation with Thioesters.

Activation of a thioester with $(CuOTf)_2.C_6H_6$ was exploited as a key step in the synthesis of a macrocyclic pyrrolizidine alkaloid ester (eq 73).[47] Since thioesters are relatively unreactive acylating agents, a highly functionalized imidazolide containing acetate and *t*-butyl thioester groups selectively acylated only the primary hydroxyl in the presence of the secondary hydroxyl group in (+)-retronecine. Completion of the synthesis required activation of the *t*-butylthio ester. ***Mercury(II) Trifluoroacetate***, that had proven effective for the synthesis of several natural products by lactonization,[48,49] failed to promote any lactonization in the present case.[47] Similarly, ***Mercury(II) Chloride*** and ***Cadmium Chloride***, that have proven effective for promoting lactonizations,[49] had no effect in the present case. Even copper(I) trifluoroacetate failed to induce the crucial lactonization. In contrast, CuOTf was uniquely effective for inducing the requisite macrolactonization by activating the thioester.

Crotonaldehyde[1]

(*E*)

[123-73-9] · C_4H_6O · Crotonaldehyde · (MW 70.09) (*Z*)

[15798-64-8]

(key electrophilic component in a wide variety of reactions[1])

Alternate Names: 2-butenal; crotonic aldehyde.

Physical Data: (*E*) isomer: mp -76.5 °C; bp 104.0 °C *d* 0.846 g cm^{-3}.

Solubility: sol H_2O (19.2 g/100 mL); sol alcohol, ether, and most organic solvents.

Form Supplied in: commercial crotonaldehyde is predominately the (*E*) isomer containing 4-6% of the (*Z*) isomer; also available as a 90% solution stabilized with 8-10% water.

Preparative Methods: pure (*E*) isomer and highly enriched (*Z*) isomer have been prepared by oxidation of (*E*)- and (*Z*)-crotyl alcohols.[2] Pure (*Z*) isomer has been prepared via a retro-Diels-Alder reaction at high temperature.[3]

Purification: fractionally distilled through a short Vigreux column.

Handling, Storage, and Precautions: to prevent polymerization and autooxidation, store under nitrogen atmosphere and refrigerate. Crotonaldehyde is readily absorbed through the skin and should be handled with gloves and protective clothing in a well ventilated fume hood. Toxicity: oral-rat LD_{50}: 300 mg kg^{-1}. Incompatible with strong acids, strong bases, oxidizing and reducing agents. Decomposes on prolonged exposure to air.

1,2-Additions.

Crotonaldehyde serves as an electrophilic target for a vast array of nucleophilic reagents. Grignard and organolithium reagents react to afford, after hydrolysis, good yields of secondary allyl alcohols.[1,4] 1,3-Dienes can be prepared by elimination of the resulting secondary allyl alcohols,[5] or via Wittig[6] and Wittig-type reactions.[7] Allyl[8] and alkynyl[9] organometallic reagents afford good yields of the allyl alcohols from crotonaldehyde, some with a good stereocontrol.[8c,d] Allylation in aqueous solvent is also possible.[10] Reformatsky reaction of difluorochloromethyl ketones utilizing a copper(I) or silver(I) catalyst with crotonaldehyde generates α,α-difluoro-β-hydroxy ketones in high yields,[11] while the corresponding dichlorofluoroacetates afford the (*Z*)-α-fluoro-α,β-unsaturated carboxylates.[12] Substituted lactones and butenolides are produced from 1,2-additions with nucleophilic reagents that possess latent carboxylate functionalities.[13] 1,3-Asymmetric induction has been achieved on addition of 2-lithio-2-(1-methyl-2-alkenyl)-1,3-dithianes to crotonaldehyde to produce predominately 1,3-*syn* adducts (eq 1).[14] Enantioselective 1,2-addition has been demonstrated using chiral allenic boranes to produce the propargyl carbinol in 97-98% ee.[15] The silylated cyanohydrin of crotonaldehyde is conveniently prepared using ***Sodium Cyanide*** impregnated on Amberlite XAD resin in the presence of ***Chlorotrimethylsilane***.[16] The enzyme mandelonitrile lyase catalyzes the enantioselective cyanohydrin formation from crotonaldehyde in as high as 95% ee.[17]

(1)

1,4-Additions.

In comparison, nucleophilic agents that preferentially add to the alkenic terminus of crotonaldehyde are few in number. Thiols,[1] sodium nitrite,[18] or imides,[1] malonate esters,[19] and nitromalonic or nitroacetic esters[1] in the presence of base generally add with good 1,4-selectivity. Methanetricarboxylic esters under phase transfer catalysis afford a 90% yield of the two-carbon elongated Michael adduct.[20] Surprisingly, the lithium dienolate of a chiral dioxinone adds in a Michael addition to give the four-carbon chain extended aldehyde with high diastereoselectivity (eq 2).[21] Cyclopropylacylsilanes are formed from initial Michael addition of an acylsilylsulfur ylide.[22] Examples of ring formation from crotonaldehyde involve an initial Michael addition followed by closure on the aldehyde carbonyl.[23] The Skraup synthesis of 2-methylquinolines utilizes this mode of cyclization.[24] Cyclization of crotonaldehyde on certain anthraquinones occurs through a Michael reaction followed by an intramolecular Marschalk reaction.[25] Organocopper reagents react predominately with 1,4-addition to produce the substituted aldehydes.[26]

(2)

Acetal Formation.

Crotonaldehyde reacts with a variety of alcohols or orthoformates, usually under acid catalysis, to form acetals.[1,27] Chiral C_2-symmetric acetals, for use as chiral auxiliaries, have been prepared (eq 3).[28] Cyclic dithioacetals of crotonaldehyde can easily be prepared from the dithiol using SiO_2-$SOCl_2$ as catalyst.[29]

(3)

Reduction.

Crotonaldehyde can be selectively reduced at either the carbonyl or the double bond to afford good yields of crotyl alcohol or butyraldehyde. Hydride transfer reagents, Meerwein-Pondorf-Verley reduction, or catalytic hydrogenation using Os on charcoal, all give crotyl alcohol.[30] Hydrogenation over Pd catalysts gives varying amounts of butyraldehyde.[1,30] Nickel catalysts at elevated temperatures fully hydrogenate crotonaldehyde to butanol.[1,30]

Aldol Condensations.

Crotonaldehyde readily participates in a wide variety of aldol condensations. Classic Knoevenagel condensation as well as Co^{II}-catalyzed Knoevenagel condensations lead to dienone products.[31] Dienones and dienoates may also be produced by reaction with the lithium enolates of ketones and esters in the presence of TMSCl at low temperature.[32] Stereoselective aldol additions to crotonaldehyde have been numerous. Many highly *anti*-[33] and *syn*-selective[34] additions to crotonaldehyde have been demonstrated, one a catalytic asymmetric *syn*-selective

aldol (eq 4).[35] An asymmetric aldol between crotonaldehyde and ***p-Tolylsulfonylmethyl Isocyanide*** catalyzed by a chiral silver(I) catalyst affords the *trans*-4-tosyl-2-oxazoline in 85% ee.[36] Diastereoselective aldols can also be achieved using chiral (η^6-arene)chromium complexes.[37]

(4)

Pericyclic Reactions.

Crotonaldehyde is a versatile participant in pericyclic reactions. In Diels-Alder reactions it may either function as a diene or dienophile. As a diene, crotonaldehyde reacts at elevated temperatures with alkenes to afford a wide variety of substituted dihydropyrans.[1,38] The addition of a lanthanide catalyst allows the cyclization to occur at significantly lower temperature.[39] Additionally, enolized forms of crotonaldehyde also function as dienes.[40] The double bond of crotonaldehyde acts as dienophile towards an array of 1,3-dienes.[1] The temperature required for these cyclizations may be reduced by the addition of Lewis acid catalysts.[41] Asymmetric catalysts have been developed for the reaction of crotonaldehyde with cyclopentadiene.[42] The *endo* isomer predominates and ee's range from 2-96%. An asymmetric catalyst that promotes the hetero-Diels-Alder reaction of crotonaldehyde with Danishefsky diene, affording product dihydropyrone in 92% ee (eq 5), has also been described.[43] Lewis-acid complexes of crotonaldehyde are normally unreactive towards ordinary alkenes in ene processes. However, a Lewis acid assisted ene-reaction of crotonaldehyde with achiral[44] and chiral[45] 2-(alkylthio)allyl silyl ethers has been reported. The achiral ene-reaction is highly *trans* selective and the chiral ene-reaction occurs with almost complete chirality transfer.

Crotyl Chloride

[591-97-9] · C_4H_7Cl · Crotyl Chloride · (MW 90.55)

(butenylating agent via Grignard and other organometallic reagents,[1,2] organoborane compounds,[3] other nucleophiles,[4] and organosilane compounds[5])

Alternate Name: 1-chloro-2-butene.

Physical Data: (*E*) isomer: bp 84.8 °C/752 mmHg; n_D^{20} 1.4350; d_4^{20} 0.9295 g cm^{-3}; (*Z*) isomer: bp 84.1 °C/758 mmHg; n_D^{20} 1.4390; d_4^{20} 0.9426 g cm^{-3}.

Solubility: (*Z*) isomer: insol H_2O; sol alcohol, acetone, and chloroform; (*E*) isomer: insol H_2O; sol acetone and chloroform.

Form Supplied in: clear liquid; widely available in 70% purity, predominantly (*E*) isomer. Main impurity: 3-chloro-1-butene.

Preparative Methods: pure isomers can be prepared by chloride displacement of corresponding alcohols via Ph_3P in various solvents,[7] and other chlorinating agents.[8]

Handling, Storage, and Precautions: flammable and corrosive; incompatible with strong oxidizing agents and strong bases; store in a cool dry place. Use in a fume hood.

Electrophilic Reactions.

Crotyl chloride, like other allylic chlorides, acts as an electrophile to undergo nucleophilic substitution with organometallic agents[1,9] which include Grignard reagents,[1,10] organolithium[11] and organocuprate reagents.[12] Extensive mechanistic studies suggest that these transformations proceed via concerted S_N2 (which gives α-substituted product) and S_N2' (which gives γ-substituted product) reactions.

In reactions with a given nucleophile, (*E*) and (*Z*) isomers often afford different ratios of α- and γ-substituted products. In the case of phenyllithium,[11] (*E*)-crotyl chloride gives an α/γ ratio of 75/25, whereas the (*Z*) isomer gives an α/γ ratio of 25/75.

The regioselectivity of α- vs. γ-substitution is enhanced in reaction with alkyl cuprates, e.g. ***Lithium Di-n-butylcuprate*** gives an α/γ ratio of 96/4. When combined with an alkylcopper in the presence of a Lewis acid, e.g. with *n*-BuCu/BF_3, regioselectivity is reversed to afford an α/γ ratio of 2/98.[9b] However, the Lewis acid does not significantly increase the regioselectivity with PhCu (the α/γ ratio remains the same at 16/84 in presence of ***Boron Trifluoride Etherate***).[9b] Higher regioselectivity for α-phenyl substitution can be achieved by converting crotyl chloride to crotyl triethylsilyloxy ether, then combining it with ***Phenylmagnesium Bromide*** in the presence of a catalytic amount of ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)*** ($PdCl_2$(dppf)). This gives a α/γ ratio of 96/4.[2,10] When $NiCl_2$(dppf) is used as the catalyst, γ-substitution is the major pathway with α/γ of 12/88. High γ-substitution (95-100%) regioselectivity is observed when crotyl chloride reacts with alkyl(aryl)zinc chlorides mediated by CuCN.2LiBr (see ***Copper(I) Cyanide***).[12]

In addition to reaction with organometallic reagents, crotyl chloride also undergoes substitution with other nucleophiles. For example, when reacted with sodium benzenethiosulfonate in ethanol at 50 °C, it gives crotyl thiosulfonates. This can then be followed by reaction with vinylalanates to generate crotyl vinyl sulfides (eq 1),[4a] which readily undergo thio-Claisen rearrangement when heated in a mixture of dimethoxyethane and water.

Another example of such nucleophilic substitution is the regioselective cross-coupling with organoboranes. Crotyl chloride can be cross-coupled with alkyl-9-BBN mediated by ***Methylcopper*** to give mainly the 1,4-diene γ-substitution products (eq 2).[3,13] The 1,5-diene α-substitution products can be obtained by reacting crotyl chloride with lithium alkylthioallyl borates.[14]

(2)

Upon deprotonation with a strong base (e.g. ***Lithium Diisopropylamide***) at -78 °C, a crotyl chloride carbanion is formed.[6] This carbanion then reacts with ***Chlorotrimethylsilane*** to generate α-chlorocrotyltrimethylsilane. Like other substituted allylsilanes, it reacts with a variety of electrophiles when activated by Lewis acids (e.g. $BF_3.OEt_2$, ***Titanium(IV) Chloride***) to afford vinyl chlorides with (*Z*) selectivity (eq 3).

(3)

Nucleophilic Reactions.

As an allylic chloride, crotyl chloride can be easily converted into a wide variety of crotyl organometallic reagents[5b] and crotylsilane compounds.[15] The reagents serve as nucleophiles for addition to various carbonyl compounds, imines, oxime silyl ethers, and other electrophiles to generate homoallylic alcohols, amines, and hydroxylamines. Crotyl chloride forms organometallic reagents with a wide range of metals including lithium, potassium, magnesium, barium, tin, zinc, copper, boron, aluminum, titanium, zirconium, chromium, etc. An extensive review on the use of crotyl organometallic and other allylic organometallic compounds has appeared.[5b]

Crotylmagnesium chloride (see ***Crotylmagnesium Bromide***), easily prepared by stirring crotyl chloride with excess magnesium in ether at rt,[15a] has recently been used to generate nitrones or *N*,*N*-disubstituted hydroxylamines by reaction with aliphatic nitro compounds.[16] More commonly, however, crotylmagnesium chloride is used for nucleophilic addition to carbonyl groups to yield homoallylic alcohols. The regioselectivity and yields of these reactions are often enhanced by addition of other metals and/or metal salts, e.g. Mn, ***Cerium(III) Chloride***, $TiCl_4$, etc.[16,17]

B-Crotyldiisopinocampheylborane[1]

(+)-(*Z*)

[99397-92-9] · $C_{24}H_{41}B$ · *B*-Crotyldiisopinocampheylborane · (MW 340.40) (+)-(*E*)

[99438-29-6] (-)-(*Z*)

[99438-30-9] (-)-(*E*)

[99493-12-6]

(reagent for the asymmetric crotylboration of aldehydes to produce either *syn*- or *anti*-β-methylhomoallylic alcohols[2])

Solubility: reagent is prepared and used in situ at -78 °C in THF.

Preparative Methods: prepared from ***B-Methoxydiisopinocampheylborane*** and either (*Z*)- or (*E*)-crotylpotassium (eq 1).

Handling, Storage, and Precautions: because of the facile isomerization of allylic boranes, crotylborane reagents should be generated and reacted at -78 °C.

Addition to Aldehydes.

B-Crotyldiisopinocampheylboranes (Ipc_2BCrt) condense with aldehydes at low temperatures (-78 °C) to provide β-methylhomoallylic alcohols in 60-80% yield and with excellent enantio- (90-94% ee) and diastereoselection (&egt;99% de).[2] Several workup procedures have been employed to decompose the initial borinate adduct and facilitate recovery of the product from the chiral auxiliary (see ***B-Allyldiisopinocampheylborane***).[3] This reaction is stereospecific, with (*Z*)-crotylboranes giving *syn* products, and (*E*)-crotylboranes providing the *anti* isomers. By varying the configuration of Ipc_2BOMe (+ or -) and the crotylpotassium alkene isomer (*Z* or *E*) used in the reagent preparation, all four isomers of the product β-methylhomoallylic alcohols can be obtained (eqs 2 and 3).

(2)

(3)

Ipc_2BCrt has been used with a variety of aldehyde structures in the synthesis of natural products containing polypropionate-derived units (eq 4).[4,5]

Addition to α-Substituted Aldehydes.

Addition of Ipc_2BCrt to α-substituted aldehydes allows the preparation of extended polypropionate arrays. In this reaction the diastereofacial selectivity is good, even in the case of mismatched double asymmetric reactions (eqs 5 and 6).[6]

As with simple allylboration (see ***B-Allyldiisopinocampheylborane***), the Ipc_2BCrt reagents provide comparable or, in many cases, superior levels of enantioselection compared to alternative methods of crotylboration[6b] (see also ***B-Allyldiisocaranylborane***, ***Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate*** and ***(R,R)-2,5-Dimethylborolane***).

Crotyldimethoxyborane[1]

(*E*)

[76347-09-6] · $C_6H_{13}BO_2$ · Crotyldimethoxyborane · (MW 127.98) (*Z*)

[76347-11-0]

(stereoselective aldehyde crotylborating agents;[1] precursors of other crotylboronic esters via hydrolysis and esterification with diols[2])

Alternate Name: dimethyl crotylboronate.

Physical Data: the title reagents are generated and used in situ.[3] The analogous diisopropyl (*E*)- and (*Z*)-crotylboronates have been isolated and characterized:[4] diisopropyl (*E*)-crotylboronate, bp 49-60 °C/3-4 mmHg; diisopropyl (*Z*)-crotylboronate, bp 40-50 °C/2-4 mmHg.[5]

Solubility: crotylboronic esters are soluble in common organic solvents (Et_2O, CH_2Cl_2, toluene, etc.). The title reagents are moisture sensitive and hydrolyze to the crotylboronic acids when exposed to water; they undergo transesterification reactions with alcohols.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: in general, allylboronic esters may be purified by distillation and characterized by ^1H, ^{13}C, or ^{11}B NMR.[3a,6,7] Chemical and isomeric purity has been determined in many cases by capillary GC analysis.[3a,7]

Preparative Methods: the title reagents have been generated and used in situ (see below).

Handling, Storage, and Precautions: allylboronates that are purified by distillation may be stored, often for months, in a refrigerator either neat or as a solution in an inert solvent such as CH_2Cl_2 or toluene.[7] Allylboronic esters are moisture sensitive and are readily hydrolyzed by water to the

allylboronic acids (which readily undergo aerial oxidation). The most stable allylboronic esters are the pinacol esters; however, these are also the least reactive members of the group.[1,8] In general, the reactions of allylboronic esters with carbonyl compounds should be performed in a well ventilated hood in a dry solvent under an inert atmosphere.

Reagent Preparation.

The title reagents are prepared in situ by metalation of (*E*)- or (*Z*)-2-butene with ***n-Butyllithium-Potassium t-Butoxide*** followed by treatment of the resulting (*E*)- or (*Z*)-crotylpotassiums with ***Fluorodimethoxyborane Diethyl Etherate*** diethyl etherate ($(MeO)_2BF.Et_2O$; typically two equiv; (eqs 1 and 2)).[3] Erratic yields and stereoselectivity are reported for reactions of the dimethyl (*E*)- or (*Z*)-crotylboronates (**1**) and (**2**) with aldehydes if two equiv of $(MeO)_2BF.Et_2O$ are not used; the second equiv is added to trap *t*-BuOLi which is generated in the metalation step.[3c] Related procedures have been used to synthesize a range of substituted allylboronic esters, including γ-alkoxyallylboronates (**3**) and (**4**).[9]

(1)

(1)

(2)

(2)

(3)

(4)

Acid hydrolysis of THF solutions of (**1**) and (**2**) provides the corresponding (*E*)- and (*Z*)-crotylboronic acids (note: air sensitive) that are readily esterified when treated with diols in the presence of a drying agent (typically

$MgSO_4$). Eqs 3 and 4 illustrate the application of this procedure for the synthesis of pinacol crotylboronates (**5**) and (**6**).[2a] The procedure was fully optimized for the synthesis of the tartrate ester modified crotylboronates (**7**) and (**8**) (eqs 5 and 6).[7] It was found that the yield and isomeric purity of the crotylboronates decreased as the scale increased when $(MeO)_2BF$ was used to functionalize the crotylpotassium intermediates. For example, on scales up to 100 mmol using $(MeO)_2BF$ as the borylating agent, (**7**) and (**8**) were obtained in 70-88% yield following distillation with isomeric purities of 96-97% for (**7**) and 97-98% for (**8**). However, the yields of (**7**) and (**8**) fell to 14-35% on scales larger than 200 mmol with isomeric purity of 94-96% and 92-95% for (**7**) and (**8**), respectively. It is believed that these problems result from competitive formation of tricrotylborane.[7] A far superior procedure involves use of ***Triisopropyl Borate*** as the electrophilic borylating agent.[10] The $(i\text{-PrO})_3B$ procedure has been performed on 100-400 mmol scales with excellent results: 70-75% yields of (**7**) (&egt;98% *E*) and (**8**) (&egt;99% *Z*) have been obtained consistently.[7] Kabalka has adopted this procedure for the preparation of the diisopropyl crotylboronates (**9**) and (**10**) (43-46% yield following distillation).[4,5]

Diastereoselective Reactions with Aldehydes.

(*E*)- and (*Z*)-crotylboronates react with aldehydes generally with excellent diastereoselectivity.[1,6] As shown in eqs 7 and 8, the reaction of propanal and (*E*)-crotylboronate (**1**) provides the *anti* homoallyl alcohol with 96:4 selectivity, while the reaction with the (*Z*)-crotylboronate (**2**) gives the *syn* diastereomer with 97% selectivity.[3c] The stereochemical outcome of the reactions of allylboronates and aldehydes is best rationalized by way of cyclic, chair-like transition states (**11**).[1a] Numerous examples of reactions of substituted allylboronates and aldehydes have been documented in the literature, and in most cases the diastereoselectivity parallels the isomeric purity of the reagent.[1a] Chiral reagents (**7**) and (**8**) can be used to perform these reactions enantioselectively (65-90% ee for most aldehydes).[7]

(1)

(7)

(2) (8)

(11)

Diastereoselective Reactions with α-Hydroxy Ketones and α-Oxocarboxylic Acids.

The addition reaction of allylboronates to ketones is very slow; for example, the reactions of ketones of (*E*)- and (*Z*)-pentenylboronates requires 4-5 day reaction times at elevated pressure.[11] However, Kabalka has demonstrated that the diisopropyl crotylboronates (**9**) and (**10**) react readily with α-hydroxy ketones (eq 9).[4] The reaction presumably involves transesterification of the α-hydroxy ketone with the reagent and then crotyl transfer by way of the chair-like transition state (**12**). Allylboronates also react with α-oxocarboxylic acids, presumably by way of a similar transition state.[12]

Crotyllithium

[16327-44-9] · C_4H_7Li · Crotyllithium · (MW 62.03) (*E*)

[13950-06-6] (*Z*)

[51760-91-9]

(crotylating agent in substitutions and additions; used to attach crotyl groups to other metals and nonmetals)

Physical Data: (*E*) and (*Z*) forms equilibrate rapidly in solution, with typical equilibrium composition 85% (*Z*)-15% (*E*) as shown by ^{1}H and ^{13}C NMR.[1,2]

Solubility: sol ethers; sparingly sol hydrocarbons.

Preparative Methods: by metallating 1-butene or (*E*)- and/or (*Z*)-2-butene with ***n-Butyllithium*/*N,N,N´,N´-Tetramethylethylenediamine***;[1b] from organotin[1a] or organoselenium[3] compounds by exchange with ***Methyllithium*** or butyllithium.

Form Supplied in: prepared in situ and used directly.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas to exclude oxygen and moisture.

Reactions.

Crotyllithium alkylates mainly at the less hindered end to give mixtures of (*E*) and (*Z*) products with the latter predominating due to the greater stability of (*Z*)-crotyllithium.[1b,4] Additions to aldehydes and ketones[5] can sometimes be made more stereo- and regioselective by adding boron,[6] zirconium,[7] or chromium[8] compounds. Crotyllithium has been used to make crotylpalladium reagents.[9]

When stereospecificity is desired, crotylpotassiums are preferable to crotyllithiums since they can be made and reacted at low temperatures with preservation of configuration,[10] e.g. to make crotyldiisopinocampheylboranes (eqs 1 and 2; Ipc = isopinocampheyl) for asymmetric syntheses (see ***B-Crotyldiisopinocampheylborane***).[11]

Related Reagents.

Table 1 lists some useful crotyllithium derivatives. The first five entries all strongly prefer the (*Z*) geometry.[12,13] The last, with no stereochemical complications, provides isoprene units in coupling reactions with alkyl bromides.[4] See also ***Allyllithium*** and ***Allylmagnesium Bromide***.

Crotylmagnesium Bromide

(X = Br)

[6088-87-5] · C_4H_7BrMg · Crotylmagnesium Bromide · (MW 159.32) (X = Cl)

[6088-88-6] · C_4H_7ClMg · Crotylmagnesium Chloride · (MW 114.86)

(agent capable of regioselective addition to carbonyl compounds[1,23-27] and derivatives,[28,34] unactivated C-C double bonds,[43] nitro compounds,[30-32] nitriles,[34] imines,[34] and aza aromatics,[35-39] and of displacement of halogens from halo compounds.[1,29,40,41])

Alternate Name: 2-butenylmagnesium bromide.

Solubility: bromide: sol diethyl ether, dibutyl ether;[3] chloride: sol diethyl ether, THF.

Form Supplied in: the precursor crotyl bromide and chloride (the latter 95% predominantly (*E*)) are commercially available.

Analysis of Reagent Purity: titration of crotylmagnesium bromide can be carried out with *s*-BuOH in xylene using 1,10-phenanthroline[12] or *N*-phenyl-1-naphthylamine[14] as indicators or with a double titration method using dibromoethane.[13] Other procedures are available.[10,15-17]

Preparative Methods: crotylmagnesium bromide and chloride can be prepared from commercial crotyl halides and ***Magnesium*** in diethyl or dibutyl ether.[2,18,19] The undesired homocoupling reaction[3] can be minimized by increasing the time of addition of the halide, the solvent/halide ratio, and by using 20-30 mesh magnesium turnings prepared just prior to use.[1] CrotylMgBr can be prepared from commercial crotyl bromide which usually contains 13% of α-methylallyl bromide as an impurity owing to an equilibration between the two isomers (eq 1). These two isomers can be separated by low-temperature distillation,[4] although this is not needed since both the bromo isomers produce the same Grignard reagent. Similarly, crotylMgCl is prepared from commercial ***Crotyl Chloride*** which is frequently[5,6] a mixture of α-methylallyl chloride and *cis*- and *trans*-crotyl chlorides separable from the former by simple fractional distillation. *cis*-Crotyl chloride can be prepared from *cis*-crotyl alcohol.[11]

(1)

Handling, Storage, and Precautions: the precursor isomeric butenyl chlorides are much more stable than the bromides and can be stored without rearrangement for long periods of time in sealed Teflon bottles over anydrous $MgSO_4$.[18] Crotylmagnesium halides are moisture sensitive reagents, inflammable, reacting violently with water.

Structure.

Crotylmagnesium halides exist as a rapidly equilibrating mixture of two forms, the less branched being the more abundant (eq 2).[7]

(2)

The isotopic perturbation technique[8] has been used to distinguish between the σ- and π-bond structures of allyl- and crotylmagnesium reagents.[9] The ^{13}C NMR spectra of the deuterated crotyl reagents have demonstrated that crotylmagnesium halides are σ-structures in which the metal is attached to the primary carbon. Alkyl-substituted allylic Grignard reagents in diethyl ether solution exist as a rapidly equilibrating mixture of (*Z*) and (*E*) primary isomers.[18] Protonation and coupling constant studies have shown that the percentage of (*Z*) isomer decreases as the size of the alkyl substituent (R) on the carbon of the Grignard reagent increases (eq 3).

(3)

Reactions.

With few exceptions, crotylmagnesium halides react with electrophiles at the internal C atom. Treatment of crotylmagnesium halides with a wide variety of protonating agents[20-22] gives rise to a mixture of 1- and 2-butene with the former usually predominating.

The reaction of unhindered carbonyl compounds with crotyl Grignards gives the γ-adduct (eq 4).[23] This regioselectivity can be reversed by addition of ***Aluminum Chloride***, which results in a predominant formation of the α-adduct.[24] With a hindered ketone,[2] such as di-*t*-butyl ketone, the α-adduct is sometimes obtained because of the reversible addition of

the allylic organometallic reagent.[25,26] CrotylMgCl gives 1,2-addition to α,β-ethylenic ketones; the relevant stereochemistry has been studied.[27]

(4)

Other typical reactions with epoxides, acid chlorides, amides, and many other classes of compounds have been extensively treated;[1,28d] the formation of tetrahydropyridines from aryl nitriles has also been reported.[34]

Alkylation of crotyl Grignard reagents in the presence of ***Copper(I) Iodide*** results in almost exclusive substitution at the α-position; the reaction is very slow in the absence of CuI.[29]

Butenylmagnesium chloride adds to nitro compounds, leading to allylic nitrones (eq 5).[30] The chemo-, regio- and stereoselectivity of this reaction,[31] as well as a possible enantioselective synthesis of nitrogen derivatives (hydroxylamines and amines) by allyl Grignard addition to optically active nitroalkanes, have been reported.[32]

(5)

In the presence of ***Dichlorobis(cyclopentadienyl)titanium***, Cp_2TiCl_2, isoprene undergoes a regioselective insertion into the allyl-magnesium bond (eq 6). This insertion has been applied to the synthesis of various natural terpenoids and related products.[33]

Crotylmagnesium halides add promptly to the C=N moiety of 2-alkylthiazolines, leading to 2-alkyl-2-α-methylallylthiazolidines,[35] and to 2-alkylbenzothiazoles, leading to 2-alkyl-2-α-methylallylbenzothiazolines or *N*-alkyl-bis(α-methylallyl)methyl-*o*-aminobenzenethiol depending upon the experimental conditions.[36] 2-Heterosubstituted benzothiazoles react with crotylmagnesium halides, regioselectively producing 2-α-methylallylbenzothiazole, 2,2-bis(α-methylallyl)benzothiazoline, or *N*-tris(α-methylallyl)methyl-*o*-aminobenzenethiol depending upon the experimental conditions.[37] Comparable results were obtained in the reaction of benzoxazole derivatives.[38,39] Cross-coupling of crotylmagnesium halides with halogenoquinoxalines,[40] -pyrimidines,[41] and -pyridines[42] provides a regioselective synthesis of the corresponding α-methylallyl derivatives.

CrotylMgCl adds regioselectively to the unactivated C-C double bond of some aza aromatics.[43]

Related Reagents.

Prenylmagnesium chloride (**1**),[44] cyclohexenylmethylmagnesium bromide (**2**),[44b] cinnamylmagnesium bromide (**3**),[45] and 2-pentenylmagnesium bromide (**4**)[46] have been prepared by reacting the appropriate halide with magnesium and their reactivity is comparable with that of crotylmagnesium halides.

Crotyltributylstannane[1]

(*E*)

[35998-93-7] · $C_{16}H_{34}Sn$ · Crotyltributylstannane · (MW 345.13) (*Z*)

[35998-94-8]

(allylating reagent for many compounds, including alkyl halides, carbonyl compounds, imines, acetals, thioacetals, and sulfoximides)

Alternate Name: 2-butenyltributyltin.

Physical Data: bp 100-110 °C/1 mmHg;[2f] ^{1}H NMR (*E*) isomer δ 5.95-5.10 (m, 2 H), 2.00-0.70 (m, 32 H); ^{13}C NMR (*E*) isomer δ 130.5, 120.3, 29.3, 27.5, 27.4, 17.9, 13.8, 9.2;[2f] ^{1}H NMR (*Z*) isomer δ 6.84-5.96 (m, 2 H), 3.30-1.43 (m, 32 H); ^{13}C NMR (*Z*) isomer δ 129.6, 118.2, 29.3, 27.5, 27.4, 13.8, 12.5, 9.4.[2f]

Solubility: sol methylene chloride, diethyl ether, tetrahydrofuran, toluene, and benzene.

Form Supplied in: not commercially available.

Preparative Methods: several methods have been described.[2]

Purification: by distillation.

Handling, Storage, and Precautions: all organotin compounds are highly toxic. This reagent therefore must be used in a well-ventilated fume hood. Contact with the eyes, skin, and respiratory system should be avoided.

Introduction.

Allylstannanes are widely used storable allyl anion equivalents.[1] Since the chemistry associated with allystannanes and crotylstannanes is, in most cases, very similar, this section will focus on the reactions of crotyltrialkylstannane and crotyl derivatives (methallyltributylstannane, β-methylcrotylstannane, pent-3-en-2-yltrialkylstannanes, and cinnamylstannane. A more comprehensive review of allylation reactions employing allylic stannanes is presented in the article on ***Allyltributylstannane***. Related allylic stannane chemistry is also found under articles on α-

alkoxyallylstannanes and ***Allyltriphenylstannane*** derivatives.

Additions to Aldehydes and Ketones.

The addition of allylic reagents to carbonyl compounds has become a very attractive synthetic strategy in carbon-carbon bond formations. γ-Substituted allylmetal reagents are especially attractive in natural product synthesis since additions can provide two new adjacent stereocenters. Thus methods to control the stereochemical outcome of both diastereofacial and bond construction selectivity have received a lot of attention.

Crotyltrialkyltin reagents can undergo transmetalation reactions in the presence of Lewis acids.[3] Competing transmetalation process can affect the mechanistic pathway and product distribution (eq 1).[4] 1,3-Isomerization results in linear (α) adducts, while branched (γ) adducts occur through the Lewis acid-carbonyl complex or the transmetalated intermediate, a crotyltin halide. The course of the reaction depends upon the Lewis acid, temperature, substrate, stoichiometry, and order of addition.

In thermal reactions, the stereochemical outcome of crotyltin additions to aldehydes is dependent upon the geometry of the but-2-enyl unit. Thus the (*E*) isomer produces *anti* alcohols while the (*Z*) isomer produces the *syn* alcohols.[5] The allylic coupling to aldehydes also occurs at rt under high pressure.[6]

The Lewis acid-mediated reactions of crotylstannanes and -silanes produces *syn* homoallylic alcohols predominantly,

regardless of the geometry of the but-2-enyl unit (eq 2). The selectivity was rationalized with an extended acyclic transition state geometry. This is in contrast to other crotyl organometallic reagents in which the crotyl geometry is linked to the observed stereoselectivity.[7]

(2)

(*E*)-Crotyltributylstannane has been shown to react faster with aldehyde-Lewis acid complexes than the corresponding (*Z*) isomer.[8] Thus even higher levels of *syn* selectivity (25:1; 94% yield) can be achieved when 2 equiv of crotylstannane, which consists of a mixture of the (*E*) and (*Z*) isomers, is employed in the ***Boron Trifluoride Etherate***-mediated addition to aldehydes (eq 3). A decrease in selectivity to 9:1 is observed when only 1 equiv of stannane is used. ***Titanium(IV) Chloride***-mediated reactions show *syn* or *anti* selectivity depending upon the order of addition. For example normal addition (crotyltin added last) shows high *syn* selectivity (93:7) and only minor amounts of the linear alcohols (<3%). Under reverse addition (stannane addition to $TiCl_4$, followed by aldehyde addition) *anti* selectivity is observed, again with only minor amounts of the linear alcohols (<5%). The use of chiral Lewis acid catalyst, as opposed to Lewis acid promoters, has also been successfully employed in the stereoselective allylations of aldehydes.[9]

Lewis acid	crotyltin equiv		
$BF_3 \cdot OEt_2$	2.1	96.1	3.9
$TiCl_4$ normal	1.05	90.5	7.0
$TiCl_4$ reverse	2.0	4.4	90.8

(3)

-	-
2.1	0.5
-	4.9

The effect of addition modes upon product distributions for (*E*)- and (*Z*)-crotyltributyltins with various Lewis acids and aldehydes has been investigated.[4d,10] The linear (α) homoallylic alcohol adduct with (*Z*) double bond geometry can be obtained selectively when (*Z*)-crotyltributylstannane is combined with an aldehyde followed by the addition of ***n-Butyltrichlorostannane*** (eq 4).[11] The reaction is believed to proceed through transmetallation to form the methallylbutyldichlorotin. The selectivity for the linear homoallylic products is reduced or lost when the order of addition of the aldehyde and $BuSnCl_3$ is reversed or when an (*E/Z*) mixture of crotylin is used. Similarly, the transmetalation of (*E*)-γ-(phenyl)allyltributyltin with $BuSnCl_3$ in the presence of an aldehyde produces the corresponding linear homoallylic alcohol adduct with (*Z*) double bond geometry.[12]

(4)

	(*Z*) Linear:branched	yield (%)
R = Ph	96:4	96
R = *n*-Hex	95:5	94

The addition of crotyltributylstannane to aldehydes in the presence of ***Cobalt(II) Chloride*** also affords the linear homoallylic alcohols exclusively (yields: 54-74%) (eq 5).[13] The regiochemistry is not affected by the steric hinderance of the aldehyde or the order of addition.

(5)

In the Lewis acid-mediated additions of crotyltributylstannane to α-alkoxyaldehydes, $MgBr_2$ and $TiCl_4$ provide chelation control diastereofacial selectivity (&egt;99:1) (eq 6). The diastereofacial selectivity for all crotylin additions is higher than the corresponding allyl additions. Both diastereofacial and bond construction selectivity increase with the size of R^1 (cyclohexyl > *n*-butyl > Me). Within the chelation control manifold, *syn* selectivity for bond construction is &egt;90:10; $MgBr_2$ is the Lewis acid of choice.[14]

The Lewis acid and hydroxy-protecting group also strongly influence stereoselectivity in the crotylstannane additions to 2-methyl-3-hydroxypropanal derivatives (β-alkoxyaldehydes). The promoter $BF_3.OEt_2$ shows high *syn* diastereofacial selectivity (Cram) with the characteristic *syn* bond construction selectivity. The *syn,syn* isomer is formed in 92% yield with high diastereofacial selectivity (18:1) and essentially complete bond construction selectivity when the *t*-butyldimethylsilyl protecting group is present. Chelation control diastereofacial selectivity (*anti*) is high for all Lewis acids capable of chelation; however, bond construction selectivity is low. $MgBr_2$ provides the *anti,syn* isomer with 91:9 *anti* facial selectivity and 89:11 *syn* bond construction selectivity.[8] Using chelation control conditions, the protected β-alkoxyaldehyde (**1**) was selectively allylated with crotyltriphenylstannane (as a 1:1 *cis*/*trans* mixture) to provide the desired stereoisomer in 60% yield and a 20% yield of a regiomeric crotyl addition product (eq 7).[15]

High *syn* diastereofacial control and *anti* bond construction selectivity is observed, under chelation control conditions, for the additions of β-methylcrotylstannanes to 2-(benzyloxy)-propanal (eq 8).[16]

(8)

The Lewis acid-mediated addition of crotyltributylstannane to pyruvates slightly favors the *anti* products when the ester group is small; however, *syn* products dominate as the size of the ester group is increased (eq 9).[17] The BF_3 etherate-mediated addition to glyoxylate esters is also influenced by the size of the ester group, providing a *syn*:*anti* ratio of 90:10 for the isopropyl ester and decreasing to 75:25 for the methyl ester.[18] Crotyltin addition to *meso*-dimethylglutaric hemialdehyde, also mediated by BF_3 etherate, shows chelation control *syn* selectivity. The selectivity is based upon the conformationally rigid substrate, which prefers a chelate-like conformation.[19]

(9)

	yield (%)	*anti*:*syn*
R = Me	84	60:40
R = 2,6-dimethylphenyl	84	35:65

Iminines and Iminium Ions.

Crotyltributylstannane additions to aliphatic and furyl imines (R^1 = *i*-Pr, Cy, furyl; R^2 = Bn) provide addition products with very high *syn* selectivity (*syn*:*anti* > 20:1) (eq 10).[20] This high selectivity requires extended Lewis acid-imine complexation at -78 °C (2.5 h) prior to crotylstannane addition, otherwise a modest 4:1 *syn* selectivity is attained.

Crotyltributylstannane additions to aromatic imines (R^1 = Ph; R^2 = Ph, *p*-tolyl) occur with much lower diastereoselectivity (*syn*:*anti* > 75:25).[21]

Methallyl- and crotyltin reagents add to pyridine activated by ***Methyl Chloroformate*** (i.e. prior iminium salt formation) with poor regioselectivity (α:γ = 48:52 to 36:64) (eq 11).[22] Allylstannanes add in a highly α-selective fashion (86-99%) while prenyltributylstannane additions occur exclusively at the γ-carbon of pyridine. Crotyltin reagents add to larger aromatic N-heterocycles with excellent regioselectivity (>95%) (eq 12).

(12)

Conjugate Addition.

Conjugate additions of crotyltributylstannanes to Michael acceptors occur with poor to modest *anti* selectivity in variable yields (eq 13).[23] ***Tin(IV) Chloride*** promotion provides the highest selectivity for the crotyltributylstannane addition to an enoate (90:10; 52%). Other Lewis acids provide slightly lower selectivities (>80:20) in higher yields (>94%). Conjugate additions to nitroalkenes occur with very low selectivity (*anti*:*syn* = 45:55 to 70:30). Yields are higher for the phenyl-substituted nitroalkene (53-92%) than for the methyl derivative (29-42%). The trialkylsilyl triflate-promoted conjugate addition of allylstannes to α,β-enones affords the corresponding β-alkylated silyl enol ethers in high yields (85-95%).[24]

(13)

Y = CO_2Et, CN

Reactions with Orthoamides.

The $BF_3.OEt_2$ promoted addition of crotyltributylstannane to orthoamides occurs with complete stereoselectivity (eq 14).[25] Interestingly, the $TiCl_4$-promoted reaction provides the other diastereomer exclusively.

(14)

Intramolecular Cyclizations.

Intramolecular condensation reactions between allylstannanes and a carbonyl group joined by a one-carbon tether afford silyloxyvinylcyclopropanes.[26] A variety of 1-butenyl- and 5-hexenyltributylstannanes undergo intramolecular cyclization in the presence of ***N-Phenylselenophthalimide*** and $SnCl_4$.[27]

Radical Reactions.[28]

The radical allyl transfer reactions from allyl- or methallyltributylstannane to a variety of substrates under various initiation conditions have been demonstrated to be synthetically useful.[29] For example, thiophenyl glycosides are converted into C-gylcosides by reaction with methallyltributylstannane. The stereoselectivity is dependent on the reaction conditions. Using photochemical initiation, the reaction of (**2**) with methallylbutylstannane gives an 87% yield of the C-glycoside with a 92:8 ratio of α:β anomers (eq 15). In contrast, the reaction in the presence of catalytic (0.2 equiv) tributylstannyl triflate provides a 95% yield preferentially of the β-isomer (99:1).[30]

Crotylstannanes are less reactive than allyltributylstannane towards carbon-centered radicals. In contrast to allylstannanes, which readily react by radical pathways with alkyl halides, the use of crotylstannane affords only reduction products under a variety of initiation processes.[31] However, the successful allyl transfer reaction of crotylstannane has been reported for a bromine-substituted glycine (eq 16).[32] Thus a mixture of (*E*) and (*Z*) isomers (ca. 1:1) of crotyltributyltin reacted with (**3**) to produce a 57% yield of the allylated product as a 1:1 mixture of diastereomers. The reduction product and 5-methylallylglycine were not observed in the reaction mixture. Radical S_H2' substitution reaction using hetero-centered radicals (RS&bdot;, RSO_2&bdot;, and PhSe&bdot;) and crotylstannane has also been demonstrated.[33]

Irradiation of benzil in the presence of (*E*)- and (*Z*)-crotyl, -pent-2-enyl-, or -hex-2-enyltributylstannane affords predominantly the linear homoallylic alcohols in good yields with retention of the double bond configuration.[34]

Related Reagents.

Allyltributylstannane; ***Allyltrimethylsilane***; ***Allyltriphenylstannane***; ***trans-Cinnamyltributylstannane***; ***Crotyltrimethylsilane***; ***Tri-n-butyl(1-methoxymethoxy-2-butenyl)stannane***; ***Trimethyl(3-methyl-2-butenyl)stannane***.

Crotyltrichlorosilane[1]

(*Z*)

[49749-84-0] · $C_4H_7Cl_3Si$ · Crotyltrichlorosilane · (MW 189.54) (*E*)

[52885-13-9]

(regio- and stereospecific crotylation of aldehydes through pentacoordinate silicate intermediates[2])

Physical Data: bp (*Z*) 140-142 °C, (*E*) 142-144 °C.

Solubility: sol hydrocarbons, halogenated hydrocarbons, and ethers. Protic solvents, especially alcohols, should not be used due to chemical reactivity.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: the reaction of isomerically pure (*E*) ***Crotyl Chloride*** and ***Trichlorosilane*** in the presence of ***Copper(I) Chloride*** and ***Triethylamine*** in ether at rt produces (*E*)-crotyltrichlorosilane in 76% yield with isomeric purity higher than 99%.[3] Purification of (*E*)-crotyl alcohol[4] is critical for preparation of the isomerically pure compound.[2] The ***Tetrakis(triphenylphosphine)palladium(0)***-catalyzed hydrosilation of ***1,3-Butadiene***[5] with trichlorosilane at -78 °C gives (*Z*)-crotyltrichlorosilane in 84% yield with isomeric purity of 99.1%.[2] The reaction temperature is of key importance for the preparation of stereohomogeneous crotyltrichlorosilane. Higher temperatures give unsatisfactory results.[2]

Purification: by distillation.

Handling, Storage, and Precautions: the reagents can be stored in a glass bottle but should be rigorously protected from moisture. The reagents should be handled in a well-ventilated hood and contact with the skin and eyes should be avoided.

Allylation Through Pentacoordinate Silicate Intermediates.

The reaction of crotyltrichlorosilane with dihydroxy compounds such as catechol gives pentacoordinate crotylsilicon

bis(catecholate). The catecholate, isolated and purified, reacts with benzaldehyde without activators to afford homoallyl alcohols with complete regioselectivity. The reaction can be performed without isolation of the intermediate catecholate (eq 1).[2,6]

Friedel-Crafts Reaction.

Like other allyltrichlorosilanes, crotyltrichlorosilane undergoes Friedel-Crafts reaction with benzene.[7] The reaction of crotyltrichlorosilane with benzene in the presence of ***Aluminum Chloride*** gives a mixture of two positional isomers, (2- and (3-phenylbutyl)trichlorosilane (eq 2). The former is the initial product, but thermally isomerizes to the latter. The equilibrium mixture of the 2-phenyl and 3-phenyl isomers is 9:91.

Conversion to Crotyltrifluorosilane.

Crotyltrichlorosilanes are readily converted to the corresponding crotyltrifluorosilanes, which are useful for regio- and stereospecific crotylation.[2]

Related Reagents.

B-Allyldiisocaranylborane; ***B-Crotyldiisopinocampheylborane***; ***Crotyldimethoxyborane***; ***Crotyltrifluorosilane***; ***Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate***; ***Triethylammonium Bis(catecholato)allylsiliconate***.

Crotyltrifluorosilane[1]

($R^1 = R^2 = H$) (allyl)

[690-19-7] · $C_3H_5F_3Si$ · Allyltrifluorosilane · (MW 126.15) (R^1 = Me, R^2 = H) (*Z*-crotyl)

[51676-18-74] · $C_4H_7F_3Si$ · Crotyltrifluorosilane · (MW 140.18) (R^2 = Me, R^2 = H) (*E*-crotyl)

[114067-35-5] ($R^1 = R^2$ = Me) (Me-crotyl)

[114067-34-4] · $C_5H_9F_3Si$ · (Methylcrotyl)trifluorosilane · (MW 154.21)

(highly regioselective and stereoselective allylation and crotylation reagent, usually activated by fluoride ions or hydroxy compounds[1a])

Physical Data: (*Z*)-crotyl: bp 52 °C; Me-crotyl: bp 71 °C.

Solubility: sol common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Purification: by distillation.

Preparative Methods: allyltrifluorosilanes are most conveniently prepared by the reaction of the corresponding trichlorosilanes with SbF_3[2] or $ZnF_2.4H_2O$.[3] Stereohomogeneous (*E*)- and (*Z*)-crotyltrifluorosilanes are prepared as shown in eqs 1 and 2.[4]

Handling, Storage, and Precautions: the reagents can be stored in a glass bottle but must be protected from moisture. Use in a fume hood.

Fluoride Ion-Mediated Allylation of Aldehydes.

Allyltrifluorosilanes undergo regiospecific and stereospecific allylation reactions with a variety of aldehydes. Thus in the presence of an excess amount of ***Cesium Fluoride***, allyltrifluorosilanes form pentacoordinate tetrafluorosilicates which undergo the allylation reaction with aldehydes, presumably through a six-membered transition state. The regio- and stereochemistry of the products are consistent with this postulate (eq 3).

$R^1 = R^2 = Me$, $R = Ph$	96%
$R^1 = H$, $R^2 = Me$, $R = C_8H_{17}$	89%
$R^1 = Me$, $R^2 = H$, $R = {}^{\backprime}Et_2CH$	88%

Hydroxy Compound-Mediated Allylation.

Allylation reactions of aldehydes with allyltrifluorosilanes can also be effected in the presence of a wide variety of hydroxy compounds and ***Triethylamine*** to give the corresponding homoallyl alcohols in a regio- and stereospecific manner.[5] Typically in the case with catechol, allyldifluorosilicon catecholate is proposed to be the intermediate (eqs 4 and 5). No rigorous drying of the reaction system is necessary. Interestingly, this reagent system can discriminate linear from α-branched alkanals. The structure-reactivity relationships in pentacoordinate allylsilicates are explained in terms of the Lewis

acidity of the silicon centers.

Allylation of α-Hydroxy Ketones.

Allyltrifluorosilanes react with α-hydroxy ketones, without protection of the hydroxy group, in the presence of triethylamine to yield tertiary homoallyl alcohols with extremely high regio- and diastereospecificity (eqs 6 and 7).[6]

Crotyltrimethylsilane[1]

[18292-28-9] · $C_7H_{16}Si$ · Crotyltrimethylsilane · (MW 128.29) (*E*)

[17486-12-3] (*Z*)

[17486-13-4]

(carbon nucleophile for the introduction of 1-methylallyl groups by Lewis acid-catalyzed reaction with aldehydes, iminium ions, enones, and similar carbon electrophiles, with some heteroatom electrophiles, and as a starting material for synthesis of α-branched allylsilanes)

Physical Data: bp 110-115 °C; (*E*) isomer: *n*25D 1.4159; (*Z*) isomer: *n*25D 1.4208.[2]

Solubility: freely sol all organic solvents.

Analysis of Reagent Purity: $\delta_H(CCl_4)$ (*E*) isomer: 5.4-5.1 (2H, m), 1.55 (3H, d, *J* = 4), 1.26 (2H, d, *J* = 5), and 0.11 (9H, s); (*Z*) isomer: 5.36 (2H, m), 1.9-1.2 (5H, br m), and 0.05 (9H, s).[2]

Preparative Methods: both (*E*)- and (*Z*)-crotyltrimethylsilane can be prepared separately from the *exo*- and *endo*-crotylpotassium compounds[3] and ***Chlorotrimethylsilane***,[4] by nickel(II)-catalyzed coupling of (*E*)- or (*Z*)-1-bromopropene with ***(Chloromethyl)trimethylsilane***,[5] and by reaction of methylmagnesium iodide on 1,3-bis(trimethylsilyl)propene oxide followed by acid- or base-catalyzed (Peterson) desilylative elimination.[6] A mixture of the (*E*) and (*Z*) isomers in a 9:1 ratio can be prepared by the reaction of ***Trichlorosilane*** and ***Triethylamine*** with ***Crotyl Chloride***, followed by treatment with methylmagnesium iodide.[7] Coupling of the crotyl Grignard reagent with chlorotrimethylsilane similarly gives mixtures of both stereoisomers, but also some of the regioisomer.[8] The three components may be separated by GC. The pure (*Z*) isomer can be prepared by hydrosilylation of ***1,3-Butadiene*** with trimethylsilane using ***Hexacarbonylchromium***.[9] The regio- and stereoisomers can be equilibrated by ***Tetra-n-butylammonium Fluoride*** (TBAF) in refluxing THF.[10] Methods for the synthesis of allylsilanes in general have been reviewed.[11]

Handling, Storage, and Precautions: crotyltrimethylsilane is inflammable.

As a Carbon Nucleophile in Uncatalyzed and in Lewis Acid-Catalyzed Reactions with Carbon Electrophiles.

Crotyltrimethylsilane is an alkene some 10^5 times more nucleophilic than propene and some 20 times more nucleophilic than ***Allyltrimethylsilane***, as judged by its reactions with diarylmethyl cations.[7,12] It reacts with cationic carbon electrophiles at the alkenic carbon remote from the silyl group to give an intermediate cation, and the silyl group is lost to create a double bond at the terminus, i.e. with allylic inversion, as illustrated for the tropylium cation (eq 1).[13]

(1)

More usually the electrophile is created by coordination of a Lewis acid to a functional group. Among the stereochemically straightforward electrophiles are ***Trichloroacetonitrile*** (eq 2),[14] ketones (eq 3),[15] linear methoxyethoxymethyl mixed acetals and monothioacetals,[16] and alkoxyalkyl halides.[18]

(2)

(3)

Somewhat more complicated are those reactions where two adjacent stereogenic centers are set up simultaneously, as in the reactions with aldehydes (eq 4),[5] acetals (eq 5),[17] the corresponding alkoxymethyl halides,[18] and α,β-unsaturated ketones and esters (eq 6).[19]

(4)

from *(E)* isomer, 91% 95:5
from *(Z)* isomer, 98% 69:31

(5)

R = *i*-Bu

from *(E)* isomer, 90% 91:9
from *(Z)* isomer, 99% 91:9

R = Ph

from *(E)* isomer, 94% 75:25
from *(Z)* isomer, 78% 28:72

There is a trend for the (*E*)-crotylsilane to produce the *syn* and the (*Z*)-crotylsilane to produce the *anti* arrangement of substituents along the backbone, but in several reactions (for example, eq 5, R = *i*-Bu) the stereochemistry of the starting material appears to make no difference. The (*E*)-crotylsilane is more diastereoselective than the (*Z*)-crotylsilane. In the reaction with acetals (eq 5, R = Ph), substituents on the phenyl ring affect the diastereoselectivity.[17]

Suitable chiral electrophiles allow enantiocontrol as well as diastereocontrol. There are examples with aldehydes (eq 7),[20] glycal 3-acetates (eq 8),[21] acyliminium ions (eq 9),[22] and α,β-unsaturated sulfoxides.[23] Some tailoring of the substituents on the silicon atom can be helpful in achieving higher levels of diastereo- and enantiocontrol.[19,21]

(8)

from *(E)* isomer, 58% 75:25
from *(Z)* isomer, 80% 25:75

(9)

from *(E)*, 94% 79:11:7:3
from *(Z)*, 90% 20:62:5:13

Fluoride ion-catalyzed reactions of crotylsilanes are not regiospecific (eq 10), the ratio of the two products (**3**) and (**4**) being much the same whether crotyltrimethylsilane (**1**) or its regioisomer (**2**) is used.[24]

(10)

	(3)	(4)
from (1)	23%	37%
from (2)	30%	41%

As a Carbon Nucleophile in Reactions with Heteroatom Electrophiles.

Crotyltrimethylsilane reacts with nitrogen[25] and sulfur electrophiles with the usual allylic shift (eq 11). In the corresponding reactions with selenium,[26] tellurium,[27] and thallium[28] electrophiles the products are themselves allylically unstable, giving overall the products that appear simply to have replaced the silyl group with the electrophile.

(11)

As a Source of the 1-Methyl-3-trimethylsilylallyl Anion.

The (*E*)- or (*Z*)-crotylsilanes react with ***n-Butyllithium*** and ***Potassium t-Butoxide*** (Schlosser's base) to give the corresponding allyl anions (**5**) and (**6**). Left for a few hours, these anions equilibrate to give largely the isomer (**6**).

Alkylation of either anion takes place α to the silyl group, to give new (*E*) or (*Z*) α-branched allylsilanes (eq 12).[4]

(12)

Related Reagents.

Allyltrimethylsilane; ***Crotyltributylstannane***.

18-Crown-6

[17455-13-9] · $C_{12}H_{24}O_6$ · 18-Crown-6 · (MW 264.32)

(solubilization of a variety of metal salts, particularly potassium salts, in nonpolar solvents; activating agent for many nucleophilic substitutions and eliminations)

Physical Data: colorless, mp 36.5-38.0 °C; IR (neat) 2875, 1450, 1350, and 1120 cm^{-1}; ^1H NMR (60 MHz, CCl_4) 3.56 ppm (singlet).

Preparative Methods: commercially available. 18-Crown-6 has been synthesized by a variety of methods involving modified Williamson ether procedures.[1-6] Crude 18-crown-6 forms a crystalline complex with ***Acetonitrile*** from which the pure crown can be isolated.[4,5] 18-Crown-6 may also be isolated from the cyclic oligomerization of ***Ethylene Oxide*** in the presence of gaseous ***Boron Trifluoride*** and alkali metal cation templates such as $CsBF_4$.[7-10]

Handling, Storage, and Precautions: use in a fume hood.

Complexation with Metal Salts: Solubilities and Reactivities.

18-Crown-6 provides a simple and efficient means of solubilizing simple metal salts in nonpolar and dipolar aprotic solvents where solvation of the anionic portion of the salt should be minimal.[11] Indeed, this ligand is an effective catalyst in liquid-liquid and solid-liquid phase transfer catalysis.[12-14] Since 18-crown-6 has cavity dimensions (2.6-3.2 Å) of the same magnitude as the ionic diameter of the potassium cation (2.66 Å), it is usually more specific for potassium salts than other alkali metal salts. Nevertheless, 18-crown-6 is reasonably effective in complexing sodium and cesium salts as well. The solubilities of potassium salts in acetonitrile at 25 °C in the presence and absence of 18-crown-6 (0.15 M) are summarized in Table 1.[11]

Table 1 Solubilities of Potassium Salts in Acetonitrile at 25 °C in the Presence and Absence of 18-Crown-6

Salt	Sol. in 0.15 M 18-C-6 in MeCN	Sol. in MeCN
KF	0.0043	0.000318
KCl	0.0555	0.000243
KBr	0.135	0.00208
KI	0.202	0.105
KCN	0.129	0.00119
KOAc	0.102	0.00050
KN_3	0.138	0.00241
KSCN	0.850	0.755

The differences between the solubilities in the presence and the absence of crown are indications of the solubility enhancements due to the presence of 18-crown-6. The solubilities of ***Potassium Fluoride*** in benzene containing 18-crown-6 at concentrations of 1.01 M and 0.34 M are reported to be 0.052 M and 0.014 M, respectively, while the solubilities of potassium acetate in benzene containing 18-crown-6 at concentrations of 0.55 M and 1.0 M are reported to be 0.4 M and 0.8 M, respectively.[11] The solubilities of ***Lithium Fluoride***, ***Sodium Fluoride***, KF, RbF, and ***Cesium Fluoride*** in acetonitrile, ***Acetone***, THF, ***N,N-Dimethylformamide***, benzene, and cyclohexane have been determined in the presence and absence of 18-crown-6.[15]

The complexation and solubilization of metal salts by 18-crown-6 produces highly reactive anions. There are at least two factors that contribute the this enhanced reactivity. Since a nonpolar aprotic solvent such as benzene or a dipolar aprotic solvent such as acetonitrile should not have a great affinity for the anion, as compared to polar, protic media, the anion is not expected to be highly solvated. In addition, the increased physical separation of the cation from the anion as a result of the complexation should decrease the coulombic interaction between these oppositely charged species.[13] This latter effect is translated directly into a decrease in activation energy. As a consequence, the anion is a potent nucleophile as well as a potent base. These anionic species have been termed naked anions. Studies related to the relative nucleophilicities of naked anions toward benzyl tosylate in acetonitrile at 30 °C are summarized in Table 2.[11,13,16] Compared to polar, protic media, there seems to be a general leveling of nucleophilicities in acetonitrile. Several reversals of the usual order of nucleophilicities may be noted.

Table 2 Second-Order Rate Constants at 30 °C in Acetonitrile for the Reaction with Benzyl Tosylate

Nucleophile	k (M^{-1} s^{-1})	Relative rates
N_3^-	1.02	10.0
OAc^-	0.95	9.6
CN^-	0.23	2.4
Br^-	0.12	1.3
Cl^-	0.12	1.3
I^-	0.09	1.0
F^-	0.14	1.4
SCN^-	0.02	0.3

Reactions.

Halides.

Potassium fluoride reacts with a variety of organic substrates under solid-liquid phase transfer catalytic conditions[17] to give both substitution and elimination products (eq 1).

(1)

The σ-anionic complex (Meisenheimer complex) resulting from the reaction of fluoride with 2,4,6-trinitrofluorobenzene (**1**) in acetonitrile has been observed using ^1H and ^{19}F NMR spectroscopy.[18]

(1)

Potassium fluoride or cesium fluoride solubilized in toluene with 18-crown-6 induces alkyl- and aryl-group rearrangement on chloromethyl-substituted silanes.[19]

Oxygen Anions.

Acetate solubilized as the potassium salt in acetonitrile or benzene containing 18-crown-6 becomes sufficiently nucleophilic to react smoothly and quantitatively, even at room temperature, with a wide variety of organic substrates.[20,21] Substitution reactions at primary, secondary, tertiary, and benzylic positions have been demonstrated.[18] In certain cases, competing elimination processes are observed. Mixed anhydrides are formed in the reaction of the potassium or sodium salts of carboxylic acids with ***Ethyl Chloroformate***, cyanuric chloride, or ***Benzyl Chloroformate*** in acetonitrile in the presence of 18-crown-6.[22] Potassium phenylacetate has been reacted with a series of 2-bromo-substituted carbonyl compounds in the presence of 18-crown-6 to form aldehydo or keto esters which were subsequently cyclized to five-membered unsaturated lactones on further heating (eq 2).[23]

(2)

3-Bromoacetyl-7-methoxycoumarin is readily coupled with a wide variety of carboxylic acids in the presence of potassium bicarbonate and 18-crown-6[24] to form fluorescent derivatives. Reaction of alcohol mesylate with cesium acetate and 18-crown-6 in benzene is an effective method for the inversion of cyclopentyl and cyclohexyl alcohols.[25]

Reaction of 3-(bromomethyl)thiophene with the potassium salt of 4-cyano-4´-hydroxybiphenyl in THF, in the presence of 18-crown-6, produces high yields of the substitution product.[26]

Potassium Superoxide, dissolved in benzene, THF, or DMF using 18-crown-6, reacts with stoichiometric quantities of primary and secondary alkyl bromides to produce dialkyl peroxides.[27] The nucleophilic displacements by the superoxide radical anion and the intermediate alkyl peroxyanion on a chiral alkyl bromide ((*R*)-2-bromooctane) proceeds with inversion of configuration.[26] The nucleophilic reaction of alkyl halides, methanesulfonates, and tosylates in ***Dimethyl Sulfoxide***, DMF, or DME with 4 equiv of potassium superoxide in the presence of 18-crown-6 produces excellent yields of the corresponding alcohols (eq 3).[28,29]

(3)

When secondary halides were used, some elimination products accompanied the formation of the alcohol product. In general, substrate reactivity varied as follows: benzyl > primary > secondary > tertiary > aryl and I > Br > OTs > Cl. Reaction of the tosylate of (+)-(*S*)-2-octanol with superoxide produced (-)-(*R*)-2-octanol.[28] The reaction of esters of carboxylic acids with approximately a threefold excess of potassium superoxide solubilized in benzene with 18-crown-6 produces, after acidic workup, the corresponding alcohols and carboxylic acids.[30] Reaction of superoxide with the acetate ester of (-)-(*R*)-2-octanol gave only (-)-(*R*)-2-octanol, indicating that the reaction proceeds by means of an acyl-oxygen cleavage.[29] Potassium superoxide dissolved in benzene with 18-crown-6 is an effective reagent for promoting the oxidative cleavage of α-keto, α-hydroxy, and α-halo ketones, esters, and carboxylic acids to carboxylic acids.[31]

18-Crown-6 enhances the rate of anionic oxy-Cope rearrangement by ion-pair dissociation.[32]

The reaction of ethyl tosylate and ***Ethyl Iodide*** with the sodium salt of ***Ethyl Acetoacetate*** in THF has been studied in the absence and presence of 18-crown-6. In the reaction with ethyl tosylate the presence of the crown increases the amount of oxygen alkylation. In contrast, the crown has little effect on the ratio of oxygen to carbon alkylation when ethyl iodide is used.[33]

An addition reaction of 3-benzyloxymethyl-3-methyloxetane with *S*-phenyl thioacetate in the presence of 18-crown-6/potassium phenoxide gave 3-benzyloxy-2-methyl-2-phenylthiomethylpropyl acetate in excellent yields.[34]

The dibenzyl ether of optically active diethyl tartrate has been prepared on a large scale using ***Sodium Hydride***, ***Benzyl Bromide***, ***Tetra-n-butylammonium Iodide***, and a catalytic quantity of 18-crown-6.[35]

Carbon Anions.

Potassium Cyanide dissolved in acetonitrile using 18-crown-6 reacts with a variety of alkyl halides to produce the corresponding alkyl cyanides.[36] As in the cases involving fluoride and acetate, some elimination processes accompanied substitution in certain cases. Under solid-liquid phase transfer catalytic conditions, primary alkyl chlorides react faster than bromides whereas the opposite is true for the corresponding secondary halides. ***Cyanotrimethylsilane*** has been synthesized from ***Chlorotrimethylsilane***.[37] *cis*-2-Chloro-4-methylcyclohexanone reacts with naked cyanide to exclusively produce the substitution product.[11] Hydrocyanation of α,β-unsaturated nitriles and ketones with naked cyanide in the presence of ***Acetone Cyanohydrin*** has been reported (eq 4).[38]

Either 1,4-, 2,4-, or 1,5-hexadiene has been deprotonated with Cs 18-crown-6 solutions to produce hexadienyl anions.[39]

The isomerization of 2-methylbicyclo[2.2.1]hepta-2,5-diene to 5-methylenebicyclo[2.2.1]hept-2-ene using excess ***Potassium t-Butoxide*** in DMSO in the presence and in the absence of an equivalent concentration of 18-crown-6 has been investigated (eq 5).[40] In the absence of crown, the order with respect to the base changed from zero order at high concentrations to first order at more dilute concentrations. In the presence of crown, the order with respect to base remained first order at all reported concentrations.

2,2,3-Triphenylpropylcesium rearranges in THF at 65 °C with 96% 1,2-migration of phenyl, whereas the corresponding lithium salt rearranges with at least 98% 1,2-migration of benzyl at 0 °C. The addition of 18-crown-6 as a ligand for the potassium and cesium salts significantly increases the extent of 1,2-benzyl migration.[41]

Treatment of trimethylsilyl trichloroacetate with α,α,α-trifluoroacetophenone in the presence of catalytic quantities of 18-crown-6 and ***Potassium Carbonate*** at 150 °C, followed by treatment with methanolic ***Potassium Hydroxide*** at 50 °C, produced excellent yields of Mosher's acid (α-methoxy-α-(trifluoromethyl)phenylacetic acid).[42]

18-Crown-6 is an effective catalyst in the dialkylation of *o*-nitrophenacyl derivatives.[43]

Nitrogen Anions.

N-Propargylpyrrole was prepared by the reaction of pyrrole with powdered potassium hydroxide in toluene, catalyzed by 18-crown-6.[44]

The reaction of naked nitrite with primary alkyl halides forms nitro compounds as the major product; the major byproducts are nitrite esters.[23]

Excellent yields of *N*-alkylation products were obtained in the reaction of dry alkali metal salts of 2-nitroimidazoles and methyl bromoacetate under homogeneous conditions at room temperature in the presence of 18-crown-6 in acetonitrile.[45]

Organic carbamates have been prepared in good yields from the reaction of primary amines, carbon dioxide, and an alkyl

halide in the presence of 18-crown-6.[46]

Nitrogen Cations.

Photolysis of 1-aminopyridinium salts, 2-aminoisoquinolinium salts, and 1-aminoquinolinium salts is reported to give aniline or a mixture of 2-, 3-, and 4-toluidines in benzene-trifluoroacetic acid or in toluene-trifluoroacetic acid.[47] An intermediate nitrenium ion is postulated. The presence of 18-crown-6 increases the yields of the above products.

Indazoles are produced in good yields from the reaction of *o*-methyl- and *o*-ethylbenzenediazonium tetrafluoroborates with two equivalents of potassium acetate in the presence of catalytic quantities of 18-crown-6 in ethanol-free chloroform.[48]

Other Anions.

Reaction of potassium dihydrogenphosphide with aromatic esters in the presence of 18-crown-6 produces potassium benzoylphosphide.[49] Reaction of potassium dihydrogenphosphide with diethyl phthalate produces the potassium 18-crown-6 complex salt of the 2*H*-isophosphindoline-1,3-dione ion (**2**).[50]

(2)

Reductions.

Alkoxysulfonium salts dissolved in methylene chloride are smoothly reduced with ***Sodium Cyanoborohydride*** dissolved in methanol or ethanol in the presence of 18-crown-6.[51] Even in the presence of aldehydes or ketones, only reduction of alkoxysulfonium salt was observed.

The titanium complex generated by the reaction of ***Dichlorobis(cyclopentadienyl)titanium*** with ***Sodium Borohydride*** promotes hydroboration of alkenes and alkynes in the presence of 18-crown-6.[52,53]

Radical anions of mesitylene, toluene, and benzene are formed in the reaction with alkali metals and 18-crown-6.[54] The alkyl-oxygen bond of oxetane is cleaved with K^-/K^+ and Na^-/K^+ complexes in which the potassium cation has been complexed with 18-crown-6 to form an organometallic alkoxide.[55]

Hydrosilylation of carbonyl groups with ***Dimethyl(phenyl)silane*** proceeds in methylene chloride, benzene, or THF, in the presence of catalytic quantities of cesium, rubidium, or potassium fluoride/18-crown-6.[56]

Oxidations.

The homogeneous photosensitization of oxygen by solubilizing the anionic dyes Rose Bengal and Eosin Y in methylene chloride and ***Carbon Disulfide*** using 18-crown-6 has been reported. The presence of singlet ***Oxygen*** was demonstrated by trapping with anthracene and tetramethylethylene.[57]

The carbanions from tri- and diarylmethanes are generated and oxidized to triaryl carbinols and diaryl ketones, respectively, using potassium hydroxide/DME/18-crown-6 in the presence of oxygen.[58]

Chromium(VI) Oxide, in the presence of 18-crown-6 catalyst in methylene chloride, is an efficient oxidizing system for the chemoselective oxidation of thiols to disulfides.[59]

Eliminations.

The generation of free carbenes was demonstrated in the reaction of ***Potassium t-Butoxide*** with ***Chloroform***, α-bromo-α-fluorotoluene, and α,α-dichlorodimethyl sulfide in the presence of 18-crown-6 from competitive reactivities toward alkenes.[60,61] ***Diazomethane*** was synthesized in 48% yield from the reaction of ***Hydrazine*** hydrate, chloroform, and potassium hydroxide in ether in the presence of catalytic quantities of 18-crown-6.[62]

Reaction of *exo*-2-norbornyl-*exo*-3*d* tosylate with the sodium salt of 2-cyclohexylcyclohexanol in triglyme produces norbornene containing no deuterium. This represents an exclusive *syn* elimination process.[63] In the presence of 18-crown-6, 27% of the product contains deuterium, thus indicating some *anti* elimination.[63] The results were interperted in terms of the effects of crown on base association and ion-pairing.

Polymerization.

In the polymerization of methacrylic esters and hindered alkyl acrylates, the presence of 18-crown-6 produces living polymers in apolar solvents, such as toluene, and at temperatures as high as 0 °C.[64] The polymerization of β-lactones proceeds smoothly in the presence of ***Potassium Naphthalenide*** only after the addition of a cation complexing ligand such as 18-crown-6.[65] The anionic polymerization of ***Propylene Oxide*** and ethylene oxide is catalyzed by the potassium salt of methoxypropanol in the presence of 18-crown-6.[66] The monomer 5-(bromomethyl)-1,3-dihydroxybenzene undergoes self-condensation in the presence of potassium carbonate and 18-crown-6 to give hyperbranched polyethers.[67] The synthesis of soluble, substituted silane high polymers by Wurtz coupling techniques is facilitated by the presence of 18-crown-6.[68] Interfacial polycondensation to produce poly(arylcarboxylate)s,[69] polyphosphates,[70] and polyphosphonates[46] has been studied in the presence of 18-crown-6. Polycondensations of 4-bromomethylbenzyl bromide were carried out with 4,4´-oxydibenzenesulfinate in the presence of 18-crown-6.[71]

Reactions on Polymers.

18-Crown-6 facilitates the alkaline hydrolysis of nitrile groups in acrylonitrile-divinylbenzene copolymer.[72] Starting from linear polycarbonate, carbonate-formal copolymers were prepared by reaction with ***Dibromomethane***, potassium hydroxide, and 18-crown-6.[73] Polystyrene has been successfully grafted onto carbon whiskers by anionic graft polymerization of styrene in which OLi groups on the surface of the carbon whiskers are activated by 18-crown-6.[74] The reaction of chloromethylated poly(styrene-*co*-divinylbenzene) with potassium superoxide in the presence of 18-crown-6 has been reported.[75]

Related Reagents.

Dibenzo-18-crown-6; ***Dicyclohexano-18-crown-6***; ***Potassium t-Butoxide-18-Crown-6***; ***Potassium Carbonate-18-Crown-6***; ***Potassium Hydroxide-18-Crown-6***.

12-Crown-4

[294-93-9] · $C_8H_{16}O_4$ · 12-Crown-4 · (MW 176.21)

(lithium-selective complexing agent, useful for activation and solubilization of lithium salts such as cyanide, diisopropylamide, and aluminium hydride, as well as organolithium reagents and lithium enolates)

Physical Data: bp 67-70 °C/0.5 mmHg, 118-119 °C/15 mmHg; IR (neat, NaCl plates) 2925, 1465, 1365, 1280, 1250, 1130, 1100, 1095, and 920 cm^{-1}; ^1H NMR 3.65 ppm (sharp singlet); ^{13}C NMR ($CDCl_3$) 70.621 ppm.

Preparative Methods: 12-crown-4 has been synthesized by a variety of modified Williamson ether procedures;[1,2] 12-crown-4 is also formed in the cyclic oligomerization of ***Ethylene Oxide*** using gaseous ***Boron Trifluoride***;[3] commercially available.

Handling, Storage, and Precautions: hygroscopic; use in a fume hood.

Complexation With Metal Salts.

The cavity diameter of 12-crown-4 is estimated to be 1.2-1.5 Å, which is ideal for complexing with a lithium cation which has an ionic diameter of 1.36 Å. While the selectivity of 12-crown-4 for lithium salts is well documented, this macrocyclic multidentate ligand will also effectively complex with other alkali metal cations.[4,6] The selectivities of 12-crown-4 for a wide variety of metal cations have been estimated from solvent extraction studies of metal picrates.[5]

Reactions.

The cycloaddition of 2-phenylallylmagnesium phenoxide and *trans*-stilbene in THF is better catalyzed by ***15-Crown-5*** than 12-crown-4.[6] No reaction takes place in the absence of a ligand or in the presence of 18-crown-6.

12-Crown-4 dissolves the alkali metals ***Sodium***, ***Potassium***, rubidium, and cesium to produce blue solutions

containing metal cations, metal anions, electrons, and cation-electron pairs.[7]

The reaction of ***Lithium Cyanide*** with enol trifluoromethanesulfonates in benzene solvent at rt in the presence of 12-crown-4 and ***Tetrakis(triphenylphosphine)palladium(0)*** gives good to excellent yields of the corresponding unsaturated nitrile (eq 1).[8]

(1)

Deprotonation of tropinone with ***Lithium Diisopropylamide*** followed by reaction with ***Methyl Cyanoformate*** in the presence of 12-crown-4 resulted in ring opening with the formation of a pyrrolidine derivative (eq 2).[9]

(2)

1,1-Dichloroallyllithium preferentially reacts at the γ-position with substituted benzaldehydes and acetophenone. In the presence of 12-crown-4 the selectivity toward the α-position is significantly increased.[10]

The regiochemistry of ring opening of 1,2-epoxides can be controlled by the presence of a chelating species. *cis*-4-(Benzyloxy)-1,2-epoxycyclohexane reacts with ***Lithium Aluminum Hydride*** to produce 3-benzyloxycyclohexanol almost exclusively. In the presence of premixed LAH and 12-crown-4 the major product was 4-benzyloxycyclohexanol (eq 3).[11]

(3)

ether	98:2
ether/12-crown-4	18:82

12-Crown-4 enhances the rate of the α-chymotrypsin-catalyzed transesterification of *N*-acetyl-L-phenylalanine ethyl ester with propan-1-ol in octane. Studies with subtilisin indicate that the catalytic effects of crown are much less pronounced.[12]

The lithium enolate of the acetonide of (*S*,*S*)-dimethyl tartrate was prepared by treatment with LDA in the presence of 12-crown-4. Addition of this enolate to acetonylacetone followed by treatment of the product with acid gave a mixture of cyclized adducts from which a single diastereoisomer was isolated (eq 4).[13] The reaction failed in the absence of 12-crown-4.

(4)

Related Reagents.

15-Crown-5; ***Hexamethylphosphoric Triamide***; ***N,N´-Dimethylpropyleneurea***; ***N,N,N´,N´-Tetramethylethylenediamine***.

15-Crown-5

[33100-27-5] · $C_{10}H_{20}O_5$ · 15-Crown-5 · (MW 220.27)

(sodium-selective complexing agent used for the activation of various sodium salts such as the hypochlorite, sulfide, hydroxide, and imidazolide; phase transfer catalyst; activation of potassium and magnesium reagents)

Physical Data: bp 78 °C/0.05 mmHg; IR (CCl_4, 0.1 mm NaCl cell) 2875, 1445, 1350, 1280, 1250, 1185, 975, and 925 cm^{-1}; ^1H NMR (CCl_4) 3.58 ppm (sharp singlet); ^{13}C NMR ($CDCl_3$) 70.621 ppm.

Preparative Methods: 15-crown-5 has been synthesized by a variety of methods involving modified Williamson ether procedures;[1,2] in addition, 15-crown-5 is formed from the cyclic oligomerization of ***Ethylene Oxide*** in the presence of gaseous ***Boron Trifluoride***;[3] commercially available.

Handling, Storage, and Precautions: use in a fume hood.

Complexation With Metal Salts.

The cavity diameter of 15-crown-5 is estimated to be 1.7-2.2 Å, which is ideal for complexing with a sodium cation (ionic diameter of 1.94 Å). While the selectivity of 15-crown-5 for sodium salts is well documented, this macrocyclic multidentate ligand will also effectively complex with other alkali metal cations.[4]

Reactions.

The cycloaddition of 2-phenylallylmagnesium phenoxide and *trans*-stilbene in THF is better catalyzed by 15-crown-5 than 12-crown-4.[4] No reaction takes place in the absence of a ligand or in the presence of 18-crown-6 (eq 1).

The benzylation of ***Potassium Thiocyanate*** yields benzyl thiocyanate as the kinetic product and benzyl isothiocyanate as the thermodynamic product. Solid-liquid phase-transfer catalytic reaction of ***Benzyl Chloride*** with potassium thiocyanate produces approximately a 50/50 mixture of the two products in the presence of 15-crown-5.[5] ***Dibenzo-18-crown-6*** produces substantially more of the isothiocyanate (eq 2).

The preparation of *N*-(arylsulfonyl)sulfoximines by oxidation of the sulfilimines with ***Sodium Hypochlorite*** in an aqueous methylene chloride-ethyl acetate two-phase system in the presence of 15-crown-5 has been reported (eq 3).[6]

4,4´-Dicyanodiphenyl thioether was prepared in excellent yield from the reaction of 4-cyanochlorobenzene and ***Sodium Sulfide*** in dipolar, aprotic solvents (DMF, *o*-dichlorobenzene) at 200 °C in the presence of 15-crown-5 (eq 4).[7]

The Wittig rearrangement of the phenyl ether of 9-fluorenol was investigated under solid-liquid phase transfer catalytic conditions using solid, powdered base and an organic phase in the presence of crown ethers (eq 5). In the presence of ***Potassium Hydroxide*** the order of effectiveness is: dibenzo-18-crown-6 < ***Dicyclohexano-18-crown-6*** < 15-crown-5 < ***18-Crown-6***. In the presence of ***Sodium Hydroxide*** the order of effectiveness is: ***12-Crown-4*** < 18-crown-6 < 15-crown-5.[8]

(5)

The sodium salt of theophylline undergoes *N*-alkylation with 1-chloro-4-iodobutane in acetonitrile in the presence of 15-crown-5. The resulting chloride reacts smoothly with the potassium salt of 2-nitroimidazole, again in the presence of 15-crown-5, to give the second *N*-alkylation (eq 6).[9]

(6)

The polymerization of phenylmethyldichlorosilane with sodium metal (Wurtz Coupling) in toluene/heptane solvent has been found to be catalyzed by 15-crown-5.[10]

Related Reagents.

12-Crown-4; ***18-Crown-6***; ***Hexamethylphosphoric Triamide***.

Cumyl Hydroperoxide[1]

[80-15-9] · $C_9H_{12}O_2$ · Cumyl Hydroperoxide · (MW 152.19)

(oxidant useful for metal-catalyzed enantioselective epoxidation of allylic alcohols[2] and enantioselective oxidation of sulfides to sulfoxides[3])

Alternate Name: cumene hydroperoxide.

Physical Data: mp 44-45 °C; bp 100-101 °C/8 mmHg; *d* 1.030 g cm^{-3}; flash point 56 °C.

Solubility: sol most organic solvents; slightly sol H_2O (15 g L^{-1}).

Form Supplied in: a colorless to light yellow solution consisting of 80% cumene hydroperoxide in cumene; widely available.

Analysis of Reagent Purity: iodometric titration.[4,5]

Handling, Storage, and Precautions: cumyl hydroperoxide (CHP) is an unusually stable hydroperoxide which is resistant but still susceptible to induced explosive decomposition.[6] Like most alkyl hydroperoxides, CHP should be stored cold (ca. 0 °C) in the absence of light in a container, such as a polyethylene bottle, that is unlikely to shatter if there is pressure build up. Exposing pure or concentrated solutions of CHP to heat, acid, reducing materials, and transition metal salts should be avoided. Upon completion of reactions involving CHP, steps should be taken to destroy any remaining reagent safely. This can usually be done by exposing the reaction mixture to a mild reducing agent such as aqueous sodium sulfite, methyl sulfide, or triphenylphosphine.

Enantioselective Epoxidation of Allylic Alcohols.

While ***t-Butyl Hydroperoxide*** (TBHP) is most often used in the Sharpless-Katsuki asymmetric epoxidation of allylic alcohols to give scalemic epoxy alcohols, CHP is sometimes used to advantage.[4] For example, CHP is reported to epoxidize allyl alcohol and methallyl alcohol enantioselectively, with yields higher than TBHP (eq 1). Epoxidation with CHP is also apparently faster than with TBHP. In general, CHP can substitute for TBHP without loss of enantioselectivity.

Enantioselective Oxidation of Sulfides to Sulfoxides.

CHP[3] has been shown to be superior to TBHP[7] as the oxidant for the enantioselective oxidation of prostereogenic sulfides to scalemic sulfoxides using ***Titanium Tetraisopropoxide***, diethyl tartrate, and water (eq 2).[8]

Related Reagents.

t-Butyl Hydroperoxide; ***Triphenylmethyl Hydroperoxide***.

Cyanamide

[420-04-2] · CH_2N_2 · Cyanamide · (MW 42.04)

(ammonia equivalent, urea equivalent, guanidine equivalent; sulfur bioequivalent)

Alternate Names: cyanoamine; carbodiimide.

Physical Data: mp 45-46 °C; bp 83 °C/380 mmHg; moist white crystals.[1]

Solubility: sol 100 g/100 g H_2O at 43 °C; also sol alcohols, amines, ethers, ketones, ethyl acetate; sparingly sol benzene and halogenated hydrocarbons; insol cyclohexane.

Form Supplied in: pure hygroscopic solid; 50% aq. solution; salts: sodium, calcium, lead, etc.

Preparative Method: widely available. A checked literature preparation is available.[2] Calcium salt is prepared from calcium carbide and nitrogen.

Handling, Storage, and Precautions: hygroscopic, caustic, highly toxic (LD_{50} rats 125 mg/kg), readily absorbed through the skin, produces dermatitis; polymerizes violently above melting point; should be stored in a cool, dry place. Incompatibilities are: various metals, acids, bases, strong oxidizing and reducing agents[1]. Use in a fume hood.

Because of its amphoteric nature, cyanamide displays both nucleophilic and electrophilic characteristics. This property makes it a useful reagent for the preparation of a variety of heterocycles.

Condensation Reactions.

Cyanamide will undergo cyclization reactions with ketols, thioketones, amino ketones, and related functionalities to yield the respective amino azoles (eqs 1-4).[3-6]

(1)

(2)

(3)

(4)

Nucleophilic Additions.

Cyanamide efficiently adds to a variety of electrophilic functionalities. Thiocyanates react with silver cyanamide to give unusual cyanocarbodiimides, albeit in low yield (eq 5).[7]

$$\text{R-NCS} + \text{Ag}_2\text{NCN} \longrightarrow \text{RNCNCN} + \text{Ag}_2\text{S} \qquad (5)$$

Xanthates and thiono esters undergo addition displacement reactions with potassium cyanamide (eqs 6 and 7).[8]

(6)

(7)

Thioureas react with lead cyanamide to give the *N*-cyanoguanidines. This technique was utilized in the preparation of the first H_2 blocker, cimetidine (eq 8).[9]

(8)

Carbodiimides bearing electron-withdrawing aryl groups can be converted to the respective cyanoguanidines with cyanamide (eq 9).[10]

(9)

Orthoesters add cyanamide in the presence of acetic anhydride to give *N*-cyanoimino esters (eq 10).[11]

(10)

N-Cyanoimino esters and related thioesters are useful intermediates for the preparation of a variety of heterocycles, as shown in (eq 11).[12]

(11)

Cyanamide and the respective sodium salts have been found to add to β-keto esters and 4-pyranones (eqs 12 and 13).[13-15]

(12)

(13)

Disubstituted cyanamides are synthesized by direct alkylation of sodium cyanamide (eqs 14-16)[14,15] (also see von Braun reaction as an alternative).[15c]

(14)

(15)

(16)

These cyanamides can be readily hydrolyzed to the respective amines (eq 17).[14,15]

(17)

Calcium cyanamide can be acylated with ***Benzoyl Chloride*** to give the *N*-cyanoamide (eq 18).[16]

(18)

Cyanamide readily adds to alkenes in the presence of ***N-Bromosuccinimide*** to give the 1,2-*trans*-bromocyanamides.[17] These bromocyanamides can be converted to 1,2-*cis*-diamines in one of two similar three-step procedures, or the bromide may be reductively removed to yield the amines (eqs 19 and 20).[17] The above reactions are reported for a number of alkenes with yields ranging from 35-70%.

Electrophilic Additions.

Amines, hydrazines, thiols, and alcohols add to cyanamide to give guanidines and pseudourea ethers (eqs 21-23).[18-20]

(21)

(22)

(23)

Cyanamide can also undergo bis addition with diamines to yield amino heterocycles (eqs 24 and 25).[21,22]

(24)

(25)

Related Reagents.

Aminoiminomethanesulfonic Acid; ***Cyanogen Bromide***; ***Guanidine***; ***O-Methylisourea***; ***S-Methylisothiourea***; ***1H-Pyrazole-1-carboxamidine Hydrochloride***.

Cyanoacetic Acid

[372-09-8] · $C_3H_3NO_2$ · Cyanoacetic Acid · (MW 85.06)

(active methylene compound for preparing α,β-unsaturated nitriles and esters, for carbolactonization of alkenes to α-cyano γ-lactones, and for converting *trans*-1,2-bromohydrins to *cis*-1,2-diols)

Physical Data: mp 70-71 °C.

Solubility: sol H_2O, ethanol, ether.

Form Supplied in: hygroscopic crystals; widely available.

Analysis of Reagent Purity: gas chromatography; titration.

Handling, Storage, and Precautions: keep container well closed. Inhalation or skin contact should be avoided. Hydrogen cyanide may be liberated in the event of overheating. This reagent should be handled in a fume hood.

Condensation with Carbonyl Compounds.

Ammonium acetate,[1] IR-4B,[2] Dowex-3,[2] pyridine,[3] and potassium hydroxide[4] are effective catalysts for the condensation of cyanoacetic acid with aldehydes and ketones to form α,β-unsaturated nitriles. Cyclohexanone reacts with cyanoacetic acid to yield cyclohexylidenecyanoacetic acid, which can be hydrolyzed to 1-cyclohexenylacetonitrile.[1] Furfural reacts with cyanoacetic acid to afford 3-(2-furyl)acrylonitrile in good yield (eq 1).[3] 2,5-Dihydroxy-3,4,6-trimethylbenzaldehyde condenses with cyanoacetic acid to form a coumarin derivative (eq 2).[4]

(1)

(2)

Carbolactonization of Alkenes to α-Substituted γ-Lactones.

Cyanoacetic acid and malonic acid react with alkenes in the presence of ***Manganese(III) Acetate*** to form α-substituted γ-lactones.[5] In this procedure, cyclohexene is converted to the α-cyano-γ-lactone (**2**) (eq 3).

(3)

Conversion of *trans*-1,2-Bromohydrins into *cis*-1,2-Diols.

Esterification of cyanoacetic acid with *trans*-2-bromocyclohexanol forms the cyanoacetate ester (**2**). The ester (**2**) is converted into the ketene acetal (**3**), which is hydrolyzed to the monocyanoacetate of *cis*-cyclohexane-1,2-diol (**4**) (eq 4).[6] Hydrolysis of (**4**) with ***Potassium Carbonate*** in methanol affords the *cis*-cyclohexane-1,2-diol (95%). Similarly, the *trans*-1,2-bromohydrin (**5**) is converted to the *cis*-1,2-diol (**6**) through the cyano ester (eq 5). Attempted dihydroxylation of the alkene precursor to (**5**) with ***Osmium Tetroxide*** led to a 1:1 mixture of the 2α,3α-diol and the 2β,3β-diol.

Other Applications.

Cyanoacetic acid is converted to cyanoacetyl chloride which is esterified with *t*-butanol to afford *t*-butyl cyanoacetate,[7] ***N-Bromosuccinimide*** converts cyanoacetic acid to dibromoacetonitrile.[8] A key step in the synthesis of 3-vinylbenzofuran was the alkylation of 3-(pyrrolidin-1-yl)benzofuran to (3-benzofuranyl)cyanoacetic acid with cyanoacetic acid.[9] Cyanoacetic acid serves as an α-ketoacetyl anion equivalent in the diastereoselective synthesis of a highly functionalized decalin fragment of the natural product insecticide azadirachtein.[10]

Related Reagents.

Acetonitrile; ***(Diethoxyphosphoryl)acetonitrile Oxide***; ***Ethyl Cyanoacetate***; ***Lithioacetonitrile***; ***Malononitrile***; ***Trimethylsilylacetonitrile***.

Cyanogen Azide[1]

[764-05-6] · CN_4 · Cyanogen Azide · (MW 68.04)

(1,3-dipolar reagent that undergoes cycloaddition and insertion reactions with alkenes[2])

Physical Data: bp 90 °C (est).[1,3]

Solubility: sol most organic solvents including acetonitrile, ethyl acetate, methylene chloride, benzene, toluene, and cyclohexane.[1,3]

Preparative Methods: by the addition of cyanogen chloride or ***Cyanogen Bromide*** to an acetonitrile solution of ***Sodium Azide*** in the temperature range of 10-25 °C. The reagent is used in solution after filtration or decantation of the inorganic salts.[1,3]

Purification: made and used in situ without further purification.[1,3]

Handling, Storage, and Precautions: should be used in solution. In acetonitrile a 27% by weight solution of cyanogen azide has a half-life of 15 days at 25 °C. The pure material is highly explosive and detonates violently when exposed to mild thermal, mechanical, or electrical shock.[1,3] This reagent should be handled in a fume hood.

Dipolar Cycloaddition.

Cycloaddition of cyanogen azide to alkenes affords both aziridines and alkylidenecyanamides. The ratio of the two products depends on the structure of the starting alkene. Isobutene, for example, yields a 1.4:1 mixture of 2-butylidenecyanamide and *N*-cyano-2,2-dimethylaziridine (eq 1).[3,4] The alkylidenecyanamide is formed by a Demjanoff-like rearrangement of a dipolar intermediate resulting from cleavage of the initially formed triazoline.

(1)

In contrast to the acyclic case, with cyclopentene the only product is the cyanamide, hydrolysis of which affords cyclopentanone in high yield (eq 2). Strained bicyclic alkenes, however, lead to the opposite result. Norbornene upon treatment with cyanogen azide affords a mixture of aziridine and cyanamide in a ratio of 4:1 (eq 3).[4]

(2)

(3)

Ring contraction is also observed for cycloalkenes with trisubstituted double bonds (eq 4).[4]

(4)

In the presence of ***Lithium Perchlorate***, methylenecyclohexanes and -cyclohexenes undergo ring enlargement to yield cyclic ketones when treated first with cyanogen azide and then with methanolic HCl (eqs 5 and 6).[5,6]

(5)

(6)

Ring enlargement is also observed in the absence of the perchlorate salt (eq 7).[7]

(7)

Dihydro-[8-10] and tetrahydropyridines[11,12] afford cyanoaziridines when treated with cyanogen azide (eqs 8 and 9).

(8)

R = H, 81%; Me, 76%

(9)

Nitrene Formation and Insertion.

Thermal decomposition of cyanogen azide leads to a nitrene intermediate which may insert into C-H bonds (eq 10); a nitrene is also proposed for the reaction of cyanogen azide with benzene to give cyanoazepine (eq 11).

Cyanogen Bromide

X-C&tbond;N

(**1**; X = Br)

[506-68-3] · CBrN · Cyanogen Bromide · (MW 105.92) (**2**; X = Cl)

[506-77-4] · CClN · Cyanogen Chloride · (MW 61.47) (**3**; X = I)

[506-78-5] · CIN · Cyanogen Iodide · (MW 152.92) (**4**; X = Ts)

[19158-51-1] · $C_8H_7NO_2S$ · *p*-Toluenesulfonyl Cyanide · (MW 181.21) (**5**; X = OPh)

[1122-85-6] · C_7H_5NO · Phenyl Cyanate · (MW 119.12)

(counter-attack reagent useful for the cleavage of carbon-heteroatom bonds,[1] cyanation,[2] and synthesis of heterocycles[3])

Physical Data: (**1**) bp 61.4 °C; mp 52 °C; *d* 2.015 g cm^{-3}; (**2**) bp 12.7 °C; mp -6 °C; *d* 1.186 g cm^{-3}; (**3**) sublimes at 45 °C; mp 146.7 °C; *d* 2.84 g cm^{-3}; (**4**) mp 49 °C; (**5**) bp 77 °C/13 mmHg; *d* 1.096 g cm^{-3}.

Preparative Methods: *p*-toluenesulfonyl cyanide (TsCN) is prepared from the reaction of sodium *p*-toluenesulfinate with ClCN.[4] Phenyl cyanate (PhOCN) is available from the reaction of phenol with BrCN.[5a,b]

Handling, Storage, and Precautions: BrCN and its analogs are highly toxic. These reagents should be handled in a fume hood.

Counter-Attack Reagent.

Cyanogen halides are representative of a class of counter-attack reagents[6] which are useful for the cleavage of carbon-heteroatom bonds. The classic Von Braun reaction[1] with BrCN provides a convenient method for the demethylation of tertiary methyl amines (eq 1).[7] The products of this reaction are a dialkyl-substituted

cyanamide and an alkyl bromide, with bromide attack occurring at the more electrophilic[8a] or sterically accessible site. Similar methodology with BrCN has been utilized to induce ring opening[8b] as well as ring expansion[8c,d] of N-heterocycles (eq 2).

(1)

(2)

Cleavage of thioethers is also accomplished with cyanogen halides. The selective reaction of BrCN with methionine in peptide chains (eq 3)[9a] has been applied to the removal of peptide chains from the resin after solid phase synthesis.[9b] In a related sequence, treatment of dithioacetals with ICN affords the α-thionitrile.[10] The synthesis of symmetrical[11a] and mixed[11b] disulfides and the intramolecular formation of disulfide bonds in peptides[11c] have been accomplished with BrCN and ICN, respectively. Another example of the counter-attack properties of BrCN and ICN is shown by their reaction with dialkylvinylboranes to produce *trans*-alkenes (eq 4).[12] In addition, vinyl bromides are available from the treatment of disubstituted vinylsilanes with BrCN and ***Aluminum Chloride***.[13]

(3)

(4)

Cyanation.

The synthesis of unsaturated nitriles is accomplished by treatment of vinyl cuprates with ClCN or TsCN[14] or more conveniently from the reaction of vinyllithium reagents with PhOCN (eq 5).[5a] Cyanation of lithium ketone enolates with TsCN proceeds in good yield (eq 6).[2] In addition, enamines react readily with ClCN to provide the α-cyanoketone.[15a] The use of BrCN in the latter reaction affords the corresponding α-bromo ketone.[15b] Alkylation of an *N*-alkylimidazole to its 2-cyano derivative proceeds through an intermediate imidazolium ylide (eq 7).[16]

(5)

(6)

(7)

Heterocycle Synthesis.

Cyanogen halides are useful for the synthesis of N-heterocycles via double attack by nitrogen and/or sulfur nucleophiles.[3] In addition, the cyano group of TsCN participates in a Diels-Alder reaction with selected dienophiles (eq 8).[17]

Cyanomethylcopper[1]

$CuCH_2CN$

[35219-76-2] · C_2H_2CuN · Cyanomethylcopper · (MW 89.58)

(reagent for the cyanomethylation of allyl halides[2])

Preparative Methods: by the reaction of cyanomethyllithium (***Lithioacetonitrile***) and ***Copper(I) Iodide*** in THF at -25 °C,[2] or by the thermal decarboxylation of ***Copper(I) Cyanoacetate***.[3]

Handling, Storage, and Precautions: can be prepared in two forms, a red solution in THF or an insoluble dark yellow solid. The solid form is stable in the absence of air to 100 °C, but both forms are air- and moisture-sensitive. Use in a fume hood.

General Discussion.

Although both the above preparations produce cyanomethylcopper, the physical characteristics of the specific reagent produced by each method are markedly different, as is the reactivity. The cyanomethylcopper obtained by transmetalation of the lithio precursor in THF is a brick-red solution which gives a negative Gilman test. The soluble reagent is reactive toward allylic electrophiles, but does not react with benzyl bromide, esters, vinyl bromides, or vinyl iodides (eqs 1-3).

(1)

(2)

(3)

Cyanomethylcopper produced by the decarboxylation route is a dark yellow solid which is insoluble in most organic solvents. Addition of 1 equiv of ***Lithium t-Butoxide*** to a suspension of the solid reagent in DMF results in a homogeneous solution which does react with benzyl bromide and iodobenzene (no yields are given). The isolated solid cyanomethylcopper is stable under nitrogen to approximately 100 °C, but is rapidly decomposed when exposed to air. The addition of acetic acid results in formation of acetonitrile and copper(I) acetate. Cyanomethylcopper can also be obtained by the reaction of copper(II) methoxide and 2 equiv of cyanoacetate. The initial copper acetate salt decomposes upon heating in DMF to generate cyanomethylcopper, succinonitrile, and carbon dioxide.[3] Decomposition of copper cyanoacetate in the presence of propene oxide produces cyanomethylcopper and propylene carbonate; therefore, copper cyanoacetate also functions as a source of activated carbon dioxide (eq 4).[4] Control reactions revealed that cyanomethylcopper was required for the transcarboxylation reaction. Cyanomethylcopper formed independently (by the decarboxylation route described above) served as a catalyst for the reaction of propene oxide with carbon dioxide gas. Other sources of copper(I) examined, such as CuCN and CuCl, were ineffective as catalysts and did not produce any propylene carbonate.

(4)

Cyanomethylation.

Cyanomethylcopper is a relatively unreactive organocopper reagent, similar to other stabilized alkylcopper species such as ***Ethoxycarbonylmethylcopper***. The reagent is ideally suited for cyanomethylation of allylic halides. Reaction occurs cleanly by direct substitution (S_N2) without significant competing allylic transposition (S_N2' alkylation). In a key step in the synthesis of cembrane lactones, Marshall and co-workers reported that cyanomethylcopper gave only the product arising from direct displacement of an allyl bromide, while other approaches to the nitrile product resulted in considerable amounts of the S_N2' alkylation product (eq 5).[5] The synthesis of the alkaloid peramine, the principal insect feeding deterrent isolated from perennial ryegrass, was achieved by an allylic displacement reaction on a 2-methylpyrrolo[1,2-*a*]pyrazin-1(2*H*)-one ring system using cyanomethylcopper (eq 6).[6]

(5)

(6)

Cyanomethylcopper does not react with carbonyl groups; however, an iron derivative has been shown to be selective for addition to aldehydic carbonyl groups in the presence of ketones.[7] Knochel and co-workers have achieved the preparation of chain-extended nitriles by the reaction of cyanomethylcopper with ***Iodomethylzinc Iodide***.[8] Subsequent reaction with a variety of electrophiles results in very good yields of products formally derived from 2-cyanoethylcopper. This reagent is more reactive than the parent cyanomethylcopper and undergoes conjugate addition reactions (eq 7) as well as alkylation reactions with allyl halides (eq 8). Reaction of copper cyanide solubilized with ***Lithium Chloride*** and iodomethylzinc iodide generates the parent cyanomethylcopper reagent in situ, thereby avoiding the need to prepare cyanomethyllithium.

Cyanomethyldiphenylphosphine Oxide

[23040-22-4] · $C_{14}H_{12}NOP$ · Cyanomethyldiphenylphosphine Oxide · (MW 243.23)

(Horner-Wittig reagent for formation of α,β-unsaturated nitriles[1]; reaction with nitrones to form aziridines or enamines[2])

Solubility: sol THF and DMF.

Preparative Methods: reaction of ***Ethyl Diphenylphosphinite***[3] with ***Chloroacetonitrile***;[4] reaction of $Ph_2P(O)CH_2CO_2H$ with urea in acetic anhydride.[5]

Handling, Storage, and Precautions: hazards unknown.

α,β-Unsaturated Nitriles.

Use of cyanomethyldiphenylphosphine oxide (**1**) in a Horner-Wittig reaction for the formation of α,β-unsaturated nitriles provides, stereoselectively, the (*E*) isomer (&egt;90%) with aromatic aldehydes and ca. 75% *(E)* with isobutanal in very good chemical yields (eq 1). The reactions are run in either THF or DMF with ***Potassium t-Butoxide*** as the base at rt. Use of THF provides greater chemical yields and improved stereoselectivity over DMF or ***Lithium t-Butoxide*** in THF. The potassium diphenylphosphinate byproduct is water soluble and easily removed from the reaction mixture.

Reaction of the anion of (**1**) with acetophenone provides the (*E*) isomer in a 94:6 ratio in 82% yield. Condensation with cinnamaldehyde provides a 90:10 ratio (*E*:*Z*) (70:30 *E*:*Z* with analogous phosphonate). Use of (**1**) generally provides greater stereoselectivity for the (*E*) isomer than other methods for the formation of α,β-unsaturated nitriles.[1]

Of the other methods available, the Doebner condensation[6] of aldehydes with cyanoacetic acid leads to mixtures of (*E*) and (*Z*) isomers.[7] The Wittig alkenation with ***Cyanomethylenetriphenylphosphorane***,[8] usually in refluxing benzene, yields a predominance of the (*E*) isomer and triphenylphosphine oxide as a byproduct. In alkenation employing the Horner-Emmons reagents, ***Diethyl Cyanomethylphosphonate***,[9] in THF at rt, the (*E*) isomer predominates (&egt;70%) with aromatic aldehydes and little or no selectivity is seen with aliphatic aldehydes.

Reaction with Nitrones.[2]

Reaction of the anion of (**1**) with 3,4-dihydroisoquinoline *N*-oxide (**2**) (eq 2) and 5,5-dimethyl-Δ^1-pyrroline *N*-oxide (**5**) (eq 3) can result in the formation of either aziridine or enamine products. The product distribution is markedly different employing (**1**) as opposed to diethyl cyanomethylphosphonate. This is thought to be due to the ability of the phenyl groups of (**1**) to better stabilize the build up of negative charge on phosphorus in the putative oxazaphospholidine intermediate, thereby decreasing the amount of fragmentation to the aziridine.

Cyanomethylenetriphenylphosphorane

[16640-68-9] · $C_{20}H_{16}NP$ · Cyanomethylenetriphenylphosphorane · (MW 301.33)

(phosphonium ylide, Wittig reagent)

Physical Data: mp 196-197 °C;[1] IR;[1] UV;[2] ^{1}H NMR;[3] ^{31}P NMR;[4] pK_a;[4] rate of hydrolysis.[2]

Preparative Methods: may be generated by deprotonation of the corresponding phosphonium salt,[5,6] by cyanation of ***Methylenetriphenylphosphorane*** with *p*-tolyl cyanate,[1] or by the reaction of ***Acrylonitrile*** with ***(Methoxycarbonylmethylene)triphenylphosphorane*** (eq 1).[7]

Wittig Reactions.

Cyanomethylenetriphenylphosphorane, as a stabilized phosphonium ylide, has been reacted in Wittig reactions with a great variety of carbonyl compounds to give α,β-unsaturated nitriles with predominantly or exclusively (*E*) configuration at the newly formed alkenic bond (eq 2) (examples,[1,8-15] special application to carbohydrates[16-20]). Besides aldehydes and ketones, activated esters,[21,22] anhydrides,[23,24] and imides[25] have been used as carbonyl reactants.

(2)

A Wittig-type reaction is also involved if cyanomethylenetriphenylphosphorane is cleaved with elemental sulfur[26] or selenium.[27,28] The thio- or selenoaldehyde intermediate reacts with a second molecule of ylide to give 1,2-dicyanoethylene (eq 3).

(3)

Reactions with Other Electrophiles.

Various electrophilic compounds have been reacted with cyanomethylenetriphenylphosphorane, affording (in most cases) substituted derivatives of the original ylide, which can then be used in typical ylide reactions (eqs 4-11).

Borane is added with formation of an alkylidenetriphenylphosphorane-borane which, in contrast to analogous compounds, does not rearrange to the triphenylphosphane-monoalkylborane adduct (eq 4).[29] Halogenation may be achieved by using ***t-Butyl Hypochlorite*** or elemental ***Bromine*** or ***Iodine***, respectively (eq 5).[30] The attack of alkylating reagents can occur at the ylide C-atom as well as at the N-atom (eq 6).[1] The reaction with acylaziridines yields 3-pyrrolines, which result from intramolecular Wittig reaction of an initially formed cyano ylide (eq 7).[31,32] The reaction with acid chlorides leads to the formation of 1-acyl-1-cyano ylides,[33-35] which can be pyrolyzed to give 1-cyanoalkynes (eq 8). In the presence of both an aldehyde and an acid chloride, the cyano ylide reacts preferentially at the acid chloride.[35] Isocyanates yield 1-cyano-1-carbamoylmethylenetriphenylphosphoranes (eq 9)[5,36] and the reaction with ***Carbon Disulfide*** followed by an *S*-alkylation leads to the formation of 1-cyano-1-dithio carboxylic derivatives (eq 10).[37] Addition of alkyne carboxylic esters to cyanomethylenetriphenylphosphorane yields 1-alkoxycarbonyl-1-(2-cyanoalkenyl) ylides, presumably via electrocyclic ring opening of an intermediate phosphacyclobutene (eq 11).[38]

(11)

Cyanomethylenetriphenylphosphorane may be deprotonated to give the corresponding ylide anion.[39-41] This reacts with electrophiles to give a wide variety of 1-substituted cyano ylides, from which various nitriles are available via Wittig reaction or thermolysis (eq 12).[39,40] Reaction with aliphatic aldehydes followed by addition of ***Chlorotrimethylsilane*** leads to the formation of 1-cyano-1-alkenyl ylides (eq 13), which are useful synthons for 2-cyano-1,3-dienes. Ring opening of epoxides by the ylide anion provides a route to γ-hydroxynitriles, γ-butyrolactones, or α-methylene-γ-butyrolactones, depending on the subsequent treatment of the initially formed adduct (eq 13).[40]

Cyano(methylthio)methyltrimethylsilane[1]

[121221-45-2] · $C_6H_{13}NSSi$ · Cyano(methylthio)methyltrimethylsilane · (MW 159.32)

(reagent for the synthesis of α-cyano-substituted vinyl sulfides[1])

Physical Data: bp 72-74 °C/4 mmHg.[1]

Solubility: sol ether, THF, and $CHCl_3$.

Analysis of Reagent Purity: ^{1}H NMR, IR.[1]

Preparative Method: prepared in 80-85% yield by the treatment of methylthioacetonitrile with ***Trimethylsilyl Trifluoromethanesulfonate*** and ***Triethylamine*** in ether at 0-5 °C for 3 h.[1]

Purification: distillation.

Handling, Storage, and Precautions: use in a fume hood.

Preparation of α-Cyano-Substituted Vinyl Sulfides.

Cyano(methylthio)methyltrimethylsilane is a Peterson alkenation reagent that was developed for the explicit purpose of preparing α-cyano-substituted vinyl sulfides in a one-step operation. Vinyl sulfides are versatile intermediates that participate in a variety of synthetically useful transformations.[2]

The lithiated anion of cyano(methylthio)methyltrimethylsilane reacts with aldehydes and ketones to give α-cyano-substituted vinyl sulfides directly (eq 1).[1]

Shown in Table 1 are representative examples that define the scope of this process. In general, cyano(methylthio)methyltrimethylsilane undergoes reaction with aromatic and nonaromatic aldehydes and ketones, and is thus useful for preparing a variety of tri- and tetrasubstituted alkenes. Longer reaction times are required in cases where steric hindrance and competitive enolization impede (entries 4-8). One limitation of the reaction is that there is a lack of stereochemical control. Reaction products are isolated as mixtures of (*E*) and (*Z*) isomers. This nonselectivity is attributed to mechanistic factors associated with the Peterson reaction.

Table 1 Reaction of Aldehydes and Ketones (R^1COR^2) with Cyano(methylthio)methyltrimethylsilane

Entry	R^1	R^2	Reaction time (h)	Yield (%)	(*E*)/(*Z*) ratio
1	Ph	H	3	85	3:4

6	$Me(CH_2)_4$	Me	6	78	1:1
7	$(CH_2)_5$		10	42	
8	$(CH_2)_4CHMe$		12	41	1:1

Alternate Methods for the Preparation of α-Cyano-Substituted Vinyl Sulfides.

Numerous methods have been described for the preparation of α-cyano-substituted vinyl sulfides that vary in complexity and scope. Three approaches that require multi-step substrate modifications include the addition of methylsulfenyl chloride

to acrylonitrile followed by dehydrochlorination (eq 2),[3] potassium bromide induced rearrangement of α-chloro-β-alkylthionitriles (eq 3),[4] and dehydrobromination of α-bromo-α-cyano thioethers (eq 4).[5]

In addition to cyano(methylthio)methyltrimethylsilane, two distinct reagent-based approaches to the synthesis of α-cyano-substituted vinyl sulfides have been reported. The first method involves the Horner-Emmons reaction of an aldehyde or ketone with a thiophenoxy-modified cyanomethylphosphonate (eq 5).[6] This method is not of general utility since the phosphonate reagent is prepared in low yield, and its reactivity is limited by steric and electronic factors. The second method involves the condensation of ethylthioacetonitrile with an aldehyde or ketone (eq 6).[5] This reaction is applicable to a variety of substrates with some limitation due to the strongly basic conditions. Products are isolated as mixtures of (*E*) and (*Z*) isomers.

4-Cyanothiolan-3-one

[16563-14-7] · C_5H_5NOS · 4-Cyanothiolan-3-one · (MW 127.11)

(precursor for α-substituted acrylonitriles,[1] 2-cyano-1,3-butadiene,[2] and substituted thiophenes;[3,4] building block for thienobenzodiazepines[5])

Alternate Name: 4-oxothiolane-3-carbonitrile.

Physical Data: mp 71-72 °C (from diethyl ether);[1,4] IR and ^{1}H NMR spectra.[1]

Form Supplied in: commercially available.

Preparative Method: [1,6] can be conveniently prepared in 50% yield by cyclization of the Michael adduct of methyl thioglycolate and acrylonitrile.

Synthetic Equivalent for the α-Acrylonitrile Anion.[1]

Alkylation of 4-cyanothiolan-3-one with a variety of alkyl halides in the presence of ***Potassium Carbonate*** provides *C*-alkylated products in excellent yields. Their treatment with aqueous ***Sodium Hydroxide*** affords α-substituted acrylonitriles through tandem Dieckmann-Michael retrograde reactions (eq 1).

(1)

Synthetic Precursor for 2-Cyano-1,3-butadiene.[2]

This rather unstable conjugated diene can be generated and trapped in situ by dienophiles using the nicely crystalline 3-cyano-2,5-dihydrothiophene 1,1-dioxide as a suitable precursor. This precursor is derived from 4-cyanothiolan-3-one in a three-step sequence involving reduction of the carbonyl group followed by dehydration and *S*,*S*-oxidation. On heating a toluene solution of the diene in the absence of dienophiles, self-condensation takes place to afford the dimer, which has been hydrolyzed to mikanecic acid (eq 2).

(2)

3,4-Disubstituted Thiophenes.

2,5-Dihydrothiophenes, derived from enamines or enol ethers of 4-cyanothiolan-3-one, can be efficiently aromatized to the corresponding thiophene derivatives by treatment with ***Chloranil***[3,5] or ***Sulfuryl Chloride*** (eq 3).[4]

(3)

Building Block for Polycondensed Heterocycles.

The cyclocondensation of 4-cyanothiolan-3-one with 1,2-diaminobenzenes followed by chloranil aromatization affords biologically interesting substituted 10-amino-4*H*-thieno[3,4-*b*][1,5]benzodiazepines (**1**).[5]

(1)

Related Reagents.

Acrylonitrile; ***2-(Dimethylamino)-3-butenenitrile***; ***Lithioacetonitrile***; ***4-Methoxycarbonylthiolan-3-one***; ***Methyl 3-(Dimethylamino)propionate***; ***Methyl 3-Hydroxypropionate***.

Cyanotributylstannane

Bu_3SnCN

[2179-92-2] · $C_{13}H_{27}NSn$ · Cyanotributylstannane · (MW 316.07)

(reagent for cyanation of halides; can add to aldehydes; catalyst for halosilane substitution)

Alternate Name: tributyltin cyanide.

Physical Data: mp 90-93 °C (from petroleum ether);[1] 93-96.5 °C (from acetonitrile).[2]

Solubility: sol common org solvents.

Form Supplied in: colorless solid.

Preparative Methods: originally from ***Tri-n-butylchlorostannane*** and ***Potassium Cyanide***.[1] Modified procedures using ***18-Crown-6***[2] or ***Lithium Cyanide***[3] give better yields.

Handling, Storage, and Precautions: hygroscopic, but stable under a dry atmosphere. Both cyano and alkyltin compounds are highly toxic.

Coupling with Halides.

Cyanation of vinyl or aryl halides is effectively catalyzed by palladium(0) complexes. The reaction can be applied to the synthesis of cyano homologs of nucleosides (eq 1),[4] nucleoside bases,[5] and *cis*-dihydrodiols derived from arenes.[6]

(1)

Aryl, vinyl, and tertiary alkyl acid halides can be cyanated by the reagent to give acyl cyanides in good yields (eq 2).[2] Primary or secondary alkyl acid halides react further to afford acyl cyanide dimers.

(2)

The three-component coupling of aryl halides, cyanotributylstannane, and isocyanides takes place in the presence of palladium(0) to yield iminoacyl cyanides in moderate yields.[7]

Addition to Aldehydes.

Cyanohydrins are obtained by the reaction of cyanotributylstannane with aldehydes. Although a chiral titanium catalyst did not effect any asymmetric induction,[8a] good 1,2-diastereoselectivity was achieved in the reaction with α-amino aldehydes.[8b]

Catalysis of Halosilane Substitution Reactions.

A catalytic amount of cyanotributylstannane facilitates the substitution of silyl chlorides by Grignard

reagents.[9]

Related Reagents.

Acetyl Cyanide; ***Cyanotrimethylsilane***; ***Hydrogen Cyanide***; ***Diethylaluminum Cyanide***; ***Potassium Cyanide***; ***Sodium Cyanide***; ***Tri-n-butylchlorostannane***; ***Zinc Cyanide***.

Cyanotrimethylsilane[1]

Me_3SiCN

[7677-24-9] · C_4H_9NSi · Cyanotrimethylsilane · (MW 99.21)

(agent for the cyanosilylation of saturated and unsaturated aldehydes and ketones;[2] powerful silylating agent;[3] reagent for carbonyl umpolung[4])

Alternate Name: trimethylsilyl cyanide.

Physical Data: mp 11-12 °C; bp 118-119 °C; *d* 0.744 g cm^{-3}.

Solubility: sol organic solvents (CH_2Cl_2, $CHCl_3$); reacts rapidly with water and protic solvents.

Form Supplied in: colorless liquid; available commercially. Can also be prepared.[1e]

Handling, Storage, and Precautions: flammable liquid which must be stored in the absence of moisture and used in an inert atmosphere. Reagent is highly toxic: contact with water produces hydrogen cyanide.

Introduction.

Cyanotrimethylsilane is a highly versatile reagent that reacts with a multitude of functional groups to yield an array of products and/or highly valuable synthetic intermediates.

Cyanohydrin Trimethylsilyl Ethers and Derivatives.

Aldehydes and ketones are readily transformed into the corresponding cyanohydrin trimethylsilyl ethers when treated with cyanotrimethylsilane in the presence of Lewis acids (eq 1),[5,6] triethylamine,[7] or solid bases such as CaF_2 or hydroxyapatite.[8] The products can be readily hydrolyzed to the corresponding cyanohydrins. The cyanosilylation of aromatic aldehydes can be achieved with high enantioselectivity in the presence of catalytic amounts of a modified Sharpless catalyst consisting of ***Titanium Tetraisopropoxide*** and L-(+)-diisopropyl tartrate (eq 2).[9] Catalysis with chiral titanium reagents yields aliphatic and aromatic cyanohydrins in high chemical and optical yields (eq 3).[10] Cyanohydrins can be subsequently transformed into a variety of useful synthetic intermediates (eq 4).[11,12]

(1)

(2)

(3)

R = Ph, 79%, 96% ee
R = Bn, 66%, 77% ee
R = phenylethyl, 89%, 89% ee

(4)

Conjugate Additions.

Cyanotrimethylsilane reacts with α,β-unsaturated ketones in the presence of Lewis acids (***Aluminum Chloride***, ***Tin(II) Chloride***, ***Triethylaluminum***) to yield, upon hydrolysis, the corresponding 1,4-addition products (eqs 5 and 6).[13] This methodology is superior to other procedures.[14] By controlling the reaction conditions and the stoichiometry of the reaction, the kinetically controlled 1,2-addition products can also be obtained in high yields (eq 7).[13,15]

Regioselective cyanosilylation of unsaturated ketones can also be effected efficiently using a solid acid or solid base support.[16] 1,4-Adducts are obtained when a strong solid acid such as Fe^{3+}- or Sn^{4+}-montmorillonite is used (see ***Iron(III) Nitrate-K10 Montmorillonite Clay***), while 1,2-adducts are obtained in the presence of solid bases such as CaO and MgO.

Reactions with Oxiranes, Oxetanes, and Aziridines.

Lewis acids, lanthanide salts, and titanium tetraisopropoxide or ***Aluminum Isopropoxide*** catalyze the reactions of cyanotrimethylsilane with oxiranes, oxetanes, and aziridines, yielding ring-opened products. The nature of the products and the regioselectivity of the reaction are primarily dependent on the nature of the Lewis acid, the substitution pattern in the substrate, and the reaction conditions. Monosubstituted oxiranes undergo regiospecific cleavage to form 3-(trimethylsiloxy)nitriles when refluxed with a slight excess of cyanotrimethylsilane in the

presence of a catalytic amount of ***Potassium Cyanide-18-Crown-6*** complex (eqs 8-10).[17] The addition of cyanide occurs exclusively at the least-substituted carbon.

(8)

(9)

(10)

Good yields of 3-(trimethylsiloxy)nitriles are also obtained from the reactions of oxiranes with cyanotrimethylsilane in the presence of lanthanide salts,[18] or when the reaction is catalyzed by $AlCl_3$ or ***Diethylaluminum Chloride*** (eq 11).[19] Ring opening of chiral glycidyl derivatives by Me_3SiCN catalyzed by $Ti(O\text{-}i\text{-}Pr)_4$ or $Al(O\text{-}i\text{-}Pr)_3$ occurs in a regiospecific and highly stereoselective manner (eq 12).[20]

(11)

(12)

Oxetanes give rise to 4-(trimethylsiloxy)propionitriles (eq 13).[19] Similar observations have been made in the reactions of *N*-tosylaziridines and cyanotrimethylsilane catalyzed by lanthanum salts (eq 14).[21]

(13)

(14)

The ambident nature of cyanotrimethylsilane[22] can lead to the formation of nitriles or isocyanides, depending on the nature of the catalyst. For example, cyanotrimethylsilane reactions with epoxides and oxetanes catalyzed by soft Lewis acids give rise to 2-(trimethylsiloxy) isocyanides arising by attack on the more substituted carbon (eqs 15 and 16).[23-25] Milder reaction conditions and better yields of isocyanides can be realized when the reaction of cyanotrimethylsilane with oxiranes is carried out in the presence of $Pd(CN)_2$, $SnCl_2$, or Me_3Ga (eq 17).[26] Isocyanides are useful precursors for the synthesis of β-amino alcohols and oxazolines.

(15)

(16)

(17)

Carbonyl Umpolung.

When deprotonated with a strong base, *O*-(trimethylsilyl) cyanohydrins can function as effective acyl anion equivalents that can be used to convert aldehydes to ketones,[27] and in the synthesis of 1,4-diketones,[28] tricyclic ketones,[29] and the highly sensitive α,β-epoxy ketone functionality (eq 18).[30]

(18)

Miscellaneous Transformations.

Cyanotrimethylsilane effects the transformation of acyl chlorides to acyl cyanides,[31] α-chloro ethers and α-chloro thioethers to α-cyano ethers[32] and α-cyano thioethers (eq 19),[33] *t*-butyl chlorides to nitriles (eqs 20 and 21),[34] 1,3,5-trisubstituted hexahydro-1,3,5-triazines to aminoacetonitriles,[35] the cyanation of allylic carbonates and acetates (eqs 22 and 23),[36] and the formation of aryl thiocyanates from aryl sulfonyl chlorides and sulfinates.[37] The reagent has been used effectively in peptide synthesis[38] and in a range of other synthetic applications.[39-46]

(19)

(20)

(21)

(22)

(23)

Related Reagents.

t-Butyldimethylsilyl Cyanide; ***Hydrogen Cyanide***.

Cyclobutanone[1]

[1191-95-3] · C_4H_6O · Cyclobutanone · (MW 70.09)

(strained cyclic ketone capable of undergoing ring-expansion, ring-contraction and ring-opening reactions to give functionalized cyclopentanones,[2] tetrahydrofurans,[3] cyclopropanes, and terminally functionalized butyric acid derivatives[1d])

Physical Data: mp -51.1 to -52.5 °C; bp 97-100 °C; *d* 0.931 g cm^{-3}; n_D^{20} 1.421.

Solubility: slightly sol H_2O; sol most organic solvents.

Form Supplied in: colorless liquid, >99% pure, limited availability; relatively expensive.

Preparative Methods: over 30 preparative methods have been reported. The most convenient methods include the ketene-diazomethane condensation[4] and the selective di-Grignard reaction using 1,3-dibromopropane with carbon dioxide.[5]

Purification: distillation by spinning band column or preparative GC.

Handling, Storage, and Precautions: flammable liquid (flash point 27 °C). Contact with skin and eyes should be avoided.

Introduction.

The strain associated with the cyclobutanone ring system permits ring-expansion reactions to occur more readily than with larger cycloalkanones.

Ring Expansion to Cyclopentanones.

The one-carbon ring expansion of cyclobutanone and its derivatives represents a convenient method for the preparation of cyclopentanones. The general scheme is represented by eq 1, in which a one-carbon nucleophile bearing a potential leaving group is added to the carbonyl function, followed by an α-carbon migration. The one-

carbon homologation of cyclobutanone with ***Diazomethane*** gives cyclopentanone as the major product (58%), along with small amounts of cycloheptanone (17%) and cyclooctanone (25%).[6] α-Functionalized cyclopentanones are readily prepared by alkylation of cyclobutanone with dithio- or trithiomethide ions followed by rearrangement of the intermediate cyclobutanols. The yields of the cyclopentanones are satisfactory for this two-step sequence (eqs 2 and 3).[2,7] α-(Phenylthio)cyclopentanone may also be obtained by addition of LiCHIS(O)Ph (88%), followed by reductive rearrangement of the β-hydroxy sulfoxide adduct with $TiCl_4$ and Zn (62%).[8]

(1)

(2)

(3)

The electrochemical condensation of ***Ethyl Trichloroacetate*** with cyclobutanone gives the five-carbon α-chloro-β-keto ester (eq 4).[9]

(4)

1-Alkenylcyclobutanols, which are readily prepared by metal alkenyl additions to cyclobutanone, undergo Lewis acid-

catalyzed ring expansion to cyclopentanones. For example, the spirocyclic cyclopentanone is readily prepared in high yields from the acid-catalyzed rearrangement of the 5-lithio-2,3-dihydrofuran condensation product (eq 5).[10]

(5)

In similar fashion, 2-chloromethyl-2-methylcyclopentanone can be prepared from 1-isopropenylcyclobutanol (eq 6); this rearrangement may involve a radical mechanism.[11] Acid-catalyzed rearrangement of this cyclobutanol in a sulfuric acid-ethanol mixture gives 2,2-dimethylcyclopentanone, isolated as the DNP in 51% yield.

(6)

2-Methylcyclopent-2-enones are readily prepared from the Pd^{II}-assisted rearrangement of 1-vinylcyclobutanols (eq 7). However, this scheme has not been applied to the unsubstituted cyclobutyl ring.[12]

(7)

The pinacol rearrangement of the reductive coupling product of cyclobutanone gives the spirooctanone (eq 8).[13] More recently, the same pinacol has been obtained in higher yields with cerium(II) iodide.[14] The same spirooctanone is obtained by the thermal rearrangement of dicyclobutylidene epoxide (eq 9).[15] Dicyclobutylidene may be obtained by thiadiazoline elimination or, in lower yield, by a direct Wittig reaction with cyclobutylphosphonium ylide.

(8)

(9)

Ring Expansions to Cyclohexenones and Cyclohexanones.

α-Alkylidene- and α,α´-dialkylidenecyclobutanones, obtained from cross-aldol condensations of cyclobutanone, rearrange readily with ***Polyphosphoric Acid*** (PPA) at elevated temperatures to the corresponding cyclohexenones (eq 10).[16]

(10)

Cyclohexanones can also be readily prepared by the base-catalyzed 1,3-sigmatropic rearrangement of 1-alkenyl-2-thiophenoxycyclobutanols which are accessible from 2-phenylthiocyclobutanone (eqs 11 and 12).[17] The latter can be obtained from nucleophilic substitution of thiophenoxy ion on 2-bromocyclobutanone,[18] the major bromination product (95%) of cyclobutanone.[19] This substituted cyclobutanone can be used as a cyclobutanone equivalent since the phenylthio group can be reductively cleaved with ***Lithium 1-(Dimethylamino)naphthalenide***.[17]

(11)

R = H, 60%; R = Me, 69%

(12)

Ring Expansions to Five-Membered Heterocycles.

Baeyer-Villiger oxidation of cyclobutanone to γ-butyrolactone is best accomplished with ***Hydrogen Peroxide*** in trifluoroethanol (eq 13).[20,21] Some regioselectivity is observed with α-substituted cyclobutanones.[1b] The photochemical ring expansion of cyclobutanones to give 2-alkoxytetrahydrofurans is a general reaction (eq 14); however, for the parent cyclobutanone, the yield is only 8%.[22]

(13)

(14)

One example of the ring expansion of a cyclobutanol derivative to a pyrrolidine has been reported in the total synthesis of nor-nicotine. This rearrangement is effected by treatment of the cyclobutanol with ***Hydrazoic Acid*** (eq 15).[23]

(15)

Ring Contraction to Cyclopropanes.

The nucleophile-assisted Favorskii rearrangement of α-halocyclobutanones gives cyclopropylcarbonyl derivatives (eq 16).[1a]

(16)

Nucleophilic substitution may accompany the rearrangement with soft nucleophiles. This transformation is best accomplished with 2-bromocyclobutanone and hard nucleophiles, although 2-chlorocyclobutanone, obtained from the ***Sulfuryl Chloride*** chlorination of cyclobutanone,[24] or 2-tosyloxycyclobutanone can be used (eq 17).

(17)

Whereas 2,2-dibromocyclobutanone undergoes ring-opening reactions (see section on ring-opening reactions), 2,4-dibromocyclobutanone, an overbromination product of cyclobutanone, gives ring-contracted products (eq 18).[24] The stereochemistry of the starting 2,4-dibromocyclobutanone and the ring-contracted products have not been assigned. An interesting thermal reaction of the ethylene acetal derivative of 2-bromocyclobutanone has been reported (eq 19).[25] The pyrolysis of cyclobutanone tosylhydrazone gives methylenecyclopropane (eq 20).[26]

(18)

(19)

(20)

Condensation and Annulation Reactions.

The carbonyl group in cyclobutanone is more reactive than that of larger ring ketones towards nucleophilic additions and condensations. For example, Wittig-type reactions occur readily with cyclobutanone (see eq 9).[15] Other examples are illustrated in eq 21. Reactions with cyclopentadiene (pyrrolidine, MeOH),[26] $PhSO_2CHLiCH_2TMS$ followed by $MeSO_2Cl$,[27] 2-pentylcyclopropyllithium,[28] 2-lithio-2-trimethylsilyl-1,3-dithiane,[29] and $CNCHLiPO_3Et_2$[30] afforded the addition or alkenation products shown.

1-Cyclobutenyl ketones and 1-cyclobutenecarbaldehyde are accessible from cyclobutanone in three steps, as shown in eqs 22 and 23.[31,32] The starting α-sulfonylvinyl isocyanide and α-chloro sulfoxide were prepared in one step using ***p-Tolylsulfonylmethyl Isocyanide*** and LiCHClS(O)Ph (93%), respectively.

The ring annulation of cyclobutanes is achieved in a Diels-Alder reaction using cyclobutenes as dienophiles or 1-alkenylcyclobutenes as dienes. The piperidine enamine of cyclobutanone readily cycloadds to conjugated ketones to give cyclobutapyrones (eq 24).[33]

(24)

1-Vinylcyclobutene, available by vinyl Grignard addition (66%) and I_2-induced elimination (72%), undergoes a [4 + 2] cycloaddition with 1,2-cyclobutenedicarboxylic acid dimethyl ester to give a key intermediate in the synthesis of the biscyclobutabenzene (eq 25).[34] The addition of methyl propiolate to 1-vinylcyclobutene gives a mixture of regioisomers in about equal amounts.[35]

(25)

Ring-Opening Reactions.

The strain associated with cyclobutanones allows ring-opening reactions to occur with ease. Cyclobutenes and

cyclobutenol derivatives are readily available from cyclobutanone, and their thermolytic ring-opening reactions give synthetically useful 1,3-butadienes.[36,37] Two examples are given (eqs 26 and 27).

Although 2-halocyclobutanones give ring-contracted products upon treatment with nucleophiles, 2,2-dihalocyclobutanones undergo ring-opening reactions. This is the result of the stabilization of the anion brought about by *gem*-dihalogen substitution (eq 28).[24]

α-Alkylations of Cyclobutanone.

α-Alkylation of cyclobutanone via its enolate anion is not an efficient method for monoalkylation. The reaction usually results in polyalkylations, accompanied by resin formation.[38] Although the trimethylsilyl enol ether[39] and the pyrolidine enamine[40] are known, alkylations of these intermediates cannot be achieved because of the acid and thermal labilities of these intermediates. Monoalkylated cyclobutanones can be prepared from base-assisted alkylation of the cyclobutanone equivalent, 2-phenylthiocyclobutanone, and subsequent reductive cleavage of the thiophenoxy group with lithium 1-dimethylaminonaphthalenide.[17]

Related Reagents.

1,2-Bis(trimethylsilyloxy)cyclobutene; ***Cyclopropanone***; ***Dichloro(ethoxy)oxovanadium(V)***; ***1,2-Dicyanocyclobutene***; ***1-Ethoxycyclopropanol***; ***2-Methoxy-3-phenylthio-1,3-butadiene***; ***Methylenecyclobutane***; ***Squaric Acid***; ***1-(Tetrahydropyranyloxy)cyclopropanecarbaldehyde***; ***p-Tolylsulfonylmethyl Isocyanide***; ***Tricarbonyl(cyclobutadiene)iron***.

1,3,5-Cycloheptatriene[1]

[544-25-2] · C_7H_8 · 1,3,5-Cycloheptatriene · (MW 92.14)

(precursor in the synthesis of troponoids,[1a,b] polycyclic compounds,[1b,c] tropylium salts[1a,b])

Physical Data: mp -79.5 °C; bp 117 °C/749 mmHg; d_4^{22} 0.888 g cm^{-3}.

Solubility: sol EtOH, Et_2O, C_6H_6, $CHCl_3$.

Form Supplied in: slightly colored liquid, purity about 90% (usually contains toluene).

Preparative Methods: 1,3,5-cycloheptatriene (tropylidene) (**1**) is synthesized through benzene ring expansion,[2a] or pyrolysis of 7,7-dibromobicyclo[4.1.0]heptane.[2b,c] These reactions represent general synthetic methods to produce derivatives of (**1**).[2c] Reaction of thiophene *S*,*S*-dioxides with cyclopropenes is extremely advantageous for the synthesis of highly substituted cycloheptatrienes.[2d]

Purification: via transformation into tropylium tetrafluoroborate.

Analysis of Reagent Purity: ^1H NMR, GLC.

Handling, Storage, and Precautions: resinifies in air; flammable liquid; toxic. This reagent should be handled in a fume hood.

Synthesis of Cycloheptatriene Derivatives and Other Monocyclic Compounds.

Several one-step methods for the transformation of (**1**) into potentially more useful functionalized monocyclics have been developed. 1,4-Addition of ***Bromine*** to (**1**) (CCl_4, 0 °C) quantitatively affords 1,4-dibromo-2,5-cycloheptadiene,[3] while reduction of (**1**) with alkali metals (***Lithium***, ***Sodium***) in ether or NH_3 proceeds with 1,6-addition to the conjugated system and produces 1,3-cycloheptadiene after quenching with *N*-methylaniline.[4] Intermediate C(5)-metalated 1,3-cycloheptadienes react with alkyl halides to give 5-alkyl-1,3-cycloheptadienes.[4] These dienes can also be prepared by electrochemical reductive alkylation of (**1**) on a Pt cathode.[5]

Friedel-Crafts acylation of (**1**) is very sensitive to the reaction temperature and nature of Lewis acid. In ***Aluminum Chloride***-catalyzed reactions, the chloro ketones initially formed via 1,6-addition of acyl chlorides are transformed into 1-acyl-1,3,5-cycloheptatrienes or are ring-contracted into benzylic ketones, depending on the workup procedure (eq 1).[6a] With ***Tin(IV) Chloride*** as a catalyst, only benzylic ketones are produced.[6b]

(1)

Stepwise anodic oxidation of (**1**) in MeOH delivers 7-methoxy-1,3,5-cycloheptatriene and then tropone,[7a] which can also be prepared by direct oxidation of (**1**) with ***Selenium(IV) Oxide***-KH_2PO_4.[7b]

Synthesis of Bicyclic Compounds.

Monocyclopropanation of (**1**) with carbenes affords bicyclo[5.1.0]octa-2,4-dienes[8,9] and can be accompanied by seven-membered ring contraction, yielding benzocyclobutenes.[9]

Cycloheptatriene reacts in [4 +2] and [6 + 4] cycloadditions.[10a] An interesting cycloaddition which is an anionic analog of [6 + 4] cycloadditions has been described (eq 2).[10b]

(2)

Synthesis with Complexed 1,3,5-Cycloheptatrienes.

The reactivity of (**1**) in complexes with various transition metals[1c,11] is usually considerably higher than that of noncomplexed (**1**). Tricarbonyl(η^4-cycloheptatriene)iron[1c] is acylated (1. KH; 2. RCOCl) at C(7) with very high diastereoselectivity (*exo*/*endo* = 35-70).[12] Cycloaddition of this complex with tetrazine affords a novel pyridazino[2,3-*d*]cycloheptatriene heterocyclic system.[13] Regiocontrolled and stereocontrolled functionalization of Mn complexes in reactions with sodium enolates has been used in the synthesis of 6-substituted cyclohepta-2,4-dien-1-ols.[14] Either thermally[15a] or photochemically[15b] induced stereospecific [$6_\pi + 4_\pi$] and [$6_\pi + 2_\pi$] cycloaddition reactions have been performed with the chromium(0) complex (**2**) (eq 3).[15b] The same transformations can also be accomplished directly for (**1**) employing only a catalytic quantity of (**2**) as a source of Cr^0.[15a]

(3)

(**2**)

Tropylium Salts.

Stable carbenium ions abstract hydride ion from C(7) of (**1**), yielding the 6π-electron aromatic system of tropylium salts (**3**).[16] Tropylium salts are also formed by mild pyrolysis of the adduct of (**1**) with Br_2[17] or by heating norcaradienecarboxylic acid azide in C_6H_6.[18] Salts of type (**3**) have been involved in several redox transformations,

such as reductive dimerization into bitropyl,[19a] oxidative ring contraction producing aromatics,[19b] and disproportionation on heating in MeCN or DMSO with formation of (**1**) and tropone.[19c]

Undoubtedly the salts (**3**) are the most powerful synthons to incorporate the cycloheptatrienyl moiety into organic substrates even with moderate reactivity. They effectively alkylate amides,[17] tosylureas,[20] H_2S,[17] and react with RLi to produce 7-alkyl- or 7-arylcycloheptatrienes.[3,21] Aldehydes are α-alkylated by (**3**; X = Br) directly[22] or after preliminary transformation into enamines.[23] The latter approach is especially successful for ketones.[23] The salts (**3**) readily react with carbanions[8,24] to provide a route to heptafulvenes (eq 4).[24b]

2,4,6-Cycloheptatrien-1-one[1]

[539-80-0] · C_7H_6O · 2,4,6-Cycloheptatrien-1-one · (MW 106.13)

(synthon for preparation of cycloheptadien-1-ones; building block in the synthesis of troponoids, azulenes,[1a,b] polycyclic compounds,[1c,d] natural products[1d,e])

Alternate Name: tropone.

Physical Data: mp -8 °C to -5 °C; bp 113 °C/15 mmHg; d_4^{22} 1.10 g cm^{-3}; *n*22D 1.6172.

Solubility: sol ether, dioxane, acetone, benzene, toluene, xylene, MeCN, CCl_4; miscible with water.

Preparative Methods: 2,4,6-cycloheptatrien-1-one (**1**) is a functionalized conjugated carbocyclic compound with diversified reactivity. The most popular and simple method of preparation involves oxidation of ***1,3,5-Cycloheptatriene*** with ***Selenium(IV) Oxide***-KH_2PO_4.[2a] Several other procedures have also been developed,[2b-f] among which electrooxidation of cycloheptatrienes[2e] and α-pyrone ring expansion via high-pressure cycloaddition of cyclopropenone acetals[2f] can be considered general methods of synthesis of tropones.

Purification: by distillation.

Analysis of Reagent Purity: ^{1}H NMR, GLC.

Handling, Storage, and Precautions: light- and oxidant-sensitive.

1,8-Additions to Tropone: Synthesis of Cycloheptadien-1-ones.

Reactions of (**1**) with various nucleophiles proceed through 1,8-addition to the troponoid system and offer an approach to conjugated cycloheptadienes.[3] Tropone (**1**) is readily reduced to 3,5-cycloheptadien-1-one through 1,8-addition of

hydride ion from ***Lithium Aluminum Hydride***[4] or adds alkylmagnesium compounds to form 2-alkyl-3,5-cycloheptadien-1-ones.[3,5] Reaction with lithium enolates provides a very efficient route for appending functionalized substituents onto the troponoid nucleus (eq 1).[6]

(1)

(1)

Annulation of Tropone: Preparation of Azulenes and Other Polyunsaturated Bicyclo[5.3.0]decane Systems.

Condensation of (**1**) with malonodinitrile in the presence of piperidine gives 2-amino-3-cyano-8*H*-cyclohepta[*b*]furan.[7] This type of reaction is widely used in a general azulene synthesis from tropone that initially involves condensation of 2-substituted tropones (**2**; X = OMe, Cl, OTs) with active methylene compounds (AMC) to give cyclohepta[*b*]furan-2-ones or -2-imines (**3**). Subsequent cycloadditions of (**3**), for example with vinyl ethers, leads to di- and trisubstituted azulenes (**4**) (eq 2).[8]

(2)
X = Cl

(3)

(2)

(4) 74%

An approach to 4-ketohydroazulenes is based on [3 + 2] cyclopentane annulation reactions of tricarbonyl(tropone)iron with η^5-$C_5H_5Fe(CO)_2R$ synthons (where R = alkenyl, alkynyl, allenyl).[9]

On refluxing in C_6H_6 with benzamidine, (**1**) undergoes amination via hydride replacement producing 1,3-diazaazulene.[10] Aza-Wittig reactions between *N*-(1-phenylvinyl)iminophosphoranes and (**1**) or 2-alkyltropones deliver 2-phenyl-8*H*-cycloheptapyrroles which can be oxidized further (***Nickel(II) Peroxide***) to afford 1-azaazulenes.[11]

Photochemical [8 + 2] cycloaddition of alkenes to (**1**) affords 8-oxabicyclo[5.3.0]deca-2,4,6-trienes.[12] Analogously, stereospecific thermally allowed [8 + 2] cycloadditions with sulfenes give bicyclic sultones, which on heating lose SO_2 with stereospecific formation of 2-(*cis*-1-alkenyl)phenols in almost quantitative yields.[13a] An efficient procedure for the synthesis of indoles is based on transformation of bicyclic sultams produced via the same cycloaddition of tropone *N*-methylimine with sulfenes.[13b]

Reactions of (**1**) with enamines derived from cycloalkanones also proceed via [8 + 2] cycloaddition. The primary adduct (**5**) is readily hydrolyzed to give a substituted 3,5-cycloheptadien-1-one (eq 3).[14] This example demonstrates the close relation between 1,8-addition and [8 + 2] cycloaddition in the tropone series.

In a similar way, the 2-oxyallyl cation generated from 2,4-dibromo-2,4-dimethylpentan-3-one and ***Nonacarbonyldiiron*** exhibits high periselectivity toward (**1**) to give the formal $[2_\pi(3C) + 8_\pi]$ adduct 9,9,11,11-tetramethyl-8-oxabicyclo[5.4.0]undeca-2,4,6-trien-10-one.[15]

In the reaction of (**1**) with $HS(CH_2)_nSH$ (n = 2,3), 1,2-annulation of the dithiols takes place instead of the expected dithioacetalization.[16]

[4 + 2] and [6 + 4] Cycloadditions: An Approach to Bicyclo[3.2.2]nona-3,6-dien-2-one and Bicyclo[4.4.1]undeca-2,4,8-trien-11-one Systems.

Two cycloaddition modes common for (**1**) involve [4 + 2] cycloaddition across C(2)-C(5) or C(2)-C(3) and [6 + 4] cycloaddition across C(2)-C(7). Tropone undergoes thermal [4 + 2] cycloadditions with both electron-deficient[17] and electron-rich[18] dienophiles and *endo* products usually predominate. With unsymmetrical electron-rich dienophiles, cycloaddition proceeds regiospecifically and only 9-substituted bicyclo[3.2.2]nona-3,6-dien-2-ones are formed[18a,b]

while, for example, electron-deficient acrylonitrile produces both regioisomeric cycloadducts (eq 4).[17e]

Tropone (**1**) also enters into thermally induced [6 + 4] cycloadditions with nonfunctionalized open-chain dienes (eq 5),[19] cyclopentadiene,[20] and functionalized dienes.[21]

The rearrangement of [6 + 4] cycloadducts into thermodynamically more stable [4 + 2] products via sigmatropic isomerization or by stepwise cycloreversion-readdition has also been reported.[22] Lower temperatures favor the [6 + 4] mode of cycloaddition. Generally, electron-rich dienes give [6 + 4] adducts kinetically, but these cycloadducts are thermodynamically less stable than the adducts derived from electron-deficient dienes.[21] [6 + 4] Adducts are always formed via an *exo* transition state whereas alternative [4 + 2] adducts often originate via an *endo* transition state.[21,22c] However, the photoinduced reaction of tricarbonyl(7,7-dimethoxy-1,3,5-cycloheptatriene)iron, as a masked version of (**1**), with (*E*)-1,3-pentadiene affords the *exo* [6 + 4] cycloadduct.[23] Therefore transition metal-mediated [6 + 4] cycloaddition extends the scope of the thermal reaction. Besides these reactions, (**1**) is also known to react with 1,3-dipoles in [6 + 4] cycloadditions.[22c]

Intramolecular [6 + 4] and [4 + 2] tropone-alkene cycloaddition reactions of 2-alkenyltropones have been used to prepare polycyclic troponoids.[24]

[6 + 3] Cycloaddition: A Route to the Bicyclo[4.3.1]decadien-9-one System.

In the presence of Pd^0 catalysts, 2-[(trimethylsilyl)methyl]allyl carboxylates undergo regioselective addition to C(2) and C(7) of (**1**) (eq 6).[25a] The stereochemistry of the reaction widely varies, depending on the nature of substituents in the trimethylenemethane (TMM) precursors. A phenylthio substituent in the TMM precursor behaves as an effective

selectivity control element.[26b]

[6 + 2] Cycloaddition.

In contrast to the low periselectivity observed in intermolecular photoinduced [6 + 2] cycloaddition reactions of (**1**),[26] intramolecular [6 + 2] reactions of 2-(4-alkenyl)- or 2-(4-alkynyl)tropones on irradiation in acidic MeOH proceed with high regioselectivity and stereoselectivity (eq 7). These reactions offer an elegant approach to bridged bicyclo[6.3.0]undecanes.[27]

Tricarbonyl[(2,3,4,5-η)-2,4,6-cycloheptatrien-1-one]iron (6).

In most instances the uncomplexed double bond of (**6**)[28] reacts as an electron-rich partner that results in nucleophilic addition to C(3),[9] periselective inverse electron demand cycloaddition across the free C(6)-C(7) double bond,[29] or acylation at C(2) under standard Friedel-Crafts conditions.[30] At the same time, in a number of reactions (**6**) exhibits reactivity which is characteristic of an electron-deficient enone. For example, (**6**) behaves like a cycloheptenone in Diels-Alder [4 + 2] cycloaddition with dienes. Stereoselective conjugate addition of nucleophiles proceeds at the C(6)-C(7) bond to give bicyclo[5.4.0]undeca-3,5,8-trien-2-ones[32,22b] or C(6)-alkylated complex (**7**) (eq 8).[31] With simple nucleophiles (***Vinylmagnesium Bromide***, ***Sodium Borohydride***/***Cerium(III) Chloride***), 1,2-addition is observed.[32] Because (**6**) serves as an equivalent of (**1**) that exhibits electron-deficient enone reactivity, it has been used as a building block in natural product synthesis. Syntheses of *cis*-hydroazulenes,[4a,9a] guaianolides,[4b] grosshemin,[5a] barbarolones,[28b] ingenane and cedrane ring systems,[24a,b] prostaglandins,[32] colchicine and its analogs,[1e,33] sesquicarene,[34] and heptitol derivatives[35] have been based on reactions of (**1**) and its derivatives.

Miscellaneous Reactions.

A unique and extremely simple route to 4-alkyltropones involves homolytic alkylation of (**1**) in the presence of a Lewis acid with alkyl radicals generated from *N*-acyloxy-2-thiopyridones.[36] Tropone oxime tosylate undergoes a stereospecific ring opening reaction with secondary amines and alkoxides to give 6-substituted (1*Z*,3*Z*,5*Z*)-hexa-1,3,5-trienecarbonitriles in almost quantitative yield.[37]

1,3-Cyclohexanedione[1]

(R = H)

[504-02-9] · $C_6H_8O_2$ · 1,3-Cyclohexanedione · (MW 112.13) (R = Me)

[1193-55-1] · $C_7H_{10}O_2$ · 2-Methyl-1,3-cyclohexanedione · (MW 126.16)

(building block for substituted cyclohexane derivatives[2] and condensed carbo- and heterocycles[3])

Physical Data: 1,3-cyclohexanedione (CHD): mp 103-105 °C; 2-methyl-1,3-cyclohexanedione (MCHD): mp 206-209 °C.

Solubility: CHD easily sol H_2O, EtOH, $CHCl_3$, acetone, and boiling benzene; MCHD sol MeOH and sparingly sol H_2O and EtOH.

Form Supplied in: CHD and MCHD are colorless solids; both reagents are commercially available.

Preparative Methods: Raney nickel-catalyzed hydrogenation of resorcinol for CHD;[4] methylation of CHD[5] with MeI or base-promoted cyclization of ethyl 5-oxoheptanoate for MCHD.[6]

Handling, Storage, and Precautions: CHD is recommended to be stored at 0-5 °C. MCHD can be kept at rt. Both reagents are stable only in pure form. They are reputed to be of low toxicity.

CHD and its 2-monoalkyl homologs are almost completely enolized.[1] Many of their reactions are very similar.

Reactions with Nucleophiles at the Carbonyl Group.

The acid-catalyzed reaction of CHD with alcohols affords β-alkoxy enones (**1**) (eq 1).[2] These compounds can be reduced with ***Lithium Aluminum Hydride*** to the corresponding 2-cyclohexen-1-ones,[7] whereas addition of organometallics affords 3-alkyl-2-cyclohexen-1-ones.[2] With *N*,*N*-disubstituted hydrazines, CHD forms

monohydrazones, which exist as tautomeric enhydrazinones (**2**) (eq 1).[8]

(1)

Reactions with Electrophiles at the Enolic Hydroxy Group.

Acylation of CHD with alkanoyl chlorides in pyridine gives rise to the enol esters (**3**), which can be isomerized to the triketones (**4**) (eq 2).[9] Alkyl tosylates[1] convert the dione into the corresponding β-alkoxy enones of type (**1**).

(2)

Reactions with Electrophiles at C-2.

The palladium(0)-catalyzed reaction of MCHD with the substituted allyl acetate (**5**) results in a clean *C*-alkylation (eq 3).[10]

(3)

The alkylation of CHD with alkyl halides affords mixtures of 3-alkoxy-2-cyclohexen-1-ones (*O*-alkylation) and 2-mono- and 2,2-dialkylated 1,3-cyclohexanediones (*C*-alkylation). ***Allyl Bromide*** and ***Benzyl Bromide*** as well as alkyl bromoacetates give *C*-alkylation products in better yields.[1] In Michael reactions, α,β-unsaturated carbonyl compounds (eq 4),[1,11] acetals of α,β-enals,[12] nitroalkenes,[13] and Mannich bases[14] add to C-2 of MCHD. Aldol cyclization of the methyl vinyl ketone adduct affords the octalindione shown (eq 4) in racemic[11a] or optically active form.[11b]

(4)

In the presence of ***Boron Trifluoride Etherate***, 2 equiv of ***Formaldehyde*** condense with CHD forming the 1,3-dioxin (**7**). With 2 equiv of CHD, formaldehyde leads to the adduct (**6**) (eq 5).[1,15]

(5)

With DMF dimethyl acetal (see ***N,N-Dimethylformamide Diethyl Acetal***), an α-aminomethylenation takes place at C-2.[16] In the presence of BF_3, carboxylic anhydrides acylate CHD at C-2.[17]

Reactions with Electrophiles at C-4 or at C-6.

The enaminone (**8**) obtained from CHD and ***Pyrrolidine*** is alkylated at C-4 by treatment with ***n-Butyllithium*** and ***Iodomethane*** (eq 6).[18]

(6)

In contrast, the enol ethers derived from CHD or MCHD can be alkylated at C-6 after deprotonation with ***Lithium Diisopropylamide*** (eq 7).[19]

(7)

Annulation Reactions.

Many examples are known for the formation of condensed carbo- and heterocycles by reactions of bifunctional compounds with two of the reactive sites of CHD or MCHD.[3,19]

Ring Cleavage and Contraction.

Hydroxide- or alkoxide-induced retro-Claisen reactions of 2-alkyl- and 2,2-dialkyl-1,3-cyclohexanediones give rise to δ-keto acids or esters (eq 8).[20] Chlorination of 2-pentynyl-1,3-cyclohexanedione at C-2 followed by heating in the presence of sodium carbonate effects a Favorskii-type ring contraction with decarbonylation to 2-pentynyl-2-cyclopentenone (eq 9), a useful intermediate for the synthesis of jasmone.[21]

(8)

Related Reagents.

1,3-Cyclopentanedione; ***2-Methyl-1,3-cyclopentanedione***; ***Methyl Vinyl Ketone***; ***2,4-Pentanedione***; ***(S)-Proline***.

N-Cyclohexylhydroxylamine[1]

[2211-64-5] · $C_6H_{15}NO$ · *N*-Cyclohexylhydroxylamine · (MW 115.18) (.HCl)

[25100-12-3] · $C_6H_{16}ClO$ · *N*-Cyclohexylhydroxylamine Hydrochloride · (MW 151.64)

(condenses with a wide variety of aldehydes to afford *N*-cyclohexyl nitrones;[2] condenses with alkynes to afford *N*-cyclohexyl nitrones;[3] reagent in the conversion of 1,2-dicarboxylic acids to α,β-unsaturated carboxylic acids;[4] hydroxylamination reagent for allyl esters under palladium(0) catalysis[5])

Alternate Name: hydroxyaminocyclohexane.

Physical Data: mp 140-141 °C; hydrochloride salt, mp 166-171 °C.

Form Supplied in: available commercially as the free hydroxylamine and as the hydrochloride salt.

Preparative Methods: oxime reduction;[6-13] nitroalkene reduction;[14-16] nitro reduction;[17-19] amine oxidation.[20,21]

Purification: by sublimation.

Handling, Storage, and Precautions: hygroscopic; use in a fume hood.

Introduction.

Because of the similarity and overlap of their uses, ***N-Benzylhydroxylamine*** and ***N-t-Butylhydroxylamine***, as well as *N*-cyclohexylhydroxylamine, are all discussed here. Indeed, most of their chemistry is that of any of the *N*-monosubstituted hydroxylamines. They undergo a wealth of condensation reactions analogous to those of amines as well as ones unique to the hydroxylamine group, affording an array of nitrogen-containing compounds too numerous to list. In terms of their use as synthetic reagents, however, they function primarily in the conversion of carbonyl compounds into nitrones. While *N*-benzyl-, *N*-*t*-butyl-, and *N*-cyclohexylhydroxylamine all participate in a few specialized reactions, it is their role in the preparation of nitrone intermediates which has led to their general usage.

Synthesis and Reactions of Nitrones.

N-Benzyl-, *N*-*t*-butyl-, and *N*-cyclohexylhydroxylamine condense with carbonyl compounds under a variety of dehydrating conditions to afford nitrones (eq 1).[2] These reactions proceed smoothly with aldehydes, but poorly or not at all with ketones, especially when the hydroxylamine has a bulky substituent, as in the compounds under consideration. Nitrones are also produced in some cases by the condensation of *N*-cyclohexylhydroxylamine[3] and *N*-*t*-butylhydroxylamine[3,22] with alkynes (eq 2). The nitrones thus formed undergo a number of reactions,[23] the most studied of which are 1,3-dipolar cycloadditions.[24,25] This chemistry encompasses a large number of unsaturated dipolarophiles, providing many different types of heterocyclic product, and is beyond the scope of this discussion.

(1)

(2)

There are, however, other reactions of nitrones which can be more clearly considered as functional group transformations. In particular, *N*-cyclohexyl-α-chloro nitrones are converted by silver ion to *N*-vinylnitrosonium ions, which readily undergo cycloaddition to unactivated alkenes (eq 3).[26] Formation of the cyanide adduct, followed by base induced rearrangement and hydrolysis, provides γ-lactones (eq 4).[27] In the case of α,β-dichloro nitrones, the same sequence affords α-methylene-γ-butyrolactones (eq 4).[28] Alternatively, treatment with base leads to an enamine-like structure, which undergoes thermal cycloreversion to yield, after hydrolysis, a product in which the original alkene has been oxidatively cleaved (eq 4).[29] Alkynes undergo analogous chemistry with the *N*-cyclohexyl-α-chloro nitrones, ultimately providing α,β-enones (eq 5).[30] Interestingly, in a polar solvent the α-chloro nitrone undergoes substitution reactions with alkenes and arenes, resulting in β,γ-unsaturated aldehydes (eq 6).[31] Similar chemistry is observed for the related *N*-cyclohexyl-α-epoxy nitrones (eq 7).[32,33]

1. $AgBF_4$
R^1—≡—H
2. KCN, base

(5)

(6)

(7)

N-*t*-Butyl and *N*-cyclohexyl nitrones undergo acylation-rearrangement when treated with an acid chloride and triethylamine, affording α-acyloxy imines. These intermediates can be hydrolyzed to α-acyloxy aldehydes (eq 8), corresponding to an overall α-oxygenation of the aldehyde from which the nitrone was prepared.[34] Alternatively, reduction of the imines affords vicinal *N*-alkylamino alcohols (eq 8), corresponding to overall α-oxygenation and reductive amination.[35]

(8)

Alkene Aminations.

Hydroxyamination of allyl esters under palladium(0) catalysis can be accomplished with both *N*-benzyl- and *N*-cyclohexylhydroxylamine (eq 9).[5] The reaction proceeds with retention of configuration and allylic transposition. Amination of unactivated alkenes, again via allylic transposition, has been accomplished using molybdenum-based metallooxaziridines, prepared from *N*-*t*-butylhydroxylamine and a dioxomolybdenum(VI) complex (eq 10).[36]

(9)

(10)

Decarboxylation and Cyclization Reactions.

The oxidative decarboxylation of 1,4-dicarboxylic acids to α,β-unsaturated acids can be accomplished regiospecifically using *N*-cyclohexylhydroxylamine.[4] The initially formed tetrahydro-1,2-oxazine-3,6-dione can be fragmented in either of two complementary fashions to afford α,β-unsaturated carboxylic acids (eq 11).

N-*t*-Butylaziridinones can be prepared from *N*-*t*-butylhydroxylamine and phenylacetyl chloride, by way of intermediate hydroxamic acids (eq 12).[37] The use of ***Trifluoromethanesulfonic Anhydride*** is critical; if a sulfonyl chloride is employed, the aziridinone is observed transiently, but it undergoes rapid ring opening by chloride.

Related Reagents.

N-Benzylhydroxylamine; ***N,O-Bis(trimethylsilyl)hydroxylamine***; ***O-(t-Butyldimethylsilyl)hydroxylamine***; ***N-t-Butylhydroxylamine***; ***C-(1-Chloroethyl) N-Cyclohexyl Nitrone***; ***N,O-Dimethylhydroxylamine***; ***Hydroxylamine***; ***N-Methyl-N,O-bis(trimethylsilyl)hydroxylamine***; ***N-Methylhydroxylamine***.

Cyclohexyl Isocyanide[1]

[931-53-3] · $C_7H_{11}N$ · Cyclohexyl Isocyanide · (MW 109.17)

(reagent for phosphorylation of phosphomonoesters;[2] formylation of secondary anilines[4])

Physical Data: bp 173-176 °C; *d* 0.878 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: toxic. Use in a fume hood.

Phosphorylation.

Cyclohexyl isocyanide has been utilized[2] in the activation of phosphates, in a mode similar to ***1,3-Dicyclohexylcarbodiimide***.[3] The method enables the generation of phosphodiesters from phosphomonoesters by selective use of the alcoholic medium (eq 1). An extension of this procedure permits the preparation of 2´,3´-cyclic phosphates of nucleosides from nucleoside 2´ (or 3´) phosphates (eq 2).

Formylation.

Employment of cyclohexyl isocyanide in the *ortho* formylation of secondary anilines, which are synthetically versatile in heteroannulation reactions, has been demonstrated.[4] In a typical sequence, the secondary aniline is treated with ***Boron Trichloride*** to generate an anilinoborane which may be isolated. Further reaction of the borane with cyclohexyl isocyanide, in the presence of ***Triethylamine***, yields the *o*-alkylaminobenzaldehyde upon acid hydrolysis (eq 3).

In this investigation, cyclohexyl isocyanide offered the highest yield and shortest reaction time for the isocyanides and secondary anilines studied. Although the method claims a practical advantage over a previous *o*-formylation approach,[5] it was found to be unsuitable for primary anilines.

Copper-Isocyanide Complexes.

The availability of a nonbonding pair of electrons in an sp-hybridized orbital on the terminal carbon atom enables isocyanides to behave as strong carbon ligands for transition metals, for which many complexes have been synthesized. Within the chemical literature, the synthetic value of copper-isocyanide complexes has been amply demonstrated. Cyclopentane- and cyclohexanecarboxylates have been prepared[6] from the stepwise cycloaddition of 1,o-diiodopropanes and -butanes, respectively, with dialkyl fumarate and maleate in the presence of cyclohexyl isocyanide and metallic ***Copper*** (eq 4).

(4)

The reported yields are greater for cyclopentane formation (90% *trans*, 89% *cis*), than for the cyclohexane cycloadduct (37% *trans*, 55% *cis*), where the occurrence of a single stereoisomer for each homolog is a consequence of maleate isomerization by the isocyanide complex prior to cyclization.

Other synthetic uses of copper (or ***Copper(I) Oxide***)-cyclohexyl isocyanide complexes include conjugate additions[7] of activated methylene species, cyclopropanations,[8] allene synthesis[9] from *gem*-dibromocyclopropanes (eq 5), dimerization of alkyl halides,[10] and hydrosilylations of acrylonitriles.[11]

(*R*)-(+)-Cyclohexyl(2-anisyl)methylphosphine[1]

(*R*)

[52885-02-6] · $C_{14}H_{21}OP$ · (*R*)-(+)-Cyclohexyl(2-anisyl)methylphosphine · (MW 236.29) (*S*)

[35144-03-7] (±)

[36293-81-9]

(ligand for transition metal catalyzed asymmetric hydrogenation of alkenes;[2] reagent for asymmetric Wittig[3] and Baylis-Hillman reactions[4])

Alternate Name: (+)-CAMP.

Preparative Method: by hydrogenation (5% Rh/C) of optically pure (2-anisyl)phenylmethylphosphine oxide[5] followed by reduction of the phosphine oxide with ***Trichlorosilane***.[2]

Handling, Storage, and Precautions: readily oxidized to the phosphine oxide and should be handled under N_2 or Ar. This reagent should be handled in a fume hood.

Asymmetric Hydrogenation.

The synthesis of L-Dopa via asymmetric rhodium-catalyzed hydrogenation was reported using a catalyst prepared from rhodium(I) complexes and (+)-CAMP.[2,6] Activation of the catalyst by pretreatment with 1 atm H_2 was necessary. Hydrogenation at lower pressures (10 psi H_2) gave the dihydrocinnamic acid in 90% yield and 88% ee (eq 1). Similar yields and enantioselectivities have been reported with related cinnamic acid derivatives which are capable of bifunctional binding to the rhodium catalyst.[2] Bidentate diphosphine ligands generally lead to higher enantioselectivities in such reactions and are, therefore, employed in the commercial synthesis of L-Dopa.[1]

Wittig Reaction.

The intramolecular Wittig reaction of an ylide obtained from (+)-CAMP occurred with 77% ee to give the (*S*)-bicyclic diketone.[3] Although a stoichiometric amount of the optically pure phosphine was required, the phosphine oxide (+)-CAMPO could be recycled. Enantiomeric excesses using CAMP were much higher than similar reactions which employed other chiral phosphines.

Baylis-Hillman Reaction.

Intramolecular cyclization of $MeCO(CH_2)_2CH{=}CHCO_2Et$ using (+)-CAMP produced the cyclopentene in 40% isolated yield.[4] A 3:1 equilibrium mixture which favored the product cyclopentene was formed after 10 days at 25 °C. CAMP was found to be superior to other phosphines, such as PBu_3. DABCO and other nitrogen bases were ineffective for the cyclization reaction. However, the enantioselectivity of the product using CAMP was only 14%.

1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide[1]

[15580-20-8] · $C_{13}H_{23}N_3O$ · 1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide · (MW 237.34)

(coupling agent for peptide synthesis; used to make sulfate esters from alcohols)

Physical Data: bp 145 °C/0.2 mmHg.

Solubility: sol DMF, CH_2Cl_2, dioxane, xylene.

Preparative Methods: from cyclohexyl isothiocyanate and *N*-(2-aminoethyl)morpholine (67% yield);[2] by dehydration of the corresponding urea with ***p-Toluenesulfonyl Chloride***, ***Potassium Carbonate***, and ***Benzyltriethylammonium Chloride*** (91% yield);[3] or by the reaction of cyclohexyl isocyanate, 2-(4-morpholinyl)ethyl diethylphosphoramidate, and potassium carbonate (82% yield).[4] The corresponding *N*-metho-*p*-toluenesulfonate salt is commercially available (see ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-p-toluenesulfonate***).

Peptide Synthesis.

Amide bonds may be formed using carbodiimides but workup procedures are sometimes complicated by the presence of the urea byproduct. 1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide (**1**) carries a tertiary amine and has a urea derivative that is soluble in dilute acid, making product separation far easier. It has been used to couple glycine ethyl ester hydrochloride and phthaloyl-L-phenylalanine to give phthaloyl-L-phenylalanylglycine ethyl ester in 81% yield (eq 1).[2]

(**1**) has been found to be superior to ***1,3-Dicyclohexylcarbodiimide*** (DCC) for the final cyclization step in the synthesis of a large-ring peptide lactone related to the antibiotic vernamycin B_{α}, with methylene chloride being the solvent of choice.[5] Of all the other coupling reagents examined, only ***N,N´-Carbonyldiimidazole*** gave any cyclization product, although in lower yields.

Preparation of Sulfate Esters.

1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide has been used to mediate the sulfation of 1-hexadecanol to give the corresponding monoalkyl sulfate in 56% yield (eq 2).[6] DCC is superior in this reaction, giving the monoalkyl sulfate in 92% yield.

Andrew M. Griffin

University of Bristol, UK

1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-*p*-toluenesulfonate[1]

[2491-17-0] · $C_{21}H_{33}N_3O_4S$ · 1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-*p*-toluenesulfonate · (MW 423.58)

(used extensively in the activation of alcohols and carboxylic acids)

Alternate Name: morpho-CDI.

Physical Data: mp 113-115 °C.

Solubility: sol DMF, MeCN.

Form Supplied in: commercially available as a colorless solid.

Preparative Methods: prepared by quaternization of the corresponding carbodiimide (see ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide***) with methyl *p*-toluenesulfonate. The carbodiimide is obtained by dehydration of the thiourea.[2]

Handling, Storage, and Precautions: assumed to be harmful by ingestion and skin contact.

Peptide Synthesis.[2]

Phthaloyl-L-phenylalanyl-L-leucine ethyl ester has been prepared in 80% yield by the 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluenesulfonate (**1**) mediated coupling of L-leucine ethyl ester hydrochloride

to phthaloyl-L-phenylalanine (eq 1). Any excess of reagent and the corresponding urea were easily separated from the product by washing with aqueous solutions. The ease of separation of byproduct is the main advantage of this reagent over ***1,3-Dicyclohexylcarbodiimide*** (DCC).

(1)

Macrocyclic Lactonization.[3]

Lactonization of secoacid (**2**) was effected with (**1**), and subsequent cleavage of the methoxymethyl ether results in the antibiotic milbemycin β_3 (**3**) in 85% overall yield (eq 2).

Cyclodehydrations of *N*-Acyl-α-amino Acids.[4]

2-Oxazolin-5-ones are conveniently prepared by dehydration of *N*-acyl-α-amino acids with (**1**) (e.g. eq 3).

(3)

Modified Moffat-Type Oxidations.[5]

(**1**) used in conjunction with DMSO has been used to oxidize alcohols to ketones, as exemplified in the total synthesis of kopsanone (eq 4). This is another example where the advantage of the water solubility of (**1**) and the corresponding urea makes the use of this reagent more attractive than DCC as the diimide component.

(4)

Dehydration of α-Hydroxymethyl Lactones.[6]

α-Hydroxymethyl lactones can be dehydrated to the corresponding α-methylene lactone with the use of (**1**) in the presence of ***Copper(II) Chloride*** (eq 5). This procedure has been successfully demonstrated in the total synthesis of isolobophytolide.

(1,5-Cyclooctadiene)[1,4-bis(diphenylphosphino)butane]iridium(I) Tetrafluoroborate

[78036-20-1] · $C_{36}H_{40}BF_4IrP_2$ · (1,5-Cyclooctadiene)[1,4-bis(diphenylphosphino)butane]iridium(I) Tetrafluoroborate · (MW 813.685)

(reagent for hydrogenation;[1] isomerization of butenyl- to allylsilanes[2])

Physical Data: dec. on attempted melting.

Solubility: insol Et_2O, pentane; sol CH_2Cl_2, MeOH, etc.

Form Supplied in: orange powder. *Drying:* used as supplied in anhydrous solvent.

Analysis of Reagent Purity: ^{31}P NMR indicates presence of free phosphine ligand and phosphine oxides.

Handling, Storage, and Precautions: store under argon in freezer; stable as solid; solutions are air sensitive. This compound should be handled in a fume hood.

The complex has enjoyed relatively little use in organic synthesis. For iridium-catalyzed homogeneous hydrogenation of alkenes, Crabtree's iridium complex (***(1,5-***

Cyclooctadiene)(tricyclohexylphosphine)(pyridine)iridium(I) Hexafluorophosphate) is generally preferred, although this readily prepared Ir complex is active.[1] It is more reactive than its rhodium counterpart in the catalytic isomerization of butenyl- to allylsilanes.[2]

(1,5-Cyclooctadiene)bis(methyldiphenylphosphine)iridium(I) Hexafluorophosphate

[38465-86-0] · $C_{34}H_{38}F_6IrP_3$ · (1,5-Cyclooctadiene)bis(methyldiphenylphosphine)iridium(I) Hexafluorophosphate · (MW 845.81)

(reagent for isomerization of allylic alcohols and ethers;[1] hydrogenation catalyst[2])

Physical Data: mp 236 °C (dec); ^{1}H NMR (CD_2Cl_2) δ 1.78 (d, J_{HP} = 8 Hz, P*Me*Ph$_2$), 2.19 (m, C*H*$_2$ of cod), 4.36 (=C*H* of cod), 7.3-7.9 (ov m, PMe*Ph*$_2$); conductivity 135 &OOmega;$^{-1}$ cm^2 mol^{-1}.

Solubility: sol CH_2Cl_2; insol diethyl ether and hexanes.

Form Supplied in: red crystalline solid; commercially available.

Preparative Methods: to a suspension of [Ir(μ-Cl)(1,5-cod)]$_2$ (0.2 g) in 10 mL of ethanol is added methyldiphenylphosphine (0.2 g) in ethanol. The mixture is stirred for ca. 10 min until the original suspension has dissolved. To this is added excess NH_4PF_6 in ethanol. After cooling to 0 °C the precipitate is filtered, washed with ethanol and then ether to give the title reagent (0.36 g) as red prisms.[3]

Handling, Storage, and Precautions: the dry solid is moderately air-stable.

Hydrogenation.

Cationic iridium complexes such as [Ir(1,5-cod)(PR$_3$)$_2$]$^+$ catalyze the homogeneous hydrogenation of cyclooctadiene to give predominant formation of cyclooctene along with minor amounts of cyclooctane and 1,3-cyclooctadiene (formed by isomerization of the starting material). Slower rates of hydrogenation are observed in comparison to reactions employing complexes of the type [Ir(1,5-cod)(PR$_3$)py]$^+$ as catalyst precursor.[4] A number of iridium complexes, including [Ir(1,5-cod)(PMePh$_2$)$_2$]PF$_6$ (**1**), are also active catalysts for the hydrogenation of soybean and other vegetable oils.[5]

Isomerizations.

Addition of dihydrogen to (**1**) produces a very active catalyst for the isomerization of allyl ethers to the corresponding *trans*-propenyl ethers (eq 1). This reaction proceeds with high stereoselectivity (*trans*/*cis* > 30) and under mild conditions.

(1)

While substituted allylic ethers can be isomerized (eq 2), the reaction appears to be limited to primary allyl ethers. Complex (**1**) also catalyzes the

isomerization of allyl ethers of glycerol or glucose having various protecting groups.[6] The corresponding propenyl ethers thus formed are converted into free hydroxy compounds by treatment with ***Mercury(II) Chloride/Mercury(II) Oxide***.[7] In a related study, (**1**) is used to catalyze the isomerization of allylic alcohols to aldehydes and ketones.[8]

Hydrogen-activated (**1**) is used to isomerize the allyl group in carbohydrates as part of a two-step deallylation procedure.[9] Initial isomerization is followed by treatment with catalytic amounts of ***Osmium Tetroxide*** and ***Trimethylamine N-Oxide*** to cleave the *trans*-1-propenyl group in the presence of an azide group at C-2 (eq 3).[10] This method avoids the formation of intramolecular 1,3-dipolar cycloaddition products which are formed using other deallylation procedures. Unlike many other metal catalysts, cationic iridium complexes are able to perform this isomerization in the absence of elevated temperatures.

(1,5-Cyclooctadiene)(1,3,5-cyclooctatriene)ruthenium

[42516-72-3] · $C_{16}H_{22}Ru$ · (1,5-Cyclooctadiene)(1,3,5-cyclooctatriene)ruthenium · (MW 315.42)

(catalyst precursor for dehydrogenative silylation of alkenes,[4,5] hydroacylations,[7] carbonylation of amines,[9] and various carbon-carbon bond forming reactions[12-17])

Physical Data: mp 92-94 °C (dec); ^{1}H NMR (C_6D_6) δ 0.9 (m, 2H), 1.64 (m, 2H), 2.22 (m, 8H), 2.92 (m, 4H), 3.79 (m, 2H), 4.78 (m, 2H), 5.22 (dd, 2H).

Solubility: sol toluene and chloroform; insol alcohols.

Form Supplied in: yellow crystalline solid.

Preparative Method: to a solution of $RuCl_3.3H_2O$ (0.34 g, 1.3 mmol) in 10 mL of ethanol is added 1,5-cyclooctadiene (8.8 g, 81 mmol) and zinc dust (3.5 g); the mixture is heated under reflux with stirring for 3 h and then filtered; the resulting brown-yellow solution is evaporated in vacuo, extracted with 20 mL of pentane and filtered through a plug of alumina (20 cm); the volume is reduced to ca. 5 mL and the yellow solution cooled to -78 °C to give yellow crystals of (1,5-cyclooctadiene)(1,3,5-cyclooctatriene)ruthenium (0.2 g, 50%).[1]

Handling, Storage, and Precautions: the compound rapidly decomposes when exposed to air.

Introduction.

While little is known about the chemistry of bis(η^5-cyclooctadienyl)ruthenium, the catalytic activities of (1,5-

cyclooctadiene)(1,3,5-cyclooctatriene)ruthenium, Ru(cod)(cot), and its derivatives in organic synthesis are well established. This article will attempt to cover the chemistry of all these low valent ruthenium compounds.[2]

Dehydrogenative Silylations.

Allylsilanes are highly versatile synthetic intermediates[3] which can be prepared selectively by the Ru(cod)(cot) catalyzed dehydrogenative silylation of alkenes (eq 1).[4] In all reactions reported, only minor amounts of vinylsilanes and alkanes (derived from hydrogenation of the starting alkene)[5] were detected. Conversely, reactions employing $Ru_3(CO)_{12}$ as the catalyst source afforded vinylsilanes as the major product.

(1)

In a related study, (benzene)(1,3-cyclohexadiene)ruthenium was found to be a moderately active and selective catalyst precursor for the hydrosilation of allyl chlorides with trimethoxysilane.[6]

Hydroacylation.

A number of low valent ruthenium complexes catalyze the intermolecular hydroacylation of alkenes with various aromatic and heteroaromatic aldehydes.[7] Unsymmetrical ketones are produced in moderate to high yields in reactions run at 180-200 °C for 24-48 h under 20 kg cm^{-2} of carbon monoxide. For example, the reaction of 2-thiophenecarbaldehyde with cyclohexene affords the corresponding cyclohexyl 2-thienyl ketone in 62% yield (eq 2). Treatment of cyclohexene with aliphatic aldehydes gives products arising from a transhydroformylation reaction, where the formyl group of the aldehyde has transferred to the alkene with concomitant formation of Tishchenko-type reaction products.[8]

(2)

Carbonylation of Amines.

Ru(cod)(cot) is a moderately effective catalyst precursor for the carbonylation of amines, affording *N*-substituted formamides. In the presence of alkenes, hydroamidation affords *N*-substituted alkanamides (eq 3).[9] In both reactions, addition of phosphine reduces catalytic activity. Indeed, $Ru_3(CO)_{12}$ was found to be the most active and selective catalyst precursor for these transformations.

(1,5-Cyclooctadiene)(1,3,5-cyclooctatriene)ruthenium

$$RNH_2 + R'CH{=}CH_2 + CO \xrightarrow{[Ru]} RNHCOCH_2CH_2R' + RNHCOCH(Me)R' + RNHCHO \quad (3)$$

Secondary amines react with carbon dioxide and terminal alkynes in the presence of a catalytic amount of Ru(cod)(cot)/tertiary phosphine to give enol carbamates with high regio- and stereoselectivity (*Z/E* ca. 9:1).[10] 2-Acetoxyallyl derivatives are produced with high selectivity and in high yield by reaction of acetic acid with propargyl alcohol derivatives at 80 °C using a bis(η^5-cyclooctadienyl)ruthenium/PCy_3/maleic anhydride catalyst system.[11]

Carbon-Carbon Bond Formation.

A number of C-C bond forming reactions catalyzed by low valent ruthenium complexes have been developed, including the oligomerization of alkenes and alkynes,[12] [2 + 2] cross addition of norbornenes with alkynes[13] and allylamines with acrylic compounds (eq 4),[14] aldol condensations, and Michael addition reactions.[15]

(4)

More recently, ruthenium complexes such as Ru(cod)(cot) were found to catalyze the dehydrohalogenative coupling of vinyl halides with electron deficient alkenes to give substituted dienes (eq 5). In some cases, ruthenium complexes were more active than the well established palladium catalysts. For instance, even the sp^2 carbon-chlorine bond in β-chlorostyrene is activated by Ru(cod)(cot).[16] Monoallylated carbonucleophiles are produced in high yields and with high regioselectivity in the presence of a catalytic amount of Ru(cod)(cot). Regioselectivities are quite different from products obtained from palladium catalyzed reactions. Furthermore, allylations using allyl methyl carbonate give diallylated carbonucleophiles selectively and in high yields. Diallylations are not easily accomplished using other metal catalysts.[17]

(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)

[12184-35-9] · $C_{13}H_{17}Co$ · (1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I) · (MW 232.11)

(catalyst for cyclotrimerization of alkynes and cotrimerization with nitriles to yield pyridine derivatives;[1,2] source of other cobalt complexes and of substituted cyclooctadienes[15-17])

Physical Data: mp 102-104 °C; subl 70 °C/0.1 mmHg.

Solubility: readily sol common org solvents; insol H_2O.

Form Supplied in: golden-yellow cryst.

Preparative Methods: of several effective synthetic routes the most efficient is the direct reaction of cobalt salts [conveniently $Co(acac)_3$] with cyclopentadiene + cycloocta-1,5-diene + anthracene-activated magnesium metal.[1]

Handling, Storage, and Precautions: air sensitive; best stored at low temp (<0 °C) under inert gas (N_2, Ar). Use in a fume hood.

General Remarks.

This compound is representative and is the most commonly used of the class of (dialkene)CoCp complexes which share similar reactivity and can be used more or less interchangeably in reactions which involve replacement of the (di)alkene moiety. The entry therefore also makes reference to derivatives with substituted cyclopentadienyl ring and to analogs, notably CpCo(cyclopentadiene) and $CpCo(C_2H_4)_2$ of which the latter is probably the most reactive, while the C_5H_6 complex is arguably the most readily accessible. $(C_5H_5)Co(C_5H_6)$ *[3302-03-0]*, MW 190.13, mp 98-99 °C, is the product of hydride addition to ***Bis(cyclopentadienyl)cobalt Hexafluorophosphate***; it forms air-sensitive, wine-red crystals, sol in hydrocarbons and sublimable in vacuo. $(C_5H_5)Co(C_2H_4)_2$ *[69393-67-5]*, MW 180.14, is efficiently

(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)

synthesized from ***Bis(cyclopentadienyl)cobalt*** and forms hydrocarbon soluble, air-sensitive, red-brown needles.

Catalysis of Alkyne Cyclotrimerization and Related Reactions.

Cyclotrimerization of alkynes and cotrimerization of two molecules of alkyne with one of a nitrile to give 2-substituted pyridines and related reactions (see below) are efficiently catalyzed by cobaltocene and by a range of cobalt complexes of the type $CpCoL_2$. Of the latter, the carbonyl (L = CO), ***Dicarbonyl(cyclopentadienyl)cobalt(I)***, and the cyclooctadiene (cod, $L_2 = C_8H_{12}$) complex are the most commonly used, but many derivatives and analogs are comparable in efficiency, consistent with the evidence suggesting that the key steps are eqs 1 and 2. Ring closure to a cobaltacyclopentadiene system is probably induced by addition of the third alkyne (eq 3) or nitrile molecule (eq 4). Further reaction with alkyne then continues a chain in which the ligands L or L_2 play no further part. They therefore influence only the conditions necessary to start the process.

$$CpCoL_2 \longrightarrow [CpCo] + 2\,L \qquad (1)$$

(2)

(3)

(4)

The complex CpCo(cod) has been most widely used for the pyridine synthesis and the effect of varying catalyst structure on the reaction temperature and selectivity has been extensively studied.[1,2] The choice of propyne reacting with propionitrile (eq 5) allowed the effect on chemo- and regioselectivity to be evaluated at the same time.

In a flow system, the temperature required for 65% conversion of propyne was 147-150 °C independent of L, although the initiation temperature varied widely, being <30 °C for L = C_2H_4, 75-85 °C for L_2 = C_5H_6, and 120-125 °C for L_2 = cod, but $CpCo(CO)_2$ was unsuitable as catalyst under these conditions, giving only 5% conversion at 150 °C. The reaction temperature was dropped to 125 °C for both the indenyl analog, $(C_9H_7)Co(cod)$, and for the tetraphenyl-substituted complex, $(C_5Ph_4H)Co(cod)$, and the latter gave the highest chemoselectivity (ratio of pyridines to arenes) of 6.9, compared to 1.8 for CpCo(cod). Moreover, the tetraphenyl derivative also gave one of the highest regioselectivities (2,4,6-:2,3,6-trisubstituted pyridine) of 2.70, compared to 1.71 for CpCo(cod). In ethylpyridine synthesis (from acetylene + propionitrile), the complex $(C_5Ph_4H)Co(cod)$ was again the outstanding catalyst with a turnover number of 6946 and 91.8% yield. It also gives relatively good results (TON 1625, 73.7% yield) in the vinylpyridine synthesis (eq 6), which must be conducted at moderate temperature to avoid polymerization.

High temperatures can be avoided by employing photolysis[3a] to effect the initiation step (eq 1). Thus an alternative route to 2-vinylpyridine[3b] employs this method to obtain intermediate 2-ethoxy- (or 2-methoxy)ethylpyridine (eq 7) with 99% selectivity (50% conversion); irradiation of acetylene and propionitrile with CpCo(cod) at 15 °C for 1.5 h gave 43% conversion to 2-ethylpyridine.[3a]

The reaction has been used in approaches to natural products, as illustrated by syntheses of (*N*-benzyloxycarbonylpyrrolidinyl)pyridine (eq 8)[4] and by a route to vitamin B_6.[5] One version of this utilizes the regioselective $CpCo(CO)_2$, Cp_2Co, or CpCo(cod) catalyzed step (eq 9).[5a] The possibility of using homochiral

substrates in such reactions without loss of optical purity has been demonstrated in the examples shown in eq 10[6a] and eq 11.[6b]

(8)

(9)

yield 68% after desilylation with CsF 16:1

(10)

R* =

(11)

The ethylene complex was used as catalyst[7] in a study of the dependence of regioselectivity on substrate structure; the same catalyst was employed in a study of the cyclooligomerization of propargyl alcohol, which yielded approximately equal amounts of the aromatic trimerization products and the cyclooctatetraene derivatives (eq 12).[8]

(12)

The use of isocyanates or carbodiimides in cotrimerization with alkynes leads to *N*-substituted pyridones (eq 13) or the corresponding imines (eq 14).[9]

(13)

(14)

Other Catalytic Reactions.

The ethylene complex $CpCo(C_2H_4)_2$ catalyzes the ring enlargement and hydrogen shifts which convert octamethyl[4]radialene to an arene (eq 15).[10] Ethylene is also added to 2,5-dimethyl-2,3,4-hexatriene, initially yielding a complexed conjugated triene; under ethylene pressure this is displaced and its formation (eq 16)[10] becomes catalytic.

(15)

(16)

Stoichiometric Reactions.

Reaction of carbodiimides with stoichiometric amounts of the ethylene complex $CpCo(C_2H_4)_2$ yields a dinuclear and a tetranuclear complex with incorporation of an ethylene ligand into the latter (eq 17).[11] Further use of these products has not been explored. An ethylene fragment is also incorporated in the reaction with diphenylketene (eq 18),[12] whereas reaction with thiocyanates involves coupling of two molecules thereof and both cleavage and formation of C-S bonds (eq 19).[13]

(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)

That complexation of alkenes or dienes as CpCo(dialkene) can serve for their protection appears to have been demonstrated only for cyclooctatetraene; its 1,2,5,6-η complex has been converted to the bis(cyclopropane) derivative, leaving the metal-bound double bonds intact, by the reaction shown in eq 20;[14] the free organic ligand was liberated by cerium(IV) oxidation in unspecified yield.

Reaction of CpCo(cod) with trityl cations leads to hydride abstraction from the 3-position of the cod ligand.[15] The

resultant cationic complex readily adds nucleophiles to give complexed 3-substituted cycloocta-1,5-dienes (eq 21).[16] A more profound change of the cod ligand involving ring closure and alkylation occurred when the complex was treated with a cationic allyliron complex (eq 22); $(C_5Me_5)Co(cod)$ reacted similarly.[17]

(1,5-Cyclooctadiene)[(3*R*,4*R*)-3,4-bis(diphenylphosphino)-1-methylpyrrolidine]rhodium Tetrafluoroborate[1]

[100366-06-1] · $C_{37}H_{41}BF_4NP_2Rh$ · (1,5-Cyclooctadiene)[(3*R*,4*R*)-3,4-bis(diphenylphosphino)-1-methylpyrrolidine]rhodium Tetrafluoroborate · (MW 737.39)

(catalyst for asymmetric hydrogenation of α-acylaminoacrylic acid derivatives[2])

Solubility: insol ether; sol CH_2Cl_2, MeOH

Analysis of Reagent Purity: ^{31}P NMR (CD_2Cl_2): δ 33.17 (d, $^2J_{Rh,P}$ = 148.2 Hz).

Preparative Methods: the ligand (3*R*,4*R*)-3,4-bis(diphenylphosphino)-1-methylpyrrolidine (**1a**) is prepared from L-tartaric acid via (3*R*,4*R*)-3,4-bis(diphenylphosphino)-1-benzylpyrrolidine (**1b**) as shown in eq 1. The title cationic rhodium complex is made by mixing bis(1,5-cyclopentadiene)rhodium tetrafluoroborate and (**1a**) in CH_2Cl_2 under nitrogen.

Asymmetric Hydrogenation Catalyst.

Since catalytic asymmetric hydrogenation of α-acylaminoacrylic acid derivatives is an important process to afford α-amino acid derivatives, many rhodium complexes possessing optically active phosphine ligands have been developed in last two decades.[3-7] [Rh{(*R*)-(**1a**)}(cod)]BF_4 (**2a**) is one of the most efficient catalysts for this purpose with respect to activity and enantioselectivity. Besides (**2a**), several derivatives, which have various substituents on the nitrogen atom of the pyrrolidine ring, will be mentioned below.

α-(Acetylamino)cinnamic acid derivatives (**3**) are hydrogenated in the presence of (**2**), which are derived from natural L-tartaric acid, to afford natural (*S*)-*N*-acetylphenylalanine derivatives with high enantioselectivity (eq 1).[8] Some examples are shown in Table 1. Less than 0.01 mol % of catalyst is needed to complete the reaction under mild conditions with high enantioselectivity. The substituents on the nitrogen atom of (**2**) have no marked influence on the catalytic activity or the selectivity. This reaction is also insensitive to the variation of substituents on the phenyl ring of (**3**).

(homogeneous catalyst for hydrogenation, especially of hindered and highly substituted alkenes;[5,6] catalyst for directed hydrogenation;[6] catalyst for alkene isomerization and hydroboration[9])

Physical Data: mp 150 °C (dec).

Solubility: sol CH_2Cl_2, acetone, and THF; insol water.

Form Supplied in: yellow microcrystals; not commercially available.

Purification: recrystallization from CH_2Cl_2/Et_2O.

Handling, Storage, and Precautions: air stable for days, but long term storage under N_2 and in the dark recommended.

General Aspects.

$[Ir(cod)(PCy_3)(py)]PF_6$, a readily prepared[1] complex, is one of the standard catalysts for hydrogenation and has also been used for the addition of Si-H and B-H bonds across C=C or C&tbond;C bonds. Room temperature should be employed in all stages of the preparation and use of the catalyst. Although the hexafluorophosphate salt has been used most often, the exact nature of the anion is not important as long as it is noncoordinating. The catalyst deactivates rapidly if exposed to H_2 in the absence of substrate and deactivates slowly in any event; lower concentrations of catalyst (e.g. 2.5 mol %) are often most useful to give adequate catalytic rates without excessive deactivation. The catalyst also deactivates slowly in the presence of substrate, so the catalyst should be added to the substrate solution and hydrogen added promptly. It is not necessary that the solvents be specially dried or that the hydrogen be scrupulously air-free.

The cationic charge gives the catalyst special advantages over neutral catalysts such as ***Chlorotris(triphenylphosphine)rhodium(I)***: better stability to air and to oxidizing solvents, such as halocarbons, and good functional group tolerance. Its unusually high activity, even for hindered substrates, is in part a result of the noncoordinating solvent used, usually CH_2Cl_2, and the low ligand-to-metal (L:M) ratio. A special feature is the very high stereospecificity that can be seen when a functional group such as OH, CO_2Me, or $CONH_2$ binds to the catalyst and directs the attack to one face of the substrate. This has only been seen for catalysts with very low L:M ratios, which allow the functional group, the C=C bond, and H_2 all to bind to the metal at the same time. The catalyst has so far proved most useful for alkene hydrogenation, isomerization, and hydroboration. Other applications have not yet been investigated. The closely related species ***(1,5-Cyclooctadiene)bis(methyldiphenylphosphine)iridium(I) Hexafluorophosphate*** and $[Rh(cod)(Ph_2P\{CH_2\}_4PPh_2)]PF_6$ are sometimes useful for the same types of catalytic reactions, but it is not yet possible to predict which will be best in a given situation. Ideally, all three should be tried.

Isomerization of Allylic Alcohols and Ethers.

$[Ir(cod)(PMePh_2)_2]PF_6$ in THF is activated by hydrogen at room temperature to give $[IrH_2(THF)_2(PMePh_2)_2]PF_6$ which is an active isomerization catalyst, e.g. for the conversion of allylic alcohols to aldehydes or ketones; in eq 1 the reaction takes 30 min at room temperature.[2]

(1)

The conversion of allyl ethers to enol ethers[3] can sometimes be accompanied by hydrolysis, especially on treatment with $HgCl_2$-HgO.[4] This constitutes a useful deprotection sequence for $-OCH_2CH{=}CH_2$ groups (eq 2).

(2)

Directed Hydrogenation of Alkenes.

$[Ir(cod)(PCy_3)(py)]PF_6$ is active for the reduction of hindered alkenes, even tri- and tetrasubstituted ones,[5] while ketone, ester, nitro, amide, and aryl groups remain unaffected. The stereochemistry of the reduction product can be dominated by directing effects[6] in suitable cases. This happens when neighboring carboxamide, hydroxyl, keto, methoxy, or ester groups (in approximate decreasing order of efficiency) bind to the catalyst and ensure addition of H_2 from the face containing the directing group. Directivities of 0.92-1.0 are common, as shown in eq 3 where OH is the directing group. The catalyst seems to work best at low loadings, such as 2.5%. Conversions are high and isomerization is usually a minor pathway. In many cases ***Palladium on Carbon*** in EtOH gave the opposite isomer preferentially, although not exclusively.

(3)

Terpinen-4-ol is a particularly effective substrate, probably because of the favorable conformation of the OH and C=C groups shown in (**1**), which facilitates chelation of the Ir by simultaneous binding to both groups.

(1)

In the case of the methyl ketone shown, the catalyst shows both its directing effect and ability to reduce highly hindered alkenes (eq 4).

(4)

In indenones, the presence of a suitable hydroxyl group can even completely override the normal tendency to give a *cis* ring junction in the indanone product formed on hydrogenation (eq 5).[6c]

(5)

The directing effect of the catalyst has been useful in key steps of a number of total syntheses, such as of daunomycin[7] and the pumilitoxins.[8]

Directed Hydroboration of Alkenes.

$[Ir(cod)(PCy_3)(py)]PF_6$ can be used at 4-5 mol % catalyst loading in the hydroboration of alkenes, a reaction which shows the same sort of directing effects as noted above for hydroboration.[9]

Cyclopentadiene[1]

[542-92-7] · C_5H_6 · Cyclopentadiene · (MW 66.10)

(undergoes a variety of cycloaddition reactions;[5] can be deprotonated to form the anion which reacts with electrophiles[27] and forms stable transition metal complexes;[3] can be used to generate polymers[31])

Physical Data: bp 41-42 °C; *d* 0.805 g cm^{-3}.

Solubility: misc. EtOH, benzene.

Form Supplied in: obtained from dicyclopentadiene

Preparative Method: the volatile diene dimerizes readily and is prepared as required by depolymerization of technical dicyclopentadiene (widely available, bp 171-173 °C). The depolymerization is done by heating the dimer carefully under a fractionating column.[2-4]

Handling, Storage, and Precautions: toxic vapor; stench; highly flammable (flash point <25 °C); can dimerize explosively; forms unstable peroxides with oxygen; avoid skin contact. This reagent should be handled only in a fume hood.

Cycloadditions.

Diels-Alder reactions of cyclopentadiene with dienophiles leads predominantly to the *endo* products. In the presence of Lewis acids the *endo* selectivity is greatly increased (eq 1).[5] The use of water as the reaction solvent,[6] or the presence of modified clays[7,8] or zeolites[9] in organic solvents, also leads to a pronounced increase in *endo* selectivity together with increases in reaction rates.

(1)

0 °C	82:18
0.1 equiv $AlCl_3 \cdot OEt_2$, 0 °C	96:4

Cyclopentadiene has also been widely used in asymmetric Diels-Alder reactions (eq 2).[10] Chromium carbene complexes form cycloadducts with cyclopentadiene at increased reaction rates compared to the organic ester analogs (eq 3).[11-13]

(2)

$(R):(S) = 200:1$
$exo:endo = 96:4$

(3)

Cyclopentadiene reacts with benzyne to afford Diels-Alder adducts in high yields (eq 4).[14] This reaction is so efficient that it has been used as a diagnostic test for the formation of benzyne. Heteroatomic dienophiles such as imines,[15,16] thioaldehydes,[17] selenoaldehydes,[18] and sulfenes (eq 5)[19] also react with cyclopentadiene in a [4 + 2] manner.

(4)

(5)

Cycloaddition with cyclopentadiene has been used for protection of double bonds, which can be subsequently revealed upon pyrolysis (eq 6).[20a] This type of retrograde Diels-Alder reaction has been reviewed.[20b,c]

(6)

Cyclopentadiene undergoes a [4 + 3] cycloaddition upon reaction with 2-oxyallyl cations, providing bicyclo[3.2.1]oct-

6-en-3-ones (eq 7).[21] These types of products have been employed as important precursors to natural products.[21]

Cyclopentadiene reacts as a simple alkene with ketenes such as 2-carbonyl-1,3-dithiane (eq 8).[22] Likewise, cyclopentadiene reacts chemoselectively with alkynes in the Pauson-Khand cycloaddition. The chemical yields are generally excellent, but the regioselectivity is only moderate (eq 9).[23]

Deprotonation.

Cyclopentadiene can be readily deprotonated by strong bases to give the stabilized (6π-electron) cyclopentadienyl anion. This anion is a ubiquitous ligand for transition metal complexes; examples are ruthenocene[24] and ferrocene (eq 10).[3]

(10)

The cyclopentadienyl anion also reacts with ketones to generate fulvenes (eq 11).[25] Aldehydes only polymerize under these conditions; however, they may be used to form the corresponding fulvenes by employing a modified method.[26] Reaction of the anion with electrophiles often leads to mixtures of regioisomers due to facile ambient temperature 1,5-hydrogen shifts (eq 12).[27a] To circumvent these hydrogen shifts, the use of cyclopentadienylthallium at low temperature has been employed.[27b]

(11)

(12)

1,4-Addition Reactions.

Cyclopentadiene reacts with ***Bromine*** to afford the *cis*-1,4-adduct in high yield (eq 13).[28] The *cis*-1,4-diol may be obtained by reaction with singlet oxygen and ***Thiourea*** (eq 14).[29] The diacetate of this diol can be desymmetrized with enzymes to afford the enantiomerically enriched alcohol, which is an important chiral building block (eq 15).[30]

(13)

Polymerization.

Cyclopentadiene undergoes polymerization in the presence of 0.1 mol % of a tungsten nitrosyl Lewis acid catalyst (eq 16).[31] The polymer is a mixture of 1,4- and 1,2-polycyclopentadiene.

Related Reagents.

5-Bromo-1,3-cyclopentadiene; ***5-(Methoxymethyl)-1,3-cyclopentadiene***.

Cyclopentadienone Diethyl Acetal[1]

(R = Et)

[2931-32-0] · $C_9H_{14}O_2$ · Cyclopentadienone Diethyl Acetal · (MW 154.21) (R = Me)

[2931-31-9] · $C_7H_{10}O_2$ · Cyclopentadienone Diethyl Acetal · (MW 126.16)

(isolable cyclopentadienone synthon(s) for use in Diels-Alder and related cycloadditions[2])

Physical Data: thermally unstable liquid which rapidly dimerizes in solution.

Solubility: sol pentane, pyridine, hexanes, ether, ethyl acetate; insol water.

Preparative Methods: cyclopentanone acetal (ethyl or methyl) is brominated with ***Pyridinium Hydrobromide Perbromide***. The 2,5-dibromo acetal is double dehydrobrominated using ***Potassium t-Butoxide-Dimethyl Sulfoxide***, the product extracted into cold pentane and used immediately.[2]

Analysis of Reagent Purity: analysis of the dimeric product.

Handling, Storage, and Precautions: pentane solutions should be used immediately.

Diels-Alder Cycloadditions.

Early attempts to utilize cyclopentadienone in Diels-Alder cycloadditions proved fruitless because spontaneous dimerization occurs.[3-5] The same was true of cyclopentadienone ethylene acetal;[3-5] thus attention turned to *n*-alkyl acetals. The diethyl acetal can be prepared in good yield from

dehydrobromination of 2,5-dibromocyclopentanone diethyl acetal, but care must be exercised during isolation.[2] A solution in pentane left to stand for 24 h produces the dimeric Diels-Alder adduct in 70-95% yield.[2] Immediate utilization of the diene allows a versatile range of cycloaddition products to be accessed. A number of phthalimide derivatives have been studied, giving good yields of cycloadducts (eq 1).[2,6-9] Elaboration of this strategy involves unmasking of the ketone function, best achieved using ***Boron Trifluoride Etherate*** (eq 2),[6] allowing full realization of the diene's potential as a cyclopentadienone equivalent. A range of electron deficient dienophiles have been examined in cycloaddition reactions with this diene (eq 3).[2,10,11] Cycloaddition with diethyl maleate has been used to prepare an important intermediate en route to norborna-2,5-dien-7-one.[10] In the cycloaddition with nitroethylene the [4 + 2] adduct is obtained with an *endo*:*exo* ratio of 2.5:1.[11] A similar ratio was observed for the product of cycloaddition with acrolein.[2]

(1)

X = O, HC=CH, S, NPh, NEt, NH

(2)

R = H, Et, Ph

(3)

Cycloaddition to the cyclobutadiene iron carbonyl complex has been accomplished; the structurally interesting adduct was used to prepare a homocubyl species (eq 4).[12] A [4 + 3] cycloaddition to cyclopentadienone diethyl acetal has been reported, the reactive dienophile involved being generated in situ using a ***Zinc/Copper Couple*** (eq 5).[13] The cycloaddition mechanism to this allyl cation was elucidated, and determined to proceed firstly by an electrophilic and then by a nucleophilic step.

(4)

(5)

Reaction of the cyclopentadieneone diethyl acetal with ***4-Phenyl-1,2,4-triazoline-3,5-dione*** (PTAD), followed by hydrogenation of the alkenic bond and liberation of the azo moiety, resulted in isolation of a novel and potentially versatile cycloadduct (eq 6).[14]

(6)

Cyclopentadienone dimethyl acetal, produced by an identical process, undergoes much of the chemistry as the analogous diethyl acetal.[2] The rates of dimerization of these acetals have been studied in depth. From these studies it emerged that at 25 °C the dimethyl acetal dimerizes 1.7 times faster than the diethyl acetal (eq 7),[2,15] but much slower than the ethylene acetal which proceeds approximately 1070 times faster. This translates into a 500-fold more rapid dimerization for the cyclopentadienone dimethyl acetal than cyclopentadiene, the short half-life explaining the lack of general utility of these dienones.[16] Using electron deficient dienes, however, reasonable yields of cycloadducts can be obtained, a pertinent example being addition to an azo-maleimide (eq 8).[11]

Chloro(cyclopentadienyl)bis[3-*O*-(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranosyl)]titanium

[119528-80-2] · $C_{29}H_{43}ClO_{12}Ti$ · Chloro(cyclopentadienyl)bis[3-*O*-(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranosyl)]titanium · (MW 667.05)

(highly enantio- and diastereoselective aldol reactions of acetic acid,[1] propionic acid,[2] and glycine[3] ester enolates with various aldehydes; stereoselective addition of allyl groups to aldehydes[4])

Physical Data: crystal structure; ^{1}H and ^{13}C NMR.[5]

Solubility: toluene (not determined, 0.155 M possible); Et_2O (not determined, 0.09 M possible).[4]

Analysis of Reagent Purity: ^{1}H NMR; test reaction.

Preparative Methods: see ***Trichloro(cyclopentadienyl)titanium***.

Handling, Storage, and Precautions: best handled as stock solution either in Et_2O (ca. 0.1 M) or toluene (ca. 1.5 M), which must be protected from moisture and UV light. If handled under an inert atmosphere (argon), such solutions can be stored in a refrigerator (8 °C) for several months (possibly much longer) without deterioration. Reactions should be carried out in dry equipment and with absolute solvents under Ar or N_2.

Aldol Reactions.

The titanium enolate (**2**) is obtained by addition of ca. 1.3 equiv of the title reagent (**1**) as a 0.1-0.15 M solution in toluene to the Li enolate of *t*-butyl acetate (**3**) generated at -78 °C with lithium dicyclohexylamide in Et_2O. This transmetalation takes about 24 h at -78 °C but is completed within 1 h at -30 °C (eq 1).[1a,b] The medium might also be important, as it has recently been reported that ***12-Crown-4*** has to be added for reproducible results in THF-Et_2O.[1c] The solution of (**2**) usually is recooled to -78 °C for the reaction with aldehydes, affording β-hydroxy esters (**4**) of high optical purity (90-96% ee) upon hydrolytic workup. Byproducts are insoluble cyclopentadienyltitanium oxides (**5**) and the ligand diacetone-glucose (DAGOH, **6**). The oxides (**5**) can be separated by filtration and may be recycled to $CpTiCl_3$. Ligand (**6**) and product are either separated by conventional methods (crystallization, distillation, chromatography), or glucose is extracted into the aqueous phase after acetonide cleavage in 0.1 N HCl (1.5 h at rt).[1a,b] In the case of isovaleraldehyde (R = *i*-Bu) it could be shown that the enantioselectivity (92-96% ee) is retained up to rt (27 °C).[1a,b]

A clear drawback of this reagent is the availability of only one enantiomer, the one favoring the *re* attack to the

aldehyde carbonyl, as only D-glucose is readily available. *si* Attack is observed with the analogous enolate prepared from ***Chloro(η^5-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O^{α},O$^{α´}$]titanium***, but only with moderate enantioselectivity (78% ee).[1c,6] The reagent (**2**) is probably the most versatile chirally modified acetate enolate. Good results have also been obtained with the Mg enolate of 2-acetoxy-1,1,2-triphenylethanol[7] and with boron enolates derived from 2,4-dialkylborolanes.[8] Chiral Fe-acetyl complexes, which can be considered as acetate equivalents, give impressive stereocontrol upon enolization and aldol reaction.[9] Except for unsaturated residues R, β-hydroxy esters (**4**) of excellent optical purity can also be obtained by enantioselective hydrogenation of the corresponding β-keto esters catalyzed by $RuCl_2$(BINAP).[10]

For the propionate aldol reaction the Li enolate (**7**), generated by deprotonation of 2,6-dimethylphenyl propionate with ***Lithium Diisopropylamide*** in Et_2O,[11] was chosen.[2] Transmetalation with 1.25 equiv of an ethereal solution of (**1**) takes 24 h at -78 °C. The completion of this step is evident by the disappearance of racemic *anti*-aldol (**9**) in favor of optically active *syn*-isomer (**10**) (91-98% ee) upon reaction with an aldehyde (RCHO) and aqueous workup. At this point, 3-11% of *anti*-aldol (**9**) remaining in the reaction mixture is optically active as well (eq 2). This *anti*-isomer (**9**) (94-98% ee) becomes the major product if the reaction mixture, containing the putative (*E*)-titanium enolate derived from (**7**), is warmed for 4-5 h to -30 °C before reaction with an aldehyde (RCHO) again at -78 °C. Isomerization to the (*Z*)-titanium enolate is a possible explanation of this behavior. Some substrates, aromatic and unsaturated aldehydes, behave exceptionally, as a high proportion of *syn*-isomer (**10**) (19-77%) of lower optical purity (47-66% ee) is formed in addition to (**9**) (94-98% ee). After hydrolysis of the acetonide (**6**) the products (**9**/**10**) are isolated and separated by chromatography in 50-87% yield. The reactions of pivalaldehyde (R = *t*-Bu) are sluggish at -78 °C and have therefore been carried out at -50 to -30 °C.

As above (eq 1), a major drawback of this reagent is the lack of a readily available enantiomer. There are many alternative methods for the enantioselective propionate aldol reaction. The most versatile chirally modified propionate enolates or equivalents are *N*-propionyl-2-oxazolidinones,[12] α-siloxy ketones,[13] boron enolates with chiral ligands,[14] as well as tin enolates.[15] Especially rewarding are new chiral Lewis acids for the asymmetric Mukaiyama reaction of *O*-silyl ketene acetals.[16] Most of these reactions afford *syn*-aldols; good methods for the *anti*-isomers have only become available recently.[8,17]

Transmetalation of the (*E*)-*O*-Li-enolate derived from the stabase-protected glycine ethyl ester (**11**) with 1.1 equiv of (**1**) affords the chiral Ti enolate (**12**), which adds with high *re* selectivity to various aldehydes.[3,18] By mild acidic cleavage of the silyl protecting group, the primary product (**13**) can be transformed to various *N*-derivatives (**14**) of D-*threo*-α-amino-β-hydroxy acids in 45-66% yield and with excellent enantio- and *syn*(*threo*) selectivity (97-99%) (eq 3). An exception with lower enantioselectivity is glyoxylic ester (ethyl ester 78% ee; *t*-butyl ester 87% ee).

(3)

In this case the enantiomers are available by the analogous conversion of glycine *t*-butyl ester using ***Chloro(*η^5*-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-*$\alpha,\alpha,\alpha',\alpha'$*-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O*$^{\alpha}$*,O*$^{\alpha'}$*]titanium***. An elegant alternative is the enantioselective addition of isocyanoacetate to aldehydes under the catalysis of a chiral Au^I complex.[19] Further methods, also for the *anti*(*erythro*) epimers, can be found in recent reviews of enantioselective α-amino acid synthesis.[20]

Allyltitanation of Aldehydes.

The allyltitanium complex (**15**) is obtained by reaction of chloride (**1**) (1.1 equiv) with allylmagnesium chloride in Et_2O for 1 h at 0 °C.[4] The compound (**15**) has been characterized by ^{13}C NMR.[5] Reaction with various aldehydes (RCHO) at -78 °C and hydrolysis affords the homoallyl alcohols (**16**) (55-88%) of high optical purity (85-94% ee) (eq 4).[4] The isolation of the product is analogous to the aldol reactions (cf. eq 1).

(4)

The enantiomers of (**16**) are obtained analogously by using ***Chloro(η^5-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O$^{\alpha}$,O$^{\alpha'}$]titanium***.[21] The stereoselectivity of this cyclic Ti complex in allyltitanations is better than the diacetone-glucose system (**1**). It is therefore advisable to use the (4*S*,*trans*) enantiomer instead of (**1**) for controlling the *re* addition to problematic substrates. For further examples of this method and for analogous reagents see the discussion provided in ***Chloro(η^5-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O$^{\alpha}$,O$^{\alpha'}$]titanium***.

Cyclopentadienylbis(triphenylphosphine)cobalt(I)[1]

[32993-07-0] · $C_{41}H_{35}CoP_2$ · Cyclopentadienylbis(triphenylphosphine)cobalt(I) · (MW 648.62)

(alkyne cyclotrimerization catalyst; co-cyclotrimerization catalyst for alkynes and nitriles, alkenes and heterocumulenes; reagent for synthesis of substituted thiophenes, selenophenes, and pyrroles)

Physical Data: mp 140-143 °C (benzene adduct).[2a]

Solubility: sol benzene, THF, toluene; insol hexane.

Form Supplied in: dark red, air-sensitive crystalline solid.

Analysis of Reagent Purity: ^{1}HMR and IR.[2a,2b]

Preparative Method: can be prepared by addition of NaCp to ***Chlorotris(triphenylphosphine)cobalt*** in THF.[2c]

Purification: recrystallization from benzene/hexane.[2c]

Handling, Storage, and Precautions: store under an inert atmosphere.

Synthesis of Cyclopentadienyl(triphenylphosphine)cobaltacyclopentadiene Complexes.

The cyclotrimerization of alkynes and co-cyclotrimerization of alkynes with alkenes, nitriles, and heterocumulenes discussed in this section employ cyclopentadienyl(triphenylphosphine)cobaltacyclopentadiene complexes (**2**), either as stoichiometric reagents or as catalysts. They are obtained from the reaction of cyclopentadienylbis(triphenylphosphine)cobalt(I) (**1**) with 2 equiv of an alkyne (eq 1; Table 1). Either symmetrical or unsymmetrical alkynes may be employed but unsymmetrical alkynes often give modest regioselectivity.[2c,2d] The regioisomers are readily separated by chromatography.

Table 1 Formation of Cobaltacyclopentadiene Complexes from 2 Equiv of Alkyne

Cpd	R^1	R^2	R^1	R^2	Yield
(2a)	Ph	Ph	Ph	Ph	88%
(2b)	CO_2Me	CO_2Me	CO_2Me	CO_2Me	14%
(2c)	CH_2OMe	CH_2OMe	CH_2OMe	CH_2OMe	36%
(2d)	Ph	CO_2Me	Ph	CO_2Me	29%
(2dϕ)	Ph	CO_2Me	CO_2Me	Ph	26%

Significantly, two different alkynes may be incorporated into the metallacycle by employing a stepwise addition of alkyne to the cobalt complex (eq 2; Table 2).[2d] Here too, regioselectivity is often modest with unsymmetrical alkynes.

Table 2 Formation of Cobaltacyclopentadiene Complexes by Sequential Addition of Two Different Alkynes

Cpd	R^1	R^2	R^3	R^4	Yield
(4a)	Ph	Ph	Me	Ph	67%
(4b)	Ph	Ph	Me	CO_2Me	48%
(4c)	Ph	Ph	Ph	CO_2Me	5%
(4cϕ)	Ph	Ph	CO_2Me	Ph	43%
(4d)	CO_2Me	Me	Ph	CO_2Me	9%
(4dϕ)	CO_2Me	Me	CO_2Me	Ph	39%

The reaction will tolerate a variety of alkyne substituents including alkyl, aryl, alkoxycarbonyl, and chloro groups, but the presence of cyano or 2-pyridyl substituents leads to the formation of byproducts.[2e,2f] The use of diynes in this reaction in place of monoalkynes gives bicyclic cobaltacyclopentadiene complexes. The yields of the latter reaction depend upon the tether length as well as the presence of substituents on the alkyne or on the tether.[2g,2h] The cobaltacyclopentadiene complexes are generally air-stable materials which will react with a variety of unsaturated organic substrates in stoichiometric or catalytic reactions.

Synthesis of Polysubstituted Unsymmetrical Benzenes, 1,3-Cyclohexadienes, and Heterocycles.

Substituted benzenes such as hexamethylbenzene can be prepared catalytically by treating an excess of the alkyne with the appropriate cobaltacyclopentadiene complex.[3a] The stoichiometric reaction of cobaltacyclopentadiene complexes with alkynes gives polysubstituted benzenes (eq 3; Table 3).[2c,2g,3b,3c]

(3)

(4) (5)

Table 3 Formation of Polysubstituted Benzenes from Cobaltacyclopentadiene Complexes

Cpd	R^1	R^2	R^3	R^4	R^5	R^6	Yield
(5a)	Ph	Ph	Me	Ph	CO_2Me	CO_2Me	13%
(5b)	Ph	Me	Me	Ph	Ph	CO_2Me	59%
(5c)	CO_2Me	Me	CO_2Me	Ph	CO_2Me	CO_2Me	36%

Substituted pyridines have been prepared in similar manner by the stoichiometric reaction of cobaltacyclopentadiene complexes with nitriles.[2h,4a] More importantly, cobaltacyclopentadiene complexes will catalytically form pyridines from 2 equiv of an alkyne and 1 equiv of a nitrile.[4b] For example, acrylonitrile reacts with acetylene in the presence of cyclopentadienyl(triphenylphosphine)cobalta(tetraphenylcyclopentadiene) to form 2-vinylpyridine (eq 4). This catalyst may also be used to prepare substituted pyridines from substituted alkynes in good yield, but the use of unsymmetrical alkynes leads to mixtures of isomeric pyridines. Use of this catalyst, however, has been supplanted by more conveniently prepared catalysts.[4c,4d]

2.3 g 1.2 g (4)

Likewise, the reaction of cobaltacyclopentadienes with heterocumulenes gives heterocycles (eq 5; Table 4).[4a,5a,5b] The reaction of alkynes with carbon disulfide, isothiocyanates, isocyanates, or carbodiimides using cobaltacyclopentadiene complexes affords dithiopyrones, thiopyridones, pyridones, or iminopyridones, respectively, in good yield. Pyridones and iminopyridones could also be prepared with catalytic cyclopentadienyl(triphenylphosphine)cobalta(tetraphenylcyclopentadiene), but unsymmetrical alkynes give mixtures of isomeric heterocycles.[5b]

(4) (6) (5)

Table 4 Formation of Heterocycles from Cobaltacyclopentadiene Complexes

Cpd	R^1	R^2	R^3	R^4	X	Y	Yield
(6a)	Ph	Ph	Ph	Ph	S	S	50%
(6b)	Ph	Ph	Ph	Ph	NPh	S	10%
(6c)	Ph	CO_2Me	CO_2Me	Ph	NPh	O	66%
(6d)	Ph	CO_2Me	CO_2Me	Ph	NMe	O	70%
(6e)	Ph	Me	Me	Ph	NPh	O	81%

Thiophenes and selenophenes have also been prepared by replacing the cobalt atom of the metallacycle with either sulfur or selenium.[2c,3b] Pyrroles may also be prepared using nitroso compounds, but the yields are low.[3b]

1,3-Cyclohexadienes or 1,3-cyclohexadiene-cobalt complexes (which render cyclohexadienes in good yield upon treatment with Ce^{IV}) are obtained in fair to good yield by reaction of the cobaltacyclopentadiene complexes with alkenes.[2h,3b,6a] *Cis*-alkenes give mainly the *endo* isomers similar to the Diels-Alder reaction. The catalytic cooligomerization of alkynes and alkenes gives either cyclic or linear products incorporating varying proportions of alkyne and alkene.[6b,6c]

Cyclopentadienyl(3,5-dimethoxybenzyl)(nitrosyl)(triphenylphosphine)rhenium[1]

(+)-(*S*)

[109283-17-2] · $C_{32}H_{31}NO_3PRe$ · Cyclopentadienyl(3,5-dimethoxybenzyl)(nitrosyl)(triphenylphosphine)rhenium · (MW 694.78) (-)-(*R*)

[109362-39-2]

(reagents for enantioselective synthesis of organic compounds with chiral methyl groups[1])

Physical Data: mp 204-205 °C; [α]21589 ±116° (CH_2Cl_2, *c* 0.3-0.6 mg cm^{-3}).

Solubility: sol CH_2Cl_2, benzene, ether, and THF; slightly sol hexane.

Form Supplied in: bright orange crystals.

Analysis of Reagent Purity: IR, and ^1H, ^{13}C, and ^{31}P NMR spectroscopies, microanalysis, and polarimetry.[1]

Preparative Methods: reaction of the methyl ester (+)-(*S*)-(Cp)Re(NO)(PPh_3)(CO_2Me) (*S*-**1**)[2] with 3,5-dimethoxyphenylmagnesium iodide in toluene at -24 °C gives 3,5-dimethoxybenzoyl complex (+)-(*S*)-(Cp)Re(NO)(PPh_3)(CO(3,5-$(MeO)_2C_6H_3$)) (*S*-**2**; 85%). Refluxing (+)-(*S*)-(**2**) with BH_3.THF or BD_3.THF in THF gives the title reagents (+)-(*S*)-(**3**) or (+)-(*S*)-(**3**)-α-d_2 (95-84%). The opposite enantiomers (-)-(*R*)-(**3**) or (-)-(*R*)-(**3**)-α-d_2 can be similarly made from (-)-(*R*)-(**1**).[1]

Purification: crystallization from benzene/hexane.

Handling, Storage, and Precautions: the solid reagent is stable for days in air. However, it should be prepared, stored, and reacted under a dry nitrogen atmosphere.

Compounds with chiral methyl groups (RCHDT) play important roles in the elucidation of biological and abiological reaction mechanisms.[3] The title compound can be utilized to prepare chiral 3,5-dimethoxytoluene, which can in turn be degraded to $CHDTCO_2H$. The enantiomeric purity of the latter can be assayed enzymatically.[1] Analogs (Cp)Re(NO)(PPh_3)(CH_2R), which can be similarly synthesized, can usually be converted to the corresponding RCHDT compounds.

Cyclopentadienyl(3,5-dimethoxybenzyl)(nitrosyl)(triphenylphosphine)rhenium

In practice, (+)-(*S*)-(**3**)-α-d_2 and $Ph_3C^+PF_6^-$ are allowed to react to give the alkylidene complex (+)-(*S*)-[(Cp)Re(NO)(PPh_3)(=CD(3,5-$(MeO)_2C_6H_3$)]$^+PF_6^-$ ((+)-(*S*)-(**4t**)-α-d_1; 91%) (eq 1). Addition of $NaBT_4$ gives (+)-(*S,S*)-(**3**)-α-d_1t_1 (87%). Subsequent reaction with HBr gives (+)-(*R*)-(Cp)Re(NO)(PPh_3)(Br) ((+)-(*R*)-(**5**); 93%) and (*R*)-dimethoxytoluene-α-d_1t_1 ((*R*)-(**6**); 85%) with retention of configuration at carbon and rhenium. The latter is treated with O_3 to give, after addition of NaOH, the chiral acetate salt (*S*)-CHDT$CO_2^-Na^+$ in 93% ee. The opposite enantiomer, (*R*)-CHDT$CO_2^-Na^+$, is made from (-)-(*R*)-(**3**)-α-d_2 in 86% ee.[1]

(+)-(*S*)-(**3**)-α-d_2 (+)-(*S*)-(**4t**)-α-d_1

(+)-(*S,S*)-(**3**)-α-d_1t_1 (+)-(*R*)-(**5**) (*R*)-(**6**)

(*R*) (1)

Thus the chiral rhenium auxiliary allows the highly stereoselective introduction of all hydrogen isotopes. The generalization of this methodology to other substrates is shown in eq 2. No complications are encountered for cases where R = *n*-alkyl or aryl. The method fails when R is a secondary alkyl group, as the reaction of (Cp)Re(NO)(PPh_3)($CH_2CHR^1R^2$) and $Ph_3C^+PF_6^-$ gives an alkene complex (β-hydride abstraction).[4]

There are several elements of synthetic flexibility. In most cases, both enantiomers of the target can be generated from the *same* enantiomer of the precursor alkyl complex. For example, the hydrogen isotopes can be introduced in different orders. Alternatively, depending upon reaction temperature, either of the two alkylidene complex Re=C geometric isomers (**7k**) and (**7t**) (eq 2) can be generated in >90% isomeric purity. The hydrogen isotope nucleophile attacks from a direction *anti* to the bulky PPh_3 ligand in each case, giving different diastereomers.[3] These in turn give

different product enantiomers. Finally, if a benzylic rhenium complex is treated with a deuterated or tritiated acid in the rhenium-carbon bond-cleavage step, some aryl C-H bonds are also labeled. The optically active bromide complex (+)-(*R*)-(**5**) can be recycled to the methyl complex (+)-(*S*)-(Cp)Re(NO)(PPh_3)(Me) without racemization.[5] The latter is easily converted to the methyl ester (+)-(*S*)-(**1**),[2] or directly to alkyl complexes.[4]

Chloro(cyclopentadienyl)dimethyltitanium[1]

[99279-72-8] · $C_7H_{11}ClTi$ · Chloro(cyclopentadienyl)dimethyltitanium · (MW 178.52)

(heteroannulation agent of alkynylamines;[2] catalyst for metathetic ring-opening of cyclic alkene;[3] thermally stable methylating agent[4])

Physical Data: orange crystals; generally prepared in situ.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 6.48 (Cp) and 1.39 (Me).

Preparative Methods: to a solution of ***Trichloro(cyclopentadienyl)titanium*** (13.7 mmol) in toluene (50 mL) is added slowly (about 10 min) a 2.6M solution of methylmagnesium chloride (1.7 equiv, 23.9 mmol) in THF at rt. The resulting mixture is stirred for 10 min and the precipitate allowed to settle for 1 h. After the solvent is removed in vacuo at 0 °C, the remaining $CpTiMe_2Cl$ is distilled out to a cold trap at -78 °C by warming the flask to room temperature. Yield of $CpTiMe_2Cl$ as orange crystals is 42% based on $CpTiCl_3$. The product is sometimes contaminated with a trace amount of $CpTiMe_3$. This contaminant can be converted to $CpTiMe_2Cl$ by adding the appropriate amount of $CpTiCl_3$ in solution and stirring until equilibration.[4] For the sake of convenience, it is highly recommended that $CpTiMe_2Cl$ be generated in situ by treating $CpTiCl_3$ with 2 equiv of ***Methyllithium*** in THF at -50 °C and stirring the mixture at -50 °C to 0 °C for 1 h.[3]

Handling, Storage, and Precautions: the isolated solid is moisture sensitive and should be stored under an inert atmosphere in a refrigerator.

Heteroannulation.

This reagent generated in situ can be used for the heteroannulation of alkynylamine derivatives through formation of metal-imido complexes (CpTiCl=NR) to give heterocyclic compounds. These reactions are the first examples of intramolecular [2 + 2] cycloaddition involving Group 4 metal-imido complexes (eq 1).[2] It is worth noting that the generation of CpMX=NR complexes from the precursors $CpTiMe_2X$ and H_2NR proceeds rapidly at <=25 °C.

Treatment of the alkynylamine with $CpTiMe_2Cl$ gives the putative azametalletine intermediate with concomitant evolution of methane. Similar intramolecular [2 + 2] reaction can be effected by using catalytic amounts of $CpTiCl_3$[2a,b] and has been applied to the synthesis of an alkaloid.[2b] The intermediate azametalletines can serve as conventional organometallics in electrophilic substitution reactions leading to selective carbon or nitrogen functionalization. Thus the direct trapping of the intermediate with isobutyronitrile followed by protonation with aqueous HCl gives the vinylogous amidine (eq 1).

Metathesis Catalyst.

For the ring-opening metathesis polymerization (ROMP) of cyclic alkenes, $CpTiMe_2Cl$ is an effective initiator (eq 2).[3b] It is also found that $CpTiMe_2Cl$ initiates the polymerization at a lower concentration and lower temperature compared to ***Bis(cyclopentadienyl)dimethyltitanium*** (dimethyltitanocene). Furthermore, the use of THF as solvent has no effect on this polymerization initiator while with other zirconium catalysts (Cp_2ZrMe_2, etc.) initiation activities are inhibited by THF. This substituent-dependent solvent effect is attributed to changes in the relative contributions of nucleophilic and neutral resonance structures. For this polymerization it is presumed to involve the in situ generation of free or complexed titanium alkylidene species.

(2)

Alkylation.

Reactions of $CpTiMe_2Cl$ (which possesses significantly greater thermal stability) with carbonyl compounds proceed similarly to other alkyltitanium reagents (eq 3). That is, in the reaction of a 1:1 ratio of $CpTiMe_2Cl$ and acetophenone, the methyl addition product along with a small amount of the *gem*-dimethylated product, *t*-butylbenzene, is obtained.[4]

1,3-Cyclopentanedione

[3859-41-4] · $C_5H_6O_2$ · 1,3-Cyclopentanedione · (MW 98.01)

(building block for the syntheses of cyclic and polycyclic compounds containing the cyclopentane ring)

Physical Data: mp 149-151 °C.

Solubility: sol H_2O (5.5 g/100 g), DMF (20 g/100 g).

Form Supplied in: yellow solid.

Analysis of Reagent Purity: HPLC.

Preparative Methods: the industrial production of 1,3-cyclopentanedione is based on methyl (*E*)-4-chloro-3-methoxy-2-butenoate.[1] Other syntheses are based on norborn-2-ene[2] or D-glucono-1,5-lactone.[3] Further methods for the laboratory preparation have been reviewed.[4]

Handling, Storage, and Precautions: stable; this compound should be handled in a fume hood.

1,3-Cyclopentanedione has found widespread synthetic applications. These include syntheses of prostaglandins,[5] antibiotics,[6] herbicides,[9] and other biologically active compounds.[7,8,10,11] The synthesis of these compounds required controlled alkylation and selective functionalization of 1,3-cyclopentanediones.

There are three possible alkylation sites of the cyclopentanedione enolate, C-2, C-4, and O. Control of the alkylation site can be achieved by proper selection of reaction conditions, in particular the counter-ion (eq 1).[12-14]

C-2 alkylation is also favored when the *O*-alkylation is reversible, e.g. with Michael acceptors[15] or in the Mannich reaction. In the Pd-catalyzed allylation with allyl acetate, the reaction proceeds further to give 2,2-diallylated product.[16]

Selective alkylation in the C-4 position is achieved by forming the dianion using a strong base,[17] ***n-Butyllithium*** (eq 2).[18]

Most common halogenating agents (***Phosphorus(III) Chloride***, ***Oxalyl Chloride***, ***Phosphorus(III) Bromide***)[19-22] give the 3-halo derivative, but the use of ***N-Bromosuccinimide*** in MeOH allows selective 2-bromination (eq 3).[23]

Condensation with amines allows access to key intermediates in 8-aza steroid syntheses (eq 4).[24]

Related Reagents.

1,3-Cyclohexanedione; ***2-Methyl-1,3-cyclopentanedione***; ***2,4-Pentanedione***.

Cyclopropanone[1]

[5009-27-8] · C_3H_4O · Cyclopropanone · (MW 56.06)

(very reactive three-carbon building block;[1] synthesis of geminally functionalized cyclopropanes[1] and methylenecyclopropanes; ring expansion to β-lactams;[2,3] ring opening to propionic acid derivatives)

Solubility: sol ether, dichloromethane; nucleophilic solvents, e.g. alcohols and water, afford the corresponding adducts (e.g. hemiacetals, hydrates).

Form Supplied in: not commercially available; prepared at low temperature (-50 to -78 °C) in solution (see below) and preferably used directly for further elaboration.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: special apparatus is required to perform the reaction of ketene with diazomethane (eq 1).[4] A solution of ***Diazomethane*** in diethyl ether is added to a solution of ***Ketene*** in dichloromethane at -78 °C at such a rate that the temperature does not rise above -60 °C. The reaction mixture is kept at -50 °C for 35 min. The reaction mixture thus obtained is a solution of cyclopropanone in dichloromethane/diethyl ether (yield 75%). This solution is suitable for further elaboration, viz. addition of nucleophiles. As an example, the addition of glacial acetic acid (1.04 equiv) in dichloromethane, at -50 °C, to the solution of cyclopropanone affords, after evaporation of the solvents at 0 °C, a residual liquid which is distilled in vacuo to give 1-acetoxycyclopropanol (bp 26-28 °C/0.5 mmHg) (eq 2) as a storable source of cyclopropanone.[2]

(1)

Handling, Storage, and Precautions: in situ preparation in solution at -78 °C as above, using dry solvents (inert atmosphere); the presence of any nucleophilic reagent is incompatible with this preparation; the storage lifetime of the solution of cyclopropanone at -78 °C is very limited as polymerization occurs under the influence of traces of water;[5] inhibition of polymerization occurs with moisture scavengers.[6] This reagent should be handled in a fume hood.

Adduct Formation.

The majority of reactions performed with cyclopropanones originate from the use of cyclopropanone adducts which are in equilibrium with cyclopropanone (eq 3). Such adducts include ***1-Ethoxycyclopropanol*** (**1**)[7] and 1-acetoxycyclopropanol (**2**)[8] (eq 4). Also the magnesium salt of (**1**), i.e. adduct (**3**),[9] and 1-piperidino-1-trimethylsilyloxycyclopropane (**4**) and its free alcohol (**5**)[10,11] have been reported as cyclopropanone sources.

Addition of water,[1] methanol,[1] ethanol,[1] acetic acid,[4,6,8] hydrogen chloride,[6] and hydrogen cyanide[12] to in situ prepared cyclopropanone affords the corresponding hydrate (eq 5), hemiacetal (eq 6), hemiacylal (eq 2), chlorohydrate (eq 7), and cyanohydrin (eq 8), respectively.

(5)

(6)

(7)

(8)

The addition of amines to cyclopropanone is more complex and is dependent upon the type of amine and the number of molar equivalents of the amine used. The reaction of cyclopropanone with 0.5 equiv ammonia afforded the bis(cyclopropyl)amine derivative as the major product, in addition to the tris(cyclopropyl)amine derivative as a minor product (eq 9).[4] Monoadducts with primary amines were obtained at -78 °C (eq 10),[13] while the same reaction at -30 °C with methylamine produced the bis(cyclopropyl) derivative, which cyclocondensed with cyclopropanone hydrate to form tris-spiro adducts (eq 11).[13] Aniline reacted with cyclopropanone to give mono- and bisadducts,[13] while ***N,N-Dimethylhydrazine*** at elevated temperature afforded the monoadduct which could be dehydrated to cyclopropanone *N*,*N*-dimethylhydrazone (eq 12).[14] Secondary amines,[15,16] such as dimethylamine, produced cyclopropanone monoadducts provided that an inverse addition of cyclopropanone was performed (eq 13).[4] Further addition of the secondary amine produced the corresponding aminals.[15,16]

(13)

Sulfur nucleophiles, such as hydrogen sulfide, behave like amines in that they afford bis(cyclopropyl) sulfides which serve as a source of methylenethiirane via flash pyrolysis of a bis-spiro carbonate (eq 14).[17] Thiols added smoothly to cyclopropanone to give the monoadducts (eq 15).[18]
