Synthesis of β-Lactams.

Sodium Azide in acetone converted cyclopropanone into 1-azidocyclopropanol, which suffered spontaneous rearrangement to azetidin-2-one in variable yields (eq 16).[19,20] A similar rearrangement is observed with the cyclopropanone adduct of *N*-*t*-butyl-*O*-benzoylhydroxylamine to form 1-*t*-butylazetidin-2-one (eq 17).[2] A more general approach to 1-substituted azetidin-2-ones consisted of the addition of primary amines to cyclopropanone at -78 °C, resulting in the monoadducts which were *N*-chlorinated using ***t-Butyl Hypochlorite*** and subsequently rearranged under the influence of ***Silver(I) Nitrate*** to give the ring expanded azetidine derivatives (eq 18).[2] Aliphatic

as well as α-amino carboxylic esters have been converted in this way into a wide range of azetidin-2-ones.[2,21-23]

(16)

(17)

(18)

Addition of Carbon Nucleophiles.

The addition of carbon nucleophiles to cyclopropanone may be accomplished by reactions with 1-ethoxycyclopropanol (**1**)[7,19,20,24-26] or its magnesium salt (**3**).[27] Organolithium[9,27-29] as well as organomagnesium reagents[7,19,20,24-26] add across the carbonyl function of cyclopropanone to afford the corresponding cyclopropanols (eq 19). Moderate yields of alkylidenecyclopropanes are obtained by condensation of the cyclopropanone precursors

with alkylidenephosphoranes (eqs 20,21).[27,30]

(19)

(20)

(21)

Ring Opening.

Addition of alcohols to cyclopropanone gives hemiacetals which are opened in a Favorskii-like way to afford propionates (eq 22).[27]

(22)

Polymerization.

Polymerization of a solution of cyclopropanone takes place at temperatures above 0 °C and is initiated by traces of water (eq 23).[1,5,34] The same polymers are obtained by thermolysis.[35]

(23)

Natural Product Synthesis.

The cyanohydrin of cyclopropanone was converted into cleonine (**6**) by a sequence of reactions involving protection of the alcohol, aldehyde formation, and Strecker reaction of the latter to give the α-amino acid cleonine (eq 24).[31] The ammonia monoadduct of cyclopropanone is stable as its hydrochloride salt, which is further elaborated to coprine (**7**) (eq 25).[32,33]

(24)

(6)

Related Reagents.

Cyclobutanone; ***Cyclopropenone 1,3-Propanediyl Acetal***; ***6,6-Dimethyl-5,7-dioxaspiro[2.5]octane-4,8-dione***; ***1-Ethoxycyclopropanol***; ***Methylenecyclopropane***; ***1-(Tetrahydropyranyloxy)cyclopropanecarbaldehyde***.

Cyclopropenone 1,3-Propanediyl Acetal[1]

[60935-21-9] · $C_6H_8O_2$ · Cyclopropenone 1,3-Propanediyl Acetal · (MW 112.12)

(cyclopropenone synthesis;[4] vinylcarbene formation;[1] acceptor of organometallic reagents;[13] dienophile[15])

Physical Data: bp 30-35 °C/1.25 mmHg.

Solubility: insol H_2O.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: GLC, NMR.

Preparative Methods: the best current preparation of cyclopropenone acetals involves the reaction of 1,3-dichloroacetone 1,3-propanediyl acetal with ***Sodium Amide*** in a liq. NH_3/Et_2O mixture.[2] The latter acetal can be prepared in high yield from commercially available 1,3-dichloroacetone and 1,3-propanediol. This method is superior to the previous method which employs the less convenient reagents KNH_2 and 1-chloro-3-bromoacetone 1,3-propanediyl acetal.[3]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: cyclopropenone acetals may be stored in a refrigerator.

Cyclopropenone Synthesis.

Alkyl-, aryl-, and vinyl-substituted cyclopropenones have been prepared by the reaction of a metalated cyclopropenone acetal with an electrophile followed by acid hydrolysis of the acetal.[4] Deprotonation of the vinylic proton of the cyclopropenone acetal with ***n-Butyllithium*** or ***Sodium Amide*** afforded the lithium or sodium salt of the cyclopropenone acetals. The lithium salt is treated with 0.5 equiv of ***Zinc Chloride*** to obtain the corresponding zinc salt. The sodium and lithium salts are useful for the synthesis of alkyl- and hydroxymethyl-substituted cyclopropenone acetals by their reaction with an alkyl halide or a carbonyl compound, respectively. Acid hydrolysis of the acetal affords the corresponding cyclopropenone in good yield (eq 1). This reaction is effective for the synthesis of biologically active

cyclopropenones, e.g. penitricin (R^1, R^2 = H) and its congeners.[5]

(1)

The zinc salt of cyclopropenone acetal is useful for the synthesis of vinyl- and aryl-substituted cyclopropenones. Thus the reaction of the zinc salt with vinyl iodide, vinyl triflate, and aryl iodide in the presence of a catalytic amount of ***Tetrakis(triphenylphosphine)palladium(0)*** affords vinyl- and aryl-substituted cyclopropenones after acid hydrolysis (eq 2).

(2)

Disubstituted cyclopropenone acetals are synthesized by repetition of the metalation/alkylation sequence on a monosubstituted cyclopropenone acetal.

Vinylcarbene Precursors.

Thermolysis of cyclopropenone acetal generates a singlet vinylcarbene, which undergoes [2 + 1] and [3 + 2] cycloaddition reactions with electron deficient alkenes. The vinylcarbene, which is generated from the cyclopropenone acetal at 70-120 °C, reacts with an alkene bearing a single electron-withdrawing group in a [2 + 1] manner to afford the cyclopropane derivative.[6] The reaction takes place through an *endo* transition state, and gives predominantly 1,2-*cis*-substituted cyclopropanes (eq 3). The ketene acetal of the product can be easily hydrolyzed to the corresponding ester with aqueous acid. On the contrary, the reaction of cyclopropenone acetal with an alkene bearing geminal electron-withdrawing groups affords exclusively the cyclopentenone acetal derivative by a single-electron transfer pathway (eq 3).[7]

(3)

In contrast to the thermal reaction, Ni^0-catalyzed [1 + 2] cycloaddition of the cyclopropenone dimethyl acetal with methyl acrylate mainly gives thermodynamically stable 1,2-*trans*-disubstituted cyclopropane derivatives.[8] The reaction of the cyclopropenone dimethyl acetal with dimethyl fumarate or maleate in the presence of a catalytic amount of ***Bis(1,5-cyclooctadiene)nickel(0)*** affords *trans*-cyclopropane derivatives with respect to the ester groups (eq 4). The loss of the stereospecificity of this reaction is due to a stepwise cycloaddition of a nickel vinylcarbene complex with an alkane.

(4)

Treatment of Eschenmoser's α-pyrone with the cyclopropenone acetal at 75 °C afforded the [4 + 3] cycloaddition compound as a single product, which is an important synthetic precursor of colchicine (eq 5).[9] Participation of the cyclopropenone acetal in a competing [4 + 2] Diels-Alder reaction with the α-pyrone is decelerated by unfavorable steric interactions of the acetal group that hinder the *exo* as well as the *endo* transition state required for the [4 + 2] cycloaddition reaction (see below).

(5)

The vinylcarbene also reacts with carbonyl compounds to give γ-lactone acetals, which hydrolyze to the corresponding γ-lactone or furan depending on the substituents (eq 6).[10]

(6)

Substituted cyclopropenone acetals are a good precursor of substituted singlet vinylcarbenes. The substituted vinylcarbenes are formed regio- and stereoselectively, and undergo regioselective [3 + 2] cycloaddition to electron deficient alkanes to give a variety of cyclopentenone acetals.[11] Phenylthio and ester groups connected to the alkenic

carbon effect highly regioselective vinylcarbene formation below rt, permitting the [3 + 2] cycloaddition to take place under extremely mild conditions (eq 7).

In addition to cycloaddition chemistry, the vinylcarbene undergoes C-H and O-H bond insertion reactions with acidic hydrogens. Thus ***Methyl Propiolate*** and methanol react with the vinylcarbene to afford an acetal of a vinyl ethynyl ketone and an orthoester of an α,β-unsaturated ester (eq 8).[12]

Acceptor of Organometallic Reagents.

Cyclopropenone acetals react with organocopper reagents to produce the copper salt of the cyclopropanone acetal, which serves as a synthetic equivalent of the inaccessible cyclopropanone enolate and reacts with a variety of electrophiles to afford substituted cyclopropanone acetals.[13] Addition of vinylcuprate to the cyclopropenone acetal followed by trapping with water, alkyl halide, and vinyl iodide in the presence of Pd^0 catalyst affords the corresponding vinyl-substituted cyclopropanone acetals (eq 9). These cyclopropane derivatives can be thermally transformed to cyclopentenone acetal, divinyl ketone acetal, and cycloheptadienone acetal by vinylcyclopropane rearrangement, 1,3-

sigmatropic rearrangement, and divinylcyclopropane rearrangement, respectively (eq 9).

Regio- and stereoselective carbocupration of a 2-substituted cyclopropenone acetal derived from a chiral 2,4-pentandiol can be used for the stereoselective synthesis of a quaternary carbon center.[14] Thus the addition of dimethylcuprate to the ethyl substituted cyclopropenone acetal followed by trapping of the resulting cyclopropylcuprate with benzoyl chloride in the presence of a Pd^0 catalyst affords the cyclopropyl ketone derivative as a single isomer. The ketone is transformed into the γ-keto acid by successive treatment with aqueous HCl, PCC, and K_2CO_3 (eq 10).

Dienophiles.

A variety of dienes, including electron rich, neutral, and electron deficient ones, react with cyclopropenone acetals under thermal or high pressure conditions.[15] The reaction proceeds through a sterically less hindered *exo* transition state. The utility of this reaction is exemplified by the synthesis of tropone derivatives. The reaction of a cyclopropenone acetal with methyl 4-methoxy-1,3-butadiene-1-carboxylate at rt affords the [4 + 2] cycloaddition adduct as a single stereoisomer that possesses the *trans* relative configuration. Treatment of the cycloadduct with a strong base (***Potassium t-Butoxide***, 25 °C) affords the 3-methoxycarbonyltroponone acetal through an elimination of methanol followed by a rearrangement of the norcaradiene intermediate. Hydrolysis of the troponone acetal provides 3-methoxycarbonylcycloheptatrienone in a good overall yield (eq 11).

Oligomerization and Polymerization.

Thermal or Pd^0 catalyzed reaction of a cyclopropenone acetal affords a dimer, which is thermally converted to a quinone diacetal derivative (eq 12).

Cyclopropenone acetals undergo ring-opening polymerization under cationic conditions.[16] Among a variety of initiators examined, ***Bromine*** is found to be a good initiator and gives polymers whose M_n values are in the region of 10 000.

Methylenecyclopropane Formation and [3 + 2] Cycloadditions via Trimethylenemethane.

Base-catalyzed isomerization of an alkyl-substituted cyclopropenone acetal gives the alkylidenecyclopropanone acetal, which is utilized for [3 + 2] cycloaddition reactions through a trimethylenemethane intermediate.[17] Upon thermolysis, the alkylidenecyclopropanone acetal generates a dipolar trimethylenemethane, which reacts with an electron-deficient alkene or a carbonyl compound to afford five-membered carbo- and heterocycles (eq 13). This reaction is also useful for the preparation of functionalized buckminsterfullerenes (C_{60}).[18]

Cyclopropyldiphenylsulfonium Tetrafluoroborate[1]

[33462-81-6] · $C_{15}H_{15}BF_4S$ · Cyclopropyldiphenylsulfonium Tetrafluoroborate · (MW 314.15)

(versatile C_3 building block; reagent for the spiroannulation of carbonyl compounds)

Physical Data: mp 136-138 °C.

Solubility: used as a suspension in THF, DME, DMSO, MeCN.

Form Supplied in: white solid; commercially available.

Preparative Methods: see eq 1.[2]

Introduction.

Cyclopropyldiphenylsulfonium tetrafluoroborate is primarily used for the generation of the corresponding ylide which is synthetically useful. The ylide can be used in a variety of transformations including synthesis of cyclobutanones, γ-butyrolactones, cyclopentanones, and spiropentanes.

Generation of Diphenylsulfonium Cyclopropylide.

The ylide can be formed by deprotonation of the sulfonium salt under reversible or irreversible conditions. Treatment with dimsylsodium in DME at -40 °C irreversibly generates the ylide.[3] Low temperatures are required in order to avoid decomposition of the ylide to cyclopropyl phenyl sulfide and benzyne. Generation of the ylide under reversible conditions with powdered ***Potassium Hydroxide*** in DMSO at room temperature[2b] minimizes thermal decomposition because the equilibrium between the sulfonium salt and ylide favors the salt.

Formation of Spiropentanes and Oxaspiropentanes.

Conjugate addition of diphenylsulfonium cyclopropylide to α,β-unsaturated esters and ketones affords spiropentanes (eq 2).[4]

(2)

Analogous to other sulfur ylides (see ***Dimethylsulfonium Methylide***), diphenylsulfonium cyclopropylide reacts with saturated aldehydes and ketones to provide epoxide-type products known as oxaspiropentanes (eq 3).[5] The reaction is general in scope and works well even for readily enolizable ketones, though exceptions are known.[5,6] The good stereoselectivity in reactions with cyclic ketone partners, such as cyclohexanone, results from attack of the ylide from the less hindered equatorial direction. When epimerization of a diastereomeric mixture of ketones occurs under the reaction conditions, formation of one oxaspiropentane can result. This results because epimerization α to the ketone occurs faster than addition of the ylide to the ketone, and because one of the epimers reacts at a faster rate than the other.[1e] Isolated alkenes, esters, alcohols, ethers, and epoxides are some of the functional groups that can be tolerated under the reaction conditions. The ylide is chemoselective for saturated ketones over conjugated enones.[1e]

(3)

The chemical versatility of these highly reactive oxaspiropentanes makes them useful building blocks. For example, such highly strained epoxides are very labile towards acid catalyzed rearrangements. This reactivity can be exploited to produce cyclobutanones (eq 3) or vinylcyclopropanol products (see below). In cases where the oxaspiropentanes possess substituents capable of stabilizing a carbonium ion, rearrangement to the cyclobutanone usually occurs under the reaction conditions.[5] In other cases the cyclobutanone can be obtained directly by acidic work-up of the ylide reaction. In general, the major diastereomer arises from inversion of configuration at the migration terminus, which is consistent with a concerted mechanism.[1e,7] If the cyclobutanone of opposite configuration is desired, an alternate procedure can be adopted. Opening of the oxaspiropentane with phenylselenide anion gives the hydroxyselenide, which is directly subjected to oxidation with ***m-Chloroperbenzoic Acid***. Under the reaction conditions, ionization of the selenoxide occurs, leading to rearrangement. The overall process involves two inversions, leading to the stereoreversed cyclobutanone.[8] Such stereoreversed cyclobutanones can be more efficiently prepared from the starting ketones using the alternative reagent 1-lithiocyclopropyl phenyl sulfide.[9] The ring strained spirocyclobutanones are useful for further structural elaborations.[10] Treatment with basic ***Hydrogen Peroxide*** affords γ-butyrolactones (via ring expansion with migration of the more substituted carbon),[11] and fused cyclopentenones by treatment of such γ-butyrolactones with acid (eq 4).[12] Direct transformation of vinylcyclobutanones to fused cyclopentenones can be effected by treatment with acid.[13] Cyclic enol esters can be formed via α-formylation and acid promoted fragmentation.[14] Synthetic elaboration of cyclobutanones via alkylation and subsequent cleavage to release ring strain results in the selective transformation of the original carbonyl group into a variety of substitution patterns. These include geminal dialkylation and reductive alkylation of the carbonyl group.[15-17]

Transformation of Oxaspiropentanes to Vinylcyclopropanol Derivatives.

Treatment of oxaspiropentanes with strong base affords vinylcyclopropanols via a *cis,syn* elimination (eq 5). The regiochemistry of ring opening is dependent on the nature of the base, solvent, and factors determining whether the reaction is under thermodynamic or kinetic control.[18] If the oxaspiropentane does not possess a suitably placed hydrogen for base abstraction, treatment with sodium phenylselenide in a nonprotic solvent at rt can afford the β-hydroxy selenide which eliminates to the vinylcyclopropanol in situ (eq 6).[19] Thus the mechanism has switched from a *cis,syn* to a *trans,anti* elimination. Solvent plays an important role in this reaction; switching the solvent to ethanol affords the hydroxy selenide, an intermediate in the formation of stereoreversed cyclobutanones (see above). Attempts to effect a selenoxide elimination (oxidation of the selenide) often affords the cyclobutanone product.[8]

(5)

(6)

Vinylcyclopropanol silyl ethers are obtained by quenching the alkoxide formed under strong base conditions with ***Chlorotrimethylsilane***. This composite functional group can undergo thermal rearrangements to cyclopentane trimethylsilyl enol ethers.[5,20] This rearrangement is accelerated by the presence of the siloxy group. The enol silyl ether produced can be further alkylated to provide substituted cyclopentanones. This sequence results in the regiospecific annulation of a cyclopentanone ring to a carbonyl group. In addition, vinylcyclopropanol silyl ethers can undergo ring expansion to cyclobutanones upon treatment with electrophiles.[17b,17c,21] Use of vinylcyclopropanol silyl ethers as cyclization terminators can result in good yields of six- to eight-membered rings (eq 7).[22] The cyclopropyl ring mediates the delocalization of the lone pair on the oxygen into the alkene, enhancing the alkene nucleophilicity, and the reaction is terminated effectively by rearrangement to the cyclobutanone.

(7)

Homologs of Cyclopropyldiphenylsulfonium

Tetrafluoroborate.

2-Methylcyclopropyldiphenylsulfonium tetrafluoroborate has also been prepared and is formed as a mixture of *trans* (major) and *cis* isomers (eq 8). The stereochemical integrity of the ylide derived from this mixture of sulfonium salts is variable, depending on the conditions under which it is generated. The reactivity profile of the ylide is the same as the parent, but the presence of an additional chiral center often leads to a mixture of stereoisomers.[23]

Cyclopropylidenetriphenylphosphorane

[14633-95-5] · $C_{21}H_{19}P$ · Cyclopropylidenetriphenylphosphorane · (MW 302.36)

(phosphorane for cyclopropylidenation of aldehydes and ketones;[1] utilized in cyclobutanone synthesis;[2] reagent applied to polyspirane synthesis[3])

Physical Data: mp 103 °C (dec); *d* 1.21 g cm^{-3}.

Solubility: sol THF, DME, DMSO.

Analysis of Reagent Purity: proton and heteronuclear NMR and X-ray data have been reported.[4]

Preparative Methods: see ***Cyclopropyltriphenylphosphonium Bromide***.

Handling, Storage, and Precautions: cyclopropylidenetriphenylphosphorane is a fairly stable ylide, capable of withstanding elevated reaction temperatures of approximately 60-65 °C. The ylide is sensitive to moisture and air and should be freshly prepared under anhydrous conditions under an inert atmosphere.

Cyclopropylidenation.

The most frequent application of cyclopropylidenetriphenylphosphorane involves the cyclopropylidenation of aldehydes and ketones. The references cited in the Ylide Generation: Cyclopropylidenetriphenylphosphorane section under the reagent ***Cyclopropyltriphenylphosphonium Bromide*** provide examples of alkene formation. In addition, further examples of alkenation are available,[5] including an application to propellane synthesis,[1a] generation of tetrasubstituted alkenes (reaction with ketones),[6] and synthesis of α,β-unsaturated aldehydes and ketones incorporating a cyclopropylidene unit (eq 1).[7]

(1)

Cyclobutanone Synthesis.

Coupling cyclopropylidenetriphenylphosphorane with an aldehyde and subsequent oxidation with ***m-Chloroperbenzoic Acid*** produces a spiro epoxycyclopropane which rearranges to a cyclobutanone (eq 2).[2,8]

(2)

Cyclopropylidenetriphenylphosphorane as a Nucleophile.

Cyclopropylidenetriphenylphosphorane adds to polarized alkenes to generate spiro compounds incorporating two cyclopropyl rings.[9] In addition, the ylide reacts with epoxides to yield 1-substituted cyclopropylphosphonium salts and with nitrile oxides to yield oxime substituted phosphonium salts (MeI workup) or spiro compounds incorporating a cyclopropyl ring on an azirine ring (thermal workup).[10] Cyclopropylidenetriphenylphosphorane reacts with CO_2 to generate the carboxylate phosphonium salt which decomposes under aqueous base and acid workup to cyclopropanecarboxylic acid.[11]

Cope Rearrangement.

Cyclopropylidenetriphenylphosphorane provides a unique substrate for studying the Cope rearrangement

(eq 3).[12]

(3)

Diels-Alder Reaction.

Cyclopropylidenetriphenylphosphorane reacts with α,β-unsaturated aldehydes to generate dienes incorporating a cyclopropylidene unit. Subsequent reaction of these unstable dienes with dienophiles results in cyclopropyl substituted cyclohexenes (eq 4).[13]

(4)

Polyspiranes.

Research in the synthesis of polyspirane systems has applied cyclopropylidenetriphenylphosphorane to the construction of these complex molecules.[3]

Cyclopropyllithium[1]

[3002-94-6] · C_3H_5Li · Cyclopropyllithium · (MW 48.02)

(organolithium reagent used in the synthesis of a variety of cyclopropyl derivatives,[2] five-membered ring nitrogen heterocycles via cyclopropylimine rearrangement,[3] and cyclopentenes via vinylcyclopropane rearrangement[4])

Alternate Name: lithiocyclopropane.

Solubility: sol pentane and ether.

Form Supplied in: solution in pentane or ether.

Analysis of Reagent Purity: cyclopropyllithium solutions should be titrated before use by one of the standard titration methods,[5] e.g. Gilman's double titration.[6]

Preparative Methods: cyclopropyllithium is usually prepared as a solution in ether by reacting highly dispersed ***Lithium*** with cyclopropyl chloride[7] or bromide.[8] The reaction can also be conducted in pentane.[2] Transmetalation methods have also been described.[7b,9]

Handling, Storage, and Precautions: solutions of organolithium reagents are highly flammable and moisture sensitive. Appropriate precautions are recommended. Use in a fume hood. Stability of cyclopropyllithium in ether is similar to that of ***n-Butyllithium***, whereas in THF its stability is greater.[8a]

Synthesis of Cyclopropyl Derivatives.

Cyclopropyllithium reacts readily with common electrophiles to form a variety of compounds containing a cyclopropyl group. Thus reaction with aldehydes[10] and ketones[2,11] leads to secondary and tertiary alcohols respectively (eqs 1 and 2).[11a]

Two- and three-carbon homologations have been realized by using ethylene oxide[7a] and oxetane[8b] as electrophiles. Reaction with vinyl-substituted epoxides (eq 3) constitutes an example of four-carbon homologation.[12]

Cyclopropyllithium condenses in a typical fashion with carboxylic acids to give cyclopropyl ketones,[13] and a controlled reaction with ***N-Formylpiperidine*** leads to cyclopropylcarbaldehyde in 75% yield.[14] Cyclopropyllithium also adds to carbon-nitrogen multiple bonds. Thus addition to imines leads to amines[15] while reaction with cyanopyridines yields ketones in good yields (eq 4).[16]

Cyclopropyllithium has also been used in the synthesis of cyclopropylpyridines,[12] ***Cyclopropyltriphenylphosphonium Bromide***,[18] cyclopropyl phosphines,[19] silanes[19,20] and organogermanium compounds.[21]

Synthesis of Five-Membered Ring Nitrogen Heterocycles.

Addition of cyclopropyllithium to α-piperidinocyclopropanenitriles leads to the intermediate imines which subsequently undergo acid catalyzed rearrangement to form nitrogen heterocycles in moderate yields. Different products can be obtained depending on the kind of acid used (eq 5).[3,22]

(5)

Synthesis of Cyclopentenes via Thermal Rearrangement of Vinylcyclopropanes.

A mixed cuprate prepared in situ from cyclopropyllithium and PhSCu readily displaces iodide in β-iodocyclopentenones to give the substitution products in high yields. The latter undergo thermal ring expansion, providing an interesting method for cyclopentene annulation (eq 6).[4]

(6)

Related Reagents.

Cis and *trans* 1-lithio-2-methoxycyclopropanes (**1**) were prepared by lithium-halogen exchange reaction from corresponding bromides and condensed with aldehydes to give the addition products which readily undergo acid-catalyzed rearrangement to β,γ-unsaturated aldehydes.[23]

(1)

(2)

(3)

Both 1-lithio-1-methyl-2-vinylcyclopropanes (**2**) and 1-lithio-2-vinylcyclopropanes (**3**) (*cis* and *trans*) were prepared in similar fashion and subsequently applied to cycloheptane annulations.[24,25] These and other substituted cyclopropyllithium reagents are configurationally stable.[26]

See also ***1-Bromo-1-lithio-2-phenylcyclopropane***; ***Cyclopropylmagnesium Bromide***; ***1-Lithio-1-methoxycyclopropane***; ***Lithium Cyclopropyl(phenylthio)cuprate***.

Cyclopropylmagnesium Bromide[1]

[23179-80-4] · C_3H_5BrMg · Cyclopropylmagnesium Bromide · (MW 145.30)

(cyclopropyl Grignard reagent used in the synthesis of a variety of cyclopropyl derivatives,[2] homoallylic bromides,[3] and dienes[4])

Solubility: sol ethereal solvents.

Form Supplied in: solution in ether or THF.

Analysis of Reagent Purity: it is highly recommended to analyze every batch of cyclopropylmagnesium bromide by using one of the standard titration methods.[5]

Preparative Methods: cyclopropylmagnesium bromide is best prepared by treating magnesium turnings with commercially available cyclopropyl bromide in THF.[6a] Yields usually range from 23 to 43%. Reaction in ether gives even lower yields,[6] mainly due to the extensive disproportionation of cyclopropyl radicals on the magnesium surface.[6a]

Handling, Storage, and Precautions: Grignard reagent solutions are highly flammable and moisture sensitive.

Synthesis of Cyclopropyl Derivatives.

Cyclopropylmagnesium bromide reacts smoothly with aldehydes and ketones to give secondary[2] and tertiary[7] alcohols, respectively (eqs 1 and 2). Controlled reaction with ***N,N-Dimethylformamide*** gives rise to the formation of cyclopropanecarbaldehyde in good yield (eq 3).[8]

(1)

(2)

(3)

Direct oxidation of cyclopropylmagnesium bromide with molecular oxygen affords the ellusive cyclopropanol, albeit in low yield (eq 4).[2] Conversion to cyclopropylmercury(II) bromide followed by reaction with aqueous KI-I_2 leads to cyclopropyl iodide (eq 5).[2]

(4)

(5)

Cyclopropylmagnesium bromide couples, in the presence of a nickel catalyst, with aryl and vinyl bromides to give the corresponding aryl- and vinylcyclopropanes (eqs 6 and 7).[9]

(6)

(7)

dppp = 1,3-bis(diphenylphosphino)propane

Other interesting synthetic applications of cyclopropylmagnesium bromide include formation of cyclopropyl ketones

from acyl halides (via dicyclopropylcadmium),[10] conversion of optically pure *p*-tolylsulfinate to cyclopropyl tolyl sulfoxide with virtually complete inversion of configuration at sulfur,[11] and coupling with methyl α-chloro-*N*-benzyloxycarbonylglycinate.[12]

Synthesis of Homoallylic Bromides.

Cyclopropylalkyl alcohols, prepared from cyclopropylmagnesium bromide and appropriate carbonyl compounds, readily rearrange to homoallylic bromides[3,13] upon treatment with ***Hydrobromic Acid***. The entire conversion can be conducted without isolation of the intermediate carbinol (eq 8).[14]

Synthesis of Dienes from Aromatic Dithioacetals.

Cyclopropylmagnesium bromide reacts with aromatic dithioacetals in boiling benzene or toluene, in the presence of a nickel catalyst, to give aryl-substituted dienes in good yields (eq 9).[4]

Related Reagents.

Cyclopropyllithium.

Cyclopropyltriphenylphosphonium Bromide

[14114-05-7] · $C_{21}H_{20}BrP$ · Cyclopropyltriphenylphosphonium Bromide · (MW 383.27)

(phosphonium salt used to generate phosphorane;[1] behaves as an electrophile and generates an ylide by ring opening if reacted with a nucleophile;[2] starting material for other functionalized phosphonium salts[3])

Physical Data: mp 183-185 °C (commercial suppliers), mp 189-190 °C when recrystallized from EtOAc.[4]

Solubility: normally used in THF, DME, or DMF, although solubility is reported to be poor.[1b]

Form Supplied in: cream-colored or white powder or crystalline solid, available from various suppliers.

Analysis of Reagent Purity: proton and heteronuclear NMR and IR data have been reported.[5]

Handling, Storage, and Precautions: cyclopropyltriphenylphosphonium bromide exhibits long-term stability and should be protected from moisture in a well-sealed vial. Present data suggest potential skin irritation if contacted and inhalation of the dust may be irritating to the respiratory system.

Ylide Generation: Cyclopropylidenetriphenylphosphorane.

A significant application of cyclopropyltriphenylphosphonium bromide involves the generation of cyclopropylidenetriphenylphosphorane[1a] (for reactions involving this ylide, see ***Cyclopropylidenetriphenylphosphorane***). Ylide generation generally involves an aprotic solvent like THF[6] or DME[7] and ***n-Butyllithium*** as a base. Alkene generation under these reaction conditions often results in poor yields. Subsequent investigations have suggested that the use of a phase transfer catalyst in cooperation with ***Sodium Hydride*** in THF results in a substantial improvement in yield (Table 1 and eq 1).[1b] NaH in DMSO and ***Sodium Hexamethyldisilazide*** in Et_2O have also been utilized in ylide formation.[8] Additional work suggests that an alternate synthetic approach involving 3-bromopropyltriphenylphosphonium bromide and 2 equiv of base (NaH in DME) generates cyclopropyltriphenylphosphonium bromide in situ and results in equivalent or better yields of alkene product.[9]

Table 1

Base	Solvent	Additive	Yield
NaH	DMF	None	Nr, dec.
NaH	DMF	18-Crown-6	13 17%
NaH	THF	18-Crown-6	Nr, dec.
NaH	THF	10 mol % TDA-1	83%
NaH	THF	None	Nr, dec.

Cyclopropyltriphenylphosphonium Bromide as an Electrophile.

The phosphonium moiety can stabilize a negative charge on the adjacent carbon atom as an ylide. This stabilization manifests itself as an intrinsic electrophilicity at the remaining two carbon atoms of the cyclopropyl ring. The anion of salicylaldehyde reacts with cyclopropyltriphenylphosphonium bromide at 160 °C to yield a mixture of two products and 75% recovered starting material (eq 2),[4] presumably through a nucleophilic opening of the cyclopropyl ring.

A synthesis of pyrrolizidines provides another application of cyclopropyltriphenylphosphonium bromide as an electrophile. Succinimide anion opens the cyclopropyl ring and the ylide generated cyclizes to yield the bicyclic product after hydrolysis (eq 3).[2] Cyclopropyltriphenylphosphonium bromide can be reduced by ***Lithium Aluminum Hydride*** to yield cyclopropyldiphenylphosphine.[4]

(3)

Investigations have generated two analogs of cyclopropyltriphenylphosphonium bromide designed to improve the yield of cyclopropyl ring opening by nucleophiles. 1-(Ethoxycarbonyl)cyclopropyltriphenylphosphonium tetrafluoroborate (**1**) undergoes facile cyclopropyl ring opening by β-keto ester carbanions (eq 4), salicylaldehyde anion (eq 5), and pyrrole-2-carbaldehyde anion (eq 6).[3a]

(1)

(4)

(5)

(6)

1-(Phenylthio)cyclopropyltriphenylphosphonium tetrafluoroborate experiences facile cyclopropyl ring opening by β-keto ester carbanions and the subsequent ylide is sufficiently reactive to generate a vinyl sulfide with the ketone moiety.[3b] Acid-catalyzed hydrolysis results in cyclopentanone products in 75-80% yield.

Decacarbonyldimanganese

$Mn_2(CO)_{10}$

[10170-69-2] · $C_{10}Mn_2O_{10}$ · Decacarbonyldimanganese · (MW 389.98)

(source of a wide range of manganese complexes; catalyst or cocatalyst for isomerization, oligomerization, radical coupling, etc.)

Alternate Names: dimanganese decacarbonyl; manganese carbonyl.

Physical Data: mp 154 °C; sublimes 80 °C/0.1 mmHg, 70 °C/0.05 mmHg.

Solubility: insol H_2O; mod sol common org solvents.

Form Supplied in: yellow crystalline solid; widely available but expensive.

Preparative Method: the most convenient laboratory synthesis is from tricarbonyl(η^5-methylcyclopentadienyl)manganese by reduction with sodium/naphthalene under carbon monoxide to yield ***Sodium Pentacarbonylmanganate***, acidification, and oxidation;[1] highly efficient stirring is essential in the first stage for good yields, and incomplete oxidation or the loss of the volatile (toxic) intermediate $HMn(CO)_5$ in the final stages must be carefully avoided.

Handling, Storage, and Precautions: use in a fume hood; toxic, but not sufficiently volatile to present handling problems. May be stored indefinitely in a well-stoppered bottle at rt.

Introduction.

The molecule consists of two $Mn(CO)_5$ fragments linked by an Mn-Mn bond such that each Mn atom has octahedral coordination.[2] Many uses of $Mn_2(CO)_{10}$ involve its initial reduction to the anion $[Mn(CO)_5]^-$ or oxidation by halogens to $XMn(CO)_5$ (X = Cl, Br) and their use in turn to produce hydrido, alkyl, acyl, η^3-allyl, η^5-cyclopentadienyl, and η^6-arene complexes, amongst others.

Catalytic Uses.

Most catalytic systems utilizing $Mn_2(CO)_{10}$ require temperatures of approximately 140 °C, sufficient for cleavage of the relatively weak Mn-Mn bond (eq 1). In contrast to such thermolysis, photolysis involves two competitive

processes: the same cleavage (eq 1), as well as loss of CO (eq 2).

$$(OC)_5Mn\text{-}Mn(CO)_5 \longrightarrow 2 \cdot Mn(CO)_5 \qquad (1)$$

$$(OC)_5Mn\text{-}Mn(CO)_5 \longrightarrow (OC)_5Mn\text{-}Mn(CO)_4 + CO \qquad (2)$$

The radicals formed by thermolysis are efficient abstractors of halide from $RCCl_3$ (eq 3),[3] for example, and hence serve to initiate selective hydrogenolysis of such halides in the presence of good hydrogen donors (eq 4)[4] or addition to activated alkenes (eq 5).[5]

$$RCCl_3 + \bullet Mn(CO)_5 \longrightarrow R\dot{C}Cl_2 + ClMn(CO)_5 \qquad (3)$$

$$2\,RCCl_3 + i\text{-}PrOH \longrightarrow 2\,RCHCl_2 + Me_2CO \qquad (4)$$

$$Cl_3CCO_2Me + CH_2{=}CH\,TMS \longrightarrow$$

(5)

Addition to unactivated alkenes (except C_2H_4) is generally less efficient[4b,5b] and, whereas $Mn_2(CO)_{10}$ is more efficient and more selective than ***Pentacarbonyliron*** for reductions of the type shown by eq 4, the opposite is true for the additions (eq 5). In such reactions, 1:1 adducts tend to predominate and even in the addition of trichloroacetate to ethylene (eq 6), which gives a significant proportion of the telomers (n = 2-4), the use of DMF as solvent largely suppresses formation of all but the 1:1 adduct (n = 1).[6]

$$Cl_3CCO_2Me + CH_2{=}CH_2 \longrightarrow Cl(CH_2CH_2)_nCCl_2CO_2Me \qquad (6)$$

Similar selective hydrogenolysis and addition reactions involving hydrogen rather than halogen abstraction as the initiating step are involved when such reactive hydrogen sources as silanes, thiols, or phosphites are used with $Mn_2(CO)_{10}$ (eqs 7-9). Detailed study of such reductions as that of 1,3,3,5-tetrachloropentane by Et_3SiH (eq 10)[7] shows clearly that &bdot;$Mn(CO)_5$ acts only as initiator with the silane (not $HMn(CO)_5$) providing the hydrogen in the propagation step and Et_3Si&bdot; abstracting the chlorine atom.

$$Et_3SiH + \bullet Mn(CO)_5 \longrightarrow Et_3Si\bullet + HMn(CO)_5 \qquad (7)$$

$$BuSH + \bullet Mn(CO)_5 \longrightarrow BuS\bullet + HMn(CO)_5 \qquad (8)$$

$$(EtO)_2P(O)H + \bullet Mn(CO)_5 \longrightarrow (EtO)P(O)\bullet + HMn(CO)_5 \qquad (9)$$

The efficiency and especially the high selectivity of $Mn_2(CO)_{10}$ in this and related reductions, both by silanes[8] and thiols (e.g. eq 11)[9] is only rarely matched or exceeded by other metal carbonyls (including $Re_2(CO)_{10}$, $Fe(CO)_5$, and $Mo(CO)_6$).

$$\mathrm{BuSH} + \mathrm{Cl_3C(CH_2)}_n\mathrm{Cl} \longrightarrow \mathrm{Cl_2CH(CH_2)}_n\mathrm{Cl} \qquad (11)$$
$$n = 4, 6, 8$$

Particularly striking is the selectivity in additions to alkenes of the radicals formed according to eqs 7-9. Here, only the 1:1 adducts are significant products in the additions, exemplified in eqs 12-14,[10-12] when $Mn_2(CO)_{10}$ is used as initiator, whereas substantial amounts of higher telomers result when peroxides or other classical initiators are employed. In a typical comparative study,[11] the addition (eq 15) using $Mn_2(CO)_{10}$ catalysis provided the products (n = 1) and (n = 2) in 99 and 0.5% yields, ***Hexacarbonylmolybdenum*** was almost as selective (but required a long reaction time), ***Decacarbonyldirhenium*** was inactive, while ***1,1-Di-t-butyl Peroxide*** catalysis gave 50% (n = 1) and 20% (n = 2).

$$\mathrm{Et_3SiH} + \mathrm{C_2H_4} \longrightarrow \mathrm{Et_4Si} \qquad (12)$$

$$\mathrm{BuSH} + \mathrm{CH_2{=}CHOAc} \longrightarrow \mathrm{BuSCH_2CH_2OAc} \qquad (13)$$

$$\mathrm{(EtO)_2P(O)H} + \mathrm{CH_2{=}CHBu} \longrightarrow \mathrm{(EtO)_2P(O)CH_2CH_2Bu} \qquad (14)$$

$$\mathrm{BuSH} + \mathrm{CH_2{=}CHCN} \longrightarrow \mathrm{BuS(CH_2CHCN)}_n\mathrm{H} \qquad (15)$$

Stoichiometric Reactions with Unsaturated Hydrocarbons.

Much of the synthetically interesting chemistry involving reactions of $Mn_2(CO)_{10}$ with alkenes and alkynes has been obscured by the fact that few of the metal complexes initially obtained have been subjected to further reactions or even to cleavage of the organic ligand from the metal. Nevertheless, the potential for specific transformations of such unsaturated hydrocarbons is clear from the reactions outlined below.

Enyl and Dienyl Complexes.

Many different dienes are known to react with $Mn_2(CO)_{10}$ to give complexes. In the case of open-chain dienes, η^3-enyl complexes are isolated as initial products of irradiation (eq 16),[13] but these may be smoothly converted to η^5-dienyl complexes (eq 17).

(16)

(17)

For cyclopentadiene[14a] (or its pentamethyl derivative[14b]), cyclohexadiene,[15] and cycloheptadiene,[16] thermal conditions have been used that lead to dienyl complexes (eq 18). These reactions occur at temperatures which enable cleavage of the Mn-Mn bond, but it is not established whether the mechanism involves initial H abstraction by &bdot;$Mn(CO)_5$ or a concerted process. Since the temperatures also suffice for decomposition of $HMn(CO)_5$ to dihydrogen and $Mn_2(CO)_{10}$, all of the manganese can be utilized in complex formation.

(18)

The synthetic potential of such dienyl complexes is perhaps most strikingly illustrated by the diene photoaddition to the open-chain complexes leading to nine-membered rings (still attached to the metal), as in eq 19.[17] Cyclohexadiene adds in a different manner, involving formation of one C-C bond and H-migration (eq 20); incorporation of a second diene unit occurs in some cases.[13a]

(19)

(20)

As open-chain dienyl and cyclohexadienyl tricarbonylmanganese complexes are more usually prepared from halopentacarbonylmanganese, $XMn(CO)_5$ (X = Cl, Br), and (alkyl)cyclopentadienyltricarbonylmanganese from $MnCl_2$ (via $(RC_5H_4)_2Mn$), only the useful reactions of the cycloheptadienyl complex are discussed further here.

Tricarbonylcycloheptadienylmanganese (formed according to eq 18, *n* = 3) is smoothly converted[16] to the cationic triene complex by hydride abstraction (eq 21) and the latter adds a wide range of nucleophiles to give *exo*-substituted cycloheptadienyl complexes (eq 22; Y = OR, NMe_2, CN, $CH(CO_2Me)_2$, Me, Ph, etc.).[16,18] If an *exo*-hydrogen could be specifically abstracted as hydride (eq 23), the product should undergo further nucleophilic addition to give vicinally (i.e. 6,7-) disubstituted cycloheptadienyl complexes. However, trityl either abstracts Y (e.g. when Y = OR, NMe_2, or CN) or fails to react (R = Me), apparently for steric reasons, and other reagents tried also fail to react or cause complete disruption (e.g. NBS to give $[Mn(CO)_4Br]_2$).

(21)

(22)

(23)

Regeneration of a cationic system, but at the dienyl level, has been accomplished using nitrosonium

hexafluorophosphate (eq 24) and the products then add nucleophiles specifically to give 5,7-disubstituted cycloheptadiene complexes (eq 25).[18,19] Analogous methods have been used to convert *exo*-substituted cyclohexadienyl complexes to vicinally (i.e. 5,6-) disubstituted cyclohexadienemanganese complexes.[19a,b]

Photolysis of $Mn_2(CO)_{10}$ with allenes leads chiefly to (μ-allene)$Mn_2(CO)_8$ complexes, but is accompanied by allene di- and even trimerization in apparently regioselective fashion (eqs 26 and 27).[13b,20]

A unique ligand dimerization and ring-opening process occurs in the reaction of $Mn_2(CO)_{10}$ with tropone (eq 28).[21]

Alkyne Complexes.

Reactions of alkynes with manganese carbonyl do not appear to have been studied systematically, but have yielded synthetically interesting products in several cases. None more so than the formation of a dihydropentalenyl complex from acetylene itself (eq 29).[22]

The reaction of diethylaminopropyne (eq 30) yields four complexes whose sequential formation involves two proton migrations, the first of which converts the alkyne to an allene ligand.[23] More obvious synthetic potential can be seen in

the reaction of ethoxy- and dimethylamino-alkynes (with $Mn_2(CO)_{10}$ activated by prior displacement of one CO); thus ethoxyacetylene itself gives a product with a divinyl ketone ligand (eq 31).[24a,b] Similar reactions with diethyl acetylenedicarboxylate have been described.[24c]

Finally, the lactone synthesis from $Mn_2(CO)_{10}$, a terminal alkyne, and iodomethane (eq 32) probably involves reaction of the alkyne with initially formed acetyl(pentacarbonyl)manganese rather than directly with the decacarbonyl.[25]

Related Reagents.

Pentacarbonylmethylmanganese; ***Pentacarbonylchloromanganese***; ***Pentacarbonylphenylmanganese***; ***Sodium Pentacarbonylmanganate***; ***Pentacarbonyl(trimethylsilyl)manganese***.

Decacarbonyldirhenium

$Re_2(CO)_{10}$

[14285-68-8] · $C_{10}O_{10}Re_2$ · Decacarbonyldirhenium · (MW 652.52)

(oligomerization catalyst)

Alternate Name: rhenium carbonyl.

Physical Data: mp 177 °C, 170 °C; sublimes 70 °C/0.1 mmHg.

Solubility: sparingly sol common org solvents; insol water.

Form Supplied in: colorless crystals; commercially available.

Handling, Storage, and Precautions: stable to air and to strong acids; may be stored indefinitely at ambient temperature; ignites in air above 140 °C.

Conversion to Other Rhenium Carbonyl Derivatives.

Decacarbonyldirhenium is the starting material for the synthesis of a wide range of organorhenium compounds. Many of these conversions depend on three key initial steps: oxidation by halogens to the halopentacarbonyls, $XRe(CO)_5$[1] (very efficient chlorination occurs with ***Sulfuryl Chloride***);[2] reduction by sodium amalgam to $Na^+[Re(CO)_5]^-$;[3] and substitution of one or more carbonyl groups by other donor ligands, e.g. PPh_3 to give $Re_2(CO)_8(PPh_3)_2$. Thus whereas tricarbonylcyclopentadienylrhenium is readily obtained directly from $Re_2(CO)_{10}$ and cyclopentadiene dimer,[4] and the cyclohexa- and -heptadienyl analogs are prepared similarly from the corresponding dienes (eq 1),[5] a wider range of substituted cyclopentadienyl complexes as well as the open-chain dienyls are available by methods employing the bromocarbonyl (eqs 2 and 3).[6]

(1)

(2)

R = H, Me; M = Li, Na, K or Tl

(3)

The chloride or bromide is also used together with ***Aluminum Chloride*** or bromide and alkenes, dienes, and arenes to generate the cationic complexes $[(alkene)Re(CO)_5]^+$, $[(diene)Re(CO)_4]^+$, or $[(arene)Re(CO)_3]^+$ (eq 4).[7]

(4)

Catalytic Uses.

Both $Re_2(CO)_{10}$ and $ClRe(CO)_5$ can catalyze chlorination of hydrocarbons. Catalysis of the reaction of cyclohexane with carbon tetrachloride (eq 5)[8] undoubtedly involves initiation by thermal dissociation of the dinuclear carbonyl to give two &bdot;$Re(CO)_5$ radicals followed by chlorine atom abstraction from CCl_4. Surprisingly, the $Re_2(CO)_{10}$ or $ClRe(CO)_5$ catalyzed reaction of toluene with SO_2Cl_2 yields the products of ionic chlorination, 2- and 4-chlorotoluene, and only traces of benzyl chloride.[2]

(5)

Decacarbonyldirhenium is more efficient than ***Decacarbonyldimanganese*** in catalyzing the selective hydrogenolysis of 1,3,3,5-tetrachloropentane (eq 6), but the reverse is true of some similar examples.[9] At 230 °C it catalyzes the quantitative hydrogenation of cyclohexene or benzene to cyclohexane.[10] $Re_2(CO)_{10}$ is also marginally better than $Mn_2(CO)_{10}$ (but both are inferior to ***Pentacarbonyliron***/HMPA) as a catalyst for addition of methyl trichloroacetate to vinyltrimethylsilane (eq 7).[11] The rhenium compound is substantially better than manganese carbonyl as catalyst for the addition of butanethiol to acrylonitrile (eq 8).[12] A conflicting picture emerges from comparison of these catalysts for the addition of triethylsilane to alkenes. With 1-hexene, $Re_2(CO)_{10}$ at 145 °C causes fairly smooth addition to yield 1-hexyltriethylsilane (60-81%),[13] whereas $Mn_2(CO)_{10}$ yields unsaturated products. $Re_2(CO)_{10}$ is also the more efficient catalyst in addition to methyl methacrylate, but the opposite is true in the case of methyl acrylate.[14] In the presence of ***Lithium Chloride***, rhenium carbonyl catalyzes the conversion of CO and H_2 to glycol.[15]

(6)

(7)

(8)

Stoichiometric Reactions.

Much of the potentially synthetically useful chemistry of rhenium carbonyl consists of transformations which leave the organic fragments bound to the metal so that further reactions have to be explored before the utility of these compounds in the synthesis of metal-free organic molecules can be properly assessed. $Re_2(CO)_{10}$, activated by photolysis with 1-hexene, reacts stepwise with two molecules of dimethylaminopropyne, leading to their combination as shown in eq 9.[16] Reaction of $NaRe(CO)_5$ with alkynyl esters involves linkage of a CO ligand to the alkyne system (eq 10).[17]

Halocarbene complexes can be obtained, e.g. by the reaction of eq 11,[18] and neutral carbenedicarbonylcyclopentadienylrhenium derivatives are prepared by the Fischer method (eq 12).[19]

With softer alkylating agents the intermediate of this reaction yields an alkyl-acyl derivative (eq 13) which, on photolysis, eliminates butane-2,3-dione.[20]

A neutral carbene complex, $CpRe(CO)_2$=C=CHPh, has also been obtained by irradiation of tricarbonylcyclopentadienylrhenium with phenylacetylene.[21] Cationic carbene complexes have been prepared from the NO-substituted cation $[CpRe(CO)_2NO]^+$, itself obtained from $CpRe(CO)_3$ with $NO[HSO_4]$.[22] Replacement of one CO in

this cation by triphenylphosphine gives the chiral cation $[CpRe(CO)(PPh_3)NO]^+$, which has been resolved into its enantiomers.[23] Replacement of the second CO by an alkene, followed by base treatment and protonation e.g. as in eq 14,[24,25] yields a carbene complex isomeric with the precursor cationic alkene complex. Alkylation of the intermediate alkenylrhenium complexes also leads to carbene derivatives in some cases.[25] The alternative route to these involves reaction of the cation $[CpRe(CO)(PPh_3)NO]^+$ with alkyllithium followed by hydride abstraction, as illustrated for the preparation of the parent methylene complex (eq 15). Some other alkyls (CH_2R) behave analogously on hydride abstraction, but alkyls with a tertiary β-H (i.e. CH_2CHR_2) lose this H to give the more stable cationic alkene complexes.[26] Vinylcarbene analogs are also readily available by two routes (eq 16).[27]

(14)

(15)

(16)

Cationic solvent complexes are formed from the neutral alkyls (or aryls) on protonation (eq 17),[28] and the use of weak donor solvents (e.g. CH_2Cl_2 or PhCl) then allows replacement of these molecules by alkenes to give $[CpRe(\eta^2\text{-}CH_2{=}CHR)(PPh_3)NO]^+$ or ketones to give $[CpRe(O{=}CR^1R^2)(PPh_3)NO]^+$ salts. Reduction of homochiral salts of the latter type has yielded alkoxides with efficient asymmetric induction (eq 18).[29]

(17)

(18)

(Pentamethylcyclopentadienyl)tricarbonylrhenium has been converted to η^2-alkene derivatives as illustrated for the propene complex (eq 19).[30] Hydride abstraction followed by alkylation of the resultant η^3-allyl complex with ***Lithium Dimethylcuprate*** (eq 20)[31] achieves homologation of the propene ligand; other carbanions (e.g. $^-CH(CO_2Et)_2$) add in similar fashion.[31b]

(19)

(20)

Acid-catalyzed ***Hydrogen Peroxide*** oxidation smoothly converts the tricarbonyl complex $(C_5Me_5)Re(CO)_3$ to the trioxide complex $(C_5Me_5)ReO_3$. This product lacks the useful alkene-hydroxylating activity of $MeReO_3$, but has served as a source of many organorhenium(III and V) complexes.[32] Reaction of the trioxide with alkynes in the presence of triphenylphosphine yields complexes which give furans on treatment with iodine (eq 21).[33]

Remarkably smooth formation of a hydroxycyclopentadienyl ligand has been reported to proceed according to eq 22, giving the product as a yellow oil in 84% yield.[34]

Decynyl(phenyl)iodonium Tetrafluoroborate[1]

[102987-32-6] · $C_{16}H_{22}BF_4I$ · Decynyl(phenyl)iodonium Tetrafluoroborate · (MW 428.06)

(used in cyclopentene annulation;[3,4] can function as alkynyl equivalent[5] and vinyl cation equivalent[6])

Physical Data: mp 59.5-65 °C.

Preparative Methods: best achieved in 85% yield by reaction of (1-decynyl)trimethylsilane with excess ***Iodosylbenzene*** and ***Boron Trifluoride Etherate***, and subsequent treatment with excess aqueous $NaBF_4$ solution (eq 1).[2] This method provides a general route for the synthesis of alkynyl(phenyl)iodonium tetrafluoroborate salts from alkynyltrimethylsilanes.

Introduction.

Alkynyl(phenyl)iodonium salts are highly electron-deficient species of formal tetraphilic nature (C_α, $C_{\alpha'}$, C_β, and I) towards nucleophilic attack.

Nucleophilic Attack At C_β.

Despite the wide scope for nucleophilic attack on alkynyl(phenyl)iodonium tetrafluoroborates, only reports of C_β attack have been detailed to date for 1-decynyl(phenyl)iodonium tetrafluoroborate.

The reagent has been employed[3] in cyclopentene annulations, by a process referred to as tandem Michael-carbene insertion, through reaction of the stabilized anion of 1,3-diketones and 1,3-diesters (eq 2). The reaction proceeds, with concomitant reductive elimination of iodobenzene, via an alkylidenecarbene intermediate which subsequently undergoes an intramolecular 1,5 C-H insertion reaction.

(2)

Similar transformations have been studied[4] with heteronucleophiles to give functionalized cyclopentenes (eq 3).

(3)

The use of alkynyl(phenyl)iodonium salts as alkynyl cation synthetic equivalents has been amply demonstrated.[5] In addition, treatment of 1-decynyl(phenyl)iodonium tetrafluoroborate with ***Azidotrimethylsilane*** generates[6] the β-azidovinyliodonium salt (eq 4). Salts of this type behave as vinyl cation equivalents in nucleophilic substitutions owing to the high leaving group potential of the hypervalent iodine(III) substituent, the use of which has been reported[7] in the synthesis of a variety of alkenes including α-cyano, α-nitro, vinyl sulfides, and α,β-unsaturated esters.

(4)

α-Acyloxy ketones have been synthesized[8] from 1-decynyl(phenyl)iodonium tetrafluoroborate under both basic and acidic

conditions. Treatment of the reagent with excess sodium acetate in THF/H_2O gave 1-acetoxy-2-decanone in 78% yield (eq 5). The use of water is reported as essential for the reaction to proceed effectively.

(5)

1-Acetoxy-2-decanone is also produced in 86% yield by refluxing the reagent in acetic acid for 15 h. Syntheses and uses of α-acyloxy ketones have been previously demonstrated.[9]

Diacetatobis(tri-*o*-tolylphosphine)palladium(II)[1]

$Pd\{P(o\text{-}Tol)_3\}_2(OAc)_2$

[69073-98-9] · $C_{46}H_{48}O_4P_2Pd$ · Diacetatobis(tri-*o*-tolylphosphine)palladium(II) · (MW 833.25)

(catalyst for coupling of aromatic halides and alkenes;[1-3] cycloisomerization reactions of enynes[4])

Alternate Name: bis(tri-*o*-tolylphosphine)palladium(II) diacetate.

Solubility: sol acetonitrile, DMF, halogenated solvents.

Preparative Method: usually generated in situ from ***Palladium(II) Acetate*** and tri-*o*-tolylphosphine and used directly.

Handling, Storage, and Precautions: air sensitive in solution.

Coupling of Aryl Halides with Alkenes.

The title reagent (**1**) has been used to make aromatic alkenes in good yield under mild conditions, tolerating a variety of functionality (eq 1). Aromatic bromides[2] and iodides[3] are coupled with alkenes in the presence of base (typically NEt_3) in refluxing acetonitrile or DMF.

This reaction can be used to produce aromatic polymers.[5] In many cases, (**1**) is superior to the triphenylphosphine analog[1] (see ***Bis(triphenylphosphine)palladium(II) Acetate***).

Cycloisomerization.

$Pd\{P(o\text{-}Tol)_3\}_2(OAc)_2$ will readily effect cycloisomerization of 1,6-enyne substrates to 1,3-dienes,[4,6] and has been used in the synthesis of sterepolide (eq 2).[7]

(Diacetoxyiodo)benzene[1-3]

$PhI(OAc)_2$

[3240-34-4] · $C_{10}H_{11}IO_4$ · (Diacetoxyiodo)benzene · (MW 322.10)

(transannular carbocyclization,[6] *vic*-diazide formation,[7] α-hydroxy dimethyl acetal formation,[8,10,11,13] oxetane formation,[9] chromone, flavone, chalcone oxidation,[11,12] arene-$Cr(CO)_3$ functionalization,[14] phenolic oxidation[16] and coupling,[17,18] lactol fragmentation,[19] iodonium ylides and intramolecular cyclopropanation,[20] oxidation of amines[24-28] and indoles,[30,31] hydrazine derivatives (diimide[32] and azodicarbonyls[33]) and radical type intramolecular oxide formation[44-46]).

Alternate Names: phenyliodine(III) diacetate; DIB; iodobenzene diacetate; IBD.

Physical Data: mp 163-165 °C.

Solubility: sol AcOH, MeCN, CH_2Cl_2; in KOH or $NaHCO_3$/MeOH it is equivalent to $PhI(OH)_2$.

Form Supplied in: commercially available as a white solid.

Preparative Method: by reaction of iodobenzene with ***Peracetic Acid***.[4,5]

Purification: recrystallization from 5 M acetic acid.[4]

Handling, Storage, and Precautions: a stable compound which can be stored indefinitely.

Reactions with Alkenes.

Reactions of simple alkenes with $PhI(OAc)_2$ are not synthetically useful because of formation of multiple products.

Transannular carbocyclization in the reaction of *cis,cis*-1,5-cyclooctadiene yields a mixture of three diastereomers of 2,6-diacetoxy-*cis*-bicyclo[3.3.0]octane, a useful precursor of *cis*-bicyclo[3.3.0]octane-2,6-dione (eq 1).[6]

(Diacetoxyiodo)benzene

(1)

$PhI(OAc)_2/NaN_3/AcOH$ yields vicinal diazides (eq 2).[7]

(2)

Oxidation of Ketones to α-Hydroxyl Dimethyl Acetals.

Ketones are converted to the α-hydroxy dimethyl acetal upon reaction with $PhI(OAc)_2$ in methanolic potassium hydroxide (eqs 3-5).[8]

(3)

(4)

(5)

Several potentially oxidizable groups are unaffected in this reaction (eq 6).[13]

In the case of a 17α-hydroxy steroid the hydroxy group acts as an intramolecular nucleophile to yield the 17-spirooxetan-20-one. It is noteworthy that the 3β-hydroxy-Δ^5-system is unaffected (eq 7).[9]

(Diacetoxyiodo)benzene

(7)

cis-3-Hydroxyflavonone is obtained via acid-catalyzed hydrolysis of *cis*-3-hydroxyflavone dimethyl acetal, which is formed upon treatment of flavanone with $PhI(OAc)_2$ (eq 8).[10,11]

(8)

α,β-Unsaturated ketones, such as chromone, flavone, chalcone, and flavanone, yield α-hydroxy-β-methoxy dimethyl acetal products (eqs 9-11).[12a]

(9)

(10)

(Diacetoxyiodo)benzene

(11)

Intramolecular participation by the *ortho* hydroxy group occurs in the reaction of substituted *o*-hydroxyacetophenones, yielding the corresponding coumaran-3-ones (eq 12).[12b]

(12)

$R^1 = R^2 = R^3 = H$ $\quad$ $R^3 = OMe$

$R^1 = R^2 = H;\ R^3 = Me$ $\quad$ $R^3 = Me$

$R^1 = R^2 = Me;\ R^3 = H$ $\quad$ $R^3 = OMe$

$R^1 = R^2 = H;\ R^3 = Bn$ $\quad$ $R^3 = Bn$

Formation of the α-hydroxy dimethyl acetal occurs without reaction of the $Cr(CO)_3$ complex of η^6-benzo-cycloalkanones (eqs 13-15).[14]

(13)

(14)

(Diacetoxyiodo)benzene

(15)

Carbon-Carbon Bond Cleavage with $PhI(OAc)_2/TMSN_3$.

$PhI(OAc)_2$/***Azidotrimethylsilane*** reacts with unsaturated compounds even at -53 °C to yield keto nitriles (eq 16).[15]

(16)

Oxidation of Phenols.

Phenols are oxidized using $PhI(OAc)_2$ with nucleophilic attack by solvent (eqs 17 and 18),[16] or with intramolecular nucleophilic addition amounting to an overall oxidative coupling as with the bisnaphthol (eq 19)[17] and also with the conversion of reticuline to salutaridine (eq 20).[18]

(17)

(18)

(19)

(20)

Fragmentation of Lactols to Unsaturated Medium-Ring Lactones.

Ring cleavage to form a medium-sized ring lactone with a transannular double bond has been observed (eq 21).[19]

(21)

Reactions with β-Dicarbonyl Systems; Formation of Iodonium Ylides; Intramolecular Cyclopropanation.

β-Dicarbonyl compounds upon reaction with $PhI(OAc)_2$ and KOH/MeOH at 0 °C yield isolable iodonium ylides (eq 22).[20] This is a general reaction which requires two stabilizing groups flanking the carbon of the C=I group, such as NO_2 and SO_2Ph.[21] Decomposition of unsaturated analogs in the presence of ***Copper(I) Chloride*** proceeds with intramolecular cyclopropanation (Table 1).[20]

(22)

Table 1 Intramolecular Cyclopropanation of Iodonium Ylides

Reactants	Iodonium ylide	Product	Yield (%)
			76
			81
			85
			82

An asymmetric synthesis of a vitamin D ring A synthon employed this intramolecular cyclopropanation reaction (eq 23).[22]

Oxidation of Amines.

Aromatic amines are oxidized with $PhI(OAc)_2$ to azo compounds in variable yield. $PhI(OAc)_2$ in benzene oxidizes aniline in excellent yield (eq 24);[23] however, substituted anilines give substantially lower yields.

Intramolecular azo group formation is a useful reaction for the formation of dibenzo[*c*,*f*]diazepine (eq 25).[24,25] Other *ortho* groups may react intramolecularly to yield the benzotriazole (eq 26), benzofuroxan (eq 27), or anthranil (eq 28) derivatives.[24-28]

(Diacetoxyiodo)benzene

(27)

(28)

A number of examples of oxidative cyclization of 2-(2´-pyridylamino)imidazole[1,2-*a*]pyridines to dipyrido[1,2-*a*:2´,1´-*f*]-1,3,4,6-tetraazapentalenes with $PhI(OAc)_2/CF_3CH_2OH$ have been reported (eq 29).[29]

(29)

In the case of the oxidation of indole derivatives, nucleophilic attack by solvent may occur (eq 30).[30] Reserpine undergoes an analogous alkoxylation.[30] In the absence of a nucleophilic solvent, intramolecular cyclization occurs, an example of which is illustrated in the total synthesis of sporidesmin A (eq 31).[31]

(30)

(31)

Hydrazine is oxidized by $PhI(OAc)_2$ to diimide, which may be used to reduce alkenes and alkynes under mild conditions (Table 2).[32]

Table 2 Diimide Reduction of Various Compounds

Compound	Product	Yield (%)
$PhSCH{=}CH_2$	$PhSCH_2Me$	85
cis-$EtO_2CCH{=}CHCO_2Et$	$EtO_2CCH_2CH_2CO_2Et$	94
$EtO_2C\ N{=}N\ CO_2Et$	$EtO_2CNH\ NHCO_2Et$	90
Maleic anhydride	$(MeCO)_2O$	83
$PhC^{o}\ CPh$	*cis*-$PhCH{=}CHPh$	80
$PhCH{=}CHCO_2Et$	$PhCH_2CH_2CO_2Et$	96
$CH_2{=}CHCN$	$MeCH_2CN$	97

The hydrazodicarbonyl group is smoothly oxidized by $PhI(OAc)_2$ to the azodicarbonyl group (eqs 32 and 33).[33]

(32)

(33)

An intramolecular application of this reaction was used in a tandem sequence with $PhI(OAc)_2$ oxidation and a Diels-Alder reaction in the synthesis of nonpeptide β-turn mimetics (eq 34).[34,35]

(Diacetoxyiodo)benzene

(34)

Oxidation of 5-Substituted Pyrazol-3(2*H*)-ones; Formation of Alkynyl Esters.

Oxidation of various 5-substituted pyrazol-3(2*H*)-ones proceeded with fragmentative loss of molecular nitrogen to yield methyl-2-alkynoates (eq 35).[36] An analogous fragmentation process with pyrazol-3(2*H*)-ones occurs with ***Thallium(III) Nitrate***[37,38] and ***Lead(IV) Acetate***.[39]

(35)

R = Me, 60%	R = Ph, 59%
R = Et, 63%	R = *p*-ClC_6H_4, 61%
R = CO_2Me, 59%	R = *p*-MeC_6H_4, 59%
R = CH_2CO_2Me, 62%	R = *p*-$MeOC_6H_4$, 64%

Oxidation of Hydrazones, Alkylhydrazones, *N*-Amino Heterocycles, *N*-Aminophthalimidates, and Aldazines.

The oxidation of hydrazones to diazo compounds is not a generally useful reaction but it was uniquely effective in the oxidation of a triazole derivative (eq 36).[40]

(Diacetoxyiodo)benzene

(36)

Oxidation of arylhydrazones proceeds with intramolecular cyclizations (eqs 37 and 38)[41] and aziridines may be formed via nitrene additions (eq 39).[42]

(37)

(38)

(39)

A linear tetrazane is formed in the oxidation of *N*-aminophthalimide (eq 40).[43]

(Diacetoxyiodo)benzene/***Iodine*** is reported to be a more efficient and convenient reagent for the generation of alkoxyl radicals than Pb^{IV}, Hg^{II}, or Ag^{I}, and this system is useful for intramolecular oxide formation (eqs 41 and 42).[44]

Fragmentation processes of carbohydrate anomeric alkoxyl radicals[45] and steroidal lactols[46] using $PhI(OAc)_2/I_2$ have been reported.

Diallyl Sulfoxide

[14180-63-3] · $C_6H_{10}OS$ · Diallyl Sulfoxide · (MW 130.20)

(source of thioacrolein in solution[1])

Physical Data: colorless oil solidifying at 5 °C.

Solubility: sol most organic solvents.

Preparative Method: conveniently prepared in 91% yield from commercially available diallyl sulfide by oxidation with 30% H_2O_2 in acetone at rt followed by recrystallization at -20 °C from pentane/ether.[1]

In Situ Generation and Trapping of Thioacrolein: Synthesis of 3,4-Dihydro-2*H*-thiopyrans.

When an excess of diallyl sulfoxide (or a homolog such as bis(2-methyl-2-propenyl) sulfoxide) is heated with dienophiles, thioacrolein Diels-Alder adducts, 3,4-dihydro-2*H*-thiopyrans, are formed in good to excellent yield (eq 1 and Table 1).[1]

Table 1 3,4-Dihydro-2*H*-thiopyrans from Allyl Sulfoxides

Sulfoxide	Reagent	Conditions	Product	Yield (%)
(1)		110 °C, 4.5 h		91
$(H_2C{=}CMeCH_2)_2SO$		127 °C, 12 h		85
(1)	(*E*)-$MeO_2CCH{=}CHCO_2Me$	107 °C, 4.5 h		95
(1)	(*E*)-PhCH=CHPh	150 °C, 3 h		28
(1)	Norbornene	87 °C, 3 d		40
(1)	$H_2C{=}CHCO_2Et$	103 °C, 5 d	 + 	50

1,2-Diaminoethane

[107-15-3] · $C_2H_8N_2$ · 1,2-Diaminoethane · (MW 60.10) (.H_2O)

[6780-13-8] · $C_2H_{10}N_2O$ · 1,2-Diaminoethane · (MW 78.11)

(base and reducing agent;[1] used to complex metal ions;[2] used as building block for linking chains;[3] used to prepare imidazolines,[4] pyrazines,[5] 1,4-diazepine derivatives,[6] N_{2n}-containing macrocycles,[7] and fused heterocycles[8])

Alternate Names: DAE; ethylenediamine; EDA.

Physical Data: mp 8.5 °C; bp 117 °C; *d*204 0.8977 g cm^{-3}; *n*20D 1.4568.

Solubility: sol H_2O and alcohol; slightly sol Et_2O (1:300).

Form Supplied in: colorless liquid, widely available.

Purification: for some applications, 1,2-diaminoethane must be dried by standard methods used for amines.[9,11]

Handling, Storage, and Precautions: the reagent has low toxic, genotoxic, and oncogenic activity and should be handled with caution.[10a-c]

Complexation of Metal Ions.

1,2-Diaminoethane forms stable complexes with heavy metal ions: Ag, Au, Cd, Co, Cr, Cu, Fe, Hg, Ni, Zn, and others. Complexes of DAE with Cd^{II}, Co^{II}, Cu^{II}, or Hg^{II} are used in quantitative analysis of this metal or, conversely, of DAE. Ten- to 18-membered macrocycles with 2*n* nitrogen atoms, which can be prepared from the reagent, selectively form polydentate complexes with metal ions.[2] These complexes have been used for specific goals in catalytic reactions. For example, Cu^{II} complexed with the Shiff base prepared from DAE and chiral aldehydes shows high enantioselectivity in catalytic cyclopropanations of styrene with ethyl diazoacetate.[12] Copper(II) complexes of chiral diaminodiamides [$HXNHCH_2CH_2XH$ (X = Ala, Phe, Val)] have been used for enantioselective recognition of amino acids.[13] Addition of DAE after reactions of aryl halides with CuCN facilitates isolation of the nitrile from the reaction mixture by removing the Cu^{II} as a complex.[14]

Chromium(II) salts, with DAE as a ligand added in situ, are easily prepared reducing agents. The DAE greatly enhances the ability of Cr^{II} to reduce primary alkyl halides to alkanes,[15a] and aryl bromides or iodides to arenes (100%).[15b] This complex in aqueous DMF will selectively reduce a bridgehead chloride (eq 1),[15c] and convert β-substituted alkyl halides and epoxides to alkenes at rt in high yields.[15b] 4´-R-$\Delta^{1,8'}$-β-Octalones (R = CH_2OH, CO_2H) have been reduced by a ***Chromium(II) Sulfate***-DAE complex with *cis* stereospecificity, to the saturated ketones in 90% yield.[16]

(1)

Complex with Borane.

The 1:1 complex of B_2H_6 with DAE in THF is a highly selective reducing agent, exhibiting reactivity comparable to ***Sodium Borohydride***. For example, it will transform cinnamaldehyde to cinnamyl alcohol.[17]

Solutions of KI_3 in DAE will iodinate phenols, anilines, tyrosines, pyrrole, and hydroxybenzoic acids.[18]

With Lithium in Reductions.

Lithium in DAE is a powerful reducing system. Reduction of alkenes, aromatic hydrocarbons, phenols, and alcohols have been reported. An example, the reduction of tetralin to octalin, is shown in eq 2.[1a] The 16,17 double bond and 20-keto group in pregnadienone were reduced to give the (20*R*)-alcohol in 95% yield.[19] Reduction of the 3α,4α- and 3β,4β-epoxides of friedel-3-ene,[20a] or the epoxides of pinene,[20b] gave the corresponding alcohols.

(2)

Isomerizations.

The lithium salt of DAE ($LiNHCH_2CH_2$-NH_2) is a very strong base. It has been used in the dehydrogenation and aromatization of vinylcyclohexene derivatives (4-vinylcyclohexene, limonene; 75-91%).[1b] Rapid and quantitative isomerization of terminal alkenes to internal alkenes has also been described (eq 3).[1b] Migration of triple bonds to terminal positions can also be accomplished. Internal alkynic hydrocarbons or alcohols are easily (40-50 °C, 20 min)

transformed to terminal isomers in yields of 74-87%.[21a] The yield of the terminal isomer can be raised by increasing base concentration and using nonpolar solvents.[21b] This reagent even rapidly shifts two triple bonds to terminal positions in 70-75% yields (eq 4).[22a,b] Similar migration of triple bonds is observed with ***Sodium Amide*** in DAE.[23]

Building Block for Synthesis.

The synthetic significance of DAE is based on specific features of its structure. The reagent reacts with electrophiles to give mono or bis derivatives. For example, DAE has been monoacylated to give 2-(*t*-butoxycarbonylamino)ethylamine.[24] Reaction of the amino group and subsequent removal of the protecting group reveals a new amine which can be used in the next stage of a synthesis.

DAE has been used as a symmetric building block for the linking of molecular fragments by 1,2-bisamino,[3a,b] 1,2-bisimino,[3c] 1,2-bisamido,[3d] 1,2-bisimido,[25] or dimethylene chains (eqs 5 and 6).[26]

(6)

DAE is an excellent synthon for the synthesis of heterocycles with two nitrogen atoms. Condensation of DAE with 4-dialkylamino-3-butyn-2-ones led to 2-acetonylimidazoline (70%).[27a] Similar reactions with 1-haloalkynes give 2-alkylideneimidazolidines[27b] or 2-alkylimidazolines.[27c] Substituted 2-methyleneimidazolines can be prepared from DAE and compounds of the type R(W)C=CX_2, as outlined in eq 7.[28]

(7)

X = Br, SMe; R = H, alkyl, aryl
W = NO_2, acyl

Reaction of DAE with acids,[4a] esters,[4b] amides,[4c] dithioesters,[4d] imidoesters,[4e] nitriles,[4d,f] 2-aryloxazolines,[4g] or 2-phenylthiazolium salts[4h] gives 2-substituted imidazolines (eqs 8-10).

(8)

(9)

(10)

Imidazoline-2-thiol has been prepared in 60% yield by condensation of DAE with CS_2.[29] 2-Methylimidazole has been prepared in three steps from DAE and acetic acid in an overall yield of 80%.[30]

Cyclic guanidines have been prepared from DAE and *O*-alkyl thiocarbamates[31a] or *N*-aryldithiocarbamates.[31b] Similarly, these compounds have been obtained from DAE and imidoyl chlorides[32a,b] or dialkyl thioacetals of isothiocyanates (eq 11).[32c]

(11)

Reactions of DAE with dialdehydes, diketones, dicarboxylic acids, and their derivatives lead to cyclic products, containing $(N\text{-}C\text{-}C\text{-}N)_n$ fragments (eq 12). Thus 1,2-dicarbonyl compounds (α-diketones, *o*-quinones, alkyl oxalates) gave dihydropyrazines and, after subsequent oxidation, pyrazines.[5] Tetrahydropyrazines were obtained from α-halo carbonyl compounds.[33a] Piperazines were formed from *vic*-diols and DAE in the presence of a ruthenium catalyst.[33b] 1,4-Diazepines were prepared from the reaction of DAE with 1,3-diketones,[6a] vinyl ketones,[6b] or enynes.[6c] Twelve- to 20-membered macro N_4-heterocycles have been synthesized by the reaction α,o-dicarbonyl compounds with two molecules of DAE.[7] This method has been used to prepare some macrocycles with unique abilities for complexation of ions.[2]

(12)

Molecules with two reaction sites react with DAE to give bicyclic products. Heterocycles prepared in this manner include pyrrolo[1,2-*a*]imidazoles,[8a] imidazo[3,4-*a*]imidazoles,[8b] imidazo[1,2-*b*]isoquinolines,[8c] and imidazo[1,2-*c*]pyrimidines.[8d] Polycyclic condensed systems with pyrazine[34a,b] and 1,4-diazepine[34c] substructures have been synthesized by means of DAE. An example is shown in eq 13.[35]

Diaminomaleonitrile[1]

[1187-42-4] · $C_4H_4N_4$ · Diaminomaleonitrile · (MW 108.10)

(useful for a preparation of substituted imidazoles,[2,4-6] pyrazines,[9-13] and nucleosides[14])

Alternate Name: DAMN.

Physical Data: mp 184 °C (dec); sublimes at 120 °C/0.1 mmHg; dipole moment 7.9 D; pK_b 2.18; heat of combustion 5230 cal g^{-1}; *d* 1.29 g cm^{-3}.

Solubility: 25 °C (g/100 mL): acetone (15), DMA (39), water (0.5), THF (14), MeCN (7), EtOAc (3.6), ether (0.4), MeOH (6.1), EtOH (3.6), isopropanol (2.6), dioxane (9.6).

Preparative Methods: can be prepared from HCN by oligomerization[1d] or by hydrogenation of diiminosuccinonitrile.[1a]

Handling, Storage, and Precautions: the title reagent has an ALD of 450 mg/kg in rats; use in a fume hood.

Heterocycle Synthesis.

Diaminomaleonitrile is a weakly basic diamine with similar reactivity to *o*-phenylenediamine. DAMN has been used to prepare a variety of heterocyclic compounds. 4,5-Dicyanoimidazole was synthesized by refluxing DAMN and ***Triethyl Orthoformate*** in anisole (eq 1).[2] One possible intermediate can also be isolated under different reaction conditions (eq 2).[3] Cyanogen chloride or *N*-dichloromethylenephenylsulfonamide reacts with DAMN to give aminodicyanoimidazole or 4,5-dicyano-2-phenylsulfonylaminoimidazole, respectively (eqs 3 and 4).[4,5]

(1)

(2)

(3)

(4)

5-Amino-4-(*C*-cyanoformimidoyl)-1,2-dimethylimidazole was made by controlled basification of the salt which was formed from DAMN and nitrilium triflate (eq 5).[6]

(5)

An efficient synthesis of 3,4-dicyano-1,2,5-thiadiazole was accomplished by reaction of DAMN with ***Thionyl Chloride*** (eq 6).[7]

(6)

Phosphorus(III) Chloride reacts with DAMN to yield 2-chloro-2,3-dihydro-1*H*-1,3,2-diazaphosphole-4,5-dinitrile (eq 7).[8]

(7)

Substituted pyrazines can be prepared by condensation of DAMN with either 1,2-diketones or β-keto sulfoxides or acylsulfonium halides (eqs 8-10).[9-11]

(8)

(9)

(10)

Oxalyl Chloride or ethyl ethoxycarbonylformimidate reacts with DAMN to afford pyrazine derivatives (eqs 11 and 12).[12,13]

(11)

DAMN has been proposed to be an essential intermediate to purines in prebiotic origins of life and it has been used to prepare some nucleosides (eq 13).[14]

2,4-Diamino-1,3-thiazole Hydrotribromide[1]

[75117-14-5] · $C_3H_6Br_3N_3S$ · 2,4-Diamino-1,3-thiazole Hydrotribromide · (MW 355.87)

(solid brominating agent[1])

Physical Data: mp 198-200 °C (dec).

Solubility: sol methanol, ethanol; slightly sol acetic acid; insol H_2O, ether, chloroform; sol but reacts with DMSO, acetone.

Preparative Methods: to a solution of 11.7 g of 2,4-diamino-1,3-thiazole *[67355-26-4]* in acetic acid or in water, 12 mL of 48% hydrobromic acid is added. Slightly less than 1 equiv of bromine is then slowly added at 0 °C. After 1-2 h, the solid hydrotribromide precipitates and is collected by filtration and washed with ether or chloroform. The solid is recrystallized from methanol (without heating) to yield 13 g (60%) of the desired reagent.[2] 4-Amino-2-dimethylamino-1,3-thiazole hydrotribromide (mp 150-153 °C) is prepared in the same way from 4-amino-2-dimethylamino-1,3-thiazole and is slightly more stable than the corresponding 2,4-diamino derivative.

Analysis of Reagent Purity: usual KJ titration indicates the amount of free bromine.

Handling, Storage, and Precautions: the dry solid is stable in the dark for several weeks.

Bromination of Aryl Ketones.[1]

α-Bromo ketones are obtained by reaction of the reagent (**1**) with aryl ketones in acetic acid at 25 °C (eq 1).

(1)

Bromination of Phenols.[1]

Bromination of phenol with this reagent produces the *para* and *ortho* monobromides in a 4:1 ratio (eq 2).

(2)

Both α- and β-naphthols are monobrominated to bromonaphthols (eq 3). β-Naphthol affords 1-bromo-2-naphthol in 82% yield.

(3)

2,4-Diaminothiazole (and 4-amino-2-dimethylaminothiazole) are slightly soluble in acetic acid and may be recovered and collected by simple filtration after each bromination run.

Dianisyl Telluroxide[1]

[57857-70-2] · $C_{14}H_{14}O_3Te$ · Dianisyl Telluroxide · (MW 357.88)

(mild oxidant for diphenols, thiols, and thio compounds;[2] aldol catalyst[11])

Alternate Name: bis(4-methoxyphenyl) telluroxide.

Physical Data: mp 190-191 °C.[2]

Solubility: poorly sol most organic solvents; sol acetic acid.

Preparative Method: by base-catalyzed hydrolysis (2N NaOH, 95 °C, 1 h) of dianisyltellurium dichloride,[2] which is itself prepared by reaction of anisole with tellurium tetrachloride.[3]

Handling, Storage, and Precautions: stable white powder; dried in vacuo over P_2O_5. All manipulations must be carried out in a well ventilated hood.

Oxidation Reactions.

Ortho and *para* diphenols are easily oxidized by dianisyl telluroxide to quinones, and 1,2-glycols are cleaved with this reagent, whereas simple phenols and alcohols are not affected.[2] Aryloxyl radicals have been observed during the reaction of 2,6-di-*t*-butylphenol derivatives with the telluroxide and these radicals were further oxidized, when possible, to the diphenoquinone.[4] Thiols are rapidly oxidized to disulfides in high yields, even in the presence of sensitive functional groups such as aromatic amines or amino acids. A number of thio or seleno compounds have been transformed into their oxo derivatives with this reagent (eqs 1 and 2), including thionoesters, selenoesters, dithioesters, thionocarbonates, trithionocarbonates, thioketones, and xanthates. In the case of thiocamphor, a more complex sequence led to a poor yield of the ketone (10%) and to the formation of the disulfide, which was slowly converted to the dimeric thioketone. The behavior of thiourea and thioamides is dependent on the nature of the substrate and the reaction conditions. Thus thiourea and *N*,*N*´-diphenylthiourea gave the corresponding ureas but *N*-phenylthiourea gave the dimeric 1,2,4-thiadiazole in 97% yield (eqs 3 and 4).[5,6]

(1)

(2)

(3)

(4)

Pyrrolidinethione gave the corresponding pyrrolidinone, but primary thiobenzamides gave either benzonitrile or underwent oxidative dimerization to 1,2,4-thiadiazoles. Thiobenzoylurea and thiobenzoylguanidine afforded only the 1,2,4-thiadiazole derivatives. Phosphines are easily oxidized to the corresponding phosphine oxides, although this method does not offer any specific advantage over classical methods.

Acylhydrazines are converted to acylhydrazides, in a reaction similar to the oxidation with diphenyl selenoxide. Arylhydrazines furnish a mixture of the corresponding arenes, of anisole, and diaryl tellurides. Benzophenone hydrazone was oxidized to diphenyldiazomethane, which was trapped with *p*-anisic acid. Phenylhydroxylamine afforded nitrosobenzene in 90% yield in 5 min without overoxidation.

A large number of functional groups are inert toward this telluroxide, including aldehydes, ketones, hydroxybenzoic acid esters, enamines, pyrrole, indole, amino acids, aromatic amines, isocyanides, hindered thionocarbonates, oximes, arylhydrazones, dithiolanes, sulfides, and selenides.

A polystyrene-bound diaryl telluroxide was reported to present the same spectrum of oxidizing properties as the monomeric reagent.[7] The reduced reagent can be easily recovered and then reused after reoxidation. However, in the case of primary thiobenzamide, the thiadiazole was formed with the polymeric reagent in acetic acid, as well as with the monomeric dianisyl telluroxide ditosylate, whereas benzonitrile was obtained with dianisyl telluroxide.

A related reagent, bis(4-methoxyphenyl) tellurone *[82342-66-3]*, is prepared by oxidation of the telluroxide with ***Sodium Periodate***. It is also a mild oxidant of thiophenols to disulfides and of hydroquinones to quinones, but slightly

more powerful than the telluroxide as it oxidized benzylic alcohols to benzaldehydes and benzoin to benzil. Glycols were also oxidatively cleaved.[8]

Catalytic Version of the Reagent.

The oxidation of thiocarbonyl compounds to their oxo analogs can also be performed with dianisyl telluride in a catalytic system with 1,2-dibromotetrachloroethane acting as a brominating agent. In the presence of aqueous base, the dibromo telluride is hydrolyzed to the telluroxide which reacts in a two-phase system.[2,9] In the course of the synthesis of 1α,25-dihydroxyvitamin D_3, oxidation of a cyclic hydrazine derivative was performed under these conditions to afford directly the very sensitive *trans*-trienic system of the vitamin (eq 5).[10]

Electrochemically generated telluroxide also reacts with thiobenzamide. The outcome of the reaction is directly related to the nature of the supporting electrolyte: with Bu_4NOAc, benzonitrile is the only product, whereas with Et_4NOTs the thiadiazole was the major or only product.[7]

Aldol Condensation Catalyst.

Dianisyl telluroxide acts efficiently as a mild catalyst for aldol condensations under aprotic conditions (toluene, reflux for 2 h, 0.1 equiv of the catalyst). Dibenzotropone, which cannot be obtained by using classical basic catalysis, was prepared in 96% yield with this catalyst (eq 6).[11,12]

(6)

However, aldol condensations with very acidic methylene compounds gave only moderate yields. This reagent also catalyzed the condensation of cinnamaldehydes with ketones and activated nitriles in high yield.[13]

1,5-Diazabicyclo[4.3.0]non-5-ene[1]

[3001-72-7] · $C_7H_{12}N_2$ · 1,5-Diazabicyclo[4.3.0]non-5-ene · (MW 124.19)

(organic soluble base for elimination reactions,[2-11] isomerizations,[12-19] esterifications,[26-31] and condensations[20-25])

Alternate Name: DBN.

Physical Data: bp 95-98 °C/7.5 mmHg; *d* 1.005 g cm^{-3}.

Solubility: sol polar solvents such as water, ethanol, benzene, methylene chloride, chloroform, THF, and DMSO.

Form Supplied in: clear, colorless or light yellow liquid.

Handling, Storage, and Precautions: stable at ambient temperatures, but is hygroscopic; contact with undiluted product may cause skin irritation or burns.

Introduction.

1,5-Diazabicyclo[4.3.0]non-5-ene is an organic soluble amidine base which has been used effectively, under relatively mild conditions, for a variety of base-mediated organic transformations including eliminations, isomerizations, esterifications, and condensations. A related reagent, ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU), is used for similar reactions.

Elimination Reactions.

DBN has been used for dehydrohalogenations as well as for the introduction of unsaturation by elimination of sulfonic acids. Typical reactions are conducted with equimolar or excess base in solvents such as DMF, DMSO, benzene, methylene chloride, and chloroform. Products may be distilled directly from the reaction mixture or separated from the DBN salt byproduct by extraction with a nonpolar solvent. Terminal as well as internal double bonds have been introduced in this manner. Additionally, DBN has been used to prepare functionalized alkenes such as vinyl thioethers.

Oediger and Möller compared DBN with DBU in the dehydrohalogenation of bromoalkanes. Conditions were equimolar base and 80-90 °C. DBN was found to be only moderately effective, affording heptenes from bromoheptanes in 36-60% yield. Corresponding yields using DBU were 78-91%.

DBN was effective, however, for the conversion of β-substituted primary alkyl iodides into terminal alkenes.[2] Thus treatment of iodide (**1**) with 1.5 equiv of DBN in benzene at 80-90 °C for 3-4 h afforded alkene (**2**) in 91% yield (eq 1).

(1)

(1) **(2)**

Both DBN and DBU have been employed in aprotic solvents for the dehydrobromination of substrates containing acetate functionality.[3-5] DBN was used in the preparation of chrysene derivative (**4**) (eq 2).[5] Diacetate (**3**) was brominated with NBS in methylene chloride, then dehydrobrominated using DBN in THF. Acetate functionality was preserved (note that DBU has been used for rt deacetylations in methanol[6]) and (**4**) was isolated in 51% yield after 16 h at -20 °C.

(2)

(3) **(4)**

DBN promoted the elimination of methanesulfonic acid in the preparation of pyranoside (**5**) (eq 3).[7] Use of $NaHCO_3$ in place of DBN also afforded the desired pyranoside; however, the yield was low (15%) and the reaction time was longer. With NaH in refluxing DME, a mixture of regioisomeric elimination products resulted.

(3)

(5)

DBN was used for the elimination of methanesulfonic acid from ester (**6**) to give *trans* α,β-unsaturated ester (**7**) in 86% yield after 4 h at rt (eq 4).[8] Interestingly, the nitrile analog of (**6**) (i.e. side chain cyano group rather than the methyl ester)

afforded a 6:5 *cis*:*trans* mixture of α,β-unsaturated nitriles, probably due to the smaller steric requirements of the cyano group.

Elimination of an intermediate thiolate in the presence of DBN was postulated to occur in a thiazolidine ring enlargement of penams (eq 5).[9,10]

Another rearrangement which has been postulated to occur via a DBU-mediated elimination is the conversion of 2-amino-5-imino-4,5-dihydrothiazoles (e.g. **8**) to imidazoline thiones (e.g. **9**) and diazolidines (e.g. **10**).[11] The rearrangement is thought to proceed through a ring-opened carbodiimide intermediate which subsequently cyclizes to (**9**) or (**10**). The relative amounts of (**9**) and (**10**) formed vary with substrate structure. A representative reaction is shown in eq 6.

Isomerizations.

DBN has been used for base-mediated epimerizations and double bond migrations. Isomerizations generally require proton abstraction at a carbon α to a carbonyl group (or related functionality) and are thermodynamically controlled.

DBN is widely used for epimerizations of 6β-substituted penicillins to the corresponding 6α-isomers.[12-17] Epimerization of penicillins occurs rapidly and without competitive formation of 1,4-thiazepines (e.g. **12**). Methylene chloride is the most frequently used solvent. Various bases were compared in the epimerization of (**11**) (eq 7).[14] DBN and ***1,1,3,3-Tetramethylguanidine*** were equally effective. Other tertiary amine bases, including *N*-methylmorpholine, *N,N*-dimethylbenzylamine, *N*-alkylpiperidines, and ***Triethylamine***, afforded considerable amounts of thiazepine (**12**).

DBN was used to achieve the equilibration of medium-ring cycloalkenones in a study of the effect of substituents on the 3-cycloalkenone/2-cycloalkenone product distribution.[18] Isomerizations were conducted in toluene or benzene from 25 to 100 °C in the presence of a catalytic amount of DBN. Generally, electron-withdrawing substituents at C-3 favored 3-cycloalkenones. Table 1 shows equilibration results for various 3-substituted cycloheptenones after treatment with a catalytic amount of DBN in toluene at 80 °C.

Table 1 Isomerization of 3-Substituted Cycloheptenones

3-Substituent	2-Cycloheptenone (%)	3-Cycloheptenone (%)
H	76.8	23.2
CO_2Me	16.8	83.2
CN	15.1	84.9
COMe	20.7	79.3

Several biomimetic methods for the conversion of amines to carbonyl compounds have used amidine bases to effect equilibration of the intermediate imine.[19-21] Corey used DBN in the oxidation of amines with mesitylglyoxal (**13**).[19] Thus cyclohexylamine and (**13**) were combined in benzene to form a Schiff base which was subsequently treated with DBN in THF/DMSO to afford cyclohexanone in 87% yield after hydrolysis (eq 8).

(8)

Condensations.

DBN has been used to effect the reaction of active methylene compounds and other substrates containing active hydrogen. Corey used a catalytic amount of DBN to effect ring closure of the ketoaldehyde (**14**) in a prostaglandin synthesis (eq 9).[22] The cyclopentanol derivative (**15**) was obtained in 45% yield upon treatment of (**14**) with 0.1 equiv of DBU in methylene chloride at 0 °C for 24 h followed by deacetylation.

(9)

An insecticide intermediate, 1-(*p*-ethoxyphenyl)-2-nitro-1-propanol, resulted from the DBN catalyzed reaction of nitroethane and *p*-ethoxybenzaldehyde (eq 10).[23]

(10)

DBN has been used to generate resonance stabilized ylides in Wittig reactions.[24,25] The synthesis of dienoate (**17**) from benzaldehyde and phosphonium salt (**16**) is representative (eq 11).

(11)

Esterifications.

There are few examples of the use of DBN in esterification reactions, although the related amidine, DBU, is widely used for this purpose.[26-30] Colvin reported a DBN mediated esterification in one of the final steps of the synthesis of the

macrolide antibiotic pyrenophorin.[31] Thus treatment of bisimidazol-1-yl ketone (**18**) with a catalytic amount of DBN afforded bis-lactone (**19**) in 60% yield (eq 12). In the same study, Colvin and Raphael also used DBN for the quantitative selective removal of a *p*-toluenesulfonylethyl protecting group (eq 13). Stronger bases cleaved the central ester.

Physical Data: mp 161 °C (subl. sample); bp 174 °C; fp 62 °C; *d* 1.14 g cm^{-3}.

Solubility: (g/100g of the solvent at 25 °C): water 45, ethanol 77, benzene 51, acetone 13, ethyl methyl ketone 26.

Form Supplied in: colorless crystalline compound; commercially available.

Analysis of Reagent Purity: HCl titration.

Purification: purified by either vacuum sublimation or azeotropic distillation with benzene followed by recrystallization from petroleum ether or methanol-ethyl ether (1:1).

Handling, Storage, and Precautions: is extremely hygroscopic, corrosive, and readily sublimes at room temperature. This reagent should be stored at 0-5 °C under nitrogen. Moderately toxic by ingestion or inhalation; skin and eye irritant. Use in a fume hood.

Crystalline Organometallic Complexes.

DABCO forms stable and crystalline complexes with organometallic compounds of Li, Zn, and Mg in hydrocarbon solvents.[2] The organolithium complexes are particularly useful in promoting inert metalations of aromatic hydrocarbons.[14] An interesting application of the DABCO-BuLi complex is the quantitative lithiation of thioanisole to phenylthiomethyllithium and its subsequent use in homologation of primary alkyl bromides and iodides (eq 1).[15,16]

Catalyst for Baylis-Hillman Reaction.

DABCO is a very effective catalyst for the Baylis-Hillman reaction[17] of α,β-unsaturated vinylic systems with electrophiles (e.g. aldehydes) to produce α-substituted acrylates (eq 2).[3,18,19]

These typically slow reactions can be accelerated by increasing the molar proportions of DABCO or by varying experimental conditions, or even by use of microwave energy.[19-21] The asymmetric Baylis-Hillman reaction with a variety of chiral auxiliaries is also effectively catalyzed by DABCO (eqs 3-5).[22 -24] The use of DABCO with chiral (arylaldehydeimine)tricarbonylchromium complexes significantly enhances the yields and diastereoselectivity (eq 6).[25]

(4)

Activation of Sodamide.

DABCO remarkably enhances the reactivity of sodamide in the Haller-Bauer cleavage of nonenolizable ketones to the corresponding carboxamides (eq 7).[4,26]

Selective Cleavage of Esters.

DABCO is a selective reagent for the single-pot dealkoxycarbonylation of β-keto esters, geminal diesters, and α-sulfonyl(alkyl)malonic esters.[5,27,28] Good selectivity was noticed with β-keto esters (eq 8) and geminal diesters (eq 9), which gave ketones and monoesters, respectively. The deethoxycarbonylation of α-sulfonyl(alkyl)malonic esters in presence of DABCO is a competitive reaction with desulfonylation and is dependent on the size of alkyl groups (eqs 10, 11).[28] As the alkyl group changes from methyl to benzyl to phenyl, more desulfonation than deethoxycarbonylation is observed. This method is very effective for the cleavage of esters over conventional methods, which are essentially multi-step.

(8)

(9)

(10)

(11)

Transalkylating Agent.

The exposed lone pair of electrons and interactions between the nitrogen atoms of DABCO, which are separated by only 2.5 Å, are the key factors in the transalkylation reactions with quaternary ammonium salts (eq 12).[6]

(12)

Dehydrohalogenating Agent.

The Ramberg-Bäcklund rearrangement of α,α-dichlorobisbenzyl sulfones to the corresponding 2,3-diphenylthiirene 1,1-dioxides involves dehydrohalogenation and can be achieved very effectively by stirring with DABCO in DMSO at rt (eq 13).[7]

(13)

DABCO is also effective in the dehydrobromination of substituted dibromocyclohexanones to the corresponding cyclohexadienes (eq 14).[29]

(14)

As a Pyrolysis Catalyst.

DABCO is very effective among the tertiary amines studied for the pyrolysis of vinyl azides.[8] The products are 1-azirines and are obtained in 44-95% yields (eq 15). Use of aprotic solvents with DABCO decreases the yields.

(15)

As a Nucleophilic Acylating Agent.

Its action as a nucleophilic acylation catalyst is significant in the formation of a large number of cyanohydrin esters from α-keto nitriles and aldehydes (eqs 16, 17).[9] The homogeneous, mild, and safe experimental conditions make this method very attractive over the two-phase PTC methods with use of excess cyanide ion.[30] Commercially useful 6´-*O*-

acylsucroses were synthesized by the DABCO-catalyzed regioselective acylation of sucrose with 3-acyl-5-methyl-1,3,4-thiadiazole-2(3*H*)-thiones (eq 18).[31]

(16)

(17)

As an Additive for Trialkylborohydrides.

Alkali metal trialkylborohydrides (Li and Na) with bulky alkyl groups are useful chiral reducing agents for carbonyl compounds. These hydrides can be prepared in high yield by the reaction of trialkylboranes with ***Lithium Aluminum Hydride*** or with $NaEt_2AlH_2$ in presence of DABCO (eqs 19, 20). The role of DABCO is to precipitate AlH_3 and Et_2AlH from the reaction medium.[10,32]

$$LiAlH_4 + R_3B \xrightarrow[\text{0-25 °C, 90\%}]{\text{DABCO, ether}} LiR_3BH + DABCO \cdot AlH_3 \quad (19)$$

$$NaEt_2AlH_2 + R_3B \xrightarrow[\text{0-25 °C, 96\%}]{\text{DABCO, ether}} NaR_3BH + DABCO \cdot Et_2AlH \quad (20)$$

As a Catalyst in Miscellaneous Reactions.

DABCO effects singlet oxygen quenching very efficiently without undergoing any chemical change.[11] It is a selective basic catalyst for the reaction of phenyl isocyanate with polyhydric alcohols to form polyurethanes.[12] DABCO is particularly effective as a base catalyst in the Michael addition reactions of α,β-unsaturated ketones with β-keto thiolesters and *S,S´*-diethyl dithiomalonate (eqs 21, 22).[13] The reaction is so specific to the base catalyst that the use of strong bases did not result in any product formation. Recently its use as a base in the phospha-Witting reaction to form C-P double bonds was also reported (eq 23).[33]

As a electron-donor reagent it forms a variety of useful adducts and complexes. The DABCO-$2Br_2$ complex (mp 155-60 °C, stable to air, light, and water) is a selective reagent for the oxidation of benzylic and secondary hydroxyls,[34] and for sulfides.[35] The DABCO-$2H_2O_2$ complex is an equivalent to anhydrous ***Hydrogen Peroxide***.[36] This on treatment with ***Chlorotrimethylsilane*** gives ***Bis(trimethylsilyl) Peroxide***, a useful reagent for the electrophilic hydroxylation of aromatic and heteroaromatic systems[37] and also for the facile conversion of sulfones to carbonyl compounds.[38]

1,8-Diazabicyclo[5.4.0]undec-7-ene[1]

[6674-22-2] · $C_9H_{16}N_2$ · 1,8-Diazabicyclo[5.4.0]undec-7-ene · (MW 152.24)

(organic soluble base for elimination reactions, isomerizations, esterifications, amidations, etherifications, condensations, carboxylations/carbonylations, and halogenations)

Alternate Name: DBU.

Physical Data: bp 259-260 °C; *d* 1.0192 g cm^{-3}.

Solubility: readily sol water, ethanol, benzene, acetone, ethyl acetate, carbon tetrachloride, diethyl ether, dioxane, 1,4-butanediol, dimethyl sulfoxide; hardly sol petroleum ether.

Form Supplied in: clear, light yellow liquid.

Handling, Storage, and Precautions: stable at ambient temperatures, but is hygroscopic; overexposure to atmosphere results in water absorption which can lead to hydrolysis; rate of hydrolysis to *N*-(3-aminopropyl)-ε-caprolactam (10 wt% soln; molar ratio 1:76) is 3×10^{-4} $mol\%^{-1}$ min^{-1}; half-life for a 0.657 molar soln is 33 min at 35 °C; contact with undiluted product may cause skin irritation or burns.

Introduction.

1,8-Diazabicyclo[5.4.0]undec-7-ene is an organic soluble amidine base which has been used effectively, and under relatively mild conditions, for a variety of base-mediated organic transformations including eliminations, isomerizations, esterifications, amidations, etherifications, condensations, carboxylations/carbonylations, and halogenations. A related reagent, ***1,5-Diazabicyclo[4.3.0]non-5-ene*** (DBN), is used for similar reactions.

Elimination Reactions.

DBU has been used widely for dehydrohalogenations as well as for the introduction of unsaturation by elimination of sulfonic acids. Reactions generally proceed under mild conditions and without side reactions. Typical procedures use equimolar base and elevated reaction temperatures (generally 80-100 °C). Reaction solvents such as DMF, benzene,

and DMSO have been used with reaction times varying from several hours to several days. Products may be distilled directly from the reaction mixture or separated from the DBU salt byproduct by extraction with a nonpolar solvent. Terminal as well as internal double bonds can be introduced with a high degree of regioselectivity. Additionally, this method has been used to prepare functionalized alkenes such as vinyl halides and vinyl ethers. Alkynes are not typically prepared using DBU-mediated eliminations; propargyl ethers, however, are an exception.

Oediger and Möller introduced DBU in 1967 for the dehydrohalogenation of bromoalkanes. DBN was found to be less effective.[2] For example, treatment of 4-bromoheptane with equimolar DBU at 80-90 °C gave 3-heptene in 91% yield; with DBN the yield was 60%. Similar treatment of 2-bromooctane gave a 4:1 mixture of 2-octene and 1-octene in 84% yield; with DBN the yield was 40%.

DBU was used in the following one-pot procedure for converting β-disubstituted primary alkyl iodides to terminal alkenes.[3] DBN was also used effectively for this procedure. The THP-protected tosylate (**1**) was converted to the corresponding iodide with NaI in DMF; subsequent addition of 1.5 equiv of DBU and heating at 80 °C for 3-4 h afforded terminal alkene (**2**) in 82% overall yield from (**1**) (eq 1). For comparison, when (**1**) was transformed into the bromide and treated with ***Potassium t-Butoxide*** in DMSO at 50 °C, a 3:2 mixture of the terminal alkene and its rearranged trisubstituted isomer resulted.[4]

(1)

DBU was found to be an effective base for converting piperidine (**3**) into 3,4-dehydropiperidine (**4**) without formation of the undesired 2,3-dehydropiperidine in a synthesis of the alkaloid sedinine (eq 2).[5]

(2)

DBU has also been used to prepare (*E*)-1-iodo-1-alkenes from 1,1-diiodoalkanes.[6] In a representative procedure (eq 3), diiodobutane (**5**) was combined with equimolar DBU and heated to 100 °C until appearance of a brown solid (15-20 min). The product, (*E*)-1-iodo-1-butene (**6**), was isolated in 80% yield by distilling directly from the reaction mixture. Higher-boiling vinyl iodides required DMSO as reaction solvent and product extraction with pentane.

(3)

DBU is not typically used to convert vinyl halides into alkynes; in general, this conversion requires alkoxides, solid alkali, or alkali metal amides.[7] However, the (*Z*)-vinyl bromide (**7**: R = H) was nearly quantitatively converted into terminal alkynes (**8**) in 2 h with DBU in refluxing benzene; the corresponding (*E*) isomer did not react (eq 4).[8] When a (*Z/E*) mixture of (**7**) was treated with ***Potassium Carbonate*** in refluxing methyl ethyl ketone (MEK), only starting material was recovered. With β-oxygen substitution (R = CH_2OH), vinyl bromides (**7**) were quantitatively converted into alkynes in 1 h with either DBU in refluxing benzene or potassium carbonate in refluxing MEK.

(4)

DBU has also been used to prepare alkenes from sulfonates. Heating tosylate (**9**) in solvent DBU for 30 min at 100 °C afforded the *cis* vinyl ether (**10**) in 72% yield (eq 5).[9] When (**9**) was treated with potassium *t*-butoxide in *t*-butanol for 30 min at 80 °C, the vinyl ether product was a 3:7 *cis*:*trans* alkene isomer mixture (72% yield).

(5)

Otter used DBU to effect the elimination of methanesulfonic acid in the final step of his preparation of 1,3-dimethyl-6-propyluracil, a synthetic pyrimidine nucleoside (eq 6).[10]

(6)

Isomerizations.

1,8-Diazabicyclo[5.4.0]undec-7-ene is used for base-mediated double bond migrations and epimerizations. Isomerizations generally require proton abstraction at a carbon α to a carbonyl group (or related functionality) and are thermodynamically controlled.

DBU was used to equilibrate a mixture of substituted pyrrolidin-2-ones in the final step of a herbicide synthesis.[11] The mixture of isomers (**11**) was allowed to stand for 1 h at rt with DBU in toluene to give the pure 3,4-*trans* isomer (**12**) in 96% yield (eq 7).

(11) (12)

(7)

Amidine bases have been used extensively for the equilibration of β-lactams. Although DBN appears to be the base of choice for such epimerizations,[12-17] the 7α-(dimethylamidino)-3-cephem ester 1α-oxide (**14**) was prepared via DBU epimerization of the corresponding 7β-isomer (**13**) (eq 8).[18]

DBU has been employed to convert esters with β,γ-unsaturation into the corresponding α,β-unsaturated isomers.[19] Thus 3-pentenoate (**15**) underwent up to 60% isomerization to 2-pentenoate (**16**) in the presence of DBU at 100 °C (eq 9). Corresponding exposure of pure *cis*-2-pentenoate (**16**) to DBU at 130 °C for 4 h afforded a similar product mixture (53% *trans*-2-pentenoate, 40% of 3-pentenoate (**15**), and 7% recovered starting material), suggesting thermodynamic equilibrium.[20] For comparison, in a continuous process using ***4-Dimethylaminopyridine*** at reflux, up to 78% of the thermodynamically favored (**16**) was converted to (**15**) over the course of 30 h.

β,γ-Unsaturated nitriles (e.g. **17**) have been isomerized to the thermodynamically favored α,β-unsaturated nitriles (e.g. **18**) in the presence of catalytic DBU or DBN (eq 10).[21]

As part of a study directed toward the synthesis of dodecahedrane, DBU was used to effect the isomerization of bis-enone (**19**) into (**20**) in 90% yield (eq 11).[22] The mechanism was presumed to involve formation of the β,γ-unsaturated isomer of bis-enone (**19**).

Several biomimetic methods for the conversion of amines to carbonyl compounds have used amidine bases to effect equilibration of the intermediate imine.[23-25] Rapoport used DBU in the oxidation of amines with 4-formyl-1-methylpyridinium benzenesulfonate (FMPBS).[25] As an example, phenylacetaldehyde (**22**) was obtained in 83% yield from β-phenylethylamine (**21**) after treatment with FMPBS and DBU in CH_2Cl_2/DMF (eq 12). ***Triethylamine*** was not effective as a DBU replacement except when the amine β-carbon had electron withdrawing substituents (e.g. acetophenone from α-phenylalanine).

Esterifications, Amidations, and Etherifications.

DBU has been used to prepare esters[26] and amides[27] from carboxylic acids as well as ethers,[28] esters,[29] and carbamates[30] from alcohols. These procedures involve proton abstraction followed by reaction of the carboxylate or alkoxide with an alkyl halide, acylating agent, or other suitable electrophile. Esterifications and amidations are generally conducted at or near rt, whereas etherifications require elevated temperatures (60-80 °C).

In 1978, Ono reported a convenient procedure for the esterification of carboxylic acids using DBU.[26] Esters were produced in high yield from acids, alkyl halides, and DBU. The advantage of this procedure is that it provides mild conditions for esterification, it is not necessary to prepare the carboxylate anion in a separate step, and side reactions, especially dehydrohalogenation, are avoided. Amino acids have been esterified without racemization using this procedure. As a representative example, benzoic acid reacted with ethyl iodide in the presence of DBU for 1 h to give ethyl benzoate in 95% yield. The same reaction using triethylamine instead of DBU afforded essentially no ethyl benzoate. With benzyl bromide, benzoic acid, and DBU in DMSO, benzyl benzoate was formed quantitatively at 30 °C in 10 min.[31] Triethylamine, when substituted for DBU, afforded benzyl benzoate in 81% after 1 h at 30 °C; ***Pyridine*** afforded a 15% yield of benzyl benzoate after 6 h.

The high yields of ester afforded by this method make it attractive for polyester synthesis.[31] Thus isophthalic acid reacted with *m*-xylylene dibromide in the presence of 2 molar equiv of DBU in DMSO at 30 °C for 3 h to afford polyester (**23**) in high yield and viscosity (eq 13). Other organic bases such as triethylamine, pyridine, *N*,*N*-dimethylaminopyridine, or a DBU-pyridine mixture did not afford any polymer.

(13)

This method has also been used for the esterification of polymers.[28,32] As an example, poly(methacrylic acid) (**24**) reacted with *p*-bromomethylnitrobenzene in the presence of equimolar DBU in DMSO at 30 °C for 3 h to afford poly(methacrylate) (**25**) at 97 mol% esterification (eq 14).

(14)

The etherification of poly(4-hydroxystyrene) (**26**) is related.[32] On treatment with equimolar *p*-bromomethylnitrobenzene and DBU in HMPA at 60 °C for 24 h, (**26**) was converted into poly[4-(4-nitrobenzyloxy)styrene] (**27**) at 98 mol% etherification (eq 15). Solvents such as DMF, DMSO, and NMP were less effective for this reaction, requiring longer reaction times, higher reaction temperatures, and excess reagent. For example, a high degree of etherification (>80%) using DMF as solvent required 2 molar equivalents each of *p*-bromomethylnitrobenzene and DBU at 80 °C for more than 24 h. No reaction was observed using triethylamine or pyridine instead of DBU.

(15)

Polyimides containing pendant carboxylic acids have also been esterified using 1-phenethyl bromide and DBU.[33,34]

In an alternative approach to esterification, DBU was used to accelerate the reaction of *N*-acylimidazoles with *t*-butanol in a one-pot conversion of carboxylic acids into their *t*-butyl esters. The general reaction is outlined in eq 16. Acids were treated with 1 molar equiv of ***N,N´-Carbonyldiimidazole*** in DMF under a nitrogen atmosphere at temperatures from 40 to 80 °C and reaction times of 5 to 24 h. Products were extracted from the reaction mixtures with diethyl ether. In this manner, *t*-butyl benzoate, *t*-butyl cinnamate, and *t*-butyl heptanoate were prepared in 91%, 64%, and 68% yield, respectively. With sodium *t*-butoxide rather than DBU, there was competitive formation of 3-oxoalkanoic esters with acids having one or two protons at C-2.[35] A similar limitation was noted for the conversion of *N*-acylimidazoles to *t*-butyl esters using *t*-butanol and NBS.[36]

(16)

Enolizable acyl cyanides have been converted into 1-cyano-1-alkenyl esters upon treatment with tertiary amines (e.g. DBU, pyridine, dimethylamine, and ***1,4-Diazabicyclo[2.2.2]octane***) and carboxylic acid chlorides or anhydrides.[37] With acid chlorides, equimolar base was required, whereas only a catalytic amount of base was necessary for reactions involving acid anhydrides. As an example, propionyl cyanide was treated with a stoichiometric amount of DBU and acetyl chloride in methylene chloride at rt to afford 1-cyanovinyl acetate in 61% yield.

DBU has also been used for certain deesterifications. In the case of acetates, deacetylation with DBU occurs under relatively mild conditions (rt to 80 °C; 5-45 h).[38] The method only works for esters derived from acetic acid. Methanol is the solvent of choice, although dichloromethane or benzene may be added to improve reactant solubility. It was speculated, though not confirmed, that the mechanism involves formation of the desired alcohol by elimination of ketene. As an example, acetate (**28**) was deacetylated in 93% yield to alcohol (**29**) with DBU in methanol at rt for 24 h (eq 17). The same reaction using DBU in xylene afforded only starting material.[39]

(17)

Methyl esters are cleaved with DBU. High reaction temperatures and extended reaction times are required; however, the corresponding acid is generally obtained in high yield (>90%) without the use of ionic nucleophiles such as ***Lithium Iodide***, lithium thiolate, or potassium *t*-butoxide.[39] Thus a solution of methyl mesitoate, 10 equiv of DBU, and 10 equiv of *o*-xylene was heated to 165 °C for 48 h, affording mesitoic acid which was isolated in 95% yield after ether extraction (eq 18).

(18)

DBU was one of several effective bases used in an amide synthesis from *N*,*N*-bis(2-oxo-3-oxazolidinyl)phosphorodiamidic chloride, primary or secondary amines, and carboxylic acids.[27] Other bases included ***1-Ethylpiperidine***, triethylamine, and *N*-ethylmorpholine. Reactions were conducted at rt for 1-2 h, avoiding racemization of optically pure substrates. Thus 3,3-dimethylacrylic acid and the acid salt of (*S*)-(-)-α-methylbenzylamine in DMA were treated with 2 equiv of DBU at rt over 30 min, then allowed to react at rt for 75 min to afford amide (**30**) in 75% yield (eq 19). Other methods require higher reaction temperatures (alkyl carbamates and alkyl amines afford amides at 200 °C in the presence of tertiary amines[40]), longer reaction times (***1,3-Dicyclohexylcarbodiimide***[41] and ***Diphenylphosphinic Chloride***[42] procedures require up to 12 h and result in only modest yields for similar conversions), or excess reagents or reactants (the cyanuric chloride method[43] requires excess acid and the *o*-nitrophenyl thiocyanate/***Tri-n-butylphosphine*** method[44] uses excess reagent and amine).

(19)

Condensations.

DBU has been used to effect condensations of active methylene compounds and other substrates containing active hydrogen. Reactions generally use equimolar DBU and aprotic solvents such as THF or benzene. Reaction times and temperatures vary.

DBU was shown to be an effective base for the Michael reaction of diethyl acetamidomalonate (**31**) with methyl acrylate in a synthesis of glutamic acid (eq 20).[45] ***1,1,3,3-Tetramethylguanidine*** and DBN were found to be equally effective. All resulted in the formation of glutamic acid derivative (**32**) quantitatively.

(20)

In the Knoevenagel condensation of ***Malonic Acid*** with hexanal, the β,γ-unsaturated isomer (**33**) was obtained with 94% selectivity and 56% yield after 10 h at 90 °C in the presence of equimolar DBU (eq 21).[46] Other bases selective for (**33**) included triethanolamine, triethylamine, ethylpiperidine, *N*,*N*-dimethylaniline, and ***2,6-Lutidine***. For comparison, pyridine, 3-methylpyridine, and 4-methylpyridine showed ~90% selectivity for the α,β-unsaturated isomer. A β,γ-unsaturated carbonyl compound was also obtained from the condensation of ***Formaldehyde*** with pentenone in the presence of catalytic DBU or DBN.[47] These results are interesting in view of the literature reports that β,γ-unsaturated carboxylates[19,20] and nitriles[21] are isomerized to the thermodynamically favored α,β-unsaturated isomers in the presence of DBU.

(21)

Diesters of homophthalic acid condensed with aromatic aldehydes in the presence of equimolar DBU in refluxing benzene for 6-10 h to give excellent yields of cinnamic esters. The reaction of dimethyl homophthalate with 3-benzyloxy-4-methoxybenzaldehyde to afford cinnamic ester (**34**) is representative (eq 22).[48] Sodium hydride, sodium alkoxides, and potassium acetate were all found to be ineffective for this reaction.

DBU catalyzed the asymmetric synthesis of δ-oxocarboxylic acids from (2*R*,3*S*)-3,4-dimethyl-5,7-dioxo-2-phenylperhydro-1,4-oxazepine (**35**).[49] The Michael reaction of (**35**) with 2-cyclopenten-1-one afforded (+)-3-cyclopentanoneacetic acid (**36**) in moderate yield (43%) and high optical purity (96%) after hydrolysis and decarboxylation (eq 23). Trityllithium (***Triphenylmethyllithium***) or potassium *t*-butoxide afforded (**36**) in similar yields (30-50%) but poorer optical purity (7-76%).

Carbonylations and Carboxylations.

DBU has been used to prepare amides or imides[50-52] and esters[53] via the sequential carbonylation/alkylation of amines and alcohols, respectively. Similarly, the carboxylation of amines and alcohols affords urethanes and carbonates.[54] Reactions use stoichiometric base and are catalyzed by palladium or nickel complexes. Product yields are generally high (80-100%). Carbonylations have been conducted in DMA at elevated temperatures (115-150 °C), whereas carboxylations have been performed at rt in a variety of solvents including methylene chloride, DMSO, THF, and glyme. Eqs (24) and (25) show the preparation of *N*-phenylbenzamide and allyl benzylethylcarbamate by these procedures. The efficacy of various bases was compared in the carboxylation/alkylation of benzylethylamine using a catalytic amount of tris(dibenzylideneacetone)dipalladium ($Pd_2(dba)_3$). DBU, *N*-cyclohexyl-*N*´,*N*´,*N*´´,*N*´´-

tetramethylguanidine, and 7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene were preferred. DBN afforded a modest 49% yield of urethane and essentially no urethane was formed using ***Diisopropylethylamine***.

(24)

(25)

Methods for the preparation of thiocarbamates from alcohols, carbon disulfide, and alkylating agents[55] or via the sulfur-assisted carbonylation of alcohols[56] are related; these do not require a metal catalyst. Thus *S*-benzyl *O*-*n*-butylcarbonothionate was isolated in 86% yield after the carbonylation of *n*-butanol in THF at 80 °C for 4 h in the presence of 3 equiv of powdered sulfur and 5 equiv of DBU followed by esterification with 1.2 equiv of benzyl bromide (eq 26).

(26)

DBU has also been used in the nickel- or palladium-catalyzed coupling of alkenes with ***Carbon Dioxide***.[57,58] As an example (eq 27), isoprene was treated with $Pd(acac)_2$, a phosphine ligand, DBU, and tributyltin ethoxide for 84 h at 80 °C under CO_2 to afford an isomeric mixture of C-10 carboxylic acids (68% after esterification and purification). It was found that DBU and tributyltin ethoxide independently promote the reaction, but not as effectively as when used as a combination.

(27)

Halogenations.

DBU-based brominating agents such as DBU/bromine,[59] DBU/hydrobromide perbromide,[60] and DBU/bromotrichloromethane,[61,62] have been used to brominate enolizable substrates and aromatic compounds. As an example, 3-halomethylcephems (e.g. **38**), convenient intermediates for the synthesis of 3´-substituted cephalosporins, were prepared by treatment of *exo*-methylene cephems (e.g. **37**) with DBU/bromine in THF over the temperature range -80 to 0 °C (eq 28).

(37)

(28)

(38)

Miscellaneous.

A synthesis of phthalocyanines and metallophthalocyanines, interesting optical and electronic materials, involves the DBU-mediated reaction of alcohols with phthalonitrile at elevated temperature.[63-67] The alkoxy-3-iminoisoindolenine (**39**) is presumed to be an intermediate (eq 29). Thus phthalonitrile was treated with equimolar DBU in refluxing ethanol to afford the corresponding phthalocyanine as a blue crystalline compound. DBN was also shown to be effective for this transformation; neither pyridine nor 1,4-diazabicyclo[2.2.2]octane promoted the formation of

phthalocyanine.

(29)

Carboxylic acids have been phosgenated in the presence of a variety of amine bases, including DBU, to afford acid chlorides.[68] Reactions are conducted with 2 mol% base at 80-100 °C. Yields of acid chlorides are generally greater than 90%.

DBU was used to promote the in situ formation of hydrogen selenide from ***Selenium***, ***Carbon Monoxide***, and water for selective reduction of α,β-unsaturated carbonyl compounds.[69] *N*-Methylpyrrolidine was also found to be effective. Thus benzylideneacetone afforded 4-phenylbutanone in 82% yield in the presence of DBU, selenium, and carbon monoxide at 50 °C or *N*-methylpyrrolidine at 80 °C after 24 h. Isophorone underwent selective reduction of the conjugated double bond and β-ionone was reduced to 4-(2,6,6-trimethyl-1-cyclohexenyl)-2-butanone.

2,5-Diazido-3,6-di-*t*-butyl-1,4-benzoquinone[1]

[29342-21-0] · $C_{14}H_{18}N_6O_2$ · 2,5-Diazido-3,6-di-*t*-butyl-1,4-benzoquinone · (MW 302.38)

(reagent for the preparation of *t*-butylcyanoketene,[2] a versatile ketene for reactions with a variety of ketenophiles[1])

Physical Data: mp 89-90 °C (dec).

Solubility: sol aromatic solvents which are used in the preparation of *t*-butylcyanoketene.

Analysis of Reagent Purity: IR (Nujol) 2110 (N_3), 1640 (CO) cm^{-1}; ^1H NMR ($CDCl_3$), δ 1.31 (s, *t*-Bu).

Preparative Method: 2,5-diazido-3,6-di-*t*-butyl-1,4-benzoquinone (**2**) is readily synthesized in five steps from commercially available 2,5-di-*t*-butyl-1,4-benzoquinone (**1**) in approximately 30% overall yield (eq 1-3).[2]

Purification: recrystallization from chloroform/ethanol.

Handling, Storage, and Precautions: during the course of any purification method that might be employed, the diazide should not be heated above 50 °C since decomposition occurs quite noticeably at that temperature. It is best to store the pure product below -5 °C in the dark since it undergoes a facile photochemical rearrangement to a cyclopentenedione.[2]

Thermolysis.

Upon heating in refluxing benzene, 2,5-diazido-3,6-di-*t*-butyl-1,4-benzoquinone (**2**) loses 2 mol of nitrogen to generate 2 mol of *t*-butylcyanoketene (TBCK, **3**) (eq 4). One advantage of this route over other classical routes to TBCK is the fact that external bases or metals are not employed. Also, when the thermolysis is accomplished in the presence of a ketenophile the concentration of TBCK is low, thus minimizing polymerization reactions.[2]

Cycloadditions.

TBCK does not undergo rapid self-condensation in benzene at 25 °C but rather cycloadds to a variety of ketenophiles including alkenes, imines, enol ethers and silyl enol ethers, alkynes, allenes, ketenes, isocyanides, stannylethynyl ethers, and a variety of heterocyclic compounds.

Cycloadditions with Alkenes.

Cycloadditions of TBCK to a variety of mono-, di-, and trisubstituted alkenes give good yields of the corresponding cyclobutanones. No examples of reactions of TBCK with tetrasubstituted alkenes have been reported.[1] The addition of TBCK to alkenes generally is stereoselective, resulting in the bulky *t*-butyl group *cis* to the larger group on the alkene. These findings best correspond to a concerted $_{\pi}2_a + {}_{\pi}2_s$ reaction mechanism.[1] The reactions of TBCK with styrene and cyclohexene demonstrate this highly stereoselective route to substituted cyclobutanones (eqs 5 and 6).[1,3]

(5)

(6)

When stabilization of a zwitterionic intermediate is energetically favored, as in the addition of TBCK to *trans,trans*-2,4-hexadiene, a stepwise mechanism may be involved (eq 7).[1] The major product of this reaction appears to be cyclobutanone (**4**) and not (**5**), which would be the expected product if a concerted mechanism was involved. Other interesting products result from the reaction of TBCK with cyclic dienes. Addition to cyclohexa-1,3-diene and

bicyclo[2.2.1]heptadiene gives both the cyclobutanone product plus a formal oxy-Cope rearrangement product (eqs 8 and 9).[1,4]

(9)

Cycloadditions with Imines.

Next to alkenes, the most studied ketenophiles of TBCK are formimidates, thioformimidates, and imines.[1] Reaction of a variety of imines such as *S*-ethyl-*N*-phenylthioformimidate with TBCK produces β-lactam products (**7**) stereospecifically; the products of these reactions are consistent with a stepwise mechanism involving a dipolar intermediate (**6**) (eq 10). In addition, 2:1 adducts are also frequently formed with imines (**8**) and (**9**) (eq 11).[1,5]

(10)

(11)

Cycloadditions with Enol Ethers and Silyl Enol Ethers.

Additions of TBCK to a variety of enol ethers typically give mixtures of stereoisomers.[1] Reaction with ethyl vinyl ether generates cyclobutanone products that could only reasonably arise from a dipolar intermediate (eq 12).[1]

(12)

Additions to silyl enol ethers behave in an analogous fashion; a stepwise mechanism is involved.[6] However, different products arise depending on the steric congestion (H vs. Me) of the zwitterionic intermediate (**10**) and (**11**) formed in the reaction (eqs 13 and 14).[7]

(10)

(13)

(11)

(14)

Cycloadditions with Alkynes.

Regiospecific cycloadditions of TBCK to simple alkynes give cyclobutenones, a transformation consistent with a concerted mechanism (eq 15).[1]

(15)

Cycloaddition with Allenes.

Cycloaddition of TBCK to allenes typically gives cyclobutanone products, as in the case of 1,1-dimethylallene (eq 16).[1] The varying ratios of regio- and stereoisomeric products lend credence to a zwitterionic intermediate.

(16)

Cycloadditions with Ketenes.

Cycloaddition of TBCK to ketenes generally produces 1,3-cyclobutanedione products (eq 17), although oxetan-2-one products (**14**) can form if the steric demands on the zwitterionic intermediate (**13**) are lessened as in the case of methylketene (**12**) (eq 18).[8]

(17)

(18)

Cycloadditions with Isocyanides.

Cycloaddition of TBCK to isocyanides gives the 2:1 adducts (**15**), presumably by a stepwise mechanism (eq 19).[9] This adduct (**15**) rearranges to the iminolactone (**16**) in refluxing benzene and further thermolysis at 130 °C gives the butenolide (**17**).

(19)

Cycloaddition with Stannylethynyl Ethers.

Cycloaddition of TBCK to various stannylethynyl ethers proceeds to zwitterionic intermediates (**18**) and (**19**) which are

in equilibrium and can either rearrange to the stannyl enol ether (**20**) or can add to another molecule of TBCK to form (**21**) (eq 20).[10]

Miscellaneous Cycloadditions.

Cycloadditions of TBCK have been attempted with a host of compounds including 1-azirines,[1] *N*-oxides,[1,11] *N*-sulfiminoaziridines,[1] spirooxaziridines,[1] sulfurdiimides,[12] carbodiimides,[12] sulfinylamines,[12] and thiooxazoles.[13] All cycloadditions listed here appear to involve a stepwise dipolar mechanism.

Cycloreversions of Cyclobutanone Adducts.

A variety of cyclobutanone products derived from the cycloaddition of TBCK with alkenes have been thermolyzed to form the original ketenes and ketenophiles (eq 21).[14] These retro [2 + 2] reactions appear to be concerted processes due to the lack of appreciable solvent effects.

Related Reagents.

2,6-Di-t-butyl-1,4-benzoquinone.

Diazidotin Dichloride

$SnCl_2(N_3)_2$

[32006-05-6] · Cl_2N_6Sn · Diazidotin Dichloride · (MW 273.64)

(electrophilic activating agent for thioacetals[1])

Physical Data: white powder; explodes on heating without melting.

Solubility: insol CH_2Cl_2 and most org solvents; sparingly sol Me_3SiCl.

Form Supplied in: white or slightly yellow high polymer.

Analysis of Reagent Purity: IR spectroscopy; explodes under microanalytical N_2 determination.

Preparative Methods: from reaction of Me_3SiN_3 with $SnCl_4$ (1:1 to 2:1) in CH_2Cl_2 or pentane at rt,[2] or by oxidative addition of halogen azides to tin(II) chloride in CCl_4 at 0 °C.[3]

Purification: almost analytically pure after washing with solvent and drying in vacuo; does not crystallize or sublime.

Handling, Storage, and Precautions: the dry solid is sensitive to hydrolysis and should be stored in the absence of moisture. Contact with metal (spatula) must be avoided and the reagent should be used only behind a safety shield. Use in a fume hood.

Thiophilic Electrophile.

Generated in situ from ***Azidotrimethylsilane*** and ***Tin(IV) Chloride***, diazidotin dichloride converts thioacetals of cyclic ketones to imino thioethers (eq 1).[1] This one step process involves generation of a thionium ion, subsequent formation of an α-azido sulfide, and Schmidt rearrangement of the latter.

Addition of ***Sodium Azide*** instead of Me_3SiN_3 gives better yields of imino thioethers (50-83%), but in this case difficulties are encountered on a large scale (>10 mmol) because of the heterogeneous nature of the process. For small-scale reactions, appreciably better yields (to 95%) can be obtained by using 0.5 equiv of preformed diazidotin dichloride and 1 equiv of $SnCl_4$ in methylene chloride.[1]

Chemoselectivity of the process is reasonably high (eq 2)[1] and thus it is possible to reverse the normal reactivity pattern of thioacetal and ketone groups.

Lewis Acid Adducts.

Diazidotin dichloride forms at rt a reasonably stable 1:1 adduct with neat Me_3SiCl, precipitated as a white solid (eq 3).[2] The complex decomposes without melting on heating with quantitative elimination of Me_3SiCl and dissociates in solutions of organic solvents (by NMR).[2,3]

$$SnCl_2(N_3)_2 + Me_3SiCl \underset{\Delta,\ 80\text{-}90\ ^\circ C}{\overset{\text{in } Me_3SiCl}{\rightleftharpoons}} Cl_2Sn(N_3)_2 \cdot Me_3SiCl \quad (3)$$

Diazoacetaldehyde[1]

[6832-13-9] · $C_2H_2N_2O$ · Diazoacetaldehyde · (MW 70.06)

(cyclopropanation of alkenes;[2] condensation with organoboranes;[3] 1,3-dipolar cycloaddition with alkynes, yielding substituted pyrazoles[2,4])

Physical Data: bp 40 °C/10 mmHg: *d* 1.159 g cm^{-3}.

Solubility: sol water, ethanol, diethyl ether, THF, and dichloromethane; insol hydrocarbon solvents.

Preparative Methods: diazoacetaldehyde is not commercially available, but can be prepared from β-*N*-methylanilinoacrolein and ***p-Toluenesulfonyl Azide***.[2] A simple and convenient preparation involves the treatment of ***Acetic Formic Anhydride*** with ***Diazomethane*** in diethyl ether.[5]

Handling, Storage, and Precautions: extreme caution must be exercised when handling diazoacetaldehyde. It is thermally unstable and will detonate violently if overheated (do not expose to temperatures above 50 °C), emitting toxic fumes of NO_x. At low temperatures, diazoacetaldehyde can be stored for several weeks without noticeable decomposition. This reagent should only be handled in a fume hood.

Cyclopropanation.

Diazoacetaldehyde can serve as a source of formylcarbene. This reactive carbenoid can readily add to an alkene, giving rise to a cyclopropyl aldehyde. A number of catalysts have been examined to effect this addition, of which ***Copper(II) Acetylacetonate*** proved to be the most promising. The generation of the formyl carbenoid with $Cu(acac)_2$ in tetramethylethylene is accompanied by rapid addition to the alkene (eq 1).[2]

(1)

1,3-Dipolar Cycloaddition.

The uncatalyzed cycloaddition of diazoacetaldehyde with a suitable dipolarophile yields a substituted pyrazole.[4] Diazoacetaldehyde reacts with ***Dimethyl Acetylenedicarboxylate*** to give 3-formyl-4,5-dimethoxycarbonylpyrazole (eq 2).[2]

(2)

Condensation.

Addition of diazoacetaldehyde to an organoborane provides a convenient method for a two-carbon homologation of an alkene, via its organoborane derivative, to an aldehyde. This reaction possesses excellent regioselectivity with unsymmetrical alkenes. Terminal alkenes are successfully homologated to give exclusively primary alkyl substituents over secondary. The organoborane of cyclopentene is condensed with diazoacetaldehyde to give cyclopentylacetaldehyde (eq 3).[3] This reaction is conveniently carried out in a THF/water solvent to afford the aldehyde in excellent yield.

(3)

Related Reagents.

Diazoacetone; α-***Diazoacetophenone***; ***Ethyl Diazoacetate***; ***Methyl Diazoacetate***.

Diazoacetone[1]

[2684-62-0] · $C_3H_4N_2O$ · Diazoacetone · (MW 84.09)

(cyclopropanation of alkenes,[2] furans,[3] and oxy alkenes;[4] condensation with carbonyls[5,6] and organoboranes;[7] 1,3-dipolar cycloaddition with acrylates[8] and alkynes,[9] yielding substituted pyrazolines and pyrazoles)

Physical Data: bp 49 °C/13 mmHg.

Solubility: sol diethyl ether, THF, DME, methanol, cyclohexane, benzene.

Preparative Methods: diazoacetone is not commercially available, but can be prepared from ***Acetyl Chloride*** and ***Diazomethane***.[10] An alternative method for preparation involves an alkaline acyl cleavage of 3-diazo-2,4-pentanedione.[11]

Handling, Storage, and Precautions: diazo ketones are known to be unstable at elevated temperatures (>50 °C) and should be handled in a fume hood. The health risks associated with diazoacetone have not been evaluated. At low temperatures diazoacetone can be stored without significant decomposition.

Cyclopropanation.

The metal-catalyzed decomposition of diazoacetone generates a reactive carbenoid species which readily adds to a variety of alkenes. This reaction can give rise to a cyclopropyl ketone in moderate yield or subsequently furnish a rearranged product. The catalyzed reaction between diazoacetone and a suitable alkene is often carried out neat or with cyclohexane as the solvent. The generation of the keto carbenoid with anhydrous ***Copper(II) Sulfate*** in cyclohexene is accompanied by rapid addition to the alkene (eq 1).[2] Diazoacetone addition to 1-ethoxycyclohexene is catalyzed efficiently with ***Copper Bronze*** at 90 °C for 2 h. Aqueous acid hydrolysis and ring opening yields a 1,4-diketone.[12] Addition of diazoacetone to furan, also catalyzed by copper bronze, furnishes a cross-conjugated dicarbonyl (eq 2).[3]

(1)

(2)

The catalyzed reaction of diazoacetone with the trimethylsilyl enol ether of cyclohexanone affords a regiospecific silyl enol ether formed through a silatropic retro-aldol (eq 3).[13] Cyclopropanation of a methyl enol ether in the presence of copper bronze yields a β-methoxycyclopropyl ketone.[14] Subsequent acid hydrolysis yields a 1,4-keto aldehyde (eq 4). The catalytic reaction between diazoacetone and 1-methoxy-1,3-butadiene provides only mild regioselectivity, with the predominant formation of the nonoxygenated cyclopropane.[15]

(3)

(4)

In addition to alkenes, diazoacetone can undergo catalytic insertion into a number of carbenoid acceptors. A substituted dihydrofuran is synthesized by the ***Copper(II) Acetylacetonate***-catalyzed insertion of diazoacetone into a ketene dimethyl acetal.[16] A benzyl ketone is obtained by the $Rh_2(O_2CCF_3)_4$-catalyzed addition of diazoacetone to benzene.[17] Cyclopropenes are formed through either catalytic or photolytic insertion into alkynes.[18,19]

Condensation.

Treatment of diazoacetone with ***Silver(I) Oxide*** in diethyl ether generates a diazomethyl carbon nucleophile that adds to most electrophiles in moderate to poor yields.[20] An improved result is seen with the condensation between diazoacetone and a ketone or aldehyde, conveniently effected under basic conditions to yield an α-diazo-β-hydroxycarbonyl.[5] 1,3-Diketones can be readily formed by the addition of 1-diazo-1-lithioacetone to an aldehyde followed by a catalytic transformation with $Rh_2(OAc)_4$ (eq 5).[21] This condensation process is quite efficient with excellent yields obtained for a variety of aldehydes. 1-Diazo-1-lithioacetone also reacts with lactones and thiolactones to give the corresponding diazo alcohol or diazo thiol. The respective 2-substituted 3-oxepanone or 2-substituted 3-thiopanone is formed upon heating in benzene with a catalytic amount of $Rh_2(OAc)_4$ (eq 6).[6,22]

(5)

(6)

The addition of diazoacetone to an organoborane provides a convenient method for a three-carbon homologation of an alkene, via an organoborane, to a ketone or regiospecific enol borane.[7,23] This enol borane can be mono α-alkylated with certain electrophiles in the presence of lithium dimethylaminoethoxide (eq 7). Di- and polyalkylation products are not observed, nor is alkylation of the methyl terminus.

An α-alkoxy ketone or an α-thioketone is prepared by the insertion of the keto carbenoid of diazoacetone into the O-H or S-H bond of an alcohol or thiol.[24,25]

1,3-Dipolar Cycloaddition.

Diazoacetone can undergo an uncatalyzed 1,3-dipolar cycloaddition with a variety of dipolarophiles to yield pyrazoles or pyrazolines.[8,9,26] Reaction with an α-substituted acrylate under mild conditions yields a 3,5,5-trisubstituted pyrazoline in good yield (eq 8).[27]

Related Reagents.

Diazoacetaldehyde; α-***Diazoacetophenone***; ***Ethyl Diazoacetate***; ***Methyl Diazoacetate***.

α-Diazoacetophenone[1]

[3282-32-4] · $C_8H_6N_2O$ · α-Diazoacetophenone · (MW 146.16)

(precursor to carbenes and carbenoids;[2] reagent for preparation of sulfonium,[3] oxonium,[4] and pyridinium[5] ylides; 1,3 dipole for heterocycle synthesis;[6] reagent for Lewis acid or transition metal-mediated insertion reactions;[7] reagent for cyclopropanation of alkenes[8] and for aromatic annulation[9])

Physical Data: pale yellow rods, mp 49-50 °C.

Solubility: sol ether, THF; slightly sol pentane.

Form Supplied in: not commercially available.

Preparative Methods: an improved method of synthesis of diazo ketones has been recently published, via acylation of the lithium enolate of the ketone with ***2,2,2-Trifluoroethyl Trifluoroacetate*** and subsequent reaction with ***Methanesulfonyl Azide***.[10] Alternatively, acylation of diazomethane with aroyl chlorides in the presence of triethylamine provides a general method for the synthesis of aromatic diazo ketones.[11]

Handling, Storage, and Precautions: diazoacetophenone is a skin irritant; therefore direct contact should be avoided. Diazoacetophenone has shown microbial mutagenicity.

Ylide Formation.

Diazoacetophenone (and other diazo ketones) react under copper catalysis with sulfides to form sulfonium ylides, which may be trapped with electron-deficient alkenes for cyclopropanation (eq 1).[3a] Sulfonium ylides are also available by acid-catalyzed reaction with sulfides, followed by base treatment.[3b] Applied to cyclic sulfides, the ylides so formed can undergo [2,3]-rearrangement, allowing for ring expansion (eq 2).[3c]

In a similar fashion, oxonium ylides, formed by rhodium(II)-catalyzed decomposition of diazoacetophenone in the presence of methyl allyl and methyl propargyl ethers, undergo [2,3]-rearrangement to provide methoxy keto alkenes (eq 3)[4a] and allenes (eq 4).[4b] Rhodium(II) perfluorobutyrate is often the preferred catalyst to minimize competing cyclopropanation.

(4)

Decomposition of diazoacetophenone in the presence of 2-(methylthio)pyridine affords the pyridinium ylide, which undergoes 1,3-dipolar cycloadditions with a variety of dipolarophiles (eq 5).[5]

(5)

Heterocycle Formation.

Diazoacetophenone reacts with nitriles under Lewis acid (eq 6) or transition metal (eq 7) catalysis to afford oxazoles.[6a,b]

(6)

(7)

Alternatively, diazoacetophenone reacts with unsaturated nitriles and esters under pyridine catalysis to yield pyrazolines. The nitrile-derived pyrazolines undergo alkoxide-induced elimination of HCN to afford the 3-benzoylpyrazoles (eq 8).[6c] A variety of activated alkenes, including enamines,[6d] and vinyltriphenylphosphonium salts,[6e] can be readily converted to the corresponding pyrazolines and pyrazoles with diazoacetophenone (eq 9). Additionally, treatment of formamidines with diazoacetophenone affords the 4-benzoyl-1,2,3-triazole (eq 10).[12]

(8)

(9)

(10)

Insertion Reactions.

Diazoacetophenone (and other diazo ketones) reacts with a variety of compounds containing acidic X-H bonds under

Lewis acid and transition metal catalysis. Included are alcohols,[7a] thiols,[7b] and trialkylsilanes (eq 11).[7c] The latter forms a general synthesis of α-silylacetophenone (and α-silyl ketones). In similar fashion, diazoacetophenone reacts with trialkylboranes affording, selectively, the (*E*)-enol boronates (eq 12).[7d]

(11)

(12)

Cyclopropanation.

Diazoacetophenone is effective in transition metal-mediated cyclopropanation of a variety of alkenic compounds. For electron-deficient alkenes, molybdenum catalysts favor cyclopropane formation over competing pyrazoline formation (eq 13).[8a] Reaction with vinylboronic acid esters follows in similar fashion, with ***Palladium(II) Acetate*** as the catalyst of choice for the formation of benzoylcyclopropylboronic acid esters (eq 14).[8b]

(13)

$(E):(Z) = 1.9$

(14)

$(E):(Z) = 2.0$

Aromatic Annulation.

Diazo ketones have been utilized in a novel aromatic annulation protocol. The use of diazoacetophenone in this fashion allows for the conversion of alkynes into naphthol derivatives (eq 15).[9]

(15)

Related Reagents.

Diazoacetaldehyde; ***Diazoacetone***; ***Ethyl Diazoacetate***; ***Methyl Diazoacetate***.

5-Diazo-2,2-dimethyl-1,3-dioxane-4,6-dione

[7270-63-5] · $C_6H_6N_2O_4$ · 5-Diazo-2,2-dimethyl-1,3-dioxane-4,6-dione · (MW 170.14)

(reagent for the synthesis of α-oxygenated ketenes for [2 + 2] cycloadditions with alkenes[2])

Alternate Name: diazo Meldrum's acid.

Physical Data: solid with a melting point of 90-91 °C.

Solubility: sol ether, dichloromethane, and acetonitrile.

Preparative Methods: most commonly by diazo transfer to Meldrum's acid. A number of procedures involving the use of sulfonyl azide reagents have been reported.[1] Typical procedures involve the addition of the sulfonyl azide to a solution of Meldrum's acid containing a tertiary amine base. Aqueous workup followed by chromatography on silica gel provide the diazo compound in yields ranging from 40 to 76%. A modification using KF on alumina is reported to provide a 90% yield of product.[1a] Diazo compounds are potentially explosive as are certain sulfonyl azides, such as tosyl azide. For this reason, extreme care must be observed in the synthesis and use of this compound, with all operations being conducted behind a blast shield in a fume hood.

Handling, Storage, and Precautions: in addition to the previously mentioned explosion hazard which this reagent presents, there are health related hazards that must also be considered. Diazo compounds, as a class, are toxic and irritating and can be sensitizers. They must be used in a well-ventilated fume hood and not come in contact with skin. For a description of the hazards associated with this class of compounds, see the handling and storage precautions listed for ***Diazomethane***.

Cycloadditions.

Diazo Meldrum's acid was at one time used for the synthesis of spiro activated cyclopropanes;[2] however, after the original report, it was found that the adduct formed was not the expected cyclopropane, but a cyclobutane which was

the result of ketene-alkene cycloaddition.[3] Thus photolysis at 254 nm promotes extrusion of N_2 to provide a carbene which undergoes a Wolff rearrangement to provide an α-alkoxy ketene. This then undergoes a [2 + 2] cycloaddition to provide the cyclobutane (eq 1). This reaction appears to work with a variety of alkenes including hindered alkenes such 1,3,3-trimethylcyclohexene (eq 2).

Diazomethane[1]

[334-88-3] · CH_2N_2 · Diazomethane · (MW 42.04)

(methylating agent for various functional groups including carboxylic acids, alcohols, phenols, and amides; reagent for the synthesis of α-diazo ketones from acid chlorides, and the cyclopropanation of alkenes[1])

Physical Data: mp -145 °C; bp -23 °C.

Solubility: diazomethane is most often used as prepared in ether, or in ether containing a small amount of ethanol. It is less frequently prepared and used in other solvents such as dichloromethane.

Analysis of Reagent Purity: diazomethane is titrated[2] by adding a known quantity of benzoic acid to an aliquot of the solution such that the solution is colorless and excess benzoic acid remains. Water is then added, and the amount of benzoic acid remaining is back-titrated with NaOH solution. The difference between the amount of acid added and the amount remaining reveals the amount of active diazomethane present in the aliquot.

Preparative Methods: diazomethane is usually prepared by the decomposition of various derivatives of *N*-methyl-*N*-nitrosoamines. Numerous methods of preparation have been described,[3] but the most common and most frequently employed are those which utilize ***N-Methyl-N-nitroso-p-toluenesulfonamide*** (Diazald®; **1**),[4] ***1-Methyl-3-nitro-1-nitrosoguanidine*** (MNNG, **2**),[5] or *N*-methyl-*N*-nitrosourea (**3**).[2]

The various reagents each have their advantages and disadvantages, as discussed below. The original procedure[6] for the synthesis of diazomethane involved the use of *N*-methyl-*N*-nitrosourea, and similar procedures are still in use today. An advantage of using this reagent is that solutions of diazomethane can be prepared without distillation,[7] thus avoiding the most dangerous operation in other preparations of diazomethane. For small scale preparations (1 mmol or less) which do not contain any alcohol, a kit is available utilizing MNNG which produces distilled diazomethane in a closed environment. Furthermore, MNNG is a stable compound and has a shelf life of many years. For larger scale preparations, kits are

available for the synthesis of up to 300 mmol of diazomethane using Diazald as the precursor. The shelf life of Diazald (about 1-2 years), however, is shorter than that of MNNG. Furthermore, the common procedure using Diazald produces an ethereal solution of diazomethane which contains ethanol; however, it can be modified to produce an alcohol-free solution. Typical preparations of diazomethane involve the slow addition of base to a heterogeneous aqueous ether mixture containing the precursor. The precursor reacts with the base to liberate diazomethane which partitions into the ether layer and is concomitantly distilled with the ether to provide an ethereal solution of diazomethane. Due to the potentially explosive nature of diazomethane, the chemist is advised to carefully follow the exact procedure given for a particular preparation. Furthermore, since diazomethane has been reported to explode upon contact with ground glass, apparatus which do not contain ground glass should be used. All of the kits previously mentioned avoid the use of ground glass.

Handling, Storage, and Precautions: diazomethane as well as the precursors for its synthesis can present several safety hazards, and must be used with great care.[8] The reagent itself is highly toxic and irritating. It is a sensitizer, and long term exposure can lead to symptoms similar to asthma. It can also detonate unexpectedly, especially when in contact with rough surfaces, or on crystallization. It is therefore essential that any glassware used in handling diazomethane be fire polished and not contain any scratches or ground glass joints. Furthermore, contact with certain metal ions can also cause explosions. Therefore metal salts such as calcium chloride, sodium sulfate, or magnesium sulfate must not be used to dry solutions of the reagent. The recommended drying agent is potassium hydroxide. Strong light is also known to initiate detonation. The reagent is usually generated immediately prior to use and is not stored for extended periods of time. Of course, the reagent must be prepared and used in a well-ventilated hood, preferably behind a blast shield. The precursors used to generate diazomethane are irritants and in some cases mutagens and suspected carcinogens, and care should be exercised in their handling as well.

Methylation of Heteroatoms.

The most widely used feature of the chemistry of diazomethane is the methylation of carboxylic acids. Carboxylic acids are good substrates for reaction with diazomethane because the acid is capable of protonating the diazomethane on carbon to form a diazonium carboxylate. The carboxylate can then attack the diazonium salt in what is most likely an S_N2 reaction to provide the ester. Species which are not acidic enough to protonate diazomethane, such as alcohols, require an additional catalyst, such as ***Boron Trifluoride Etherate***, to increase their acidity and facilitate the reaction. The methylation reaction proceeds under mild conditions and is highly reliable and very selective for carboxylic acids. A typical procedure is to add a yellow solution of diazomethane to the carboxylic acid in portions. When the yellow color persists and no more gas is evolved, the reaction is deemed complete. Excess reagent can be destroyed by the addition of a few drops of acetic acid and the entire solution concentrated to provide the methyl ester.

Esterification of Carboxylic Acids and Other Acidic Functional Groups.

A variety of functional groups will tolerate the esterification of acids with diazomethane. Thus α,β-unsaturated carboxylic acids and alcohols survive the reaction (eq 1),[9] as do ketones (eq 2),[10] isolated alkenes (eq 3),[11] and amines (eq 4).[12]

(1)

(2)

(3)

(4)

Other acidic functional groups will also undergo reaction with diazomethane. Thus phosphonic acids (eq 5)[13] and phenols (eq 6)[14] are methylated in high yields, as are hydroxytropolones (eq 7)[15] and vinylogous carboxylic acids (eq 8).[16] The origin of the selectivity in eq 6 is due to the greater acidity of the A-ring phenol.

(5)

(6)

(7)

(8)

Selective monomethylation of dicarboxylic acids has been reported using ***Alumina*** as an additive (eq 9).[17] It is thought that one of the two carboxylic acid groups is bound to the surface of the alumina and is therefore not available for reaction. Carboxylic acids that are engaged as lactols will also undergo methylation with diazomethane to provide the methyl ester and aldehyde (eq 10).[18]

(9)

(10)

Methylation of Alcohols and Other Less Acidic Functional Groups.

As previously mentioned, alcohols require the addition of a catalyst in order to react with diazomethane. The most commonly used is boron trifluoride etherate (eq 11),[19] but ***Tetrafluoroboric Acid*** has been used as well (eq 12).[20] Mineral acids are not effective since they rapidly react with diazomethane to provide the corresponding methyl halides. Acids as mild as silica gel have also been found to be effective (eq 13).[21] Monomethylation of 1,2-diols with diazomethane has been reported using various Lewis acids as promoters, the most effective of which is ***Tin(II) Chloride*** (eq 14).[22]

(11)

(12)

(13)

(14)

An interesting case of an alcohol reacting with diazomethane at a rate competitive with a carboxylic acid has been reported (eq 15).[23] In this case, the tertiary structure of the molecule is thought to place the alcohol and the carboxylic acid in proximity to each other. Protonation of the diazomethane by the carboxylic acid leads to a diazonium ion in proximity to the alcohol as well as the carboxylate. These species then attack the diazonium ion at competitive rates to provide the methyl ether and ester. No reaction is observed upon treatment of the corresponding hydroxy ester with diazomethane, indicating that the acid is required to activate the diazomethane.

(15)

Amides can also be methylated with diazomethane in the presence of silica gel; however, the reaction requires a large excess of diazomethane (25-60 equiv, eq 16).[24] The reaction primarily provides *O*-methylated material; however, in one case a mixture of *O*- and *N*-methylation was reported. Thioamides are also effectively methylated with this procedure to provide *S*-methylated compounds. Finally, amines have been methylated with diazomethane in the

presence of BF_3 etherate, fluoroboric acid,[25] or copper(I) salts;[26] however, the yields are low to moderate, and the method is not widely used.

(16)

The Arndt-Eistert Synthesis.

Diazomethane is a useful reagent for the one-carbon homologation of acid chlorides via a sequence of reactions known as the Arndt-Eistert synthesis. The first step of this sequence takes advantage of the nucleophilicity of diazomethane in its addition to an active ester, typically an acid chloride,[27] to give an isolable α-diazo ketone and HCl. The HCl that is liberated from this step can react with diazomethane to produce methyl chloride and nitrogen, and therefore at least 2 equiv of diazomethane are typically used. The α-diazo ketone is then induced to undergo loss of the diazo group and insertion into the adjacent carbon-carbon bond of the ketone to provide a ketene. The ketene is finally attacked by water or an alcohol (or some other nucleophile) to provide the homologated carboxylic acid or ester. This insertion step of the sequence is known as the Wolff rearrangement[28] and can be accomplished either thermally (eq 17)[29] or, more commonly, by treatment with a metal ion (usually silver salts, eq 18),[30] or photochemically (eq 19).[31] It has been suggested that the photochemical method is the most efficient of the three.[32] As eqs 18 and 19 illustrate, retention of stereochemistry is observed in the migrating group. The obvious limitations of this reaction are that there must not be functional groups present in the molecule which will react with diazomethane more rapidly than it will attack the acid chloride. Thus carboxylic acids will be methylated under these conditions. Furthermore, electron-deficient alkenes will undergo [2,3] dipolar cycloaddition with diazomethane more rapidly than addition to the acid chloride. Thus when the Arndt-Eistert synthesis is attempted on α,β-unsaturated acid chlorides, cycloaddition to the alkene is observed in the product. In order to prevent this, the alkene must first be protected by addition of HBr and then the reaction carried out in the normal way (eq 20).[33] Cycloaddition to isolated alkenes, however, is not competitive with addition to acid chlorides.

(17)

(18)

(19)

(20)

Other Reactions of α-Diazo Ketones Derived from Diazomethane.

Depending on the conditions employed, the Wolff rearrangement may proceed via a carbene or carbenoid intermediate, or it may proceed by a concerted mechanism where the insertion is concomitant with loss of N_2 and no intermediate is formed. In the case where a carbene or carbenoid is involved, other reactions which are characteristic of these species can occur, such as intramolecular cyclopropanation of alkenes. In fact, the reaction conditions can be adjusted to favor cyclopropanation or homologation depending on which is desired. Thus treatment of the dienoic acid chloride shown in eq 21 with diazomethane followed by decomposition of the α-diazo ketone with silver benzoate in the presence of methanol and base provides the homologated methyl ester. However, treatment of the same diazoketone intermediate with Cu^{II} salts provides the cyclopropanation products selectively.[34] This trend is generally observed; that is, silver salts as well as photochemical conditions (eqs 18 and 19) favor the homologation pathway while copper or rhodium salts favor cyclopropanation.[35] Using copper salts to decompose the diazo compounds, hindered alkenes as well as electron-rich aromatics can be cyclopropanated as illustrated in eqs 22 and 23,[36,37] respectively.

(21)

(22)

(23)

In addition to these reactions, α-diazo ketones will undergo protonation on carbon in the presence of protic acids[38] to provide the corresponding α-diazonium ketone. These species are highly electrophilic and can undergo nucleophilic attack. Thus if the proton source contains a nucleophile such as a halogen then the corresponding α-halo ketone is isolated (eq 24).[39] However, if the proton source does not contain a nucleophilic counterion then the diazonium species may react with other nucleophiles that are present in the molecule, such as alkenes (eq 25)[40] or aromatic rings (eq 26).[41] Note the similarity between the transformations in eqs 26 and 23 which occur using different catalysts and by different pathways. Also, eq 26 illustrates the fact that other active esters will undergo nucleophilic attack by

diazomethane.

(24)

(25)

(26)

Lewis acids are also effective in activating α-diazo ketones towards intramolecular nucleophilic attack by alkenes and arenes.[42] The reaction has been used effectively for the synthesis of cyclopentenones (eq 27) starting with β,γ-unsaturated diazo ketones derived from the corresponding acid chloride and diazomethane. It has also been used to initiate polyalkene cyclizations (eq 28). Typically, boron trifluoride etherate is used as the Lewis acid, and electron-rich alkenes are most effective providing the best yields of annulation products.

(27)

The Vinylogous Wolff Rearrangement.

The vinylogous Wolff rearrangement[43] is a reaction that occurs when the Arndt-Eistert synthesis is attempted on β,γ-unsaturated acid chlorides using copper catalysis. Rather than the usual homologation products, the reaction proceeds to give what is formally the product of a [2,3]-sigmatropic shift, but is mechanistically not derived by this pathway.[44] The mechanism is thought to proceed by an initial cyclopropanation of the alkene by the α-diazo ketone to give a bicyclo[2.1.0]pentanone derivative. This compound then undergoes a fragmentation to a ketene alkene before being trapped by the solvent (eq 29). Inspection of the products reveals that they are identical with those derived from the Claisen rearrangement of the corresponding allylic alcohols, and as such this method can be thought of as an alternative to the Claisen procedure. However, the stereoselectivity of the alkene that is formed is not as high as is typically observed in the Claisen rearrangement (eq 30), and in some substrates the reaction proceeds with no selectivity (eq 31).

(30)

(31)

Insertions into Aldehyde C-H Bonds.

The α-diazo ketones (and esters) derived from diazomethane and an acid chloride (or chloroformate) will also insert into the C-H bond of aldehydes to give 1,3-dicarbonyl derivatives.[45] The reaction is catalyzed by $SnCl_2$, but some simple Lewis acids, such as BF_3 etherate, also work. The reaction works well for aliphatic aldehydes, but gives variable results with aromatic aldehydes, at times giving none of the desired diketone (eq 32). Sterically hindered aldehydes will also participate in this reaction, as illustrated in eq 33 with the reaction of ethyl α-diazoacetate and pivaldehyde. In a related reaction, α-diazo phosphonates and sulfonates will react with aldehydes in the presence of $SnCl_2$ to give the corresponding β-keto phosphonates and sulfonates.[46] This reaction is a practical alternative to the Arbuzov reaction for the synthesis of these species.

$PhCH_2CH_2$	Ph	0

(33)

R^2	Yield (%)
t-Bu	65
Ph	50

Additions to Ketones.

The addition of diazomethane to ketones[47] is also a preparatively useful method for one-carbon homologation. This reaction is a one-step alternative to the Tiffeneau-Demjanow rearrangement[48] and proceeds by the mechanism shown in eq 34. It can lead to either homologation or epoxidation depending on the substrate and reaction conditions. The addition of Lewis acids, such as BF_3 etherate, or alcoholic cosolvents tend to favor formation of the homologation products over epoxidation.

(34)

However, the reaction is limited by the poor regioselectivity observed in the insertion when the groups R^1 and R^2 in the starting ketone are different alkyl groups. What selectivity is observed tends to favor migration of the less substituted carbon,[49] a trend which is opposite to that typically observed in rearrangements of electron-deficient species such as in the Baeyer-Villiger reaction. Furthermore, the product of the reaction is a ketone and is therefore capable of undergoing further reaction with diazomethane. Thus, ideally, the product ketone should be less reactive than the starting ketone. Strained ketones tend to react more rapidly and are therefore good substrates for this reaction (eq 35).[50] This method has also found extensive use in cyclopentane annulation reactions starting with an alkene. The overall process begins with dichloroketene addition to the alkene to produce an α-dichlorocyclobutanone. These species are ideally suited for reaction with diazomethane because the reactivity of the starting ketone is enhanced due to the strain in the cyclobutanone as well as the α-dichloro substitution. Furthermore, the presence of the α-dichloro substituents hinders migration of that group and leads to almost exclusive migration of the methylene group. Thus treatment with diazomethane and methanol leads to a rapid evolution of nitrogen, and produces the corresponding α-dichlorocyclopentanone, which can be readily dehalogenated to the hydrocarbon (eq 36).[51] Aldehydes will also react with diazomethane, but in this case homologation is not observed. Rather, the corresponding methyl ketone derived from migration of the hydrogen is produced (eq 37).

(35)

(36)

(37)

Cycloadditions with Diazomethane.

Diazomethane will undergo [3 + 2] dipolar cycloadditions with alkenes and alkynes to give pyrazolines and pyrazoles, respectively.[52] The reaction proceeds more rapidly with electron-deficient alkenes and strained alkenes and is controlled by FMO considerations with the HOMO of the diazomethane and the LUMO of the alkene serving as the predominant interaction.[53] In the case of additions to electron-deficient alkenes, the carbon atom of the diazomethane behaves as the negatively charged end of the dipole, and therefore the regiochemistry observed is as shown in eq 38. With conjugated alkenes, such as styrene, the terminal carbon has the larger lobe in the LUMO, and as such the reaction proceeds to give the product shown in eq 39. Pyrazolines are most often used as precursors to cyclopropanes by either thermal or photochemical extrusion of N_2. In both cases the reaction may proceed by a stepwise mechanism with loss of stereospecificity. As shown in eq 40, the thermal reaction provides an almost random product distribution, while the photochemical reaction provides variable results ranging from 20:1 to stereospecific extrusion of nitrogen.[54]

(38)

(39)

(40)

Δ	1.2:1
$h\nu$	20:1
	to >100:1

Cyclopropanes can also be directly synthesized from alkenes and diazomethane, either photochemically or by using transition metal salts, usually ***Copper(II) Chloride*** or ***Palladium(II) Acetate***, as promoters. The metal-mediated

reactions are more commonly used than the photochemical ones, but they are not as popular as the Simmons-Smith procedure. However, they do occasionally offer advantages. Of the two processes, the Cu-catalyzed reaction produces a more active reagent[55] which will cyclopropanate a variety of alkenes, including enamines as shown in eq 41.[56] These products can then be converted to α-methyl ketones by thermolysis. The cyclopropanation of the norbornenol derivative shown in eq 42 was problematic using the Simmons-Smith procedure and provided low yields, but occurred smoothly using the $CuCl_2$/diazomethane method.[57]

(41)

(42)

The $Pd(OAc)_2$-mediated reaction can be used to cyclopropanate electron-deficient alkenes as well as terminal alkenes. Thus selective reaction at a monosubstituted alkene in the presence of others is readily achieved using this method (eq 43).[58] The example shown in eq 44 is one in which the Simmons-Smith procedure failed to provide any of the desired product, whereas the current method provided a 92% yield of cyclopropane.[59]

(43)

(44)

In the case of the photochemical reaction, irradiation of diazomethane in the presence of *cis*-2-butene provides *cis*-1,2-dimethylcyclopropane with no detectable amount of the *trans* isomer (eq 45).[60] This reaction is thought to proceed via a singlet carbene. However, if the same reaction is carried out via a triplet carbene, generated via triplet sensitization, then a 1.3:1 mixture of *trans* to *cis* dimethylcyclopropane is observed (eq 46).[61] The yields in the photochemical reaction are typically lower than the metal-mediated processes, and are usually accompanied by more side products.

(45)

(46)

Additions to Electron-Deficient Species.

Diazomethane will also add to highly electrophilic species such as sulfenes or imminium salts to give the corresponding three-membered ring heterocycles. When the reaction is performed on sulfenes, the products are episulfones which are intermediates in the Ramberg-Backlund rearrangement, and are therefore precursors for the synthesis of alkenes via chelotropic extrusion of SO_2. The sulfenes are typically prepared in situ by treatment of a sulfonyl chloride with a mild base, such as ***Triethylamine*** (eq 47).[62] Similarly, the addition of diazomethane to imminium salts has been used to methylenate carbonyls.[63] In this case, the intermediate aziridinium salt is treated with a strong base, such as ***n-Butyllithium***, in order to induce elimination (eq 48).

(47)

(48)

Miscellaneous Reactions.

Diazomethane has been shown to react with vinylsilanes derived from α,β-unsaturated esters to provide the corresponding allylsilane by insertion of CH_2 into the C-Si bond (eq 49).[64] The reaction has been shown to be stereospecific, with *cis*-vinylsilane providing *cis*-allylsilanes; however, the mechanism of the reaction has not been defined. Diazomethane has also been used in the preparation of trimethyloxonium salts. Treatment of a solution of dimethyl ether and trinitrobenzenesulfonic acid with diazomethane provides trimethyloxonium trinitrobenzenesulfonate, which is more stable than the fluoroborate salt.[65]

(49)

Related Reagents.

2-Diazopropane; ***Diphenyldiazomethane***; ***Phenyldiazomethane***; ***1-Diazo-2-propene***.

2-Diazopropane

[2684-60-8] · $C_3H_6N_2$ · 2-Diazopropane · (MW 70.11)

(reagent for the cyclopropanation of alkenes[2])

Physical Data: the reagent is a gas at rt.

Solubility: the reagent is most commonly prepared and used as a solution in ether.

Analysis of Reagent Purity: titration with benzoic acid has been used to estimate the concentration of 2-diazopropane solutions; however, this method underestimates the yield by as much as 50% since the reaction of benzoic acid with the reagent is not quantitative. Spectrophotometric determination by measuring the absorbance at 500 nm has also been used; however, the ε value for this band is not precisely known.

Preparative Method: 2-diazopropane is most commonly prepared by the oxidation of ***Acetone Hydrazone*** with ***Mercury(II) Oxide*** in the presence of base.[1] The reaction is carried out in ether and the product is codistilled with the ether to provide an ethereal solution of the reagent which is used immediately. The reagent is unstable and undergoes a first-order decay with a half-life of 3 h at 0 °C. Diazo compounds are potentially explosive (especially on contact with objects containing rough or jagged surfaces such as ground glass) and for this reason extreme care must be observed in the synthesis and use of this compound with all operations being conducted behind a blast shield in a hood. Furthermore, the use of glassware which does not contain ground glass joints is essential.

Handling, Storage, and Precautions: in addition to the previously mentioned explosion hazard which this reagent presents, there are health related hazards that must also be considered. Diazo compounds, as a class, are toxic and irritating and can be sensitizers. They must be used in a well-ventilated fume hood and not come in contact with skin. For a description of the hazards associated with this class of compounds, see the handling and storage precautions listed for ***Diazomethane***.

Cyclopropanation of Alkenes.

2-Diazopropane is most commonly used to prepare *gem*-dimethylcyclopropyl derivatives. Like most diazoalkanes, this reagent will readily undergo cycloadditions with alkenes to provide the corresponding pyrazolines which can be induced to lose N_2 to provide the desired cyclopropanes. As with other dipolar cycloadditions, this reaction occurs most readily with electron-deficient alkenes. Extrusion of N_2 from these species can be accomplished photochemically, either by

direct irradiation or with the aid of a triplet sensitizer such as benzophenone.[2] Photochemical reactions without the sensitizer are typically slower, and can provide two side products, the retro cycloaddition to give the starting alkene, and the product of insertion into the vinylic C-H bond to provide the isopropyl-substituted alkene.[3] In some systems, thermal extrusion of N_2 also provides a substantial amount of the insertion product (eq 1). This is not always observed, however, and in certain cases thermal reactions can provide the desired cyclopropane in high yield.

(1)

Δ, 70 °C	20%	80%	-
hν	62%	21%	17%
hν, sensitizer	>99%	-	-

The regiochemistry of the addition step of the reaction depends on the sterics of the system but, typically, the carbon of the diazoalkane adds to the more electrophilic β-carbon of the alkene. However, if this carbon is disubstituted, then the opposite regiochemistry can be observed, but frequently with diminished yields (eq 2).[4] Ultimately, the regiochemistry is inconsequential to the overall reaction because extrusion of N_2 provides the same cycloalkane in either case.

(2)

It is possible to cyclopropanate an electron-deficient alkene in the presence of an isolated alkene. Thus treatment of the steroid derivative shown in eq 3 with 2-diazopropane provided only addition to the conjugated alkene.[5] Photolysis of this compound provided the dimethylcyclopropane in 50% yield. Furthermore, differentiation between two electron-deficient alkenes on steric grounds is possible with this reagent. Thus addition of 2-diazopropane to the steroid derivative shown in eq 4 provided only the product of addition to the alkene containing a single substituent at the β-carbon. Photolysis again provided the desired cyclopropane, but in only 25% yield.

(3)

Strained alkenes will also undergo cycloadditions with 2-diazopropane (eq 5).[6] This particular case is interesting because the reagent adds predominantly to the more hindered face of the alkene, suggesting that the reaction is directed[7] by the acetate groups. In reactions with diazomethane the preference for addition to the more hindered face is even greater.

Additions of 2-diazopropane to chiral bicyclic lactams have also been explored (eq 6).[8] These reagents are known to add nucleophiles from the more hindered *endo* face of the alkene. Thus cyclopropanation with diphenylsulfonium isopropylide provided the expected *endo* product in a greater than 200:1 ratio. However, addition of 2-diazopropane provided a 1:1 mixture of *endo* and *exo* products. This difference in behavior has been explained on the basis of frontier molecular orbital theory.

$Ph_2S{=}CMe_2$	>200:1
Me_2CN_2, $h\nu$	1:1

A similar loss in stereoselectivity was observed in the cyclopropanation of menthyl fumarates. Thus cyclopropanation with isopropylidenetriphenylphosphorane provided an 87:13 ratio of diastereomers while the use of 2-diazopropane provided a 53:47 mixture (eq 7).[9]

R = (-)-menthyl

$PPh_3{=}CMe_2$	87:13
Me_2CN_2, $h\nu$	53:47

The synthesis of α-cyclopropyl amino acids from suitably protected dehydro amino acids has been accomplished using 2-diazopropane.[10] The overall transformation is stereospecific with the (*Z*)-alkene isomer providing the corresponding *cis*-cyclopropane (eq 8). The regiochemistry in the cyclopropanation of tropone derivatives has been controlled by first converting the tropone to the dieneiron tricarbonyl complex. The uncomplexed alkene then reacts with 2-diazopropane to provide the pyrazoline which undergoes thermal extrusion of N_2 to give the desired cyclopropane (eq 9).[11]

(9)

Cyclopropanation of Allenes.

Allenes are also suitable substrates for cyclopropanation by 2-diazopropane, with the most reactive substrates being those that are conjugated to an electron-withdrawing group. As with alkenes, the regiochemistry of the pyrazoline that is formed depends on the sterics of the system. With allenes that contain one or fewer carbon substituents at the γ-carbon, the carbon of the diazopropane will add to the more electron-deficient carbon of the double bond (eq 10). If the γ-carbon is disubstituted, then the opposite regiochemistry is observed (eq 11).[12]

(10)

(11)

An interesting example of a cyclization to an allene which is not electron deficient has been reported.[13] Addition of 2-diazopropane to the allene shown in eq 12 provided the pyrazoline shown, which upon photolysis provided a 2:1 mixture of the two cyclopropanes in the equation. This synthesis was used to disprove an erroneous structure for the sex attractant of the American cockroach.

Cyclopropenation of Alkynes.

Alkynes can be converted to the corresponding cyclopropene via the pyrazole with 2-diazopropane. As with other systems, the reaction works best with electron-deficient alkynes, and the regiochemistry of the pyrazole that is formed depends on the sterics of the alkyne. Thus terminal alkynes provide the usual regiochemistry, whereas internal alkynes provide the opposite regiochemistry (eq 13).[14] Photolysis of the pyrazoles induces a rearrangement to a diazoalkene species which then undergoes photochemical extrusion of N_2 to give a carbene which inserts into the π-bond of the alkene to provide the cyclopropene (eq 14).

(14)

Evidence for the intermediacy of the diazoalkene has been obtained by trapping this species with acetic acid.[15] An interesting side reaction has been observed in reactions with trimethylsilyl-substituted alkynes. Irradiation of the pyrazole derived from these alkynes provides the expected carbene which, rather than inserting into the π-bond, inserts into the σ-bond of the acyl group to provide the product of a 1,2-acyl shift in high yield (eq 15).[16] The generality of this reaction has not yet been established. Other substrates that do not provide the cyclopropene are those that provide products which are sterically hindered. Thus irradiation of the pyrazole shown in eq 16 provides the product of insertion into the tertiary C-H bond rather than the alkene.[17]

(15)

(16)

The cyclopropenes produced in this reaction have been used in the synthesis of *cis*-chrysanthemic methyl ester.[18] The key step involves cyclopropenation of the ene-yne shown in eq 17. Addition of 2-diazopropane to the alkyne occurs in

preference to the alkene to give both regioisomeric pyrazoles. Photochemical extrusion of N_2 from both isomers provides the desired cyclopropene. This was converted to *cis*-chrysanthemic methyl ester by diimide reduction of the more reactive cyclopropene alkene.

Another use for these cyclopropene reagents is a formal [3 + 2] annulation reaction which provides cyclopentenols. The process involves [2 + 2] cycloaddition of the cyclopropene with an eneamine to provide a strained bicyclic product which undergoes ring opening with acid and water to provide a cyclopentenol (eq 18).[19] This strategy has been employed in the synthesis of several natural products including hirsutene,[20] silphenene,[21] and dihydroilludine M.[22]

A disadvantage of this strategy is that with certain substrates, the cycloaddition product is accompanied by a substantial amount (at times the major product) of the product of Michael addition of the eneamine to the cyclopropylcarboxylate. A related annulation has therefore been developed which avoids this problem. This strategy involves the addition of 2-diazopropane to a cyclobutene to provide a similar bicyclic intermediate to that obtained previously. This species can also undergo acid-catalyzed ring opening with water (eq 19) to provide the cyclopentenol.[23]

(19)

Insertion into Vinylic C-H Bonds.

A common side reaction which occurs during attempted cyclopropanation of alkenes with diazopropane is an overall insertion into a C-H bond of the alkene. This reaction is favored by thermal extrusion of N_2 and, for this reason, photolysis is the preferred method of decomposing pyrazolines to cyclopropanes (eq 1). However, it has been observed that alkenes which bear two electron-withdrawing groups will exclusively provide the insertion product upon reaction with 2-diazopropane with mild or no heating. The reaction has been used to introduce an isopropyl residue into 3-cyanocoumarins[24] and iron tricarbonyl complexes of acetyltropone[25] in excellent yield (eqs 20 and 21). Furthermore, it has been used in diminished yield to alkylate alkenes with a single electron-withdrawing group, as previously discussed.[26]

(20)

(21)

Miscellaneous Reactions.

Interestingly, 2-diazopropane is not commonly used to esterify carboxylic acids. The reaction has been studied with excess acetic acid and has been shown to proceed in 35%-52% yield based on the diazo compound, with the major byproduct being tetramethylethylene.[27] This should not be a serious problem to utilizing the reaction with other carboxylic acids since the byproduct is volatile. The reagent has been used to selectively esterify the more hindered carbonyl of a vinylogous acid when other reagents failed (eq 22).[28]

(22)

2-Diazopropane has also been used in the synthesis of episulfides from thioketones. The reaction works even for very hindered substrates (eq 23). Extrusion of sulfur with triphenylphosphine provides the corresponding alkene, thus rendering this a method for the synthesis of hindered alkenes.[29]

1-Diazo-2-propene

[2032-04-4] · $C_3H_4N_2$ · 1-Diazo-2-propene · (MW 68.08)

(reagent for the cyclopropanation of alkenes)

Alternate Name: vinyldiazomethane.

Solubility: vinyldiazomethane is most commonly prepared and used as a solution in ether or THF, or as an alcoholic solution in either of those solvents.

Analysis of Reagent Purity: the amount of active diazo compound contained in a solution has been determined by measuring the volume of nitrogen evolved upon reaction of an aliquot of the diazo compound with an excess of *p*-nitrobenzoic acid in THF.[3]

Preparative Methods: the reagent is most commonly prepared by the action of base on various *N*-allyl-*N*-nitroso derivatives. Thus ethyl-*N*-allyl-*N*-nitrosocarbamate has been used,[1] as has *N*-allyl-*N*-nitrosourea.[2] The reagent is light sensitive and should therefore be shielded from light during its preparation. It undergoes isomerization to pyrazole at rt[1c] and is therefore prepared immediately prior to use, and not usually stored for any length of time. Furthermore, it is potentially explosive and for this reason the chemist is advised to follow carefully the exact procedure given for a particular preparation and perform all operations behind a blast shield in a well ventilated fume hood.

Handling, Storage, and Precautions: in addition to the previously mentioned explosion hazard which this reagent presents, there are health related hazards that must also be considered. Diazo compounds, as a class, are toxic and irritating and can be sensitizers. They must be used in a well ventilated fume hood and not come in contact with skin. For a description of the hazards associated with this class of compounds, see the handling and storage precautions listed for ***Diazomethane***.

Cycloadditions.

Vinyldiazomethane is commonly used to prepare vinylcyclopropane derivatives from alkenes, either via transition metal-catalyzed cyclopropanation, or via an intermediate pyrazoline. In the case of the transition metal-catalyzed process, the product cyclopropane contains an alkene which can react further with the starting vinyldiazomethane. The procedure is therefore limited to alkenes which can be used in large excess, or which are substantially more reactive than the product alkene. Thus low boiling, electron-rich alkenes have been used in large excess with various copper(II)

salts as the catalysts.[3] Of the various copper salts examined, ***Copper(II) Trifluoromethanesulfonate***, copper(II) trifluoroacetate, and ***Copper(II) Hexafluoroacetylacetonate*** were found to provide low to moderate yields (12-40%) of the desired cyclopropane from cyclohexene. Copper(I) iodide and copper(II) chloride, carbonate, and sulfate were found to be ineffective. The reaction is stereospecific, with *cis*- and *trans*-alkenes providing the corresponding *cis*- and *trans*-cyclopropanes, respectively (eqs 1 and 2).

(1)

(2)

Rhodium(II) complexes have also been examined as catalysts for cyclopropanation, and have been found to be more effective than copper salts.[4] The reaction works well for enol ethers and dienol ethers, with cyclopropanation preferentially occurring at the alkoxy-substituted alkene (eq 3). The reaction has been used to prepare cycloheptadiene derivatives by cyclopropanation of dienes followed by [3,3]-sigmatropic rearrangement of the resulting divinylcyclopropane.

(3)

Vinyldiazomethane will readily undergo dipolar cycloaddition with electron-deficient alkenes to provide vinylpyrazolines.[5] Vinylpyrazolines are less stable than typical alkylpyrazolines, and will undergo loss of N_2 to provide the corresponding vinylcyclopropane with either thermal or photochemical activation. The reaction has been used to prepare vinylcyclopropyl steroid derivatives from Δ^{16}-20-oxo-steroid derivatives (eq 4).[2] Thermal extrusion of N_2

provides the desired cyclopropane in 90% yield.

(4)

An interesting side reaction has been observed with alkenes that bear two electron-withdrawing substituents. These substrates do not provide the cyclopropane upon thermolysis, but give the product of insertion into C-H bonds on the carbon that is β to the carbonyl (eq 5).[6] This is a general reaction which will work with other diazoalkanes.

(5)

Conjugated dienes will also undergo dipolar cycloaddition with vinyldiazomethane. The reaction occurs preferentially at the less substituted alkene, as predicted by FMO theory.[7] The resulting pyrazolines undergo extrusion of N_2 at rt or below to provide the corresponding divinylcyclopropyl derivatives. These compounds will then undergo [3,3]-sigmatropic rearrangement to provide cycloheptadiene derivatives. The *cis*-divinylcyclopropanes undergo sigmatropic rearrangement very rapidly, at times below rt. This has hindered attempts to obtain kinetic data for these substrates. However, they can be synthesized by low temperature (-40 °C) photolysis of pyrazolines derived from vinyldiazomethane and conjugated dienes.[8] The reaction has been used to synthesize the algae metabolite dictyopterene D´ via a vinylcyclopropyl derivative (eq 6).[9]

Allylation of Heteroatoms.

Vinyldiazomethane can be used to convert carboxylic acids to the corresponding allyl carboxylate.[1c,3] However, the reaction has not been widely utilized. An interesting example of the allylation of an alcohol has been reported.[10] Treatment of the vicinal steroidal diol shown in eq 7 with boric oxide provides the corresponding borate ester. Treatment of this compound with vinyldiazomethane provides the monoallyl ether with preferential reaction at the less hindered oxygen. Presumably, the reaction proceeds by protonation of the vinyldiazomethane by the borate ester to provide an allyldiazonium species which undergoes nucleophilic attack by oxygen.

Diazo(trimethylsilyl)methyllithium[1]

[84645-45-4] · $C_4H_9LiN_2Si$ · Diazo(trimethylsilyl)methyllithium · (MW 120.16)

(nucleophilic diazo species for introduction of one carbon; used in homologation and alkenylation of ketones,[2,4,5] preparation of diazo ketones,[6] acylsilanes,[7] vinylsilanes,[8] and heterocycles[9,10])

Alternate Names: lithiotrimethylsilyldiazomethane; trimethylsilyldiazomethyllithium.

Solubility: sol THF/hexane mixtures in which it is generated; precipitates out of ether/hexane.

Preparative Method: prepared in situ by lithiation of ***Trimethylsilyldiazomethane*** using ***n-Butyllithium***.

Handling, Storage, and Precautions: handle as for other organolithium reagents; stable in solution below 0 °C. Use in a fume hood.

Homologation Reactions of Ketones.

When generated in pentane/THF at -100 °C, diazo(trimethylsilyl)methyllithium reacts with ketones (three examples) and benzaldehyde to give the unstable 1-diazo-1-trimethylsilyl-2-alkanols (eq 1).[2] On gentle warming, the diazo alcohols rapidly lose N_2 to give trimethylsilyl epoxides. Since such epoxides readily give aldehydes on treatment with acid,[3] the method represents an overall homologation of a ketone to the next higher aldehyde.

When diaryl ketones are used, diarylalkynes are formed in good yield (eq 2).[4] The reaction presumably proceeds via the diazoalkene followed by aryl migration with loss of nitrogen.

In contrast to the above, a more recent study, using slightly different conditions, reports that whereas aldehydes give terminal alkynes (eq 3), ketones give cyclopentene derivatives, presumably by intramolecular C-H insertion of intermediate alkylidenecarbenes (eq 4).[5] No detectable amounts of diazo alcohols or epoxysilanes were produced.

Preparation of Diazo Ketones.

Diazo(trimethylsilyl)methyllithium reacts with lactones to give the product of ring opening, the diazo alcohol, although the silyl group is lost during workup (eq 5).[6] The diazo alcohol can subsequently be cyclized to the corresponding oxepane by treatment with ***Dirhodium(II) Tetraacetate***.

Preparation of Acylsilanes.

Diazo(trimethylsilyl)methyllithium is alkylated by a range of alkyl halides RX (R = alkyl, benzyl) to give the corresponding diazosilanes, which are oxidized to the acylsilanes in reasonable yield by treatment with ***m-Chloroperbenzoic Acid*** (eq 6).[7]

Preparation of Vinylsilanes ((*E*)-Trimethylsilylalkenes).

Treatment of trimethylsilyldiazoalkanes, obtained by alkylation of diazo(trimethylsilyl)methyllithium with RCH_2X, with ***Copper(I) Chloride*** gives excellent yields of (*E*)-1-trimethylsilylalkenes (eq 7).[8]

(7)

Preparation of Heterocycles.

On reaction with methyl esters, diazo(trimethylsilyl)methyllithium (2 equiv) gives 2-substituted 5-trimethylsilyltetrazoles in 50-90% yield (eq 8).[9a] Similarly, reaction with nitriles gives 1,2,3-triazoles in high yield (eq 9).[9b] Reaction with $(Me_3Si)_2C{=}PCl$ leads to 1,2,4-diazaphospholes (eq 10).[10]

(8)

(9)

(10)

Related Reagents.

Triisopropylsilyldiazomethane can be similarly converted into its lithium derivative.[11] Diazo compounds containing tin (R_3SnCHN_2) and germanium (R_3GeCHN_2) are also known,[1] but have not been used in synthesis. Other lithiated diazo compounds (for example, see ***Ethyl Diazolithioacetate***) are covered elsewhere, as are other lithiated silanes.

Dibenzenechromium

[1271-54-1] · $C_{12}H_{12}Cr$ · Dibenzenechromium · (MW 208.22)

(dehydrogenation catalyst[1])

Alternate Name: bis(η^6-benzene)chromium.

Physical Data: mp 284-285 °C.

Solubility: sol benzene; slightly sol ether.

Form Supplied in: brown-black crystals.

Purification: sublimed at 160 °C in vacuo.

Handling, Storage, and Precautions: air sensitive.

Dehydrogenation Catalyst.

Treatment of dibenzenechromium with potassium produces the corresponding radical anion (eq 1), which is an effective catalyst for the conversion of 1,4-cyclohexadiene to benzene (eq 2).[1] The scope and

limitations of the process have not been tested.

$$(C_6H_6)_2Cr \xrightarrow{K} [(C_6H_6)_2Cr]^{-}\cdot \quad (1)$$

Dibenzo-18-crown-6

[14187-32-7] · $C_{20}H_{24}O_6$ · Dibenzo-18-crown-6 · (MW 360.41)

(solubilization and activation of a variety of potassium salts)

Physical Data: mp 162.5-163.5 °C. UV maxima: (MeOH solution) 223 nm (ε 17 500) and 275 nm (ε 5500). ^{1}H NMR: ($CDCl_3$) 6.8-7.0 ppm (8H multiplet) and 3.8-4.3 ppm (16H multiplet).

Form Supplied in: white fibrous needles.

Preparative Methods: dibenzo-18-crown-6 was first prepared in 39-48% yield from the reaction of catechol and bis(2-chloroethyl) ether using sodium hydroxide as the base and *n*-butanol as the solvent.[1] The ditosylate of diethylene glycol has been substituted for the dichloride with accompanying yields of 32-35%.[2]

Handling, Storage, and Precautions: toxic; use in a well-ventilated fume hood.

Complexation With Metal Salts.

The cavity diameter of dibenzo-18-crown-6 is estimated to be 2.6-3.2 Å, which is ideal for complexing with a potassium cation (ionic diameter 2.66 Å).[3] While the selectivity of dibenzo-18-crown-6 for

potassium salts is well documented, this macrocyclic multidentate ligand will also effectively complex with other alkali metal cations.[3] The solubility of potassium acetate in ***Acetonitrile*** is greater in the presence of dibenzo-18-crown-6 compared to ***18-Crown-6***.[4] The solubility of potassium acetate in the presence of a variety of other ligands was also reported. Arguments related to cavity diameter, lipophilicity, and rigidity were advanced to explain, at least partially, the observed structure-solubilization order.

Reactions.

Halides.

The catalytic activity of a number of macrocyclic polydentate ligands in the reaction of 1-octyl bromide with ***Potassium Iodide*** to produce the 1-octyl iodide has been reported.[5] Dibenzo-18-crown-6 appears to be less effective than ***Dicyclohexano-18-crown-6***.[5]

Oxygen Anions.

The reaction of potassium acetate activated by a wide variety of macrocyclic polydentate ligands with benzyl chloride in acetonitrile indicates that dibenzo-18-crown-6 is somewhat less effective than 18-crown-6 or dicyclohexano-18-crown-6.[4] At -45 °C in dry THF, sodium 3-(fluoren-9-ylidene)-2-phenylacrylate decarboxylated very slowly. In the presence of dibenzo-18-crown-6 the reaction proceeded at a rapid rate, indicating that the nature of the ion pair was critical in influencing the reaction rate profile.[6]

Dibenzo-18-crown-6 has been used in the reaction of an acetylated halo sugar with a series of alcohols catalyzed by ***Silver(I) Nitrate*** (Koenigs-Knorr reaction). The reaction proceeds in good yield with inversion of configuration.[7,8]

The rates of alkylation of potassium phenoxide with 1-bromobutane in dioxane at 25 °C in the presence of linear and cyclic polyether additives has been reported.[9] Dicyclohexano-18-crown-6 was more effective than dibenzo-18-crown-6. A comparison has been made between the rates of reaction of *t*-butoxide in *t*-butanol with 2-nitrofluorobenzene and 4-nitrofluorobenzene where the counter cation was potassium and potassium/dibenzo-18-crown-6 and the corresponding reaction of potassium methoxide in methanol.[10] Potassium methoxide was 30 times more reactive than ***Potassium t-Butoxide*** but in the presence of dibenzo-18-crown-6 the reverse was true.

Dibenzo-18-crown-6 is an effective phase-transfer catalyst in the reactions of 4-chloromethyl-1,3-dioxolane with mono- and dihydric phenols in the presence of metal hydroxides.[11]

The effect of dibenzo-18-crown-6 on the reaction of sodium 9-fluorenone oximate with ***Iodomethane*** in 33.5% acetonitrile and 66.5% *t*-butyl alcohol has been studied. The crown ether increased the fractional *O*-alkylation.[12,13]

Carbon Anions.

The effects of dibenzo-18-crown-6 on (a) the simultaneous base-catalyzed racemization, isotopic exchange, and isomerization of optically pure (-)-3-*t*-butyl-1-methylindene-1-*h* and its deuterated counterpart in the 1-position to 1-*t*-butyl-3-methylindene under a variety of conditions,[14] (b) the isotopic exchange and racemization of (-)-4-biphenylylphenylmethoxydeuteromethane with potassium *t*-butoxide,[15] (c) the stereochemistry accompanying the cleavage of (+)-4-phenyl-3,4-dimethyl-3-hexanol with potassium *t*-butoxide,[12] and (d) the rates of isotopic exchange and racemization of (+)-2-methyl-2,3-dihydro-2-deuterobenzo[*b*]thiophene 1,1-dioxide with potassium methoxide[12] have been reported.

The lithium, sodium, and potassium salts of 4*H*-cyclopenta[*def*]phenanthrene radical anion are considerably more stable in the presence of dibenzo-18-crown-6, especially when sodium or potassium is the counter cation.[16] The presence of crown also affected the rate of decay of the radical anion.

The use of dibenzo-18-crown-6 as a liquid-liquid phase-transfer catalyst in the generation and reaction of carbanions and halocarbenes has been studied.[17] Among the reactions studied were the alkylation of carbon acids, reactions involving trichloromethyl anions and dichloromethylene, reactions of carbanions with nitro compounds, and Darzens condensations.

Sulfur Anions.

The solid-liquid phase-transfer catalytic reaction between ***Benzyl Chloride*** and ***Potassium Thiocyanate*** produces a ratio of benzyl thiocyanate to benzyl isothiocyanate of 71:29 in the presence of dibenzo-18-crown-6.[18]

Reductions.

Studies related to the use of ***Sodium Borohydride*** in toluene in the reduction of a variety of ketones (acetophenone, cyclohexanone, methyl *n*-pentyl ketone, methyl isopropyl ketone) in the presence of equivalent amounts of dibenzo-18-crown-6, diglyme, or dimethoxyethane have been reported.[19] In general, the crown was the most effective ligand. Potassium borohydride required longer reactions times.

Oxidations.

The preparation of *N*-(arylsulfonyl)sulfoximines by oxidation of the sulfilimines with ***Sodium Hypochlorite*** in an aqueous methylene chloride-ethyl acetate two-phase system has been reported.[20]

The reaction of ***Potassium Chromate*** with primary alkyl halides in HMPA containing dibenzo-18-crown-6 at 100 °C produces aldehydes in good yields.[21] The chromate ion behaves as both a nucleophile and an oxidant.

The oxidation of 1-octene to *n*-heptanoic acid with a saturated aqueous ***Potassium Permanganate***-benzene two-phase system proceeds in 80% yield at rt in the presence of dibenzo-18-crown-6.[22]

Related Reagents.

18-Crown-6; ***Dicyclohexano-18-crown-6***.

Dibenzoyl Peroxide[1-4]

[94-36-0] · $C_{14}H_{10}O_4$ · Dibenzoyl Peroxide · (MW 242.23)

(initiator for radical reactions such as allylic and benzylic halogenation,[5] radical addition to carbon-carbon multiple bonds to form C-heteroatom (halogen, S, Si, Ge, P, and N) bonds,[2] C-H additions across multiple bonds[4] in an intermolecular[1] and intramolecular[6] fashion, homolytic aromatic substitution in electron-deficient heteroaromatics;[7] reagent for benzoyloxylation of enolates, enamines, and other electron-rich systems;[8] oxidizing agent for N, P, Si, S, and Se compounds; oxidizing agent in redox chain reactions with transition metals[9])

Alternate Name: DBP.

Physical Data: mp 103-106 °C (dec).

Solubility: sparingly sol water or alcohol; sol benzene, chloroform, and ethers.

Form Supplied in: white crystalline powder.

Analysis of Reagent Purity: the peroxide content can be established by iodometric titration.[10]

Handling, Storage, and Precautions: explosive; harmful if exposed by ingestion or skin contact; strong oxidizer; susceptible to explosion by shock, friction or heat; autoignition temperature 79 °C. *Caution*: all experiments involving peroxy compounds should be carried out behind a safety shield. Excess peroxide should be destroyed before working up the reaction.[11]

Introduction.

Dibenzoyl peroxide is a widely used initiator for radical reactions. It undergoes thermal homolytic cleavage of the O-O bond with a half-life of about 1 h at 95 °C (eq 1).[12] This homolysis may also be effected by light as well as transition metal catalysts.[9]

$$(PhCO_2)_2 \longrightarrow 2\ PhCO_2\cdot \longrightarrow Ph\cdot + CO_2 \qquad (1)$$

Initiator for Halogenation Reactions.

Even though DBP has been used as an initiator for functionalization of unactivated hydrocarbons (eq 2), more common are the applications for halogenations of allylic (eqs 3 and 4)[5,13] and benzylic (eq 5)[14] positions. DBP also serves as an initiator for halogenation of silanes by replacement of a Si-H bond.[15]

(2)

(3)

(4)

(5)

Initiator for Radical Additions to Unsaturated Compounds.

The primary steps in the radical addition of X-Y to unsaturated compounds are shown in eqs 6-10. By far the largest application of this reagent[16] is in radical chain polymerization of vinyl compounds such as vinyl chloride, vinyl acetate,

butadiene derivatives, styrene, and various acrylic monomers. The topic of polymerization is beyond the scope of this article. Excellent monographs and reviews dealing with this subject are available.[17]

when X-Y contains an activated C-H:

Formation of a 1:1 adduct (eq 9) will be favored when X-Y is an efficient chain transfer agent. For reactions of short chain lengths, an excess of X-Y and a steady concentration of the initiator should be present in the reaction medium.[2] Since the original discoveries of the anti-Markovnikov addition of HBr (eq 11),[18] and of carbon tetrachloride to alkenes (eq 12),[1] a large number of related reactions have been reported. DBP catalyzes the addition of a wide variety of X-Y type compounds to carbon-carbon multiple bonds. These include H-Br, thiols, mercapto acids, thiophosphoric acids, hydrogen sulfide, silanes, germanes, phosphorus halides, phosphorus acids and esters, and various oxides of nitrogen.[2] The important C-C bond-forming reactions are described below.

(11)

(12)

Intermolecular Carbon-Carbon Bond Forming Reactions.

When the compound X-Y contains an activated C-H bond, initiators such as DBP and di-*t*-butyl peroxide initiate the radical reactions by abstraction of this hydrogen (eq 10) from the substrate, and the resultant radical enters the radical chain cycle. Substrates of this kind are poor chain transfer agents and typically a higher concentration of the substrate and a steady supply of the initiator are needed for a viable reaction. Representative examples of carbon-carbon bond forming reactions initiated by DBP are listed in Table 1[11,41-45] (see also ***1,1-Di-t-butyl Peroxide***). A more complete list is available in two excellent reviews.[1,4]

Table 1 Intermolecular C-C Forming Reactions via Radicals

Precursor	Alkene	Reaction conditions	Product
MeOH		DBP (cat), 120 °C, 3h [11]	 67%
		DBP (cat), 65 °C [41]	 70%
			

The intermolecular additions may be coupled to an intramolecular cyclization (eq 13)[19] or an S_H2 reaction.[20] The S_H2 reactions are useful for the synthesis of epoxy compounds (Scheme 1) or lactones (eq 14). Radicals from nitriles, ketones, ethers, and polyhaloalkanes also undergo similar addition-substitution reactions.

(13)

Scheme 1 Intermolecular addition-S_H2 reaction of peresters

(14)

Addition of various α-carboxyl radicals to alkenes is best carried out with a high temperature initiator such as di-*t*-butyl peroxide, although reports of using DBP are known. This subject has been extensively reviewed.[21]

Intramolecular Additions.

The intramolecular versions of the C-H additions mentioned above have been extensively studied by Julia and co-workers (eqs 15 and 16).[6] These reactions, while not very practical from a synthetic standpoint, nonetheless have played a key role in the development of radical synthetic methodology.[22,23] A related cyclization (eq 17) was used by Barton and co-workers for the synthesis of a tetracycline intermediate.[24] An interesting variant of this reaction is the cyclization of geranyl acetate to a benzoyloxyfarnesyl acetate (eq 18).[25] The radical reaction is initiated by DBP and the Cu salt serves as an oxidant for

the final cyclized radical.

(15)

(16)

(17)

(18)

Initiator for Radical Additions to Electron-Deficient Heteroaromatic Compounds.

Minisci and co-workers have developed radical-mediated homolytic substitution reactions for various electron-deficient aromatic nuclei.[7] Radicals derived from alkyl halides, dioxane,[26] dimethylformamide,[27] and even cyclohexane[26] can be added to protonated heteroaromatic compounds. The addition of a cyclohexyl radical (eq 19) proceeds in good yields even when the reaction medium contains a large excess of chloroform and acetonitrile. The highly electrophilic nature of the

&bdot;CCl_3 and &bdot;CH_2CN completely inhibits the reaction towards the protonated heterocycle. Under these conditions, ethyl acetate gives the electrophilic radical &bdot;CH_2CO_2Et and the nucleophilic radical $MeCO_2$&bdot;CHMe, but only the latter adds.

As an Oxidant.

Benzoyl peroxide oxidizes ethers to α-benzoyloxy ethers, and alkyl sulfides to α-benzyloxy sulfides (eq 20).[28] Tertiary amines are oxidized to amine oxides, while secondary amines give *N*-benzoyloxy amines (eq 21).[29] In the presence of a mild base, DBP acts as a very selective oxidizing agent for hydroquinones.[30] Aldehydes and benzylic positions are not affected. Two key steps in the Eschenmoser synthesis of the corrin nucleus make use of DBP (eqs 22 and 23).[31] Secondary alcohols are oxidized to ketones with dibenzoyl peroxide and ***Nickel(II) Bromide*** (eq 24).[32] A benzoyl peroxide-mediated annulation used by Kishi in the synthesis of sporidesmin B (eq 25)[33] is likely to be an ionic (vis-á-vis radical) reaction. A 1:1 mixture of DBP and ***Hexamethyldisilazane*** has been used as an epoxidizing agent for acid-sensitive alkenic substrates.[34]

As a Benzoyloxylation Agent.[8]

Under catalysis by ***Iodine***, benzoyloxylation of aromatic and heteroaromatic compounds takes place. Nucleophilic compounds such as malonates,[35] phenols,[36] enamines, and indoles[37] also react with DBP to give benzoyloxylation products. Secondary amines are converted into *N*-benzyloxy amines (eq 20).[29] An improved protocol[38] for this reaction and an application for synthesis of N^5-hydroxy-L-ornithine[39] have appeared in the literature.

Benzoyl peroxide has been used for α-benzoyloxylation of an enolate (eq 26).[40]

Dibenzyl Azodicarboxylate[1]

[2449-05-0] · $C_{16}H_{14}N_2O_4$ · Dibenzyl Azodicarboxylate · (MW 298.30)

(efficient diene in the hetero Diels-Alder reaction with furanoid and pyranoid glycals;[2] source of positive nitrogen, used in the preparation of α-hydrazino and α-amino acids from chiral lithium enolates[3])

Alternate Name: DBAD.

Physical Data: mp 44-46 °C.

Solubility: sol CH_2Cl_2; insol cyclohexane.

Form Supplied in: orange solid.

Hetero Diels-Alder Reaction.

Dibenzyl azodicarboxylate adds to furanoid and pyranoid glycals,[2] under irradiation at 350 nm in cyclohexane/CH_2Cl_2 solution, to provide [4 + 2] cycloadducts in high yields (eq 1). The photoisomerization[4] of *trans*-DBAD to the *cis* isomer is essential to allow the cycloaddition reaction to take place (eq 2). This cycloaddition reaction is highly stereoselective; the adduct is usually obtained as a single isomer. The approach of DBAD to the glycal double bond is directed by the orientation of the C-3 substituent to give the cycloadduct with the 2-amino function *trans* to the C-3 substituent. The cycloaddition reaction of DBAD and glycals allows, in a single operation, the introduction of an amino moiety at C-2 of a carbohydrate and a latent nucleofugal group at the C-1 position. The dibenzyl adducts, namely dihydrooxadiazines, can be efficiently opened by various nucleophiles such as alcohols, hydrides, and acids, in the presence of an activator (eq 1). The resulting hydrazides can then be converted to their corresponding free amines under hydrogenolysis conditions. This methodology has been applied to the synthesis of simple and complex 2-amino saccharides.[5] The cycloaddition reaction of DBAD with galactal and glucal was used for the synthesis of subunits of tunicamycin.[6]

It has been observed that the rate of cycloaddition is related to the electronic nature of the C-3 substituent.[2a,b] The cycloaddition reaction does not take place with substrates having electron-withdrawing groups at the C-3 position.

Under thermal conditions, DBAD undergoes a [4 + 2] cycloaddition reaction with derivatized 2-oxazolones. The reaction shows moderate diastereofacial selectivity (eq 3).[7]

Synthesis of α-Hydrazino and α-Amino Acids.

DBAD is an efficient source of electrophilic nitrogen and has been used in the preparation of α-hydrazino and α-amino acids.[3] Aminated carboximides were obtained from the condensation of (*Z*)-lithium enolates of chiral carboximides with DBAD (eq 4). The selectivity observed in this amination reaction was generally greater than 85% de, depending on the bulk of the side chain (Me < CH_2Ph < *i*-Pr). Similar results were obtained in studies with other azodicarboxylates such as ***Di-t-butyl Azodicarboxylate***.[8] The aminated products were then converted to their corresponding α-hydrazino acids under hydrogenolysis conditions (***Palladium on Carbon***, H_2) and then to their free amines with ***Raney Nickel***/H_2.

Dibenzyl *N,N*-Diethylphosphoramidite

[67746-43-4] · $C_{18}H_{24}NO_2P$ · Dibenzyl *N,N*-Diethylphosphoramidite · (MW 317.40)

(phosphorylation of simple alcohols,[1] serine,[2] threonine,[3] and tyrosine;[4] synthesis of glycosyl phosphites and phosphates[5])

Physical Data: bp 131-132 °C/10^{-4} mmHg,[6] 150-152 °C/0.01 mmHg,[7] 154-156 °C/0.3 mmHg.[8]

Preparative Methods: by the reaction of dichloro *N,N*-diethylphosphoramidous acid with 2 equiv of benzyl alcohol.[3,7] An alternative synthesis, described on a 1 mol scale, combines phosphorus trichloride, diethylamine, and 2 equiv of benzyl alcohol in a one-pot reaction.[8] An earlier route to this reagent involved heating phosphorus hexaethyltriamide with 2 equiv of benzyl alcohol.[6]

Purification: by distillation at reduced pressure.

Handling, Storage, and Precautions: reported to be stable at rt and has been kept for at least 6 months.[5]

Preparation of Organic Phosphite and Phosphate Esters.

While dibenzyl *N,N*-diethylphosphoramidite will form phosphite triesters upon heating with 1,2-diacylglycerols in an uncatalyzed reaction (eq 1),[6] phosphitylation of alcohols has more recently been accomplished at ambient temperature in nearly quantitative yield in the presence of added 5-methyl-1*H*-tetrazole, 1*H*-tetrazole, or 1,2,4-triazole.[1,3,8] The phosphate triester has commonly been obtained by in situ oxidation of the phosphite ester intermediate using ***m-Chloroperbenzoic Acid***,[1] ***t-Butyl Hydroperoxide***,[3] or aqueous 30% ***Hydrogen Peroxide***.[8] *t*-Butyl dibenzyl phosphate has been obtained in excellent yield (eq 2).[1]

(1)

t-BuO-P(O)(OBn)$_2$ (2)

Protected serine and threonine derivatives have been phosphorylated for subsequent incorporation into peptides as the phosphate triesters (eq 3).[2,3,9,10] Similarly, dibenzyl *N*,*N*-diethylphosphoramidite has been used to prepare both Boc and Fmoc tyrosine derivatives for use in peptide synthesis.[4,11-14] Use of dibenzyl *N*,*N*-diethylphosphoramidite in phosphorylation of the side chain hydroxyls of serine- and threonine-containing peptides has been demonstrated.[2,7,15-18]

(3)

Dibenzyl *N*,*N*-diethylphosphoramidite has been used in phosphorylation sequences yielding dihydroxyacetone phosphate, D-*myo*-inositol 1,3,4,5-tetrakisphosphate (eq 4), and an inositol monophosphatase inhibitor.[8,19,20] Phosphitylation of the anomeric hydroxy groups of a series of sugars has been examined. The resulting glycosyl dibenzyl phosphites are effective as glycosylating reagents (eq 5), or they may be oxidized to the phosphates and used in the synthesis of sugar nucleotides.[5,21]

(4)

Related Reagents.

Dibenzyl N,N-Diisopropylphosphoramidite.

Dibenzyl *N,N*-Diisopropylphosphoramidite[1]

[108549-23-1] · $C_{20}H_{28}NO_2P$ · Dibenzyl *N,N*-Diisopropylphosphoramidite · (MW 345.42)

(phosphitylating reagent for alcohols; the resulting alkyl dibenzyl phosphite is transformed to the phosphoric monoesters by oxidation and subsequent debenzylation)[2]

Solubility: insol cold H_2O; sol CH_2Cl_2, THF, acetonitrile.

Analysis of Reagent Purity: NMR: δ_P ($CDCl_3$) +148.2.

Preparative Methods: there are several synthetic methods,[2-4] among which the reaction of benzyl alcohol with *N,N*-diisopropylphosphoramidous dichloride in the presence of *t*-amine in diethyl ether, THF, or dioxane is convenient.[5]

Purification: chromatography on silica gel.

Handling, Storage, and Precautions: can be stored in the absence of moisture and air for more than several months. A stock solution can be also prepared.

Phosphoric Monoester Synthesis.

Dibenzyl phosphoramidites such as dibenzyl *N,N*-diisopropylphosphoramidite (**1**) (see also ***Dibenzyl N,N-Diethylphosphoramidite***) react quickly with various alcohols in the presence of 1*H*-tetrazole at room temperature to afford the phosphorus triesters which are oxidized in situ with an oxidant such as ***m-Chloroperbenzoic Acid***, ***t-Butyl Hydroperoxide***, or 30% ***Hydrogen Peroxide*** to give the corresponding alkyl dibenzyl phosphoric triesters in excellent yields. The triesters are deprotected by simple and clean catalytic hydrogenolysis on a Pd catalyst such as ***Palladium on Carbon*** or ***Palladium(II) Hydroxide***. The usefulness of the sequence has been demonstrated by many examples which involve synthesis of phosphate derivatives of amino acids,[2,6] peptides,[7] sugars,[8] and cyclitols (eq 1).[4]

Dibenzyl phosphoric triesters are prepared alternatively by using ***Dibenzyl Phosphorochloridate***, tetrabenzyl pyrophosphate, or dibenzyl phosphorofluoridate. See also cyclic homologue of (**1**), ***o-Xylylene N,N-Diethylphosphoramidite***. These amidite reagents are more effective than P^V reagents, especially for phosphorylation of sterically hindered or base-sensitive alcohols, due to their high reactivity under milder conditions.

Dibenzyl Phosphorochloridate[1]

[538-37-4] · $C_{14}H_{14}ClO_3P$ · Dibenzyl Phosphorochloridate · (MW 296.69)

(phosphorylating reagent for alcohols,[2] phenols,[3] amines,[4] and amides;[5] removal of benzyl groups from the products affords phosphoric monoesters and monoamides respectively)

Alternate Name: BPC.

Physical Data: undistillable thick oil.

Analysis of Reagent Purity: NMR: δ_P +4.7, +3.5 ppm.

Preparative Methods: oxidative halogenation of dibenzyl phosphite using Cl_2 or *N*-chlorosuccinimide[6] yields dibenzyl phosphorochloridate (BPC). The reaction of dibenzyl hydrogen phosphate with PCl_5 is also used.[7] The latter procedure is employed for the preparation of *p*-substituted benzyl derivatives such as *p*-nitrobenzyl[8] and *p*-chlorobenzyl.[9] These substituted benzyl phosphates are crystalline and more stable than BPC but have reactivities similar to the parent chloridate.

Handling, Storage, and Precautions: dibenzyl phosphorochloridate may be stored in the cold but preferably prepared just prior to use. Distillation of the chloridate may cause violent decomposition.

Phosphorylation.

A variety of hydroxy compounds including nucleosides,[10] 1-hydroxy sugars (eq 1),[2] cyclitols,[11] and amino acids (eq 2),[12] as well as amines[4] and amides (eq 3),[5] have been phosphorylated with dibenzyl phosphorochloridate in the presence of a base, or after deprotonation, to afford the corresponding triesters and phosphoramidates, respectively.

Deprotection of the dibenzyl phosphate derivatives is readily achieved by hydrogenolysis on a palladium catalyst such as ***Palladium on Carbon*** or Pd black, resulting in the formation of phosphoric monoesters and monoamides. Removal of the benzyl groups can be also carried out by ***Sodium-Ammonia***,[13] and ***Bromotrimethylsilane***[14] is useful when hydrogenation should be avoided. When removal of one of two benzyl groups is desired, various halides such as ***Sodium Iodide***[7] and other nucleophiles[15] are applied.

Synthetically Analogous Reagents.

Dibenzyl phosphorofluoridate (colorless oil), a fluoro analog of BPC, is prepared by the action of 2-fluoro-1-methylpyridinium *p*-toluenesulfonate on dibenzyl hydrogen phosphate or by the reaction of tetrabenzyl pyrophosphate with CsF.[16] Unlike BPC, and dibenzyl phosphorobromidate and -iodidate, the fluoridate can be purified by distillation

under reduced pressure (bp ca. 150 °C/0.2 mmHg) or chromatography on SiO_2. It reacts with alcohols and preferably with phenols in the presence of ***Cesium Fluoride*** (eq 4)[16] to give alkyl or aryl dibenzyl phosphates.

(4)

Tetrabenzyl pyrophosphate (needles, mp 60-61 °C), which is derived from dibenzyl hydrogen phosphate in the presence of ***1,3-Dicyclohexylcarbodiimide***,[17] can be used also for the phosphorylation of alcohols involving polyols (eq 5)[18] and amines. In the case of alcohols, generation of alkoxide by the action of strong bases such as ***n-Butyllithium***, ***Lithium Diisopropylamide***, ***Sodium Hydride***, or ***Potassium Hydride*** is necessary due to decreased reactivity relative to BPC. The pyrophosphate is crystalline solid and easy to handle, and can be stored in a desiccator.

(5)

Related Reagents.

Dibenzyl N,N-Diethylphosphoramidite; ***o-Xylylene N,N-Diethylphosphoramidite***.

Diborane

B_2H_6

[19287-45-7] · B_2H_6 · Diborane · (MW 27.67)

(strong reducing agent for many functional groups; extremely efficient hydroborating reagent)

Physical Data: bp -92.5 °C; mp -165.5 °C; *d* 0.437 g cm^{-3} (liquid at -92.5 °C); heat of vaporization 3.41 kcal mol^{-1} (at -92.5 °C).

Solubility: slightly sol pentane and hexane; forms BH_3 adduct with DMS, THF, and other ethers; reacts with H_2O and protic solvents, releasing flammable hydrogen gas.

Form Supplied in: commercially available as a compressed gas.

Analysis of Reagent Purity: supplied as either 99.99% or >99.0% B_2H_6.

Handling, Storage, and Precautions: diborane is a toxic, pyrophoric gas and must be stored and handled accordingly. Feed lines and reactors should be flushed with N_2 and kept free of moisture. Cylinders should be hard-piped directly to reactor. When not in use, cylinder valve should be securely closed and capped. Cold (-20 to 0 °C) storage is recommended to ensure product purity. Decomposition products include higher boron hydrides and hydrogen gas.

Diborane and Borane Reagents.

Borane complexes have been used in industrial-scale applications for years. In addition to their unique ability to add across carbon-carbon multiple bonds, boron hydrides reduce ketones, carboxylic acids, amides, and nitriles (eqs 1-3).[1] By the appropriate choice of borane reagent and reaction conditions, a significant degree of chemical selectivity can be achieved. This high level of selectivity and reactivity has found utility not only in classical organic synthesis,[2,3] but also in the area of asymmetric synthesis with the Corey-Itsuno catalyst serving as a prime example of a highly reactive and enantioselective reagent.[4]

(1)

(2)

(3)

Chemically, diborane is the parent of all the borane complexes. Diborane will react with a Lewis base to form an adduct in which the electron pair from the Lewis base is donated to the borane. This complexation alters the reactivity of the borane, subsequently changing its physical form. Diborane is a gas with a boiling point of -92.5 °C, whereas the borane complexes are either liquids or solids. As illustrated in the molecular model (**1**), diborane has some unusual bonding characteristics. The boron is so electron deficient that it resorts to sharing the electrons in the B-H bond, giving rise to bridging hydrogens. This electron deficiency allows formation of borane complexes with Lewis bases such as tetrahydrofuran (THF), dimethyl sulfide (DMS), and amines (Scheme 1).

(1)

Scheme 1

In the search for better borane reagents, a variety of complexes have been synthesized; almost all fit under one of the three following classifications: ether-borane complexes, sulfide-borane complexes, or amine-borane complexes.

A general trend of borane complexes is that the stronger the Lewis base, the weaker the reducing power of the resulting borane.[5] ***Borane-Tetrahydrofuran*** (THFB) is more reactive than ***Borane-Dimethyl Sulfide*** (DMSB), which in turn is more reactive than most amine-boranes. When reducing a carboxylic acid or hydroborating a carbon-carbon double bond, THFB and DMSB are both effective reagents, while amine-boranes generally are not suitable choices.

Comparison of Borane Reagents.

THFB and DMSB, however, do have drawbacks which can be of some concern in an industrial setting. The maximum workable concentration for THFB is 1 molar. Therefore a large reactor volume is required to achieve the desired reduction. The low loading in a given size reactor, and ultimately solvent waste, increase the cost-per-pound of product.

DMSB is commercially available as a neat solution (~10M); thus solvent volume is determined by reactor loading of other reactants (substrate). However, anyone who has had the opportunity to use dimethyl sulfide can attest to the fact that the human nose can detect DMS in the ppm range. Various schemes have been used in an attempt to scrub the DMS from reaction streams, but none are truly effective.

When diborane is added to an ether solvent, ether-borane complexes are formed. If the solvent is THF, then THFB is formed in situ, and reacts in the same manner without the high dilution effect of using the 1M THFB solution. By using diborane rather than THFB, reactor loading can be increased, thereby reducing costs. Use of diborane will also reduce the amount of waste solvent remaining at the end of the process. The advantage of diborane over DMSB is the avoidance of odor control problems inherent in dimethyl sulfide, again reducing costs.

Although much of the literature describing borane reductions involves coordinating solvents such as ethers, diborane can be employed in nonpolar hydrocarbon solvents.[6-9] Table 1 shows an appreciable solubility of diborane in hexanes. It should be noted that the reactivity of diborane in hydrocarbons may be distinctly different from the reactivity of borane complexes. For example, because it is uncomplexed, diborane is generally much more reactive than sulfide boranes such as DMSB.

Table 1 Solubility of Diborane in Various Solvents

Solvent	Solubility (g B_2H_6/100 g solvent)	Temperature (°C)	B_2H_6 pressure (atm)
n-Pentane	0.996	19.6	0.958
n-Hexane	4.22	room	2.55
neo-Hexane	3.18	room	4
cis-Decalin	1.86	room	2.44
Mesitylene	0.323	25	0.653
Ethyl ether	1.1	20	1
1,4-Dioxane	3.37	room	2.38
Tetrahydrofuran	8.1	20	1

However, diborane should not be used in every reaction where THFB or DMSB are currently in use.

- 1)DMSB is a good choice if the reduction requires heat to push the reaction to completion, because DMSB is stable at higher temperatures than ether-borane complexes.
- 2)THFB is a good choice when addition of substrate to an excess of borane is required, and reactor loading is not a major concern. THFB solutions should not be heated above 50 °C, since diborane will be lost from the complex and reductive ring opening of the THF will occur.
- 3)Diborane is a good choice when it is desirable to add borane to the substrate in the reactor. With diborane, higher reactor loadings can be achieved than with either of the other two reagents.

Generally, if the reaction is fast at or below ambient temperature, diborane is an effective replacement for either THFB or DMSB.

The classic synthesis of ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) from *cis,cis*-1,5-cyclooctadiene (cod) serves as a good model for hydroboration reactions (eq 4). The route described in the literature[10] advises the use of DMSB in dimethoxyethane (DME). Following the hydroboration and removal of DMS, crystalline 9-BBN precipitates out of the DME solvent. Unfortunately, the resulting product is contaminated with the odor of dimethyl sulfide which is not readily removed from the 9-BBN. The use of THFB as the hydroborating reagent does alleviate the DMS odor, but the product remains solubilized as a dilute solution in THF and DME. When diborane is added as a gas to a DME solution of cod, the resulting 9-BBN is obtained as a clean crystalline product with a typical purity of >96%. No further processing is required from the diborane-produced 9-BBN.[11]

(4)

Reduction of a substituted xanthone to a xanthene, shown in eq 5, was accomplished using three borane reagents.[12] THFB was an effective reagent for this transformation, and was the most desirable for small-scale preparations because of its ease of use. The reduction utilizing DMSB could not be driven to completion. Diborane proved to be the most effective reagent and was highly desirable for commercial-scale synthesis of the xanthene. With the higher loading achievable using diborane, the THFB route was considered to be economically unfeasible.

(5)

Practical Considerations.

Introduction of diborane into a reactor requires some careful consideration of the reactor system. Diborane, like almost all hydrides, is very reactive. It is critical that the reactor be under an inert gas, such as nitrogen, since diborane is a pyrophoric material. The addition of diborane to a solution is best accomplished by feeding gaseous diborane under the surface of the solvent. If the product formed by reaction of diborane is a solid, diborane can be added to the reactor head space provided that a back pressure on the reactor keeps it contained. Given a reactor which is free of oxygen and moisture, diborane is used as any other compressed gas.

Diborane cylinders are packaged in dry ice for shipment. The vapor pressure of diborane at -78 °C is 15 psig (776 Torr). This allows for a convenient method to control the pressure of diborane gas being fed to a reactor. The rate at which diborane is fed into the reactor is dictated by the thermodynamics and kinetics of the reaction, and the temperature constraints of the system.

Conclusion.

In many cases, diborane can be used as a cost effective reagent for reduction or hydroboration. Use of diborane in place of THFB can significantly increase the loading in a given reaction. Used in place of DMSB, it can eliminate the handling of dimethyl sulfide as a waste. All three reagents (diborane, THFB, and DMSB) have application in organic synthesis, and each should be evaluated for potential use.

Related Reagents.

Borane-Ammonia; ***Borane-Dimethyl Sulfide***; ***Borane-Pyridine***; ***Borane-Tetrahydrofuran***; ***Ephedrine-borane***;

Norephedrine-Borane.

Dibornacyclopentadienyltrichlorozirconium[1]

[126035-93-6] · $C_{21}H_{29}Cl_3Zr$ · Dibornacyclopentadienyltrichlorozirconium · (MW 479.07)

(chiral Lewis acid for enantioselective C-C coupling of pyruvic esters with active arenes[1])

Physical Data: ^{1}H NMR ($CDCl_3$, 200 MHz): δ 2.73, 3.05 (4,4´-H), 0.8-1.0, 1.8-2.2, 2.68 (5,5´,6,6´-H), 6.11 (8-H), 0.26, 0.92, 0.93, 0.95, 1.19, 1.46 (1,1´,7,7´-CH_3). ^{13}C NMR ($CDCl_3$, 50 MHz, ^1J(CH) in Hz): δ 11.6, 12.5 (1,1´-CH_3), 19.8, 20.6 (double intensity), 29.8 (7,7´-CH_3), 25.8 (122) and 00.0 (125; 5,5´), 32.1 (131) and 38.5 (137; 6,6´), 50.5 (149) and 51.6 (147; 4,4´), 55.8 (triple intensity), 68.6 (1,1´,7,7´), 106.4 (173; 8), 144.9, 146.9, 152.7, 159.7, 159.2 (2,2´,3,3´).

Solubility: sol dichloromethane.

Preparative Method: reaction of dibornacyclopentadienyllithium with $ZrCl_4$ (40% yield).[1]

Preparation.

Both the title zirconium catalyst (**1**), and the corresponding hafnium derivative (**2**) have been synthesized according to Scheme 1. Addition of 2 equiv of 2-bornen-2-yllithium (**4**) (generated via the Shapiro reaction[2] from (+)-camphor (**3**)) to ethyl formate gives bis(2-bornen-2-yl)methanol (**5**). Cyclization of alcohol (**5**) is carried out with ***Potassium Hydrogen Sulfate*** at 100-150 °C to afford dibornacyclopentadiene (**6**). Deprotonation of (**6**) with ***n-Butyllithium*** followed by reaction with ***Zirconium(IV) Chloride*** affords (**1**). Reaction with $HfCl_4$ affords (**2**).

Scheme 1

Arylation of α-Keto Esters.

Zirconium complex (**1**) has been used as a catalyst for the synthesis of optically active 2-(2-hydroxyaryl)lactic acid ethyl ester (**7**) (eq 1).[1]

(1)

It was found that lowering the reaction temperature from rt to -10 °C resulted in an increased enantiomeric excess (from 27% ee to 54% ee). Surprisingly, the addition of small amounts of water (ca. 20 mol %) also increased the chiral induction observed (up to 89% ee).

Solubility: freely or fairly sol most organic solvents.

Form Supplied in: colorless or slightly yellow liquid or crystals; usually prepared in the laboratory.

Purification: the pure liquid compounds can be obtained by distillation or passage through basic alumina, while the pure crystalline derivatives are obtainable by recrystallization.

Handling, Storage, and Precautions: dibromo ketones, especially cyclic analogs, are allergenic and

lachrymatory and hence should be handled in a well-ventilated hood. Use of rubber gloves is recommended for handling. Since the dibromo ketones are sensitive to moisture and light, they should be stored in a tightly stoppered brown bottle or a brown ampule in a refrigerator. Occasionally, the compounds bear deep yellow or orange color on long storage. All procedures of the iron carbonyl-promoted reactions, including workup, should be carried out in a well-ventilated hood.

Generation of 2-Oxyallyl Species.

Two-electron reduction of an α,α´-dibromo ketone, generating a reactive zwitterionic 2-oxyallyl or related species, is effected with many low-valent metallic reagents such as ***Sodium Iodide-Copper*** in acetonitrile,[17,18] ***Zinc/Copper Couple*** in DME or acetone,[19] ***Zinc/Silver Couple*** in THF,[20] and ***Nonacarbonyldiiron*** in benzene (eq 1).[21] A similar species is generated by the reduction with ***Sodium Iodide*** in acetone or acetonitrile.[13,22] The reactive C_3 intermediates undergo cycloaddition to certain alkenes or 1,3-dienes to give five- or seven-membered cyclic ketones, respectively.

(1)

The [3 + 2 -> 5] Cyclocoupling Reactions.

Reduction of an α,α´-dibromo ketone with $Fe_2(CO)_9$ in the presence of an aryl-substituted alkene gives a 3-arylcyclopentanone (eq 2).[23] The reaction of an unsymmetrically substituted dibromo ketone proceeds with high regioselectivity.[24,25]

(2)

$R^1 = Me$; $R^2 = Ph$; 95%
$R^1 = Ph$; $R^2 = H$; 49%, 100% regioselective

Enamines serve as excellent C_2 substrates in the $Fe_2(CO)_9$-promoted cyclocoupling. Secondary dibromides initially form labile 3-aminocyclopentanones which readily eliminate amines to give 2-cyclopentenones (eq 3).[2,26] $Fe_2(CO)_9$ is the only efficient reducing agent for this cyclopentenone-forming reaction. The reaction with a tertiary dibromide gives a stable 3-aminocyclopentanone[26b,27] or 2-amino-5-alkylidenetetrahydrofuran.[26b] The latter type of product is obtained

by the reaction with 1,1-dimethoxyethylene promoted by Cu-NaI.[18]

(3)

The secondary dibromides similarly cyclocouple with *N*,*N*-dimethylcarboxamides with the aid of $Fe_2(CO)_9$ to give 3(2*H*)-furanones (eq 4).[28] Use of Zn/Cu couple usually affords 2-amino-4-alkylidene-1,3-dioxolanes, which readily rearrange to the 3(2*H*)-furanones.[29] A similar 1,3-dioxolane product is formed in the reaction with a ketone promoted by ultrasonically dispersed Hg.[30] The NaI-assisted cyclocoupling with tetracyanoethylene or diethyl azodicarboxylate affords the corresponding five-membered products but in low yield.[13] Reduction of tertiary dibromo ketones with Zn/Cu couple[31] or $Fe_2(CO)_9$[14b] in the presence of acetonitrile produces 5-alkylidene-2-oxazolines in low yields.

(4)

The $Fe_2(CO)_9$-aided [3 + 2] cyclocoupling with 2-methylpropene does not proceed smoothly,[32] while the intramolecular version gives a bicyclic product (eq 5).[33]

(5)

The [3 + 4 -> 7] Cyclocoupling Reactions.

Reduction of an α,α´-dibromo ketone with $Fe_2(CO)_9$ in the presence of open-chain 1,3-dienes affords the [3 + 4] products, 4-cycloheptenones.[34] High yields are obtained with the dienes having a high population of the *s-cis* conformation. The butadiene-$Fe(CO)_3$ complex acts as a good reducing agent and receptor (eq 6). $Fe(CO)_5$[34] or Zn/Cu couple[31,35] promotes the reductive coupling but less effectively.

(6)

Substituted and unsubstituted cyclopentadienes,[13,17,19,22,31,34,36,37] 1,3-cyclohexadiene,[38] fulvenes,[17b] *N*-protected pyrroles,[34b,39-41] and furans,[13,17,19,22,34b,36,39,42-45] in which the diene is frozen to the *s-cis* conformation, serve as excellent C_4 components (eq 7). Intramolecular [3 + 4] reaction has also been achieved.[33,46] Pyrrole and its *N*-alkyl derivatives can be employed for the Cu-NaI assisted reaction of acyclic dibromo ketones,[39,41] whereas cyclic dibromides give the substitution products. The reaction using Zn/Cu couple or iron carbonyls results only in the substitution products.[34b,39,40a] The aromatic substitution of furan is often observed in the $Fe_2(CO)_9$-promoted reaction of cyclic dibromides.[34b]

(7)

X	Reducing agent	Yield (%)
CH_2	Zn/Cu	65
CH_2	$Fe_2(CO)_9$	82
NMe	Cu, NaI	89
NCO_2Me	$Fe_2(CO)_9$	60
O	Cu, NaI	48
O	Zn/Cu	85
O	Zn/Ag	80
O	$Fe_2(CO)_9$	90

α,α´-Dibromoacetone itself cannot be used as the C_3 unit. However, ***1,1,3,3-Tetrabromoacetone*** acts as its synthetic equivalent. Iron carbonyls,[34b,37b,47,48] Zn-$(EtO)_3B$,[45b] Zn/Cu couple,[40c] or Zn/Ag couple[20,48c] promote the [3 + 4] cyclocoupling with reactive 1,3-dienes. Debromination of the resulting dibromo ketones with Zn/Cu couple and ammonium chloride in methanol gives the desired ketonic products (eq 8). This modification is generally applicable to the reaction of other methyl ketone polybromides.[20,36,34b,39,44,49]

(8)

X	Reducing agent	Yield (%)
CH_2	$Fe(CO)_5$	60
NCO_2Me	$Fe_2(CO)_9$	57
O	Zn/Ag	55
O	$Fe_2(CO)_9$	63

Miscellaneous Reactions.

Reaction of α,α´-dibromo ketones and η^1-allyl(cyclopentadienyl)iron dicarbonyl affords substituted cyclohexanones (eq 9).[27] Reaction of the dibromide and an isocyanide assisted by Cu in benzene or Zn in pyridine-benzene provides a facile way to a 2-(*N*-alkylimino)cyclobutanone (eq 10).[50] Reaction of an α,α´-dibromo ketone and an organocuprate is used to prepare α-monoalkylated and α,α´-dialkylated ketones (eq 11).[42]

Dibromoacetonitrile

$CHBr_2CN$

[3252-43-5] · C_2HBr_2N · Dibromoacetonitrile · (MW 198.84)

(reagent used to introduce an α-bromo acid[1] or ester moiety[1,2] directly on a substrate having a carbonyl group; can be also used for heterocyclic syntheses;[8,10] and other miscellaneous reactions[18,19])

Physical Data: bp 68-69 °C/24 mmHg; *d* 2.296 g cm^{-3}; n_D^{20} 1.5390.

Solubility: insol H_2O; sol ether, alcohol, THF.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: dibromoacetonitrile is reputed to be relatively toxic, lachrymatory, and light sensitive. Usual precautions of storage in darkness between 0-5 °C and handling in a fume hood are recommended.

Homologation of Carbonyl Groups into α-Bromo Acids or Esters.

Divergent pathways have been described in the Darzens reaction of aldehydes or ketones with ***Dichloroacetonitrile***[3] and dibromoacetonitrile[1] in a basic alcoholic medium. Whereas α-chlorinated glycidic imino ethers are obtained in the reaction with dichloroacetonitrile, α-bromo acids or α-bromo esters are the products of the Darzens reaction with dibromoacetonitrile. The reaction is carried out in one pot and leads to α-bromo acids or esters in rather good yields (eq 1).[1,2] The reaction combined with a subsequent substitution of the bromine by ammonia[4,5] or by potassium phthalimide[6] on the α-bromo carbonyl compound holds important synthetic potential for the conversion of a carbonyl group into an α-amino acid.

Heterocycle Syntheses.

Very few methods exist for the introduction of halogen at the 2- and 3-positions of the pyridine ring.[7] It was reported that dibromoacetonitrile adds smoothly under mild conditions to methacrolein, in the presence of a catalytic amount of ***Copper(I) Chloride*** and ***Tri-n-butylphosphine*** as co-catalysts, to afford an adduct that readily cyclizes to give 2,3-dibromo-5-methylpyridine. No trace of the primary adduct was detected in the isolated product (eq 2). Under the same reaction conditions, dichloroacetonitrile leads to a mixture of 2,3-dichloro-5-methylpyridine and 2,4-dichloro-4-methyl-5-oxopentanenitrile.[8]

Special emphasis has also been given to the development of synthetic procedures for the preparation of polyhalogenation products from trialkyl-1,3,5-triazines.[9] Dibromoacetonitrile trimerizes in the presence of ***Aluminum Bromide*** in acidic medium and yields tris(dibromomethyl)-1,3,5-triazine (eq 3),[10] which constitutes the precursor of a synthetic equivalent of the unstable triformyl-1,3,5-triazine (eq 4) not previously isolated.[11,12] The alternative, classical method for the synthesis of tris(dibromomethyl)-1,3,5-triazine requires the availability of the trimethyl-1,3,5-triazine as starting material.[9]

(3)

(4)

Miscellaneous Reactions.

Addition of HCN to nitriles having hydrogen atoms on the α-carbon atom occurs in only a few special cases.[13-15] For the addition to be successful, the cyano group has to be activated by one or more strongly electron-withdrawing groups on the α-carbon.[16,17] A selected example reports that dichloro- and dibromoacetonitrile react with HCN to give β,β-dihalo-α-aminoacrylonitriles, a new class of acrylonitrile compounds, in good yields (eq 5).[18]

(5)

In certain reactions dibromoacetonitrile reacts as the bromocyanomethyl radical. For instance, $CHBr_2CN$ was used to prepare several 1-cyano-2-(trichloroethyl)cyclopropanes of importance in pyrethroid chemistry.[19] The sequence of reactions involves homolytic displacement of cobaloxime(II) from an allylcobaloxime(II) complex by the bromocyanomethyl radical (bis(dimethylglyoximato)pyridine = $(dmgH)_2py$). The bromocyanomethyl radical attacks regiospecifically at the γ-carbon of the allyl ligand to afford the 2-bromo-4-phenylpent-4-enenitrile (eq 6).[20] Subsequent treatment with the $((dmgH)_2py)$cobaltate(II) ion in aqueous methanol at ambient temperature (eq 7) and then with trichloromethanesulfonyl chloride leads to the corresponding 1-cyano-2-(trichloroethyl)cyclopropane (eq 8).[19]

Dibromoalane

Br_2AlH

[15576-93-9] · $AlBr_2H$ · Dibromoalane · (MW 187.80)

(reagent for reduction of acetals;[1,2] selective carbonyl reductions[3,4])

Physical Data: mp -15 °C; bp 95 °C under high vacuum.[5]

Solubility: sol benzene, chloroform, ether, THF.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: normally prepared in situ as a solution in ether and used without purification or analysis; however, the bis-THF adduct has been characterized by NMR, IR, and elemental analysis.[6]

Preparative Methods: generally prepared in situ from ***Lithium Aluminum Hydride*** (1 equiv) and ***Aluminum Bromide*** (3 equiv) in ether at 0 °C;[2,3] alternatively, the reagent can be prepared in pure form by reaction of ***Aluminum Hydride*** (1 equiv) with $AlBr_3$ (2 equiv) in ether followed by vacuum distillation.[5] The bis-THF adduct [$Br_2AlH.2(THF)$] is a stable crystalline compound (mp 64-67 °C) which can be prepared by either of the methods described above (substituting THF for ether as the solvent).[6]

Purification: by distillation; see above.

Handling, Storage, and Precautions: generally prepared in situ and used immediately; handle under dry nitrogen in a fume hood.

Reduction of Acetals.

Dibromoalane (**1**) is a useful reagent for the reductive cleavage of acetals to the corresponding hydroxy ethers. For example, reduction of a bicyclic acetal with (**1**) in ether afforded the *cis* and *trans* hydroxy ethers (*cis*:*trans* = 97:3) in 72% yield (eq 1).[1] Note that substitution of ***Dichloroalane*** or ***Diisobutylaluminum Hydride*** (DIBAL) for (**1**) in this reaction led to a decrease in the *cis*:*trans* product ratio (possibly due to the higher reaction temperatures required for these less reactive reagents).

Chiral acetals can be reduced with dibromoalane to afford the corresponding ether with varying degrees of stereoselectivity. For example, reduction of the chiral acetal derived from cyclohexyl methyl ketone and (-)-(2*R*,4*R*)-2,4-pentanediol afforded the hydroxy ether as a 23:1 mixture of diastereomers in 99% yield (eq 2).[2] Dibromoalane generally gives better results than dichloroalane or DIBAL but stereoselectivity is somewhat lower with less hindered substrates. Note that the ethers generated by this reduction can subsequently be converted to the corresponding alcohol via an oxidation-elimination sequence (eq 3).[2] The net result of the overall sequence is thus a stereoselective reduction of the original ketone.

Selective Carbonyl Reduction.

Dibromoalane (**1**), in combination with a hindered alkoxyaluminum compound, is an excellent reagent for the selective reduction of a hindered ketone in the presence of a less-hindered ketone (eq 4).[3] The less hindered of the two ketones forms a complex with the alkoxyaluminum additive (e.g. ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)***), leaving the more hindered ketone accessible for reduction by the hydride reagent. A variety of hydride reagents may be used but (**1**) usually gives the best selectivity.[3]

(4)

In combination with ***Copper(I) Iodide***, (**1**) can also effect 1,4-reduction of α,β-unsaturated ketones. However, lithium aluminum hydride/copper iodide is generally superior for this purpose.[4]

Related Reagents.

Dichloroalane; ***Diisobutylaluminum Hydride***; ***Lithium Aluminum Hydride-Copper(I) Iodide***.

Dibromobis(triphenylphosphine)nickel(II)[1]

$NiBr_2(PR_3)_2$

(**1**; R = Ph)

[14126-37-5] · $C_{36}H_{30}Br_2NiP_2$ · Dibromobis(triphenylphosphine)nickel(II) · (MW 743.08) (**2**; R = Bu)

[15242-92-9] · $C_{24}H_{54}Br_2NiP_2$ · Dibromobis(tributylphosphine)nickel(II) · (MW 623.14) (**3**; R = Et)

[19224-77-2] · $C_{12}H_{30}Br_2NiP_2$ · Dibromobis(triethylphosphine)nickel(II) · (MW 454.81)

(catalysts for the cross-coupling reactions of various RX with Grignard reagents,[1] C-X bond reduction,[9,10] homocoupling of C_{sp^2} halides,[11] displacement of aryl halides,[2] and oligomerization of dienes[12,13])

Alternate Name: bis(triphenylphosphine)nickel(II) bromide.

Physical Data: (**1**) mp 222-225 °C; dark green. (**2**) mp 51-53 °C; red. (**3**) mp 106-107 °C; dark red.

Solubility: sol acetone, benzene, THF.

Form Supplied in: most nickel bromide phosphine complexes are commercially available.

Preparative Methods: conveniently synthesized by mixing a stoichiometric amount of ***Nickel(II) Bromide*** with the appropriate phosphine ligand.[15]

Handling, Storage, and Precautions: these complexes are somewhat air sensitive. Like other Ni^{II} compounds, they are cancer suspect agents and corrosive. These reagents should be handled in a fume hood.

General Considerations.

Most reactions promoted by ***Dichlorobis(triphenylphosphine)nickel(II)*** or related complexes can also be mediated by $NiBr_2(PPh_3)_2$ or the like. This section covers certain specific applications using the nickel bromide reagents.

Displacement Reactions.

Aryl triflates readily participate in an in situ generated Ni^0-catalyzed nucleophilic displacement with cyanide anion, thereby providing a convenient method for the preparation of aryl cyanides (eq 1).[2]

(1)

Reaction of allylic alcohols with morpholine in the presence of a catalytic amount of $NiBr_2(PPh_3)_2$ and ***Potassium t-Butoxide*** gives the corresponding amines in good yields (eq 2).[3]

(2)

The regioselective rearrangement of propene oxide to propionaldehyde is reportedly promoted by $NiBr_2(PPh_3)_2$.[4] Surprisingly, the reaction of methylmagnesium iodide with *t*-BuO^- in the presence of $NiBr_2(PPh_3)_2$ yields isobutylene oxide (eq 3).[5]

(3)

Cross-Coupling Reactions.

Most of the cross-coupling reactions that use nickel halide phosphine complexes as the catalyst are discussed in the article on ***Dichlorobis(triphenylphosphine)nickel(II)***.[1] The addition of the phosphine ligand to a solution of nickel bromide also serves as a useful catalytic system for this purpose.

In an electrochemical process, aryl halides react with α-haloacetic acid esters to give the corresponding arylacetic acid derivatives.[6] The reaction of (*E*,*E*)-1,4-dilithio-1,4-diphenyl-1,3-butadiene at -78 °C with $(Et_3P)_2NiBr_2$ produces the nickel complex of 1,2,5,6-tetraphenylcyclooctatetraene in good yield. The cot ligand can easily be liberated upon air oxidation.[7]

When chiral ligands are used, enantioselective cross-coupling reactions can be achieved. To illustrate, $NiBr_2$[(*S*)-(*R*)-PPFOME] has been used for the synthesis of chiral ternaphthyl (eq 4).[8]

(*S*)-(*R*)-PPFOME

Reduction.

The carbon-sulfur bonds of thiols, thioethers, dithioacetals, and sulfoxides as well as sulfones are reduced upon treatment with $NiBr_2(PPh_3)_2$ and ***Lithium Aluminum Hydride*** in moderate to good yields.[1f,9] As sulfoxides and sulfones can readily be reduced to thioethers by low valent transition metal complexes or by complex hydrides,[10] it has been suggested that nickel reagents first reduce sulfoxides or sulfones to the corresponding sulfides which are further reduced under the reaction conditions. Therefore an excess amount of the reducing agent is usually required to effectively reduce these substrates.

The reaction of cumulenes with zero valent nickel catalyst generated in situ from $NiBr_2(PPh_3)_2$, zinc, and Ph_3P proceeds smoothly at rt to give the dimeric radialenes in moderate yield (eqs 5 and 6).[11]

(5)

(6)

1,1-Dibromo-2,2-diphenylethylene also dimerizes under similar conditions in benzene to give the butatriene (eq 7).[11]

(7)

Although low valent nickel complexes are very useful for the dimerization and oligomerization of alkenes or

butadienes, the use of $NiBr_2(PPh_3)_2$ or related complexes for this purpose is relatively rare (eq 8), because a number of isomeric products are occasionally obtained.[12] Alternatively, $NiBr_2(PPh_3)_2$-***n-Butyllithium*** has been shown to catalyze the cyclodimerization of butadiene to give the five-membered ring product in excellent yield (eq 9).[13]

(8)

(9)

Allylic acetals react with allylzinc reagents in the presence of a catalytic amount of $NiBr_2(PPh_3)_2$ followed by treatment with electrophiles, leading to double functionalization of α,β-unsaturated acetals (eq 10).[14]

Dibromobis(triphenylphosphine)palladium(II)[1]

$PdBr_2(PPh_3)_2$

(*cis*)

[25044-96-9] · $C_{36}H_{30}Br_2P_2Pd$ · Dibromobis(triphenylphosphine)palladium(II) · (MW 790.81) (*trans*)

[22180-53-6]

(catalyst for carbonylation of aromatic and vinylic bromides;[1-5] arylation of allylic alcohols;[6] silylation[7] and stannation[8] of aromatic bromides)

Physical Data: mp 230-250 °C (dec).

Solubility: sol acetonitrile, DMF, halogenated solvents.

Preparative Method: from commercially available $PdCl_2(PPh_3)_2$.[1b,1c]

Handling, Storage, and Precautions: hygroscopic, air sensitive in solution.

Carbonylation.

$PdBr_2(PPh_3)_2$ (**1**) is a catalyst that has been used for the carbonylation of aromatic bromides to give carboxylic acids.[2] Use of this reagent in a synthesis of anthranilic acids is shown in eq 1.

Aromatic and vinyl bromides have been carbonylated in the presence of amines to give amides (eq 2).[3]

(2)

Carboxylic acid esters are formed from carbonylation of aromatic and vinylic bromides and iodides in the presence of an amine and an alcohol (eq 3).[4]

(3)

Aryl halides and vinyl halides react with carbon monoxide and hydrogen in the presence of amines and (**1**) to yield aldehydes (eq 4).[5]

(4)

Arylation.

The title reagent has been used to couple aromatic halides with allylic alcohols (eq 5).[6] This process is formally equivalent to a conjugate addition between the halide and an unsaturated ketone.

(5)

Silylation.

$PdBr_2(PPh_3)_2$ will catalyze the silylation of aromatic and alkyl bromides with disilanes (eq 6).[7]

(6)

Stannation.

The title reagent has been used to prepare organostannanes from functionalized aromatic bromides and distannanes (eq 7).[8] The reaction is especially useful where normal Grignard or organolithium reagents cannot be used.

Dibromoborane-Dimethyl Sulfide[1]

$BHBr_2.SMe_2$

[55671-55-1] · $C_2H_7BBr_2S$ · Dibromoborane-Dimethyl Sulfide · (MW 233.77)

(hydroborating agent providing access to alkyl-[2] and alkenyldibromoboranes[3] and boronic acids[2,4])

Alternate Name: DBBS.

Physical Data: mp 30-35 °C; bp 75 °C/0.1 mmHg.

Solubility: sol dichloromethane, carbon disulfide, carbon tetrachloride.

Form Supplied in: white solid or liquid, 7.8 M in $BHBr_2$.

Preparative Methods: by redistribution of $BH_3.SMe_2$ and $BBr_3.SMe_2$ or $BH_3.SMe_2$ and BBr_3;[5] by the reaction of bromine with $BH_3.SMe_2$ in CS_2.[6]

Analysis of Reagent Purity: ^1H NMR (CCl_4) δ 2.48, (CS_2) 2.69 ppm; ^{11}B NMR (CCl_4) δ -7.3 (d, J_{B-H} = 160 Hz),[5] (CS_2) -8.2 ppm.[6] Hydrolysis of an aliquot and measuring the hydrogen evolved according to the standard procedure.[7]

Handling, Storage, and Precautions: corrosive liquid; air and moisture sensitive; flammable; stench. Handle and store under nitrogen or argon. Stable indefinitely when stored under nitrogen at 25 °C. Reacts violently with water. This reagent should be handled in a fume hood.

Hydroboration of Alkenes.

Dibromoborane-dimethyl sulfide hydroborates alkenes directly without need for a decomplexing agent (see ***Dichloroborane Diethyl Etherate***) (eq 1).[2]

$$RCH{=}CH_2 + BHBr_2 \cdot SMe_2 \xrightarrow[71\text{-}93\%]{CH_2Cl_2} RCH_2CH_2BBr_2 \cdot SMe_2 \quad (1)$$

Regioselectivity of DBBS in the hydroboration of alkenes and derivatives is high, approaching ***9-Borabicyclo[3.3.1]nonane***, e.g. 1-hexene, styrene, 2-methyl-1-pentene, 2-methyl-2-butene and 4-(dimethylphenylsilyl)-2-pentene, react by placing the boron atom at the less hindered position with &egt;99% selectivity.[2,8a] Lower regioselectivity of the hydroboration-oxidation is observed if an excess of alkene is used, due to hydrobromination, which is a side reaction in the hydrolysis-oxidation step.[8b] The reactivity of DBBS toward structurally different alkenes and alkynes is different from that of other hydroborating agents (Table 1).[3,9]

Table 1 Relative Reactivity of Representative Alkynes and Alkenes with $BHBr_2{\cdot}SMe_2$, 9-BBN, and Sia_2BH

Compound	$BHBr_2{\cdot}SMe_2$	9-BBN	Sia_2BH
1-Octene	100	100	100
(*Z*)-3-Hexene	20	0.55	1.25
1-Hexyne	290	15	345
3-Hexyne	5900	0.74	208

Reactions of Alkyldibromoboranes.

Alkyldibromoboranes are versatile synthetic intermediates. They are resistant to thermal isomerization, a feature of considerable importance for the regio- and stereoselective synthesis of organoborane intermediates from highly labile alkenic structures.[10]

Standard oxidation of alkyldibromoboranes with alkaline ***Hydrogen Peroxide*** affords alcohols.[2,8b] Conversion of terminal alkenes to carboxylic acids using alkyldibromoboranes works well, although hydrolysis prior to oxidation is needed.[11] Chiral alkyldibromoboranes have been used as catalysts for the asymmetric Diels-Alder reaction.[12,13]

The hydridation-stepwise hydroboration procedure provides a convenient general approach to monoalkylbromoboranes, mixed dialkylbromoboranes, dialkylboranes, totally mixed trialkylboranes, ketones, alcohols (eq 2),[14] and stereodefined alkenes, dienes, and haloalkenes (see below). Mixed alkylalkenylalkynylboranes are also available by this methodology.[15]

(2)

Hydrolysis and alcoholysis of alkyldibromoboranes provide simple access to alkylboronic acids and esters respectively,[4] which are important synthetic intermediates and reagents for protection of hydroxy groups of diols[16a-f] and derivatizing agents for GC and GC-MS analysis.[16g,h]

Selective Hydroboration of Dienes and Enynes.

The opposite reactivity trends of DBBS and other hydroborating agents makes possible the selective hydroboration of dienes (eq 3)[9] and enynes.[9] In conjugated systems, however, bromoboration of the triple bond is observed.[17]

(3)

Reactions of Alkenyldibromoboranes and Alkenylalkylbromoboranes.

Synthesis of Alkenylboronic Acids, Alkenes, Aldehydes, and Ketones.

Alkenyldibromoboranes undergo many of the characteristic reactions of alkenylboranes. The presence of dimethyl sulfide does not interfere in their transformations. Protonolysis with acetic acid in refluxing dichloromethane gives the corresponding

alkene. Oxidation leads to aldehydes or ketones (eq 4).[3] Hydrolysis and alcoholysis yields alkenylboronic acids and esters, respectively.

The (*E*)-alkenylboronic acids are directly available from 1-alkynes by hydroboration-hydrolysis (eq 4).[4] The (*Z*)-isomers are prepared from 1-bromo-1-alkynes by hydroboration-hydride reduction (eq 5).[18]

Synthesis of (*E*)- and (*Z*)-Alkenes, Trisubstituted Alkenes, 1,2-Disubstituted Alkenyl Bromides, Ketones, and Enolborates.

The synthesis of (*Z*)-alkenes, according to eq 4, is a simple, convenient method, provided the alkynic precursor is readily available. A general Zweifel (*E*)- and (*Z*)-alkene synthesis starts with 1-alkynes and 1-bromo-1-alkynes, respectively. The precursors are hydroborated with monoalkylbromoborane to give the corresponding alkylalkenylbromoboranes. Migration of the alkyl group completes the formation of the carbon skeleton (eq 6).[19-21] The procedure allows full utilization of the alkyl group.

(6)

(*Z*)-9-Tricosene (muscalure), the sex pheromone of the housefly (*Musca domestica*), has been prepared by this method in 69% yield and >99% purity.[20,22] Extension of the methodology to trisubstituted alkenes is based on the iodine-induced migration of the second alkyl group R^3 (eq 7).[23]

(7)

The key alkenylboronate intermediate used for the introduction of the R^3 group (eq 7) is of the same structure as the one shown in eq 6. The procedure works well both for alkyl and aryl R^3 groups. However, a methyl group shows poor migratory aptitude in these reactions.[20,23] If the two *trans*-alkyl groups in the product alkene are the same or differ significantly in steric bulk, an internal alkyne may serve as a starting material (eq 8).[24]

(8)

Other approaches to trisubstituted alkenes via organoboranes involve alkynyltrialkyl borates,[25] alkenyltrialkyl borates[26] or the cross-coupling reaction of alkenylboronic acids with alkyl halides.[27]

Both (*E*)- and (*Z*)-1,2-disubstituted alkenyl bromides can also be prepared by the methodology shown in eq 7.[28] The ***Boron Trifluoride Etherate***-mediated 1,4-addition of 1,2-disubstituted alkenylboronates affords γ,δ-unsaturated ketones (eq 9).[29] The boronates can also be converted into chiral enolborates for the enantioselective addition to aldehydes.[30]

(9)

Synthesis of (*E*)- and (*Z*)-1-Halo-1-alkenes and α-Bromoacetals.

Stereodefined alkenyl halides are important starting materials for the synthesis of alkenyl Grignard[31] and lithium[32] derivatives, pheromones,[33] and (*E*,*E*)-, (*E*,*Z*)-, (*Z*,*E*)- and (*Z*,*Z*)-dienes by the cross-coupling reaction.[34] An efficient, general (*E*)- and (*Z*)-1-halo-1-alkene synthesis starts with 1-alkynes and 1-halo-1-alkynes respectively, which are converted into the corresponding (*E*)- and (*Z*)-alkenylboronic acids or esters via alkenyldibromoboranes, according to eqs 4 and 5. The alkenylboronic acids and esters react with halogens directly[35-38] or via alkenylmercurials[39] to give the haloalkenes in high stereochemical purity in 70-100% yield (eq 10). In some of these halogenation reactions, alkenyldibromoboranes can be used directly.[35,36] Alternatively, (*Z*)-1-halo-1-alkenes are simply obtained by hydroboration-protonolysis of 1-halo-1-alkynes with 9-BBN or ***Disiamylborane***.[40]

(10)

Synthesis of Conjugated Dienes.

The cross-coupling reaction of alkenylboronates with alkenyl halides is a general method for the synthesis of stereodefined 1,3-dienes (eq 11).[41]

(11)

Other Applications.

DBBS is an excellent precursor for the formation of bulk powders and ceramic fiber coatings of boron nitride.[42] It has been used for the synthesis of the small carborane *closo*-2,3-$Et_2C_2B_5H_5$,[43] 3-*O*-carboranylcarbene,[44] silver and sodium isocyanoborohydrides,[45] and dications based on the hydrotris(phosphonio)borate skeleton.[46]

Related Reagents.

1,4-Dibromobutane

[110-52-1] · $C_4H_8Br_2$ · 1,4-Dibromobutane · (MW 215.92)

(useful for annulation as bis-electrophile[1] or as precursor to organobis(metallics)[2])

Alternate Name: tetramethylene dibromide.

Physical Data: bp 194-196 °C, 63-65 °C/6 mmHg; *d* 1.808 g cm^{-3}.

Solubility: sol THF, toluene, HMPA, benzene, DMF, Et_2O.

Form Supplied in: colorless liquid, 99%.

Analysis of Reagent Purity: ^1H NMR: δ 3.48 (m), 2.05 (m).

Handling, Storage, and Precautions: store in a cool dry place. Lachrymator; this reagent should be handled in a fume hood.

Uses as a Bis-Electrophile.

1,4-Dibromobutane reacts with a wide variety of nucleophiles to give displacement of one or both bromine atoms, depending upon the stoichiometry of the reaction. When 1 equiv of nucleophile is present, monoalkylation occurs. In general, subsequent functionalization of the remaining bromide is performed in the course of the synthesis. In this way the reagent is a precursor to many 1,4-difunctionalized butanes. When 2 equiv of nucleophile are used, symmetrically substituted butanes are the result. Many different nucleophiles have been utilized in these reactions. Carbon nucleophiles include alkynyl,[3] alkenyl,[4] allyl,[5] aryl,[6] benzyl,[7] and cyclopentadienyl anions.[8] In addition, a number of enolate anions have been alkylated including those derived from dissolving metal reductions of carbonyl-substituted arenes.[9] Heteroatom nucleophiles include halides,[10] alkoxides,[11] phenoxides,[12] and *N*-deprotonated amides.[13]

Electrophilic Annulation.

When two nucleophilic sites exist in the same molecule, 1,4-dibromobutane can react to form a ring. Typically these reagents are carboxylic acid derivatives having two geminal α-hydrogens. When 2 equiv of base are added, the dibromide reacts twice at the same carbon center to give a cyclopentane. If the acidic carbon is part of a pre-existing

ring, then a spirocycle is formed.[1] Esters,[14] ketones,[15] and nitriles[16] all work well for these annulation reactions, but any compound with two geminal acidic hydrogens can exhibit similar reactivity.[17] The iminonitrile (**1**) was annulated by this method in a route to cycloleucine (eq 1).[16] α,β-Unsaturated carbonyl compounds can react via their extended enolates at the α-position to give deconjugated annulated products[18] or, if the structure permits, at the α´-position.[19] If the nucleophilic moieties are vicinally related, fused-ring compounds are obtained.[20] This is the case for the isoquinoline formamidine (**2**), which is alkylated at its benzylic position with the aid of lithium chelation and then directly cleaved with ***Hydrazine*** to give a benzo[*a*]quinolizidine (eq 2).[21] Metallacyclopentenes, prepared by the reaction of 1,3-dienes with activated ***Magnesium***, react with 1,4-dibromobutane and lead to spiroannulated products.[22]

(1)

(2)

Formation and Uses of Organobis(metallics).

The electrophilic nature of 1,4-dibromobutane can be inverted by the formation of organobis(metallics). These compounds can be used with substrates bearing two electrophilic sites to form new rings. The bis-Grignard reagents have been used extensively. Reaction with esters and lactones gives cyclopentanols[23] and cyclic dicarboxylic acid anhydrides lead to spirolactones.[24] The bis-cuprate has been utilized in a novel class of spiroannulations via 1,4-addition to 3-halocycloalk-2-enones followed by elimination of the halide atom and a second 1,4-addition (eq 3).[25]

Dibromodifluoromethane

CF_2Br_2

[75-61-6] · CBr_2F_2 · Dibromodifluoromethane · (MW 209.82)

(fluorinating reagent; can function as a precursor for the introduction of CF_2Br, CF_3, and $=CF_2$ groups into organic compounds)

Physical Data: bp 22.78 °C.[1]

Solubility: sol ether, acetone, alcohol, benzene.

Form Supplied in: colorless liquid.

Preparative Methods: dibromodifluoromethane is prepared by the reaction of $CFBr_3$ with AgF (50-60%),[2] by the reaction of CBr_4 with $SbBr_2F_3$ (80%),[3] or by the reaction of $CBrF_2CO_2Ag$ with Br_2 (81%).[4] Industrially, gas-phase reactions are employed to prepare CF_2Br_2. For example, CF_2Br_2 is formed from the reaction of CF_2H_2 and Br_2 at 500 °C,[5] the reaction of CF_2BrCl and HBr at 600 °C,[6] and the reaction of $ClCF_2C(O)CF_2Cl$ and Br_2 at 580-650 °C.[7]

Handling, Storage, and Precautions: use in a fume hood.

Addition to Alkenes and Alkynes.

Radical addition of CF_2Br_2 to alkenes and alkynes is initiated by irradiation,[8] metals,[9] boranes,[10] and peroxide[11] to give the corresponding adducts (eq 1). Reaction of CF_2Br_2 with an enamine (without any initiator) followed by hydrolysis produces α-bromodifluoromethylated ketones.[12]

(1)

Reactions with Nucleophiles.

Treatment of carbanions, such as $[(EtO_2C)_2CR]^-$,[13] RC&tbond;C$^-$,[14] and $[PhCH{=}NC(Me)CO_2Me]^-$[15] with CF_2Br_2 gives the corresponding bromodifluoromethylated compounds. Reaction of CF_2Br_2 with phosphines or phosphites affords high yields of bromodifluoromethylphosphonium salts and bromodifluoromethylphosphonates, respectively (eqs 2 and 3).[16] CF_2Br_2 also reacts with sulfur and oxygen nucleophiles to produce bromodifluoromethyl sulfides[17] and ethers,[18] respectively. Reaction of pyrazole with CF_2Br_2 and NaH yields *N*1-bromodifluoromethylpyrazole.[19]

$$CF_2Br_2 + Nu \longrightarrow NuCF_2Br \qquad (2)$$

$$Nu = \text{carbanion}, RO^-, RS^-, Ph_3P, R^1R^2N^-$$

$$CF_2Br_2 + (RO)_3P \longrightarrow (RO)_2P(O)CF_2Br \qquad (3)$$

Difluoromethylenation.

CF_2Br_2 is a precursor in the Wittig reaction for the introduction of the $=CF_2$ moiety into organic molecules. In the presence of CF_2Br_2 and ***Hexamethylphosphorous Triamide*** or ***Triphenylphosphine***, aldehydes and ketones can be converted to the corresponding 1,1-difluoroalkenes (eq 4).[20] Alternatively, in the presence of phosphines or metals (***Zinc*** or Cd), treatment of the phosphonium salt $[R_3PCF_2Br]^+ Br^-$ with aldehydes and ketones also gives the corresponding 1,1-difluoroalkenes.[21]

$$CF_2Br_2 + 2\,R^1{}_3P + R^2COR^3 \longrightarrow R^2R^3C{=}CF_2 \qquad (4)$$

$$R^1 = Ph, NMe_2$$

Formation and Reactions of CF_3Cu.

CF_3Cu is readily prepared from CF_2Br_2. Treatment of CF_2Br_2 and Zn or Cd in DMF forms CF_3ZnX or CF_3CdX.[22] Metathesis of the CF_3ZnX or CF_3CdX with CuX gives the CF_3Cu reagent,[23] which couples with aryl and vinyl iodides, allyl chloride,[23] and activated aryl chlorides (eq 5 and 6).[24]

$$CF_2Br_2 + M \longrightarrow CF_3MX \xrightarrow{Cu^I} 'CF_3Cu' \qquad (5)$$

$$M = Zn, Cd; X = Br, CF_3$$

$$'CF_3Cu' + RY \longrightarrow RCF_3 \qquad (6)$$

$$Y = Cl, I; R = aryl, vinyl, allyl$$

Formation and Reactions of Difluorocarbene.

CF_2Br_2 is a precursor of difluorocarbene. In the presence of Zn or ***Lithium Aluminum Hydride-Titanium(IV) Chloride***, reaction of CF_2Br_2 with alkenes gives 1,1-difluorocyclopropane derivatives (eq 7);[25] difluorocarbene has been proposed as the active intermediate in the reaction. Alternatively, difluorocarbene has been generated from $[Ph_3PCF_2Br]^+ Br^-$ and fluoride ion, which is prepared from the reaction of CF_2Br_2 and triphenylphosphine (eq 8).[26] More conveniently, difluorocarbene has also been generated from CF_2Br_2, a tertiary phosphine, and fluoride ion.[26a] Treatment of aldehydes or ketones with the CF_2Br_2/Zn reagent gives *gem*-difluoroalkanes.[27]

$$CF_2Br_2 + R_2C{=}CR_2 \xrightarrow{Zn \text{ or } TiCl_4/LiAlH_4}$$

(7)

$$Ph_3PCF_2Br^+ Br^- + R_2C{=}CR_2 \xrightarrow{MF}$$

5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione

[66131-14-4] · $C_6H_6Br_2O_4$ · 5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione · (MW 301.92)

(selective α-bromination of aldehydes[1] and α´-bromination of α,β-unsaturated ketones;[1] reductive coupling to an ethylenetetracarboxylate[3,4])

Physical Data: mp 75-76 °C.

Solubility: sol diethyl ether, carbon tetrachloride, and most other organic solvents.

Form Supplied in: white solid.

Analysis of Reagent Purity: ^{1}H NMR; elemental analysis (Br).

Preparative Methods: by bromination of Meldrum's acid (***2,2-Dimethyl-1,3-dioxane-4,6-dione***)[2] (commercially available) with ***Bromine*** in the presence of ***Potassium Hydroxide*** or ***Sodium Hydroxide*** eq 1).[3]

Purification: recrystallization from CCl_4.

Handling, Storage, and Precautions: can be stored for months at 0 °C.

Bromination of Aldehydes and Ketones.

This brominating reagent is especially useful for the synthesis of α-monobromoaldehydes[1] and the preparation of α´-brominated α,β-unsaturated ketones.[1] The bromination is usually carried out by stirring an ether solution of the reagent and the carbonyl compound (1:2 ratio) at rt. The bromination product is easily isolated by extracting the Meldrum's acid byproduct into aqueous sodium hydrogen carbonate. Heptanal is thus cleanly α-monobrominated (eq 2),[1] as are aldehydes having a methine at the α-position such as isobutanal and cyclohexanecarbaldehyde. Methyl ketones with no α´-hydrogens, such as acetophenone, are smoothly monobrominated as well.[1] However, the regioselectivity in the bromination of unsymmetrical ketones, e.g. 2-methylcyclohexanone and 4-methyl-2-pentanone, is not good, and this is not a synthetically useful process (eq 3).[1]

(2)

(3)

65:35

5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione selectively monobrominates α,β-unsaturated ketones at the α´-position without side reactions, such as addition to the double bond or allylic bromination (eq 4).[1] In the case of ketones which enolize with difficulty, it is advantageous to enhance the rate of the reaction by the addition of catalytic amounts of ***Hydrogen Bromide*** or by heating to reflux. Representative selective brominations of some α,β-unsaturated ketones are presented in eqs 4-7.[1] In contrast, the bromination of 3-methyl-2-cyclopenten-1-one with this reagent in

5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione

CCl_4 under reflux gave no selectivity, resulting in 18% 5-bromo-, 11% 4-bromo-, 2% 5,5-dibromo- and 2% 4,5-dibromo-3-methyl-2-cyclopenten-1-one.[4]

(4)

(5)

(6)

(7)

Synthesis of Ethylenetetracarboxylate.

Reductive coupling of 5,5-dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione takes place spontaneously in DMF at rt to afford diisopropylidene ethylenetetracarboxylate (eq 8).[3] It was subsequently reported that repeated attempts to prepare this diisopropylidene ethylenetetracarboxylate according to this procedure gave erratic results, and that more reliable results and improved yields could be obtained by adding 5-bromo-2,2-dimethyl-1,3-dioxane-4,6-dione to a solution of 1 equiv of 5,5-dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione in dry DMF which had been standing for 1 week in a well-illuminated place.[5] Dissolution of the 5-bromo derivative was quickly followed by the precipitation of the required ethylenetetracarboxylate in 57% yield (mp 230 °C, dec.) (eq 9).[5] This dimeric compound was used as a precursor to tricarbon monoxide via pyrolytic decomposition (eq 10).[6]

(8)

(9)

C_3O + acetone + CO_2 + CO (10)

Synthesis of Isocyanoamines.

5,5-Dibromo-2,2-dimethyl-1,3-dioxane-4,6-dione reacts with *N*,*N*-disubstituted hydrazines to produce hydrazone derivatives, which serve as starting materials for dialkylisocyanoamines upon pyrolysis (eq 11).[7]

1,3-Dibromo-5,5-dimethylhydantoin

[77-48-5] · $C_5H_6Br_2N_2O_2$ · 1,3-Dibromo-5,5-dimethylhydantoin · (MW 285.93)

(benzylic bromination of arenes; bromoperoxylation and bromofluorination of alkenes)

Alternate Names: DBH; 1,3-dibromo-5,5-dimethylimidazolidine-2,4-dione; dibromantin.

Physical Data: mp 197-199 °C (dec).

Solubility: slightly sol acetone, THF, 1,4-dioxane, H_2O (hot), CCl_4 (reflux).

Form Supplied in: white powder or crystals; widely available.

Analysis of Reagent Purity: determined by the standard iodide-thiosulfate titration method.

Preparative Methods: DBH has been prepared by reaction of Br_2 (1 mol) with 5,5-dimethylhydantoin (0.5 mol) and NaOH (1 mol) in ice-water at 0 °C.[1a] 5,5-Dimethylhydantoin is widely available commercially, and can be prepared from KOCN, $(NH_4)_2CO_3$, and acetone in water at 85 °C.[1a] After removal of water and excess reagents by distillation, the resulting solution can be used directly for the preparation of DBH. 1,3-Dibromo-5-ethyl-5-methylhydantoin has also been prepared and has the advantage of greater solubility.[1b]

Purification: in an efficient fume hood (*caution*: bromine evolution), an impure sample of DBH (40 g) is dissolved as quickly as possible in 4 L of preheated water at 90-95 °C. The solution is filtered if necessary, and the filtrate is then immediately chilled well in an ice bath to effect crystallization. After most of the aqueous portion has been decanted, the white crystals are collected by filtration through a bed of ice and washed with water. The crystals are dried in vacuo (63-70% recovery).[1a]

Handling, Storage, and Precautions: 1,3-dibromo-5,5-dimethylhydantoin should be stored refrigerated and protected from light and moisture to avoid decomposition. DBH is an irritating solid and precautions should be taken to avoid inhalation of the powder or contact with skin.

Benzylic Bromination.

1,3-Dibromo-5,5-dimethylhydantoin has been used frequently for the radical bromination of benzylic positions of arenes and heterocycles. Using 0.5 molar equiv of DBH in CCl_4 at reflux in the presence of ***Dibenzoyl Peroxide***, high yields of the benzylic bromide are obtained under mild conditions. The use of DBH has been found to be advantageous for the preparation of particularly acid-sensitive benzylic bromides, as shown in eqs 1 and 2.[2,3] The use of NBS in the former case affords a debenzoylated product, while in the latter example, elimination of AcOH and HBr leads to the aromatized product. DBH was also found to be the most satisfactory reagent for the dehydrogenation of azlactones (eq 3).[4]

(1)

(2)

(3)

Electrophilic Bromination of Alkenes.

DBH is regularly substituted for ***N-Bromosuccinimide*** in industrial applications due to its low cost and high bromine content. Electrophilic brominations of alkenes often proceed in higher yield using DBH, as shown for the bromohydration of synthesis of epoxides via bromohydrins (eq 4).[5] DBH is the preferred reagent for the preparation of bromohydroperoxide precursors to 1,2-dioxetanes from alkenes using ***Hydrogen Peroxide***.[6] DBH has also been found to be the most effective reagent for the bromofluorination of alkenes in combination with ***Hydrogen Fluoride-Pyridine*** complex or ***Silicon(IV) Fluoride*** (eq 5).[7] Alkynes can be converted to (*E*)-bromofluoroalkenes with good stereoselectivity; these are suitable substrates for palladium-catalyzed coupling (eq 6).[8] In an analogous sense to the use of ***N-Iodosuccinimide***, DBH has been employed for the coupling of glycals to alcohols affording 2-bromoglycosides which can be converted to 2-deoxyglycosides.[9]

(4)

(5)

(6)

Electrophilic Bromination of Thioethers.

The use of DBH for the deprotection of dithioacetals and dithianes has been found to be superior to many other methods. Transacetalation of dithianes to diethyl acetals is achieved by treatment with 1 equiv of DBH in ethanol at rt.[10] In addition, dithiolanes can be converted to the corresponding geminal difluoro compounds in good yield by reaction with DBH and ***Pyridinium Poly(hydrogen fluoride)*** in dichloromethane at -78 °C.[11]

1,2-Dibromoethane

[106-93-4] · $C_2H_4Br_2$ · 1,2-Dibromoethane · (MW 187.86)

(used as an entrainment reagent[1,2] and for bromination of carbanions[5,7,8])

Alternate Name: ethylene dibromide.

Physical Data: bp 131.7 °C; mp 9-10 °C

Solubility: sol most organic solvents.

Form Supplied in: commercially available as a colorless liquid in 99% purity.

Analysis of Reagent Purity: NMR, GC, bp.

Purification: distillation.

Handling, Storage, and Precautions: 1,2-dibromoethane is toxic and carcinogenic. Exposure causes irritation of the skin, mucus membranes, eyes, and upper respiratory tract. Animal tests indicate that overexposure may cause reproductive disorders. Chronic toxic effects include damage to the liver, kidneys, and lungs. Contact with vapor should be avoided. This reagent should only be handled in a fume hood using proper protective equipment.

Entrainment Reagent.

1,2-Dibromoethane is commonly used to chemically activate ***Magnesium*** metal for use in forming Grignard reagents. It reacts with magnesium to expose a clean, reactive surface capable of converting otherwise unreactive halides into Grignard reagents.[1,2] When used as an entrainment reagent, 1,2-dibromoethane is added slowly so as to allow the halide with poor reactivity adequate time to react with freshly exposed magnesium surfaces. Pearson and Cowan's conversion of hexachlorobenzene to pentachlorobenzoic acid is a good example of this application (eq 1).[2] In this instance, 1,2-dibromoethane is added in dropwise fashion over a 48 h period to a refluxing mixture of hexachlorobenzene and magnesium turnings in ether. This reagent is often used in preference to other alkyl halides for entrainment because ethylene and $MgBr_2$ are produced as byproducts rather than a second Grignard reagent.

1,2-Dibromoethane is also a useful reagent for activating ***Zinc***.[3,4] For example, upon heating with this reagent in ethanol, zinc powder reacts exothermically to produce activated zinc that will reduce triple bonds to *cis*-double bonds in a variety of compounds (eq 2).[4] The zinc powder can be further activated by addition of a solution of ***Copper(I) Bromide*** and ***Lithium Bromide***.

Reagent for Bromination of Carbanions.

This reagent can be used as a source of positive bromine for bromination of α-methyl lactone enolates.[5] Ourisson et al used this methodology effectively in the synthesis of α-methylene-γ-lactones, including (-)-frullanolide (eq 3). Because 1,2-dibromoethane is unreactive toward the lactone product, it may offer advantages over bromine. However, bromination of enolates by this reagent is not a general reaction. With many enolates, 1,2-dibromoethane acts instead as an alkylating agent.[6]

(3)

1,2-Dibromoethane also reacts with aryl-[7] and vinyllithiums[8] to produce the corresponding bromides in good yield. For example, Snieckus and Miah have used this reagent to efficiently convert lithiated *O*-pyridyl carbamates to the bromides (eq 4).

(4)

More recently, the reagent 1,2-dibromotetrafluoroethane, which often gives superior yields, has been used in a similar fashion for the bromination of anions.[9]

1,1-Dibromo-2-ethoxycyclopropane

[55249-20-2] · $C_5H_8Br_2O$ · 1,1-Dibromo-2-ethoxycyclopropane · (MW 243.93)

(cyclopropyllithium reagent; cyclopropene precursor)

Alternate Name: 2,2-dibromocyclopropyl ethyl ether.

Physical Data: bp 45-48 °C/4 mmHg.

Analysis of Reagent Purity: ^{1}H NMR (CCl_4-Me_4Si, 60 MHz) δ 1.27 (t, *J* = 7.0 Hz, 3H), 1.55-1.95 (m, 2H), 3.35-4.05 (m, 3H).

Preparative Method: [1] to a mixture of ethoxyethylene (1 equiv), *n*-Bu_3N (0.024 equiv), and $CHBr_3$ (1.5 equiv), is added aq. NaOH solution (50%, 6.25 equiv of NaOH) at rt. The reaction mixture is stirred for 48 h and poured into water and extracted with Et_2O. The organic phase is washed with water, dried over anhydrous Na_2SO_4, filtered and concentrated using a rotary evaporator at 25 °C/60 mmHg. The residue is distilled at 25 °C/0.2 mmHg and further purified by silica gel column chromatography (petroleum ether/CH_2Cl_2 = 4:1) to give pure 1,1-dibromo-2-ethoxycyclopropane (**1**) (eq 1).

Purification: distillation followed by silica gel column chromatography.

Cyclopropylidenating Reagent.

A carbenoid reagent, 1-bromo-2-ethoxycyclopropyllithium (**2**), is generated from (**1**) upon treatment with 1 mol equiv of ***n-Butyllithium*** in THF at -95 °C. The lithium reagent reacts with various electrophiles to give 1-substituted

cyclopropane derivatives. The electrophile is introduced preferentially *cis* to the ethoxyl group.

The cyclopropyllithium (**2**) reacts with 2-cyclopentenone in a 1,2-addition manner to give the corresponding alcohol, which is converted into an ethanol adduct of chalicene (eq 2).[2]

Cyclopropene Precursor.

Reduction of (**1**) with ***Zinc*** in methanol gives a mixture of *cis*- and *trans*-1-bromo-2-ethoxycyclopropane (**5**). The cyclopropane (**5**) is dehaloalkoxylated with ***Magnesium*** in THF at reflux to afford cyclopropene (**6**) (eq 3),[3] which is trapped with cyclopentadiene or bromine to give tricyclo[3.2.1.0^{2,4}]-6-octene (**7**) (eq 4) or *trans*-1,2-dibromocyclopropane (**8**) (eq 5), respectively.

(5)

Solvolytic Ring Opening.[4]

Treatment of (**1**) with ***Sodium Ethoxide***/EtOH gives 3,3-diethoxy-1-propyne (**9**) (eq 6). When ***Potassium Fluoride*** is used as a base, 1,1,3-triethoxy-2-bromopropane (**10**) is the product (eq 7).

(6)

(7)

The 1-substituted cyclopropanes (**11**) undergo solvolysis in ethanol/***Potassium Carbonate*** to give 2-substituted 3,3-diethoxy-1-propene derivatives (**12**), which upon hydrolysis afford α-substituted acroleins (**13**) (eq 8). Thus the carbenoid reagent (**2**) is a synthetic equivalent of acrolein α-anion. This method is applied to the synthesis of β-sinensal (eq 9) and juvenile hormone JH-II.[5]

(2) **(11)** **(12)**

E = H, Br, TMS, SPh
n-HexCH(OH)-

1,3-Dibromoisocyanuric Acid

[15114-43-9] · $C_3HBr_2N_3O_3$ · 1,3-Dibromoisocyanuric Acid · (MW 286.87)

(electrophilic bromination of aromatic compounds, oximes)

Alternate Name: DBI.

Solubility: sol CH_2Cl_2, H_2SO_4.

Preparative Method: dibromoisocyanuric acid has been prepared by treatment of isocyanuric acid (0.1 mol) and LiOH (0.2 mol) with Br_2 (0.4 mol) in water (1 L) at 20 °C.[1] After vigorous stirring to effect dissolution of Br_2, the mixture is cooled slowly in a refrigerator for 24 h. The product is collected by filtration, washed with ice-cold bromine water, and then dried in vacuo, first over KOH, then over P_2O_5 (88% yield).

Handling, Storage, and Precautions: dibromoisocyanuric acid should be stored refrigerated and protected from light and moisture to avoid decomposition. DBI is an irritating solid and precautions should be taken to avoid inhalation of the powder or contact with skin.

Bromination of Aromatic Compounds.

Dibromoisocyanuric acid is reputed to be the most powerful reagent known for the electrophilic bromination of aromatic compounds. Nitrobenzene, which is brominated using ***Bromine***/Fe or ***N-Bromosuccinimide***/50% H_2SO_4 only at elevated temperatures, is converted to the *m*-bromo derivative (88% yield) upon reaction with DBI in conc. H_2SO_4 in 5 min at 20 °C. Similarly, *m*-dinitrobenzene, benzoic acid,

acetophenone, and trifluoroacetophenone (eq 1)[2] are all smoothly converted to the expected monobromides by reaction with 0.5 equiv of DBI in conc. H_2SO_4 at rt.[1] Due to the mild conditions of the reaction, alkyl groups attached to the aromatic ring are not affected (eq 2).[3] Furthermore, perbrominations of a variety of aromatic compounds may be achieved under more forcing conditions (eq 3).[4]

(1)

(2)

(3)

Bromination of Oximes and Preparation of Azoxy Compounds.

Reaction of oximes with DBI and $NaHCO_3$ in aqueous dioxane affords acceptable yields of the geminal bromonitro compounds (eq 4). The higher reactivity of DBI effects in situ oxidation of the bromonitroso intermediate to the bromonitro compound, in contrast to the reagents NBS and DBH (***1,3-Dibromo-5,5-dimethylhydantoin***) which require supplemental oxidation with ***Ozone***.[5] In the presence of amines as well as cyanamide and *O,O*-diethyl amidophosphate (eq 5), oxidative coupling of *C*-nitroso compounds by DBI leads to the formation of the corresponding azoxy compounds.[6]

Dibromomethane

CH_2Br_2

[74-95-3] · CH_2Br_2 · Dibromomethane · (MW 173.83)

(converts diols to cyclic methylene acetals;[1] reagent with Zn and $TiCl_4$ converts C=O to C=CH_2;[2,3] with Zn, cyclopropanates alkenes[4])

Alternate Name: methylene bromide.

Physical Data: mp -52.7 °C;[5] bp 96.95 °C;[6] *d*204 2.4921,[7] 2.496 g cm^{-3};[8] *n*20D 1.53559,[7] 1.5419.[8]

Solubility: sol water: 11.70 g L^{-1} (15 °C); 11.93 g L^{-1} (30 °C).[9]

Form Supplied in: commercially available.

Preparative Method: patents suggest manufacture from CH_2Cl_2 and HBr[10] or NaBr.[11]

Handling, Storage, and Precautions: toxicity hazard greater than CH_2Cl_2, less than CH_2I_2 or most alkyl bromides. Absorbed through skin;[12] mutagenic in Ames test[13] but not in assay in *Drosophila* because it kills the flies (LC_{50} 120 mg m^{-3} in air);[14] not hepatotoxic in mice ($CHCl_3$ is);[15] should be handled in a fume hood with the usual protective gloves and clothing.

General Behavior toward Nucleophiles.

The reactivity of dibromomethane toward nucleophiles is generally less than that of ordinary alkyl bromides, and falls between diiodomethane and dichloromethane. For example, toward PhSNa in MeOH, rates (10^4 *k*, s^{-1}, per C-X bond) at 0 °C are EtBr, 3.79; CH_2I_2, 1.19; CH_2Br_2 0.08; CH_2Cl_2, 0.0013 (extrapolated).[16] Toward NaI in acetone, rates (10^5 *k*, s^{-1}) at 50 °C are EtBr, 1700; CH_2Br_2, 69; CH_2Cl_2 0.2.[17] Accordingly, nucleophilic substitutions that are unsatisfactory with CH_2Cl_2 may proceed at useful rates with CH_2Br_2, which is much cheaper than CH_2I_2. Monosubstitution products of CH_2Br_2 are usually more reactive toward nucleophiles than CH_2Br_2 itself, and the net result is that disubstitution generally occurs unless the substituent is sufficiently branched to provide steric hindrance. Alkoxy substituents greatly accelerate the second substitution and make it impossible to isolate any monosubstitution product.[18]

For substitutions where the reactivity of CH_2Br_2 or CH_2I_2 is insufficient, it should be possible to use methylene ditosylate or methylene chlorotosylate,[18] though the reactions of these promising new reagents have not been

extensively studied yet.

Methylene Acetals.

Dibromomethane is particularly useful for making methylene acetals because the reaction is irreversible. Thus not only the usual *cis*-fused acetals but also the less stable *trans*-fused acetals can be made from carbohydrates (eq 1).[1] The basic phase transfer conditions are mild and compatible with much other functionality.

(1)

Similar reactions have been carried out with DMSO as solvent (eq 2).[19]

(2)

Analogous reactions with an alkyltrimethylammonium phase transfer catalyst provide methylene acetals of catechols (eq 3)[20] and monothioacetals of mercaptophenols (eq 4).[21]

(3)

(4)

Reaction of phenol (PhOH) with CH_2Br_2, aqueous base, and a phase transfer catalyst ($Bu_4N^+X^-$) yields the methylene

acetal $CH_2(OPh)_2$ (90%).[22] Benzoic acid with NaOH and CH_2Br_2 in HMPA yields $CH_2(O_2CPh)_2$ (86%).[23]

Bromomethylation of Carbanions.

Enolates often provide sufficient steric hindrance to allow bromomethylation rather than disubstitution of CH_2Br_2. Recent and typical examples include a cyclobutanecarboxylic ester (eq 5)[24] and a tetralonecarboxylic ester (eq 6).[25]

(5)

(6)

Bromomethylation of a chiral lithiated heterocycle provides intermediates useful in the asymmetric synthesis of unusual amino acids (eq 7).[26] Diastereomeric excesses were 84-95%.

(7)

Cross coupling of ArMgBr with CH_2Br_2 in the presence of ***Copper(I) Bromide*** has yielded $ArCH_2Ar$ (60-90%).[27]

Methylenation of Carbonyls.

A remarkably mild and effective reagent for converting C=O to $C{=}CH_2$ is obtained by reaction of dibromomethane with Zn and $TiCl_4$ in THF (see ***Dibromomethane-Zinc-Titanium(IV) Chloride***).[2] Steric factors are minimal, and camphor was converted to the methylene derivative (92%).[2] The reagent is particularly useful because it does not enolize ketones, and for example reacted with a gibberellin-related intermediate to produce the methylene derivative (eq 8) where the normal Wittig reagent yielded mainly epimerized product.[28]

(8)

An *Organic Syntheses* procedure for the use of the CH_2Br_2-Zn-$TiCl_4$ reagent with (+)-isomenthone (eq 9) has been published.[3] It has been found best to add the $TiCl_4$ to the zinc and CH_2Br_2 in THF at -40 °C, then stir 3 days at 5 °C before use.

(9)

Other examples that illustrate the utility of this reagent include methylene-substituted nucleosides (eq 10)[29] and an intermediate for chiral synthesis derived from glucose (eq 11).[30]

(10)

(11)

A related reagent from CH_2Br_2, Zn, and ***Dichlorobis(cyclopentadienyl)zirconium*** has been reported, though at the present stage of development it does not give as high yields.[31]

An earlier alternative for the methylenation of ketones was methylenebis(magnesium bromide), $CH_2(MgBr)_2$, or the corresponding iodide.[32] However, this reagent is difficult to prepare, requiring magnesium amalgam, and offers no advantage. It does have some use in the preparation of other methylenedimetallic compounds.[33]

Cyclopropanations.

Dibromomethane can be used in place of ***Diiodomethane*** in the Simmons-Smith cyclopropanation process. (Bromomethyl)zinc bromide is presumably the active intermediate. In order to obtain satisfactory yields, a number of processes for activating the zinc metal have been tested. The best activator in addition to ***Copper(I) Chloride*** now appears to be a small amount of ***Acetyl Chloride***, and previous methods have been declared obsolete.[4] Typical results are illustrated in eqs 12 and 13.

(12)

(13)

Previously tested methods of activating the zinc included ultrasound[34] and ***Titanium(IV) Chloride***.[35] Electrolytic

activation using a zinc anode has also proved successful,[36] though it appears to offer no significant advantage over less cumbersome methods.

Bromocarbene can be generated by treatment of CH_2Br_2 with ***Sodium Hexamethyldisilazide***, and converts alkenes to bromocyclopropanes in yields ~40%.[37] Bromochlorocarbene has been generated by treatment of CH_2Br_2 with $PhCCl_3$ and 60% aqueous KOH in the presence of the phase transfer catalyst Bu_4N^+, and converts alkenes in situ to bromochlorocyclopropanes (45-75%).[38]

Related Reagents.

Bromomethyllithium; ***Chloroiodomethane***; ***Dibromomethane-Zinc-Titanium(IV) Chloride***; ***Dibromomethyllithium***; ***Diiodomethane***; ***Iodomethylzinc Iodide***.

Alternate Name: bromomethylzinc bromide.

Physical Data: CH_2Br_2: mp -52 °C; bp 96-98 °C; *d* 2.477 g cm^{-3}. Zn: mp 419.5 °C; *d* 7.140 g cm^{-3}.

Solubility: sol Et_2O, THF.

Preparative Methods: the original method for the preparation of a ***Zinc/Copper Couple*** that will react with ***Dibromomethane*** calls for the formal preparation of the Zn/Cu couple from 30-mesh granular ***Zinc*** instead of zinc dust.[2] In this procedure, 35 g of granular zinc (30 mesh) is added to a hot solution of 50 mL of acetic acid containing 0.5 g of $CuOAc.H_2O$ (see ***Copper(I) Acetate***). The mixture is kept hot and shaken for 1-3 min. The acetic acid is carefully decanted from the couple. The couple is then washed with 50 mL of acetic acid and three 50 mL portions of Et_2O. The couple is shaken for 1 min with each washing. The Et_2O moistened couple is ready for use or can be dried with a stream of nitrogen. More recently a number of different methods for activation of the Zn/Cu couple have appeared. These newer modifications include the use of ultrasound[3] or catalytic amounts of ***Titanium(IV) Chloride***[4] or ***Acetyl Chloride***.[5] They require no prior preparation of the couple. The couple is prepared in situ by reaction of zinc dust and ***Copper(I) Chloride***.[6] The method of choice appears to be the acetyl chloride method.

Handling, Storage, and Precautions: CH_2Br_2 is toxic. Zn is a moisture-sensitive, flammable solid. When the reactions are complete, the reaction mixture is filtered from the zinc residue. It is recommended that the residue be wetted with water prior to disposal.

Cyclopropanations.

The use of CH_2Br_2 in place of the more commonly employed ***Diiodomethane*** in the cyclopropanation of an alkene[1] has the advantages that it is less expensive and more stable. It has not been used as extensively because of the lower reactivity of the dibromide with the various forms of the Zn/Cu couple. The first reported form of a Zn/Cu couple that would react effectively with the dibromide was made from granular zinc.[2] It suffered from long reaction times and lower yields in

comparison with the diiodomethane derived reagent. It was found that sonication could be used to effect cyclopropanations of alkenes with dibromomethane[3] and an in situ generated Zn/Cu couple prepared from Zn dust and CuCl.[6] The ultrasound method, however, suffered from irreproducibility. A more convenient method for activation involves the use of a catalytic amount (2 mol %) of $TiCl_4$. The use of more than 2% $TiCl_4$ results in unmanageable reactions. Activation of the couple with $TiCl_4$ is also effective when using diiodomethane. In either the dibromo- or diiodomethane reactions there is a competing formation of ethylene. This problem is greater for dibromomethane than for diiodomethane. The only drawback in the titanium mediated procedure is that it is not always tolerant of Lewis acid sensitive groups.[4] Acetyl chloride has been found to activate the Zn/Cu couple as well as $TiCl_4$ and has the advantage that Lewis acid sensitive groups are tolerated. This now appears to be the method of choice.[5] Table 1 shows the results[3-11] of some representative alkenes under some of the different cyclopropanation conditions. When the difference in yield between the diiodo and dibromo conditions are minimal and the alkene is not the limiting reagent, the dibromomethane conditions offer an inexpensive alternative. The somewhat lower yields obtained are offset by the cost savings.

Table 1 Comparison of Cyclopropanation Conditions for Various Alkenes

	Yield (%)					
	CH_2I_2 Zn/Cu	CH_2I_2 Zn/Cu $TiCl_4$[4]	CH_2Br_2 Zn/Cu	CH_2Br_2 Zn/Cu ultrasound[3]	CH_2Br_2 Zn/Cu $TiCl_4$[4]	CH_2Br_2 Zn/Cu AcCl[5]

	65[9]	-	-	-	-	60
	8[10]	-	-	-	-	22

The regioselectivity of the reagent in its reactions with limonene (eq 1) and 4-vinylcyclohexene (eq 2) has been studied. Using a ratio of diene:CH_2Br_2:Zn of 1:1:1.5, the major product of the reaction was recovered diene (47%). The monocyclopropanated products were isolated in ~28% yield with a 2.5:1.0 ratio of exocyclic cyclopropane:ring cyclopropane. There was little stereoselectivity observed in ring cyclopropanated products, with a 1:1.1 ratio of *cis* and *trans* isomers being produced. A small (4%) amount of biscyclopropanation was obtained under these conditions. If the diene:CH_2Br_2:Zn ratio was changed to 1:2:3, the amount of recovered diene decreases but the amount of biscyclopropane increased. For 4-vinylcyclohexene with the 1:1:1.5 ratio, the ring cyclopropane was favored over the exocyclic cyclopropane by 1.75:1. The combined yield of these two products is again low (~7%). The major product was recovered diene (53%).[12]

(1)

(2)

Miscellaneous.

Reaction of ***Triethylsilane*** with dibromomethane and Zn/Cu couple results in an insertion of methylene into the Si-H bond. The reaction with triethylsilane (eq 3) produces triethylmethylsilane. The reaction with diiodomethane produces the insertion product in 64% yield.[13]

(3)

The ^{1}H and ^{13}C NMR data for bromomethylzinc bromide and bis(bromomethyl)zinc have been reported.[14]

Dibromomethane-Zinc-Titanium(IV) Chloride[1]

CH_2Br_2-Zn-$TiCl_4$

(CH_2Br_2)

[74-95-3] · CH_2Br_2 · Dibromomethane-Zinc-Titanium(IV) Chloride · (MW 173.83) (Zn)

[7440-66-6] · Zn · Dibromomethane-Zinc-Titanium(IV) Chloride · (MW 65.39) ($TiCl_4$)

[7550-45-0] · Cl_4Ti · Dibromomethane-Zinc-Titanium(IV) Chloride · (MW 189.69)

(reagent for the methylenation of ketones[1-5] and aldehydes;[1] it methylenates highly enolizable[1,4,6] and sterically hindered ketones;[1] it selectively methylenates ketones and aldehydes in the presence of esters, while some variations allow the chemoselective methylenation of aldehydes and ketones;[7] in combination with TMEDA it methylenates esters and lactones;[1] similar reagents made from other 1,1-dibromoalkanes allow the alkylidenation of esters,[8] lactones,[8] silyl enol esters,[9] thioesters,[10] and amides[10])

Alternate Name: Lombardo's reagent.

Solubility: partially sol solvents usually used for the reaction (THF and CH_2Cl_2).

Form Supplied in: not available commercially.

Preparative Methods: Oshima method:[2,3] a suspension of ***Zinc*** dust (4.5 equiv) and ***Dibromomethane*** (1.5 equiv) in dry THF, stirred under N_2 at rt, is treated with a 1.0 M solution of ***Titanium(IV) Chloride*** (1.1 equiv) in CH_2Cl_2. After 15 min the resulting dark brown mixture is treated dropwise with a solution of the ketone (1 equiv) in dry THF, and the mixture is stirred at rt for 4-40 h. *Lombardo's reagent*:[4,5] to a suspension of Zn dust (4.3 equiv) and CH_2Br_2 (1.4 equiv) in dry THF, stirred under N_2 at -40 °C, is added dropwise neat $TiCl_4$. The mixture is then allowed to warm to 5 °C and is stirred for 1-3 days to produce a thick gray slurry of the active reagent. The cold slurry is added to a solution of the ketone in CH_2Cl_2 or THF. Usually, the reaction is complete within a few minutes.

Handling, Storage, and Precautions: moisture sensitive; decomposes at rt. Lombardo's reagent may be stored at -20 °C up to a year with only 5-10% loss of reactivity.

Methods for Carbonyl Methylenation.

The methylenation of aldehydes and ketones is often performed with the Wittig reagent, CH_2=PPh_3 (see ***Bis(cyclopentadienyl)dimethyltitanium***), or by the addition of other P-, Si-, or S-stabilized methylene anions.[11] As a result of the inherent basicity of these reagents, however, several limitations exist for their synthetic utility. Among the major drawbacks of the Wittig-type alkenation methods is their inability to alkenate readily enolizable carbonyls or substrates that undergo facile nucleophilic addition or elimination reactions. Furthermore, sterically hindered substrates are often methylenated only in low yields, while the alkenation of esters and lactones is usually not possible with these methods. Several alternative methylenation procedures have been developed that avoid most of the problems encountered with Wittig-type processes. Among these, the Tebbe reagent (see ***μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium***)[1,12] has been used for the methylenation of a variety of carbonyls, including aldehydes, enolizable ketones, esters, and lactones. This reagent, however, is not suitable for highly acid-labile substrates and requires strenuous inert-atmosphere techniques due to its high sensitivity to air and water. An experimentally convenient alternative to the Tebbe reagent is dimethyltitanocene (see ***Bis(cyclopentadienyl)dimethyltitanium***)[13] which is easier to prepare and handle and is suitable for the methylenation of both ketone and ester carbonyls, including highly enolizable and acid-labile substrates. Another widely used carbonyl methylenation procedure is the combination of CH_2Br_2-Zn-$TiCl_4$, which was first reported by Oshima,[2,3] and later modified by Lombardo[4,5] and Takai.[6,7]

According to the initial procedure,[2,3] a suspension of ***Zinc*** dust and ***Dibromomethane*** in THF are reacted with a solution of ***Titanium(IV) Chloride*** in CH_2Cl_2; after stirring for 15 min the dark brown mixture is combined with the carbonyl substrate in CH_2Cl_2 or THF. In this manner the completion of the methylenation reaction often requires prolonged stirring at rt. This in situ procedure is most effective for the methylenation of ketones and is less effective with aryl ketones and aldehydes, which undergo a competing pinacol-type reductive coupling.

Lombardo[4,5] found that prior low temperature aging of the CH_2Br_2-Zn-$TiCl_4$ system, which presumably alters the composition of the reagent, significantly speeds up the methylenation process and limits the exposure of the carbonyl substrate to Zn and $TiCl_4$. This methodology leads to increased methylenation yields and suppressed side reactions. The use of CD_2Br_2 or $^{13}CH_2Br_2$ in these reactions allows the incorporation of D or ^{13}C into the substrate.

Takai[6] has reported that a more reactive system consisting of ***Diiodomethane-Zinc-Titanium(IV) Chloride*** is very effective for the methylenation of highly enolizable ketones. Two other variations, CH_2I_2-Zn-Ti(O-*i*-Pr)$_4$ and CH_2I_2-Zn-Me_3Al, allow the chemoselective methylenation of aldehydes in the presence of ketones.[7]

Methylenation of Ketones.

The Oshima procedure effectively methylenates a variety of ketones which, under the usual Wittig conditions, are unreactive or give much lower yields. The presence of carboxylic ester groups, which often interfere with the Wittig methylenation of ketones, do not present such problems with this methylenation process. A similar advantage can exist over the use of the Tebbe reagent which also alkenates the ester functionality.[14] Due to the nonbasic conditions, this method is suitable for substrates that undergo facile enolization, such as β,γ-unsaturated ketones (eq 1)[15] and cyclopentanones (eq 2).[14]

(1)

(2)

Lombardo's reagent is often the best choice for the methylenation of base-sensitive ketones. This system has been employed extensively in the synthesis of gibberellins[4,16,17] and related compounds. Although this type of bridged ketone is susceptible to enolization and epimerization, the desired alkenes are obtained in high yield without any loss of stereochemistry (eqs 3 and 4).[4,17] Free hydroxy and carboxylic acid groups are also tolerated by this reagent.

(3)

(4)

R^1	R^2	
Me	H	93%
H	H	80%
Me	OH	38%

This methylenation method proceeds without enolization of the carbonyl group, even in cases where this is a very facile process. For example, while Wittig-type methodologies often fail completely with β,γ-unsaturated ketones, the use of Lombardo's reagent gives excellent yields of the corresponding alkenes (eqs 5 and 6).[18,19]

(5)

(6)

This reagent has been used widely in prostaglandin synthesis. A variety of cyclopentanones bearing the usual protective groups were successfully methylenated without epimerization or elimination of the β-silyloxy (eq 7)[20] or even β-acyloxy functionalities (eq 8).[21]

(7)

(8)

β-Acyloxy ketones are methylenated more efficiently with CH_2I_2-Zn-$TiCl_4$ (eq 9).[6]

(9)

These reagents are also suitable for the methylenation of sterically hindered ketones (eq 10)[22] and enones (eq 11),[23] reactions that often fail with Wittig-type methods.

(10)

(11)

In some cases the methylenation products undergo subsequent cyclopropanation (eq 12),[24] a reaction that can be more efficient in the presence of copper.[25]

(12)

The CH_2I_2-Zn-$TiCl_4$ system is effective for the methylenation of nonracemic α-amino ketone derivatives (eq 13).[26]

(13)

Substituents containing other heteroatoms, such as tin (eq 14),[27] sulfur (eq 15),[28,29] or selenium (eq 16),[29] are well tolerated in this process.

(14)

(15)

(16)

Methylenation of Aldehydes.

Aldehydes are not as good substrates as ketones for the methylenation with the CH_2Br_2-Zn-$TiCl_4$ system due to complications arising from reductive coupling of the carbonyl. In some cases, however, an aldehyde moiety can be methylenated even in the presence of the phosphonoacetate group (eq 17).[30]

(17)

The chemoselective methylenation of aldehydes in the presence of ketones (eq 18) can be done with CH_2I_2-Zn-Ti(O-*i*-Pr)$_4$ or CH_2I_2-Zn-Me_3Al.[7] The reverse selectivity, i.e. the methylenation of a ketone in the presence of an aldehyde, can be accomplished by the in situ protection of the aldehyde with ***Titanium Tetrakis(diethylamide)***, followed by reaction with CH_2I_2-Zn-$TiCl_4$ and deprotection (eq 19).[7]

(18)

CH_2I_2-Zn-Ti(O-*i*-Pr)$_4$, 25 °C, 4 h 83%
CH_2I_2-Zn-$AlMe_3$, 25 °C, 3 h 96%

(19)

Methylenation of Esters.

The CH_2Br_2-Zn-$TiCl_4$ reagent is selective for ketones and aldehydes, and it alkenates these carbonyls in the presence of esters. Although the reagent of choice for the methylenation of esters and lactones is often the Tebbe reagent[1,12] or dimethyltitanocene,[13] it is possible to alkenate esters with the CH_2Br_2-Zn-$TiCl_4$ system if TMEDA is mixed with $TiCl_4$ prior to its exposure to Zn and CH_2Br_2.[8] These conditions were used to convert allyl esters to allyl enol ethers (eq 20)[31] and to alkenate carbohydrate ester intermediates (eq 21).[32]

(20)

A lactone methylenation was similarly accomplished by using an excess of all of the ingredients (eq 22).[33]

Alkylidenation of Carbonyl Compounds.

This methodology was extended to the alkylidenations of carbonyls by the use of 1,1-dihaloalkanes in the presence of TMEDA.[8] In this manner, esters and lactones are converted to the corresponding enol ethers in good yields and with (*Z*) selectivities (eq 23).[8] This type of reaction was utilized in a synthesis of spiroacetals (eq 24).[34]

(23)

(24)

Silyl esters afford silyl enol ethers when they are subjected to these conditions with the geometry of the products being predominantly (*Z*) (eq 25).[9]

(25)

Alkylidenation of thioesters (eq 26) and amides (eq 27), to produce alkenyl sulfides and enamines respectively, is also possible with this methodology.[10]

[Dibromo(methoxycarbonyl)methyl]phenylmercury[1]

[22060-04-4] · $C_9H_8Br_2HgO_2$ · [Dibromo(methoxycarbonyl)methyl]phenylmercury · (MW 508.56)

(by thermolysis, transfers **:**$CBrCO_2Me$ to alkenes, giving cyclopropanes,[2] and to silanes, inserting into Si-H bond[2,3])

Physical Data: mp 154-156 °C (dec).

Solubility: sol THF, $CHCl_3$, chlorobenzene, benzene.

Analysis of Reagent Purity: spectroscopic data: IR,[3] ^{1}H NMR.[3]

Preparative Method: reaction of $HCBr_2CO_2Me$ with ***Phenylmercury(II) Chloride*** and ***Potassium t-Butoxide*** in THF at -60 °C,[2,3] according to the general method to prepare phenyl(trihalomethyl)mercurials.[4] The yield, though typically in the range of 55%, can be as high as 68%.

Purification: recrystallization from chloroform/hexane (1:1).

Handling, Storage, and Precautions: flame-dried glassware and an atmosphere of dry nitrogen are used for the reactions. Organomercury compounds should be carefully handled, and skin contact and inhalation should be particularly avoided. All reactions must be conducted in a well-ventilated fume hood.

Cyclopropanation of Alkenes.

The observed high thermal stability of $PhHgCBr_2CO_2Me$ (**1**) restricts its application in synthesis. An additional drawback is related to the long reaction times and high reaction temperatures required, which results in significant side reactions, as is clear from the disparity between the amounts of phenylmercury(II) bromide recovered and the cyclopropane formed. Nevertheless, the cyclopropanation of several alkenes has been reported.[3] For instance, reaction of cyclooctene with (**1**) in chlorobenzene gives rise to the cyclopropane derivative (eq 1), with greater yields of cyclopropane ring formation as the reaction temperature is raised (50% at reflux, 19% at 130 °C).

Allyltrimethylsilane is also an efficient partner for (**1**) in the cyclopropanation process (eq 2).[3] The cyclopropane product is formed as a mixture of stereoisomers in a 1.5:1 ratio. The major isomer has been tentatively assigned to that having a *syn* disposition for the Me_3SiCH_2 and Br groups on the basis of the larger steric bulk of the CO_2Me group.

Trisubstituted alkenes gave very modest yields. Thus 2-methyl-2-butene affords 9% of cyclopropane formation, while phenylmercury(II) bromide is recovered in 92% after 24 h at 130 °C in chlorobenzene.[3]

Insertion into Si-H Bond.

This is another representative reaction for α-haloorganomercurials that is also observed for (**1**) (eq 3).[3]

In spite of the limitations found, $PhHgCBr_2CO_2Me$ is an interesting reagent to transfer the functional divalent $CBrCO_2Me$ group to several alkenes.

Dibromomethyllithium

$LiCHBr_2$

[37555-63-8] · $CHBr_2Li$ · Dibromomethyllithium · (MW 179.77)

(reagent used for bromocyclopropanation, nucleophilic dibromomethylation, ring expansion, bromomethylenation, chain elongation)

Physical Data: low temperature ^{13}C and ^{6}Li NMR data are available,[1] as are matrix IR data.[2]

Preparative Methods: solutions of the title compound can be obtained by treatment of ***Dibromomethane*** with slightly less than 1 equiv of ***Lithium Diisopropylamide*** in THF/ether (1:3) at -100 °C for 15 min.[3] Amine-free solutions may be obtained by deprotonation of CH_2Br_2 with ***Dichloromethyllithium*** in THF at -100 °C.[4]

Handling, Storage, and Precautions: the reagent is generally stable from -110 to about -80 °C depending on the solvent. There is evidence that carbenoids of this nature show greater thermal stability in THF than in ether.[5] Further, transmetalation with ***Titanium Tetraisopropoxide*** is reputed to give a reagent with greater thermal stability,[5e] although subsequent reports confirming this have not appeared.

General Considerations.

Alkyllithiums bearing halogens on the α-carbon are frequently referred to as carbenoids, reflecting a major mode of reactivity. Good general reviews of such species are available.[6] At very low temperatures, however, the reagent reacts like a typical alkyllithium.

Cyclopropanations.

When α-haloorganolithium reagents are treated with alkenes, a rapid low temperature reaction takes place resulting from α-elimination of LiX to a carbene followed by cyclopropanation of the alkene (see also ***2,2,2-Tribromoethyl Chloroformate***, ***Trichloromethyllithium***, and ***Dichloromethyllithium***). This mode of reactivity has been reported for both $LiCHBr_2$ and $NaCHBr_2$ (eq 1).[7] Yields were reported only for the organosodium reagent and were generally moderate. Details of this process were sketchy.

(1)

An apparently noncarbenic bromocyclopropanation of fulvenes has been described by Grohmann.[8] When LDA was slowly added to a THF solution of a fulvene and CH_2Br_2 at -75 °C followed by slow warming to 0 °C, a mixture of *cis*- and *trans*-halospiro[2.4]heptadienes were formed (eq 2). Evidence indicates a nucleophilic addition-displacement mechanism as opposed to a carbene reaction. A related reaction involving ring enlargement of silacycles has also been reported.[9]

(2)

Nucleophilic Additions to Carbonyls and Subsequent Processes.

As with ***Tribromomethyllithium***, ***Trichloromethyllithium***, and ***Dichloromethyllithium***, $LiCHBr_2$ can be generated in the presence of aldehydes and ketones when a solution of CH_2Br_2 and the carbonyl compound in THF is treated with 2 equiv of lithium dicyclohexylamide at -78 °C (eq 3). Addition of $LiCHBr_2$ to the carbonyls forms dibromocarbinols in excellent yield.[10] Alternatively, $LiCHBr_2$ may be generated by the LDA method followed by addition of the aldehyde or ketone.[3a] Such intermediates are quite versatile, undergoing a variety of synthetically useful transformations.

(3)

Preparation of Terminal Bromoalkenes.

Treatment of such dibromo alcohols with excess Zn dust and 2-6 equiv of HOAc (see ***Zinc-Acetic Acid***) in CH_2Cl_2 at reflux provides the bromoalkene as a mixture of (*E*) and (*Z*) isomers.[11] Overall yields for the two-step process are generally >40% (eq 4). Kobrich had previously reported similar alkene forming processes whereby elimination proceeds via the trimethylsilyl ether derivatives of the alcohol adducts (Scheme 1).[12] Treatment with LDA at -100 °C promoted loss of TMS-OH and formation of terminal dibromoalkenes in good yield, while treatment with ***n-Butyllithium*** at the same temperature promoted Li-halogen exchange and elimination of TMSO-Li to give a mixture of monobromoalkenes.

Scheme 1

Preparation of α,α-Dibromo Ketones.

The dibromo alcohols have been oxidized with the Swern reagent (***Dimethyl Sulfoxide-Oxalyl Chloride***), ***Pyridinium Dichromate***, or ***Pyridinium Chlorochromate*** to the corresponding ketones in 44-60% yield (eq 5).[13] A higher yield process is the direct addition of $LiCHBr_2$ to esters, proceeding in 68-78% yield.[14]

(5)

Ring Expansions of Derived β-Oxidocarbenoids.

A facile ring expansion (Scheme 2) has been developed by Nozaki[15] based on a well-known carbene rearrangement. Dibromo alcohols such as (**1**) can be treated with 2 equiv of *n*-BuLi in THF at low temperature to generate the alkoxycarbenoid (**2**). This can undergo α-elimination to the carbene (**3**) which undergoes ring-expanding rearrangement to enolate (**4**), eventually resulting in the ring-expanded ketone (**5**). Yields are good to excellent. There is some regioselectivity in the rearrangement step (eq 6).[16] For example, the dibromo alcohol (**6**) provides the ketone (**7**) as the major product, resulting from migration of the more substituted center. This appears to be general, although there are clear temperature and solvent effects on the degree of regioselectivity.

Scheme 2

(6)

(6) (7) 95:5

In addition, cyclic conjugated enones undergo expansion by migration of the unsaturated group to give β,γ-unsaturated cyclic ketones. However, there is a lack of regiospecificity with conjugated cyclopropyl ketones as substrates.[17] An analogous ring expansion occurs if intermediate lithioalkoxides such as (**8**) are deprotonated with an amide base like ***Lithium 2,2,6,6-Tetramethylpiperidide*** (eq 7).[18] In these cases the result is a ring expanded α-bromo ketone.

(7)

(8)

Ester Homologation.

Related to this rearrangement is an ester homologation process developed by Kowalski which proceeds without isolation of intermediates.[19] In this procedure, $LiCHBr_2$ is generated using LiTMP and is added to an ester at low temperature. A second addition of excess base promotes the collapse to the enolate (**10**) which undergoes Li-halogen exchange to the carbenoid (**11**). Fritsch-Buttenberg-Wiechell rearrangement of the derived (**12**) gives the ynolate (**13**) which is quenched into acidic ethanol, eventually giving the homologated ester (Scheme 3). Lactones also undergo the process. The intermediate ynolate (**13**) may be captured by silyl halides, resulting in one of the few methods of preparing ynol silyl ethers (**14**) (Scheme 4). Such species have been utilized in a stereoselective alkenation alternative to the Wadsworth-Emmons process (**14**) -> (**15**).[20]

Chain Homologation of Boronic Esters.

$LiCHBr_2$ is capable of chain elongating boronic esters to give α-bromoboronic esters, useful intermediates in synthesis. Treatment of a boronic ester, generally of the cyclic variety, with $LiCHBr_2$ at low temperature and allowing it to stand at rt for a period of hours results in the familiar B -> C migration of an alkyl group in the ate complex (**17**) with expulsion of bromine to form a boronic ester (**18**) elongated by a bromomethylene group (Scheme 5). Boronic esters (**18**) are quite stable intermediates which undergo facile displacement of the halide by nucleophiles with inversion of

configuration, providing more highly functionalized boronic esters.[22]

Scheme 5

Use of optically active boronic esters provides the opportunity for asymmetric induction at the newly formed chiral carbon. Ate complexes of pinanediols undergo nearly enantiospecific ***Zinc Chloride***-catalyzed migration of alkyl groups, resulting in production of a new versatile chiral carbon.[23] It was found that $LiCHBr_2$ gives better yields and diasteromeric ratios than $LiCHCl_2$ in the migration step.[24] Also, Br was found to be more readily displaced by $LiOCH_2Ph$, enabling more efficient syntheses of small carbohydrates by an iterative approach. This is illustrated in the first few steps of a synthesis of (+)-ribose, (**19**) -> (**21**), which proceed in excellent yield and stereoselectivity (Scheme 6).

(Dibromomethyl)trimethylsilane

$Me_3SiCHBr_2$

[2612-42-2] · $C_4H_{10}Br_2Si$ · (Dibromomethyl)trimethylsilane · (MW 246.03)

(reagent for the preparation of vinylsilanes)

Alternate Name: trimethyl(dibromomethyl)silane.

Physical Data: bp 49.5-51.5 °C/12 mmHg; *d* 1.519 g cm^{-3}.[1b]

Solubility: sol most organic solvents.

Preparative Method: to a dry, 1.0 L three-neck flask, equipped with a mechanical stirrer, a pentane thermometer, a nitrogen inlet tube, and a pressure-equalizing addition funnel, was added 62.0 g (0.245 mol) of ***Bromoform*** and 300 mL of dry THF. The reaction was cooled to -90 °C and 0.25 mol of isopropylmagnesium chloride in 200 mL of THF was added during 30 min at such a rate that the temperature was kept at -80 °C or below. The reaction was stirred at -90 °C for 15 min and then 0.25 mol of ***Chlorotrimethylsilane*** in 100 mL of THF was added at such a rate that the temperature did not exceed -80 °C. After 1 h, the reaction was allowed to warm to rt. The reaction mixture was hydrolyzed with saturated NH_4Cl solution until large lumps of salt cake formed. The organic layer was poured off, dried over anhydrous Na_2SO_4, and distilled at atmospheric pressure to remove most of the THF. A trap-to-trap distillation of the residue at 0.1 mmHg was followed by distillation through an 11 in. Vigreux column. The fraction boiling at 49.5-51.5 °C/12 mmHg was collected, affording 47.9 g (79%) of (dibromomethyl)trimethylsilane.[1a]

Lithium-Halogen Exchange.

Reaction of (dibromomethyl)trimethylsilane with ***n-Butyllithium*** at -110 °C results in the formation of trimethylsilylbromomethyllithium. The silane and the *n*-BuLi are added simultaneously in order to suppress side reactions. Treatment of the intermediate lithium reagent with ***Chlorotrimethylsilane*** (eq 1) or mercury(II) bromide (eq 2) affords bis(trimethylsilyl)bromomethane or bis(trimethylsilylbromomethyl)mercury, respectively. If the lithium reagent is allowed to warm in the presence of cyclohexene, the only reaction observed is an alkylation with the *n*-butyl bromide formed in the exchange reaction. The alkylated product is formed in 89% yield.[1a]

$$TMSCHBr_2 \xrightarrow[\text{2. TMSCl}]{\text{1. BuLi, -110 °C}} (TMS)_2CHBr \qquad (1)$$

52%

$$TMSCHBr_2 \xrightarrow[\text{2. } HgBr_2]{\text{1. BuLi, -110 °C}} (TMSCHBr)_2Hg \qquad (2)$$

44%

In an alternative procedure, the lithium reagent was obtained by reaction with ***Lithium*** metal. Subsequent reaction with a trialkylborane (eq 3) followed by oxidation provided access to α-hydroxysilanes. The yields are good for simple trialkylboranes but are diminished as the alkyl groups become more hindered.[2]

$$TMSCHBr_2 \xrightarrow[\text{3. } H_2O_2,\ OH^-]{\text{1. 2 equiv Li, THF; 2. } (C_5H_{11})_3B} TMSCH(OH)C_5H_{11} \qquad (3)$$

79%

Deprotonation.

(Dibromomethyl)trimethylsilane can be deprotonated with ***Lithium Diisopropylamide*** at -78 °C. Reaction of the intermediate anion with *n*-butyl iodide (eq 4) furnished the alkylated product in 93% yield.[3,4] If the anion was allowed to warm to 20 °C in the absence of an electrophile, the bis(trimethylsilyl)ethylene (eq 5) was produced.[4]

$$TMSCHBr_2 \xrightarrow[\text{2. BuI}]{\text{1. LDA, -78 °C}} TMSCBr_2Bu \qquad (4)$$

93%

$$TMSCHBr_2 \xrightarrow[\text{2. 20 °C}]{\text{1. LDA, -78 °C}} TMSBrC{=}CBrTMS \qquad (5)$$

50%

Vinylsilanes.

Two reports have appeared on the formation of the 1,1-di-Grignard reagent using ***Magnesium Amalgam***. In the first

report, the di-Grignard, prepared indirectly from the dizinc reagent, was combined with cyclohexanone to produce the vinylsilane in 40% yield.[5] In the second, satisfactory results were obtained only with the non-enolizable benzophenone (eq 6). Cyclohexanone afforded only 13% of the vinylsilane. In addition, the di-Grignard was treated with ***Chlorotrimethylstannane*** to furnish bis(trimethylstannyl)trimethylsilylmethane in 94% yield.[6]

(6)

The *gem*-dichromium reagent was prepared by reduction of the dibromide with ***Chromium(II) Chloride***. This reagent will stereoselectively produce (*E*)-alkenylsilanes in excellent yield. The reagent can chemoselectively react with an aldehyde (eq 7) in the presence of a ketone.[7]

(7)

Esters (eq 8) and thioesters (eq 9) can be silylmethylenated by the action of the dibromide with low-valent titanium prepared from ***Titanium(IV) Chloride*** and ***Zinc***. The reaction produces β-hetero-substituted vinylsilanes and was (*Z*) selective.[8]

(8)

(9)

Miscellaneous.

The kinetics of the cleavage of the dibromomethyl group by ammonia buffer have been reported.[9]

2,4-Dibromo-3-pentanone[1]

[815-60-1] · $C_5H_8Br_2O$ · 2,4-Dibromo-3-pentanone · (MW 243.93)

(a good source of the dimethyloxyallyl cation; especially useful for [4 + 3] and [3 + 2] cycloadditions[1])

Physical Data: bp 194-5 °C/732 mmHg; *d* 1.771 g cm^{-3} (18 °C).

Solubility: quantitative data unavailable. Sol moderately polar to polar organic solvents.

Form Supplied in: not generally commercially available and should be prepared as needed.[2,3]

Analysis of Reagent Purity: obtained as a mixture of (+)-, (-)-, and *meso* isomers which can be assayed by NMR.

Handling, Storage, and Precautions: is a powerful lachrymator and a skin irritant. If contact with the skin occurs the affected area should be thoroughly washed with soap followed by a solution of sodium bicarbonate.[2]

[4 + 3] Cycloadditions.

The chemistry of 2,4-dibromo-3-pentanone (**1**) is dominated by its ability to form oxyallylic cations (**2**) and (**3**) under a variety of conditions (eq 1). Though other reaction pathways are possible, these intermediates, particularly (**2**), have been used in most cases as dienophiles in a [4 + 3] cycloaddition with dienes.[1] 2,4-Dibromo-3-pentanone serves as a prototype for other polyhalogenated ketones which exhibit similar chemistry (see ***1,1,3,3-Tetrabromoacetone***).

(1)

The reactivity of (**2**) is determined to a considerable extent by the reaction conditions under which it is generated. Of particular importance is the nature of the reagent used in the reductive debromination of (**1**). Reagents which have found

application in this process include ***Diethylzinc***,[4] ***Zinc/Copper Couple***,[5] ***Sodium Iodide-Copper***,[2,5b] ***Nonacarbonyldiiron***,[1c,3] ***Cerium(III) Chloride-Tin(II) Chloride***,[6] and ***Zinc/Silver Couple***.[7] These reagents preclude the formation of (**2**) as such and require inclusion of a counterion(s) which, in combination with solvent and other effects, modifies the reactivity of (**2**) with respect to scope, yield, and stereoselectivity in its [4 + 3] cycloaddition reaction with various dienes.

For the reaction of (**2**) with furan, expected products include isomers of 2,4-dimethyl-8-oxabicyclo[3.2.1]oct-6-en-3-one (**4**) (eq 2). Table 1 summarizes the results obtained with several different reagents. Yields are generally high and stereoselectivity good in most cases. The need for excess furan in many of these processes limits the generality of the reaction. The high stereoselection in the Zn/Ag reaction is noteworthy.[7] All of the methods are convenient, though concerns about the toxicity and expense of nonacarbonyldiiron make its use less attractive.

Table 1 Reaction of (2) with Furan (eq 2)

Reagent	Furan	Product ratio of (4) a,a:b,b:a,b	Yield (%)
Et_2Zn	Solvent	9:1:0	53[4]
$Fe_2(CO)_9$	Solvent	1:1.3:0	90[3b]
NaI, Cu	4 equiv	30:1:2	80[2,5b]
$CeCl_3$, $SnCl_2$	10 equiv	6.2:2.8:1	90[6]
Zn/Ag	10 equiv	1:0:0	80[7]
Zn/Cu	10 equiv	9:1:1	85[2a]

A variety of other furans have successfully undergone [4 + 3] cycloaddition with (**2**). However, it appears that an

exhaustive study of substituent effects on the cycloaddition process has not been made. The reaction of pinofuran (**5**) with (**2**) gave (**6**) as a mixture of isomers, resulting from a sterically controlled approach of the oxyallyl *anti* to the *gem*-dimethyl group of (**5**), but through both extended and compact transition states (eq 3).[8]

The cycloadducts derived from (**2**) and various furans have found considerable application in synthesis. They have been used in the synthesis of the Prelog-Djerassi lactone,[9] nonactic acid,[10] and fragments of rifamycin S[11] and ionomycin[12] and hold considerable promise as templates for the stereoselective synthesis of polyfunctional acyclic systems.[13]

Other dienes have been used to trap (**2**). Cyclopentadienes,[3b,5c] fulvenes,[5c,14] anthracenes,[15] and acyclic butadienes[3b] have been successfully employed, especially with (**2**) generated using the reaction of (**1**) with $Fe_2(CO)_9$ (eq 4). Iron tricarbonyl complexes of the dienes may also be used to both generate (**2**) and subsequently trap it. Cycloadducts from the reaction of (**2**) with acyclic butadienes have been converted in a general fashion to tropones and tropolones.[16]

Pyrroles can also be effective traps for (**2**), leading to [4 + 3] cycloadducts. *N*-Methylpyrrole gave a [4 + 3] cycloadduct

upon reaction with (**2**) generated from NaI/Cu but only Friedel-Crafts substitution products with the oxyallyl generated from Zn/Cu or $Fe_2(CO)_9$ (eq 5).[3b,17] Better results were obtained in the latter case using *N*-methoxycarbonyl- or *N*-acetylpyrroles (eq 6).[18]

(5)

(6)

Generally, thiophenes give only Friedel-Crafts substitution products upon attempted [4 + 3] cycloaddition with oxyallyls.[1] However, 2,5-dimethylthiophene gave [4 + 3] cycloadducts with (**2**) generated from $Fe_2(CO)_9$ (eq 7).[19] This result strongly suggests that the use of substituted thiophenes in [4 + 3] cycloaddition processes may be generally feasible.

(7)

More unusual heterocycles, including selenophene and tellurophene,[19] diphenylisobenzofuran and *N*-*t*-butylisoindole,[20] and 1-phenyl-1-thio-3,4-dimethylphosphole,[21] have been used to trap (**2**). In the latter case, an unexpected hydrolysis took place in the course of the reaction to give bicycle (**7**) as the sole [4 + 3] cycloadduct, albeit in low yield (eq 8).

[3 + 2] Cycloadditions.

The trapping of (**2**) with π-systems in a [3 + 2] sense has been the subject of a number of studies. The reaction of (**2**) with morpholino enamines has been shown to lead to cyclopentenones in a general fashion (eq 9).[3a,22] ***Iron-Graphite*** ($C_{24}Fe$) has been introduced as a reagent for the conversion of (**1**) to (**2**) in the context of this annulation process.[23] Related cycloadditions also occur with *N*,*N*-bis-silyl enamines and *N*-tosyl enamines (eq 10).[24,25]

Aromatic alkenes are also capable of trapping (**2**) to afford cyclopentanones (eq 11).[26] Dienes can also exhibit regioselectivity characteristic of [3 + 2] cycloadditions in their reactions with (**2**).[27]

A general synthesis of 3(2*H*)-furanones based on the reaction of (**2**) with dimethylamides has been developed (eq 12).[28] An interesting example is the synthesis of (**8**), which, while derived from (**2**), is also a precursor of this species (eq 13).[29]

(13)

The reaction of (**2**) with 1,1-dimethoxyethylene resulted in the formation of heterocycle (**9**) in high yield (eq 14). Attempted trapping with alkynes did not produce [3 + 2] cycloadducts but led to low yields of substituted allenes (eq 15).[30]

(14)

(15)

[3 + 3] Cycloadditions.

Only one example of this type of reaction with (**2**) has been reported. Reaction of (**2**) with η^1-allyl(cyclopentadienyl)dicarbonyliron in the presence of $Fe_2(CO)_9$ followed by oxidation resulted in the synthesis of 2,6-dimethyl-4-methoxycarbonylcyclohexanone in low yield (eq 16).[25]

Miscellaneous Reactions.

A number of other synthetically useful transformations of (**1**) have been developed. Treatment of (**1**) with isopropylamine gave imino ketone (**10**) and diimine (**11**) in 72% yield in a ratio of 98:2 (eq 17).[31] All proposed mechanistic possibilities for this transformation involve oxyallylic species, including (**2**) and (**3**).

Nucleophilic trapping of (**2**) with methanol served to support the intermediacy of this oxyallyl in various cycloaddition processes (eq 18).[32] This trapping reaction has not been synthetically exploited.

A palladium-mediated reductive dehalogenation of (**1**) may hold promise as a new means of generating (**2**).[33] An electrochemical reduction of (**1**) apparently resulted in the formation of a cyclopropanone which was nucleophilically trapped under the reaction conditions (eq 19).[34]

2,4-Dibromo-3-pentanone

(19)

Finally, treatment of (**1**) with cuprates resulted in a unique reductive alkylation. Alkylative trapping of the resulting enolate gave reasonable yields of ketones not easily accessible by other routes (eq 20).[35]

1,3-Dibromo-2-pentene

[59838-04-9] · $C_5H_8Br_2$ · 1,3-Dibromo-2-pentene · (MW 227.93)

(ethyl vinyl ketone equivalent used in the synthesis of sesquiterpenes)

Physical Data: bp 88 °C/3 mmHg.

Form Supplied in: colorless liquid stabilized with silver wool.

Preparative Method: is prepared in two steps from commercially available 2-pentyn-1-ol (eq 1). Reduction of the alkynic alcohol with ***Lithium Aluminum Hydride*** in the presence of ***Sodium Methoxide*** followed by bromination of the intermediate aluminate afforded the vinyl bromide which was then converted to the final product by treatment with ***Phosphorus(III) Bromide*** in pyridine.[1]

Handling, Storage, and Precautions: lachrymator; stored cold in an amber bottle to protect from light. Use in a fume hood.

Ethyl Vinyl Ketone Equivalent.

1,3-Dibromo-2-pentene has been used as an ethyl vinyl ketone equivalent in cases where a Michael addition to the unsaturated ketone failed. β-Cyperone was synthesized using this strategy via alkylation of 6-methyl-3-butylthio-2-cyclohexen-1-one using ***Lithium Diisopropylamide*** as the base to yield the 6,6-dialkylated enone system in 60% yield (eq

2). Further elaboration resulted in the synthesis of the target sesquiterpene.[1]

In a related strategy, 1,3-dibromo-2-pentene was used as a building block in the synthesis of compounds related to sclerosporal (eq 3). Alkylation of (-)-carvone with the allylic bromide using ***Potassium t-Butoxide*** as base in refluxing benzene afforded two stereoisomeric products in 55% and 22% yields. These isomers could be separated by chromatography and subsequently converted to the known enones which were dehydrogenated and photochemically rearranged to guaienones.[2]

1,1-Dibromopentyllithium[1]

[41294-30-8] · $C_5H_9Br_2Li$ · 1,1-Dibromopentyllithium · (MW 235.88)

(used in conjunction with *n*-butyllithium for homologation of carbonyl compounds[1])

Solubility: sol ether, THF.

Preparative Method: prepared by the reaction of 1,1,1-tribromopentane with butyllithium in THF-ether at -100 °C.[1]

Handling, Storage, and Precautions: stable only at very low temperature (-100 °C); cannot be stored.

Homologation of Ketones.

1,1-Dibromo-1-pentyllithium adds readily to aldehydes or ketones. In the presence of a second equiv of ***n-Butyllithium***, a further lithium carbenoid[2,3] can be generated which undergoes a rearrangement in which a preferential migration of a hydrogen over an organic group is observed (eq 1). After hydrolysis, a mixture of two isomeric carbonyl compounds is observed (eqs 2 and 3). In some cases, only one rearrangement product is produced (eq 4)[1]. The reaction can be extended to other 1,1-dibromides (eq 5),[1] as well as to the performance of ring expansions (eq 6).[1] The related homologation of esters using ***Dibromomethyllithium*** has been extensively investigated.[4]

2,3-Dibromopropene

[513-31-5] · $C_3H_4Br_2$ · 2,3-Dibromopropene · (MW 199.87)

(a bifunctional reagent, widely employed in coupling reactions, and as a precursor of key intermediates for cycloaddition reactions)

Alternate Names: 1,2-dibromo-2-propene; 2-bromoallyl bromide.

Physical Data: bp 140-142 °C; 75-76 °C/75 mmHg; 42-43 °C/18 mmHg; *d* 2.045 g cm^{-3}; *n*20D 1.544.

Form Supplied in: colorless oil; commercially available.

Purification: may be distilled under atmospheric pressure with very slight decomposition, but becomes highly colored on standing in a glass-stoppered bottle.

Handling, Storage, and Precautions: irritating to skin, eyes, and respiratory system. Use in a fume hood.

Introduction.

Interesting products can be prepared by taking advantage of the different reactivity of the allylic and vinylic halogen atoms. The products obtained can be further elaborated in a variety of manners, frequently leading to polycycles.

Coupling Reactions with Organometallic Reagents.

The allylic and the vinylic bromine atoms of 2,3-dibromopropene (**1**) can be selectively substituted in two consecutive cross-coupling steps.[1] Thus 1,1-disubstituted ethylenes (**2**) can be easily prepared by first adding the appropriate Grignard reagent to a solution of (**1**) in THF at rt. After completion of the coupling reaction, a catalytic amount of $NiCl_2$(dppp) is added, and a solution of the second Grignard reagent is added to the mixture containing the intermediate alkenyl bromide (eq 1).

The allylic bromide can be also substituted by terminal alkynes in the presence of a catalytic amount of a copper(I) salt and tetra-*n*-butylammonium chloride[2] or by alkenylcopper reagents.[3,4] Highly functionalized 2-bromo-1-alkenes are prepared[5] by Cu^{I}-catalyzed reaction of functionalized organozinc halides. Alkylation (***Lithium Diisopropylamide***, THF/HMPA) of methyl 2-(trimethylstannyl)-1-cyclohexene-3-carboxylate with 2,3-dibromopropene affords the ester (**3**) which can be smoothly cyclized to compound (**4**) by using 2-3 equiv of ***Copper(I) Chloride*** in DMF at 60-70 °C (eq 2).[6]

The coupling reactions are widely utilized for the synthesis of several intermediates (e.g. **5**-**8**) (eq 3), which are versatile reagents in cycloaddition reactions. In particular, (**5**) is synthesized[7] in two steps: 2,3-dibromopropene is coupled with ***Trimethylsilylmethylmagnesium Chloride*** and the intermediate obtained, after transformation into a Grignard reagent, is combined with vinyl bromide in the presence of a Ni^{II} catalyst. Product (**6**) is formed by combining lithium (trimethylsilyl)cyanocuprate in a 3:1 THF-HMPA mixture at 0 °C with 2,3-dibromopropene.[8] An alternative synthesis of (**6**) requires treatment of (**1**) with ***Trichlorosilane*** and Et_3N in the presence of a catalytic amount of CuCl, and direct addition of the allyltrichlorosilane to an ether solution of ***Methylmagnesium Bromide***.[9] Diene (**7**) can be obtained by oxidative dimerization of the cuprate derived from (**6**).[10] Compound (**6**) can be also directly transformed, by a coupling reaction, into the diene (**8**).[11]

Dienes (**5**) and (**8**) work well in consecutive Diels-Alder reactions.[7,12] In particular, (**5**) reacts with two dienophiles via consecutive cycloaddition-1,2-elimination-cycloaddition, leading to the polycycle reported in eq 4. Furthermore, the diene (**7**) represents a conjunctive reagent for tandem Diels-Alder cycloaddition (eq 5).[10]

(5)

Sequential alkylation of the 9-fluorenyl anion with 1-bromo-2,4-pentadiene and with 2,3-dibromopropene leads to (**9**),[13] which under Heck reaction conditions affords (**10**) (eq 6).

Reactions with Nitrogen Nucleophiles.

α-Methylene-β-lactams are synthesized from various 2-bromoallylamine derivatives using a catalytic amount of ***Palladium(II) Acetate*** and ***Triphenylphosphine*** under pressure of CO (eq 7).[14] Other procedures involving the use of 2,3-dibromopropene and nitrogen nucleophiles have been reported.[15-18]

Reactions with Oxygen and Sulfur Nucleophiles.

Intramolecular radical cyclization reactions are widely used in organic synthesis for the construction of carbocycles.[19] A rapid access to the hexahydrobenzofuran unit of avermectin A_{2b},[20] which has a high antiparasitic activity, is shown in eq 8, where an important step is the construction of a 2-bromoallyl ether by phase transfer allylation with 2,3-dibromopropene.[21]

Reaction of PhSNa with 2,3-dibromopropene leads to 3-phenylthio-2-bromopropene, a useful reagent for radical allylations.[22]

α,α´-Dibromo-*o*-xylene

[91-13-4] · $C_8H_8Br_2$ · α,α´-Dibromo-*o*-xylene · (MW 263.97)

(a source of *o*-quinodimethane, a highly reactive diene useful in Diels-Alder reactions;[1] an electrophile for the synthesis of carbo- and heterocyclic compounds including macrocycles (cyclophanes, crown ethers, hemispherands, spherands),[2] cryptands,[3] hemicarcerands,[4] vaulted cappedophanes,[5] bicyclic compounds,[6] spirocyclic compounds;[7] a protective group reagent for diols[8])

Alternate Name: 1,2-bis(bromomethyl)benzene.

Physical Data: mp 95 °C ($CHCl_3$-EtOH); bp 140 °C/20 mmHg; *d* 1.960 g cm^{-3}; dipole moment (hexane, 20 °C) 1.98 D.

Solubility: sol ethanol, ether, chloroform; slightly sol petroleum ether.

Form Supplied in: commercially available as a solid.

Purification: recrystallization from 95% ethanol (3 mL g^{-1}), petroleum ether (bp 60-80 °C) (19 mL g^{-1}), chloroform (1 mL g^{-1}). Column chromatography (silica gel, cyclohexane-ethyl acetate).

Handling, Storage, and Precautions: avoid moisture; corrosive (forms HBr on hydrolysis); lachrymator; not mutagenic in Ames test; decontaminate by soaking apparatus, etc. in alcoholic alkali for 24 h or longer.

Precursor of *o*-Quinodimethane.

A reductive 1,4-elimination[1] of two bromide ions generates the reactive diene which can be intercepted by dienophiles and by iron[9] or cobalt[10] carbonyl reagents to form stable complexes. The elimination may be accomplished by activated ***Zinc***,[11] particularly with ultrasonication at rt (eq 1),[12] activated ***Nickel***,[13] ***Sodium Iodide***[14] in DMF, sodium benzenetellurolate,[15] ***Chromium(II) Chloride***,[16] and elemental ***Copper***[17] (as the *t*-butyl isocyanide complex). The dibromide is a precursor of 1,3-dihydrobenzo[*c*]thiophene 2,2-dioxide (**2**)[18] and 1,4-dihydro-2,3-benzoxathiin 3-oxide (**3**),[19] which yield *o*-quinodimethane on thermolysis (eqs 2 and 3).

Cyclization Reactions.

Any reagent capable of functioning as a bis-nucleophile can, in principle, yield a cyclic product with (**1**). Benzocyclobutene may be formed in reactions yielding *o*-quinodimethane,[18a] and fused ring compounds containing five or more atoms in the second ring are available from (**1**). Examples of various fused ring compounds obtained from (**1**) are as follows: five-membered (eqs 2 and 4),[18b,20] six-membered (eqs 3 and 5),[19a,19b,21] seven-membered (eq 6),[22] and eight-membered (eq 7).[23] The attachment of larger rings is not uncommon, as shown in eq 8 for a macrocycle.[2d]

(7)

(8)

Bicyclic ring systems have been obtained by the appropriate choice of nucleophile (e.g. the cryptand shown in eq 9),[3a] and spirocyclic compounds have been prepared (eq 10).[7b] Four molecules of (**1**) were used in a critical step in the construction of a globe-shaped hemicarcerand by uniting two bowl-like units via reaction with eight phenolic hydroxy groups on the rims of the two bowls.[4] A monensin ionophore bridged by treatment with (**1**) shows excellent chiral recognition ability for salts of amino acids and amines.[2g]

(9)

(10)

In addition to undergoing cyclizations with nucleophiles, (**1**) also dimerizes in 65% yield to 1,2;5,6-dibenzocyclooctadiene by treatment with 2 equiv of ***Ethylenebis(triphenylphosphine)nickel(0)*** at -20 °C in ether[2f] and in 80% yield by ultrasonication with ***Lithium*** in THF.[24]

Protective Group Reagent for Diols.

1,2- and 1,3-diols containing primary or secondary alcohol functions, catechols, and ene-1,2-diols are protected by reaction with (**1**). Deprotection involves hydrogenolysis of the protecting group (eq 11).[8]

(11)

Miscellaneous Uses.

The dichloride rather than dibromide (**1**) is preferable for synthesis of the bis-Grignard reagent which is obtained in good yield, especially by treatment with Mg(anthracene)$(THF)_3$ in THF, hexane, or toluene under moderately high dilution to forestall Wurtz coupling.[25] A 75% yield of *o*-dibenzylbenzene is obtained by Friedel-Crafts reaction of (**1**) catalyzed by ***Aluminum Chloride-Nitromethane***.[26] Yields are poor if $AlCl_3$ alone is used.

Related Reagents.

1,3-Dihydrobenzo[c]thiophene 2,2-Dioxide.

Di-*t*-butoxyacetylene

***t*-BuO-C&tbond;C-O-*t*-Bu**

[66478-63-5] · $C_{10}H_{18}O_2$ · Di-*t*-butoxyacetylene · (MW 170.25)

(a synthon for oxocarbons,[1] it transfers a protected enediol fragment by cycloaddition)

Physical Data: mp 8.5 °C; bp 30 °C/0.05 mmHg; *n*25D = 1.4365.

Solubility: completely sol hydrocarbons, ethers, chlorinated solvents, and ethyl acetate; insol water.

Form Supplied in: pale yellow oil; not commercially available.

Analysis of Reagent Purity: IR (CCl_4) cm^{-1}: 2972, 2922, 1470, 1450, 1390, 1367, 1301, 1263, 1245, 1150, 825; ^1H NMR (CCl_4) δ: 1.31 (s, CH_3).

Preparative Methods: from 1,2-dichloro-1,2-dimethoxyethane[2] or from *trans*-2,3-dichloro-1,4-dioxane.[2b,3] This latter procedure has been thoroughly optimized[4] and involves six steps, beginning with dioxane.

Purification: usual impurities can be removed by column chromatography on neutral alumina using a column refrigerated at 0 °C and eluting with pentane under N_2 pressure.

Handling, Storage, and Precautions: most conveniently stored as a solid at -20 °C. It slowly decomposes at rt through elimination of 2-methylpropene.[5]

Cycloadditions and Cyclooligomerizations of Di-*t*-butoxyacetylene.

Different carbenes equivalent to CO add to di-*t*-butoxyacetylene (**1**) to afford di-*t*-butoxycyclopropenone (**2**) (eq 1).[1,6] This compound has been quantitatively converted to deltic acid (dihydroxycyclopropenone) by treatment with ***Trifluoroacetic Acid*** (TFA).

(1)

(1) **(2)**

CO equivalent	Source	Yield (%)
CCl_2	$CHCl_3$, aq NaOH, TEBA	12-26
CClF	$CHCl_2F$, aq KOH, 18-crown-6	21-27

Simple heating under reflux of a benzene solution of (**1**) leads to the quantitative formation of 2,3,4-tri-*t*-butoxycyclobutenone (**3**) via a [2 + 2] cycloaddition with thermally generated *t*-butoxyketene (eq 2).[6] Compound (**3**) has been converted to 3-hydroxycyclobutene-1,2-dione (semisquaric acid) by trifluoroacetolysis,[7] and to 3,4-dihydroxycyclobutene-1,2-dione (squaric acid) by an oxidation-trifluoroacetolysis sequence.[6] The cyclodimerization of (**1**) can be also induced by Pd^{II}. Di-*t*-butyl squarate is obtained and converted without isolation to squaric acid by treatment with TFA (eq 3).[7]

(2)

(1) **(3)**

(3)

(1)

Both ***Dicarbonyl(cyclopentadienyl)cobalt(I)*** and ***Nonacarbonyldiiron*** efficiently induce cyclopentadienone formation from (**1**) (eq 4).[7,8] Demetalation of complex (**4**) leading to tetra-*t*-butoxycyclopentadienone has been achieved electrochemically,[9] whereas complex (**5**) is most conveniently demetalated with ***Trimethylamine N-Oxide***.[8] Tetra-*t*-butoxycyclopentadienone has been converted to 2,4,5-trihydroxycyclopent-4-ene-1,3-dione (hydrocroconic acid) and to 4,5-dihydroxycyclopent-4-ene-1,2,3-trione (croconic acid).[8,9]

(4)

Catalytic amounts of ***Octacarbonyldicobalt***[6] or, better, ***Tetracarbonylnickel***,[1,10] induce cyclotrimerization of (**1**) leading to hexa-*t*-butoxybenzene (**6**) under unusually mild conditions (eq 5). Trifluoroacetolysis of (**6**) affords quantitatively hexahydroxybenzene, the classical precursor of 5,6-dihydroxycyclohex-5-ene-1,2,3,4-tetrone (rhodizonic acid).

1,3-Dibutoxy-1-lithio-1-propene[1]

[-] · $C_{11}H_{21}LiO_2$ · 1,3-Dibutoxy-1-lithio-1-propene · (MW 192.23)

(nucleophilic reagent equivalent to an umpoled enone formed from 1,3-dibutoxypropene and *t*-butyllithium)

Solubility: sol THF/HMPA.

Preparative Method: metalation of 1,3-dibutoxypropene with *t*-BuLi in THF/HMPA.[1]

Handling, Storage, and Precautions: sensitive to air, water, and temperature.

A mixture of (*E*)- and (*Z*)-1,3-dibutoxypropene is prepared[1] from 1,3-dichloro-2-hydroxypropane, through the formation of the known dibutyl ether of glycerol[2] and the generation of the final alkene mixture (*Z*/*E* = 4:1) through elimination of the tosylate (eq 1). The exclusive formation of the vinyl anion (e.g. 1,3-dibutoxy-1-lithio-1-propene) is observed when the isomeric mixture is treated with ***t-Butyllithium*** in THF/HMPA (10:1) at -65 °C (eq 1). Gould and Rossi[3] used theoretical calculations to suggest a weakened α-vinyl C-H bond in the (*Z*)-1,3-dibutoxypropene. Methylated products are observed in the same (*Z*/*E*) ratio (i.e. 4:1) as the starting alkenes (eq 1). Other alkylations with low molecular weight primary bromides or iodides give 70-90% yields of products alkylated at the vinyl position. Other electrophiles such as carbonyls or epoxides were not examined. The overall process corresponds to the generation of a synthetic equivalent of a carbonyl enone synthon (eq 2). This umpoled synthon has been investigated extensively and includes such synthetic equivalents as (**1**),[4] (**2**),[5] and (**3**).[6]

(1) **(2)** **(3)**

This work contrasts with that of Funk (eq 3),[7] where the allylic metalation and alkylation of 4*H*-1,3-dioxin provides a 3-acylvinyl equivalent. Theoretical calculation of bond energies for the 1,3-dioxin system was not performed. Vinyl anions are observed for other cyclic vinyl ethers.[8,9] 1,3-Hetero allylic systems, e.g. (**4**)[10] and (**5**),[11] containing sulfur also provide the allylic carbanion.

Related Reagents.

1-Ethoxy-1-(trimethylsilyloxy)cyclopropane; ***1-Methoxyallenyllithium***; ***(E)-3-Methylthio-2-propenyl p-Tolyl Sulfone***.

Dibutylamine

Bu_2NH

[111-92-2] · $C_8H_{19}N$ · Dibutylamine · (MW 129.28)

(strong hindered base capable of catalyzing water elimination with $SOCl_2$,[1] detosylation,[2] isomerization around a double bond,[3] rearrangement of epoxides,[4] and cyclocondensations[5])

Physical Data: mp -62 °C; bp 159 °C; *d* 0.767 g cm^{-3}; *n*20D 1.4170; p*K*H_2Oa 11.25.

Solubility: very sparingly sol H_2O; sol most organic solvents.

Preparative Methods: from butyl bromide and ammonia;[5b] separation of the mono-, di-, and tributylamines is required.

Form Supplied in: liquid; commercially available.

Purification: can be dried over and distilled from fresh potassium hydroxide immediately before use.

Handling, Storage, and Precautions: is a flammable, colorless liquid. Harmful by inhalation and by eye and skin contact.

Purification of Carboxylic Acids.

Dibutylamine can be used for the purification of diterpene carboxylic acids,[6] long-chain fatty acids,[7] and benzoic acids.[8] The free carboxylic acids can be regenerated by treatment of the amine salts in ethanol with ***Acetic Acid***. Other secondary amines (e.g. diisopentylamine,[6] diisobutylamine[6b]) can also be used.

Eliminations.

Dibutylamine can also be used in different elimination reactions as a hindered strong base. When 1,1,1-trichloro-2-methyl-2-propanol is treated with 4 equiv of ***Thionyl Chloride***, a catalytic amount of dibutylamine at reflux then affords pure 3,3,3-trichloro-2-methyl-1-propene in good yield by water elimination, similar to ***t-Butylamine***, ***Triethylamine***, aniline, and dimethylaniline (eq 1).[1] In the presence of other amines, such as octylamine, ***Piperidine***, ***Pyridine*** or tetramethylammonium chloride, isomerized product is also formed.

(1)

The base-catalyzed detosylation rate of 1-(*p*-toluenesulfonyl)-2-propyl *p*-toluenesulfonate depends on the polarity of the solvent used (eq 2).[2] In acetonitrile and 50% aqueous dioxane the strongest catalytic base is dibutylamine, followed by hexylamine and triethylamine. In solvents with a medium dielectrict constant (e.g. chloroform, chlorobenzene), the above the order is reversed.[2]

(2)

Isomerizations, Rearrangements.

For the amine-catalyzed nucleophilic isomerization of ethyl *cis*-2-cyano-3-(2-methoxyphenyl)acrylate to the *trans* derivative (eq 3)[3] in benzene the order of reactivity of the amines is dibutylamine > dipropylamine > diisobutylamine > tributylamine > diisopropylamine > triethylamine > pyridine > ***2,6-Lutidine***. This isomerization can also be influenced by solvent[3] and other oxygen[9] and carbon nucleophiles.[9]

(3)

Base-induced rearrangement of epoxides with lithium alkylamides can yield allylic alcohols, isomerized derivatives, ketones, or, by direct nucleophilic substitution, amine alcohols. Cyclohexene oxide (**1**) gives 2-cyclohexen-1-ol (**2**) near quantitatively with lithium dibutylamide[4] (prepared in situ from a 15% solution of ***n-Butyllithium*** in hexane and an ethereal solution of dibutylamine) or lithium dipropylamide, while other lithium amides afford low to moderate yields of the allylic alcohol (**2**), very little ketone (**3**) and 3-cyclohexen-1-ol (**5**), and extensive amounts of the amino alcohol adduct (**4**) (eq 4).

R^1	R^2	Reaction time (h)	Yield (%)			
H	Pr	17	15	0.5	77	trace

i-Pr	*i*-Pr	3	38	33	28	-
Pr	Pr	2	99	<0.5	-	<0.5
Bu	Bu	4	97	-	3	<0.5
		0.5	31	62	7	-

Cyclocondensations.

2-Unsubstituted 3-nitro-2*H*-chromenes can be prepared in fair to excellent yields either by the reaction of 2-hydroxybenzaldehydes and ***Nitroethylene*** in boiling chloroform, or by the reaction of 2-hydroxybenzaldehydes, 2-nitroethanol, and 2 equiv of phthalic anhydride in boiling toluene in the presence of 0.2-0.5 equiv of dibutylamine (eq 5).[5] Other amines, like ***Diisopropylethylamine*** and ***1,4-Diazabicyclo[2.2.2]octane***, lead to a rapid polymerization of nitroethylene. Ammonium chlorides[10] like dibutylammonium, diisopropylammonium, diethylammonium, dioctylammonium, piperidinium, and morpholinium chlorides in boiling isopentyl acetate lead to lower yields or more difficult purification.

Di-*t*-butyl Azodicarboxylate[1]

[870-50-8] · $C_{10}H_{18}N_2O_4$ · Di-*t*-butyl Azodicarboxylate · (MW 230.26)

(reagent for the electrophilic amination[2] of enolates; Diels-Alder dienophile)

Alternate Names: DBAD; TBAD.

Physical Data: mp 90-92 °C.

Solubility: sol most organic solvents.

Form Supplied in: yellow solid; widely available.

Preparative Method: a detailed description is given in *Organic Syntheses*.[3]

Handling, Storage, and Precautions: light sensitive; more stable than its methyl or ethyl analogs.

Reactions with Carbon Nucleophiles.

Although the electrophilic reactivity of azodicarboxylates towards C-nucleophiles was recognized long ago,[4] the first reaction of di-*t*-butyl azodicarboxylate (**1**) with an organometallic reagent was reported only in 1961. The addition of *t*-butylmagnesium chloride to DBAD, to give the protected *t*-butylhydrazine (**2**) in 50% yield (eq 1), has been described.[5] This type of reaction is not limited to aliphatic Grignard reagents; aryllithium and aryl Grignard reagents (**3**) add analogously to DBAD to afford arylhydrazines (**5**) after final deprotection (eq 2).[6]

R = OMe, SMe, CF_3, CF_3CH_2, etc

(2)

(5)

Although in principle other azodicarboxylates give the same reaction, the advantage of using DBAD is the ease of removal of the protecting group. The *t*-butoxycarbonyl (Boc) group is readily cleaved by ***Trifluoroacetic Acid*** or ***Hydrogen Chloride***, whereas the harsher acidic or basic conditions required for the removal of methyl or ethyl analogs can interfere with the hydrazine moiety. A comparison of anionic attack on DBAD and related azodicarboxylates with subsequent deprotection is available (eq 3).[7] Deprotonation of the chiral carboximides (**6**) followed by reaction with azodicarboxylates produces the hydrazino acid precursors (**7**) in high yields. Dimethyl and diethyl azodicarboxylate give only moderate diastereoselectivity, whereas the dibenzyl and di-*t*-butyl derivatives afford excellent stereoselection. The phenylalanine-derived carboximide (**8**) adds DBAD upon deprotonation with ***Lithium Diisopropylamide*** in a similar fashion (eq 4).[8]

R^2 = *t*-Bu, Bn, 90-94% de

(4)

(8) R = Me, Bn, *i*-Pr, *t*-Bu, Ph, allyl **(9)**

Heterocycles (**7**) and (**9**) can each be cleaved to either (*S*)-α-hydrazino acids (**10**) or, if desired, to (*S*)-α-amino acids (**11**), both of which are obtained in enantiomerically pure form within detection limits (eq 5). Since the enantiomers of (**6**) and (**8**) are readily available, (*R*)-α-amino acids and (*R*)-α-hydrazino acids can also be made. This approach has allowed generation of [^{14}C]phenylalanine[9] and 2-adamantylalanine.[10] An elegant application of this methodology is seen in the synthesis of (*R*)- and (*S*)-piperazic acids (eq 6).[11] Deprotonation and reaction of the carboximide (**12**), derived from 5-bromovaleric acid, with DBAD produces an aza anion capable of displacing bromide to give, upon final deprotection, (*S*)-piperazic acid (**15**) as a single isomer. Its enantiomer was made using the antipode of the chiral auxiliary. The asymmetric synthesis of 1,6-dihydropiperazic acid has been elaborated in a similar way; however, its TFA salt was reported to be unstable.[12]

Several related syntheses of either α-amino acids or α-hydrazino acids have been developed, all of them using electrophilic amination of enolates to construct the stereogenic center at the α-carbon. 10-Sulfonamidoisobornyl esters (**16**) are useful tools for such processes.[13] These esters can be selectively deprotonated at -78 °C and converted to their corresponding *O*-silyl ketene acetals, which upon Lewis acid promoted addition of DBAD yield the amination products (**17**) in high yields (eq 7). These compounds are generally obtained with high stereoselectivity, and are diastereomerically pure after chromatography. α-Amino acids are synthesized from these precursors via a four-step procedure; the amino acids (**18**) are nearly enantiomerically pure (ee &egt; 95%).

(16)

(7)

(17) **(18)**

R = alkyl, *i*-alkyl, Bn, 1-adamantyl-CH_2

(1R,2S)-N-Methylephedrine is also a suitable chiral auxiliary for the diastereoselective amination of *O*-silyl ketene acetals.[14] The silyl ketene acetals (**19**), derived from corresponding esters and *N*-methylephedrine, react smoothly with a preformed DBAD/***Titanium(IV) Chloride*** complex to generate the hydrazino derivatives (**20**) (eq 8). The major diastereomers are chromatographically separated and converted to their corresponding α-hydrazino acids (**21**) (from which a single isomer can also be obtained by recrystallization) or to the α-amino acids (**22**), respectively. Both (**21**) and (**22**) are obtained in good yields as single enantiomers.

β-Hydroxy esters (**23**), available in both enantiomeric forms, can be deprotonated at the α-carbon without protection of the hydroxy group. These react with DBAD to give an easily separable mixture of *syn*- and *anti*-adducts. The *anti*-adduct (**24**) is formed in up to 88% de (eq 9).[15] These adducts are very useful tools since compounds with *anti* (allo) stereochemistry are not easily accessible by other established methods for amino acid synthesis. As in the previous cases, either amino acids or hydrazino acids are obtainable via several deprotection steps. One compound, (**26**; R = Me), was synthesized as a single enantiomer, but the others were initially prepared as racemic mixtures. Subsequently, as an application of this method, D-*ribo*-C_{18}-phytosphingosine was stereoselectively synthesized.[15b] Closely related processes were published afterwards and show analogous results.[16]

(23) (24)

(25) (26)

R = Me, CF_3, hexyl, Cy

(*S*)-Trifluorothreonine methyl ester (**28**) has been synthesized from (**27**) using a related approach (eq 10).[17] Although an additional bulky *t*-butyl group is required for stereoinduction, this method gives the amination products with complete control of stereochemistry. Subsequent deprotection and hydrogenation reactions yield the desired product (**28**). A diastereoselective synthesis of (-)-2,3-diaminobutanoic acid from β-aminobutanoic acid has also been described (eq 11).[18] The synthesis of enantiomerically pure β-aminobutanoic acid is described in the same contribution, but the amination reaction of the protected derivative (**29**) with DBAD was performed on the racemic mixture, giving only one diastereomer (**30**) as a mixture of enantiomers. Several deprotection steps produced the desired (-)-2,3-diaminobutanoic acid as its diastereomerically pure hydrochloride (**32**).

(27) (28)

Methyl dithioacetate (**33**), upon deprotonation with ***n-Butyllithium***, is a suitable nucleophile for reaction with DBAD (eq 12).[19] The amination product (**34**), a precursor of α-amino thioacids, was obtained in 57% yield along with 15% of a side product resulting from attack of DBAD at the sulfur atom of the intermediate thioenolate.

The procedures described above demonstrate the potential for electrophilic amination of enolates with DBAD to yield various α-amino acids or α-hydrazino acids with high optical purity. However, other condensations with carbanions have been published recently. After deprotonation with *n*-BuLi, the 1,2-oxazine (**35**) attacks DBAD with high γ-selectivity to produce (**36**) (eq 13).[20] Carbonyl compounds and D_2O also show high γ-selectivity, whereas alkyl halides react primarily in the α-position. The oxazine (**36**) is useful as a precursor of a 1,4-diamino compound.

Reactions with Sulfur Nucleophiles.

Thiols readily react with DBAD to form sulfenohydrazides.[21] For example, *t*-butyl thiol (**37**) adds to the azodicarboxylate upon treatment with catalytic amounts of sodium alcoholate to give the sulfenohydrazide (**38**). These compounds can transfer a thio moiety to thiols. For example, attack by a second sulfur nucleophile, such as cysteine (**39**) (eq 14), leads to *t*-butyl thiocysteine (**40**). The overall result is a selective (and reversible) protection of cysteine at sulfur, thus providing an alternative to the commonly used protecting groups (e.g. trityl). A useful application is the synthesis of unsymmetrical cystine peptides (**44**) (eq 15).[21] A cysteine-containing peptide (**41**) is activated by DBAD, and the resulting sulfenohydrazide (**42**) is attacked by a different cysteine-containing peptide (**43**), to link two peptide chains via a disulfide. Several biologically important unsymmetrical cystine peptides and derivatives were prepared by this procedure.

Sulfides (**45**) react with azodicarboxylates to yield adducts (**47**), where the addition has not proceeded in the manner described above, but rather to the carbon adjacent to the sulfur (eq 16).[22] Some of these reactions require the addition of ***Dibenzoyl Peroxide*** and/or UV irradiation to initiate the process. The reactivity order for hydrogens adjacent to sulfur atoms appears to be CH_2CO_2Me > benzyl > methyl, thus suggesting a carbanionic intermediate or transition state. The authors consider that association of the sulfide with the azo linkage might be accompanied by proton transfer to generate the ylide (**46**) in one step. Subsequent rearrangement furnishes the functionalized sulfides (**47**), providing a method to oxidize carbon atoms adjacent to sulfur; thus (**47**) can be considered a compound with a masked carbonyl group.

(16)

(47)

Diels-Alder[23] and Related Cycloadditions.

Azodicarboxylates have been long known to react with dienes in a [4 + 2] cycloaddition.[24] DBAD undergoes a variety of cycloadditions, e.g. Diels-Alder reactions, but is somewhat less reactive in these processes than its methyl or ethyl counterparts due to the bulky Boc groups. However, since the two Boc groups are more easily cleaved in the later steps of a reaction sequence than methoxycarbonyl groups, DBAD is still an attractive dienophile. In addition, DBAD has a higher thermal stability than its methyl or ethyl analog (e.g. dimethyl azodicarboxylate has to be distilled behind a safety shield). The condensation of cyclopentadiene with diethyl azodicarboxylate has been known since 1925, but the reaction can be done with DBAD in a similar manner (eq 17).[5,25] Several substituents and an additional keto function do not affect cycloadditions with azodicarboxylates, but interestingly, the intermediate Diels-Alder adducts rearrange and give oxadiazines (**52**) (eq 18).[26]

(17)

(48) (1) (49)

(50) (51)

(18)

(52)

o-Quinoidal bismethylene arenes like (**54**) are very reactive dienes, which are prepared in situ via iodide-induced 1,4-elimination, and can be trapped with various dienophiles. The use of DBAD in this case leads to pyridazines (**55**) (eq 19).[27] A related reaction affords tetrahydroindeno[1,2-*d*]pyridazine (**58**). The process involves a similar 1,4 elimination of the precursor (**56**) followed by subsequent cycloaddition (eq 20).[28]

(53) (54)

(19)

(55)

The thermal valence isomerization between the benzenoid structure (**59**) and the *o*-quinoidal structure (**60**) allows a range of [8 + 2] cycloadditions; condensation with DBAD leads to 2*H*-3,4-dihydro-1,2,3-benzothiadiazine (**61**) (eq 21).[29] 2-Vinyl-1,4-benzodioxin (**62**) undergoes facile Diels-Alder reaction with DBAD to produce the hydrazino aminal derivative (**63**) (eq 22).[30] 3-Vinylpyridines, 4-vinylpyridines, and 2-vinylthiophene undergo similar cycloadditions with DBAD.[31]

Mitsunobu-Type Reactions.

One of the most common reactions for dimethyl and diethyl azodicarboxylate is the Mitsunobu reaction.[1b] Surprisingly, very little is known about Mitsunobu reactions using DBAD. Only one publication, studying the mechanism of the Mitsunobu reaction, describes a comparative study of several azodicarboxylates, concluding that such reactions can be performed using DBAD.[32] A Mitsunobu-type reaction has been published recently, starting from alcohol (**64**). Treatment with triphenylphosphine and DBAD gives the hydrazine derivative (**65**) in one step (eq 23), presumably by a displacement reaction of the intermediate hydrazide anion and the triphenylphosphine/alcohol adduct.[33]

3,5-Di-*t*-butyl-1,2-benzoquinone

[3383-21-9] · $C_{14}H_{20}O_2$ · 3,5-Di-*t*-butyl-1,2-benzoquinone · (MW 220.31)

(reacts with primary amines to give different products depending on the alkyl substituent: benzoxazoles from primary amines and α-amino acids; ketones from *s*-alkyl primary amines; dioxazepines from cyclopropylamines; aromatic aldehydes from *vic*-aminobenzyl alcohols; skatole from tryptophan)

Alternate Name: DTBBQ.

Physical Data: mp 114-115 °C.

Solubility: sol most organic solvents; insol water.

Form Supplied in: dark red needles; commercially available.

Analysis of Reagent Purity: by TLC (silica gel plate Bakerflex-IBF, hexane/methylene chloride (1:1), R_f 0.53);[5] UV-vis λ_{max} 402 (ε = 821).[3]

Preparative Methods: by PbO_2 oxidation of 3,5-di-*t*-butylcatechol;[7] by chemical and electrochemical oxidation of 3,5-di-*t*-butyl-2-hydroxyaniline.[3]

Purification: recrystallization from toluene or by vacuum sublimation.

Handling, Storage, and Precautions: avoid exposure to light; toxicity unknown.

General Characteristics.

As a result of the steric hindrance caused by two *t*-butyl groups, the reactions are centered at the less hindered carbonyl, producing an unstable quinoneimine which is prone to a spontaneous aromatization. All reactions occur under mild conditions. In several reactions DTBBQ mimics pyridoxal.[8]

Reactions with Amines.

Primary alkyl primary amines, e.g. benzylamine[1] and ethanolamine,[2] react with DTBBQ to give benzoxazole derivatives via a quinoneimine and a Schiff base that undergoes cyclization and dehydrogenation with DTBBQ present in excess (eq 1).

(1)

s-Alkyl primary amines undergo oxidative deamination (Corey's reaction) to give ketones produced in 84-97% yield. A small quantity of a phenoxazinone derivative is responsible for the pink color of the reaction mixture (eqs 2 and 3).[1,3]

(2)

(3)

The tertiary cyclopropyl primary amine 1-phenylcyclopropylamine reacts via a ring-opening step to form a substituted dibenzoxazepine and an azospirodecatrienone (eq 4). Also the products obtained with cyclopropylamine show evidence of ring cleavage.[4]

3,5-Di-t-butyl-1,2-benzoquinone

(4)

Vicinal aminobenzyl alcohols with 2 equiv of DTBBQ undergo C-C bond cleavage to form the respective aromatic aldehydes and benzoxazoles in high yields (eq 5). With an equimolar ratio of the reactants, benzaldehyde condenses with a portion of the amino alcohol to give the Schiff base (**1**).[2,6]

(5)

R = SMe	91:95
R = H	95:91

3,5-Di-t-butyl-1,2-benzoquinone

(1)

α-Amino acids form 2-substituted benzoxazoles via a decarboxylation step.[5] Tryptophan is an exception, undergoing retroaldol cleavage and formation of skatole (eqs 6 and 7).[6]

2,6-Di-*t*-butyl-1,4-benzoquinone[1]

[719-22-2] · $C_{14}H_{20}O_2$ · 2,6-Di-*t*-butyl-1,4-benzoquinone · (MW 220.31)

(precursor for 4-aryl-2,6-di-*t*-butylphenols;[2] for 4-alkynyl-2,6-di-*t*-butylphenols;[3] oxidation of amines to amides via oxygenation of 4-(*N*-arylmethyleneamino)-2,6-di-*t*-butylphenols[4])

Physical Data: mp 65-67 °C.

Solubility: insol H_2O; sol organic solvents.

Form Supplied in: yellow solid.

Analysis of Reagent Purity: TLC, NMR.

Preparative Method: Co(salen)-catalyzed oxygenation of 2,6-di-*t*-butylphenol in DMF.[1]

Purification: silica gel column chromatography; recrystallization from hexane.

Preparation of 4-Substituted 2,6-Di-*t*-butylphenols.

2,6-Di-*t*-butyl-1,4-benzoquinone (**1**) is conveniently utilized for the preparation of a variety of 4-substituted 2,6-di-*t*-butylphenols. The reaction of (**1**) with Grignard reagents derived from aryl bromides, alkynes, and ***Ethylmagnesium Bromide*** gives the corresponding 1,4-quinols (**2**) in >90% yield from aryl Grignard reagents[2] and in 65-77% yield from RC&tbond;CMgBr (R = Ph, *n*-Bu, *t*-Bu).[3] The reduction of (**2**) with ***Zinc***/HCl in ethanol then affords the corresponding phenols (**3**) in 74-96% yield (eq 1).[3]

(1)

Oxidation of Amines to Amides.

Quinone (**1**) can conveniently be used for the selective oxidation of an α-methylene group in amines to give the corresponding amides, normally a difficult transformation. Treatment of (**1**) with $ArCH_2NH_2$ in ethanol at reflux first leads to 4-(*N*-arylmethyleneamino)-2,6-di-*t*-butylphenol (**4**) (eq 2) (yields: Ar = Ph (82%), 4-MeC_6H_4 (61%), 4-$MeOC_6H_4$ (72%), 4-ClC_6H_4 (49%), 3-pyridyl (62%), 2-furyl (42%)).[4] Base-promoted oxygenation of (**4**) then affords (**1**) and the corresponding amide (eq 2). The yield of amide depends on the reaction conditions; oxygenation with ***Potassium t-Butoxide*** in *t*-BuOH provides the amide in 36-85% yield, but the recovery of (**1**) is only 10% because (**1**) is unstable under the conditions. On the other hand, the use of ***Potassium Hydroxide*** in ethanol leads to the amide in 15-79% yield with better recovery of (**1**) (70%).[4] The oxygenation of (**5**) with Co(salpr) in dichloromethane reveals that hydroperoxide (**5**) is a likely intermediate in this reaction.[5]

Di-*n*-butylboryl Trifluoromethanesulfonate

***n*-Bu_2B-OSO_2CF_3**

[60669-60-4] · $C_9H_{18}BF_3O_3S$ · Di-*n*-butylboryl Trifluoromethanesulfonate · (MW 274.11)

(Lewis acid for the preparation of vinyloxyboranes,[1-6] boryl azaenolates;[7,8] catalyst for macrolactonization[9])

Physical Data: bp 60 °C/2.0 mmHg.

Solubility: sol common inert organic solvents such as Et_2O, CH_2Cl_2, and hexane.

Form Supplied in: 1.0 M solution in CH_2Cl_2 and Et_2O.

Preparative Method: ***Trifluoromethanesulfonic Acid*** is added slowly to an equimolar amount of ***Tri-n-butylborane*** with gentle warming (50 °C) until butane evolution commences. The remaining acid is added at such a rate to maintain a reaction temperature of less than 50 °C. After the addition is complete, the mixture is stirred for an additional 30 min at 25 °C and then the product is isolated by vacuum distillation.[1c]

Handling, Storage, and Precautions: the neat liquid as well as solutions are moisture and air sensitive. Therefore the material should be stored and transferred under a dry inert atmosphere. Use in a fume hood.

Vinyloxyboranes (Boron Enolates).

Dibutyl vinyloxyboranes are conveniently prepared from active methylene carbonyl containing compounds utilizing Bu_2BOTf in combination with a sterically hindered amine base. Typically the base, ***Diisopropylethylamine*** or ***2,6-Lutidine*** (2,6-lut), and Bu_2BOTf are premixed in Et_2O or CH_2Cl_2 at -78 °C and then the carbonyl component is added. Enolate generation is allowed to occur over the next 15-30 min at temperatures ranging from -78 °C to 0 °C, resulting in the formation of vinyloxyboranes which are suitable for reaction with aldehydes in a crossed aldol reaction. Other boryl triflate reagents have similar or complimentary utility in this process (see ***9-Borabicyclononyl Trifluoromethanesulfonate*** (9-BBNOTf) and ***Dicyclopentylboryl Trifluoromethanesulfonate*** ($(c\text{-}C_5H_9)_2BOTf$)).

With unsymmetrical methyl ketones, use of Bu_2BOTf and *i*-Pr_2NEt results in the regioselective formation of the vinyloxyborane at the least hindered carbon. However, if 9-BBNOTf and 2,6-lut are used, the regioselectivity of vinyloxyborane formation is reversed (eq 1).[10]

Bu_2BOTf, *i*-Pr_2NEt	100:0
9-BBNOTf, 2,6-lut	12:88

The relative stereochemistry of the two new chiral centers formed in the aldol product is a direct consequence of the vinyloxyborane enolate geometry with *Z*(O) enolates affording the 2,3-*syn* aldol products and the *E*(O) vinyloxyboranes leading to the 2,3-*anti* isomers. As a result, a number of studies have examined the effects of various boryl triflates and amines on the ratio of kinetic enolates formed. In general, it has been found that with a given base, more sterically hindered boryl triflates lead to increased amounts of the *E*(O) enolate. For example, when 3-pentanone is treated with Bu_2BOTf or $(c\text{-}C_5H_9)_2BOTf$ in the presence of *i*-Pr_2NEt, the ratio of *Z*(O):*E*(O) enolates drops from 32:1 to 4:1 (eq 2).[1c]

R_2	
Bu_2	>97:3
$(c\text{-}C_5H_9)_2$	82:18

With ketones in which no combination of boryl triflate and amine produces a vinyloxyborane of predominately one geometry, Bu_2BOTf has been utilized to catalyze the exchange with a trimethylsilyl enol ether of defined stereochemistry (eq 3). In order to maintain high stereoselectivity in the subsequent aldol reaction, it is necessary to remove the TMSOTf byproduct prior to the addition of the aldehyde (eq 3).[11]

Probably the greatest utility of this reagent has been in the stereoselective formation of chiral vinyloxyboranes with defined enolate geometries from which the absolute stereochemistry of the new chiral centers formed in the aldol process are controlled. A number of chiral masked propionate equivalents useful for the synthesis of polypropionate-like natural products have been developed for this purpose. Chiral α-hydroxy ethyl ketones derived from both enantiomers of hexahydromandelic acid have been shown to form the *Z*(O) vinyloxyborane stereospecifically with 9-BBNOTf, Bu_2BOTf, and $(c\text{-}C_5H_9)_2BOTf$. However, the size of the ligands attached to boron has a measurable effect upon the extent of the enantioselectivity achieved in the aldol process, as exemplified in eq 4.[1b]

(4)

R_2	
9-BBN	14:1
Bu_2	40:1
$(c\text{-}C_5H_9)_2$	75:1

The other major class of chiral boron enolate reagents developed for this purpose employs a propionate unit attached to a chiral auxiliary. These are typified by the chiral oxazolidinones derived from α-amino alcohols initially developed by Evans (eq 5),[2a] with subsequent variants involving thiazolidinethiones, oxazolidinethiones,[3] sultams,[4] and camphor-derived oxazolidinones[2b] being reported more recently.

Xc		
	>500:1	88%
	<1:500	89%

Other functional groups which can be utilized for further synthetic manipulation are well tolerated on the chiral vinyloxyborane. These have included thioethers,[12a] selenoethers,[12b] carboxylic esters,[2a] and halogens. For example, the bromoacetyl oxazolidinone in eq 6 has been utilized in a Darzens-like condensation for the enantioselective synthesis of *cis*-substituted epoxides.[12c] This procedure is complemented by the synthesis of *trans*-substituted epoxide derivatives from the *E*(O) vinyloxyborane derived from α-bromo-*t*-butylthioacetate.

Vinyloxyboranes also react with electrophiles other than aldehydes. For example, the chiral vinyloxyborane generated

from an *N*-propionyloxazolidinone, Bu_2BOTf, and *i*-Pr_2NEt reacts with ***N-Bromosuccinimide*** to produce the chiral bromide shown in eq 7 as the principal adduct.[13] High enantioselectivity has also been achieved in sulfenylation and selenation reactions with chiral boron enolates, an example of which is shown in eq 8.[14]

(7)

(8)

88:12

The boron enolate of *t*-butyl thioacetate has been employed in the condensation with a variety of Schiff bases to produce β-amino acid derivatives. Reported yields range from 40-80% and the conditions are sufficiently mild to allow for the preparation of a highly functionalized intermediate used in the synthesis of bleomycin (eq 9).[5] The boron component of various vinyloxyboranes is also capable of activating ***Bis(dimethylamino)methane***, resulting in a convenient one-pot procedure for the preparation of β-dimethylamino carbonyl compounds (eq 10).[15]

(9)

(10)

Simple carboxylic esters are not active enough to form enolates in the reaction with a boryl triflate and an amine; however, glycolate and thioglycolate esters are readily transformed into vinyloxyboranes which upon further reaction with aldehydes yield predominately the 2,3-*syn* aldol products (eq 11).[6]

(11)

Boryl Azaenolates.

Nitrile derivatives react with Bu_2BOTf and *i*-Pr_2NEt to produce enolates which condense with various substituted benzaldehydes to yield β-hydroxy nitrile products. Poor yields result when aliphatic aldehydes are utilized as reactants, thus limiting the scope of this reaction.[7] 2-Ethylpyridine yields predominately the 2,3-*syn* aldol product when the enolate is generated with Bu_2BOTf in the presence of ***Triethylamine*** (eq 12). No reaction occurs when *i*-Pr_2NEt is used.[8]

Macrolactonization.

Trimethylsilyl o-trimethylsilyloxycarboxylates cyclize to the corresponding macrolides in the presence of 1 equiv of a dialkylboryl triflate. Pr_2BOTf gives higher yields of product than either Et_2BOTf or Bu_2BOTf (eq 13).[9]

Di-*t*-butyl Chromate[1]

[1189-85-1] · $C_8H_{18}CrO_4$ · Di-*t*-butyl Chromate · (MW 230.22)

(selectively oxidizes allylic methylene groups to carbonyl groups; oxidizes alcohols to aldehydes and ketones)

Alternate Name: *t*-butyl chromate.

Physical Data: red crystals; oil at rt; mp -5 to 0 °C.

Solubility: sol CH_2Cl_2, C_6H_6, BuOH, *t*-BuOH, CCl_4, petroleum ether, C_6H_6 or CCl_4 or $Cl_2C{=}CCl_2/Ac_2O$/HOAc.

Preparative Method: prepared from *t*-butanol and ***Chromium(VI) Oxide*** or ***Chromyl Chloride***.

Handling, Storage, and Precautions: should be used as prepared. Chromium(VI) compounds are toxic and should be handled with care; the mutagenicity of Cr^{VI} compounds is well documented.[1f] Use in a fume hood.

Oxidation of Allylic Methylene Groups to Carbonyl Groups.

Good to excellent yields of α,β-unsaturated ketones have been obtained from the di-*t*-butyl chromate oxidation of allylic methylene groups.[2-4] The oxidation of cyclohexene affords cyclohexen-3-one and benzoquinone (eq 1).[2] Carvomenthene (**1**) is oxidized to carvotanacetone (**2**) and piperitone (**3**) (eq 2).[5-7] Similarly, verbenone may be obtained from β-pinene in 40% yield[7] and limonene (**4**) affords carvone (**5**) and isopiperitenone (**6**) (eq 3).[8]

Di-*t*-butyl chromate, in refluxing *t*-butanol, oxidizes α-ionone (**7**) to small amounts of the α,β-unsaturated ketone (**8**) and 1-hydroxy-4-keto-α-ionone (**9**) in 23-27% yield (eq 4).[9] Allylic methine carbon-hydrogen bonds are more resistant to oxidation than methylene carbon-hydrogen bonds in nonpolar solvents. Ketone (**8**) is obtained (14%, 14 days) in tetrachloromethane at 0 °C. The hydroxy ketone (**9**) was converted into abscisic acid, which is a plant hormone involved in flower and leaf abscission. Di-*t*-butyl chromate is superior to ***Chromium(VI) Oxide*** or ***Potassium Permanganate*** for oxidation of (+)-car-3-ene (**10**) to (-)-car-3-en-5-one (**11**) (eq 5).[10] Di-*t*-butyl chromate does not attack methylene groups adjacent to the cyclopropane ring, as (-)-*cis*-carane and (+)-caren-3-ol are stable under the experimental conditions.

(4)

(5)

Di-*t*-butyl chromate was found superior to ***Selenium(IV) Oxide*** or ***Dipyridine Chromium(VI) Oxide*** for oxidation of the trienone (**14**) to (**15**) (eq 6).[11] Compound (**16**) is used in the synthesis of yomogin. Oxidation of the 1,4-diene (**17**)

affords dienones (**18**) and (**19**) in the ratio 1:3 (65% total yield, eq 7).[12] Complementary regioselectivity (**18**/**19** = 9:1, 70% yield) is obtained with ***Pyridinium Chlorochromate*** (PCC). Chromium(VI) oxide-pyridine gave results similar to di-*t*-butyl chromate.

The 17β-epimer of Δ^1-5β-pregnen-20-one (**20**) was converted to progesterone (**21**) by oxidation with di-*t*-butyl chromate in tetrachloroethylene/Ac_2O/HOAc (eq 8).[13] Selective hydrogenation of progesterone (**21**) afforded 5β-pregnane-3,20-dione. Pregnenolone acetate (**22**) is oxidized at the C-7 position to afford (**23**) (eq 9).[4] Similarly, 3β,21-diacetoxypregn-5-ene-20-one has been oxidized to 3β,21-diacetoxypregn-5-ene-7,20-dione (71%).[4] Di-*t*-Butyl chromate oxidizes cholesteryl acetate (**24**) to (**25**) (eq 10).[2,14-16] 3β-Substituted (20*S*)-20-[(benzenesulfonyl)methyl]pregn-5-en-7-ones, which are useful as intermediates for hormones, growth regulators, and calcium metabolism, were prepared by allylic oxidation of the pregn-5-enes with di-*t*-butyl chromate in acetic anhydride/acetic acid.[17]

(22)

$$\xrightarrow[CCl_4,\ Ac_2O,\ AcOH]{CrO_2(O\text{-}t\text{-}Bu)_2}$$

(23) (9)

(10)

Allylic oxidation of steroidal glycosides by di-*t*-butyl chromate affords the corresponding carbonyl compounds in high yields.[18] Oxidation of a methylene group adjacent to a double bond or aromatic ring to a carbonyl group was effected in a group of diterpenes and triterpenes.[19]

Oxidation of tetrasubstituted alkenes generally leads to a mixture of products. For example, methyl 13β-abiet-8(9)-en-18-oate is oxidized to five products in tetrachloromethane.[20]

Di-*t*-butyl chromate oxidizes the substituted ether (**26**) to the 2,6-naphthoquinone derivative (**27**) in low yield (eq 11).[6] Presumably the methyl group is oxidized to a carboxyl group which undergoes decarboxylation.

(11)

Conjugated homoannular dienes are oxidized to α-diketones. 3β-Benzoyloxy-4,4,9-trimethyl-1,2,3,4,8,9-hexahydronaphthalene (**28**) is oxidized to the corresponding 6,7-dione (**29**) in tetrachloromethane containing acetic anhydride and acetic acid (eq 12).[21] Similarly, (+)-occidentalol, a sesquiterpene containing a homoannular diene, is oxidized to four products in benzene containing acetic anhydride and glacial acetic acid.[22]

Oxidation of Alcohols to Aldehydes and Ketones.

Di-*t*-butyl chromate oxidizes alcohols in nonpolar solvents.[23,24] Although aliphatic primary alcohols are oxidized to the corresponding aldehydes in low yields, allylic and benzylic primary alcohols give aldehydes in good to excellent yields. Cyclohexanol affords cyclohexanone (89%), cyclohexane-1,2-diol yields adipic acid, and cyclic vicinal glycols with one secondary and one tertiary hydroxy group are oxidized at the secondary position to give the corresponding hydroxy ketones.[25] The ultrasound-mediated di-*t*-butyl chromate ester oxidation of alcohols in dichloromethane affords aldehydes and ketones in excellent yields.[26]

The oxidation of alcohols with anhydrous ***Di-t-butyl Chromate-Pyridine*** gives high yields of aldehydes and ketones and permits large scale reactions.[27,28] The use of excess di-*t*-butyl chromate in the presence of 3,5-dimethylpyrazole selectively oxidized an allylic methylene position to a carbonyl group in the final step in the synthesis of (-)-solavetivone.[29]

Other Applications.

In CCl_4/Ac_2O/HOAc, di-*t*-butyl chromate is more effective than ***Ruthenium(VIII) Oxide*** in converting spiroethers to spirolactones.[30]

Di-*t*-butyl Chromate-Pyridine

[1189-85-1] · $C_8H_{18}CrO_4$ · Di-*t*-butyl Chromate-Pyridine · (MW 230.22)

[110-86-1] · C_5H_5N · Di-*t*-butyl Chromate-Pyridine · (MW 79.10)

(reagent for oxidizing alcohols and silyl ethers to aldehydes and ketones)

Alternate Name: *t*-butyl chromate-pyridine; chromyl chloride-pyridine-*t*-butanol.

Preparative Methods: prepared in situ from chromyl chloride, pyridine, and *t*-butanol to afford the tripyridine (x = 3) complex[1] or from chromium(VI) oxide, *t*-butanol, and pyridine to yield a complex which may contain 1 to 3 equivalents (x = 1-3) of pyridine.[2]

Handling, Storage, and Precautions: all chromium(VI) reagents must be handled with care; the mutagenicity of Cr^{VI} compounds is well documented.[3] This reagent should be handled in a fume hood.

Oxidation of Alcohols to Carbonyl Compounds.

Addition of ***Chromyl Chloride*** to a solution of pyridine in dichloromethane, cooled in a dry ice-acetone bath, gave a strong oxidizing mixture which oxidized primary alcohols to aldehydes in good to excellent yields on a small scale.[1] Addition of *t*-butanol generated a milder oxidant which could be ***Di-t-butyl Chromate*** or a di-*t*-butyl chromate-tripyridine complex.[1,4,5] This reagent is suitable for both small and large scale reactions. Cinnamyl alcohol, cyclododecanol, citronellol (eq 1), 1-dodecanol, and geraniol (eq 2) are oxidized to the corresponding carbonyl compounds in 86, 97, 93, 99, and 100% yield, respectively.[1] Although this reagent is inferior to the Collins reagent (see ***Dipyridine Chromium(VI) Oxide***) for oxidizing allylic alcohols owing to isomerization of the carbon-carbon double bond (eq 2), it offers advantages for the oxidation of simple saturated primary alcohols.

(1)

(2)

3:1

The reagent prepared from chromium(VI) oxide oxidizes primary trimethylsiloxy groups to aldehydes and does not attack acid-labile groups, double bonds, ether groups, or allylic methylene groups in the same molecule.[3] Although secondary silyl ether groups are oxidized to ketones by the reagent, they are stable to the experimental conditions used for the oxidation of primary silyl ether groups. For example, (±)-[(1*R*,2*S*,3*R*,5*S*)-2-[(trimethylsiloxy)methyl]-3-(trimethylsiloxy)-6-oxabicyclo[3.3.0]octan-7-one is oxidized to (±)-[(1*R*,2*S*,3*R*,5*S*)-2-formyl-3-(trimethylsiloxy)-6-oxabicyclo[3.3.0]octan-7-one.

It is of interest to note that di-*t*-butyl chromate oxidizes primary aliphatic alcohols in benzene or petroleum ether at room temperature to a mixture of the aldehyde, acid, and the ester of the acid.[5] It oxidizes cinnamyl alcohol and geraniol to the corresponding aldehydes in 61 and 77% yield, respectively.[5]

Di-*t*-butyl Dicarbonate

[24424-99-5] · $C_{10}H_{18}O_5$ · Di-*t*-butyl Dicarbonate · (MW 218.25)

(efficient *t*-butoxycarbonylating agent for amines,[1,2] phenols, and thiols; *t*-butoxycarbonylation of alcohols, amides,[3] lactams, carbamates[4] and NH-pyrroles[5] occurs in the presence of 4-dimethylaminopyridine)

Alternate Names: di-*t*-butyl pyrocarbonate; Boc anhydride; Boc_2O.

Physical Data: mp 22-24 °C; bp 56-57 °C/0.5 mm Hg; fp 37 °C; *d* 0.950 g cm^{-3}; n_D^{20} 1.4103.

Solubility: insol cold H_2O; sol most organic solvents such as decalin, toluene, CCl_4, THF, dioxane, alcohols, acetone, MeCN, DMF.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: IR 1810 and 1765 cm^{-1}; NMR 1.50 (CCl_4).

Preparative Method: prepared by the action of ***Phosgene*** on potassium *t*-butyl carbonate, followed by conversion of the obtained di-*t*-butyl tricarbonate under the action of basic catalysts such as ***1,4-Diazabicyclo[2.2.2]octane***.[6]

Handling, Storage, and Precautions: the liquid is flammable and must be stored in a refrigerator in the absence of moisture. Do not heat above 80 °C.

t-Butoxycarbonylation of Amines.

Owing to the instability of the corresponding chloride (***t-Butyl Chloroformate***), the Boc_2O reagent is widely used for the introduction of the *t*-butoxycarbonyl amino protecting group (Boc). This group is easily removed under moderately acidic conditions such as treatment with ***Trifluoroacetic Acid***, or by thermolysis. The Boc-NHR group is not hydrolyzed under basic conditions and is inert to many other nucleophiles.[1] Therefore the use of this amino protecting group is not limited to amino acid and peptide synthesis; it has been extended to the synthesis of amino sugars, alkaloids, etc. The great importance of the *t*-butyl carbamate function in peptide synthesis is not only due to the ease of its cleavage, but also to the fact that the oxazolones formed from the activated *N*-alkoxycarbonyl amino

acids do not usually epimerize (racemize) during coupling with amines.[7]

Boc_2O reacts smoothly and rapidly with amino compounds in organic solvents, or aqueous organic solvent mixtures, to form pure derivatives in high yields, the only byproducts being the innocuous and easily removable *t*-butanol and carbon dioxide (eq 1). Innumerable examples are available.[8-11] ***Hydroxylamine*** slightly accelerates the reaction through the in situ formation of the Boc-ONH_2 intermediate.[12] The reaction is also accelerated by sonication of the amine salts.[13]

Aliphatic,[14] alicyclic,[15] aromatic,[16,17] and heterocyclic amines[18,19] have been *t*-butoxycarbonylated under a variety of conditions. Anilines are sometimes heated at reflux in THF to obtain the corresponding Boc derivatives in good yields. However, *t*-butoxycarbonylation also occurs at rt,[17] and 4-aminobenzoic acid reacts in DMF/aq NaOH at rt.[20] The Boc-NHR substituent is an *ortho*-directing group in heteroatom-facilitated lithiations of aromatic and heterocyclic amines.[16,18,19,21] Reaction of the resultant carbanions (eq 2), as well as that of the analogous benzylic carbanions, with electrophiles is a powerful method for the synthesis of substituted anilines and heterocycles.[16,22]

Asymmetric deprotonation of Boc-pyrrolidine with ***s-Butyllithium/(-)-Sparteine*** gives a chiral organolithium reagent, which undergoes reaction with electrophiles to give enantiomerically enriched products.[23] The sequence of equatorial α-lithiation followed by an electrophilic substitution of a series of *N*-Boc cyclic amines provides amines which are substituted adjacent to the nitrogen atom.[15]

A suspension of 4-dimethylaminopyridinium fluoroborate in ethyl acetate reacts with Boc_2O to give the corresponding 1-*t*-butoxycarbonyl-4-dimethylaminopyridinium salt, which is an efficient water-soluble agent for the *t*-butoxycarbonylation of amines (eq 3).[24]

Interesting chemo- and regioselective alkoxycarbonylation of polyfunctional substrates, e.g. diamines, amino alcohols, and amino acids, can be achieved under mild conditions. Treatment of α,o-alkanediamines (6-10 molar excess) with the reagent in dioxane or acetone as solvent leads to the corresponding mono-Boc diamines in 75-90% yields (eq 4).[25,26]

*N*ε-Boc-L-lysine has been selectively prepared from the copper complex of lysine.[27] This complex, as well as that

of N^{δ}-Boc-L-ornithine, has been directly benzyloxycarbonylated to give the corresponding α-Cbz-ε-Boc amino acids (eq 5).[28]

In CH_2Cl_2 at low temperature, selective *t*-butoxycarbonylation of a β-amino- in the presence of an α-amino-ester function has been recently realized (eq 6).[29]

The substitution of a secondary amino group in the presence of a primary amine has been performed by an indirect route: formation of the labile Schiff base of the primary amine and then *t*-butoxycarbonylation of the secondary nitrogen (eq 7).[30] Selective protection of polyamines may also be achieved by an indirect route in the presence of DMAP (see below).

The Boc_2O reagent has been widely used for the *N*-protection of amino acids and peptides. When a carboxylic acid function is present in the molecule, 1 equiv of base (NaOH, Et_3N, Triton B) is necessary (eq 8).[10,11,31]

To avoid loss of the *O*-labeling, trialkylammonium salts of amino acids have been *t*-butoxycarbonylated in dry methanol or DMF.[32] *N*-*t*-butoxycarbonylation of an alkaline labile and hindered 2,2-dimethylthiazolidine-4-carboxylic acid has been performed in acetonitrile (eq 9).[33]

In the presence of pyridine, a free carboxylic function reacts with the reagent to give a mixed anhydride (see below). This reaction also occurs during the acylation of an amino acid salt with Boc_2O and is responsible for the formation of small amounts of dipeptide byproducts by aminolysis of the mixed anhydride intermediate (eq 10).[34]

t-Butoxycarbonylation of phenolic amino acids in aqueous ***Potassium Hydroxide*** gives the *N*,*O*-bis-Boc derivatives.[35] Under phase-transfer conditions, selective *N*-*t*-butoxycarbonylation of tyrosine ethyl ester has been observed (see below). The SH group of cysteine,[36] the imidazole of histidine,[37] and even the guanidine function of arginine[38] have been acylated. Boc_2O has been used for the chemical modification of histidine residues of proteins.[39] For the *t*-butoxycarbonylation of insulin, Boc_2O is much more reactive than the corresponding succinimidyl and *p*-nitrophenyl esters.[40] Bamberger ring-cleavage of the imidazole nucleus slowly occurs in the presence of ***Potassium t-Butoxide***.[41] Selective *N*-protection of amino alcohols is also easily performed (eq 11).[42]

At pH 10.3, hydroxylamine itself gives the *O*-substituted product,[12] whereas treatment of *N*-alkylhydroxylamines in dioxane furnishes the *N*-Boc derivatives (eq 12).[43] The *O*-Boc hydroxylamine[12,44] as well as *O*-Boc oximes[45] are themselves efficient *t*-butoxycarbonylating agents.

Hydrazines and hydrazides are acylated by the reagent.[46] The mono-Boc derivatives of hydrazine or phenylhydrazine, obtained in isopropanol, react further with Boc_2O in benzene or dioxane to give the $(Boc\text{-}NR)_2$ diacylated derivatives. Regioselective N^{α}-protection of ethyl hydrazinoacetate is performed at 0 °C and the product used for the synthesis of hydrazino peptides (eq 13).[47]

Boc-amines can also be prepared directly from azides by hydrogenation in the presence of Boc_2O (eq 14).[48]

The alkylation of Boc-amines, particularly that of the more acidic Boc-anilines[17] and the selective alkylation of *N*-Boc amino acids,[49-51] has been done by using an alkylating agent and ***Sodium Hydride*** or ***Silver(II) Oxide*** as a base. For the *N*-perbenzylation of *N*-Boc peptides a P4-phosphazene base (see ***Phosphazene Base P_4-t-Bu***) has been used at -100 °C.[52]

Exchange of Amino-Protecting Groups.

N-Benzyloxycarbonyl (Cbz) and 9-fluorenylmethyloxycarbonyl (Fmoc) amino protecting groups are also widely used in peptide synthesis.[2] The choice of protecting groups, and hence of the conditions for their cleavage (Cbz: hydrogenolysis or HBr/HOAc; Fmoc: piperidine or F^-)[1] plays a key role in the planning of a synthesis. For instance, orthogonal protection (Boc/Cbz or Fmoc/Boc or Cbz) is of crucial importance in the case of the trifunctional amino acids. For a given peptide segment, chemoselective transformation of an amino protecting group into another one under neutral conditions may be very useful for the synthesis.

In the presence of a slight excess of Boc_2O, conversion of a benzyl carbamate into a *t*-butyl carbamate has been achieved by catalytic hydrogenation,[53] or by the use of cyclohexadiene as an hydrogen donor (eq 15).[54] The catalytic transfer hydrogenation is the more selective: benzyl and BOM ethers are stable under the reaction conditions. The Cbz -> Boc transformation can also be performed using triethylsilane and a palladium catalyst.[53] The replacement of a Fmoc group by a Boc group has recently been achieved by the in situ cleavage of the Fmoc group with ***Potassium Fluoride*** in DMF (eq 15).[55]

Ar = Ph

t-Butoxycarbonylation of Phenols, Alcohols, Enols, and Thiols.

In alkaline media the nucleophilic phenolate salts are easily *t*-butoxycarbonylated.[35,56] Acylation of *p*-dimethylsulfoniophenol gives a sulfonium salt which is a new water-soluble *t*-butoxycarbonylating agent for amino acids.[57] Under anhydrous conditions, thiolate salts are also substituted in good yields using the Boc_2O reagent.[56] Under phase-transfer conditions, *t*-butoxycarbonylation of phenols as well as enols, thiols, or alcohols can be realized. For phenols, enols, and thiols, K_2CO_3 (powder)/18-crown-6/THF are the best experimental conditions. Biphasic

conditions (Bu_4NHSO_4/CH_2Cl_2/aq. NaOH) are also effective with sluggish alcoholic groups.[56] Using 1 equiv of Boc_2O, selective *N*-*t*-butoxycarbonylation of tyrosine ethyl ester can be achieved. *N*,*S*-Bis(Boc)-cysteine ethyl ester has also been prepared.[56] The *t*-butoxycarbonylation of alcohols to give alkyl *t*-butyl carbonates is efficiently catalyzed by DMAP.[58]

t-Butoxycarbonylation of Amides, Lactams, and Carbamates.

In the presence of ***4-Dimethylaminopyridine***, Boc_2O is a strong acylating agent able to react with the weakly nucleophilic amide and carbamate groups under anhydrous conditions. The reaction probably involves a 1-*t*-butoxycarbonyl-4-dimethylaminopyridinium ion intermediate (eq 3).[24] This enhanced reactivity has led to numerous interesting synthetic applications. A wide range of amides, lactams, and urethanes have been converted to the corresponding Boc derivatives using Boc_2O as reagent and DMAP as catalyst.

Secondary amides and lactams react with Boc_2O in the presence of both ***Triethylamine*** and DMAP in CH_2Cl_2 to give stable *N*-*t*-butoxycarbonylated products (eq 16).[3] In the reaction of disubstituted pyrrolidones, the yields are much higher using THF as solvent than with dichloromethane.[59]

(16)

Exhaustive acylation of a series of secondary amides has also been performed with Boc_2O in dry acetonitrile at ambient temperature using DMAP as catalyst. The method has some steric limitations. For instance, it is retarded in the case of the *ortho*-substituted benzamides. The reaction has been extended to the acylation of carbamates and other amide type functions: sulfonamides, sulfenamides, and phosphinamides.[60] β-Lactams are also *N*-protected in good yields (eq 17).[61]

(17)

Primary carboxamides react with 2 equiv of Boc_2O and 1 equiv of DMAP to give isolable *N*-acylimidodicarbonates which are acylating agents for amines (eq 18).[62] Formamide itself furnishes the unstable di-*t*-butyl *N*-formylimidodicarbonate (eq 19).[63]

(18)

(19)

Grieco has shown that the regioselective hydrolysis or methanolysis of *N*-*t*-butoxycarbonyl derivatives of amides and lactams affords the corresponding carboxylic acids or methyl esters, respectively (eq 16).[3] ***1,1,3,3-Tetramethylguanidine*** efficiently catalyzes the methanolic cleavage.[64] Grieco's method has been applied to a formal synthesis of gabaculine, in which ***Lithium Hydroxide*** treatment induces both sulfoxide elimination and lactam cleavage (eq 20).[65]

(20)

Other regioselective attacks at the acyl function are known. Aminolysis of substituted pyrrolidones gives the corresponding *N*-Boc γ-amino acid amides.[59] The *N*-Boc five- to eight-membered lactams are cleaved with Grignard reagents at the endocyclic carbonyl group to give o-Boc-amino ketones,[66-68] which can be deprotected with TFA and cyclized with NaOH to yield cyclic imines.[67] Regioselective ring opening of the *N*-Boc-pyroglutamate ethyl ester with the lithium enolates of carboxylic esters, dithiane anion, alcohols, amines, and thiols occurs without epimerization.[69-71] Selective cleavage of cyclic carbamates gives *N*-protected amino alcohols (eq 21). In this reaction, methyl ester substituents are not transformed into acids by using ***Cesium Carbonate*** as a base.[72]

(21)

The selective deacylation of *N*-Boc carboxamides has also been achieved by aminolysis to give *N*-Boc amines. 2-Diethylaminoethylamine in acetonitrile is particularly convenient, but other conditions such as hydrazine in methanol can also be used.[64,73] Aminolysis of di-*t*-butyl *N*-formylimidodicarbonate affords di-*t*-butyl imidodicarbonate, $HN(Boc)_2$ (eq 19).[63] This compound, as well as the unsymmetrical benzyl *t*-butyl imidocarbonate, has been used as a substitute for ***Phthalimide*** in the Gabriel and Mitsunobu reactions to give primary amines. Compared to the classical method, which requires the hydrazinolysis of the phthaloyl protecting group, the main advantage of these novel Gabriel reagents is the much milder and rather specific conditions for the final deprotection step.[74] The lithium salt of $HN(Boc)_2$ has also been used in a palladium-catalyzed allylic amination.[75] Labeled di-*t*-butyl imidodicarbonate leads to ^{13}C and ^{15}N glycine derivatives.[76] Alkylation with triflates prepared from α-hydroxy acid esters gives ^{15}N-labeled chiral Boc-amino acids suitable for the synthesis of labeled peptides.[77]

t-Butoxycarbonylation of benzyl or allyl *N*-Boc or *N*-Cbz amino acid esters using Boc_2O/DMAP gives *N*-bis(alkoxycarbonyl) amino acid esters. Specific cleavage of the allyl protecting group with ***Chlorotris(triphenylphosphine)rhodium(I)***, or hydrogenolysis of the benzyl ester function, respectively, gives N^{α}-benzyloxycarbonyl, N^{α}-*t*-butoxycarbonyl or N^{α}-di-*t*-butoxycarbonyl amino acids (eq 22).[78,79]

where H_2, Pd/C is used, R^2 = Bn, Y = Boc
where $(PPh_3)_3RhCl$ is used, R^2 = allyl, Y = Cbz or Boc

The di-*t*-butoxycarbonyl amino acids have been applied to solution peptide synthesis using the ***1,3-Dicyclohexylcarbodiimide*** or *p*-nitrophenyl ester method in DMF for coupling[79]

Reaction of a bis(alkoxycarbonyl)amino acid pyridinium salt with cyanuric fluoride at -30 °C gives a *N*-bis(alkoxycarbonyl)amino acid fluoride (eq 23). Owing to the high electronegativity and small size of the fluorine atom, this derivative is an efficient acylating agent for amines and pyrrole anions.[80] Use of the Vilsmeier reagent instead of cyanuric fluoride leads to a chemically and optically pure *N*-Boc or *N*-Cbz amino acid *N*-carboxy anhydride (Boc- or Cbz-NCA) without the use of phosgene and the unstable *t*-butyl chlorocarbonate (eq 23).[80] Peptide synthesis with these urethane protected amino acid *N*-carboxy anhydrides (U-NCAs) is a very clean reaction which liberates only CO_2 as a byproduct.[81]

(23)

Treatment with $Boc_2O/DMAP_{cat}$ allows exhaustive *N*-*t*-butoxycarbonylation of some peptides.[82] The *t*-butoxycarbonylation of the internal amide bonds favors the cyclization of the peptides.[83] Interestingly, one Boc group can be selectively removed from a bis(Boc)-amine[75,76] with a slight excess of trifluoroacetic acid. Use of the $Boc_2O/DMAP_{cat}$/MeCN conditions also allows selective protection of mixed primary-secondary diamines. *t*-Butoxycarbonylation of a *N*,*N*´-bis(benzyloxycarbonyl)diamine followed by hydrogenolysis of the Cbz groups furnishes the *t*-butoxycarbonylated derivative of the primary amino function (eq 24).[84] Analogous strategies have been used for the selective indirect acylation of polyamines such as spermidine.[85,86]

(24)

The *t*-butoxycarbonylation of the sodium salt of thiourea does not require DMAP catalysis. The resulting *N*,*N*´-bis(*t*-butoxycarbonyl)thiourea reacts with amines to give bis(*t*-butoxycarbonyl)guanidines (eq 25).[87]

Sequential diacylation of 1-guanidinylpyrazole gives the *N*,*N*´-bis(Boc)-guanidinylpyrazole, which is also an efficient reagent for the conversion of amines to protected monosubstituted guanidines and therefore for the synthesis of arginine-containing peptides from their ornithine counterparts (eq 26).[88]

N-*t*-Butoxycarbonylation of Pyrroles and Indoles.

A series of substituted pyrroles and indoles[89-92] react smoothly with Boc_2O in the presence of catalytic amounts of DMAP in CH_2Cl_2 or acetonitrile to give the corresponding *N*-Boc pyrrole or indole derivatives. The *N*-*t*-butoxycarbonylation allows direct lithiation α to the indole and pyrrole nitrogen at low temperature. Alternatively, lithium-halogen exchange of *N*-Boc-2-bromopyrroles generates the *N*-protected 2-lithiopyrroles (eq 27).[91] After reaction with an electrophile, the Boc protecting group is easily removed either by methoxide ion in methanol or by thermolysis.[90,93]

(27)

X = H, LiB = lithium tetramethylpiperidide
X = Br, LiB = BuLi

In the reaction with Boc_2O/DMAP, N^{α}-Boc-tryptophan methyl ester affords the N^{α},N^{in}-di-Boc derivative in almost quantitative yield. This product has been used in peptide synthesis. Moreover, selective cleavage of the N^{α}-Boc group is possible in the presence of the N^{in}-Boc function by using 2.7 N HCl in dioxane.[94]

Activation of the Carboxyl Group. Formation of Esters and Anhydrides.

In the presence of ***Pyridine*** in aprotic solvents, the carboxyl function of a carboxylic acid or a *N*-Boc-amino acid is activated with the Boc_2O reagent. The resulting mixed anhydride can react further with one molecule of the starting acid to give a symmetrical anhydride. At an equimolar ratio of the acid and the Boc_2O reagent a mixture of the mixed and the symmetrical anhydrides is formed. If 2 equiv of acid are used, the symmetrical anhydride becomes the main reaction product. Addition of certain nucleophilic agents to the Boc_2O/carboxylic acid/pyridine mixture leads to the acylation of the nucleophile (eq 28).[58]

(28)

From a preparative point of view, it is essential that Boc_2O reacts much more rapidly with the carboxylate function than with the nucleophile. The reaction has been applied to the synthesis of aryl and alkyl esters and anilides such as *o*-nitrophenyl, benzyl, or trifluoroethyl esters and *p*-nitroanilides of *N*-protected amino acids. The formation of esters derived from secondary alcohols (benzhydryl, menthyl, or cholesteryl esters) is accelerated by addition of DMAP.

Depsipeptides are obtained in good yields. DMAP is a necessary catalyst for the synthesis of *t*-butyl esters and the esterification of *N*-protected amino acids occurs without epimerization.[58]

t-Butoxycarbonylation of Carbanions.

Preferential *C*-*t*-butoxycarbonylation of diethyl acetamidomalonate occurs by treatment with $Boc_2O/DMAP_{cat}$ in acetonitrile (eq 29).[60] From the reaction of the potassium salt of diphenylphosphinyl isocyanide and Boc_2O in CH_2Cl_2 at -70 °C, the corresponding Wittig-Horner reagent, *t*-butyl (diphenylphosphinyl)isocyanoacetate, is formed in near quantitative yield.[95] Similarly, treatment of α-lithioalkylphosphonates with Boc_2O gives *C*-*t*-butoxycarbonylated enolates which react with aldehydes to give substituted *t*-butyl acrylates.[96] The lithium salt of the Schiff base derived from the aminomethyldiphenylphosphine oxide reacts with Boc_2O at low temperature to give the imine of *t*-butyl α-(diphenylphosphinoyl)glycinate.[97]

t-Butoxycarbonylation of Imines.

In previous examples, the acylation occurred either at the amino function[30] or at the carbanionic center[97] and not at the imine function. However, the reaction of a nucleophilic imine possessing an electron-releasing substituent (Ar = *p*-$MeOC_6H_4$) with Boc_2O in ethanol proceeds through the intermediacy of an *N*-alkoxycarbonyl iminium ion to give an α-ethoxy carbamate (eq 30). As the trapping of the iminium ion by the alcohol is a reversible process, the α-ethoxy *t*-butyl carbamate is a precursor of the electrophilic *N*-Boc iminium ion in an intermolecular condensation with propargyltrimethylsilane.[98]

Di-*t*-butyldichlorosilane

t-Bu_2SiCl_2

[18395-90-9] · $C_8H_{18}Cl_2Si$ · Di-*t*-butyldichlorosilane · (MW 213.22)

(reagent for the protection of diols; used as a silylene precursor)

Physical Data: mp -15 °C; bp 190 °C/729 mmHg; *d* 1.009 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: liquid.

Preparative Methods: can be conveniently prepared by chlorination of di-*t*-butylsilane ($CCl_4/PdCl_2$ (cat), 85%)[1,2] but various other methods of preparation have been reported.[3-6]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; reacts with hydroxylic solvents, corrosive; lachrymator. Use in a fume hood.

Protection of Alcohols.

The presence of the bulky *t*-butyl groups in di-*t*-butyldichlorosilane has been found to increase the Si-C bond lengths slightly and to widen the CSiC bond angles by 11.1° relative to ***Dichlorodimethylsilane*** as determined by electron diffraction and molecular mechanics calculations.[7]

The di-*t*-butylsilylene protecting group for diols was introduced by Trost and Caldwell[4] and used in a total synthesis of deoxypillaromycinone.[5] It is introduced by the reaction of di-*t*-butyldichlorosilane with a 1,2- or 1,3-diol in acetonitrile in the presence of ***Triethylamine*** and ***1-Hydroxybenzotriazole*** (HOBt) at 45-90 °C (eq 1). For a related, highly reactive reagent see ***Di-t-butylsilyl Bis(trifluoromethanesulfonate)***.

(1)

When at least one of the hydroxy groups is phenolic or primary, reactions proceed smoothly at 25-65 °C, but when both hydroxy groups are secondary, more forcing conditions (95 °C, sealed tube) are required. In all cases, yields range from 64% to 85%. No examples have been reported with tertiary alcohols. ***Pyridinium Poly(hydrogen fluoride)*** is used for deprotection and under those conditions a *t*-butyldimethylsilyl ether and a β-hydroxy ketone are unaffected (eq 2).

(2)

This protecting group has seen limited use but has been applied in ribonucleoside chemistry.[8-10] The reagent reacts slowly with nucleosides in the presence of imidazole/DMF but formation of the more reactive di-*t*-butylsilyl dinitrate in situ, followed by addition of cytidine, results in a protected 3´,5´-silylene derivative in excellent yield (90%) (eq 3). The protecting group can be removed conveniently with tributylamine hydrofluoride.[11]

(3)

A one-pot procedure has been reported for the selective protection of a secondary alcohol over a primary alcohol in a 1,3-diol in 2´-deoxynucleosides (eq 4).[12,13]

Derivatization of Diols and Hydroxy Acids.

Di-*t*-butyldichlorosilane has been used to derivatize α-hydroxy acids, β-hydroxy acids, alkylsalicyclic acids, anthranilic acid, catechols, and 1,2- and 1,3-diols for analysis by gas chromatography-electron impact mass spectrometry (eq 5).[14,15] These derivatives are useful for separation. The major fragmentation is that of Si-C bonds. The 1,2-diol in the antibiotic sorangicin has also been derivatized with di-*t*-butyldichlorosilane.[16]

m/z 304 (M^+), 247 (M^+ - Bu), 205 (B, 247 - C_3H_6)

Silylene Precursor.

Di-*t*-butyldichlorosilane can be reduced using ***Lithium***/THF to give a putative silylene derivative that will react with double bonds to give 1,1-silirane derivatives[17-19] or react with triethylsilane to give an Si-H insertion product (eq 6).[17]

(6)

Reaction of di-*t*-butyldichlorosilane with ***Lithium Naphthalenide*** in DME gives compound (**1**) which upon irradiation gives, in addition to naphthalene, tetra-*t*-butyldisilene that subsequently reacts with 2,3-dimethylbutadiene to give a Diels-Alder adduct along with a product arising from an ene reaction (eq 7).[20]

(1)

(7)

Reduction of di-*t*-butyldichlorosilane with lithium in THF at 0 °C in the presence of an excess of ***Dichlorodimethylsilane*** gives compound (**2**).[21] Reaction of di-*t*-butyldichlorosilane with lithium and 1,4-diaza-1,3-butadienes gives 1,3-diaza-2-sila-4-cyclopentenes (eq 8).[22]

(2)

(8)

Other Substitution Reactions.

The chlorine atoms in di-*t*-butyldichlorosilane can be replaced with various nucleophiles. Di-*t*-butyldifluorosilane has been prepared by using SbF_3,[23,24] ZnF_2,[25] or $(NH_4)_2SiF_6$.[26,27] Reaction of di-*t*-butyldichlorosilane with ***Lithium Aluminum Hydride*** gives di-*t*-butylsilane[28] and reaction with ***Sodium Azide*** gives di-*t*-butyldiazidosilane; upon irradiation this gives a putative di-*t*-butylsilylene which undergoes various reactions depending on the conditions.[29] Reactions of di-*t*-butyldichlorosilane with LiPHMe[30] and $LiPH_2$[31] yield (**3**) and (**4**), respectively.

(3)

(4)

Treatment of di-*t*-butyldichlorosilane with ***Trimethylsilyllithium*** gives di-(*t*-butyl)bis(trimethylsilyl)silane.[32]

Di-*t*-butyl Hyponitrite[1]

[14976-54-6] · $C_8H_{18}N_2O_2$ · Di-*t*-butyl Hyponitrite · (MW 174.24) (*E*)

[82554-97-0]

(a convenient, low-temperature source of *t*-butoxyl radicals;[1] induces serial cyclization of polyunsaturated hydroperoxides,[2] rearrangement of allylic hydroperoxides,[3] and reduction of alkyl halides or dialkyl sulfides with Et_3SiH;[4] used in radical-trapping experiments;[5] and as initiator for dimerization[6] and polymerization[7])

Alternate Names: DTBN; TBHN; DBH.

Physical Data: white crystals mp 84.5 °C (dec);[1d] volatile (0.1 mmHg at rt).[1a]

Solubility: insol H_2O; sol common organic solvents (e.g. hexane, benzene, toluene, CCl_4, and EtOH).

Analysis of Reagent Purity: NMR ($CDCl_3$, δ) ^1H 1.33 (s); IR (cm^{-1}) 2959, 1368, 1183, 995;[1a] for IR and Raman band assignments, see Ogle et al.;[8] UV (λ_{max}, pentane) 223.4 nm (ε 7140 M^{-1} cm^{-1});[1d] the *trans* structure has been established by X-ray analysis.[8]

Preparative Method: obtained in 80-90% yield by reaction of sodium hyponitrite with *t*-BuBr in the presence of ***Iron(III) Chloride*** or ***Zinc Chloride***.[9] The preparation of sodium hyponitrite (from Na, benzophenone, and nitric oxide)[10a] must be performed with extreme care.[10b]

Handling, Storage, and Precautions: although DTBN appears to be insensitive to scratching and is considered as safe,[1a] it can detonate when struck.[1d] Mixtures of DTBN with formamides undergo violent reaction or explosion when heated at 60-70 °C.[6] Due to the potential risk of explosion, it is strongly recommended that all operations involving DTBN be carried out behind a safety shield using tongs, gloves, and a safety mask. Since DTBN is quite volatile, most of the unchanged material can be conveniently removed at the end of a reaction by flushing the mixture with N_2 or Ar.[5,11a] Solid DTBN can be kept intact for several months at -10 °C or below.

Thermal Decomposition.

DTBN is used as a clean source of *t*-butoxyl radicals in the temperature range of 20 to 90 °C (eq 1).[1b] Decomposition probably involves a simultaneous two-bond scission.[1c,d] In low viscosity solvents, 4-10% of *t*-butoxyl radicals are wasted through cage recombination to form di-*t*-butyl peroxide.[1a,b] Compared to ***Di-t-butyl Peroxyoxalate*** (DBPO), which also delivers *t*-butoxyl radicals at rt, DTBN decomposes more slowly and is far less sensitive to shock or scratching.[1a] From published data,[1a] the half-life ($t_{1/2}$) of DTBN in isooctane is calculated to be ca. 425 min at 45 °C ($t_{1/2}$ of DBPO at 45 °C in benzene is about 44 min).[12] Unlike DBPO, DTBN is resistant to induced decomposition in both protic and aprotic solvents even at high concentrations.[1a]

Peroxyl Radical Serial Cyclizations.

In the presence of DTBN and oxygen, polyunsaturated hydroperoxides undergo multiple cyclizations to form polycyclic peroxides.[2,13] Thus compound (**1**) cyclizes by a 6-*exo*-trig mode to afford, after selective reduction of the resulting hydroperoxides (**2**), five diastereomeric hydroxy-bis-1,2-dioxanes (**3**) in nearly 70% overall yield (eq 2).[2] Similarly, bis-1,2-dioxolanes are accessible from suitable substrates through a 5-*exo* closure.[13] For a more detailed discussion and further examples of peroxyl radical cyclizations, see ***Di-t-butyl Peroxyoxalate***.

Allylic Hydroperoxide Rearrangement.

The [2,3]-rearrangement of allylic hydroperoxides is catalyzed by radical initiators or by light.[3] With few exceptions,[14] DTBN is particularly effective in accelerating the process at 20-40 °C.[3,15] Rearrangement is highly stereoselective at rt, as illustrated by the transformation of (**4**) (>99% ee) into a 1.7:1 mixture of (**4**) and (**5**), which are obtained with ee's of 97-99% (eq 3).[15a] Both experimental[15b] and theoretical[16] results suggest that an allyl radical-dioxygen pair is involved.

Radical Chain Reductions.[4]

Saturated primary, secondary, or tertiary alkyl halides undergo essentially quantitative reduction to the corresponding alkanes upon treatment with DTBN, ***Triethylsilane***, and *t*-dodecanethiol (mixture of isomers). An example is shown in eq 4. Likewise, dialkyl sulfides are reduced to alkanes in excellent yields. The thiol acts as a polarity reversal catalyst which mediates hydrogen-atom transfer from the silane to the alkyl radical.

Miscellaneous Applications.

In several cases, dimerization of organic compounds can be achieved in better yields by using DTBN instead of conventional initiators such as ***1,1-Di-t-butyl Peroxide*** or acetyl peroxide (eq 5).[6]

DTBN is also used as an initiator for autoxidation,[11] radical polymerization,[7,17] and in radical-trapping experiments.[5]

Related Reagents.

t-Butyl Hydroperoxide; ***Dibenzoyl Peroxide***; ***1,1-Di-t-butyl Peroxide***; ***Di-t-butyl Peroxyoxalate***; ***m-Nitrobenzenesulfonyl Peroxide***; ***p-Nitrobenzenesulfonyl Peroxide***; ***Triethylsilane***.

Dibutylmagnesium

[3988-32-8] · $C_8H_{18}Mg$ (mainly) · Dibutylmagnesium · (MW 145 (av))

(magnesiating agent of various activated C-H bonds[1] and protic functional groups; can be halogenated to make finely divided anhydrous magnesium chloride or bromide)

Alternate Name: DBM.

Physical Data: waxy solid; for 1 M heptane solution, *d* 0.72 g cm^{-3}, viscosity 0.91 cP at 25 °C and 0.76 cP at 35 °C.

Solubility: moderately sol (<1.3 M) aliphatic and aromatic hydrocarbons; highly sol ethereal solvents; reacts exothermically with water and protic solvents.

Form Supplied in: available as 0.7-1 M solution in heptane.[2]

Analysis of Reagent Purity: determined by total alkalinity and magnesium content using standardized EDTA. Will react with oxygen to form soluble alkoxides which could lead to incorrect assay.

Preparative Method: via a two-step process (eq 1).[3,4]

Handling, Storage, and Precautions: commercial solution is stable indefinitely if kept cool and sealed under inert atmosphere; however, isolated solids are pyrophoric. Main hazard is possibility of solvent ignition due to exothermic reaction between dibutylmagnesium and water in any form (including moist air).

Introduction.

Dibutylmagnesium is a stable and Lewis base-free organomagnesium composition. Hydrocarbon solubility of DBM results from the 1:1 ratio of *n*-alkyl to *s*-butyl groups. In synthesis, DBM is used as a metalating or magnesiating agent. Care must be taken to ensure that both equivalents of alkyl groups react because the second equivalent reacts more slowly than the first.

Magnesiation of Hydrocarbyl Substrates.

Cyclopentadiene (eq 2) and phenylacetylene (eq 3) are metalated with DBM.[1] Magnesiated substrates of cyclopentadiene undergo metathesis with transition metal halides.[5] Although sulfones[1] and α-picoline[6] derivatives can be magnesiated in heptane, toluene and triphenylmethane cannot.[1]

(2)

$$2\ PhC{\equiv}CH + DBM \xrightarrow[\text{25 °C, 1 h; 93\%}]{\text{heptane}} (PhC{\equiv}C)_2Mg \qquad (3)$$

Magnesiation of More Acidic Substrates.

Carboxylic acids,[7] alcohols,[5,8] and amines[5,9] can be deprotonated with DBM. Metalation of β-branched secondary amines, such as ***Diisopropylamine*** and ***2,2,6,6-Tetramethylpiperidine***, produce magnesium bis-organoamides which are hydrocarbon soluble.[9] Several magnesium organoamides have been used for magnesiation, reduction,[10] and amidation.[11]

Finally, DBM has many uses in polymerization, e.g. it provides a source of magnesium chloride[12] for Ziegler-Natta catalysts. For synthesis, anhydrous and Lewis base-free magnesium bromide is easily prepared at 30-45 °C by controlled, sparged addition of anhydrous HBr (2.01 mol) to 0.5 M DBM in heptane (2.0 mol). When the resulting slurry becomes acidic, excess HBr is removed by reflux with proper scrubbing. The solids are isolated, washed with pentane, and dried by an inert gas using an enclosed filter.

(2,6-Di-*t*-butyl-4-methylphenoxy)methylaluminum Trifluoromethanesulfonate

[82866-56-6] · $C_{17}H_{26}AlF_3O_4S$ · (2,6-Di-*t*-butyl-4-methylphenoxy)methylaluminum Trifluoromethanesulfonate · (MW 410.43)

(designer Lewis acid for allylic ether cleavage and its application to biogenetic-type terpene synthesis[1])

Solubility: sol toluene and CH_2Cl_2; slightly sol hexane.

Form Supplied in: prepared and used in situ.

Preparative Method: treatment of 2,6-di-*t*-butyl-4-methylphenol in dry CH_2Cl_2 with a 1-2 M hexane solution of ***Trimethylaluminum*** at -78 °C for 10 min and at 0 °C for 30 min affords ***Dimethylaluminum 2,6-Di-t-butyl-4-methylphenoxide*** which, after cooling to -78 °C, is reacted with ***Trifluoromethanesulfonic Acid*** (TfOH). Upon warming to 0 °C, gas evolution is observed to give a pink solution after further stirring at 0 °C for 30 min.[2]

Handling, Storage, and Precautions: the dry solid and solutions are flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Intramolecular Prenyl Transfer Reaction.

This modified organoaluminum reagent has been developed for effecting the intramolecular version of prenyl transfer reactions.[2] Thus reaction of isopentenyl prenyl ether with the highly oxygenophilic organoaluminum reagent in CH_2Cl_2 at 25 °C enables head-to-tail condensation, resulting in formation of the two C_{10} alcohols in a 1:3 ratio (eq 1). Conventional strong Lewis acids such as ***Titanium(IV) Chloride***, ***Tin(IV) Chloride***, and ***Boron Trifluoride Etherate***

readily attack both ethereal oxygen and alkenes in isopentenyl prenyl ether to furnish a number of side-reaction products. With weaker acids it is difficult to cleave the allylic C-O bond of isopentenyl prenyl ether. Clearly, the present oxygenophilic aluminum reagent is strong enough to coordinate to the ether oxygen, but not to double bonds. It could thus play a key role in promoting a combined C-O bond fission/rearrangement. In addition, the bulky 2,6-di-*t*-butyl-4-methylphenoxy group in the aluminum reagent may assist anchimerically the through-space interaction of the π-electron orbital of the prenyl cation via a six-membered transition state.

(1)

Ar = 2,6-di-*t*-butyl-4-methylphenyl

The organoaluminum reagent can also effect the biogenetic-type head-to-head condensation of C_5 units. Thus treatment of diprenyl ether with the reagent at 0 °C for 1.5 h affords the C_{10} alcohol lavandulol exclusively, in 33% yield (eq 2). This method provides a very simple route to lavandulol, hitherto accessible only by multi-step synthesis.[3]

(2)

Asymmetric Cyclization.

Biogenetic-type asymmetric cyclization of (*R*)-(+)-binaphthol mononeryl ether to optically active limonene can be realized using this type of reagent in $CFCl_3$ at -130 °C (eq 3). Among various oxygenophilic organoaluminum triflates examined, (2,4,6-tri-*t*-butylphenoxy)isobutylaluminum trifluoromethanesulfonate gives the best result.[4]

(3)

i-Bu_2OTf	39% ee
i-$BuAl(OTf)_2$	40% ee

64% ee

77% ee

Asymmetric cyclization of (*R*)-(+)-binaphthol (*Z*,*Z*)-monofarnesyl ether can be executed equally well with this aluminum reagent, giving (+)-β-bisabolene in 76% ee (eq 4).

(4)

Polymerization.

The aluminum reagent possesses high activity in both cationic polymerization and electrophilic reactions.[5]

Di-*t*-butylmethylsilyl Trifluoromethanesulfonate[1]

t-$Bu_2MeSiOSO_2CF_3$

[105866-92-0] · $C_{10}H_{21}F_3O_3SSi$ · Di-*t*-butylmethylsilyl Trifluoromethanesulfonate · (MW 306.42)

(bulky trialkylsilylating agent; useful for preparation of hydrolytically stable, sterically congested enol silyl ethers and silyl carboxylic esters; t-Bu_2MeSi- also serves as a reactivity control element)

Alternate Name: DTBMSOTf.

Physical Data: colorless, water-sensitive liquid; bp 63-65 °C/1.5 mmHg.

Solubility: sol THF, Et_2O.

Form Supplied in: not available commercially.

Preparative Method: addition of ***Trifluoromethanesulfonic Acid*** (TfOH) to neat di-*t*-butylmethylsilane[2] at 4 °C, stirring 16 h at 20 °C, followed by distillation in vacuo.[1]

Purification: vacuum distillation through a Vigreux column.

Handling, Storage, and Precautions: stable in the absence of moisture. Fumes in moist air, producing TfOH by hydrolysis. Owing to the high corrosivity of TfOH, breathing the vapor or the fumes produced by reaction with moist air should be avoided. Use in a fume hood.

Enol Silylation.

Di-*t*-Butylmethylsilyl triflate converts a hydroxymethylene ketone into the corresponding DTBMS enol silyl ether (eq 1).[1] DTBMS ethers were prepared previously by the reaction of alcohols with DTBMS perchlorate.[2] The bulky substituents on silicon suppress 1,4-addition of MeLi to the DTBMS ethers of hydroxymethylene ketones. Thus the proportion of 1,2-adduct versus 1,4-adduct improves as the steric bulk of the silyl substituents increases from trimethylsilyl (TMS) to *t*-butyldimethylsilyl (TBDMS) to DTBMS enol ethers (eq 2).[1] Dehydration in conjunction with hydrolysis of the DTBMS enol ether group delivers an α,β-unsaturated aldehyde in excellent yield (eq 3).

R = TMS	59%	39%
R = TBDMS	70%	25%
R = DTBMS	90%	10%

TMSCl accelerates the conjugate addition of Grignard reagents catalyzed by copper salts.[3] Therefore the influence of silyl substituents on the reaction of 2-cyclohexenone with ***Ethylmagnesium Bromide*** in the presence of a chiral nonracemic copper catalyst was examined (eq 4).[4] The anticipated silyl enol ether intermediate was rapidly hydrolyzed in the workup, delivering optically active 3-ethylcyclohexanone. The bulky silyl reagent, DTBMSOTf, afforded better enantioselectivities than TMSCl in the addition of EtMgBr to cyclohexenone (eq 4). However, for the reaction with *n*-BuMgBr, enantioselectivities obtained with TMSCl, DTBMSOTf, and Ph_2(*t*-Bu)SiCl were 51% ee, 40% ee and 78% ee, respectively. The ability of the silyl reagent structure to influence the enantioselectivity suggests that a silylated species is involved in the rate-determining step of the conjugate addition.

Silyl Esterification.

Carboxylic acids are converted into DTBMS esters by treatment with DTBMSOTf and ***Triethylamine*** in THF (eq 5). Although hydroxy carboxylic acids can be selectively converted to hydroxy silyl carboxylic esters (eq 5), the extraordinary stability of DTBMS esters allows an alternative route. Thus silyl esterification of a tetrahydropyranyloxy carboxylic acid followed by selective removal of the THP ether protecting group by treatment with ***Pyridinium p-Toluenesulfonate*** in ethanol[5] delivers a hydroxy DTBMS ester (eq 6).[1]

R = H, 44%
R = THP, 92%

The bulky substituents on silicon confer resistance to nucleophilic attack at the carbonyl group of DTBMS esters. Thus selective reduction of a butyrolactone in the presence of a *t*-butyl or DTBMS ester gives a much better yield than the corresponding methyl ester (eq 7).[1,6]

(7)

R = Me, 20%
R = *t*-Bu, 50%
R = DTBMS, 49%

Removal of the DTBMS ester protecting group under mild acidic conditions is achieved in better yield than removal of the *t*-butyl group, but in neither case can deprotection be accomplished without concomitant dehydration (eq 8).[1,6]

(8)

Conversion of DTBMS esters to carboxylic acids can also be achieved by treatment with ***Tetra-n-butylammonium Fluoride*** in wet THF. Under these conditions, both TBDMS ether and DTBMS ester protecting groups are removed (eq 9).[1]

1,1-Di-*t*-butyl Peroxide[1-3]

[110-05-4] · $C_8H_{18}O_2$ · 1,1-Di-*t*-butyl Peroxide · (MW 146.23)

(radical initiator, initiates anti-Markovnikov addition of HX to alkenes (X = halogen, S, Si, P);[4] initiates, by H-abstraction, the following radical reactions of compounds with an activated C-H bond: (a) dehydrodimerization;[5,6] (b) intra-[7] and intermolecular additions[3,8,9] to alkenes, alkynes, and carbonyl compounds; (c) addition to protonated heterocycles;[10,11] (d) fragmentation;[12,13] mediates alcohol deoxygenation via silane reduction of esters[14] and chlorohydrin formation by reaction with $TiCl_4$ and alkene[15])

Alternate Names: *t*-butyl peroxide; DTBP.

Physical Data: bp 109 °C/760 mmHg, 63 °C/119 mmHg; *d* 0.796 g cm^{-3}.

Solubility: freely soluble in organic solvents.

Form Supplied in: clear colorless liquid.

Analysis of Reagent Purity: Kropf describes various procedures (chemical and chromatographic) for the analysis of peroxides.[1b]

Handling, Storage, and Precautions: explosive; harmful if exposed by inhalation or skin contact; strong oxidizer; flammable; keep away from heat. Caution: All experiments involving peroxy compounds should be carried out behind a safety shield. Use in a fume hood.

General Discussion.

Di-*t*-butyl peroxide is a commonly used initator for radical reactions. It undergoes facile unimolecular thermal decomposition to the *t*-butoxy radical, which in turn fragments to a methyl radical and acetone. The half-lives of DTBP are approximately 3 h at 140 °C and 24 h at 120 °C.[2] Accordingly, radical reactions that proceed at 110-150 °C can be initiated by DTBP, since a steady concentration of the initiating radical would be available for the reactions. Alkoxy radicals are electrophilic and they initiate the reaction by abstraction of a C-H bond α to a heteroatom. The resultant radicals undergo a variety of carbon-carbon bond forming reactions, including polymerization.[16] Scheme 1 shows the primary steps involved in useful C-C bond forming reactions. Use of precursors having an activated C-H bond is advantageous for this purpose, since the chain-transfer step also produces the primary adducts along with the propagating radical, which is also one of the reactants. However, because of the high bond energy associated with the C-H bond, these types of compound are poor H-atom donors. Chain lengths of these reactions are generally short; the use of a large excess of the C-H precursor and a steady supply of the initiator are important for success in many instances.

Scheme 1 Primary radical processes

Abstractions of H adjacent to ethers and amines are important examples, the heteroatom adjacent to the site of reaction providing a favorable polar contribution to the transition state for abstraction by the electrophilic oxy radical, and providing stabilization for the product radical. Examples of the use of DTBP in this way include the study of anomeric radicals by Ingold and co-workers (eq 1),[17] and a synthesis of substituted tetrahydrofurans (eq 2).[18]

(1)

(2)

In the first case the radicals were generated by UV photolysis of the reaction mixture in the cavity of the NMR instrument used for studying the configuration at the anomeric center. By contrast, the substitution of THF was carried out under more typical thermal conditions by heating in a sealed autoclave. In this study it was found that similar substitution of tetrahydro-2-furanone could also be carried out, although generally in modest yield.

Hydrogen atom abstraction from amino acid derivatives is especially facile, since the resulting captodative radicals are highly stabilized. Treatment of an alanine derivative with DTBP led to a mixture of an α-methylated product and a diastereomeric mixture of dimers (eq 3).[19] The first product is formed as a result of radical combination between the captodative amino acid radical and a methyl radical formed by scission of a *t*-butoxy radical. Substitution of protected dipeptides can be carried out using this approach, by including an alkylating agent such as toluene in the reaction medium (eq 4).[20] The reaction relies on the action of biacetyl (***2,3-Butanedione***) as a photoinitiator, hydrogen atom abstraction occurring preferentially at glycine residues.

(3)

Tfa-Phe-Gly-OMe + Tfa-Gly-Phe-OMe + Tfa-Phe-Phe-OMe (4)

30% 29% 10%

Reactions involving phosphorus centered radicals derived from diethyl hydrogen phosphite are also initiated by DTBP under thermal conditions (eq 5).[21] Under modified reaction conditions, diphosphonate products, resulting from further addition to the initially formed unsaturated phosphonate, were also observed.

(5)

Typical reactions of radicals with alkene acceptors, initiated by DTBP and used in synthesis, are listed below.

Intermolecular Additions.

The radical chain nature and the anti-Markovnikov regiochemistry of radical addition reactions were originally discovered by Kharasch in the 1930s. Since then, these reactions have been used extensively for the formation of carbon-carbon[3,8] and carbon-heteroatom[4] bonds. Substrates that are suitable for the former include polyhalomethanes, alcohols, ethers, esters, amides, and amines. The prototypical examples compiled in Table 1 are from reviews by Walling[8] and Ghosez et al.[3]

Table 1 Intermolecular C-C Bond Forming Reactions via Radicals

Precursor	Alkene	Reaction conditions	Product(s)
EtOH		DTBP, 120 °C, 48 h	 60%
		DTBP, 120 °C, 48 h	 54%
		DTBP, 132 °C, 18 h	 +  22% 34%
		DTBP, 0.01 equiv, 6 h	 87%
		DTBP, 137 °C, 24 h			DTBP, 150 °C	 56%
			
1,1-Di-t-butyl Peroxide

Among the other notable applications are addition of the radical from diethyl malonate to alkynes and alkenes (eq 6),[9] addition of a 1,3-dioxalane-derived radical to formaldehyde (eq 7),[22] and addition of *s*-alcohols to alkenes (eq 8).[23] Novel radical mediated alkylations of a dipeptide makes use of DTBP as an initator (eqs 9 and 10).[20]

Intramolecular Addition Reactions.

Early studies by Julia and his co-workers on the cyclization of hexenyl (eq 11) and heptenyl radicals played a key role in the development of radical synthetic methodology, and many of the earlier studies were conducted with peroxides as initiators.[7] Cyclization of stabilized radicals such an malonates and cyanoesters are reversible, and the course of ring closure can be controlled by the appropriate choice of precursors and reaction conditions. Thus the cyanoacetate in eq 12[24] with 2 equiv of DTBP gives the products shown, whereas under kinetic conditions, using the tin hydride method, a different product distribution is obtained (eq 13).

Dehydrodimerization.

Radicals that are stabilized by an α-heteroatom, when produced in sufficiently high concentrations, will undergo dimerization. Use of DTBP is particularly effective for dehydrodimerizations of polyhaloalkanes,[25] alcohols, ethers,[5,25] amides, and esters (Table 2).[5,6] Viehe, who pioneered this work, has used α-*t*-butylmercaptoacrylonitrile as a trapping agent for the above mentioned C-centered radicals.[26] The adduct radical is stabilized by captodative effects[27] and do not participate in further chain transfer chemistry. These radicals undergo ready dimerization, thereby providing a facile route to compounds with a four-carbon bridge between the original radicals (eq 14).

Table 2 Dimerization of Radicals

Precursor	Reaction conditions	Products
$PhCH_2OH$	DTBP, 140 °C, 10 h	 69%
	DTBP, 135 °C	

Fragmentation Reactions.

The tetrahydrofuranyl radical undergoes fragmentation at 140 °C to give an open-chain acyl radical. The THF radical as well as the rearranged radical are trapped by excess of alkene (eq 15).[12] Benzylidene acetals undergo similar fragmentation to give a benzoate ester (eq 16).[13]

Homolytic Substitution Reactions.

Alkylation of electron-deficient heteroaromatic compounds developed by Minisci and co-workers is a powerful method for their functionalization.[10,28] Three examples are illustrated in eqs 17, 18 and 19. The product distribution often depends on the oxidant used. For example, as shown in eq 19, DTBP gives a 1:2 mixture of two products (A and B) upon alkylation of 4-methylquinoline. ***t-Butyl Hydroperoxide*** and Fe^{II} salts give almost exclusively the dimethylaminocarbonyl radical adduct A (eq 19).[11]

Miscellaneous Reactions.

DTBP has been used as a hydrosilylation catalyst,[4] even though catalysis[29] by transition metal complexes have largely replaced the radical methods. DTBP has also been used as an oxidant for silanes.[30,31] Other applications of DTBP include its use as an initiator for radical mediated deoxygenation of alcohols via the corresponding chloroformate[32] or acetate ester[14] (eq 20). It has also been used as an initiator for the reduction of lactones and esters to ethers using ***Trichlorosilane***.[33] In a rare example of a nonradical reaction, DTBP has been used in conjunction with ***Titanium(IV) Chloride*** for the formation of chlorohydrin from alkenes (eq 21).[15]

The carbonylation reaction of disulfides, catalyzed by ***Octacarbonyldicobalt***, normally leads to the production of thioesters. However, in the presence of DTBP and in the absence of CO the reaction takes an alternative course, with benzyl disulfides undergoing clean desulfurization to give the corresponding sulfides (eq 22).[34]

DTBP has also been employed in palladium catalyzed carbonylation reactions. Depending on the type of catalyst used, or on the reaction conditions, the carbonylation reaction of primary amines can be used to prepare either ureas (eq 23)[35] or carbamate esters (eq 24).[36]

(23)

catalyst = montmorillonite(bipyridyl)palladium(II) acetate

(24)

Using the ***Palladium(II) Chloride*** system, the reaction involving secondary amines was found to give mixtures of carbamate ester and an oxamate ester resulting from double carbonylation.[36] Analogous carbonylations of alcohols can lead to a range of products, including dialkyl carbonates, oxalates, and succinates.[37]

Di-*t*-butyl Peroxyoxalate[1]

[1876-22-8] · $C_{10}H_{18}O_6$ · Di-*t*-butyl Peroxyoxalate · (MW 234.25)

(useful for clean, low-temperature generation of *t*-butoxyl radicals;[1] induces cyclization of alkenyl hydroperoxides;[2] used in radical-trapping experiments,[3] and as initiator for alkene autoxidation[4] and polymerization[5])

Alternate Name: DBPO.

Physical Data: white crystals, mp 50.5-51.5 °C (dec).[1a]

Solubility: sol most organic solvents (e.g. CH_2Cl_2, CCl_4, PhH, PhCl, and pentane).

Analysis of Reagent Purity: NMR (C_6D_6, δ) ^{1}H: 1.12 (s), ^{13}C: 25.7, 85.4 (no signal is observed for the carbonyl carbon);[6] iodometric titration.[1a]

Preparative Methods: readily obtained by reaction of ***Oxalyl Chloride*** with *t*-butyl hydroperoxide and pyridine in anhydrous pentane.[1a,7] It is recommended to collect the crystals of DBPO on a precooled filter (-78 °C).

Handling, Storage, and Precautions: the preparation and manipulation of DBPO must be conducted behind a safety shield. Tongs, gloves, and safety masks should be used throughout every operation. DBPO is highly sensitive to scratching or shock especially when the crystals are dry.[1a] In one instance, a violent explosion occurred during the transfer of solvent-wetted, recrystallized DBPO from one glass vessel to another.[4a,b] Consistent with the risk of explosion, it is recommended to use the reagent as prepared. If it must be stored, it should be kept in a flask under Ar at -20 °C or below. Ethers should not be used as solvents since they are known to accelerate perester decomposition.[1a] For most applications, benzene is the best solvent. Chemists new to the manipulation of organic peroxides are urged to read the appropriate literature before commencing experimental work.[8]

Thermal Decomposition.

DBPO is a convenient source of *t*-butoxyl radicals in the temperature range of 20 to 60 °C (eq 1). Its half-life ($t_{1/2}$) in benzene is about 1470 min at 20 °C and 6.8 min at 60 °C.[1a] Thermal decomposition is believed to proceed via concerted three-bond cleavage.[1,5,9] In low viscosity solvents such as pentane or benzene, about 5% of *t*-butoxyl radicals are wasted through cage recombination to give di-*t*-butyl peroxide.[10]

Peroxyl Radical Cyclizations.

On a per hydrogen basis, *t*-butoxyl radicals abstract hydrogen 200-1000 times faster from a hydroperoxyl than an allylic methylene or methyl.[11] Thus specific peroxyl radicals are accessible on treatment of alkenyl hydroperoxides with DBPO. Intramolecular addition to the alkene, followed by oxygen entrapment of the resultant carbon-centered radical and hydrogen atom transfer, leads to cyclic peroxides.[2] By this method, 1,2-dioxolanes (eq 2)[12] and 1,2-dioxanes (eq 3)[13] are obtained in modest yields. In general, there is a strong bias for *exo* cyclization[2,14,15] and, when there is a choice, the 5-*exo*-trig mode is preferred over the 6-*exo*-trig.[16] Although DBPO is the most frequently used initiator for these reactions,[16,17] ***Di-t-butyl Hyponitrite*** is also effective.[18] Further, similar transformations have been achieved at -20 to 5 °C with ***Copper(II) Trifluoromethanesulfonate***-octanoic acid in MeCN.[19]

A mechanistically related approach to 1,2-dioxolanes relies on DBPO-initiated thiol-oxygen cooxidation with 1,4-dienes (eq 4)[20] or 1,3,6-trienes.[21,14]

Autoxidation.

The use of DBPO in conjunction with an excess of ***t-Butyl Hydroperoxide*** (TBHP) allows clean autoxidation of simple alkenes at 30-50 °C to provide allylic hydroperoxides (eq 5).[4] The main role of TBHP is to trap product peroxyl radicals as hydroperoxides, thereby preventing side-reactions.[4a,b] Unlike auto-initiated autoxidation, which often leads to complex mixtures containing many nonperoxide products,[4a] the DBPO-TBHP procedure is of comparable preparative value to the widely utilized singlet oxygen route.[4c]

Homolytic Alkylation.

Aldoximes bearing electron-withdrawing groups undergo *C*-alkylation upon treatment with DBPO in a hydrogen donor solvent at 60 °C (eq 6).[22] The alkylation of heteroaromatic compounds with alkyl bromides can be realized in a highly

regioselective fashion by using DBPO in conjunction with phenylsilane and ***Trifluoroacetic Acid*** (eq 7).[23] Other initiators, such as TBHP, ***1,1-Di-t-butyl Peroxide***, or ***Dibenzoyl Peroxide***, are less effective than DBPO.[23]

(6)

(7)

Miscellaneous Applications.

DBPO has been extensively employed as a low-temperature initiator for radical polymerization and related mechanistic studies,[5,24] as well as in radical-trapping experiments.[3] It is also known to accelerate rearrangement of allylic hydroperoxides[25] and to effect oxidative coupling of phenols.[26] For an equally useful reagent for producing *t*-butoxyl radicals at rt and a comparison with DBPO, see ***Di-t-butyl Hyponitrite***.

Related Reagents.

t-Butyl Hydroperoxide; ***Dibenzoyl Peroxide***; ***Di-t-butyl Hyponitrite***; ***1,1-Di-t-butyl Peroxide***; ***m-Nitrobenzenesulfonyl Peroxide***; ***p-Nitrobenzenesulfonyl Peroxide***.

2,6-Di-*t*-butylpyridine[1]

[585-48-8] · $C_{13}H_{21}N$ · 2,6-Di-*t*-butylpyridine · (MW 191.32)

(weak base and proton scavenger;[2-4] prevention of acid-catalyzed side reactions;[5-7] vinyl triflate synthesis[8,9])

Alternate Names: 2,6-bis(1,1-dimethylethyl)pyridine; BDMEP.

Physical Data: mp 2.2 °C; bp 100-101 °C/23 mmHg; *n*20D 1.4733; pK_a 3.58 (50% EtOH);[2] pK_a 0.81 (DMSO).[3]

Solubility: insol H_2O; sol alcohol, acetone, and hexane.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: potentially toxic; handle with care. Use in a fume hood.

Proton Scavenger.

BDMEP has high basicity in the gas phase,[4] but is an abnormally weak base in solution.[2,3] The low basicity of BDMEP is due to steric hindrance of solvation.[10] Therefore BDMEP forms an HCl salt and compounds with Br_2, but does not react with MeI or BF_3.[2]

BDMEP has been used to prevent acid-catalyzed side reactions or nucleophilic reactions by the base in the synthesis of [*trans*-2,3-*trans*-5,6-$^2H_4$]-1,4-dioxane (eq 1),[5] labeled [1-^{13}C]acid chlorides (eq 2),[6] steroidal dienes,[11] and divinyl ketones. In the last case, Amberlyst/15 pretreated with BDMEP was used (eq 3).[7]

Catalysis of Enolization and Addition Reactions.

It has been shown that BDMEP and its analogs (e.g. 4-methyl-BDMEP) can be used to prepare vinyl triflates from carbonyl compounds and triflic anhydride.[12] Good results were obtained with a polymer-bound BDMEP, which may be easily recycled (eq 4).[8] Intermediate vinylsilanes have been obtained from 2,3-dihydro-4*H*-pyran-4-one derivatives. These have been used in Diels-Alder reactions with alkynes to prepare silyl phenyl ethers (eq 5).[9] In the presence of BDMEP, formaldehyde acetals react with trimethylsilyl enol ethers to form β-alkoxy ketones (eq 6).[13]

(6)

$R^3 = Me, Bn$

Inhibition of Acid-Catalyzed Reactions.

BDMEP was used to eliminate protic acid catalysis in aminium cation-radical initiated Diels-Alder reactions of dienes,[14] and vinylcyclopropane-cyclopentene isomerizations.[15] Cationic polymerization of isobutene and α-methylstyrene by Ziegler-type catalysts in the presence of BDMEP resulted in a polymer with a higher molecular weight and noticeably narrower molecular weight distribution.[16]

Di-*t*-butylsilyl Bis(trifluoromethanesulfonate)

t-$Bu_2Si(OSO_2CF_3)_2$

[85272-31-7] · $C_{10}H_{18}F_6O_6S_2Si$ · Di-*t*-butylsilyl Bis(trifluoromethanesulfonate) · (MW 440.44)

(reagent for the protection of diols)

Physical Data: bp 73-75 °C/0.35 mmHg; *d* 1.208 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: liquid.

Preparative Method: by the treatment of di-*t*-butylchlorosilane with ***Trifluoromethanesulfonic Acid***, followed by distillation (71% yield).[1]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; reacts with hydroxylic solvents; corrosive.

Protection of Alcohols.

Di-*t*-butylsilyl bis(trifluoromethanesulfonate) is a reagent for the selective protection of polyhydroxy compounds. This reagent reacts with 1,2-, 1,3-, and 1,4-diols under mild conditions to give the corresponding dialkylsilylene derivatives in high yield (0-50 °C, 79-96%). Deprotection is conveniently achieved by using aqueous ***Hydrofluoric Acid*** in acetonitrile (eq 1).

Unlike ***Di-t-butyldichlorosilane***, this reagent reacts with hindered alcohols. Even pinacol reacts to give the silylene derivative (100 °C, 24 h, 70%). Di-*t*-butylsilylene derivatives of 1,2-diols are more reactive than those of 1,3- and 1,4-diols and undergo rapid hydrolysis (5 min) in THF/H_2O at pH 10, while the 1,3- and 1,4-derivatives are unaffected at pH 4-10 (22 °C) for several hours. This protecting group is stable under the conditions of PDC oxidation of alcohols (CH_2Cl_2, 25 °C, 27 h) and tosylation of alcohols (pyridine, 25 °C, 27 h).

The reagent has seen limited use for the protection of alcohols but has been used to protect nucleosides (eq 2).[2-5] The procedure consists of sequential addition of the ditriflate and ***Triethylamine*** to the nucleoside in DMF. The choice of solvent is critical.

The ribonucleosides of uracil, adenine, and guanine give the protected derivative in 94-95% yield.[2] Cytidine gives a low yield of the desired product under these conditions. Subsequent studies suggested that O^2 of cytosine participates in the reaction. Addition of ***Trifluoromethanesulfonic Acid*** or ***Silver(I) Trifluoromethanesulfonate*** at 0 °C prior to addition of the silylating agent results in a 99% yield of the desired derivative.[3] The derivatives are acid sensitive, presumably due to the proximity of the 2´-hydroxy group. Acetylation, tetrahydropyranylation, methoxytetrahydropyranylation, and silylation of the 2´-hydroxy group are accomplished without affecting the dialkylsilylene protecting group. The 2´-deoxyribonucleosides, including 2´-deoxycytidine, can also be prepared by the aforementioned procedure (yields 90-99%). These cyclic silylene derivatives of nucleosides can be deprotected

conveniently using tributylamine hydrofluoride in THF (5 min, 1 M, rt, 20 equiv).[4] A one-pot procedure has been reported for simultaneously protecting the 2´-, 3´-, and 5´-hydroxys of a ribonucleoside, which utilizes the acid generated upon silylating the 3´- and 5´-hydroxys for catalyzing the formation of a THP acetal at the 2´-position (eq 3).[5]

(3)

Derivatization of Alcohols.

Di-*t*-butylsilyl bis(trifluoromethanesulfonate) has been used to derivatize hindered diols, to give derivatives such as (**1**), for analysis by gas chromatography-electron impact mass spectrometry.[6] The major fragmentation is that of the Si-C bonds.

(1)

m/z 366 (M^+), 309 (M^+ - Bu), 191 (*B*)

Reagent in Enantioselective Additions.

In a study of enantioselective conjugate addition to cyclohexanone it was found that the presence of HMPA and various silyl reagents markedly increases the enantioselectivity (eq 4).[7] Di-*t*-butylsilyl bis(trifluoromethanesulfonate) gives a 67% yield and 40% ee but ***t-Butyldiphenylchlorosilane*** gives a 97% yield and 78% ee.

Other Substitution Reactions.

An extremely hindered silyl reagent, tri-*t*-butylsilyl trifluoromethanesulfonate, was prepared from di-*t*-butylsilyl bis(trifluoromethanesulfonate) and ***t-Butyllithium*** (eq 5).[8] This reagent might find use in the protection of alcohols.

In conjunction with the study of alkyl-substituted silyl triflates, (**2**) and (**3**) have been prepared from the corresponding alkynyllithium reagents and di-*t*-butylsilyl bis(trifluoromethanesulfonate).[9]

(2) **(3)**

The preparation of other derivatives of di-*t*-butylsilyl bis(trifluoromethanesulfonate) using germanium[10] and phosphorus[11] nucleophiles has been reported and provides bifunctional silanes such as (**4**) and (**5**).

(4) **(5)**

X = -C≡CPh, -$SiPh_3$, -$N(TMS)_2$, -PHPh, -O-*i*-Pr, -SPh

A compound closely related to di-*t*-butylsilyl bis(trifluoromethanesulfonate) is di-*t*-butylchlorosilyl

trifluoromethanesulfonate, which has been used to tether two structurally different alcohol derivatives in order to effect an intramolecular Diels-Alder reaction (eq 6).[12]

2,2-Dibutyl-2-stanna-1,3-dithiane[1]

[7191-32-4] · $C_{11}H_{24}S_2Sn$ · 2,2-Dibutyl-2-stanna-1,3-dithiane · (MW 339.20)

(reagent for synthesizing 1,3-dithianes from aldehydes and acetals[2,3])

Alternate Name: DSDT.

Physical Data: mp 63-64 °C; bp 170 °C/0.5 mmHg.

Solubility: insol H_2O; sol most organic solvents.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 0.93 (t, 6H, *J* = 7.32 Hz), 1.61 (m, 14H), 2.94 (t, 4H, *J* = 6.10 Hz); ^{13}C NMR ($CDCl_3$) δ 13.40, 24.51, 26.50, 27.82, 30.16.

Preparative Method: to a CH_2Cl_2 solution (400 mL) of Bu_2SnCl_2 (45.8 g, 0.15 mol) and $HS(CH_2)_3SH$ (15.1 mL, 0.15 mol) is added Et_3N (41.8 mL, 0.3 mol) at 0 °C. The solution is stirred at rt overnight and diluted with CH_2Cl_2 (200 mL). The combined solution is washed with H_2O (200 mL × 2). The organic layer is dried (Na_2SO_4) and evaporated. Distillation of the residue affords DSDT (39.5 g, 78%): bp 170 °C/0.5 mmHg.

Handling, Storage, and Precautions: stable in air and to moisture and thus can be handled and stored in air; odorless.

Synthesis of 1,3-Dithianes from Aldehydes and Acetals.[2,3]

Treatment of aldehydes with DSDT (1.2 equiv) in the presence of $Bu_2Sn(OTf)_2$ (DBTT) in 1,2-dichloroethane affords 1,3-dithianes in 70-99% yields (eq 1). ***Boron Trifluoride Etherate*** may also be used in this procedure; however, use of DBTT results in cleaner reactions and better yields. 1,3-Dithianes are conventionally prepared with ***1,3-Propanedithiol*** under acidic conditions and are occasionally contaminated by yellow-colored byproducts. No such byproducts are detected in reactions with DSDT. Of more synthetic value is the mildness of the reaction. Acid-labile substrates can be successfully employed: aldehydes having siloxy or tetrahydropyranyloxy groups, which are unmasked under conventional reaction conditions, are converted to 1,3-dithianes smoothly. However, α,β-unsaturated aldehydes undergo isomerization of the double bond.

(1)

The reactions with acetals also proceed smoothly (eq 2). 1,3-Dithiolanes are obtained by an analogous procedure employing 2,2-dialkyl-2-stanna-1,3-dithiolanes in place of DSDT. In some respects this method is comparable to the Evans' thiosilane protocol,[4] which, however, is applied to carbonyls only; no reaction with acetals has been described. Moreover, the following merits of the present dithioacetalization method are worthy of note. Thiostannanes can be readily prepared from various organotin sources such as oxides, alkoxides, and halides. They are entirely air and moisture stable and, thus, can be used even in the presence of water. Because they are odorless, they can be stored in the air.

(2)

Differentiation between Carbonyls and Acetals.

In competition reactions employing an equimolar mixture of various types of carbonyls and acetals, one of the substrates reacts preferentially. Representative results are described briefly in the following sections.

Competition between Aldehydes and Ketones (or Acetals).

An aldehyde reacts preferentially over a ketone (eq 3), while the preference is reversed in the reaction of the corresponding acetals (eq 4). The reaction of the carbonyl is initiated by coordination of the carbonyl to tin. Thus the enhanced reactivity of the aldehyde can be accounted for by the fact that the aldehyde forms a complex with tin more readily than the ketone does. In contrast, the reaction of the acetal proceeds via an oxocarbenium ion, which is generated from ketone acetals more easily than from aldehyde acetals.

(3)

Competition between Aldehydes.

Differentiation between two of the same type of carbonyl functions often requires highly elaborate methods. Organotin triflates effect such differentiations successfully. As shown in eq 5, competition between benzaldehyde and pentanal leads to predominant formation of the 1,3-dithiane of the latter.

Competition between Acetals.

An aromatic acetal can be differentiated from an aliphatic acetal (eq 6).

Dibutyl Telluride[1]

R_2Te

(R = *n*-Bu)

[38788-38-4] · $C_8H_{18}Te$ · Dibutyl Telluride · (MW 241.83) (R = *i*-Bu)

[83817-01-0]

(nucleophilic agent for the synthesis of telluronium salts, which undergo many transformations;[2] used as a halophilic[3] and reducing[4] reagent)

Physical Data: *n*-Bu_2Te bp 75-76 °C/4 mmHg; *i*-Bu_2Te bp 68-70 °C/6 mmHg.

Solubility: insol H_2O, ethanol; sol ether, petroleum ether, THF, etc.

Preparative Methods: dibutyl telluride and diisobutyl telluride are prepared from *n*-butyl bromide and isobutyl bromide with ***Sodium Telluride***, which is prepared in situ from ***Tellurium*** powder, rongalite (***Sodium Hydroxymethanesulfinate***), and ***Sodium Hydroxide*** in H_2O.[5]

Handling, Storage, and Precautions: stored and handled under N_2. Care should be taken in handling Bu_2Te and *i*-Bu_2Te; because of their bad smell, experiments should be carried out in an efficient fume hood.

Organotelluronium Salts.

The reaction of dibutyl telluride or diisobutyl telluride with halides affords telluronium salts, which can mediate the syntheses of alcohols, alkenes, epoxides, and cyclopropanes.

Formation of Alcohols.

Treatment of the telluronium salts with an alkyl- or aryllithium reagent results in a lithium-tellurium exchange reaction via an unstable transient tetraorganyltellurium intermediate. The in situ generated lithium species react with carbonyl compounds to give various alcohols in high yields. In this way, homobenzylic alcohols,[6] β-hydroxy nitriles,[7] and (trimethylsilyl)propargyl alcohols[8] are synthesized in excellent yields (eq 1-3).

Formation of Alkenes via Telluronium Ylides.

Stabilized telluronium ylides, formed from telluronium salts with ***Potassium t-Butoxide***, react with carbonyl compounds to give α,β-unsaturated esters,[9] carboxamides,[10] ketones, and nitriles[11] in high yields (eq 4).

Due to the ease of conversion of dibutyl telluride to the telluronium salts, these alkenation reactions can be carried out

at rt in a one-pot procedure. Thus α,β-unsaturated carboxylic acid amides can be obtained in excellent yields with high (*E*) stereoselectivity.[12] The dibutyl telluroxide formed during the reaction can be reduced back to dibutyl telluride by ***Triphenyl Phosphite***. Thus alkenes can be obtained using a catalytic amount of dibutyl telluride (eq 5).[13]

(5)

Dibutyl or diisobutyl telluride reacts with carbenes or nitrenes to form telluronium ylides or tellurimides, which react with carbonyl compounds to afford alkenes or *N*-tosylimines (eqs 6 and 7).[14,15]

(6)

(7)

Formation of Epoxides via Telluronium Ylides.

Diisobutyltelluronium allylide, generated from allyldiisobutyltelluronium bromide, reacts with aldehydes to give vinyl epoxides in good yields.[16] In the presence of ***Cesium Carbonate*** the epoxidation reaction can be promoted by a catalytic amount of diisobutyl telluride (eq 8).[17] Allyl[18] and propargyl[8,18] telluronium ylides can also be formed by deprotonation with ***Lithium 2,2,6,6-Tetramethylpiperidide*** (eq 9), giving high *cis* selectivity in some cases.

Formation of Cyclopropane Derivatives via Telluronium Ylides.

Trimethylsilylated diisobutyltelluronium allylide reacts with α,β-unsaturated esters to afford trimethylsilylvinylcyclopropane derivatives via Michael addition in excellent yields with high stereoselectivity (eq 10).[19,20]

Halophilic Reactions of Dibutyl Telluride.

Owing to the great halophilicity of dibutyl telluride, several alkenation reactions have been developed. Thus in the presence of dibutyl telluride, (iodomethyl)triphenylphosphonium iodide reacts with aldehydes to afford the methylenation products (eq 11).[3] A one-pot reaction of α-halo esters, malonic esters, nitriles, and ketones with aldehydes gives α,β-unsaturated esters, nitriles, and ketones in high yields (eq 12).[11,21-23] A similar reaction of ***Diethyl Dibromomalonate*** with electron-deficient alkenes affords cyclopropanation products (eq 13).[23]

(13)

Reducing Agent.

Diisobutyl telluride reduces ***Titanium(IV) Chloride*** to ***Titanium(III) Chloride***, which can mediate pinacolizations, carbonyl reductions, and reductive aromatization (eq 14).[4]

(14)

Related Reagents.

Tri-n-butylstibine; ***Triphenylphosphine***.

Di-*n*-butyltin Oxide[1,2]

Bu_2SnO

[818-08-6] · $C_8H_{18}OSn$ · Di-*n*-butyltin Oxide · (MW 248.92)

(converts diols to *O*-stannylene acetals[2] which undergo regioselective acylation, alkylation, oxidation, and condensation with activated carboxylic acid derivatives; activates α,o-hydroxy acids and α,o-amino acids for lactone and lactam formation, respectively;[3] mediates epoxidation of allylic alcohols by *t*-butyl hydroperoxide;[4] catalyzes $TMSN_3$ addition to nitrile;[5] useful as a source of tin for Otera transesterification[6] and organotin phosphate condensate[7] catalysts)

Alternate Name: DBTO.

Physical Data: mp >300 °C.

Solubility: insol most organic solvents with which it does not react. However solvents like toluene, benzene, and methanol are routinely used for reactions of hydroxylic substrates.

Form Supplied in: white powder.

Handling, Storage, and Precautions: toxic and irritant;[8,9] use in a fume hood.

Introduction.

Di-*n*-butyltin oxide, because of its biocidal and antifouling properties, is one of the most widely used industrial chemicals.[9] It is the final product of hydrolysis of dialkyltin halides (eq 1) and exists as an amorphous polymeric solid insoluble in nonreacting solvents. A reticulated network (**1**) consisting of four-membered rings of alternating tin and oxygen has been suggested as a possible structure for this compound.[10] The interaction of diorganotin oxides with various biomolecules like amino acids, peptides, carbohydrates, and nucleic acid components has been reviewed[9] and is beyond the scope of this article.

$$R_2SnX_2 \longrightarrow R_2Sn(X)OSn(X)R_2 \longrightarrow R_2(X)SnOSnR_2(OH) \longrightarrow R_2SnO \quad (1)$$

(1)

Formation and Reactions of Dibutylstannylenes.

By far the largest application of DBTO in organic chemistry is in the generation and reactions of stannylenes from polyhydroxy compounds. Dibutylstannylenes are prepared in nearly quantitative yields by heating stoichiometric amounts of DBTO and the polyol in a solvent such as benzene or toluene with concomitant removal of water (eq 2).[11] Compounds (**2**)[12] and (**3**)[13] are other prototypical stannylenes that have been prepared by this method. Formation and reactions of 1,6-stannylenes from monosaccharides have also been reported recently.[14] While the stannylene from ethylene glycol (eq 2) is an infinite coordination chain polymer with hexacoordinated Sn,[15] the stannylenes from cyclohexane-1,2-diols and the methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (**3**)[16] are dimeric (e.g. **4**).

(3)

(4)

Regioselective Alkylation, Acylation, and Sulfonylation.

Synthetic applications of stannylenes have followed the elegant studies of Moffatt[17] and Ogawa,[18] who showed that the inherent differences in the nucleophilicities of carbohydrate hydroxys can be amplified by the formation of trialkyltin ethers. Several selective acylations and alkylations could thus be accomplished. Further it was noted that while acylation proceeds without any catalyst, alkylation is a sluggish reaction and needs assistance from tetrabutylammonium halides (eq 3).[19]

Reactions of stannylene (**2**) are typical and are shown in eq 4.[2]

The stannylene (**3**) reacts with benzoyl chloride or tosyl chloride to give the corresponding 2-*O*-derivative (eq 5). The alkylation is less selective.[20] Use of nonpolar solvents and tetrabutylammonium halide has been a significant improvement (eq 6) in this alkylation procedure.[21] Several other examples of selective acylation and alkylations are given by David and Hanessian.[2] An intramolecular ether formation using DBTO has been used for the synthesis of octosyl acid.[22] Monoacylation of dimethyl L-tartrate has been carried out using this procedure (eq 7).[23] Two highly readable accounts of how the anomer composition and stoichiometry of reagents affect the regiochemistry of acylation[24] and tosylation[25] have recently appeared.

(5)

(6)

(7)

(also reactions with *t*-BuCOCl and TBDMS-Cl)

The structure of the dimeric complex (**4**) has been used to explain the observed preferential reactivity of the C-2 hydroxy groups.[2] It is argued that the divalent oxygens that occupy the axial position within the tin cordination sphere (i.e. this case, the C-2 oxygens) are not only more nucleophilic, but also are more accessible sterically. It is believed that the orientational preference of the hydroxy group is related to its acidity, and thus by forming a Sn complex with the more acidic hydroxy group in the axial position, its reactivity towards nucleophiles is enhanced. The stannylene procedure can be used to reverse the stereochemistry of the classical monoacylation regiochemistry observed in some unsymmetrical diols.[26]

Regioselective Oxidation.

Following the original discovery by David and Thieffrey,[27] several stannylenes have been oxidized by bromine to acyloins (eq 8). Hanessian employed this reaction for the synthesis of a densely functionalized intermediate which was converted into (+)-spectinomycin.[28] A detailed study of monooxidation of unprotected carbohydrates has also appeared.[29] Stannylenes are oxidized the same way as diols, with ***Sodium Periodate*** and ***Lead(IV) Acetate***.[2]

Esterification Catalyst.

In the presence of DBTO, alcohols react with carboxylic acids to give esters[30] and the reaction can be extended to make lactones and lactams (eqs 9 and 10).[3] It should be noted that the stereochemistry of the alcohol center is unaffected. A template-driven extrusion process, in which an intermediate where the hydroxy and the carboxyl groups are brought into close proximity by tin oxide, has been proposed for this reaction.

Stannylenes derived from diols react with bifunctional carboxylic acid derivatives to give macrocyclic polyolides of various sizes.[31,32] This approach has been used for the synthesis of (+)-dicrotaline (eq 11).[33]

Dibutyltin oxide is the best source of tin for the Otera transesterification catalysts (eq 12),[6] which have found wide use in organic synthesis. DBTO has also been used as a catalyst for hydrolysis of amides in very sensitive molecules, where other procedures have failed.[34]

Catalyst in Oxidation Reactions.

DBTO has been used as a catalyst in Fe^{III}-mediated oxidation of thiols to disulfides, even though ***Tri-n-butyl(methoxy)stannane*** seems to be better suited for this purpose.[35] Epoxidation of terminal alkenes in a two-phase system (chloroform-water) containing H_2O_2/ammonium molybdate/DBTO has also been reported.[36] A combination of DBTO and ***t-Butyl Hydroperoxide*** oxidizes allylic alcohols with moderate regio- and stereoselectivity.[4] Tri- and tetrasubstituted double bonds are most easily oxidized and the selectivities are comparable to those of the corresponding ***Vanadyl Bis(acetylacetonate)*** mediated reactions.

Miscelleneous Applications.

The method of choice for the regioselective opening of benzylic and tertiary epoxides with alcohols (eq 13) appears to be a reaction mediated by organotin phosphate condensate (OPC), which is readily prepared from DBTO and tributyl phosphate.[7] DBTO catalyzes rearrangement of 3-hydroxy-2-oxo carboxylic acid esters (eq 14), a reaction reminiscent of a similar one mediated by the enzyme reductoisomerase.[37] DBTO has been used as a catalyst for the addition of ***Azidotrimethylsilane*** to nitriles[5] for the production of tetrazoles (eq 15).

Di-*n*-butylbis(cyclopentadienyl)zirconium

[80005-41-0] · $C_{18}H_{28}Zr$ · Di-*n*-butylbis(cyclopentadienyl)zirconium · (MW 335.64) (*n*-BuLi)

[109-72-8] · C_4H_9Li · Di-*n*-butylbis(cyclopentadienyl)zirconium · (MW 64.06) (*n*-BuMgCl)

[693-04-9] · C_4H_9ClMg · Di-*n*-butylbis(cyclopentadienyl)zirconium · (MW 116.87) (Cl_2ZrCp_2)

[1291-32-2] · $C_{10}H_{10}Cl_2Zr$ · Di-*n*-butylbis(cyclopentadienyl)zirconium · (MW 292.32)

(a reagent generated in situ as a $ZrCp_2$ equivalent useful for the preparation of $ZrCp_2$ π-complexes containing alkynes,[1,2] alkenes,[1,2] dienes,[5] aldehydes,[14] and nitriles as well as five-membered zirconacycles and their bicyclic and polycyclic derivatives)

Alternate Name: di-*n*-butylzirconocene.

Physical Data: Cl_2ZrCp_2; mp 245 °C.

Form Supplied in: *n*-BuLi: solutions in cyclohexane, hexanes and pentane. *n*-BuMgCl: solutions in diethyl ether and THF. Cl_2ZrCp_2: colorless crystals. All are commercially available.

Preparative Methods: generated in situ by the addition of 2 equiv of ***n-Butyllithium*** in hexanes or pentane, or *n*-BuMgCl in diethyl ether or THF, to ***Dichlorobis(cyclopentadienyl)zirconium*** dissolved in THF at -78 °C in an inert atmosphere of N_2 or Ar.

Handling, Storage, and Precautions: *n*-butyllithium and *n*-butylmagnesium chloride are sensitive to air, moisture, and a wide variety of heterofunctional and carbofunctional compounds. They must be used and stored under an inert atmosphere of N_2 or Ar. Zirconocene dichloride may be handled in air, but it is advisable to avoid extensive exposure to air, moisture, and light. Use in a fume hood.

Reaction of *n*-Butyllithium with Cl_2ZrCp_2.

The reaction of Cl_2ZrCp_2 with 2 equiv of *n*-BuLi in THF at -78 °C cleanly produces *n*-Bu_2ZrCp_2 (**1**) in essentially quantitative yield within 1 h.[1] At or above 0 °C, (**1**) decomposes smoothly to form thermally unstable (1-butene)zirconocene (**2**), which can be stabilized with PMe_3 and other phosphines to give the corresponding 1-butene-zirconocene-phosphine complex (eq 1). Some such complexes, e.g. $(EtCH{=}CH_2)ZrCp_2(PMe_3)$ (**3**), have been isolated and fully identified.[1c,2] Detailed studies of the decomposition reaction of dialkylzirconocenes indicate that the reaction is first-order, unimolecular,[3] and nondissociative.[4] Thus neither free $ZrCp_2$ nor free alkene is formed during the conversion of dialkylzirconocenes into alkene-zirconocene complexes. In the absence of any other reagents, $(EtCH{=}CH_2)ZrCp_2(PMe_3)$, which exists as an 80:20 to 90:10 mixture of the distal and proximal stereoisomers (**3a** and **3b**), respectively, further decomposes at 50 °C to give a dimeric species (**4**), which is relatively stable and inert to various compounds.[2] Unstabilized alkene-zirconocene complexes are even more prone to a similar dimerization. Consequently, the generation and use of these compounds, e.g., (**2**) and (**3**) is best carried out in the presence of additional reagents that can react with alkene-zirconocene derivatives in a synthetically desirable manner before decomposition of the zirconocene complexes

occurs.

Alkene Displacement Reactions.

The 1-butene-zirconocene complexes (**2**) and (**3**) can react with alkynes,[1,2] alkenes,[1,2] and conjugated dienes[5] to give the corresponding π-complexes with concomitant expulsion of 1-butene. Even some single-bonded reagents, e.g. silanes,[6] allyl ethers,[7] and propargyl ethers,[8] can react similarly with (**2**) or (**3**) to give oxidative addition products with extrusion of 1-butene. Some representative examples are shown in Scheme 1. The complexes (**4**), (**5**),[1b] (**6**),[10] (**7**),[2,9] (**8**),[6] and (**9**)[11] have been fully identified by spectroscopic and other analytical methods, including X-ray analysis.

Scheme 1

Synthesis of Five-Membered Zirconacycles via (1-Butene)zirconocene.

Depending on substrate structures, quantities, and whether or not other reagents, such as phosphines, are present, the reactions of (1-butene)zirconocene with π-compounds, such as alkynes, alkenes, dienes, aldehydes, and nitriles, may give either displacement products as discussed above or five-membered zirconacycles with or without incorporation of 1-butene. Although the exact courses of these reactions depend on various kinetic and thermodynamic factors and often are difficult to predict, the following results indicate some general trends for prediction. In general, 1-butene is a relatively weak and readily displaceable ligand, as shown above. However, in cases where the 1-butene displacement products are relatively unhindered, 1-butene may ultimately be incorporated to give five-membered zirconacycles. Some reagents may be capable of directly interacting with (**2**) to give the corresponding five-membered zirconacycles with incorporation of 1-butene. Some of these reactions are shown in Scheme 2. The

reactions of (**2**) with alkenes have been shown to give thermodynamically equilibrated products,[12,13] In the thermally equilibrated products, alkyl groups prefer to be β to the Zr atom, while aryl and alkenyl groups end up in the α-position, as in (**10**)-(**12**). In the aldehyde reaction, the sterically less hindered C-Zr bond must selectively react with aldehydes to produce (**13**) in an irreversible manner.[14]

Scheme 2

Synthetically more useful are those reactions in which five-membered zirconacycles are formed with extrusion of 1-butene. Particularly attractive are the bicyclization reactions of nonconjugated enynes,[15-17] diynes,[1,18,19] and dienes[20-22] as well as related heterocycle-producing reactions (Scheme 3).[23] These products can be readily converted to a variety of organic derivatives via various reactions including protonolysis, iodinolysis, and carbonylation (Scheme 4).[1,12-23] The intermolecular versions of these reactions are more difficult to control. Nonetheless, some highly favorable and clean results have been obtained with selected alkenes.[24] In some of these reactions (Scheme 3), zirconacyclopentanes are undoubtedly the initial products which then undergo ring contraction and reexpansion to give the final zirconacyclopentenes and other products.

Scheme 4

The Zr-promoted bicyclization reactions of enynes and dienes have been applied to the efficient synthesis of some complex natural products, e.g. phorbol (**14**),[25] pentalenic acid (**15**),[26] iridomyrmecin (**16**),[27] and dendrobine (**17**).[28]

(17)

Zirconocene derivatives derived from *n*-BuMgCl and Cl_2ZrCp_2 effectively catalyze cyclic[29,30] and acyclic[31] dimerization of alkenes, as exemplified by eq 2. Significant differences between Et_2ZrCp_2[30,32-34] and higher dialkylzirconocenes such as $(n\text{-Bu})_2ZrCp_2$ have been noted.

Dicarbonylbis(cyclopentadienyl)hafnium[1]

[59487-86-4] · $C_{12}H_{10}HfO_2$ · Dicarbonylbis(cyclopentadienyl)hafnium · (MW 364.70)

(couples alkynes to form hafnacyclopentadienes[3])

Physical Data: subl at 80 °C/10^{-4} mmHg.[2a]

Solubility: sol hydrocarbons, THF.

Analysis of Reagent Purity: IR, NMR.[2]

Preparative Method: reduction of ***Dichlorobis(cyclopentadienyl)hafnium*** with ***Magnesium Amalgam*** under CO atmosphere.[2b]

Purification: hexane solution is filtered through alumina and cooled to -20 °C to induce crystallization; sublimation at 80 °C/10^{-4} mmHg.[2]

Handling, Storage, and Precautions: store and handle under an inert atmosphere. Use in a fume hood.

Dicarbonylbis(cyclopentadienyl)hafnium reacts with alkynes to form hafnacyclopentadiene complexes (eq 1), which may be isolated and purified prior to further manipulations.[3] Carbonylated products are not observed, indicating that the carbonyl ligands serve only as labile ligands which are lost during the reaction. Hafnacyclopentadiene complexes prepared by alternate methods have been converted into various 1,3-butadienes (see also ***Dichlorobis(cyclopentadienyl)hafnium***).

R = Ph, 68%; R = C_5F_5, 71%; R = Et, 74%

Dicarbonylbis(cyclopentadienyl)titanium[1]

[12129-51-0] · $C_{12}H_{10}O_2Ti$ · Dicarbonylbis(cyclopentadienyl)titanium · (MW 234.09)

(deoxygenates sulfoxides;[3] forms alkenes by reductive coupling of aromatic aldehydes;[4a] reduces alkynes[5])

Physical Data: mp 90 °C (dec), subl 40-80 °C/0.001 mmHg.[1a]

Solubility: sol most common organic solvents; reacts with $CHCl_3$ and CH_2Cl_2.

Analysis of Reagent Purity: IR, NMR.[2]

Preparative Method: reduction of ***Dichlorobis(cyclopentadienyl)titanium*** with ***Magnesium Amalgam*** under CO atmosphere.[2]

Purification: recrystallization from toluene or sublimation at 40-80 °C/0.001 mmHg.

Handling, Storage, and Precautions: pyrophoric; store and handle under an inert atmosphere.[1a] Use in a fume hood.

Deoxygenation of Sulfoxides.

Sulfoxides are readily deoxygenated by dicarbonylbis(cyclopentadienyl)titanium to form sulfides in high yield.[3] It is noteworthy that this deoxygenation is not accompanied by byproducts that sometimes result from Pummerer rearrangement in other methods. A range of alkyl and aryl sulfoxides are reduced in yields which are generally higher than 80% (see eq 1, for example).

(1)

Reductive Coupling of Aromatic Aldehydes.

Reductive coupling of aromatic aldehydes forms stilbene derivatives in good yields (eq 2).[4a] These reactions apparently proceed through the intermediacy of pinacol derivatives which are often observed as byproducts of the reaction, especially at short reaction times, and in the presence of substoichiometric quantities of dicarbonylbis(cyclopentadienyl)titanium. Related reductive dimerizations have also been reported for diethyl ketomalonate,[4b] *N,N´*-di-*p*-tolylcarbodiimide,[4b] and carbon disulfide.[4c]

(2)

R = H, 98%; R = Me, 99%; R = Cl, 59% (88% with 4 equiv $Cp_2Ti(CO)_2$)

Reduction of Alkynes.

Terminal alkynes are hydrogenated to terminal alkenes using dicarbonylbis(cyclopentadienyl)titanium as the catalyst. Aryl alkynes are reduced to the corresponding ethane derivatives under the same conditions (Table 1).[5a] A more potent catalyst is obtained by treating $Cp_2Ti(CO)_2$ with ***Diphenylacetylene***. The resulting π-acetylene complex rapidly and completely reduces diphenylacetylene, styrene, *trans*-stilbene, 1-octene, and 1,4-diphenylbutadiene to the corresponding ethane derivatives.[5b]

Table 1 Hydrogenation of Alkynes with Catalytic Dicarbonylbis(cyclopentadienyl)titanium

Substrate	Product	Yield (%)
Acetylene	No reaction	
1-Pentyne	1-Pentene	95
1-Hexyne	1-Hexene	90
t-Butylacetylene	3,3-Dimethylbut-1-ene	40
	2,2-Dimethylbutane	60
3-Heptyne	No reaction	
Phenylacetylene	Ethylbenzene	95
Diphenylacetylene	Dibenzyl	90

Stoichiometric alkyne reductions have also been reported. Low yields of *cis* alkenes are obtained by treatment of internal alkynes with $Cp_2Ti(CO)_2$ in wet hexane followed by cleavage of the resulting complex with HCl in CH_2Cl_2.[5c] The reaction of several unsaturated diacids with $Cp_2Ti(CO)_2$ gave the corresponding saturated carboxylate complexes in fair to excellent yields, rather than the expected unsaturated complexes.[5d]

Dicarbonylbis(cyclopentadienyl)zirconium[1]

[59487-85-3] · $C_{12}H_{10}O_2Zr$ · Dicarbonylbis(cyclopentadienyl)zirconium · (MW 277.44)

(couples alkynes to form zirconacyclopentadienes[3])

Physical Data: subl 70 °C/10^{-2} mmHg.[1a]

Solubility: sol hydrocarbons, THF.

Analysis of Reagent Purity: IR, NMR.[2]

Preparative Method: reduction of ***Dichlorobis(cyclopentadienyl)zirconium*** with ***Magnesium Amalgam*** under CO atmosphere.[2]

Purification: hexane solution is filtered through alumina and cooled to -20 °C to induce crystallization; sublimation at 70 °C/10^{-2} mmHg.[2]

Handling, Storage, and Precautions: store and handle under an inert atmosphere. Use in a fume hood.

Dicarbonylbis(cyclopentadienyl)zirconium is one of several zirconocene derivatives which give zirconacyclopentadiene complexes when reacted with alkynes (eq 1) (see also ***Bis(cyclopentadienyl)diphenylzirconium*** and ***Dichlorobis(cyclopentadienyl)zirconium***).[3] Zirconacyclopentadiene complexes may be isolated and purified prior to further manipulations. Significantly, CO insertion usually does not occur, except when the reaction is done in a closed vessel (thereby preventing escape of CO).

A number of reagents, including ***Hydrogen Chloride***, ***Iodine***, and ***Carbon Monoxide***, stereospecifically replace the metal to form substituted 1,3-butadienes.[4] For example, the zirconacyclopentadiene (**1**) reacts with HCl to give (*Z*,*Z*)-1,2,3,4-tetrakis(pentafluorophenyl)butadiene (eq 2).[3]

Zirconacyclopentadiene complexes have also been reported to react with excess alkyne producing expanded zirconacycles, and eventually alkyne oligomers and polymers.[5]

Dicarbonylbis(triphenylphosphine)nickel(0)

[13007-90-4] · $C_{38}H_{30}NiO_2P_2$ · Dicarbonylbis(triphenylphosphine)nickel(0) · (MW 639.32)

(carbonylation of vinyl and aryl halides;[1,2] oxidative bisdecarboxylation;[3-5] oligomerization reactions;[6-8] homo-Diels-Alder reactions)

Physical Data: mp 213-218 °C (dec).

Solubility: sol HMPA, THF, diglyme, triglyme, benzene, acetonitrile, ethanol, cyclohexane.

Form Supplied in: nonvolatile, light-yellow, air-stable solid.

Preparative Methods: by treating ***Tetracarbonylnickel*** with 2 equiv of ***Triphenylphosphine***[6] or by dissolving ***Dichlorobis(triphenylphosphine)nickel(II)*** in ethanol and treating it with CO in the presence of MeSNa.[10]

Purification: recrystallize from benzene.

Handling, Storage, and Precautions: catalytic activity decreases with storage. Likely to be toxic, similar to nickel carbonyl, but low volatility makes it easy to avoid ingestion.[1,11] Use in a fume hood.

Carbonylation Reactions.

The title reagent (**1**) is useful in the preparation of α-methylene lactones from appropriately substituted vinyl halides (eqs 1-3).[1] These reactions are commonly carried out at reflux under an inert atmosphere in THF using stoichiometric quantities of (**1**), triethylamine, and the substrate. The byproducts of this reaction are HBr and regenerated zerovalent nickel, so the process is formally catalytic in nickel. Attempts, however, to make this synthetic method catalytic have been unsuccessful.

(1)

(2)

(3)

The title reagent has also been used in the carbonylation of aryl halides (eqs 4 and 5).[2] These reactions normally proceed at 120 °C in HMPA and 20 atm CO pressure. This process proceeds efficiently with ***Tetramethylstannane*** yet fails when Ph_4Sn is used under analogous conditions.

(4)

(5)

Oxidative Bisdecarboxylation.

This reaction using (**1**) has been used to prepare norbornenes (eq 6)[3,4] and other bicyclic compounds[5] from anhydride and thioanhydride precursors. These reactions are typically run in refluxing diglyme with stoichiometric (**1**). The application of this chemistry to other systems has been less effective particularly when the substrate contains abstractable β-hydrogens.[3]

(6)

Cycloligomerization Reactions.

Complex (**1**) catalyzes the trimerization of alkynes to aromatic compounds (eq 7) under pressure in benzene.[6] The selective dimerization of butadiene to 4-vinylcyclohexene is mediated with catalytic (**1**) under CO pressure in high yield (eq 8).[7] When this process is allowed to proceed under acetylene pressure, a 4:1 mixture of 1,5-cyclooctadiene and 4-vinylcyclohexene is obtained in moderate yield (55%).[8]

(7)

(8)

Homo-Diels-Alder Reactions.

The title reagent (**1**) catalyzes the homo-Diels-Alder condensation of vinyl compounds with norbornadiene (eq 9).[9] This process is typically carried out in a sealed tube while heating to 120 °C for 15 h.

Dicarbonyl(cycloheptadienyl)(triphenyl phosphite)iron Hexafluorophosphate

[85956-40-7] · $C_{27}H_{24}F_6FeO_5P_2$ · Dicarbonyl(cycloheptadienyl)(triphenyl phosphite)iron Hexafluorophosphate · (MW 660.27)

(synthesis of functionalized cycloheptadienes)

Physical Data: obtained as an amorphous powder.

Solubility: sol CH_2Cl_2, MeCN, acetone.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: IR (MeCN) 2067, 2028 cm^{-1}; ^1H NMR (CD_3CN) δ 7.49 (15H, m, $P(OPh)_3$), 6.36 (1H, t, *J* = 6.5 Hz, 3-H), 6.03 (2H, m, 2-H, 4-H), 4.92 (2H, m, 1-H, 5-H), 2.65 (2H, m, *endo*-6-H, *endo*-7-H), 1.80 (2H, m, *exo*-6-H, *exo*-7-H).

Preparative Methods: ***Triphenylmethyl Hexafluorophosphate*** (124 g) is dissolved in the minimum volume of dry CH_2Cl_2 and to that solution, dicarbonyl(cycloheptadiene)(triphenyl phosphite)iron[1] (150 g) is added. The mixture is swirled to dissolve the complex and set aside at rt for 2 h. The product is precipitated by pouring the mixture into wet ether, collected by filtration, and washed thoroughly with wet ether to afford pure (**1**) (190 g, 99%). The corresponding tetrafluoroborate salt is prepared from dicarbonyl(η^4-cycloheptatriene)(triphenyl phosphite)iron and ***Tetrafluoroboric Acid***.[2]

Regio- and Stereocontrolled Functionalization of Cycloheptadiene.[1,3]

By reacting the dienyl complex (**1**) with a range of nucleophiles, a variety of substituted cycloheptadienes are obtained. The addition of nucleophile is stereospecific, *trans* to the $Fe(CO)_2P(OPh)_3$ group. The regioselectivity of the

addition to the complex (**1**) is strongly dependent on the nature of the nucleophile, soft nucleophiles attacking C-1 and hard nucleophiles attacking C-2 of the dienyl ligand. For example, hard nucleophiles such as lithium or magnesium alkyls give predominant C-2 addition to give complexes (**2**) in good to excellent yield (eq 1), while organocuprate reagents (soft nucleophiles) result in predominant, in many cases exclusive, C-1 addition to give diene complexes (**3**) (eq 2).

(2)

(1)

(3a) R = Me
(3b) R = Bu
(3c) R = Ph

The dienyl complexes also undergo very clean, high-yielding addition of stabilized enolates, $NaCH(CO_2Me)_2$, $NaCH(COMe)CO_2Me$, $NaCH(SO_2Ph)CO_2Me$, and $NaCH(CN)CO_2Me$, to give diene complexes (**4**) as the exclusive products (eq 3).

(3)

(1)

(4a) $R = R^1 = CO_2Me$

(4b) $R = COMe,\ R^1 = CO_2Me$

(4c) $R = SO_2Ph,\ R^1 = CO_2Me$

(4d) $R = CN,\ R^1 = CO_2Me$

To expand the synthetic utility, the monosubstituted diene complexes can be converted to the dienyl complexes (**5**) with the triphenylmethyl carbocation (eq 4) and reacted with nucleophiles to give disubstituted cycloheptadienes. The reactions with (**5**) are stereospecific, regiospecific, and give high yields. For example, reactions of (**5**) with alkyllithium, Grignard reagents, and cuprates give products (**6**) of C-1 addition, *cis* to the already present substituent (eq 4). As expected, the complex (**5**) also reacts with stabilized enolates to give stereochemically defined disubstituted complexes (**6e-h**) in very high yield (eq 4).

(3a) R = Me
(3b) R = Bu

(5)

(6a) R = R^1 = Me
(6b) R = Me, R^1 = Bu
(6c) R = Me, R^1 = Ph
(6d) R = Me, R^1 = $CH_2CH{=}CH_2$
(6e) R = Me, R^1 = $CH(CO_2Me)_2$
(6f) R = Me, R^1 = $CH(COMe)CO_2Me$
(6g) R = Me, R^1 = $CH(SO_2Ph)CO_2Me$
(6h) R = Bu, R^1 = $CH(CO_2Me)_2$

The complex (**1**) is a better reagent for preparing functionalized cycloheptadiene than its tricarbonyl analog, where yields of the products are very low with very poor regioselectivities.

Stereocontrolled Multiple Functionalization of Cycloheptadiene.[4]

The complex (**1**) is also used for the preparation of stereocontrolled trisubstituted cycloheptadiene complex (**10**) (eq 5). Deprotonation of complex (**1**) provides the η^4-triene complex (**7**) in quantitative yield. Hydroboration of the

complex (**7**) gives a single alcohol (**8**) in 92% yield. The alcohol is converted to the ketone (**9**) in 81% yield by Swern oxidation. The ketone is used for the stereospecific synthesis of multiply functionalized cycloheptadiene complex (**10**) in two steps (eq 5).

Asymmetric Synthesis of Cycloheptadienes.[5]

The complex (**1**) is also used in the preparation of optically active mono- and disubstituted cycloheptadiene iron complexes with sulfoximine chiral auxiliaries (eq 6). The treatment of the enolate anion of ester (**11**) with (**1**) gives the diene complex (**12**) as a mixture of diastereomers (98-99% yield). The desulfonylation of (**12**) gives up to 50% ee of monoester (**13**) in 80-83% yield. The optically active monoester (**13**) is used for the preparation of optically active disubstituted dienes (**14**) in good yield (eq 6).

Synthesis of Precursors of Biologically Active Compounds.

Dimethylcycloheptadiene complex (**6a**) serves as an intermediate for the synthesis of (+)-Prelog-Djerassi lactonic acid (**15**) (eq 7).[6] This lactone is isolated as a degradative product of methymycin and related compounds, narbomycin, picromycin, and neomethymycin.[7] The racemic monoester complex (**14a**) has been utilized as an intermediate for the synthesis of precursor (**16**) of the antibiotic carbomycin B (eq 8).[8] The monoester (**14a**) has also been used as an intermediate for the synthesis of the lactone (**17**), a subunit of the antibiotic tylosin (eq 9).[6]

Dicarbonyl(cyclohexadiene)(cyclopentadienyl)molybdenum Tetrafluoroborate

(BF_4 salt)

[115252-55-6] · $C_{13}H_{13}BF_4MoO_2$ · Dicarbonyl(cyclohexadiene)(cyclopentadienyl)molybdenum Tetrafluoroborate · (MW 383.99) (PF_6 salt)

[84117-10-2] · $C_{13}H_{13}F_6MoO_2P$ · Dicarbonyl(cyclohexadiene)(cyclopentadienyl)molybdenum Hexafluorophosphate · (MW 442.15) (cation)

[84117-09-9] · $C_{13}H_{13}MoO+2$ · Dicarbonyl(cyclohexadiene)(cyclopentadienyl)molybdenum Tetrafluoroborate · (MW 297.18)

(reagent for stereocontrolled multiple functionalization of cyclohexene rings[1])

Physical Data: dec >300 °C.

Solubility: sol most polar organic solvents; very sol methylene chloride; insol diethyl ether and alkanes.

Form Supplied in: yellow crystals generally prepared by user from $Mo(CO)_6$.

Analysis of Reagent Purity: carbonyl stretching bands at 2017 and 1962 cm^{-1} (CH_2Cl_2) are characteristic.

Preparative Methods: straightforwardly prepared in 97% yield by hydride abstraction from $CpMo(CO)_2$(cyclohexenyl),[2] which in turn is

prepared following a procedure developed for the parent allyl complex by Hayter[5] (>70% yield). This involves reflux of $Mo(CO)_6$ in acetonitrile to produce $Mo(CO)_3(MeCN)_3$, addition of 3-bromo-1-cyclohexene, and subsequent treatment with lithium cyclopentadienide.

Handling, Storage, and Precautions: should be handled under nitrogen or argon. The crystals can be handled in air for short periods with no significant decomposition. Solutions of the compound are air sensitive, but can be handled with brief exposure to air or can be reduced in volume with a rotary evaporator. Use in a fume hood.

Introduction.

The use of this versatile reagent was originally developed by Faller and his co-workers[2] and has been applied extensively in organic syntheses by Pearson[3] and Liu.[4]

Hydride Abstraction From the Allyl Complex.

Hydride abstraction is one of several important processes that establish the routes available for multiple functionalization of the ring (eq 1).

(1)

Nucleophilic Addition to the Cationic Diene Complex.

The positive charge on the diene complex makes it susceptible to nucleophilic attack, which occurs on the side of the ring opposite to the metal. This yields a new substituted η^3-cyclohexenyl complex, which can undergo a second hydride abstraction-nucleophilic addition process to yield a disubstituted η^3-cyclohexenyl species (eq 2).[2,3] Most soft nucleophiles, such as dimethyl malonate, cyanoborodeuteride, or enamines, are effective. Reactions with Grignard reagents provide access to the methyl and phenyl derivatives.

Deprotonation of the Cationic Diene Complex.

The positive charge on the complex renders the methylene protons adjacent to the bound double bonds acidic. Treatment with ***Triethylamine*** yields the η^3-cyclohexadienyl complex (eq 3).[6] Usually in this type of system both additions and abstractions of hydride occur on the side of the ring opposite to the metal.

Further Functionalization of the Ring.

The availability of the η^3-cyclohexadienyl complexes allows further elaboration of the ring. For example, the η^3-cyclohexadienyl complex undergoes a ***Boron Trifluoride***-promoted ene reaction with aldehydes (-40 °C, toluene) (eq 4).[4]

An alternative to activation of the ring to nucleophilic attack is replacement of a carbonyl in the η^3-cyclohexenyl complexes by NO^+ (eq 5).[7] Usually the addition occurs *cis* to the nitrosyl, although a number of factors can affect the stereochemistry of the addition.[8]

Removal of the Metal.

The functionalized cyclohexadiene can be decomplexed by oxidation of the cationic complex with Et_3NO. Another alternative is to prepare the cyclohexene complex via NO^+ addition to the η^3-cyclohexenyl dicarbonyl and treat this with another nucleophile or cyanoborohydride to produce the η^2-alkene

complex. These η^2-alkene complexes can be oxidized by ***Cerium(IV) Ammonium Nitrate*** (buffered with acetate)[9] or air[7] to yield the decomplexed cyclohexene. Pearson has also developed an iodolactonization methodology for decomplexation of the ring which is applicable in some cases (eq 6).[9]

(6)

Enantioselective Syntheses.

The sequential additions to the complexed cyclohexadienyl moiety should allow the development of a powerful strategy for asymmetric syntheses of substituted six-membered rings. Since the parent $[CpMo(CO)_2(cyclohexenyl)]^+$ complex has a plane of symmetry, attention has focused on obtaining nonracemic substituted derivatives. The η^4-cyclohexadiene complex is essentially a *meso* structure since the bound alkenic carbons are all stereogenic centers. It follows that diastereoselectivity would be observed for one side or the other of a given face of the ring in nucleophilic attack by chiral nucleophiles. Moderate de's (78%) have been obtained on selective addition of (+)-*t*-butyldimethylsilyl sulfoximinyl ester enolates.[10] The products then contain three new stereogenic centers, with the $S_{(S)}$-enolate yielding primarily the (*S*,*S*,*S*)-product (eq 7).

Since the addition of chiral allylic acetates[11,12] and presumably phosphonates[13] to $Mo(CO)_3(MeCN)_3$ apparently occurs with retention of configuration, an alternative route into asymmetric cyclohexenols would be the use of enantiomerically pure cyclohexenols as starting materials. Although this has not yet been exploited extensively, Liebeskind[12] recently reported stereocontrolled syntheses of a number of dihydropyrans and tetrahydropyrans using the $[CpMo(CO)_2(oxacyclohexadienyl)]^+$ system.

Dicarbonyl(cyclopentadienyl)cobalt(I)

[12078-25-0] · $C_7H_5CoO_2$ · Dicarbonyl(cyclopentadienyl)cobalt(I) · (MW 180.05)

(catalyst, especially for alkyne trimerization and cotrimerization;[3-5] source of a wide range of cyclopentadienylcobalt complexes and of cyclopentadienones, pyridones,[10] etc.)

Alternate Names: cyclopentadienyldicarbonylcobalt; cyclopentadienylcobalt dicarbonyl.

Physical Data: bp 139-140 °C/710 mmHg; 37-38.5 °C/2 mmHg.

Solubility: very sol all common org solvents; insol H_2O.

Form Supplied in: dark red liquid; available commercially.

Preparative Methods: synthesized quantitatively from ***Octacarbonyldicobalt*** and ***Cyclopentadiene***[1] or from ***Bis(cyclopentadienyl)cobalt*** and ***Carbon Monoxide***.[2]

Handling, Storage, and Precautions: somewhat air sensitive; toxic; best stored under CO or inert gas (N_2, Ar) at low temperature (<0 °C). Use in a fume hood.

General Remarks.

Many of the reactions in which $CpCo(CO)_2$ acts as catalyst involve dissociation of CO to leave the catalytically active species, regarded as CpCo. As this can readily arise from other $CpCoL_2$ complexes (e.g. L = PR_3, $P(OR)_3$, C_2H_4; L_2 = diene) or from Cp_2Co, useful reactions of the phosphine complexes are included here and the entries for ***Bis(cyclopentadienyl)cobalt*** and ***(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)***, the preferred catalyst for pyridine synthesis, should also be consulted.

Catalytic Reactions.

General.

Dicarbonylcyclopentadienylcobalt is the most widely used catalyst for alkyne cyclotrimerization and can effectively catalyze such related processes as pyridine synthesis from two alkyne molecules and one nitrile molecule, cyclohexadiene synthesis from two alkyne molecules and one alkene molecule, and participate in the (usually stoichiometric) formation of cyclopentadienones from two alkyne molecules and CO. It is known that the first step in these processes is the thermally or photochemically induced dissociation of CO and there is strong evidence for intermediate formation of bis(alkyne) complexes (eq 1) which can react with the third substrate molecule to give the above products.

The reaction in eq 1 must be assumed to proceed by coordination of one alkyne, followed by dissociation of the second CO. Although monoalkyne complexes $CpCo(CO)(R^1C_2R^2)$ have not been isolated from such systems, their analogs, $CpCo(PPh_3)(R^1C_2R^2)$ are well known. They are accessible, inter alia, by the sequence shown in eqs 2 and 3,[3,4] followed by eq 4.[5]

$$CpCo(CO)_2 + PR_3 \longrightarrow CO + CpCo(CO)(PR_3) \qquad (2)$$

$$ClCo(PR_3)_3 + CpLi \longrightarrow PR_3 + CpCo(PR_3)_2 \qquad (3)$$

$$CpCoL(PR_3) + R^1C{\equiv}CR^2 \longrightarrow L + CpCo(PR_3)(R^1C_2R^2) \qquad (4)$$

$$L = CO \text{ or } PR_3$$

The products $CpCo(PR_3)(R^1C_2R^2)$ also yield bis(alkyne) complexes $CpCo(R^1C_2R^2)_2$ on further treatment with alkyne.[6] It is uncertain whether cyclization of these bis(alkyne) complexes to cobaltacyclopentadiene systems (eq 5) precedes or is induced by addition of the third ligand L. When L is a third alkyne this leads to the immediate precursor of the aromatic cyclotrimerization product; it is also the step which determines the regiochemistry of that product. The cobaltacyclopentadienes arising according to eq 5 have been well characterized for L = PPh_3, but the compounds with L = alkyne, nitrile, alkene, or CO presumably collapse rapidly to the above-mentioned endproducts. In the cases where these are dienes (eqs 6 and 7), these can remain bound as stable complexes, but arenes and 2-substituted pyridines are too readily displaced by alkyne, regenerati ng the bis(alkyne) complexes $CpCo(R^1C_2R^2)_2$ and making the reactions catalytic. Only very exceptionally (eq 8) has an η^4-arene complex been isolated.[7]

(5)

(6)

(7)

Cyclotrimerization, Including Mixed Cyclotrimerization of Alkynes.

Simple cyclotrimerizations can be achieved efficiently with a wide range of metal carbonyl[8] and other complexes. With unsymmetrical alkynes, different catalysts may lead to widely different regioselection. Thus whereas $CpCo(CO)_2$ converts diphenyl-1,3-butadiyne chiefly to the unsymmetrical trimer (eq 9), use of ***Dicarbonylbis(triphenylphosphine)nickel(0)*** gives exclusively the symmetrical isomer (83%).[9]

However, the special value of $CpCo(CO)_2$ with respect to trimerization arises from its ability to promote controlled mixed trimerization reactions when one alkyne molecule carries bulky substituents, e.g. trimethylsilyl, and cannot undergo self-trimerization, apparently for steric reasons. It is then possible to employ that bulky alkyne in excess, e.g. in reactions with dialkynes, so as to suppress their trimerization (eq 10) in favor of the mixed condensation (eq 11). Surprisingly, when a polymer-supported form of the catalyst was substituted, only the reaction in eq 10 was observed (e.g. with $n = 3$). With $CpCo(CO)_2$ itself, many high-yielding examples of reactions of the type in eq 11, have been studied and reviewed.[10]

Examples include the remarkably efficient formation of benzocyclobutenes from 1,2,4,5-tetraethynylbenzene (eq 12) and the reaction of an enediyne designed as a steroid synthon (eq 13); in the latter case the intermediate benzocyclobutene is not isolated but ring opens as shown to allow an intramolecular Diels-Alder reaction. The product was converted to (±)-estrone in 80% yield via selective protodesilylation at the 2-position with ***Trifluoroacetic Acid*** followed by replacement of the second silyl group by OH using ***Lead(IV) Trifluoroacetate***. The alternative protodesilylation under basic conditions (using ***Potassium t-Butoxide***) or replacement of $SiMe_3$ by halogens adds to the versatility of such silyl-substituted products in synthesis. Approaches to other natural products are exemplified for protoberberine-type isoquinoline alkaloids (eq 14). This example also illustrates the highly regioselective formation of the more sterically demanding arene as a result of the initial coupling of the least hindered alkynic carbons.[10]

(14)

Pyridine Synthesis.

Dicarbonylcyclopentadienylcobalt-catalyzed reactions have been reviewed;[10] see ***(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)***, the more frequently used catalyst, for a fuller discussion. As in cyclotrimerization (cf. e.g. eq 14), high regioselectivity is often observed; an example is shown in eq 15.[10]

Pyridones result from alkynes and alkyl isocyanates, but with low regioselectivity.[10] This problem is avoided in condensations using o-alkynyl isocyanates (eq 16).[11]

Other Catalytic Reactions.

Dicarbonylcyclopentadienylcobalt and ***Octacarbonyldicobalt*** are alternative catalysts for pyrrole synthesis from alkynes and ***Cyanotrimethylsilane*** (eq 17).[12] The known addition of ***Phenyl Isocyanide*** to the complex $CpCo(PPh_3)(PhC_2Ph)_2$ (eq 18)[13] may provide a model for this reaction, which may be initiated by isomerization of Me_3SiCN to Me_3SiNC and continue as in eq 19.

Stoichiometric Reactions.

Cyclohexadiene Formation.

As noted above, highly substituted cyclohexadienes can be obtained (eq 6) by treating the isolated cobaltacyclopentadiene complexes with a range of terminal alkenes or dimethyl maleate; subsequent oxidation using cerium(IV) salts liberates the free dienes.[14,15] The complex formed from $MeN(CMe_2C_2Me)_2$ and $CpCo(PPh_3)_2$ has similarly been added to diethyl fumarate.[16] Cyclohexadiene complexes are obtained more commonly and conveniently, without isolation of cobaltacyclopentadienes. Thus tolan or dimethyl acetylenedicarboxylate reacts with norbornene and $CpCo(CO)_2$ according to eq 20 to yield mixtures of two stereoisomeric complexes.[17]

R = Ph or CO_2Me

Alkynes or diynes have been added in similar fashion to uracil derivatives (eqs 21 and 22).[18]

(22)

Even the 2,3-bond of *N*-acylindoles can function as the ene component in such condensations (eq 23).[19] The free tetracyclic ligand was liberated from the resultant complex in excellent yield by ***Copper(II) Chloride*** or ***Iron(III) Chloride*** oxidation and the aromatized ligand was obtained when Ce^{IV} was used. Cyclization of enediynes[10] (eq 24) has been followed by liberation of the organic ligands using oxidation with $CuCl_2/Et_3N$ and by other transformations.[20] An efficient approach to steriods by enediyne cyclization is shown in eq 25.[21] The free organic ligand is liberated from the resultant cobalt complex in 81% yield by oxidation.

(23)

(24)

$X = CH_2CH_2$ or O, $n = 3$ or 4, R = H or TMS

(25)

The sequence of steps for cyclohexadiene formation can be altered as in eq 26 followed by eq 27.[22,23] Again $CuCl_2$ proves to be an efficient oxidizing agent to liberate the free cyclohexadiene with only a small amount of aromatization, whereas the use of cerium(IV) leads to extensive dehydrogenation.[23] Loss of PPh_3 from the cobaltacyclopentene intermediate (eq 27) is assisted in this case by coordination of an ester carbonyl. The same intermediates also add carbon monoxide or isocyanides, yielding cyclopentenones or aminocyclopentadienes, respectively (eq 28).[23]

(26)

Pyran Synthesis.

Under photochemical conditions, ketones (or aldehydes) can take the place of alkenes and add to diynes to yield pyrans. Examples include the addition of acetone to 1,7-octadiyne (eq 29) with the more reactive maleic anhydride substituted catalyst and the tricyclization of a diynone (eq 30). In the latter case a ring-opened product accompanies the pyran.[24] In other examples an ynone is condensed with a silylalkyne (eq 31).[24]

(29)

(30)

(31)

Formation of Cyclopentadienone Complexes and

Competing Reactions.

(Cyclopentadienone)cyclopentadienylcobalt derivatives are major products of the reaction of $CpCo(CO)_2$ with internal alkynes and terminal alkynes, RC_2H, which have bulky groups, R. Irradiation was used to obtain the earliest examples (eq 32, R = Me or Ph)[25] and remains the method of choice in most cases, but thermal activation has also been widely used. Three other types of product are frequently produced under thermal conditions: (cyclobutadiene)cyclopentadienylcobalt, cyclopentadienyl(*p*-quinone)cobalt, and (cyclopentadienyl)maleylcobalt derivatives. Formation of the cyclobutadiene complexes has been reviewed.[26] CO-free precursors, e.g. ***(1,5-Cyclooctadiene)(cyclopentadienyl)cobalt(I)***, are preferable for this purpose since they cannot yield the other products, but $CpCo(CO)_2$ can also give excellent yields as in the examples shown in eqs 33 and 34.[27,28] The latter example contrasts with the low-temperature photochemical reaction of the same precursors (eq 35).[29] Liberation of the free dienone from the product by Ce^{IV} oxidation as well as partial or complete displacement of $SiMe_3$ by Br or H[30] emphasizes the synthetic utility of such reactions.

(32)

(33)

The reaction of 2-butyne under thermal conditions (eq 36)[31] shows that quinone complexes are formed more quickly than cyclopentadienone complexes and perhaps decarbonylate to the latter under the reaction conditions. Similarly at 100 °C, 3-hexyne yields the tetraethylquinone complex but at 110-130 °C it yields the tetraethylcyclopentadienone complex as the major product.[32] In a series of alkynes, MeC_2R, both the electronegativity and size of R affects the product ratios.[33] The maleyl complexes appear only as minor products (eq 36) and hence cannot be considered to be synthetically significant.

(36)

yields after 19 h 3:3:27%
yields after 90 h 62:1:16%

Tolerance of highly polar substituents is illustrated by the reaction of di-*t*-butoxyacetylene (eq 37).[34] The ionic catalyst, [K(crown)][CpCo(CO)CN], obtained from [K(crown)]CN and $CpCo(CO)_2$, has been used[35] in the reaction with tolan, but although the conditions were fairly mild (reflux in butyronitrile), the modest yield (43%) of the tetraphenylcyclopentadienone complex does not encourage use of this procedure.

(37)

In contrast to its efficient incorporation into cyclobutabenzenes (see above), $Me_3SiC_2(CH_2)_2C_2SiMe_3$ gives a very complex mixture of (largely polynuclear) cyclobutadiene and cyclopentadienone complexes in the absence of added alkyne.[28] Presumably the monomeric cyclobutenocyclopentadienone is too strained, whereas a derivative with four methyl substituents on the cyclobutene ring is formed as the sole product according to eq 38.[36]

When the terminal alkyne Me_3SiC_2H is used, the 2,5-disubstituted cyclopentadienone complex is the major product (eq 39)[29] (a 76% yield is reported[37] under only marginally different conditions) with $CpCo(CO)_2$, but the corresponding 2,4-disubstituted compound predominates in the product from $(C_5Me_5)Co(CO)_2$.[29]

In a reaction closely analogous to the CO insertion, cobaltacyclopentadienes react with isocyanides to give iminocyclopentadiene complexes, e.g. according to eq 40.[38]

Other Products from Cobaltacyclopentadienes.

In addition to the above alkene and CO insertions, isolated cobaltacyclopentadienes have been shown to react with diazo compounds to yield cyclopentadiene complexes and hence substituted cyclopentadienes (e.g. eq 41),[39] and similarly with azides to yield pyrroles (eq 42).[40] Acid azides, $RCON_3$, react similarly to give the corresponding *N*-acylpyrroles while tosyl azide reacts according to eq 43.[40]

(42)

(43)

Reaction with sulfur yields thiophenes (eq 44).[41] Replacement of triphenylphosphine by phosphites also results in ring formation, leading to cyclic 1-alkoxyphosphole oxide complexes (as mixtures of two stereoisomers) with loss of alkyl groups (eq 45).[42]

(44)

(45)

Oxidation of the tetraphenyl- or dimethyldiphenylcobaltacyclopentadiene complex with ground-state oxygen at 70 °C or singlet oxygen at room temperature yields dibenzoyldiphenylethylene or 2,3-dibenzoyl-2-butene, respectively, via the corresponding CpCo complex (eq 46).[43]

(46)

Insertion Reactions.

Cyclobutenediones react smoothly when heated with $CpCo(CO)_2$ to yield cobaltacyclopentenediones (eqs 47 and 48). Both the cyclopentadienyl complex and its pentamethyl derivative have been used with benzocyclobutenedione.[44] As shown in eq 48, despite the high temperature required the latter reaction proceeds quantitatively. The product complexes react photochemically with alkynes to give complexes of benzoquinones from which the free quinone may be liberated by cerium(IV) oxidation (eq 49).[44]

(47)

(48)

(49)

The related insertion into cyclobutenones has been effected using indenylbis(triphenylphosphine)cobalt (eq 50), initially yielding ketene complexes which add alkynes to give phenols.[45]

(50)

Another four-membered ring is expanded when $CpCo(CO)_2$ adds to a disilacyclobutene, e.g. in the reaction sequence shown in eq 51. The initially formed complex reacts photochemically with butadiene or its derivatives, at low temperature merely replacing the CO ligand, but at 60 °C giving disilacyclooctadienes.[46]

Miscellaneous Reactions.

Azoarenes react with $CpCo(CO)_2$ as exemplified for azobenzene (eq 52). The complexes formed may be carbonylated to yield *N*-arylbenzimidazolones (eq 53).[47] Most diazoalkanes react according to eq 54 yielding dinuclear, methylene-bridged complexes,[48] but diethyl diazomalonate yields a cobaltafuranone complex (eq 55).[49]

(53)

(54)

(55)

The products of the reaction in eq 55 and other cobaltacycles, formed inter alia from alkyne complexes (eq 56)[50] or from the isocyanide-phosphine complexes, $C_5H_5Co(PMe_3)(RNC)$,[51] have not been utilized in further reactions which would constitute synthetically useful transformations of the organic fragments.

Dicarbonylcyclopentadienylcobalt is the source (via reaction with 3,4-dichlorocyclobutene or with photopyrone) of the cyclobutadiene complex $(C_5H_5)Co(C_4H_4)$ whose substitution reactions provide potential routes to many cyclobutadiene derivatives; however, it is not known to have any advantages in this respect over the more commonly used ***Tricarbonyl(cyclobutadiene)iron***.[26]

Dicarbonylcyclopentadienylcobalt is reduced by ***Sodium*** metal to the salt of a dinuclear radical anion (eq 57).[52] Alkyl halides convert this anion to dialkyl complexes (eq 58) which react with carbon monoxide, yielding ketones and regenerating $CpCo(CO)_2$ (eq 59).[53] Use of dihalides in this sequence leads to cyclic ketones; thus the complex obtained from 1,3-diiodopropane affords cyclobutanone (eq 60), but the same intermediate can be used to generate cyclopropane on treatment with iodine (eq 60).[54] In the case of the product from dibromo-*o*-xylene, $C_6H_4(CH_2Br)_2$, the initial complex disproportionates at 22 °C and the product is carbonylated (eq 61), whereas direct carbonylation of the intermediate leads to dimeric hydrocarbon products (eq 62).[55]

Dicarbonyl(cyclopentadienyl)[(dimethylsulfonium)methyl]iron Tetrafluoroborate[1]

[72120-26-4] · $C_{10}H_{13}BF_4FeO_2S$ · Dicarbonyl(cyclopentadienyl)[(dimethylsulfonium)methyl]iron Tetrafluoroborate · (MW 339.93)

(stable precursor of a cationic carbene, or methylene, complex of iron; reacts directly with alkenes to give cyclopropanes[2])

Physical Data: mp 129-130 °C; *d* 1.57 g cm^{-3}.

Solubility: insol or slightly sol most solvents at rt; sol very polar solvents such as nitromethane at rt; sol other polar solvents (e.g. dioxane) at reflux.

Form Supplied in: yellow-orange powder or crystals.

Analysis of Reagent Purity: ^1H NMR.

Preparative Methods: the preparation of this reagent has gone through several revisions and improvements since its introduction in 1979. The most recently improved preparations[3] are satisfactory for large-scale applications and have been adapted for commercial use. In a one-pot operation, the stable, crystalline, dinuclear complex $[Cp(CO)_2Fe]_2$ is reductively cleaved with sodium dispersion to generate a THF solution of the highly nucleophilic sodium ferrate, $Na[Cp(CO)_2Fe]$. This species is immediately alkylated with chloromethyl methyl sulfide, and the resulting iron alkyl, $Cp(CO)_2FeCH_2SMe$, is subjected to *S*-alkylation with methyl iodide. Finally, the resulting sulfonium salt, initially produced as an iodide, is subjected to in situ anion exchange and simultaneous crystallization by treatment with hot aqueous $NaBF_4$, followed by cooling to give the reagent as a yellow-orange, or amber-colored, crystalline solid (eq 1) which has been characterized spectroscopically and by single-crystal X-ray diffraction.[4] The anion exchange is performed in order to assure that a nonnucleophilic counterion is present during the subsequent cyclopropanation reactions; a nucleophilic anion such as iodide may apparently intercept reactive intermediates on the pathway leading to the desired cyclopropane products. A remarkable property of the reagent is its unusually high stability compared to most other organometallic reagents. This point is especially clear from the fact that it can be recrystallized from hot water exposed to the air.

Purification: recrystallization from nitromethane, acetone, or other polar solvents.

Handling, Storage, and Precautions: stable indefinitely as a solid, even when exposed to air; slowly decomposes in solution if exposed to air for long periods of time (although reactions with alkenes can be done in the presence of air and even moisture); decomposes upon heating to release dimethyl sulfide (stench). Use in a fume hood.

Alkene Cyclopropanation.

Once this reagent has been prepared (or purchased commercially) it can be used directly in reactions with a wide range of alkenes without the need for using any further activation agents in order to obtain cyclopropanes (eq 2). An iron carbene complex is apparently generated as a reactive intermediate upon dissociation of dimethyl sulfide which ultimately recombines with the iron moiety to give the principal byproduct of the reaction.

The procedure is very simple; the reagent and the alkene are mixed with a polar solvent and then heated in the temperature range of typically 80-100 °C for a few hours. Among the solvents that have been used successfully are 1,4-dioxane, DMF, ethanol, and nitromethane. The last of these, nitromethane, typically and reproducibly gives the highest yields of cyclopropanes. Excess reagent is commonly used to assure complete conversion of alkene to cyclopropane; 2 mol equiv is usually sufficient, but in some cases of less reactive alkene substrates the use of 3 mol equiv is necessary for obtaining optimum yields of cyclopropanes. The products are isolated very easily by adding pentane or another suitable nonpolar solvent to the cooled reaction mixture to precipitate the organometallic byproducts. Filtration of the mixture and use of routine distillation or chromatographic purification techniques then provide the cyclopropanes.

The reaction occurs most efficiently with mono- and disubstituted alkenes. More highly substituted alkenes generally react too slowly and exhibit very poor conversion to cyclopropanes. Some illustrative examples of efficient cyclopropanation are gathered in Table 1. Entries 1[2] and 2[2] are representative of relatively simple, nonfunctionalized alkenes. Entries 3[5] and 4[6] indicate both compatibility with other simple functional groups (ethers, sulfides, and acetals have also been used[2]) and the typical selectivity of an electrophilic reagent for more electron-rich alkenes in the presence of electron-deficient double bonds.

Table 1 Cyclopropanation of Alkenes with $Cp(CO)_2FeCH_2SMe_2^+$ BF_4^-

Entry	Alkene	Product	Yield (%)

2			88
3			86
4			68

Alternative Reagents.

The classical method for the addition of a simple methylene group to an alkene is the Simmons-Smith reaction.[7] Indeed, it is still probably the most highly used

method for effecting this transformation. It is compatible with a wide range of functional groups, and it appears to be less sensitive to the degree of double bond substitution than the present iron reagent. On the other hand, the Simmons-Smith reagent appears to show reactivity towards both electron-deficient and electron-rich alkenes in some cases; the selectivity is less pronounced than in the case of the iron reagent. More specifically, the conversions shown in entries 3 and 4 of Table 1 were also attempted with the Simmons-Smith reagent, but the iron reagent gave superior results.[5,6] A minor disadvantage of the Simmons-Smith reaction is that the active reagent must be prepared freshly before use from ***Diiodomethane*** and ***Zinc/Copper Couple*** or related combinations of sometimes air-sensitive reagents,[8] whereas the iron reagent can be stored as a highly stable solid for indefinite periods of time before use and then be used directly with no further activation being necessary. ***Diazomethane*** may also be used as an alternative reagent,[1c] but the hazards and difficulties of preparing and handling this reagent are well known.

Dicarbonyl(cyclopentadienyl)(isobutene)iron Tetrafluoroborate

[41707-16-8] · $C_{11}H_{13}BF_4FeO_2$ · Dicarbonyl(cyclopentadienyl)(isobutene)iron Tetrafluoroborate · (MW 319.87)

(exchange reagent for synthesis of Fp-alkene$^+$ and Fp-alkyne$^+$ complexes; Fp$^+$ protecting group for alkenes; cycloadditions of alkenes and alkynes)

Physical Data: yellow-orange crystalline solid.

Solubility: sol CH_2Cl_2, THF; insol Et_2O, benzene, hexane; decomposes at varying rates in DMSO, $MeNO_2$, MeCN, acetone, and other coordinating solvents.

Analysis of Reagent Purity: ^{1}H NMR (CD_3CN): δ 5.52 (Cp), 3.81 (=CH_2), 1.84 (CH_3). ^{13}C NMR (CD_3CN): δ 209 (CO), 118 (=*C*Me_2), 87 (Cp), 51 (=CH_2), 26 (Me).[2] NMR shifts are highly solvent dependent.

Preparative Method: by reaction of NaFp (Fp = $CpFe(CO)_2$) with methallyl chloride followed by protonation of the resulting alkyl complex with HBF_4 (eq 1).[1]

Handling, Storage, and Precautions: stable indefinitely under Ar or N_2 at 0 °C.

Alkene Exchange.[3]

Isobutene-Fp^+ BF_4^- is a convenient reagent for the synthesis of Fp-alkene$^+$ complexes. Exchange reactions occur readily in 1,2-dichloroethane (65-70 °C) or CH_2Cl_2 (at reflux) to form π-complexes with a wide variety of alkenes,[4] dienes,[5] allenes,[6] and alkynes,[7] and to form σ-complexes with heteroatomic donors (eq 2).[8]

Protecting Group for Alkenes.

Isobutene-$FpBF_4$ has also been used successfully to protect alkenes from hydrogenation[3] and halogenation (eq 3).[9]

Activation of Alkynes and Allenes; Ring Formation.[10]

Reaction of isobutene-$FpBF_4$ with homopropargylic alcohols or hydroxyallenes gives substituted dihydrofurans, as their Fp complexes (eq 4).

Isobutene-$FpBF_4$ has also been reported to catalyze the cycloaddition of alkynic esters to alkenes to give cyclobutenes and lactones (eq 5).[11] The complex Fp-THF^+ BF_4^- has been used in a similar fashion.[12]

Dicarbonyl(cyclopentadienyl)(1-phenylthioethyl)iron[1]

[77418-50-9] · $C_{15}H_{14}FeO_2S$ · Dicarbonyl(cyclopentadienyl)(1-phenylthioethyl)iron · (MW 314.18)

(stable precursor of a cationic methylcarbene, or ethylidene, complex of iron; for conversion of alkenes into methyl-substituted cyclopropanes[2])

Physical Data: mp 59 °C.

Solubility: sol most common solvents; methylene chloride is the solvent of choice.

Form Supplied in: yellow crystals.

Analysis of Reagent Purity: ^{1}H and ^{13}C NMR.

Preparative Methods: the stable, crystalline, dinuclear complex $[Cp(CO)_2Fe]_2$ is reductively cleaved with sodium amalgam to generate a THF solution of the highly nucleophilic sodium ferrate, $Na[Cp(CO)_2Fe]$. This species is immediately alkylated with 1-chloroethyl phenyl sulfide to give $Cp(CO)_2FeCH(Me)SPh$, which is purified chromatographically to give the reagent as a yellow, crystalline solid (eq 1) which has been characterized spectroscopically.[2] An alternative preparation employs the addition[4] of methyllithium or methylmagnesium bromide to the stable, readily available, phenylthiocarbene complex $Cp(CO)_2Fe{=}CHSPh^+\ PF_6^-$.[5]

Purification: silica gel chromatography.[3]

Handling, Storage, and Precautions: stable indefinitely as a solid when protected from air; can be exposed to air for short periods of time (weighing, setting up reactions, etc.) without noticeable decomposition; decomposes in solution if exposed to air.

Alkene Cyclopropanation.

Alkenes undergo reaction with the iron reagent in the presence of reactive methylating agents such as ***Trimethyloxonium Tetrafluoroborate***[6] (*caution*: volatile, highly toxic alkylating agent) to give methyl-substituted cyclopropanes (eq 2). The reaction apparently occurs via *S*-methylation of the iron reagent to produce a sulfonium salt, which in turn undergoes dissociation of thioanisole to generate a carbene complex of iron as the reactive intermediate.

The iron reagent and the alkene are normally used in equimolar amounts, but a slight excess of the methylating agent (total of 1.25 mol equiv) is usually employed to permit optimum conversion to products. The cyclopropane products are isolated very easily by adding pentane or another suitable nonpolar solvent to the reaction mixture to precipitate the organometallic byproducts. Filtration of the mixture and use of routine distillation or chromatographic purification techniques then provides the cyclopropanes.

The product yields are typically modest, usually being in the range of 40-70%. The reaction occurs best with mono- and disubstituted alkenes. More highly substituted alkenes generally react too slowly and exhibit very poor conversion to cyclopropanes. Some illustrative examples are gathered in Table 1.[2] Two important stereochemical features of these reactions are: (1) the stereospecific retention of configuration of the initial alkene double bond upon conversion to the cyclopropanes (see entry 4); and (2) the notable preference for *endo* or *syn* stereoselectivity with respect to the orientation of the reagent-derived methyl group in the cyclopropanes (see entries 1, 2, and 4).

Alternative Reagents.

The classical method for the cyclopropanation of alkenes is the Simmons-Smith reaction.[7] Indeed, this reaction is still probably the most highly used method for effecting this transformation. It is compatible with a wide range of functional groups, and it appears to be less sensitive to the degree of double bond substitution than the present iron reagent. However, the Simmons-Smith reaction has been used most commonly for transfer of the parent methylene group. Extensions to more highly substituted alkylidene groups have been limited in investigation. When ethylidene transfer has been studied,[8] poor *endo* stereoselectivity is seen compared to the present iron reagent. The same observation of lower stereoselectivity has been made for a more recent, aluminum-based modification of the Simmons-Smith reaction.[9] Diazoalkanes may also be used as alternative reagents,[1c] but the hazards and difficulties of preparing and handling these reagents are well-known. Much more closely related to the present reagent is the iron derivative, $Cp(CO)_2FeCH(Me)OMe$.[1a,10] Results of cyclopropanations using either of the iron reagents are quite comparable.

Dichlorine Monoxide[1]

Cl_2O

[7791-21-1] · Cl_2O · Dichlorine Monoxide · (MW 86.91)

(powerful chlorinating reagent; induces ene-type and aromatic ring/side chain chlorination)

Alternate Names: chlorine oxide; hypochlorite.

Physical Data: mp -116 °C; fp -120.6 °C; bp 2.0 °C; pale orange-yellow gas.

Solubility: sol carbon tetrachloride, water (contact with water forms hypochlorous acid), ether, benzene, CH_2Cl_2, ethyl acetate, dioxane.

Form Supplied in: usually prepared as needed, as a solution in CCl_4.[2]

Analysis of Reagent Purity: iodometric titration.[2,3]

Preparative Methods: gaseous dichlorine monoxide is prepared by passing ***Chlorine*** through a column containing dry yellow ***Mercury(II) Oxide***.[2,4] A carbon tetrachloride solution of dichlorine monoxide is obtained as follows:[2,5] into a solution of chlorine in carbon tetrachloride is added 3.36 g of dry yellow mercury(II) oxide per gram of chlorine (1.1 mol/mol of chlorine) at 25 °C. After being stirred for 45 min at this temperature, the solids are removed by filtration through a coarse sintered-glass funnel to give a solution of dichlorine monoxide in ca. 75% yield.

Handling, Storage, and Precautions: explosions of the gas may result from a spark, by heating, or by contact with rubber, cork, or other forms of organic matter. A carbon tetrachloride solution is easier to obtain and safer to handle. It can be stored for a long time at -78 °C, but decomposes at a moderate rate at rt. Strong oxidant. Use in a fume hood.

Chlorination of Alkanes and Alkenes.

Gas-phase chlorinations of alkanes such as methane and propane with dichlorine monoxide have been reported.[6] More conveniently, a carbon tetrachloride solution of the reagent can be used for chlorination of various saturated compounds, such as 1-chlorobutane, 1-chloropropane, and butyronitrile.[7] Each mole of dichlorine monoxide produces nearly 2 moles of chlorinated products and 1 mole of water. In the dark, a very long induction period is required, but this is significantly shortened by exposure to light or addition of ***Azobisisobutyronitrile*** (AIBN). A radical chain reaction mechanism has been proposed (eqs 1-7).

$$Cl_2O \longrightarrow Cl\cdot + ClO\cdot \quad (1)$$

$$ClO\cdot + RH \longrightarrow HOCl + R\cdot \quad (2)$$

$$R\cdot + Cl_2O \longrightarrow RCl + ClO\cdot \quad (3)$$

$$HOCl \longrightarrow Cl\cdot + \cdot OH \quad (4)$$

$$RH + Cl\cdot \longrightarrow R\cdot + HCl \quad (5)$$

$$HCl + HClO \longrightarrow H_2O + Cl_2 \quad (6)$$

$$R\cdot + Cl_2 \longrightarrow RCl + Cl\cdot \quad (7)$$

The chlorination of alkenes with dichlorine monoxide usually gives a mixture of allylic chlorides, β-chloroalkanols, α-chloroalkanones, and other products.[1] For instance, the reaction of Cl_2O with a large excess of cyclohexene at -20 °C in the dark proceeds instantaneously to give a mixture of the addition and substitution products (eq 8).[8]

Ene-Type Chlorination.[9]

Ene-type chlorination of alkenes with dichlorine monoxide in various organic solvents, such as methylene chloride, diethyl

ether, benzene, dioxane, and ethyl acetate, proceeds smoothly at ambient conditions, affording the corresponding allylic chlorides in good to excellent yields. Each reaction is completed by use of 0.5 mol equiv of dichlorine monoxide, indicating that both chlorine atoms are utilized in the chlorination. Double ene-type chlorination is also performed by use of 1 mol equiv of the reagent (eq 9).

(9)

The ene-type chlorination proceeds in a highly regio- and chemoselective manner; indeed, ene-type chlorination of the terminal double bond of azetidinone derivatives is achieved by treatment with dichlorine monoxide at rt for 10 min, affording the desired chlorinated products in 85-93% yields (eqs 10 and 11).

(10)

$R^1 = PhOCH_2$, $R^2 = CH_2Ph$

(11)

$R^1 = PhCO,\ R^2 = CH_2Ph$

Side Chain or Ring Chlorination of Aromatic Compounds.[10]

Dichlorine monoxide is a powerful and selective reagent for either side chain or ring chlorination of inactive aromatic substrates; it gives excellent yields under mild conditions where conventional reagents fail or require harsh conditions. For instance, side chain chlorination of inactive alkyl aromatic compounds, such as *p*-nitrotoluene, can be performed by treatment with dichlorine monoxide in carbon tetrachloride at 25 °C for 96 h, affording the corresponding tri- or dichlorinated compounds in high purity (see Table 1). At 75 °C, the reaction affords equivalent yields in about 3 h.

Table 1 Chlorination of Inactive Alkyl Aromatic Compounds with Cl_2O in CCl_4

Substrate	Product	Yield (%)
		99[a]
		89[b]
		99[a]
		96[b]
		100[b]
		97[b]

[a] Reaction temperature 25 °C. [b] Reaction temperature 75 °C.

Exclusive ring chlorination of inactive aromatic compounds e.g. *p*-nitrotoluene, proceeds smoothly at 0-50 °C if a strong protic acid, e.g. H_2SO_4, is added to the Cl_2O reaction medium. Dichlorine monoxide is among the most reactive and

selective agents known for chlorination of inactive aromatic ring systems; the degree of chlorination is controlled by the quantity of dichlorine monoxide employed, yielding mono- and perchlorinated products, respectively (Table 2). The mechanistic aspects of the reaction have been studied based on isotope effects, linear free-energy relationships, and related kinetics.

Table 2 Chlorination of Inactive Aromatic Rings with Cl_2O/Acid at 20-40 °C

Substrate	Product	Acid	Yield (%)
		H_2SO_4	99[a]
		CF_3SO_3H	97[b]
		H_2SO_4	94[b]
		CF_3SO_3H	99[b]

Cl Cl

[a] 0.5 equiv of Cl_2O. [b] >2.5 equiv of Cl_2O.

Chlorinations of phenols, aryl ethers,[1] sulfamides,[11] lignin,[12] hydrazines,[13] cyanic acid,[14] and polymers[15] with dichlorine monoxide have been investigated. The reactions are conducted in carbon tetrachloride, yielding mono- and/or polychlorinated products.

Bleaching.[16]

Dichlorine monoxide has been found to be an effective reagent for the bleaching of wood pulp and textiles. This method promises not only to increase process efficiency, but also reduce stream pollution significantly.

Related Reagents.

1,3-Dichloroacetone[1]

[534-07-6] · $C_3H_4Cl_2O$ · 1,3-Dichloroacetone · (MW 126.97)

(starting material for the synthesis of cyclopropanols[2] and cyclopropenones[3])

Alternate Name: 1,3-dichloro-2-propanone.

Physical Data: mp 39-41 °C; bp 173 °C; *d* 1.383 g cm^{-3}.

Solubility: sol organic solvents.

Form Supplied in: solid; commercially available.

Handling, Storage, and Precautions: highly corrosive and toxic. Use in a fume hood.

The reagent is useful as starting material for a simple one-pot synthesis of many 1-arylcyclopropanols (eq 1).[4,5] In this procedure the initially formed 1,3-dichloro-2-aryl isopropoxide is reduced to the 1-aryl cyclopropoxide by low-valent iron, generated in situ by the reaction of ***Ethylmagnesium Bromide*** with ***Iron(III) Chloride***.[6] The general method can be extended to the synthesis of 1-alkylcyclopropanols by using an excess of ***Lithium*** powder as the reducing agent in place of the EtMgBr/$FeCl_3$.[7] A somewhat related synthesis of 1-alkyl- or 1-arylcyclopropanols makes use of the reaction of ethyl 3-bromopropionate with 1 equiv of Grignard reagent in the presence of 2 equiv of ***Samarium(II) Iodide***.[8]

(1)

1,3-Dichloroacetone also serves as the starting reagent in a general synthesis of cyclopropenones and their acetals (eq 2).[3] The initially formed cyclopropenone acetal (**1**) can be alkylated a second time if desired, and then hydrolyzed to a dialkylcyclopropenone.

---

Dichloroacetonitrile

Cl_2CHCN

[3018-12-0] · C_2HCl_2N · Dichloroacetonitrile · (MW 109.94)

(used in synthesis of α-chloro- and α,α-dialkyl-substituted nitriles;[1] building block for synthesis of pyrimidines[2] and pyridines;[3] undergoes Darzens reaction with aldehydes and ketones[4])

Physical Data: bp 110-112 °C; *d* 1.369 g cm^{-3}.

Solubility: insol H_2O; sol hexane, benzene, EtOH, ether, acetone, CH_2Cl_2.

Form Supplied in: colorless liquid; commercially available.

Handling, Storage, and Precautions: lachrymator; avoid inhalation of vapors or skin contact; flammable (toxic fumes); possible mutagen. Store under N_2. Since Cl_2CHCN is a byproduct of drinking water disinfection with chlorine, its toxicity has been studied in detail.[5] Use in a fume hood.

Alkylation of dichloroacetonitrile with trialkylboranes (eq 1) (R = primary or secondary alkyl) affords α-chloro nitriles or α,α-dialkyl-substituted nitriles in good yield.[1] The use of the hindered phenoxide base (p*K* 11.7) is advantageous because it minimizes self-condensation of both starting nitrile and the product. Since nitriles are readily hydrolyzed to acids, this procedure represents an alternative to the classical malonic ester synthesis.[6]

Treatment of 2-amino aromatic nitriles with Cl_2CHCN affords either 4-chloro- or 4-aminopyrimidines depending on the substrate (eq 2).[2] Halogenated pyridines are obtained via the copper-catalyzed addition of Cl_2CHCN to methacrolein (eq 3).[3] The first step of eq 3 represents a special case of the more general reaction in which copper salt-catalyzed addition of Cl_2CHCN to alkenes yields a variety of 2,4-dichlorobutyronitriles,[7] via an oxidation-reduction chain mechanism.

Aldehydes and ketones condense with Cl_2CHCN in the presence of alkoxide bases at -78 °C to afford isolable α,α-dichloro-β-hydroxy nitriles in good yield (eq 4).[4] At higher temperatures the chloroglycidimidates are obtained. Analogous reactions utilizing nonnucleophilic bases allow retention of the nitrile functionality.[4,8]

Reaction of Cl_2CHCN with ***Hydrogen Cyanide*** (or, more safely, with ***Acetone Cyanohydrin***) yields a versatile enamino nitrile which can form Schiff bases, be acylated, react with thiolates and alkoxides, and (in two steps) form amino-substituted oxazoles (eq 5).[9]

The dimerization of Cl_2CHCN in the presence of HCl gives an *N*-(α-chloroalkenyl)alkylamidine hydrochloride, which upon treatment with ***Phosgene*** provides an unusual 4(3*H*)-pyrimidinone (eq 6).[10] Novel selenium-containing heterocycles are available via Diels-Alder cyclization of selenoaldehydes prepared in good yield from Cl_2CHCN (eq 7).[11]

Related Reagents.

Dibromoacetonitrile; ***Ethyl Dibromoacetate***; ***Methyl Dichloroacetate***.

Dichloroalane

Cl_2AlH

[13497-97-7] · $AlCl_2H$ · Dichloroalane · (MW 98.90)

(reduction of acetals,[1] orthoesters,[2] oxazolidines,[3] and ozonides;[4] hydrogenolysis of ethers,[5] and alcohols;[6] ring opening of epoxides[7] and oxetanes;[8] reduction of ketones,[9] azetidinones,[10] and phosphonates;[11] hydroalumination of alkenes[12])

Physical Data: bp 95 °C in high vacuum.[13a]

Solubility: sol benzene, chloroform, ether, THF.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: normally prepared in situ as a solution in ether and used without purification or analysis; however, the bis-THF adduct has been characterized by NMR, IR, and elemental analysis.[13b]

Preparative Methods: generally prepared in situ from ***Lithium Aluminum Hydride*** (1 equiv) and ***Aluminum Chloride*** (3 equiv) in ether at 0 °C;[4,11b] alternatively, can be prepared in pure form by reaction of AlH_3 (1 equiv) with $AlCl_3$ (2 equiv) in ether followed by vacuum distillation.[13a] The bis-THF adduct [$Cl_2AlH.2(THF)$] is a stable crystalline compound (mp 90-95 °C) which can be prepared by either of the methods described above (substituting THF for ether as the solvent).[13b]

Purification: by distillation.

Handling, Storage, and Precautions: generally prepared in situ and used immediately; handle under dry nitrogen in a fume hood.

Reduction of Acetals, Orthoesters, and Oxazolidines.

Dichloroalane (**1**) may be used for the reduction of acetals to ethers.[1] However, ***Dibromoalane*** is generally superior for this purpose. For the reduction of orthoesters to acetals, either (**1**) or alane (AlH_3) is suitable (eq 1).[2] Similarly, oxazolidines may be reduced to amino alcohols with either (**1**) or alane.[3] Substitution of alane for (**1**) may result in a different stereochemical outcome in some cases.[2,3]

(1)

Reduction of Ozonides to Ethers.

Ozonides can be reduced to ethers with (**1**) in low to moderate yields (varying amounts of diol are obtained as the major byproduct) (eq 2).[4] Substitution of ***Sodium Borohydride-Trifluoroacetic Acid*** for (**1**) in this reaction results in considerable differences in product ratios and yields.

(2)

Hydrogenolysis of Fluorenyl Ethers and Benzylic/Allylic Alcohols.

Dichloroalane (**1**) reductively cleaves fluoren-9-yl ethers in refluxing dichloromethane/ether (eq 3).[5] The necessity of elevated temperatures may lead to formation of byproducts in some cases. Benzylic alcohols (and some chlorides) can also be cleaved by reaction with (**1**), although the necessary conditions are again relatively harsh and byproduct formation is common.[6a] Catalytic hydrogenolysis (H_2, ***Palladium on Carbon***) is probably superior for most substrates. Limited examples of hydrogenolysis of allylic alcohols with (**1**) also exist.[6b]

Ring Opening of Epoxides and Oxetanes.

Dichloroalane (**1**) has been used to reduce epoxides, although rearrangement and/or byproduct formation is common due to the Lewis acidity of the reagent.[7] For example, attempted reduction of an alkene-substituted cyclohexane epoxide afforded predominantly cyclized products with no reduced product present (eq 4).[7a] The best reduction substrates are phenyl-substituted epoxides with limited rearrangement options.[7c] Similar results have been reported for reduction of oxetanes with (**1**).[8]

Reduction of Ketones.

In combination with ***Copper(I) Iodide***, (**1**) can effect 1,4-reduction of α,β-unsaturated ketones. However, lithium aluminum hydride/copper iodide is generally superior for this purpose.[9a] There are several examples of the reduction of ketones with (**1**).[9b,c,d] However, (**1**) has no apparent advantage over more readily accessible hydride reagents (e.g. sodium borohydride or lithium aluminum hydride) for this purpose. Dibromoalane is superior to (**1**) for selective reduction of the more hindered of two ketones.[9e]

Reduction of Azetidinones to Azetidines.

Azetidin-2-ones can be efficiently reduced with (**1**) in refluxing ether to afford azetidines in excellent yield (eq 5).[10] This reagent is markedly superior to other reducing agents for this purpose.

(5)

Reduction of Phosphonates to Phosphines.

Dichloroalane (**1**) is an excellent reagent for the preparation of alkynylphosphines,[11a] allenylphosphines,[11a] or vinylphosphines[11b] by reduction of the corresponding phosphonates. For example, vinylphosphine has been prepared on a gram scale by reduction of a vinylphosphonate with (**1**) (eq 6).[11b] Attempts to effect this reduction with lithium aluminum hydride or alane were unsuccessful.

(6)

Hydroalumination of Alkenes.

Alkylaluminum species derived by reaction of (**1**) with alkenes can react with a variety of electrophiles. The net result of this process is the addition of HX across the double bond in an anti-Markovnikov sense. The reaction may be catalyzed by an organoborane[12a] or a transition metal hydride.[12b] For example, organoborane-catalyzed hydroalumination of 1-dodecene with (**1**) followed by reaction of the intermediate organoaluminum species with ***Bromine*** affords 1-bromododecane in excellent yield (eq 7).[12a]

(7)

Bis(dialkylamino)alanes are also excellent reagents for this purpose and may be superior to (**1**).[12b] It is possible to obtain alcohols via hydroalumination-oxidation of alkenes,[12c] but hydroboration-oxidation is preferred for this transformation. It has also been reported that propargylic ethers and amines can be reduced to the corresponding *trans* allylic ethers and amines by the action of (**1**).[12f] However, (**1**) appears to be inferior to other hydride reagents for this purpose.

Related Reagents.

Aluminum Hydride; ***Dibromoalane***; ***Lithium Aluminum Hydride-Copper(I) Iodide***.

1,1-Dichloroallyllithium

[51522-97-5] · $C_3H_3Cl_2Li$ · 1,1-Dichloroallyllithium · (MW 116.90)

(ambient allyl anion; reacts with a variety of electrophiles to give α- and/or γ-substituted products;[1-5] can serve as a ketone annulating agent to form cyclopentenones;[5] an equivalent of chlorovinyl carbene[6])

Solubility: sol THF.

Preparative Methods: 1,1-dichloroallyllithium (**2**) can be prepared[1] by the lithium-halogen exchange reaction between *n*-butyllithium and 3,3,3-trichloropropene (**1**) at -105 °C (eq 1), but transmetalation of 3,3-dichloro-2-propenyltriphenyllead (**3**) with *n*-butyllithium in THF at -95 °C is cleaner (eq 2).[1]

Handling, Storage, and Precautions: highly unstable; generated only at -95 °C, in the presence of electrophiles in an inert atmosphere. Use in a fume hood.

Reaction of (**2**) with ***Chlorotrimethylsilane*** gave exclusively the α-silylated product (**4**) in 99% yield (eq 3). In contrast, the γ-isomer (**5**) was the sole product when (**2**) was treated with Me_3SnBr (eq 4).

(2) **(4)**

(2) **(5)**

Similar regioselective reaction was observed with $HgCl_2$ to afford a γ-mercurated product (i.e. CCl_2=CH-CH_2HgCl) in 83% yield, while its reaction with iodomethane yields the corresponding α-alkylated product (i.e. $MeCCl_2$-CH=CH_2) in 98% yield. Only trimethylchlorogermane gives a mixture (5.66:1) of α- and γ-isomers.[1]

The reaction of (**2**) with ketones is governed by the ambident nucleophilic character of (**2**), whose two reacting termini differ substantially in terms of both steric and electronic factors. Several ketones and aldehydes give either exclusive α- or γ-products, with two exceptions (PhCHO, PhCOMe) where a mixture of both isomers is obtained in each case (eq 5). The regioselectivity can be explained on the basis of HSAB principle.[2,3] There is also a strong effect of the counterion. When (**2**) is generated by treatment of 3,3-dichloro-1-propene with ***Lithium Diisopropylamide***, benzaldehyde gives mostly γ-product, whereas with ***Potassium t-Butoxide*** present, mostly α-product is obtained (eq 6).[4]

(6) $R^1 = R^2 =$ alkyl

(7) $R^1 = Ph, R^2 = H$
$R^1 = R^2 = Ph$
$R^1 = R^2 = CF_3$

Ar = Ph, *p*-$CF_3C_6H_4$, *o*-ClC_6H_4, *p*-ClC_6H_4 , *o*-$MeOC_6H_4$, *p*-$MeOC_6H_4$, *o*-MeC_6H_4, *p*-MeC_6H_4

The reaction of (**2**) with both cyclic and acyclic ketones gives dichlorohomoallylic alcohols (**11**) exclusively. The alcohols have been transformed to the cyclopentenones (**14**) in good yields (eq 7).[5] This conversion is a modified Nazarov cyclization.

(11)

(12) **(13)**

$R^1 = R^2 = -(CH_2-)_n$ $n = 4, 5, 6, 10$
$R^1 = Me$; $R^2 = C_5H_{11}$

(7)

(14)

The anion (**2**) generated by treatment of 3,3-dichloropropene with ***Lithium 2,2,6,6-Tetramethylpiperidide*** in the presence of alkenes yields, after hydrolytic work-up, the corresponding *gem*-chlorovinylcyclopropanes (**15**) (eq 8) in good yields.[6] With 1,3-butadiene a mixture of *cis*- and *trans*-1-chloro-1,2-divinylcyclopropanes is formed. The *cis* isomer (**16**) (eq 9), however, rapidly undergoes Cope rearrangement to the chloroheptadiene (**17**) in 31% yield.

(8)

(15) $R^1 = R^2 = R^3 = R^4 = H, Me$

1,1-Difluoroallyllithium (**19**) is of interest as a reagent for the introduction of fluorine into organic molecules. It was first generated[7,8] at -95 °C in THF by treating 3,3-difluoroallyltrimethyltin (**18**) with ***n-Butyllithium*** (eq 10). The reagent is unstable, even at -95 °C to -130 °C, in the absence of an electrophile. However, when (**19**) is generated in the presence of Me_3SiCl, the corresponding α-silylated product (Me_3SiCF_2-CH=CH_2) is obtained in 75% yield. A more effective route to (**19**) involves the Li/Br exchange reaction of CH_2=CH-CF_2Br with BuLi (eq 11) in the presence of various electrophiles.[9]

Chlorosilanes, aldehydes, ketones, and esters give α-substituted products such as (**18**) from esters and (**20**) from ketones and aldehydes (eq 12).[10]

Related Reagents.

1-Chloroallyllithium; ***Dichloromethyllithium***; ***Trichloromethyllithium***.

Dichloroaluminum Phenoxide[1]

$PhOAlCl_2$

[33715-52-5] · $C_6H_5AlCl_2O$ · Dichloroaluminum Phenoxide · (MW 190.99)

(Lewis acid catalyst for carbocyclic ring-expansion reactions)

Physical Data: trimeric structure in benzene solution; forms a stable 1:1 complex with benzonitrile as a yellowish-white solid.

Solubility: sol benzene and methylene chloride.

Preparative Methods: the reagent should be freshly prepared in situ by the careful addition of commercially available dichloromethylaluminum to a 0 °C solution of 1 equiv of phenol in CH_2Cl_2, making provision for the evolution of methane.

Handling, Storage, and Precautions: moisture sensitive; should be prepared and handled under an inert atmosphere. Use in a fume hood.

Ring Expansions.

Dichloroaluminum phenoxide is a powerful Lewis acid that has been shown to be superior to dichloromethylaluminum as a catalyst for the one-carbon ring enlargement of α-(trimethylsilylmethyl)cycloalkanecarbaldehydes to the corresponding α-(trimethylsilylmethyl)cycloalkanones (eq 1).[2] This 1,2-migration is facilitated in part by stabilization of an incipient carbocation by the β-silicon substituent.

(1)

$n = 1$, 100%
$n = 3$, 97%
$n = 7$, 85%

In a related process, treatment at 0 °C of a methylene chloride solution of 1-acyl-2-vinylcyclobutanes (eqs 2 and 3) with the reagent leads to a two-carbon ring enlargement, affording the corresponding 4-acylcyclohexenes.[3] As before, the oxygenophilic character of this aluminum reagent facilitates the formation of a stabilized carbocationic intermediate.

Di-μ-chlorobis(1,5-cyclooctadiene)diiridium(I)[1]

[12112-67-3] · $C_{16}H_{24}Cl_2Ir_2$ · Di-μ-chlorobis(1,5-cyclooctadiene)diiridium(I) · (MW 671.71)

(active catalyst precursor for Claisen rearrangements,[2] [2 + 2] cycloadditions,[3] hydrosilations,[4] and hydroboration[5] reactions)

Physical Data: mp 190 °C (dec); ^{1}H NMR ($CDCl_3$) δ 4.22 (m, =C*H*$_2$), 2.15 (m, C*H*$_2$), 1.40 (C*H*$_2$).[6]

Solubility: sparingly sol acetone; sol CH_2Cl_2 and toluene; insol diethyl ether.

Form Supplied in: orange-red crystalline solid.

Preparative Method: a solution of 6 mL of 1,5-cyclooctadiene in 35 mL of ethanol and 20 mL of water is added to 2.0 g of $IrCl_3.3H_2O$ in a round-bottomed flask. The mixture is refluxed under nitrogen for 24 h, during which time an orange-red product precipitates from solution. The mixture is cooled to rt and di-μ-chlorobis(1,5-cyclooctadiene)diiridium(I) is collected by filtration, washed with cold methanol, and dried in vacuo at 25 °C for 8 h.[1]

Handling, Storage, and Precautions: the dry solid is moderately air-stable.

Claisen Rearrangements.[2]

Cope and Claisen [3,3]-sigmatropic thermal rearrangements are of considerable utility in synthetic organic

chemistry. Although such reactions proceed at high temperatures (ca. 200 °C), transition metals can be employed to accelerate the rearrangements. Indeed, $[Ir(\mu\text{-}Cl)(1,5\text{-cod})]_2$ is a fairly active catalyst precursor for the rearrangement of allyl imidates to allyl amides,[2a] as well as allylic thionobenzoates to allylic thiolobenzoates[2b] under mild conditions. Reactions are not selective, as both [3,3]- and [1,3]-rearrangement products are generated in approximately equal amounts (eq 1). Use of palladium(II) complexes circumvents this complication, giving exclusive [3,3] regioselectivity. The mechanism of iridium(I) catalysis seems to involve carbonium ion intermediates formed by allyl-oxygen bond cleavage.

(1)

In another rearrangement reaction, $[Ir(\mu\text{-}Cl)(1,5\text{-cod})]_2$ can be used in conjunction with ***Iodomethane*** to catalyze the isomerization of methyl formate to acetic acid (eq 2).[7] Reactions are conducted in a carboxylic acid solvent. Water inhibits acetic acid formation and allows an alternative pathway to proceed that affords methane and carbon dioxide as principal products.

$$HCO_2Me + RCO_2H \longrightarrow HCO_2H + RCO_2Me \qquad (2)$$

[2 + 2] Cycloaddition Reactions.

The dimerization of bicyclo[2.2.1]heptadiene is promoted by $[Ir(\mu\text{-}Cl)(1,5\text{-cod})]_2$, giving exclusive formation of a dimer with *exo-trans-exo* configuration (eq 3).[3] Evidence has been presented that suggests this dimerization proceeds via a metal-carbon σ-bonded intermediate.

(3)

H-X Additions.

Hydrosilation of allylic halides with ***Triethoxysilane*** carried out in the presence of a catalytic amount of

$[Ir(\mu\text{-}Cl)(1,5\text{-cod})]_2$ affords predominantly halopropyltrialkoxysilanes.[4] Disilane formation is observed, however, in analogous hydrosilations of 1-hexene using H_2SiEt_2.[7] Finally, while $[Ir(\mu\text{-}Cl)(1,5\text{-cod})]_2$ can be used to catalyze the hydroboration of vinylarenes, selectivities are poor and product distributions are complicated by significant amounts of alkane formation derived from hydrogenation of the substrate.[5] Regioselectivities for this reaction are dependent upon the nature of the catalyst precursor employed.[8]

Dichlorobis(cyclopentadienyl)hafnium[1]

[12116-66-4] · $C_{10}H_{10}Cl_2Hf$ · Dichlorobis(cyclopentadienyl)hafnium · (MW 379.59)

(starting material to prepare many kinds of hafnocene(II or IV) derivatives;[2] in combination with Ag^I salt, is an effective activator for glycosyl fluoride[3])

Physical Data: mp 230-233 °C.

Solubility: sol aromatic solvents, chloroform; slightly sol THF, ether; insol hexanes.

Form Supplied in: colorless crystals; commercially available.

Analysis of Reagent Purity: ^{1}H NMR (THF-d_8) δ 6.62 (s, C_5H_5).

Handling, Storage, and Precautions: the dry solid is reasonably stable to air and moisture and can be handled in an ordinary manner. However, it should be stored in a tightly-sealed nitrogen-flushed bottle to preclude moisture.

Transmetalation and Generation of Cp_2Hf Equivalent.

Cp_2HfCl_2 is an important starting material for the preparation of Hf^{IV} and Hf^{II} derivatives, just as ***Dichlorobis(cyclopentadienyl)zirconium*** is used to prepare zirconium compounds. While the chemistry of Cp_2ZrCl_2 and its derivatives is well-developed, a corresponding surge in the study of hafnium compounds has not ensued. In general, the chemistry of Cp_2HfCl_2 and its derivatives is similar to that of zirconium. Transmetalation reactions of Cp_2HfCl_2 with organometallics containing lithium, sodium, potassium, and magnesium are a general method to prepare $Cp_2Hf(R)Cl$ and Cp_2HfR_2 (R = alkyl, alkenyl, aryl, and alkynyl) (eq 1).[2,4] Alkylhafnocenes are thermally more stable than the corresponding alkylzirconocenes in the solid state and in solution. For example, while dibutylzirconocene rapidly eliminates butane to give a zirconocene-butene complex, thermolysis of the hafnocene analog at 80 °C is required for this process.[2a] Heating *n*-butyl-*t*-butylhafnocene at 45 °C in the presence of trimethylphosphine gives a hafnocene-isobutene complex, which reacts with diphenylacetylene to give an alkyne complex. It also promotes C-H

bond activation with benzene or alkoxide (eq 2).[2a] Alkyl-alkene coupling (eq 3)[2b] and skeletal rearrangement by C-C bond activation[5] to form hafnacyclopentanes have been reported. Generation of Cp_2Hf equivalent can be achieved by reduction of Cp_2HfCl_2 with ***Magnesium-Mercury(II) Chloride***[6] or 2 equiv ***n-Butyllithium***.[2] This Cp_2Hf reacts with a series of unsaturated compounds (alkyne and alkene) through a ligand exchange process to give a hafnocene complex; this reaction has been applied to bicyclizations of nonconjugated dienes, enynes, and/or diynes (eq 4).[6]

Glycosidation.

The combination of metallocene dichloride (Cp_2ZrCl_2 or Cp_2HfCl_2) and silver salt (AgX: X = ClO_4, OTf, BF_4) is a highly effective reagent system for activating glycosyl fluoride to give the *O*-,[7] *C*-,[8] or *N*-glycoside[9] stereoselectively under mild conditions (eq 5). Selection of the center metal (Zr or Hf), the molar ratio of metallocene dichloride and Ag^I salt, and the solvent used are crucial factors for controlling the reactivity and stereoselectivity in this glycosidation reaction.[7a,10] The Cp_2HfCl_2 based activators are more reactive than the Cp_2ZrCl_2 ones[9] and the former are more effective than the latter in the case of amino sugar derivatives.[11] Regio- and stereocontrolled *C*-aryl glycosidation of phenols based on the *O*-*C* glycoside rearrangement is efficiently carried out by using the Cp_2HfCl_2-***Silver(I) Perchlorate*** system (eq 6).[12] The high β-selectivity achieved without neighboring group assistance in glycosyl fluoride is a key synthetic advantage of these reagent systems.

[26042-63-7] · AgF_6P · Dichlorobis(cyclopentadienyl)hafnium-Silver(I) Salts · (MW 252.83)

(can activate glycosyl fluorides for *O*-glycosidation;[2] can convert aryl *O*-glycosides to the corresponding aryl *C*-glycosides[3])

Physical Data: see entries for ***Dichlorobis(cyclopentadienyl)hafnium*** and individual silver salts.

Handling, Storage, and Precautions: the reagents are combined just before use by adding the Ag salt to a solution of Cp_2HfCl_2. $AgClO_4$ leads to the best reactivity, but has a potential hazard of explosion.[4] AgOTf is recommended as a safe alternative with slightly decreased reactivity. Other silver salts (e.g. $AgBF_4$, $AgPF_6$, $AgAsF_6$) are less effective, but sometimes offer unique stereochemical preferences.[2,3] Molecular sieves 4Å are often used for removal of water in small scale runs, but are not necessarily essential.

Glycosyl fluorides are widely used in glycoside synthesis, because of their stability, ease of handling and availability

of specific activation methods.[5] Although ***Tin(II) Chloride***-$AgClO_4$[5a] is most often utilized, the extremely high reactivity offered by Cp_2HfCl_2-$AgClO_4$[2] renders it the promoter of choice for the glycosidation of sterically demanding substrates. Intermediate cationic hafnocene complexes are believed to be the origin of the high reactivity, which led to the finding that the use of the combination in 1:2 ratio leads to an even more increased reactivity (eq 1).[2d] The efficiency of this new protocol is clearly demonstrated in the synthesis of oligo- or even polysaccharides.[6e]

(1)

A number of useful applications are reported for the synthesis of various classes of glycoconjugates ranging from macrolides, e.g. (**1**),[2a,b,c] to oligosaccharide structures embedded in glycolipids.[6] One of the highlights in the latter context is the block synthesis of sialyl Le^X related oligosaccharides via the coupling of the glycosyl fluoride (**2**).[6a,b] Applicability to glycosidation of amino sugars is another notable feature of this activation method.[2b,c,6]

(1)

(2)

A Lewis acid-mediated synthetic reaction of aryl *C*-glycosides is reported, which involves (1) the initial formation of aryl *O*-glycosides at low temperature, and (2) its in situ rearrangement to the corresponding aryl *C*-glycosides (eq 2).[3] A particularly useful feature is that the C-C bond is formed regioselectively at the position *ortho* to the phenol.

(3)

(2)

Cp_2HfCl_2-$AgClO_4$, 79% $\alpha:\beta = 1:9$
$BF_3 \cdot OEt_2$, 50% $\alpha:\beta = 1:1$ + **(3)** 41%

Both processes can be promoted by general Lewis acids, but Cp_2HfCl_2-$AgClO_4$ is prominent in terms of the reactivity and stereoselectivity. These features are well illustrated by their application in the total syntheses of vineomycinone

B_2 methyl ester (**4**)[7] and gilvocarcin M (**5**).[8] Donor solvents, such as Et_2O or MeCN, retard the second step, thereby providing a useful synthetic method for aryl *O*-glycosides.[3b]

(4)

(5)

Cp_2HfCl_2-$AgClO_4$ is useful in nucleoside synthesis via the coupling of glycosyl fluorides and bis(trimethylsilyl)uracil (eq 3).[9]

(3)

$\alpha:\beta = 5:95$

Dichlorobis(cyclopentadienyl)titanium[1]

[1271-19-8] · $C_{10}H_{10}Cl_2Ti$ · Dichlorobis(cyclopentadienyl)titanium · (MW 248.98)

(used in hydrometalation and reduction; pinacol coupling reagent; carbometalation reagent; deoxygenation reagent; addition to carbonyls; Lewis acid catalyst; alkenation reagent)

Alternate Name: titanocene dichloride.

Physical Data: mp 289 °C; *d* 1.600 g cm^{-3}.

Solubility: sol toluene, chloroform, alcohol, and other hydroxylic solvents; sparingly sol water, petroleum ether, benzene, ether, carbon disulfide, carbon tetrachloride.

Form Supplied in: purple solid; commercially available.

Preparative Methods: see Wilkinson and Birmingham[2a] and Clearfield et al.[2b]

Handling, Storage, and Precautions: moisture sensitive; irritant; combustible.

Hydromagnesiation of Alkenes and Alkynes.[3]

Hydromagnesiation of alkynes, where metal hydride addition occurs with *syn* stereochemistry, can be carried out with *i*-BuMgCl and 1-10 mol % of Cp_2TiCl_2 (eq 1).[4] Eq 2 illustrates the hydromagnesiation product of a silylalkyne formed after equilibration, where the C-Mg bond is formed α to the silyl unit (or aryl group with aryl alkylalkynes)[5] and *syn* to the magnesium alkoxide (presumably because of heteroatom-metal coordination).[6] The carbon-metal bond may then be used in reactions with a variety of electrophiles (e.g. ketones, alkyl or allyl halides).[7] The synthesis of dihydrojasmone represents one of the applications of titanium-catalyzed hydromagnesiation.[7a]

(1)

(2)

Hydromagnesiation of allylic and homoallylic alcohols is catalyzed by Cp_2TiCl_2 as well; however, this transformation is only operative with monosubstituted alkenes, wherein a primary C-Mg bond is generated (eq 3).[8] MgH_2 and 5 mol % Cp_2TiCl_2 have been used in the hydromagnesiation of terminal alkenes (>90% yield).[9] In addition, as shown below, Cp_2TiCl_2 catalyzes the hydrometalation of conjugated dienes to afford allyl Grignard reagents, which may then be utilized for further functionalization (eq 4).[10]

(3)

(4)

Hydroalumination of Alkenes.

Cp_2TiCl_2 is an effective catalyst for hydroalumination of mono- and disubstituted alkenes (representative aluminum hydrides: ***Bis(diisopropylamino)aluminum Hydride*** and ***Lithium Aluminum Hydride***).[11]

Hydrogenation Catalysts.

Titanocene dialkyls (formed by the addition of alkyllithiums to Cp_2TiCl_2) are effective alkene hydrogenation catalysts. Catalytic activity is enhanced when polymer-supported titanocene is used.[12]

Reduction of Carbonyls.

As shown in eqs 5 and 6, in the presence of 1-3 mol % of Cp_2TiCl_2, *i*-BuMgCl is an effective carbonyl-reducing agent.[13] Carboxylic acids and esters are reduced to aldehydes[14] and alcohols,[15] respectively. When methyl and ethyl Grignard reagents are employed, competing direct alkylation occurs. The proposed reducing agent is Cp_2TiH, and the reaction is most effective with saturated carbonyls. Aryl and benzylic acids are suitable substrates, whereas α,β-unsaturated acids are recovered unchanged.

(5)

(6)

Reduction of Bromides.

Treatment of vicinal dibromides with 2 equiv of Cp_2TiCl_2 and excess ***Zinc*** affords the corresponding alkene in high yield (eq 7).[16] Alternatively, Cp_2TiCl_2 may be used catalytically (20 mol %) but longer reaction times are required. Stoichiometric amounts of Cp_2TiCl_2 and *i*-PrMgCl effect coupling of allylic and benzylic bromides (eq 8) and debromination of α-bromo ketones (eq 9).[17] In addition, debromination of aryl and vinyl bromides proceeds

selectively and quantitatively in the presence of catalytic amounts of Cp_2TiCl_2 (2-5 mol %) and excess *i*-PrMgCl (eq 10).[18] The proposed mechanism involves insertion of Cp_2TiH into the carbon-bromine bond, followed by reductive elimination of the product alkene.

(7)

(8)

(9)

(10)

Pinacol Coupling Reactions.

Stereoselective pinacol coupling reactions can be effected by a complex derived from Cp_2TiCl_2 and *s*-BuMgCl[19] or ***Magnesium***.[20] Coupling of aromatic and α,β-unsaturated aldehydes typically provides >90% yield and >50:1 *threo*:*erythro* (eq 11), whereas saturated aldehydes are unreactive. Pinacol coupling with diaryl ketones has also been achieved;[21] the reaction is stoichiometric in Cp_2TiCl_2 and the active organometallic agent is believed to be a Ti^{III} species.

(11)

Carbometalation Reactions.

As shown in eq 12, reaction of *syn*-1,2-dimethyltitanacyclobutane with I_2 affords the corresponding alkyl iodide; subsequent intramolecular carbometalation affords *syn*-1,2-dimethylcyclopropane stereoselectively.[22] Reaction of Cp_2TiCl_2 with ***Trimethylaluminum***, ***Dimethylaluminum Chloride***, or ***Diethylaluminum Chloride*** and silyl alkynes[23] proceeds smoothly (25 °C, 2 h) to afford a carbon-metal bond α to the silyl group (eq 13).[24] Similar reactions with terminal alkenes afford 1,1-disubstituted alkenes (eq 14).[25] As shown in eq 15, selective formation of five- and six-membered ring carbocycles may be accomplished through an alkene or alkyne insertion into a carbon-titanium bond.[26]

(12)

(13)

(14)

(15)

99:1

Cyclization of diynes and enynes to five- and six-membered rings has been effected by dibutyltitanocene (eq 16).[27] Such cyclization reactions are stoichiometric in Ti and may not be extended to dienes. As shown in eq 17, treatment of an epoxide with Cp_2TiCl (from Cp_2TiCl_2 and Zn powder) in the presence of an alkene results in alkene alkylation. This reaction has been carried out inter-[28] and intramolecularly.[29] The levels of stereocontrol for the intermolecular reactions are generally low (~2:1). Cp_2TiCl_2 and *i*-PrMgBr catalyze the intramolecular cyclization reaction of 1,5-dienes (eq 18;[30] these transformations proceed only when the two alkenes are monosubstituted.

(16)

(17)

M = Cp_2TiCl

endo:*exo* = 90:10

(18)

Deoxygenation Reactions.

As shown in eqs 19 and 20, treatment of aldehydes, esters, and epoxides with Cp_2TiCl_2 (10 equiv, pretreated with Na sand) affords deoxygenated adducts in good yields.[31] The titanocene reagent is ineffective when alcohols, alkoxides, or acyclic ethers are employed as substrates. A complementary reductive deoxygenation for diaryl and aryl alkyl ketones and alcohols has also been reported (eq 21).[32]

(19)

(20)

(21)

Cp_2TiCl cleaves epoxides by a radical mechanism, affording the regiochemistry opposite to that obtained from the corresponding nucleophilic epoxide opening. In addition, as illustrated in eq 22, depending on the reaction conditions, various epoxides may either be regioselectively converted to the alcohol, or reduced to the derived alkenes.[33]

(22)

Addition of Alkyl Titanocenes to Carbonyls.

Alkylation of aldehydes and ketones with π-allyltitanium complexes (stoichiometric, eq 23) formed from Cp_2TiCl_2 and various dienes (see eq 4) affords *anti* homoallylic alcohols selectively.[34] Such π-allyltitanium reagents do not react with esters or alkyl halides. Similar alkylation reactions have been carried out with trimethylsilyl[35] and 1,3-disubstituted allyl anions.[36] Addition to aldehydes (eq 24) followed by hydroxy-silyl elimination yields *cis,trans* or *trans,trans* alkenes (basic or acidic conditions, respectively).

(23)

(24)

Lewis Acid Catalysis with Titanocene Derivatives.[37]

$[Cp^*_2Ti(H_2O)_2](CF_3SO_3)_2$, a readily made derivative of $Cp^*_2TiCl_2$,[38] is an effective catalyst (1%) for Diels-Alder cycloadditions (eq 25); these cycloadditions may be carried out in the presence of water. $Cp_2Ti(CF_3SO_3)_2$ (made from Cp_2TiCl_2 and ***Silver(I) Trifluoromethanesulfonate*** catalyzes aldol reactions as well.[39]

(25)

Alkenation Reactions.

Me_3Al addition to Cp_2TiCl_2 affords an Al-Ti bimetallic complex (Tebbe's reagent, see ***μ-Chlorobis(cyclopentadienyl)(dimethylaluminum)-μ-methylenetitanium***) which has been used for methylenation of ketones, esters (eq 26), and alkenes.[40] A variety of alkyl groups have been used on titanium to achieve similar alkenations.[41]

(26)

Titanocene dichloride reacts with $CH_2(MgBr)_2$ to yield a magnesium analog of Tebbe's reagent; the Mg complex is used to convert alkenes and alkynes to the derived titanacyclobutanes and -butenes, respectively.[42] The combination of alkenation of carbonyls and formation of titanacyclobutanes leads to the synthesis of substituted allenes (eq 27), where stoichiometric amounts of the titanacyclobutane are utilized.[43] Titanacyclobutane has been shown to serve as a catalyst for ring opening metathesis polymerization reactions.[44]

(27)

Nitrogen fixation reactions have been accomplished with various titanocene systems. For example, titanocene-benzyne complexes react with molecular nitrogen to provide aniline and NH_3, albeit in low yield.[45]

Dichlorobis(cyclopentadienyl)zirconium[1]

[1291-32-3] · $C_{10}H_{10}Cl_2Zr$ · Dichlorobis(cyclopentadienyl)zirconium · (MW 292.32)

(good starting material to prepare many kinds of zirconocene(II or IV) derivatives;[2] in combination with organometallics (Al, Zn, or Mg) it is a catalyst for stereo- and regioselective alkylation of unsaturated compounds;[3] in combination with an Ag^I salt (AgX; X = ClO_4, OTf, BF_4) it is an effective activator for glycosyl fluorides; in combination with MAO, it is a good catalyst for polymer synthesis[4])

Physical Data: mp 247-249 °C; sublimes at 150-180 °C.

Solubility: sol aromatic solvents, chloroform; slightly sol THF, ether; insol hexanes.

Form Supplied in: colorless crystals; widely available.

Analysis of Reagent Purity: ^{1}H NMR (THF-d_8) δ 6.62 (s, C_5H_5).

Handling, Storage, and Precautions: the dry solid is reasonably stable to air and moisture and can be handled in the ordinary manner. However, it should be stored in a tightly sealed nitrogen-flushed bottle.

Hydrozirconating Agent.

Cp_2ZrCl_2 is a very important starting material for the preparation of Zr^{IV} and Zr^{II} derivatives. Cp_2ZrCl_2 is a key compound for the preparation of the so called Schwartz reagent (***Chlorobis(cyclopentadienyl)hydridozirconium***),[5] which is a versatile hydrozirconating agent. Among the methods for reduction of Cp_2ZrCl_2,[6] an economical method for the isolation (eq 1)[7] and a method for the generation[8] of Cp_2ZrHCl in situ (eq 2) are recommended for organic synthesis.

Transmetalation.

Transmetalation of Cp_2ZrCl_2 with organometallics containing lithium, sodium, potassium, and magnesium appears to be a general method to prepare Cp_2ZrR_2 (R =alkyl, allyl, benzyl, alkenyl, aryl, and alkynyl). The reaction of 1 mol of organometallic with 1 mol of Cp_2ZrCl_2 to produce Cp_2ZrRCl requires precise reaction conditions and judicious choice of organometallic to avoid the formation of Cp_2ZrR_2 (eq 3). One example of the importance of reaction conditions and the ligand to obtain a Cp_2ZrRCl-type compound is seen in a contrasting pair of reactions (eqs 4 and 5).[9]

Carbometalation Catalyst.

In a valuable synthetic transformation, stereo- and regioselective addition of organometallics to unsaturated compounds can be catalyzed by Cp_2ZrCl_2 to give carbometalated compounds. Reaction of terminal or internal alkynes with organoaluminum in the presence of Cp_2ZrCl_2 gives the *syn* addition products (>98%) in good to excellent yields (eq 6).[10] The reactions of terminal alkynes with ***Trimethylaluminum*** are regioselective, with the addition of the methyl group to the internal carbon (95%), but the regioselectivity drops to the 75-85% range for other alkyl groups.

Although addition of organozinc can also be catalyzed by Cp_2ZrCl_2, higher yields are obtained using Cp_2ZrI_2 (eq 7).[11] These regio- and stereoselective carbometalations have been applied to the synthesis of natural products.[12] Interestingly, in the Cp_2ZrCl_2-catalyzed carboalumination, the addition of 1-2 equiv of water to the reaction mixture significantly increases the rate of the carboalumination.[13] The effect of the added water is considered to be due to formation of an oxo-bridged dimer and not to formation of methylaluminoxane, which is a cocatalyst for the polymerization of α-alkenes. When an alkyl group of R_3Al has β-hydrogens, hydroalumination via hydrozirconation becomes a serious side reaction.[14] It can, however, be suppressed by the use of the R_2AlCl-Cp_2ZrCl_2 reagent system. With *i*-Bu_3Al and Cp_2ZrCl_2, a clean hydroalumination is observed.[15]

(6)

+ regioisomer (7)

Carbometalation of alkenes catalyzed by Cp_2ZrCl_2 proceeds using aluminum (eq 8) and/or magnesium reagents (eq 9). The carbomagnesation reaction of alkenes is known to proceed through a totally different process from that of the carboalumination of alkynes (eq 10).[16] That is, prior formation of a zirconocene-ethylene complex by the reaction of Cp_2ZrCl_2 with ***Ethylmagnesium Bromide*** and the subsequent coupling reaction with vinyl compounds has been confirmed. The stereochemistry and rate of ethyl magnesation are influenced by the presence of an allylic or homoallylic oxygen functionality (eqs 11 and 12).[17]

(11)

(12)

Generation of Cp_2Zr and its Equivalent.

Generation of Cp_2Zr can be achieved by reduction of Cp_2ZrCl_2 with ***Magnesium-Mercury(II) Chloride*** (eq 13)[18] or 2 equiv ***n-Butyllithium*** (eq 14).[19] The latter method is recommended since the metal reduction of Cp_2ZrCl_2 is prone to a side reaction leading to Zr^{III} species.[20] Low valent Zr^{II} generated with 2 equiv *n*-BuLi exists as a Cp_2Zr-butene complex (eq 15). The Cp_2Zr-butene complex reacts with a series of unsaturated compounds (alkynes, alkenes,[10b,21] imines,[22] and azadienes[23]) through a ligand exchange process to give the desired zirconocene complexes (eqs 16 and 17). Therefore the Cp_2Zr-butene complex is often called zirconocene equivalent (Cp_2Zr). When the reaction of Cp_2Zr with an unsaturated compound is hampered by the presence of the butene, which is released in situ by ligand exchange, use of ***t-Butyllithium*** instead of *n*-BuLi is recommended.[24] The isobutene generated in situ by ligand exchange in the modified procedure is much less reactive than butene toward the Cp_2Zr-substrate complex. The Cp_2Zr equivalent is largely applied to bicyclizations of nonconjugated dienes, enynes, and/or diynes (eq 18).[21] These Cp_2Zr-promoted cyclizations, which proceed with high regio- and stereoselectivity,[25] have been applied to the syntheses of many natural products.[26]

(18)

Apart from the Cp_2Zr-mediated cyclization chemistry, various allylic zirconium derivatives can be generated from allylic ethers and Cp_2Zr (eq 19).[27] This process is a result of the initial formation of zirconacyclopropane and the subsequent elimination of a β-alkoxyl group. In a similar way, the generation of allenic[28] and γ-alkoxyallylic[29] zirconium has been achieved from propargylic ethers and acrolein diethyl acetal, respectively. Allylic zirconium derivatives can also be generated in situ by the metal-exchange reaction of allylic Grignard reagents with Cp_2ZrCl_2.[30] The reactivity of these allylic or allenic zirconium species towards carbonyl compounds is much larger than that of other alkyl zirconocene derivatives. In general, the nucleophilic reactivity of the organozirconium compound having a cyclopentadienyl ligand is low. The Cp_2ZrCl_2/2 mol *n*-BuLi reagent, which generates the zirconocene equivalent in situ, is also applicable as a efficient catalyst in the hydrosilylation of alkenes,[31] Tishchenko reaction[32] of aldehydes, and a cross-aromatization of cyclohexanone derivatives.[33]

Zirconium Enolate.

Cp_2ZrCl_2 is often used to generate very important metal enolates. Zirconocene enolates generated in situ from lithium enolates of carbonyl compounds play a very important role in the stereoselectivity of the products in the crossed aldol reaction (eq 20)[34] and [2,3]-Wittig rearrangements (eq 21).[35] In the aldol reactions a zirconium enolate reacts with carbonyl compounds to give aldol products in a highly *erythro* selective manner regardless of the geometry of the enolate. The rationale for the excellent selectivity in these reactions can be explained by the σ-bond angle, geometry of the coordination site, and the oxophilic nature of zirconocene(IV) derivatives.[36]

Glycosidation.

The combination of Cp_2ZrCl_2 and a silver salt (AgX, X = ClO_4, OTf, and BF_4) is a highly effective reagent system for activating glycosyl fluoride to give the *O*-[37] or *C*-glycoside[38] stereoselectively under very mild conditions (eq 22). This activation process is presumed to involve a cationic zirconocene species as an actual activator (eq 23) and has been applied to the synthesis of a natural product.[37]

Methylenation of Carbonyls.

The methylenation of carbonyls (aldehydes, ketones, and enones) is effectively carried out by treating the carbonyls with Cp_2ZrCl_2, CH_2X_2 (X = Cl or Br), and ***Zinc*** powder (eqs 24 and 25).[39] This system is presumed to form a bimetallic complex. This bimetallic complex attacks the carbonyl compound to afford metallaoxacyclobutane, which rapidly collapses to zirconocene oxide and the methylenated product (eq 26). Unlike the Tebbe reagent (μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***),[40] this zirconium system does not successfully methylenate esters and lactones.

Polymerization Catalyst.

Another important application of Cp_2ZrCl_2 as a catalyst is found in polymer chemistry. The combination of Cp_2ZrCl_2 and methylaluminoxane (MAO) is a famous system (Ziegler-type system) for polymerization of ethylene to polyethylene.[41]

Related Reagents.

Chlorobis(cyclopentadienyl)hydridozirconium; ***Dichlorobis(cyclopentadienyl)titanium***; ***Dichlorobis(cyclopentadienyl)zirconium-Silver(I) Salts***; ***Dichlorobis(cyclopentadienyl)zirconium-Zinc-Dibromomethane***.

[26042-63-7] · AgF_6P · Dichlorobis(cyclopentadienyl)zirconium-Silver(I) Salts · (MW 252.83)

(activates glycosyl fluorides for *O*-glycoside synthesis;[2] effects Friedel-Crafts coupling of glycosyl fluorides with arenes to give aryl *C*-glycosides[3])

Physical Data: see entries for ***Dichlorobis(cyclopentadienyl)zirconium*** and individual silver salts.

Handling, Storage, and Precautions: the reagents are combined just before use by adding the Ag salt to a solution of Cp_2ZrCl_2. ***Silver(I) Perchlorate*** leads to the best reactivity but has a potential hazard of explosion.[4] ***Silver(I) Trifluoromethanesulfonate*** is recommended as a safe alternative with slightly decreased reactivity. Other silver salts (e.g. ***Silver(I) Tetrafluoroborate***, $AgPF_6$, $AgAsF_6$) are less effective, but sometimes offer unique stereochemical preferences.[2d] Molecular sieves 4A are often used for removal of water in small scale runs but are not necessarily essential.

Cp_2ZrCl_2-$AgClO_4$ is used for the activation of glycosyl fluorides which, upon reaction with alcohols (glycosyl acceptors), give various *O*-glycosides.[1,2] The reactivity is slightly less than its hafnium counterpart, Cp_2HfCl_2-$AgClO_4$ (see ***Dichlorobis(cyclopentadienyl)hafnium-Silver(I) Salts***). Use of the combination in a 1:2 ratio increases the reactivity.[2d] A number of useful applications have been reported for the synthesis of various classes of glycoconjugates, ranging from macrolides[2] to oligosaccharide structures embedded in glycopeptides or glycolipids.[5] Fine tuning of the reactivity/stereoselectivity[2,5] can be made by the suitable choice of the solvent, the metal center (Zr or Hf), and also the silver salt (eqs 1 and 2).

(1)

(2)

α:β = 3.7:1

MBn = 4-methoxybenzyl

Cp_2ZrCl_2-$AgClO_4$ effects Friedel-Crafts coupling of glycosyl fluorides with activated aromatic compounds to give aryl *C*-glycosides (eq 3).[3] The hafnium counterpart is often too reactive.

Related Reagents.

Dichlorobis(cyclopentadienyl)hafnium-Silver(I) Salts; ***Dichlorobis(cyclopentadienyl)zirconium***.

Dichlorobis(cyclopentadienyl)zirconium-Zinc-Dibromomethane[1]

(Cp_2ZrCl_2)

[1291-32-3] · $C_{10}H_{10}Cl_2Zr$ · Dichlorobis(cyclopentadienyl)zirconium-Zinc-Dibromomethane · (MW 292.32) (Zn)

[7440-66-6] · Zn · Dichlorobis(cyclopentadienyl)zirconium-Zinc-Dibromomethane · (MW 65.37) (CH_2Br_2)

[74-95-3] · CH_2Br_2 · Dichlorobis(cyclopentadienyl)zirconium-Zinc-Dibromomethane · (MW 173.85)

(methylenating reagent for aldehydes, ketones, and enones[1])

Physical Data: Cp_2ZrCl_2: mp 245 °C. Zn: mp 419.5 °C; *d* 7.14 g cm^{-3}. CH_2Br_2: mp -52 °C; bp 96-98 °C; *d* 2.477 g cm^{-3}.

Solubility: Cp_2ZrCl_2: sol THF, CH_2Cl_2, and $CHCl_3$. Zn: insoluble in organic solvents. CH_2Br_2: miscible in common organic solvents.

Form Supplied in: Cp_2ZrCl_2: white crystalline powder; widely available. Zn: metallic gray granules or powder. CH_2Br_2: clear, colorless liquid.

Preparative Method: prepared in situ.

Handling, Storage, and Precautions: Cp_2ZrCl_2: store under N_2. Zn: flammable solid. CH_2Br_2: harmful if inhaled or swallowed; may cause irritation.

The reagent is prepared in situ by the addition of ***Dibromomethane*** to a mixture of ***Zinc***, ***Dichlorobis(cyclopentadienyl)zirconium***, and the aldehyde or ketone in dry THF. Typical reaction time is 3 h at room temperature.[1,3] The yield of methylenated products is good with enones, aldehydes, and ketones (Table 1), but the

reagent will not methylenate lactones or esters.[1]

Table 1 Conversion of Carbonyls (X = O) to Alkenes (X = CH_2) using $Cp_2Zr_2Cl_2$-CH_2Br_2-Zn[a]

1 h (64%)

2 h (76%)

Dichloro[1,4-bis(diphenylphosphino)butane]nickel(II)

[18750-53-3] · $C_{28}H_{28}Cl_2NiP_2$ · Dichloro[1,4-bis(diphenylphosphino)butane]nickel(II) · (MW 556.07)

(catalyst for allylic alkylation[1] of stable enolates, dialkylation[2] of dithioacetals and electrochemical carboxylation of terminal alkynes[3])

Physical Data: light fawn-colored powder.

Solubility: sol benzene. *Drying:* the powder can be dried under vacuum.[4]

Preparative Method: prepared by adding a solution of $NiCl_2.6H_2O$ in *n*-butanol to a solution of 1,4-bis(diphenylphosphino)butane (dppb) in *n*-butanol and refluxing until the complex drops out of solution as a light purple powder.

Handling, Storage, and Precautions: should be stored in dry, dark-colored bottles under an inert atmosphere.

Allylic Alkylation.

The title reagent has been used to catalyze alkylation of stabilized enolates with allylic acetates. The regioselectivity depends on the ligands present around nickel.[1] For example, 1,4-diphenylphosphinobutane (dppb) shows better regioselectivity than 1,2-diphenylphosphinoethane (dppe) in the nickel-catalyzed alkylation of *trans*-2-buten-1-yl acetate with the anion of malonic ester even though the stereoselectivity is about the same (eq 1).[5]

Ligand	Yield	I (*E*:*Z*)	II
dppb	97	98 (81:19)	2
dppe	78	72 (80:20)	28

Regioselective Alkylation of Allylic Dithioacetals.

$NiCl_2$(dppb) shows higher regioselectivity than triphenylphosphine in the dialkylation of dithioacetal derivatives of α,β-unsaturated carbonyl compounds with Grignard reagents. The *gem*-dimethylation of cinnamaldehyde dithioacetal with MeMgI using $NiCl_2$(dppb) as a catalyst occurs regiospecifically in 90% yield (eq 2).[2] In contrast, ***Dichlorobis(triphenylphosphine)nickel(II)*** gives a 70/30 mixture of the *gem*-dimethyl adduct and 1-phenylbutadiene. Generally, the regioselectivity of all nickel catalysts decreases as the size of the 2-substituent on the allylic moiety increases.[2]

Ligand	Yield	A:B
dppb	90	100:0
PPh_3	85	70:30

Electrochemical Carboxylation of Terminal Alkynes.

The product ratio in nickel-catalyzed electrochemical carboxylations of terminal alkynes depends strongly on the ligand.[3] For example, 1-octyne has been electrochemically carboxylated with $NiCl_2$(dppb) to give the diacid only (eq 3), whereas $NiCl_2$(dppe) gives a mixture of alkynyl acid and trihexylbenzene (eq 4).[3]

Dichloro[1,4-bis(diphenylphosphino)butane]palladium(II)

[29964-62-3] · $C_{28}H_{28}Cl_2P_2Pd$ · Dichloro[1,4-bis(diphenylphosphino)butane]palladium(II) · (MW 603.80)

(useful for the catalysis of styrene carbonylation,[1] coupling of alkyl Grignard reagents with organic halides,[2] selective monoalkylation of organic polyhalides,[3] and modification of the dihalovinyl moiety of synthetic pyrethroids[4])

Solubility: commonly used in ethanol, benzene, and ethereal solvents.

Form Supplied in: cream colored powder.

Preparative Methods: can be prepared conveniently in situ by mixing the bidentate phosphine ligand and $(PhCN)_2PdCl_2$ in either benzene or chloroform.[1] The preparation of $(dppb)PdCl_2$ is also possible through the reaction of $PdCl_2$ with dppb in acetone, a process that slowly forms the catalyst as a white precipitate which can be isolated in 51% yield.[5] Preparation of the hydrate complex is possible via the reaction of $Na_2[PdCl_4]$ with dppb in a mixture of CH_2Cl_2 and water.[5]

Handling, Storage, and Precautions: hygroscopic.

Carbonylation of Styrene.

One of the earliest uses of $(dppb)PdCl_2$ was for the catalytic carbonylation of styrene (eq 1).[1] The product distribution from this reaction depends on the nature of the phosphine ligand, $Ph_2P(CH_2)_nPPh_2$, and was examined for n = 1-6 and 10 (the n = 2 ligand did not show catalytic activity). The selectivity appears to depend on the coordinating power of the phosphine ligand, where strongly coordinating bidentate ligands (n = 3 or 4) create a steric environment that suppresses formation of the branched ester (**2**). The highest selectivity for the formation of (**2**) is obtained with a derivative of the dppb ligand, DIOP (***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane***).

n	1	3	4	5	6	10	DIOP
(1)	33%	12%	22%	37%	78%	88%	23%
(2)	29%	29%	48%	42%	16%	5%	67%

Coupling Reactions.

Investigation of the activity of various bisphosphine-Pd and -Ni complexes in the coupling of *s*-butylmagnesium chloride with aryl or vinyl bromides shows that (dppb)$PdCl_2$ is relatively selective (eq 2).[2] In comparison, ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)***, (dppf)$PdCl_2$, is far more effective. The increased selectivity of the dppf ligand is attributed to the larger P-Pd-P angle and smaller Cl-Pd-Cl angle imposed by the presence of the ligand. Overall, the selectivity for the ligands is: (dppf)$PdCl_2$ >> (dppb)$PdCl_2$ &egt; (dppp)$PdCl_2$ > $(PPh_3)_4Pd$ > $(PPh_3)_2PdCl_2$ > (dppe)$PdCl_2$. Although (dppp)$NiCl_2$ is the most selective nickel catalyst for such transformations, (dppf)$PdCl_2$ is even more effective. The use of these catalysts allows for coupling with secondary alkyl groups and with alkyl groups containing β-hydrogens.[2]

LM	(3)	(4)
(dppf)Pd	95%	0%
(dppb)Pd	51%	25%
(dppp)Ni	29%	3%

The use of (dppb)$PdCl_2$ promotes selective monoalkylation of organic polyhalides to produce 1-substituted (*Z*)-1-chloroalkenes from 1,1-dichloro-1-alkenes and either Grignard or organozinc reagents (eq 3).[3] Alkyl, aryl, and heteroaryl Grignard or zinc reagents are effective in this coupling reaction. Even trichloroethylene undergoes this coupling reaction at the expected position. The regioselectivity of this reaction depends upon the presence of substituent R^1.[3] In addition, the use of $(PPh_3)_2PdCl_2$ rather than (dppb)$PdCl_2$ gives mainly diarylation products. This procedure provides a viable alternative to Wittig alkenation for the preparation of unsymmetrically trisubstituted alkenes since aldehydes can easily be transformed into 1,1-dichloroalkenes.

R^1 = Ph, 4-$MeOC_6H_4$, 2-thienyl, Me, Cl; R^2MX = PhMgBr, 4-$MeOC_6H_4MgBr$, PhZnCl, 4-ClC_6H_4MgBr, *n*-BuZnCl, *n*-hexylMgBr

Work toward modification of the dihalovinyl moiety of synthetic pyrethroids such as permethrin, cypermethrin, and deltamethrin, which are present in many household and agricultural insecticides, has progressed due to the application of similar palladium catalyzed coupling reactions.[4] The reaction of an organozinc complex in the presence of (dppb)$PdCl_2$ provides a pathway for the direct stereoselective transformation of (2,2-dihalovinyl)dimethylcyclopropanecarboxylates into [(*Z*)-2-substituted 2-halovinyl]dimethylcyclopropanecarboxylates (eq 4).[4]

Similar reactions are known for the catalytic system formed from $Pd(OAc)_2$ and dppb. This system is used for affecting regioselective hydrocarboxylation of alkenes,[6] and for regioselective arylation of unsymmetrical alkenes[7] and acyclic enol ethers.[8]

In addition, the combination of $(dppb)PdCl_2$ and CuO has been shown to be a useful catalytic system for the Stille cross coupling of 2-tributylstannylpyridine with halobenzenes and aromatic heterocyclic halides.[9]

Dichloro[1,2-bis(diphenylphosphino)ethane]palladium(II)

[19978-61-1] · $C_{26}H_{24}Cl_2P_2Pd$ · Dichloro[1,2-bis(diphenylphosphino)ethane]palladium(II) · (MW 575.75)

(catalyst for carbonylation[1] and biscarbonylation[2,3] of aryl halides with amines)

Alternate Names: [1,2-bis(diphenylphosphino)ethane]palladium(II) chloride; dichloro[ethylenebis(diphenylphosphino)]palladium(II).

Physical Data: mp >300 °C.

Form Supplied in: orange powder; available from several suppliers.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$-DMSO-d_6) δ 3.5 (t, CH_2), δ 3.8 (q, CH_2); ^{1}H NMR ($CDCl_3$) δ 3.45 (t, CH_2), δ 3.6 (q, CH_2); ^{31}P NMR (121.5 MHz, CH_2Cl_2) 58.3 (s).

Preparative Methods: prepared by treating commercially available K_2PdCl_2 (in DMF) with bis(diphenylphosphino)ethane (in CH_2Cl_2).[4,5] It can also prepared from K_2PdCl_2 (in H_2O) and bis(diphenylphosphino)ethane (in CH_2Cl_2) using Bu_4NCl (in CH_2Cl_2) as a phase-transfer catalyst.[6]

Purification: recrystallization from DMF-ether.

Handling, Storage, and Precautions: moisture sensitive.

N-Substituted Phthalimides.

The title reagent is useful in carbonylation and coupling of *o*-dihalo aromatics and primary amines to form *N*-substituted phthalimides.[1] Optimal conditions for the reaction of *o*-diiodobenzene and aniline use DMA (0.2 M),

115 °C, 90 psi of CO, 3% $PdCl_2$(dppe), and 2.4 equiv of DBU (eq 1). This procedure tolerates a wide variety of functional groups and gives a good yield of desired products. An exception is the reaction of aniline with 1,2-dibromocyclopentene under the above conditions, which has been reported to give a variety of products.

α-Keto Amides.

The title reagent is used as a catalyst to prepare α-keto amides and amides from aryl halides upon treatment with secondary amines and ***Carbon Monoxide*** (eq 2).[2,3] These reactions are most commonly carried out without solvent at 100 °C at 10 atm of CO using a 1:3:0.1 molar ratio of aryl halide/secondary amine/$PdCl_2$(dppe).

Allylation of Allylic Alcohols.

Allylation of carbonyl compounds is carried out via the formation of π-allylpalladium complexes using the title reagent as a catalyst and ***Tin(II) Chloride*** as a reducing agent (eq 3).[7] The reactivity order of allylating agents is allylic carbonate > allylic alcohol > allylic acetate and that of carbonyl compounds is aldehyde > ketone. Polar solvents such as DMF, DMSO, or ***1,3-Dimethyl-2-imidazolidinone*** (DMI) are preferred for higher regioselectivity.

Other Uses.

The title reagent is used as a catalyst for cross coupling of primary, secondary, and tertiary Grignard and alkylzinc reagents with organic halides, but results are reported to be unsatisfactory.[8,9] ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)*** [$PdCl_2$(dppf)] is the preferred catalyst in the case of primary and secondary Grignard and alkyl zinc reagents,[8] whereas 1,1´-[bis(diphenylphosphino)ferrocene)]nickel(II) chloride is an effective catalyst in the case of tertiary alkyl Grignard reagents.[9] Allylic *p*-tolyl sulfones are desulfonylated to the corresponding alkanes in moderate yield by ***Lithium Triethylborohydride*** in the presence of a catalytic amount of the title reagent under mild conditions with preservation of the original stereochemistry. Dichloro[1,3-bis(diphenylphosphino)propane]palladium(II) [$PdCl_2$(dppp)] gives better results in the desulfonylation.[10]

Related Reagents.

$PdCl_2(PPh_3)_2$ has shown similar results in carbonylation and coupling of *o*-dihalo aromatics and primary amines to form *N*-substituted phthalimides, but ***Palladium(II) Chloride***, ***Palladium(II) Acetate***, $PdCl_2$.2MeCN, and $PdCl_2$.2BzCN have shown inferior results.[1] ***Dichlorobis(methyldiphenylphosphine)palladium(II)*** and $PdCl_2(PBuPh_2)_2$ are reported to be more effective as catalysts among the palladium complexes containing tertiary phosphine ligands.[2] ***Bis(benzonitrile)dichloropalladium(II)*** is a better catalyst for carbonyl allylation using allylic alcohols because of its stability towards air and moisture.[7]

Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)

[72287-26-4] · $C_{34}H_{28}Cl_2FeP_2Pd$ · Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II) · (MW 731.72)

(catalyst for cross-coupling reactions)

Physical Data: mp 265-268 °C (dec).

Solubility: sol ether, THF, benzene.

Form Supplied in: reddish brown solid; commercially available.

Purification: recrystallization from $CHCl_3$ under inert atmosphere.

Handling, Storage, and Precautions: the complex is an irritant; store under an inert atmosphere.

Cross Coupling.

Like other Pd^{II} and Ni^{II} phosphine complexes, $PdCl_2$(dppf) is a very useful catalyst for the cross-coupling reactions of vinyl or aryl halides or triflates with Grignard reagents, leading to carbon-carbon bond formation.[1] $PdCl_2$(dppf)-catalyzed reaction of vinyl bromide with *s*-BuMgCl gives exclusively the desired coupling product (eq 1), while other Pd catalysts also yield isomerized and reduced by-products.[1a] (*E*)-1-Bromo-1-alkenes are more reactive than the (*Z*)-isomers.[1c] Selective monoalkylation of dichlorobenzene under refluxing conditions using $PdCl_2$(dppf) catalyst has been recorded.[2] Whereas palladium catalysts are usually unreactive in cross couplings of organosulfur compounds,[3] reactions of 2-methylthio-4,4-dimethyl-2-oxazoline with aryl Grignard reagents are catalyzed efficiently by $PdCl_2$(dppf) (eq 2).[4] Phototoxic terthiophenes have been prepared and the SMe group remains intact under the reaction conditions (eq 3).[5] Organozinc reagents behave similarly in these cross coupling reactions.[6] $PdCl_2$(dppf) has been found to catalyze iodine-zinc exchange reactions which lead to an interesting Pd-catalyzed intramolecular carbozincation of alkenes (eq 4).[7] It is

noteworthy that various functional groups remain intact under these conditions.

(1)

(2)

(3)

(4)

Aliphatic iodides are reduced upon treatment with alkyl Grignard reagents in the presence of $PdCl_2$(dppf) catalyst.[8] Aryl triflates are efficiently reduced by ***Sodium Borohydride*** or ***Ammonium Formate*** in the presence of $PdCl_2$(dppf).[9]

$PdCl_2$(dppf) also promotes the Stille reaction[10,11] as well as the Suzuki reaction.[12] Selective alkyl transfer in the Stille coupling reaction is effectively catalyzed by $PdCl_2$(dppf) (eq 5).[10a] Distannanes have been found to promote the $PdCl_2$(dppf) catalyzed allylation of aryl halides with allyl acetate.[10b] Intramolecular cyclization and cross coupling of alkynic aryl triflates with organotin reagents is promoted by $PdCl_2$(dppf) (eq 6).[10c] The $PdCl_2$(dppf)-catalyzed inter- and intramolecular coupling reactions of vinyl or aryl triflates with organostannanes in the presence of carbon monoxide and ***Lithium Chloride*** takes place under mild conditions to give good yields of vinyl or aryl ketones (eq 7).[11] Similar reactions have been performed with aryl triflates (eq 8).[13]

(5)

(6)

(7)

(8)

The title reagent has also been used to hydroesterify trimethylsilylalkynes, affording conjugated vinylsilanes in good yield (eq 9).[14]

Dichlorobis(methyldiphenylphosphine)palladium(II)

[52611-08-2] · $C_{26}H_{26}Cl_2P_2Pd$ · Dichlorobis(methyldiphenylphosphine)palladium(II) · (MW 577.75)

(catalyst for biscarbonylation of aryl halides with amines[3,4])

Alternate Name: bis[(diphenylphosphino)methane]palladium(II) chloride.

Physical Data: ^{1}H NMR ($CDCl_3$) δ 4.2 (t, CH_3).

Preparative Methods: by treating commercially available K_2PdCl_2 (in DMF) with methyldiphenylphosphine (in CH_2Cl_2),[1] or from K_2PdCl_2 (in H_2O) and methyldiphenylphosphine (in CH_2Cl_2) using Bu_4NCl (in CH_2Cl_2) as a phase-transfer catalyst.[2]

α-Keto Amides.

The title reagent ($PdCl_2$(dppm)) is one of the most effective catalysts among transition-metal complexes for the preparation of α-keto amides and amides from aryl halides by treatment with secondary amines and carbon monoxide.[3,4] These reactions are most commonly carried out without solvent at 100 °C at 10 atm of CO using a 1:3:0.1 molar ratio of aryl halide/secondary amine/$PdCl_2$(dppm) (eq 1).

The reactivity of phenyl halides decreases in order of PhI > PhBr > PhCl,[3] although the selectivity of biscarbonylation is higher with the bromo than with the iodo derivative.[4] Introduction of electron-withdrawing substituents into the para position of phenyl halides enhances the reactivity but decreases the selectivity for α-keto amides.[3] Amines with high basicity ($pK_b < 4$) are essential for accomplishing the catalytic biscarbonylation. Sterically hindered amines favor formation of the α-keto amides.[3]

Related Reagents.

$PdCl_2(PBuPh_2)_2$ has shown good results in the formation of α-keto amides from aryl halides upon treatment with secondary amines with ***Carbon Monoxide***.[3]

(catalysts for the cross-coupling reactions of various RX with Grignard reagents,[1-34] C-X bond reduction,[35,36] homocoupling of C_{sp^2} halides,[37-40] displacement of aryl halides,[41] and oligomerization of dienes[47])

Physical Data: $NiCl_2(PPh_3)_2$: dark green; mp 205-206 °C. $NiCl_2(PEt_3)_2$: dark red; mp 112-113 °C. $NiCl_2(PBu_3)_2$: red; mp 48-49 °C. $NiCl_2$(dppe): orange; mp 263-265 °C. $NiCl_2$(dppp): red; mp 213 °C (dec). $NiCl_2$(dppb): light violet; mp 270-272 °C. $NiCl_2$(dppf): dark green; mp 283-284 °C.

Solubility: sol benzene, acetone, THF, hot alcohol.

Preparative Methods: most nickel chloride phosphine complexes are commercially available. They can also be conveniently synthesized by mixing the stoichiometric amount of $NiCl_2$ with the appropriate phosphine ligand.[48]

Handling, Storage, and Precautions: nickel chloride phosphine complexes are corrosive and cancer suspect agents. Most of these complexes are air stable in solid form. Handle in a fume hood.

Cross-Coupling Reactions.

Transition metal catalyzed cross-coupling reactions of R-X with organometallic nucleophiles are well documented.[1] R can be an aryl, vinyl, or allyl group, and X can be any leaving group ranging from the more reactive triflates and halides to less labile thioalkoxides, sulfoxides, sulfones, hydroxides, alkoxides, and even amido groups. Aryl, vinyl, as well as alkyl Grignard reagents are commonly used organometallic nucleophiles. These reactions provide extremely versatile carbon-carbon bond formation processes. Eqs 1-4 summarize representative examples.[2-4] Even acid chlorides undergo the cross-coupling reaction (eq 5).[5]

(1)

(2)

(3)

(4)

(5)

Palladium and nickel complexes are the most useful catalysts for this purpose. Although nickel compounds without phosphine ligands can mediate cross-coupling reactions, those bearing phosphine ligands occasionally give much better results, with bidentate phosphine ligands providing the greatest catalytic activity for simple aryl, vinylic, or allyl substrates.

The choice of catalyst is particularly important for reactions of secondary alkyl Grignard reagents. When secondary Grignard reagents that bear β-hydrogens are employed, competitive β-hydride elimination results in the formation of both reduced and isomerized byproducts. These side reactions are particularly bothersome in reactions with hindered alkenyl halides. It is noteworthy that the use of the $NiCl_2$(dppf) catalyst can minimize these side reactions by accelerating the rate of desired reductive elimination relative to undesired β-elimination.[6] For example, $NiCl_2$(dppf) is the most selective catalyst for the cross-coupling reaction of β-bromostyrene with *t*-BuMgCl, giving (*E*)-β-*t*-butylstyrene exclusively (eq 6).[6] Other nickel complexes, $NiCl_2(PPh_3)_2$, $NiCl_2$(dppe), $NiCl_2$(dppp), and $NiCl_2$(dppb), also catalyze the coupling reaction, but it is accompanied occasionally by *t*-butyl isomerization to give (*E*)-β-isobutylstyrene as a byproduct. Moreover, there are only limited cases which are known for the cross-coupling reactions of alkyl iodides with Grignard reagents. $NiCl_2$(dppf) again demonstrates a unique reactivity for this transformation.[7] It is interesting to note that only neopentyl iodide can undergo coupling reactions with aromatic Grignard reagents (eq 7). Other coupling reactions including the activation of aliphatic carbon-sulfur bonds will be discussed later.

(6)

(7)

In general, reactions of alkenyl halides exhibit predominant retention of alkene geometry (eq 8),[8] while reactions of alkenyl Grignard reagents are complicated by competing (*Z*) to (*E*) isomerization.[1]

(8)

Coupling reactions of unsymmetric allylic substrates normally gives a mixture of isomers. However, when a zinc reagent is used, allyl chlorides undergo regioselective displacement reactions giving S_N2-like products predominantly, if not exclusively (eq 9). It is noted that copper-catalyzed reactions give S_N2' substitution products selectively.[9]

(9)

Vinyl and aryl ethers also react with Grignard reagents under nickel catalysis, although they are less reactive than the corresponding bromides.[10] Reactions of dihydrofuran and dihydropyran derivatives with Grignard reagents, giving homoallylic and bishomoallylic alcohols, respectively, are particularly noteworthy (eqs 10 and 11).[11] Retention of alkene geometry is predominantly observed. Silyl enol ethers[12a] and enol phosphates[12b,c] behave similarly.

(10)

(11)

Allylic alcohols also give the corresponding coupling products upon treatment with a Grignard reagent in the presence of the nickel catalyst (eq 12),[1e,13] and propargylic ethers yield the allene products (eq 13).[14a] It is noteworthy that soft nucleophiles can also displace the allylic ethers in the presence of the nickel catalyst (eq 14).[14b]

(12)

(13)

(14)

The nickel-catalyzed substitution of vinyl sulfides by Grignard reagents forms the basis of a procedure for the stereoselective synthesis of alkenes by sequential cross-coupling reactions (eq 15).[1c-g,15,16] The cross-coupling reactions of thiophenes under the same conditions lead to stereoselective synthesis of substituted butadienes (eq 16).[15d,e] Unlike halide and triflate leaving groups, where palladium is also effective, the nickel catalyst plays a unique role in the displacement of the carbon-sulfur bonds. Thiols, sulfoxides, sulfones, as well as sulfonates also undergo coupling reactions smoothly (eq 17).[15] Among vinylic substrates, the reactivity trend of various leaving groups in these nickel-catalyzed cross-coupling reactions appears to be in the following order: I > Br > SR > Cl > OR.

(15)

R^1, R^2 = alkyl, aryl, vinyl

(16)

(17)

X = SH, SOMe, SO_2Me, $SO_3C_6H_4Me$

Optically active alkenylsulfoximines undergo nickel-catalyzed cross-coupling with organozinc reagents in the presence of an additional magnesium, lithium, or zinc salt. The reaction proceeds with more than 98% retention of alkene geometry (eq 18).[17]

(18)

Dithioacetals have two carbon-sulfur bonds attached to the same carbon atom. Sequential displacements of these two bonds in allylic substrates (eq 19) and *o*-amino-substituted benzylic substrates (eq 20) result in the net conversion of a carbonyl equivalent into a geminal dimethylated product.[1f,g,18] It is noteworthy that only nickel complexes containing bidentate ligands catalyze the desired geminal dimethylation. When $NiCl_2(PPh_3)_2$ is used, a mixture of alkenation and dimethylation products is obtained.

(19)

(20)

As mentioned earlier, β-hydride elimination is a major side reaction in the cross-coupling. However, this elimination process has been used in cross-coupling reactions of dithioacetals leading to alkenation products.[1g] In this case, one of the carbon-sulfur bonds is substituted by a carbon-carbon bond, and subsequently the second carbon-sulfur bond is eliminated to produce an alkene (eq 21).[1f,g,19] In this respect, $NiCl_2(PPh_3)_2$ is the best catalyst and the sulfur leaving group may coordinate to the nickel catalyst throughout the catalytic process.[20] The reaction has particularly useful applications for the synthesis of various silyl-substituted alkenes and dienes (eqs 22 and 23).[21] When the cyclopropyl Grignard reagent is employed, the reaction provides an interesting ring opening route for the synthesis of substituted dienes (eq 24).[22] This reaction demonstrates an interesting example using cyclopropyl anion as an allyl anion synthon. Reactions of dithioacetals with allylmagnesium halides under similar conditions, on the other hand, afford

1,4-pentadienes as the predominant, if not exclusive, products.[21b] Benzylic and allylic orthothioesters also give the corresponding alkylative alkenation products in satisfactory yields.[21c,e]

(21)

(22)

(23)

(24)

Whereas simple aliphatic dithioacetals do not undergo the cross-coupling reaction, tetrathioorthocarbonate interestingly serves as a C^{4+} synthon under these reaction conditions.[23] For example, tris(trialkylsilyl)isobutene is conveniently synthesized as shown in eq 25. When an appropriately located heteroatom is present for chelation of the nickel catalyst, aliphatic dithioacetals can also undergo cross-coupling reactions. Depending on the nature of the substrates, bisdithioacetals undergo either selective monoalkenation or a tandem coupling process via an allylic dithioacetal intermediate (eqs 26 and 27).[24]

(25)

(26)

(27)

Since the reaction medium is basic, benzylic dithioacetal-*S*-oxides undergo a Pummerer-type rearrangement followed by the reaction with the Grignard reagent to give the dithioacetals which then undergo the nickel-catalyzed alkenation process to yield the corresponding alkylative alkenation products (eq 28).[25]

(28)

Carbon-tellurium bonds can be replaced[26] and quarternary ammonium ion can also serve as a leaving group in the

nickel-catalyzed cross-coupling reactions (eq 29).[27]

(29)

Cross-coupling reactions of Si-O and Si-H bonds with Grignard reagents are also catalyzed by nickel complexes (eqs 30 and 31).[28,29]

(30)

(31)

Cross-Coupling Reactions Using Chiral Ligands.

When chiral phosphine ligands are used, the coupling reaction can be enantioselective.[1l-n] Thus the cross-coupling reaction of 3-cyclohexenyl ether with EtMgBr yields the corresponding hydrocarbons with excellent selectivity when [(*S*,*S*)-chiraphos]$NiCl_2$ is employed (eq 32).[30]

(32)

The cross-coupling reaction between 1-phenylethylmagnesium bromide and vinyl bromide in the presence of a [(*S*,*S*)-norphos]$NiCl_2$ catalyst yields the corresponding coupling product in 95% yield with 67% ee (eq 33).[31]

(33)

Higher enantioselectivities are achieved when certain chiral aminophosphines derived from amino acids are used. In general, ligands derived from (*S*)-amino acids give rise to the (*S*)-product, but it has been reported that this trend is reversed in the presence of ZnX_2. It is worth noting that a sulfide-containing side chain appended to the dimethylaminophosphine ligands improves the enantioselectivity. The sulfide moiety offers a third site for coordination to the metal, and such intramolecular participation would accelerate the rate of reductive elimination, minimizing the loss of enantiomeric purity resulting from competitive β-elimination (eq 34).[32]

(34)

R = *p*-Tol, *p*-(*i*-Bu)C_6H_4, *p*-PhC_6H_4, Ph
R' = *i*-Pr, *t*-Bu, *s*-Bu, Cy, MeS$(CH_2)_3$

It is particularly noteworthy that cross-coupling reactions of 1-bromonaphthalenes with 1-naphthyl Grignard reagents in the presence of a ferrocene-based chiral nickel catalyst [(*S*)-(*R*)-PPFOMe]$NiCl_2$ furnish a useful entry for the preparation of a various chiral binaphthyl derivatives (eq 35).[33] Chiral ternaphthyl derivatives are obtained similarly.[33] It is interesting to note that other ferrocene-based chiral ligands do not behave well under the reaction conditions.[34]

(35)

[(*S*)-(*R*)-PPFOMe]

Reduction.

Nickel hydride species, generated in situ from the reaction of secondary Grignard reagents and $NiCl_2(PPh_3)_2$ catalyst, are active for the reductive cleavage of the carbon-sulfur bonds (eq 36).[35] Vinylic or aryl thiols, sulfides, sulfoxides, and sulfones can be reduced with ease under these conditions. The reduction is stereospecific, with no over reduction being detected. Si-X bonds are also reduced under similar conditions.[36]

Homocoupling.

A Ni^0 catalyst generated in situ from the reduction of $NiCl_2(PPh_3)_2$ with zinc promotes homocoupling of aryl or vinyl halides in good yields (eq 37).[37,38] DMF is the most suitable solvent. Esters, amides, ketones, aldehydes, and ether functionalities are stable under the reaction conditions. Bicinnamyl is obtained from cinnamyl chloride in 50% yield.[38] (*E*/*Z*) isomerization may occur in the homocoupling of alkenyl halides.[38b] Et_4NI or KI or thiourea have been shown to assist the reduction of Ni^{II} with zinc and also to convert the alkenyl bromides to the corresponding alkenyl iodides.[38e,f] The extension of this reaction to the synthesis of heterocyclic biaryls, such as bipyridyls and bithienyls, has been executed.[39] The generation of a Ni^0 species by electrochemical reduction of $NiCl_2(PPh_3)_2$ is useful for the reductive homocoupling of aryl bromides.[40]

Displacement.

Aryl bromides are readily displaced by iodide in the presence of nickel catalysts.[38e,f] In a similar manner, carbon-sulfur bonds are produced when an aryl iodide is treated with thiourea in the presence of a Ni^0 catalyst generated in situ from the reaction of $NiCl_2(PEt_3)_2$ and ***Sodium Cyanoborohydride*** (eq 38).[41] Hydrolysis of the thiouronium salt gives the corresponding thiols.

(38)

Reductive Heck-Like Reactions.

In the presence of the zinc, $NiCl_2(PPh_3)_2$ promotes reductive coupling reactions of aryl bromides with excess α,β-unsaturated esters in the presence of pyridine and a trace amount of water (eq 39).[42] Alkyl bromides also give similar coupling products.

(39)

Miscellaneous.

Octa-1,7-diynes bearing ester groups on the terminal positions react with propargyl alcohols in the presence of stoichiometric amounts of a nickel(0) reagent derived from $NiCl_2(PPh_3)_2$ and ***n-Butyllithium*** to give tetralin lactones in moderate yields (eq 40).[43]

(40)

The formation of ketones from reaction of a carboxylic acid with a Grignard reagent is catalyzed by $NiCl_2$(dppe) (eq 41).[44] The *cis* addition of the Grignard reagent to triple bond is also catalyzed by $NiCl_2(PPh_3)_2$ (eq 42).[45] Elimination of HBr from a terminal bromo compound is reportedly promoted by $NiCl_2(PPh_3)_2$ (eq 43).[46]

(41)

(42)

(43)

Although low-valent nickel complexes are very useful for dimerization and oligomerization of alkenes, the use of $NiCl_2(PPh_3)_2$ or related complexes for this purpose is relatively rare (eq 44). Occasionally, a number of isomeric products are obtained.[47]

Dichlorobis(triphenylphosphine)platinum(II)-Tin(II) Chloride

($PtCl_2(Ph_3P)_2$)

[10199-34-5] · $C_{36}H_{30}Cl_2P_2Pt$ · Dichlorobis(triphenylphosphine)platinum(II)-Tin(II) Chloride · (MW 790.58) (*cis*)

[15604-36-1] (*trans*)

[14056-88-3] ($SnCl_2.2H_2O$)

[10025-69-1] · Cl_2Sn · Dichlorobis(triphenylphosphine)platinum(II)-Tin(II) Chloride · (MW 225.63)

(a homogeneous catalyst for hydroformylation,[1] hydrogenation, and isomerization of alkenes)

Physical Data: cis-$PtCl_2(Ph_3P)_2$: mp 310 °C (dec); *trans*-$PtCl_2(Ph_3P)_2$: mp > 300 °C; $SnCl_2.2H_2O$: mp 37.7 °C (dec), bp 652 °C, *d* 2.710 g cm^{-3}.

Solubility: $SnCl_2.2H_2O$ sol alcohol, ether.

Form Supplied in: $PtCl_2(Ph_3P)_2$: solid; $SnCl_2.2H_2O$: white crystals, widely available.

Handling, Storage, and Precautions: $PtCl_2(Ph_3P)_2$: irritant, hygroscopic; $SnCl_2.2H_2O$: corrosive, toxic.

Hydroformylation.

In combination with an excess of tin(II) chloride as cocatalyst, $PtCl_2(Ph_3P)_2$[2] catalyzes the hydroformylation[1,3] of a variety of α-alkenes in high yield and selectivity (eq 1).

The yields and the selectivity for linear aldehydes depend on alkene structure, temperature, H_2/CO pressure, and solvent composition. Cyclic alkenes have also been hydroformylated (e.g. cyclopentene, 79% yield). Competing alkene isomerization (ca. 7%) and reduction to the alkane (ca. 4%) are generally observed. The catalytic activity of this system has been enhanced by the use of various other ligands in place of triphenylphosphine.[1,3] Good chemo- and regioselectivity can be obtained in the hydroformylation of functionalized alkenes (eq 2).[4] Enantioselective hydroformylations have been achieved using chiral phosphine ligands.[5]

The mechanism of this hydroformylation has been investigated and some putative intermediates have been identified.[6] When the reaction is carried out in ethanol in the absence of H_2, terminal esters are obtained, but in low yield.[7] More effective catalysts for this alkoxycarbonylation have been developed.

Hydrogenation.

This catalyst system has been utilized for the hydrogenation of nonaromatic polyalkenes to monoenes.[8] The reaction proceeds via migration of the double bonds into conjugation, followed by reduction. The ability of this catalyst to place double bonds into conjugation has been exploited for the conversion of 1,5-cyclooctadiene to 1,3-cyclooctadiene, and for placing the double bonds of methyl linoleate into conjugation.[9]

Miscellaneous Reactions.

The catalyst system promotes the conversion of primary alkylamines to the corresponding dialkylamines.[10] It has also been reported that in methanol this system rearranges steroidal allylic alcohols to the allyl methyl ethers (eq 3).[11]

Dichlorobis(tri-*p*-tolylphosphine)palladium(II)

[60802-43-9] · $C_{42}H_{42}Cl_2P_2Pd$ · Dichlorobis(tri-*p*-tolylphosphine)palladium(II) · (MW 786.06)

(catalyst for linear carbonylation of α-alkenes with alcohols[2-4])

Alternate Name: trans-dichlorobis(tri-*p*-tolylphosphine)palladium(II).

Preparative Method: by treating an aqueous solution of commercially available K_2PdCl_2 with tri-*p*-tolylphosphine in dichloromethane using Bu_4NCl as a phase-transfer catalyst.[1]

Linear Carboxylic Acid Esters.

The title reagent has been used in bimetallic complexes with Group 14 metal halides for linear carbonylation of α-alkenes with alcohols.[2-4] Several alkyl and aryl esters of alkanoic acids have been prepared by reaction of α-alkenes with carbon monoxide and nucleophilic co-reactants using $Et_4N^+SnCl_3^-$ and $[(p\text{-Tol})_3P]_2PdCl_2$ as a catalyst system. In a typical procedure, a mixture of 1-octene (400 mmol), ethanol (400 mmol), $Et_4N^+SnCl_3^-$ (40 mmol), and $[(p\text{-Tol})_3P]_2PdCl_2$ (4 mmol) was heated for 3-6 h at 80-95 °C under nitrogen while introducing CO at 1500 psi to give 84% ethyl nonanoate with 91% conversion and 83% selectivity (eq 1).[2]

Arylacetones.

The title reagent has been used as a catalyst in aromatic acetonylation to obtain arylacetones from acetonyltri-*n*-butyltin (prepared from ***Tri-n-butyl(methoxy)stannane*** and ***Isopropenyl Acetate*** in situ, eq 2) and aryl halides.[5] In a typical procedure, a solution of methoxytributylstannane (15 mmol), isopropenyl acetate (15 mmol), aryl bromide (10 mmol), and the palladium complex (0.1 mmol) in toluene (5 mL) was heated for 5 h (eq 3).

Related Reagents.

$(Ph_3As)_2PtCl_2$-$SnCl_2$ has been used for linear carbonylation of α-alkenes with alcohols and has shown good regioselectivity.[6] $(Ph_3P)_2PdCl_2$-$SnCl_2$ has also been reported to give similar results.[4] ***Dichlorobis(tri-o-tolylphosphine)palladium(II)*** is a preferred catalyst in aromatic acetonylation to prepare arylacetones.[5]

Dichlorobis(tri-*o*-tolylphosphine)palladium(II)

[40691-33-6] · $C_{42}H_{42}Cl_2P_2Pd$ · Dichlorobis(tri-*o*-tolylphosphine)palladium(II) · (MW 786.07)

(catalyzes arylation of organozinc reagents;[1] catalyzes carbon-carbon bond formation via stannyl enolates;[2] catalyzes aromatic cyanomethylation and amination[3])

Physical Data: mp 285-295 °C (yellow crystals from toluene).[4]

Preparative Method: prepared by stirring $PdCl_2$ and P(*o*-Tol)$_3$ in methanol at rt for 2 h.[4,5]

Arylation of Organozinc Reagents.

The coupling of organozinc reagents with electron-rich (eq 1) or electron-deficient (eq 2) aryl iodides proceeds in good yield with Pd catalysis.[1] $PdCl_2[P(o\text{-Tol})_3]_2$ is superior to $PdCl_2(PPh_3)_2$ (see ***Palladium(II) Chloride***) and ***Tetrakis(triphenylphosphine)palladium(0)*** because biaryls are not produced during the reaction. This catalyst is not useful, however, for coupling organozinc compounds with vinyl iodides or triflates. Zinc-substituted aromatic ketones also react with aryl iodides under $PdCl_2[P(o\text{-Tol})_3]_2$ catalysis in excellent yield (eq 3).[6] Enantiomerically pure, protected 3-aryl-α-amino acids can be prepared by coupling a protected zinc homoenolate with an aryl iodide under Pd catalysis (eq 4).[7] The sterically smaller catalyst $PdCl_2(PPh_3)_2$ produces the desired product in only 15% yield.

(1)

(2)

(3)

(4)

Carbon-Carbon Bond Formation via Stannyl Enolates.

Tri-*n*-butyltin enolates, generated in situ by treatment of enol acetates with ***Tri-n-butyl(methoxy)stannane*** undergo $PdCl_2[P(o\text{-Tol})_3]_2$-catalyzed coupling with vinyl bromides (eq 5)[2] or bromobenzene (eq 6).[8] Although the reaction is sensitive to steric hindrance caused by substituents on the enol acetate, the number and position of substituents on the vinyl bromide does not have a serious effect on the product yield. The configuration of the alkenyl bromide is completely retained in the product.

(5)

(6)

Stannyl enolates, generated in situ from silyl enol ethers by Bu_3SnF-mediated silyl/stannyl exchange, undergo $PdCl_2[P(o\text{-Tol})_3]_2$-catalyzed aldol reactions with aromatic (eq 7) and aliphatic aldehydes.[9] The products are isolated as the hydroxy ketones. Tin enolates produced from silyl enol ethers can also be coupled with both electron-deficient (eq 8) and electron-rich aryl bromides with almost equal success.[10] The silyl/stannyl exchange induced by Bu_3SnF is useful only for silyl enol ethers of methyl ketones. The remarkable difference in reactivities may arise from the steric repulsion between the alkyl group(s) attached to the alkenic moiety and the approaching tributyltin fluoride. This relative reaction rate phenomena has been utilized for the $PdCl_2[P(o\text{-Tol})_3]_2$-catalyzed chemoselective desilylation of silyl enol ethers (eq 9).[11]

(7)

Aromatic Cyanomethylation and Amination.

Aryl bromides react with cyanomethyltributyltin in the presence of $PdCl_2[P(o\text{-Tol})_3]_2$ catalyst to afford cyanomethylated products (eq 10).[3] The aryl bromides can be substituted with methyl, methoxy, or chloro groups, but not π-electron withdrawing groups such as nitro. Bromobenzene can be aminated with *N*,*N*-diethylaminotributyltin (eq 11).[12] The best catalyst is $PdCl_2[P(o\text{-Tol})_3]_2$ and the reaction also gives good yields with methyl substituted bromobenzenes.

Dichloroborane Diethyl Etherate[1]

$BHCl_2.OEt_2$

[41156-66-5] · $C_4H_{11}BCl_2O$ · Dichloroborane Diethyl Etherate · (MW 156.85)

(hydroborating agent providing access to alkyldichloroboranes and alkenyldichloroboranes;[2] reagent for deoxygenation of sulfoxides[3] and cleavage of cyclic acetals[4])

Physical Data: bp 59 °C/1.5 mmHg;[5] mp -30 to -25 °C.[6,7]

Solubility: sol benzene, carbon tetrachloride, diethyl ether; not miscible with pentane.

Analysis of Reagent Purity: the hydride content is determined by hydrolyzing an aliquot and measuring the hydrogen evolved according to the standard procedure.[8] The chloride is estimated by hydrolyzing an aliquot and titrating the HCl produced with $NaHCO_3$ using methyl orange as indicator. Coulometric titration has also been used for the determination of $BHCl_2.OEt_2$.[9a] ^{11}B NMR: δ, ppm 8.1;[9b] 7.9 (J_{B-H} = 152 Hz).[9c]

Preparative Methods: an approximately 1.5 M solution in diethyl ether can be prepared by the reaction of ***Lithium Borohydride*** with ***Boron Trichloride***.[2] The neat reagent can be isolated by removing excess diethyl ether. It is a colorless liquid, 6.6 M in $BHCl_2$, containing about 4-6 mol % of $BCl_3.OEt_2$ as impurity. Less conveniently, $BHCl_2.OEt_2$ can also be prepared by reacting BCl_3 with ***Diborane*** in the presence of diethyl ether.[6,7] The deuterated reagent is known.[7]

Handling, Storage, and Precautions: corrosive, flammable, air- and moisture-sensitive liquid. Reacts violently with water. The reagent is not stable over long periods of time, cleaving the ether solvent at a significant rate, even with storage at 0 °C. The neat reagent is not stable for more than 2 days at rt. Handle in a fume hood.

Hydroboration of Alkenes and Dienes.

The reaction of alkenes with dichloroborane diethyl etherate is slow and accompanied by disproportionation. In contrast, dichloroborane reacts readily with alkenes in the gas phase.[10] Apparently, strong complexation with ether significantly decreases the reactivity. This difficulty can be circumvented by the addition of boron trichloride, a strong Lewis acid, liberating dichloroborane from the complex with instantaneous precipitation of $BCl_3.OEt_2$ (eq 1).[2] (For direct hydroboration of alkenes, see ***Dibromoborane-Dimethyl Sulfide***).

$$\text{alkene} + BHCl_2 \cdot OEt_2 + BCl_3 \xrightarrow[77\text{-}97\%]{\text{pentane}} RBCl_2 + BCl_3 \cdot OEt_2\downarrow \quad (1)$$

The pentane solution contains essentially pure alkyldichloroborane applicable directly for further transformations. Alternatively, the product can be isolated by distillation. The directive effects of $BHCl_2.OEt_2$ are comparable to ***Monochloroborane Diethyl Etherate***, e.g. 1-hexene and styrene react, placing the boron atom at the terminal position with 99.3% and 96.3% selectivity, respectively. Alkyldichloroboranes can also be prepared by the redistribution reaction.[11,12]

Ethyl Diazoacetate reacts readily with aryl- and alkyldichloroboranes to give the corresponding two-carbon homologated ethyl esters. Essentially quantitative yields are obtained in the reactions of aryldichloroboranes (eq 2).[13]

$$PhBCl_2 + N_2CH_2CO_2Et \xrightarrow[2.\ ROH]{1.\ THF,\ -25\ °C,\ -N_2} PhCH_2CO_2Et \quad (2)$$

The homologations of alkyldichloroboranes proceed in the range of 57-71% yield, so in these cases this procedure has little advantage over that involving the more conveniently synthesized dialkylchloroboranes (see ***Monochloroborane Diethyl Etherate***). A remarkable enhancement of reactivity relative to trialkylboranes is observed in the reaction of alkyldichloroboranes with organic azides. Secondary amines are formed in 84-100% yields (eq 3).[14,15]

(3)

An extension of this reaction to 2-iodoalkyl azides provides β-iodo derivatives of secondary amines which undergo ring closure upon treatment with base, producing the corresponding *N*-alkylaziridines in 73-94% yields (eq 4).[15,16]

(4)

The procedure is not applicable to 1-azido-2-iodophenylpropane, which undergoes elimination of β-methylstyrene under the reaction conditions.[15] In all of the reactions described above the migrating group retains its configuration. Optically active amines can be prepared from optically active alkyldichloroboranes.[17] Another useful transformation of alkyldichloroboranes is the controlled oxidation with oxygen, providing hydroperoxides (eq 5).[18,19] The reaction is a radical process and the configuration of the alkyl group is not completely retained.

$$RBCl_2 + O_2 \xrightarrow[\text{84-94\%}]{Et_2O,\ -15\ ^\circ C} ROOH \qquad (5)$$

Dihydroboration of allene with dichloroborane diethyl etherate gives a 1,3-dibora product which can be transformed into the 1,2-diborole derivative.[20]

Hydroboration of Alkynes.

The monohydroboration of alkynes with dichloroborane diethyl etherate in the presence of an equimolar amount of boron trichloride gives alkenyldichloroboranes (eq 6),[2] which can be transformed into alkenylboronates, alkenes, or ketones by alcoholysis, protonolysis, and oxidation, respectively.

$$R^1 = R^2 = \text{alkyl};\ R^1 = \text{alkyl},\ R^2 = H$$

α-Silyl ketones are obtained from 1-trimethylsilyl-1-alkynes.[21] A 10-40% excess of the silylalkyne is necessary to minimize dihydroboration. The dihydroboration of alkynes with dichloroborane diethyl etherate has been studied only briefly.[2,22] 1-Alkynes are hydroborated to 1,1-diboraalkanes (eq 7).[22]

$$RC{\equiv}CH + 2\,BHCl_2 \cdot OEt_2 + 2\,BCl_3 \xrightarrow[\text{30\%}]{\text{pentane, -30 °C}} RCH_2CH(BCl_2)_2 \quad (7)$$

Deoxygenation of Sulfoxides and Cleavage of Cyclic Acetals.

Aliphatic sulfoxides are rapidly deoxygenated to the corresponding sulfides in excellent yields by dichloroborane in THF at 0 °C.[3] Other reducible functionalities, such as ketones, esters, and amides, are not affected. Since dichloroborane in THF is a very poor hydroborating agent,[23,24] unsaturated sulfoxides might be expected to undergo selective reduction. Cyclic acetals are cleaved under mild conditions[4] (see also ***Monochloroborane Diethyl Etherate*** and ***Monochloroborane-Dimethyl Sulfide***).

Related Reagents.

Dibromoborane-Dimethyl Sulfide; ***Dichloroborane-Dimethyl Sulfide***; ***Monochloroborane Diethyl Etherate***; ***Monochloroborane-Dimethyl Sulfide***.

Dichloroborane-Dimethyl Sulfide[1]

$BHCl_2.SMe_2$

[63462-42-0] · $C_2H_7BCl_2S$ · Dichloroborane-Dimethyl Sulfide · (MW 144.85)

(hydroborating agent suitable for the hydroboration of labile alkenic structures;[2] provides access to alkyldichloroboranes and alkenyldichloroboranes[3,4])

Alternate Name: DCBS.

Physical Data: d_4^{20} = 1.255 g cm^{-3}.

Solubility: sol benzene, carbon tetrachloride, dichloromethane, diethyl ether, THF.

Form Supplied in: colorless to pale yellow liquid.

Analysis of Reagent Purity: hydrolyze an aliquot and measure the hydrogen evolved according to the standard procedure.[7a] ^{11}B NMR (CCl_4): δ, ppm, 2.0;[7b] 1.7 (d);[7c] 2.2 (d, J_{B-H} = 157.42 Hz).[5]

Preparative Methods: by redistribution of ***Borane-Dimethyl Sulfide*** (BMS) and $BCl_3.SMe_2$.[5] A mixture containing $BHCl_2.SMe_2$ (73%) and BMS, $BH_2Cl.SMe_2$, and $BCl_3.SMe_2$ is obtained by the reaction of BMS with Ph_3CCl.[6]

Handling, Storage, and Precautions: corrosive, air- and moisture-sensitive, flammable liquid; stench. Reacts violently with water. Handle and store under nitrogen or argon. Stable indefinitely when stored under nitrogen at 25 °C. Destructive to upper respiratory tract, eyes, and skin. Handle in a fume hood.

Hydroboration of Alkenes and Alkynes.

The hydroboration of alkenes with dichloroborane-dimethyl sulfide (DCBS) in refluxing dichloromethane produces considerable quantities of R_2BCl and R_3B as impurities, presumably as the result of disproportionation of the reagent. The addition of boron trichloride liberates dichloroborane and the hydroboration proceeds cleanly at 25 °C (eq 1)[3] (see ***Dibromoborane-Dimethyl Sulfide*** for direct hydroboration of alkenes).

$$RCH{=}CH_2 + BHCl_2 \cdot SMe_2 + BCl_3 \xrightarrow[\text{69-85\%}]{\text{pentane, 25 °C}} RCH_2CH_2BCl_2 + BCl_3 \cdot SMe_2\downarrow \quad (1)$$

DCBS is highly regioselective,[8] exhibiting the directive effects similar to those observed for ***Monochloroborane Diethyl Etherate***.[9] Alkyldichloroboranes are readily isolated by distillation under vacuum. Methanolysis provides the corresponding alkylboronic esters (eq 2).[3] Alkenylboronic esters can be obtained from alkynes (eq 3).[4]

$$RCH_2CH_2BCl_2 \xrightarrow{MeOH} RCH_2CH_2B(OMe)_2 \quad (2)$$

(3)

A characteristic feature of alkyldichloroboranes is their exceptional resistance to thermal isomerization, making possible the regio- and stereoselective synthesis of organoborane intermediates from highly labile alkenic structures. Thus the organoborane intermediate initially formed in the hydroboration of 1-methylcyclooctene with ***Borane-Tetrahydrofuran*** undergoes facile isomerization, even at 0 °C, to a mixture of regio- and stereoisomeric organoboranes (eq 4).[10] In contrast, the hydroboration of 1-methylcyclooctene with DCBS at 0 °C affords cleanly *trans*-(2-methylcyclooctyl)dichloroborane in excellent yield and purity (eq 5).[2]

(4)

(5)

An intramolecular version of the reaction of alkyldichloroboranes with organic azides has been employed in a highly stereoselective synthesis of *trans*-cycloalkanopiperidines and cycloalkanopyrrolidines (eq 6)[11] (for the synthesis of other secondary amines, see ***Dibromoborane-Dimethyl Sulfide*** and ***Dichloroborane Diethyl Etherate***).

(6)

Alkyldichloroboranes can be converted into a host of valuable organoborane intermediates via the hydridation-stepwise hydroboration procedure.[12] The procedure enables a general synthesis of unsymmetrical dialkylboranes and totally mixed trialkylborane intermediates for the synthesis of ketones and tertiary alcohols, respectively.[12b]

Transmetalation.

The reagent has been used in the synthesis of bis(2,4,6-triisopropylphenyl)borane ($(trip)_2BH$) by the transmetalation reaction (eq 7).[13] $(Trip)_2BH$ belongs to the family of highly hindered borane reagents like dimesitylborane.[14] It is a rare example of a monomeric disubstituted borane.[13]

1,4-Dichloro-2-butanone

[16714-78-6] · $C_4H_6Cl_2O$ · 1,4-Dichloro-2-butanone · (MW 141.00)

(reactive electrophile, precursor for 1,4-disubstituted 2-butanones and 2-butenones)

Alternate Name: 2-chloroethyl chloromethyl ketone.

Physical Data: bp 65 °C/3 mmHg; vap. *d* 4.9 g cm^{-3}.[1]

Solubility: freely sol organics; may react with amides, amines, alcohols, sulfoxides, water.

Form Supplied in: neat liquid.

Analysis of Reagent Purity: IR, UV, NMR (δ 3.08, 2H, t, *J* = 6 Hz; 3.71, 2H, t, *J* = 6 Hz; 4.00 ppm, 2H, s).[2]

Preparative Methods: can be prepared by the Friedel-Crafts acylation of ethylene with ***Chloroacetyl Chloride*** catalyzed by ***Aluminum Chloride***[4] or the treatment of 2-chloropropionyl chloride with ***Diazomethane*** followed by concentrated HCl.[5] The Friedel-Crafts process can be used with other alkenes and acid chlorides to yield α,β´-dichloroalkyl ketones.[4]

Handling, Storage, and Precautions: highly irritating to the skin, eyes, and mucous membranes via oral inhalation and skin contact. A lacrimator type of military poison. Dangerous; when heated to dec, burns and emits highly toxic fumes of chlorides.[3] Use in a fume hood.

Alkylation Reactions.

The title reagent (**1**) can react at either of the halide positions or at the carbonyl. With weak nucleophiles such as alkoxide,[6] acetate,[6] thiolate,[7] or phthalimide,[8] (**1**) yields (**2**) or (**3**). Compound (**2**) can be converted into (**3**) with base treatment. Diamine (**2**) (X = NH_2) has been converted into histamine (eq 1).[8] The carbonyl group of (**1**) is the electrophilic site in reactions with organolithium or Grignard reagents. The intermediate alkoxide can be converted into a diorganolithio trianion which can be trapped with several electrophiles (eq 2).[9]

(2) (3)

Enones such as (**3**) have found extensive use as the dienophiles in Diels-Alder reactions.[10] They should also be valuable 2π electron components in other cycloadditions. Compound (**1**) was used to generate (**3**) (X = Cl) in situ for a Robinson annulation with β-dicarbonyls (eq 3).[11] The normal aldol product is trapped in about 50% yield to afford an epoxy ketone. This process has been called epoxyannulation. Other examples of epoxyannulation have included treatment of enolates with ***2-Chloroacrylonitrile***[12a] or 1-butadienylsulfonium salts[12b] and the cyclization of o-ketosulfonium salts.[12c,d]

The other major use of (**1**) has been to construct functionalized azoles. Although only thiazoles[13] (eq 4) appear to have been reported, oxazoles and imidazoles should be available from (**1**) since other chloromethyl ketones yield all of these azoles.[14]

1,4-Dichloro-2-butene

(*cis/trans*)

[764-41-0] · $C_4H_6Cl_2$ · 1,4-Dichloro-2-butene · (MW 125.00) (*cis*)

[1476-11-5] (*trans*)

[110-57-6]

(a versatile four-carbon synthon useful in cycloalkylations[1-7] and cycloadditions[11-14]; forms heterocyclic systems in reactions with heteroatom nucleophiles[15-18])

Physical Data: cis (95%): mp 48 °C; bp 152 °C; *d* 1.188 g cm^{-3}. *trans* (98%): bp 74-76 °C/40 mmHg; *d* 1.183 g cm^{-3}. *cis*/*trans* (95%): bp 72-75 °C/40 mmHg; *d* 1.183 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: available as neat liquid as pure *cis* or *trans* forms and a *cis*/*trans* mixture.

Handling, Storage, and Precautions: flammable liquid; lachrymator, irritant, and corrosive, handle in a fume hood.

Carbocycles via Dianion Alkylations.

gem-Dianions generated from active methylene compounds react with *trans*-1,4-dichloro-2-butene to give vinylcyclopropanes, which can be thermally rearranged to cyclopentenes (**1**) (eq 1).[1] If the malonates are chiral, optically active cyclopropanes are formed.[2] Acetoacetic ester in place of malonate yields cyclohepten-4-one (**2**) (eq 2) after alkaline hydrolysis.[4]

(1)

(1)

(2)

(2)

cis-1,4-Dichloro-2-butene, on the other hand, yields the cyclopentene exclusively, or a mixture with the vinylcyclopropane, depending on the active methylene compound (eq 3).[3]

(3)

E = CN	0:100
E = CO_2Me	42:58

Reactions with *vic*-diester dianions or with 1,3-dianions afford monocyclic[6,7] (**3**), (**4**), or fused carbocycles[5,8] (**5**), depending on the anionic compound (eqs 4-6). Bicyclo[4.*n*.1] ring systems are easily made by use of enolates[9] or enamines[10] where reactions in the carbonyl form prove difficult.

(4)

(3)

(5)

(4)

(6)

(5)

Carbocycles via Cycloadditions.

[2 + 2] Additions.

Trans-1,4-Dichloro-2-butene adds to fused cyclopentenones to produce a tricyclic system (eq 7).[11]

(7)

Using *trans*-1,4-dichloro-2-butene, access to *anti*-tricyclo[3.1.0.0^{2,4}]hexanes is made very easy.[12] The route is via a [2 + 2] addition to maleic anhydride, followed by two intramolecular displacements.

[4 + 2] Additions.

Reactions with anthracene give benzocarbocycles, providing quick access to the triptycenes (eq 8).[13]

(8)

The synthetic utility of these cycloadditions is further enhanced by the base-induced dehydrohalogenation to generate new 1,4-diene units.

cis-1,4-Dichloro-2-butene is easily converted to an electron-rich diene on treatment with sodium aryloxide. This

reaction has been used in the synthesis of phyllanthocin (eq 9).[14]

(9)

Synthesis of Heterocycles.

cis-1,4-Dichloro-2-butene affords 1,4-dihydropyrroles with ammonia or amines (eq 10).[15,16]

(10)

Similarly, tetrahydropyridines are accessible using diethyl acetamidomalonates (eq 11).[17]

(11)

1,3-Butadienylphosphonium dichloride (obtained by treating 1,4-dichloro-2-butene with PPh_3) reacts with α-mercapto aldehydes or ketones, leading to unexpected vinylthiophenes (eq 12).[18]

(12)

The bis Wittig salt is formed extremely easily with 1,4-dichloro-2-butene, but not with its dibromo counterpart.

6-*trans*-Styryl-3-azabicyclo[3.1.0]hexane.[19]

This reagent has been made by a novel N to C transannular rearrangement following an intramolecular carbenoid insertion starting from 1,1-dichloro-*cis*-2,3-bis(chloromethyl)cyclopropane, obtained by dichlorocarbene addition to *cis*-1,4-dichloro-2-butene.

The reagent is a good source of enyne carbanions,[20a] generated using ***Lithium Amide***/liq NH_3, which can be used for C-C bond formations (eq 13).[20b]

(13)

The reagent also finds use as a coupling promoter to obtain biaryls from aryl Grignard reagents.[21]

Related Reagents.

1,4-Dibromobutane; ***1,4-Dichloro-2-butyne***.

(aldol, alkenyl radical, organopalladium/Heck annulations; methyl ketone precursor; alkyne precursor; alkenyl organometallic precursor; allylic nucleophile precursor)

Alternate Name: Wichterle reagent (**1**).

Physical Data: (*E*)-(**1**) bp 40 °C/20 mmHg; (*Z*)-(**1**) bp 35 °C/20 mmHg; (*Z*)-(**4**) bp 66 °C/13 mmHg.

Preparative Methods: see appropriate reference: (**1**),[2a,3] (**2**),[7a] (**3**),[12a] (**4**),[14b,15d,e] (**5**),[15c,f] (**6**).[15a]

Handling, Storage, and Precautions: reagent (**1**) shows an acute LD_{50} (inhalation, 4 h) of 546 ppm in rats.[2a] Acute and chronic toxicity to the kidney and other major organs is well established.[2] As low molecular weight allylic halides, these reagents can be expected to be lachrymatory, irritating to and absorbed through

the skin and mucous membranes, especially hazardous via inhalation, and suspect carcinogens. The usual stability order I < Br < Cl applies for both X and Y. The iodoallyl reagent (**3**) is photolabile;[12a] the iodoalkenyl reagent (*Z*)-(**5**) is reported to decompose above 25 °C.[15f]

Annulation (Aldol); Methyl Ketone Precursor.[4-10]

In 1948, Wichterle reported that treatment of a chloroalkenyl keto ester with concentrated sulfuric acid resulted in cyclization (eq 1),[4a] effecting a formal equivalent of the Robinson annulation with 1,3-dichloro-2-butene (**1**) serving as a substitute for ***Methyl Vinyl Ketone*** (MVK). The Wichterle reaction has proven useful in many syntheses in which MVK gives poor results due to polymerization or other side reactions. The alkylation step has been performed with unstabilized as well as stabilized enolates and with enamines. The Roussel-Uclaf synthesis of 19-norprogesterone, which exploited the selective condensation of pyrrolidine with a cyclohexenone in the presence of a saturated methyl ketone, is exemplary (eq 2).[4b] In this case, the allylic iodide (**3**) was formed in situ; the bromo (**2**) or iodo derivative (**3**) is often prepared in a separate Finkelstein reaction. Although (*E*)-(**1**) and (*Z*)-(**1**) are more reactive than allyl chloride to substitution with ***Potassium Iodide*** or ***Sodium Ethoxide***,[3a] (**3**) failed a demanding test of regioselective alkylation of a sterically hindered enolate (eq 3).[4c] Catalytic ***Tetrakis(triphenylphosphine)palladium(0)*** has been shown to enhance the reactivity of (**1**), allowing regioselective alkylation of potassium enoxyborates.[4d]

(2)

(3)

When concentrated H_2SO_4 is used for solvolysis, high yields are favored by short (<1 h) reaction times at 0 °C, use of a diluent (CH_2Cl_2), and rapid dilution upon aqueous workup.[5a,b] Starting ring size, substitution, and unsaturation affect the course of cyclization.[5] Saturated ketones tend to cyclize to bridged bicyclic enones, sometimes (eq 4)[5a] to

the exclusion of the usually desired fused product. Unsaturation can prevent premature cyclization (eq 5);[5a] in eq (2), a bridged enone would violate Bredt's rule. Fused products can be obtained from saturated ketones by using milder acidic conditions (eq 6).[5d,7a] Treatment with Hg^{II} salts or ***Titanium(IV) Chloride*** is often preferred,[4d] giving the dione which is cyclized in a separate aldol step (e.g. eqs 7 and 8). Chloroalkenes also react with carbocations intramolecularly as cyclization terminators, but are inferior to fluoroalkenes in this role.[6]

(4)

(5)

(6)

Reductive alkylation by (**2**) of a dienone (eq 7),[7b] or related enedione,[7a] proceeded regio- and stereoselectively to provide a concise synthesis of adrenosterone. The stabilized Michael acceptor α-(trimethylsilyl)-MVK[7c] failed in this case. Alkylation of an optically active β-hydroxybutyrate dianion proceeded with high *anti* selectivity to form a quaternary chiral center (eq 8);[8a,b] the 1,5-diketone thereby obtained could be cyclized to either regioisomeric cyclohexenone by varying aldol conditions. Phase-transfer alkylation of a 1-indanone in the presence of a *Cinchona* alkaloid-derived chiral catalyst proceeded with pronounced enantioselectivity, again leading to a chiral quaternary enone after cyclization (eq 9).[8c] Reaction of a lithiothiomethyl phosphonate with (**1**), followed by a second lithiation and condensation with an aldehyde, afforded in one flask a dienic 1,4-diketone precursor (eq 10).[8d]

(8)

The Wichterle reaction has found use in heterocyclic synthesis, of the pyrido[1,2-*a*]benzimidazole system (eq 11).[10a] En route to camptothecin, a planned aldol cyclization route to a dihydropyridone using ***Methyl Magnesium Carbonate*** (MMC) took an unexpected course, via transient benzylic methoxycarbonylation (eq 12).[10b] In a model study for mesembrine synthesis, alkylation with (**1**) followed by a regioselective imide reduction paved the way to an iminium ion cyclization (eq 13).[10c]

Alkyne Precursor.[11,12]

Vigorous basic treatment of (**1**) provides vinylacetylene (eq 14).[11a] Under appropriate conditions, chloroalkenes derived from (**1**) are transformed into either the internal (eq 15)[11b] or terminal alkyne (eq 16).[12a-c] δ,ε-Alkynyl ketones undergo reductive[12a,b] or photochemical cyclization;[12c] Hg^{II}-catalyzed hydration to the 1,5-diketone is an alternative to direct hydrolysis of the chloroalkene.[12d]

(14)

(15)

(16)

Allylic Nucleophile.[13]

The allyllithium derivative of (**1**) can be prepared at -90 °C via an allyllead intermediate;[13a] preparation of the Grignard reagent in the usual way, near rt, presumably results in decomposition. Electrochemical coupling of (**1**) with $ClSiMe_2Ph$ yields the allylsilane.[13b] Reaction of (**3**) with Ph_3P gives the phosphonium salt and thence the phosphorane unexceptionally.[13c]

Alkenyl Radical Cyclization.[14]

Treatment of an iodo- or bromoalkene with ***Tri-n-butylstannane*** generates the alkenyl radical which can add intramolecularly to a double bond (eqs 17 and 18).[14a,b] A strong preference for enolate alkylation *syn* to the double bond (eq 18)[14b] was exploited. The (*E*)-bromoalkene can be used because alkenyl radical inversion is rapid.

(17)

(18)

Alkenyl Organometallic Precursor.[15]

Eq 19[15a,b] demonstrates use of a catalytic intramolecular Heck reaction of a (*Z*)-iodoalkene in a cyclopentene annulation sequence. Cyclization of the related (1-alkenyl) triflate using the chiral ligand *S*-BINAP gave the *exo*-methylene product in 80% ee. En route to rapamycin, reagent (*E*)-(**5**) provided an allylic sulfone that was deployed sequentially in a Cr^{II}-mediated (Nozaki-Kishi) aldehyde addition and a Julia coupling (eq 20).[15c]

1,4-Dichloro-2-butyne

$ClCH_2$-C&tbond;C-CH_2Cl

[821-10-3] · $C_4H_4Cl_2$ · 1,4-Dichloro-2-butyne · (MW 122.98)

(undergoes electrophilic additions, 1,3-dipolar additions,[17] trimerizations;[19] source of four-carbon synthons such as butadienes[3-5,8-10] and allenes;[16] serves as coupling promoter[18])

Physical Data: colorless liquid, bp 165-168 °C; *d* 1.258 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: neat liquid of high purity.

Preparative Method: conveniently prepared by treating 1,4-butynediol with ***Thionyl Chloride***.[1] However, as a precautionary measure the medium is diluted with CH_2Cl_2 and cooled to -30 °C before adding thionyl chloride to avoid hazards associated with the exothermicity of the reaction.[2]

Handling, Storage, and Precautions: flammable liquid, lachrymator, and irritant; use in a fume hood.

Substituted Butadienes.

A variety of polysubstituted 1,3-butadienes are conveniently prepared by a two-step sequence involving addition-elimination (eq 1). Thus halogens/pseudohalogens,[3] aryl selenosulfonates,[4] and silanes[5] can be added followed by reductive dehalogenation with ***Zinc***. These functionalized butadienes can be used as dienes in cycloadditions[3,6] and in the synthesis of allenes[4] (eq 2). Silylbutadienes find use as adhesion promoters[5] and in complexes with iron tricarbonyl undergo unprecedented diacylations under Friedel-Crafts conditions.[7]

(2)

2,3-Disubstituted butadienes are also accessible by Grignard addition[8] or by thermal rearrangement,[9] while alkylborane addition[10] is a means of obtaining 2-alkylbutadienes (eq 3).

(3)

Bisalkynes.

With ***Sodium Amide***, the bisacetylide anion is formed, which on being quenched with ***Iodomethane*** gives 1,3-pentadiyne.[11] Alternatively, the carbanion can be treated with a carbonyl compound to obtain dialkynyl alcohols. In one instance a dialkynyl alcohol has been elaborated to a hydroxy fatty acid (eq 4)[12] and in the other, following a different strategy, to a marine natural product.[13]

(4)

Fused Carbocycles.[14]

Polycyclic compounds are accessible by successive addition of two carbenes under rhodium catalysis (eq 5).

Cumulated Trienes.[15]

These can be obtained by addition of dithiocarbonate followed by desulfurization, as an alternative to the traditional Zn reduction (eq 6).

A novel allenol nucleoside[16] with pronounced anti-HIV activity is synthesized making use of the base-catalyzed alkyne-allene rearrangement. The allene nucleoside can be cyclized to the dideoxydidehydronucleoside under more basic conditions (eq 7).

1-Glycosyl(halomethyl)-1,2,3-triazoles.[17]

These are useful as potential alkylating agents in cancer chemotherapy and can be obtained by a 1,3-dipolar addition of the reagent to a glycosyl azide.

The reagent is used as a coupling promoter to obtain biaryls from aryl Grignard reagents.[18] 1,4-Bisthioglycosyl-2-butene trimerizes under transition-metal catalysis to give cluster glycosides.[19]

Related Reagents.

1,4-Dichloro-2-butene.

Dichloro(1,5-cyclooctadiene)palladium(II)

[12107-56-1] · $C_8H_{12}Cl_2Pd$ · Dichloro(1,5-cyclooctadiene)palladium(II) · (MW 285.49)

(alcohol protection; synthesis of carbamates, bicyclooctanes; alkene carbonylation)

Physical Data: yellow solid, mp 210 °C (dec).

Solubility: slightly sol $CHCl_3$, tetrahydrothiophene 1,1-dioxide (sulfolane), and nitrobenzene.

Preparative Method: prepared in 96% yield by treating ***Palladium(II) Chloride*** with 1,5-cyclooctadiene in concentrated hydrochloric acid.[1]

Purification: recrystallization from methylene chloride.

Handling, Storage, and Precautions: the reagent is air-stable.

Protection of Hydroxyl Groups.

Alcohols can be protected as acetals by treatment with 2-benzyloxy-1-propene in the presence of the title reagent (**1**) as catalyst in very good yields (eq 1).[2] This protection strategy is useful for the following reasons: (a) both the protection and the regeneration of the alcohols are carried out under neutral conditions; (b) primary hydroxyl groups are selectively protected; (c) the acetal prepared is stable toward organometallic reagents, including hydrides, and alkaline hydrolytic conditions. This methodology has been extended to the preparation of mixed orthoesters from allylic alcohols and ketene acetals in the presence of (**1**) as catalyst (eq 2).[3] These orthoesters can be used to prepare γ,δ-unsaturated esters by the Claisen rearrangement.[3]

(1)

Preparation of 4-Cyclooctenylcarbamates.

Carbamates such as ethyl carbamate react with (**1**) to give the corresponding 4-cyclooctenylcarbamate in moderate yields (eq 3).[4]

Alkene Carbonylation.

Reagent (**1**) reacts with aqueous ***Sodium Carbonate*** to give a hydroxypalladation enyl complex (**2**), which on carbonylation in water gives exclusively *trans*-2-hydroxy-5-cyclooctenecarboxylic acid β-lactone (eq 4).[5] Carbonylation of (**2**) in methanol gives the *trans*-hydroxy ester (**3**) (eq 5).

(5)

Synthesis of Bicyclo[3.3.0]octanes.

Treatment of (**1**) with excess of ***Diethyl Malonate*** in the presence of ***Sodium Hydride*** in DMSO gives tetraethyl bicyclo[3.3.0]octane-2,6-dimalonate as the major product in a transannular reaction (eq 6).[6]

2,3-Dichloro-5,6-dicyano-1,4-benzoquinone[1]

[84-58-2] · $C_8Cl_2N_2O_2$ · 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone · (MW 227.01)

(powerful oxidant, particularly useful for dehydrogenation to form aromatic[1a-d] and α,β-unsaturated carbonyl compounds;[1] oxidizes activated methylene[1a-c] and hydroxy groups[1b] to carbonyl compounds; phenols are particularly sensitive[1c])

Alternate Name: DDQ.

Physical Data: mp 213-216 °C; E_0 &AApprox; 1000 mV.

Solubility: very sol ethyl acetate and THF; moderately sol dichloromethane, benzene, dioxane, and acetic acid; insol H_2O.

Form Supplied in: bright yellow solid; widely available.

Analysis of Reagent Purity: UV (λ_{max} [dioxane] 390 nm) and mp.

Purification: recrystallization from a large volume of dichloromethane.

Handling, Storage, and Precautions: indefinitely stable in a dry atmosphere, but decomposes in the presence of water with the evolution of HCN. Store under nitrogen in a sealed container.

Introduction.

Quinones of high oxidation potential are powerful oxidants which perform a large number of useful reactions under

relatively mild conditions. Within this class, DDQ represents one of the more versatile reagents since it combines high oxidant ability with relative stability[1] (see also ***Chloranil***). Reactions with DDQ may be carried out in inert solvents such as benzene, toluene, dioxane, THF, or AcOH, but dioxane and hydrocarbon solvents are often preferred because of the low solubility of the hydroquinone byproduct. Since DDQ decomposes with the formation of hydrogen cyanide in the presence of water, most reactions with this reagent should be carried out under anhydrous conditions.[1a]

Dehydrogenation of Hydrocarbons.

The mechanism by which quinones effect dehydrogenation is believed to involve an initial rate-determining transfer of hydride ion from the hydrocarbon followed by a rapid proton transfer leading to hydroquinone formation.[1d] Dehydrogenation is therefore dependent upon the degree of stabilization of the incipient carbocation and is enhanced by the presence of functionality capable of stabilizing the transition state. As a consequence, unactivated hydrocarbons are stable to the actions of DDQ while the presence of alkenes or aromatic moieties is sufficient to initiate hydrogen transfer.[1d,2] The formation of stilbenes from suitably substituted 1,2-diarylethanes[3] and the synthesis of chromenes by dehydrogenation of the corresponding chromans (eq 1)[4] are particularly facile transformations. Similar reactions have also found considerable utility for the introduction of additional unsaturation into partially aromatized terpenes and steroids, where the ability to control the degree of unsaturation in the product is a particular feature of quinone dehydrogenations.[5] Moreover, the ability to effect exclusive dehydrogenation in the presence of sensitive substituents such as alcohols and phenols (eq 2)[5b] illustrates the mildness of the method and represents a further advantage.

(1)

(2)

DDQ is a particularly effective aromatization reagent and is frequently the reagent of choice to effect facile dehydrogenation of both simple (eq 3)[6] and complex hydroaromatic carbocyclic compounds.[1d,7] Skeletal rearrangements are relatively uncommon features of quinone-mediated dehydrogenation reactions, but 1,1-dimethyltetralin readily undergoes aromatization with a 1,2-methyl shift when subjected to the usual reaction

conditions (eq 4).[8] Wagner-Meerwein rearrangements have also been observed in the aromatization of steroids (eq 5), although in this instance considerably longer reaction times are required.[9] Such reactions provide a unique method for the aromatization of cyclic systems containing quaternary carbon atoms without the loss of carbon.

(3)

(4)

(5)

DDQ is also an effective reagent for the dehydrogenation of hydroaromatic heterocycles, and pyrroles,[10] pyrazoles,[11] triazoles,[12] pyrimidines,[13] pyrazines,[14] indoles,[15] quinolines,[16] furans,[17] thiophenes,[18] and isothiazoles[19] are among the many aromatic compounds prepared in this manner. Rearomatization of nitrogen heterocycles following nucleophilic addition across a C=N bond (eq 6)[13] is a particularly useful application of DDQ,[13,16] and similar addition and reoxidation reactions in acyclic systems have also been reported.[20]

One particularly important use of DDQ has been in the dehydrogenation of reduced porphyrins, where the degree of aromatization of the product is highly dependent on the relative reagent:substrate stoichiometry.[1b] Under optimal conditions, excellent yields of partially or fully conjugated products may be isolated.[1b,21] The formation of porphyrins from tetrahydro precursors on reaction with 3 equiv of DDQ under very mild conditions (eq 7) typifies one of the more commonly described transformations.[21] More recently, DDQ has been used as part of a one-pot sequence for the formation of porphyrins from simple intermediates, although the overall yields in such reactions are generally comparatively low.[22]

(7)

In addition to the formation of neutral aromatic compounds, DDQ is also an effective agent for the preparation of the salts of stable aromatic cations. High yields of tropylium (eq 8) and triphenylcyclopropenyl (eq 9) cations have been isolated in the presence of acids such as perchloric, phosphoric, and picric acid,[23] and oxonium,[24] thioxonium,[23,25] and pyridinium[23,26] salts may be prepared in reasonable yields from appropriate starting materials under essentially similar conditions. The formation of the perinaphthyl radical has been reported on oxidation of perinaphthalene with DDQ under neutral conditions,[23] although such products are not usually expected.

(8)

(9)

Dehydrogenation of Carbonyl Compounds.

DDQ and other high oxidation potential quinones are versatile reagents for the synthesis of α,β-unsaturated carbonyl compounds,[1e] a reaction that has found extensive application in the chemistry of 3-keto steroids.[1b] The regiochemical course of this dehydrogenation is highly dependent on the initial steroidal geometry; thus the 5α- and the 5β-series usually furnish Δ^1- and Δ^4-3-keto steroids, respectively (eq 10).[1b] The selection of one isomer over the other is likely to reflect the relative steric crowding of the C-4 hydrogen atom in the two series, but other factors may play a role in those instances where the anticipated product is not formed.[1b]

(10)

A rather more unusual situation exists during the dehydrogenation of Δ^4-3-keto steroids where the product formed is dependent on the oxidizing quinone. Thus whereas DDQ gives the $\Delta^{4,6}$ ketone, chloranil and a number of other quinones yield only the $\Delta^{1,4}$ isomer (eq 11), a result that has been rationalized on the basis of DDQ proceeding via the kinetic enolate while less reactive quinones proceed via the thermodynamic enolate.[27]

(11)

While DDQ is an effective reagent for the formation of α,β-unsaturated steroidal ketones, the dehydrogenation of cyclohexanones to the corresponding enone only proceeds well when the further reaction is blocked by *gem*-dialkyl substitution.[1b,28] Tropone, by contrast, has been prepared from 2,4-cycloheptadienone (eq 12), although the yield was somewhat low.[29] Heterocyclic enones such as flavones[30] and chromones[31] may be efficiently prepared from flavanones and chromanones, respectively, under similar conditions to those used for the dehydrogenation of steroids, and the dehydrogenation of larger ring heterocyclic ketones has been described.[32] Ketone enol ethers have also been shown to undergo facile dehydrogenation to α,β-unsaturated ketones with DDQ, although the nature of the product formed may be dependent on the presence or absence of moisture.[33] Prior formation of the silyl enol ether is a potentially more versatile procedure that has been shown to overcome the problems generally associated with the dehydrogenation of unblocked cyclohexanones (eq 13),[34] particularly when the acidic hydroquinone formed during the reaction is neutralized by the addition of ***N,O-Bis(trimethylsilyl)acetamide*** (BSA)[34] or a hindered base.[35] Preparation of the enone derived from either the kinetic or the thermodynamic enolate is possible in this manner.[34,35a]

(12)

(13)

Quinone dehydrogenation reactions of carbonyl compounds are mostly limited to the more readily enolized ketones, and analogous reactions on esters[36] and amides[37] require stronger conditions and are far less common unless stabilization of the incipient carbonium ion is possible. Oxidation in the presence of the silylating agent bis(trimethylsilyl)trifluoroacetamide (BSTFA) considerably improves the dehydrogenation of steroidal lactams (eq 14) by facilitating the breakdown of the intermediate quinone-lactam complex.[38] Similar dehydrogenations of carboxylic acids are rare, but reaction of the α-anion of carboxylate salts generated in the presence of HMPA has given modest yields of a number of α,β-unsaturated fatty acids.[39]

(14)

Oxidation of Alcohols.

Saturated alcohols are relatively stable to the action of DDQ in the absence of light, although some hindered secondary alcohols have been oxidized in reasonable yield on heating under reflux in toluene for extended periods of time (eq 15).[40] It has been suggested that oxidation proceeds in this instance as a result of relief of steric strain.[40] Allylic and benzylic alcohols, on the other hand, are readily oxidized to the corresponding carbonyl compounds,[1b,41] and procedures have been developed which utilize catalytic amounts of the reagent in the presence of a stoichiometric amount of a second oxidant.[42] Since the rate of oxidation of allylic alcohols is greater than that for many other reactions,[43] the use of DDQ provides a selective method for the synthesis of allylic and benzylic carbonyl compounds in the presence of other oxidizable groups.

(15)

Benzylic Oxidation.

The oxidation of benzylic alkyl groups proceeds rapidly in those instances in which stabilization of the incipient carbonium ion is possible[44,45] and a number of polycyclic aromatic compounds have been oxidized in good yield to the corresponding benzylic ketones on brief treatment with DDQ in aqueous acetic acid at rt.[44] The reaction is postulated to proceed via an intermediate benzylic acetate which is hydrolyzed and further oxidized under the reaction conditions.[44] It is interesting that 1-alkylazulenes, which are cleaved by many of the more common oxidants, are cleanly oxidized following a short exposure to DDQ in aqueous acetone (eq 16), while under the same conditions no oxidation of C-2 alkyl substituents takes place.[46] As expected, the oxidation was shown to be disfavored by the presence of strongly electron-withdrawing substituents.[46]

(16)

The stabilization of benzylic carbonium ions is also a feature of arenes containing electron-donating substituents, especially those having 4-alkoxy or 4-hydroxy groups, and such compounds are particularly effective substrates for oxidation by DDQ. Thus 6-methoxytetralone has been prepared in 70% yield from 6-methoxytetralin on treatment with DDQ in methanol,[47] although it is possible to isolate intermediate benzylic acetates if the oxidation is carried out in acetic acid (eq 17).[48] An interesting variant of the oxidation in inert solvents in the presence of either ***Cyanotrimethylsilane***[49] or ***Azidotrimethylsilane***[50] results in the isolation of good to excellent yields of benzyl cyanides and azides, respectively.

(17)

Benzylic oxidation of alkoxybenzyl ethers is particularly facile, and since some of the more activated derivatives are cleaved under conditions which leave benzyl, various ester, and formyl groups unaffected, they have found application in the protection of primary and secondary alcohols.[51] Deprotection with DDQ in dichloromethane/water follows the order: 3,4-dimethoxy > 4-methoxy > 3,5-dimethoxy > benzyl and secondary > primary, thus allowing the selective removal of one function in the presence of another.[51] 2,6-Dimethoxybenzyl esters are readily cleaved to the corresponding acids on treatment with DDQ in wet dichloromethane at rt, whereas 4-methoxybenzyl esters are stable under these conditions.[52] Oxidative cleavage of N-linked 3,4-dimethoxybenzyl derivatives with DDQ has also been demonstrated.[53]

DDQ is a powerful oxidizing agent for phenols, and carbonium ion stabilization via the quinone methide makes

benzylic oxidation of 4-alkylphenols a highly favored process.[47,54] With methanol as the solvent it is possible to isolate α-methoxybenzyl derivatives in reasonable yield.[55]

Phenolic Cyclization and Coupling Reactions.

The oxidation of phenolic compounds which either do not possess benzylic hydrogen atoms, or which have an alternative reaction pathway, can result in a variety of interesting products. Cyclodehydrogenation reactions leading to oxygen heterocycles represent a particular application of phenolic oxidation by DDQ, and is common when intramolecular quenching of the intermediate phenoxyl radical is possible (eqs 18-20).[56-59] These reactions necessarily take place in nonpolar solvents and have given such products as coumarins,[56] chromenes (eq 18),[57] benzofurans (eq 19),[58] and spiro derivatives (eq 20).[59]

(18)

(19)

(20)

Phenols and enolizable ketones that cannot undergo α,β-dehydrogenation may afford intermolecular products arising from either C-C or C-O coupling on treatment with DDQ in methanol.[60] 2,6-Dimethoxyphenol, for example, results predominantly in oxidative dimerization (eq 21), while the hindered 2,4,6-tri-*t*-butylphenol generates the product of quinone coupling (eq 22).[60] Various other unusual products have been observed on DDQ oxidation of phenols and enolic compounds, their structure being dependent on that of the parent compound.[41,60,61]

Miscellaneous Reactions.

In addition to the key reactions above, DDQ has been used for the oxidative removal of chromium,[62] iron,[63] and manganese[64] from their complexes with arenes and for the oxidative formation of imidazoles and thiadiazoles from acyclic precursors.[65] Catalytic amounts of DDQ also offer a mild method for the oxidative regeneration of carbonyl compounds from acetals,[66] which contrasts with their formation from diazo compounds on treatment with DDQ and methanol in nonpolar solvents.[67] DDQ also provides effective catalysis for the tetrahydropyranylation of alcohols.[68] Furthermore, the oxidation of chiral esters or amides of arylacetic acid by DDQ in acetic acid provides a mild procedure for the synthesis of chiral α-acetoxy derivatives, although the diastereoselectivity achieved so far is only 65-67%.[69]

While quinones in general are well known dienophiles in Diels-Alder reactions, DDQ itself only rarely forms such adducts.[70] It has, however, been shown to form 1:1 adducts with electron-rich heterocycles such as benzofurans and indoles where it forms C-O and C-C adducts, respectively.[71]

Dichlorodi-μ-methoxybis(pyridine)dicopper

[15338-24-6] · $C_{12}H_{16}Cl_2Cu_2N_2O_2$ · Dichlorodi-μ-methoxybis(pyridine)dicopper · (MW 418.27)

(oxidizing agent for aromatic alcohols;[1] useful in preparation of muconic acid monoesters and mononitriles;[2] preparation of cyclic orthoesters,[3] cyclic imides,[2a] and lactones[1d,2a,4])

Alternate Names: chloromethoxy(pyridine)copper *[28733-06-4]*; di-μ-chlorodimethoxybis(pyridine)dicopper *[15094-30-1]*.

Solubility: modestly sol pyridine; slightly sol methanol, NMP, DMF.

Form Supplied in: green solid.

Preparative Methods: easily prepared by oxidation of ***Copper(I) Chloride*** using O_2 in methanol/pyridine solution (eq 1).[5] There are several other methods for obtaining this reagent, or generating it in situ without isolation (eqs 2-4).[5,6]

$$4\ CuCl + O_2 + >4\ C_5H_5N \xrightarrow[rt]{MeOH} \underset{\textbf{(1)}}{2\ [(C_5H_5N)CuClOMe]_2} \quad (1)$$

$$4\ CuCl + O_2 + 4\ MeOH \xrightarrow[rt]{py} \underset{\textbf{(1)}}{[(C_5H_5N)CuClOMe]_2} \quad (2)$$

$$(C_5H_5N)_2CuCl_2 + NaOMe \xrightarrow{MeOH} [(C_5H_5N)CuClOMe]_2 \quad (3)$$

(1)

$$(C_5H_5N)_2CuCl_2 + Cu(OMe)_2 \xrightarrow{MeOH} [(C_5H_5N)CuClOMe]_2 \quad (4)$$

(1)

Handling, Storage, and Precautions: the freshly prepared dry solid may be stored briefly at rt and weighed without special precautions. The crystals may be stored indefinitely at rt when sealed under a dry N_2 atmosphere to preclude moisture.

Introduction.

The reagent (**1**) is a selective oxidizing agent for phenol and catechol derivatives, as well as for *o*-benzoquinones. Pyridine is the preferred solvent. In the solid state (**1**) exists as methoxy-bridged dimers.[7]

Oxidative Cleavage of Catechol in the Presence of Water or Oxygen.

Under anaerobic conditions in a pyridine solution of water, methanol, and 3 mol equiv of (**1**), catechol rapidly undergoes a four-electron oxidative ring opening to *cis,cis*-muconic acid monomethyl ester at rt (eq 5).[1d,3] 4-Substituted catechols and *o*-benzoquinones are also readily cleaved to the corresponding muconic acid ester (eq 6). *o*-Methoxyphenols are unreactive.

(5)

The same cleavage reactions occur in the presence of oxygen. Thus by using different alcohols in the method of eq 2 for generating (**1**) in situ, monoalkyl and monoaryl esters of muconic acid are available (eq 7).[1d] Interestingly, phenol undergoes a net six-electron oxidative ring opening only in the presence of oxygen, and at a much slower rate than the other aromatic derivatives already mentioned.

Overall, (**1**) reacts as a two-electron oxidant, and the suggestion that this oxidant system exemplifies the activation of molecular oxygen[1a-c] is inconsistent with experimental findings.[1d,3,8] Mechanistic studies continue to probe the complex interaction of O_2 with similar copper species.[9]

Oxidations in the Presence of Ammonia.

In the presence of ammonia, (**1**) oxidizes catechols and *o*-benzoquinones to a ring-expanded cyclic imide (eq 8).[2a] Replacing MeOH with ammonia in the method of eq 2 generates a reactive Cu^{II} oxidant, related to (**1**), that cleaves phenols, catechols, and *o*-benzoquinones to muconic acid mononitriles (eq 9).[2,10]

Oxidations Under Anaerobic, Anhydrous Conditions.

Under combined anaerobic/anhydrous reaction conditions in pyridine, phenol undergoes no net oxidation in the presence of (**1**), whereas catechol polymerizes, possibly by forming unstable quinone intermediates. However, 4-*t*-butylcatechol or 4-*t*-butyl-6-substituted catechols are subjected overall to a six-electron oxidation, forming a novel cyclic orthoester ester (eq 10).[3] Under similar conditions, cyclic anhydrides cleave to a mixture of muconic acid monoester isomers, except in the case of the di-*t*-butyl anhydride, in which ring opening, lactonization, and chlorination occur (eq 11).[4]

Dichlorodimethylsilane[1]

Me_2SiCl_2

[75-78-5] · $C_2H_6Cl_2Si$ · Dichlorodimethylsilane · (MW 129.06)

(additive for pinacol cyclization;[2] protecting group for diols[3] and carbonyl compounds;[4] precursor for a wide variety of silicon-based reagents)

Physical Data: mp -76 °C; bp 70-71 °C; *d* 1.064 g cm^{-3}.

Solubility: sol chlorinated solvents and ethereal solvents; reacts with protic solvents.

Form Supplied in: liquid form from laboratory to commercial scale (typical purities >95%).

Purification: can be purified by distillation.

Handling, Storage, and Precautions: reacts with water, amines, alcohols, amides, and other protic species with the evolution of hydrogen chloride. Use in a fume hood.

Pinacol Reaction.

Dichlorodimethylsilane (**1**) allows clean pinacol cyclization of a keto aldehyde to occur without competition from an aldol reaction (eq 1).[2]

(1)

Protection.

The success of the pinacol cyclization is due to the formation of a siliconide, the silicon equivalent of an acetonide.

Reaction of a diol with (**1**) in the presence of base also provides these cyclic silicon compounds (eq 2).[3,5] However, the labile dimethylsiliconide does not afford a widely applicable form of protection for this functional group, although it has found some use with pericyclic reactions.[6]

Enolates derived from aldehydes can also form bisenol ethers with (**1**), but the reaction fails with aldehydes containing four or fewer carbons.[7] Ketone lithium enolates provide bisenol ethers in good yields when treated with (**1**). These bisenol ethers can then be employed in further reactions such as intramolecular aldol reactions.[8] The formation of bisenol ethers by treatment of ketones with the silyl dichloride (**1**) in the presence of ***Triethylamine*** and ***Sodium Iodide*** has been advocated. However, the yields can still be variable and the use of *N*,*N*-diethylaminodimethylchlorosilane is suggested as a superior silylating agent.[4] The lithium enolate derived from pinacolone reacts with an equivalent of (**1**) to provide the monoenol silyl chloride that can then be treated with a wide variety of oxygen and nitrogen based nucleophiles.[9] Chiral enol ethers are also available through the use of the dichloride (**1**) as the silicon source (eq 3).[10]

Silanes.

Dichlorodimethylsilane (**1**) is a precursor to a wide variety of silicon reagents. For example, reaction with an

organometallic reagent, such as phenyl- or *t*-butyllithium, results in the corresponding silyl chloride (eq 4).[11] Many of these silyl chlorides have found application for the protection of functional groups.[12]

(4)

The presence of two leaving groups allows for the introduction of two different nucleophilic species.[13] In addition to carbon, heteroatom nucleophiles have been used.[14] A wide variety of heterocyclic derivatives are available when difunctional, nucleophilic compounds are treated with (**1**) (eq 5).[15] The synthetic potential of all of these derivatives is as wide as organosilicon chemistry.[16]

(5)

The dichloride (**1**) has also found widespread application for the formation of polysiloxanes and other high molecular weight silanes.[17] In addition to water, the chlorine atoms can be displaced by a wide variety of nucleophiles to provide some useful reagents, such as dimethyldiacetoxysilane.[18]

A controlled reaction of dichloride (**1**) with lithium in THF affords dodecamethylsilane,[19] a reagent that has been used for the preparation of silyl enol ethers through photolytic cleavage.[20] Silanes and polysilanes are readily available from the addition of an organometallic species to (**1**). Thus the bisvinylsilane (**2**) can be prepared from (**1**) (eq 6).[21]

(6)

Related Reagents.

Di-t-butyldichlorosilane; ***Di-t-butylsilyl Bis(trifluoromethanesulfonate)***.

Dichloro(ethoxy)oxovanadium(V)

[1801-77-0] · $C_2H_5Cl_2O_2V$ · Dichloro(ethoxy)oxovanadium(V) · (MW 182.91)

(Lewis acid capable of one-electron oxidation; effects oxidative cleavage and oxidative coupling reactions)

Physical Data: bp 32-34 °C/1 mmHg; yellow liquid;[1] *d*204 1.47 g cm^{-3}.

Solubility: sol most organic solvents such as alcohol, dichloromethane, hexane.

Preparative Method: $VO(OEt)Cl_2$ is prepared by addition of ethanol to ***Vanadyl Trichloride***.[2]

Handling, Storage, and Precautions: moisture sensitive; should be handled under dry inert atmosphere and refrigerated in the dark to prevent decomposition (orange fumes). Avoid breathing the vapor; skin irritant and corrosive. Use in a fume hood.

Introduction.

$VO(OR)Cl_2$ (R = Et, *i*-Pr, etc.) are Lewis acids with one-electron oxidation capability, which effect oxidative transformations of carbonyl and organosilicon compounds in organic solvents. These oxovanadium(V) compounds have widely been used as catalysts in copolymerization.

Oxidation of Carbonyl Compounds.

The regioselective oxidative α-cleavage of cyclic ketones is catalyzed by $VO(OEt)Cl_2$ in ethanol under oxygen to give diesters or keto esters (eq 1).[2] The presence of α,β-unsaturation alters the reaction course. Oxidation of 2-cyclohexen-1-ones is induced by $VO(OEt)Cl_2$ in ethanol, resulting in dehydrogenative aromatization to ethyl aryl ethers. An oxovanadium compound obtained from $VO(OEt)Cl_2$ and ***Silver(I) Trifluoromethanesulfonate*** or ***Trimethylsilyl Trifluoromethanesulfonate*** is more efficient in the latter

reaction.[3] In the case of α,β-unsaturated ketones such as 2-cyclopenten-1-ones and 1-acetyl-1-cyclohexene, allylic oxidation is achieved to introduce an oxo or alkoxy group at the γ-position as exemplified by the formation of 4-methyl-4-cyclopentene-1,3-dione (eq 2).[4] 2-Phenylglycine derivatives undergo the $VO(OEt)Cl_2$-induced oxidative deamination and/or decarboxylation to give ethyl benzoate and ethyl phenylglyoxylate.[5]

(1)

(2)

Oxidative cleavage of cyclobutanone in the presence of ***Copper(II) Chloride*** or $BrCCl_3$ affords ethyl 4-chloro- or ethyl 4-bromobutanoate (eq 3).[6] 1-Chlorooctan-4-one is produced upon addition of ***n-Butyllithium*** followed by oxidative fragmentation (eq 4). Conjugate addition of the ethoxycarbonylpropyl fragment occurs in the presence of electron-deficient alkenes such as acrylonitrile or methacrylonitrile (eq 5). The oxidative coupling of diketene and styrenes gives ethyl 2-methyl-4,5-dihydrofuran-3-carboxylates.[7]

(3)

(4)

(5)

Oxidation of Organosilicon Compounds.

Oxidative desilylation can be selectively performed by one-electron oxidation with $VO(OEt)Cl_2$. Silyl enol ethers undergo $VO(OEt)Cl_2$-induced oxidative dimerization and cross-coupling reactions, affording symmetrical and unsymmetrical 1,4-diketones (eq 6).[8] Allylsilanes dimerize regioselectively to 1,4-dialkyl-1,5-hexadienes (eq 7).[9]

(6)

(7)

Related Reagents.

Copper(I) Trifluoromethanesulfonate; ***Lead(IV) Acetate***; ***Silver(I) Oxide***; ***Vanadyl Trichloride***.

1,2-Dichloroethylene[1]

(*E*)

[156-60-5] · $C_2H_2Cl_2$ · 1,2-Dichloroethylene · (MW 96.94) (*Z*)

[156-59-2]

(useful reagent for the synthesis of chloroenynes, enediynes, chlorodienes, conjugated trienes, and tetraenes)

Physical Data: mp -80.5 °C (*Z*), -50 °C (*E*); bp 60.3 °C (*Z*), 48.4 °C (*E*); *d* 1.284 g cm^{-3} (*Z*), 1.257 g cm^{-3} (*E*).

Solubility: insol water; sol alcohol, ether, and most other organic solvents.

Form Supplied in: colorless liquid; widely available. *Drying:* before use, (*E*)- or (*Z*)-1,2-dichloroethylene must be distilled under an inert atmosphere.

Handling, Storage, and Precautions: (*E*)- or (*Z*)-1,2-dichloroethylene has a slightly acrid odor; it is gradually decomposed by air, light, and moisture, forming HCl; it must be stored in a refrigerator. Exposure to vapor may produce nausea and weakness. Use in a fume hood.

Derived Organolithium Reagents.

(*E*)-1,2-Dichloroethylene can be metalated with ***n-Butyllithium*** at -110 °C to give, after carboxylation, (*E*)-2,3-dichloroacrylic acid (eq 1).[2] With (*Z*)-1,2-dichloroethylene the reaction leads to lithium chloroacetylide, which can be trapped with an appropriate electrophile (eq 2).[3,4]

Acetylene Equivalent.

Reaction of (*E*)-1,2-dichloroethylene with enones leads to dichlorocyclobutanes and, after reduction, to cyclobutenes (eq 3).[5]

Coupling Reactions.

When treated with nucleophilic agents such as sodium arenethiolate,[6] sodium acetate,[7] or lithium diphenylphosphide,[8] (*Z*)- or (*E*)-1,2-dichloroethylene lead to disubstituted products (eq 4).

The nickel- or palladium-catalyzed coupling reaction between organometallics and (*Z*)- or (*E*)-1,2-dichloroethylene[9,10] allows for the preparation of vinyl chlorides (eqs 5 and 6).[10a,b]

The stereospecific Pd/Cu-catalyzed cross-coupling reaction[10,11] of terminal alkynes with (*E*)- or (*Z*)-1,2-dichloroethylene is a chemoselective and efficient route to (*E*) or (*Z*) conjugated chloroenynes or enediynes (eq 7).[10b]

Applications to the synthesis of esperamycins and related substances[12] have been described (eq 8).[12a]

(*Z*)-Chloroenynes are converted into 1,3-diynes under mild conditions by treatment with ***Tetra-n-butylammonium***

Fluoride (eq 9).[13]

Selective reduction of enediynes, dienynes, and trienynes, prepared from 1,2-dichloroethylenes, allows for the stereocontrolled synthesis of conjugated trienes[14] (eq 10)[10b] and tetraenes (eq 11)[15] having a defined geometry.

Related Reagents.

1-Chloro-2-iodoethylene.

[12084-42-3]

(determination of % ee of alkenes and allenes via ^{195}Pt NMR;[1] resolution of alkenes;[2] asymmetric epoxidation of alkenes[3])

Physical Data: trans isomer: mp 71 °C, [α]21D + 15.5-16.9° (*c* 1.0, CH_2Cl_2), usually obtained as a viscous oil but can be crystallized upon further purification;[2g] *cis* isomer: mp 164 °C, [α]25D -54.5° (*c* 1.3, acetone), obtained as pale green-yellow needles.[4]

Solubility: both the *cis* and *trans* isomers are sol acetone and dichloromethane.

Analysis of Reagent Purity: trans isomer: ^{1}H NMR (CD_2Cl_2) δ 7.39 (s, 5H), 4.62 (t, *J* = 30.5 Hz, 4H), 1.78 (d, *J* = 6.5 Hz, 3H);[2g] for ^{13}C and ^{195}Pt NMR data see Pregosin et al.[5]

Preparative Methods: trans isomer: synthesized from Zeise's salt [K_2PtCl_3(ethylene)] by adding (+)- or (-)-α-methylbenzylamine under acidic conditions;[2g] *cis* isomer: synthesized by adding 2 equiv of (+)- or (-)-α-methylbenzylamine to an aqueous solution of K_2PtCl_4 and then exposing this material to ethylene under pressure.[4]

Purification: trans isomer: chromatography over silica with CH_2Cl_2 as eluent;[2g] *cis* isomer: recrystallization from 1:1 acetone/*n*-heptane or toluene.[4]

Handling, Storage, and Precautions: both isomers are air and water stable.

Determination of % ee via ^{195}Pt NMR.

The *cis* chiral complex has been used to determine enantiomeric purity of asymmetric allenes[1a] and allylic alcohols and ethers[1b] via complexation and ^{195}Pt NMR spectroscopy. The complexes (**3**) and (**4**) are generated by displacement of ethylene from (**1**) by the alkene; recovery of the alkene and (**1**) is effected by the reverse sequence employing excess ethylene.[1b]

(3)

(4)

Resolving Agent.

A variety of chiral alkenes have been resolved via complexation and crystallization including alkenes (**5**)-(**7**) (via **1**),[2a] *cis*,*trans*-1,5-cyclooctadiene (**8**) (via **2**),[2b] 2-vinyltetrahydropyran (**9**) (via **1**),[2c,d] 1,2-cyclononadiene (**10**) (via **2**),[2e] *trans*-cyclooctene (**11**) (via **2**),[2f] and spiro[3.3]hepta-1,5-diene (**12**) (via **2**).[2g]

Dichloro[2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane]palladium(II)

(2*R*,3*R*) or (-)

[63598-08-3] · $C_{31}H_{32}Cl_2O_2P_2Pd$ · Dichloro[2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane]palladium(II) · (MW 675.87) (2*S*,3*S*) or (+)

[59634-23-0]

(chiral catalyst used in asymmetric hydrocarboxylation[1] or hydroalkoxycarbonylation reactions,[2] allylation of β-diketones or β-keto esters,[3] double carbonylation,[4] cross-coupling reactions,[5] preparation of optically active Pd^0 derivatives and their subsequent reactions[6])

Alternate Name: (DIOP)$PdCl_2$.

Physical Data: crystalline pale yellow solid; ((-)-(2*R*,3*R*)-DIOP)$PdCl_2$, $[\alpha]_D$ -7.9° ($CHCl_3$, *c* 1.0);[6b] mp 278-279 °C (dec).[7b]

Solubility: sol dichloromethane; insol heptane.

Analysis of Reagent Purity: for ((-)-(2*R*,3*R*)-DIOP)$PdCl_2$: crystal structure,[7a] ^{1}H NMR,[6b,7b] ^{13}C NMR,[6b] ^{31}P NMR.[6b]

Preparative Methods: prepared from commercially available ***Palladium(II) Chloride*** and (-)-(2*R*,3*R*)-***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane*** in ether,[7a] or by treating a stoichiometric

amount of (-)-(2*R*,3*R*)-DIOP in ethanol with Li_2PdCl_4 in water,[5] or from (+)-(2*S*,3*S*)-DIOP and $Pd(PhCN)_2Cl_2$ in benzene[6b] or acetone.[3c]

Handling, Storage, and Precautions: relatively stable to air oxidation.

Asymmetric Hydrocarboxylation.

The title reagent was used in the first example of an asymmetric hydrocarboxylation (eq 1).[1a,1c] With the α-methylstyrene, the straight chain isomer was formed. The regiospecificity was much less pronounced, however, for other alkenic substrates.[1b] The influence of some reaction variables on the reaction shown in eq 1 was studied. For example, the presence of a solvent such as THF or benzene, the alcohol source, the effect of CO pressure, the effect of substitution on the phenyl ring, the $PdCl_2$/DIOP molar ratio, or the presence of PPh_3 along with DIOP, were varied to improve the optical yield.[1c-e]

(1)

Methyl methacrylate has been hydromethoxycarbonylated with ((-)-(2*R*,3*R*)-DIOP)$PdCl_2$ as a catalyst to afford (*S*)-dimethyl succinate with excellent regioselectivity, but only modest enantioselectivity (eq 2).[2a,2b]

(2)

Asymmetric Allylic Alkylation.

In early investigations of Pd-mediated allylations of alkenes and allylic acetates, Trost and his co-workers used (+)-(2*S*,3*S*)-DIOP along with $PdCl_2$ or $Pd(PPh_3)_4$ and obtained optical yields in the range of 12-46%.[3a,3b] In the allylation of β-diketones or β-keto esters using allyl phenyl ether or allylic esters, use of the title reagent as a chiral catalyst afforded allylated compounds in good yields, but with low enantioselectivity (eq 3).[3c]

Double Carbonylation of Aryl Halides.

(DIOP)$PdCl_2$ catalyzed the double carbonylation of phenyl iodide in the presence of diethylamine to afford the α-ketoamide in a very good yield along with a minor amount of the benzamide derivative (eq 4).[4]

Cross-Coupling of Halides.

4,4-Dimethyl-1-phenylpenta-1,2-diene has been prepared using a ((-)-(2*R*,3*R*)-DIOP)$PdCl_2$-catalyzed cross-coupling reaction, although low enantioselectivity was observed (eq 5).[5]

Other Pd^0 Derivatives and Related Reactions.

Other chiral palladium complexes, such as $(DIOP)_2Pd^0$ or (DIOP)(alkene)Pd^0, can be prepared from (DIOP)$PdCl_2$.[6a,6d] These catalysts have afforded low levels of asymmetric induction (10% ee) in the hydrocyanation of norbornene derivatives.[6b,6c]

Oxirane Formation.

The reaction of acetonyltributyltin with α-bromoacetophenone to yield 2-acetonyl-2-phenyloxirane has been investigated using ((+)-(2*S*,3*S*)-DIOP)$PdCl_2$ as a catalyst, but no asymmetric induction was observed.[8]

Dichloroketene[1]

[4591-28-0] · C_2Cl_2O · Dichloroketene · (MW 110.93)

(dichloroacetylating agent;[2] undergoes cyclizations with numerous substrates[3])

Solubility: sol ether, pentane, hexane.

Form Supplied in: not commercially available.

Preparative Methods: typically prepared in situ by dehalogenation of trichloroacetyl halides or dehydrohalogenation of dichloroacetyl halides. Elimination of dichloroacetyl chloride with ***Triethylamine*** affords the desired ketene,[4] although material formed in this manner is of limited reactivity.[5] Reduction of ***Trichloroacetyl Chloride*** with ***Zinc/Copper Couple*** activated with either ***Phosphorus Oxychloride***[6] or ***1,1-Dimethoxyethane***[7] provides fully reactive dichloroketene. Recently, thermal activation of ***Zinc*** dust was used to generate dichloroketene.[8]

Handling, Storage, and Precautions: given the propensity of dichloroketene to dimerize or polymerize, the reagent must be made and used immediately. Polymeric material is obtained on heating or concentration of solutions of dichloroketene, and anhydrous conditions must be maintained.

Dichloroacetylation.

In his original preparation of dichloroketene, Brady formed the reagent in the presence of aniline to form the corresponding acetanilide (eq 1).[2] Given the wealth of methods to perform this transformation, this is of limited synthetic utility.

(1)

Cyclizations.

The propensity of dichloroketene to undergo cycloaddition reactions with a variety of π-systems has rendered this reagent a powerful synthon.[1,3] Treatment of dichloroketene with numerous alkenes such as 1-pentene causes a [2 + 2] cycloaddition to occur (eq 2).[9] These cyclizations have been shown to occur in a *syn* fashion, as reaction of dichloroketene with *cis*- and *trans*-cyclooctene affords the corresponding *cis* and *trans* bicyclic products (eqs 3 and 4).[10] The cycloadditions of dichloroketene are often sensitive to the method of preparation. For example, conjugated dienes react with dichloroketene in a [2 + 2] fashion to form cyclobutanones, but the ketene must be generated by the dehydrohalogenation of dichloroacetyl chloride, as Lewis acids promote the polymerization of most dienes (eq 5).[11] In fact, the cyclization of acid sensitive alkenes such as vinyl ethers and styrene can only be realized with dichloroketene formed in this fashion.[3a,9] Cyclizations with tri- and tetrasubstituted alkenes are also possible, although in this case the dichloroketene must be generated from activated zinc (eq 6).[12] The cyclobutanones formed in this manner can undergo a vast array of transformations (see below).

(2)

(3)

(4)

(5)

(6)

Cyclization of dichloroketene with unsymmetrical alkenes typically occurs in a regiospecific fashion. For example, cyclization of 1-methylcyclohexene with dichloroketene gives a single product (eq 7).[12] Exocyclic methylenes undergo facile conversion to the corresponding cyclobutanones, allowing easy access to spiro compounds (eq 8).[13]

(7)

(8)

Dichloroketene also reacts with carbonyls to generate 2-oxetanones.[1,3] However, the method of preparation of the ketene is critical. Cyclohexanone, for example, is smoothly converted to the corresponding β-lactone on exposure to dichloroketene prepared via the activated zinc pathway (eq 9).[14] It has been proposed that the zinc present in the reaction activates the ketone carbonyl toward cycloaddition.[15] Dehydrohalogenation of dichloroacetyl chloride in the

presence of acetone does not lead to useful product. However, dichloroketene generated in this fashion reacts readily with monosubstituted benzaldehydes (eq 10).[16] The 3,3-dichloro-2-oxetanones formed in this fashion can be made to undergo thermolysis under elevated temperatures, resulting in the generation of dichlorostyrenes (eq 11).[16] Cycloalkanones react with dichloroketene to form spirolactones (eq 12).[17] Thermolysis leads to exocyclic dichloroalkenes, and ***Sodium-Ammonia*** reduction affords the exocyclic methylene (eq 13).[17] This provides a useful complement to the methodology developed by Wittig and Tebbe. The chlorinated β-lactones formed via these cycloadditions are useful synthetic intermediates (see below).

(9)

(10)

(11)

(12)

(13)

Dichloroketene undergoes [2 + 2] cyclizations with numerous other unsaturated compounds. Imines, for example, serve as excellent cycloaddition partners, providing a rapid route to the synthesis of β-lactams (eq 14).[18] Diimides also react readily with dichloroketene to form β-iminoazetidinones (eq 15).[19] Addition of trichloroacetyl chloride to alkynes in the presence of activated zinc yields 2-cyclobutenones (eq 16).[7] These reactions also occur in a regiospecific manner. Ethoxyacetylene adds to dichloroketene, and subsequent hydrolysis gives the vinylogous acid (eq 17).[20] Cyclization of vinyl ethers with dichloroketene gives a single product, and chiral ethers have been used to generate optically pure cyclobutanones (eqs 18 and 19).[21,22] α-Alkylidenecyclobutanones can be formed on cyclization of dichloroketene with allenes (eq 20).[23]

(18)

(19)

(20)

While [2 + 2] cyclizations are more common, dichloroketene does undergo [4 + 2] cycloaddition reactions in some cases. For example, β-dialkylamino-α,β-unsaturated enones add in an apparent [4 + 2] sense and, upon elimination of hydrogen chloride, furnish 2-pyrones (eq 21).[24] Some imines are also substrates for this reaction, and 2-pyridones can be prepared (eq 22).[25]

(21)

(22)

Reaction of vinyl sulfoxides with dichloroketene gives a novel synthetic route to butyrolactones (eq 23).[26] With the ready availability of optically pure sulfoxides, this provides an asymmetric source of γ-lactones (eq 24).[27] Allylic ethers and sulfides react with dichloroketene via a Claisen-type rearrangement to give esters, albeit in modest yields

(eq 25).[28] This method can be used as a novel entry into macrolide synthesis (eq 26).[29]

(23)

(24)

(25)

(26)

Reactions of Dichloroketene Adducts.

The cycloadduct of cyclopentadiene with dichloroketene can be hydrolyzed to furnish tropolone (eq 27).[30] This is a fairly mild and general reaction, and a number of annulated tropolones can be formed in this fashion (eq 28).[3,31]

(27)

(28)

The reductive removal of one or both of the chlorine atoms of dichloroketene cycloadducts lends considerable flexibility to the synthetic utility of this reagent.[3,4,32] Reduction of the cyclopentadiene addition product with ***Tri-n-butylstannane*** or ***Zinc-Acetic Acid*** gave the bicyclo[3.2.0]heptenone (eq 29).[4] This compound can also be selectively reduced to give exclusively the *endo*-monochloro derivative (eq 30).[33,34] The facile removal of both chlorine substituents renders dichloroketene as a synthetic equivalent of the parent ketene. Since dichloroketene is considerably more reactive than ketene and can be made from inexpensive starting materials, it is superior to ketene in most cases.[1,3] In addition, many of the other adducts can also undergo dehalogenation, providing easy access to the β-lactones, β-lactams, and spiroalkanones (eq 31).[35] In fact, these compounds are substrates for many of the same reactions known for the cyclobutanones.[1,3,4]

(29)

(30)

(31)

The dichlorocyclobutanones can easily be expanded or contracted, thereby providing a synthetic source of cyclopropanes or cyclopentanes. Reaction of diazomethane with the cycloadduct of cyclohexene and dichloroketene results in the formation of the corresponding cyclopentanone (eq 32).[36] These can undergo several reactions, including dehalogenation (eq 33),[36] reductive alkylation (eq 34),[37] and conversion to cyclopentenes (eq 35).[38,39]

(32)

(33)

(34)

(35)

While these reactions are well precedented for the cyclopentanones, most are also amenable to the cyclobutanones.[1,3,4] Ring contractions of α-chlorocycloalkanones via Favorskii rearrangements are well known.[40] Direct exposure of dichloroketene cycloadducts to strong base, however, does not typically lead to ring contraction but rather to ring cleavage (eq 36).[41] One method that has been developed to circumvent this shortcoming is the reduction of the carbonyl of the cyclobutanone followed by treatment with base, which causes ring contraction to the corresponding cyclopropane carbaldehyde (eq 37).[42] Both *endo*- and *exo*-carbaldehydes can be made in this manner.[43]

(36)

(37)

An alternative method of ring expansion is via oxidation. Baeyer-Villiger oxidation of the cyclobutanone adducts supplies a synthetic route to *cis*-bicyclic lactones (eq 38).[44] Ring expanded lactams can also be made, with migration of either of the alkyl substituents (eqs 39 and 40).[45]

(38)

(39)

(40)

The dichlorocyclobutanones can be converted into several other useful materials. Following reductive removal of the chlorines, ***Selenium(IV) Oxide*** generates the 1,2-cyclobutanediones (eq 41).[46] Lithium-halogen exchange followed by acetylation of the enolate and ***Ruthenium(VIII) Oxide*** oxidation affords a one-pot conversion to vicinal dicarboxylic acids (eq 42).[47] In tandem with the cycloaddition of dichloroketene, this provides a mild and general method for *syn*-vicinal dicarboxylations. In a similar fashion, the α-chloroenol acetates can be isolated (eq 43).[48] Thermolysis of these compounds results in a retrocyclization reaction to give exclusively the (*Z*)-α-chloroenone (eq 44).[48]

(41)

(42)

(43)

(44)

Related Reagents.

Chlorosulfonyl Isocyanate; ***Diiodomethane-Zinc-Titanium(IV) Chloride***; ***Trichloroacetyl Chloride***; ***Zinc/Copper Couple***.

Diisopropyl (Dichloromethyl)boronate[1]

[63360-99-5] · $C_7H_{15}BCl_2O_2$ · Diisopropyl (Dichloromethyl)boronate · (MW 212.91)

(reacts with RLi to form α-chloroalkyl boronic esters;[2] chiral 1,2-diol ester derivatives react highly stereoselectively with RLi to form chiral α-chloroalkyl boronic esters[1])

Physical Data: bp 65 °C/10 mmHg,[2] 50-52 °C/5 mmHg;[3] *n*25D 1.4208.[2]

Form Supplied in: commercially available as pure liquid.

Preparative Method: addition of LDA to CH_2Cl_2 and triisopropyl borate in THF at -78 °C, then anhydrous HCl, filtration, and fractional distillation.[3]

Handling, Storage, and Precautions: is hydrolyzed to (dichloromethyl)boronic acid on contact with atmospheric moisture, and should be stored well sealed under nitrogen. It can be transferred and weighed in air without difficulty. The toxicity is unknown, but it should be regarded as a typical reactive alkyl halide.

Reagent Preparation.

The first preparation of diisopropyl (dichloromethyl)boronate was from preformed Cl_2CHLi, generated from BuLi and CH_2Cl_2 in THF at -100 °C, which was treated with $B(OMe)_3$ and worked up with aqueous acid and ether to yield crude (dichloromethyl)boronic acid, which was esterified with 2-propanol (60%).[2]

The most efficient method reported is the dropwise addition of ***Lithium Diethylamide*** to a vigorously stirred solution of CH_2Cl_2 and ***Triisopropyl Borate*** in THF with the internal temperature kept strictly below 0 °C with an ice-salt bath, followed by vacuum distillation of the diethylamine and THF, treatment with diethyl ether, anhydrous HCl, filtration under an inert atmosphere, and distillation of diisopropyl (dichloromethyl)boronate (69%) (eq 1).[3] The preparation works equally well at -78 °C with ***Lithium Diisopropylamide*** in place of $LiNEt_2$ (yield 70%), except that diisopropylamine is not as easily removed by distillation as diethylamine, and the voluminous amine salt is a nuisance to filter.

Diol Esters.

1,2-Diols or 1,3-diols react rapidly and irreversibly with diisopropyl (dichloromethyl)boronate[4,5] or (dichloromethyl)boronic acid.[2,6] For example, transesterification with (*R*,*R*)-2,3-butanediol readily yields [4*R*-(4α,5β)]-2-(dichloromethyl)-4,5-dimethyl-1,3,2-dioxaborolane (**1**) (eq 2).[4] The 1,3,2-dioxaborolanes can be purified by vacuum distillation,[2-6] and the (4*S*)-4,5-dicyclohexyl derivative can be recrystallized.[7]

α-(Chloroalkyl)boronic Esters.

Diisopropyl (dichloromethyl)boronate reacts with organolithium reagents to form α-(chloroalkyl)boronic esters, which can be oxidized to aldehydes or treated with a second mole of RLi to form *s*-alkylboronic esters.[2]

1,3,2-Dioxaborolanes are generally easier to handle than diisopropyl boronic esters and have been employed in all of the more recent chemistry of this type.[1] For example, 2-(dichloromethyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane with vinylmagnesium chloride yields 2-(1-chloroallyl)-4,4,5,5-tetramethyl-1,3,2-dioxaborolane (eq 3).[8] The 2-(dibromomethyl) analog behaved similarly.[8]

2-(Dichloromethyl)-1,3,2-dioxaborolanes and -1,3,2-dioxaborinanes have been reduced with ***Tri-n-butylstannane*** to the corresponding 2-chloromethyl derivatives,[5] though better routes to these compounds now exist (see ***Pinacol (Chloromethyl)boronate***).

The most useful 1,2-diol esters are those having C_2 symmetry, systematically named (4α,5β)-2-(dichloromethyl)-4,5-dialkyl-1,3,2-dioxaborolanes. With Grignard or lithium reagents these yield [2(*S**),4α,5β]-2-(1-chloroalkyl)-4,5-dialkyl-1,3,2-dioxaborolanes.[1,4] For example, [4*R*-(4α,5β)]-2-(dichloromethyl)-4,5-dimethyl-1,3,2-dioxaborolane (**1**) with ***n-Butyllithium*** yields intermediate borate (**2**), which rearranges at rt in the presence of ***Zinc Chloride*** to form {4*R*-[2(*S**),4α,5β]}-(1-chloropentyl)-4,5-dimethyl-1,3,2-dioxaborolane (**3**) (eq 4).[4] Diastereomeric excesses (de's) in this reaction as well as those with other lithium or Grignard reagents are generally ~90%.[4]

Higher stereoselectivities were obtained with larger 4,5-substituents on the dioxaborolane (eq 5). [4*S*-(4α,5β)]-4,5-Diisopropyl-2-(dichloromethyl)-1,3,2-dioxaborolane (**4a**) of ~95-98% ee and a series of Grignard or lithium reagents yielded (α*S*)-α-chloroethyl boronic esters (**5a**) in &egt;92-94% ee and de.[9] The measurement technique was inadequate to establish the true de's, which later work suggests may be 98-99% (see Alternative Route below).

(a) $R^1 = i$-Pr; R^2 = Me, Bu, Ph, *i*-Pr, Bn, $H_2C{=}CH$

(b) R^1 = Cy; R^2 = Me

A higher de, &egt;99%, has been reported for conversion of [4*S*-(4α,5β)]-2-(dichloromethyl)-4,5-dicyclohexyl-1,3,2-dioxaborolane (**4b**) via the (α*S*)-α-chloroethyl boronic ester (**5b**) (eq 5) to the (*Z*)-(α*R*)-α-methyl-2-butenyl boronic ester (**6**) (eq 6).[7]

(6)

Limitations.

The more easily accessible 4,5-diphenyl analog of (**4**) does not yield satisfactory diastereoselection (62-72% de).[10] Problems have been encountered in the attempted utilization of this chemistry for the preparation of α-chloroallylic boronic esters. Although vinylmagnesium chloride with (**1**) yielded 73% of (α*S*)-α-chloroallylboronic ester of >82% de,[10] attempted use of 1-propenylmagnesium halides led to allylic rearrangement of the initially formed α-chlorocrotylboronic esters if zinc chloride was used or led to low de's if it was not.[11] An unrelated enantioselective synthesis of α-halocrotylboronic esters was devised.[11,12]

Alternative Route.

It is important to note that the C_2 symmetry of [4*R*-(4α,5β)]-2-(dichloromethyl)-4,5-dimethyl-1,3,2-dioxaborolane (**1**) makes both faces of the boron atom equivalent, and that there is only one diastereomer of the derived borate complex (**2**). Thus the mode of assembly of (**2**) does not matter, and the reaction of [4*R*-(4α,5β)]-2-butyl-4,5-dimethyl-1,3,2-dioxaborolane (**7**) with ***Dichloromethyllithium*** (eq 7) yields the same intermediate (**2**) as that from (**1**) and butyllithium in (eq 4) and produces (**3**) in similar yield and diastereomeric purity.[4]

(7)

(3) 90% de

The use of [4*S*-(4α,5β)]-2-alkyl-4,5-diisopropyl-1,3,2-dioxaborolanes (**8**) in this alternative route has led to *s*-alkylboronic esters (**10**) of 99.8% de (eq 8).[13] It was shown that the de was enhanced in the reaction of the chloro intermediate (**9**) with R^2MgX. It should be noted that (**9**) (eq 8) is the same as (**5a**) (eq 5). In addition to the conversion of (**9**) to (**10**) by organometallic reagents, useful products are obtained from (**9**) with a variety of other nucleophiles.[1,14]

(8) **(9)**

(8)

(10)

With chiral dioxaborolanes that lack C_2 symmetry, the two faces of the boron atom are nonequivalent, and entirely different results may be obtained depending on the route to the borate intermediate. Pinanediol derived from either enantiomer of α-pinene is a relatively inexpensive and effective chiral director. Reaction of dichloromethyllithium with (*S*)-pinanediol alkylboronates (**11**) leads to borates (**12**), which rearrange in the presence of zinc chloride to α-chloroalkylboronic esters (**13**) having de's in the 97-99% range (eq 9).[15] This chemistry provides a broadly useful method of asymmetric synthesis.[1,16]

In contrast, reactions of pinanediol dichloromethylboronate (**14**) with alkylmagnesium halides yield borate intermediates (**15**) diastereomeric to (**12**), which rearrange to gross mixtures of diastereomers (**13**) and (**16**) (eq 10).[6] Accordingly, (**14**) is not useful for asymmetric synthesis.

Dimethyl (1,1-dichloroethyl)boronate, $CH_3CCl_2B(OMe)_2$, has been prepared[3] and converted to the pinanediol ester.[17] Pinanediol (1,1-dichloroethyl)boronate does not yield useful asymmetric inductions, and the alternative route via pinanediol boronates (**11**) and (1,1-dichloroethyl)lithium did so only when R = Ph.[17] Pinanediol (1,1-dichloroethyl)boronate has been converted to the (1-chlorovinyl)boronate.[18]

Related Reagents.

Dichloromethyllithium; ***Pinacol (Chloromethyl)boronate***.

N-Dichloromethylene-*N,N*-dimethyliminium Chloride[1]

[33842-02-03] · $C_3H_6Cl_3N$ · *N*-Dichloromethylene-*N,N*-dimethyliminium Chloride · (MW 162.46)

(converts alcohols into halides;[5] useful in heterocycle synthesis;[20-22] reacts with active methylenes to afford α-chloroenamines[1,30])

Alternate Names: PI; phosgeniminium chloride.

Physical Data: mp ~186 °C (dec); 194-196 °C from acetonitrile (sublimation).[2]

Solubility: sol liquid SO_2, thionyl chloride (for NMR measurements), nitromethane, acetonitrile; sparingly sol chloroform, dichloromethane, and polychloroethanes; insol benzene, ether, toluene; THF and dioxane are slowly decomposed; protic solvents and DMSO react violently.

Form Supplied in: white solid, commercially available. Dimethylcarbamoyl chloride and complexed HCl may be present.

Analysis of Reagent Purity: hydrolysis and titration, NMR (CD_3NO_2) δ = 4.07 ppm.

Preparative Methods: chlorination of ***Dimethylthiocarbamoyl Chloride*** using ***Chlorine***,[1,2] ***Phosphorus(V) Chloride***,[2,3] ***Phosgene*** or ***Sulfuryl Chloride***.[1] When exposed to excess chlorine the title reagent forms a yellow complex, PI.Cl_2.[2,4] Dimethyldithiuram and dithiocarbamates are also cheap starting materials for the preparation of the reagent.[3,4]

Purification: washing with dry dichloromethane and drying on a rotary evaporator at 40-60 °C/12 mmHg.

Handling, Storage, and Precautions: moisture sensitive. In the absence of moisture, has a shelf life of a few years. The reaction apparatus should be flame dried. The hydrolysis product, dimethylcarbamoyl chloride, is reportedly mutagenic.

Reactions with Alcohols, Amines, and Thiols.

Alcohols are invariably converted to the corresponding alkyl halides since the intermediate alkoxychloromethyleniminium salts are unstable when treated with PI. With phenols and thiols, selective mono- and disubstitution are possible.[5-7] Diols lead to cyclic iminium carbonates, which are opened by the chloride counterion in a strictly S_N2 fashion. This has important implications in carbohydrate chemistry. One free hydroxy group is replaced stereo- and regioselectively by a chlorine atom, leading to chlorodeoxy sugars. *Vic*-diols form iminium carbonates, which give chloro-*O*-carbamoyldeoxy sugars in a selective fashion (eq 1).[8]

Bromodeoxy sugars are available on treatment with the PI-$FeCl_3$ complex and subsequent addition of ***Lithium Bromide***.[9] Recent developments have been detailed by Copeland[10] and Benazza.[11] Carboxylic and even sulfonic acids are converted smoothly to the corresponding chlorides.[1] ***Hydrogen Selenide*** affords *N*,*N*-dimethyldiselenocarbamate, which may be converted to 1,3-diselenolium salts, the starting materials for selenafulvalene-type organic conductors (eq 2).[12]

The reagent even reacts with unreactive primary and secondary amines, e.g. tosylamides,[13] to give the corresponding chloroformamidines or chloroformamidinium salts.[1]

Primary enamines react both at the nitrogen and at the nucleophilic carbon atom, thereby forming versatile azapentamethine cyanines (eq 3).[14]

(3)

Substituted nitriles lead, in the presence of HCl, to analogous compounds (R = Cl).[15] Dimethylcyanamide adds smoothly to PI giving 1,3-dichloro-2-azatrimethine cyanines, which have found widespread use in heterocyclic synthesis (eq 4).[1,16] Carbodiimides form nonconjugated adducts (eq 5).[17]

(4)

(5)

Chloroazidoiminium salts are obtained from PI and ***Azidotrimethylsilane***.[18] They transfer a diazonium group to nucleophilic aromatic substrates, whereas diazo transfer occurs with activated methylene compounds.[19]

Heterocycle Synthesis.

PI salts have almost unlimited potential in heterocyclic chemistry, readily forming cyclic systems with 1,4- and 1,5-bisnucleophilic compounds (eqs 6-8).[20-22]

X = O, N, S

(6)

(7)

(8)

Ester or cyano groups (after prior addition of HCl) can also act as nucleophiles (eqs 9 and 10).[23,24]

(9)

(10)

ortho-Hydroxybenzonitriles lead, after hydrolysis, to 2-dimethylamino-1,3-benzoxazines.[25] Aliphatic enamino esters and nitriles react completely analogously to their aromatic counterparts (eq 11).[26,27]

(11)

Reactions with Carbon Nucleophiles.

Ketones react smoothly with PI in refluxing chloroform to form the corresponding chlorides of 3-chloroacrylamides (eqs 12 and 13).[1]

(12)

(13)

Cyclic ketones react too, but the reagent is very sensitive to steric hindrance. Aliphatic ketones (e.g. acetone) lead to complicated mixtures. Acid chlorides probably react via ketene intermediates, affording α-chloro-β-chlorocarbonylenamines.[28] Diphenylketene leads to 4,4-dichloroazetidin-2-one.[28]

Only very activated (hetero) aromatics undergo *C*-acylation with PI. Thus 1,3-dimethoxybenzene is acylated, generating the corresponding amide chloride, which can be hydrolyzed to the amide or, interestingly, thermolyzed to the nitrile (eq 14).[29] In this manner, PI can be considered as a $[CN]^+$ equivalent. Similar chemistry is observed with electron-rich indoles[29] and pyrroles.[30]

(14)

Activated methylene groups condense readily with PI to form push-pull α-chloroenamines.[1,30] This transformation is also successful for vinylogous methyl and methylene groups in ethylidene malononitriles and cyanoacetates (eq 15).[31]

(15)

Cyanoacetate condensation products cyclize spontaneously to aminocyanopyrones, via attack by the ester group.[31] Tricyanomethane reacts at the cyano nitrogen.[32]

Enamines react readily with PI to give trimethine cyanines.[1] Vinylogous aminofulvenes undergo attack on the cyclopentadiene moiety.[33] 1,2,3,4-Tetrachloro-1,3-cyclopentadiene[34] and 4,5-dichlorocyclopent-4-ene-1,3-dione[35] afford the corresponding chlorodimethylaminofulvene and fulvenequinone, respectively.

As a reasonably strong chlorinating agent, PI transforms tertiary amides into amide chlorides. Substituted acetamides react further to give the very versatile 1,3-dichlorotrimethine cyanines (eq 16).[36] Vinylogous acetamides (e.g. crotonamide) react as well (eq 17).[30,37] This reaction does not occur when R is a strong electron-withdrawing group (e.g. NO_2, ester, CF_3). Tertiary lactams produce unsymmetrical trimethine cyanines.[1,30,38]

(16)

(17)

Secondary acetamides (or ketenimines) lead to versatile *N*-α-chlorovinyl chloroformamidinium salts (eq 18).[1,39]

Dichloromethylenetriphenylphosphorane[1]

$Ph_3P{=}CCl_2$

[6779-08-4] · $C_{19}H_{15}Cl_2P$ · Dichloromethylenetriphenylphosphorane · (MW 345.21)

(Wittig reagent for the formation of 1,1,-dichloroalkenes from aldehydes and ketones)

Physical Data: yellow powder, mp 115 °C (dec).

Solubility: sol THF and ether; insol hydrocarbons; reacts with acidic protons.

Handling, Storage, and Precautions: the ylide is generally prepared in situ and used immediately, but the solid can be stored under N_2 for several days. It reacts with air, water, or other acidic protons.

Preparation of the Ylide.

The dichloromethylene Wittig reagent can be prepared in three different ways:

- 1)reaction of Ph_3P with dichlorocarbene (generated from base and $CHCl_3$);
- 2)reaction of Ph_3P with CCl_4 or $BrCCl_3$;
- 3)deprotonation of the phosphonium salt $Ph_3{+}PCHCl_2\ X^-$ with strong base.

Preparation from Phosphines and Dichlorocarbene.

Dichloromethylenetriphenylphosphorane was first prepared by generation of dichlorocarbene (from ***Chloroform*** and ***Potassium t-Butoxide***) in the presence of ***Triphenylphosphine*** (eq 1).[2] Under these conditions, dichlorocarbene is immediately trapped by the phosphine to give the ylide as a suspension in heptane. This method has been used to transform aliphatic[2,3] and aromatic[2,4] aldehydes and ketones to the corresponding dichloroalkenes in yields of 50-80%. For best results the *t*-butanol formed during ylide generation should be removed by vacuum distillation prior to carbonyl condensation.[4]

Preparation from Phosphines and Tetrahalomethane.

The most popular method for synthesis of dichloromethylenetriphenylphosphorane is the reaction of Ph_3P with a large excess of CCl_4 in the presence of a carbonyl compound.[5] The ylide is formed in situ and reacts with the substrate to give dichloroalkenes (eq 2).[6] Recent improvements include the use of $BrCCl_3$ in place of carbon tetrachloride[7,8] and acetonitrile as solvent.[9]

Aldehydes,[5,10] ketones,[5,9] and keto esters[9] react under these conditions to give good yields of the $R_2C{=}CCl_2$ products. A useful variation of the reaction used ***Hexamethylphosphoric Triamide*** in place of triphenylphosphine,[8,11] although under these conditions certain ketones did not react.[8] Synthetic applications of the ylide include preparation of steroid derivatives[8,10] and insecticide analogs.[12,13]

Preparation from Phosphonium Salt and Base.

The dichloromethyltriphenylphosphonium salt has been prepared from triphenylphosphine and $BrCHCl_2$[2] or more simply from reaction of 2 equiv Ph_3P with CCl_4 in the presence of a small amount of water (eq 3).[14] Only a few Wittig reactions have been reported for the ylide formed by phosphonium salt deprotonation. Treatment of the salt with ***Sodium Hydride*** in THF gave the dichloro ylide, which was then used to convert a 4-substituted cyclohexanone into the dichloromethylene derivative in 57% yield (eq 4).[9] When phenyllithium was used to form the ylide, reaction with benzophenone did not afford any of the expected dichloroalkene.[2]

Alternatives to the Wittig reaction for the formation of dichloroalkenes from carbonyl compounds include the Horner-Emmons reaction of Cl-substituted phosphonate anions,[15] and a unique example of the Peterson alkenation reaction[16] using the lithium anion of TMS-$CHCl_2$. The above reactions generally use aldehydes or ketones as substrates; Wittig reaction of other carbonyl compounds such as esters with this ylide have not been reported. For an example of alkenation with a lactone, see Chapleur.[11]

Dichloromethyllithium

$LiCHCl_2$

[2146-67-0] · $CHCl_2Li$ · Dichloromethyllithium · (MW 90.87)

(reagent used for chlorocyclopropanation, nucleophilic dichloromethylation, ring expansion, α-chloro aldehyde preparation, α-hydroxy aldehyde preparation, chain homologation)

Physical Data: low temperature ^{13}C and ^{6}Li NMR data are available,[1] as are matrix IR data.[2]

Preparative Methods: solutions of the title compound can be obtained by treatment of CH_2Cl_2 with ***n-Butyllithium*** in THF/ether/pentane (4:1:1) at -110 °C for 20 min;[3] alternate conditions include *n*-BuLi-***N,N,N´,N´-Tetramethylethylenediamine*** as the base in ether/THF (60:40) for 1 h at -90 °C.[4] One may also deprotonate CH_2Cl_2 with amide bases at -100 to -78 °C.[5]

Handling, Storage, and Precautions: the reagent is generally stable from -110 to about -80 °C, depending on the solvent. There is evidence that carbenoids of this nature show greater thermal stability in THF than in ether.[6] Solutions of $LiCHCl_2$ in THF/ether mixtures of greater than about 20% (v/v) THF are quite stable for ~20 h at -74 °C.[6a] Further, transmetalation with ***Titanium Tetraisopropoxide*** is reputed to give a reagent with greater thermal stability,[6e] although subsequent reports confirming this have not appeared.

General Considerations.

Alkyllithiums bearing halogens on the α-carbon are frequently referred to as carbenoids, reflecting a major mode of reactivity. Good general reviews of such species are available.[7] At very low temperatures, however, the reagent reacts like a typical alkyllithium. The reactivity of $LiCHCl_2$ is mirrored by ***Dibromomethyllithium*** in many respects. It is noteworthy that $LiCHCl_2$ has been used as a base in the generation of other carbenoids, including $LiCHBr_2$.[8]

Cyclopropanations.

Unlike the carbenoids $LiCHBr_2$, ***Tribromomethyllithium***, and ***Trichloromethyllithium***, $LiCHCl_2$ has not been reported as a general precursor to chlorocarbene for use in cyclopropane synthesis. An apparently noncarbenic bromocyclopropanation of fulvenes has been described by Grohmann.[9] When ***Lithium Diisopropylamide*** was slowly added to a THF solution of a fulvene and CH_2Cl_2 at -75 °C followed by slow warming to 0 °C, a mixture of *cis*- and *trans*-halospiro[2.4]heptadienes was formed (eq 1).

(1)

Alternatively, $LiCHCl_2$ may be preformed and the fulvene added slowly at -95 °C. Evidence indicates a nucleophilic addition-displacement mechanism as opposed to a carbene reaction. A related reaction involving ring enlargement of silacycles has also been reported.[10]

Nucleophilic Dichloromethylation Reactions.

$LiCHCl_2$ is an excellent reagent for incorporating the dichloromethyl group into molecules via nucleophilic displacement and addition reactions. Alkylation of primary alkyl halides proceeds well (eq 2).[4,11] The reaction of the terminal dichlorides with 3 equiv of *n*-BuLi/THF at -30 to -40 °C results in production of the terminal alkynes in good yield (eq 3).

$$\text{R-X} + LiCHCl_2 \xrightarrow[\text{TMEDA or HMPA}]{\text{THF, ether}} RCHCl_2 \qquad (2)$$

R-X	% yield	
$3\text{-}ClC_6H_4CH_2Br$	62	
$C_{12}H_{25}Br$	92	
$Cl(CH_2)_3Br$	89	(Br displaced)
$PhCH{=}CHCH_2Br$	70	
Et_2CHCH_2I	55	

(3)

Carbonyl addition reactions are also quite facile. As with other α-haloorganolithiums, $LiCHCl_2$ may be generated by

deprotonation with lithium dicyclohexylamide in the presence of aldehydes and ketones to subsequently provide polyhalomethylcarbinol adducts in excellent yield (eq 4).[12] The adducts may be trapped in situ by ***Chlorotrimethylsilane*** to provide silyl ethers[13] which serve as precursors to terminal dichloroalkenes on treatment with *n*-BuLi in THF/ether/petroleum ether at -110 °C (eq 5).[14]

(4)

(5)

α-Chloro Ketones and Ring Expansions by Fritsch-Buttenberg-Wiechell Rearrangement.

The intermediate lithioalkoxides have been treated with *n*-BuLi, which results in deprotonation of the halogen-containing carbon to generate another carbenoid intermediate (Scheme 1). Such species undergo synthetically useful carbene rearrangements. For example aldehyde-$LiCHCl_2$ adducts undergo migration of hydrogen to provide one-carbon homologated α-chloro ketones in 50-70% overall yield (eq 6).[15] ***Lithium Piperidide*** may also be used as the base in this process.[15b] Side products may include α-chloro aldehydes via migration of the alkyl group instead of hydrogen, although these tend to be minor products. Cyclic ketones undergo an analogous reaction, resulting in ring expanded α-chloro ketones (eq 7). Symmetrical acyclic ketones also undergo the transformation in good yield. A rough migratory aptitude order has been determined. An analogous series of reactions occurs with carbonyl-$LiCHBr_2$ adducts (see ***Dibromomethyllithium***).

migratory aptitude: H > Ph > R_3C, R_2CH > RCH_2

Scheme 1

(6)

(7)

Rearrangements to α-Chloro Aldehydes.

If the aldehyde-$LiCHCl_2$ adducts (**1**) are heated in refluxing THF, the α-chloro aldehydes (**3**) are formed, presumably by ring opening of intermediate α-chlorooxiranes (**2**). Elimination of HCl from (**3**) results in α,β-unsaturated aldehydes in overall 50-80% yield (Scheme 2). Cyclic ketones also undergo the transformation in good yield.[16]

Scheme 2

α-Hydroxy Aldehyde Preparation.

Hydrolysis of $LiCHCl_2$-phenyl alkyl ketone adducts provides α-hydroxy aldehydes in moderate yield (eq 8).[17] Oxidation of the aldehydes with ***Potassium Permanganate*** gives rise to the corresponding carboxylic acids in poor yield.

Reaction with Esters to Provide α,α-Dichloromethyl Ketones.

Esters undergo an addition-elimination process when treated with $LiCHCl_2$ to provide α,α-dichloromethyl ketones in moderate yields (eq 9).[18] Reaction with acyl chlorides gives dichloromethyl ketones, bis(dichloromethyl)carbinols, and/or α-chloro-β-(dichloromethyl)oxiranes, depending on the substrate and the reaction conditions.[19]

(9)

Chain Homologation of Boronic Esters.

$LiCHCl_2$ is capable of chain elongating boronic esters to give α-chloroboronic esters, useful intermediates in synthesis. Treatment of a boronic ester, generally of the cyclic variety, with $LiCHCl_2$ at low temperature and allowing it to stand at rt for a period of hours results in the familiar B -> C migration of an alkyl group in the ate complex (**6**), with expulsion of a chlorine resulting in a boronic ester (**7**) elongated by a chloromethylene group (Scheme 3). A variety of procedures were examined in order to optimize the process and it was concluded by Brown that in situ generation by deprotonating CH_2Cl_2 with LDA at 0 °C in the presence of the boronic ester was the method of choice for this homologation.[5b] Boronic esters (**7**) are quite stable intermediates which undergo facile displacement of the halide by nucleophiles with inversion of configuration, providing more highly functionalized boronic esters (eq 10).[20]

Scheme 3

(10)

(7) (8)

Nu = NaSPh, $LiOCH_2Ph$
BuLi, PhMgBr, enolates

Use of optically active boronic esters provides the opportunity for asymmetric induction at the newly formed chiral carbon. Ate complexes of pinanediols undergo nearly enantiospecific ***Zinc Chloride*** catalyzed migration of alkyl groups, resulting in production of a new versatile chiral carbon.[21] The utility of this technology can be seen in a synthesis of (+)-*exo*-brevicomin (**9** -> **15**) (Scheme 4). The final product was obtained contaminated with only 3% of an epimer, indicative of the stereospecificity of the three migration and two displacement steps. Subsequent reports state that $LiCHBr_2$ gives better yields and diastereomeric ratios than $LiCHCl_2$ in the migration step.[22] Also, Br was found to be more readily displaced by $LiOCH_2Ph$, enabling more efficient syntheses of small carbohydrates by an iterative approach.

Dichloromethyl Methyl Ether

$MeOCHCl_2$

[4885-02-3] · $C_2H_4Cl_2O$ · Dichloromethyl Methyl Ether · (MW 114.96)

(carbon monoxide equivalent in reactions with boranes and borinates; formylating reagent for aromatic compounds and vinylsilanes; formation of α-keto acid chlorides)

Alternate Names: dichloromethoxymethane; DCME.

Physical Data: bp 85 °C; *d* 1.271 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: commercially available in 98% purity.

Preparative Method: from ***Methyl Formate*** and ***Phosphorus(V) Chloride***.[1]

Purification: by distillation.

Handling, Storage, and Precautions: dichloromethyl methyl ether is moisture sensitive, a lachrymator, and a suspect carcinogen. Handle in a fume hood.

Carbon Monoxide Equivalent.

Dichloromethyl methyl ether functions as a carbon monoxide equivalent in the reaction with boranes to yield tertiary alcohols. The reaction works well with both symmetrical and unsymmetrical boranes and for boranes containing tertiary alkyl groups (eq 1).[2,3] Hindered lithium alkoxides are the preferred bases.

$$Bu_3B + MeOCHCl_2 \xrightarrow[\text{94\%}]{\text{1. } LiOCEt_3 \text{ 2. } H_2O_2, NaOH} Bu_3COH \qquad (1)$$

A similar reaction occurs with borinate esters to yield ketones.[4] This reaction has been used in a facile synthesis of bicyclo[3.3.0]nonan-9-one from ***9-Borabicyclo[3.3.1]nonane*** (eq 2).[5] The insertion reaction proceeds with retention of

configuration of the migrating alkyl groups and provides a route to optically active ketones from chiral borinates and boronates (eq 3).[6] This reaction is applicable to the enantioselective synthesis of α-alkynyl ketones[7] and alkenones,[8] and as in the reaction of boranes with dichloromethyl methyl ether, hindered lithium alkoxides are the preferred bases. Borinates also undergo an elimination-rearrangement reaction to yield alkenes on treatment with dichloromethyl methyl ether and heat or ***Silver(I) Nitrate*** (eq 4).[9]

(2)

(3)

(4)

Formylation of Aromatic Compounds.

Dichloromethyl methyl ether has been used extensively to formylate aromatic compounds.[10-12] The reaction works well for the formylation of arenes and heterocycles such as indoles and pyrroles. ***Titanium(IV) Chloride*** has generally been used as the Lewis acid but an improved procedure recommending ***Tin(IV) Chloride*** has been reported.[13] A typical example is shown in eq 5.[14]

Formylation of Vinylsilanes.

Vinylsilanes are formylated by reaction with dichloromethyl methyl ether, providing a route to α,β-unsaturated aldehydes (eq 6).[15,16] This reaction is also works well for the synthesis of dienals from 1-trimethylsilyl-1,3-dienes.[17]

α-Keto Acid Chlorides.

Dichloromethyl methyl ether is used in the preparation of α-keto acid chlorides. Conventional reagents such as oxalyl chloride or phosphorus halides give poor results (eq 7).[18]

Related Reagents.

Carbon Monoxide; ***N-Dichloromethylene-N,N-dimethyliminium Chloride***; ***Potassium Cyanide***.

1,1-Dichloro-2,2,2-trimethyl-1-phenyldisilane

[57519-88-7] · $C_9H_{14}Cl_2Si_2$ · 1,1-Dichloro-2,2,2-trimethyl-1-phenyldisilane · (MW 249.29)

(silylating agent for π-allylpalladium complexes[1] and palladium-catalyzed allylic silylation, giving allylsilanes;[2] for asymmetric 1,4-disilylation of α,β-unsaturated ketones, giving optically active β-hydroxy ketones after oxidation[3])

Physical Data: bp 50-60 °C/0.5 mmHg.

Solubility: sol THF, benzene.

Form Supplied in: oil, with some 1-chloro-2,2,2-trimethyl-1-phenyldisilane.[2]

Analysis of Reagent Purity: NMR, MS.

Preparative Method: the disilane is prepared in 75% yield by selective chlorodephenylation of 2,2,2-trimethyl-1,1,1-triphenyldisilane with ***Hydrogen Chloride*** in the presence of a catalytic amount of ***Aluminum Chloride*** in benzene.[2,4]

Purification: fractional distillation.

Handling, Storage, and Precautions: the disilane reacts with air and water, and should be kept sealed to preclude decomposition. The reagent is a potential acidic corrosive. It should be handled in a well ventilated hood.

1,4-Disilylation of α,β-Unsaturated Ketones.

In the presence of palladium-phosphine catalysts such as ***Tetrakis(triphenylphosphine)palladium(0)***, the unsymmetrically substituted disilane $PhCl_2SiSiMe_3$ reacts with α,β-unsaturated ketones in refluxing benzene to give γ-(phenyldichlorosilyl) silyl enol ethers, which can be converted into β-(phenyldiethoxysilyl) ketones by treatment with ethanol and ***Triethylamine*** (eq 1).[3] Oxidation of the phenyldiethoxysilyl group with ***Hydrogen Peroxide*** in the presence of fluoride gives β-hydroxy ketones in high yields. γ-(Phenyldimethylsilyl) lithium enolates, generated by treatment of the γ-(phenyldichlorosilyl) silyl enol ethers with ***Methyllithium***, undergo alkylation with alkyl halides to give β-(phenyldimethylsilyl)-α-alkyl ketones with high *anti* selectivity (eq 2). These β-(phenyldimethylsilyl) ketones are subjected to fluorodephenylation followed by oxidation to give *anti*-β-hydroxy-α-alkyl ketones. The 1,4-addition of the disilane is enantioselective when catalyzed by

$PdCl_2$[(*R*)-BINAP], thereby providing optically active *anti*-β-hydroxy-α-alkyl ketones with 66-92% ee (Table 1).[3a]

Pd catalyst = $Pd(PPh_3)_4$, $PdCl_2$[(*R*)-BINAP]

Silylation of π-Allylpalladium Complexes and Palladium-Catalyzed Allylic Silylation.

The disilane is a highly reactive reagent for the silylation of π-allylpalladium complexes, producing phenyldichloro(allyl)silanes in high yields.[1] The retention of configuration observed in the silylation of an optically active π-allylpalladium complex indicates that the silylation occurs by way of a π-allyl(phenyldichlorosilyl)palladium intermediate (eq 3). Palladium-catalyzed allylic silylation of allylic chlorides is also effected with the disilane reagent. In the presence of 1 mol % of palladium catalyst coordinated with triphenylphosphine or ***1,1´-Bis(diphenylphosphino)ferrocene*** (dppf), the silylation gives allylsilanes in high yields (eq 4).[2] The functionalized allylsilanes may be oxidized to allylic alcohols.

2,3-Dichloropropionaldehyde

[10140-89-3] · $C_3H_4Cl_2O$ · 2,3-Dichloropropionaldehyde · (MW 126.97)

(undergoes condensation reactions, ene reactions, 1,2-additions; α-chloro nitrone precursor)

Alternate Name: 2,3-dichloropropanal.

Physical Data: bp 45 °C/12 mmHg; n_D^{20} 1.4762; d^{20} 1.3712 g cm^{-3}.

Solubility: sol most common organic solvents such as hexane, ether, THF, methylene chloride, ethanol, etc.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: NMR.

Preparative Methods: the reagent is best prepared by bubbling an equimolar amount of dry ***Chlorine*** gas into neat ***Acrolein*** at 5 °C.[2] The reaction temperature thereby rises spontaneously and is kept at 40 °C until the reaction has ended. Spinning band distillation at reduced pressure (12 mmHg) affords pure 2,3-dichloropropionaldehyde as a colorless liquid in 65% yield.

Handling, Storage, and Precautions: as the reagent is prone to polymerization it should be used as prepared for best results. For a limited time it can be stored under nitrogen at 5 °C in tightly sealed bottles. Use in a fume hood.

Condensation Reactions.

In the presence of Lewis acid catalysts such as ***Aluminum Chloride*** or ***Tin(IV) Chloride***, 2,3-dichloropropionaldehyde undergoes ene reactions[1] with acyclic[3-5] and cyclic alkenes[6,7] to afford alkenyl-substituted dichlorohydrins (eqs 1 and 2), which after treatment with base can easily be converted to the corresponding epichlorohydrins (eq 1).[6] With unsymmetrical alkenes such as 1-methylcyclohexene a mixture of products is obtained (eq 2),[7] in which the regioisomer resulting from methylene hydrogen abstraction dominates.

Asymmetric induction (70-75% ee) has been achieved in this ene reaction if a chiral catalyst such as (-)-menthoxyaluminum dichloride is employed.[4] In the absence of alkenes, Lewis acids such as $AlCl_3$ or ***Triethylaluminum*** initiate at low temperature the polymerization of the reagent to give high molecular weight poly[oxy(2,3-dichloropropylidene)].[8]

Similarly substituted dichlorohydrins or epichlorohydrins can also be generated by the addition of Grignard reagents to 2,3-dichloropropionaldehyde (eq 3).[9,10]

Precursor to Other Reagents.

Besides its role as precursor for the preparation of 2-chloroacrolein or its diethyl acetal (eq 4),[2] the reagent has also served as an intermediate to 2,3-dichloro-*N*-cyclohexylpropanaldonitrone.[11] The latter, which is formed upon treatment of the reagent with *N*-cyclohexylhydroxylamine, is able to undergo Ag^+-induced stereospecific *cis* additions to isolated

double bonds,[11] thus formally entering a Diels-Alder reaction with inverse electron demand. The resulting cyanide-trapped addition products are obtained as diastereomeric mixtures, which then may be converted in two steps to α-methylene-γ-butyrolactones in good yields (eq 5), thereby providing a preparative route to this unit often encountered in natural products. When the same α,β-dichloro nitrone is combined with a quinoidal vinologous ester system, an unusual course of the cycloaddition reaction is observed.[12]

Finally, 2,3-dichloropropionaldehyde has also served as a precursor for the preparation of pyrazoles[13] and a new type of phosphorus-containing betaine.[14]

1,3-Dichloropropene

(*E*)

[10061-02-6] · $C_3H_4Cl_2$ · 1,3-Dichloropropene · (MW 110.97) (*Z*)

[10061-01-5]

(bifunctional alkylating agent)

Alternate Name: 1,3-dichloropropylene.

Physical Data: (*E*) isomer: bp 112 °C; *d*204 1.224 g cm^{-3}. (*Z*) isomer: bp 104.3 °C; *d*204 1.217 g cm^{-3}.

Solubility: sol ethers, hydrocarbons; slightly sol H_2O.

Form Supplied in: available as a mixture of (*E*) and (*Z*) isomers.

Handling, Storage, and Precautions: flammable liquid; suspect carcinogen. Handle in a fume hood.

Bifunctional Alkylating Agent.

1,3-Dichloropropene can be functionalized at each terminus by either nucleophiles or electrophiles. Most nucleophiles react with this reagent, as well as other 1,3-dihalopropenes, in an S_N2 substitution reaction to yield terminal vinyl halides that are unreactive towards further substitution.[1] Bis-substitutions with thiolate,[2a] selenate,[2a] or formate[2c] anions are effected under strongly basic conditions, leading to the useful propenone synthons 1,3-bis(phenylthio)- or 1,3-bis(phenylseleno)propene.[2a,b] Functionalized copper-zinc reagents, RCu(CN)ZnX, add to 1,3-dichloropropene with a high degree of S_N2' selectivity (>98%) to afford bis-functionalized alkenes in good to excellent yields with good stereoselectivity for formation of the (*E*) isomer (eq 1).[3]

(1)

R	(*E*):(*Z*)	Yield (%)
$(CH_2)_3CN$	87:13	88
$(CH_2)_6OAc$	70:30	80
CH_2Ph	100:0	94
CH_2-2-thienyl	100:0	84

Under Arbuzov conditions a 1,3-dienyl phosphonate results from reaction of 1,3-dichloropropene with triethyl phosphite.[6]

Terminal bis-trimethylsilylation of 1,3-dichloropropenes can be effected by metalation with ***Lithium Diisopropylamide***, with in situ trapping by ***Chlorotrimethylsilane*** in THF/ether mixtures at -75 °C (eq 2).[4]

(2)

A simple synthesis of 1,3-butadienes in moderate yields and excellent stereoselectivity (*trans*:*cis* > 95:5) is accomplished by reaction of aldehydes or ketones with 1,3-dichloropropene and ***Zinc*** powder in an aqueous medium (eq 3).[5]

(3)

R^1	R^2	Yield (%)
Ph	H	53
$(CH_2)_2Me$	H	53
CH=CHPh	H	38
Ph	Me	53

Homoallylic alcohols result from addition to aldehydes that is mediated by ***Samarium(II) Iodide*** (eq 4).[7]

(4)

Vinylcyclopropanes are obtained in moderate yields by reaction of 1,3-dichloropropenes with α,β-unsaturated esters in the presence of ***Copper-t-Butyl Isocyanide*** complexes in benzene at 80 °C (eq 5).[8]

2,3-Dichloropropene

[78-88-6] · $C_3H_4Cl_2$ · 2,3-Dichloropropene · (MW 110.97)

(general purpose alkylating agent)

Physical Data: bp 94 °C; n_D 1.4611; *d* 1.204 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Preparative Method: can be prepared from 1,2,3-trichloropropane in 87% yield by the elimination of hydrogen chloride, using NaOH in a refluxing aqueous or ethanolic solution.[1] Recently it has been shown that the addition of quaternary basic salts such as $[Me(CH_2)_7]_3$+NMe Cl^- can improve the yield (94%) and selectivity of the elimination.[2]

Handling, Storage, and Precautions: highly flammable liquid (fp 10 °C); toxic; corrosive. Use in a fume hood.

Alkylations.

2,3-Dichloropropene (**1**) is a general purpose alkylating agent, useful for the incorporation of allyl side chains. Additions to carbonyl enolate anions are common,[3,4] for instance in the final stages of the total synthesis of (-)-hypnophilin (eq 1).[5]

(1)

The additions of (**1**) to alcohols,[6] amines,[7] sulfones,[8] ketimines,[9] and Schiff bases[10] are also known.

In a number of cases the disposition of the (2-chloro)allyl side chain allows the alkylation to be followed by a Claisen rearrangement,[6,11,12] for instance in the bis(chloroallyl) ether (**3**) of anthrarufin (**2**) (eq 2).[13]

Grignard Reactions.

2,3-Dichloropropene also undergoes alkylation reactions with Grignard reagents.[14-16] This has been used in the synthesis of cyclic ketones by cyclization of the allyl side chain onto an alkene using 97% ***Formic Acid*** (eq 3).[17]

2,3-Dichloropropene

(3)

Palladium Coupling Reactions.

Cyclization of alkynylanilines to indoles under palladium catalysis, in the presence of allyl chlorides, gives 3-allylindoles in good yields (eq 4).[18] The reaction mixture must contain proton scavengers to avoid trapping of the intermediate organopalladium species by H^+.

(4)

Allene Formation.

Although many routes to ***Allene*** are described in the literature, most give a mixture of allene and methylacetylene. However, reductive elimination of 2,3-dichloropropene with ***Zinc*** dust gives allene in a reproducible manner in good yield, with 2-chloropropene as the only impurity (eq 5).[19]

(5)

Aryl Coupling Reactions.

2,3-Dichloropropene acts as an electron acceptor in the radical coupling of aryl Grignard reagents (eq 6).[20] The high yield and avoidance of toxic thallium compounds give this method an advantage over other aryl coupling reactions. This method has been extended to the production of aryl polymers. Poly(*p*-phenylene) (PPP) has been produced using 2,3-dichloropropene and difunctional aryl Grignards (eq 7).[21]

(6)

(7)

Halogen Substitution.

In the presence of ***Sodium Iodide***, 2,3-dichloropropene undergoes halogen exchange in the 3-position (eq 8).[22]

(8)

Organometallic Compounds.

2,3-Dichloropropene has been shown to undergo oxidative addition to form complexes with transition metals, for instance with ruthenium.[23]

Radical Reactions.

Functionalized cyclopentanes can be prepared from vinylcyclopropanes and 3-substituted propenes (e.g. **1**) by both photochemical and DBU initiation methods (eq 9).[24]

Michael J. Cherry

University of Cambridge, UK

1,3-Dichloro-1,1,3,3-tetraisopropyldisiloxane

[69304-37-6] · $C_{12}H_{28}Cl_2OSi_2$ · 1,3-Dichloro-1,1,3,3-tetraisopropyldisiloxane · (MW 315.43)

(simultaneous protection of the 3´- and 5´-hydroxyl functions of furanose nucleosides;[2,3] protecting group for carbohydrates;[4,5] protecting group reagent for open-chain polyhydroxy compounds;[6] preparation of cyclic bridged peptides[7])

Alternate Name: TIPSCl.

Physical Data: bp 70 °C/0.5 mmHg; *d* 0.986 g cm^{-3}.

Solubility: unaffected by water, 0.3M TsOH in dioxane, 10% TFA in chloroform, 5M NH_3 in dioxane-water (4:1), or isobutylamine-methanol (1:9), or tertiary amines (Et_3N, pyridine).

Form Supplied in: liquid; commercially available.

Preparative Method: can be prepared starting from ***Trichlorosilane*** by treatment with *i*-PrMgCl, H_2O, and ***Acetyl Chloride***.[1]

Handling, Storage, and Precautions: the liquid is corrosive and moisture sensitive.

Protection of the 3´- and 5´-Hydroxy Functions.

The reagent design was based upon the fact that triisopropylsilyl chloride reacts 1000 times faster with primary alcohols than secondary alcohols. Thus in the case of 3´,5´-dihydroxy nucleosides the reagent initially silylates at the 5´-position. This is then followed by intramolecular reaction with the secondary alcohol at the 3´-position to give the doubly protected derivative (eq 1).[2,3,8]

Rendering this protecting group of further utility is the fact that, in DMF under acidic conditions, silyl migration occurs affording the 2´,3´-disilyl derivative (eq 2).[4] This migration has been employed in the synthesis of carbohydrates (eq 3).[5,9]

Protection of Open-Chain Polyhydroxy Compounds.

The utility of 1,3-dichloro-1,1,3,3-tetraisopropyldisiloxane was extended to include open-chain polyhydroxy compounds. Glycerol reacted to form the eight-membered ring (eq 4) while the D-erythropentose derivative gave only the seven-membered ring (eq 5).[6] This strategy was used as a key step in the synthesis of the steroid 19-norcanrenone.[10]

(4)

(5)

Preparation of Cyclic Bridged Peptides.

As part of a study aimed at improving the transport of peptides by derivatization with silyl reagents, the feasibility of restricting the conformational mobility of the enkephalin peptide backbone by bridging two serine residues with a disiloxane bridge was investigated. TIPSCl was chosen due to its specificity for primary alcohols as well as its ability to bridge secondary alcohols if present in the correct spatial environment.[7] Thus the solution phase syntheses of protected [Ser^2,Ser^5]- and [D-Ser^2,Ser^5]enkephalins were carried out followed by the reaction of the two free hydroxy groups in each with TIPSCl to afford the bridged disiloxane structures.

Dichlorotitanium Diisopropoxide[1]

[762-99-2] · $C_6H_{14}Cl_2O_2Ti$ · Dichlorotitanium Diisopropoxide · (MW 236.962)

(a Lewis acid commonly used for the preparation of chiral titanium complexes;[2-5] a highly effective catalyst for Diels-Alder reactions,[4] [2 + 2] cycloadditions,[4] and carbonyl-ene reactions,[5] including asymmetric versions of these processes; reagent for the formation of titanium enolates;[6,7] component of catalysts used for the stereoselective additions of cyanide[3,8] and allyltin[9] nucleophiles to aldehydes[2])

Alternate Name: dichlorodiisopropoxytitanium.

Physical Data: crystalline solid.

Solubility: sol CH_2Cl_2, toluene, and other solvents.

Preparative Method: prepared by adding slowly at rt an equimolar amount of ***Titanium(IV) Chloride*** to a hexane solution of ***Titanium Tetraisopropoxide***; following mixing, during which heat is evolved, the mixture is allowed to stand at rt for 6 h and the precipitate is collected and washed with hexane; dibromotitanium diisopropoxide is prepared similarly.[10]

Purification: recrystallization from hexane, followed by drying under vacuum.[11,12]

Handling, Storage, and Precautions: corrosive; moisture sensitive; use in a fume hood; can be stored under nitrogen in pure form or in solution.

Preparation of Chiral Titanium Complexes.[2-5]

A variety of Lewis acid promoted transformations which are mediated by titanium complexes can take place with significant enantiocontrol by incorporating chiral nonracemic alkoxy ligands on titanium. One of the most common titanium sources for the synthesis of these derivatives is the title reagent (**1**), although ***Chlorotitanium Triisopropoxide*** and ***Titanium Tetraisopropoxide*** are also used. Usually, the two isopropoxy groups are replaced with a chiral diol either by the azeotropic removal of isopropyl alcohol or by simply mixing (**1**) and the chiral diol in the presence of 4Å molecular sieves. The latter method has been used successfully in several catalytic asymmetric

reactions. Among the most effective catalysts for this purpose are the titanium complexes derived from (**1**) and (*S*)- or ***(R)-1,1´-Bi-2,2´-naphthol*** (BINOL) (eq 1)[5,12] and TADDOL, a bulky tartrate-derived diol (eq 2).[3,4,13]

[4 + 2] Cycloadditions.

Even when they are generated in situ, the above titanium complexes are very effective catalysts for the asymmetric Diels-Alder reactions of certain dienes and dienophiles, such as acyloxyoxazolidinones (eq 3).[13]

Very high enantioselectivity is observed in the Diels-Alder reactions of some chiral dienophiles in the presence of (**1**) (eq 4).[14]

The reagent derived from (**1**) and BINOL is an excellent catalyst for the hetero Diels-Alder reactions of glyoxylates (eq 5).[5,15]

[2 + 2] Cycloadditions.[3,4]

The chiral titanium derivative in eq 2 is an efficient catalyst for the asymmetric [2 + 2] cycloadditions of alkynyl,[16] allenyl,[17] and alkenyl sulfides (eq 6).[18]

Carbonyl-Ene Reaction.[5]

The combination of (**1**) with BINOL (eq 1) is a very effective catalyst for the asymmetric carbonyl-ene reaction of glyoxylates (eq 7).[11] The bromo analog of (**1**) is also effective in this process.[11,12] The kinetic resolution of racemic alkenes, the desymmetrization of symmetrical dialkenes, as well as certain intramolecular variants of this reaction,[19] proceed with equally high diastereo- and enantioselectivity.[5] Similar ene-type products are also obtained during the addition of silyl enol ethers to glyoxylates.[20]

Titanation of Enolates.

The enolates derived from the imines of α-amino esters in the presence of (**1**) or ***Chlorotitanium Triisopropoxide*** react with α,β-unsaturated carbonyl compounds to form pyrrolidine derivatives.[6,21] They also react with aldehydes to form *anti*-amino alcohol products upon hydrolysis of the intermediate oxazolidines (eq 8).[7]

Enantioselective Additions to Aldehydes.

The chiral titanium complexes formed in situ from (**1**) can efficiently catalyze the asymmetric addition of cyanide,[3,8] as well as allyltin nucleophiles to aldehydes (eq 9).[9]

1,3-Dichloro-2-trimethylsiloxy-1-butene

[80422-55-5] · $C_7H_{14}Cl_2OSi$ · 1,3-Dichloro-2-trimethylsiloxy-1-butene · (MW 213.18)

(1,3-dichloro-2-butanone equivalent; presursor of 1-chloro-3-methyl-2-oxyallyl cation;[1] substrate for double alkylation or selective arylation[2])

Alternate Name: [2-chloro-1-(chloromethylene)propoxy]trimethylsilane.

Physical Data: colorless oil; bp 54.5-55.5 °C/5 mmHg; IR (neat) 1630 cm^{-1} ($\nu_{C=C}$); ^1H NMR (60 MHz, CCl_4) δ 0.31 (s, 9H, $SiMe_3$), 1.60 (d, *J* = 6.6 Hz, 3H, allylic methyl), 4.40 (q, *J* = 6.6 Hz, 1H, allylic), and 5.56 (s, 1H, alkenic).

Solubility: sol common organic solvents (THF, Et_2O, CH_2Cl_2, $MeNO_2$).

Preparative Method: a solution of 1,3-dichloro-2-butanone (14 g, 0.1 mol) in ether (25 mL) is added dropwise into a stirred mixture of ***Chlorotrimethylsilane*** (12 g) and ***Triethylamine*** (12 g) in ether (100 mL) at ambient temperature. The mixture is stirred under reflux for 7 h and poured into ice water. The organic layer is washed with cold water, dried ($MgSO_4$), and concentrated. Distillation of the resulting oil under reduced pressure (5 mmHg) gives the reagent (18 g, 83%), which is exclusively of (*Z*) configuration;[1] the stereochemistry of the enol silylation depends on the solvent and base employed.[3] 1-Chloro-2-trimethylsiloxy-1,3-butadiene is sometimes an impurity (less than 5%).

Handling, Storage, and Precautions: the reagent is sensitive to moisture, especially under acidic conditions. If protected from moisture, it can be stored for years without significant decomposition.

2-Oxyallyl Cation.

Silver perchlorate induces ionization of this reagent, generating the 1-chloro-3-methyl-2-(trimethylsiloxy)allyl cation, which reacts with ***Furan*** or ***Cyclopentadiene*** to give corresponding seven-membered bicyclic ketones.[1] Thus a treatment of the reagent (5 mmol) with ***Silver(I) Perchlorate*** (2 equiv) in nitromethane in the presence of furan (25 mmol) and calcium carbonate (15 mmol as a buffer) yields 2-chloro-4-methyl-8-oxabicyclo[3.2.1]oct-6-en-3-one as a mixture of two stereoisomers bearing an axial Cl group (eq 1); with cyclopentadiene, a mixture of all four possible stereoisomers is formed (76%). Electrophilic substitution instead of cycloaddition occurs when the reaction with furan is carried out in THF/ether (1:2) in place of nitromethane (eq 2).

(1)

(2)

Alkylation and Arylation.

Reaction with 2 equiv of alkyl Grignard reagents in the presence of 10% ***Copper(I) Iodide*** in THF/HMPA (10:1) results in double alkylation via successive S_N2' displacements (eq 3). The allylic chlorine is selectively replaced with an aryl group upon treatment with 2.5 equiv of bis(aryl)copper(I) lithium in ether (eq 4).[2]

Dichlorotris(triphenylphosphine)ruthenium(II)[1a]

[15529-49-4] · $C_{54}H_{45}Cl_2P_3Ru$ · Dichlorotris(triphenylphosphine)ruthenium(II) · (MW 958.86)

(used in the hydrogenation of nitro groups,[10,12] imines,[15] and ketones,[14] and the selective oxidation of alcohols[21-23])

Physical Data: mp 132-134 °C.

Solubility: sol toluene, benzene, CH_2Cl_2.

Form Supplied in: red-brown or shiny black crystals.

Preparative Method: by refluxing hydrated ***Ruthenium(III) Chloride*** and ***Triphenylphosphine*** in ethanol according to the procedure of Wilkinson.[1b]

Carbocycles.

The title reagent (**1**) is a versatile homogeneous catalyst. It is used in the reduction, oxidation, cyclization, and isomerization of a variety of organic compounds. It is an effective catalyst for the Kharasch addition of a range of halogenated substances to alkenes.[3,4] α-Chloro-γ-lactones (eq 1)[5a] or carbocyclic α,γ-dichloroesters[5b] are formed by reaction of alkenic α,α-dichloro acids and esters in the presence of (**1**). The process occurs through a metal-complex radical and provides highly functionalized products. The reagent is also used in radical cyclizations of *N*-allylacetamides[6-8] and the stereoselective addition cyclization of 1,6-dienes (eq 2).[9] The synthesis of α,β-unsaturated ketones from primary alcohols and allyl acetates is catalyzed by (**1**).[10]

(1)

(2)

Reductions.

The reagent (**1**) can promote hydrogen transfer from alcohols,[14,15] acids,[17] and amides, as well as other hydrogen donors, to activated double bonds,[14,15] carbonyl compounds, and nitro groups. It is an efficient homogeneous catalyst for the hydrogenation of nitroalkanes to amines,[11] nitroarenes to amino arenes,[12,13] and imines to amines (eq 3).[16]

(3)

The ruthenium-catalyzed reduction of diallyl-α-oxalyl carboxylates with ***Formic Acid*** provides α-hydroxycarboxylic acids in good yields.[17]

Oxidations.

The reagent (**1**) can catalyze the oxidation of alkanes to tertiary alcohols,[18] amides to *t*-butyldioxyamides,[19] and tertiary amines to α-(*t*-butyldioxy)alkylamines[20] using ***t-Butyl Hydroperoxide***. *N*-Demethylation of tertiary methylamines is accomplished by hydrolysis of the α-(*t*-butyldioxy)alkylamine (eq 4). Alcohols have been oxidized to aldehydes and ketones in the presence of (**1**) and oxidants such as ***Bis(trimethylsilyl) Peroxide***,[21] molecular ***Oxygen***,[22] ***Acetone***,[23a] or ***N-Methylmorpholine N-Oxide***.[23b]

(4)

Isomerizations.

The reagent (**1**) catalyzes the isomerization of α,β-ynones to (*E*,*E*)-α,β,γ,δ-dienones,[24] allylic alcohols to ketones,[25a] and 2-ynols to α,β-unsaturated aldehydes.[25b] The Claisen rearrangement of unsymmetrical diallyl ethers is catalyzed by (**1**) to yield α,δ-unsaturated aldehyes or ketones.[25c]

The reagent can be immobilized on a polystyrene support. The immobilized complex can be reused, thereby making this heterogeneous system more efficient than the homogeneous one. This heterogeneous catalyst has been used in the isomerization of allylarenes.[2,26]

Heterocycles.

The reagent (**1**) is used in the *N*-alkylation of NH groups of azoles with alcohols under neutral conditions,[27] and in the synthesis of indoles[28] via an intramolecular *N*-alkylation. It is also used in the syntheses of important biologically active compounds such as imidazo[1,2-*a*]pyridines (eq 5).[29] Other important heterocycles such as 1,3-disubstituted 2,3-dihydroimidazol-2-ones are effectively prepared from *N*,*N*-disubstituted ureas and vicinal diols in presence of (**1**).[30] The reagent catalyzes the oxidation of the vicinal diol to the corresponding acyloin, and condensation of the urea with the acyloin followed by dehydration yields the desired product (eq 6).[31]

N,N-Dichlorourethane[1]

[13698-16-3] · $C_3H_5Cl_2NO_2$ · *N,N*-Dichlorourethane · (MW 157.98)

(stable but reactive pseudohalogen which adds to alkenes to give β-chlorocarbamates;[1] useful for the chlorination of tertiary hydrocarbons[2] and activated aromatics[3])

Alternate Name: DCU.

Physical Data: bp 55-56 °C/15 mmHg; 74-76 °C/15 mmHg;[6] *d* 1.349 g cm^{-3}.

Solubility: insol H_2O; sol benzene, acetic acid, acetonitrile.

Form Supplied in: liquid; widely available; purity of commercial material 90-98%.

Analysis of Reagent Purity: by iodometric titration for positive halogen.[5,6]

Purification: vacuum distillation affords the reagent with a purity of >99.5%.[6]

Handling, Storage, and Precautions: lachrymatory liquid; fairly stable in the dark for at least several weeks at 25 °C.[6,7] Store under inert atmosphere. This reagent should be handled in a fume hood.

Addition to Alkenes to give β-Chlorocarbamates.

Simple alkenes add DCU by a radical mechanism to afford, initially, β-chloro-*N*-chlorocarbamates, which are hydrolyzed to β-chlorocarbamates. Terminal alkenes give the products of anti-Markovnikov addition in 50-80% yields.[6,7] For example, 1-hexene provides *N*-(2-chloro-*n*-hexyl)carbamate (eq 1).[6]

(1)

Addition to nonterminal alkenes is complicated by competing allylic chlorination; in these cases, yields of β-chlorocarbamates are generally only 30-40% (eq 2).[6] Styrene and *trans*-stilbene give better yields of addition products with DCU (80% and 65%, respectively).[6]

(2)

The β-chlorocarbamate products are useful intermediates for conversion to oxazolidones (eq 3) or aziridines (eq 4).[7,8]

(3)

(4)

The addition of DCU to indenes,[9,10] unsaturated silanes,[11] and a variety of alkenes containing electron-withdrawing groups[12] has been described. A review of the addition reactions of DCU with alkenes has been published.[1]

Chlorination of Tertiary Hydrocarbons.

Unactivated tertiary hydrogens in some steroids can be selectively replaced with chlorine by reaction with DCU under

UV irradiation. The resulting chlorides have been treated with ***Silver(I) Perchlorate*** to afford alkenes (eq 5),[2] or hydrolyzed to alcohols (eq 6).[13]

(5)

(6)

Chlorination of Activated Aromatics.

Anisole gives 4-chloroanisole in high yield with DCU; 2,4-dichloroanisole is also formed (eq 7).[3] Selective monochlorination of some isoflavones has been reported.[14]

(7)

Other Reactions.

Organoboranes afford alkyl chlorides with DCU;[4] however, other reagents, such as ***Chloramine-T*** or ***Trichloramine*** are generally more effective. 2-Substituted indoles give chlorinated 2-indolinones with DCU.[15] Nitroso derivatives are oxidized with DCU in the presence of ***Copper(II) Bromide*** to provide azoxy compounds.[5] Alkyl ethers can undergo cleavage reactions with DCU, to afford β-chloro(biscarbamates).[3]

Dichlorovinylene Carbonate[1]

[17994-23-9] · $C_3Cl_2O_3$ · Dichlorovinylene Carbonate · (MW 154.94)

(dienophile for aromatics;[1] 1,2-dione synthesis;[2] ketene generation[3])

Alternate Name: 4,5-dichloro-1,3-dioxolen-2-one.

Physical Data: mp 19 °C; bp 39-40 °C/10 mmHg.

Solubility: sol acetone, benzene, xylene.

Preparative Method: by chlorination/dechlorination of ethylene carbonate.[2,4]

Handling, Storage, and Precautions: lachrymator; may be stored indefinitely in the refrigerator; slowly decomposes to CO and oxalyl chloride in the liquid state or in dilute aprotic solvents; decomposes at rt with phosphorus nucleophiles.

Reactivity Pattern.

Dichlorovinylene carbonate (**1**) is used primarily as a dienophile (weak) in thermal and photocycloaddition reactions. Once formed, the cycloadducts are hydrolyzed to give 1,2-dione or glyoxylic acid derivatives that are generally used as precursors of target molecules. As such, it may be considered a synthon for dicarbon suboxide (eq 1).

(1)

Cycloaddition Reactions.

Benzene, anthracene, and phenanthrene derivatives undergo cycloadditions with (**1**) to give 1,2- or 1,4-adducts. Acetophenone is generally used as the photosensitizer.[5] Typical chemistry is illustrated (eq 2) by its photocycloaddition with benzene to give adduct (**2**) that was then hydrolyzed to dione (**3**).[2]

(1) (2)

(2)

(3)

Phenanthrene and (**1**) give predominately one stereoisomer (shown) in a [2 + 2] photoreaction. Hydrolysis to the diketone followed by a benzilic acid rearrangement gives the cyclopropyl-α-hydroxy acid (eq 3).[6]

With anthracene, a thermal cycloaddition (refluxing in *p*-xylene) gives a 1,4-adduct (84%) and its dione (78%) upon hydrolysis (eq 4; X = H).[7] Ketene derivatives are available through this chemistry (eq 4; X = OMe).[3]

(4)

Alkenes,[8] alkynes,[1,9] and dienes[7,10] undergo cycloaddition as well. Eq 5 shows a two-step synthesis of a cyclobutenedione derivative[11] (see ***N,N-Diethyl-1-propynylamine*** for an alternate route). Less substituted alkenes such as ethylene also work well in this type of reaction.[8]

Cyclopentadienes give bicyclo[2.2.1]heptenediones in thermal [4 + 2] cycloadditions (eq 6),[12] where intermediate adducts are usually a mixture of *endo* and *exo* products. Addition rates depend on the cyclopentadiene used. Acyclic dienes tend to add in a [2 + 2] manner.[10] Other reactions include addition to norbornenes,[13] annulenes,[14] 3-phospholenes,[15] and *o*-benzoquinones.[16]

Dicyanoacetylene[1]

[1071-98-3] · C_4N_2 · Dicyanoacetylene · (MW 76.06)

(nucleophilic addition;[4,5] [4 + 2] cycloaddition reactions;[2] metal complexes insertion reactions[3])

Physical Data: bp 76.5 °C; mp 20.5 °C; *d* 0.9703 g cm^{-3}; IR 2268 cm^{-1} (w), 2212 cm^{-1} (m).

Solubility: sol all organic liquids.

Form Supplied in: clear colorless liquid.

Preparative Methods: see eq 1.

Purification: by simple vacuum sublimation or atmospheric distillation.

Handling, Storage, and Precautions: the solid compound can be stored indefinitely at dry-ice temperatures and is handled at rt. It is much more sensitive to the presence of oxygen, a polymerization or condensation reaction probably taking place.

Nucleophilic Addition.

Dicyanoacetylene is very susceptible to nucleophilic addition reactions. Thus it reacts at or below rt with ammonia and primary and secondary amines. The stereochemical aspects of this reaction have been investigated in the case of the piperidine and only the product of *cis* addition could be detected (eq 2).[4] Preference for *cis* stereochemistry has also been observed in the addition reaction of methanol and isopropyl alcohol. *t*-Butyl alcohol gives an equal mixture of both isomers (eq 3).[5]

(2)

(3)

Dicyanoacetylene also reacts readily with hydrogen halides and halogens. They add to dicyanoacetylene at rt to give halodicyanoethylenes of unspecified stereochemistry. Addition of bromine to dicyanoacetylene affords the *trans* adduct in 57% yield (eq 4).[6]

(4)

[4 + 2] Cycloaddition.

Because of the nature of the electron deficiency of the π-system of dicyanoacetylene, it is a more active dienophile than any other activated alkyne including hexafluoro-2-butyne and acetylenedicarboxylate esters. It has the added advantage over the latter of being thermally more stable, and any excess is readily removed due to its low boiling point. Although no direct comparison has been made, it seems likely that dicyanoacetylene is also more reactive in most Diels-Alder reactions than ***Maleic Anhydride*** and ***Tetracyanoethylene***; in fact it is probably only surpassed by benzyne, and some of the cyclic azo compounds. It reacts with cyclopentadiene, 1,3-cyclohexadiene, and butadiene at or below rt[7] and adds, albeit with decreasing ease, to anthracene, naphthalene, and even benzene itself. The latter addition requires heating at 180 °C for extended periods and the yields are low. However, the reaction can be catalyzed with ***Aluminum Chloride*** and ***Aluminum Bromide***. High yields of the adduct are obtained at rt; small amounts of phenylmaleo- and phenylfumaronitrile, the products of a Friedel-Crafts addition of dicyanoacetylene to benzene, are also isolated (eqs 5 and 6).

+ HC≡CH (5)

Dicyanoacetylene reacts with styrenes by sequential Diels-Alder addition and ene reaction to give adducts as illustrated (eq 7).[8] The intermediate adduct from a 1:1 molar ratio of starting materials could not be isolated. The reaction again occurs under exceptionally mild conditions.

Dicyanoacetylene reacts at rt with quadricyclane (eq 8)[9] and norbornadiene (eq 9)[10] in good yields. With bicyclo[2.1.0]pentane it undergoes both a cycloaddition and an ene reaction (eq 10).[11]

(9)

(10)

Other examples of the high reactivity of dicyanoacetylene in the Diels-Alder reaction are its additions to furan and furan derivatives,[12] fulvenes,[13] 1,4-diphenylnaphthalene,[14] cyclooctatetraene,[15] and [2.2]paracyclophane.[16] Dicyanoacetylene acts as a 1,3-dipolarophile in reactions with diazomethane,[17] ethyl diazoacetate,[18] and benzonitrile oxide.[19]

In more recent studies, dicyanoacetylene was reacted with more complicated systems. It can react with linear fused aromatic and heteroaromatic compounds with good regioselectivity. The example shows its reaction with anthra[2,3-*b*]thiophene in refluxing toluene to give an 82% yield of cycloaddition adduct (eq 11).[20]

(11)

Under promoted conditions, dicyanoacetylene reacts with *syn-o,o´*-dibenzene derivatives at rt to give domino- and pincer-type products. This specific reaction gives exclusive domino-type product; in some other cases the ratio could be lower (eq 12).[21]

(12)

Vinylcycloheptatriene derivatives also undergo Diels-Alder reactions with dicyanoacetylene exclusively via the cycloheptatriene form to give 68-96% yields of adducts (eq 13).[22]

(13)

With excess of cyclopentadiene, *anti*-sesquinorbornene can be made through the Diels-Alder reaction with dicyanoacetylene in good yield (eq 14).[23]

(14)

Reactions of antiaromatic compounds such as cyclobutadiene and azete with dicyanoacetylene yields Dewar benzene and 1-Dewar pyridine derivatives in fairly good yields. They can be converted by irradiation to benzene and pyridine intermediates (eqs 15 and 16).[24]

(15)

Dicyanoacetylene also serves as an important starting material in the synthesis of 1*H*-cyclopropa[*l*]phenanthrene (eq 17).[25]

Treatment of a solution of $[2_2](1,4)$cyclophane in CH_2Cl_2 with dicyanoacetylene in the presence of $AlCl_3$ afforded 15,16-dicyano$[2_2](1,6)$cyclooctatetraenyl(1,4)cyclophane in 33% yield (eq 18).[26]

(18)

Radical Reaction with [1.1.1]Propellane.

The reaction of [1.1.1]propellane with dicyanoacetylene in chloroform proceeds extremely rapidly. It involves initial attack of the alkene under the flap of the bicyclopentane to produce a biradical intermediate which leads to the final product (eq 19).[27]

(19)

Cyclosubstitution Reaction.

On heating in toluene, 4,4-disubstituted 1,3-thiazole-5(4*H*)-thiones and dicyanoacetylene undergo a cyclosubstitution reaction to yield 2-methylidene-1,3-dithiol derivatives in 63% yield (eq 20).[28]

(20)

The regioselectivity of the cycloaddition of tetrasulfur tetranitride to dicyanoacetylene has been shown to favor 2,4-addition across nitrogen, or 1,5-addition across sulfur (eq 21).[29]

(21)

Photolysis.

Cycloaddition reactions of dicyanoacetylene with different alkenes not only can be initiated by heating and Lewis acids, but also can be promoted by photolysis. Subjected to UV radiation with ethylene, it forms 2,3-dicyano-1,3-butadiene at 254 nm (eq 22) or 1,2-dicyano-1-cyclobutene at 185 nm (eq 23).[30]

(22)

(23)

Metal Complex Insertion Reactions.

Insertion of alkynes into transition metal-hydride bonds is a key step in many important catalytic processes such as hydrogenation or polymerization. It also receives considerable attention by virtue of its utility in organic synthesis. Many transition metal complexes of Groups 6-10 play an important role in alkyne dimerization, oligomerization, and polymerization reactions, and in the formation of organometallic complexes that may be precursors for these reactions.[31] It was thus of interest to study the reactions of cyanoalkynes towards these metals (Zr, Nb, Mo, W, Re, Fe, Co, Ni). The following are just a few examples of metal complexes with dicyanoacetylene (eqs 24-26).[32-34]

(24)

(25)

Related Reagents.

1,2-Dicyanocyclobutene; ***Dimethyl Acetylenedicarboxylate***; ***Maleic Anhydride***; ***Tetracyanoethylene***.

Dicyanobis(triphenylphosphine)nickel(II)[1]

$Ni(PPh_3)_2(CN)_2$

[21946-42-9] · $C_{38}H_{30}N_2NiP_2$ · Dicyanobis(triphenylphosphine)nickel(II) · (MW 635.31)

(nickel(II) complex useful for the oligomerization of norbornadiene[2] and the isomerization of alkenes[3])

Physical Data: mp 212 °C (dec).

Solubility: only sparingly sol most organic solvents; most sol CH_2Cl_2.

Preparative Method: dry nickel(II) cyanide (11 g) was refluxed in 1 L ethanol with 78 g ***Triphenylphosphine*** for 48 h. The yellowish-gray $Ni(CN)_2$ turned to a light yellow coarse crystalline mass. The solvent was decanted and the solid was rinsed with ethanol to remove unreacted PPh_3. The remaining solid product was dried, extracted with CH_2Cl_2, and filtered to exclude insoluble $Ni(CN)_2$. Removal of solvent provided 39 g (62%) of light yellow crystals.[4]

Handling, Storage, and Precautions: air stable. Store at rt.

Oligomerization of Norbornadiene.

Dicyanobis(triphenylphosphine) nickel(II) catalyzes the [2 + 2 + 2] cycloaddition between norbornadiene and electron-deficient alkenes and alkynes. Thus norbornadiene (**1**) reacts with acrylonitrile in the presence of the nickel catalyst to give a 93% yield of the homo-Diels-Alder adduct (**2**) as a mixture of epimers (eq 1).[4] This catalyst is similar to ***Dicarbonylbis(triphenylphosphine)nickel(0)***, which gives 86% yield in the same reaction, but is easier to handle due to its lack of oxygen sensitivity (see also ***Bis(acrylonitrile)nickel(0)*** and ***Bis(1,5-cyclooctadiene)nickel(0)***.[5] Alkynes also form adducts with norbornadiene; however, the yields are lower than with alkenes.

(1)

Isomerization of Alkenes.

When this complex is combined with ***Sodium Borohydride***, it can be used as a catalyst for the isomerization of alkenes. The mechanism occurs through nickel hydride addition across the alkene and subsequent β-hydride elimination. Acceptance of another hydride by the organonickel intermediate followed by reductive elimination leads to overall hydrogenation of the alkene. In this way, dimethyl maleate is converted to a 95:5 mixture of the isomerized product, dimethyl fumarate, and the hydrogenated product, dimethyl succinate (eq 2).[6] Other nickel(II) cyanide complexes such as $Ni(CN)_2$(phen) and $Ni(CN)_4^{2-}$ give rise to greater proportions of hydrogenated product. With $Ni(CN)_2(PPh_3)_2$, 1,5-cyclooctadiene can be isomerized to a mixture of 1,4- and 1,3-cyclooctadiene with no trace of the hydrogenated byproduct.

(2)

A *cis* selectivity was observed for the isomerization of 1-butene to 2-butene.[3] With $Ni(CN)_2(PPh_3)_2$, the *cis* isomer was favored by a factor of 2:1. Greater *cis* selectivities were observed for some cobalt complexes and other nickel(II) catalysts. These selectivities are dependent upon the cone angle of the phosphorus ligand, the size of the anionic ligands, and the steric congestion in the organometallic complexes.

1,2-Dicyanocyclobutene

[3716-97-0] · $C_6H_4N_2$ · 1,2-Dicyanocyclobutene · (MW 104.11)

(reactive dienophile in [4 + 2],[1] [3 + 2],[2] and [2 + 2][3] Diels-Alder additions; reactive diene in [4 + 2] inverse electron demand Diels-Alder additions upon in situ thermolytic cleavage to 2,3-dicyanobutadiene)

Alternate Name: cyclobutene-1,2-dicarbonitrile.

Physical Data: bp 58-60 °C/0.06 mmHg; *n*20D 1.4926; *d*420 1.033 g cm^{-3}; IR (neat) cm^{-1}: 3002, 2957, 2230, 1612, 1422, 1251, 1169, 1003, 623; ^1H NMR δ 2.91 (s, 2H).

Solubility: insol H_2O; sol most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Preparative Methods: may be prepared by several methods.[4] The most convenient involves the chlorination of 1,2-dicyanocyclobutane with ***Phosphorus(V) Chloride*** followed by dechlorination with ***Triethylamine*** in refluxing benzene to give the reagent in good yield[1,5] (eq 1).

Purification: prepared by the method described, the reagent may be used directly for most cycloadditions. To remove trace impurities (1-4%) and obtain the pure compound, stir for 4 h over Raney cobalt under N_2 at 70 °C, then distill directly under vacuum; purity may be assessed by gas chromatography.[5]

Reactive Dienophile.

1,2-Dicyanocyclobutene (**1**) functions as a reactive dienophile in [4 + 2] cycloadditions to numerous diene systems. *Endo* versus *exo* selectivity is dependent on the presence of sp^3 carbon atoms in the diene (eqs 2-4).[1] The reactions are generally run without solvent.

(2)

(3)

(4)

1,2-Dicyanocyclobutene is easily converted to 2,3-dicyanobutadiene (eq 5). Thermolytic cleavage in situ generates the diene which undergoes inverse electron demand Diels-Alder cycloaddition to a number of dienophiles.[1,5] The in situ generation procedure has the advantage of avoiding the tendency of the diene to polymerize in the pure state (eqs 6-8).

X = O, 58%
X = NEt, 50%

1,2-Dicyanocyclobutene also undergoes [3 + 2] cycloadditions with diazomethane and ethyl diazoacetate (eq 9).[2,3] Yields were not reported.

(9)

Photocatalyzed [2 + 2] cycloadditions of 1,2-dicyanocyclobutene with various alkenes have been demonstrated.[3] The reagent is strongly absorbent at 234 nm in acetonitrile, and the high degree of ring strain allows it react where other alkenes do not. Yields are moderate (eq 10).

Dicyanodimethylsilane

$Me_2Si(CN)_2$

[5158-09-8] · $C_4H_6N_2Si$ · Dicyanodimethylsilane · (MW 110.19)

(protecting reagent of β-diketones[1,2] and β-hydroxy ketones,[1,3] diols, and alcohols[4])

Physical Data: mp 85-87 °C; bp 108-109 °C/54 mmHg.

Solubility: sol dichloromethane, chloroform; slightly sol ether.

Preparative Methods: dicyanodimethylsilane is conveniently prepared by the reaction of dibromodimethylsilane[5] or ***Dichlorodimethylsilane***[6] with ***Silver(I) Cyanide***. ***Lithium Cyanide***,[4] ***Sodium Cyanide***,[7] and ***Potassium Cyanide***[7] can also be used in place of silver cyanide. A method which uses ***Hydrogen Cyanide*** as a source of cyano groups[8] and a procedure which utilizes transcyanation with ***Cyanotrimethylsilane*** have also been reported.[9] Dicyanodimethylsilane is obtained as colorless crystals via these methods.

Handling, Storage, and Precautions: dicyanodimethylsilane reacts instantly with water to form highly toxic hydrogen cyanide and siloxane oligomers. Therefore it should be handled carefully in a fume hood. If possible, it is recommended that CH_2Cl_2 solutions of this reagent be transferred by using syringe techniques.

Reaction with β-Diketones.

While enol silylations and cyanosilylations of β-diketones with cyanotrimethylsilane often give mixtures of products, the reactions with dicyanodimethylsilane give 5-cyano-2,6-dioxa-1-silacyclohex-3-enes in good yields (eq 1).[1] For enolizable β-diketones, the concurrent silylation and cyanosilylation takes place immediately without catalysts. On the other hand, ***Zinc Iodide*** catalysis is effective for reactions with less easily enolizable β-diketones (eq 2). Methyl 2,4-dioxopentanoate also reacts with dicyanodimethylsilane to give the corresponding cyclic product.[2] Treatment of the adducts in methanol (rt, overnight) furnishes the parent 1,3-diketones in good yields. Taking advantage of the stepwise nature of the methanolysis, a formal cyanosilylation can be achieved by treating the adduct with 1 equiv of methanol in dichloromethane at rt (eq 3).[1]

Reaction with β-Hydroxy Ketones and Alcohols.

The reaction of dicyanodimethylsilane with diacetone alcohol occurs according to eq 4.[1] The reaction, which is initiated at -78 °C, proceeds by way of the indicated cyanodimethylsilyl ether. When warmed to rt, the intermediate silyl ether cyclizes to give a mixture of the cyanosilylation product and the cyclic enol silyl ether. The cyanosilylation of secondary β-hydroxy ketones is highly diastereoselective (eq 5).[3] After desilylation, the cyanohydrins are obtained with high *syn* selectivity (de > 95%). The stereochemical result is rationalized by assuming a silyl-bridged chair-type transition state. Dicyanodimethylsilane reacts readily with alcohols, with liberation of hydrogen cyanide, to give bis(alkoxy)silanes in high yields (eq 6).[4]

Dicyanodiethylsilane, Dicyanodiphenylsilane, and Dicyanomethylphenylsilane.

Dicyanodimethylsilane, dicyanodiethylsilane,[7,10] dicyanodiphenylsilane,[7,11] and dicyanomethylphenylsilane[12] are a family of related $R_2Si(CN)_2$ reagents that can be used as protecting groups for bifunctional compounds. The silyl-protection of 1,2- and 1,3-diols with these dicyanosilanes is well documented, affording the corresponding five- and six-membered ring compounds (eqs 7 and 8).[4] The reaction of dicyanomethylphenylsilane with ketones is reported to give biscyanosilylated products, but the yield is modest due to competitive aldol condensations.[12]

Dicyclohexylborane[1]

[1568-65-6] · $C_{12}H_{23}B$ · Dicyclohexylborane · (MW 178.12)

(reagent for the reduction of ketones[2] and α,β-unsaturated ketones;[3] used for the hydroboration of alkynes, alkenes, and allenes[4])

Physical Data: mp 103-105 °C.

Solubility: sol THF, diethyl ether, dichloromethane, pentane.

Analysis of Reagent Purity: a method to determine reagent purity by hydrogen gas evolution is available.[26]

Preparative Methods: is a stable white solid available via the hydroboration of cyclohexene with either ***Borane-Tetrahydrofuran*** or ***Borane-Dimethyl Sulfide***.[5] Recently, dicyclohexylborane has been prepared via the hydroboration of cyclohexene with borane-1,4-thioxane.[6]

Purification: may be purified by sublimation under vacuum.[5a]

Handling, Storage, and Precautions: must be used immediately upon generation or stored as a solid under dry nitrogen.[7] Use in a fume hood.

Reduction of Ketones and α,β-Unsaturated Ketones.

Dicyclohexylborane has proven to be a useful reagent for the stereoselective reduction of cyclic, bicyclic, and polycyclic ketones.[2] In reductions of substituted cyclic ketones this reagent often displays stereoselectivities that are opposite to those observed for the hydride reagents. For example, the reduction of 2-methylcyclohexanone with dicyclohexylborane in THF yields predominantly the *cis* diastereomer, while the reduction with ***Lithium Aluminum***

Hydride in THF leads to preferential formation of the *trans* diastereomer (eq 1).

Dicyclohexylborane has also been used to obtain (*Z*)-vinyloxyboranes via the conjugate reduction of (*E*)-α,β-unsaturated ketones (eq 2). Treatment of the hydroboration mixture with aldehydes has allowed the preparation of stereochemically pure *syn* aldols in good yields.[3] Similar reactivity has also been demonstrated with catecholborane.[8]

Hydroboration of Alkenes and Allenes.

Dicyclohexylborane has found many applications in the hydroboration of alkenes. It may be used to advantage for the hydroboration of sterically hindered alkenes where other regioselective hydroborating agents (e.g. ***Disiamylborane*** and ***Diisopinocampheylborane***) may suffer from significant amounts of retrohydroboration. In addition, dicyclohexylborane is less prone to isomerization than disiamylborane although the regioselectivity characteristics of the two reagents are comparable. The sterically encumbered nature of the reagent also allows for the possibility of selective hydroboration of different alkenes within the same molecule, although selective monohydroboration of conjugated dienes may be difficult.[4a]

The transformations of the trialkylborane products deriving from the hydroboration of alkenes have been extensively reviewed.[1,4] The trialkylborane products may be converted to alkenes, alkyl halides, alcohols, amines, aldehydes, ketones, and carboxylic acids. Trialkylboranes readily undergo isomerization at elevated temperatures, thus making it possible to isomerize an internal alkene to a terminal one.[1,4,9] Brown has extensively studied and optimized conditions for the hydroboration of vinyl and propenyl heterocycles with dicyclohexylborane as well as other representative hydroborating reagents.[10] Although dicyclohexylborane has not seen the widespread use that other hydroborating reagents have, virtually all of the transformations described for trialkylboranes may be adapted to trialkylboranes derived from hydroboration of alkenes with this reagent; this is particularly useful if a highly discriminating hydroboration reagent is desired. Some of its recent applications for the hydroboration of alkenes and allenes are outlined below.

A synthesis of carboxylic acids via the hydroboration of terminal alkenes has recently been developed (eq 3).[11] Several hydroborating reagents were evaluated for this transformation and it was determined that dicyclohexylborane and thexylborane are the reagents of choice.

(3)

Dicyclohexylborane has shown useful levels of diastereoselection in the hydroboration of steroidal alkenes (eq 4).[2b] Several hydroborating reagents were studied, including ***Thexylborane***, ***9-Borabicyclo[3.3.1]nonane***, disiamylborane, and ***Borane-Dimethyl Sulfide***. Only the sterically hindered bis(*trans*-2-methylcyclohexyl)borane proved to be superior to dicyclohexylborane in this application.

(4)

Allenes have also been used as substrates in reactions mediated by dicyclohexylborane.[12] The types of hydroboration products obtained in these reactions have been found to depend upon the type of allene employed. For example,

internal allenes yield preferentially vinylborane products with dicyclohexylborane, whereas 9-BBN will result in preferential formation of allylboranes.[12a] Terminal allenes give rise to allylborane products.[12a]

Hydroboration of Alkynes.

Dicyclohexylborane is an extremely useful reagent for the hydroboration of alkynes. The transformations of the resulting vinylboranes have been reviewed.[1,4] Both terminal and internal alkynes react readily with dicyclohexylborane to provide the corresponding vinylborane. Dihydroboration, which is often a problem with reagents such as 9-BBN, is kept to a minimum even with excess reagent.[13] Conjugated diynes may be monohydroborated with dicyclohexylborane.[14] In addition, it is possible to selectively reduce an alkyne in the presence of an alkene,[14,15] and hydroboration of alkynes in the presence of other functional groups is possible.[16]

Alkyl group transfer reactions of vinylborane intermediates have proven to be of enormous value in organic synthesis. Perhaps the most well known of these transformations is the Zweifel *cis*-alkene synthesis.[17] Treatment of the dialkylborane adduct with ***Sodium Hydroxide*** and ***Iodine*** results in the transfer of an alkyl group and the formation of the *cis*-alkene (eq 5).

(5)

The capacity of alkyl groups to migrate from boron ate complexes have made possible the stereoselective synthesis of several additional alkene derivatives from vinylboranes.[1,4] In addition, methods have been developed for the coupling of alkenyldialkylboranes via alkenylcopper intermediates which leads to the stereoselective production of (*E*,*E*)-[18] and (*Z*,*Z*)-1,3-dienes[19] as well as 1,4-dienes (eq 6).[20]

(6)

Several recent applications of dicyclohexylborane for the hydroboration of alkynes have been reported. The alkenyldialkylborane intermediates have been converted into 2-alkylbuta-1,3-dienes,[21] (*E*)-1-alkenylboronic esters,[22]

α,β-unsaturated nitriles,[23] and (*Z*)-1-halo-1-alkenes.[24] Several additional hydroboration applications have been reported.[25]

1,3-Dicyclohexylcarbodiimide[1]

[538-75-0] · $C_{13}H_{22}N_2$ · 1,3-Dicyclohexylcarbodiimide · (MW 206.33)

(powerful dehydrating agent commonly used for the preparation of amides,[2] esters,[3] and anhydrides;[4] used with DMSO for the mild oxidation of alcohols to ketones;[5] used in the dehydrative conversion of primary amides to nitriles,[6] β-hydroxy ketones to α,β-unsaturated ketones,[7] and can effect the stereochemical inversion of secondary alcohols[8])

Alternate Name: DCC.

Physical Data: mp 34-35 °C; bp 122-124 °C.

Solubility: highly sol dichloromethane, THF, acetonitrile, DMF.

Form Supplied in: opalescent solid; widely available.

Handling, Storage, and Precautions: is an acute skin irritant in susceptible individuals. Because of its low melting point, it is conveniently handled as a liquid by gentle warming of the reagent container. It should be handled with gloves in a fume hood, and stored under anhydrous conditions.

Amide Formation.

Since the initial reports,[9,10] DCC has become the most common reagent in peptide synthesis[2,11,12] and in other amide bond-forming reactions of primary and secondary amines with carboxylic acids. The mechanism is considered to be well understood.[2,5]

Typically, DCC (1.1 equiv) is added to a concentrated solution (0.1-1.0 M) of the carboxylic acid (1.0 equiv), amine (1.0 equiv), and catalyst (when used) in methylene chloride or acetonitrile at 0 °C. The hydrated DCC adduct, dicyclohexylurea (DCU), quickly precipitates and the reaction is generally complete within 1 h at rt. The solvents THF and DMF can be used, but are reported to reduce reaction rates and encourage the formation of the *N*-acylurea side product, as well as increasing racemization in chiral carboxylic acids.[13-16] If the amine is initially present as the salt (i.e. amine hydrochloride), it may be neutralized by adding 1 equiv of ***Diisopropylethylamine*** prior to adding DCC; however, the addition of tertiary amines (particularly ***Triethylamine***) can facilitate *N*-acylurea formation and

racemization.[2] Racemization occurs via the formation of an oxazalone intermediate.[2] The addition of coupling agents (acylation catalysts) such as ***1-Hydroxybenzotriazole*** (HOBt),[17] 1-hydroxy-7-azabenzotriazole (HOAt),[18] ***N-Hydroxysuccinimide*** (HOSu),[19] and 3-hydroxy-3,4-dihydro-1,2,3-benzotriazin-4-one[20] can generally ameliorate both problems. These additives are required for the coupling of sterically hindered components, or when the amine is weakly nucleophilic.

Another potential problem with DCC is that at the completion of the reaction some DCU remains in solution with the product, necessitating additional purification. Water-soluble carbodiimide derivatives such as ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide Metho-p-toluenesulfonate***[21] and ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride*** (EDCI)[22] obviate this problem, as they are removed by a simple extraction. Many newer coupling agents have been developed for peptide synthesis and other acylation reactions. These include ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (BOP),[23] ***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate*** (HBTU),[24] ***Bis(2-oxo-3-oxazolidinyl)phosphinic Chloride***[25] (BOP-Cl), and (1*H*-1,2,3-benzotriazol-1-yloxy)tris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP).[26] In addition to linear and polymeric amides, lactams of various ring sizes have been synthesized using these methods (eq 1).[27]

(1)

$R = (CH_2)_n$, $n = 0\text{-}6$

Ester and Thioester Formation.

These reactions occur through the same *O*-acylurea or anhydride active intermediate as in the amide coupling reactions, and the discussion of associated problems applies here as well. In general, alkyl and (particularly) aryl thiols can be efficiently coupled to carboxylic acids using DCC.[28] Reactions of primary and secondary alcohols proceed reliably, but require the presence of an acylation catalyst. This is usually ***4-Dimethylaminopyridine*** (DMAP),[29,30] (see also ***1,3-Dicyclohexylcarbodiimide-4-Dimethylaminopyridine***), but others have been used including 4-pyrrolidinopyridine[31] and pyridine (solvent) with catalytic ***p-Toluenesulfonic Acid***.[32] The acylation of more hindered alcohols often results in reduced yields; however, even *t*-butanol can be acylated, providing a useful route to *t*-butyl esters.[3,31] Various other carbodiimide derivatives have also been used in the preparation of esters.[33,34] As with amides, which are not limited to intermolecular reactions, a wide variety of lactones can also be synthesized.[35,36]

Anhydride Formation.

Among other anhydride-forming reagents, including ***Acetic Anhydride***, ***Trifluoroacetic Anhydride***, and ***Phosphorus(V) Oxide***, DCC is one of the simplest, mildest, and most effective reagents for the preparation of symmetrical anhydrides,[4,37] including formic anhydride,[38] which is useful in the preparation of formamides (eq 2).

Anhydride formation is associated with each of the reaction types involving carboxylic acids. The anhydride is often the reactive species, to the extent that it competes with the *O*-acylurea or covalent catalyst adduct (see discussion of amide bond formation reactions).

Sulfinate and Phosphate Esters.

Anhydrides of sulfinic and sulfonic acids[39,40] and phosphate monoesters can be prepared using DCC. Further reaction with alcohols or phenols gives the corresponding sulfinates[41] and phosphate diesters.[42,43] Pyrophosphates can be prepared from mono- and disubstituted phosphate esters.[44] Reaction of activated sulfinates with amines gives the corresponding sulfinamides.[45]

Oxidation of Alcohols to Aldehydes and Ketones: Moffatt Oxidation.

The oxidation of primary and secondary alcohols[46] to aldehydes and ketones, respectively, can be carried out by reaction with DMSO activated by DCC (see ***Dimethyl Sulfoxide-Dicyclohexylcarbodiimide***).[5,47,48] In comparison to the many metal-mediated oxidative reactions, the Moffatt oxidation is carried out under very mild conditions, and has found widespread use for reactions in the presence of sensitive functional groups (eq 3).[49] In addition, over-oxidation of aldehydes to form carboxylic acids is not observed. Under typical reaction conditions, a solution of the alcohol (1 equiv), DCC (3 equiv), and a proton source (pyridinium trifluoroacetate) (0.5 equiv) is stirred in DMSO or DMSO/benzene overnight at rt. After quenching the reaction with aqueous acetic acid and removing DCU by filtration, the product can be isolated by extraction. In modifications of this reaction,[46] DCC can be replaced by other DMSO-activating agents including acetic anhydride (see ***Dimethyl Sulfoxide-Acetic Anhydride***),[50] trifluoroacetic anhydride (see ***Dimethyl Sulfoxide-Trifluoroacetic Anhydride***),[51] and oxalyl chloride (see ***Dimethyl Sulfoxide-Oxalyl Chloride***).[52,53]

Dehydrative-Type Couplings.

Because of the power of DCC as a dehydrating agent, it has found many uses in a variety of other dehydrative coupling reactions. These include the reaction of primary amines with DCC and ***Carbon Dioxide*** or ***Carbon Disulfide*** to form ureas (eq 4)[54] or isothiocyanates (eq 5),[55] respectively.

Symmetrical peroxides can be synthesized from benzoic acid derivatives and hydrogen peroxide (eq 6).[56] Unsymmetrical peroxides can be synthesized from the corresponding carboxylic acid and peroxy acid.[56]

Aromatic and aliphatic alcohols and thiophenols can be coupled to form ethers (eq 7)[57,58] and thioethers (eq 8),[59,60] respectively, using DCC.

(8)

In cases where sensitivity of the compound precludes the formation of an acid chloride, α-diazo ketones can be synthesized by the DCC-mediated coupling of diazomethane to carboxylic acids (eq 9).[61,62]

(9)

Dehydration to Alkenes, Epoxides, Nitriles, and Ketenes.

β-Hydroxy ketones and β-hydroxy esters can be dehydrated, using DCC, to α,β-unsaturated ketones (eq 10)[7,63] and esters (eq 11),[64] respectively. Cyclopropanes can be synthesized by the dehydration of γ-hydroxy ketones (eq 12).[65]

(10)

(11)

(12)

Other dehydration reactions include the conversion of primary amides to nitriles,[6] aldehydes to nitriles (via the hydroxylamine) (eq 13),[66,67] and carboxylic acids to ketenes (eq 14).[68]

(13)

(14)

Dehydroxylation of Alcohols.

Alcohols and phenols can be dehydroxylated to the corresponding alkane by hydrogenation of the *O*-acylurea adduct formed from the reaction of the alcohol with DCC (eq 15).[69,70]

(15)

Inversion of Secondary Alcohols.

Secondary alcohols can be stereochemically inverted by formylation (or esterification) with DCC, followed by saponification (eq 16).[8]

(16)

Heterocyclization Reactions.

DCC has frequently been used both as a reagent and as a reactant in the synthesis of heterocycles.[1] For example, DCC-mediated cyclodesulfurative annulation reactions[71] have been used to synthesize guanosine-type nucleotide analogs (eq 17).[72]

1,3-Dicyclohexylcarbodiimide-Copper(I) Chloride[1]

(DCC)

[538-75-0] · $C_{13}H_{22}N_2$ · 1,3-Dicyclohexylcarbodiimide-Copper(I) Chloride · (MW 206.33) (CuCl)

[7758-89-6] · ClCu · 1,3-Dicyclohexylcarbodiimide-Copper(I) Chloride · (MW 99.00)

(dehydrating reagent used for preparation of α,β-enones,[2,3] enimines,[4] and nitroalkenes;[5] used for esterification of secondary alcohols with inversion of configuration[6])

Physical Data: for details see individual entries for ***1,3-Dicyclohexylcarbodiimide*** and ***Copper(I) Chloride***.

Dehydration.

DCC in the presence of a catalytic amount of CuCl efficiently dehydrates alcohols with a β-substituted acceptor group. Reaction of β-hydroxy ketones, 2-hydroxyimines, and nitroaldols with DCC/CuCl affords α,β-unsaturated ketones (60-80% yield) (eq 1),[2,3] enimines (31-75% yield) (eq 2),[4] and nitroalkenes (60-99% yield) (eq 3),[5] respectively.

(1)

(2)

(3)

The mild reaction conditions provide an alternative to methods utilizing acidic conditions that promote polymerization and interfere with other functional groups. Yields for the DCC/CuCl method are comparable to the acidic conditions.[2-5]

α-Cyclopropyl ketones (eq 4) can be prepared by DCC/CuCl dehydration of γ-hydroxy ketones[7] which compares to other methods, e.g. alkylation of γ-chloro ketones or Simmons-Smith cyclopropanation of α,β-unsaturated ketones. A drawback to this method is the formation of dihydrofurans in the event of ketone enolization (eq 5). This phenomenon offers insight into the reaction mechanism, suggesting a *syn* elimination of H_2O.[3,8]

(4)

(5)

Esterification.

DCC/CuCl reacts with secondary alcohols (eq 6), affording an isourea ether or carbamidate adduct (**1**). Treatment of (**1**) with a carboxylic acid gives an ester with inverted configuration[9] in good yield (50-83%) with high enantioselectivity (>99% ee)[6] and compares to the Mitsunobu procedure.[10] Saponification of the resulting ester produces an alcohol with inversion of configuration, which is a viable alternative to existing methods.[11]

1,3-Dicyclohexylcarbodiimide-4-Dimethylaminopyridine[1]

(DCC)

[538-75-0] · $C_{13}H_{22}N_2$ · 1,3-Dicyclohexylcarbodiimide-4-Dimethylaminopyridine · (MW 206.33) (DMAP)

[1122-58-3] · $C_7H_{10}N_2$ · 1,3-Dicyclohexylcarbodiimide-4-Dimethylaminopyridine · (MW 122.17)

(powerful dehydrating mixture used for the preparation of esters,[2] lactones,[3,4] and amides from carboxylic acids and alcohols or amines)

Alternate Name: DCC/DMAP.

Physical Data: DCC: mp 34-35 °C; bp 122-124 °C. DMAP: mp 108-110 °C.

Solubility: DCC: highly sol dichloromethane, THF, acetonitrile, DMF. DMAP: sol dichloromethane, THF, acetonitrile, DMF, ethyl acetate.

Form Supplied in: DCC: opalescent solid; widely available. DMAP: yellow to tan crystals; widely available.

Handling, Storage, and Precautions: DCC is an acute skin irritant in susceptible individuals. Because of its low melting point, it is conveniently handled as a liquid by gentle warming of the reagent container. It should be handled with gloves in a fume hood, and stored under anhydrous conditions. DMAP causes skin and eye burns, and is readily absorbed through the

skin. It should be handled with gloves in a fume hood and stored under dry conditions.

Ester Synthesis.

The combination of the powerful dehydrating agent ***1,3-Dicyclohexylcarbodiimide*** (DCC) and the nucleophilic acylation catalyst ***4-Dimethylaminopyridine*** (DMAP)[1] is widely used in the preparation of esters from carboxylic acids and alcohols. The coupling of carboxylic acids with phenols, thiophenols, and thiols can generally be carried out in the absence of any acylation catalyst,[5] but reactions with alcohols do require a catalyst. DMAP is most commonly used, although other related derivatives such as 4-pyrrolidinopyridine (PPY) have in some cases been more effective.[6] These reactions are quite general, although yields typically decrease as steric bulk increases. *t*-Butyl esters can frequently be synthesized in yields greater than 80%.[6-8] To facilitate purification of the product, water-soluble carbodiimides such as ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride*** (EDCI)[9] can be used in place of DCC.

Under typical conditions, DCC (1.1 equiv) is added to a concentrated solution (0.1-1.0 M) of the carboxylic acid (1.0 equiv), alcohol (1.0-3.0 equiv), and DMAP (0.01-0.10 equiv) in dichloromethane or dichloromethane/DMF at 0 °C. After 1 h the solution is allowed to warm to rt and stirring is continued for an additional 1-5 h. After removal of the precipitated dicyclohexylurea (DCU) by filtration, the product can be recovered by extraction.

Because DMAP and its related derivatives (in conjunction with a coupling agent) are such powerful acylating agents, racemization has frequently been observed in reactions with chiral carboxylic acids, particularly with amino acids. For example, in the synthesis of the *t*-butyl ester of Boc-Asp(OBz)-CO_2H, greater than 60% racemization was observed[2] using EDCI with DMAP (0.5 equiv). The degree of racemization is highly dependent upon the components, and generally increases with steric bulk. Racemization can be suppressed by using low temperatures, short reaction times, and a minimum of DMAP.

The role of DMAP in these reactions is two-fold. First, the pyridine nitrogen can undergo nucleophilic attack upon the *O*-acyl active ester, forming the *N*-acylpyridinium. This charge-separated adduct facilitates electrophilic attack of the nucleophile and increases the leaving group ability. The second role of DMAP is its function as a base (pK_a9.70). As such, it can assist in the deprotonation of the nucleophile. If DMAP is used in stoichiometric amounts, it can be used to neutralize acids formed if the activating agent is an anhydride rather than a carbodiimide.

Lactones.

DCC/DMAP has been frequently used in the synthesis of lactones of various ring sizes. The reaction

conditions and considerations are essentially the same as for ester formation. In several cases, however, the catalyst was effective only when used as the hydrochloride or trifluoroacetate salt.[4,10,11]

Amides.

Although amide bond formation reactions can often be carried out without any acyl-transfer catalyst, the use of DMAP can dramatically increase the reaction rate. For example, the rate of reaction between *m*-chloroaniline and benzoyl chloride was increased by a factor of nearly 6×10^3 when pyridine was replaced by DMAP as the catalyst.[12] However, DMAP is not frequently used for this purpose[13] because of the potential for racemization with chiral carboxylic acids. In these cases, less powerful acyl-transfer catalysts are used.

Dicyclohexano-18-crown-6

cis-syn-cis

cis-anti-cis

(*cis-syn-cis*)

[15128-65-1] · $C_{20}H_{36}O_6$ · Dicyclohexano-18-crown-6 · (MW 372.50) (*cis-anti-cis*)

[56468-35-0]

(complexation agent; promoter of halide reactions, carbon, oxygen, and sulfur anion reactions, eliminations, oxidations, and reductions)

Physical Data: mp 38-54 °C (mixture of isomers); *cis-syn-cis* isomer mp 61-62 °C; *cis-anti-cis* isomer (two forms) mp 69-70 °C and 83-84 °C. ^{1}H NMR: (mixture of isomers, C_6D_6) 3.3-4.0 ppm (20H multiplet) and 0.9-2.2 ppm (16H multiplet).

Form Supplied in: all isomers are colorless crystals.

Preparative Methods: a mixture of diastereomers is prepared in 58-69% yield by the hydrogenation of ***Dibenzo-18-crown-6*** in *n*-butanol over 5% ruthenium on alumina at 1000 psi.[1] This mixture has been separated into the *cis-syn-cis* and *cis-anti-cis* isomers.[2] Direct synthesis of the *trans-syn-trans* (mp 120-121 °C) and *trans-anti-trans* (mp 77-80 °C) isomers from *trans*-1,2-cyclohexanediol has been reported.[3,4]

Handling, Storage, and Precautions: toxic orally; eye and skin irritant, with possible permanent injury; absorbed by skin. Use in a fume hood.

Complexation With Metal Salts.

The cavity diameter of dicyclohexano-18-crown-6 is estimated to be 2.6-3.2 Å, which is ideal for complexing with a potassium cation, which has an ionic diameter of 2.66 Å. While the selectivity of dicyclohexano-18-crown-6 for potassium

salts is well documented, this macrocyclic multidentate ligand will also effectively complex with other alkali metal cations.[5]

Reactions.

Halides.

The ***Potassium Fluoride***/dicyclohexano-18-crown-6 promoted elimination reaction of *cis*-β-bromo-*p*-styrene in the solvents ***Acetonitrile***, ***N,N-Dimethylformamide***, and *n*-butyl cellosolve has been studied.[6]

The reaction of dimethyl 2-chloroethylene-1,1-dicarboxylate with potassium fluoride/dicyclohexano-18-crown-6 in sulfolane produces dimethyl 2-fluoroethylene-1,1-dicarboxylate.[7] Modest yields of dechlorodecarboxymethylation products promoted by potassium chloride/dicyclohexano-18-crown-6 in sulfolane have also been observed (eq 1).[7]

(1)

Dicyclohexano-18-crown-6 enhances the reactivity of potassium bromide and ***Potassium Iodide*** in nucleophilic substitution and elimination reactions.[8] Second-order kinetics are observed for the reaction of *n*-butyl brosylate with bromide and iodide ions in ***Acetone***. Potassium iodide/dicyclohexano-18-crown-6 complex acts as a base in aprotic solvents.[8] Reaction with 2-bromooctane in DMF at 100 °C for 6 h produced only 2-octene in 75-80% yield. In acetone the crown complex of potassium iodide gives a low yield of 2-octene; the major product is mesityl oxide from the condensation of acetone.

Dicyclohexano-18-crown-6 was used as a liquid-liquid phase transfer catalyst in the reaction of the mesylate of 1-octanol, 1-bromooctane, 1-iodooctane, and the mesylate of 2-octanol with a variety of sodium and potassium halides in the form of saturated aqueous solutions.[9] The relative nucleophilicity of the halides is $I^- > Br^- > Cl^- > F^-$; secondary substrates react more slowly than primary; excess iodide quantitatively displaces bromide. In general, dicyclohexano-18-crown-6 shows greater anion activation than ***Dibenzo-18-crown-6***.[10]

Oxygen Anions.

A wide variety of *p*-bromophenacyl esters have been synthesized by the reaction of potassium carboxylates with *p*-bromophenacyl bromide in acetonitrile or benzene in the presence of dicyclohexano-18-crown-6.[11-13] Sodium salts give excellent yields of product but the reaction times are longer.

Dicyclohexano-18-crown-6 activates potassium acetate more in its reaction with benzyl chloride than does ***18-Crown-6*** or dibenzo-18-crown-6.[14]

Sterically hindered esters of 2,4,6-trimethylbenzoic acid can be saponified with the ***Potassium Hydroxide***/dicyclohexano-18-crown-6 complex in aromatic hydrocarbons. The reaction proceeds by acyl-oxygen cleavage.[15] It was subsequently reported that using this procedure only 11% of the anions in toluene were hydroxide: the major species was methoxide ion.[16] Reaction of this solution with *o*-dichlorobenzene produced *o*-chloroanisole. The reaction was shown to be consistent with an addition-elimination aromatic nucleophilic substitution mechanism.

The rates of alkylation of potassium phenoxide with 1-bromobutane in dioxane in the presence of a series of linear and cyclic polyether additives have been compared.[17] Dicyclohexano-18-crown-6 is more effective than 18-crown-6 and dibenzo-18-crown-6.

The rates of reaction of ***Potassium t-Butoxide*** with 2-nitrofluorobenzene and 4-nitrofluorobenzene has been studied in the absence and presence of dicyclohexano-18-crown-6.[18] Upon addition of a molar equivalent of crown, the rate of reaction of 2-nitrofluorobenzene increased by a factor of 3, and that of 4-nitrofluorobenzene by a factor of 2000.[18]

The rates of reaction of a number of oxygen nucleophiles with *p*-nitrophenyl phosphinate and with *p*-nitrophenyl benzoate in toluene containing dicyclohexano-18-crown-6 have been reported. The anions studied include *t*-$BuOO^-K^+$, *t*-BuO^-K^+, *n*-$BuOO^-K^+$, and *p*-$MeC_6H_4O^-K^+$.[19]

Potassium Superoxide was successfully solubilized in ***Dimethyl Sulfoxide***, benzene, THF, and DMF containing dicyclohexano-18-crown-6.[20,21] Reaction with primary and secondary alkyl halides, tosylates, and mesylates was reported to produce reasonable yields of dialkyl peroxides.[21] Alcohol side products accompanied peroxide formation. Using (-)-(*R*)-2-octyl bromide it was demonstrated that the superoxide radical anion, as well as the intermediate alkyl peroxy anion, reacted with the alkyl halide with inversion of configuration.

Dicyclohexano-18-crown-6 is an effective phase transfer catalyst in the reactions of 4-chloromethyl-1,3-dioxolane with substituted mono- and dihydric phenols in the presence of metal hydroxide bases.[22]

Carbon Anions.

Dicyclohexano-18-crown-6 is used as a liquid-liquid phase-transfer catalyst in the reaction of ***Potassium Cyanide*** with 1-chlorooctane[10] and in the alkylation of phenylacetone with *n*-butyl bromide using 50% aqueous sodium hydroxide.[10] A series of kinetic studies involving the alkylation of sodio diethyl *n*-butylmalonate with *n*-butyl bromide in the solvents benzene and cyclohexane in the presence of varying concentrations of dicyclohexano-18-crown-6 has been reported.[23] In benzene solution containing only 0.036 M dicyclohexano-18-crown-6 the alkylation rate is equal to that observed in neat DMF. The addition of dicyclohexano-18-crown-6 to the alkali metal salts of ***Ethyl Acetoacetate*** in dioxane causes the destruction of ionic agglomerates and formation of monomeric ion pairs.[23] In the reaction of this enolate with ethyl tosylate a marked acceleration of rate is observed in the presence of the crown.[24]

The phase-transfer catalytic methylation of deoxybenzoin by ***Dimethyl Sulfate*** produces an oxygen-to-carbon alkylation ratio of approximately unity in the presence of dicyclohexano-18-crown-6.[25] Similar results were obtained with 18-crown-6.

Eliminations.

The effect of ionic association upon positional and geometrical orientation in base-promoted β-elimination processes from 2-butyl halides and *p*-toluenesulfonate systems in solvents of low polarity has been extensively explored.[24] The results of the reactions of 2-bromobutane and 2-butyl *p*-toluenesulfonate with a number of base-solvent systems to produce 1-butene and *cis*- and *trans*-2-butene in the presence and absence of dicyclohexano-18-crown-6 has been reported.[26]

The competition between *syn* and *anti* elimination in the reaction of *trans*-2-phenylcyclopentyl tosylate with potassium *t*-butoxide in *t*-butyl alcohol has been investigated.[24] The 1-phenylcyclopentene was produced by a *syn* elimination, while the 3-phenylcyclopentene was produced via an *anti* pathway. Using 0.1 M potassium *t*-butoxide, 89% *syn* elimination was realized; in the presence of an equivalent quantity of dicyclohexano-18-crown-6, however, the *syn* product was reduced to 30%.

Base association effects have been studied using conformationally mobile systems. The effect of dicyclohexano-18-crown-6 on the *syn* vs. *anti* elimination in the reaction of 4,4,7,7-tetramethylcyclodecyl bromide and tosylate,[27] chlorocyclodecane,[28] and 5-decyltosylate[29] has been reported.

The stereochemical course of reaction of *cis*- and *trans*-1-methoxy-d_3-2-*d*-acenaphthene with potassium *t*-butoxide is dependent on the nature of the counter cation.[30] The amount of *syn* elimination decreases in the order $Li^+ > K^+ > Cs^+ > NMe_4^+ > K^+$-crown. It is believed that the elimination mechanism proceeds through a carbanion intermediate.

The effect of dicyclohexano-18-crown-6 on the base-promoted *syn* and *anti* elimination pathways on the diastereomeric 1-deutero-2-fluoro-2-phenylthioethyl phenyl sulfone has been reported.[31] The bases used were potassium phenoxide in dioxane and sodium *t*-butoxide in benzene/*t*-butanol. With potassium phenoxide, in the absence of crown the *syn* elimination pathway dominates, while in the presence of crown the *anti* pathway becomes more important. The corresponding reaction with sodium *t*-butoxide shows little or no effect of crown on the stereochemical course of reaction.

Sulfur Anions.

Dicyclohexano-18-crown-6 serves as an efficient phase transfer catalyst in the reaction of thiophenoxide (see ***Thiophenol***) with 1-bromooctane under liquid-liquid phase-transfer catalytic conditions.[32]

Oxidations.

Dicyclohexano-18-crown-6 solubilizes ***Potassium Permanganate*** in benzene.[33] The solid complex was isolated but it was unstable and slowly decomposed to adipic acid. The solubilized permanganate provides a convenient, mild, and efficient oxidant for a wide variety of organic compounds, e.g. alkenes, alcohols, aldehydes, and alkyl aromatics.

The reaction of ***Potassium Chromate*** with primary alkyl halides in ***Hexamethylphosphoric Triamide*** containing dicyclohexano-18-crown-6 produces aldehydes in good yields.[34] The chromate functions both as a nucleophile and an oxidant.

Reductions.

Dicyclohexano-18-crown-6 has been employed as a liquid-liquid phase transfer catalyst in the reduction of 2-octanone in a benzene/aqueous ***Sodium Borohydride*** two-phase system.[10]

The solubilization of ***Potassium*** and cesium metals in THF and diethyl ether using dicyclohexano-18-crown-6 has been reported.[35] Metal concentrations of approximately 0.0001 M were obtained using 0.005 M solutions of crown. Solution of the metals in THF was carried out at rt, while solution of potassium in diethyl ether was conducted at -78 °C. At -78 °C the THF solutions were stable for days. Optical absorption spectra indicated that the major anionic species in the presence of the crown was the alkali metal anion, M^-.

The solubility enhancement of sodium and potassium metals in secondary amines and in straight and branched chain ethers in the presence of dicyclohexano-18-crown-6 has been studied.[36] The alkali metal anions Na^- and K^- were identified from optical spectra.

Related Reagents.

Dicyclohexyl(ethyl)amine

[7175-49-7] · $C_{14}H_{27}N$ · Dicyclohexyl(ethyl)amine · (MW 209.37)

(highly basic, nonnucleophilic amine; useful in alkylation of amines[3] and in dehydrohalogenations;[6] proton acceptor in esterifications[7])

Physical Data: bp 132-134.2 °C/10 mmHg; *d* 0.909 g cm^{-3}; fp 230 °C; absorbs CO_2 from the air.

Solubility: sol acetone, cyclohexane, 1,2-dichloroethane, dichloromethane.

Preparative Method: although commerically available in small quantities, the reagent can be conveniently prepared from dicyclohexylamine and diethyl sulfate.[1,2]

Alkylation of Amines.

Dicyclohexyl(ethyl)amine is an excellent hindered (Hünig's) base. Compatible alkylating agents include alkyl halides, dialkyl phosphates, and trialkyloxonium species.

Dialkylation of aniline with butyl bromide in the presence of dicyclohexyl(ethyl)amine proceeds in high yield (90-180 °C, 3 h, 97%).[3] Alkylation of amine hydrochlorides can be effected using this base and ***Dimethyl Sulfate***, as demonstrated in the final step of the total synthesis of (±)-terramycin.[4] The alkylation of 2-methylbenzimidazole with trialkyloxonium tetrafluoroborate in the presence of dicyclohexyl(ethyl)amine yields 1,3-dialkyl-2-methylbenzimidazolium tetrafluoroborates (0 °C, 70-90%).[5]

Dehydrohalogenation.

Dehydrohalogenation of alkyl halides proceeds in high yields in the presence of dicyclohexyl(ethyl)amine. *n*-Dodecyl bromide yields 1-dodecene (190 °C, 20 h, 98%). The reaction is applicable to the dehydrohalogenation of α-halo ethers to yield the corresponding enol ethers. Similar results can be obtained with other hindered amines, although yields are often inferior.[6]

Proton Acceptor.

Dicyclohexyl(ethyl)amine has been used as a proton acceptor, or proton sponge, in the preparation of esters of carboxylic acids. The reaction is applicable to the derivatization of low-melting fatty acids as their highly crystalline phenacyl bromides. Phenacyl esters are rapidly prepared in high yields (60 °C, 5 min, ~90%.[7] Similarly, methyl and ethyl esters of carboxylic acids can be prepared on micro or preparative scale by alkylation with a dialkyl sulfate: $EtCy_2N + ROS(O_2)OR$ (5 min, steam bath, 84-97%).[8] The procedure is particularly useful as an alternative to ***Diazomethane*** esterification when the latter is inappropriate. The present amine is advantageous over more commonly available alternatives, such as tris(hydroxypropyl)amine, in that it does not remove dimethyl sulfate as the quaternary ammonium salt, and hence can be used in excess. The proton scavenging ability of dicyclohexyl(ethyl)amine is also exploited in the Friedel-Crafts silylation of ferrocene, where it suppresses the protodesilylation reaction and hence allows maximal yields to be achieved (80 °C, 4 h, 36%).[9]

Acylation of alkenes by acetyl hexachloroantimonate yields β,γ-unsaturated ketones. As a buildup of acid is detrimental to the outcome of the reaction, a proton scavenger is necessary. The present amine maximizes yield of the desired product (-50 °C to -25 °C, 1 h, 83%).[10]

Arylated alkenes can be obtained, in good yield, by reaction of aroyl chlorides with activated alkenes in the presence of a hindered amine, such as dicyclohexyl(ethyl)amine, and a catalytic quantity of ***Palladium(II) Acetate***.[11]

Dicyclohexyl(ethyl)amine favors the organopalladium arylation of allylic alcohols by suppressing the formation of halides from the allylic alcohols and hydrogen chloride generated during the course of the reaction.[12] Similar effects are observed in the arylation of crotyl acetate.[13] Yields are in any case modest.

Alkoxycarbonylation.

Alkoxycarbonylation of alkyl halides, sulfates, and sulfonates can be carried out, in modest yields, in the presence of ***Carbon Monoxide***, an alcohol, a hindered base such as dicyclohexyl(ethyl)amine, and a catalytic quantity of ***Sodium Tetracarbonylcobaltate*** (50 °C, 1 atm, 16-20 h, 20-56%).[14] More

nucleophilic bases yield instead the corresponding amides by competitive nucleophilic attack.

Similarly, reaction of trimethylene oxide, carbon monoxide, and tetracarbonylhydridocobalt followed by treatment with dicyclohexyl(ethyl)amine yields γ-butyrolactone (0 °C, 3 h).[15]

Related Reagents.

Diisopropylethylamine; ***2,6-Lutidine***; ***Triethylamine***.

N,N´-Dicyclohexyl-4-morpholinecarboximidamide

[4975-73-9] · $C_{17}H_{31}N_3O$ · *N,N´*-Dicyclohexyl-4-morpholinecarboximidamide · (MW 293.45)

(strong base; used as a catalyst for phosphorylation reactions in nucleoside chemistry)

Alternate Names: N,N´-dicyclohexyl-4-morpholineformamidine; DMC.

Physical Data: mp 105.5 °C.

Solubility: sol pyridine.

Form Supplied in: white powder.

Preparative Methods: easily prepared by refluxing morpholine and ***1,3-Dicyclohexylcarbodiimide***.[1]

Phosphorylating Reagent.

DMC is a strong base that acts as a catalyst for phosphorylating reactions. It can be used to increase the solubility of salts of nucleoside 5´-phosphoromorpholidates, and to catalyze their cyclization to cyclic 3´,5´-nucleoside phosphates in the presence of DCC (eq 1).[2]

Reaction of DMC salts of nucleoside 5´-phosphoromorpholidates with phosphomonoesters gives nucleoside diphosphate derivatives.[3] Similar reactions have been used for the synthesis of neosamine *C*-nucleoside diphosphates (eq 2).[4]

Preliminary formation of a morpholidate is not a necessary requirement and cyclization to 3´,5´-monophosphate derivatives is possible from DMC salts of the corresponding 5´-monophosphate. Ring closure is obtained by action of DCC in dry pyridine (eq 3).[5]

Catalyst for Acylation Reactions in Nucleoside Chemistry.

DMC catalyzes acylation of nucleosides by carboxylic anhydrides. As an example, reaction with succinic anhydride

gives a mixture of isomers but refined conditions have been described to yield N^6-succinyl adenosine (eq 4).[6]

DMC allows simultaneous 2-hydroxybenzylation and phosphorylation when used together with methylthio-4*H*-1,2,3-benzodioxaphosphorin 2-oxide (MTBO) (eq 5).[7]

10-Dicyclohexylsulfonamidoisoborneol[1]

(1*S*)-*exo*; R = cyclohexyl

[96303-88-7] · $C_{22}H_{39}NO_3S$ · 10-Dicyclohexylsulfonamidoisoborneol · (MW 397.69) (1*S*)-*exo*; R = isopropyl

[89156-11-6] · $C_{16}H_{31}NO_3S$ · 10-Diisopropylsulfonamidoisoborneol · (MW 317.55)

(chiral auxiliary: enoate derivatives undergo stereoselective Diels-Alder[2,3] and 1,3-dipolar[3] cycloadditions and 1,4-cuprate additions;[4] enol ether derivatives undergo stereoselective [2 + 2] cycloadditions with dichloroketene;[5] ester enolate derivatives participate in stereoselective imine condensation,[6] alkylation,[4a] aldolization,[7] acetoxylation,[8] halogenation,[9] and amination[10] reactions)

Physical Data: R = cyclohexyl: mp (from hexane) 163-164 °C; [α]21D -25.7 (*c* = 0.76, EtOH). R = isopropyl: mp (from hexane) 102-103 °C; [α]21D -34.4 (*c* = 4.74, EtOH).

Form Supplied in: white crystalline solids.

Preparative Methods: crystalline, enantiomerically pure 10-diisopropyl- and 10-dicyclohexylsulfonamidoisoborneol auxiliaries are readily prepared from the appropriate enantiomer of ***10-Camphorsulfonyl Chloride*** by successive amidation and *exo* selective reduction (eq 1).[2]

Simple acyl derivatives are prepared in good yields from carboxylic acids using Mukaiyama's ***2-Chloro-1-methylpyridinium Iodide*** coupling reagent[2] or from carboxylic acid chlorides using ***Silver(I) Cyanide***.[9a] The former method is also suitable for the preparation of enoyl derivatives, although a Horner-Wadsworth-Emmons reaction has also been employed for this purpose.[4b] The *cis*-propenyl enol ether derivative of 10-diisopropylsulfonamidoisoborneol was prepared by base-promoted isomerization of the corresponding allyl ether (the preparation of which was not described).[5]

Handling, Storage, and Precautions: these reagents are stable indefinitely at ambient temperature in sealed containers.

Introduction.

The 10-dialkylsulfonamidoisoborneol auxiliaries exert a powerful topological bias over the π-facial reactivity of enoate, enol ether, and ester enolate derivatives in a wide range of asymmetric transformations. However, the subsequently developed ***10,2-Camphorsultam*** chiral auxiliary outperforms these auxiliaries both in terms of stereoinduction and ease of nondestructive cleavage for most applications. Consequently, only transformations for which the 10-dialkylsulfonamidoisoborneol auxiliaries are particularly advantageous, or for which the analogous transformations of the 10,2-camphorsultam have not been reported, are described here. It should be noted, however, that the origin of the stereoinduction provided by these two camphor-derived auxiliaries is fundamentally different;[1] hence key references for all transformations are provided above.

Reactions of Enoate, Enol Ether, and Acyl Derivatives.

1,4-Organocopper Addition (Alkene to β-Functionalized Product).[4]

Tri-*n*-butylphosphine-stabilized organocopper reagents add in a conjugate fashion to *trans*-enoate derivatives of the 10-dicyclohexylsulfonamidoisoborneol auxiliary from the less hindered C(α)-*si* π-face with excellent selectivity (eq 2) (Table 1). This type of reaction has formed the basis of several natural product syntheses.[4]

Table 1 Conjugate Addition of Organocopper Reagents (**2**) ® (**3**)

R^1	R^2	Yield (%)	de (%)
Bu	Me	93	97
Me	Bu	89	97

[2 + 2] Dichloroketene Addition (Enol Ether to β-Alkoxy-α-dichlorocyclobutanone).[5]

Of six different chiral auxiliaries screened for their ability to control stereochemistry in the reaction of dichloroketene with derived *cis*-propenyl enol ethers, the 10-diisopropylsulfonamidoisoborneol auxiliary was the best. Thus, following ring expansion of the initially formed cyclobutanone (**4**) with ***Diazomethane-Chromium(II) Perchlorate***, α-chloro-γ-methylcyclopentenone was isolated in ~60% yield and 80% ee [C(α)-*si* face attack of the ketene] (eq 3). The auxiliary was also recovered in unspecified yield.

(3)

(4)
80% de
(major isomer shown)

Imine Condensation (Acyl Species to β-Lactam).[6]

Lithium enolates of acyl 10-diisopropylsulfonamidoisoborneols condense with *N*-aryl aldimines to give *cis*-disubstituted β-lactams with 56-92% ee, accompanied by 2.5-9% of their *trans* isomers (in undetermined ee) (eq 4) (the key step in a synthesis of the carbapenem antibiotic (+)-PS-5). Menthol was found to be a less efficient auxiliary for this application.[6]

(4)

79% (FC), 91% ee
(+ recovered auxiliary 95%)

α-Acetoxylation and α-Halogenation (Acyl Species to α-Acetoxy or α-Halo Acyl Product).[8,9]

α-Acetoxylations of *O*-silyl enol ether derivatives of acyl 10-dicyclohexylsulfonamidoisoborneols with ***Lead(IV) Acetate*** proceed in high yield with excellent π-facial stereocontrol (95-100% de, with C(α)-*re* topicity).[8] Mechanistically related α-halogenations with *N*-halosuccinimides also proceed smoothly to afford α-halo acyl products in 76-96% de, but with C(α)-*si* topicity.[9] The observed topicities are consistent with initial attack of the electrophilic species from the less hindered C(α)-*si* face to give transient plumbonium/bromonium/chloronium ions. The plumbonium intermediates undergo S_N2-type attack by acetate at the β-position, whereas the bromonium/chloronium intermediates fragment with retention at C(β).[9a] The stereofacial influence of the auxiliary overrides any preexisting β-stereocenter. Hence, consecutive alkylcopper conjugate addition, then α-acetoxylation or α-bromination, allows the concise and stereocontrolled formation of two contiguous

stereocenters. α-Acetoxy ester derivative (**6**) formed in this way is a precursor to a key intermediate for the synthesis of the elm bark beetle pheromone (eq 5), and α-bromo ester derivative (**7**) was converted via azide displacement, trans-esterification, and hydrogenolysis into L-*allo*-isoleucine (eq 6).[9b] α-Halo esters are also useful precursors of enantiomerically pure epoxides.[9a]

α-Amination (Acyl Species to α-Amino Acyl Product).[10]

Although asymmetric bromination and stereospecific azide displacement of *O*-silyl enol ethers of acyl 10-dicyclohexylsulfonamidoisoborneols (as described above) is a generally applicable route to optically active α-amino acids,[9b] a complementary and more direct approach to this important class of compounds is via electrophilic amination of these same compounds using ***Di-t-butyl Azodicarboxylate*** (DBAD). The initially formed α-(di-*N*-Boc-hydrazido)amino acid derivatives (**8**) (eq 7) may be efficiently converted to the corresponding α-amino acid hydrochlorides by successive deacylation, hydrogenolysis, transesterification, and hydrolysis. This reaction sequence has been shown to be efficient for the preparation of a wide range of α-amino acids in excellent enantiomeric purity[10] and compares favorably with closely related methods using alternative auxiliaries.[11]

Nondestructive Auxiliary Cleavage.

The hindered ester linkage present in acyl derivatives of 10-dialkylsulfonamidoisoborneols is less readily cleaved than the corresponding sulfonamidic linkage of *N*-acyl-10,2-camphorsultam derivatives. However, it can be hydrolyzed and the auxiliary recovered intact under basic conditions using ***Potassium Hydroxide***[7] or ***Potassium Carbonate***[8] in MeOH, ***Sodium Hydroxide*** in aq EtOH,[4a] or ***Lithium Hydroxide*** in aq THF. Elevated temperatures are required to achieve acceptable reaction rates for all but the latter procedure which, although sluggish at ambient temperature, was employed for unmasking sensitive aldol products.[7] Nonbasic transesterification using $Ti(OBn)_4$/BnOH affords benzyl esters which may be subject to hydrogenolysis to give the corresponding carboxylic acids.[9b] Alternatively, transesterification with $Ti(OEt)_4$/EtOH[10b] may be followed by hydrolysis under acidic conditions.[10]

Primary alcohols can be obtained by hydride reduction using either ***Lithium Aluminum Hydride*** in ether[2,8] or $Ca(BH_4)_2$ in THF,[9a] and this latter reagent is compatible with halogen functionality. A dimethyl tertiary alcohol was obtained by addition of 2 equiv of methyllithium in ether.[4b]

Related Reagents.

α-***Methyltoluene-2,α-sultam***.

Dicyclopentylboryl Trifluoromethanesulfonate

[72251-50-4] · $C_{11}H_{18}BF_3O_3S$ · Dicyclopentylboryl Trifluoromethanesulfonate · (MW 298.13)

(Lewis acid for the preparation of vinyloxyboranes[1-4])

Alternate Name: dicyclopentylboryl triflate.

Physical Data: colorless liquid, bp 70-72 °C/1.0 mmHg.

Solubility: sol common inert organic solvents such as Et_2O, CH_2Cl_2, and hexane.

Form Supplied in: 0.5 M solution in CH_2Cl_2.

Preparative Method: ***Trifluoromethanesulfonic Acid*** is added dropwise to an equimolar amount of tricyclopentylborane, with intermittent cooling to maintain the reaction temperature at approximately rt. Upon completion of the addition the reaction is stirred at rt for an additional 30 min followed by isolation of the product by vacuum distillation.[2b]

Handling, Storage, and Precautions: the neat liquid as well as solutions are moisture and air sensitive. Therefore the material should be stored and transferred under a dry inert atmosphere.

Vinyloxyborane Enolates.

Dicyclopentyl vinyloxyboranes are conveniently prepared from active methylene carbonyl compounds utilizing $(c\text{-}C_5H_9)_2BOTf$ in combination with a sterically hindered amine base. Typically the base, ***Diisopropylethylamine*** or ***2,6-Lutidine*** (2,6-lut), and reagent are premixed in Et_2O or CH_2Cl_2 at -78 °C to 0 °C and then the carbonyl component is

added. Enolate generation is allowed to occur over the next 15-30 min, resulting in the formation of vinyloxyboranes which are suitable nucleophiles for reaction with aldehydes in a crossed aldol reaction. Other boryl triflate reagents have been shown to have similar or complementary utility in this process (see ***9-Borabicyclononyl Trifluoromethanesulfonate*** (9-BBNOTf) and ***Di-n-butylboryl Trifluoromethanesulfonate*** (Bu_2BOTf)).

The relative stereochemistry of the two new chiral centers formed in the aldol product is a direct consequence of the vinyloxyborane enolate geometry with *Z*(O) enolates affording the 2,3-*syn* aldol products and the *E*(O) vinyloxyboranes leading to the 2,3-*anti* isomers. Consequently, a number of studies have examined the effects of various boryl triflates and amines on the ratio of kinetic enolates formed. In general, it has been found that with a given base, the more sterically hindered boryl triflates increase the selectivity for the formation of the *E*(O) enolate. For example, when the vinyloxyboranes of ethyl cyclohexyl ketone are generated with $(c\text{-}C_5H_9)_2BOTf$ or 9-BBNOTf in the presence of $i\text{-}Pr_2NEt$, reaction of the resulting enolates with benzaldehyde results in a ratio of crossed aldol products which varies dramatically. As shown in eq 1, the enolate derived from $(c\text{-}C_5H_9)_2BOTf$ yields a preponderance of the 2,3-*anti* aldol product while that from 9-BBNOTf produces almost exclusively the 2,3-*syn* isomer.[1]

The propionate synthon *S*-*t*-butyl propanethioate upon reaction with $(c\text{-}C_5H_9)_2BOTf$ and $i\text{-}Pr_2NEt$ yields selectively the *E*(O) vinyloxyborane. Condensation of this enolate with various aldehydes affords the crossed aldol products, with the 2,3-*anti* diastereomer predominating (eq 2).[2] This combination of enolate substrate and reactants complements the results obtained from *S*-phenyl propanethioate, 9-BBNOTf, and $i\text{-}Pr_2NEt$ in which the 2,3-*syn* aldol product predominates (see ***9-Borabicyclononyl Trifluoromethanesulfonate***). Other functionality is also well tolerated on the thioester enolates. For example, the *E*(O) enolate derived from *t*-butyl α-bromothioacetate has been utilized in a Darzens-like condensation that selectively yields the *trans*-substituted epoxides (eq 3).[3] This procedure complements the synthesis of *cis*-substituted epoxide derivatives which are produced via aldol reactions of the *Z*(O) vinyloxyborane derived from a bromoacetyl oxazolidinone (see ***Di-n-butylboryl Trifluoromethanesulfonate***).

Probably the greatest utility of this reagent has been in the stereoselective formation of chiral vinyloxyboranes with defined enolate geometries from which the absolute stereochemistry of the new chiral centers formed in the aldol process are controlled. A number of chiral masked propionate equivalents useful for the synthesis of polypropionate-like natural products have been developed for this purpose. Chiral α-hydroxy ethyl ketones derived from both enantiomers of hexahydromandelic acid are such reagents and have been shown to form the *Z*(O) vinyloxyborane stereospecfically with 9-BBNOTf, Bu_2BOTf, and $(c\text{-}C_5H_9)_2BOTf$. However, the size of the ligands attached to boron does have a measurable effect upon the extent of the enantioselectivity achieved in the aldol process, as exemplified in (eq 4).[4]

1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene[1]

[90054-58-3] · $C_{12}H_{28}O_4Si_2$ · 1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene · (MW 292.52)

(synthetic equivalent of the acyl anion $^-C(O)CO_2Et$; useful in $ZnCl_2$-mediated nucleophilic additions to aldehydes and ketones,[1] Michael additions to enones,[1] and substitution reactions of S_N1-active alkyl halides[1] and carboxylic acid chlorides[2])

Physical Data: bp 68-70 °C/5 mmHg.

Solubility: sol CH_2Cl_2, toluene, THF.

Preparative Method: can be prepared in one step from ***Diethyl Oxalate*** using the Rühlmann version[2] of the acyloin condensation (eq 1).[3] Although a yield of 64% of isolated product was reported,[3] this could not be reproduced in a careful series of experiments.[1,4] Rather, yields of 21-25% are consistently obtained (0.1-1.0 molar scale).[1,4] The product consists of a (*Z*/*E*) isomeric mixture which is of no consequence for synthetic applications.

Handling, Storage, and Precautions: somewhat air and moisture sensitive and should therefore be handled and stored under an atmosphere of an inert gas such as N_2 and in nonprotic solvents. Use in a fume hood.

Reactions Forming Carbon-Carbon Bonds.

The reagent described herein has the structural features of an *O*-silyl ketene acetal, and it therefore undergoes the typical reactions known for this class of compounds, especially Lewis acid-mediated C-C bond-forming processes.[5] Since the reagent is extremely electron rich[6] and therefore very reactive, catalytic amounts of mild Lewis acids such as

ZnX_2 suffice.[1,4] The nucleophile which reacts with electrophilic organic substrates is a special case of an acyl anion equivalent (synthon) (**1**).

(1)

Group transfer-type[7] of Mukaiyama aldol addition[8] to aldehydes or ketones affords the isolable *O*-silylated aldol adducts, which can be hydrolyzed under acidic conditions to provide α-keto esters in high yield (eq 2).[1] In the case of aldehydes the initial products are *O*-silyl-protected reductones.[1]

(2)

Group transfer-type of Michael additions to α,β-enones are just as smooth, with acidic workup affording α,δ-diketo esters (eq 3).[1,4]

(3)

S_N1-active alkyl halides require longer reaction times (typically 3-6 h),[1,4] and the yields are lower. *t*-Butyl chloride and adamantyl bromide have been used successfully, but the generality of the procedure needs to be demonstrated (eq 4). In contrast, acylation reactions using a wide variety of carboxylic acid chlorides have been carried out (eq 5).[9,10] The initial products are protected forms of α,β-diketo esters which can be isolated in yields of 72-93%. Deprotection is accomplished using MeOH/HCl.[9,10] The products are vicinal tricarbonyl compounds having the usual characteristic chemical properties such as rapid formation of hydrated derivatives.[11] The protected forms can be used directly in the synthesis of heterocycles.[9,10]

(4)

(5)

R = Me, 72%; R = Ph, 82%;
R = *o*-Me-C_6H_4, 91%;
R = *i*-Pr, 93%; R = *t*-Bu, 88%

In summary, the title compound, readily available from diethyl oxalate, is a synthetically useful synthon in various C-C bond-forming reactions, requiring only catalytic amounts of mild Lewis acids such as ***Zinc Chloride***. Alternatives to such an acyl anion equivalent include dithiane derivatives of glyoxylic acid esters, which have not been tested as widely and which require some synthetic effort in the final deprotection step.[12]

Diethoxymethyl Acetate[1]

[14036-06-7] · $C_7H_{14}O_4$ · Diethoxymethyl Acetate · (MW 162.19)

(reactive orthoformic acid derivative in which the acetate group can be easily substituted by a variety of nucleophiles, e.g. alkoxy, amino, thiolo, and carbon nucleophiles[1])

Alternate Name: DEMA.

Physical Data: mp 27 °C; bp 70 °C/15 mmHg; *d* 0.993 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: colorless liquid or solid of 99% purity; widely available.

Preparative Method: best prepared from triethyl orthoformate and formic acid/acetic anhydride.[2]

Handling, Storage, and Precautions: the compound is sensitive to moisture and should be handled and stored under dry conditions. At temperatures above 120 °C it decomposes into ethyl acetate and ethyl formate.

DEMA is often used as a more reactive alternative for ***Triethyl Orthoformate***. In contrast to the latter it reacts under neutral or basic conditions with nucleophiles due to the better leaving ability of the acetoxy group compared to the ethoxy group. The acetate group can be easily exchanged for other carboxylic groups, leading to different diethoxymethyl esters.[2] Reactions with alcohols or thiols under basic conditions yield mixed orthoformates (eq 1).[1,3]

(1)

Preparation of the same compounds from triethyl orthoformate needs acid catalysis, which also leads to disproportionation of the formed mixed orthoester. The high reactivity of DEMA with amines is used in the synthesis of heterocyclic ring systems, e.g. formation of purines from vicinal diamines (eq 2).[4]

(2)

Analogous results have been reported for the synthesis of pyrimidines.[5] In the older literature, mixtures of triethyl orthoformate and acetic anhydride have been used, from which DEMA is supposed to be formed in situ.[1] The same holds for the reaction of acidic methynes with DEMA or triethyl orthoformate/acetic anhydride, leading to acetals or enol ethers (eq 3).

(3)

The advantages of the in situ procedures over pure DEMA have not been systematically investigated. The applicability of DEMA in the synthesis of acetals from the reaction with Grignard reagents has been demonstrated,[6] and the results compared with those of the related reagent ***Diethyl Phenyl Orthoformate***. It has been demonstrated that, prepared in this way, α-stannyl acetals (eq 4) are useful synthons in further synthesis.

(4)

DEMA has also been used for the introduction of an acetoxy group in the synthesis of the related reagent 2-acetoxy-1,3-dioxolane (eq 5).[7]

(5)

Diethoxymethyl formate, which is easily prepared from DEMA,[2] has been used in one of the first syntheses of formic anhydride.[8]

Related Reagents.

Acetic Anhydride; ***Acetic Formic Anhydride***; ***Diethyl Phenyl Orthoformate***; ***N,N-Dimethylformamide Diethyl Acetal***; ***Triethyl Orthoformate***.

(Diethoxymethyl)diphenylphosphine Oxide

[20570-20-1] · $C_{17}H_{21}O_3P$ · (Diethoxymethyl)diphenylphosphine Oxide · (MW 304.32)

(readily accessible Horner-Wittig reagent for the conversion of aldehydes and ketones into homologous *O,O*-ketene acetals[1])

Physical Data: mp 77-79 °C; NMR: ^{31}P δ -25.5 ppm (H_3PO_4 = 0 ppm); ^{13}C δ(CH) 104.7 ppm; ^{1}H δ(CH) 4.98 ppm.

Solubility: sol benzene, THF, and ether.

Analysis of Reagent Purity: ^{31}P NMR; mp.

Preparative Method: the reagent (**1**) can be conveniently prepared by reaction of ***Chlorodiphenylphosphine*** with ***Triethyl Orthoformate***.[2] Adduct (**2**) is formed in a fast, exothermic, step. Upon heating, an Arbuzov reaction occurs to give the phosphine oxide (eq 1). Other *O,O*-acetals of formyldiphenylphosphine oxide can be prepared equally well.[2]

The usual procedure is for chlorodiphenylphosphine (88.2 g, 0.4 mol) to be added dropwise to triethyl orthoformate (59.3 g, 0.4 mol) over a period of 45 min. Subsequent heating of the reaction mixture (2 h, 110 °C) leads to formation of 24 g (93% of theory) of ethyl chloride. Upon cooling, a practically quantitative yield of (**1**) is obtained, mp 74-77 °C. Addition of some solvent, when (**1**) starts precipitating, avoids the formation of a solid cake that is hard to remove from the reaction flask. Crystallization from benzene/petroleum ether (80-110) affords the pure phosphine oxide.

Handling, Storage, and Precautions: infinitely stable at rt. It should be protected from moisture.

Synthesis of Ketene *O,O*-Diethyl Acetals.

Aldehydes and ketones, aliphatic as well as aromatic and α,β-unsaturated, can be converted into their homologous ketene *O,O*-diethyl acetals by Horner-Wittig reaction with the anion of (**1**).[1,3] This conversion represents a considerable improvement over existing methods.[4] The metalation of (**1**) with ***Lithium Diisopropylamide*** as well as subsequent reactions of the anion should be carried out at below -90 °C as the anion is unstable at higher temperatures. Best results are obtained if the intermediate adducts (**3**) are isolated and subsequently treated with a potassium base to bring the Horner-Wittig reaction to completion (eq 2). By applying a water-free workup procedure, the ketene *O,O*-diethyl acetals (**4**) are obtained in the yields listed in Table 1. Also included in this table are some characteristic ^{13}C and, where applicable, ^{1}H NMR data of the ketene acetals. These products are sufficiently pure for most applications. Analytically pure ketene acetals can be obtained by distillation, but only at appreciable loss of product.

[a] Short-path distillation.

In contrast to ketene *S*,*S*- and *S*,*O*-acetals,[5] the possibilities to prepare ketene *O*,*O*-acetals by Horner-Wittig or Peterson alkenation reactions appear to be restricted to phosphine oxides. Attempts to lithiate the corresponding phosphonates failed.[5] Horner-Wittig synthesis of ketene *O*,*O*-acetals is not restricted to the diethoxy compounds (**4**). Other (dialkoxymethyl)phosphine oxides perform equally well. The use of phosphine oxide (**5**), prepared in analogy to (**1**) from 2-ethoxy-5,5-dimethyl-1,3-dioxane,[2] can be especially advantageous because the corresponding ketene acetals have higher melting points. The reported examples (corresponding to entries 1, 10 and 13 in Table 1) are solids that can be conveniently purified by crystallization.[1]

(5)

General Procedure.

To a solution of (**1**) (3.04 g, 10 mmol) in 200 mL of THF/diethyl ether (3:1), cooled to -100 °C, is added a solution of LDA (1.17 g, 11 mmol) in 25 mL of THF.[1,3] After stirring for 1 min, a solution of 10 mmol of the carbonyl compound in 25 mL of THF is added to the deeply colored solution at such a rate that the temperature of the reaction mixture is kept at all times below -90 °C. After stirring for an additional 5 min at this temperature, the mixture is quenched by the addition of 40 mL of water. After warming to rt, solid ***Potassium Carbonate*** is added and the organic layer is separated and dried. Evaporation of the solvents at reduced pressure affords the adducts (**3**) in almost quantitative yields. To a solution of the adduct in 50 mL of THF, ***Potassium t-Butoxide*** (1.23 g, 11 mmol) in 50 mL of THF is added in one portion. After stirring for 1 h at rt, the solvent is removed at temperatures not exceeding 40 °C. The residue is taken up in 100 mL of hexane. After centrifugation, the solution is decanted. Upon evaporation of the solvent, the ketene acetal is obtained as a pale yellow oil.

(Diethoxyphosphoryl)difluoromethyllithium

[94993-99-4] · $C_5H_{10}F_2LiO_3P$ · (Diethoxyphosphoryl)difluoromethyllithium · (MW 194.04)

(useful for the introduction of $(EtO)_2P(O)CF_2$ and $=CF_2$ into organic compounds)

Preparative Methods: by the deprotonation of diethyl difluoromethylphosphonate with LDA at -78 °C,[1] or generated in situ from diethyl bromodifluoromethylphosphonate and BuLi.[2]

Reaction with Carbonyl Compounds.

Deprotonation of diethyl difluoromethylphosphonate with ***Lithium Diisopropylamide*** at -78 °C gives the carbanion of diethyl difluoromethylphosphonate, which is only stable at or below -78 °C.[1] Reaction of the carbanion of diethyl difluoromethylphosphonate with aldehydes and ketones at -78 °C followed by decomposition (heating THF solution) of the intermediate forms the corresponding 1,1-difluoroalkenes.[1,3] The intermediate could be trapped by electrophiles, such as proton[1,4] and acid chlorides,[5] to form the corresponding phosphonates (eq 1).

(1)

Reaction with Alkyl and Allyl Halides, and Alkyl Triflates.

The carbanion of diethyl difluoromethylphosphonate also reacts with alkyl halides,[1,6-8] alkyl triflates,[9] oxalate,[10] and allyl bromide[1] to form the corresponding 1,1-difluoro phosphonates (eq 2).

(2)

R = alkyl, allyl; X = I, Br, Tf

Reaction with Other Electrophiles.

The carbanion of diethyl difluoromethylphosphonate can be trapped with ***Chlorotrimethylsilane*** or trialkylchlorostannane to produce the corresponding trimethylsilylated and trialkyltin-substituted 1,1-difluoro phosphonates (eq 3).[1]

(3)

R = alkyl; M = Si, Sn

The carbanion also reacts with diethyl chlorophosphate or benzoyl chloride to give the corresponding α,α-difluoro bisphosphonate and β-ketophosphonate, respectively (eq 4).[1,11,12] Treatment of the carbanion of diethyl difluoromethylphosphonate with ***Carbon Dioxide*** at -78 °C leads to the formation of the carboxylic acid. The thiocarboxylic acid was formed by a similar reaction of the carbanion with ***Carbon Oxysulfide*** (eq 5).[13] The carbanion reacts in a 1,4-addition with 4-chloro-β-nitrostyrene to give the nitro phosphonate (eq 6).[14]

(4)

[113847-95-3] · $C_6H_{12}NO_4P$ · (Diethoxyphosphoryl)acetonitrile Oxide · (MW 193.14)

(nitrile oxide bearing an additional functionality)

Preparative Method: the reagent is a highly reactive intermediate and cannot be isolated. It is generated in situ from (diethoxyphosphoryl)acetaldehyde oxime[1] by bromination with ***N-Bromosuccinimide*** and elimination with ***Triethylamine***,[2] and used in synthesis by trapping with a coexisting dipolarophilic reagent.

Handling, Storage, and Precautions: Use in a well ventilated fume hood.

3-Acylisoxazoline Synthesis.

(Diethoxyphosphoryl)acetonitrile oxide, like other nitrile oxides, undergoes exclusive regioselective cycloadditions to monosubstituted alkenes to give 5-substituted 3-(phosphorylmethyl)isoxazolines which can be regioselectively lithiated with ***Lithium Diisopropylamide*** at the side chain and then alkylated in good yields (eq 1).[2,3] The alkylated products can be further lithiated with ***n-Butyllithium***. Air oxidation of the lithiated intermediates gives 3-acylisoxazolines in good yields. Horner-Emmons alkenations of the lithiated 3-phosphorylmethylisoxazolines and alkylated derivatives offer a convenient synthetic route to 3-[(*E*)-1-alkenyl)]isoxazolines.[3]

Furanone Synthesis.

Cycloaddition reactions of (diethoxyphosphoryl)acetonitrile oxide with unprotected propargylic alcohols proceed smoothly to give 5-(1-hydroxyalkyl)isoxazoles. The adduct to 1-methyl-3-butyn-2-ol is then lithiated with butyllithium at the side chain (-78 °C, THF), alkylated with ***Iodomethane*** (-78 °C, 94%), and finally reduced with ***Raney Nickel*** to cause a cleavage of the nitrogen-oxygen bond (W-2, ethanol, AcOH, rt) to give 5-(phosphorylmethyl)-3(2*H*)-furanones (eq 2).[4] These compounds are useful for the synthesis of 5-[1-(*E*)-alkenyl]-3(2*H*)-furanone derivatives through a Horner-Emmons alkenation procedure. One application has been shown by the effective synthesis of geiparvarin (eq 2).[4]

Furan Synthesis.

Cycloadditions of (diethoxyphosphoryl)acetonitrile oxide to THP-protected allylic alcohols followed by alkylation of the phosphorus-stabilized anion produces 5-(1-hydroxyalkyl)isoxazolines. These can be reductively cleaved and aromatized (sodium acetate in AcOH) to give 2-(1-phosphoryl)alkylfurans (eq 3) whose Horner-Emmons alkenations lead to 2-[1-(*E*)-alkenyl)furan derivatives.[5]

Synthetic applications to 2-hydroxy-4-oxo-5-alkenoates,[6] 5-[(*E*)-1-alkenyl]-3-hydroxy-4,5-dihydro-2(3*H*)-furanones,[6] (*Z*)-5-alkylidene-2(5*H*)-furanones,[6] and (*E*)-4-oxo-5-alkenoates[7] have also been reported.

3,3-Diethoxy-1-propene[1]

[3054-95-3] · $C_7H_{14}O_2$ · 3,3-Diethoxy-1-propene · (MW 130.19)

(reagent for ethoxyallylation of activated carbonyl compounds;[2,3] forms enol ethers with organocopper reagents;[4-6] acrolein equivalent for ionic Diels-Alder reaction;[7] precursor for ethoxyallyl cation;[7] acrolein synthon for Heck coupling with halides[8,9])

Alternate Name: acrolein diethyl acetal.

Physical Data: bp 125 °C; *d* 0.862 g cm^{-3}.

Solubility: slightly sol water; very sol ethanol and ether.

Form Supplied in: clear liquid, 95% pure; widely available.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 1.20 (t, 6H, *J* = 7 Hz), 3.5 (m, 2H), 3.6 (m, 2H), 4.85 (d, 1H, *J* = 2 Hz), 5.26 (d, 1H, *J* = 7 Hz), 5.38 (d, 1H, *J* = 11 Hz), 5.85 (m, 1H).

Purification: generally used as supplied; can be purified by distillation at atmospheric pressure from anhydrous sodium carbonate.

Handling, Storage, and Precautions: store under nitrogen.

Introduction.

The extreme reactivity of acrolein, which often results in extensive polymerization under many reaction conditions, is moderated by an acetal function in 3,3-diethoxy-1-propene (**1**) and thus (**1**) is a useful three-carbon reagent for many synthetic transformations.

Ethoxyallylation.

Thermal reaction of active methylene compounds with (**1**) furnishes ethoxyallyl products (eq 1).[2] In a detailed study it was found that the reaction was sluggish for the less acidic β-keto esters, but was effectively catalyzed by ***Nickel(II)***

Acetylacetonate (Ni(acac)$_2$) (eq 2).[3] The mechanism of this transformation is believed to involve a Claisen rearrangement of the initially formed mixed acetal; however, direct *C*-alkylation of the substrate at the γ-position of the ethoxyallyl cation is also possible.

Allylic Displacement.

Copper(I) Bromide catalyzed additions of Grignard reagents to (**1**) give mostly (*Z*)-enol ethers, which are hydrolyzed to the corresponding aldehyde by aq HCl (eq 3).[4] In a later study it was shown that the (*E*) isomers predominate if a Lewis acid-modified organocopper reagent is used,[5] and in another report a nickel(II) phosphine catalyst (NiCl$_2$(dppp)) gave only the (*E*) isomer.[6]

Ionic Diels-Alder Reaction.

The ethoxyallyl cation produced by ionization of (**1**) is a very potent dienophile which reacts with a variety of dienes below 0 °C to give Diels-Alder adducts (eq 4).[7] The yields of the addition products generally improved when a cyclic acetal (2-vinyl-1,3-dioxolane) was used.[7]

Heck Coupling.

The palladium-catalyzed (***Palladium(II) Acetate***, Pd(*o*-Tol)$_3$) coupling of (**1**) with aryl and vinyl halides in the presence of secondary amines such as piperidine and morpholine proceeds smoothly, in contrast to acrolein and other α,β-unsaturated aldehydes which tend to polymerize.[8,9] The reaction with vinyl halides furnishes a mixture of acetals and aminoacetals which are hydrolyzed to dienals by aqueous acid (eq 5).[8] However, with aryl halides the products are ethyl esters, probably arising from hydrolysis of the ketene acetal formed by elimination of the acetal hydrogen (eq 6).[9] With an isolated arylpalladium complex, formation of an aldehyde and its cyclization to a quinoline derivative are also reported.[10]

3,3-Diethoxy-1-propen-2-ylcopper

[57428-12-3] · $C_7H_{13}CuO_2$ · 3,3-Diethoxy-1-propen-2-ylcopper · (MW 192.72)

(reagent for the synthesis of α-methylene lactones;[1] 1,2-addition of the 2-substituted acrolein moiety;[2] 1,4-addition of the 2-substituted acrolein moiety[3])

Alternate Name: 1-(diethoxymethyl)vinylcopper.

Preparative Method: by reaction of 2-lithio-3,3-diethoxy-1-propene and copper iodide in THF at -55 °C.

Handling, Storage, and Precautions: sensitive to air and moisture; decomposes above -20 °C. Use in a fume hood.

The discovery of natural products containing the α-methylene lactone moiety stimulated the development of several 2-metallo acrylate and acrolein derivatives. Marino and Farina prepared 3,3-diethoxy-1-propen-2-ylcopper from the corresponding functionalized vinyl lithio reagent and 1 equiv of ***Copper(I) Iodide*** in THF at -55 °C and examined the reactivity of this reagent with cyclohexene monoepoxide.[1] The neutral copper reagent gave predominantly the *anti* 1,4-addition product in good yield. Formation of the homocuprate reagent from copper iodide using 2 equiv of the lithio anion gave a more reactive reagent that led to the *anti* 1,2-adduct as the major product. Mixed cuprates employing the nontransferable *t*-butylacetylene or cyano ligands were also prepared; the lower order cyanocuprate gave the lowest yields in the addition reaction, but was as selective for the 1,4-addition product as the neutral copper reagent (eq 1). The regioselectivity for 1,2-addition was enhanced using the homocuprate and carrying out the reaction in ether instead of THF. After hydrolysis of the acetal, the 1,2- and 1,4-adducts were stereospecifically converted to *trans*- or *cis*-α-methylene lactones, respectively, by oxidation to the acrylate and subsequent ring closure (eqs 2 and 3).

(1)

M	*n*	1,2:1,4	Yield (%)
Cu	1	0.6	71
Cu(Li)	2	1.5 (THF), 2.7 (Et_2O)	94
Cu(CC-*t*-Bu)	1	1.5	72
Cu(CN)Li	1	0.7	50

(2)

(3)

Grieco and co-workers also compared the reactivity of the 3,3-diethoxy-1-propen-2-ylcopper reagent and the thiophenoxy mixed cuprate in reactions with allyl halides (eq 4).[2] Both the neutral copper and cuprate reagents appeared to be specific for reaction with allylic halides and did not react with either benzyl bromide or 1-iodo-*trans*-oct-1-ene. Interestingly, the thiophenoxy mixed cuprate provided the 1,4-addition product with cyclohexenone (eq 5), while the neutral copper reagent resulted only in 1,2-addition to cyclohexenone (eq 6).

(4)

M = Cu, 85%
M = Cu(SPh)Li, 90%

(5)

(6)

The reactivity of the neutral copper reagent toward carbonyls was also employed by Roush and Peseckis in the synthesis of 2-substituted acrolein derivatives, which underwent intramolecular Diels-Alder reaction to provide angularly oxygenated perhydroindenes.[4] Boeckman and Ramaiah observed better results in 1,4-addition reactions using the *t*-butylalkynic mixed cuprate reagent.[3] Lower yields of 1,4-addition were observed in reactions with β-substituted cyclohexenones or sterically hindered enones such as 4-*t*-butylcyclohexenone. It was also indicated that 3,3-diethoxy-1-propenylcuprate reagents did not react with primary or secondary alkyl bromides, vinyl bromides, or iodides; the major product isolated in attempted alkylation reactions was the 1,4-diene resulting from oxidative dimerization.

Conjugate addition reactions of the homocuprate derived from 2-lithio-3,3-diethoxy-1-propene have been reported in the synthesis of (+)-hanegokedial (eq 7),[5] and in an approach to ciliarin (eq 8).[6] 1,4-Addition of the cuprate to the cycloheptenone derivative, with in situ trapping of the derived enolate with gaseous ***Formaldehyde***, led to the α,β-

dialkylated product in good yield. The 1,4-addition stereochemistry was controlled by the cyclopropyl substituent, while the alkylation of the enolate led to a mixture of isomers. In the approach to ciliarin, stereospecific conjugate addition to the unsaturated lactone was achieved using in situ ***Chlorotrimethylsilane***. The chemistry of 2-metallo acrylates[7] and β-substituted acrylates[8] has also been developed. These functionalized cuprates exhibit atypical cuprate reactivity, favoring 1,2- over 1,4-addition in reactions with enones; however, reactions with acid chlorides provide α,α´-dienyl ketones in good yield.[9]

3,3-Diethoxy-1-propyne

(R = H)

[10160-87-9] · $C_7H_{12}O_2$ · 3,3-Diethoxy-1-propyne · (MW 128.17) (R = Li)

[51756-42-4] · $C_7H_{11}LiO_2$ · 3,3-Diethoxy-1-propyne · (MW 134.10)

(intermediate for the synthesis of unsaturated and polyunsaturated compounds and numerous heterocycles[1])

Alternate Names: propiolaldehyde diethyl acetal; propargylaldehyde diethyl acetal.

Physical Data: bp 138-139.5 °C; *d* 0.894 g cm^{-3}.

Solubility: sol standard organic solvents.

Form Supplied in: colorless liquid; commercially available.

Analysis of Reagent Purity: IR: 3260, 2125 cm^{-1}; ^1H NMR ($CDCl_3$): δ 1.24 (t, *J* = 7, 6H), 2.58 (d, *J* = 2, 1H), 3.71 (q of d, *J* = 7, 2, 4H), 5.21 (d, *J* = 2, 1H).

Preparative Methods: the synthesis of this reagent can be accomplished according to eq 1. The dehydrobromination step can be carried out with ***Potassium Hydroxide*** in ethanol,[2] with ***Sodium Amide*** in liquid ammonia,[3] or by using ***Sodium Hydroxide*** in the presence of a phase transfer agent.[1a,4] 3,3-Diethoxy-1-propyne can also be prepared according to eq 2.[5]

The lithio derivative, named (3,3-diethoxy-1-propynyl)lithium, is easily prepared by reaction of 1 equiv of a saturated lithium compound (e.g. ***n-Butyllithium***) with a solution of the acetal in ether or THF.[6]

Purification: by distillation at reduced pressure, bp 95-96 °C/170 mmHg.[1a]

Handling, Storage, and Precautions: should be stored in a refrigerator and protected from moisture.

Alkylation Reactions.

Reaction of the lithio derivative with organic halides and carbonyl compounds leads to the synthesis of unsaturated and polyunsaturated acetals and aldehydes.[6-8] Alkylation can also be performed by reaction of 3,3-diethoxy-1-propyne with halides (catalyzed by transition metal compounds)[9] or by Cadiot-Chodkiewicz coupling.[10]

Addition Reactions.

Interesting results are obtained by addition of organocuprates to 3,3-diethoxy-1-propyne owing to the regio- and stereoselectivity of the reaction (eq 3).[11,12]

Recently, the stannocupration of 3,3-diethoxy-1-propyne has been found to lead to a bifunctional adduct, providing a useful synthon for further synthetic elaboration (eq 4).[13,14]

Heterocycle Synthesis.

The acetal and its lithio derivative have been used in the synthesis of numerous heterocyclic compounds, including furans,[8,9a] pyrazoles (eq 5),[15] isoxazoles,[16] and triazoles.[2]

(5)

Some natural products have been synthesized by using 3,3-diethoxy-1-propyne and its lithio derivative as intermediates.[12,17-20]

Diethyl Acetamidomalonate

[1068-90-2] · $C_9H_{15}NO_5$ · Diethyl Acetamidomalonate · (MW 217.22)

(glycine anion equivalent for amino acid synthesis)

Physical Data: mp 95-96 °C.

Form Supplied in: commercially available.[1]

Amino Acid Synthesis.

Diethyl acetamidomalonate is the starting material for the classical Sörensen synthesis of amino acids, first reported in 1903.[2-4] The protected glycinate is deprotonated with base [typically ***Sodium Ethoxide***/EtOH or ***Sodium Hydride*** in THF, DMF or DMSO; more recently by phase-transfer catalysis (PTC)[5-13]], reacted with an electrophile (generally an alkyl halide or Michael acceptor), hydrolyzed and then decarboxylated (eq 1).[14] Although the second ester group acidifies the α-proton and avoids the common problem of dialkylation of an active methylene compound,[15] it is not possible to induce chirality at the α-carbon of amino acid derivatives by carbon-carbon bond formation with diethyl acetamidomalonate.[16]

E^+ = alkyl halide, carbonyl compound, imine, Michael acceptor, other electrophiles

Numerous examples of this methodology exist and a brief listing of recent reports serves to highlight the possibilities in terms of reaction types (alkylations,[5,6,9,13,17-54] 1,2-carbonyl or imine additions,[55,56] Michael additions,[7,8,10-12,57,58] and an arylation[59]).

Amino acids with the following side chains have been produced by the Sörensen method: alkane,[19,21,26,30,60] alkene,[6,7,11,17,23,25,31,34,42,54,60-63] alkyne,[6,39,51,53,60,62] aromatic,[8,10,12,18,22,24,25,27,32,34,35,37,38,40,41,46,48,50,54,60] carbocycle,[61] fluoro,[6,35,52,57,58,64] halo (Cl, Br),[5,9,13,22,23,43,48,52] heterocycle,[17,20,28,29,37,43-45,49,52,55,57,59,60,64] iron,[18] ^{13}C label,[30,56] ^{2}H label,[40,56] ^{3}H label,[19,22] ^{15}N label,[49] nitrogen,[5,9-11,20,23,24,29,38,40-45,50,52,55-57,59,60,65,66] oxygen,[5,7,8,10-13,17,20,22,24,27-29,31,33,35-38,43-46,48-50,52,55,57-60,62,64,66] phosphorus,[5,48,50,52,60] platinum,[65] pro(cyclic imino),[5,9,37,42,47] sulfur,[7,23,33,44,45] and tin.[51]

New synthetic methodologies, such as catalytic enantioselective synthesis, are of special interest. Examples include phase-transfer catalyzed Michael addition to give (**1**) in 68% ee,[8,12] and palladium-catalyzed allylation to give (**2**) in up to 97% ee.[17,25,34,54] The chiral catalysts are a quaternarized *Ephedra* alkaloid derivative and a chiral phosphine ligand, respectively. In both of these cases the enantioselective reaction occurs at the indicated β-carbon center. Palladium-catalyzed carbopalladation of allenes to form 1,3-diene-containing amino acid derivatives,[63] conversion of the normally nucleophilic malonate into an electrophile by bromination followed by reaction as a glycine cation equivalent with a variety of nucleophiles,[60,62,66] and the synthesis of either heterocycles[67,68] or polymers[69] using compounds prepared from the parent malonate have also been reported.

(1)

(2)

As noted above, the amino acid derivatives prepared by this methodology are achiral at the α-carbon. Recently, kinetic resolution by enantioselective hydrolysis with enzymes has been used for the direct preparation of the individual enantiomers.[61,70-73]

Diethyl Acetonylmalonate

(R = Et)

[23193-18-2] · $C_{10}H_{16}O_5$ · Diethyl Acetonylmalonate · (MW 216.23) (R = Me)

[24889-15-4] · $C_8H_{12}O_5$ · Dimethyl Acetonylmalonate · (MW 188.18)

(doubly functionalized reagent, the ketone acting as an internal trapping agent after the reaction of the malonate anion;[1] for synthesis of five-membered rings)

Alternate Names: diethyl acetylmethylmalonate; diethyl 2-oxopropylmalonate.

Physical Data: R = Et: bp 102 °C/0.9 mmHg; R = Me: bp 75 °C/0.1 mmHg.

Preparative Methods: a detailed procedure reports the alkylation of ***Diethyl Malonate*** by chloroacetone on a 100 g scale, giving diethyl acetonylmalonate (**1**) with a yield of 55% after distillation.[1] Since chloroacetone is toxic and highly irritating to the eyes, skin, and mucous membranes,[2] an alternative procedure using ***Isopropenyl Acetate***, a mild irritant and a much less toxic compound than chloroacetone, should be seriously considered. Thus the reaction of dimethyl malonate with isopropenyl acetate in the presence of ***Cerium(IV) Ammonium Nitrate*** (CAN) followed by a mild basic treatment affords dimethyl acetonylmalonate in a yield of 82% on a 5-10 g scale (eq 1).[3] This procedure offers advantages regarding the yield and reaction conditions, and it uses available starting materials.

Handling, Storage, and Precautions: use in a fume hood.

Alkylation.

In a study toward the synthesis of ryanodine, Deslongchamps et al. reported the protection of the keto group of (**1**) and alkylation with 2-chlorocyclopentanone. Acid treatment of the crude product accomplishes the hydrolysis of the esters and acetal functions, decarboxylation, aldol condensation, and dehydration (eq 2).[1]

(2)

Michael Addition.

The conjugate addition of the potassium salt of (**1**) with ***2-Chloroacrylonitrile*** gives an intermediate which reacts with the keto group to give an epoxide by an intramolecular Darzens condensation (eq 3).[4] The reaction works equally well with methyl α-chloroacrylate. With α,β-unsaturated aldehydes, the Michael addition is followed by an intramolecular aldol reaction which can lead to lactonization (eq 4) or, as in the case of ***Acrolein***, dehydration (eq 5).[5] The sodium salt of (**1**) adds in a 1,4-fashion to α-diethoxyphosphoryl-$\Delta^{\alpha,\beta}$-butenolide to give an intermediate which reacts by an intramolecular Horner-Emmons reaction, providing an α,β-carbocyclic fused γ-lactone by a very simple route (eq 6).[6]

(3)

(4)

(5)

(6)

Conjugate Addition on Vinylphosphonium Compounds.

Treatment of the sodium salt of (**1**) with ***Vinyltriphenylphosphonium Bromide*** generates an intermediate phosphorane which undergoes an intramolecular Wittig reaction to give a cyclopentene derivative in good yield (eq 7).[7] Similarly, other phosphonium reagents such as (1-phenylthiovinyl)triphenylphosphonium chloride and 1-cyclobutenyl)triphenylphosphonium perchlorate can be used to synthesize cyclopentanones (eq 8)[8] and cyclobutane annulated compounds (eq 9),[9] respectively.

Diethyl Acetonylphosphonate

[1067-71-6] · $C_7H_{15}O_4P$ · Diethyl Acetonylphosphonate · (MW 194.17)

(Horner-Emmons reagent for the conversion of aldehydes and ketones to α,β-unsaturated methyl ketones;[1] can react via the corresponding derived metallic dianions to yield other β-ketophosphonates[2])

Alternate Name: diethyl acetylmethylphosphonate.

Physical Data: bp 126 °C/9 mmHg; *d* 1.010 g cm^{-3}; *n*D20 1.4330; δ ^{31}P 93.7 ppm (from P_4O_6 as reference),[3] -20 ppm (from 85% H_3PO_4 as external reference).[4]

Solubility: sol THF, ether, dichloromethane, chloroform.

Form Supplied in: colorless liquid.

Horner-Emmons Reagent.

Diethyl acetonylphosphonate is a very efficient reagent for the preparation of a variety of α,β-unsaturated methyl ketones via the Horner-Emmons modification[5] of the Wittig reaction and has the advantage over the equivalent Wittig ylide of much greater reactivity.[1] The corresponding derived sodium anion that realizes the carbonyl alkenation is usually obtained in aprotic medium with a limited range of solvents and bases, such as ***Sodium Hydride***/THF, NaH/DME,[6] or ***Sodium Hydroxide***/DMF.[7]

Excellent yields are obtained from aldehydes, often leading to exclusive *trans* stereochemistry for the α,β-unsaturated ketones formed (eq 1).[8] The lower electrophilic behavior of ketones combined with the increased steric hindrance results in lower yields,[6] and therefore allows, in the case of keto aldehydes, a chemoselective aldehyde alkenation (eq 2).[9]

(1)

(2)

Often the carbonyl alkenation with diethyl acetonylphosphonate is part of a multistep synthesis of natural or bioactive products (eqs 3-5).[10-12]

Acromelic acid (3)

(4)

(5)

Diethyl acetonylphosphonate has also been used in an annulation sequence for building a cyclohexadienone ring onto a cyclic ketone (eq 6).[13]

(6)

The Horner-Emmons reaction with diethyl acetonylphosphonate can be carried out in a protic solvent such as ethanol, with ***Potassium Hydroxide***[14] or ***Potassium Carbonate***[15] as base. Recently, two-phase liquid-liquid or solid-liquid procedures have been described and often represent a significative improvement for the Horner-Emmons reaction. Typical results are obtained in water, in the absence of organic solvents, using 6 M potassium carbonate as base (eq 7).[16]

(7)

R^1	R^2	Base	Temperature	Times	Yield (%)
Et_2CH	H	6M K_2CO_3	100 °C	10 min	93
Et_2CH	H	6M K_2CO_3	20 °C	15 h	90
$-(CH_2)_5-$		6M K_2CO_3	20 °C	18 h	62

Under similar heterogeneous conditions, an aqueous solution of glutaraldehyde gives 1-acetyl-1-cyclohexen-6-ol (eq 8).[17]

(8)

α-Labeled α,β-unsaturated methyl ketones (%D > 95%) can also be prepared with this procedure in the presence of 6 M K_2CO_3 in deuterium oxide solution at rt (eq 9).[18]

(9)

Microcrystalline ***Barium Hydroxide*** C200 [$Ba(OH)_2.0.8H_2O$, or $Ba(OH)_2.0.2H_2O$] has been used in very efficient solid-liquid Horner-Emmons reactions with β-ketophosphonates.[19] Under these conditions, Claisen-Schmidt and Horner-Emmons syntheses of acyclic enones using, respectively, acetone and diethyl acetonylphosphonate as reagents have been compared. The comparison shows that the Horner-Emmons reaction is more efficient and selective, while the Claisen-Schmidt condensation leads to a mixture of enone and dienone. The (*E*) stereoselectivity of the reaction is the same in both cases (eq 10).[20]

(10)

Preparation of Other β-Ketophosphonates.

α-Substituted or γ-substituted alkyl β-ketophosphonates can be prepared from, respectively, the monoanion[21] or the dianion of diethyl acetonylphosphonate. Prior α-alkylation of the sodium enolate, before the carbonyl alkenation step, is often employed (eq 11).[22]

(11)

Prior α-alkylation is also required for other subsequent reactions as, for instance, an intramolecular aza-Wittig (Staudinger) reaction (eq 12).[23]

If desired, the dianion generated from diethyl acetonylphosphonate by successive treatment with NaH and ***n-Butyllithium*** can be alkylated at the γ-position with homoallyl bromide to yield diethyl 2-oxo-6-hepten-1-ylphosphonate (eq 13).[2a] Other examples of this γ-alkylation have been described with the dianion derived from diethyl acetonylphosphonate.[2b]

The Derived Metallic Dianion as Reagent.

The dianion derived from diethyl acetonylphosphonate gives γ-hydroxyalkylation with carbonyl compounds. After dehydration, the resulting 2-oxo-3-alkenylphosphonates serve as heterodienes in thermal reactions with vinyl ethers, leading ultimately to 5-substituted 2-phosphinyl-2-cyclohexen-1-ones.[24] Formed on the surface of solid K_2CO_3/MeOH, in the presence of ***Iodine***, the dianion can be exclusively γ-iodinated and gives in situ a novel ambident iodinated dianion where the two CH groups have approximately equivalent reactivity. Aromatic aldehydes react with this last intermediate in a simultaneous Horner-Emmons and Darzens reaction to yield epoxy enones (eq 14).[25]

(14)

The dianion can be also formylated or acylated with ethyl esters or acyl chlorides in the γ-position to yield diethyl 2,4-dioxoalkylphosphonates. The deprotonation is carried out with NaH/THF at 20 °C with 1 equiv of sodium hydride followed by 2 equiv of ***Lithium Diisopropylamide*** at 0 °C. The excess of LDA is essential for a quantitative formation of the dianion because of proton transfer from the acylated product (eq 15).[26]

Miscellaneous Reactions.

Diethyl acetonylphosphonate can be used to prepare indolylphosphonates via a Fischer cyclization.[27] It also undergoes reductive amination in the presence of an amine and ***Sodium Cyanoborohydride*** in MeOH at pH 7-7.5 to yield the corresponding β-amino phosphonates (eq 16).[28]

Strecker reaction leads to phosphonate analogs of α-methylaspartic acid.[29] Diethyl nitromethylphosphonate is obtained from the reaction between diethyl acetonylphosphonate and HNO_3/Ac_2O in 70% yield.[30]

Diethylaluminum Chloride[1]

Et_2AlCl

[96-10-6] · $C_4H_{10}AlCl$ · Diethylaluminum Chloride · (MW 120.56)

(strong Lewis acid that can also act as a proton scavenger; reacts with HX to give ethane and EtAlClX)

Alternate Names: chlorodiethylaluminum; diethylchloroalane.

Physical Data: mp -50 °C; bp 125 °C/50 mmHg; *d* 0.961 g cm^{-3}.

Solubility: sol most organic solvents; stable in alkanes or arenes.

Form Supplied in: commercially available neat or as solutions in hexane or toluene.

Analysis of Reagent Purity: solutions are reasonably stable but may be titrated before use by one of the standard methods.[1e]

Handling, Storage, and Precautions: must be transferred under inert gas (Ar or N_2) to exclude oxygen and water. Use in a fume hood.

Introduction.

The general properties of alkylaluminum halides as Lewis acids are discussed in the entry for ***Ethylaluminum Dichloride***. Dialkylaluminum halides are less acidic than alkylaluminum dihalides. Et_2AlCl is much cheaper than ***Dimethylaluminum Chloride*** and is used more frequently than Me_2AlCl since comparable results are usually obtained. In some cases, most notably the ene reactions of carbonyl compounds, use of Me_2AlCl is preferable since its methyl groups are less nucleophilic than the ethyl groups of Et_2AlCl, which can act as a reducing agent.

Catalysis of Diels-Alder Reactions.

Et_2AlCl has been extensively used as a Lewis acid catalyst for Diels-Alder reactions. *N*-Acyloxazolidinones can form both 1:1 (eq 1) and 1:2 complexes with Et_2AlCl (eq 2).[2] The 1:2 complex is ~100 times as reactive as the 1:1 complex and gives greater *endo* selectivity and higher de. Me_2AlCl gives similar selectivity with fewer byproducts.

(1)

(2)

Et_2AlCl has been extensively used as a Lewis acid catalyst for intermolecular[3] and intramolecular[4] Diels-Alder reactions with α,β-unsaturated ketones and esters as dienophiles. It also catalyzes inverse electron demand Diels-Alder reactions of alkenes with quinone methides[5] and Diels-Alder reactions of aldehydes as enophiles.[6]

Catalysis of Ene Reactions.

Et_2AlCl has been used as a catalyst for ene reactions with ethyl propiolate as an enophile,[7] for intramolecular ene reactions of aldehydes,[8] and for intramolecular ene reactions with α,β-unsaturated esters as enophiles (eq 3).[3e,9]

(3)

Catalysis of Claisen and Vinylcyclopropane Rearrangements.

Et_2AlCl has been used as a catalyst for Claisen rearrangement of aryl allyl ethers.[10] The rearrangement of 2-vinylcyclopropanecarboxylate esters to cyclopentenes is catalyzed by Et_2AlCl (eq 4).[11]

(4)

Generation of Electrophilic Cations.

Complexation of Et_2AlCl to ketones and aldehydes activates the carbonyl group toward addition of a nucleophilic alkyl- or allylstannane or allylsilane.[12] Et_2AlCl has been used to initiate Beckmann rearrangements of oxime mesylates. The ring-expanded cation can be trapped intermolecularly by enol ethers and cyanide and intramolecularly by alkenes (eq 5).[13]

(5)

Formation and Reaction of Aluminum Enolates.

Et_2AlCl has been used in modified Reformatsky reactions. Aldol adducts are obtained in good yield by reaction of an α-bromo ketone with a ketone in the presence of ***Zinc*** and Et_2AlCl in THF (eq 6).[14] Lithium enolates of esters do not react with epoxides. Reaction of lithium enolates with Et_2AlCl affords aluminum enolates that react with epoxides at the less substituted carbon (eq 7).[15]

(6)

(7)

Formation and Reaction of Alkynylaluminum Reagents.

Lithium acetylides react with Et_2AlCl to form LiCl and diethylaluminum acetylides. The aluminum acetylides are useful reagents for carrying out S_N2 reactions on epoxides (eq 8)[15c,16] and undergo conjugate addition to enones that can adopt an *S-cis* conformation (eq 9).[17]

(8)

(9)

Reaction as a Nucleophile.

Et_2AlCl reacts analogously to ***Ethylmagnesium Bromide*** and transfers an ethyl group to many electrophiles. Since EtMgBr and ***Ethyllithium*** are readily available, use of Et_2AlCl to deliver an ethyl group is needed only when the stereochemistry of addition is an important issue. High levels of asymmetric induction are obtained in the conjugate addition of Et_2AlCl to unsaturated acyloxazolidinones with carbohydrate-derived chiral auxiliaries (eq 10).[18] Et_2AlCl opens epoxides to chlorohydrins.[19]

Related Reagents.

Tris(acetylacetonato)cobalt-Diethylaluminum Chloride-NORPHOS.

Diethylaluminum Cyanide[1]

Et_2AlCN

[5804-85-3] · $C_5H_{10}AlN$ · Diethylaluminum Cyanide · (MW 111.12)

(hydrocyanation of α,β-unsaturated ketones;[2] preparation of α-cyanohydrins from carbonyl compounds[3])

Physical Data: bp 162 °C/0.02 mmHg; colorless syrup; exists as a tetra- or pentamer in boiling benzene or diisopropyl ether and as a dimer in boiling THF.

Solubility: sol benzene, toluene, diisopropyl ether.

Form Supplied in: solution in toluene.

Preparative Method: by reaction of ***Triethylaluminum*** with a slight excess of ***Hydrogen Cyanide*** below rt.[1]

Handling, Storage, and Precautions: highly toxic. It can be stored as 1-2 M solutions in benzene, toluene, or diisopropyl ether. Use in a fume hood.

Hydrocyanation of α,β-Unsaturated Ketones.

Diethylaluminum cyanide is a reagent for the conjugate hydrocyanation of α,β-unsaturated ketones. The reaction is carried out simply by adding a stock solution of the reagent to a solution of the substrate α-enone in an aprotic solvent with ice cooling, and then allowing the reaction mixture to stand at rt (eqs 1 and 2).[2,3] This hydrocyanation is reversible and therefore can be controlled both kinetically and thermodynamically; that is, the product is kinetically controlled in the early stage.

Diethylaluminum Ethoxide[1]

Et_2AlOEt

[1586-92-1] · $C_6H_{15}AlO$ · Diethylaluminum Ethoxide · (MW 130.17)

(base for aldol condensations;[2] reducing agent for preparation of Ni catalysts[3])

Physical Data: colorless liquid; dimeric structure; mp 2.5-4.5 °C; bp 108-109 °C/10 mmHg; *d* 0.850 g cm^{-3}.

Solubility: sol hydrocarbons and ether.

Form Supplied in: commercially available, usually as a 25% solution in toluene.

Handling, Storage, and Precautions: the reagent itself is pyrophoric and its solutions are highly flammable and air and moisture sensitive and should be handled under an inert atmosphere. Use in a fume hood.

Aldol Condensations.

Diethylaluminum ethoxide is a useful base for promoting intramolecular aldol condensations in highly hindered systems. Thus 10 equiv of the reagent in toluene solution are used for effecting the condensation of polycyclic diketones (eqs 1 and 2).[2] Other bases fail to give any appreciable amount of the corresponding cyclization products.

(1)

Reducing Agent.

When used to reduce $Ni(acac)_2$ to Ni^0, the reagent gives a selective catalyst for the [4 + 4] cyclodimerization of pentadienoic acid esters in the presence of 1,3-butadiene (eq 3).[3] Use of other reducing agents gives lower selectivity and greater amounts of [4 + 2] products.

The reagent has also been used as a cocatalyst for terminal alkene isomerizations.[4]

Diethylaluminum Ethoxyacetylide

Et_2Al-C&tbond;C-OEt

[59212-00-9] · $C_8H_{15}AlO$ · Diethylaluminum Ethoxyacetylide · (MW 154.19)

(functionalized alane for the ring opening of epoxides to *trans*-ethoxyalkynyl alcohols which can be converted to *trans*-fused γ-lactones[1-3])

Solubility: sol toluene.

Preparative Method: prepared in situ by treating lithium ethoxyacetylide (generated from the reaction of equimolar amounts of ***n-Butyllithium*** and ***Ethoxyacetylene***) with an equivalent amount of ***Diethylaluminum Chloride*** in toluene at -40 °C (eq 1).[1]

Epoxide Ring Opening and γ-Lactone Formation.

Initial studies using cyclohexene oxide and 2,3-epoxy-*trans*-decalin indicated that ring opening occurs via a *trans*-diaxial pathway (eqs 2 and 3). The stereochemistry in each case was demonstrated by converting the intermediate *trans*-ethoxyethynyl alcohols into the *trans*-γ-lactones. This reaction presumably proceeds via the corresponding hydroxy esters (eqs 4 and 5).[1]

(4)

In an extension of this methodology, the epoxide ring opening was investigated in the presence of a neighboring oxygen functionality and a variety of α-hydroxycyclohexene epoxides were reacted with the alane reagent. The resultant *trans*-ethoxyalkynyl alcohols were converted into the corresponding ethyl esters by treatment with HCl/ethanol, and lactonization was effected with TsOH-benzene to give the *trans*-γ-lactones in 50-60% yield (eq 6).[2]

The ring opening of the α-oxygenated epoxides by the alane reagent was interpreted as being *trans*-diaxial in nature, assuming a preferred equatorial conformation of the neighboring oxygen substituent. It was noted that the course of the reaction is mainly dependent upon the stereochemical relationship of the oxy function and the epoxide and, to an insignificant extent, upon whether or not the oxygen was initially in the form of a hydroxyl or a trimethylsilyl ether. In this case, no directing effect of the neighboring oxygen functionality on the alane was observed since the attack occurs *trans* to the oxygen.

Diethylaluminum Iodide

Et_2AlI

[2040-00-8] · $C_4H_{10}AlI$ · Diethylaluminum Iodide · (MW 212.01)

(ethylating agent; catalyst)

Alternate Names: diethyliodoaluminum; diethyliodoalane.

Physical Data: bp 118-120 °C/4 mmHg; *d* 1.609 g cm^{-3}.

Solubility: sol toluene, benzene.

Form Supplied in: colorless liquid; commercially available, either neat or in toluene solution.

Preparative Methods: by reaction of ***Triethylaluminum*** and ***Aluminum Iodide*** in THF or benzene.[1]

Handling, Storage, and Precautions: moisture-sensitive and pyrophoric. Reacts with water to form an explosive and flammable gas. Extremely harmful if vapors are inhaled. The reagent is absorbed through skin. Wear gloves. Corrosive. Air-sensitive; must be stored under inert atmosphere. Use in a fume hood.

Addition to a Carbonyl Group.

In using the reagent to deliver the ethyl group to a carbonyl, there appears to be a preference for equatorial attack on cyclohexanones (eq 1).[1] A preference was also noted for 1,2-attack over 1,4-attack (eq 2).

Addition to a Carbanion.

An alkylation-deoxygenation reaction provides an interesting approach to substituted alkenes from epoxides (eq 3).[2]

Diethylaluminum 2,2,6,6-Tetramethylpiperidide

[54159-47-6] · $C_{13}H_{28}AlN$ · Diethylaluminum 2,2,6,6-Tetramethylpiperidide · (MW 225.35)

(combined Lewis acid-base reagent for oxygen-containing functional groups; can isomerize epoxides[1] and oxetanes;[3] can function as a base;[4] can enolize *meso*-cyclic acetals[5])

Alternate Name: DATMP.

Solubility: sol benzene, toluene, hexane, CH_2Cl_2.

Form Supplied in: prepared and used in situ.

Preparative Method: prepared in situ from ***Diethylaluminum Chloride*** and ***Lithium 2,2,6,6-Tetramethylpiperidide*** in benzene at 0 °C.[1]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. Use in a fume hood.

Isomerization of Epoxides to Allylic Alcohols.

This reaction is usually carried out with a lithium dialkylamide base (see ***Lithium Diethylamide***). However, organoaluminum amides of the type $Et_2AlNR^1R^2$ are also highly effective because of the high affinity of aluminum for oxygen. Among various organoaluminum amides, DATMP is the most satisfactory with respect to reactivity and selectivity.[1] The reagent effects the isomerization of (*E*)-cyclododecene oxide to (*E*)-2-cyclododecen-1-ol in 99% yield under very mild conditions (eq 1). The effectiveness of DATMP is clearly demonstrated by comparison with other organoaluminum amides in the conversion of (*E*)-cyclododecene oxide to (*E*)-2-cyclododecen-1-ol in benzene at 0 °C for 1 h: $Et_2AlN(i\text{-}Pr)_2$, 65%; Et_2AlNCy_2, 36%; Et_2AlNEt_2, 5%; $i\text{-}Bu_2AlNPh_2$, 48%; $i\text{-}Bu_2AlNMePh$, 69%; $i\text{-}Bu_2AlN(i\text{-}Pr)_2$, 30%. 6,7-Epoxygeraniol and squalene terminal epoxide give (*E*)-3,7-dimethyl-2,7-octadiene-1,6-diol and

(6*E*,10*E*,14*E*,18*E*)-2,6,10,15,19,23-hexamethyl-1,6,10,14,18,22-tetracosahexaen-3-ol, respectively, in high yields under very mild conditions (eqs 2 and 3). Notably, no cyclized byproducts are observed in these two cases. Unfortunately, the oxides of cyclopentene, cyclohexene, and cycloheptene are stable under similar reaction conditions.

(1)

(2)

(3)

DATMP enables the regioselective isomerization of trisubstituted epoxides. Thus (*Z*)-6-methyl-5-undecene oxide is converted to the disubstituted allylic alcohol in high yield, while its (*E*)-isomer is transformed mainly into the trisubstituted allylic alcohol (eqs 4 and 5).[1] The bulk of the amide base may play a significant role in determining the course of the isomerization.

(4)

(5)

The remarkable selectivity inherent in DATMP is further demonstrated by the selective transformation of diepoxyfarnesol. Thus diepoxyfarnesol gives (*E*)-3,11-dimethyl-7-methylene-2,11-dodecadiene-1,6,10-triol upon exposure to lithium diethylamide, while treatment of the diepoxide with DATMP affords (2*E*,7*E*)-3,7,11-trimethyl-2,7,11-dodecatriene-1,6,10-triol as the sole isolable product (eq 6).

1,3-Diene Synthesis.

DATMP has been applied to a 1,3-diene synthesis which involves: (1) epoxidation of an allylic alcohol with ***t-Butyl Hydroperoxide*** in the presence of a vanadium catalyst followed by trimethylsilylation; (2) selective epoxide opening by means of DATMP and subsequent desilylation, producing a 3-ene-1,2-diol; and (3) removal of both hydroxy groups through bromination with a mixture of ***Phosphorus(III) Bromide*** and ***Copper(I) Bromide*** followed by ***Zinc*** debromination.[2] The reaction sequence has been used for the synthesis of β-myrcene from nerol, *trans*-β-ocimene from geraniol, and α- and β-farnesenes from their biological precursors (eqs 7 and 8). A C_{12} sex pheromone of red bollworm moth has been prepared efficiently using this methodology.

(7)

(8)

Conversion of Oxetanes to Homoallylic Alcohols.

Oxetanes can also be cleaved by organoaluminum amides, particularly by diethylaluminum methylanilide, providing (*E*)-homoallylic alcohols (eqs 9 and 10).[3] A higher reaction temperature and a longer reaction time are required compared to the epoxide cleavage. With this methodology, a fundamental medium ring sesquiterpene, humulene, has been synthesized in a highly stereoselective manner (eq 11).

(9)

(10)

(11)

humulene

Aluminum Enolates.

Organoaluminum enolates are conveniently prepared from carbonyl substrates such as ketones and *t*-butyl acetate using DATMP as the base. Subsequent addition of aldehydes and ketones affords the desired aldol adducts in good yields (eqs 12 and 13).[4]

(12)

(13)

Asymmetric enolization of *meso*-cyclic acetals of (2*R*,4*R*)-pentanediol is effected with a series of trialkylaluminums and organoaluminum amides (eq 14).[5] Among a series of organoaluminum amides, diisobutylaluminum *t*-butyl(*t*-butylcyclohexylmethyl)amide is most effective for this transformation.

Polymerization.

The DATMP reagent can be used as a polymerization catalyst for ethylene and propylene.[6]

Diethylaluminum Thiophenoxide[1]

Et_2AlSPh

[58921-09-8] · $C_{10}H_{15}AlS$ · Diethylaluminum Thiophenoxide · (MW 194.30)

(preparation of *O*,*S*-acetals, catalyst for Claisen rearrangements;[3,4] 1,4-addition to vinyl epoxides[7])

Solubility: sol hexane, toluene.

Form Supplied in: generated in situ from commercially available materials.

Preparative Method: prepared by the reaction of ***Triethylaluminum*** in toluene with 1.2 equiv of ***Thiophenol*** (0 °C, 20 min),[2] or similarly in hexane solution (25 °C, 20 min).[3]

Handling, Storage, and Precautions: moisture sensitive. It is typically prepared in situ and used directly. Use in a fume hood.

Claisen Rearrangement.[3,4]

Allyl vinyl ethers undergo Claisen rearrangement in the presence of 2.5 equiv of the title reagent in 67-86% yields under extremely mild conditions (15 min to 1 h, 25 °C), as shown in eq 1. Similar results are obtained with ***Diethylaluminum Chloride-Triphenylphosphine***, but no rearrangement is observed with Et_2AlSEt. The (*E*/*Z*) selectivity is not impressive; better selectivity is observed with sealed tube thermolyses.[4]

(1)

1,3-Cycloalkanediones.[5]

δ-Alkylidene-δ-lactones and an ε-alkylidene-ε-lactone have been converted to 1,3-diones, probably

via aluminum enolates (eq 2). These reactions are also effected with dimethylaluminum thioethoxide and ***Dimethylaluminum Methylselenolate***, but less effectively with iodomagnesium thiophenoxide and lithium thiophenoxide.

(2)

O,S-Acetals.[2,6]

Acetals have been cleanly converted to *O,S*-acetals in 63-89% yields using diethylaluminum thiophenoxide (eqs 3-5).

(3)

(4)

(5)

Reaction with Vinyl Epoxides.[7]

The reagent adds regio- and stereoselectively to vinyl epoxides in 1,4-fashion to afford (*Z*)-4-phenylthio-2-buten-1-ols at rt (eq 6). Performing the reaction at -78 °C in toluene or using polar solvents such as ether and

THF results in much reduced regio- and stereoselectivity. This stereoselectivity complements the reaction of the same vinyl epoxides with ***Thiophenol*** and ***Triethylamine*** in methanol, which gives almost exclusively the (*E*)-isomer. The products can be alkylated at the 4-position or converted into furans by oxidation with ***Lead(IV) Acetate***.

(6)

Rearrangement of Pinacol Monoacetates.[8]

Upon treatment with the title reagent, vicinal diol derivatives afford rearrangement products with different regioselectivity when compared to acid-catalyzed pinacol rearrangement. For example, 1,1-diphenyl-2-acetoxy-1-hydroxypropane affords 72% of 2-phenylpropiophenone and 24% of 2,2-diphenylacetone, while 1,1-diphenyl-1,2-dihydroxypropane affords 80% of 2,2-diphenylacetone as the sole product upon acid catalysis (eqs 7 and 8).

(7)

(8)

2-Methyl-5-methylene-2-vinyltetrahydrofuran and 2,5-dimethyl-2-vinyl-2,3-dihydrofuran afford 3-methyl-1-phenylthio-2-hepten-6-one (eq 9).[9]

(9)

N,N-Diethylaminoacetonitrile[1]

Et_2NCH_2CN

[3010-02-4] · $C_6H_{12}N_2$ · *N,N*-Diethylaminoacetonitrile · (MW 112.17)

(application as formyl anion and formaldehyde dianion equivalents; synthesis of α-amino nitriles, α-amino-β-hydroxy nitriles, aldehydes, ketones, and α,β-enals)

Physical Data: bp 53 °C/10 mmHg,[2] 61-63 °C/14 mmHg,[3] 170 °C;[4] *d* 0.866 g cm^{-3}.

Solubility: sol water and most common organic solvents.

Form Supplied in: liquid; commercially available.

Preparative Method: prepared from diethylamine, formaldehyde, sodium cyanide, and sodium disulfite.[3]

Handling, Storage, and Precautions: is an organic cyanide and should be handled with due care in a fume hood.

Lithiation.

Lithio-*N,N*-diethylaminoacetonitrile *[67685-64-7]* is generated from *N,N*-diethylaminoacetonitrile using ***Lithium Diisopropylamide*** in ether or THF at -78 °C.

Alkylation.

Lithio-*N,N*-diethylaminoacetonitrile functions as a formyl anion equivalent. Other analogs of *N,N*-diethylaminoacetonitrile having different alkyl groups on nitrogen have been reviewed elsewhere.[1] Alkylation of *N,N*-diethylaminoacetonitrile with alkyl chlorides, bromides, iodides, and tosylates,[5,6] as well as Michael acceptors, and hydrolysis of the monoalkylation and dialkylation products with ***Oxalic Acid***,[5] ***Copper(II) Sulfate***,[5,7] or ***Hydrochloric Acid***[6] in aqueous THF, furnishes aldehydes and ketones, respectively. Oxalic acid[5] will not hydrolyze dialkylation products unless β,γ-unsaturation is present. The deprotection method using copper(II) sulfate leaves acetal groups intact and allows the preparation of keto aldehyde acetals (eq 1).[5] Alkylation with allylic bromides followed by hydrolysis proceeds with concomitant isomerization of the alkene to afford α,β-unsaturated aldehydes.[8] Similar alkylations with epoxides followed by acid-catalyzed hydrolysis proceed with concomitant dehydration to provide α,β-unsaturated aldehydes.[5] An unusual addition to azulene and a subsequent oxidation and hydrolysis of the amino nitrile

with aqueous ***Silver(I) Nitrate*** furnishes a mixture of 4- and 6-azulenecarbaldehydes.[9]

(1)

In contrast to *N*,*N*-diethylaminoacetonitrile, alkylations[10] of *N*,*N*-dimethylaminoacetonitrile with allylic halides proceed through *N*-alkylation and subsequent [2,3]-sigmatropic rearrangement. However, alkylation with 2-octyl iodide occurs at carbon.[11] Addition of lithio-*N*,*N*-diethylaminoacetonitrile to saturated[12-14] or α,β-unsaturated carbonyl compounds[15] leads to diastereomeric β-hydroxy-α-diethylamino nitriles, and a subsequent dehydration affords α-(diethylamino)acrylonitriles in modest yield.[13]

Reactions with Heteroelectrophiles.

The anion of *N*,*N*-diethylaminoacetonitrile reacts with ***Dimethyl Disulfide***[16] and ***Chlorotrimethylgermane***[17] to give the α-methylthio and α-trimethylgermyl derivatives, respectively. Direct silylation of the anion of *N*,*N*-diethylaminoacetonitrile with ***Chlorotrimethylsilane*** failed,[12] but the LDA-induced rearrangement of a silylammonium salt[12] formed from *N*,*N*-diethylaminoacetonitrile and chlorotrimethylsilane gives the α-trimethylsilyl derivative (eq 2).[18]

(2)

Other Reactions.

N,*N*-Diethylaminoacetonitrile undergoes a Ritter reaction with 1-adamantol[19] to give an α-(diethylamino)acetamide, and participates in a ***Bis(cyclopentadienyl)cobalt***-catalyzed reaction with acetylene to form 2-(diethylaminomethyl)pyridine.[20]

Related Reagents.

N,N-Dimethyldithiocarbamoylacetonitrile; ***2-(2,6-Dimethylpiperidino)acetonitrile***; ***(4aR)-(4aα,7α,8aβ)-Hexahydro-4,4,7-trimethyl-4H-1,3-benzoxathiin***; ***2-Lithio-1,3-dithiane***; ***Methoxyacetonitrile***; ***Nitromethane***; ***1,1,3,3-Tetramethylbutyl Isocyanide***; ***p-Tolylthiomethyl Isocyanide***; ***2-(Trimethylsilyl)thiazole***.

N,N-Diethylaminodimethylsilane

$Et_2NSiHMe_2$

[13686-66-3] · $C_6H_{17}NSi$ · *N,N*-Diethylaminodimethylsilane · (MW 131.29)

(reagent for intramolecular hydrosilation of allyl alcohols[1] and intermolecular hydrosilation of 1,7-diynes[2])

Physical Data: bp 112 °C/760 mmHg; *n*20D 1.4087; *d*204 mr3000.7505 g cm^{-3}.

Solubility: sol common aprotic organic solvents.

Preparative Method: by treatment of commercially available ***Chlorodimethylsilane*** ($ClMe_2SiH$) and diethylamine in the presence of triethylamine in ether, followed by filtration and distillation.

Handling, Storage, and Precautions: moisture sensitive and corrosive. Must be stored under nitrogen in a tightly capped bottle in a freezer and transferred or weighed quickly via syringe. Use in a fume hood.

Intramolecular Hydrosilation Agent.

For a detailed description of the intramolecular hydrosilation procedure, see ***1,1,3,3-Tetramethyldisilazane***. *N,N*-Diethylaminodimethylsilane is a useful reagent for the conversion of hydroxy groups of allyl or homoallyl alcohols into hydrodimethylsilyl ethers for use in intramolecular hydrosilation reactions. In some cases, *N,N*-diethylaminodimethylsilane gives superior results compared to the more commonly employed 1,1,3,3-tetramethyldisilazane (eq 1).[1]

Hydrosilation Agent.

Another application of this difunctional hydrosilane is in the nickel-catalyzed hydrosilation of 1,7-octadiyne, which affords a 1,2-dialkylidenecyclohexane with a (*Z*)-vinylsilane moiety. This exocyclic silyl diene is treated with an allyl alcohol to give a silicon-tethered triene that undergoes intramolecular Diels-Alder reaction and subsequent oxidative cleavage of the silicon-carbon bond to afford a bicyclic diol (eq 2).[2]

N,N-Diethylaminosulfur Trifluoride[1]

Et_2NSF_3

[38078-09-0] · $C_4H_{10}F_3NS$ · *N,N*-Diethylaminosulfur Trifluoride · (MW 161.18)

(mild reagent for converting primary, secondary, tertiary, allylic, and benzylic alcohols to the corresponding fluorides,[1] aldehydes and ketones to difluorides,[1a,15,19] carboxylic acids to acyl fluorides,[22] and sulfoxides to α-fluoro sulfides[23])

Alternate Name: DAST.

Physical Data: bp 30-32 °C/3 mmHg; *d* 1.220 g cm^{-3}.

Solubility: sol ethereal, chlorinated, and hydrocarbon solvents; reacts violently with water and rapidly with hydroxylic solvents.

Form Supplied in: amber yellow oil; widely available.

Purification: discolored (brown) samples give increasingly lower yields of fluorinated products. Freshly distilled oil is satisfactory for use.

Handling, Storage, and Precautions: can be stored for extended periods of time in the freezer under inert atmosphere. Use in a fume hood.

Fluorodehydroxylation of Alcohols.

DAST, like several other variants of dialkylaminotrifluorosulfuranes, converts primary, secondary, tertiary, allylic, and benzylic alcohols to monofluorides.[1] The reaction conditions are mild (temperature as low as -78 to 0 °C for reactive substrates), and a variety of functionalities such as acetonides, isolated double/triple bonds, esters, ethers, amides, and unactivated halides are tolerated (eqs 1-3).[1b,8-10]

(1)

(2)

(3)

The solvents usually employed are dichloromethane, chloroform, carbon tetrachloride, fluorotrichloromethane, ether, THF, benzene, and toluene. Generally, DAST is superior to classical fluorinating agents such as ***Sulfur Tetrafluoride*** in that the latter requires much higher temperatures (typically 100 °C) and gives undesired side products. With DAST, rearrangements are sometimes observed, albeit to a lesser extent (eq 4).[1a,2,7] Thus β-elimination,[1a] ether formation,[3] Friedel-Crafts alkylation,[4] and skeletal rearrangements involving norbornyl cations[5] have been reported. The DAST reaction with isobutyl alcohol yields a mixture of 49% isobutyl fluoride and 21% of *t*-butyl fluoride.[1a] Other functionalities can interfere with the normal course of reaction. A case in point is a pinacol rearrangement with concomitant ring contraction (eq 5).[2a]

(4)

(5)

S_N2' rearrangement may occur on reacting DAST with allylic alcohols (eq 6).[6]

(6)

Highly varied stereochemical outcomes have been obtained in the reactions of DAST with secondary alcohols. Thus,

although products of partial or complete racemization through ionic or ion-pair mechanisms[1a] have not been widely observed, the usual steric course is complete inversion or complete retention at the reaction center. An example is the formation of (-)-2-fluorooctane (97.6% optical purity) from (+)-*S*-2-octanol.[30] On the other hand, a mixture of products of inverted and retained stereochemistry are obtained in the reaction of DAST with some protected *myo*-inositol derivatives (eq 7).[11] Interestingly, in unprotected or minimally protected sugars,[12a,b] and inositols,[12c,d] where more than two hydroxy groups are present, only one or two hydroxy groups react regio- and stereoselectively (eq 8).[12d]

(7)

(8)

Several synthetically useful transformations involving neighboring group participation exist.[13] An example is the reaction of DAST with *N,N*-dibenzyl-L-serine benzyl ester (eq 9).[13b]

(9)

Geminal Difluorination of Aldehydes and Ketones.

The carbonyl group of aldehydes and ketones can be converted to a 1,1-difluoro group in moderate to high yields.[1a,8,14] The reaction conditions are mild (rt to 80 °C). The solvents generally used are dichloromethane and chloroform. Functional groups compatible with the fluorination of alcohols are also tolerated in the 1,1-difluorination of aldehydes and ketones (see above). An aldehyde carbonyl reacts much faster than a ketone carbonyl and selective difluorination of keto aldehydes at the aldehyde carbonyl has been reported.[14] The general order of reactivity is alcohols > aldehydes > ketones. A variety of aliphatic,[15] aromatic,[1a] and heterocyclic[16] aldehydes have been converted to 1,1-difluorinated compounds (eqs 10-12).[14b,18,19]

(10)

(11)

(12)

While the reactivity of ketones is similar to aldehydes in scope, vinyl fluoride formation is a complication and

sometimes DAST, in conjunction with fuming ***Sulfuric Acid*** in glyme,[17a,b] or a mixture of ***Lithium Chloride*** and ***Copper(II) Chloride***,[17b] is used for the preparation of vinyl fluorides (eq 13).

(13)

β-Diketones and β-keto esters are oxidatively fluorinated with DAST to furnish α,β-difluoro-α,β-unsaturated ketones and esters, respectively (eq 14).[20]

(14)

Reaction with Epoxides.

The reactivity of DAST with epoxides varies with structure. Thus cyclopentene oxide and cyclohexene oxide give a mixture of 1,1-difluoro and bis(α-fluoro) ethers (eq 15).[21] A stereospecific synthesis of *meso*- or (±)-difluorides has been accomplished in two steps using, respectively, *cis*- or *trans*-epoxides as starting materials (eq 16).[22]

(15)

(16)

Reaction with Organic Acids.

Acyl fluorides can be prepared by the reaction of DAST with carboxylic acids in good to excellent yields.[23] α-Hydroxy acids give α-fluoroacyl fluorides which hydrolyze on workup to form α-fluoro acids.[24] Sulfur tetrafluoride, on the other hand, converts the carboxylic group into a trifluoromethyl group.[21]

Reaction with Halides and Sulfonates.

Reactive halides such as iodides, allylic, and benzylic halides, and chlorides of organic acids (sulfinic, sulfonic, and phosphonic) react with DAST to form the corresponding fluorides.[1a]

Reaction with Sulfoxides.

DAST reacts with α-hydrogen containing dialkyl and aralkyl sulfoxides to form α-fluoroalkyl sulfides in high yields (eq 17).[25] This reaction can be extended to less reactive sulfoxides by catalysis with certain Lewis acids, e.g. ***Antimony(III) Chloride*** (eq 18)[26] and ***Zinc Iodide***.[27]

(17)

(18)

Miscellaneous Reactions.

Lactones containing α-hydrogen or fluorine do not react with DAST. However, α-hydroxy lactones undergo normal fluorodehydroxylation along with geminal difluorination at the lactone carbonyl.[28] Glycosyl fluorides can be obtained in high yield, and in a stereospecific manner, either by reacting DAST with hemithioacetals in the presence of ***N-Bromosuccinimide*** or, more simply, hemiacetals.[29b] An interesting fluorination of a phenyl ring of *N*-benzylphenylhydroxylamine has been reported (eq 19).[30]

(19)

An attempt to convert the C-7 hydroxy group of 7-*epi*-taxol to a fluoride failed. Instead, a high yield of a cyclopropanated product with A-ring contraction was obtained (eq 20). A cyclopropane intermediate corner-protonated at C-19 was postulated to explain this anomalous transformation.[31]

(20)

Related Reagents.

Pyridinium Poly(hydrogen fluoride); ***Sulfur Tetrafluoride***.

Diethyl Azodicarboxylate[1]

[1972-28-7] · $C_6H_{10}N_2O_4$ · Diethyl Azodicarboxylate · (MW 174.16)

(functional group oxidations;[5] dealkylation of amines;[16] enophile;[24] dienophile[33])

Alternate Names: diethyl azidoformate; DEAD; DAD.[2]

Physical Data: bp 108-110 °C/15 mmHg; bp 211 °C/760 mmHg; fp 110 °C, *d* 1.11 g cm^{-3}.

Solubility: sol CH_2Cl_2, Et_2O, toluene.

Form Supplied in: orange liquid; 90% (technical grade) and 95% purity are commonly available, as is a 40% solution in toluene.

Preparative Method: although widely available, diethyl azodicarboxylate can be readily prepared from ethyl chloroformate and hydrazine, followed by oxidation of the resulting diethyl hydrazodicarboxylate.[3]

Purification: in most cases commercial samples are used without purification. Distillation is possible, but *not recommended*.

Handling, Storage, and Precautions: flammable; may produce toxic combustion byproducts. Heat and light sensitive; should be stored in dark containers under refrigerated conditions. These containers should also be vented periodically to reduce pressure. DAD has been reported to occasionally decompose violently when heated.[3a,4] Use in a fume hood.

Introduction.

See ***Triphenylphosphine-Diethyl Azodicarboxylate*** for reactions involving the use of the combination of PPh_3 and DAD.

Functional Group Oxidations by Dehydrogenation.

The strong electron withdrawing character of diethyl azodicarboxylate makes it suitable for certain types of oxidations. In general, diethyl hydrazocarboxylate is formed as a product of any oxidation. Primary and secondary alcohols are oxidized to aldehydes and ketones, respectively, although application of this method has been limited.[5] Thiols, similarly, are oxidized to disulfides. Unsymmetrical disulfides are also available by a variation of this method.[6] The oxidation of formamides to isocyanates has been accomplished at high temperatures with DAD, although the yields are frequently low and the method does not appear to be general.[7]

Arylhydroxylamines are readily converted into nitroso compounds with DAD at 0 °C (eq 1).[8] One example of the conversion of an *N*,*N*-dimethylhydrazone to a nitrile has been reported.[9] Sulfur-containing amino acids like methionine and *S*-ethylcysteine can be oxidized to their sulfoxides in virtually quantitative yields, although another reaction pathway occurs with most other thioethers.[10] Thioethers and ethers usually react with DAD to yield α-hydrazo derivatives by hydrogen abstraction.[11] The initial ether/DAD adducts can be formed thermally at 100 °C[12] or photochemically at much lower temperatures.[13]

(1)

The oxidation of propargylic hydrazine derivatives with DAD to the corresponding propargylic diazenes (with subsequent spontaneous loss of N_2) forms the basis of a powerful, yet mild, allene synthesis (eq 2).[14]

(2)

Dealkylation of Amines.

Treatment of a secondary or tertiary amine with diethyl azodicarboxylate in nonpolar solvents followed by acidic hydrolysis leads to the formation of monodealkylated amines.[15] The mechanism of this reaction is believed to involve the formation of a triaza adduct (by Michael addition) followed by a two-step ylide rearrangement yielding an alkyl-substituted hydrazocarboxylate.[12a] Research on unsymmetrically substituted amines suggests that benzyl groups are more easily removed than alkyl groups; methyl groups are the hardest to remove except in cyclic amines like *N*-methylpiperidine (eq 3).[16] The *N*-dealkylation of imines has also been reported.[17]

(3)

Purine Synthesis.

Aminopyrimidines and aminouracil derivatives can be converted into purines with diethyl azodicarboxylate in a number of closely related synthetic methods. Treatment of compound (**1**) with an aldehyde leads to the formation of imine (**2**), which is converted to purine (**3**) with DAD (eq 4).[18] A number of researchers have applied variations of this approach.[19]

(1) (2)

(4)

(3)

Treatment of 6-aminouracils[20] or 6-aminopyrimidines[21] (unsubstituted at the 5-position) with DAD leads to the initial formation of hydrazino Michael adducts. Treatment of these adducts with excess DAD leads to cyclization (eq 5).

(5)

This methodology has been applied to the synthesis of the antibiotic fervenulin[22] and 8-dimethylaminotheophylline.[23] In general, high temperatures (>100 °C) are required to complete the cyclization.

Pericyclic Reactions.

In general, α-carboxyazo compounds participate in a number of pericyclic processes as noted below.

Ene Reactions.

Diethyl azodicarboxylate reacts with most simple alkenes possessing an allyl hydrogen to yield the corresponding ene products, allylic hydrazocarboxylates.[24] The uncatalyzed reaction takes place at moderate temperatures (80 °C) and bis-adducts can be formed if excess DAD is used.[25] The use of ***Tin(IV) Chloride*** catalyzes the reaction, allowing for rapid reaction at -60 °C.[26] This reaction proceeds with a surprising degree of selectivity for (*E*)-alkene geometry (eq 6). A particularly useful application of the ene reaction with DAD is in the synthesis of allyl amines, which are readily available by reduction of the initial adducts with Li/NH_3.[27]

Cycloheptatriene reacts with DAD to afford exclusively ene products,[28] as do the enols of some triazene derivatives.[29] Allenes with alkyl substituents react with DAD to yield ene products in most cases (eq 7).[30] Ene reactions with DAD have also been found to be a useful way of cleaving allyl ethers.[31]

Diels-Alder [4 + 2] Cycloadditions.

Except as noted below, diethyl azodicarboxylate reacts with conjugated dienes to yield [4 + 2] cycloadducts.[32] When the diene moiety is a vinyl aromatic, cycloaddition with DAD is a powerful route for the preparation of annulated tetrahydropyridazine derivatives.[33] Thus the indole derivative (**4**) reacts with DAD at rt to afford cycloadduct (**5**) (eq 8).[34]

The reaction of vinylfurans with DAD usually affords intractable mixtures;[33b,e] however, furan itself undergoes cycloaddition readily, provided suitable reaction conditions[35] are employed to avoid decomposition of the reactive products.[36] Oxazole derivatives readily participate in [4 + 2] cycloadditions with DAD.[37] An asymmetric Diels-Alder reaction between DAD and pyridazin-3-ones facilitated by ***Baker's Yeast*** has been reported with ee's in the range of 9.1-62.7%.[38] The reactions of a number of acyclic heterodienes with DAD have also been reported recently, including 2-aza-1,3-dienes,[39] α,β-unsaturated thioketones,[40] and 1-thia-3-aza-1,3-dienes.[41] The quinodimethane derivatives of a number of heterocycles have been used in cycloadditions with DAD (eq 9).[42]

Competition Between Ene and Diels-Alder Reactions.

One area of considerable research centers on the reactivity of diethyl azodicarboxylate with conjugated dienes, systems in which two pericyclic reaction pathways are possible: Diels-Alder and ene. Although a number of researchers have investigated this area, no clear explanation for the preference of one pathway over another has emerged.[43] In most cases, one reaction course seems to be strongly predominant. At this time, only generalizations are possible.

Acyclic 1,3-dienes, for example, in which alkyl groups are present at the terminus of the diene system, tend to give ene products with DAD, while those with internal alkyl substituents yield [4 + 2] adducts. 2,3-Dimethylbutadiene therefore reacts with DAD to give the cycloadduct in 94% yield, while 2,5-dimethyl-2,4-hexadiene gives only ene products.[44,55] In cases where mixed substitution is present, predictive methods fail completely.[46]

Reactivities among cyclic dienes are equally complicated. Cyclopentadiene gives exclusively [4 + 2] adducts.[47,48] 1,3-Cyclohexadiene, however, has been reported to give solely ene products,[49] but careful reexamination of this reaction reveals that 5-15% yields of [4 + 2] cycloadducts can be obtained.[50] The reaction can be optimized to yield exclusively

cycloadducts by altering experimental conditions.[43,51] In steroidal systems, dienes in internal rings tend to undergo ene reactions,[52] while dienes located in the terminal ring give mixtures where cycloadditions are the predominant pathways (eq 10).[53] In cholesterol derivatives, reduction of the ene adducts with Li/$EtNH_2$ is a convenient way to isomerize the diene system (eq 11).[54] It has been reported that treatment with DAD will aromatize certain cyclohexadiene systems.[44,55]

Other Cycloadditions.

Diethyl azodicarboxylate has seen little application to other types of pericyclic reactions. DAD has been reported to undergo [2 + 2][56] cycloadditions with tetramethoxyallene.[57] Two reports of [8 + 2] cycloadditions involving DAD have emerged recently, one involving 7-alkylidene-1,3,5-cyclooctatrienes[58] and the other 3-methoxy-3a-methyl-3a*H*-indene.[59] Indolizine, which is known to undergo [8 + 2] reactions with electron deficient alkenes,[60] reacts with DAD exclusively in Michael fashion.[61] A photochemically induced 1,3-dipolar cycloaddition involving DAD has been reported.[62]

Similar Reagents.

In most of the reactions involving diethyl azodicarboxylate, two closely related compounds can be employed instead. In many cases, 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) (**6**) and ***4-Phenyl-1,2,4-triazoline-3,5-dione*** (PTAD) (**7**) exhibit greater reactivity than DAD.[15,30a,37b,63]

N,N-Diethylbenzeneselenenamide[1]

PhSe-NR$_2$

(R = Et)

[57584-86-8] · $C_{10}H_{15}NSe$ · *N,N*-Diethylbenzeneselenenamide · (MW 228.22) (R = Me)

[57584-85-7] · $C_8H_{11}NSe$ · *N,N*-Dimethylbenzeneselenenamide · (MW 200.16) (NR_2 = morpholino)

[82737-08-4] · $C_{10}H_{13}NOSe$ · *N*-Phenylselenomorphine · (MW 242.24)

(reagent for α-selenenylation of aldehydes[2] and β-dicarbonyl compounds;[3] areneselenenamides are electrophilic selenium agents for enamines,[4] silyl enol ethers,[4] and α,β-unsaturated carbonyl compounds,[2] and have a more basic character than arenesulfenamides[5])

Alternate Name: *N*-phenylseleno-*N,N*-diethylamine.

Physical Data: bp 75 °C/0.1 mmHg.

Solubility: sol aprotic solvents; hydrolyzed in water; reacts with alcohols.

Form Supplied in: pale yellow oil, often with diphenyl diselenide as impurity.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$)[6] 7.56 (m, 2H) 7.2 (m, 3H) 3.0 (q, *J* = 7 Hz, 4H) 1.2 (t, *J* = 7 Hz, 6H). ^{13}C NMR[7] 131.0, 128.5, 126.9, 53.8, 14.6, 3.0.

Preparative Methods: from ***Benzeneselenenyl Chloride*** and diethylamine (eq 1).[3] ***Benzeneselenenyl Bromide***, formed from ***Diphenyl Diselenide*** and ***Bromine***, can also be used.[6] The more stable morpholino analog is obtained by the same procedure.[4,9] Optically active areneselenenamides have been prepared from chiral amines.[10,11] Selenenamides are also obtained from *N*-(trimethylsilyl)dialkylamines (eq 2)[7a,12] and used without purification.[7a]

$$\mathrm{PhSeCl} \xrightarrow[\text{hexane, 50 °C}]{\text{2 equiv } Et_2NH} \underset{59\%}{\mathrm{PhSeNEt_2}} + \overset{+}{Et_2NH_2}\ Cl^- \qquad (1)$$

(2)

Handling, Storage, and Precautions: can be stored for several weeks below 0 °C in the absence of moisture; like its morpholino analog *N*-phenylselenomorpholine,[8] it can be prepared just before use. Use in a fume hood.

α-Selenenylation of Carbonyl Compounds.

$PhSeNEt_2$,[2] like its morpholino analog,[4,8] reacts with aldehydes to give α-phenylseleno aldehydes (eq 3). Linear aldehydes react very quickly (5 min). The reaction has been used in natural products synthesis.[6,9,13] With the morpholino analog, (phenylseleno)acetaldehyde gives a bis(phenylseleno)enamine, which is hydrolyzed to bis(phenylseleno)acetaldehyde; this is then converted into tris(phenylseleno)acetaldehyde (eq 4).[4a,b] $PhSeNEt_2$[3] and *N*-phenylselenomorpholine[8] react also with 1,3-dicarbonyl compounds (eqs 5 and 6).

(3)

(4)

(5)

R = H, 80%; OMe, 92%

(6)

Using $PhSeNMe_2$, a reverse Claisen reaction sometimes occurs.[3] Ketones and selenenamides lead to mixtures. Chiral selenenamides and 4-alkylcyclohexanones produce α-phenylselenocyclohexanones in refluxing solvent (THF, benzene) in poor yields (20-52%) and modest enantiomeric excess.[10] 2-Phenyl-2-(*p*-chlorophenylseleno)propionaldehyde is prepared from 2-phenylpropionaldehyde and the *p*-chlorobenzeneselenenamide derived from *S*-methyl prolinate, in optically pure form.[11] α-Oxo esters react also, under the same conditions (eq 7).[4b]

(7)

Reactions with Enamines and Silyl Enol Ethers.

Selenenamides add to enamines with elimination of an amine (eqs 4 and 8).[4b] Silyl enol ethers give α-phenylseleno ketones (eq 9)[4b] and conjugated dienoxysilanes allow access to γ-phenylseleno-α,β-unsaturated carbonyl compounds (eq 10).[4b]

(8)

(9)

(10)

Additions to Electron-Deficient Alkenes.

$PhSeNEt_2$, formed with the PhSeOH resulting from a *syn*-elimination reaction of α-phenylseleninyl ketones, adds to the newly created double bond to give α-phenylseleno enones (eq 11).[3]

(11)

$PhSeNMe_2$ reacts also with α-alkylated enones (eq 12). The adduct is isolated and oxidized to an α-aminomethyl enone, which is the major product.[3] Selenenamides add to conjugated enals to give α-phenylseleno enals (eq 13).[4b] A demethylation occurs on a 6-methylenemisotane by treatment with *N*-phenylselenomorpholine and also when the 6-methyl-6-(phenylseleno)misotane is oxidized and treated with a secondary amine. PhSeOH, liberated during the elimination step, is transformed into a selenenamide which adds to the double bond. A retro-Mannich reaction explains the demethylation.[14]

$PhSeNMe_2$ and ***Dimethyl Acetylenedicarboxylate*** give a mixture of isomers. The maleate kinetic product (**1**) partially isomerizes to the fumarate form (**2**) (eq 14).[15] The sulfenamides add only under forcing conditions.[15] Selenenamides react with butynone and ***Methyl Propiolate***.[4b]

Related Reagents.

Diethyl *N*-Benzylideneaminomethylphosphonate

[50917-73-2] · $C_{12}H_{18}NO_3P$ · Diethyl *N*-Benzylideneaminomethylphosphonate · (MW 255.25)

(reagent for preparation of β-lactams[1] and α-aminophosphonic acids;[3] agent for quaternary carbon formation[4])

Physical Data: bp 145-149 °C/0.05 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: light yellow oil.

Analysis of Reagent Purity: readily ascertained by NMR.

Preparative Methods: 1,3,5-tribenzylhexahydro-*s*-triazine is reacted with ***Diethyl Phosphonite*** at 100 °C to yield *N*-benzylaminomethylphosphonate. *N*-Debenzylation with H_2-***Palladium on Carbon*** and subsequent Schiff base formation with PhCHO affords the title reagent in virtually quantitative yield.[1a] Alternatively, the reagent may be prepared from the *N*,*N*-bis(TMS)aminomethylphosphonate and PhCHO in the presence of a catalytic amount of ***Trimethylsilyl Trifluoromethanesulfonate***.[2] A different approach to the aminomethylphosphonate intermediate starts with conversion of *N*-hydroxymethylphthalimide to the *N*-bromomethyl compound followed by an Arbuzov reaction with ***Triethyl Phosphite***. Treatment of the resultant phthalimidomethylphosphonate with ***Hydrazine*** yields diethyl aminomethylphosphonate which is then subjected to imine formation with PhCHO.[4a]

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: stable to air and moisture. Conveniently stored under N_2 at ambient temperature or lower. Shelf life undetermined.

β-Lactams.

Diethyl *N*-benzylidineaminomethylphosphonate (**1**) has served as a starting point in three approaches to β-lactam antibiotics. Deprotonation and acylation (eq 1) yields phosphonoacetate (**2**) which is utilized in the preparation of α-thioformamido(diethylphosphono)acetates (**3**). These serve as key intermediates for further elaboration to 6-H cephalosporins (**4**) (eq 2).[1a] An attempt to extend this approach to carbapenem ring systems was unsuccessful due to the instability of later intermediates.[1b]

(1) (2) (1)

(3) (4) (2)

An example of a novel synthesis of substituted β-lactams was demonstrated by photolytic decomposition of chromium carbene complex (**5**) in the presence of (**1**) to afford the trisubstituted lactam (**6**) with a high degree of stereoselectivity and in 90% yield (eq 3).[1c]

(5) (6) (3)

α-Aminophosphonic Acids.

Alkylation of the anion prepared by deprotonation of (**1**) provides, after hydrogenolysis of the benzylidene group and hydrolysis of the phosphonate esters, convenient access to α-aminophosphonic acids (**7**) (eq 4).[3a] Yields of alkylated product are generally quite high (>80%) and suitable electrophiles include primary, allylic, and benzylic halides as well as α-$BrCH_2CO_2Et$ and halomethylpyridines.[3b,3c] The 1-amino-2-arylethylphosphonic acids can be viewed as

phosphorus-based phenylalanine analogs.

(4)

Quaternary Carbon Formation.

Probably the most innovative use of (**1**) has been in the preparation of quaternary carbon centers via geminal acylation-alkylation at a carbonyl center.[4a,4b] Lithiation of (**1**) followed by condensation with a carbonyl substrate affords, upon warming, the azadiene (**8**) (eq 5). Regioselective addition of ***n-Butyllithium*** to (**8**) generates a metalloenamine which, on alkylation followed by hydrolysis of the resultant imine, gives products of general structure (**9**) (eq 6). The entire sequence may be conveniently carried out in a single reaction vessel without isolation of intermediates with moderate to high overall yields. Judicious choice of electrophile in the alkylation may introduce functionality suitable for subsequent elaboration to 4,4-disubstituted cyclopentenones or 4,4-disubstituted cyclohexenones.[4b] This strategy has been a key feature in the syntheses of mesembrine and various Amaryllidaceae alkaloids.[4c-e]

(5)

(6)

1,4-Additions.

The anion of (**1**) undergoes Michael addition to ethylidenebisphosphonate (**10**), affording functionalized *gem*-bisphosphonates (**11**) (eq 7).[5a]

(7)

(10) **(11)**

Conjugate addition of the anion of (**1**) to acrylates affords Δ^1-pyrrolines by intramolecular cyclization via nucleophilic addition of the resultant enolate to the imine moiety (eq 8).[5b] The reaction is regioselective and stereospecific and the product distribution depends on reaction conditions and the steric nature of the substrate.

Diethyl-*t*-butoxycarbonylmethylaluminum[1]

$Et_2AlCH_2CO_2$-*t*-Bu

[59211-98-2] · $C_{10}H_{21}AlO_2$ · Diethyl-*t*-butoxycarbonylmethylaluminum · (MW 200.26)

(nucleophilic reagent for epoxide opening[1,3])

Preparative Method: prepared in situ from *t*-butyl lithioacetate (Rathke's salt)[2] and ***Diethylaluminum Chloride*** in toluene at -40 °C (eq 1). Instantaneous deposition of lithium chloride is observed and the resulting suspension is used directly in reactions with epoxides.[1] Other solvents, such as THF and DME, are also used successfully.[3]

Handling, Storage, and Precautions: the reagent should be used without isolation immediately after preparation. Reactions must be performed under an inert atmosphere (N_2, Ar).

Epoxide Opening.

Reaction of diethyl-*t*-butoxycarbonylmethylaluminum with cyclohexene oxide at ambient temperature gives the *trans*-γ-hydroxy ester, which in turn can be converted into a *trans*-γ-lactone (eq 2). In contrast, the reaction of cyclohexene oxide and *t*-butyl lithioacetate gives the hydroxy ester in very poor yield (eq 3).[1]

(2)

(3)

Ring opening reactions of sterically hindered epoxides, however, are not successful with this aluminum reagent in toluene (eq 4).

(4)

Regio- and stereospecific opening reactions of unsymmetrical epoxides may be carried out under various conditions. The reactions are much faster in THF and DME than in toluene, and the yields of hydroxy esters are also greatly improved (eqs 5 and 6).[3] Remarkably, the reactions of allylic epoxides proceed by direct S_N2 pathways (eq 5).

(5)

Diethyl Carbonate

(R = Et)

[105-58-8] · $C_5H_{10}O_3$ · Diethyl Carbonate · (MW 118.13) (R = Me)

[616-38-6] · $C_3H_6O_3$ · Dimethyl Carbonate · (MW 90.08)

(*C*-alkoxycarbonylations of carbanions[2-12] and other nucleophiles;[13] synthesis of ketones[14] and tertiary alcohols;[15] allylations with allyl alkyl carbonates;[16] alkylations of nucleophilic substrates;[17-20] heterocyclic synthesis[21])

Physical Data: R = Et: bp 127 °C; *d* 0.975 g cm^{-3}. R = Me: bp 90.3 °C; *d* 1.070 g cm^{-3}.

Solubility: miscible organic alcohols, esters, ethers. R = Et: insol H_2O. R = Me: sol 13.9 g per 100 g H_2O at 20 °C.

Form Supplied in: readily available; inexpensive.

Handling, Storage, and Precautions: inhalation of the vapors of dimethyl carbonate may cause irritation.

Alkoxycarbonylations of Carbanions.

Diethyl and dimethyl carbonate are valuable reagents for the *C*-alkoxycarbonylation of enolate anions derived from active methylene compounds.[1,2] The yields, in general, are comparable to those found using other electrophilic alkoxycarbonylating agents. Various bases such as ***Sodium Hydride***, NaH-KH mixtures, metal alkoxides, and nonnucleophilic species such as ***Lithium Diisopropylamide*** at low temperature have been utilized to generate enolate anions. The latter method is particularly useful, since enolate formation is complete, and competitive condensations of the enolate anions with the substrate are avoided. Ketones[3] can readily be converted into β-keto esters and esters into malonate esters.[4] Selected examples for the conversion of a cyclic (eq 1)[3f] and an alicyclic ketone (eq 2)[3b] to the respective β-keto esters are illustrated. In the acyclic example, the kinetically formed enolate is *C*-ethoxycarbonylated.

(1)

(2)

The conversion of *t*-butyl acetate to the *t*-butyl methyl malonate ester (eq 3)[4] and a *C*-methoxycarbonylation of γ-butyrolactone (eq 4) have been described.[5]

(3)

(4)

Aryl and alkyl cyanides are readily alkoxycarbonylated.[6] The α-ethoxycarbonylations of phenylacetonitrile (eq 5)[6c] and cyanopentanecarbonitrile (eq 6)[6a] are typical examples.

(5)

(6)

The transformations of primary nitro compounds (eq 7)[7] and isocyanides (eq 8)[8] into the α-ethoxycarbonylation products have been reported.

(7)

(8)

The conversion of 2,6-dimethylpyridine to ethyl 6-methylpyridine-2-acetate has been accomplished using ***Potassium Amide*** and diethyl carbonate (eq 9).[9]

(9)

The dianions formed from cyclic or acyclic carboxylic acids on treatment with dimethyl or diethyl carbonate lead to

monoesters of malonic acid (eq 10).[10]

(10)

Carboxylic acid esters can be synthesized from aryl[11] or alkyl halides[11b] by treatment of the corresponding Grignard reagents with dimethyl or diethyl carbonate. For example, addition of ***Phenylmagnesium Bromide*** in THF to a THF solution of dimethyl carbonate (2.0 equiv) at 0-5 °C leads to methyl benzoate (87%).[11]

Carbanions formed via directed metalations undergo facile α-alkoxycarbonylations.[12] Lithiation of 1-(*t*-butoxycarbonyl)-1,2-dihydropyridine followed by addition of dimethyl carbonate leads to the α-methoxycarbonylated product (eq 11).[12a] The retention of configuration found in the alkoxycarbonylation of a benzyllithium analog is of interest (eq 12).[12b]

(11)

(12)

Other nucleophiles such as amines and hydrazines react with dimethyl or diethyl carbonate to yield the corresponding carbamates or carbazates. Treatment of hydrazine with diethyl carbonate leads to ethyl hydrazinecarboxylate (77-85%).[13]

Ketone Synthesis.

The synthesis of ketones can be effected by treatment of organometallics with diethyl carbonate.[14] The addition of 2 equiv of 4-chloro-3-lithiopyridine to diethyl carbonate affords bis(4-chloro-3-pyridyl) ketone (eq 13).[14c]

(13)

Tertiary Alcohol Synthesis.

Dimethyl or diethyl carbonate on treatment with organometallics lead to tertiary alcohols.[15]

Allylations and Alkylations.

The allylations of β-keto esters, β-diketones, malonate esters, nitriles, and nitro analogs can be accomplished under neutral conditions by use of a variety of allylic carbonates in the presence of a palladium-phosphine catalyst.[16] A typical procedure is shown (eq 14).[16a]

(14)

The selective mono-*N*-methylation of aromatic amines such as aniline[17] and mono-*C*-methylations of arylacetonitriles[18] by dimethyl carbonate can be performed by gas-liquid phase transfer catalysis. Dimethyl carbonate in the presence of potassium carbonate and ***18-Crown-6*** (or Aliquat 336) is useful for the *S*-methylation of alkyl or aryl thiols (eq 15), the *O*-methylation of phenols, and the *N*-methylation of imidazole.[19]

(15)

The α-methylation and α-methoxycarbonylation of primary esters has been accomplished by addition of the ester in dimethyl carbonate to a mixture of NaH in dimethyl carbonate (eq 16).[20]

Synthesis of Heterocycles.

Many substrates react with dimethyl or diethyl carbonate to form heterocyclic compounds. Treatment of 1,2-amino alcohols with dimethyl carbonate affords 2-oxazolidinones.[21] The preparation of (*S*)-4-(phenylmethyl)-2-oxazolidinone (eq 17) is illustrative.[21c]

Related Reagents.

Benzyl Chloroformate; ***Carbon Dioxide***; ***Carbon Oxysulfide***; ***Di-t-butyl Dicarbonate***; ***Diethyl Oxalate***; ***Ethyl Chloroformate***; ***Methyl Magnesium Carbonate***; ***Methyl Cyanoformate***.

Diethyl Chloromethylphosphonate

[3167-63-3] · $C_5H_{12}ClO_3P$ · Diethyl Chloromethylphosphonate · (MW 186.58)

((diethylphosphono)- or chloro(diethylphosphono)methylating agent for different functional groups; reacts mainly via the corresponding derived lithiated anion as an organometallic reagent;[1] can function as an electrophile[2])

Physical Data: bp 109-111 °C/10 mmHg; *d* 1.200 g cm^{-3}; *n*20D 1.439; δ ^{31}P 18 ppm (from 85% H_3PO_4); on a comparative scale of different phosphonates and reference compounds, the acidity of $(EtO)_2P(O)CH_2Cl$ is 1.74 pK_a units superior to that of phenylacetylene and 1 pK_a unit inferior to that of acetonitrile. Relative to other phosphonates, $(EtO)_2P(O)CH_2Cl$ is more acidic than $(EtO)_2P(O)Me$, by approximately 3 pK_a units and less acidic than $(EtO)_2P(O)CH_2Ph$ by 1.74 pK_a units.[3]

Solubility: sol THF, ether, dichloromethane, chloroform.

Form Supplied in: colorless liquid.

Preparative Methods: synthesis on a preparative scale of $(EtO)_2P(O)CH_2Cl$ and other (1-chloroalkyl)phosphonates is relatively difficult.[5-8] Ethanolysis of (chloromethyl)phosphonic dichloride is the most general and useful procedure (eq 1).[6] However, (chloromethyl)phosphonic dichloride is expensive and only commercially available in small amounts. Its preparation has been realized by reaction of ***Phosphorus(III) Chloride*** with dichloromethane in a closed metallic vessel heated at 100 °C for 24 h (eq 2).[7]

Other preparations using classical glass vessel apparatus can be used to obtain $(EtO)_2P(O)CH_2Cl$ on a small

scale (up to 10 g) from diethyl (hydroxymethyl)phosphonate (eq 3).[8]

Analysis of Reagent Purity: the methyl hexyl ketone-acetone-heptane (4:1:5) system ensures effective thin-layer chromatographic separation on silufol plates of normal esters of methylphosphonic and (chloromethyl)phosphonic acids and a procedure has been developed for the identification of ^{32}P-labeled (chloromethyl)phosphonic acid esters in CCl_4 and $CHCl_3$.[4]

(Diethylphosphono)- or Chloro(diethylphosphono)methylation.

$(EtO)_2P(O)CH_2Cl$ (**1**) reacts with ***n-Butyllithium*** at low temperature in THF to give a lithiated anion which can be used as a (diethylphosphono)- or chloro(diethylphosphono)methylating agent for electrophilic compounds. As this carbanion degrades at temperatures above -30 °C to give unidentified oligomeric products,[3] it is advantageous to metalate (**1**) with an excess of ***Lithium Diisopropylamide*** (2 equiv) in THF. Under these conditions a stoichiometric amide-carbanion (1:1) association stabilizes the carbanion at 0 °C for at least 1 h (eq 4).[9]

The Grignard reagent of (**1**) is known, but it has to be prepared by an exchange reaction between diethyl(iodomethy)phosphonate and isopropylmagnesium chloride. It reacts with some electrophiles such as ***Bromine***, ***Benzeneselenenyl Chloride***, and ***Benzeneselenenyl Bromide*** better than the corresponding lithiated anion (eq 5).[10]

(5)

Chloro(diethylphosphono)methylation of various electrophiles such as carboxylic acid esters, diethyl carbonate, diethyl oxalate,[1] and chlorophosphates or -phosphinates[11] using the lithiated anion of (**1**) gives direct access to chloro(diethylphosphono)methyl-substituted ketones, carboxylic acid esters, and α-ketocarboxylic acid esters,[1] and chloromethylenediphosphonates or chloromethylphosphinophosphonates.[11] The reaction can be adjusted to deliver chloro(diethylphosphono)acetaldehyde (eq 6).[1]

(6)

In these reactions, only the intermediate lithiated enolate prepared from ethyl carbonate[1] or ethyl chloroformate,[12] or the

intermediate lithiated anions prepared from chlorophosphates[13] or -phosphinates[14] in the presence of excess LDA, can react with aldehydes or ketones in a Horner-Emmons type reaction. The reaction leads to diethyl α-chlorinated α,β-unsaturated phosphonates when diethyl chlorophosphate is used in the initial phosphorus acyl chloride phosphonomethylation (eq 7).[13] This carbonyl alkenation reaction has been extended to the preparation of diphenyl(chlorovinyl)phosphine oxides by use of chlorodiphenylphosphine oxide as phosphonoalkylating reagent.[14] It is worth noting that (chlorovinyl)phosphonates or (chlorovinyl)phosphine oxides are obtained with predominant (*Z*) stereoselectivity.

(7)

Reaction of aldehydes or ketones with the lithiated derivative of (**1**) in a mixture of THF and hexane at low temperature results in the almost immediate formation of lithiated (1-chloro-2-hydroxyalkyl)phosphonate alkoxides, which afford epoxy phosphonates on warming.[15] Under these conditions, (**1**) undergoes a Darzens-type reaction instead of a Horner-Emmons reaction. With aldehydes, this (diethylphosphono)methylation reaction can take a different course leading to (2-oxoalkyl)phosphonates, if the intermediate alkoxide anion is treated at low temperature with LDA (eq 8).[16]

In an analogous reaction, the lithiated derivative of (**1**) reacts with aromatic imines to give aziridinylphosphonates with high stereoselectivity (eq 9).[17]

The carbanion $(EtO)_2P(O)CHClLi$ can be also carbonated,[18] chlorinated,[19] or silylated.[20] The (carboxychloromethyl)phosphonate and (dichloromethyl)phosphonate obtained serve further as reagents in Horner-Emmons alkenation reactions.[18,22-24] (Trimethylsilylchloromethyl)phosphonate can be used for the preparation of α-bromo- and α-iodophosphonates[20] and chloro(diethylphosphono)sulfine.[21]

Often these reactions can be carried out using an efficient and simple one-pot procedure. For instance, the carboxychloroalkenation takes place in two independent steps, leading to α-chloro-α,β-unsaturated acids.[18] The one-step α-chlorination or α-bromination Horner-Emmons procedure allows the preparation of dichloro-[22,23] or dibromoalkenes,[24] respectively. The method can be applied to sterically hindered cyclic ketones as an alternative to the Corey procedure,[25] with the lithium phosphate byproduct being soluble in aqueous media. It is important to note that the stabilization of the lithiated anion derived from the (dichloromethyl)phosphonate formed in situ requires the presence of the lithium salts ***Lithium Bromide*** and ***Lithium Chloride*** (eqs 10 and 11).[26]

Diethyl Chloromethylphosphonate as an Electrophilic Reagent.

$(EtO)_2P(O)CH_2Cl$ can function as an electrophilic reagent to introduce a (diethylphosphono)methyl moiety to a nucleophilic substrate. The chlorine atom can be substituted by dimethyl sulfide,[27] phosphites,[28] arylcopper,[2] and phenolic compounds[29] to afford the corresponding (diethylphosphono)methylated products. For example, copper reagents prepared from aryl bromides react with (**1**) to yield diethyl (arylmethyl)phosphonates. In certain cases this method is better than the classical Michaelis-Arbuzov reaction[30] applied to arylmethyl halides because the synthesis of these last compounds by benzylic bromination is often not selective and requires a number of steps (eq 12).[2] Thiolates react with (**1**) partially by chlorine substitution and dealkylation.[31] The ethoxy group in (**1**) can also be substituted. As a specific case of the preparation of an α-functionalized chlorophosphonic acid monoester by a selective chlorination of the corresponding phosphonic acid diesters, ethyl (chloromethyl)chlorophosphonic acid ester was obtained by the reaction between (**1**) and ***Phosphorus Oxychloride*** (eq 13).[32]

(12)

(13)

Reduction of diethyl (chloromethyl)phosphonate and other (chloroalkyl)phosphonates with different hydride reagents has been studied. Whereas ***Lithium Aluminum Hydride*** gives primary phosphines without chemoselectivity when a C-Cl bond is in an α-position to the phosphoryl group, reduction of (**1**) with AlH_3 affords (chloromethyl)phosphine with good chemoselectivity (eq 14).[33]

Diethyl Chlorophosphite

[589-57-1] · $C_4H_{10}ClO_2P$ · Diethyl Chlorophosphite · (MW 156.55)

(synthesis of allenyl phosphonates,[11] β-ketophosphonates;[8,12] phosphorylation of alcohols;[15] coupling agent[19])

Alternate Names: diethyl phosphorochloridite; diethyl chlorophosphonite; ethyl phosphorochloridite.

Physical Data: bp 153-155 °C/760 mmHg, 56-57.5 °C/30 mmHg; *d* 1.082 g cm^{-3}; fp 1 °C.

Solubility: benzene, THF, diethyl ether, methylene chloride, acetonitrile.

Form Supplied in: colorless liquid.

Preparative Methods: the reaction of ***Phosphorus(III) Chloride*** with ***Triethyl Phosphite***,[1] anhydrous ethanol,[2] or ***Sodium Ethoxide***[3] has been employed, although diethyl chlorophosphite is commercially available.

Purification: vacuum distillation.

Handling, Storage, and Precautions: the neat liquid is flammable and combustion produces toxic byproducts. Caution should be taken when handling the material due to its toxicity. Bottles of diethyl chlorophosphite should be sealed and stored under N_2 to prevent contact with moisture, which produces HCl vapor. Use in a fume hood.

General Notes.

Diethyl chlorophosphite is a reactive electrophile for the introduction of phosphorus into organic compounds. It is known to react readily with a variety of nucleophiles including amines,[4] amides,[5] alcohols (see below), and various organometallic derivatives including Grignard reagents,[6] enolates, and Reformatsky reagents.[7] Oxidation of the initial phosphorus(III) species to a phosphorus(V) species, typically from phosphite to phosphate or phosphonite to phosphonate, is accomplished with a number of reagents including air (O_2),[8] ***Iodine***,[9] ***Ozone***,[5] and ***t-Butyl Hydroperoxide***.[10]

Arbuzov-Type Rearrangements Leading to Allenyl and Allyl Phosphonates.

Reaction of diethyl chlorophosphite with propargyl alcohols in the presence of base results in the rapid formation of allenylphosphonates (eq 1).[11] This general method is believed to proceed through a cyclic transition state with rearrangement occurring at or below rt in many cases. Substitution greatly affects the rate of rearrangement. Allenylphosphonates react with a variety of nucleophiles, including alkoxides and secondary amines, to form β-ketophosphonates after hydrolysis of the intermediate enamine or enol ether (eq 2).[12]

(1)

(2)

Allyl alcohols can be similarly treated to afford allylphosphonates where the selectivity in alkene geometry is dependent upon substitution (eq 3).[13] Rearrangement of the intermediate diethyl allyl phosphites takes place at 70-100 °C. A related rearrangement involves the conversion of 2,3-butadienyl phosphites (homoallenyl phosphites) to 1,3-butadienyl-2-phosphonates.

(3)

Phosphorylation of Alcohols.

Protein phosphorylation is now recognized as a critical reaction in the control of cell metabolism.[14] Diethyl chlorophosphite has been shown to be a more effective and reactive phosphorus electrophile than diphenyl

chlorophosphonate.[15] In the case of *N*-protected serine derivatives (eq 4), an excess of the phosphite is required due to the competitive reaction with the carboxylic acid.[9] Oxidation to the phosphate takes place under a variety of conditions already described.

(4)

Organophosphates are also available from alcohols using diethyl chlorophosphite. In compounds containing multiple alcohol functionalities, such as derivatives of inositol (eq 5), chlorophosphites are preferred over more traditional phosphorus(V) reagents which suffer from not only lower relative reactivity, but also the tendency of the intermediate phosphate triesters to form cyclic phosphates or undergo acid-induced rearrangements.[16] Phosphate triesters can be dealkylated to the phosphates with ***Bromotrimethylsilane***.[10]

(5)

Diethyl Chlorophosphite as a Coupling Agent.

Schmidt and Martin have demonstrated the use of phosphite as a leaving group in the sialylation of sugars with catalytic ***Trimethylsilyl Trifluoromethanesulfonate***. Their procedure allows for higher yields than could be obtained using other methods for the formation of the glycosidic bond.[17] Diethyl chlorophosphite activation of amines allows for the formation of peptides.[18] In certain cases, diethyl anilinophosphite (formed by the reaction of the chlorophosphite with aniline) has also been used as the phosphite source. The researchers found that the corresponding phosphorus(V) reagents do not work as well with this coupling protocol. Reaction of 3´-(diethyl phosphonite) thymidine derivatives with a 5´-azidothymidine leads to the formation of the dinucleotide at room temperature with extrusion of N_2 (eq 6). This coupling procedure is easily accomplished and high yielding.[19]

Preparation of Horner-Wadsworth-Emmons Alkenation Reagents.

Treatment of an α-hydroxy ketone with diethyl chlorophosphite in the presence of a Lewis acid results in a rapid rearrangement to the corresponding β-ketophosphonate (eq 7).[20] Treatment of an α-hydroxy ester results in the formation of an H-phosphonate diester instead of the expected rearrangement product. Horner-Wadsworth-Emmons condensation reagents[21] can also be prepared by the reaction of ketone or ester enolates with diethyl chlorophosphite followed by oxidation of the resultant phosphite (eq 8).[8] This methodology offers several advantages to the Michaelis-Arbuzov reaction,[22] including application to cyclic ketones and availability of starting materials. The competitive formation of enol phosphates by this method is not a problem as it is with phosphorylating agents.[23] Reaction of diethyl chlorophosphite with phosphoryl-stabilized anions has been reported with the products leading to 1,3-butadienylphosphonites.[24]

N,N-Diethyl-2-chloro-1,1,2-trifluoroethylamine[1]

[357-83-5] · $C_6H_{11}ClF_3N$ · *N,N*-Diethyl-2-chloro-1,1,2-trifluoroethylamine · (MW 189.61)

(converts alcohols to alkyl fluorides,[2] carboxylic acids to acid fluorides;[3] used as acylating agent[4])

Alternate Names: FAR; CCT; Yarovenko's reagent.

Physical Data: bp 32-33 °C/6 mmHg; *d* 1.19 g cm^{-3}.

Solubility: sol ether, CH_2Cl_2, acetonitrile.

Preparative Method: from diethylamine and chlorofluoroethylene (87%).[5]

Form Supplied in: liquid (97%).

Handling, Storage, and Precautions: store at <0 °C. Use within 4 weeks of delivery. Fluorinating agent; handle with caution in a fume hood. Readily reacts with H_2O, alcohols, and amines.

Reactivity Pattern.

N,N-Diethyl-2-chloro-1,1,2-trifluoroethylamine, also known as Yarovenko's reagent,[6] is a relatively safe fluorinating agent that is easy to use. The reagent is tolerated by many functional groups including carbon-carbon double and triple bonds, aldehydes, ketones, esters, amides, and nitriles.[1] It is quantitatively hydrolyzed to its amide (eq 1).[2,7] This illustrates its primary reaction mode: elimination of fluorine α to nitrogen to give an iminium ion.

(1)

Reaction with Alcohols and Acids.

Alcohols react with FAR under mild conditions to give the corresponding fluorocarbons with inversion of stereochemistry (S_N2 process). Yields and enantioselectivities are comparable with those obtained with phenyltetrafluorophosphorane, ***N,N-Diethylaminosulfur Trifluoride*** (DAST) and ***Potassium Fluoride*** (eq 2).[2] This interconversion works well for primary, secondary, benzylic,[8] and bridgehead alcohols (eq 3),[9] but gives poor results with α- and β-hydroxy nitriles. DAST is superior in the latter application.[10] Cyclic secondary and tertiary alcohols tend to give elimination products.

(2)

(3)

The α-hydroxycyclopropenone (**1**) reacts with FAR to give an allenic acyl fluoride that was used to synthesize allenic acid and β-keto ester derivatives (eq 4).[11]

Fluorination of steroidal homoallylic alcohols with FAR gives a variety of products (cyclopropanes, B-ring expansion), depending on the conditions employed. They are thought to be derived from carbocation intermediates.[12] Fluorinated cephalosporin derivatives have been prepared as well.[13] The title reagent has also been used to prepare α-chloro-α-fluoroacetates derived from carbohydrates.[14]

Carboxylic acids can be converted to the acyl fluorides in good yields (eq 5).[6,15] Perfluoroaryl acids decarboxylate under the same conditions. FAR has been used in the synthesis of a light-stable rhodopsin.[3]

Heterocyclic Synthesis and Acylation.

Reaction of FAR with *o*-aminophenol gives the benzoxazole derivative (**2**) (eq 6). Benzimidazoles, 4-quinazolones, benzothiazoles, and 1,3-benzodioxoles have also been prepared in this manner.[16]

(6)

Indole has been acylated by FAR under mild conditions using a Lewis acid catalyst (eq 7). Thiophene gives 2-acylated products (52%). Electron-rich aromatics give only the *para* regioisomer (37-78%).[4]

(7)

Miscellaneous Transformations.

FAR has been used in reactions with isocyanates,[17] cyanoacetic ester,[18] and organosilicon compounds[19] and to make fluoroacetic acids.[20] It has also been used to convert benzaldehydes to difluoromethylarenes.[21] A reagent that behaves much like FAR has been derived from $Et_2NCF_2CHFCF_3$ and $Et_2NCF{=}CFCF_3$.[22]

Diethyl Cyanomethylphosphonate

[2537-48-6] · $C_6H_{12}NO_3P$ · Diethyl Cyanomethylphosphonate · (MW 177.14)

(modified Wittig reagent, Wadsworth-Emmons modification, producing α,β-unsaturated nitriles as products from reaction with aldehydes and ketones)

Physical Data: bp 101-102 °C/0.4 mmHg; *d* 1.095 g cm^{-3}.

Solubility: sol THF, DME, methylene chloride.

Form Supplied in: oil; widely available.

Preparative Methods: prepared by the Michaelis-Arbuzov reaction[1] utilizing ***Triethyl Phosphite*** and a haloacetonitrile.[2] More recently, a preparation was reported utilizing ***Trimethyl Phosphite*** and ***Chloroacetonitrile***.[3] Thus a mixture of the two reagents was heated at 140-150 °C for 18 h under nitrogen to give a 75% yield of the closely related dimethyl cyanomethylphosphonate. Alternatively, ***Acetonitrile*** is treated with 2 equiv of ***Lithium Diisopropylamide*** in THF at -78 °C followed by diethyl chlorophosphate (***Diethyl Phosphorochloridate***) to provide a 47% yield of diethyl cyanomethylphosphonate.[4]

Handling, Storage, and Precautions: corrosive.

Modified Wittig Reagent.

The most common use of the reagent is the preparation of α,β-unsaturated nitriles from ketones or aldehydes. The stereochemistry of the α,β-unsaturated nitriles is variable, depending on the substrate[5] and the reaction conditions.[6] Pasto reported a (*Z*)-favored alkenation on 3-hydroxy-3-methylbutanal (eq 1).[7] In contrast, Paquette reported the alkenation shown in eq 2 where the (*E*)-isomer predominates.[8]

(1)

(2)

Sodium Hydride in THF or DME is the most popular base-solvent combination used to effect the Horner-Emmons reaction with diethyl cyanomethylphosphonate. Other useful but less popular conditions include: phase transfer,[9] polymer bound diethyl cyanomethylphosphonate,[10] and electrochemical methods.[11] A vast array of other reaction conditions have been reported in the literature.[12]

Other Uses.

Cyano-substituted cyclopropanes can be prepared by the reaction between diethyl cyanomethylphosphonate and epoxides (eq 3).[2]

(3)

Diethyl cyanomethylphosphonate anions react with aryl iodides in the presence of copper(I) to give α-arylated alkanenitriles (eq 4).[13]

(4)

Nitrones react with diethyl cyanomethylphosphonate to yield aziridines (eq 5).[14]

Diethyl β-(Cyclohexylimino)ethylphosphonate

[20061-84-1] · $C_{12}H_{24}NO_3P$ · Diethyl β-(Cyclohexylimino)ethylphosphonate · (MW 261.30)

(reagent for formylalkenation at carbonyl centers[1])

Physical Data: mp 58-61 °C; bp 151-152 °C/0.04 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: crystalline solid.

Analysis of Reagent Purity: readily ascertained by NMR.

Preparative Methods: $(EtO)_2CHCH_2P(O)(OEt)_2$ is prepared by reaction of ***Triethyl Phosphite*** with $BrCH_2CH(OEt)_2$. Acetal hydrolysis affords diethyl formylmethylphosphonate, which is combined with an equimolar quantity of cyclohexylamine in MeOH. The product is isolated by fractional distillation in the presence of K_2CO_3, to prevent acid-catalyzed dimerization, and at reduced pressure, followed by crystallization from cold pentane.[1b] Yields are 65-75%. A modified procedure for imine formation uses MeCN as solvent with isolation of product from Et_2O at -40 °C to afford white crystalline material in 70% yield.[3]

Purification: distillation at reduced pressure. Crystallization from pentane at 0 °C.

Handling, Storage, and Precautions: crystalline material is stable for several months when stored under anhydrous conditions at 0 °C.

Homologation Reactions.

Diethyl β-(cyclohexylimino)ethylphosphonate (**1**) is an excellent reagent for the conversion of aldehydes and ketones to the corresponding α,β-unsaturated aldehydes.[1a,1c,1d] Anion generation is accomplished by treatment of (**1**) with 1

equiv of a strong base and a solution of the carbonyl substrate is added slowly to maintain a temperature <=5 °C. Warming to ambient temperature yields an unsaturated aldimine which is promptly hydrolyzed under biphasic conditions (aqueous ***Oxalic Acid*** or a pH 4 acetate buffer solution), thereby affording an α,β-unsaturated aldehyde of general structure (**2**) (eq 1).

(1) (2) (1)

Attributes of this Horner-Wadsworth-Emmons reaction include (1) its simplicity in operation, (2) the generally high yields of products, (3) the fact that $Ph_3P{=}CHCHO$ and $(EtO)_2P(O)CH_2CH(OEt)_2$ do not react with ketones, and (4) the stereoselectivity for the formation of the (*E*)-alkene. A limitation is the slow reaction of the anion of (**1**) with an ester group or a free hydroxy group. Consequently, these functionalities should be masked if the substrate carbonyl is slow to react.

During spectral studies on all-*trans*-geranylgeraniol, (**1**) was utilized in the preparation of the 4´-normethyl analog by reaction with trienal (**3**) to provide *trans*-enal (**4**) in 33% yield (eq 2).[2]

(3)

(2)

(4)

Homologation of the cyclopropanecarbaldehyde (**5**) yielded enal (**6**) in 68% yield (eq 3).[3] Conversion of (**6**) to the corresponding tosylhydrazone and subsequent pyrolysis provided a carbene-based approach to $C_{12}H_{12}$ species.

(3)

Also described was the preparation of deuterated (**1**) (eq 4). Spectroscopic studies estimated 90% deuteration at the carbon adjacent to phosphorus in a distribution of 67% d_2, 28% d_1, and 5% d_0.

(4)

Synthetic investigations towards preparation of stable thromboxane A_2 analogs saw attempts at homologation of [3.3.1] and [3.2.1] bicyclic ketones (eqs 5 and 6).[4] While reaction of (**1**) with bicyclo[3.3.1]nonanone (**8**) yields the desired product only in low yield, the corresponding bicyclo[3.2.1]octanone (**10**) affords product in 40% yield.

(5)

(6)

Application to the two-carbon extension of heteroaromatic aldehydes has met with limited success. Condensation of

the anion of (**1**) with 2-thiophenecarbaldehyde affords 3-(2-thienyl)propenal in 80% yield (eq 7).[5] However, treatment of 2-methyl-3-(pyrrol-2-yl)propenal (**14**) with the phosphonate anion produces the homologous dienal (**15**) in low yield (eq 8).[6]

(7)

(8)

The facile synthesis of dienes was demonstrated in an approach to the galanthan alkaloid ring system.[7] Condensation of (**1**) with 2-carboxybenzaldehyde provides the substituted cinnamaldehyde (**17**) in 50% yield after esterification (eq 9). Peterson alkenation provides diene (**18**); this can be elaborated to triene (**19**) (eq 10) which undergoes intramolecular cycloaddition upon heating.

Diethyl Diazomethylphosphonate[1]

(R = Et)

[25411-73-8] · $C_5H_{11}N_2O_3P$ · Diethyl Diazomethylphosphonate · (MW 178.13) (R = Me)

[27491-70-9] · $C_3H_7N_2O_3P$ · Dimethyl Diazomethylphosphonate · (MW 152.09)

(nucleophilic diazo species for the preparation of substituted diazophosphonates,[3,4] β-ketophosphonates,[5] alkynes,[6-8] electron-rich alkenes,[9] various cyclopropane derivatives,[10-12] and five-membered rings[13,14])

Alternate Name: DAMP.

Physical Data: yellow liquid, bp 51 °C/0.1 mmHg; 86-88 °C/0.2 mmHg.

Solubility: sol organic solvents.

Preparative Method: by diazotization of diethyl or dimethyl (aminomethyl)phosphonate using ***Sodium Nitrite*** under acidic conditions.[2]

Handling, Storage, and Precautions: should be stored under an inert atmosphere at 4 °C, and handled as any other diazo compound; *all distillations should be carried out behind a blast shield.*

Introduction.

The corresponding dimethyl ester, dimethyl diazomethylphosphonate, is also widely used; this entry discusses both reagents. The acronym DAMP is used for both the ethyl and methyl derivatives.

Preparation of Diazophosphonates.

Diethyl diazomethylphosphonate is readily lithiated (***n-Butyllithium***, THF, -100 °C) and the resulting lithio derivative can be acylated (***Phenacyl Bromide***, 33%) (eq 1) or silylated (poor yield).[3] The corresponding silver derivative, formed

by treatment with ***Silver(I) Oxide***, can be alkylated with reactive allylic halides.[3] α-Diazo-β-hydroxyphosphonates result when the lithio derivative is treated with aryl aldehydes; alternatively, these can be prepared by direct reaction of DAMP with aldehydes in the presence of ***Triethylamine*** (eq 2).[4]

(1)

(2)

Preparation of β-Ketophosphonates.

In the presence of ***Tin(II) Chloride***, DAMP adds to aldehydes to give β-ketophosphonates in reasonable yield (eq 3).[5]

(3)

Preparation of Alkynes.

Diaryl ketones are converted into alkynes by reaction of the lithium (or potassium) salt of DAMP. The reaction presumably involves a Horner-Wadsworth-Emmons-like elimination to give the diazoalkene, followed by aryl migration with loss of nitrogen (eq 4)[6] (see also ***Diazo(trimethylsilyl)methyllithium***).

Aldehydes react to give the homologous terminal alkyne by a similar mechanism involving hydrogen migration. The reaction appears to be quite general and has been applied to complex aldehydes for natural product synthesis (eqs 5 and 6).[7,8]

Preparation of Electron-Rich Alkenes.

Both acyclic and cyclic ketones are homologated to enol ethers or enamines by reaction with DAMP/***Potassium t-Butoxide*** followed by an alcohol or secondary amine (eqs 7 and 8).[9] The reaction presumably involves a diazoalkene intermediate, but, because alkyl groups migrate poorly, an alkyne is not formed; instead, reaction with the nucleophile occurs.

(7)

R = Me, 58%
R = *t*-Bu, 56%

(8)

Preparation of Cyclopropanes.

When the above reactions of ketones are carried out in the presence of alkenes, alkylidenecyclopropanes are formed in good yield by addition to the alkylidenecarbene (eq 9).[10]

(9)

$R^1 = Me$, $R^3R^4 = (CH_2)_4$, 58%
$R^1 = R^3 = Me$, $R^4 = i\text{-Pr}$, 45%
$R^1R^1 = R^3\ R^4 = (CH_2)_4$, 70%

The reaction has been extended to α-phenylseleno ketones; in this case the resulting phenylseleno-substituted alkylidenecyclopropanes undergo rearrangement to vinylcyclopropanes.[2c,11]

An alternative route to alkylidenecyclopropanes involves ***Copper*** powder or ***Copper(I) Trifluoromethanesulfonate*** catalyzed reaction of the alkene with DAMP to give cyclopropylphosphonates, followed by Horner-Wadsworth-

Emmons reaction with an aldehyde or ketone (eq 10).[2a,12]

Preparation of Five-Membered Rings.

The alkylidenecarbenes generated from diazoalkenes (resulting from reaction of ketones with DAMP) undergo intramolecular C-H insertion reactions to give cyclopentenes (eq 11)[13] and dihydrofurans, and hence furans (eq 12).[14]

Diethyl Dibromomalonate[1]

[631-22-1] · $C_7H_{10}Br_2O_4$ · Diethyl Dibromomalonate · (MW 317.96)

(used for selective bromination of polyunsaturated ester enolates;[1,3] converts alkenes into cyclopropanes in the presence of suitable heavy metal reagents[4-6])

Alternate Name: ethyl dibromomalonate.

Physical Data: bp 108-110 °C/4 mmHg.

Solubility: sol benzene, CCl_4, DMSO, THF.

Form Supplied in: commercially available in 98% purity as a liquid.

Analysis of Reagent Purity: NMR, combustion analysis.

Preparative Method: prepared in 95% yield by reaction of diethyl malonate with bromine.[1,2]

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: lachrymator; light sensitive. Store in the dark under nitrogen. This toxic reagent should be handled in a fume hood.

Enolate Bromination.

Esters can be selectively α-brominated by reaction of this reagent with the lithium enolate at -78 °C (eqs 1 and 2). The esters can then be converted to the corresponding carboxylic acids.[1,3] This bromination can be carried out on substrates bearing remote alkenic functionality. Bromination of the lithium enolate in eq 1 using Br_2 at -78 °C gave a poor yield of α-brominated ester.

(1)

27%

70%

(2)

Synthesis of Cyclopropanes.

Alkenes can be cyclopropanated in a nonstereospecific fashion by treatment with diethyl dibromomalonate in the presence of ***Copper*** powder or ***Copper(I) Bromide***.[4] Higher yields are obtained when this reaction is run in DMSO (eq 3). The yield of cyclopropane product is highly dependent on the amount of copper used. Tetraethyl ethylenetetracarboxylate is commonly observed as a side-product in this transformation.

Nonstereospecific cyclopropanation of Michael acceptors can be accomplished by use of this reagent in combination with ***Tri-n-butylstibine*** (eq 4)[5] or indium.[6] Carbonyl groups can also react with diethyl dibromomalonate in the presence of tri-*n*-butylstibine to form alkenes.[7]

Diethyl Dichloromethylphosphonate

[3167-62-2] · $C_5H_{11}Cl_2O_3P$ · Diethyl Dichloromethylphosphonate · (MW 221.02)

(Horner-Emmons reagent for the synthesis of 1,1-dichloro-1-alkenes; precursor for dichloromethylphosphine)

Physical Data: bp 133 °C/10 mmHg;[1] 66 °C/0.02 mmHg;[2] *d* 1.26 g cm^{-3}; *n*25D 1.4529.

Solubility: very sol most organic solvents (ether, THF, CH_2Cl_2, hexane).

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$) δ (ppm): 1.39 (t, CH_3), 4.32 (quint, CH_2O), 5.65 (d, $^2J_{HP}$ = 2.0 Hz, CH); ^{31}P NMR ($CDCl_3$) δ (ppm): 11.10.

Form Supplied in: not commercially available.

Preparative Methods: obtained on a large scale through the Kinnear and Perren reaction of ***Phosphorus(III) Chloride*** and ***Chloroform*** in the presence of ***Aluminum Chloride***, and subsequent treatment with a large excess of EtOH (eq 1).[3,4]

(1)

On a laboratory scale, the preferred synthesis employs the commericially available diethyl trichloromethylphosphonate: this is partially reduced by means of ***n-Butyllithium*** (eq 2)[2] or by α-lithiochloromethylphosphonate in the presence of lithium salts (eq 3).[5] The resulting phosphonate carbanion is stabilized at low temperature by lithium salts and can be protonated in acidic medium or used in situ for further reactions.

A few other methods for the reduction of trichloromethylphosphonate have been reported. These include an electrochemical approach (85%)[7] and the reaction of trivalent phosphorus reagents, such as ***Triethyl Phosphite*** (65%)[1] and ***Hexamethylphosphorous Triamide*** (72%)[8] with trichloromethylphosphonate. Diethyl dichloromethylphosphonate is also obtained by chlorination of the chloromethylphosphonate with CCl_4 or of the methylphosphonate with ***Benzenesulfonyl Chloride*** in the presence of bases (*n*-BuLi or ***Lithium Diisopropylamide***).[6]

Purification: distillation.

Handling, Storage, and Precautions: stable compound; must be stored in the absence of moisture.

Preparation of 1,1-Dichloro-1-alkenes.

This involves a Horner-Emmons reaction between $(EtO)_2P(O)CCl_2Li$ and various carbonyl compounds. This method is suitable for the preparation of large quantities of 1,1-dichloro-1-alkenes (up to 1 mol) in moderate to good yields (eq 4).[2,9,10]

The reaction takes place smoothly and cleanly with aldehydes or ketones, even in the case of hindered carbonyl derivatives, such as adamantanone (to give **1**) or camphor (to give **2**), of enolizable ketones, and of α,β-unsaturated aldehydes and ketones.

(1)

(2)

It has been applied to the synthesis of chrysanthemic[11] and pyrethric esters (e.g. **3**), their nitrogen analogs (e.g. **4**),[12] and prostacyclin analogs (e.g. **5**).[13]

(3)

(4)

(5)

The Horner-Emmons reaction has also been tested on the phosphonate carbanion generated under electrochemical conditions. Yields are limited by side reactions, even in conditions optimized for the purpose of synthesis (see Le Menn et al.[7] and references therein). Further treatment of the *gem*-dichloroalkenes $RCH{=}CCl_2$ with butyllithium in ether or THF at a suitable temperature affords the corresponding alkynyllithium derivatives, which can be hydrolyzed or alkylated to give terminal and internal alkynes, respectively (eq 5).[13-15]

(5)

Preparation of Dichloromethylphosphine.

H_2PCHCl_2 has been prepared by reduction of diethyl dichloromethylphosphonate. The best results are obtained with ***Dichloroalane*** as reducing agent (eq 6).[16] The half-life of the dichloromethylphosphine is 6 h at rt in THF solution.

Diethyl Difluoromethylphosphonate

[1478-53-1] · $C_5H_{11}F_2O_3P$ · Diethyl Difluoromethylphosphonate · (MW 188.11)

(precursor for the introduction of $(EtO)_2P(O)CF_2$- and $=CF_2$ groups into organic compounds)

Preparative Methods: prepared by the reaction of sodium diethyl phosphite with ***Chlorodifluoromethane*** in hexane (49% yield)[1] or in THF (77% yield);[2] or generated in situ from diethyl bromodifluoromethylphosphonate and BuLi.[3]

Reaction with Carbonyl Compounds.

Deprotonation of diethyl difluoromethylphosphonate with ***Lithium Diisopropylamide*** at -78 °C gives the carbanion (eq 1) which is only stable at or below -78 °C.[2] Reaction of the carbanion with aldehydes and ketones at -78 °C, followed by decomposition (heating THF solution) of the intermediate, gives the corresponding 1,1-difluoroalkenes (eq 2).[2,4] The intermediate can be trapped by electrophiles, such as proton[2,5] and acid chlorides,[6] to form the corresponding phosphonates.

$$(EtO)_2P(O)CF_2H + LDA \xrightarrow[-78\ °C]{} [(EtO)_2P(O)CF_2Li] \qquad (1)$$

$$[(EtO)_2P(O)CF_2Li] \xrightarrow[-78\ °C]{RCOR'} [(EtO)_2P(O)CF_2C(OLi)RR'] \qquad (2)$$

$$[(EtO)_2P(O)CF_2C(OLi)RR'] \nearrow RR'C{=}CF_2$$

$$[(EtO)_2P(O)CF_2C(OLi)RR'] \xrightarrow{E^+} (EtO)_2P(O)CF_2C(OE)RR'$$

$$E = H,\ Ac$$

Reaction with Alkyl and Allyl Halides and Alkyl Triflates.

The carbanion of diethyl difluoromethylphosphonate also reacts with alkyl halides,[2,7,8] alkyl triflates,[9] oxalate,[10] and allyl bromide[2] to form the corresponding 1,1-difluoro phosphonates (eq 3).

$$[(EtO)_2P(O)CF_2Li] + RX \longrightarrow (EtO)_2P(O)CF_2R \qquad (3)$$

$$R = \text{alkyl, allyl; } X = I, Br, Tf$$

Reaction with Other Electrophiles.

The carbanion of diethyl difluoromethylphosphonate can be trapped with ***Chlorotrimethylsilane*** or trialkylchlorostannanes to produce the corresponding trimethylsilylated and trialkyltin-substituted 1,1-difluoro phosphonates (eq 4).[2]

$$[(EtO)_2P(O)CF_2Li] + R_3MCl \longrightarrow (EtO)_2P(O)CF_2MR_3 \qquad (4)$$

$$R = \text{alkyl; } M = Si, Sn$$

The carbanion also reacts with diethyl chlorophosphate or benzoyl chloride to give the corresponding α,α-difluoro bisphosphonate and β-ketophosphonate, respectively (eq 5).[2,11,12] Treatment of the carbanion of diethyl difluoromethylphosphonate with ***Carbon Dioxide*** at -78 °C leads to the formation of the carboxylic acid (eq 6). The thiocarboxylic acid is formed by a similar reaction of the carbanion with ***Carbon Oxysulfide*** (eq 6).[13] The carbanion reacts in a 1,4 addition with 4-chloro-β-nitrostyrene to give the nitro phosphonate (eq 7).[14]

$$[(EtO)_2P(O)CF_2Li] + RCl \longrightarrow (EtO)_2P(O)CF_2R \qquad (5)$$

$$R = (EtO)_2P(O), PhCO$$

$$[(EtO)_2P(O)CF_2Li] \xrightarrow[2.\ H^+]{1.\ COY} (EtO)_2P(O)CF_2C(O)YH \qquad (6)$$

$$Y = O, S$$

Diethyl[dimethyl(phenyl)silyl]aluminum

$PhMe_2SiAlEt_2$

[86014-18-8] · $C_{12}H_{21}AlSi$ · Diethyl[dimethyl(phenyl)silyl]aluminum · (MW 220.36)

(can silylaluminate terminal alkynes;[1] can cross couple with alkenyl, allyl, and aryl phosphates;[3] can deoxygenate epoxides[5])

Physical Data: see ***Diethylaluminum Chloride*** and ***Dimethylphenylsilyllithium***.

Solubility: commonly prepared and used in THF-hexane.

Preparative Method: prepared in situ by adding $PhMe_2SiLi$ in THF to a hexane solution of Et_2AlCl at 0 °C.[1]

Handling, Storage, and Precautions: see ***Diethylaluminum Chloride*** and ***Dimethylphenylsilyllithium***.

Silylalumination of Alkynes and Alkenes.

The reagent adds to 1-alkynes in a regio- and stereoselective (*cis* addition) manner. Transition metal catalysts alter the regioselectivity (eq 1).[1]

In addition reactions with allenes, $PhMe_2SiAlEt_2$ gives, albeit in low yield, allylsilanes as the major product, while contrasting regioselectivity is observed in the Cu-catalyzed silylmagnesiation by a related silylmagnesium reagent, $PhMe_2SiMgMe$ (eq 2).[2]

(2)

$PhMe_2SiAlEt_2$, cat. $PdCl_2(P(o\text{-Tol})_3)_2$, rt	10:90	36%
$PhMe_2SiMgMe$, cat. CuI, 0 °C	>95:<5	74%

Coupling with Allylic and Enol Phosphates.

The reagent converts allylic phosphates into allylsilanes (eq 3).[3] Reaction with (2-vinyl-1,1-cyclopropanedicarboxylate gives the 1,7-homoconjugate addition product (eq 4).[4] In the presence of a Pd catalyst, $PhMe_2SiAlEt_2$ converts enol phosphates into vinylsilanes (eq 5).[3] Higher yields are usually obtained with $PhMe_2SiMgMe$.

(3)

70% 15%

Deoxygenation of Epoxides.

The reagent deoxygenates epoxides in a stereospecific manner, although the reaction is limited to aryl-substituted epoxides (eq 6). A related reagent, [*n*-$Bu_3SnAlMe_3$]$^-Li^+$, has broader applicability.[5]

Diethyl Ethoxymagnesiomalonate[1]

[35227-78-2] · $C_9H_{16}MgO_5$ · Diethyl Ethoxymagnesiomalonate · (MW 228.53)

(synthesis of acyl malonates[1] or methyl ketones[2])

Preparative Methods: prepared from ***Diethyl Malonate***, ***Magnesium***, ethanol, and a catalytic amount of CCl_4, as described in several procedures.[1,2a]

Handling, Storage, and Precautions: typically prepared and used immediately as a solution in solvents such as ether or benzene. The reagent is moisture sensitive; best yields are obtained when the reagent is used under anhydrous conditions.

Use in Synthesis.

Diethyl ethoxymagnesiomalonate (**1**) can be acylated with many activated carboxylic acid derivatives and alkyl chloroformates. It is soluble in aprotic solvents such as ether and benzene, and undergoes exclusive *C*-acylation.[3] A number of acylmalonates have been prepared from (**1**) including tris(ethoxycarbonyl)methane,[1a] diethyl benzoylmalonate,[1b] diethyl phenylacetylmalonate,[1c] and diethyl cyclopropylmalonate.[1d]

Several hydroxycoumarin analogs have been prepared by the addition of (**1**) to salicylic acid derivatives (eq 1).[4] A similar protocol has been utilized in the preparation of hydroxybutenolides.[5]

Methyl ketones can be conveniently obtained from the acylmalonate intermediate following a more vigorous hydrolysis (eq 2).[2b] Substituted acetophenones have also been prepared in this manner.[2]

(2)

Methanetricarboxylic esters are generally prepared by the reaction of (**1**) with an alkyl chloroformate.[6] Thus ***Triethyl Methanetricarboxylate*** is obtained in high yield from (**1**) and ***Ethyl Chloroformate*** (eq 3).[1a]

(3)

The magnesium enolate of diethyl malonate can also be generated and acylated with acid chlorides under milder conditions in a single step. Complexation of the malonate with $MgCl_2$ increases the acidity to a degree such that tertiary amines can be employed for deprotonation.[7] A number of acylmalonates can be conveniently prepared (eq 4), with optimal yields obtained using ***Triethylamine*** (2 equiv).

(4)

Other workers have extended this procedure to an efficient preparation of methyl ketones following bis-dealkoxycarbonylation of the intermediate acylmalonate.[8] The Michael addition of diethyl malonate to α,β-unsaturated ketones and aldehydes under these conditions has also been examined (eq 5).[9] ***Magnesium Oxide*** is also an effective base for the acylation of diethyl malonate, generating acyl malonates in moderate yields.[10]

(5)

Related Reagents.

Bis(trimethylsilyl) Malonate; ***Diethyl Malonate***; ***Ethyl 3,3-Diethoxyacrylate***; ***Ethyl Trimethylsilyl Malonate***; ***Magnesium Ethyl Malonate***; ***Magnesium Methoxide***; ***Malonic Acid***; ***Triethyl Methanetricarboxylate***.

Diethyl Ethoxymethylenemalonate

(R = Et)

[87-13-8] · $C_{10}H_{16}O_5$ · Diethyl Ethoxymethylenemalonate · (MW 216.23) (R = Me)

[22398-14-7] · $C_7H_{10}O_5$ · Dimethyl Methoxymethylenemalonate · (MW 174.15)

(push-pull alkene;[1] 1,4-addition-elimination (Ad_N-E);[2] quinoline derivatives;[3] 1,4-addition;[4] [3 + 2] cycloadditions;[5] Diels-Alder reaction;[6] protecting group for amino sugars[7] and amino acids;[8] oxo-Meldrum's acid[9])

Physical Data: R = Et: bp 108-110 °C/0.25 mmHg; *d* 1.070 g cm^{-3}. R = Me:[2h] mp 44-45 °C; bp 106 °C/0.7 mmHg.

Solubility: sol ethanol and diethyl ether.

Form Supplied in: clear liquid; widely available.

Analysis of Reagent Purity: *n*20D = 1.4612-1.4623.

Preparative Method: prepared by heating ***Triethyl Orthoformate***, ***Diethyl Malonate***, ***Acetic Anhydride***, and catalytic amounts of ***Zinc Chloride***.[10]

Purification: fractional vacuum distillation.

The ethoxy group of diethyl ethoxymethylenemalonate or dimethyl methoxymethylenemalonate can be substituted by various nucleophiles in an Ad_N-E mechanism. Malonates (eq 1),[2c,e,g,h] Grignard reagents,[2i] enolates,[2b] quaternary salts of heterocyclic bases containing an active methylene group,[2a,f] amines,[2d,k] hydrazines,[11] etc., can be used as nucleophiles in this way. In contrast, only 1,4-addition is observed with organometallic compounds at low temperature (eq 2)[4a-c] or in the oxymercuration-demercuration reaction (eq 3).[4d,12]

Quinoline derivatives are prepared in a sequential substitution-cyclization process (eq 4).[3] In similar reactions, various heterocycles such as 1,8-naphthyridines, 2*H*-pyrido[1,2-*a*]pyrimidin-4-ones,[3d,e] pyrazolinones,[11,13] pyrones,[2b,c] xanthyrones,[2e,h] guanidine derivatives,[14] pyrroles,[15] 1,2,4-triazoles,[16] 3-oxo-1,2,6-thiadiazine 1,1-dioxides,[17] 8-oxoimidazo[1,2-*a*]pyridiumides,[2a] 3*H*-pyrrolo[1,2-*a*]indol-3-one derivatives,[18] and 1*H*-1,4-benzodiazepines[19] can be obtained.

(4)

Cyclopentenones are formed in [3 + 2] cycloadditions of dimethyl methoxymethylenemalonate and cyclopropenone acetals (eq 5).[5b,e] Similarly, reaction with benzonitrilium isopropylide, which is generated in situ by a photoinduced cleavage of the corresponding azirine, leads to pyrrolines,[5f] and reaction with diazo compounds to pyrazolines.[5a,c,d,20]

(5)

Diethyl ethoxymethylenemalonate is also used for the protection of the amino group of amino sugars and amino acids. The *N*-protecting group of amino acids can be removed using ***Bromine*** in chloroform.[8] Elimination of the 2,2-diacylvinyl group of amino sugars has been described using ***Chlorine***, ***Ammonia***, or Amberlite IRA-400 (HO^-) resin.[7]

β-Ribofuranosylmalonates can be synthesized stereoselectively through high-pressure Diels-Alder reaction of furan with dimethyl acetoxymethylenemalonate.[6] The unstable diethyl methylenemalonate is obtained from diethyl ethoxymethylenemalonate by catalytic reduction and elimination of ethanol.[21] Ozonolysis of methoxymethylene-Meldrum's acids[22] yields oxo-Meldrum's acids after workup with ***Phosphorus(III) Chloride***.[9]

Related Reagents.

Diethyl Ethylidenemalonate

[1462-12-0] · $C_9H_{14}O_4$ · Diethyl Ethylidenemalonate · (MW 186.21)

(2,4-dienoates;[1] Michael acceptor; 1,4-addition;[2] [3 + 2] cycloaddition;[3] cyclopropanes;[4] cyclopentenes[5])

Physical Data: bp 115-118 °C/17 mmHg; *d* 1.019 g cm^{-3}.

Solubility: sol ethanol and diethyl ether.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: *n*20D = 1.4420.

Preparative Method: obtained by heating paraldehyde, ***Acetic Anhydride***, and ***Diethyl Malonate***.[6]

Purification: fractional vacuum distillation.

Handling, Storage, and Precautions: store at 5 °C. Use in a fume hood.

The reaction of diethyl ethylidenemalonate with benzaldehyde derivatives in the presence of methanolic ***Benzyltrimethylammonium Hydroxide*** (Triton B)[1b] or ***Tetramethylammonium Hydroxide***[1e] yields methyl (2*E*,4*E*)-dienoates (eq 1).[1] The reagent is used for the synthesis of cannabinoids.[1a,c]

(1)

Diethyl ethylidenemalonate reacts as a Michael acceptor with nucleophiles such as enolates,[2d,p] germanium-masked dienolates,[2c] acyl anions (thiazolium salt catalyzed; eq 2),[2k] organometallic compounds (Li,[2m] Mg,[2q] Mn,[2e] Cu,[2a] Zn[2n,o]), activated nitriles (ruthenium catalyzed),[2f] and lithium trialkylalkynylborates.[2i,l]

(2)

The 1,4-addition of crotylorganometallics of B, Ti, Zr, and Sn produces the *anti* adduct predominantly (eq 3).[2g,h]

(3)

Radicals such as the cyclohexyl radical, formed in situ by photolysis of the dicarbonyl(η^5-cyclopentadienyl)iron dimer in the presence of cyclohexyl iodide, can be trapped by diethyl ethylidenemalonate to give the 1,4-addition products (eq 4).[2b]

(4)

Cyclopentenones are formed in a [3 + 2] cycloaddition with cyclopropenone acetals (see ***Diethyl Ethoxymethylenemalonate***).[3] The double bond of diethyl ethylidenemalonate can be cyclopropanated in high yield with ***Bromoform*** and ***Sodium Hydroxide*** in the presence of benzyltriethylammonium chloride (**2**) (eq 5).[4] Cyclopentene derivatives can be obtained in moderate yields by treatment of diethyl ethylidenemalonate with propargyl bromides and zinc in THF at low temperature (eq 6).[5]

(5)

Dialkyl benzylidenemalonates obtained by Knoevenagel reaction[7] of dialkyl malonates and benzaldehyde are useful substrates for the synthesis of dialkyl mesoxalates by ozonolysis.[8]

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***Diethyl Malonate***; ***Diethyl Methylenemalonate***; ***2,2-Dimethyl-1,3-dioxane-4,6-dione***; ***Methyl 6-Oxo-1-cyclohexenecarboxylate***.

Diethyl(1,1,2,3,3,3-hexafluoropropyl)amine[1]

$Et_2NCF_2CHFCF_3$

[309-88-6] · $C_7H_{11}F_6N$ · Diethyl(1,1,2,3,3,3-hexafluoropropyl)amine · (MW 223.16)

(conversion of the hydroxy group of alcohols to the fluoro group; preparation of 2,3,3,3-tetrafluoropropionate esters and other fluorine-containing carbonyl compounds)

Alternate Names: PPDA; Ishikawa reagent.

Physical Data: bp 56-57 °C/58 mmHg, 51 °C/40 mmHg.

Solubility: sol diethyl ether.

Analysis of Reagent Purity: ^{19}F NMR (see Takaoka et al.).[2]

Preparative Methods: diethyl(1,1,2,3,3,3-hexafluoropropyl)amine, commonly called the perfluoropropene-diethylamine adduct (PPDA) or the Ishikawa reagent, is readily prepared in yields of 72-89% by reaction of hexafluoropropene (F-propene) with diethylamine in diethyl ether solution (eq 1).[2,3] The reaction is conducted in a glass pressure vessel cooled to -70 °C and liquefied F-propene is added to the amine-ether solution. The mixture is brought to rt overnight and worked up. The resulting product is a 3:1 molar mixture of the fluoroalkylamine and the (*E*)-fluoroenamine (established by ^{19}F NMR), bp 56-57 °C/58 mmHg. When prepared by bubbling F-propene into Et_2NH-Et_2O at 0-5 °C, the reagent with molar ratio 1:1, bp 51 °C/40 mmHg, is obtained.[3] The reagent may be used directly, without distillation.

$$Et_2NH + CF_2{=}CFCF_3 \longrightarrow Et_2NCF{=}CFCF_3 + Et_2NCF_2CFHCF_3 \quad (1)$$

Handling, Storage, and Precautions: after distillation, the oil may be stored in a tightly stoppered vessel at or below rt. Only a slight discoloration is observed after six months. The reagent should be handled in a fume hood.

Conversion of Alcohols to Alkyl Fluorides.

The typical reaction of this reagent is the one-step conversion of alcohols to the corresponding fluoro compounds with concomitant formation of tetrafluorodiethylpropionamide (eq 2).[2] Similarly, acyl fluorides are readily obtained from carboxylic acids (eq 3).[2] The reaction is markedly enhanced when ***Sodium Fluoride*** is added as a scavenger for the liberated

HF.[3] The pure (*E*)-fluoroenamine, prepared by another route, shows no fluorinating ability.

Primary alcohols react with the reagent at rt with diethyl ether as solvent during 6-20 h to give the corresponding alkyl fluorides in yields of 50-89%.[2,4,5] With benzyl alcohol, a 25% yield of dibenzyl ether is also obtained.[2] Secondary and tertiary alcohols give generally good yields of fluoride (55-80%), but significant amounts of alkenes and dialkyl ethers (formed via carbocation intermediates) are also isolated. Thus 2-octanol affords 62% 2-fluorooctane and 25% of a mixture of *trans*-2-octene, *cis*-2-octene, and 1-octene (4:3:1). In MeCN as solvent the yield of alkene exceeds 50%. While cholesterol in CH_2Cl_2 at 0-5 °C gives 83% of fluoride, borneol forms a rearranged fluoride and camphene. Notably, *t*-butyl alcohol in CCl_4 yields 78% of *t*-butyl fluoride and 9% of isobutene. 1-Adamantanol in THF gives 81% of 1-fluoroadamantane (eq 4).[2] Several mechanisms, involving S_N1 and S_N2 processes, have been proposed to account for the observed products (eq 5).[2]

Aliphatic bromo- and chloro-substituted alcohols react with PPDA to give 40-70% yields of the corresponding fluorides.[4] However, cyclic halogenated alcohols provide very little fluoride but, primarily, tetrafluoropropionate esters. Thus 3-bromoborneol affords the fluoro ester in 65% (eq 6). A suggested mechanism for this side reaction involves the formation of an aminoacetal which undergoes fragmentation with HF (eq 7).[4]

(6)

α,β-Unsaturated alcohols do not give the corresponding fluorides with PPDA because undesirable reactions, such as isomerization, cyclization, and dehydration, may occur in the presence of the HF produced by fluorination. In order to obviate these side reactions, ***Diisopropylethylamine*** is added to neutralize the HF. Under these conditions, geraniol is converted into geranyl 2,3,3,3-tetrafluoropropionate in 41% yield (eq 8). No fluoride is isolated.[6]

Long-chain alcohols provide fluorides and esters on treatment with PPDA.[7] For example, lauryl alcohol forms $Me(CH_2)_{10}CH_2F$ (45%) and $Me(CH_2)_{10}CH_2O_2CCHFCF_3$ (22%). 1,2-Diols yield dioxolanes and 1,3-diols give dioxanes on reaction with PPDA.[8] The use of THF, instead of Et_2O or CH_2Cl_2, is essential to mitigate side reactions. Eq 9 illustrates the reaction with 1,3-propanediol. Monoesters of ethylene glycol and PPDA provide a mixture of fluoro ester and diester (eq 10).[9] α-Hydroxy carboxylic acids, such as mandelic acid,[10] and esters[11,12] are readily fluorinated in 50-70% yields to the α-fluoro carboxylates. The reaction proceeds with inversion of configuration, as evidenced by the conversion of (*R*)-(-)-mandelic acid ethyl ester to (*S*)-(+)-2-fluoro-2-phenyl acetate with 74% ee.

Miscellaneous Applications.

The tetrafluoropropionamide obtained by hydrolysis of PPDA reacts with ArMgX to yield $ArCOCHFCF_3$ and, subsequently, $ArCOCHFCO_2R$.[13] PPDA serves as a useful dehydrating agent for the synthesis of alkynic ketones from β-diketones in the presence of freeze-dried ***Potassium Fluoride*** in MeCN.[14] Monofluorocarboxylic acids are prepared using PPDA, directly from hydroxy esters, or indirectly from monofluorinated alkylbenzenes, followed by oxidation of the phenyl ring to -CO_2H.[15] PPDA and ureas form an intermediate which undergoes cyclization in ROH to yield 6-alkoxy-1-alkylfluorocytosines.[1] *o*-Bifunctional benzenes give heterocycles on reaction with PPDA.[1]

Related Reagents.

N,N-Diethyl-2-chloro-1,1,2-trifluoroethylamine.

Diethyl Isocyanomethylphosphonate

[41003-94-5] · $C_6H_{12}NO_3P$ · Diethyl Isocyanomethylphosphonate · (MW 177.14)

(reagent for the elongation of aldehydes and ketones with a one-carbon unit;[1] connective reagent;[2,3] *N,P*-acetals;[3] reagent for the conversion of nitroalkenes into 2-pyrrolephosphonates[4])

Physical Data: bp 90 °C/0.2 mmHg.

Form Supplied in: commercially available as a nearly odorless, colorless liquid.

Analysis of Reagent Purity: IR (neat) 2140 (N=C), 1300-1250 (P=O), 1040-1010 cm^{-1} (P-O); ^1H NMR (CCl_4) δ 3.9 (d, J_{H-P} = 16 Hz, CH_2).

Preparative Method: by dehydration of *N*-(diethoxyphosphorylmethyl)formamide.[5]

Handling, Storage, and Precautions: can be stored for long periods of time at 0 °C or below.

Introduction.

Diethyl isocyanomethylphosphonate (**1**), a reagent developed in 1973 by Schöllkopf et al.,[5] belongs to the category of (hetero)-substituted derivatives of methyl isocyanide, which includes ***p-Tolylsulfonylmethyl Isocyanide*** (TosMIC), ***p-Tolylthiomethyl Isocyanide***, ***Methyl N-(p-Tolylsulfonylmethyl)thiobenzimidate*** (a TosMIC derivative), and ***Ethyl Isocyanoacetate***. Aldehydes and ketones are the main substrates in the reactions of (**1**), which result in the formation of three different types of products, wherein the phosphonate group may or may not be retained.

Horner-Wadsworth-Emmons Reactions.

Horner-Wadsworth-Emmons (HWE) type reactions of (**1**) with aldehydes and ketones provide vinyl isocyanides,[1] which have been used as intermediates in the synthesis of erbstatin (eq 1)[1a,b] and of homologous aldehydes (eq 2).[1c,d]

Erbstatin (1)

(2)

Knoevenagel Condensation Products.

A method has been developed, which avoids the HWE reaction of (**1**) (eqs 1 and 2), to prepare (formal) Knoevenagel products (**2**) by elimination of water (eq 3).[3a] Compound (**2**) has been converted into progesterone by reduction of the C17-C20 double bond, followed by C20 methylation and acid hydrolysis of $(EtO)_2P(O)CR(Me)NC$(R = 3-methoxyandrosta-3,5-dien-17-yl) (*N*,*P*-acetal behavior; eq 3).[3a] In these processes, (**1**) is used as a connective reagent to form a CO bridge between Me and a 17-steroidal group, as in eq 3. Partial hydrolysis of disubstituted derivatives of (**1**) $[(EtO)_2P(O)CR^1R^2NC]$ provides α-aminomethylphosphonic acids (esters).

The HWE reaction of Knoevenagel products (**2**) with aldehydes, followed by acid hydrolysis to Δ^{16}-steroids, provides another example of the use of (**1**) as a connective reagent (eq 4).[2]

Oxazolines and Derivatives.

The first part of eq 3 (i.e. the formation of **2**) proceeds via oxazolines (**3**) (eq 5), which have been hydrolyzed to α-amino-β-hydroxyalkylphosphonic acids,[6a] and which have been subjected to base-induced electrocyclic ring opening to the formamide precursors (**4**) of isocyanides of type (**2**).[6a]

(5)

The reaction to give compounds of type (**3**) has been carried out with high asymmetric induction (>98%) using a chiral ferrocenylphosphine-gold complex as catalyst.[6b,c]

Miscellaneous.

(**1**) has been used in Passerini-type reactions,[7] and in a recent synthesis of pyrroles from nitroalkenes (eq 6).[4]

(6)

Several derivatives of (**1**) have also been used as reagents. For example, $(EtO)_2P(O)CR^1R^2NC$: (i) R^1 = H, R^2 = Me in the synthesis of corticosteroids;[8] (ii) R^1 = H, R^2 = Cl in the synthesis of indisodine;[9] (iii) R^1 = H, R^2 = S-aryl in the

synthesis of ketene *N*,*S*-acetals.[10]

Form Supplied in: dimethyl and diethyl malonates are colorless liquids with a minimum assay of 99% (GC) which are widely available.

Preparative Methods: dibenzyl malonate is prepared by refluxing malonic acid with benzyl alcohol with

catalytic amount of sulfuric acid.[2] Di-*t*-butyl malonate is usually obtained from malonic acid and isobutene with catalytic amount of sulfuric acid.[3] *t*-Butyl methyl and *t*-butyl ethyl malonates can be obtained through reaction of methyl and ethyl malonyl chlorides with *t*-butyl alcohol, e.g. over activated alumina as a catalyst.[4a] Unsymmetrical methyl, ethyl, and benzyl malonates may be prepared by reaction of the corresponding monoalkyl malonates with alkyl chloroformates.[4b]

Handling, Storage, and Precautions: no specific health hazard if handled with the usual precaution.

Introduction.

The principal synthetic utility of the malonate esters may be summarized as follows:[1]

- 1) the acidity of the methylene group (pK_a &AApprox; 13) is such that metal salts can be easily formed with the metal alkoxides. The resulting carbanions undergo acylation, alkylation,[5] aldol,[6] and Michael reactions;[7]
- 2) the possibility of hydrolyzing and subsequently decarboxylating only one of the ester functions;
- 3) the usual reactions of the ester functions.

In many syntheses reported in the literature, malonates react at both the methylene group and the ester functions, which make them very useful reagents, especially in the formation of heterocycles.

The main feature of di-*t*-butyl, dibenzyl, and the *t*-butyl and benzyl alkyl malonates is that the *t*-butyl ester and benzyl ester groups can easily be cleaved by hydrolysis/decarboxylation or by hydrogenolysis/decarboxylation, respectively. Selective removal of *t*-butyl and benzyl esters may also be accomplished with ***Iodotrimethylsilane***.[8] Cleavage and decarboxylation of dimethyl, diethyl, and unsymmetrical methyl and ethyl malonates can be effected by S_N2 attack on the methyl or ethyl ester carbon with strong nucleophilic anions such as chloride, iodide, cyanide, alkylthiolates, and phenylselenate.[9]

Acylation.

Acylation of diethyl malonate followed by partial hydrolysis and decarboxylation is one of the methods used for synthesizing β-keto esters.[10] Nevertheless, further malonate derivatives such as Meldrum's acid (***2,2-Dimethyl-1,3-dioxane-4,6-dione***),[11a] and mixed malonates such as *t*-butyl ethyl malonate[11b] or potassium ethyl malonate,[11c] can also be advantageously used. The latter allows the synthesis of β-keto esters in high purity without the partial hydrolysis step so that they can be used without isolation in subsequent transformations to, for example, quinolone moieties (eq 1).[11c]

Acylation of dibenzyl malonate[12a] or di-*t*-butyl malonate[12b] followed by hydrogenolysis/decarboxylation (eq 2) or hydrolysis/decarboxylation (eq 3) of the acylmalonates yields methyl ketones.

A similar synthesis of methyl 7-(2-hydroxy-5-oxo-1-cyclopentenyl)heptanoate has been reported (eq 4).[13] Condensation of orthoformates with malonates affords alkoxymethylene malonates which are widely used for heterocyclic synthesis.

(4)

Alkylation.

[1,5] Both α-hydrogens can be replaced by alkyl substituents (eq 5).[14]

(5)

Mono- and dialkyl malonates can be further modified by partial hydrolysis and decarboxylation of an ester function,[9,14] or by reduction of both ester functions with ***Lithium Aluminum Hydride*** to give 2-substituted 1,3-propanediols (eq 6).[15] A useful synthesis of primary α-methylene alcohols involves $LiAlH_4$ reduction of the sodium salts formed from α-alkyl malonates (eq 7).[16] Cyclocondensation with *N*-ethylaniline affords a 4-hydroxy carbostyril (eq 8).[17]

(6)

(7)

(8)

α,α-Dialkylation of malonates with dihaloalkanes and intramolecular α-alkylation with α-(o-haloalkyl)malonates provides effective approaches for construction of carbocyclic rings containing 3-21 carbon atoms.[18] Alkylation of sodio diethyl malonate with chiral 2,3-epoxybutane affords enantiomerically pure (>99% ee) *cis*-β,γ-dimethyl-γ-butyrolactone (eq 9).[19] Although α-alkylation of malonate carbanions with tertiary alkyl halides cannot usually be effected in practically useful yields owing to competing elimination, *t*-butylation of diethyl malonate could be accomplished in 56% yield under Lewis acidic conditions (BF_3, CS_2/$ClCH_2CH_2Cl$, Δ, 18 h), presumably via an S_N1-type mechanism involving the *t*-butyl carbenium ion (eq 10).[20]

(9)

(10)

An important advance in the potential applications of malonate chemistry is the development of efficient procedures for α-allylation of malonate anions with allylic esters and lactones as well as vinyl epoxides (e.g. cyclopentadiene monoepoxide) by means of Pd^0 catalysts (eq 11).[21,22]

(11)

Less economically attractive, but still quite useful, are the allyl coupling reactions that occur between π-allylpalladium complexes and malonate anions. The former Pd^0-catalyzed allylations usually occur with retention of the C-O bond stereochemistry as a consequence of the two configurational inversions which occur during the formation of the π-allylpalladium intermediate and its subsequent displacement by the malonate group. It should be noted that mixtures of allylic isomers are often formed from unsymmetrical allylic esters owing to malonate attack at both C-1 and C-3 of the π-allylpalladium intermediate.

α-Alkylation of malonate esters by monosubstituted alkenes and isobutene occurs in the simultaneous presence of ***Manganese(III) Acetate*** (limiting stoichiometric oxidant) and catalytic amounts of ***Copper(II) Acetate***. The resulting α-alkenylmalonates (40-70% based on Mn^{III}) undergo hydrolysis and decarboxylation to γ,δ-unsaturated carboxylic acids.[23] α-Arylation of α-alkylmalonate diesters may be accomplished by means of coupling reactions with aryllead triacetates [$ArPb(OAc)_3$].[24] However, the unsubstituted parent malonates do not undergo arylation under the same

conditions.

Knoevenagel Reactions.

Such reactions[6] with aldehydes or ketones are frequently followed by cyclocondensation at one of the ester functions (eq 12).[25] When reacted with acetaldehyde, diethyl ethylidenemalonate is obtained which in turn can be ozonolyzed to diethyl oxomalonate (eq 13), a versatile reagent for organic synthesis.[26]

(12)

(13)

Michael Reaction.

The Michael addition[7] to activated double bonds such as those of α,β-unsaturated carbonyl compounds is frequently described in the literature. Followed by a ring-closing Claisen condensation and a subsequent decarboxylation, this sequence leads to the formation of 1,3-cyclohexanedione derivatives (eq 14).[27] They can further be aromatized to substituted resorcinols,[28] reduced to 5-substituted 2-cyclohexenones,[29] or involved in cyclocondensation reactions.[27]

In the case of β,β-bis(trifluoromethyl)acrylic esters as starting material, an anti-Michael addition followed by a fluoride elimination has been reported (eq 15).[30]

Other Reactions.

A further reaction at the central methylene group is nitrosation with ***Sodium Nitrite***, giving oximinomalonates which are subsequently reduced to the corresponding 2-aminomalonates (eq 16).[31]

(16)

Usual reactions at the ester functions include, for example, transesterification to mixed malonates like benzyl ethyl malonate[2] or base-catalyzed cyclocondensation with ureas, thioureas, guanidines, or amidines yielding the corresponding 2-substituted pyrimidines.[32]

Related Reagents.

Bis(trimethylsilyl) Malonate; ***Diethyl Ethoxymethylenemalonate***; ***Diethyl Ethylidenemalonate***; ***Diethyl Methylenemalonate***; ***Diethyl Oxomalonate***; ***2,2-Dimethyl-1,3-dioxane-4,6-dione***; ***Diethyl Ethoxymagnesiomalonate***; ***Ethyl Malonate***; ***Ethyl Trimethylsilyl Malonate***; ***Magnesium Ethyl Malonate***; ***Manganese(III) Acetate***; ***Tetrakis(triphenylphosphine)palladium(0)***.
