Diethyl Methoxymethylphosphonate

(**1a**; R = Me)

[332806-04-5] · $C_6H_{15}O_4P$ · Diethyl Methoxymethylphosphonate · (MW 182.16) (**1b**; R = $MeOCH_2CH_2$)

[70080-14-7] · $C_8H_{19}O_5P$ · Diethyl Methoxyethoxymethylphosphonate · (MW 226.21) (**1c**; R = THP)

[71855-51-3] · $C_{10}H_{21}O_5P$ · Diethyl Tetrahydropyranyloxymethylphosphonate · (MW 252.25) (**1d**; R = TBDMS)

[71855-52-4] · $C_{11}H_{27}O_4PSi$ · Diethyl (*t*-Butyldimethylsilyl)oxymethylphosphonate · (MW 282.39) (**1e**; R = $TMSCH_2CH_2$)

[90490-19-0] · $C_{10}H_{25}O_4PSi$ · Diethyl (Trimethylsilyl)ethoxymethylphosphonate · (MW 268.36)

(Horner-Emmons reagents for carbonyl homologation;[1-4] preparation of vinyl ethers[1-4] and ketene *O,S*-thioacetals[5])

Physical Data: (**1a**): bp 65-67 °C/0.1 mmHg;[6] n_D^{20} 1.4250. (**1b**): bp 105 °C/0.8 mmHg.[1] (**1c**): bp 105 °C/0.1 mmHg.[1] (**1d**): bp 85 °C/0.1 mmHg.[1] (**1e**): bp 80-82 °C/0.05 mmHg.[7]

Solubility: sol organic solvents (THF, diglyme, ether, ethyl acetate, DMF); low sol water.

Analysis of Reagent Purity: the phosphonates are isolable and can be fully characterized by standard analytical and spectroscopic techniques.[1,6,7] (**1a**) ^{31}P NMR (C_6D_6) δ -22 ppm.[8]

Preparative Methods: phosphonates (**1a**) (85%),[1] (**1b**) (74%),[1] and (**1e**) (82%)[7] are readily prepared by the Michaelis-Arbuzov reaction of ***Chloromethyl Methyl Ether***, ***2-Methoxyethoxymethyl Chloride*** (MEMCl), and ***2-(Trimethylsilyl)ethoxymethyl Chloride*** (SEMCl), respectively, with ***Triethyl Phosphite***. Reagents (**1c**) (82%) and (**1d**) (45%) are prepared from $HOCH_2PO(OEt)_2$ and ***3,4-Dihydro-2H-pyran***/***Phosphorus Oxychloride*** or ***t-Butyldimethylchlorosilane***/***Imidazole*** respectively.[1]

Handling, Storage, and Precautions: dialkyl phosphonates are irritants and their chloromethyl ether precursors are highly toxic carcinogens (or cancer suspect agents). Organolithium reagents and the other bases employed for the conversions of (**1**) are caustic and some are potentially pyrophoric. Proper handling

and special safety practices information should be obtained from the supplier and individuals should thoroughly familiarize themselves with these techniques prior to using these reagents.

Vinyl Ethers from the Horner-Emmons Alkenation.[9]

Dialkyl alkoxymethylphosphonates such as (**1**) are α-deprotonated at low temperatures (e.g. -60 °C) with strong base (***Lithium Diisopropylamide***,[10] ***n-Butyllithium***/***Potassium t-Butoxide***[5]), and the reaction of the resulting anion (Kluge reagent)[1] with aldehydes and ketones gives 1,2-adducts which undergo thermal elimination (M = Li, THF, reflux, aryl derivatives (2-4 h), aliphatic (16-72 h)).[1] Alternatively, these intermediates can be quenched to give isolable α-alkoxy-β-hydroxyalkylphosphonates which, after treatment with *t*-BuOK, undergo a more facile elimination (THF, reflux, 5 min). Polyunsaturated aldehydes are converted to polyenyl ethers using (**1a**) in 40-50% with high (*E*) stereoselectivities.[3] The MEM derivative (**1b**) is a more effective reagent for this process,[1b] while (**1d**) is ineffective because of the lability of the silyl group with respect to rearrangement.[1a] Kluge employed (**1c**) for the homologation of an intermediate ketone in his approach to the construction of the ajmaline nucleus (eq 1).[2] Heathcock also found the reagent effective for the homologation of mesityl oxide (eq 2, ca. 90% nonconjugated isomer),[4] a useful intermediate in the stereoselective synthesis of the C-1 to C-7 moiety of erythronolide A.

(2)

The reagents have not always been successful and several examples include the attempted homologation of thienocyclohexanones,[11] bicyclic ketones,[12,13] amides,[14] and penicillanic acid derivatives.[15] However, some polycyclic systems are effectively homologated employing (**1**) (50-60%),[16] but for others,[12] ***Methoxymethylenetriphenylphosphorane*** may be better. The sequential α-alkylation of (**1e**) (***s-Butyllithium***, RX) has been used to prepare branched α-hydroxyalkylphosphonates.[7] Related α-alkylated derivatives of (**1**) have been investigated as alkenating agents with mixed results.[17]

Ketene *O,S*-Thioacetals from (1).

An extension of these processes has been effectively employed for the synthesis of ketene *O,S*-thioacetals.[5c] Deprotonation of (**1a**) with LiBu/*t*-BuOK followed by sulfuridation and methylation produces the corresponding *O,S*-thioacetals of formylphosphonates.[5] These are lithiated with ***t-Butyllithium*** at -78 °C and condensed with aldehydes and ketones to afford ketene *O,S*-thioacetals in ca. 80% yield as essentially 1:1 (*E*)/(*Z*) mixtures (eq 3).

[116280-23-0] · $C_{10}H_{14}O_6$ · Ethoxycarbonylmethyl Ethyl Methylenemalonate · (MW 230.22)

(Michael acceptor; Diels-Alder dienophile; polymerizes by an anionic mechanism)

Alternate Name: diethyl methylidenemalonate.

Physical Data: bp:[1a] (**1**) 60-61 °C/0.25 mmHg; (**2**) 80-82 °C/6 mmHg; (**3**) 67-68 °C/0.3 mmHg; (**4**) 67 °C/0.1 mmHg;[2] (**5**) 65-67 °C/0.3 mmHg; (**6**) 98-99 °C/0.1 mmHg.

Solubility: freely sol diethyl ether, dichloromethane, chloroform, methanol; solvent should be dry and free of nucleophile to avoid polymerization.

Form Supplied in: the diethyl ester analog is commercially available as its Diels-Alder adduct with anthracene. The reagent can be deprotected by a retro Diels-Alder reaction (see eq 1).[1a]

Analysis of Reagent Purity: GC analysis.[1a]

Preparative Methods: the classical method of preparation is a Knoevenagel condensation between ***Formaldehyde*** and ***Diethyl Malonate*** in glacial acetic acid catalyzed by ***Copper(II) Acetate*** and potassium acetate.[3] The diethyl methylenemalonate obtained polymerizes spontaneously to form a wax during the workup. The monomer can be recovered from the wax by thermal depolymerization under vacuum. Unlike other analogs, the sterically hindered

di-*t*-butyl ester does not polymerize under these conditions, and it can be isolated directly from the condensation mixture by vacuum distillation.[2] More recently, anthracene was introduced to trap the formed alkene in situ (eq 1).[1a] The Diels-Alder adduct obtained in this one-pot procedure is stable and can be purified by recrystallization. After purification, a retro Diels-Alder reaction in a high boiling fraction of mineral oil at 200-250 °C under strictly anhydrous conditions followed by vacuum distillation regenerates the methylenemalonate.

This latter method is of more practical use and affords a wide array of analogs of high purity with improved shelf stability compared to material obtained by other methods. It was used on a semimicro scale for the synthesis of the carbon-14 labeled diethyl methylenemalonate starting with carbon-14 paraformaldehyde.[4] Moreover, this strategy allows easy access to nonsymmetric and functionalized ester analogs by partial hydrolysis of the symmetric adduct with ***Potassium Hydroxide*** and subsequent alkylation of the resulting salt in DMF, as exemplified for the ethyl propargyl analog in eq 2.

Handling, Storage, and Precautions: as methylenemalonate is very prone to anionic polymerization initiated even by water itself, it should be stored under dry inert gas in the cold. For a very long period it can be stored under SO_2 in a sealed glass container. Any glassware intended to be in contact with the reagent should be acid-washed and oven-dried and the solvent used should be dry. Due to its alkylating property, great care should be taken in handling the reagent and any contact should be avoided.

Introduction.

Only a few examples of the use of methylenemalonate esters can be found in the literature to date.

Radical Reactions.

An addition reaction of cycloalkyl radicals to diethyl methylenemalonate has been reported,[5,6] and a radical addition-cyclization reaction was described with diethyl α-(4-chlorobenzyl)malonyl radical (eq 3).[7]

Michael Reactions.

As electrophilic alkenes, methylenemalonates are Michael acceptors and the resulting adducts are monoalkylated malonates, suitable for further elongation of the carbon chain (eq 4).[8]

(4)

Reaction with the potassium salt of 2-nitropropane yields in one pot the corresponding *gem*-dimethylcyclopropane (eq 5).[9]

(5)

Epoxidation.

The reactivity of methylenemalonate toward epoxidation by peracid is somewhat surprising[10] (Prilezhaev reaction): even though the widely accepted rule is that reactivity parallels electron density, methylenemalonate esters afford fair yields of the oxirane upon treatment with ***m-Chloroperbenzoic Acid*** in dichloromethane, while alkyl acrylate and maleic acid do not react at all. Further, under the same conditions, allyl methyl methylenemalonate yields chemoselectively the product of epoxidation of the malonic double bond (eq 6).

(6)

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***Diethyl Ethylidenemalonate***; ***Diethyl Malonate***; ***Formaldehyde***; ***N-(Methylthiomethyl)piperidine***.

N,N-Diethyl-*N*-methyl-*N*-(methylsulfonyl)ammonium Fluorosulfate[1]

[55791-04-3] · $C_6H_{16}FNO_5S_2$ · *N,N*-Diethyl-*N*-methyl-*N*-(methylsulfonyl)ammonium Fluorosulfate · (MW 265.32)

(reagent for converting, under mild conditions, alcohols into methanesulfonate (mesylate) esters, and primary and secondary amines into methanesulfonamides[1,2])

Alternate Name: easy mesyl.

Physical Data: mp ~115 °C (dec).[2]

Solubility: sol dry MeCN (solutions decompose over a few hours at rt).[2]

Form Supplied in: not commercially available.

Preparative Method: reaction of $MeSO_2NEt_2$ with excess neat $MeOSO_2F$ at 50 °C for 72 h.[2]

Analysis of Reagent Purity: ^{1}H NMR (CD_3CN) δ: 1.40 (t, 6H), 3.11 (s, 3H), 3.60 (q, 4H), 3.70 (s, 3H).[2]

Handling, Storage, and Precautions: hygroscopic; hydrolyzed by moist air (products corrosive); stable indefinitely in a sealed ampoule at rt.

Mesylating Agent.

N,N-Diethyl-*N*-methyl-*N*-(methylsulfonyl)ammonium fluorosulfate[2]), and related compounds of the general structure $MeSO_2{+}NR^1R^2R^3$ X^- (X = FSO_3 or CF_3SO_3), are effective reagents for formation, under very mild conditions, of mesylates (from alcohols) and methanesulfonamides (from amines).[2] Good to excellent yields are obtained with easy mesyl plus a weakly basic tertiary amine (usually a catalytic amount) such as pyridine or dimethylaminoacetonitrile (DMAA) at temperatures ranging from -70 °C to rt, e.g. (-)-menthol (1 mmol), DMAA (10 µL) in CH_2Cl_2 (15 mL) at 0 °C on mixing with easy mesyl (1.2 mmol) in MeCN (1 mL) followed by workup after 10 min gave clean (-)-menthyl

mesylate (99%).[2] With relatively hindered alcohols (borneol, 5α-cholestan-3α-ol) the product may show contamination with the mesylmesylate ester ($ROSO_2CH_2SO_2Me$), the formation of which is (a) minimized by the use of (i) weak bases (py or DMAA as opposed to Et_3N or *N*-ethylmorpholine) and (ii) low concentrations of the amine, and (b) maximized by (i) strong bases and (ii) premixing of easy mesyl and the base.[2,3] Related *N*-methylsulfonylammonium salts also yield mesylates; $MeSO_2{+}NMe_3\ FSO_3^-$ is more readily prepared (85% yield in 1 h at rt) but is less soluble in MeCN and sometimes gives a poorer yield of the mesylate (35% vs. 80% of cyclohexyl mesylate under one set of conditions). In a set of comparison experiments[3] with 5α-cholestan-3β-ol (0 °C, excess py, 30 s) the yields with ***Methanesulfonyl Chloride***, ***Methanesulfonic Anhydride***, and $MeSO_2{+}NMe_3\ FSO_3^-$ were, respectively, <1%, 60%, and >98%. The cyclic sulfonylammonium salt prepared by *N*-methylation of *N*-methylpropanesultam with $MeOSO_2F$ is used in the preparation of 3-(trimethylammonio)-1-propanesulfonate esters ([3]betylates).[4]

Easy mesyl has proved useful in the preparation of fragile mesylates (e.g. *t*-BuOMs[2]), especially for immediate further transformation (eqs 1 and 2);[5,6] use of $MeSO_2Cl$ in these cases gave inferior results.

Diethyl Methylsulfinylmethylphosphonate

[50746-61-7] · $C_6H_{15}O_4PS$ · Diethyl Methylsulfinylmethylphosphonate · (MW 214.22)

(used for the preparation of vinyl sulfoxides and *O,S*-acetals of formyl phosphonates)

*Physical Data: n*20D = 1.4766;[1] disproportionates before boiling.

Solubility: sol acetone, CH_2Cl_2, MeOH, THF.

Preparative Methods: diethyl methylsulfinylmethylphosphonate can be obtained by controlled oxidation of ***Diethyl Methylthiomethylphosphonate***, as shown in eq 1.[1-4] The procedure using Br_2/aq. $NaHCO_3/CH_2Cl_2$ is notable because use of $H_2{}^{18}O$ allows for the preparation of ^{18}O sulfoxides.[2]

Handling, Storage, and Precautions: Diethyl methylsulfinylmethylphosphonate is reasonably stable for storage. Reactions involving this reagent are best conducted under anhydrous conditions, under nitrogen, in a well ventilated fume hood.

Reactions.

The sulfinylmethylphosphonate can be metalated with ***n-Butyllithium*** in THF and then reacted with a variety of aldehydes and ketones to form vinyl sulfoxides via the Horner-Emmons reaction (eq 2).[5] Alternatively, the reaction can be conducted under phase transfer conditions, and is then specific for aromatic aldehydes.[6] Initially a tetraalkylammonium salt was used as catalyst, but it was discovered that the phosphonate could function as its own phase transfer catalyst.[7] Subsequent reports showed that it can function generally as a phase transfer catalyst, for example in the alkylation of benzyl methyl ketone with butyl bromide.[8]

(2)

$R^1 = H$, $R^2 = Ph$, 70%, $(E):(Z) = 1:1$
$R^1 = R^2 = -(CH_2)_{4-6}$, 70-80%

Diethyl methylsulfinylmethylphosphonate undergoes the Pummerer reaction, resulting in oxidation of the α-carbon with concomitant reduction of the sulfoxide to a sulfide (eq 3).[9-12] Limited success in the transfer of chirality from sulfur to carbon has been achieved.[11]

(3)

Reagent	X
I_2, ROH, R = Me, Et	OR
$(RCO)_2O$, R = Me, *t*-Bu, Ph, CF_3	OCOR
PhCOCl	Cl

If the Pummerer reaction is conducted in an aromatic solvent, Freidel-Craft products are produced (eq 4).[12,13] In a similar manner, treatment of Pummerer products with alkenes gives ene style products (eq 5).[14]

Diethyl Methylsulfonylmethylphosphonate

[40137-11-9] · $C_6H_{15}O_5PS$ · Diethyl Methylsulfonylmethylphosphonate · (MW 230.22)

(used for the preparation of synthetically versatile vinyl sulfones from aldehydes and ketones)

Physical Data: mp 96 °C.[1]

Solubility: sol acetone, CH_2Cl_2, DME, THF.

Preparative Methods: conveniently prepared by oxidation of ***Diethyl Methylthiomethylphosphonate*** (eq 1). Both inorganic oxidants (e.g. ***Potassium Permanganate*** in water[1,2] or ***Hydrogen Peroxide/Selenium(IV) Oxide***[4]) and organic oxidants (e.g. ***Peracetic Acid*** in ether[3] or ***m-Chloroperbenzoic Acid*** in CH_2Cl_2[5]) have been used to accomplish this transformation.

Handling, Storage, and Precautions: diethyl methylsulfonylmethylphosphonate is reasonably stable for storage. Reactions involving this reagent are best conducted under anhydrous conditions, under nitrogen, in a well ventilated fume hood.

Reactions.

Diethyl methylsulfonylmethylphosphonate has been extensively used for the preparation of synthetically useful vinyl sulfones from aldehydes and ketones via the Horner-Emmons reaction. This generally involves treatment of the phosphonate with a base (a wide variety of bases and solvents have been employed) followed by quenching with a carbonyl compound, resulting in the (often) stereoselective formation of vinyl sulfones.

Sodium Hydride, ***Sodium Methoxide***, or ***n-Butyllithium*** are commonly used to generate the phosphonate anion, which can be reacted with aryl and aliphatic aldehydes to give alkylidine sulfones (eq 2).[1-3] Enals,[6] ketones,[7] and heterocyclic aldehydes[8] also participate in this reaction, giving the corresponding vinyl sulfones.

(2)

R = alkyl, aryl, heteroaryl, alkenyl
base = NaH, NaOMe, NaOEt, BuLi

Even the sterically hindered C-17β steroidal aldehyde reacts readily with the phosphonate anion to furnish the vinyl sulfone in excellent yield (eq 3).[8]

(3)

Mikolajczyk et al. have shown that the reaction can be carried out under phase transfer conditions, catalyzed by quaternary ammonium salts.[9] This reaction was found to be specific for aromatic aldehydes, and fails for enolizable aldehydes and ketones. Among the several quaternary ammonium salts investigated, ***Benzyltriethylammonium Chloride*** (TEBA) gave the best yields and was also totally stereoselective in that only (*E*)-sulfones were produced (eq 4).

(4)

Reaction of diethyl methylsulfonylmethylphosphonate anion with enolizable ketones is often problematic and leads to unsatisfactory yields of vinyl sulfones. Fillion and co-workers have shown that the yields are improved when the reaction is conducted under sonication conditions (eq 5).[10]

(5)

Certain ketones readily undergo the reaction, including the sensitive β-lactam dione shown in eq 6.[11]

(6)

The direct synthesis of allenyl sulfones was simply accomplished by the reaction of the sulfonylphosphonate anion with ketenes (eq 7).[12] The yields of this reaction are also improved under sonication conditions.[13]

(7)

Minami et al. have shown that diethyl methylsulfonylmethylphosphonate readily undergoes the Knoevenagel reaction, resulting in the formation of 1,1-phosphonosulfonoalkenes.[14] A typical example is the condensation of the phosphonate with cinnamaldehyde in the presence of piperidine. The initially formed aldol eliminates water when treated with catalytic ***p-Toluenesulfonic Acid***, furnishing the (*E*,*E*)-isomer of 1,3-butadienylsulfonylphosphonate in excellent yield (eq 8).

(8)

A similar sequence with formaldehyde constitutes an efficient synthesis of the simplest member of the family (eq 9).[15]

Diethyl Methylthiomethylphosphonate

[28460-01-7] · $C_6H_{15}O_3PS$ · Diethyl Methylthiomethylphosphonate · (MW 198.22)

(used for the conversion of aldehydes and ketones to vinyl sulfides, which can be hydrolyzed to yield homologated aldehydes and ketones)

Physical Data: bp 70-72 °C/0.2 mmHg,[1] *d* 1.465 g cm^{-3}.[2]

Solubility: sol acetone, CH_2Cl_2, THF.

Form Supplied in: neat liquid.

Preparative Methods: although the reagent has recently become commercially available, a number of methods are available for its preparation.

The Arbuzov reaction between methylthiomethyl chloride and ***Triethyl Phosphite*** (no solvent, 110 °C for 6 h) gives good yields of diethyl methylthiomethylphosphonate (eq 1).[1,3]

Another convenient preparation involves a nucleophilic displacement reaction between dialkyl chloromethylphosphonates and alkanethiolates (eq 2).[4]

Metalated diethyl methylphosphonate reacts with elemental ***Sulfur*** to give isolable α-phosphorylthiols in high yields.[2] Alkylation with ***Iodomethane*** under phase transfer conditions gives the desired reagent (eq 3).

Handling, Storage, and Precautions: diethyl methylthiomethylphosphonate has a stench and is an irritant, but is reasonably stable for storage. Reactions involving this reagent are best conducted under anhydrous conditions, under nitrogen, in a well ventilated fume hood.

Reactions.

The chief utility of diethyl methylthiomethylphosphonate lies in the synthesis of vinyl sulfides from carbonyl compounds such as aldehydes or ketones via the Horner-Emmons reaction. These vinyl sulfides are stable, easily handled intermediates which upon hydrolysis furnish homologated aldehydes or ketones. Green initially showed that such a procedure was viable for the synthesis of homologous aldehydes.[1] Corey's more practical adaptation extended Green's original procedure to the synthesis of homologous ketones.[5] Thus diethyl methylthiomethylphosphonate can be metalated and alkylated with MeI to give diethyl (1-methylthio)ethylphosphonate, which can itself be metalated at -70 °C in THF with ***n-Butyllithium*** to give a lithio derivative which reacts with aldehydes or ketones. The initially formed adduct eliminates phosphonate to give vinyl sulfides (eq 4). It should be noted that the reaction often fails with readily enolizable ketones. The vinyl sulfides thus produced are easily hydrolyzed using ***Mercury(II) Chloride*** in aqueous acetonitrile to give good yields of homologated aldehydes and ketones.

(4)

The reaction can be conducted so that water is lost instead of phosphonate, leading to the synthesis of phosphonovinyl sulfides.[6] Thus treatment of lithiated diethyl methylthiomethylphosphonate with benzaldehyde furnishes an adduct which can be isolated. Conversion of the hydroxy moiety to chloride followed by β-elimination gives phosphonovinyl sulfides. Phosphonovinyl sulfides can be oxidized to phosphonovinyl sulfoxides or sulfones, which are powerful Michael acceptors (eq 5).

(5)

Lithiated diethyl methylthiomethylphosphonate can also react with ***Carbon Dioxide***, which upon acidification provides diethyl α-(methylthio)phosphonoacetic acid.[7] This bifunctional reagent can undergo inter- or intramolecular Horner-Emmons reactions, furnishing α-methylthio-α,β-unsaturated carboxylic acids or γ- and δ-lactones (eq 6).

(6)

The reaction of lithiated diethyl methylthiomethylphosphonate with ketones has achieved only limited success. For example, reaction with a β-lactam dione stops at the stage of addition (eq 7) and, unlike lithiated ***Diethyl Methylsulfonylmethylphosphonate***, does not eliminate to give the corresponding vinyl sulfide.[8]

(7)

Mikolajczyk et al. examined the reaction between lithiated diethyl methylthiomethylphosphonate and an α,β-unsaturated ketone and found that the initially formed 1,2-addition product does not eliminate phosphonate, but rearranges to the more stable 1,4-addition product (eq 8).[9] The detailed mechanism of this rerrangement has not been investigated.

(8)

Lithiated diethyl methylthiomethylphosphonate can react with a wide variety of electrophiles to furnish a variety of α-substituted derivatives which are otherwise difficult to obtain. For example, reaction of lithiated diethyl methylthiomethylphosphonate with dialkyl disulfides to give *S*,*S*-acetals proceeds in good yields (eq 9).[10] Similarly, reaction with ***Chlorotrimethylsilane*** gives diethyl methylthio(trimethylsilyl)methylphosphonate, which after metalation undergoes a highly stereoselective Peterson alkenation with aldehydes to give (*E*)-vinylphosphonates in good yields (eq 9).[11] Zwanenberg and co-workers demonstrated that the isolation of the moisture sensitive diethyl methylthio(trimethylsilyl)methylphosphonate was not necessary in certain cases, and in one pot lithiated and treated with ***Sulfur Dioxide*** to produce very reactive sulfines (eq 10).[12]

(9)

(10)

The sulfur atom in diethyl methylthiomethylphosphonate can be easily oxidized to either the sulfoxide or the sulfone, depending upon the choice of oxidant.[13] Other more unconventional oxidations of diethyl methylthiomethylphosphonate include facile anodic oxidation in NaOMe/MeOH (saturated with CO_2) to give the *O*,*S*-acetal of diethoxyphosphinylformaldehyde (eq 11).[14]

(11)

α-Chlorination of diethyl methylthiomethylphosphonate has been accomplished by lithiation followed by reaction with ***N-Chlorosuccinimide*** (NCS) as shown in eq 12.[15] The diethyl chloro(methylthio)methylphosphonate so obtained undergoes a facile Friedel-Crafts reaction with aromatic compounds, giving diethyl 1-arylmethylthiomethylphosphonates in excellent yields.

(12)

Kondo et al. have prepared sulfur ylides from diethyl methylthiomethylphosphonate by reaction with MeI/$AgClO_4$ to give a

sulfonium salt, which when treated with ***Sodium Hydride*** gave an ylide (eq 13).[16] The ylide reacts with benzaldehyde to give vinylidene sulfonium salts.

Diethyl Morpholinomethylphosphonate

[27353-29-3] · $C_9H_{20}NO_4P$ · Diethyl Morpholinomethylphosphonate · (MW 237.24)

(for spiroannulation at carbonyl centers;[2] formyl anion equivalent[3])

Physical Data: bp 137 °C/3 mmHg.

Solubility: sol most organic solvents.

Analysis of Reagent Purity: readily ascertained by NMR.

Preparative Method: by the addition of ***Formaldehyde*** to a stirred mixture of equimolar quantities of ***Morpholine*** and ***Diethyl Phosphonite***. Vacuum distillation affords pure product in 92% yield.[1]

Purification: distillation at reduced pressure.

Amino Phosphonic Acid Esters.

During investigations on the synthesis of substituted α-amino phosphonic esters, the title compound (**3**) was obtained in high yield, exemplifying the generality of the synthetic route presented for the preparation of α-aminophosphonates (eq 1).[1]

(1)

Quaternary Carbon Formation.

The utility of (**3**) for quaternization by geminal alkylation at a carbonyl center has been demonstrated.[2] Anion formation and Horner-Emmons reaction with a ketone afforded the morpholine enamine of the homologous aldehyde (eq 2), which was shown to undergo Michael addition to methyl vinyl ketone. Subsequent acid hydrolysis of the resultant imine was accompanied by intramolecular aldol condensation and dehydration, thereby resulting in the formation of 4,4-disubstituted 2-cyclohexenones (eq 3).

(2)

(3)

This procedure was shown to be applicable to acyclic, cyclic, aromatic, and α,β-unsaturated ketones. Use of cyclic ketones illustrated the facile production of spirocyclic ring systems. For substrates possessing conformational constraints, a reasonable degree of stereoselectivity was observed (eq 4).

(4)

Enamine Synthesis.

Other investigations on enamine synthesis using reagent (**3**) provided an interesting but conflicting result.[3] Addition of the phosphonate anion of (**3**) to a carbonyl substrate resulted only in isolation of the α-morpholino-β-hydroxyphosphonate addition product (**10**) (eq 5). Elimination to form the enamine could not be induced even upon

treatment of (**10**) with KH. On this basis the authors suggested that the mechanism of the reaction may not be as straightforward as originally thought.

(5)

Miscellaneous.

An attempt at using the morpholinophosphonate in the preparation of sulfides by displacement of the diethyl phosphinate moiety with a thiolate anion resulted instead in the mono-dealkylation of the reagent (eq 6).[4]

(6)

Oxidation of (**3**) with excess mercury(II) ion afforded the corresponding lactam but only in 7% yield (eq 7).[5] Based on literature precedent and experimental investigations, the transformation was proposed to occur via an intermediate iminium ion with internal participation of the phosphonate oxygen.[5]

Solubility: completely sol ether, alcohol and acetone; slightly sol hot water. The solubility of dimethyl oxalate is similar, except that it is more soluble in water. The solubilities of the other esters are similar in organic solvents, but they are insoluble in water.

Form Supplied in: the diethyl and dimethyl esters are readily available commercially in ca. 98% purity.

Preparative Methods: dimethyl oxalate;[7] di-*t*-butyl oxalate;[8] others.[9]

Handling, Storage, and Precautions: diethyl oxalate is harmful if swallowed and is irritating to the eyes. Care should be taken not to inhale the vapor. It is sensitive to moisture. It should be disposed of by burning in an approved incinerator. Dimethyl oxalate has similar properties to the diethyl ester and is harmful by inhalation and through skin. It should be disposed of by burning in an approved incinerator. Little is known about the other esters, which have been much less used. These reagents should be handled in a fume hood.

Esters of Oxalic Acid.

The diethyl ester has been most commonly used in synthesis, but the methyl ester would appear to serve equally well. Other esters may have specific applications.[10]

Electrophile in Acylation Reactions.

Ketone enolates add to one ester group of diethyl oxalate with the loss of ethanol to give the α,γ-diketo ester. The diketo ester can be converted to the β-keto ester by pyrolytic loss of CO. Both steps are exemplified in the synthesis of pimelic acid (eq 1).[11] The α,γ-diketo ester is enantiotopically reduced by ***Baker's Yeast*** to give a diastereomeric mixture of α-hydroxy-γ-keto esters which on Clemmensen reduction gives the α-hydroxy ester as a single enantiomer (eq 1).[12] *Proteus vulgaris* reduces α-keto acids to the corresponding (*R*)-α-hydroxy acids.[13]

Diethyl oxalate acylates diethyl succinate in the presence of ***Sodium Ethoxide***, and the resulting triester can be hydrolyzed to α-ketoglutaric acid with the loss of CO_2 (eq 2).[14]

Dimethyl oxalate acylates 3-substituted dimethyl glutarates in the presence of ***Sodium Methoxide*** to give substituted cyclopentadienes (eq 3).[15] α,β-Unsaturated esters are acylated in the same way to give dimers. These are in equilibrium with the corresponding monomer and react with dimethyl malonate under basic conditions to give hydroxycyclopentenones (eq 4).[16]

(3)

(4)

Organometallic reagents react with diethyl oxalate in THF to give α-keto esters,[17-19] usually in high yield (eq 5). The reaction was successful with a lithiated indole derivative (eq 6).[20]

(5)

(6)

Rambaud and co-workers obtained a range of β,γ-unsaturated α-keto esters by modification of this method (eq 7).[10,13]

(7)

Benzyl chromium tricarbonyl complexes can be acylated with diethyl oxalate in the presence of ***Potassium t-Butoxide*** and the resulting potassium enolate can be hydrolyzed with water or trapped with ***t-Butyldimethylchlorosilane*** (eq 8).[21]

(8)

Preparation of Heterocycles.

Urea condenses with diethyl oxalate in the presence of sodium methoxide to give, after neutralization, parabanic acid (eq 9).[3]

(9)

o-Nitrotoluene adds to diethyl oxalate in the presence of potassium ethoxide to give the enolate which on hydrogenation gives ethyl 2-indoylcarboxylate (eq 10).[22]

When the formimidate group is available to the enolate at the adacent *ortho* position, then a 4-nitroindole is obtained (eq 11).[23]

Naphthalene-1,8-diamine reacts on heating with diethyl oxalate to give a pyrimidine derivative (eq 12).[24]

Activating Group in the Preparation of α,β-Unsaturated Ketones.

Ksander and McMurry[4] developed a sequence in which a methyl ketone is acylated by diethyl oxalate and the resulting α,γ-diketo ester acts as a nucleophile on treatment with an aldehyde. The resulting diketo lactone is pyrolyzed with the loss of CO and CO_2 to give the α,β-unsaturated ketone (eq 13).

(13)

Activating Group for Regiospecific Alkylation.

An enol ester has been introduced as a directing group for alkylations, particularly in steroids, by acylation with diethyl oxalate. Methylation can be directed to C-2 rather than C-4 by this procedure, and the directing group is readily removed (eq 14).[5,25,26]

(14)

Activating Group for the Preparation of Diazo Ketones.

Acylation of a methyl ketone with diethyl oxalate in the presence of sodium ethoxide gives the sodium enolate which on treatment with ***p-Toluenesulfonyl Azide*** gives the corresponding diazomethyl ketone (eq 15).[6]

(15)

Related Reagents.

Carbon Dioxide; ***Diethyl Carbonate***; ***Methyl Magnesium Carbonate***; ***Methyl Chlorooxalate***; ***Methyl Cyanoformate***; ***Oxalic Acid***; ***Oxalyl Chloride***.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: *n*20D 1.425.

Preparative Methods: diethyl oxomalonate can be prepared by bromination of ***Diethyl Malonate*** to the dibromomalonic ester, exchange of one bromine atom for acetate and α-elimination of acetyl bromide.[25] Alternatively, diethyl malonate is condensed with benzaldehyde to afford the Knoevenagel product which is cleaved by ozonolysis.[26]

Purification: fractional vacuum distillation.

Handling, Storage, and Precautions: diethyl oxomalonate is stable for at least 6 months if stored in the refrigerator.

Diethyl oxomalonate (**1**) undergoes Diels-Alder reactions as an electron-poor heterodienophile.[1a] Thus reactions with electron-rich butadienes furnish the *gem*-diesters (**2**)[1] (eq 1), which can be converted to the monoacid (**3**) by decarboxylation[1d] or to the unsaturated δ-valerolactones (**4**) either by a Curtius degradation sequence[1b,c] or ***Cerium(IV) Ammonium Nitrate*** (CAN) oxidation (Scheme 1).[7]

Scheme 1

The reaction is run either at elevated temperature (120-140 °C, MeCN or toluene),[1b-d] under high pressure conditions (10 kbar)[1e,f] or under Lewis acid catalysis.[1a] Chiral Lewis acids have also been applied, but gave only very modest enantioselectivities (<15% ee).[2]

Azadienes (**5**) undergo hetero Diels-Alder reactions with diethyl oxomalonate (**1**) in THF at 80 °C (eq 2).[3] 2,3-Dihydropyran-4-ones (**6**) are formed in the reaction with Danishefsky's diene (**7**) under Lewis acid catalysis at ambient temperature (eq 3).[4]

(5) (1) (2)

(7) (1) (6)

Reagent (**1**) has been used in [3 + 2] dipolar cycloadditions as a heterodipolarophile.[5] *N*-(Silylmethyl)-substituted ketene *N*,*S*-acetals (**8**) are converted to the 1,3-dipolar reagent (**9**) with ***Cesium Fluoride*** in MeCN, which undergoes the cycloaddition with (**1**) to afford the alkylideneoxazolidines (**10**) in modest yield, but with complete regioselectivity (eq 4).

Diethyl oxomalonate has been shown to be reactive towards 1,3-diyls.[6] Heating the diazene (**11**) produces the 2-alkylidene-1,3-diyl (**12**), which is trapped in situ by (**1**) to form the fused cycloadduct (**13**) as a sole isomer in good yield (eq 5). Other diyls, however, give mixtures of isomers.

An example of a 1,4-dipolar cycloaddition of (**1**) with 6-oxo-3,6-dihydro-1-pyrimidinium-4-olate (**14**) has been described which leads to diazabicyclo[2.2.2]octanediones (**15**) (eq 6).[7]

(14) (15)

[2 + 2] Cycloadditions of (**1**) and electron-rich alkenes like 1,1-dimethoxy-2-propene (**16**) have also been investigated.[8] Oxetanes (**17**) are formed in good yield with complete regioselectivity in a thermal reaction (eq 7). Under photochemical conditions, addition does not take place.

(16) (17)

Diethyl oxomalonate reacts with alkenes that have an allylic hydrogen atom in an ene reaction (eq 8).[9] The reaction is run either thermally or under Lewis acid catalysis. Occasionally the ene reaction is followed by a cyclization to form a tetrahydrofuran diester (**18**), which can be converted to the butyrolactone (**19**) by CAN oxidation (eq 8).[10]

(18) (19)

Due to the adjacent ester groups, (**1**) is a highly reactive carbonyl compound which reacts with a variety of nucleophiles. Thus benzoxazinones (**20**) are formed in the reaction with aminophenols (eq 9).[11] Similarly, 6-

ethoxycarbonyl-7-oxopyrazinothiadiazines (**21**) are accessible by the reaction of 3,4,5-triamino-2*H*-1,2,6-thiadiazine 1,1-dioxide (**22**) with diethyl oxomalonate (eq 10).[12]

(9)

(10)

Enamines (**23**) react with diethyl oxomalonate to furnish aldol products which can be dehydrated and cyclized to the butenolides (**24**) by acid catalysis (eq 11).[13] *N*-Methylindole (**25**) smoothly adds to (**1**) to afford 3-indolylhydroxymalonate (**26**) (eq 12).[14] In the presence of ***Ethylaluminum Dichloride*** a second addition takes place and the 3,3´-bisindolyl derivative (**27**) is formed (eq 12).

(11)

(12)

The high-pressure addition of 2,5-dialkylfurans (**28**) to (**1**) very selectively affords the addition product (**29**) (eq 13).[15] No double addition is observed. The reaction has been shown to proceed through a [1,5]-suprafacial shift of the diethyl oxomalonate moiety.

(13)

Diethyl trimethylsilyl phosphite (**30**) adds to diethyl oxomalonate in a redox process to yield α-hydroxyphosphonic ester (**31**) (eq 14).[16] Only very electron-poor ketones display such a reactivity towards trimethylsilyloxyphosphorus(III) derivatives.

Even aromatic compounds are sufficiently reactive to add to (**1**). The reaction of *p*-xylene (**32**) with (**1**) is promoted by ***Tin(IV) Chloride*** at ambient temperature (eq 15).[17]

Diethyl oxomalonate has frequently been used in Wittig reactions. Thus the phosphorus ylide (**33**) of a cephalosporin derivative is smoothly converted to the unsaturated diester (**34**) (eq 16).[18] The ylide (**35**) of a dithioacetal furnishes the ketene dithioacetal (**36**) (eq 17).[19] An imino-Wittig-type reaction has been used for the construction of the side chain of the mycosporins.[20] The iminophosphorane (**37**), obtained by a Staudinger reduction of the corresponding azide, is condensed with (**1**); the resulting imine (**38**) is reduced in situ with ***Sodium Cyanoborohydride*** (eq 18).

(35) (36) (17)

(37) (38) (18)

Reagent (**1**) has also been applied to a phospha-Wittig reaction with (**39**) to yield the phospha-alkene complex (**40**) (eq 19).[21] These complexes have been shown to take part in [2 + 2] processes with enol ethers, enamines, and ethoxyacetylene to give phosphetanes.[22]

(39) (40) (19)

Amines can easily be condensed with diethyl oxomalonate by heating at reflux with water removal (Dean-Stark trap). The imines (**41**) undergo electrophilic cyclization with an internal electron-rich double bond under Lewis acid or ***Trimethylsilyl Trifluoromethanesulfonate*** catalysis to produce various nitrogen heterocycles, including piperidines, octahydroisoquinolines, azepines, and pyrrolidines (eq 20).[23] Depending on the reaction conditions *cis*-lactones (**42**) are formed in a second step very selectively (eq 20).

Reagent (**1**) has also been used in Pictet-Spengler reactions of tryptamine-2-carboxylic acids (**43**) (eq 21).[24] The reaction is run in refluxing benzene/dioxane/trifluoroacetic acid solution with water removal (Dean-Stark trap). Rearrangement of the initially produced iminium ion gives rise to the 1,2,3,4-tetrahydro-β-carbolin (**44**).

In addition to the transformations of diethyl oxomalonate described above, several achiral and chiral dialkyl oxomalonates, such as dimethyl oxomalonate,[27-40] have been used in related reactions. The esters are best prepared by ozonolysis of the Knoevenagel products of benzaldehyde and the corresponding dialkyl malonates.[23,26]

Diethyl 2-Pentenedioate

(R = Et)

[2049-67-4] · $C_9H_{14}O_4$ · Diethyl 2-Pentenedioate · (MW 186.21) (*E*)-(R = Et)

[73178-43-5] (R = Me)

[5164-76-1] · $C_7H_{10}O_4$ · Dimethyl 2-Pentenedioate · (MW 158.15) (*E*)-(R = Me)

[41527-39-3]

(effects annulations that involve the reagent's alkenic group,[1] and annulations in which the reagent functions as a bis-nucleophile[2])

Alternate Name: diethyl glutaconate.

Physical Data: diethyl: bp 236-238 °C, 125 °C/12 mmHg; *d* 1.053 g cm^{-3}.

Solubility: sol DME, DMSO, MeOH, HOAc.

Form Supplied in: the diethyl ester is more readily available commercially. It is supplied as a liquid (*E*)/(*Z*) mixture in 98% purity.

Analysis of Reagent Purity: diethyl: ^{1}H NMR.[3]

Purification: vacuum distillation.

Annulations Involving the Reagent's Alkenic Bond.

A number of applications of this reagent require the central, alkenic carbon to serve as one point of attachment in annulation processes. Eq 1[4] demonstrates a straightforward conjugate addition-intramolecular Friedel-Crafts acylation tandem, whereas a conceptually if not mechanistically related electrochemical process is shown in eq 2.[5]

An additional transformation of this type in which the reagent provides both conjugate addition and nucleophilic reaction sites for ring formation is shown in eq 3.[1]

(3)

Annulations without Reaction at an Alkenic Site.

Processes that append a five-carbon unit derived from the reagent without the attachment of substituents at the reagent's central carbon are also known. In eq 4,[6] eq 5,[7] and eq 6[2] the reagent acts as a bis-nucleophile in ring-forming processes.

Diethyl Phenyl Orthoformate[1]

[14444-77-0] · $C_{11}H_{16}O_3$ · Diethyl Phenyl Orthoformate · (MW 196.25)

(mixed orthoformate which undergoes monosubstitution with Grignard reagents and other organometallic reagents to give diethyl acetals)

Alternate Name: diethoxy(phenoxy)methane.

Physical Data: bp 112 °C/13 mmHg; *n*20D 1.4799; *d* 1.016 g cm^{-3}

Solubility: insol cold H_2O; sol most organic solvents.

Analysis of Reagent Purity: ^1H NMR.[2]

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: store in absence of water. Possibility of hydrolysis and disproportionation.[2] Irritates eyes, skin, and lungs. Use in a fume hood.

Diethoxymethylation.

The reagent reacts with various nucleophiles, especially Grignard reagents (RMgX) under mild conditions, and gives good yields of the homologous aldehyde diethyl acetals (eq 1).[3]

Owing to the lack of reviews, the scope of the reaction is best shown by grouping the possible Grignard reagents: alkyl-MgX;[3-5] alkenyl-MgX (other than allyl);[6] allyl-MgX (allyl rearrangements possible);[4,7] vinyl-MgX;[4] cycloalkadienylmethyl-MgX;[8] alkynyl- or alkynylalkyl-MgX (an important group);[4,9] aryl-MgX;[3,10] 1-phenyl-1-

ethyl-MgX;[11] 3-quinolizidinemethyl-MgX;[12] bullvalenyl-MgX;[13] arylsulfonylchloromethyl-MgX;[14] Bu_3Sn-MgX (important source of various organotin reagents);[15] *t*-butylMgX does not react.[4] Propargylorgano-Al, -Mg, and -Zn derivatives (propargyl-allene rearrangements) react analogously,[16] as do some cyclic organolithium compounds,[17] a dilithiocarborane,[18] some organozinc ester enolates,[4] and cyclohexanone magnesium enolate.[4]

Related Reagents.

Simple orthoformates like ***Triethyl Orthoformate*** react analogously,[19] but yields are generally low. Ethyl diphenyl orthoformate reacts with 2 equiv of ***Phenylmagnesium Bromide*** to give ethylbenzhydryl ether in 87% yield.[3]

See also ***Carbon Monoxide***; ***N,N-Dimethylformamide***; ***1,1,3,3-Tetramethylbutyl Isocyanide***; ***Triethyl Orthoformate***.

Diethyl Phenylsulfinylmethylphosphonate

[65915-25-5] · $C_{11}H_{17}O_4PS$ · Diethyl Phenylsulfinylmethylphosphonate · (MW 276.29)

(used for the preparation of vinyl sulfoxides and *O,S*-acetals of formyl phosphonates)

*Physical Data: n*20D = 1.5236.[1]

Solubility: sol acetone, MeOH, CH_2Cl_2, THF.

Preparative Method: most conveniently prepared by controlled oxidation of ***Diethyl Phenylthiomethylphosphonate*** (eq 1).[1-3]

Handling, Storage, and Precautions: diethyl phenylsulfinylmethylphosphonate is reasonably stable for storage. Reactions involving this reagent are best conducted under anhydrous conditions, under nitrogen, in a well ventilated fume hood.

Reactions.

The applications of diethyl phenylsulfinylmethylphosphonate center on its ability to undergo Horner-Emmons and Pummerer reactions.

In the Horner-Emmons reaction, the sulfinylphosphonate can be metalated with ***n-Butyllithium*** in THF and then reacted with aldehydes or ketones to form vinyl sulfoxides. For example, this sequence, followed by intramolecular Michael addition, has been used to synthesize chroman sulfoxide, an important intermediate in the synthesis of α-tocopherol (eq 2).[4] Modest transfer of chirality from the sulfoxide to the bicyclic product has been observed in this

reaction.

$(E):(Z) = 1:1$

Alternatively, the reaction can be conducted under phase transfer conditions, and is then specific for aromatic aldehydes (eq 3).[5] Initially a tetraalkylammonium salt was used as catalyst, but it was discovered that the phosphonate could function as its own phase transfer catalyst (eq 3).[6] Subsequent reports showed that it can function generally as a phase transfer catalyst, for example in the alkylation of benzyl methyl ketone with butyl bromide.[7]

A: CH_2Cl_2, 50% aq NaOH — 53%, $(E):(Z) = 82:18$

B: CH_2Cl_2, 50% aq NaOH, $Et_3N^+Bn\ Cl^-$ — 48-57%

Diethyl phenylsulfinylmethylphosphonate undergoes the Pummerer reaction under a variety of conditions, resulting in oxidation of the α-carbon with concomitant reduction of the sulfoxide to a sulfide (eq 4).[8-11] Limited success in the transfer of chirality from sulfur to carbon has been achieved.[10]

(4)

Reagent	X
I_2, ROH (R = Me, Et)	RO
$(RCO)_2O$ (R = Me, *t*-Bu, Ph, CF_3)	RCO_2
PhCOCl	Cl

If the Pummerer reaction is conducted in an aromatic solvent, Freidel-Crafts products are produced (eq 5).[11]

Diethyl Phenylthiomethylphosphonate

[38066-16-9] · $C_{11}H_{17}O_3PS$ · Diethyl Phenylthiomethylphosphonate · (MW 260.29)

(used for the conversion of aldehydes and ketones to vinyl sulfides, which can be hydrolyzed to yield homologated aldehydes and ketones)

Physical Data: bp 145-150 °C/0.5 mmHg.[1]

Solubility: sol CH_2Cl_2, THF, MeOH.

Form Supplied in: neat liquid.

Preparative Methods: although the reagent is commercially available, there are a number of methods available for its preparation.

The Arbuzov reaction between phenylthiomethyl chloride (***Chloromethyl Phenyl Sulfide***) and ***Triethyl Phosphite*** is the most commonly used method of preparation (eq 1).[2,3]

A useful alternative to the Arbuzov reaction is the Michaelis-Becker reaction between phenylthiomethyl chloride and sodium diethyl phosphite (eq 2).[3]

An umpolung version of the Michaelis-Becker reaction involves the treatment of ***Diethyl Phosphorochloridate*** with lithiated methyl phenyl sulfide (eq 3).[1]

Moderate yields have been obtained in the Mitsunobu coupling of diethyl 1-hydroxyalkylphosphonates and thiophenol (eq 4).[4]

Handling, Storage, and Precautions: has a stench and is an irritant, but is reasonably stable for storage. Reactions involving this reagent are best conducted under anhydrous conditions, under nitrogen, in a well ventilated fume hood.

Reactions.

In general, anions generated from diethyl phenylthiomethylphosphonate can be alkylated or reacted with aldehydes or ketones to make vinyl sulfides or vinylphosphonates. We shall consider only selected examples here because most of the reactions of diethyl phenylthiomethylphosphonate are strictly analogous to those of ***Diethyl Methylthiomethylphosphonate*** and the reader is referred to that entry.

The reaction of metalated diethyl phenylthiomethylphosphonate with ketones to give vinyl sulfides often proceeds in excellent yields (eq 5).[5]

(5)

The reaction of lithiated diethyl phenylthiomethylphosphonate with aryl nitriles to give ketimines, followed by hydrolysis, provides a simple route to synthetically useful β-keto sulfides (eq 6).[6] Alternatively, the anion can be quenched with ***Carbon Dioxide*** to furnish α-phenylthiodiethylphosphonocarboxylic acids (eq 6).[7]

(6)

Reaction of the lithiated reagent with alkyl halides, followed by oxidation to a sulfoxide and elimination, constitutes an efficient synthesis of predominately *trans*-vinylphosphonates (eq 7).[8]

(7)

Treatment of the reagent with ***N-Chlorosuccinimide*** gives diethyl α-chlorophenylthiomethylphosphonate,[3,9] which can be reacted with alcohols to furnish *O,S*-acetals or metalated and reacted with aldehydes and ketones in the usual way to furnish 1-chloro-1-phenylthioalkenes (eq 8).[9] Initial oxidation to the sulfone followed by metalation and condensation with aromatic aldehydes furnishes 1-chloro-1-phenylsulfonylalkenes (eq 8).[10]

(8)

77-90%

Controlled oxidation of the reagent to give ***Diethyl Phenylsulfinylmethylphosphonate*** is discussed separately under the section for that reagent.

Diethyl Phosphonite

[762-04-9] · $C_4H_{11}O_3P$ · Diethyl Phosphonite · (MW 138.10)

(weak acid whose anion can function as a nucleophile at phosphorus, engaging in S_N2 displacement reactions and carbonyl additions; can hydrophosphonylate imines, ketenes, and enamines; can phosphonylate vinyl and aryl halides with Pd^0 catalysis; can function as an amine-protecting group[1])

Alternate Names: diethyl phosphite; DEP.

Physical Data: bp 50-51 °C/2 mmHg; *d* 1.072 g cm^{-3}.

Solubility: sol water, THF, alcohol.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: should be stored in absence of moisture and freshly distilled before use if any suspicion exists regarding purity.

Nucleophilic Displacement.

The anion of DEP can be formed using strong bases (i.e. alkali metals, alkoxides, or hydrides) and can undergo a variety of displacement reactions which are generally known as Michaelis-Becker reactions.[1] The mechanism of these reactions is viewed as proceeding via classical S_N2 attack by phosphorus on the electrophilic center.[2] A variety of phosphonates have been prepared by this method (eqs 1 and 2).[3,4]

(1)

(2)

R^1, R^2, Yield (%) = Me, H, 70; C_3H_7, H, 90; C_5H_{11}, H, 87; CH_2=CHMe, H, 82; Me, Me, 60; Me, Ph, 75; Et, Ph, 78

As with trialkyl phosphites, reaction of DEP anion with α-halo ketones results in Perkov-type products produced from phosphorus attack at the carbonyl carbon rather than that bearing the halide (eq 3).[5]

(3)

Reaction of the anion with α-halo esters[6] or α-halo phosphonates[7] is reported to proceed cleanly with simple displacement of the halogen.

Reactions with Multiple Bond Systems.

In addition to displacement reactions, the anion of DEP can add to a carbonyl carbon, forming the corresponding α-hydroxy phosphonate. This reaction, known as the Pudovik reaction, has been shown to be catalytic in the amount of phosphite salt necessary to promote the reaction.[8] Typically, a small amount of alkoxide is added to the reaction mixture (eqs 4 and 5).[9,10]

(4)

(5)

It has been shown that the rate of the reaction increases in a manner directly proportional to the solvating power of the medium.[11] Other approaches which have been successfully employed to promote the Pudovik reaction with aldehydes or ketones include (a) neutral amine bases (eq 6),[12] (b) chiral amine bases where asymmetric induction resulted,[13] (c) phase-transfer catalysis,[14] (d) solid phase basic catalysis with alumina,[15] and (e) solid phase basic catalysis with fluoride salts (eq 7).[16]

(6)

(7)

In addition to carbonyl systems, DEP adds to imines (eq 8),[17] ketene acetals (*O*,*N*-;*S*,*N*-;*N*,*N*-) (eq 9),[18] and enamines (eq 10).[19]

(8)

(9)

(10)

Another aspect of multiple bond addition by DEP is conjugate addition to α,β-unsaturated esters,[20] amides,[21] and nitriles[20] via the sodium salt and the addition to nitroalkenes in the presence or absence of neutral amine bases.[22] With α,β-unsaturated ketones and aldehydes, product mixtures arise, resulting from competing 1,2- vs.1,4-addition and can be influenced by factors such as steric hindrance and reaction temperature.

Palladium-Catalyzed Phosphonylation.

Complexes of palladium(0) have been used to catalyze the addition of DEP to aryl (eq 11)[23] and vinyl (eq 12)[24] halides. As is typical, the bromo and iodo compounds were significantly more reactive than the chloro. For the arylation reactions, good yields were obtained irrespective of substitution. In the case of the vinylation reactions, addition occurs stereospecifically.

(11)

(12)

Amine Protecting Group.

The use of DEP in peptide synthesis has found successful application as both an amine protecting group and carboxylic acid activating group.[25] Interestingly, the amine protection aspect of its use has been exploited in other areas of organic synthesis (eq 13).[26]

(13)

Radical Reactions.

The photostimulation of aryl iodides in the presence of DEP as its sodium or potassium salt presents a highly efficient approach to prepare diethyl arylphosphonate esters.[27] This reaction has been explored mechanistically and is believed to be operating via a radical chain S_N1 mechanism. With diiodo, iodobromo and iodochloro (except *meta*) arenes, bis substitution occurs. Other radical reactions which involve DEP include use as a hydrogen atom source in radical

deoxygenations[28] and radical additions to terpenes.[29]

Specialized Reactions.

DEP is known to react with diazo compounds, in the presence of copper(II) salts, to form diethyl phosphonates.[30] The reaction is sensitive to stoichiometry and has been largely applied with α-diazo esters and 2-diazo-1,3-diketones (eq 14).[30]

A reagent prepared from the sodium salt of DEP and ***Tellurium*** metal (either catalytic or stoichiometric) is useful for the deoxygenation of terminal epoxides to the corresponding alkenes.[31] The deoxygenation occurs on nonterminal epoxides but is significantly slower and therefore allows for selective reaction to take place.

Phosphate esters can be prepared from reacting triflates with potassium DEP.[32] The reactivity follows the order aryl > cyclohexenyl > cyclopropyl > alkyl.

When *gem*-dibromocyclopropanes or *gem*-dibromoalkenes are reacted with DEP (neat) in the presence of ***Triethylamine***, high yields (90%) of the monobromo compounds are obtained.[33] This method contrasts with other approaches generally involving the use of metallic reagents.

Diethyl Phosphorobromidate[1]

[51761-27-4] · $C_4H_{10}BrO_3P$ · Diethyl Phosphorobromidate · (MW 217.00)

(β-lactam formation; peptide synthesis; formation of trifluoroacetyl bromide)

Alternate Names: diethoxyphosphorus oxybromide; diethyl bromophosphate.[1]

Physical Data: bp 75 °C/1.5 mmHg, bp 58-59 °C/0.25 mmHg.

Solubility: sol CH_2Cl_2, Et_2O, toluene.

Preparative Methods: prepared in good yield from the reaction between ***N-Bromosuccinimide*** and diethyl hydrogen phosphite,[1] or from the bromination of ***Triethyl Phosphite*** with ***Bromine*** at -30 °C to -25 °C.[2] It can also be prepared in almost quantitative yield by reacting diethyl hydrogen phosphite with ***Chlorotrimethylsilane*** followed by bromine at -78 °C.[3]

Purification: distilled under reduced pressure.[1]

Handling, Storage, and Precautions: highly toxic, corrosive, and a lachrymator. It should be used in a fume hood. It is highly moisture sensitive and undergoes thermal decomposition. It generates toxic byproducts when decomposition occurs. Should be stored under nitrogen in a cool dry place.

Formation of β-Lactams from β-Amino Acids.

Diethyl phosphorobromidate is a very effective condensing reagent for the formation of β-lactams from β-amino acids.[4] This methodology works well for *N*-substituted β-amino acids, which cyclize to the corresponding β-lactams in moderate to high yield (eq 1). In the case of *N*-unsubstituted β-amino acids, the β-lactam formation does not give good results. This methodology allows the products to be easily isolated by simple aqueous work-up.

(1)

$R^1 = Bn, i\text{-}Pr;\ R^2 = H, Me;\ R^3 = H, Me, Ph, CO_2Me;\ R^4 = H, Me$

Peptide Formation.

A number of organophosphorus compounds, such as ***Diphenyl Phosphorazidate*** and ***Diethyl Phosphorocyanidate***, have been used for peptide synthesis. The expense and rather limited availability of these reagents prevents their general laboratory use. Diethyl phosphorobromidate has been shown to be a useful and inexpensive reagent for the synthesis of amides and, in particular, racemization-free peptide synthesis.[2] It forms reactive diethylphosphoric-carboxylic mixed anhydride intermediates with carboxylic acids (eq 2). These reactive intermediates are susceptible to nucleophilic attack at the carbonyl carbon. Diethyl phosphorobromidate is particularly effective for coupling sterically hindered α,α-disubstituted amino acids, while most of the usual coupling methods are of limited value for incorporating these amino acids into peptides.

(2)

Trifluoroacetyl Bromide.[3]

Diethyl phosphorobromidate reacts with ***Trifluoroacetic Anhydride*** at ambient temperature in the presence of catalytic amounts of ***N-Methylimidazole*** to yield quantitative amounts of trifluoroacetyl bromide and diethylphosphoric-trifluoroacetyl mixed anhydride (eq 3). These can be readily separated.[3]

Diethyl Phosphorochloridate[1]

[814-49-3] · $C_4H_{10}ClO_3P$ · Diethyl Phosphorochloridate · (MW 172.55)

(highly electrophilic phosphorylating reagent easily installed on anionic carbon,[2] oxygen,[3] nitrogen,[4] and sulfur;[5] ketones are converted to enol phosphates which can be reduced to alkenes[6] or alkanes,[7] or coupled with organometallic reagents to form substituted alkenes;[8] enol phosphates can be tranformed into β-keto phosphonates,[9] useful for Horner-Emmons homologation, or into terminal alkynes;[10] used to convert carboxylic acids to other carboxylic derivatives[11])

Alternate Name: diethyl chlorophosphate.

Physical Data: bp 60 °C/2 mmHg; *d* 1.194 g cm^{-3}.

Handling, Storage, and Precautions: highly toxic, corrosive. Use in a fume hood.

Phosphorylation.

Diethyl phosphorochloridate is highly electrophilic and can be cleanly reacted at an anionic center provided that prior metalation is regio- and chemoselective. For example, phenols,[12] thiophenols,[5] and anilines[4] can be phosphorylated under basic conditions (eq 1). The phosphorylated compound can be isolated, or treated further with bases, resulting in orthometalation followed by a facile 1,3-phosphorus migration from the heteroatom to carbon. If carbon phosphorylation is desired, simply treating thiophenol with 2 equiv of ***n-Butyllithium*** followed by diethyl phosphorochloridate gave a moderate yield (58%).[5]

(1)

(1) **(2)** **(3)**

X	Step 1 (% yield **(2)**)	Step 2 (% yield **(3)**)
OH	NaH, THF; $(EtO)_2P(O)Cl$ (50-85%)	LDA, THF -78 °C to rt (90%)
SH	NaH, THF, rt; $(EtO)_2P(O)Cl$ (63%)	LDA, THF -78 to 0 °C (16%)
HNMe	$(EtO)_2P(O)Cl$, Et_3N, THF (97%)	LDA, THF -78 to rt (63%)

Synthetic preparation of oligonucleotides in a cost-efficient manner can be complicated by low chemoselectivity during phosphorylation, suggesting the need for prior nitrogen protection. It has been determined that despite the higher acidity of guanosine and thymidine over a hydroxy, addition of 1 equiv of the phosphorylating agent provided only the phosphates (eq 2).[3] Adenosine and cytidine bases were compatible as well.

(2)

(4) R1	(4) R2	(4) B	Conditions	(5) R1	(5) R2	% Yield
TBS	H	guanosine	*t*-BuMgCl (2 equiv) THF, rt (EtO)$_2$P(O)Cl	TBS	P(O)(OEt)$_2$	94
H	TBS	thymidine	*t*-BuLi, (2 equiv) THF, -50 °C (EtO)$_2$P(O)Cl	P(O)(OEt)$_2$	H	85

Phosphorylation of substituted 1,4-dihydropyridine dianions occurred selectively (eq 3).[2b] Other reports documented selective phosphorylation at C-5 of thiophenes[2a] and the *ortho* position of various substituted benzenes.[13] It has been noted that certain heterocycles demonstrated alternative pathways, such as nucleophilic attack at carbon rather than phosphorus (eq 4).[14]

(3)

(4)

Trapping of ester, lactone, or ketone enolates results in rapid *O*-phosphorylation, thus providing the enol phosphate (eq 5).[9] Further treatment with base resulted in facile rearrangement to the β-ketophosphonate (eq 5).[15] However, regioisomeric β-ketophosphonates can often be observed from a regiochemically pure enol phosphate (eq 6).[9a] Since the classical Arbuzov reaction is limited to primary alkyl iodides (competing Perkov reaction is known with secondary halides), an alternative method was sought. Installation of an alkene blocking group sufficed (eq 7).[9a] Dienol phosphates have also been prepared and the authors note that ***Lithium 2,2,6,6-Tetramethylpiperidide*** was the preferred base for regiochemical control.[16]

(5)

(6)

(7)

β-Ketophosphonates are valuable intermediates in the realm of Horner-Emmons alkenation methodology. Acyclic variants are difficult to obtain from enol phosphates due to competing alkyne and allene formation. One solution utilized the dianion derived from α-bromo ketones and trapping with diethyl phosphorochloridate;[17] however, only moderate yields of β-keto phosphonates were reported. The most efficient procedure utilizes the anion derived from dialkyl methylphosphonate, addition to an aldehyde, followed by oxidation (eq 8).[18]

(8)

Interconversion of Carboxylic Acid Derivatives.

Diethyl phosphorochloridate is useful for activation of carboxylic acids toward nucleophilic attack. Subsequent treatment of the phosphate ester with thallium sulfides produced thiol esters.[19] Variations[11] on this theme included prior formation of a heterocyclic phosphonate followed by treatment with alcohols, amines, or thiols, thus providing a racemization-free method to prepare esters, amides, and thiol esters, respectively (eq 9).[11b]

(9)

Amines can be readily transformed to an alcohol surrogate (eq 10)[20] and phenols to anilines.[21]

(10)

Deoxygenation of Phenols and Ketones.

Excision of oxygen from a molecule is often encountered in a synthetic sequence. Phenols are readily deoxygenated by formation of the phosphate followed by reduction under dissolving metal conditions.[22] It has been noted that the Birch conditions result in low yields, whereas an alternative method utilizing activated ***Titanium*** metal is superior (eq 11).[23] Under this protocol, enol phosphates are efficiently reduced as well.[6b] Conversion of an enone to a regiochemically defined alkene was accomplished via 1,4-reduction, enolate trapping, and reduction of the trapped enol phosphate (eq 12).[6a] Enol phosphates can be fully reduced to alkanes by hydrogenation of palladium catalysts[7] or converted to vinyl iodides when treated with ***Iodotrimethylsilane***.[24]

(11)

(12)

Synthesis of Alkenes and Alkynes.

Enol phosphates are smoothly transformed into substituted alkenes when treated with organometallic reagents. If the enol phosphate was derived from a β-keto ester, cuprate reagents are generally reactive enough to encourage conjugate addition-phosphate elimination (eq 13).[25] In the event that this coupling fails, the combination of Pd^0 and ***Trimethylaluminum*** results in regio- and stereospecific methylation.[8b] Substrates lacking an ester moiety on the enol phosphate can be alkylated with Grignard reagents under nickel catalysis (eq 14).[8a]

(13)

(14)

One of the most useful applications of β-keto phosphonates is the Horner-Emmons alkenation procedure (eq 15).[18] Variations of this theme have employed β-imino[26] and β-sulfonyl phosphates.[27]

(15)

Alkynes are available from methyl ketones[10] by elimination of the enol phosphate (eq 16).[28] When the ketone contains α-branching, lithium tetramethylpiperidide has been recommended to circumvent allene formation.

(16)

Miscellaneous.

Allylic phosphates have found applications in π-allyl palladium chemistry. It has been demonstrated that allylic phosphates undergo oxidative addition more readily than the corresponding acetate, such that chemoselectivity could be achieved when these functionalities were present in the same molecule (eq 17).[29] Finally, β-keto phosphonates were coupled with epoxides to provide useful yields of spirocyclopropanes (eq 18).[30]

(17)

Diethyl Phosphorocyanidate[1]

[2942-58-7] · $C_5H_{10}NO_3P$ · Diethyl Phosphorocyanidate · (MW 163.11)

(synthesis of amides,[3] esters,[2] α-aminonitriles,[12] aryl thiocyanates,[15] and cyanophosphates[17])

Alternate Names: diethyl cyanophosphonate; diethylphosphoryl cyanide; diethoxyphosphoryl cyanide; diethyl cyanophosphate; DEPC.

Physical Data: bp 93-96 °C/14 mmHg; fp 80 °C; *d* 1.075 g cm^{-3}.

Solubility: sol DMF, THF, Et_2O, toluene.

Form Supplied in: pale yellow liquid; 93% (technical grade).

Preparative Method: can be readily prepared from ***Triethyl Phosphite*** and ***Cyanogen Bromide***.[2]

Purification: in most cases, commercial samples are used without purification. However, freshly prepared DEPC contains an impurity of diethyl phosporoisocyanidate. Addition of anhydrous ***Cobalt(II) Chloride*** to a sample of crude DEPC, followed by dilution with ether forms a green precipitate which is removed by filtration; distillation of the filtrate gives pure DEPC.[2]

Handling, Storage, and Precautions: is very toxic and corrosive. It must be handled in a fume hood. The reagent is moisture sensitive and should be stored under nitrogen in a refrigerator.

Synthesis of Amides.

DEPC is an efficient and useful reagent for amide formation and is applicable to racemization-free peptide synthesis. Amides of various types can be obtained by the simple mixing of carboxylic acids and amines with DEPC in the presence of ***Triethylamine*** (eq 1).[3] Both aromatic and aliphatic acids easily react with aromatic and aliphatic amines. The reaction is rapid, clean, and usually free of contamination from side products.

(1)

Studies of selected coupling methods for the attachment of amino acid derivatives to *cis*- and *trans*-4-aminocyclohexanecarboxylic acid have shown DEPC to be the reagent of choice as coupling agent.[4] A study directed towards racemization during peptide coupling of benzyloxycarbonyl-L-phenylalanyl-L-valine with L-proline *t*-butyl ester revealed that, among different coupling agents, DEPC coupling afforded the least racemization.[5]

Following their application as effective peptide coupling agents in the solution phase, both DEPC and ***Diphenyl Phosphorazidate*** (DPPA)[6] have been shown to be useful in solid-phase peptide synthesis.[7,8] Using these reagents, synthesis of porcine motilin, comprising 22 amino acids, was successfully achieved.[7]

Synthesis of Esters and Thioesters.

Reaction of DEPC with carboxylic acids in the presence of triethylamine gives transient acyl cyanides, which in the presence of alcohols[2] or thiols[9] results in the formation of the corresponding esters or thiolesters (eq 2).

(2)

Although esterification yields are not generally satisfactory, the advantage of this method is that the reaction proceeds under mild and almost neutral conditions. The method can be efficiently applied to the synthesis of thiolesters in high yields with little racemization, as demonstrated by the formation of the ethylthiol ester of benzoyl-L-leucine.[9]

C-Acylation.

A direct *C*-acylation of active methylene compounds can be achieved using a carboxylic acid and DEPC in the presence of base under exceptionally mild conditions (eq 3).[10,11] The reactions are best carried out in DMF solution, though hexane, toluene, ether, or THF may be used. Triethylamine, ***1,8-Diazabicyclo[5.4.0]undec-7-ene***, ***N,N,N´,N´-Tetramethylethylenediamine***, ***Sodium Hydride***, or ***Potassium Carbonate*** may be used as a base.

(3)

Synthesis of α-Aminonitriles.

α-Aminonitriles can be efficiently prepared from carbonyl compounds with DEPC and amines under mild conditions, in a modified Strecker synthesis.[12] Since the nitrile functionality of α-aminonitrile can be easily converted to the acid, this constitutes a convenient method for the preparation of α-amino acids. The superiority of this method over the classical Strecker synthesis of α-aminonitriles was demonstrated by the reaction of 4-cholesten-3-one (**1**) with DEPC and ***Pyrrolidine***, which afforded the α-aminonitrile (**2**) in 62% yield (eq 4). The classical Strecker conditions using a mixture of KCN and pyrrolidine hydrochloride in aqueous THF did not yield any α-aminonitriles.

(4)

Modified Reissert-Henze Reaction.

The α-cyanation of aromatic amine oxides (Reissert-Henze reaction) is usually carried out using benzoyl chloride and potassium cyanide.[13] Alternatively, α-cyano-substituted aromatic nitrogen heterocycles can be prepared by reaction of their corresponding *N*-oxide with DEPC in the presence of triethylamine (eq 5).[14]

Synthesis of Aryl Thiocyanates.

Aryl thiocyanates can be prepared in one step from the sodium salt of the arylsulfinic acid by treatment with DEPC in refluxing THF. The thiocyanates are obtained in good yields and even hindered substrates like adamantane give the corresponding thiocyanate in moderate yield (eq 6).[15]

Epoxidation of Alkenes.

A mixture of DEPC and ***Hydrogen Peroxide*** smoothly epoxidizes alkenes at rt in the presence of ***2-Hydroxypyridine*** or ***1,2,4-Triazole***.[16] Methylene chloride is reported to be the solvent of choice. Various alkenes were epoxidized in 60-93% yields. *trans*-Stilbene and 1-dodecene, which are less susceptible to electrophilic attack by peroxycarboxylic acids, smoothly underwent this DEPC/H_2O_2 reaction.

Synthesis of Cyanophosphates as Versatile Intermediates.

Reaction of aldehydes or ketones with DEPC in the presence of a catalytic amount of ***Lithium Diisopropylamide*** (LDA) in THF gives cyanophosphates in high yield (eq 7).[17] Various cyclic and aromatic ketones react with DEPC to give cyanophosphates. Even conjugated or hindered ketones such as α-tetralone or benzophenone, which are known

not to give cyanohydrins under the usual reaction conditions, react smoothly with DEPC to give cyanophosphates.

(7)

Reductive Cyanation of Ketones and Aldehydes.

Saturated and unsaturated carbonyl compounds react with DEPC and ***Lithium Cyanide*** to give intermediate cyanophosphates which can be reduced with ***Samarium(II) Iodide*** in the presence of *t*-butanol to give nitriles (eq 8).[18]

(8)

α,β-Unsaturated Nitriles.

Cyanophosphates prepared by the reaction of aromatic ketones in the presence of lithium cyanide can be readily converted into α,β-unsaturated nitriles by treatment with ***Boron Trifluoride Etherate*** at rt (eq 9).[19] This reaction was used to convert 4-isobutylacetophenone to α-cyanostyrene, which upon hydrogenation followed by hydrolysis gives ibuprofen in 70% overall yield (eq 10).[19a]

(9)

(10)

Deoxygenation of α,β-Unsaturated Ketones.

Cyanophosphates, prepared from α,β-unsaturated ketones or aromatic ketones by treatment with DEPC and lithium cyanide, can be reductively cleaved with ***Lithium*** in liquid ammonia to give the corresponding methylene compounds (eq 11).[20] In the case of α,β-enones, this procedure is superior to the more commonly employed thioacetal and desulfurization deoxygenation method. This method for α,β-enones is simple and the products are obtained in excellent yields without isomerization or reduction of the double bond.

N,N-Diethyl-1-propynylamine[1]

[4231-35-0] · $C_7H_{13}N$ · *N,N*-Diethyl-1-propynylamine · (MW 111.19)

(for dehydrations;[1b,2] synthesis of amino-furans[3] and -amides,[4] cyclobutadienes,[5] cyclobutenes,[6] cyclobutanones,[7] vinylogous amides[8])

Alternate Names: 1-(*N,N*-diethylamino)propyne; DAP.

Physical Data: colorless liquid; amine odor; bp 130-132 °C.

Solubility: sol MeCN, THF, CH_2Cl_2, toluene, ether, CCl_4.

Preparative Methods: from commercially available 1-diethylamino-2-propyne,[9,10] *N,N*-diethylpropanamide,[11,12] miscellaneous methods.[1d]

Purification: by distillation under reduced pressure (bp 80-85 °C/100 mmHg).

Handling, Storage, and Precautions: reacts with H_2O, CO_2; slowly oxidizes in air/UV light. This reagent should be used in a fume hood.

Addition Reactions.

N,N-Diethyl-1-propynylamine (**1**) participates in many types of reactions with alkynes, alkenes, dienes, benzynes, and 1,3-dipoles, giving products that arise either by concerted or polar processes involving zwitterionic intermediates.[1] Much of its chemistry may be explained by considering its resonance structures.

(1)

Reaction of (**1**) with electron-deficient alkenes such as α,β-unsaturated sulfones (eq 1),[7] α,β-unsaturated nitriles (α-chloroacrylonitrile,[13] 1-cyanocyclopentene[6]), and trifluorochloroethylene[14] gives cyclobutenes such as (**2**), (**3**), and (**4**) that can be converted into cyclobutanones.

(2) 75% **(3)** 75% **(4)** 76%

In reactions with 1-alkynyl sulfones, the intermediate cyclobutadienes can be trapped as metal complexes or as Diels-Alder adducts (eq 2).[5]

A [2 + 2] reaction with a sulfene gives thiete 1,1-dioxide (**5**).[15] Michael addition of (**1**) to electrophilic isoxazoles yields bicyclic adducts.[16]

(5) 79%

1,3-Oxazin-6-ones and (**1**) provide pyridine derivatives by an inverse electron demand [4 + 2] cycloaddition-elimination reaction sequence (eq 3).[17] Fused-bicyclic oxazinones behave similarly and have been converted into thienopyridines,[18] quinolones,[19] and quinolines.[19] Pyridazinecarboxylates are converted either into 2-aminopyridines or into aniline derivatives with (**1**), depending on pyridazine ring carboxylate substitution patterns.[20] 2-Substituted pyrimidines and (**1**) give azetodiazocines by a series of reactions that include a formal [4 + 2] cycloaddition, 1,3-sigmatropic shift, [2 + 2] cycloaddition, and isomerization.[21]

Ring Interconversions and Expansions.

N,*N*-Diethyl-1-propynylamine has been used to convert heterocyclic systems into other heterocyclic or carbocyclic systems. Reactions occur by addition-elimination (eq 4)[22] and dipolar addition (eq 5)[23a] pathways.

6-Oxo-1,3,4-oxadiazines are readily converted into substituted 2-pyrones (eq 6).[24] Likewise, pyridines are derived from pyrimidines[25] and 1,2,3-triazines.[26] Oxathiadiazines give 1,2,6-thiadiazines on addition of (**1**).[27]

Many ring expansions have been reported with (**1**). They generally proceed through dipolar addition mechanisms. Depending on their substitution patterns, 1,2-diacylcyclopropenes give either aminofurans (eq 7) or

aminocyclopentadienes.[3]

(7)

Thiophosphonic acid anhydrides and (**1**) give thiaphosphorinanes (eq 8).[28] Thioazetidinones give 1,3-thiazines[29] and 1,2-dithioles give thiopyrans on reaction with (**1**).[23]

(8)

Oxazolidinones and dioxolanones react with (**1**) via 1,7-dipolar intermediates to produce oxazepinones (eq 9) and dioxepinones.[30]

(9)

Acylation Reactions.

N,*N*-Diethyl-1-propynylamine reacts with carbonyl and carboxyl groups to give acylated products. The reaction pathway (stepwise or cycloaddition) depends upon substitution patterns and solvent polarity.[1] α,β-Epoxy ketones and (**1**) give vinylogous epoxy amides (eq 10).[8] Alkyl and aryl dithioaryl esters form (*E*)-α,β-unsaturated thioamides on

reaction with (**1**) (eq 11).[31] Acyclic and cyclic trithiocarbonates, as well as thiazolthiones, provide similar derivatives in good yields.[31-33]

(10)

(11)

Ar = Ph, 4-MeC$_6$H$_4$
R = Me, Ph

Acylation of *N*-acylhydroxylamines by (**1**) provides an entry to α-aminoamides after deprotection (eq 12).[4] Betaines also react with (**1**) to give triazinediones[34] and pyrimidines.[35]

(12)

Acylations also occur with metal-coordinated thioaldehydes and thioketones to yield thioacrylamides[36] and with *N*-acyl-*S*-alkyl(aryl)thiobenzimidates to give *N*-acylaza-1,3-butadienes.[37]

Reactions with Isocyanates and Ketenes.

Products derived from reactions of isocyanates or ketenes with (**1**) depend strongly on the electrophile structure. Cycloaddition occurs by oxygen attack on an intermediate ketiminium salt, followed by ring opening.[1] Ketene and (**1**) give an allenecarboxamide (eq 13).[38] With silicon-substituted ketenes, silylalkyne (**6**) is produced via silicon migration from an initially formed allenecarboxamide.[39] Similarly, CO_2 yields allene dicarboxamide (**7**) in a reaction with 2 equiv of (**1**).[40] Isothiocyanates and (**1**) give α-sulfinylamidines via ring-opening of intermediate 1,2-dihydro-1,2-

thiazetes.[41]

(13)

(6) 83% (7) 100%

Dehydrations.

The title reagent has been used for carboxyl activation in the conversion of acids to anhydrides[2] (ynamines are faster than carbodiimides or ***Ethoxyacetylene***),[1c] acids and amines to amides,[2] benzaldoximes to benzonitriles,[42] and in peptide synthesis.[43] Heterocyclic systems have been prepared by cyclizing *o*-diheteroaromatics, β-amino alcohols, and 1,2-diamines with (**1**).[44]

Miscellaneous Transformations.

Arenesulfenyl chlorides add to (**1**) to give (*E*)- and (*Z*)-2-arylthio-1-chloro-*N*,*N*-diethylenamines that can be cyclized to benzothiophenes with ***Zinc Chloride***.[45] Phosphinous halides add to *N*,*N*-diethyl-l-butynylamine to give phosphirenes.[46]

(acyloin condensation,[1] self-condensation,[2] Stobbe condensation,[3] and various enolate reactions)

Physical Data: (**1**): mp 18-19 °C; bp 217.7 °C; *d* 1.047 g cm^{-3}. (**2**): mp -20 °C; bp 200 °C; *d* 1.117 g cm^{-3}. (**3**): bp 247 °C; *d* 0.99 g cm^{-3}. (**4**): mp 62-64 °C; bp 200-205 °C/2 mmHg.

Solubility: sol H_2O (19.2 g L^{-1} at 20 °C).

Acyloin Condensation.[1]

A simplification and improvement of the acyloin condensation of diethyl succinate (**1**) to give 1,2-bis(trimethylsilyloxy)cyclobutene has been reported (eq 1).[4]

(1)

Self-Condensation.

Diethyl 2,5-dioxo-1,4-cyclohexanedicarboxylate can be prepared by the self-condensation of (**1**) in the presence of a strong base catalyst (eq 2).[2]

(2)

Stobbe Condensation.[3]

The succinates react with ketones (eq 3)[5] or aldehydes (eq 4)[6] in the presence of ***Sodium Hydride*** or alkoxides to form monoesters of α-alkylidene succinic acids. The Stobbe condensation products are important synthetic intermediates which have been used in the preparation of various natural products such as lignan isolariciresinol, cordigerine, and hinokinin.[7]

(3)

Metal enolates of (**1**) also react with various esters (eqs 5 and 6).[8,9]

Diethyl Dilithiosuccinate.

This reagent (**5**) is readily prepared[10] by treatment of (**1**) with ***Lithium Diisopropylamide*** (2 equiv) at -78 °C in THF (eq 7). The dianion can be isolated and trapped to give the bis-silylated product (eq 8).[10] Interestingly, using only 1 equiv of LDA also gave the same compound as the major product (45%) together with unreacted (**1**) (30%) and only a small amount of the monosilylated product (5%), suggesting that the di-enolate (**5**) is preferentially formed in the reaction.

mixture of isomers

γ-Butyrolactone Synthesis.

The di-enolate (**5**) reacts with aldehydes and ketones (eq 9)[11] and α-keto esters (eq 10)[12] to give γ-butyrolactones in good yields. These types of lactones are useful intermediates in the synthesis of cyclopentenones.[13]

cis:*trans* = 2:1

Alkylation.

The dianion (**5**) can be mono- or dialkylated with reactive halides in good yields in the presence of ***Hexamethylphosphoric Triamide***.[10,11] Successive alkylation of (**5**) with ***Benzyl Bromide*** and ***Iodomethane*** gave the

mixed alkylated product in 60% yield (eq 11).[10]

(11)

Carbocyclization.

Alkylation of the dianion (**6**) with dihalides provides a facile method for the preparation of carbocycles.[14] The reaction has been successfully applied to the synthesis of a natural propellane, modhephene (eq 12).[15]

(12)

Modhephene

An efficient asymmetric carbocyclization to give three- to six-membered ring compounds can be achieved using the dianion of chiral dimenthyl succinate (**8**) (eq 13).[16]

Direct condensation of dianion (**7**) with 2-(bromomethyl)acrylate provides a one-pot preparation of cyclopentanones (eq 14).[17] The use of the diisopropyl ester in this reaction is superior to diethyl or dibenzyl derivatives, both of which gave lower yields of the coupling products.

Related Reagents.

N-Chlorosuccinimide; ***2,5-Dihydro-2,5-dimethoxyfuran***; ***2,5-Dimethoxytetrahydrofuran***; ***Succindialdehyde***; ***Succinic Anhydride***; ***Succinimide***.

Diethyl(tributylstannyl)aluminum

n-$Bu_3SnAlEt_2$

[92074-24-3] · $C_{16}H_{37}AlSn$ · Diethyl(tributylstannyl)aluminum · (MW 375.15)

(in the presence of $Pd(PPh_3)_4$ or CuCN catalyst, is a reagent for synthesis of allylstannanes or vinylstannanes from allylic acetates or alkynes; mediates Reformatsky reactions)

Physical Data: see entries for ***Diethylaluminum Chloride*** and ***Tri-n-butylstannyllithium***.

Solubility: sol THF.

Preparative Methods: Et_2AlCl (hexane, toluene, or THF solution, 1.0 equiv) is added to n-Bu_3SnLi[1] (1.0 equiv) derived from ***n-Butyllithium*** (3.0 equiv) and anhydrous ***Tin(II) Chloride*** (1.0 equiv) in THF at 0 °C. The mixture is stirred for 20 min at 0 °C and the reagent is used directly for further reactions.

Synthesis of Allylstannanes.

Addition of the reagent (**1**) to allylic acetates or allylic phosphates in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** catalyst affords allylstannanes (eqs 1-3).[2,3] The reagent reacts with the less substituted carbon of allylic substrates to form allylstannanes with inversion of configuration. Reaction of the crude products, generated from allylic acetates and (**1**), with aldehydes catalyzed by ***Boron Trifluoride Etherate*** provides homoallylic alcohols.[3] The allylic phosphate protocol does not require the extra Lewis acid since the aluminum phosphate serves as a Lewis acid. Alternatively, the presence of an equimolar amount of aldehyde in the reaction system results in the direct formation of homoallylic alcohols (eq 4).[2] n-$Bu_3SnAlEt_2$ and a Pd^0 complex catalyze the intramolecular reductive coupling of allyl acetates with vinyl and aryl bromides (eq 5).[4]

(1)

(2)

(3)

(4)

(5)

Stannylalumination of Alkynes.

Reaction of 1-alkynes with (**1**) in the presence of ***Copper(I) Cyanide*** catalyst provides a mixture of (*E*)-1-tributylstannyl-1-alkenes and their regioisomers in good yield (eq 6).[5] The intermediate adducts undergo electrophilic substitution reactions to provide alkenylstannanes. The kinetically favored regioisomer is the 1-stannylalkene, whereas the thermodynamically favored regioisomer is the 2-stannyl derivative.[1d,6] This reaction has been applied to functionalized alkynes,[7a] enynes,[7b] and allenes.[8] Stannylalumination of propargyl or homopropargyl acetals affords vinylstannanes (eq 7).[7a] Reaction of 5-hydroxy-1,2-pentadiene with (**1**) gives 5-hydroxy-2-tributylstannyl-1-pentene in the presence of a Co catalyst (eq 8).[8]

R = Ph, 88%, **(2)**:**(3)** = 79:21
R = $C_{10}H_{21}$, 87%, **(2)**:**(3)** = 38:62

(7)

(8)

Reformatsky-Type Reaction.[9]

Treatment of α-bromo carbonyl compounds with the reagent affords aluminum enolates which react with ketones or aldehydes to give β-hydroxy carbonyl compounds in good yields (eq 9). Yields are generally improved by addition of catalytic amounts of $Pd(PPh_3)_4$. Treatment of a mixture of 2-bromo-2-methylcyclohexanone and benzaldehyde with the reagent provides the expected β-hydroxy ketone (eq 10). Reaction of methyl γ-bromocrotonate gives α-adducts exclusively (eq 11). $Bu_3PbAlEt_2$ can be used in the same way.[9]

Diethyl Trimethylsilyl Phosphite[1]

[122289-10-5] · $C_7H_{19}O_3PSi$ · Diethyl Trimethylsilyl Phosphite · (MW 210.32)

(nucleophilic, trivalent phosphorus reagent capable of forming a diethyl phosphonate derivative by displacement reaction or silylphosphonylation of multiple bond functionalities such as aldehydes and ketones, both saturated and unsaturated[1d])

Alternate Name: DTP.

Physical Data: bp 63-65 °C/15 mmHg.

Preparative Methods: generally prepared by reacting the sodium salt of ***Diethyl Phosphonite*** with ***Chlorotrimethylsilane*** in ether.[1a] Alternatively, the reagent has been prepared by reacting diethyl phosphonite with chlorotrimethylsilane in ether/TEA.[1b]

Handling, Storage, and Precautions: is susceptible to hydrolysis and should be prepared immediately prior to use. The salts generated during preparation of the compound are typically removed by filtration and the solution of DTP used without further purification or simply evaporated and the crude material used without purification.

Carbonyl Addition.

The 1,2-addition of DTP to carbonyl moieties is known as the Abramov reaction. Several reports of this smooth addition reaction have been published. Representative examples are given in Table 1. The initially formed diethyl α-trimethylsiloxyphosphonates are typically isolated via distillation and result from intramolecular transfer of silicon (eq 1).[1b]

(1)

Table 1 Reactions of DTP With Saturated Carbonyl Substrates

Carbonyl	Yield (%)	Conditions
MeCHO[2]	72	3 h, 20 °C
PhCHO[2]	66	1.5 h, 50 °C
EtCOMe[3]	55	1.5 h, 120 °C
Cyclopentanone[3]	52	1.5 h, 20 °C
Cl_3CCHO[4]	92	- 20 °C
CF_3COCF_3[5]	95	- 25 °C
PhCOMe[1b]	73	3 h, 110 °C
MeCOMe[1b]	63	3 h, 110 °C
Cyclohexanone[1b]	91	3 h, 110 °C

A convenient method to prepare ketones (eq 2)[6] and α-hydroxy ketones (eq 3)[7] has been developed using these 1,2-carbonyl addition products.

(2)

Conjugate Additions.

The reaction of DTP with α,β-unsaturated aldehydes, ketones, esters, and nitriles has been reported by several workers.[8] In general, reactions with α,β-unsaturated aldehydes occur at rt via a 1,2-addition mode. With ***Methyl Vinyl Ketone***, addition requires heating and occurs in a 1,4-manner. However, 1,2-addition products begin to compete as the steric bulk of the β-carbon increases. To circumvent the forcing conditions required for additions to α,β-unsaturated esters and ketones, a method involving Lewis acid catalysts has been developed using diethyl phosphonite and ***Trimethylaluminum***.[9]

Ketene and β-Dicarbonyl.

The reaction of DTP with ketene is exothermic and requires cooling. The resultant [1-(trimethylsiloxy)vinyl]phosphonate can be isolated by distillation (eq 4).[3a,8b]

With β-dicarbonyl reaction partners, the reaction course is dependent upon the dicarbonyl component. For ***Ethyl Acetoacetate***, an exothermic reaction occurs upon addition of the ester to DTP and the predicted 1,2-addition product is isolated after distillation (eq 5).[8c]

For ***2,4-Pentanedione***, multiple products as well as the 1,2-addition product are formed, resulting from competing reactions such as (a) silylation of the enol form of the dione, (b) addition of a second molecule of DTP to the 1,2-addition product, forming an oxaphospholane upon cyclization and loss of methoxytrimethylsilane.[10] In the case of ethyl phenylglyoxylate, rearrangement of the initial 1,2-addition product occurs by transfer of the diethyl phosphonate to produce the diethyl phosphate product (eq 6).[11]

With phenylglyoxylonitrile, an exothermic reaction occurs with DTP to provide a mixture of the phosphonate 1,2-addition product and phosphate rearrangement product. Finally, with α-ketophosphonates such as diethyl acetylphosphonate, straightforward 1,2-addition occurs to provide the bis-phosphonate (eq 7).[12]

Epoxides.

The addition of DTP to epoxides is reported to occur most effectively under Lewis acid (***Zinc Iodide***, ***Iron(III) Chloride***, ***Tin(II) Chloride***, ***Tin(IV) Chloride***) or basic (***n-Butyllithium***) catalysis. Reaction generally occurs at moderate temperatures (55 °C), undergoing exclusive ring opening at the terminal carbon.[13] This method has been used to prepare fructophosphonic acids (eq 8).[14]

Diethylzinc[1]

Et_2Zn

[557-20-0] · $C_4H_{10}Zn$ · Diethylzinc · (MW 123.50)

(useful organometallic reagent for organic synthesis;[1] polymerization catalyst)

Physical Data: mp -28 °C; bp 118 °C; bp 27 °C/30 mmHg; *d* 1.187 g cm^{-3}.

Solubility: sol most organic solvents; reacts with acidic hydrogens; pyrophoric; reacts violently with water.

Form Supplied in: colorless liquid; available as 1.0 M solution in hexanes and 1.1 M solution in toluene, or neat in a metal cylinder.

Analysis of Reagent Purity: can be titrated by iodometric methods[4] or by complexometry.[5]

Preparative Methods: prepared by the reaction of ***Zinc/Copper Couple*** with ***Ethyl Iodide*** followed by distillation (81-84%).[2] It can also be prepared via a B/Zn exchange reaction.[3]

Handling, Storage, and Precautions: highly flammable liquid; spontaneous ignition in air; reacts violently with water. Should be kept under an inert atmosphere.[6] Neat diethylzinc is best destroyed by first diluting with THF, followed by slow addition of ethanol at 0 °C.

Addition to Carbonyl Compounds.

Diethylzinc, like other dialkylzincs, reacts only slowly with carbonyl compounds. ***Carbon Dioxide*** can be used as protecting gas for reactions performed with diethylzinc and the formation of a zinc propionate is observed only under a high pressure of CO_2 and at higher temperatures.[7] Whereas the reaction of ***Acetaldehyde*** with neat diethylzinc is complete within a few hours, the reaction with higher homologs requires several days.[8] Higher diorganozinc derivatives do not add to aldehydes in solution. The addition of magnesium salts to diethylzinc considerably accelerates the addition to the carbonyl group (eq 1).[9] Similarly, the addition of a tetraalkylammonium chloride or of a catalytic amount of ***N,N,N´,N´-Tetramethylethylenediamine*** accelerates the addition reaction and limits the formation of reduction product.[10]

(1)

Neat diethylzinc does not add to ketones and its reaction with benzophenone produces only diphenylmethanol.[11] As in the case of aldehydes, the addition of diethylzinc is accelerated by the presence of magnesium salts.[9] With 1,2-diketones, diethylzinc undergoes an addition in the reverse way to the carbonyl group, producing an α-alkoxy ketone (eq 2).[12] A similar reaction with α-diimines leads to zincated enamines which can be converted to indolizidines after the addition of an aldehyde and heating (eq 3).[13]

(2)

(3)

The presence of a heteroatom at the α-position to the carbonyl group accelerates the addition and diethylzinc adds to the aldehyde (**1**) via a chelate controlled transition state producing the alcohol (**2**), which was further converted to *exo*-brevicomin (eq 4).[14] The addition of diethylzinc to (-)-menthyl phenylglyoxylate gives, after saponification, an α-hydroxy acid with a good diastereoselectivity (eq 5).[15] The low reactivity of diethylzinc with aldehydes has been

advantageously exploited by performing the addition reaction in the presence of a chiral catalyst.[16]

(4)

(5)

Mukaiyama showed that the chiral proline derivative (**3**) catalyzes the addition of diethylzinc to benzaldehyde, unfortunately without any asymmetric induction.[17] Oguni found a few years later that (*S*)-leucinol (**4**) also catalyzes the reactions and the same addition proceeds with 48% ee.[18] Since this discovery, a variety of amino alcohols were found to catalyze the addition of diethylzinc to aldehydes with high enantioselectivity (up to 99% ee).[16,19-34] (-)-3-*Exo*-(dimethylamino)isoborneol, (-)-DAIB (**5**), has a particularly high catalytic activity. In the presence of 2 mol % of this catalyst, the addition of diethylzinc to benzaldehyde in toluene is complete within 6 h at 0 °C (98% ee).[20] This catalyst is effective for aromatic aldehydes but gives lower enantioselectivities with aliphatic aldehydes. A series of readily available pyrrolidinylmethanols (**6**), derived from proline, give excellent results both with aliphatic and aromatic aldehydes (eq 6).[21] Remarkably, chiral quaternary ammonium salts such as (**7**) catalyze in the solid state the addition of benzaldehyde to diethylzinc with a good enantioselectivity (eq 7).[22] Chiral metal complexes can also be used as catalysts, and the reaction of diethylzinc with aldehydes in the presence of a chiral oxazoborolidine produces ethylated secondary alcohols in 52-95% ee.[23]

(3) (4) (5) (6)

(6)

(7)

Very active titanium catalysts (**8**) and (**9**) have been developed respectively by Yoshioka and Ohno,[24] and Seebach.[25] Their high catalytic activity allows the extension to the enantioselective addition of higher dialkylzincs (eq 8)[25] and to both functionalized aldehydes and dialkylzincs (eqs 9-11).[26,27] The excellent functional group tolerance allows the use of many functionalized aldehydes.

(8)

(9)

(8)

(9)

(10)

(11)

A new method for the enantioselective synthesis of lactones is based on the enantioselective addition of 3- or 4-formyl esters in the presence of catalytic amounts of the amino alcohol (**10**) (eq 12).[28] γ-Hydroxy ketones can be prepared enantioselectively by the addition of diethylzinc to the ketoaldehyde (**11**) (eq 13).[29] Optically active hydroxy aldehydes are obtained with high enantioselectivity by the addition of diethylzinc to monoprotected dialdehydes (eq 14).[30] A variety of other functionalized aldehydes have been ethylated under similar conditions (eqs 15 and 16).[31]

(12)

The addition of diethylzinc to activated imines such as *N*-diphenylphosphinoylimines of type (**12**) proceeds in good yields and excellent enantioselectivity, allowing the synthesis of enantiomerically enriched secondary amines (eq 17).[32a] An enantioselective ethylation on *N*-(amidobenzyl)benzotriazoles catalyzed by chiral amino alcohols is also possible.[32b]

(17)

Polymer-bound chiral catalysts[33] and chiral catalysts supported an silica gel and alumina[34] have been successfully employed for the enantioselective addition of diethylzinc to aldehydes. Little success was obtained in the addition of diethylzinc to esters or lactones. However, the addition to ***Diethyl Oxalate*** produces ethyl 2-ethyl-2-hydroxybutanoate in 75% yield.[9] The reaction with acid chlorides[1,35] or anhydrides[1,36] proceeds in some cases satisfactorily;[35,36] however, Pd^0 [37] or Cu^I [26,38] catalysis gives more predictable results and allows the extension of the reaction to higher functionalized homologs (eq 18).[26,38]

(18)

Addition of Diethylzinc to Double or Triple Bonds.

Diethylzinc, like higher homologs, is able to add to activated alkynes such as propiolic esters in the presence of a THF soluble copper salt such as CuCN.2LiCl (eq 19).[26] Less reactive alkynes such as 1-(methylthio)-1-hexyne or phenylacetylene also react with the reagent EtCu(CN)ZnEt.2LiCl, leading stereospecifically to the *syn* adducts (eq 20).[39] Diethylzinc can be added to unfunctionalized alkynes in the presence of $ZrCp_2I_2$.[40] In the case of terminal alkynes, the addition shows a low regioselectivity, producing a mixture of alkenylzinc species (eq 21).[40] Remarkably, the addition to internal alkynes proceeds well, leading after iodolysis to tetrasubstituted alkenyl iodides (eq 22).[40] The addition to alkenes is more difficult. However, the intramolecular carbozincation of alkenes mediated by a palladium or nickel catalysis is possible (eq 23).[41] The role of diethylzinc in this reaction is to transmetalate the palladium(II) intermediate back to an organozinc reagent and to generate the Pd^0 catalyst. This Pd catalysis can also be used for an efficient generation of primary alkylzinc iodides (eq 24).[41] In the absence of palladium salts, the iodine-exchange reaction requires a temperature of 50 °C.[26,27b] This I/Zn exchange reaction constitutes a unique method for preparing functionalized dialkylzincs (eq 25).[26] The Michael addition of diethylzinc to α,β-unsaturated ketones proceeds well in the presence of a nickel catalyst. In the presence of a chiral nickel catalyst, good to excellent enantioselectivities are observed (eq 26).[42]

Cyclopropanation.

The reaction of diethylzinc with ***Diiodomethane*** rapidly produces ICH_2ZnEt (see ***Ethyliodomethylzinc*** and ***Iodomethylzinc Iodide***).[1,43] A further exchange can occur, leading to $(ICH_2)_2Zn$.[43] Both of these iodomethylzinc derivatives are excellent cyclopropanation reagents, and their generation with diethylzinc (Furukawa method) allows convenient cyclopropanation reactions (eq 27).[44]

(27)

The reaction gives especially good results with electron-rich alkenes (eq 28).[45] The cyclopropanation was originally performed under the strict absence of oxygen. It was later found that the presence of air accelerates the reaction and improves the yields (eq 29).[1,46] An extension of the cyclopropanation using higher 1,1-diiodoalkanes is possible, and leads preferentially to the *syn* products (eqs 30 and 31).[47] An *anti* stereoselectivity is observed with allylic alcohols (eq 32).[47] Benzene and polynuclear aromatic compounds are cyclopropanated by ***1,1-Diiodoethane*** and diethylzinc in moderate yields (eq 33).[48] Highly diastereoselective cyclopropanations can be performed with chiral allylic and homoallylic alcohols and acetal derivatives (eq 34).[49] The cyclopropanation of silylated ketene acetals using ***Bromoform*** and diethylzinc allows the generation of polyfunctional zinc carbenoids and the performance of intramolecular cyclopropanations (eq 35).[50]

Miscellaneous Reactions.

Diethylzinc undergoes a variety of substitution reactions with tertiary halides.[51] The elimination of HX is an important side reaction. By treating dithioacetals with ***Diiodomethane*** and diethylzinc, vinyl sulfides are obtained in satisfactory yields.[52] A direct treatment of diethylzinc with a dithioacetal produces the substitution product.[53] Ketocarbenoids have also been generated from α,α-dibromo ketones (eq 36).[54] Finally, diethylzinc has been used to prepare zinc enolates (eq 37)[55] or mixed lithium-zinc enolates (eq 38).[56]

Diethylzinc-Bromoform-Oxygen

Et_2Zn-$CHBr_3$-O_2

(Et_2Zn)

[557-20-0] · $C_4H_{10}Zn$ · Diethylzinc-Bromoform-Oxygen · (MW 123.50) ($CHBr_3$)

[75-25-2] · $CHBr_3$ · Diethylzinc-Bromoform-Oxygen · (MW 252.73)

(cyclopropanation reagent[1])

Preparative Method: the reaction of bromoform with diethylzinc generates dibromomethylzinc bromide in situ.[1]

Handling, Storage, and Precautions: the reagent cannot be stored and should be used directly after its preparation.

Cyclopropanation Reactions.

The treatment of ***Diethylzinc*** and ***Bromoform*** with an alkene in the presence of ***Oxygen*** produces monobromocyclopropanes in good yields (eq 1).[1] Low yields are obtained if no oxygen is passed through the reaction mixture. The cyclopropanation of *cis*-cyclooctene (see ***Iodomethylzinc Iodide***) and *cis*-2-butene give *syn*-bromocyclopropanes with high stereoselectivity (eqs 2 and 3).[1] Styrene was found to inhibit the cyclopropanation, suggesting a radical reaction. A related system can also be used to perform a ring expansion of alkylbenzenes (eq 4).[1] The reaction is possible with ***Diethylzinc-Iodoform***, leading to ethylated cycloheptatrienes.[2] A novel cyclopropanation is observed by reacting bromoform and diethylzinc with ketene acetals, leading to spiro- and bicyclic esters in good yields (eqs 5 and 6).[3] If no allylic hydrogen or unsaturation is present in the molecule, a different reaction is observed (eq 7).[3] The new cyclopropanation procedure has been applied in a synthesis of (±)-sabinene (**1**) (eq 8).[3]

Diethylzinc-Iodoform

Et_2Zn-CHI_3

(Et_2Zn)

[557-20-0] · $C_4H_{10}Zn$ · Diethylzinc-Iodoform · (MW 123.50) (CHI_3)

[75-47-8] · CHI_3 · Diethylzinc-Iodoform · (MW 393.73)

(combination reagent for monoiodocarbene formation and cyclopropanation)

Physical Data: Et_2Zn: mp -28 °C; bp 117 °C; *d* 1.205 g cm^{-3}. CHI_3: mp 120-123 °C; *d* 4.008 g cm^{-3}.

Solubility: sol alkene substrates.

Preparative Method: prepared in situ by addition of iodoform to a mixture of alkene and diethylzinc.

Handling, Storage, and Precautions: diethylzinc is pyrophoric and moisture sensitive. Iodoform is toxic and an irritant.

General Discussion.

The reaction of cyclohexene with the monoiodocarbene generated from the action of ***Diethylzinc*** on ***Iodoform*** in light petroleum produced a mixture of stereoisomeric monoiodocyclopropanes. The yield was only 10% for this reaction.[1] It was later found that the reaction was highly dependent on the concentration of the alkene and the temperature. If the reaction was performed with the alkene as the solvent and the temperature lowered to 0 °C, it produced a 70% yield of a mixture of cyclopropyl iodides (eq 1).[2] The lowered yield and altered ratio of *syn*:*anti* isomers was attributed to the thermal instability of the *syn* isomer. The reaction of *n*-butyl vinyl ether resulted only in the formation of polymeric material. None of the cyclopropyl derivative was observed.

(1)

light petroleum, 10%, *syn*:*anti* = 0.5
50 °C, neat alkene, 50%, *syn*:*anti* = 45:55
0 °C, neat alkene, 70%, *syn*:*anti* = 66:34

The reaction of diethylzinc and iodoform in benzene produces ethylcycloheptatriene in 48% yield (eq 2). The reaction is believed to proceed via the tropylium cation, which undergoes subsequent transformation to the ethyl substituted product by further reaction with ***Ethylzinc Iodide***. If toluene was used in place of benzene, a mixture of the three regioisomeric cycloheptatrienes was formed.[3]

(2)

R = H, 48%
R = Me, 60%, 57:22:21

An investigation of the stereoselectivity of the iodocyclopropanation process has shown that for cycloalkenes the ratio of *syn*:*anti* isomers increases as the ring size increases. For cyclopentene, only the *anti* isomer was obtained due to decomposition of the *syn* isomer. Cyclohexene produces a 0.63:1.0 *syn*:*anti* ratio in 40% yield. The *syn*-iodocyclopropane predominates in a ratio of 3.8:1 for the reaction with cycloheptene. Only the *syn* compound was produced with cyclooctene, but the yield was only 18% (eq 3). The photolysis of iodoform in the presence of cyclooctene provides the same compound in 72% yield. Cyclodecene and cyclododecene also afford only the *syn* adducts.[4]

(3)

For the acyclic diene *cis*-2-butene, the stereochemical integrity of the methyl groups was maintained in the final iodocyclopropane (eq 4). In this case, only the *syn* product was formed.

Difluoramine

NHF_2

[10405-27-3] · F_2HN · Difluoramine · (MW 53.01)

(reagent for introducing difluoroamine groups into organic molecules;[1-3] synthesis of diazirines;[4] deamination of primary amines[5])

Alternate Name: fluoroimide.

Physical Data: bp -23 °C.

Preparative Methods: difluoramine can be generated from tetrafluorohydrazine, which is made by reaction of NF_3 with various metals at 375 °C.[6] Conversion into difluoramine is accomplished by heating tetrafluorohydrazine with ***Thiophenol*** in an evacuated bulb.[7] Difluoramine is also generated by heating *N*,*N*-difluorourea with conc. ***Sulfuric Acid***.[8]

Handling, Storage, and Precautions: is shock sensitive. Reactions should be carried out in a fume hood.

Synthesis of Diazirines.

The reaction of *t*-octylazomethine or *t*-butylazomethine with difluoramine has been shown to give diazirine (eq 1).[4] Other substituted imines produce substituted diazirines, α-fluoroazo compounds, or α-fluoroalkylidene hydrazines in relative yields dependent upon the structure of the imine (eq 2).[9]

R = Me	37%	40%	-
R = Ph	-	-	62%

Reactions of Carbonyl Compounds with Difluoramine.

Difluoramine reacts with aldehydes and ketones to give α-difluoroamino alcohols of varying stability (eq 3).[1] Aliphatic ketones and aldehydes react with difluoramine in H_2SO_4 or oleum with replacement of the carbonyl by two difluoroamino groups (eq 4).[2]

Carbocation precursors in the γ-position cyclize to give difluoroamino substituted lactones (eq 5) and tetrahydrofurans.[2] Michael addition of difluoramine takes place with α,β-unsaturated carbonyl compounds (eq 6).

(6)

Difluoramine undergoes reaction with α-hydroxy ketones and 1,2-diketones in fuming H_2SO_4 to form 4-difluoroamino or 4,5-bis(difluoroamino) substituted 1,3-dioxa-2-thiolane 2,2-dioxides, respectively (eq 7).[8] Difluoramine is generated in situ by the interaction of *N*,*N*-difluorourea with concentrated H_2SO_4 in these reactions. Difluoramine reacts vigorously with acetone phenylhydrazone to give *N*-fluorodimethylketimine (eq 8).[10]

(7)

$+ Me_2C{=}N\text{-}NHPh \cdot HF$ (8)

Reaction of Alkynes with Difluoramine.

The reaction of 3-hexyne with difluoroamine, catalyzed by the ***Boron Trifluoride*** complex of ***Phosphoric Acid***, gives 3-hexanone, 3,3-bis(difluoroamino)hexane, 3-difluoroamino-3-fluorohexane, and *N*-(α-difluoroaminopropyl)propionamide in various yields.[11]

Alkylation of Difluoramine.

Difluoramine can be alkylated with an alkyl halide, alcohol, alkene, or ether to yield difluoroamino substituted alkanes.[3] Ether derivatives require no catalysis; with alkenes the boron trifluoride complex of phosphoric acid or H_2SO_4 is used (eq 9). Yields are sensitive to time and temperature and range from 50-60 % for the alkene reactions to quantitative for the ethers.

$$Me_2C{=}CH_2 + NHF_2 \xrightarrow{96\%\ H_2SO_4} Me_3CNF_2 \qquad (9)$$

Deamination of Primary Amines.

Difluoramine converts primary amines to alkanes (eq 10). Secondary amines, such as aziridine, azetidine, and dibenzylamine, react with difluoramine to yield, respectively, ethylene (eq 11), cyclopropane, and bibenzyl by releasing nitrogen and coupling the remaining fragments.[5,12]

$$BuNH_2 + NHF_2 \xrightarrow[61\%]{rt} BuNH_3^+F^- + N_2 + C_4H_{10} \qquad (10)$$

Reaction of *C*-Nitroso Compounds with Difluoramine.

The reaction of difluoramine with *C*-nitroso compounds affords *N*-substituted *N*´-fluorodiimide *N*-oxides (eq 12); *N*-aryl substituted *N*´-fluorodiimide *N*-oxides can be converted to azoxy compounds with Grignard reagents (eq 12).[13]

Difluoromethylenetriphenylphosphorane[1]

$Ph_3P{=}CF_2$

[33558-14-4] · $C_{19}H_{15}F_2P$ · Difluoromethylenetriphenylphosphorane · (MW 312.30)

(utilized for the introduction of $=CF_2$ into organic compounds)

Alternate Name: triphenylphosphonium difluoromethylide *[34034-84-9]*.

Preparative Methods: prepared in situ by the reaction of lithium or ***Sodium Chlorodifluoroacetate*** with ***Triphenylphosphine***[2-6] (or, analogously, with ***Tri-n-butylphosphine***[7,8]); by the reaction of ***Dibromodifluoromethane*** with 2 equiv of tertiary phosphines;[6,9] or by the dehalogenation of bromodifluoromethyltriphenylphosphonium bromide with tertiary phosphines[9] or metals.[10]

Reactions with Carbonyl Compounds.

Treatment of sodium or lithium chlorodifluoroacetate and triphenylphosphine with aldehydes or perfluoroalkyl aryl ketones gives the corresponding 1,1-difluoroalkenes in 52-78% yields (eq 1).[1-6,11] Monoglyme (MG), diglyme (DG), and triglyme (TG) have been employed as solvents in the above reaction. In DMF, DMSO, dimethylacetamide, tetramethylurea, and *N*-methyl-2-pyrrolidone, reaction of sodium chlorodifluoroacetate and tributylphosphine with ketones bearing α-protons affords the corresponding 1,1-difluoroalkenes in 35-46% yields.[7,8] However, Burton reported that less than 10% of 1,1-difluoroalkenes were obtained from the reaction of sodium chlorodifluoroacetate and tributylphosphine with non-activated ketones[9] and a different type of reaction was observed with activated ketones.[12]

$$Ph_3P + ClCF_2CO_2Na + R^1C(O)R^2 \xrightarrow{100\ ^\circ C} R^1R^2C{=}CF_2 \qquad (1)$$

Difluoromethylenation of aldehydes and ketones has also been accomplished in 81-87% yields by the reaction with dibromodifluoromethane and 2 equiv of triphenylphosphine[6] or ***Hexamethylphosphorous Triamide***[9] in DG, TG, and DMF solvents (eq 2). Alternatively, bromodifluoromethyltriphenylphosphonium bromide or bromodifluoromethyltris(dimethylamino)phosphonium bromide,[10] generated from dibromodifluoromethane and triphenylphosphine or tris(dimethylamino)phosphine, can be treated with carbonyl compounds and 1 equiv of the corresponding phosphine[1] or metals (Zn, Cd, and Hg)[10] to obtain 1,1-difluoroalkenes (eq 3).

$$2\,R^1{}_3P + CF_2Br_2 + R^2C(O)R^3 \xrightarrow{70\ ^\circ C} R^2R^3C{=}CF_2 \qquad (2)$$

$$[R^1{}_3PCF_2Br]^+ Br^- + R^1{}_3P \text{ (or metals)} \xrightarrow{R^2C(O)R^3} R^2R^3C{=}CF_2 \quad (3)$$

$R^1 = Ph_3P, (Me_2N)_3P$
$R^2, R^3 = H$, alkyl, aryl
metals = Zn, Cd, Hg

1,3-Dihydrobenzo[*c*]thiophene 2,2-Dioxide

[2471-91-2] · $C_8H_8O_2S$ · 1,3-Dihydrobenzo[*c*]thiophene 2,2-Dioxide · (MW 168.21)

(a source of *o*-quinodimethanes[1] that are useful diene intermediates in Diels-Alder reactions; a source of benzocyclobutene)

Physical Data: mp 150-151 °C.

Solubility: sol EtOH, $CHCl_3$, C_6H_6, boiling water; slightly sol Et_2O.

Preparative Methods: by oxidation of 1,3-dihydrobenzo[*c*]thiophene;[2] from ***α,α´-Dibromo-o-xylene***, rongalite (***Sodium Hydroxymethanesulfinate***, $HOCH_2SO_2Na.2H_2O$), and ***Sulfur Dioxide***.[3]

Purification: recrystallization (H_2O; H_2O-EtOH; CH_2Cl_2-petroleum ether; $CHCl_3$-C_6H_6; C_6H_6-petroleum ether).

Handling, Storage, and Precautions: unstable to alkali and concentrated H_2SO_4.

Source of *o*-Quinodimethane.

Since Cava and Deana proposed and trapped *o*-quinodimethane as an intermediate in the thermal conversion of 1,3-dihydrobenzo[*c*]thiophene 2,2-dioxide to benzocyclobutene and 1,2,5,6-dibenzocyclooctadiene,[2a] its synthetic utility as a diene in Diels-Alder reactions has been investigated extensively. Its isomer, the sultine 1,4-dihydro-2,3-benzoxathiin 3-oxide, also is a precursor of *o*-quinodimethane, and is especially useful because it decomposes at a lower temperature (80 °C) than does the sulfone.[3,4]

Substitution of the sulfone via its anion occurs readily,[5] thus providing a convenient source for a variety of *o*-quinodimethane diene components. Both intermolecular (eq 1)[6] and intramolecular (eqs 2-5)[5] Diels-Alder reactions of *o*-quinodimethanes have been achieved via thermolysis of the sulfone either in a high boiling solvent or by passing a solution in an inert solvent through a hot (300 °C) quartz tube.[5b] In one case (eq 6) the cycloaddition occurs across a carbonyl group instead of a vinyl group.[5c] Steroidal systems have been accessed through intramolecular cyclizations (eq 2)[5b,d,e] Benzocyclobutenes are obtained from benzo[*c*]thiophene sulfones,[7] and these occasionally are used as sources of *o*-quinodimethanes. 1-Aryl[8] and 1-alkoxy, hydroxy, thioalkyl, and amino[9] derivatives of 1,3-dehydrobenzo[*c*]thiophene

2,2-dioxide are obtained by cyclization reactions and not from the parent compound. Other 1- and 1,3-substituted sulfones are obtained by rhodium(II)-catalyzed cyclization of α-diazo-β-arylmethanesulfonyl esters.[10] Chiral 1-alkoxy-1,3-dihydrobenzo[*c*]thiophene 2,2-dioxides lead to asymmetric induction in the Diels-Alder reaction via the chiral substituent of the *o*-quinodimethane.[9a-c]

2,5-Dihydro-2,5-dimethoxyfuran

[332-77-4] · $C_6H_{10}O_3$ · 2,5-Dihydro-2,5-dimethoxyfuran · (MW 130.14)

(masked 1,4-dialdehyde; convenient for the synthesis of substituted furans and tetrahydrofurans)

Physical Data: colorless liquid; bp 160-162 °C; *d* 1.0730 g cm^{-3}.

Solubility: practically insol H_2O; sol MeOH, Et_2O, THF.

Form Supplied in: commercially available as a mixture of *cis* and *trans* isomers.

Preparative Method: electrolytic methoxylation of ***Furan***.[1]

Handling, Storage, and Precautions: flammable liquid; must be stored in a cool, ventilated place. Noxious by inhalation, ingestion, or contact with skin. Use in a fume hood.

2-Substituted Furans.

2,5-Dihydro-2,5-dimethoxyfuran (**1**) reacts with 1,3-dicarbonyl compounds in the presence of Lewis acids to give 2-substituted furans after elimination of MeOH (eq 1).[2]

X = Me, OEt; Y = Me, OEt

In the same manner, ***Chlorodiphenylphosphine*** affords furan-2-phosphine oxide,[3] in contrast to ***Cyanotrimethylsilane*** which leads to 2-cyano-5-methoxydihydrofuran.[4]

Reaction of the Double Bond.

Photocycloadditions of (**1**) to anisole,[5] triazolo[4,3-*b*]pyridazine,[6] or ***Maleic Anhydride***[7] give 2,3,4,5-tetrasubstituted furans. 1,3-Dipolar cycloaddition can be performed with nitrones[8] and nitrile oxides.[9] The thermal [4 + 2] reaction between (**1**) and ***Cyclopentadiene*** proceeds in good yield.[10] Permanganate oxidation of the isomer mixture of (**1**) affords exclusively the diol from the *cis* isomer (eq 2).[11]

(2)

Ozonolysis of (**1**) followed by reduction leads to a monoprotected glyoxal useful for reactions with stabilized phosphoranes (eq 3).[12]

(3)

γ-Aldehydo esters are obtained from (**1**) by double bond migration mediated by a ruthenium hydride complex (eq 4),[13] or by treatment with ***Iodotrimethylsilane*** (in lower yield).[14]

(4)

Related Reagents.

α,β-***Butenolide***; ***2,5-Dimethoxytetrahydrofuran***; ***Furan***; ***Glyoxal***; ***Succindialdehyde***; ***2-Trimethylsilyloxyfuran***.

1,2-Dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile

[54585-47-6] · $C_8H_8N_2S$ · 1,2-Dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile · (MW 164.22)

(for access to the corresponding disulfide for use in synthesis of esters, lactones, and amides from carboxylic acids)

Physical Data: mp 250-264 °C (dec).

Solubility: sparingly sol toluene and CH_2Cl_2.

Form Supplied in: crystalline solid.

Preparative Method: the reagent (**1**) is prepared in essentially quantitative yield by reaction of 2-cyanothioacetamide with ***2,4-Pentanedione***.[1] The corresponding disulfide (**2**) [bis(3-cyano-4,6-dimethylpyridinyl) disulfide] is prepared by oxidation of (**1**) with ***Iodine*** under basic conditions.[2]

Handling, Storage, and Precautions: the reagent should be treated as a potential irritant.

The principal synthetic application of the reagent (**1**) is as a source of the corresponding symmetrical disulfide (**2**) (eq 1).[2] The disulfide (**2**) is used to effect esterifications (eqs 2-4)[3,4] and amidations (eqs 5 and 6)[5,6] (see also ***2,2´-Dipyridyl Disulfide***).

(versatile chiral building blocks used in the synthesis of a wide variety of natural products[1a-d] and other biologically important molecules,[2] including anti-HIV dideoxynucleosides;[1e,f] also useful for preparing optically active ligands[3])

Alternate Names: (*R*)- and (*S*)-γ-hydroxymethyl-γ-butyrolactones; 5-oxotetrahydrofuran-2-methanol; 5-hydroxymethylpentanolide.

Physical Data: (**1**) bp 101-102 °C/0.048 mmHg;[4,5] (**2**) bp 122-130 °C/0.6 mmHg;[5,6] (**3**) bp 160-170 °C/0.4-0.6 mmHg;[7] (**4**) bp 160-164 °C/0.02 mmHg; 152-160 °C/0.04 mmHg;[8,9] (**5**) mp 153-154 °C;[10] (**6**) mp 153-154 °C;[10] (**7**)-;[11] (**8**) bp 88-92 °C/0.05 mmHg;[12] (**9**) mp 72-73 °C;[13] (**10**) mp 75-76 °C;[14] (**11**) mp 84.5-86 °C;[15,16] (**12**) mp 85-87 °C.[15,17]

Preparative Methods: both enantiomers of dihydro-5-(hydroxymethyl)-2(3*H*)-furanone and their trityl derivatives are commercially available but expensive. The simplest and by far most popular method for preparing (*S*)-dihydro-5-(hydroxymethyl)-2(3*H*)-furanone (**2**)[1e,f] consists of enantiospecific deamination of L-glutamic acid[5] and subsequent selective reduction[15] of the resulting carboxylic acid (**13**) (eq 1). Purification of the intermediate acid (**13**) by crystallization[5] and not by distillation[18] is recommended in order to secure an excellent optical yield (>98% ee). Likewise, (*R*)-dihydro-5-(hydroxymethyl)-2(3*H*)-furanone (**1**) (>98% ee) can be obtained from D-glutamic acid.[5] As the latter is considerably more expensive than its natural antipode, an appealing option is to convert the (*S*)-lactone into its enantiomer (eq 2).[17] Also available and equally useful is an inversion route to (*R*)-dihydro-5-(trityloxymethyl)-2(3*H*)-furanone (**5**) by way of the Mitsunobu reaction (eq 3).[10]

Synthetic Applications.

(*S*)-Dihydro-5-(hydroxymethyl)-2(3*H*)-furanone (**2**) was first described in 1971 as an intermediate in the synthesis of D-ribose from L-glutamic acid.[19] Since then, this lactone and its (*R*)-enantiomer[4] have found widespread use as chirons for constructing a rich variety of natural products ranging from simple pheromones[16,20] to complex macrocycles[1b,21] and ionophore antibiotics.[22] The chemical manipulation of these chirons often involves lactone cleavage at an early stage,[3,21,23] as illustrated by the preparation of suitable intermediates for the synthesis of the *Vespa orientalis* pheromone (*R*)-δ-*n*-hexadecanolactone (**14**) (eq 4),[6] the antiviral fungal metabolite brefeldin A (**15**) (eq 5),[24] and (7aα)-*epi*-hemibrevetoxin B (**16**) (eq 6).[9]

Optically active γ-alkyl-γ-butyrolactones are readily available from the tosylates through a one-pot reductive procedure[25a] or by alkylative side-chain elongation with the appropriate organocuprate (eq 7).[15]

Protection of the alcohol moiety with a bulky group, such as trityl or *t*-butyldiphenylsilyl (TBDPS), shields the *syn* face of the lactone, thereby forcing incoming reagents to attack *anti* to the side chain.[26,2c] This scenario has been heavily exploited for the stereocontrolled introduction of one or two ring substituents through alkylation[2c,26-29] or aldolization.[30] For instance, sequential dialkylation of (*S*)-dihydro-5-(trityloxymethyl)-2(3*H*)-furanone provides products of high diastereomeric purity which can be transformed into β,β-disubstituted γ-butyrolactones (eq 8).[26] Various optically active lactones with predetermined substitution patterns, available in a similar way, have been utilized as key intermediates in the synthesis of

indole alkaloids,[27] lignans,[1d,9] β-lactams,[31] and other natural products.[1a,32]

The initial *trans*-alkylated lactones can be easily epimerized in situ by enolization and protonation from the less hindered face[29] using *t*-butyl bromide as the proton source (eq 9).[2b] Further handling of the so-formed *cis* isomers allows for the total synthesis of dihydromevinolin (**17**) and several analogs of import as cholesterol lowering agents.[2b]

Stereoselective *trans* α-hydroxylation of (*S*)-dihydro-5-(*t*-butyldiphenylsiloxymethyl)-2(3*H*)-furanone can be realized in good yield by enolization and reaction with the ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** complex (MoOPH) (eq 10).[33] Appropriate manipulation of the resulting *trans*-hydroxylactone provides 1,3-polyols[1b] typified by (**18**),[33a] as well as tetrahydropyran (**19**) which is a key intermediate in mevinic acid syntheses.[33b]

Owing to the urgent need of new drugs for the treatment of AIDS, many methods for converting the title lactones into antiviral dideoxynucleosides have been devised within the past few years.[1e,f,12,34] A viable synthesis of the potent anti-HIV agent 3´-deoxy-2´,3´-dehydrothymidine (d4T, **21**) relies on *trans* selective sulfenylation of the lactone-derived silyl ketene acetal (**20**) with *N*-(phenylthio)-ε-caprolactam (eq 11).[35] In comparable fashion, (**21**) and related nucleosides have been prepared through selenenylation of (**20**).[36]

Related Chirons.

The commercially available (*R*)-(-)- and (*S*)-(+)-enantiomers of 5-hydroxymethyl-2(5*H*)-furanone (**22** and *ent*-**22**) and their various protected derivatives have also been extensively used in the synthesis of natural products,[1b -d,37,38] nucleosides,[1e,f] and other bioactive substances.[39,40] A cost-effective, versatile route to these chirons[14,37,40b] is illustrated by the preparation of (**22**) (eq 12).[38]

Related Reagents.

(2*S*)-(+)-2,5-Dihydro-2-isopropyl-3,6-dimethoxypyrazine[1]

[78342-42-4] · $C_9H_{16}N_2O_2$ · (2*S*)-(+)-2,5-Dihydro-2-isopropyl-3,6-dimethoxypyrazine · (MW 184.24)

(Schöllkopf-Hartwig bislactim ether reagent for asymmetric synthesis of amino acids by reaction of the metalated reagent with alkyl halides,[2] aldehydes,[3] ketones,[4] epoxides,[5] and enones,[6] and subsequent hydrolysis of the resulting bislactim ether adduct)

Physical Data: bp 103-104 °C/15 mmHg; *d* 1.03 g cm^{-3}; [α]20D -109 (*c* = 1, EtOH).

Solubility: sol ether, THF, *n*-hexane.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: NMR.[2]

Purification: distillation.

Handling, Storage, and Precautions: store refrigerated.

Bislactim Ether Method.

The commercially available bislactim ethers of cyclo(L- and D-Val-Gly) and cyclo(L- and D-Val-Ala)[7] are very versatile reagents for the preparation of nonproteinogenic amino acids in high yields and with excellent enantioselectivities (typically >95%).[1]

Reactions of the Lithiated Bislactim Ether.

The procedure involves metalation with ***n-Butyllithium*** in THF at -70 °C and reaction of the resulting azaenolate with alkyl halides (eq 1).[2] The latter enters with high diasteroselectivity *trans* to the isopropyl group. The alkylation products

are hydrolyzed under mild acidic conditions to give the desired amino acid ester and the chiral auxiliary L-Val-OMe, which can be separated by distillation or chromatography (eq 1). As well as reacting with primary and secondary alkyl halides and sulfonates,[8] the lithiated bislactim ether reacts in good yields and with high *trans* diastereoselectivities (in general >95%) with a variety of other electrophiles such as ketones,[9] acyl chlorides,[10] thioketones,[11] epoxides,[5] α,β-unsaturated esters,[12] and arene-manganese tricarbonyl complexes.[13]

Reaction of the Titanated Bislactim Ether.

The titanium derivative of the bislactim ether of cyclo(L-Val-Gly) reacts with alkyl aldehydes,[3] aryl aldehydes,[14] and α,β-unsaturated aldehydes[15] highly diastereoselectively to give almost exclusively the *syn* addition products (eq 2). Hydrolysis with dilute ***Trifluoroacetic Acid***[3c] affords (2*R*, 3*S*)-β-hydroxy-α-amino acid methyl esters. α-Amino-γ-nitro amino acids can be obtained by 1,4-addition of the titanated bislactim ether to nitroalkenes and subsequent hydrolysis of the adduct.[16]

(2S)-(+)-2,5-Dihydro-2-isopropyl-3,6-dimethoxypyrazine

Reactions of the Bislactim Ether Cuprate.

The lithiated bislactim ether can be converted to an azaenolate cuprate by treatment with CuBr.SMe_2 (see ***Copper(I) Bromide***).[6] Conjugate addition of the cuprate to enones (eq 3)[6] and dienones,[17] or alkylation[6] with base labile electrophiles like ethyl 3-bromopropionate, proceeds with high *trans* diastereoselectivity. Hydrolysis of the Michael adducts and subsequent protection afford (2*R*,3*R*)-*N*-Boc-δ-oxo-α-amino acid methyl esters (eq 3).

(2S)-(+)-2,5-Dihydro-2-isopropyl-3,6-dimethoxypyrazine

Reactions of the Bislactim Ether Carbene.

Diazotization of the lithiated bislactim ether generates an electrophilic carbene species, which reacts in good yields and with high diastereomeric excess (<95%) with alkenes[18] and aryl alkynes[19] (eq 4) to give spirocyclopropanes and spirocyclopropenes, respectively. Hydrolysis of the latter affords the novel (*R*)-1-amino-2-arylcyclopropene-1-carboxylic acids.[19]

Related Reagents.

1-Benzoyl-2-t-butyl-3,5-dimethyl-4-imidazolidinone; ***(2S,4S)-3-Benzoyl-2-t-butyl-4-methyl-1,3-oxazolidin-5-one***.

3,4-Dihydro-2*H*-pyran[1]

[110-87-2] · C_5H_8O · 3,4-Dihydro-2*H*-pyran · (MW 84.12)

(widely used OH-protecting reagent;[1] applicable to alkanols, phenols, thiols; stable at high pH; labile at low pH; generally resistant to nucleophiles and organometallic reagents; resistant to hydride reductions; labile under Lewis acidic conditions)

Physical Data: mp -70 °C; bp 86 °C; fp -15 °C; *d* 0.922 g cm^{-3}.

Solubility: sol water, ethanol.

Handling, Storage, and Precautions: it has been reported that the tetrahydropyranyl (THP) ethers form sensitive organic peroxides when in contact with peroxy reagents. Violent explosions have occurred during purification of these compounds. Precautions normally sufficient in isolation of such products have failed to destroy the sensitive components.[2]

Tetrahydropyranylation of Alcohols.

Protection of alcohol functionality as the THP ether is an often-utilized tool in organic synthesis. It must be noted that the reaction of a chiral alcohol with dihydropyran introduces an additional asymmetric center and hence a diastereomeric mixture is obtained (eq 1). This can lead to difficulties with purification, assignment of spectral features, etc., but does not prevent successful implementation.[3]

(1)

A variety of reaction conditions for the synthesis of THP derivatives, the majority acidic, have been proposed in the literature (eq 2). The techniques have been highly optimized and increasingly mild conditions have been developed. Mineral acids have classically been used to effect the reaction.[4] Products have been obtained in 20-93% yields using these methods. However, the use of mineral acids is clearly limiting with respect to substrates containing sensitive

functionality. Nevertheless, many applications in steroid[5] and saccharide[6] chemistry are possible using this technology. Significantly, tetrahydropyranyl ethers are not known to migrate in 1,2-diol systems.

≡ R-OTHP (2)

The standard acid catalyst for effecting tetrahydropyranylation of alcohols has become ***p-Toluenesulfonic Acid***. Reaction of even tertiary alcohols with excess dihydropyran is usually complete in 0.5-1 h at rt, although sometimes reflux temperatures are required. Yields range from 60 to 84% for tertiary alcohols.[7] Catalysis by *p*-TsOH can give very high yields, depending on conditions and choice of solvent: *p*-TsOH (dioxane, 20 °C, 5 min, 71-97%).[8]

Tetrahydropyranylation of primary and secondary alcohols can give high yields under mild and neutral conditions using ***Iodotrimethylsilane*** (25 °C, 30 min, 80-95%). Workup is particularly convenient, consisting of evaporation of volatiles and chromatography when required. Tertiary alcohols, however, yield the corresponding iodide rather than the THP ether.[9]

Reaction using ***Boron Trifluoride Etherate*** (Et_2O-petroleum ether, 25 °C, 47-76%) gives moderate yields with evaporation of volatiles being the only workup required.[10]

Pyridinium p-Toluenesulfonate (25 °C, 4 h, 94-100%) is a mild and efficient catalyst, particularly applicable to the protection of highly acid sensitive alcohols. Yields were markedly superior to procedures employing $BF_3.Et_2O$, *p*-TsOH, and ***Hydrogen Chloride***.[11]

Tetrahydropyranylation of tertiary alcohols, while more difficult owing to the hindered nature of the substrates or competitive elimination, can be carried out using dihydropyran and ***Triphenylphosphine Hydrobromide*** (25 °C, 6-24 h, 80-96%).[12] The method is applicable to even very sensitive substrates such as mevalonolactone (eq 3).

(3)

Tetrahydropyranylation of alcohols can be carried out under very mild conditions in the presence of bis(trimethylsilyl) sulfate (0 °C, 1 h, 89-100%). No rearrangement is observed even with tertiary allylic alcohols.[13]

Protocols have been developed which utilize an insoluble solid catalyst in combination with dihydropyran to effect the protection of alcohols as their corresponding THP ethers. These procedures are advantageous in that the catalyst may be recovered by simple filtration and the products isolated by evaporation of volatiles. In many cases the catalyst can be reused without regeneration. Reaction of alcohols with dihydropyran in the presence of Amberlyst H-15 (25 °C, 1 h, 90-98%) yields THP derivatives. Alternatively, a solution of dihydropyran and the alcohol may be passed slowly through a column of silica overlaid with Amberlyst H-15 to yield the THP ethers directly (73-97%).[14] The acidic clay

Montmorillonite K10 (25 °C, 15-30 min, 63-95%) is similarly applicable.[15] Reillex® 425 resin (86 °C, 1.5 h, 84-98%)[16] is applicable with the advantage that it does not promote the sometimes troublesome polymerization of dihydropyran.[17] Polymeric derivatives of pyridinium *p*-toluenesulfonate are also effective. Poly(4-vinylpyridinium *p*-toluenesulfonate) and poly(2-vinylpyridinium *p*-toluenesulfonate) catalysts yield tetrahydropyranyl derivatives of primary, secondary, and tertiary alcohols (24 °C, 3-8 h, 72-95%).[18]

Cleavage of Tetrahydropyranyl Derivatives.

Deprotection of THP ethers has been carried out using ***Acetic Acid*** (H_2O-THF (3:3:2), 50 °C, 5 h, 97%),[19] HOAc (H_2O-THF (2:1:as required), 47 °C, 4 h, 82%),[20] HOAc (THF-H_2O (4:2:1), 45 °C, 3.5 h),[21] aqueous ***Oxalic Acid*** (MeOH, 50-90 °C, 1-2 h),[22] *p*-TsOH (MeOH, 25 °C, 1 h, 94%),[23] pyridinium *p*-toluenesulfonate (EtOH, 55 °C, 3 h, 98-100%),[24] bis(trimethylsilyl) sulfate (MeOH, 25 °C, 10-90 min, 93-100%).[13] Cleavage with Amberlyst H-15 (MeOH, 45 °C, 0.5-2 h, 93-98%)[25] is advantageous in that the acid catalyst can be recovered by filtration and no aqueous workup is required. Organotin phosphate condensates are effective in the selective cleavage of THP ethers (MeOH, reflux, 2 h, 80-90%) in the presence of MEM ethers, MOM ethers, and 1,3-dioxolanes.[26] The catalyst is insoluble in the reaction medium and can be reused repeatedly.

Selective cleavage of THP ethers in the presence of *t*-butyldimethylsilyl ethers can be accomplished by treatment with mild Lewis acids: ***Dimethylaluminum Chloride*** (-25 °C to 25 °C, 1 h, 98%) or ***Methylaluminum Dichloride*** (-25 °C, 0.5 h, 90%).[27] Selective cleavage of THP ethers of primary, secondary, and tertiary alcohols can be carried out in the presence of *t*-butyldimethylsilyl, acetyl, mesyl, and methoxymethyl ethers, in the presence of thiostannane catalysts: $Me_2Sn(SMe)_2$-$BF_3.Et_2O$ (-20 °C or 0 °C, 3-25 h, 80-97%).[28]

Tetrahydropyranylation of Thiols.

Tetrahydropyranyl derivatives of thiols have been utilized for the masking of this functional group (eq 4).

≡ R-STHP (4)

Thiols react with dihydropyran in the presence of $BF_3.Et_2O$ (0 °C, 0.5 h, 25 °C, 1 h) to yield (*S*)-2-tetrahydropyranyl hemithioacetals in satisfactory yields.[29] In contrast to *O*-tetrahydropyranyl ethers, an *S*-tetrahydropyranyl ether is stable to 4 N HCl-MeOH.[30] Deprotection is conveniently accomplished with ***Silver(I) Nitrate*** (0 °C, 10 min)[31] or ***Hydrogen Bromide-Trifluoroacetic Acid*** (90 min)[32] in quantitative yields. Oxidation to disulfides can be carried out with ***Iodine***[33] or ***Thiocyanogen***.[34]

Tetrahydropyranylation of Amides.

Aromatic amides, alkyl amides, ureas, sulfonamides, and imides undergo reaction with dihydropyran-***Hydrogen Chloride*** (benzene, reflux, 2 h, 22-73%), yielding the expected adducts.[35]

Tetrahydropyranylation of Amines.

Purines react with dihydropyran in the presence of a catalytic amount of *p*-TsOH to give the 9-tetrahydro-2-pyranyl derivatives (50-87%) (eq 5).[36]

(5)

Functional Group Manipulation of Tetrahydropyranyl Derivatives.

While tetrahydropyranyl derivatives are often utilized as masked equivalents of alcohols, etc., it is possible to perform functional group manipulation on such species. In these cases the tetrahydropyranyl derivatization serves to activate the alcohol rather than protect it.

Conversion of alcohols to their corresponding alkyl halides can be accomplished in two steps by conversion to the THP ethers followed by treatment with ***Triphenylphosphine-Carbon Tetrabromide*** (23 °C, 24 h, 62-87%).[37] In the case of tertiary substrates, 15-25% elimination is observed. Similarly rapid conversion of tetrahydropyranyl derivatives to their corresponding bromides or iodides can be carried out with 1,2-bis(diphenylphosphino)ethane tetrahalides (0.1-4 h, 0 °C to 23 °C, 81-96%).[38] Methyl esters and *t*-butyldimethylsilyl ethers and alkenes are unreactive under these reaction conditions. Direct conversion of alcohol tetrahydropyranyl ethers to bromides, chlorides, trifluoroacetates, methyl ethers, or nitriles can be effected with ***Triphenylphosphine Dibromide*** (25 °C, 30 min, 43-89%).[39] Tetrahydropyranyl ethers may be converted to benzyl ethers, MEM ethers, benzoates, or tosylates by reaction with the appropriate electrophile in the presence of $Bu_3SnSMe\text{-}BF_3.EtO_2$ (0 °C, 7-70 h, 75-78%). Oxidation of the intermediate alkoxystannane with ***Pyridinium Chlorochromate*** yields aldehydes (83%).[40]

Ring Opening Reactions of Dihydropyran.

Treatment of dihydropyran with *n*-pentylsodium,[41] or ***n-Butyllithium***[42] yields *trans*-1-hydroxy-4-nonene (73%) (eq 6).

(6)

Cleavage of dihydropyran with HCl(aq) (30 min, 25 °C) constitutes a convenient preparation of 5-hydroxypentanal (eq 7).[43]

(7)

Tetrahydropyranyl ethers are unstable to reduction with ***Lithium Aluminum Hydride-Aluminum Chloride*** (eq 8). Cleavage occurs in the tetrahydropyranyl ring or exocyclicly.[44] The reaction is seldom useful synthetically since the two modes are competitive. In marked contrast, tetrahydropyranyl derivatives of thiols are cleaved selectively at the ring carbon-oxygen bond, giving hydroxyalkyl thioethers (58-82%) (eq 9).[45]

(8)

(9)

Tetrahydropyranyl derivatives of amines are hydrogenolized by $LiAlH_4$ in the absence of any Lewis acid (eq 10).[46]

(10)

Dihydropyran is a convenient starting material for the preparation of (*E*)-4-hexen-1-ol, in three steps (eq 11).[47]

(11)

Anion Chemistry.

Dihydropyran and derivatives can be quantitatively deprotonated with ***t-Butyllithium*** (-78 °C to 5 °C, 0.5 h, THF) (eq 12). The resulting anion reacts with electrophiles such as ketones and alkyl halides in good yields. Cuprates derived from this anion add smoothly in conjugate fashion to α,β-enones in excellent (91%) yields (eq 13).[48]

(12)

(13)

Electrophilic Addition to Dihydropyran.

Electrophilic addition of acetals and orthoesters to dihydropyran occurs in the presence of mild catalyst systems such as ***Chlorotrimethylsilane-Tin(II) Chloride*** (0 °C, 2 h, 55-84%) (eq 14).[49] The synthetic utility of the reaction is however limited by the lack of stereocontrol.

(14)

Specific Applications.

The THP protecting group has been widely applied in the field of organic synthesis and no attempt can be made to comprehensively review its use in these pages. However, several specific applications may be of interest.

Introduction of the *trans*-CH=CHCH$_2$OH moiety may be conveniently accomplished using a mixed Gilman cuprate reagent bearing a terminal THP-protected ether (eq 15).[50] The transformation is of considerable utility in several fields of synthesis, including prostaglandin chemistry.

(15)

The tetrahydropyranyl derivative of propargyl alcohol, tetrahydro-2-(2-propynyloxy)-2*H*-pyran, can be converted to methyl 4-hydroxy-2-butynoate in four steps.[51] Diethyl [(2-tetrahydropyranyloxy)methyl]phosphonate is a convenient Wadsworth-Emmons reagent.[52] Tetrahydropyranyl esters of α-bromo acids can be used in the Reformatsky reaction for the preparation of β-hydroxy acids.[53] Elimination of a tetrahydropyranyloxy moiety from butyne-1,4-diols with lithium hydride constitutes an efficient method for the synthesis of allenic alcohols.[54]

Related Reagents.

2-Chloroethyl Chloromethyl Ether; ***Dimethoxymethane***; ***Ethyl Vinyl Ether***; ***p-Methoxybenzyl Chloride***; ***(p-Methoxybenzyloxy)methyl Chloride***; ***2-Methoxyethoxymethyl Chloride***.

3,4-Dihydro-2*H*-pyrido[1,2-*a*]pyrimidin-2-one

[5439-14-5] · $C_8H_8N_2O$ · 3,4-Dihydro-2*H*-pyrido[1,2-*a*]pyrimidin-2-one · (MW 148.16)

(synthesis of esters and amides from carboxylic acids; glycosylation)

Physical Data: mp 155-156 °C; mp (HCl salt) 284-285.5 °C (dec); mp (HBr salt) 299-300 °C (dec); mp (HI salt) 263-264 °C (dec).

Solubility: sol MeOH, EtOH, H_2O.

Form Supplied in: both the free base and salts are obtained as colorless solids.

Analysis of Reagent Purity: the reagent has a betaine-like structure and behaves as a salt in terms of the reagent's solubility. The literature reports various melting points values for both the anhydrous and hydrated forms of the reagent but the conditions used to determine melting point have been shown to be critical and care must be exercised if this property is to be used as a measure of reagent purity.[1]

Preparative Methods: is prepared by reaction of 2-aminopyridine with either ***Acrylic Acid*** itself or an equivalent (2-bromo- or 2-iodopropionic acid, ***Methyl Acrylate***, ethyl 2-bromopropionate, β-***Propiolactone***).[1,2]

Purification: the free base and salts are readily recrystallized from MeOH-Et_2O.[1]

Handling, Storage, and Precautions: the reagent may be dried over P_2O_5 in vacuo (135 °C/17 mmHg).

Introduction.

The principal synthetic application of 3,4-dihydro-2*H*-pyrido[1,2-*a*]pyrimidin-2-one (**1**) is an acid scavenger; it is an example of a proton sponge (see ***1,8-Bis(dimethylamino)naphthalene***). The reagent has been used in the esterification and amination of alkyl and aryl carboxylic acids and also in glycosylation of 2-amino-2-deoxy sugars.

Synthesis of Esters from Carboxylic Acids.[3]

Esterification (eq 1) proceeds by activation of the carboxyl component using a 2-halopyridinium salt (**2**; X = Cl, Y = I or X = F, Y = OTs) and (**1**) (2.4 equiv) in the presence of an alcohol. The best solvents for this process are CH_2Cl_2 or MeCN, but a range of other solvents may also be used.

Synthesis of Amides from Carboxylic Acids.[4]

In the corresponding amidation process (eq 2) there is a requirement for the addition of 1 equiv of a tertiary amine (***Tri-n-butylamine***) to ensure efficient utilization of the amine component (R^2R^3NH). Once again, carboxyl activation is achieved using a 2-halopyridinium salt (**2**) but, unlike the esterification reaction, amidation is best carried out as a two-step one-pot process.

Yields for both the esterification (eq 1) and amidation (eq 2) reactions are generally high, but the advantages associated with use of (**1**) over other reagents for these types of transformation have yet to be clearly defined.

Glycosylation.[5]

3,4-Dihydro-2*H*-pyrido[1,2-*a*]pyrimidin-2-one has been used in conjunction with ***Silver(I) Trifluoromethanesulfonate*** as a reagent combination to mediate the glycosylation of *N*-protected 2-amino-2-deoxy sugars using a glycosyl bromide as the glycosyl donor (eq 3).

Dihydroquinidine Acetate[1]

(R = Ac)

[72989-10-7] · $C_{22}H_{28}N_2O_3$ · Dihydroquinidine Acetate · (MW 368.47) (R = *p*-$ClC_6H_4C(O)$-)

[113162-02-0] · $C_{27}H_{29}ClN_2O_3$ · Dihydroquinidine *p*-Chlorobenzoate · (MW 464.99) (R = H)

[1435-55-8] · $C_{20}H_{26}N_2O_2$ · Dihydroquinidine · (MW 326.44)

(asymmetric dihydroxylation;[2] conjugate additions;[3] carbonyl additions[3])

Alternate Name: DHQD-Ac.

Physical Data: *p*-$ClC_6H_4C(O)$-: mp 102-105 °C; $[\alpha]_D$ -73° (*c* = 1, EtOH).

Solubility: *p*-$ClC_6H_4C(O)$-: sol CH_2Cl_2, Et_2O, EtOH, EtOAc.

Form Supplied in: the *p*-chlorobenzoate is available as a white foam.

Preparative Methods: the acetate is prepared from dihydroquinidine[4] and the *p*-chlorobenzoate is commercially available. The phthalazine-derived bis(dihydroquinidine) ligand is commercially available.[5] A formulation of the standard reactants for the asymmetric dihydroxylation (AD-mix-β) on the small scale has been developed and is commercially available.[6] AD-mix-β (1 kg) consists of potassium osmate (0.52 g), the phthalazine-derived ligand (5.52 g), $K_3Fe(CN)_6$ (700 g), and powdered K_2CO_3 (294 g).

Purification: the recovery of dihydroquinidine *p*-chlorobenzoate after a dihydroxylation reaction is accomplished in the following manner:[7] the crude dihydroquinidine *p*-chlorobenzoate (DHQD-CLB) is dissolved in ether, cooled to 0 °C, and HCl gas is bubbled into the solution until a pH of 1-2 is obtained using wet pH paper. The pale yellow precipitate of the hydrochloride salt is collected by filtration and dried under high vacuum (0.01

mmHg). The free base is liberated by suspending the salt in EtOAc, cooling the heterogeneous mixture to 0 °C, and adding 28% NH_4OH (or 15% NaOH) until a pH = 11 is obtained. After separation, the aqueous layer is extracted with portions of EtOAc, the combined organic layers are dried over Na_2SO_4, and the solvent removed in vacuo to give the pure DHQD-CLB as a white foam.

Handling, Storage, and Precautions: toxic; use in a fume hood.

Chiral Ligand for the Asymmetric Dihydroxylation of Alkenes.

Dihydroquinidine acetate (DHQD-Ac) was found to be one of the first efficient cinchona-derived chiral ligands for the asymmetric dihydroxylation reaction of substituted alkenes.[8] For example, styrene could be dihydroxylated in 61% ee (62% yield) using a mixture of 1.1 equiv of DHQD-Ac and 1.1 equiv of ***Osmium Tetroxide*** in toluene. An osmium-catalyzed asymmetric process, in which the co-oxidant is ***N-Methylmorpholine N-Oxide*** (NMO) and the chiral ligand is DHQD-CLB, was described later.[9] The other enantiomer of the diol could also be obtained by using the analogous dihydroquinine ester (***Dihydroquinine Acetate***), which acts as a pseudoenantiomer of the dihydroquinidine ester. Significant increases in the level of asymmetric induction of the dihydroxylation were later observed if the re-oxidant NMO was replaced by potassium hexacyanoferrate(III) ($K_3Fe(CN)_6$) (eq 1).[10]

(1)

NMO (slow addition)	86% ee
NMO (no slow addition)	65% ee
$K_3Fe(CN)_6$	91% ee

The nature of the group attached to the 9-*O* position of dihydroquinidine was found to have a profound impact on the level of stereochemical induction in these reactions and a variety of new ligands have been developed (see **1**-**5**).[11]

The phthalazide bis(cinchona) derivatives [$(DHQD)_2$-PHAL][5,6,12] are the best ligands for the asymmetric dihydroxylation of *trans*, 1,1-disubstituted,[13] and trisubstituted alkenes, enol ethers,[14] α,β-unsaturated ketones,[15] and α,β- and β,γ-unsaturated esters,[16] whereas the DHQD-IND ligand[17] turns out to be superior for *cis*-alkenes (Table 1). The bis(cinchona) alkaloid-substituted pyrimidine ligand was found to be the best for monosubstituted terminal alkenes.[18] The addition of ***Methanesulfonamide*** to enhance the rate of osmate(VI) ester hydrolysis is recommended for all nonterminal alkenes.

Table 1 Alkenes Dihydroxylated using DHQD Ligands

 (DHQD)$_2$-PHAL 99% ee	(DHQD)$_2$-PHAL 97% ee	 (DHQD)$_2$-PHAL >99.5% ee

Asymmetric dihydroxylation of substituted aryl allyl ethers also proceeds with high enantioselectivities (89-95% ee) providing that there are no *ortho* substituents on the aryl group.[19] Dienes,[20] polyenes,[21] and enynes[22] can also be regioselectively dihydroxylated (eqs 2-5). In some cases, such as in the asymmetric dihydroxylation of α,β- and β,γ-unsaturated amides,[23] the amount of ligand and potassium osmate in the AD-mix content has to be increased fivefold to achieve good catalytic turnover rates.

$(DHQD)_2$-PHAL 73% ee
DHQD-PHN 53% ee

The prediction of the absolute stereochemistry of the predominant enantiomer obtained is provided by the model shown in Scheme 1.

Scheme 1

By employing polymer-bound alkaloid derivatives, heterogeneous catalytic asymmetric dihydroxylation has been achieved with good to excellent enantioselectivities in the dihydroxylation of *trans*-stilbene.[24] These polymers can be recovered and reused while both the yields and the optical purities of diols were maintained.

Double Diastereoselection in the Dihydroxylation Reaction.

The dihydroxylation reaction of chiral nonracemic substrates using the cinchona-derived ligand leads to a matched and mismatched pair (eq 6).[25] Kinetic resolution of several racemic secondary alcohols has also been examined.[26]

Additional examples of asymmetric dihydroxylation are provided under the entry for ***Dihydroquinine Acetate***.

Chiral Ligand for other Stereoselective Reactions.[1]

The effect of the addition of dihydroquinidine-derived alkaloids on the product enantioselectivity has also been investigated in the addition reaction of ***Diethylzinc*** to aldehydes,[27] in the addition of aromatic thiols to conjugated cycloalkenones,[28] and in the heterogeneous hydrohalogenation of α,α-dichlorobenzazepinone-2.[29] In these cases, the dihydroquinidine derivatives were not the optimal ligands.

(asymmetric dihydroxylation;[2] conjugate additions;[3] carbonyl additions[3])

Alternate Name: DHQ-Ac.

Physical Data: *p*-$ClC_6H_4C(O)$-: mp 130-133 °C; $[\alpha]_D$ +150° (*c* = 1, EtOH).

Solubility: *p*-$ClC_6H_4C(O)$-: sol CH_2Cl_2, Et_2O, EtOH, EtOAc.

Form Supplied in: the *p*-chlorobenzoate is available as a white foam.

Preparative Methods: the acetate is prepared from dihydroquinine[4] and the *p*-chlorobenzoate is commercially available. The phthalazine-derived bis(dihydroquinine) ligand is commercially available.[5] A formulation of the standard reactants for the asymmetric dihydroxylation (AD-mix-α) on the small scale has been developed and is commercially available.[6] AD-mix-α (1 kg) consists of potassium osmate (0.52 g), the phthalazine-derived ligand (5.52 g), $K_3Fe(CN)_6$ (700 g), and powdered K_2CO_3 (294 g).

Purification: dihydroquinine *p*-chlorobenzoate is recovered after a dihydroxylation reaction using the same method as that described for ***Dihydroquinidine Acetate***.

Handling, Storage, and Precautions: toxic; use in a fume hood.

Chiral Ligand for the Asymmetric Dihydroxylation of Alkenes.

Dihydroquinine-derived chiral ligands have been used as pseudoenantiomers of the dihydroquinidine analog in the catalytic asymmetric dihydroxylation of alkenes. In general, the enantioselectivities with these ligands are as good as or slightly lower than those obtained with the dihydroquinidine ligand. For example, styrene could be dihydroxylated in 62% ee using a mixture of dihydroquinidine *p*-chlorobenzoate (DHQD-CLB, 0.13 equiv), ***Osmium Tetroxide*** (0.13 equiv), and ***N-Methylmorpholine N-Oxide***, whereas the analogous reaction with dihydroquinine *p*-chlorobenzoate produced the diol of opposite absolute stereochemistry in 54% ee.[7]

As in the dihydroquinidine series, the phthalazide cinchona derivative [$(DHQ)_2$-PHAL] (**1**)[6] is the best ligand for the asymmetric dihydroxylation of terminal, *trans*, 1,1-disubstituted, and trisubstituted alkenes, and enol ether,[8] whereas the DHQ-IND ligand (**2**)[9] turns out to be superior for *cis*-alkenes (Table 1). The addition of ***Methanesulfonamide*** to enhance the rate of osmate(VI) ester hydrolysis is recommended for all nonterminal alkenes.

For additional examples and an extensive discussion on the use of these ligands in asymmetric dihydroxylation reactions, see ***Dihydroquinidine Acetate***.

Chiral Ligand for Other Stereoselective Reactions.

The effect of the addition of dihydroquinine-derived alkaloids on the product enantioselectivity has also been investigated in the addition reaction of ***Diethylzinc*** to aldehydes,[12] in the addition of aromatic thiols to conjugated cycloalkenones,[13] and in the heterogeneous hydrohalogenation of α,α-dichlorobenzazepinone-2.[14]

Dihydridotetrakis(triphenylphosphine)ruthenium(II)

$(Ph_3P)_4RuH_2$

[19529-00-1] · $C_{72}H_{62}P_4Ru$ · Dihydridotetrakis(triphenylphosphine)ruthenium(II) · (MW 1152.26)

(catalyst for hydration of nitriles,[3] isomerization of alkynes,[5,6] Knoevenagel reactions and conjugate additions,[8] and transfer hydrogenation[9])

Physical Data: light yellow dimagnetic solid, mp 180 °C.

Solubility: slightly sol benzene, toluene, THF.

Preparative Methods: prepared from ***Ruthenium(III) Chloride*** or ruthenium(III) acetylacetonate by reduction with ***Triethylaluminum*** in the presence of ***Triphenylphosphine*** in THF or benzene under nitrogen at room temperature.[1] The complex can also be prepared by reaction of ***Dichlorotris(triphenylphosphine)ruthenium(II)*** with ***Sodium Borohydride*** and triphenylphosphine.[2]

Purification: recrystallization from benzene, toluene, or THF.

Handling, Storage, and Precautions: is air and light sensitive and should be stored under argon in the dark.

Amide Synthesis.

The hydration of nitriles with two equivalents of water in the presence of the title reagent (**1**) as catalyst gives the corresponding amide in good yields (eq 1).[3] This reaction has been used in the transformation of δ-ketonitriles to ene-lactams (eq 2). The ruthenium reagent also catalyzes reactions of amines with nitriles in aqueous medium at 160 °C to give amides in 75-95% yield (eq 3).[4] This process has been extended to the preparation of polyamides.

(1)

(2)

(3)

Isomerization of Alkynes to Conjugated Dienes.

(*E*,*E*)-α,β,γ,δ-Dienones can be prepared stereoselectively from their corresponding α,β-unsaturated alkynyl ketones using the title reagent (**1**) as catalyst in a single step in good yields (eq 4).[5] Other routes used to synthesize these compounds include the Horner-Wadsworth-Emmons reaction and the Knoevenagel condensation, which involve multiple steps and strong basic conditions and may provide isomeric mixtures of products. Aryl α,β-unsaturated alkynyl ketones rearrange more readily than alkyl α,β-unsaturated alkynyl ketones. Similarly, α,β-unsaturated alkynyl esters rearrange stereoselectively to the corresponding (2*E*,4*E*)-dienoic esters in the presence of (**1**) (eq 5).[6] Inclusion of ***Tri-n-butylphosphine*** improves the yield of the reaction. This transformation has been extended to the preparation of o-alkoxy-(2*E*,4*E*)-dienoates, o-oxo-(2*E*,4*E*)-dienoates, and δ-oxo-α,β,γ,δ-dienones.[7]

(4)

(5)

Aldol and Michael Reactions of Activated Nitriles.[8]

Nitriles react with aldehydes or ketones in the presence of (**1**) to give the corresponding α,β-unsaturated nitriles (eq 6). Michael addition of nitriles to α,β-unsaturated carbonyl compounds proceeds smoothly in the presence of (**1**) at rt under neutral conditions with high diastereoselectivity (eq 7). None of the corresponding aldol products is formed in the reaction.

(6)

(7)

Transfer Hydrogenation of Aldehydes and Ketones.[9]

The title reagent (**1**) has been used as a catalyst in the transfer of hydrogen from alcohols, such as isopropanol, cyclohexanol, and benzyl alcohol, and ethers, such as 2,5-dihydrofuran, to aldehydes and ketones in excellent yields (eq 8).

5,6-Dihydro-2,4,4,6-tetramethyl-1,3(4*H*)-oxazine[1]

[26939-18-4] · $C_8H_{15}NO$ · 5,6-Dihydro-2,4,4,6-tetramethyl-1,3(4*H*)-oxazine · (MW 141.21)

(α-carbanion serves as acetate or acetaldehyde enolate equivalent for synthesis of α,β-unsaturated aldehydes, aliphatic aldehydes, α-amino ketones, unsymmetrical ketones, and substituted carboxylic acids)

Physical Data: bp 47-49 °C/17 mmHg.

Preparative Method: prepared by the acid-catalyzed condensation of ***Acetonitrile*** and 2-methyl-2,4-pentanediol in 65% yield (eq 1).[2]

Handling, Storage, and Precautions: no special precautions required; this reagent can be stored for months at rt under an inert atmosphere.

Synthetic Utility.

The lithio anion, or the potassio anion generated using ***Potassium-Graphite***,[3] of this reagent can be alkylated with a variety of electrophiles to form α-substituted oxazines.[2] Reduction of the oxazine with ***Sodium Borohydride*** followed by hydrolysis with ***Oxalic Acid*** affords the corresponding aldehyde. However, the oxazine could not be hydrolyzed by this procedure when the electrophile was a nitrile or ester.[4] Thus aliphatic aldehydes can be readily prepared via this protocol (isolation of the intermediates is not necessary) (eq 2, Table 1).[2,5] By substituting $NaBD_4$ or $NaBT_4$ for $NaBH_4$ in the reduction, the corresponding C_1 deuterated and tritiated aldehydes are obtained.[6]

(2)

Table 1 Aldehydes via Eq 2

Electrophile	Aldehyde	Yield (%)
		65
		54
		47

Retreatment of the initially alkylated oxazine with ***t-Butyllithium*** and alkylation with a second electrophile forms, after reduction and hydrolysis, α,α-disubstituted aldehydes. Cycloalkanecarbaldehydes are produced by α,α-dialkylation with 1,*n*-dihalides (eq 3).[2,7]

(3)

Acid-catalyzed hydrolysis of the oxazine allows for the formation of functionalized carboxylic acids (eq 4).[8]

The *N*-methyloxazinium salts formed by alkylation of the dihydro oxazines with ***Iodomethane*** undergo Grignard addition to the iminium double bond. Aqueous hydrolysis affords unsymmetrical ketones (eq 5).[9]

The lithio anion of the title reagent adds in a 1,2-fashion to carbonyl compounds. Reduction of the oxazine followed by hydrolysis and dehydration affords the α,β-unsaturated aldehydes (eq 6).[2,10]

Improved (*E*)/(*Z*) ratios can be obtained by using oxazine phosphonates (**1**)[11] and phosphonium ylides (**2**)[11] and Peterson-type α-trimethylsilyl oxazines (**3**) and (**4**).[12]

(1)

(2)

(3)

(4)

The title reagent can also be used as a precursor to α-amino ketones.[13] In addition, the *N*-oxide of the title reagent cycloadds with dipolarophiles in 1,3-dipolar cycloadditions.[14]

Related Reagents.

Acetaldehyde N-t-Butylimine; ***Dilithioacetate***; ***Ethyl Lithioacetate***; ***(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline***; ***2-Methylbenzothiazole***; ***2-Methyl-2-thiazoline***; ***2,4,4-Trimethyl-2-oxazoline***.

Dihydroxy(phenyl)borane[1]

$PhB(OH)_2$

[98-80-6] · $C_6H_7BO_2$ · Dihydroxy(phenyl)borane · (MW 121.93) (anhydride)

[3262-89-3] · $C_{18}H_{15}B_3O_3$ · Dihydroxy(phenyl)borane Anhydride · (MW 311.74)

(protective group for diols,[1c] template for C-C bond formation; phenylating agent;[2] catalyst for hydroalumination;[3] chromatography agent[1c])

Alternate Name: phenylboric acid.

Physical Data: mp 216 °C (anhyd); dipole moment 1.72 D (dioxane); pK_a 8.86 (25 °C, H_2O).

Solubility: sol H_2O 2.5%, benzene 1.75%, xylene 1.2%, ether 30.2%, methanol 178%.

Form Supplied in: white solid, widely available; contains varying amounts of the anhydride.

Preparative Method: from ***Phenylmagnesium Bromide*** and ***Trimethyl Borate***.[1d]

Purification: crystallization from H_2O.

Handling, Storage, and Precautions: readily forms trimeric anhydride upon standing or heating (eq 1); moderately toxic by ingestion; mildly toxic by skin contact.[4]

Reactions with Diols, Amino Alcohols, Diamines, Hydroxy Acids, and Catechols.[1c]

Most of the chemistry of dihydroxy(phenyl)borane (**1**) centers around its ready formation of cyclic boronate esters (eq 2). With diols the ease of formation follows the order $n = 3 > 2 > 4$. *cis*-Cycloalkene-1,2-diols readily form the cyclic boronates, whereas the *trans*-diols react with 2 equiv of (**1**) (eq 3) or form polymeric diesters. This latter feature has been used to separate *cis*/*trans* mixtures of polyols by distillation of the butylboronates or by crystallization of the phenylboronates. In the total synthesis of anthracyclines, the desired 7,9-*cis*-diol relationship was established by reaction of (**1**) with a *cis*/*trans* mixture of an early intermediate, which gave the *cis*-boronate exclusively (eq 4).[5]

(2)

X,Y = O, N, CO_2, CONH

(3)

(4)

Catalytic osmylation of alkenes in the presence of (**1**) immediately gives the cyclic boronates. In this way a bisboronate with host properties was prepared (eq 5).[6]

In alkaline aqueous solutions, (**1**) forms stable anionic adducts with diols (eq 6).[7] A large variety of anionic ligands has been prepared through the condensation of (**1**) with 3 equiv of pyrazole under basic conditions.[8]

Azeotropic reflux is the most frequently used method of preparation of cyclic boronate esters; simple heating in polar solvents like acetone, pyridine, DMF, or even 2-methoxyethanol can be used with polar diols. Most cyclic boronates can be hydrolyzed easily by adding water to their solutions in organic solvents. In more reluctant cases, alkaline or acidic solutions or aqueous ***Hydrogen Peroxide*** have been used. In the latter case, (**1**) is concomitantly oxidized to phenol.[9] If the use of water is precluded, exchange with ***Ethylene Glycol*** or more particularly ***1,3-Propanediol*** followed by removal of the volatile adduct offers a useful alternative.

Protective Group.

Due to its easy attachment and removal, (**1**) is ideally suited as protective group for diols, particularly carbohydrates[1c] and nucleosides.[10] The phenylboronate protective group is compatible with the following reaction types, mostly on hydroxy groups: acylation, sulfonation, methylation (***Diazomethane-Boron Trifluoride***), phosphorylation, tritylation, silylation, bromination (***Bromoform-Triphenylphosphine***), reaction with ***Phenyl Isocyanate***, nucleophilic substitution, and Swern oxidation.[1c]

Chromatographic Separations.

Cyclic esters of polyols, amino alcohols, or catechols with either (**1**) or dihydroxy(butyl)borane have been used for gas chromatographic analysis, particularly for the measurement of drugs in biological fluids.[1c,11] Addition of (**1**) to eluents for paper chromatography[1c] or TLC[12] leads to a much increased separation of polyols that differ mainly in relative

configuration but are very similar in polarity, such as carbohydrates and glycosides. An affinity gel or HPLC stationary phase suited for the separation of carbohydrates, glycosides, nucleosides, and enzymes can be prepared by covalent attachment of (**1**) to a solid support like agarose, polyacrylamide, polystyrene, or silica. Many of these are commercially available.[13]

Template for C-C Bond Formations.

Dihydroxy(phenyl)borane is ideally suited as a template, serving to facilitate and direct reactions between two oxygen-containing substrates. Hydroxyalkylation of phenols with aldehydes, in the presence of 1 equiv of (**1**), gave the *ortho* products exclusively via the cyclic boronate esters (eq 7).[14] Pyrolysis of the same esters resulted in formation of *ortho*-quinone methides (**2**) which could be trapped in the usual way (eq 7).[15] Condensation of (**1**) with benzoin gave the dioxaborole, which by virtue of its enforced *cis* configuration could be easily photocyclized (eq 8). The product gave 9,10-phenanthrenequinone upon hydrolysis with base in the presence of air.[16] The dioxaboroles obtained from azeotropic reflux of acyloins and (**1**) undergo aldol condensation with aldehydes to give α,β-dihydroxy ketones after hydrolytic workup (eq 9).[17] The parent compound polymerizes when treated with catalytic amounts of ***Zinc Chloride*** and a starter aldehyde (eq 10).[18]

(7)

(8)

(9)

(10)

Suzuki and Heck Reactions.

Cross-coupling reactions of (**1**) with Ar-X (X = Br, I, OTf) (eq 11),[2] heteroaryl-X (X = Cl, Br, I, or OTf),[19] and vinyl-X (X = Br,[20] OTf[21]) are catalyzed by several Pd compounds in the presence of base. The reaction can be performed in two-phase or aqueous solvents.[22] Because of the ready availability and stability of (**1**) this method has superseded earlier approaches using Grignard reagents and organostannanes. If the Suzuki reaction is performed in the presence of CO, diaryl ketones, biaryls, or arylcarboxylic acids may be obtained, depending on the conditions.[23]

(11)

Heck reactions of (**1**) with styrene (eq 12) and ***Acrylic Acid*** have been reported.[24]

(12)

Hydroalumination.

The hydroalumination of alkenes with ***Dichloroalane*** is catalyzed by (**1**) (eq 13).[3]

(13)

Asymmetric Synthesis.

Homologation of the boronate ester of (+)-pinanediol with ***Dichloromethyllithium***, followed by alkylation with ***Methylmagnesium Bromide***, proceeds with 97% diastereoselectivity (eq 14).[25] The sequence was repeated and the product oxidized with $NaBO_3$ to give (2*S*,3*S*)-3-phenyl-2-butanol in high optical purity. Treatment of several chiral boronate esters with ***Potassium Hydride*** gave chiral dialkoxymonoalkylborohydrides, which were used for the asymmetric reduction of ketones with moderate enantioselectivity.[26]

Diimide[1]

HN=NH

(*cis*)

[15626-42-3] · H_2N_2 · Diimide · (MW 30.03) (*trans*)

[15626-43-4]

(mild, noncatalytic reducing agent for the *syn* reduction of C=C and C&tbond;C bonds; does not react with O-O, N-O, or other easily reduced single bonds, or with C=O, C=N, or aromatic π-bonds)

Alternate Name: diazene.

Form Supplied in: generated in situ.

Preparative Methods: the most widely used methods involve the Cu^I-catalyzed ***Oxygen*** or ***Hydrogen Peroxide*** oxidation of hydrazine, and the acid-catalyzed decarboxylation of ***Potassium Azodicarboxylate***.

Introduction.

The reduction of C-C π-bonds in the presence of various N-N-containing compounds ultimately capable of producing diimide dates back to 1905;[2] however, it was not until the early 1960s that the role of *cis*-diimide (diazene) was recognized.[3-6] The results of stereochemical studies[7] and theoretical calculations[8] indicate that *cis*-diimide is the active reducing agent, and that the reduction occurs via a concerted, symmetry allowed transfer of the hydrogen atoms of *cis*-diimide to the C=C or C&tbond;C bond, as illustrated in eq 1. In competition with the reduction of C-C π-systems, diimide undergoes a more facile disproportionation reaction to produce nitrogen and hydrazine[9] which requires the use of considerable excesses of the diimide precursor.

An important feature of the reduction of C-C π-systems is that many highly reactive functional groups can be present which would not survive under other chemical reducing or catalytic hydrogenation conditions. Such functional groups include allylic and benzylic derivatives, halides, sulfur-containing systems, O-O and N-O containing systems, and complex

bioorganic molecules. Examples of the latter systems are shown in eqs 2 and 3.[10,11]

(2)

(3)

Relative Reactivity Toward Reduction by Diimide.

Carbon-carbon triple bonds, in general, are more reactive than double bonds toward reduction by diimide.[7,12] The relative reactivity of double bonds toward reduction decreases as the degree of alkyl substitution on the double bond increases,[12] and increases with increasing strain (see Table 1).[12] 1,3-Dienes are more reactive than monoenes, with the degree of substitution affecting the relative reactivity as observed with alkenes.[13] Examples of intramolecular selectivity are illustrated in eqs 4-6.[14-16]

Table 1 Relative Reactivities of Substituted Alkenes and 1,3-Dienes Toward Reduction by Diimide

Substrate	k_{rel}[12]
Cyclohexene	1.00
1-Pentene	20.2
trans-2-Pentene	2.59
cis-2-Pentene	2.65

(4)

(5)

(6)

Electronegatively substituted double bonds (e.g. α,β-unsaturated carboxylic acids) are more reactive toward reduction by diimide than are alkyl- or electron donating-substituted π-systems. (The attempted reduction of α,β-unsaturated aldehydes,

ketones, and esters generally results in the formation of products deriving from the reaction of the carbonyl compound with hydrazine, which is formed by the disproportionation of the diimide.)

Facial Selectivity of Reduction.

The results of experimental and theoretical studies suggest that the transition state for diimide reduction lies very early along the reaction coordinate with the *cis*-diimide approaching the less sterically hindered face of the π-system (eq 6).

Electronic factors also play a role in determining the chemoselectivity of reduction by diimide; this is illustrated in eq 7, in which *anti-exo* reduction occurs preferentially to *syn-exo* reduction.[17]

(7)

$R = OH, O_2CMe, OCMe_3$

Methods of Generation of Diimide.

Numerous methods have been discovered for the generation of diimide.[1a] Of these, only two processes find wide use: firstly, the air (oxygen) or ***Hydrogen Peroxide*** oxidation of hydrazine in the presence of copper(I) and a catalytic amount of a carboxylic acid (eq 8) (the carboxylic acid apparently being required to catalyze the isomerization of *trans*- to *cis*-diimide); secondly, the reaction of ***Potassium Azodicarboxylate*** with a carboxylic acid in aprotic solvents (eq 9).[18] The azodicarboxylate salt is formed by the reaction of ***Potassium Hydroxide*** with azodicarboxamide (commercially available). The latter procedure is especially useful for the position-specific and stereochemically controlled incorporation of deuterium or tritium into organic systems. An example is shown in eq 10, illustrating both the facial and stereoselectivity of the reaction.[19]

$$N_2H_4 \xrightarrow[Cu^I,\ RCO_2H]{O_2 \text{ or } H_2O_2} HN{=}NH \qquad (8)$$

HN=NH (9)

Diiminosuccinonitrile[1]

[28321-79-1] · $C_4H_2N_4$ · Diiminosuccinonitrile · (MW 106.09)

(adds to electron-rich alkenes to give dicyanotetrahydropyrazines;[2] reacts with ketones to yield dicyanoisoimidazoles[3])

Alternate Name: DISN.

Physical Data: mp 165-166 °C (dec); sublimes at 100 °C/1 mmHg; heat of combustion 5.09 kcal g^{-1};[4] dipole moment 1.59 D.

Solubility: (25 °C, g 100 mL^{-1}): acetone (21), THF (21), MeCN (18), DMAc (5.9), ether (1.5); insol benzene and hydrocarbons.

Preparative Method: a solution of dry ***Triethylamine*** (1.5 mL) in CH_2Cl_2 (15 mL) is added dropwise over 45 min to a solution of ***Hydrogen Cyanide*** (20 g, 0.74 mol) and cyanogen (17.4 g, 0.34 mol) in CH_2Cl_2 (120 mL) at -45 to -40 °C; the reaction is mildly exothermic and DISN precipitates as the triethylamine is added; after 30 min the product is collected while still cold and washed with CH_2Cl_2 and ether to give 33.6 g (95%) of DISN as a fine tan powder of sufficient purity for synthetic use.[4]

Purification: dissolve in hot ethyl acetate with Darco treatment, evaporate the solution to a slush, suction filter, and wash the solid with ether and dry in inert atmosphere; an air-stable white crystalline solid is obtained.

Handling, Storage, and Precautions: oral toxicity is ALD 90 mg/kg in rat; causes severe irritation on contact with rabbit eyes and permanent damage is prevented only by immediate flushing with water; causes mild skin and nose irritation; use only in a fume hood or in very well-ventilated areas with adequate protection (it produces HCN when wet or in contact with hydroxylic solvents); slowly discolors on exposure to light, and decomposes in water ($t_{1/2}$ about 2 weeks at ambient conditions).

Heterocycle Synthesis.

DISN is similar in reactivity to benzoyl cyanide in reactions with alcohols and aromatic amines. Dimethyloxaldiimidate is formed when DISN is treated with methanol under acid or base catalysis (eq 1).[3] Depending on the conditions, from neutral, to an equivalent amount of acid, to strong acidic medium, the reaction between DISN and *o*-phenylenediamine can afford three different products (eq 2).[3] DISN also has the same reactivity toward ***Diaminomaleonitrile*** (eq 3), although only one example is shown here.[5]

(1)

(2)

(3)

Oxalyl cyanide can be isolated from controlled hydrolysis of DISN (eq 4).[3]

(4)

DISN undergoes [4 + 2] cycloadditions with electron-rich alkenes (eq 5).[2a]

(5)

2,2-Dimethyl-4,5-dicyanoisoimidazole is formed in high yield by the addition of DISN to ***2,2-Dimethoxypropane*** under acidic conditions (eq 6).[3]

(6)

DISN reacts with ***Sulfur Dichloride*** or seleninyl chloride in methylene chloride to give dicyano-1,2,5-thiadiazole[3] or dicyano-1,2,5-selenadiazole (eqs 7 and 8).[6]

(7)

(8)

Trifluoroacetic Anhydride reacts with DISN to yield 4,5-dicyano-2-hydroxy-2-trifluoromethyl-2*H*-imidazole (eq 9).[7]

1,3-Diiodo-5,5-dimethylhydantoin

[2232-12-4] · $C_5H_6I_2N_2O_2$ · 1,3-Diiodo-5,5-dimethylhydantoin · (MW 379.92)

(electrophilic iodination)

Alternate Name: DIH.

Solubility: sol acetone; slightly sol CH_2Cl_2.

Preparative Method: by reaction of ***Iodine Monochloride*** (0.11 mol) with 5,5-dimethylhydantoin (0.05 mol) and ***Sodium Hydroxide*** (0.1 mol) in ice-water at 0 °C;[1] the product is used without further purification.

Handling, Storage, and Precautions: store under nitrogen at 0 °C and protect from light and moisture to avoid decomposition; irritating solid; avoid inhalation of the powder.

DIH has been used for the same electrophilic iodination of many organic compounds for which ***N-Iodosuccinimide*** is used. The advantages of DIH include its high iodine content, satisfactory stability, and its economical preparation (which does not require expensive silver salts), whereas its disadvantages include its limited solubility. In the few reported examples, DIH has been found to achieve the electrophilic iodination of organic compounds with results comparable to or better than those obtained using *N*-iodosuccinimide. These applications have included the electrophilic iodination of electron-rich arenes using DIH in acetone and the preparation of α-iodo ketones by reaction of enol acetates with DIH in dioxane at 90 °C.[1] In addition, DIH has been used for the preparation of 1,2-dioxetanes by iodohydroperoxylation of alkenes and for the cleavage of dithiane protecting groups.[2,3]

Diiododimethylsilane

Me_2SiI_2

[15576-81-5] · $C_2H_6I_2Si$ · Diiododimethylsilane · (MW 311.96)

(reducing agent; preparation of *N*-(iododimethylsilyl)trialkylphosphinimines, bis(2,2´-bipyridine) complexes of silicon, di-μ-iodo-bis(tetracarbonyltungsten); chemistry of 7-silanorbornadienes and dimethylsilylene)

Alternate Name: dimethylsilyl diiodide.

Physical Data: bp 170 °C; *d* 2.203 g cm^{-3}.

Solubility: sol most organic solvents.

Preparative Method: 8.2 g (21 mmol) of ***Boron Triiodide*** and 7.4 g (57 mmol) of ***Dichlorodimethylsilane*** are refluxed for 3 days at 120 °C; the crude product is then isolated by adding ***Copper*** powder until the color disappears followed by fractional distillation in a spinning band column apparatus (65% yield).[1]

Handling, Storage, and Precautions: reacts vigorously with water, but without spattering; highly toxic, flammable liquid; use in a fume hood.

Reduction of α-Aryl Alkanols.

This reaction can be accomplished in CH_2Cl_2 at rt with 1 equiv of diiododimethylsilane (eq 1).[2]

Ar	R^1	R^2	Yield (%)
Ph	Ph	Ph	94
Ph	Ph	Me	100
Ph	Me	Me	50
Ph	Ph	H	100
Ph	PhCO	H	45

72

79

The reaction is far milder and more effective than comparative reductions of alcohols with ***Aluminum Chloride***-palladium and ***Lithium-Ammonia***. This method also permits reduction in the presence of other functional groups. A neighboring β-keto group, for example, is not reduced by diiododimethylsilane. The reaction is rapid, and reduction occurs best with secondary and tertiary α-aryl alkanols to give the corresponding alkanes in good yields.

Reductive Condensation of Ketones.

Diiododimethylsilane reacts with various ketones in the presence of ***Zinc*** to give the corresponding reductive condensation products in good yield (eq 2).[3]

Reductive condensation products have been obtained from this reaction for *t*-BuCOMe, MeCOMe, EtCOEt, and cyclohexanone. The reaction of Me_2SiI_2 with Ph_2CO in the presence of zinc gave benzopinacolone.

Preparation of *N*-(Iododimethylsilyl)trialkylphosphinimines.

N-(Iododimethylsilyl)trialkylphosphinimines are accessible by transsilylation of the corresponding *N*-trimethylsilyl compounds or by the reaction of bis(trialkylphosphinimino)dimethylsilane with diiododimethylsilane (eq 3).[4]

In a subsequent reaction, most of the compounds undergo dimerization to form dicationic four-membered systems (eq 4). Only compounds with bulky groups at the phosphorus atom are stable as monomers.

Preparation of Bis(2,2´-bipyridine) Complexes of Silicon.

A bis(2,2´-bipyridine) complex of silicon was synthesized by the direct reaction of 2,2´-bipyridine with diiododimethylsilane in chloroform (eq 5).[5] An ionic compound is formed. In solution it contains the *cis*-octahedral $[SiMe_2(bipy)]^{2+}$ cation (**1**).

(1)

Preparation of Di-μ-iodobis(tetracarbonyltungsten).

Hexacarbonyltungsten reacts with diiododimethylsilane to give $[(CO)_4WI]_2$ (eq 6).[6] The dinuclear complex (**2**) is diamagnetic. The iodine atoms serve as bridging ligands between metal atoms.

$$W(CO)_6 \xrightarrow[h\nu]{Me_2SiI_2} [(CO)_4WI]_2 \qquad (6)$$

(2)

Chemistry of 7-Silanorbornadienes and Dimethylsilylene, Me_2Si.

7-Silanorbornadienes react rapidly with halogens at -20 °C to +20 °C to yield Me_2SiX_2 (X = Cl, Br, I) and the naphthalene or benzene derivatives (eq 7).[7]

R^1	R^2	R^3
H	H	benzo
H	Ph	cycloocteno
Ph	Me	cycloocteno
Ph	Ph	benzo

Halogen can be abstracted from the C-Hal bond in benzyl iodide (or bromide), leading to Me_2SiX_2 and toluene (eq 8).[7]

$$2\ PhCH_2X \xrightarrow[X = Br,\ I]{Me_2Si} 2\ PhMe + Me_2SiX_2 \qquad (8)$$

High-Purity Alkali Metal Halides.

Alkali metal halides are refined by reaction in the gas phase with alkyl-, aryl-, or alkoxyhalosilanes.[8] This brings about an exchange between the Si-bound halogen and the anion of the contaminant, while the C-containing radical has a reducing effect. Diiododimethylsilane is used to purify ***Sodium Iodide*** in this manner.

Related Reagents.

Diiodosilane.

1,1-Diiodoethane

$MeCHI_2$

[594-02-5] · $C_2H_4I_2$ · 1,1-Diiodoethane · (MW 281.86)

(reagent for methylcyclopropanation of alkenes and ethylidenation of carbonyl compounds)

Alternate Name: ethylidene iodide.

Physical Data: bp 179-180 °C; *d* 2.84 g cm^{-3}.

Solubility: sol most organic solvents.

Preparative Methods: mix 39.6 g (0.40 mol) of 1,1-dichloroethane, 187 g (1.2 mol) of ethyl iodide, and 2.0 g of ***Aluminum Chloride*** and heat on a steam bath for 3 h; wash the mixture with H_2O and then $NaHSO_3$, and dry over $MgSO_4$; distillation provides 67.3 g (60%) of the product boiling at 75-76 °C/25 mmHg.[1] An alternative procedure utilizes the reaction of ***Iodine***, ***Triethylamine***, and the hydrazone of ***Acetaldehyde***: from 1 mol of acetaldehyde, 95 g (34% from acetaldehyde) of 1,1-diiodoethane can be isolated; this procedure is a little more involved, but provides a viable alternative if 1,1-dichloroethane is not available.[2]

Handling, Storage, and Precautions: corrosive and irritant; emits toxic fumes if heated to decomposition or comes in contact with acids. Use in a fume hood; store over copper powder and protect from light.

Methylcyclopropanation of Alkenes.

Various reagents will react with 1,1-diiodoethane to effect the methylcyclopropanation of alkenes. These reagents include ***Diethylzinc***,[3] ***Ethylzinc Iodide***,[4] ***Copper*** powder,[5] ***Zinc/Copper Couple***,[4] ***Zinc/Silver Couple***,[4] trialkylaluminum reagents,[6] and ***Samarium(0)***.[7] For simple alkenes, the diethylzinc (eq 1) and trialkylaluminum methods (eq 2) appear to be the ones of choice. The various zinc couples and copper powder provided lower yields of methylcyclopropane products. For cyclohexene (eq 1), diethylzinc afforded predominantly the *endo*-isomer.[3] The use of copper powder gave the *exo*-isomer as the major product.[5]

(1)

(2)

Reactive alkenes, such as enol ethers, can be methylcyclopropanated effectively using Zn/Cu couple. Trimethylsilyloxycyclohexene (eq 3) produces a 3.1:1.0 mixture of isomers, with the *exo*-isomer being the major product.[8] The reaction of 1-methoxy-1,4-cyclohexadiene was regioselective as well as stereoselective, yielding exclusively the *endo*-isomer (eq 4).[9] A cyclohexenediol bis-silyl ether has been methylcyclopropanated using either diethylzinc or Zn/Cu couple.[10] A ketene acetal was cyclopropanated using the diethylzinc procedure.[11]

(3)

(4)

Allylic alcohols may be methylcyclopropanated using a number of different conditions. In Table 1 are shown the results for some cyclic allylic alcohols under different reaction conditions.[3b,4a,4b,7] For 2-cyclopenten-1-ol and 2-cyclohexen-1-ol, the yields as well as the ratios of the isomeric products formed were found to be very similar for different zinc reagents. The samarium-promoted reaction for cyclohexenol provided the cyclopropane with a higher *exo*:*endo* diastereoselectivity (83:17).[7]

Table 1 Comparison of Methylcyclopropanations of Cyclic Allylic Alcohols with 1,1-Diiodoethane

(1) **(2)** **(3)** **(4)**

n	Reagent	Yield (%)	Ratio of products (**1**:**2**:**3**:**4**)
5	Zn(Cu) (30 mesh)	62[4a]	78:22:0:0
	Zn(Ag) (30 mesh)	78[4a]	76:24:0:0
	Zn-CuCl (dust)	71[4a]	76:24:0:0
	EtZnI	67[4a]	73:27:0:0
	Et_2Zn	60[4b]	76:24:0:0
6	Zn-CuCl	84[4b]	72:28:0:0
	Et_2Zn	60[3b]	63:37:0:0
	Sm(Hg)	100[7]	83:17:0:0
7	Zn-CuCl	74[4b]	59:19:20:2
	Et_2Zn	72[4b]	49:20:21:10
8	Zn-CuCl	88[4b]	0:0:72:28
	Et_2Zn	76[3b]	0:0:71:29

Substrate: 
The allylic alcohols derived from the bislactim ether of cyclo(-L-Val-Gly-) have been methylcyclopropanated (eq 5) using the diethylzinc method in good yields with good diastereoselectivities.[12]

(5)

(*E*)-Ethylidenation of Aldehydes.

The reduction of 1,1-diiodoethane by ***Chromium(II) Chloride*** produces a *gem*-dichromium reagent which will react with aldehydes, selectively affording (*E*)-alkenes in excellent yield. The reaction conditions also work well for enolizable ketones. The reaction of α-tetralone produced the alkene in 85% yield as a 16:84 mixture of (*E*):(*Z*) isomers, respectively.[13] The lactol (eq 6) on reaction with $CrCl_2$ and 1,1-diiodoethane delivered the alkene with >95:5 (*E*):(*Z*) selectivity.[14] The corresponding reactions with the ethylidene triphenyl- or triethylphosphorane were less selective.

(6)

The α-alkoxyaldehyde (eq 7) was ethylidenated in excellent yield under these conditions. Again, the reaction was highly (*E*) selective (>99%); more importantly, no epimerization was observed.[15]

A deuterated vinylcyclobutane (eq 8) was synthesized using 1,1-diiodoethane-1-*d*. The (*E*):(*Z*) ratio in this case was 19.5:1. The deuterated reagent was prepared using the hydrazone method. The reaction was accompanied by a small amount of epimerization (1.7%).[16]

Miscellaneous.

1,1-Diiodoethane has been used to prepare ethylidene ditriflate by reaction with ***Silver(I) Trifluoromethanesulfonate***.[17] It has also been utilized to prepare 1,1-bis(bistrifluoromethyl)phosphano)ethane[18] and octacarbonyl (μ-ethylidene)diiron.[19]

Related Reagents.

1,2-Dibromoethane; ***Diiodomethane***; ***1,3-Diiodopropane***.

Diiodomethane

CH_2I_2

[75-11-6] · CH_2I_2 · Diiodomethane · (MW 267.84)

(precursor to methylene transfer reagents: in combination with various metals or alkyl metals, generates carbenoids which cyclopropanate alkenes[1] or methylenate carbonyls;[2] precursor to ICH_2Met and I_2CHMet nucleophiles;[3] participates in radical-mediated couplings[4])

Alternate Name: methylene iodide.

Physical Data: mp 6 °C; bp 181 °C; *d* 3.325 g cm^{-3}.

Solubility: slightly sol H_2O; sol Et_2O, $CHCl_3$, EtOH, hexane, etc.

Form Supplied in: pale yellow liquid; crystallizes as pale yellow needles or plates; typically stabilized with copper powder.

Purification: fractional distillation from CaH_2 generally provides reagent of sufficient purity for typical uses.

Handling, Storage, and Precautions: store over copper powder to inhibit radical-induced decomposition; protect from light; incompatible with many metals (Al, Mg, Na, etc.) and strong bases; mildly corrosive; toxicity presumed to be on par with CH_2Cl_2, i.e. moderately toxic, mutagenic; use in a fume hood.

Methylenations.

A wide variety of carbonyl methylenating reagents utilize CH_2I_2 as the carbon source. Several of these have proven to be useful alternatives to the Wittig reaction.[5] Cainelli and co-workers found that treatment of CH_2I_2 with 2 equiv of ***Magnesium Amalgam*** in the presence of ketones affords alkenes in good yields (eq 1).[6] The intermediate in these reactions is presumed to be $CH_2(MgI)_2$, and the reaction works well with ketones and aldehydes of variable structure. This reagent is particularly useful for the formation of dideuterated terminal alkenes (using CD_2I_2, eq 2),[7] since methylenation using deuterated Wittig reagents is often accompanied by various degrees of scrambling of the deuterium label.[8]

Chromium(II) also mediates the alkenation of aldehydes by geminal diiodides (eq 3).[9] This transformation presumably proceeds via a 1,1-bis[chromium(III)] species, and works best with substituted diiodides. Generally, high levels of (*E*) selectivity are obtained.

Certain methylenating reagents utilize CH_2I_2 in combination with 2 equiv of ***Zinc*** and a Lewis acid.[2,10,11] A Lewis acid is not essential for this transformation,[11] but greatly accelerates the reaction and improves selectivity and yields. The most commonly used Lewis acids include ***Trimethylaluminum***,[2,10a] ***Titanium Tetraisopropoxide***,[10a] ***Titanium(IV) Chloride***,[10b,10c] ***Dichlorobis(cyclopentadienyl)zirconium***,[10d] and ***Dichlorobis(cyclopentadienyl)titanium***.[10e] Of a variety of Lewis acids and dihalomethanes examined, Takai and co-workers found that $CH_2I_2/Zn/Me_3Al$ and $CH_2Br_2/Zn/TiCl_4$ afforded the best results.[10f] Substrates for these reactions can vary from simple ketones such as acetophenone (eq 4)[2] to complex steroidal ketones.[10b] Chemoselective methylenation of an aldehyde in the presence of a ketone can also be achieved (eq 5).[10a] Other unsaturated functionalities also react with these reagents. For example, the Eisch reagent[10e] $[CH_2(ZnI)_2/Cp_2TiCl_2]$ has been shown to react with benzonitrile to afford, after hydrolysis, acetophenone (eq 6).

(5)

(6)

Cyclopropanations.

A variety of metallic species mediate the cyclopropanation of alkenes in the presence of CH_2I_2 (vide infra). A much simpler procedure is the photolysis of CH_2I_2 in the presence of alkenes.[12] Although this method was initially reported to give a mixture of products in poor yields,[12a] the addition of iodine scavengers and acid scavengers to the reaction medium results in clean, high-yielding reactions.[12b-d] Sterically hindered alkanes are cyclopropanated much more readily than with metal-based reagents (eq 7), and double bond geometry is generally retained (eq 8). Remarkably, products arising from C-H bond insertion are not observed, ruling out the formation of free carbene in these reactions. The iodomethyl cation (ICH_2^+) has been proposed as an intermediate in these reactions.[12c,12d]

(7)

(8)

$R^1 = Et, R^2 = H$; 75%
$R^1 = H, R^2 = Et$; 76%

Perhaps the most common use of CH_2I_2 in organic synthesis is in metal-mediated cyclopropanations. Foremost among these are zinc-mediated cyclopropanations (Simmons-Smith reaction).[1,13] This is a widely utilized and versatile transformation. Treatment of CH_2I_2 and an alkene with ***Zinc/Copper Couple*** in refluxing Et_2O affords the corresponding cyclopropane, generally in good yield (eq 9).[14] The source of the zinc is crucial to the success of the

reaction, and several reliable protocols exist.[15] The use of ***Diethylzinc*** place of the Zn/Cu couple generates a similar reagent;[16] this modification has several advantages, including the option of using noncoordinating solvents. In many cases, the use of ***Chloroiodomethane***/Et_2Zn in place of CH_2I_2/Et_2Zn is desirable, as the former is more reactive.[17] Regardless of the method of reagent generation, the stereochemical course of the reaction is strongly influenced by proximal oxygen substituents (eq 10), and several effective chiral auxiliaries have been developed.[18]

(9)

(10)

Similarly, treatment of CH_2I_2 with a trialkylaluminum reagent (e.g. ***Triisobutylaluminum***) in the presence of alkenes also affords cyclopropanes.[19] This reagent system exhibits a reactivity pattern complementary to the zinc- and samarium-based systems, reacting preferentially with isolated alkenes rather than with allylic alcohols (eq 11).[19a]

(11)

A very versatile reagent for the cyclopropanation of alkenes is derived from CH_2I_2 and Sm(Hg) or ***Samarium(II) Iodide***.[20] These reagents react well with allylic alcohols (eq 12)[20a,b] and enolates (eq 13),[20d] and are subject to the same hydroxy-directing effects[20a,b,f,g] as the zinc-based reagents (vide supra). In fact, an oxygen substituent is required for cyclopropanation to occur.[20b] A diastereoselective cyclopropanation utilizing a chiral acetal as a chiral auxiliary has also recently been reported (eq 14).[20g] The substitution of $ClCH_2I$ for CH_2I_2 in these reactions often results in higher yields.[20b] Interestingly, a comparison of the response of the CH_2I_2/Sm(Hg) and CH_2I_2/SmI_2 reagents towards various allylic alcohols showed little or no difference in either reactivity, chemoselectivity, or stereoselectivity.[20b]

(12)

(13)

(14)

Nucleophilic Additions of ICH_2.

Halomethyllithium reagents are generally unstable except at very low temperatures (<-90 °C),[21] but the use of additives such as ***Lithium Bromide*** results in greater stability, particularly for ***Chloromethyllithium*** and ***Bromomethyllithium***.[21c,22] The utility of ICH_2Li is still limited, however.[23] Fortunately, an alternative method for the generation of an iodomethyl nucleophile has been developed which utilizes ***Samarium(0)*** as the metal.[3,20c] Aldehydes, ketones, and enones all participate well in this reaction, and yields range from moderate to excellent (eq 15). In the illustrated example, the alkene is not cyclopropanated, consistent with the observation that tertiary allylic alcohols react sluggishly with samarium carbenoids.[20b]

(15)

The replacement of an allylic alcohol oxygen by CH_2I has also been achieved by the use of aluminum reagents.[24] The combination of ***Triethylaluminum***, Et_2AlCl, and Et_2AlOEt mediates this reaction (eq 16).

(16)

Nucleophilic Additions of I_2CH.

Deprotonation of CH_2I_2 by base affords I_2CHMet derivatives which are more stable than the corresponding ICH_2Met species and react well with a variety of electrophiles.[25] Among the bases used successfully are Cy_2NLi,[25a] ***Sodium Hexamethyldisilazide*** (NaHMDS),[25b] ***Lithium Hexamethyldisilazide*** (LiHMDS),[25b] and ***Lithium Diisopropylamide*** (LDA).[25c] I_2CHLi reacts well with aldehydes (eq 17),[25a] and also with silacyclobutanes, affording 2-iodosilacyclopentanes after ring enlargement of the intermediate five-coordinate siliconate (eq 18).[25c] I_2CHNa has been shown to react with electrophiles such as ***Chlorotrimethylsilane***, ***Ethyl Iodide***, and ***Allyl Iodide***.[25b]

(17)

(18)

A convenient synthesis of vinyl iodides using I_2CHLi has been reported by Julia and co-workers.[25b] Treatment of CH_2I_2 with LiHMDS followed by the addition of a lithiated sulfone affords vinyl iodides after aqueous workup. The selectivity is generally low, however (eq 19).

(19)

Radical Additions Utilizing CH_2I_2.

The radical addition of the ICH_2 fragment to α,β-unsaturated ketones mediated by ***Triethylborane*** provides a route to γ-iodo ketones (eq 20).[4] The intermediate boron enolates can be either hydrolyzed or alkylated in some cases.[4] Vinylsilacyclobutanes are also alkylated by the putative ICH_2 radical, affording highly functionalized silylcyclobutane derivatives (eq 21).[26]

(20)

(21)

Alkylation Reactions.

CH_2I_2 has seen limited use as an alkylating reagent, since heterodihalomethanes such as $ClCH_2I$ and $ClCH_2Br$ are preferred for these reactions.[27,28] CH_2I_2 has been used for alkylative cyclizations, however. A recent interesting application is the formation of 2-imino-1,3-dithiazetidines from thioureas (eq 22).[29a] Mixtures of isomers are obtained unless one of the urea nitrogen atoms is deactivated as a sulfonamide, amide, or carbamate. In addition, diamines are known to react with CH_2I_2: slow addition of the diamine to a solution of CH_2I_2 is necessary to obtain good yields (eq 23).[29b]

(22)

In a mechanistically distinct but related example, dithianes are produced by the Pt-catalyzed coupling of CH_2I_2 with thiols (eq 24).[30]

Other Uses.

Several other transformations also utilize CH_2I_2. For example, heating CH_2I_2 with 2 equiv of ***Tin(II) Bromide*** and a catalytic amount of ***Triethylamine*** affords a di-tin compound[31a] which can be exhaustively methylated to afford bis(trimethylstannyl)methane (eq 25).[31b] In addition, a convenient procedure for the in situ preparation of the valuable reagent SmI_2 involves simply treating Sm powder with CH_2I_2 in THF.[32]

Related Reagents.

Chloroiodomethane; ***Dibromomethane***; ***1,1-Diiodoethane***; ***Diiodomethane-Zinc-Titanium(IV) Chloride***; ***Iodomethylzinc Iodide***.

Diiodomethane-Zinc-Titanium(IV) Chloride

CH_2I_2-Zn-$TiCl_4$

(CH_2I_2)

[75-11-6] · CH_2I_2 · Diiodomethane-Zinc-Titanium(IV) Chloride · (MW 267.84) (Zn)

[7440-66-6] · Zn · Diiodomethane-Zinc-Titanium(IV) Chloride · (MW 65.37) ($TiCl_4$)

[7550-45-0] · Cl_4Ti · Diiodomethane-Zinc-Titanium(IV) Chloride · (MW 189.71) (Ti(O-*i*-Pr)$_4$)

[546-68-9] · $C_{12}H_{28}O_4Ti$ · Diiodomethane-Zinc-Titanium Tetraisopropoxide · (MW 284.26)

(reagent combination for methylenation of aldehydes and ketones)

Physical Data: CH_2I_2: mp 6 °C; bp 181 °C; *d* 3.325 g cm^{-3}. Zn: mp 419.5 °C; *d* 7.140 g cm^{-3}. $TiCl_4$: mp -24 °C; bp 136.4 °C; *d* 1.730 g cm^{-3}. Ti(O-*i*-Pr)$_4$: mp 20 °C; bp 58 °C/1 mmHg; *d* 0.955 g cm^{-3}.

Solubility: sol THF.

Preparative Methods: prepared in situ.

Handling, Storage, and Precautions: CH_2I_2 is corrosive and is light sensitive; it is usually stabilized with a small amount of copper. $TiCl_4$ is highly toxic and extremely moisture sensitive. Ti(O-*i*-Pr)$_4$ is an irritant and is flammable. Zn is a moisture-sensitive, flammable solid.

General Discussion.

The reagent prepared by the combination of ***Diiodomethane***, ***Zinc***, and ***Titanium(IV) Chloride*** is very effective at converting enolizable aldehydes and ketones into their methylene derivatives (eq 1).[1] The reaction many times provides improved yields over the conventional ***Methylenetriphenylphosphorane***. The β-acetoxy ketone was transformed into the alkene (eq 1) in 73% yield with minimal side reactions. The standard Wittig conditions produced only a 39% yield of the desired methylenated product along with a number of other side products derived from elimination reactions.[2]

(1)

In the case of α-tetralone, the CH_2I_2 reagent combination was superior to the ***Dibromomethane-Zinc-Titanium(IV) Chloride*** reagent. The former conditions deliver the product in 88% yield, while the latter set produces only an 11% yield of alkene (eq 2).[2]

(2)

By the appropriate choice of reaction conditions, chemoselective methylenations can be performed. One can chemoselectively convert an aldehyde into the methylene derivative in the presence of a ketone (eq 3). This requires that the reagent's reactivity be moderated slightly by using ***Titanium Tetraisopropoxide*** in place of $TiCl_4$. The reagent prepared from $TiCl_4$ is too reactive to offer any appreciable levels of selectivity. Alternatively, a ketone may be methylenated selectively in the presence of an aldehyde if the keto-aldehyde is first pretreated with ***Titanium Tetrakis(diethylamide)*** (eq 4). The ketones still require the $TiCl_4$ prepared reagent.[3]

(3)

(4)

A number of optically active α-amino ketones have been converted to allylic amines using this reagent (eq 5). The yields were moderate and the enantiomeric excesses generally were very high (>98%). The one exception was the α-phenylglycine-derived ketone which provided the alkene in only 48% ee.[4]

Diiodo(methyl)bis(triphenylphosphine)rhodium(III)[1]

[47829-28-7] · $C_{37}H_{33}I_2P_2Rh$ · Diiodo(methyl)bis(triphenylphosphine)rhodium(III) · (MW 896.35)

(used in cross-coupling of organomercurials with alkyl halides[2])

Physical Data: mp 170 °C (dec); ^{1}H NMR (CD_2Cl_2) δ 2.8 (dt, *J* = 2.9, 5.3 Hz, C*H*$_3$), 7.39 (m, $H_{m,p}$ of Ph), 7.63 (m, H_o of Ph); λ_{max} (log ε in CH_2Cl_2) 250 (sh), 340 (3.71), 500 (sh), 610 (2.31); *d* 1.67 g cm^{-3}.

Solubility: sparingly sol benzene and chloroform; sol CH_2Cl_2 and nitromethane; insol acetone or petroleum.

Form Supplied in: dark green crystalline solid.

Preparative Methods: ***Chlorotris(triphenylphosphine)rhodium(I)*** (1.0 g, 1.08 mmol) is allowed to stir in ***Iodomethane*** (20 mL) for 1 h; excess solvent is removed in vacuo and the resulting mass extracted with acetone; recrystallization from benzene affords green crystals of $MeRhI_2(PPh_3)_2.C_6H_6$;[1] an alternate method of preparing uncomplexed $MeRhI_2(PPh_3)_2$ involves addition of iodomethane in dichloromethane to $(Ph_3P)_3Rh^+HC(SO_2CF_3)_2^-$.[2]

Handling, Storage, and Precautions: the dry solid is moderately air-stable but rapidly air-oxidizes in solution.

Methylation of Organomercurials.[3]

The stoichiometric cross-coupling of organomercurials with alkyl halides proceeds in moderate to excellent yields using $MeRhI_2(PPh_3)_2$. Optimal conditions for cross-coupling alkenylmercurials include addition of excess ***Lithium Chloride***, using HMPA as solvent, and running the reaction at 70 °C for 24 h. Indeed, addition of $MeRhI_2(PPh_3)_2$ to styrylmercury(II) chloride under these conditions affords propenylbenzene in excellent yield (eq 1). Only small amounts of product formed, however, in reactions where the rhodium complex was prepared in situ with subsequent attempts at cross-coupling.

(1)

Dialkynylmercury compounds transmetalate with $MeRhI_2(PPh_3)_2$ to give products with complete methylation of both organic moieties

(eq 2). Attempted methylation of *n*-decylmercury(II) chloride gives only *n*-decane, 1-decene, and other isomeric decenes. Methylation of benzylmercury(II) chloride and α-chloromercurioacetophenone has also failed.

(2)

Arylmercurials react with $MeRhI_2(PPh_3)_2$ in the presence of excess iodomethane to give the corresponding methyl-substituted arenes (eqs 3 and 4). This reaction is general for arylmercurials containing electron donating and withdrawing groups, as well as heterocyclic organomercurial derivatives.

(3)

(4)

Unfortunately, attempts to catalyze the methylation of alkenylmercurials using $MeRhI_2(PPh_3)_2$ afford significant amounts of dimerized product.[4] Better yields of cross-coupling products are obtained in catalyzed reactions of dialkynylmercurials (ca. 60%). This catalyst system is also effective for the cross-coupling of arylmercurials with alkenyl halides.

1,3-Diiodopropane

[627-31-6] · $C_3H_6I_2$ · 1,3-Diiodopropane · (MW 295.89)

(electrophilic trimethylene synthon)

Physical Data: bp 111-113 °C/31 mmHg; *d* 2.576 g cm^{-3}.

Form Supplied in: light brown liquid stabilized with copper.

Handling, Storage, and Precautions: light sensitive; must be stored in the dark. Use in a fume hood.

Ring Forming Reactions.

Stepwise ring closure using 1,3-diiodopropane as an electrophile is an important method for the construction of four- to six-membered rings. The ketimine (**1**) is converted into (**2**) (a pivotal intermediate for preparation of clinically useful antihypertensive eburnane alkaloids) by treatment with 1,3-diiodopropane in the presence of ***Diisopropylethylamine*** in acetonitrile under an inert atmosphere. The presence of oxygen leads to the formation of the corresponding 1-hydroxy derivative, presumably via a radical chain oxidation process initiated by iodine generated by the thermal decomposition of 1,3-diiodopropane (eq 1).[1]

A chiral α-sulfinyl ketimine anion undergoes annulation with 1,3-diiodopropane to give a cyclic β-sulfinyl enamine which is a precursor for various indolizidine alkaloids (eq 2).[2]

The α,α´-dianion generated by treatment of (*p*-tolylsulfinyl)acetone with 2.2 equiv of ***Lithium Diisopropylamide*** (LDA) reacts with 1,3-diiodopropane to afford the α´-substituted product (**3**), which is intramolecularly cyclized with LDA to give 2-(p-tolylsulfinyl)cyclohexanone (eq 3).[3]

Treatment of 2,5-dihydrothiophene 1,1-dioxide with 2 equiv of ***Lithium Hexamethyldisilazide*** and 1,3-diiodopropane affords the fused bicyclic sulfone (eq 4).[4] On the other hand, 2-trimethylsilyl-2,5-dihydrothiophene 1,1-dioxide gives the spiro sulfone on treatment with ***n-Butyllithium*** and 1,3-diiodopropane in the presence of ***Hexamethylphosphoric Triamide*** (HMPA) (eq 5).[5]

Copper Isocyanide Mediated Annulation with α,β-Unsaturated Esters.

1,3-Diiodopropane reacts with α,β-unsaturated esters to give cyclopentanecarboxylates in the presence of copper isocyanide (eq 6).[6,7] The intermediacy of a 3-iodopropylcopper isocyanide complex is proposed; 1,3-dibromopropane and 1,3-dichloropropane give much inferior yields. Diethyl fumarate and diethyl maleate both afford trans-1,2-dicarbethoxycyclopentane, presumably because diethyl maleate is converted to diethyl fumarate prior to the cyclization and/or because *cis*-1,2-diethoxycarbonylcyclopentane, once formed, isomerizes to the *trans* isomer under the conditions

(eq 7).

Reaction with Heteroatom Nucleophiles.

1,3-Diiodopropane reacts with 2 equiv of heteroatom nucleophiles, i.e. carboxylates or amines, to give trimethylene-linked dimers. For example, the ammonium salt of monobenzyl tartaric acid is alkylated by 0.5 equiv of 1,3-diiodopropane to give (**4**), which is used as a ligand for titanium in a complex for asymmetric epoxidation of allylic alcohols (eq 8).[8] A C_2 symmetric dimer of (1*R*,2*S*)-(-)-ephedrine is also prepared by alkylation with 1,3-diiodopropane and used as an asymmetric catalyst for addition of ***Diethylzinc*** to aldehydes (eq 9).[9]

Diiodosilane

H_2SiI_2

[13760-02-6] · H_2I_2Si · Diiodosilane · (MW 283.91)

(strong, oxophilic Lewis acid, converts alcohols, ethers, and acetals to iodoalkanes;[1,3] converts carboxylic acid derivatives to acyl iodides;[2] mild reducing agent[3])

Alternate Name: DIS.

Physical Data: colorless liquid; mp -1 °C; bp 149.5 °C; bp 58 °C/25 mmHg; bp 0 °C/3.8 mmHg; fp 38 °C; *d* 2.7943 g cm^{-3}.

Solubility: highly sol hydrocarbons and chlorinated solvents; reacts with oxygen- and nitrogen-containing solvents.

Form Supplied in: pale yellow liquid packed under nitrogen in ampules.

Preparative Method: phenylsilane and iodine are mixed in a 1:1 molar ratio without solvent at -20 °C in the presence of catalytic amounts of ethyl acetate; fractional distillation removes volatile side products (benzene and HI) and affords the reagent in the form of a colorless oil.

Handling, Storage, and Precautions: is sensitive to moisture; handle and store under nitrogen; stabilized by metallic copper; refrigeration and absence of light recommended for storage over long periods of time.

Introduction.

All transformations described below are conveniently carried out in either chloroform or dichloromethane at temperatures between -40 and 50 °C. Aqueous work-up with sodium hydrogencarbonate (in which all silicon compounds, including excess reagent, form insoluble polymers) is applicable in most cases. Water-sensitive products are isolated by direct fractional distillation of the reaction mixture.

Diiodosilane (DIS) exhibits properties and reactivities that are either similar or complementary to those of ***Iodotrimethylsilane*** (TMSI). These reagents share two dominant characteristics: both are strong, hard, oxophilic Lewis acids and effective sources of nucleophilic, soft iodide ions. The differences between them arise from the facts that DIS is a stronger Lewis acid than TMSI, it is less sensitive to steric effects, and it can also behave as a hydridic reducing agent.

Conversion of Alcohols and Ethers to Iodoalkanes.[1]

Although both TMSI and DIS react with alcohols and alkyl ethers to produce the corresponding iodoalkanes (with inversion of configuration at carbon), they exhibit complementary selectivities. While TMSI reacts with primary oxygen functions more readily than with secondary ones, DIS exhibits the opposite preference, reacting with secondary alcohols and ethers faster than with the primary functions. As illustrated by the case of butane-1,3-diol (eq 1), this preference of DIS is applicable for regioselective transformations of polyols.

Synthesis of Acyl Iodides.[2]

Various carboxylic acid derivatives, including carboxylic acids, esters, lactones, anhydrides, and acyl chlorides are converted by DIS to acyl iodides. These transformations are accelerated by ***Iodine***. These reactions, when followed by addition of an appropriate alcohol, represent an overall esterification or transesterification method which is particularly useful for sterically hindered and/or poorly nucleophilic alcohols. In the absence of iodine, DIS reacts with carboxylic acids and esters, much as does TMSI, to form the corresponding silyl carboxylates as the final product. Lactones react with DIS to produce either silyl o-iodocarboxylates or o-iodoacyl iodides (eq 2), depending on the reaction conditions. The reaction between DIS and 1 equiv of a carboxylic anhydride affords, in the presence of iodine, 2 equiv of acyl iodide.

Deprotection of Acetals.[3]

At low temperatures (-42 °C) and short reaction times (few minutes), DIS (5-10 mol %) catalyzes clean deprotection of various acetals, affording the parent ketones and aldehydes with no apparent reduction of the latter (eq 3). These reactions proceed much more rapidly with DIS than with TMSI, probably due to the higher Lewis acidity and lower steric demands of DIS relative to TMSI. The reactivity difference between the two reagents is particularly apparent with

sterically congested acetals, e.g. 4,5-dimethyldioxolane. While these compounds react with TMSI quite sluggishly, their reactions with DIS proceed almost as rapidly as observed with sterically nonhindered acetals.

(3)

Reductive Cleavage of Acetals to Iodoalkanes.[3]

At temperatures above 0 °C, DIS effectively reduces acetals as well as unprotected ketones and aldehydes to iodoalkanes (eqs 3-6). Reaction rates are highly dependent on the substrate, with the following tendencies:

- 1)Aromatic acetals are generally more reactive than their aliphatic counterparts.
- 2)Acetals are rapidly reduced to the corresponding iodoalkanes, while free aldehydes, and particularly ketones, are essentially inert under the reaction conditions (but can be significantly activated by catalytic amounts of iodine).
- 3)Dimethyl acetals form the parent ketones preferentially, while all other acetals, including diethyl acetals and dioxolanes, are reduced to iodoalkanes.

(4)

(5)

(6)

This reactivity pattern represents inversion of the normal order of reactivity of protected and unprotected carbonyl compounds. In polyfunctional molecules containing both free and protected carbonyls, acetals are chemoselectively reduced by DIS to iodoalkanes in preference to unprotected ketones and aldehydes (eqs 7 and 8).[4]

(7)

(8)

The reaction of DIS with tetrahydropyranyl (THP) derivatives can be controlled by the amount of reagent used (eqs 9 and 10).[3] While 1 equiv of DIS yields 2-iodo-THP exclusively, excess reagent produces 1,5-diiodopentane.

(9)

(10)

Dehalogenation of α-Halo Ketones.[5]

α-Halo ketones react readily with DIS between 0 °C and rt to produce the parent ketones. Reactions are faster with DIS than with TMSI but the same order of substrate reactivity, i.e. primary > secondary > tertiary halides, is observed with both reagents. The same transformation can be achieved with phenylsilane (the precursor of DIS) and catalytic amounts of iodine.

Miscellaneous.

Cyclopropyl ketones react with either DIS or TMSI to produce γ-iodo ketones. Again, reaction occurs much faster with DIS than with TMSI (eq 11). Sulfoxides are reduced readily with both reagents to sulfides. Phosphine oxides may be reduced to phosphines provided that an iodine scavenger is present.

Diisobutylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide

[56252-56-3] · $C_{23}H_{41}AlO$ · Diisobutylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide · (MW 360.62)

(selective reducing agent for enones,[4] particularly prostaglandins,[1,3] β-keto esters,[5] and epoxides;[6] hydroalumination agent;[7] polymerization catalyst[8])

Solubility: sol toluene, CH_2Cl_2, hexane.

Form Supplied in: prepared from commercially available reagents and used in situ.

Preparative Method: prepared by reaction of ***Diisobutylaluminum Hydride*** with 2,6-di-*t*-butyl-4-methylphenol in toluene at 0 °C for 1 h.[1,2]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable; use in a fume hood and protect from oxygen and moisture; solution is stable at 0 °C for several weeks.

Selective Reduction of Enones.

One of the most crucial problems in prostaglandin syntheses is the stereoselective reduction of the C_{15} keto group to the desired (15*S*)-alcohol. The title compound has been devised as the key reagent for a simple and practical solution to this problem.[1] Thus a prostaglandin intermediate is reduced to dihydroxylactone with 92% stereoselectivity (eq 1). In marked contrast, the acetate of the prostaglandin intermediate is reduced without any stereoselectivity, thereby implying the importance of the coordination of the bulky aluminum reagent with the 11-hydroxy group. This reagent has been successfully used for stereoselective reduction of several other prostaglandin intermediates.[3]

This reducing agent has also been used to reduce an oxodienelactone to a dienol as a key step in the synthesis of the lichen macrolide (+)-aspicilin (eq 2).[4] Dihydroxylation of the dienol with ***Osmium Tetroxide*** and pyridine followed by ***Hydrogen Sulfide*** reduction gave the macrolide in 40% yield.

Diastereoselective Reduction of β-Keto Esters.

Reduction of β-keto esters of the chiral α-naphthylborneol is stereoselective because one face of the carbonyl group is blocked by the naphthyl group (eq 3).[5]

Selective Reduction of Epoxides.

The regioselective reduction of methylenecycloalkane oxides has been studied with a variety of reducing agents. Among these, the title reducing agent and its analogs (diisobutylaluminum 2,4,6-tri-*t*-butylphenoxide and diisobutylaluminum 4-bromo-2,6-di-*t*-butylphenoxide) were found to be most satisfactory, giving the desired less-substituted alcohols with good selectivity (eqs 4-6).[6]

(6)

Hydroalumination.

The hydroalumination of alkenes with diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide is carried out in the presence of ***Dichlorobis(cyclopentadienyl)zirconium*** and ***Diisobutylaluminum Hydride*** as catalysts.[7]

Polymerization.

The combination of ***Lithium*** and diisobutylaluminum 2,6-di-*t*-butyl-4-methylphenoxide was found to be effective as an initiator for several types of polymerization of methyl methacrylate at elevated temperature.[8]

Diisobutylaluminum Hydride[1]

***i*-Bu$_2$AlH**

[1191-15-7] · $C_8H_{19}Al$ · Diisobutylaluminum Hydride · (MW 142.22)

(reducing agent for many functional groups; opens epoxides; hydroaluminates alkynes and alkenes)

Alternate Names: DIBAL; DIBAL-H; DIBAH.

Physical Data: mp -80 to -70 °C; bp 116-118 °C/1 mmHg; *d* 0.798 g cm^{-3}; fp -18 °C.

Solubility: sol pentane, hexane, heptane, cyclohexane, benzene, toluene, xylenes, ether, dichloromethane, THF.

Form Supplied in: can be purchased as a neat liquid or as 1.0 and 1.5 M solutions in cyclohexane, CH_2Cl_2, heptane, hexanes, THF, and toluene.

Handling, Storage, and Precautions: neat liquid is pyrophoric; solutions react very vigorously with air and with H_2O, and related compounds, giving rise to fire hazards; use in a fume hood, in the absence of oxygen and moisture (see ***Lithium Aluminum Hydride*** for additional precautions); THF solutions should only be used below 70 °C, as above that temperature ether cleavage is problematic.

Reduction of Functional Groups.[2]

Diisobutylaluminum hydride has several acronyms: DIBAH, DIBAL-H, and DIBAL. For the purpose of this article, DIBAL will be used.

In general, aldehydes, ketones, acids, esters, and acid chlorides are all reduced to the corresponding alcohols by this reagent. Alkyl halides are unreactive towards DIBAL. Amides are reduced to amines, while nitriles afford aldehydes upon hydrolysis of an intermediate imine. Isocyanates are also reduced to the corresponding imines. Nitro compounds are reduced to hydroxylamines. Disulfides are reduced to thiols, while sulfides, sulfones, and sulfonic acids are unreactive in toluene at 0 °C. Tosylates are converted quantitatively to the corresponding alkanes. Cyclic imides can be reduced to carbinol lactams.

Comparable stereochemistry[2] is observed in the reduction of ketones with DIBAL, ***Aluminum Hydride***, and ***Lithium Aluminum Hydride***. Excellent 1,3-asymmetric induction is possible with DIBAL (eq 1); however, this is strongly solvent dependent.[3a]

In addition to the hydroxy directing group, amines and amides also showed excellent 1,3-asymmetric induction.[3b] In conjunction with chiral additives, DIBAL can reduce ketones with moderate to good enantioselectivity (eq 2).[4] The use of the Lewis acid ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD) along with DIBAL allows discrimination between carbonyl groups (eq 3).[5,6]

Reduction of α-halo ketones to the carbonyl compounds can be accomplished with DIBAL in the presence of ***Tin(II) Chloride*** and ***N,N,N´,N´-Tetramethylethylenediamine*** (eqs 4 and 5).[7] Under these conditions, vicinal dibromides are converted to the corresponding alkenes.

(4)

(5)

DIBAL is the reagent of choice (see also ***Aluminum Hydride***) for the reduction of α,β-unsaturated ketones to the corresponding allylic alcohols (eq 6).[8a] A reagent derived from DIBAL and ***Methylcopper*** in HMPA alters the regiochemistry such that 1,4-reduction results (eq 7).[8b] Reductions of chiral β-keto sulfoxides occur with high diastereoselectivity.[9] The choice of reduction conditions makes it possible to obtain both epimers at the carbinol carbon (eqs 8 and 9).

(6)

(7)

(8)

(9)

In conjuction with ***Triethylaluminum***, DIBAL has been used to mediate a reductive pinacol rearrangement[10] with enantiocontrol, as shown in eq 10.[22]

(10)

DIBAL is an excellent reagent for the reduction of α,β-unsaturated esters to allylic alcohols without complications from 1,4-addition (eq 11).[11]

(11)

Due to its Lewis acidity, DIBAL can be used in the reductive cleavage of acetals (see also ***Aluminum Hydride***). Chiral acetates are reduced with enantioselectivity (eq 12).[12] Oxidation of the intermediate alcohol followed by β-elimination gives an optically active alcohol, resulting in a net enantioselective reduction of the corresponding ketone.

(12)

At low temperatures DIBAL converts esters to the corresponding aldehydes (eq 13)[13] and lactones to lactols (eq 14).[14] DIBAL reduction of α,β-unsaturated γ-lactones followed by an acidic work-up transforms the intermediate lactol to the furan (eq 15).[15] The reduction of nitriles can lead to aldehydes after hydrolysis of an intermediate imine (eq 16).[16] However, cyclic imines can be produced if a ***Sodium Fluoride*** work-up follows the reduction of halonitriles (eq 17).[17] Furthermore, imines can be reduced with excellent stereocontrol (eq 18).[18]

(13)

(14)

(15)

(16)

(17)

(18)

DIBAL can also be used for the reductive cleavage of cyclic aminals and amidines (eq 19).[19] Oximes can be reduced to amines. Due to the Lewis acidity of DIBAL, however, rearranged products are obtained (eq 20).[20] This chemistry was used to prepare the alkaloid pumiliotoxin C via the Beckmann rearrangement/alkylation sequence shown in eq 21.[21]

(19)

(20)

(21)

While sulfones are unreactive with DIBAL at 0 °C in toluene,[2] reduction to the corresponding sulfide has been accomplished at higher temperatures.[22] This reaction can be accomplished with ***Lithium Aluminum Hydride***, but fewer equivalents are required and yields are better using DIBAL (eq 22).

(22)

The reagent combination of DIBAL and ***n-Butyllithium***, which is most likely lithium diisobutylbutylaluminum hydride, has also been used as a reducing agent.[23]

Epoxide Ring Opening.

As a result of its Lewis acidity, several reaction pathways are followed in the reductive ring opening of epoxides by DIBAL. Attack at the more hindered carbon via carbenium ion-like intermediates (see also ***Aluminum Hydride***) or S_N2' type reactions, are both known with vinyl epoxides. These modes stand in contrast to results with $LiAlH_4$ (eqs 23-25).[24]

(23)

(24)

(25)

Hydroalumination Reactions.

DIBAL reacts with alkynes and alkenes to give hydroalumination products. *Syn* additions are usually observed; however, under appropriate conditions, equilibration to give a net *anti* addition is possible.[25] If the substrate has both an alkene and an alkyne group, then chemoselectivity for the alkyne is observed (eq 26).[26]

(26)

The intermediate alkenylalane can be used in several ways. If a protiolytic work-up is used, then formation of the corresponding (*Z*)-alkene is observed (eq 27).[27] Treatment of the alkenylalane with ***Methyllithium*** affords an ate complex which is nucleophilic and reacts with a variety of electrophiles, e.g. alkyl halides, CO_2, MeI, epoxides, tosylates, aldehydes, and ketones (eq 28).[1c,1h,26]

(27)

n	*m*	
5	6	82%
3	8	94%
2	9	87%

(28)

Hydroalumination of a terminal alkene followed by treatment of the intermediate alane with oxygen gives a primary alcohol (eq 29).[28]

(29)

Alkenylalanes can dimerize to afford 1,3-butadienes (eq 30),[29] and can be cyclopropanated under Simmons-Smith conditions to give cyclopropylalanes (eq 31),[30] which can be used for further chemistry.

(30)

(31)

Alkenylalanes can also be transmetalated (eq 32),[31] or coupled with vinyl halides via palladium catalysis (eq 33).[32]

(32)

(33)

Addition of DIBAL to allenes has been observed to occur at the more highly substituted double bond (eq 34).[33]

(34)

$R^1 = C_7H_{15}$; $R^2 = H$ (88%), TMS (74%)

The conversion of unconjugated enynes to cyclic compounds has also been accomplished using DIBAL (eq 35).[34]

(35)

Related hydroalumination reactions have been reported using ***Lithium Aluminum Hydride***.

Diisobutylaluminum Phenoxide[1]

***i*-Bu$_2$AlOPh**

[4165-53-1] · $C_{14}H_{23}AlO$ · Diisobutylaluminum Phenoxide · (MW 234.32)

(base for aldol condensation of methyl ketones[2])

Solubility: sol toluene and THF.

Preparative Method: prepared in situ by careful addition of ***Diisobutylaluminum Hydride*** to a THF solution of 1 equiv of phenol.[2]

Handling, Storage, and Precautions: solutions are moisture and air sensitive and should be prepared and handled under an inert atmosphere; use in a fume hood.

Aldol Condensations.

Diisobutylaluminum phenoxide has been used as a base in conjunction with ***Pyridine*** for effecting regiospecific aldol condensations of methyl ketones via the corresponding kinetic aluminum enolates. As an intermolecular example, the condensation of 2-octanone gave a mixture of isomeric 9-methylpentadecenones in good yield (eq 1).[2]

The intramolecular aldol condensation of 2,15-hexadecanedione, which required the use of the reagent in large excess, gave a mixture of isomeric 3-methylcyclopentadecenones (eq 2).[3] Subsequent hydrogenation over ***Palladium on Carbon*** gave (±)-muscone in good overall yield, compared to earlier efforts using the corresponding magnesium enolate.[4]

Diisobutylaluminum Phenyl Selenide

***i*-Bu$_2$AlSePh**

[85028-55-3] · $C_{14}H_{23}AlSe$ · Diisobutylaluminum Phenyl Selenide · (MW 297.28)

(phenylselenylation agent for Beckmann rearrangement of oxime sulfonates,[1,2] acetal cleavage,[4,5] and epoxide opening[6])

Solubility: sol toluene, CH_2Cl_2, hexane.

Form Supplied in: prepared in situ from commercially available reagents.

Preparative Methods: by addition of ***Diphenyl Diselenide*** (1 equiv) to a 1 M hexane solution of ***Diisobutylaluminum Hydride*** (2 equiv) in CH_2Cl_2 at 0 °C for 30 min.[1]

Handling, Storage, and Precautions: use in a fume hood; the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture; the solution should be used as prepared for best results.

Imino Selenoether Synthesis.

Treatment of cyclododecanone and acetophenone oxime methanesulfonates with diisobutylaluminum phenyl selenide (1.1 equiv) in hexane/CH_2Cl_2 at 0 °C for 30 min provides the corresponding imino selenoethers in good yields via organoaluminum-promoted Beckmann rearrangement of oxime sulfonates and subsequent trapping of the intermediary iminocarbocation by phenyl selenide (eqs 1 and 2).[1,2] Dimethylaluminum methyl selenide is also employable for this transformation.[3]

(1)

(2)

Monoselenoacetal Synthesis.

A new method for preparation of monoselenoacetals has been developed which involves the reaction of acetals with diisobutylaluminum phenyl selenide.[4] When ***Dimethoxymethane*** was treated with diisobutylaluminum phenyl selenide (1 equiv) in hexane/toluene at 40 °C for 5 h, methoxy(phenylseleno)methane was formed in 98% yield (eq 3). Diethylaluminum ethyl selenide is also employable as a selenolate agent. Alkyl methoxymethyl ethers are transformed to the alkyl phenylselenomethyl ethers with high selectivity under similar reaction conditions (eq 4). Diselenoacetals are accessible with excess amounts of diisobutylaluminum phenyl selenide (eq 5).

(3)

(4)

(5)

1-Methoxy-1-(phenylseleno)ethane, prepared in this way, generates the 1-methoxyethyl radical upon treatment with

catalytic ***Azobisisobutyronitrile*** and ***Tri-n-butylstannane*** in benzene at 80 °C for 2 h, and this radical adds to methyl acrylate to furnish a Michael adduct in good yield (eq 6).[5]

(6)

Contra-*trans*-Diaxial Opening of Epoxides.

Treatment of an α,β-epoxy alcohol with NaSePh affords the 1,3-diol exclusively in 90% yield. However, use of diisobutylaluminum phenyl selenide in CH_2Cl_2 at 0 °C to rt exhibits the opposite regioselectivity, furnishing the 1,2-diol as a major product (eq 7).[6] When diisobutylaluminum phenyl selenide is combined with ***Titanium Tetraisopropoxide*** as a cocatalyst, the selectivity of epoxide opening is considerably lowered. ***Dimethylaluminum Methylselenolate*** was less selective for this transformation, giving two isomeric diols in a 1:2 ratio. This tendency is also observed with the epoxy *t*-butyldimethylsilyl ether substrate (eq 8).

(7)

PhSeNa	100:0	90%
(*i*-Bu)$_2$AlSePh	20:80	80%

Diisopinocampheylborane

(+)

[21947-87-5] · $C_{20}H_{35}B$ · Diisopinocampheylborane · (MW 286.31) (-)

[21932-54-7]

(chiral hydroborating reagent for asymmetric hydroboration of *cis*-alkenes to provide access to optically active secondary alcohols;[1] precursor for the preparation of a large number of chiral reagents for asymmetric synthesis.[1])

Alternate Name: Ipc_2BH.

Physical Data: white crystalline dimer.

Solubility: sparingly sol THF.

Analysis of Reagent Purity: active hydride is determined by hydrolysis of an aliquot and measuring the hydrogen evolved according to the standard procedure;[2] enantiomeric purity is determined by measuring the rotation of the α-pinene liberated in its reaction with 0.5 equiv of ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA)[3] or reaction with aldehydes.[4]

Preparative Method: (+)-diisopinocampheylborane is prepared in high enantiomeric purity and good yield (Table 1) by hydroboration of commercially available (-)-α-pinene (of low enantiomeric purity) with ***Borane-Dimethyl Sulfide*** (BMS) complex, carried out by mixing the two reagents to make a solution of known molarity in THF at 0 °C or rt (eq 1); the mixture is left without stirring at 0 °C for ~12 h for the development of crystals (the slow crystallization facilitates the incorporation of the major diastereomer in the crystalline product, leaving the undesired isomer in solution); the supernatant solution is decanted using a double-ended needle; the crystalline lumps are broken and washed with diethyl ether and dried under vacuum (~12 mmHg) at rt.[3,4]

Table 1 Synthesis of Diisopinocampheylborane (Ipc_2BH) of High Optical Purity via Selective Single Crystallization in THF (Optimized Conditions)

(+)-a-Pinene % ee	Molar ratio[a]	Molarity M (in borane)	Temp (°C)	Isolated (% yield)	(-)-Ipc_2BH % ee[b]
92.0	2.3:1	1	0	70 75	>99
91	2.5:1	1.25	20 25[c]	>90	>99
84	2:1	1	0	50 60	98.3

[a] Molar ratio of a-pinene to BMS. [b] Based on measuring the rotation of the (+)-a-pinene obtained from (-)-Ipc_2BH. [c] At times, Ipc_2BH starts precipitating immediately; in such cases the reaction mixture should be redissolved at 50 55 °C, followed by slow recrystallization.[4]

Handling, Storage, and Precautions: air sensitive, reacting instantaneously with protic solvents to liberate hydrogen; must be handled under an inert atmosphere (N_2 or Ar); can be stored at 0 °C under inert atmosphere for several months without loss of hydride activity.[4]

Asymmetric Hydroboration.

Brown and Zweifel originally carried out the hydroboration of α-pinene to study the sensitivity of the α-pinene structure towards rearrangement. Surprisingly, the hydroboration reaction proceeded without rearrangement and stopped at the dialkylborane (R_2BH) stage.[5] This important reaction (reported in 1961) thus gave birth to a unique reagent, diisopinocampheylborane (Ipc_2BH). The failure of this reagent to hydroborate a third molecule of α-pinene suggested the possibility of its application in asymmetric hydroboration of less sterically hindered alkenes.

The first substrate which was asymmetrically hydroborated using Ipc_2BH was *cis*-2-butene, and the enantiomeric purity of the product 2-butanol (87% ee) obtained in this preliminary experiment was spectacular (eq 2), since Ipc_2BH was made from α-pinene of low optical purity.[5] This reaction represents the first nonenzymatic asymmetric synthesis for achieving high enantioselectivity. Its discovery marked the beginning of a new era of practical asymmetric synthesis obtained via reagent control.[1,5]

Later, Brown and co-workers developed the method described above for the preparation of enantiomerically pure Ipc_2BH (>99% ee)[3,4] and applied the reagent in the asymmetric hydroboration of prochiral alkenes. Oxidation of the trialkylboranes provided optically active alcohols. In the case of *cis*-alkenes, secondary alcohols were obtained in excellent enantiomeric purity (Figure 1). The reaction is general for most types of *cis*-alkene, e.g. *cis*-2-butene forms (*R*)-2-butanol in 98.4% ee, and *cis*-3-hexene is converted to (*R*)-3-hexanol in 93% ee. However, the reagent is somewhat limited in reactions with unsymmetrical alkenes; e.g. *cis*-4-methyl-2-pentene yields 4-methyl-2-pentanol with 96% regioselectivity but only 76% ee (Figure 1).[6]

Asymmetric hydroborations of heterocyclic alkenes are highly regio- and enantioselective. For example, hydroboration of 2,3-dihydrofuran with Ipc_2BH followed by oxidation provides 3-hydroxyfuran in 83% ee, which can be upgraded to essentially the enantiomerically pure form (>99% ee) (Figure 2).[7]

Applications.

The ability of Ipc_2BH to hydroborate *cis*-alkenes has been elegantly applied to the preparation of key intermediates which have been utilized in syntheses of valuable target molecules.[1a] For example, asymmetric hydroboration-oxidation of 5-methylcyclopentadiene to the corresponding optically active alcohol has been applied in the synthesis of loganin (eq 3).[8a] In another example, a prostaglandin precursor was obtained by the asymmetric hydroboration-oxidation reaction of methyl cyclopentadiene-5-acetate (eq 4).[8b] Ipc_2BH has also been used in the preparation of $PGF_{2\alpha}$.[9]

(3)

(4)

Both the enantiomers of Ipc_2BH have been elegantly applied in the asymmetric hydroboration of safranol isoprenyl methyl ether for the synthesis of carotenoids (3*R*,3´*R*)-, (3*S*,3´*S*)-, and (3R,3´S;*meso*)-zeaxanthins (eq 5).[10] (3*S*,5*R*,3´*S*,5´*R*)-Capsorubin, a carotenoid found in the red paprika *Capsicum annuum*, was synthesized via a key step involving asymmetric hydroboration of the unsaturated acetal followed by an aldol condensation (eq 6).[11] Asymmetric hydroboration using Ipc_2BH was also applied in the stereocontrolled synthesis of a linearly fused triquinane, (+)-hirsutic acid (eq 7).[12]

(5)

[3*S*,3'*S*]-Zeaxanthin

(7)

(+)-Hirsutic acid

Diisopinocampheylborane is not an effective asymmetric hydroborating agent for 2-substituted 1-alkenes. High selectivities have, however, been achieved where one of the substituents is very bulky. This aspect has been elegantly demonstrated by the synthesis of both enantiomers of a precursor of tylonolide, the aglycone of tylosin, which is one of the members of the polyoxomacrolide antibiotics. In both cases the isomeric ratio was at least 50:1 (eqs 8 and 9).[13]

(8)

99% ee

Application of Various Chiral Reagents Derived from Ipc_2BH.

Diisopinocampheylborane does not normally yield satisfactory ee's in hydroboration reactions of 1,1-disubstituted alkenes, *trans*-alkenes, or trisubstituted alkenes. This problem has been partially solved by the introduction of ***Monoisopinocampheylborane***, $IpcBH_2$, which is derived from Ipc_2BH. $IpcBH_2$ handles *trans*-alkenes and trisubstituted alkenes effectively, since it is of lower steric requirement than Ipc_2BH (Table 2). Moreover, $IpcBH_2$ and Ipc_2BH provide an entry into the synthesis of a large variety of optically active borinate and boronate esters. These esters have been successfully converted into α-chiral aldehydes, acids, amines, α-chiral *cis*- and *trans*-alkenes, α-chiral alkynes, β-chiral esters, ketones,[1] etc.

Table 2 Asymmetric Hydroboration of Alkenes with Ipc_2BH and $IpcBH_2$

		% ee of alcohol	
Class[a]	Alkene	Ipc_2BH	$IpcBH_2$
I	2-Methyl-1-alkenes	~20	~1
II	*cis*-Alkenes	³ 99	~25
III	*trans*-Alkenes	~20	70 90[b]
IV	Trisubstituted alkenes	~20	60 ³ 99[b]

[a] Steric requirement increases from class I to class IV. [b] The ee of initial product can be upgraded to 99% ee via crystallization.

Other reagents which have been derived from Ipc_2BH include ***Diisopinocampheylboron Trifluoromethanesulfonate*** (Ipc_2BOTf),[14] ***B-Methoxydiisopinocampheylborane*** (Ipc_2BOMe), and ***(+)-B-Chlorodiisopinocampheylborane*** and its bromo- and iodo analogs (Scheme 1).[1] Ipc_2BOTf and Ipc_2BOMe reagents are used in stereoselective C-C bond forming reactions (aldol condensation and allylboration); Ipc_2BCl (DIP-chloride™) is used for asymmetric reduction of prochiral ketones, and Ipc_2BX(X = Br or I) for enantioselective opening of *meso*-epoxides to nonracemic halohydrins. Numerous applications of all these reagents have been reviewed in detail.[1]

Diisopinocampheylboron Trifluoromethanesulfonate

(+)

[108266-89-3] · $C_{21}H_{34}BF_3O_3S$ · Diisopinocampheylboron Trifluoromethanesulfonate · (MW 434.36) (-)

[108161-70-2]

(enolboration reagent for enantio- and diastereoselective aldol condensation of oxazolines[1] and ketones;[2] also used for Ireland-Claisen rearrangement[3])

Alternate Name: diisopinocampheylboron triflate; Ipc_2BOTf.

Physical Data: colorless, viscous oil; bp <=150 °C/0.01 mmHg (bulb-to-bulb distillation); (-)Ipc_2BOTf $[\alpha]_D$ -43.5° (*c* = 30.4, hexane); ^{11}B NMR (hexane) broad singlet at δ = 60 ppm (with reference to $BF_3.OEt_2$).

Solubility: highly sol in both polar and nonpolar aprotic solvents, e.g. diethyl ether, THF, dichloromethane, pentane, hexane, etc.

Preparative Methods: the (+) enantiomer of the reagent (first reported in 1981)[1] is prepared from commercially available (-)-α-pinene (~87% ee) by hydroboration with ***Borane-Dimethyl Sulfide*** in THF at 0 °C, which generates ***Diisopinocampheylborane***, (+)-Ipc_2BH, in more than 99% ee.[4] The crystalline Ipc_2BH is isolated and treated with ***Trifluoromethanesulfonic Acid*** at 0 °C either in dichloromethane[5a] or hexane.[5b] The reagent develops color in dichloromethane. However, it has been prepared in hexane as a clear and colorless solution which separates from an immiscible colored lower layer. In calculating the molarity of the reagent solution, a 60-70% conversion to triflate is assumed.[2] The reagent is usually prepared in situ from Ipc_2BH, and then its aldol reaction is carried out in the same flask by sequential addition of the required reagents[5,11] (procedure A).[6] Alternatively, the enantiomerically pure reagent can be conveniently prepared by treatment of commercially available (-)- or ***(+)-B-Chlorodiisopinocampheylborane*** (DIP-Cl™) with triflic acid at 0 °C in hexane (Scheme 1).[7] This method (procedure B) generates Ipc_2BOTf instantaneously in almost quantitative yield. The reagent generated by procedure B can be utilized for aldol reaction in the same manner as described for procedure A.

Scheme 1

Handling, Storage, and Precautions: air sensitive; reacts instantaneously with protic solvents to liberate triflic acid; should be freshly prepared prior to use; the freshly prepared reagent turns from pale yellow to clear red upon standing. All transformations involving this reagent should be carried out under N_2 using standard techniques for air sensitive reagents; use in a fume hood.

Boron Azaenolates from Oxazolines.

The reagent is useful for asymmetric aldol condensations of achiral oxazolines. Treatment of 2-ethyl-4-dimethyl-2-oxazoline with Ipc_2BOTf in the presence of a tertiary amine furnishes a boron azaenolate. Without isolation, treatment with an aldehyde in ether at -78 °C provides an alkylated oxazoline, which is hydrolyzed and converted to β-hydroxy ester via treatment with ***Diazomethane***. Although the yields for the four-step sequence are only moderate, the *anti* selectivities of the hydroxy acids are excellent with enantioselectivities of 77-85% ee (eq 1).[1]

Boron Enolates from Ketones.

Boron enolates are highly versatile intermediates in organic synthesis.[8] Their high reactivity and stereoselectivity are often utilized for aldol condensation reactions.[9,10] The reagent has been elegantly applied for regio- and stereoselective enolboration of ketones and subsequent enantio- and diastereoselective aldol reactions with aldehydes.[11] For example, the aldol reaction between ethyl ketones and aldehydes using the (+) or (-) reagent in the presence of a tertiary amine in dichloromethane gives (via the desired (*Z*)-enolborinate) *syn*-α-methyl-β-hydroxy ketones in good enantiomeric excess (66-93% ee) and with high diastereoselectivity (&egt;95%) (eq 2). In contrast, the *anti* selectivity of the aldol product derived from diethyl ketone via formation of the (*E*)-enolate, derived from Ipc_2BCl (DIP-Cl™) with ***Methacrolein***, proceeds with negligible enantioselectivity.[11a] However, use of both the triflate and the chloride reagents in the aldol reaction of methyl ketones with aldehydes have been reported to give β-hydroxy ketones in moderate enantiomeric excess (53-78% ee) with a reversal in the enantioface selectivity of the aldehyde compared to the corresponding ethyl ketone *syn*-aldol. This variable selectivity is interpreted as evidence for the participation of competing chair and boat transition states.[11]

(2)

The aldol methodology mediated by Ipc_2BOTf was successfully applied to a macrolide antibiotic synthesis. Paterson reported a convenient asymmetric synthesis of a C_{19}-C_{27} segment of rifamycin S used in the Kishi synthesis, based on ethyl ketone aldol reactions mediated by optically pure reagent.[12a] He also reported the novel aldol approach to the synthesis of an enantiomerically pure C_7-C_{15} segment of tirandamycin A.[12b] This was prepared via enolboration of the (*R*)-ethyl ketone by (-)-Ipc_2BOTf in the presence of a tertiary amine. Addition of aldehyde to the corresponding enolborinate, followed by oxidative workup and chromatographic purification, led to the two separated *syn*-aldol isomers (8:1 ratio with 63% combined yield) with no *anti*-aldol product detected by HPLC. The major 1,2-*syn*-3,4-*syn* diastereomer is reported to be enantiomerically pure. Moreover, it was observed that enantiomeric excess of the major aldol isomer is significantly enhanced relative to the starting ketone. The corresponding aldol product is reduced to the 1,3-diol (eq 3) and subsequently converted to the enantiomerically pure C_7-C_{15} segment of tirandamycin A via pyranone synthesis.[12b]

Dihydropyrones are valuable intermediates for the synthesis of a variety of substituted tetrahydropyran rings. Recently, stereoselective aldol reactions of β-chlorovinyl ketones using the dienol boronate derivative derived from chiral Ipc_2BOTf was utilized for enantioselective formation of dihydropyrones. No detectable racemization was reported on the cyclization step (eq 4).[12c]

Ireland-Claisen Rearrangement.

Oh et al. recently reported the Ireland-Claisen rearrangement of a variety of *O*-protected 2-butenyl glycolates via chelated boron and tin triflates to give, after esterification, methyl 2-methoxy/benzyloxy-3-methyl-4-pentenoates.[3] In

reactions using Ipc_2BOTf, diastereoselection as high as 99.5% was reported. The diastereoselection obtained in reactions using ***Tin(II) Trifluoromethanesulfonate***, ***Zinc Trifluoromethanesulfonate***, and ***Di-n-butylboryl Trifluoromethanesulfonate*** was far lower than in reactions with Ipc_2BOTf. Moreover, the rate of rearrangement with boron enolates was found to be higher than the rates of rearrangement of the silyl ketene acetals or lithium enolate. As anticipated the *cis*-alkene gives better diastereoselectivity than the *trans* isomer (eq 5). With this high diastereoselection obtained using Ipc_2BOTf, it is surprising that the enantioselectivity of this reaction is only 0-10% ee.[3]

Related Reagents.

(*R**,*R**)-α-(2,6-Diisopropoxybenzoyloxy)-5-oxo-1,3,2-dioxaborolane-4-acetic Acid[1]

(*R*,*R*)

[131703-55-4] · $C_{17}H_{21}BO_9$ · (*R**,*R**)-α-(2,6-Diisopropoxybenzoyloxy)-5-oxo-1,3,2-dioxaborolane-4-acetic Acid · (MW 380.16) (*S*,*S*)

[131703-56-5]

(chiral Lewis acid catalyst for Diels-Alder,[1,2] aldol-type,[3] allylation,[4] and hetero Diels-Alder[5] reactions)

Solubility: sol dichloromethane, propionitrile, THF.

Form Supplied in: the acyloxyborane.THF complex is available as a 0.1-0.2 M solution in dichloromethane or propionitrile.

Analysis of Reagent Purity: ^{1}H NMR (CD_2Cl_2, -95 °C, 500 MHz) δ 1.07-1.13 (m, 6H, 2CH_3), 1.24 (br, 6H, 2CH_3), 4.50 (br, 2H, 2$(CH_3)_2$C*H*), 4.70-4.92 (m, 1H, $CHCO_2B$), 5.45-5.72 (m, 1H, C*H*CO_2H), 6.48 (br, 2H, 2*m*-H), 7.21 (br, 1H, *p*-H).

Preparative Methods: to a solution of (*R*,*R*)- or (*S*,*S*)-mono-(2,6-diisopropoxybenzoyl)tartaric acid (74 mg, 0.2 mmol) in dry dichloromethane or propionitrile (1 mL) is added BH_3.THF (0.189 mL of 1.06 M solution in THF, 0.2 mmol) at 0 °C under an argon atmosphere. The reaction mixture is stirred for 1 h at 0 °C to produce the chiral acyloxyborane. Only 2 equiv of hydrogen gas should evolve under these reaction conditions (0 °C). See also Furuta.[1]

Handling, Storage, and Precautions: the acyloxyborane solution should be flushed with Ar and stored

tightly sealed (to preclude contact with oxygen and moisture) below 0 °C. Use in a fume hood.

Acyloxyborane as an Activating Device for Carboxylic Acids.[2a]

The reduction of carboxylic acids by borane is an important procedure in organic synthesis. The remarkable reactivity of borane towards carboxylic acids over esters is characteristic of this reagent. Such selectivity is rarely seen with other hydride reagents.

The rapid reaction between carboxylic acids and borane is related to the electrophilicity of the latter. The carbonyl group of the initially formed acyloxyborane intermediate, which is essentially a mixed anhydride, is activated by the Lewis acidity of the trivalent boron atom. Addition of 1/3 equiv of the ***Borane-Tetrahydrofuran*** complex to acrylic acid in dichloromethane followed by addition of a diene at low temperature results in the formation of Diels-Alder adducts in good yield (eq 1). Further, the reaction is successful even with a catalytic amount of borane.

Asymmetric Diels-Alder Reaction of Unsaturated Carboxylic Acids.[2a]

A chiral acyloxyborane (CAB) complex (**1**) prepared from mono(2,6-dimethoxybenzoyl)tartaric acid and 1 equiv of borane is an excellent catalyst for the Diels-Alder reaction of α,β-unsaturated carboxylic acids and dienes. In the CAB-catalyzed Diels-Alder reaction, adducts are formed in a highly diastereo- and enantioselective manner under mild reaction conditions (eq 2). The reaction is catalytic: 10 mol % of catalyst is sufficient for efficient conversion, and the chiral auxiliary can be recovered and reused.

Asymmetric Diels-Alder Reaction of Unsaturated Aldehydes.[1,2b-e]

The boron atom of acyloxyborane is activated by the electron-withdrawing acyloxy groups, and consequently acyloxyborane derivatives are sufficiently Lewis acidic to catalyze certain reactions. Thus, asymmetric Diels-Alder reactions of α,β-enals with dienes using (**1**) as a Lewis acid catalyst have been developed. For example, the reaction of cyclopentadiene and methacrolein gives the adduct in 85% yield (*endo*:*exo* = 11:89) and 96% ee (major *exo* isomer) (eq 3). Some additional examples are listed in Figure 1. The α-substituent on the dienophile increases the enantioselectivity, while β-substitution dramatically decreases the selectivity. In the case of a substrate having substituents in both α- and β-positions, high enantioselectivity is observed; thus the α-substituent effect overcomes that of the β-substituent.

The intramolecular Diels-Alder reaction of 2-methyl-(*E*,*E*)-2,7,9-decatrienal with CAB catalysis proceeds with high diastereo- and enantioselectivities.[2c]

Asymmetric Aldol-Type Reaction.[3]

CAB complex (**2**) is an excellent catalyst for the Mukaiyama condensation of simple achiral enol silyl ethers of ketones with various aldehydes. The CAB-catalyzed aldol process allows the formation of adducts in a highly diastereo- and enantioselective manner (up to 96% ee) under mild reaction conditions (eqs 4 and 5). The reactions are catalytic: 20

mol % of catalyst is sufficient for efficient conversion, and the chiral auxiliary can be recovered and reused.

$(E):(Z) = 4:1$ 96%, 96% ee, $syn:anti = 94:6$
$(E):(Z) = 1:49$ 97%, 96% ee, $syn:anti = 93:7$

Almost perfect asymmetric induction is achieved in the *syn* adducts, reaching 96% ee, although a slight reduction in both the enantio- and diastereoselectivities is observed in the reactions with saturated aldehydes. It is noteworthy that, regardless of the stereochemistry of the starting enol silyl ethers, the CAB-catalyzed reaction is highly selective for *syn* adducts. The high *syn* selectivity and the independence of selectivity on the stereochemistry of silyl ethers in the CAB-catalyzed reactions are fully consistent with Noyori's ***Trimethylsilyl Trifluoromethanesulfonate***-catalyzed aldol reactions of acetals,[6] and thus may reflect the acyclic extended transition state mechanism postulated in the latter reactions (Figure 2). Judging from the product configurations, the CAB catalyst (from natural tartaric acid) should effectively cover the *si*-face of carbonyl following its coordination and the selective approach of nucleophiles from the *re*-face should result.

A catalytic asymmetric aldol-type reaction of ketene silyl acetals with achiral aldehydes also proceeds with the CAB catalyst (**2**), which can furnish *syn*-β-hydroxy esters with high enantioselectivity (eq 6).

This reaction is sensitive to the substituents of the starting ketene acetals. The use of ketene silyl acetals from phenyl

esters leads to good diastereo- and enantioselectivities with excellent chemical yields.

Analogous with the previous results of enol silyl ethers of ketones, nonsubstituted ketene silyl acetals are found to exhibit lower levels of stereoregulation, while the propionate-derived ketene silyl acetals display a high level of asymmetric induction. The reactions with aliphatic aldehydes, however, resulted in a slight reduction in optical and chemical yields. With phenyl ester-derived ketene silyl acetals, *syn* adducts predominate, but the selectivities are moderate in most cases in comparison with the reactions of ketone-derived silyl enol ethers. Exceptions are α,β-unsaturated aldehydes, which revealed excellent diastereo- and enantioselectivities. The observed *syn* selectivity and *re*-face attack of nucleophiles on the carbonyl carbon of aldehydes are consistent with the aforementioned aldol reactions of ketone-derived enol silyl ethers.

Asymmetric Allylation (Sakurai-Hosomi Allylation).[4]

Condensation of achiral aldehydes with allylsilanes promoted by CAB catalyst (**2**) (20 mol %) at -78 °C in propionitrile produces homoallylic alcohols with excellent enantioselectivity (eq 7).

Alkyl substitution at the alkene of the allylsilanes increases the reactivity, permitting lower reaction temperature and improved asymmetric induction. γ-Alkylated allylsilanes exhibit excellent diastereo- and enantioselectivities, affording *syn* homoallylic alcohols with high enantiomeric purity. The *syn* selectivity of these reactions is independent of the allylsilane stereochemistry. Thus regardless of the geometry of the starting allylsilane, the predominant isomer in this reaction has *syn* configuration. The observed preference for relative and absolute configurations for the adduct alcohols derived from reaction catalyzed by the (2*R*,3*R*)-ligand-borane reagent can be rationalized on the basis of an extended transition state model similar to that for the CAB-catalyzed aldol reaction (see Figure 2).

Allystannanes are more nucleophilic than allylsilanes. Addition of achiral allylstannanes to achiral aldehydes in the presence of (**1**) (20 mol %) and ***Trifluoroacetic Anhydride*** (40 mol %) also affords homoallylic alcohols with high diastereo- and enantioselectivities (eq 8).

Asymmetric Hetero Diels-Alder Reaction.[5]

In contrast to the CAB catalyst (**2**; R = H) which is stable and both air and moisture sensitive, the *B*-alkylated CAB catalyst (**3**; R = Ph or alkyl) is stable and can be stored in a closed container at rt. A solution of the CAB (**3**; R = Ph) catalyzes Diels-Alder, aldol, and Sakurai-Hosomi reactions. Although the asymmetric inductions achieved by these complexes are slightly less efficient than that of the corresponding hydride-type catalyst, the CAB catalyst (**3**; R = Ph) is shown to be an excellent system for hetero Diels-Alder reactions.

The *B*-alkylated CAB catalyst (**3**) is easily prepared in situ by mixing a 1:1 molar ratio of tartaric acid derivative and phenylboronic acid in dry propionitrile at room temperature for 0.5 h. The hetero Diels-Alder reaction of aldehydes with Danishefsky dienes is promoted by 20 mol % of this catalyst solution at -78 °C for several hours to produce dihydropyranone derivatives of high optical purity (eq 9).

(Diisopropoxymethylsilyl)methylmagnesium Chloride

[85719-58-0] · $C_8H_{19}ClMgO_2Si$ · (Diisopropoxymethylsilyl)methylmagnesium Chloride · (MW 235.08)

(a nucleophilic hydroxymethylating agent for organic halides, in combination with metal-catalyzed coupling reaction followed by oxidative cleavage of the silicon-carbon bonds)

Solubility: sol THF.

Preparative Method: prepared under nitrogen by reaction of commercially available chloromethyl(diisopropoxy)methylsilane *[2212-08-0]* with ***Magnesium*** in THF, using essentially the same method as that described for the preparation of the monoisopropoxy analog (see ***(Chloromethyl)isopropoxydimethylsilane***).

Analysis of Reagent Purity: the yield of the reagent is usually >90%, but may be titrated before use by one of the standard methods.

Handling, Storage, and Precautions: can be stored under nitrogen at rt for at least two days without loss of activity.

Nucleophilic Hydroxymethylating Agent.

The Grignard reagent serves as a versatile nucleophilic hydroxymethyl anion equivalent in combination with the ***Hydrogen Peroxide*** oxidation of the silicon-carbon bond (eq 1).[1,2] The primary products, $(i\text{-PrO})_2MeSiCH_2E$, are stable to weakly basic and acidic aqueous workup and silica gel chromatography. The method is suitable for the nucleophilic hydroxymethylation of halides via a transition metal-catalyzed cross-coupling reaction, but works poorly with carbonyl groups because of the formation of complex mixtures in the first step. When transition metal catalysts such as copper, nickel, or palladium are used, care should be taken to remove them before the oxidation, otherwise vigorous decomposition of hydrogen peroxide may occur.

Allylic halides, such as geranyl and neryl chlorides (eq 2), are hydroxymethylated without loss of regio- and stereochemistry.[2] This method, among others, has been reported to be successfully used for the nucleophilic hydroxymethylation of a 2,3-epoxyalkyl bromide (eq 3).[3] The hydroxymethylation of alkenyl and aryl halides can be attained via a nickel- or palladium-catalyzed cross-coupling reaction with the Grignard or zinc reagent, followed by hydrogen peroxide oxidation (eqs 4 and 5).[2] An enol phosphate can also be hydroxymethylated via the nickel-catalyzed cross-coupling (eq 6).[2] Since the enol phosphate is readily available from ketone, this transformation provides a novel method for the regioselective dehydration-hydroxymethylation of ketones.

Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate[1,2]

L-(*R*,*R*)

[99417-55-7] · $C_{13}H_{21}BO_6$ · Diisopropyl 2-Allyl-1,3,2-dioxaborolane-4,5-dicarboxylate · (MW 284.12) D-(*S*,*S*)

[99493-25-1]

(reagent for the asymmetric allylboration of aldehydes to produce homoallylic alcohols[2])

Alternate Name: tartrate allylboronate.

Physical Data: bp 88-90 °C/0.03 mmHg.

Solubility: sol toluene, THF, ether, CH_2Cl_2.

Analysis of Reagent Purity: ^{11}B NMR (δ 35, $CDCl_3$); capillary GC;[2c] solutions are easily standardized via reaction of an aliquot with cyclohexanecarbaldehyde.[2c]

Preparative Method: prepared by the reaction of ***Triisopropyl Borate*** and ***Allylmagnesium Bromide*** in Et_2O followed by an acidic extractive workup and direct esterification with diisopropyl tartrate (DIPT) (eq 1).[2c]

Handling, Storage, and Precautions: allylboronates are typically handled as a solution in toluene (0.5-1.0 M) and transferred by syringe under an inert atmosphere. The reagent, stored neat or as a solution in toluene over 4Å molecular sieves under an argon atmosphere in a refrigerator (-20 °C), is stable for several months. In the presence of water, (**1**) rapidly hydrolyzes to DIPT and the achiral allylboronic acid.

Reactions with Achiral Aldehydes.

The reaction of tartrate allylboronates with achiral aldehydes proceeds with moderate to excellent enantioselectivity (60-92% ee) and high yield (80-90%). Simple aliphatic aldehydes give good enantioselectivities (decanal 86% ee, CyCHO 87% ee, eq 2),[2] while β-alkoxy and conjugated aldehydes give diminished selectivities (60-80% ee) (eq 3).[3] The enantioselectivity is highly temperature and solvent dependent. Best results for reactions with the vast majority of aldehydes are obtained in toluene at -78 °C.[2c] 4Å molecular sieves are included to ensure that the reaction is anhydrous. Other tartrate esters (e.g. diethyl tartrate) may also be used without loss of enantioselectivity.

(2)

(3)

An allylboronate reagent with a conformationally rigid tartramide auxiliary was designed to improve the enantioselectivity of the reactions with achiral aldehydes.[4] The *N,N´*-dibenzyl-*N,N´*-ethylenetartramide modified allylboronate (**2**) (R = CH_2Ph) is considerably more enantioselective than (**1**) (CyCHO, 97% ee) but has very poor solubility in toluene at -78 °C. Consequently, reactions of (**2**) often require up to 48 h. *N,N´*-Bistrifluoroethyl-*N,N´*-ethylenetartramide modified allylboronate (**3**) (R = CH_2CF_3) is much more soluble at -78 °C than the dibenzyl derivative and therefore reacts with aldehydes much more efficiently (CyCHO, -78 °C, THF, 5 h, 91%, 94% ee).[5]

(2) R = CH_2Ph
(3) R = CH_2CF_3

The poor results obtained with various unsaturated aldehydes have been overcome by conversion of these substrates to the corresponding metal carbonyl complexes.[6,7] For example, allylboration of 2-decynal proceeds with 72% ee, while that of its cobalt complex proceeds with excellent enantioselection (eqs 4 and 5).[6]

(4)

(5)

A second example of the allylboration of a metal carbonyl containing substrate is a highly group- and face-selective allylboration of a *meso* iron-diene dialdehyde complex (eq 6).[7] Efficient kinetic resolutions of racemic diene aldehyde-$Fe(CO)_3$ complexes have also been demonstrated.[7]

Reactions with Chiral Aldehydes.[1,8]

The tartrate allylboronates have been shown to serve as highly useful chiral acetate enolate equivalents in the reactions with α-chiral aldehydes. The diastereoselectivities obtained are good to excellent, depending on whether the reaction is a matched or mismatched case (eqs 7 and 8).[3] These reagents have been applied to several complex problems in natural product synthesis.[8,9] As shown in eq 8, the diastereoselection is significantly improved by using the rigid tartramide reagent (**3**).[5]

(R, R)-**(1)**	matched case	79:21 (72%)
(S,S)-**(1)**	mismatched case	13:87
(R, R)-**(3)**		8:92 (82%)
(S,S)-**(3)**		3:97

The tartrate-derived allylboronate reagents in the best cases compare favorably with other allylboration reagents in their reactions with both achiral and chiral aldehydes (e.g. ***B-Allyldiisopinocampheylborane***; β-allyl-2-(trimethylsilyl)borolane; 2,5-dimethyl-β-allylborolane; 1,2-diamino-1,2-diphenylethane modified allylboranes). The advantage of the tartrate-modified allylboronate reagent rests with its ease of preparation and its capability of prolonged storage without noticeable deterioration.

Related Allylboronate Reagents.

A stereoselective synthesis of *anti* 1,2-diols has been achieved by using a DIPT-modified (*E*)-γ-[(cyclohexyloxy)dimethylsilyl]allylboronate reagent.[10] This reagent is best applied in double asymmetric reactions with chiral aldehydes such as D-glyceraldehyde acetonide (eq 9).

(9)

A chiral allylic alcohol β-carbanion equivalent has also been developed which utilizes a DIPT-modified (*E*)-γ-(dimethylphenylsilyl)allylboronate reagent.[10] This method involves treating the product homoallylic alcohol with ***Dimethyldioxirane*** and subjecting the derived epoxide to an acid-catalyzed Peterson elimination. This sequence has been applied in the synthesis of the trioxadecalin ring system of the mycalamides (eq 10).[11]

(10)

Highly stereoselective introduction of a β,β-dimethylhomoallylic alcohol subunit was also accomplished in this synthesis by using a DIPT-modified prenylboronate (eq 11).[11]

(11)

All the reagents discussed above are readily prepared using techniques described for the preparation of the tartrate-modified crotylboronates, and can be handled in a similar manner.

Diisopropylamine

***i*-Pr$_2$NH**

[108-18-9] · $C_6H_{15}N$ · Diisopropylamine · (MW 101.19)

(strong hindered base capable of catalyzing asymmetric protonation in photodeconjugation of α,β-unsaturated esters;[1] deracemizes amino acids;[2] forms quinquevalent cyclic phosphoranes with triflic anhydride;[3] useful reagent in isocyanate synthesis;[4] promotes thermal rearrangements of cyclopropylimines to pyrroles;[5] in combination with HF, stereoselectively opens epoxides to *trans*-fluorohydrins[6])

Physical Data: mp -61 °C; bp 83-84 °C; *d* 0.7178 g cm^{-3}; *n*20D 1.3915; p$K_a^{H_2O}$ 11.13; pK_a^{THF} 35.7.

Solubility: very sparingly sol H_2O; sol most organic solvents.

Form Supplied in: neat colorless liquid; widely available.

Purification: can be dried over and distilled from fresh potassium hydroxide immediately before use.

Handling, Storage, and Precautions: highly flammable, corrosive liquid with a strong ammonia-like smell; irritating to eyes, respiratory system, and skin; use in a fume hood.

Diastereo- and Enantioselective Protonations.

Photodeconjugation of acyclic α,β-unsaturated esters, containing at least one hydrogen in the γ-position, is a useful synthetic method for preparation of their thermodynamically less stable β,γ-unsaturated isomers in high yield.[7] It was proposed[7b,7e] that this process proceeded via photoenolization involving a pseudocyclic transition state, since cyclic esters were found to be completely inert to photochemical deconjugation.[7b,7e,8] If the starting α,β-unsaturated ester is α-substituted, and either a chiral amino alcohol is added to the reaction mixture,[9] or the ester group contains a chiral alcohol moiety,[1] then photodeconjugation leads to enantio- or diastereoselective protonation, respectively.

In the latter case, diastereoselectivity of the protonation of the new asymmetric center is enhanced in the presence of 0.1 equiv of diisopropylamine in hexane at -40 to -70 °C (eq 1).[1] Methanol, diethylamine, dibutylamine, *N*-ethylbenzylamine, (+)- and (-)-ephedrine, (+)-*O*-methylephedrine, and *N*-(2-hydroxy- and 2-methoxyethyl)benzylamines proved to be less effective additives, while dicyclohexylamine gave similar diastereoisomeric excess (de).

Deracemization of *N*-benzylidene methyl esters of racemic amino acids by a lithium amide, followed by asymmetric protonation by a chiral acid, yields optically active amino acids.[10] The enantiomeric excess (ee) and yield are increased by an amine exchange involving diisopropylamine after the metalation step by ***Lithium Hexamethyldisilazide*** (LHMDS) and prior to the asymmetric protonation by means of ***(2R,3R)-Dipivaloyltartaric Acid*** (DPTA) (eq 2).[2] By this method, the asymmetric induction exceeds or equals that obtained in the classical procedure using ***Lithium Diisopropylamide*** as the base, and the yield is somewhat higher. Use of other amines (e.g. ethylamine, ***Piperidine***, chiral *N*-ethyl-α-methylbenzylamine), but not triethylamine, may enhance the asymmetric induction more than does diisopropylamine.

Synthesis of Cyclic Phosphoranes.

Quinquevalent cyclic phosphoranes can be prepared[3] in good yields from readily available phosphine oxides by treatment with ***Trifluoromethanesulfonic Anhydride*** in dichloromethane at 0 °C, followed by an ether solution of diisopropylamine (2 equiv) and 1,2-diols or catechols at -78 °C (eq 3). Earlier, five-coordinate phosphoranes were prepared from tetravalent phosphorus compounds. Diisopropylammonium triflate can be readily precipitated by the addition of ether to the reaction mixture. This method could not be extended to cyclic phosphonates and phosphinates.

Isocyanate Synthesis.

General methods[11] for the preparation of isocyanates include the dehydration of formamides by ***Phosgene***,[12] diphosgene,[13] and ***Phosphorus Oxychloride***[14] in combination usually with tertiary amines. The replacement of ***Triethylamine*** by diisopropylamine enhances the average yields of the phosphoryl chloride method to the levels of the phosgene or diphosgene procedures.[4] In addition, the isocyanates are often obtained in higher purity. Less bulky secondary amines, e.g. diethylamine, do not give any trace of the isocyanate. Phosphoryl chloride (1.1 equiv) is added dropwise to a dichloromethane solution of formamide and diisopropylamine (2.7 equiv) at 0 °C. In the case of simple alkylformamides, e.g. methyl *N*-formylaminoacetate, formamide is added to a mixture of phosphoryl chloride and diisopropylamine.

This method is considerably milder than the diphosgene method. It gives ferrocenylalkyl isocyanates in fair yields, whereas diphosgene/triethylamine fails to give isocyanates or leads to a mixture of isocyanate and cyanide. Chiral isocyanates derived from amino acids yield racemic isocyanates. With diisopropylamine, a combination of *O*-silylation and dehydration affords a one-pot preparation of the 2-siloxyphenyl isocyanate (eq 4).

Synthesis of *N*-Alkyl-2-chloropyrroles.

The thermolysis of *N*-*t*-alkyl-2,2-dichlorocyclopropylimines in *N*-methylpyrrolidine (NMP) gives 3-chloropyrroles in high yields via fission of the 1,3-bond (eq 5).[4] When Lewis bases in ethyl phenyl ether are added, thermal ring opening via 1,2-bond cleavage is favored, yielding 2-chloro isomers (eq 5). Among the bases studied, diisopropylamine guided this reaction path most effectively;[4] CaO and K_2CO_3 also facilitated this rearrangement, but to a lesser extent than diisopropylamine. In contrast to other cyclopropylimines, the ring transformation was not effected by NH_4Cl or HBr additives.[4,15]

Synthesis of Fluorohydrins.

The addition of ***Hydrogen Fluoride*** to an oxirane is a synthetic method for the preparation of fluorohydrins.[16] Diisopropylamine trihydrofluoride (Jullien's reagent[6]), prepared by lyophilization of a solution of a 1:3 mol ratio of diisopropylamine and 48% aqueous HF solution in a Nalgene polyethylene bottle,[17] serves as an attenuated source of HF. It stereospecifically converts epoxides into *trans*-fluorohydrins (eq 6).

(6)

During the regioselective opening of epoxides, diisopropylamine trihydrofluoride initially donates a fluoride ion, and then HF donates a proton. Jullien's reagent can be stored in a desiccator at rt for periods longer than 6 months without noticeable decomposition,[17] and can be used at 78-150 °C (typically at 110 °C) in an excess of 1.5-5 equiv for up to 30 h.[6,17,18,19] Olah's reagent, ***Pyridinium Poly(hydrogen fluoride)***,[20] employed below -5 °C for 15 min, gives somewhat lower yields of fluorohydrins with decreased regioselectivity (eq 7).

(7)

Jullien's reagent	$n = 1$, 110 °C	15:1	75%
	$n = 2$, 110 °C	6:1	81%
Olah's reagent	$n = 1$, -5 °C	1.1:1	60%
	$n = 2$, -5 °C	1:4	68%

The regioselective ring opening of epoxides by Jullien's reagent is governed primarily by steric factors.[17] *trans*-Epoxides afford a mixture of *erythro* isomers, while *cis*-epoxides yield *threo* isomers (eqs 8 and 9).[6a]

(8)

R = Me	74%	9%
R = Ph	62%	

(9)

R = Me	76%	9%
R = Ph	75%	

Other di- and trialkylamine trihydrofluorides[6a,6b] and diisopropylamine dihydrofluoride[6a] afford lower yields; use of HF in polar basic solvents, KF_2, or boron trifluoride etherate with or without HF frequently results in polymerization or rearrangement of the products.[16]

(*E*)-1-(*N,N*-Diisopropylcarbamoyloxy)crotyllithium[1a,1b]

[81725-22-6] · $C_{11}H_{20}LiNO_2$ · (*E*)-1-(*N*,*N*-Diisopropylcarbamoyloxy)crotyllithium · (MW 205.23)

(homoenolate reagent for the stereoselective introduction of the butyric acid β-enolate synthon onto aldehydes and ketones;[1,2a,2b] prototype of several analogous reagents)

Preparative Method: prepared in situ from (*E*)-2-butenyl *N*,*N*-diisopropylcarbamate[3a,3b] by deprotonation at -78 °C with ***n-Butyllithium*** in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA) in ether or hexane (eq 1).

Handling, Storage, and Precautions: must be prepared and handled under inert gas (Ar or N_2) to exclude oxygen and moisture;[3a] solutions in ether decompose slowly above -60 °C.

Diastereoselective Homoaldol Reaction.[1]

The lithium-TMEDA complex adds γ-selectively to aldehydes and ketones[3] to give *anti*-(*Z*)-4-hydroxy-1-(*N*,*N*-diisopropylcarbamoyloxy)-1-alkenes as a consequence of the intervention of a five-membered chelate (eq 1). The stereoselectivity is enhanced to >97% ds by in situ metal exchange with ***Titanium Tetraisopropoxide***.[4-6] The pure (*E*)-carbamate (>97%)[3] must be used for achieving high stereoselectivities.[5b,6] 2-Enals react with clean 1,2-regioselectivity.[4,7]

Enantiopure aldehydes furnish 1:1 diastereomeric mixtures due to the reagent-controlled chirality transfer[5b,5c] and the configurational stability[8] of the racemic titanium intermediate (eq 2). The enantiomerically enriched reagent is also available (see ***(-)-Sparteine***).[9] The *O*-(4-hydroxy-1-alkenyl) carbamates were converted by hydroxy-directed epoxidation via stable *O*-(1,2-epoxy-4-hydroxyalkyl) carbamates[5b,10] to methyl 3-deoxy-3-*C*-methylhexofuranosides (eqs 3 and 4)[5b,5c] and to 2-heterosubstituted γ-lactones.[10b]

$OCb = OC(=O)N(i\text{-}Pr)_2$

(3)

(E)-1-(N,N-Diisopropylcarbamoyloxy)crotyllithium

(4)

The mercury(II) salt-catalyzed methanolysis furnishes 2-methoxytetrahydrofurans, which can be oxidized to *trans*-3,4-disubstituted γ-lactones (eq 5).[3a,5a] 1,4-Alkanediols are accessible by a hydroboration sequence.[11]

(5)

The enol carbamates can be used for further C-C coupling reactions. The Lewis acid-catalyzed condensation with carbonyl compounds leads to stereochemically homogeneous tetrahydrofuran-3-carbaldehydes.[12] Both the acidic vinylic proton[6,13] and the carbamate group in enol carbamates undergo stereospecific substitution reactions.[6,13a] The racemic reagent has also been applied in the total synthesis of rifamycin S intermediates[14] and of doubly *C*-branched sugar analogs.[7]

Alkylation does not offer useful levels of regioselectivity.[3a] The reaction with *p*-toluenesulfonyl fluoride yields (*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-1-(4-methylphenylsulfonyl)-2-butene,[15] which is a useful reagent for nucleophilic crotonoylation.[15b] (*Z*)-1-(*N*,*N*-Diisopropylcarbamoyloxy)butenyllithium reacts, after metal exchange by diisobutylaluminum methanesulfonate, with modest *syn*-(*E*) diastereoselectivity.[16]

Related Reagents.

Up to three alkyl groups, aryl groups, and several types of hetero substitutents in the allyl moiety are permitted in 1-lithio-2-alkenyl carbamates.[1a,3a] The addition of 1-(1-cyclopentenyl)-1-(*N*,*N*-diisopropylcarbamoyloxy)methyllithium[11] or of 3-(dimethylphenylsilyl)-1-(*N*,*N*-diisopropylcarbamoyloxy)-2-propenyllithium[17] to (*S*)-2-aminoalkanals was utilized to prepare several dipeptide isosteres. A higher analog was used in the total synthesis of (±)-anisomelic acid.[18] The homoaldol adducts from 1-(*N*,*N*-diisopropylcarbamoyloxy)-3-(trimethylsilyl)-2-propenyllithium offer a flexible and highly diastereoselective access to all four possible geometric isomers of 1,3-alkadienyl carbamates.[19] Enantiomerically enriched 1,3-disubstituted 1-lithio-2-alkenyl carbamates, such as (1*S*,2*E*)- or (1*R*,2*Z*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-1-methyl-2-butenyllithium[20] are configurationally stable below -70 °C in ether or hexane and are prepared by deprotonation of the nonracemic carbamate esters[21] (see also ***(-)-Sparteine***). Trapping these by trialkylstannyl chlorides proceeds with $S_{E'}$ *anti* stereochemistry[22] to provide enantiomerically enriched (*Z*)-1-methyl-3-trialkylstannyl-1-butenyl *N*,*N*-diisopropylcarbamates, which are valuable chiral homoenolate reagents.[23]

Alternative reagents for some of the transformations described above include (*E*)-1-methoxycrotylboronates[24] and (1-alkoxycrotyl)tributylstannanes.[25]

Diisopropyl 2-Crotyl-1,3,2-dioxaborolane-4,5-dicarboxylate[1,2]

(**1**) L-(*R*,*R*)-tartrate (*E*)-crotyl

[99745-86-5] · $C_{14}H_{23}BO_6$ · Diisopropyl 2-Crotyl-1,3,2-dioxaborolane-4,5-dicarboxylate · (MW 298.14) D-(*S*,*S*), (*Z*)

[99687-40-8] L-(*R*,*R*), (*Z*)

[106357-20-4] (**2**) D-(*S*,*S*), (*E*)

[106357-33-9]

(reagents for the asymmetric crotylboration of aldehydes to produce either *syn* or *anti* β-methylhomoallylic alcohols)[2]

Physical Data: bp 80 °C/0.1 mmHg.

Solubility: sol toluene, THF, ether, or CH_2Cl_2.

Analysis of Reagent Purity: ^{11}B NMR, data for (*E*)-crotyl: (δ 34.8, C_6D_6);[2b] the purity of the reagent is best determined by capillary GC;[2b] solutions of the reagent can be standardized using cyclohexanecarbaldehyde.[2b]

Preparative Method: prepared by treatment of (*E*)- or (*Z*)-crotylpotassium with ***Triisopropyl Borate*** followed by acidic extractive workup and direct esterification with diisopropyl tartrate (DIPT) (eqs 1 and 2).[2]

Handling, Storage, and Precautions: typically the reagents are handled as solutions in toluene (0.5-1M) and transferred by syringe under an inert atmosphere; stored neat or as a solution in toluene over 4Å molecular sieves under an argon atmosphere in a refrigerator (-20 °C), the reagent is stable for many months. In the presence of water, (**1**) rapidly hydrolyzes to achiral crotylboronic acid, the presence of which leads to reduced enantioselectivity in reactions with aldehydes.

Reactions with Achiral Aldehydes.

The tartrate ester modified (*E*)- and (*Z*)-crotylboronates undergo rapid additions to aldehydes at -78 °C. The enantioselectivities obtained for aliphatic linear or α-monobranched aldehydes range from 72 to 91% ee.[2] When cyclohexanecarbaldehyde is treated with the (*E*)-crotylboronate reagent at -95 °C in toluene, the homoallylic alcohol is obtained in 98% yield and 91% ee (eq 3). The (*Z*)-crotylboronate reagent gives slightly lower selectivity (83% ee, eq 4). The *anti*:*syn*/*syn*:*anti* ratios obtained are also excellent for this reagent (typically greater than 98:2 and 2:98 for (**1**) and (**2**), respectively).

(4)

As with the corresponding allylboronate, the enantioselectivity of reactions with β-alkoxy and conjugated aldehydes are lower (55-74% ee). In the case of benzaldehyde (91%, 66% ee), selectivity can be improved by the use of the derived chromium tricarbonyl complex. The homoallylic alcohol is obtained after oxidative decomplexation in high yield and 92% enantiomeric purity (eq 5).[3]

(5)

Reactions with Chiral Aldehydes.

Addition of the (*E*)- or (*Z*)-crotylboronate reagent to optically active β-alkoxy-α-methylpropionaldehydes gives the corresponding polypropionate structures with good to excellent diastereoselection (eqs 6 and 7).[4] Three of the four stereochemical triads can be prepared in high yield with useful levels of selectivity. The all-*syn* stereoisomer of eq 7 is best prepared using other methods, such as the crotyltin methodology developed by Keck and co-workers.[5] The polypropionate structures with 1,3-*anti* relationships between branching methyl groups are prepared with excellent diastereoselection (via matched double asymmetric reactions). Those with a 1,3-*syn* relationship are more difficult to prepare. The relative diastereoselectivity of the reaction of α-methyl chiral aldehydes with (*E*)- and (*Z*)-crotylboronates can be predicted by use of the *gauche* pentane model.[6]

R = TBDPS, *(S,S)*-**(2)**	27:73	

Both (*E*)- and (*Z*)-crotylboronates have been used in several applications in natural product synthesis.[4b,7] One application of both the allylboronate and (*E*)-crotylboronate reagents is found in the synthesis of the C(19)-C(29) segment of rifamycin S. The desired stereochemistry at C(25)-C(26) of the rifamycin ansa chain is set with excellent stereocontrol (>95:5) and high yield (87%) (eq 8).[4b,7a]

The (*E*)- and (*Z*)-crotylboronates provide selectivity in the best cases comparable to that obtained with other crotylboration procedures. Combining ease of preparation, stability, and selectivity the tartrate-modified (*E*)- and (*Z*)-crotylboronates are highly useful propionate enolate equivalents.

Related Reagents.

B-Allyldiisocaranylborane; ***B-Crotyldiisopinocampheylborane***; ***(R,R)-2,5-Dimethylborolane***.

Diisopropylethylamine

***i*-Pr$_2$NEt**

[7087-68-5] · $C_8H_{19}N$ · Diisopropylethylamine · (MW 129.24)

(hindered non-nucleophilic amine base used in alkylations, selective generation of enolates, aldol-like reactions, and eliminations)

Alternate Names: DIPEA; DIEA; Hünig's base.

Physical Data: bp 127 °C; *d* 0.742 g cm^{-3}.

Solubility: sol most organic solvents.

Handling, Storage, and Precautions: corrosive and flammable liquid; flush containers with nitrogen or argon to prevent exposure to carbon dioxide; vapors are harmful; avoid absorption through the skin; use in a fume hood.

Metal-Catalyzed Couplings.

DIPEA can be used as a base in the palladium(0)-catalyzed alkoxycarbonylation of both allyl phosphates and acetates.[1] Treatment of diethyl (*E*)-2-hexenyl phosphate with ***Tris(dibenzylideneacetone)dipalladium*** and ***Triphenylphosphine*** in the presence of 1 equiv of DIPEA in ethanol under 30 atm CO pressure leads to an 84:16 mixture of *trans*- and *cis*-ethyl heptenoates in 88% yield (eq 1). The base used neutralizes the phosphoric acid generated. Without DIPEA, the alkyl ester is not produced. Allyl acetates behave in a similar manner (eq 2). Use of other tertiary bases, such as triethylamine, leads to lower yields of products.

(2)

In an asymmetric variation of the Heck reaction,[2] the sterically demanding DIPEA is used in combination with (*R*)-***2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl*** ((*R*)-BINAP) for generating enantiomerically enriched 2-aryl-2,3-dihydrofurans from aryl triflates.[3] However, in a comparison study, the base ***1,8-Bis(dimethylamino)naphthalene*** (proton sponge) was found to be superior in regards to enantiomeric purity for the arylation reaction (eq 3).[4,5]

(3)

base	% ee (yield)	% ee (yield)
DIPEA	82 (92)	60 (8)
Et_3N	75 (98)	9 (2)
proton sponge	96 (71)	17 (29)

Selective Enolate Formation.

This base, in combination with boryl triflates, is widely applied in the enolate generation of ketones for use in directed cross-aldol reactions.[6] Reaction of 4-methyl-2-pentanone with DIPEA and ***Di-n-butylboryl Trifluoromethanesulfonate*** in ether at -78 °C produces the unisolated boron enolate. Subsequent treatment with hexanal yields the cross-aldol product in 70% yield as the sole regioisomer (eq 4).[7] Reaction takes place at the methyl group of the ketone, while none of the ketone or aldehyde self-condensation products are observed. In a complementary fashion, substitution of ***2,6-Lutidine*** for DIPEA and ***9-Borabicyclononyl Trifluoromethanesulfonate*** (9-BBN triflate) for di-*n*-butylboryl triflate yields the opposite regioisomer as the sole product (eq 4).[8]

(4)

Proper choice of boron reagent, reaction solvent, and tertiary amine base influences the enolate geometry of ketones[9] and esters.[10] The use of dialkylboron triflates or dialkylboron halides, such as *B*-chloro-9-BBN, with DIPEA in ether at -78 °C favors the (*Z*)-enol borinates of ketones, while the more sterically demanding dialkylboron halides, such as dicyclohexylboron chloride (Chx_2BCl), with ***Triethylamine*** favor the (*E*)-enol borinates (eq 5).[9a,9b]

(5)

Similar complementary methodologies exist for generating both the (*E*) and (*Z*) boron enolates of esters. The

combination of chiral nonracemic bromoborane (**1**) and DIPEA in CH_2Cl_2 selectively converts *trans*-crotyl propionate into the (*E*)-boron enolate (**2**), which subsequently undergoes a highly enantioselective and diastereoselective Ireland-Claisen rearrangement to generate the *threo* product (**3**) in 75% yield and >97% ee. In comparison, use of triethylamine in a solvent mixture of toluene and hexane leads to a 90:10 mixture of (*Z*)- and (*E*)-boron enolates (**4**), which rearranges to generate the *erythro* product (**5**) as the major isomer in 65% yield and high enantiomeric excess (eq 6).[10a,11]

(6)

The stereoselective generation of silylketene acetals from alkyl esters and ***Triethylsilyl Perchlorate***[12] is quite effective

using DIPEA as the base at -70 °C in a 1:1 solvent mixture of CH_2Cl_2 and CCl_4 (see ***2,2,6,6-Tetramethylpiperidine***).

Phenols and enols can be *O*-methylated in moderate to good yields using ***Trimethylsilyldiazomethane*** with DIPEA in methanol-acetonitrile.[13]

Thioesters[10c,10d] and oxazolidones[14] can also be selectively converted into dialkylboryl enolates using DIPEA as base and the appropriate boron triflates. The thioester enolates readily react with imines to generate β-amino thioesters (eq 7),[10e] whereas the oxazolidone boron enolates can undergo alkylation with acetoxyazetidinones (eq 8).[14] *S*-*t*-Butyl bromothioacetate undergoes a highly stereospecific Darzens condensation with substituted benzaldehydes using ***Dicyclopentylboryl Trifluoromethanesulfonate*** and DIPEA at -78 °C to afford the *trans*-glycidic ester (eq 9).[15]

(7)

(8)

73%, β:α = >99:1

Aldol-like reactions between aldehydes and nitriles,[16] alkylpyridines,[17] 2-methyloxazoles, 2-methylthiazoles,[18] glycolates, and thioglycolates[19] are possible in the presence of boryl triflates and DIPEA. Methyl-*O*-allyl glycolate tin(II) (or boron) enolates, prepared easily using DIPEA as base, undergo Wittig rearrangement to afford α-hydroxy esters with a high degree of diastereoselectivity (eq 10).[20]

Diisopropylethylamine also finds application in the preparation of titanium enolates from esters,[21] aryl ketones,[22] and oxazolidones.[23]

Base-Promoted Alkylation.

This sterically hindered amine is widely used in organic synthesis as a proton scavenger. Its lack of quaternization makes it an excellent choice of a base for use with very reactive alkylating agents.[24] In the field of protecting group chemistry, DIPEA is a particularly useful base for protection of alcohols as substituted ethers.[25] For example, the tertiary alcohol of mevalonic lactone can be protected as the *p*-methoxybenzyloxymethyl ether using an excess of DIPEA and 3 equiv of *p*-methoxybenzyl chloromethyl ether (eq 11).[26]

(11)

2,4-Disubstituted oxazolones are alkylated in high yields using alkyl halides with DIPEA as a base in DMF (eq 12).[27] DIPEA can be used together with ***Triethyloxonium Tetrafluoroborate*** for the esterification of sterically hindered carboxylic acids.[28]

(12)

The alkylsulfination of diacetone-D-glucose with sulfinyl chlorides and DIPEA in toluene at -78 °C produces the (*S*)-sulfinates as the major products. Simply changing the base from DIPEA to pyridine and the solvent from toluene to THF results in a remarkable stereochemical reversal, affording the (*R*)-sulfinates as the major products (eq 13).[29]

(13)

The alkylation of protected uracils with alkyl halides using DIPEA in DMF or acetonitrile furnishes the alkylated uracils in good to moderate yields (eq 14). The alkylations involving ribofuranosyl bromides furnish the β-isomers as the sole products.[30]

(14)

Exposure of hydroxyl vinyl ethers to ***Trifluoromethanesulfonic Anhydride*** and DIPEA in CH_2Cl_2 at -78 °C results in a stereospecific cyclization to afford cyclic hemiacetals in near quantitative yield (eq 15).[31]

(15)

Addition of DIPEA to a mixture of phenylsulfenyl chloride and an unsaturated alcohol or carboxylic acid results in high yields of cyclic ethers or lactones, respectively.[32] The presumed mechanism involves the intermediacy of an episulfonium ion (eq 16).

(16)

Eliminations.

The eliminative deoxygenation of acetals into enol ethers is accomplished using ***Trimethylsilyl Trifluoromethanesulfonate*** and a slight excess of DIPEA (eq 17);[33] similarly, treatment of 2-alkyloxazolidines with ***Chlorotrimethylsilane*** and DIPEA leads to *N*-(trimethylsilyloxyalkyl)enamines (eq 18).[34] Thioacetals follow similar chemistry to furnish vinyl sulfides.[35] Deoxygenation of sulfoxides with DIPEA and ***Iodotrimethylsilane*** produces vinyl sulfides.[36]

(17)

(18)

Peptide Couplings.

Diisopropylethylamine, as well as triethylamine, *N*-methylmorpholine, and other tertiary amines, find utility in the coupling of amino acids to prepare peptides.[37] The basicity and steric nature of the tertiary amine utilized during the coupling reaction influences the degree of racemization.[38]

Minor dipeptide impurities, which sometimes are difficult to remove, can form during the *N*-acylation of amino acids. Acylation of alanine using benzoyl chloride and aqueous NaOH yields *N*-benzoylalanine (60%), which contains about 1.2% of the dipeptide impurity. Use of DIPEA nearly eliminates the impurity and results in a 72% yield of *N*-acylated product.[39]

The coupling of *N*-methylated amino acids is sometimes problematic. However, the combination of 3 equiv of DIPEA and 1 equiv of bromotris(dimethylamino)phosphonium hexafluorophosphate (BroP) in CH_2Cl_2 results in good yields of desired dipeptides. Methyl *N*-methylvalinate successfully couples with other amino acids using these reaction conditions. Epimerization during the coupling is not observed (eq 19).[40]

9-*O*-(1,2;5,6-Di-*O*-isopropylidene-α-D-glucofuranosyl)-9-boratabicyclo[3.3.1]nonane, Potassium Salt

[101696-41-7] · $C_{20}H_{34}BKO_6$ · 9-*O*-(1,2;5,6-Di-*O*-isopropylidene-α-D-glucofuranosyl)-9-boratabicyclo[3.3.1]nonane, Potassium Salt · (MW 420.40)

(chiral borohydride reagent for enantioselective reduction of ketones[1])

Alternate Names: K-glucoride; K 9-*O*-DIPGF-9-BBNH.

Solubility: usually prepared and stored in THF solution.[1]

Analysis of Reagent Purity: ^{11}B NMR (δ 1.33, br s) and strong absorption at 2038 cm^{-1} in the IR spectrum (B-H str); stoichiometric ratio of K:B:H as 1:1:1 by analysis.[1]

Preparative Method: 9-BBN, by reaction with the chiral alcohol 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose (DPGF) (both commercially available), is transformed into the borinic ester 9-*O*-DIPGF-9-BBN which, by treatment with a modest excess (1.1-1.5 equiv) of

potassium hydride, is completely transformed within 2 h into K-glucoride.[1]

Handling, Storage, and Precautions: K-glucoride is relatively stable toward disproportionation at rt, especially when the THF solution is stored over excess potassium hydride under a positive pressure of nitrogen.[1]

Enantioselective and Diastereoselective Reduction of Carbonyl Compounds.

K-Glucoride is the first example of a well-defined chiral borohydride reagent containing a monosaccharide as chiral auxiliary;[2] moreover, it has only one hydride per reagent molecule.[1a] K-Glucoride allows the reduction of various ketones[1a-c] to the corresponding alcohols in THF, even at -78 °C; it was first used for hindered alkyl phenyl ketones (like pivalophenone)[1a] and it gave considerably higher enantioselectivity than Noyori's BINAL-H reagent (see ***Lithium Aluminum Hydride-2,2´-Dihydroxy-1,1´-binaphthyl***).[1a] Reduction of unhindered aliphatic ketones (like 2-butanone) with the same reagent gave only very low optical yields; for such compounds the lithium hydrido-9-BBN-nopol benzyl ether adduct (NB-Enantride™)[1a] is much more favorable. On the other hand, the reduction of pinacolone, which is relatively hindered, gave a reasonable enantioselectivity (70%), while NB-Enantride gave only 2%. A significant effect of reaction temperature on optical induction was demonstrated for propiophenone,[1c] with ee's varying from 92% at -78 °C to 76% at 0 °C. It is noteworthy that the alcohols obtained were always enriched in the (*R*) enantiomer.

Prochiral ketones bearing various functionalities near the carbonyl group can be reduced by K-glucoride; for example very good optical yields can be obtained in the reduction of α-keto esters[3a] to the corresponding α-hydroxy esters. The ee's obtained are always close to 100%, even with relatively hindered derivatives. Moreover, all of the α-hydroxy esters obtained were enriched in the (*S*) enantiomer. In contrast, *B*-isopinocampheyl-9-borabicyclo[3.3.1]nonane (Alpine-borane®)[3a] usually gave lower optical yields and very slow reactions with relatively hindered compounds; in this case the absolute configuration of product depends on the starting α-keto ester. While α-hydroxy esters can be obtained with high ee by reduction with K-glucoride, the same procedure gave only poor results in the asymmetric reduction of β-keto esters.[3a]

Secondary or tertiary β-amino alcohols can be obtained by reduction of α-amino ketones with K-glucoride;[3b] best results were obtained starting from aromatic α-amino ketones (44-73% ee), while aliphatic amino ketones gave only low enantioselectivity (9-33% ee). Interestingly, the amino alcohols obtained are enriched in the (*S*) enantiomer and the enantioselectivity increases with the bulkiness of the substituents on the amino group.

α,β-Alkynic ketones can be reduced to the corresponding (*R*)-alkanols with K-glucoride;[3c] ee's are good with compounds bearing an internal triple bond (61-87%), while they drop with terminal alkynes (in this case the (*S*) configuration is preferred). K-glucoride can also be used for the diastereoselective reduction of chiral racemic cyclic and bicyclic ketones to give the less stable alcohol with excellent diastereoselectivity.[1c]

Other Reductions.

There is an example of a reduction (resolution) of racemic 1,2-epoxyalkanes to give the corresponding (*R*)-2-alkanols with moderate ee (up to 43.3%).[4]

The enantioselective synthesis of optically active secondary amines via asymmetric reduction of prochiral ketimines was studied by screening various chiral hydrides.[5a,b] In this case, K-glucoride gave only disappointing results and was inferior to other reagents. Better results were obtained in the asymmetric reduction of prochiral *N*-diphenylphosphinylimines to chiral *N*-(diphenylphosphinyl)amines (eq 1),[5c] which can then be readily converted into optically active primary amines. For this reaction the stereochemical course depends dramatically on the relative bulkiness of the groups R^1 and R^2. The reaction conditions for reduction of C=N double bonds are the same as used for ketones, but the high reactivity of diphenylphosphinylimines dramatically reduces the reaction time.

(1)

Finally, K-glucoride can also be used for the enantioselective reduction with moderate ee (52%) of 1-substituted 2-methylisoquinolinium salts, which are employed in the preparation of 1-substituted 2-methyltetrahydroisoquinoline alkaloids.[5d]

Diisopropylsilyl Bis(trifluoromethanesulfonate)

$$i\text{-}Pr_2Si(OSO_2CF_3)_2$$

[85272-30-6] · $C_8H_{14}F_6O_6S_2Si$ · Diisopropylsilyl Bis(trifluoromethanesulfonate) · (MW 412.39)

(bifunctional silyl protecting group for 1,2-, 1,3-, and 1,4-diols)

Physical Data: bp 85-86 °C/2 mmHg; *d* 1.396 g cm^{-3}; fp 110 °C.

Preparative Method: conveniently prepared by the slow addition of 2 equiv of ***Trifluoromethanesulfonic Acid*** to a stirring mixture of ***Chlorodiisopropylsilane***, followed by direct distillation of the product from the reaction flask to yield the product as a pale yellow oil.[1]

Handling, Storage, and Precautions: store in the refrigerator under an inert atmosphere of argon or nitrogen. Special care should be used when handling since diisopropysilyl bis(trifluoromethanesulfonate) has been classified as a corrosive.

The use of silyl protecting groups in organic synthesis has been limited to monofunctional silicon compounds. Their use has been enhanced by the fact that they may be put on and removed under mild conditions. Diisopropylsilyl bis(trifluoromethanesulfonate) and its analog, ***Di-t-butylsilyl Bis(trifluoromethanesulfonate)***, go one step further in protecting group technology. The two electrophilic sites on silicon allow for the simultaneous protection of 1,2-, 1,3-, and 1,4-diols, and in some cases form a rigid system which allows for asymmetric stereocontrol in subsequent organic transformations.[1]

Polyfunctional silicon protecting groups have been employed by researchers before the use of silicon ditriflates. Trost and co-workers found in the development of methodology towards the synthesis of erythronolide A that ***Di-t-butyldichlorosilane*** was relatively unreactive under standard silylation conditions and required forcing conditions (65-95 °C, ***1-Hydroxybenzotriazole***, MeCN, or DMF) for its employment.[2] These two factors make dichlorosilanes limited in their applicability. Silicon ditriflates will react readily with many diols in the presence of 3 equiv of ***2,6-Lutidine*** in chloroform at temperatures ranging from 0-25 °C. The generality of this polyfunctional protecting group is illustrated by the formation of the silyl-protected diols (**1**), (**2**), and (**3**).

(1) 83%

(2) 88%

(3) quant

Corey and Link utilized diisopropylsilyl bis(trifluoromethanesulfonate) as a silylating agent for catechols in the first enantioselective synthesis of pure (*R*)- or (*S*)-isoproterenol (eq 1).[3]

(1)

Related Reagents.

Di-t-butyldichlorosilane; ***Di-t-butylmethylsilyl Trifluoromethanesulfonate***; ***Di-t-butylsilyl Bis(trifluoromethanesulfonate)***; ***Dichlorodimethylsilane***; ***Dichlorodiisopropylsilane***.

Dichlorodiisopropylsilane

***i*-Pr$_2$SiCl$_2$**

[7751-38-4] · $C_6H_{14}Cl_2Si$ · Dichlorodiisopropylsilane · (MW 185.17)

(nucleoside 3´,5´-hydroxy protection; component in Peterson alkenation reaction)

Physical Data: bp 50-55 °C/5 mmHg.[1,2]

Solubility: sol most organic solvents.

Preparative Method: conveniently prepared by the reaction of diisopropylsilane in carbon tetrachloride with ***Palladium(II) Chloride*** at 140 °C for 8 h in a steel bomb. Washing the residue with ether and removing the ether by rotary evaporation yields the product which is purified by distillation to yield a clear colorless oil.

Handling, Storage, and Precautions: special care should be used when handling since the reagent is corrosive.

Nucleoside-protecting Group.

The use of silicon groups as protection for hydroxy groups has been widely exploited.[3] One potentially useful way to protect a nucleoside is by using a protecting group which spans the 3´- and 5´-hydroxy groups. One of the useful groups which can be used as a bifunctional protecting group in nucleosides is the diisopropylsilyl group. Reaction of the nucleoside with dichlorodiisopropylsilane and ***Imidazole*** in DMF gives the protected nucleoside (eq 1).[4] This method has not been widely used; the more common 3´,5´-hydroxy-bridging protecting group is a tetraisopropyldisiloxy group.[5]

(1)

Nucleosides are generally linked together through phosphate linkages. Studies are being directed toward synthesizing alternative linkages that will impart different solubilities to oligonucleotides. A diisopropylsilyl protecting group has

also been used as a phosphate linker isostere (eq 2).[1]

(2)

A diisopropylsilyl group has also been used as a linker in a radical cyclization reaction to form eight-membered rings (eq 3).[6]

(3)

Modified Peterson Alkenation.

The Peterson alkenation is a useful method for the alkenation of carbonyl compounds. Dichlorodiisopropylsilane has been used in a Peterson alkenation modification (eq 4).[7]

Diketene[1]

[674-82-8] · $C_4H_4O_2$ · Diketene · (MW 84.07)

(acetoacetylation reagent; acetylketene equivalent for heterocyclic synthesis)

Alternate Name: 4-methyleneoxetan-2-one.

Physical Data: mp -7.5 °C; bp 69-70 °C/100 mmHg; *d* 1.090 g cm^{-3}.

Solubility: sol most organic solvents; immiscible H_2O, hexane.

Form Supplied in: neat liquid.

Analysis of Reagent Purity: IR (2150 cm^{-1}), NMR.

Preparative Method: via dimerization of ketene.[2]

Purification: vacuum distillation.

Handling, Storage, and Precautions: lachrymator; best stored as a solid (refrigerated) in plastic containers; avoid contamination; prepare for exothermic reactions. Handle in a fume hood.

Acetoacetylation Reagent.

Diketene is most commonly used as a reagent for the acetoacetylation of nucleophiles, including alcohols, phenols, amines, anilines, thiols, and carbanions. ***4-Dimethylaminopyridine***[3] and tertiary amines are often the catalysts of choice, but sodium acetate, sulfuric acid, and a variety of other catalysts can also be used (eq 1). Amines can usually be acetoacetylated at 0-20 °C without any catalyst.

Alternate reagents for acetoacetylation include *t*-butyl acetoacetate[4] and ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one*** (the diketene-acetone adduct). Both are prepared from diketene and are less reactive but easier to handle.

Acetoacetate esters are versatile synthetic intermediates; their chemistry is more thoroughly described elsewhere.[1a,b] Acetoacetate esters can be converted into γ,δ-unsaturated ketones (via Carroll rearrangement, eq 2),[5] into a variety of heterocycles via diazotization/cyclization (eq 3)[6] or the Hantzsch pyridine synthesis (eq 4),[7] or in the direct synthesis of other heterocycles, as discussed below.

(4)

Preparation of Ketene.

Diketene is a convenient laboratory source of ketene. The dimer can be cracked at temperatures above 500 °C in a hot tube with a glowing filament (eq 5) to provide two molecules of ketene, free from the methylketene contaminant which is observed during the preparation of ketene by pyrolysis of acetone.[8]

(5)

Malonic Anhydride.

The ozonolysis of diketene provides malonic anhydride, which can be trapped with nucleophiles at low temperatures to afford malonate half-esters (eq 6).[9]

(6)

Preparation of 3-Methylenepropanoic Acids.

Grignard reagents, in the presence of specific transition metal catalysts, react with diketene to afford 3-substituted 3-butenoic acids (eq 7).[10] The process has been optimized for large-scale synthesis of 3-aryl-3-butenoic acids.[11]

Acetoacetate Dianion Equivalent.

In the presence of ***Titanium(IV) Chloride***, diketene reacts with aldehydes in a ring opening/condensation sequence to provide 4-substituted acetoacetate esters without the need for dianion formation (eq 8).[12] Reaction with ketones requires the use of the corresponding acetals.[13]

Halogenated Acetones and Acetoacetic Acid Derivatives.

Diketene reacts with hydrogen chloride or chlorine to afford acetoacetyl chloride and 4-chloroacetoacetyl chloride, respectively.[14] These compounds can be further chlorinated, initially at C-2, to provide other chlorinated materials (eq 9). This work is thoroughly described in the patent literature.[1a] Workup with alcohols provides chloroacetoacetate esters, while hydrolysis and decarboxylation can be used to prepare substituted acetone derivatives.[15]

Acetone Enolate Equivalent.

The careful hydrolysis of diketene with sodium hydroxide provides sodium acetoacetate which reacts with

electrophiles at C-2 to form unstable β-keto acids; these decarboxylate on workup to provide substituted acetone derivatives (eq 10).[16]

β-Butyrolactone.

β-Butyrolactone, which is a valuable reagent for the preparation of β-hydroxybutyric acid derivatives and polymers, is easily prepared by reduction of diketene over ruthenium (eq 11).[17] Enantioselective reduction processes have been developed.[18] *Caution*: β-butyrolactone is a known carcinogen.

4-Substituted Acetoacetic Acid Derivatives: Radical, Carbene, and [2 + 2] Photocycloaddition.

Radical and carbene additions, and photochemical [2 + 2] reactions of diketene, all involve the exocyclic methylene group of the diketene molecule. Carbene[19] and nitrene[20] additions (eq 12), as well as photocycloaddition (eq 13),[21] give spirocyclobutyrolactones. Ring opening these spirocyclic butyrolactones provides a synthesis of 4-substituted acetoacetates.

Likewise, radical addition to the double bond of diketene provides routes to substituted β-lactones and acetoacetic acid derivatives (eq 14).[22]

(14)

Preparation of Heterocycles.

Diketene is used extensively for the preparation of heterocycles. The products can often be predicted by viewing diketene as an acetylketene equivalent. A leading example is provided for each of several types of heterocyclization; many other substrates react analogously. The reader is referred to more detailed reviews for further discussion.[1,23]

Pyrone and Pyridone Formation via Acetoacetylation of an Active Methylene Group: Dehydroacetic Acid.

The fungicide dehydroacetic acid is prepared via the base-catalyzed dimerization of diketene (eq 15),[1a,24] which is based upon the acetoacetylation of the activated methylene group of a ring-opened diketene molecule. Other 4-pyrones are similarly formed when diketene reacts with compounds containing active methylene groups.[25]

(15)

Likewise, diketene reacts with simple enamines to afford pyrones (eq 16).[26] Enamides, however, more commonly provide pyridones upon treatment with diketene (eq 17).[27] Because of the multiple functional groups normally present during heterocyclic synthesis with diketene, several different products can often be produced, depending on the reaction conditions.

(16)

(17)

6-Methyluracil.

The reaction of diketene with urea to afford 6-methyluracil (eq 18) is one of the classic heterocyclic syntheses which utilizes diketene;[28] many analogous heterocycles can be prepared by reaction of bisnucleophilic species with diketene.

(18)

Preparation of Furanones (Butenolides) and Pyrrolidinones.

Diketene acetoacetylates α-hydroxy ketones[29] and α-hydroxy acids,[30] and α-amino ketones[31] and acids,[32] which undergo intramolecular condensation to afford five-membered heterocycles as shown (eqs 19 and 20).

(19)

(20)

β-Lactams.

The imidazole-promoted reaction of imines with diketene can be used to prepare β-lactams (eq 21).[33]

(21)

Related Reagents.

Acetoacetic Acid; ***Ethyl Acetoacetate***; ***Ethyl 4-Chloroacetoacetate***; ***Methyl Dilithioacetoacetate***; β-***Methyl***-β-***propiolactone***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

Robert J. Clemens

Dilithioacetate[1]

[31509-80-5] · $C_2H_2Li_2O_2$ · Dilithioacetate · (MW 71.92)

(metalated species used to elaborate or functionally substitute the α-carbon of carboxylic acids;[3] useful for highly substituted examples;[4] possible alternatives for the malonic ester synthesis and the Haller-Bauer, Reformatsky,[23] and Wittig[28] reactions)

Physical Data: colorless solid.

Solubility: slightly sol THF; reacts with H_2O, air (O_2, CO_2), and protic solvents. Ethylene glycol-based solvents may react with lithium amides from which the dianions are formed. Dianions derived from disubstituted acetic acids are soluble in THF; less sol other ether solvents. Most carboxylate dianions are stable up to the boiling point of THF.

Formation and Reactivity.

The metalation of carboxylic acids is a general phenomenon and many aliphatic, alicyclic, araliphatic, and functionally substituted acetic acids have been used in various applications.[1] The intermediate carboxylate dianions are commonly generated by one of four methods: (1) a carboxylic acid and 2 equiv of lithium (sodium) naphthalenide[2] or preferably (2) 2 equiv of LDA;[3] (3) a carboxylate salt and 1 equiv of LDA;[4] (4) a metathetical reaction of a dilithium carboxylate dianion and a metal halide. The more traditional method of reacting 2 equiv of a Grignard reagent with carboxylic acids (Ivanov reagents[1e]) is restricted to examples in which the carboxylate α-protons are relatively acidic, principally arylacetates (pK_a <= 22).[5]

Accordingly, carboxylate dianions have been formed (method 3) from ***Lithium Diisopropylamide*** and Li, Na, K, Ca, Mg, and Zn carboxylates. Metathesis of dilithium dianions with ***Copper(I) Iodide***, ***Zinc Chloride***, and several other metal halides produced carboxylate dianions with more selective reactivity.[6-8] Monosubstituted acetic acids yield dilithium or lithium-sodium dianions with limited solubilities, presumably due to polymeric aggregation of the metalated species.[9,10] HMPA has been recommended as cosolvent.[9] Monosubstituted acetic acids with bulky substituents (Ph, *t*-Bu) and disubstituted acetic acids form soluble (THF) dianions. Glycol ether solvents may react with LDA and THF is preferred.[11,12] LDA is preferred as base[1c] and, although more hindered bases[13] may be necessary for special applications, amines from less hindered lithium amides can react competitively with some electrophiles (TMSCl).[11] The lithium amide of hexamethyldisilazane is not sufficiently basic (pK_a &egt; 26 (THF))[14] for general use

(LDA, pK_a &egt; 36 (THF)).[15] In examples where the carboxylate dianion is soluble, as little as 3 mol % of the amine can be used for metalation (eq 1).[1c] The latter is a useful variation for reactions with highly reactive electrophiles where diisopropylamine might compete for electrophiles (acylation).[16]

$$Me_2CHCO_2Na + LDA \xrightarrow[25\text{-}30\ ^\circ C]{BuLi} i\text{-}Pr_2NH + [Me_2CCO_2]^{2-}\ Li^+Na^+ \quad (1)$$

Unsaturated carboxylic acids as their Cu dianions react selectively at the γ-rather than the α-position with allyl bromide and vinylic epoxides[6,7] The reaction occurs by an S_N2' process and the yields and selectivity are impaired with substituted allyl bromides. Other electrophiles react poorly; however, unsaturated ketones react with the Cu dianion of acetic acid[8] predominantly by 1,2-addition.

LDA or LTBA metalation of Zn or Mg carboxylates offers considerable promise because they are soluble.[17,18] Small, aliphatic carboxylic acids, aromatic, and arylacetic acids form crystalline zinc carboxylates as their TMEDA complexes which are soluble in THF and hot toluene (eq 2). Butyric acid and larger aliphatic zinc carboxylates are soluble in hot toluene without TMEDA. The lithium amide displaces TMEDA as ligand on metalation and an additional equivalent abstracts the α-protons (eq 3). Reaction with carbonyl compounds provides adducts in yields equivalent to the Reformatsky reaction (eq 4). This metalated species is especially useful for acetic and propionic acids. Unlike alkali metal dianions, alkylation is not selective and disubstituted products are formed except when activating substituents are present (R = Ph). Like *t*-butylacetate anion,[19,20] alkylation of acetic acid dianion (**1**) (R = H) fails in the absence of dipolar solvents.

$$RCH_2CO_2H + ZnO + TMEDA \xrightarrow[90\text{-}95\%]{\Delta,\ toluene} [RCHCO_2]_2Zn \cdot TMEDA \quad (2)$$

$$[RCHCO_2]_2Zn \cdot TMEDA + 4\,LTBA \longrightarrow [(RCHCO_2)_2Zn\,(NH\text{-}t\text{-}Bu)_2]^{4-}\ 4Li^+ \quad (3)$$

R = Me, H

(1)

(4)

Reactions with Electrophiles.

Carboxylate dianions have been treated with many electrophiles,[1] but reactions with alkyl halides and carbonyl compounds have been used most widely. Most common carboxylate dianions have been reported to react successfully except acetic acid and cyclopropanecarboxylic acids where carboxyl derivatives must be used with few exceptions.[21] Carboxylate dianions are especially useful where forcing conditions are required, as in reactions with epoxides,[22] or in reactions with carbonyl substrates where hydrolysis of a carboxyl derivative causes product degradation.[23] Carbonyl addition is sensitive to steric effects, but steric hindrance must be severe to prevent adduct formation (eq 5).[23] The adduct may cyclize spontaneously on isolation, forming a β-lactone in highly constrained examples.[23b]

(5)

A *C*-silylated analog, the trimethylsilylacetic acid dianion (**2**), forms carbonyl adducts which undergo spontaneous Peterson elimination (eq 6).[24] Mixtures of (*E*) and (*Z*) products are obtained. The limited accessibility of (**2**) has been overcome by use of a softer, *C*-silylating reagent (eq 7)[25]

(6)

(7)

Unsaturated carboxylate dianions have been used to demonstrate the reversibility of carbonyl addition. The α:γ ratio of adducts depends on the metal ion, temperature, solvent polarity, time, and steric effects (eqs 8 and 9).[26] Reaction with

aldehydes gives *threo* products predominantly, and the *threo*:*erythro* ratio can reach 49:1 if the substituents are sufficiently large and thermodynamic conditions are used (eq 10).[27] The major *threo* isomer (**5**) can produce either *trans* (**8**) or *cis* (**9**) alkene in many cases (eqs 11 and 12). Formation of β-lactone (**7**) is a general reaction[28] and *cis* elimination of carbon dioxide makes this sequence a useful alternative to the Wittig reaction.[28] Use of DMF acetals or DEAD effects an *anti* elimination through a charged intermediate and produces (*Z*)-alkene (**9**).[29] Lactones (**7**) can be alkylated stereospecifically (eq 13) if the lactone is sufficiently stable.[30,31] Combination of these procedures allows substantial control to be exercised over syntheses of di- and trisubstituted alkenes.

(12)

(13)

Alkylation of carboxylate dianions in which one cation is lithium and the other an alkali metal is a simple synthetic operation.[1] Many primary and secondary halides (tosylates) have been used and success is independent of the leaving group and the order of introduction of the substituents.[1c] Further, successful reaction does not depend on obtaining a homogeneous solution of the dianion. Simple functionally substituted (ethers, double bonds, acetals, carboxylates) alkylating agents can be accommodated. Alkyl halides sensitive to elimination proceed normally unless steric hindrance in the dianion is extreme.[4] The stability of carboxylate dianions is important in uses with epoxides[22] or acylaziridines[32] where extended reaction times or forcing conditions may be necessary (eq 14). The scale and low temperatures are not important requirements. The production of the hypolipidemic agent gemfibrozil uses typical reaction conditions (eq 15).[1 7,33]

(14)

(15)

Chiral Syntheses.

Asymmetric syntheses with carboxylate dianions requires a chiral amide that can also act as a chiral auxiliary by remaining associated with the dianion without being covalently bonded to it. Carbonyl addition gave as much as 85% ee in a carefully chosen model (eq 16).[34] Alkylation is much less stereospecific than carbonyl addition and it proved to be much less selective in the formation of a chiral product (eq 17).[35]

1,4-Dilithiobutane[1]

[2123-72-0] · $C_4H_8Li_2$ · 1,4-Dilithiobutane · (MW 69.99)

(converts various functional groups into cyclopentanes and synthetic metallacyclopentane intermediates; useful synthon for preparing α,o-bifunctional compounds; precursor of other organobimetallic reagents)

Alternate Name: 1,4-butanediyldilithium.

Solubility: sol ether, THF, hydrocarbons.

Form Supplied in: generally prepared in ether and used in solutions which range from 0.5 to 1.2 M.

Analysis of Reagent Purity: titration;[2,3] ^{1}H NMR: α-CH_2 signals at δ -0.8 to -1.1 ppm;[4] quenching with chlorotrimethylsilane;[2,3,5] GLC.[6]

Preparative Method: see ***1,5-Dilithiopentane***.

Handling, Storage, and Precautions: solutions are highly flammable and must be stored and handled in the absence of proton sources, carbon acids, and oxygen. Flasks and Schlenk tubes should be flushed with dry Ar or N_2. At -20 °C, ether solutions have a useful life of 1 to 4 months.[5,7] At higher temperature (~30 °C), organolithiums react readily with ethers.[8]

Structure.

MO calculations suggest for 1,4-dilithiobutane a doubly bridged structure which is 34.6 kcal mol^{-1} more stable than the extended form (eq 1).[9] That structure, along with others,[1a] would be responsible for the relative stability of the reagent.

(1)

Synthetic Applications.

Organolithium and organomagnesium bifunctional compounds usually react with various carbon electrophiles and metal halides in a comparable manner, whether as such or as biscuprates, and are often used interchangeably. However, because of a generally more convenient method of preparation, di-Grignard reagents are more widely used in organic synthesis (see ***1,4-Bis(bromomagnesio)butane*** and ***1,5-Bis(bromomagnesio)pentane***).

Cyclopentane Derivatives.

1,4-Butanediyldilithium can directly lead to cyclopentane derivatives by consecutive additions to dielectrophiles such as esters, lactones, and anhydrides, to give 1-substituted cyclopentanols. This annulation strategy has been successfully used for the synthesis of spiro compounds. Thus a spirobutenolide is readily prepared from 1-ethoxy-2,5-dihydrofuran-2-one and 1,4-dilithiobutane (eq 2).[10]

(2)

Organobiscuprates.[11]

1,4-Dilithiobutane, as organobiscuprate, reacts directly with ***Carbon Monoxide*** to give cyclopentanone, but yields are low (eq 3).[12] For the formation of cycloalkanones, the reaction between a metallacycle and carbon monoxide is much more efficient (see eq 5, below).

(3)

In presence of ***Phenylthiocopper(I)*** (2 equiv),[13] 1,4-dilithiobutane affords the corresponding organobis(heterocuprate), as formulated in eq 4, which reacts with β-bromocyclopent-2-en-1-one, 3-chlorocyclohex-2-en-1-one, and 3-chloro-5,5-dimethylcyclohex-2-en-1-one to form spiro[4.4]nonan-2-one, spiro[4.5]decan-7-one, and 9,9-dimethylspiro[4.5]decan-7-one (eq 4), respectively, in excellent yields.[14] This annulation methodology was applied to 3-bromo-2-methylcyclopent-2-en-1-one and 3-chloro-2-methylcyclohex-2-en-1-one to form 1-methylspiro[4.4]nonan-2-one and 6-methylspiro[4.5]decan-7-one with similar results.

(4)

Metallacyclopentanes.[15]

The synthesis of various metallacyclopentanes starting with metal halides constitutes an important and useful application of 1,4-dilithiobutanes.[16] These metallacycles readily produce cyclopentanones via carbonylation. The formation of hexahydroindan-3-one illustrates such an approach (eq 5).[5]

(5)

The reaction of 1,4-dilithiobutane with ***Chlorotriphenylsilane*** provides, as major product, the corresponding silacyclopentane rather than the expected 1,4-bis(triphenylsilyl)butane (eq 6).[17]

(6)

α,ο-Bifunctional Compounds.

1,4-Dilithiobutane has also been used for the preparation of α,ο-bifunctional compounds such as 1,6-hexanedioic acid and 1,6-hexanedial (see ***1,5-Dilithiopentane***). This procedure is typified by the transformation of 1,10-phenanthroline to 1,4-bis(1,10-phenanthrolinyl)butane, which was further transformed to a molecular trefoil knot (eq 7).[18]

(7)

Organocopper/Zinc Reagents.[19]

1,4-Heterobimetallic reagents of zinc and copper were prepared by reaction of 1,4-diiodobutane with ***Zinc*** dust in THF and subsequent transmetalation with CuCN.2LiCl (see ***Copper(I) Cyanide***) (eq 8). This reagent, which contains two different metals, undergoes selective coupling with electrophiles (E^1) such as aldehydes, iodoalkynes, enones, and nitroalkenes, leading to a monocoupled zinc and copper organometallic compound. Exposure of this intermediate to a second electrophile (E^2) provides the corresponding polyfunctional compound. The second electrophile may be ***Allyl Bromide***, 3-iodocyclohex-2-en-1-one, ***Chlorotrimethylstannane***, or benzaldehyde.[20] Less than 5% of symmetrical dicoupling adducts are observed as byproducts.

A typical example of this type of coupling involves the use of this reagent with cyclohex-2-en-1-one (E^1) and α-(bromomethyl)acrylate (E^2) (eq 9).

Related Reagents.

The quaternization methodology based on organobis(heterocuprates) is fairly general. Thus spiroannulation can be achieved with a variety of unsaturated organodilithio reagents such as 1,4-dilithiopent-4-ene (eq 10), 1-lithio-2-(2-lithiophenyl)ethane (eq 11), and 2,2´-dilithiobiphenyl (eq 12) providing, respectively, 1-methylenespiro[4.5]decan-7-one, spiro[cyclohexane-1,1´-indan]-3-one, and spiro[cyclohexane-1,9´-fluoren]-3-one.[12]

Lithium α-Lithiomethanenitronate[1]

[-] · $CHLi_2NO_2$ · Lithium α-Lithiomethanenitronate · (MW 72.91)

(highly nucleophilic derivatives of nitromethane and of other primary nitroalkanes[2] for alkylation,[2-6] hydroxyalkylation,[2,5,7-12] and acylation[2,5,8,13])

Preparative Methods: the reagent may be generated in THF solution.[4,10,12] A solution of the nitroalkane in THF is treated with ~2 equiv ***n-Butyllithium*** or ***Lithium Diisopropylamide*** at temperatures between -75 and -95 °C; the yields of the subsequent reactions are higher when the double lithiation is carried out in the presence of the cosolvent HMPA or, preferably, of the nonmutagenic ***N,N´-Dimethylpropyleneurea*** (DMPU).[14] The solutions are usually bright yellow and are stable for a few hours at temperatures below about -50 °C; evaporation of the solvents at low temperature leads to residues which decompose spontaneously.

Reactivity of Doubly Lithiated Nitroalkanes (1).

While nitronates (**2**) are readily generated from nitroalkanes (**3**) (pK_a &AApprox; 10), their C-nucleophilicity is generally poor.[1,15,16] Alkylations of (**2**) with alkyl halides occur preferentially on oxygen, but the addition to aldehydes and ketones is highly reversible; the acylation is only possible with acylimidazolines or other special reagents.[1,17] The most useful reaction of (**2**) is their Michael addition to α,β-unsaturated carbonyl compounds. There have been several preparative improvements in recent decades: the use of silyl nitronates (see ***Trimethylsilyl Methanenitronate***), employment of new catalyst systems such as Al_2O_3 and ***Potassium Fluoride***,[15] application of high pressure,[18] and the use of dilithio derivatives (**1**). They are highly nucleophilic and react at carbon irreversibly with all electrophiles tested, including alkyl halides,[2-6] aldehydes and ketones,[2,5,7-12] acid chlorides,[2,5,8,13] and halogens such as bromine:[19] with α,β-enals[5] and α,β-enones[8] they add in a 1,2- not in a 1,4-fashion. The structure of reagents (**1**) is unknown; thus in the formulae used here they are shown with the lithium at carbon, since this is where reactions with electrophiles occur.

(1)

(2)

(3)

Applications of Simple Dilithionitronates (1) in Synthesis.

Some products from reactions of the lithiated lithionitronates with electrophiles are shown in the accompaning equations. Thus nitropropane can be hexylated to give 3-nitrononane (**4**) in 50% yield (eq 1).[3,4] Nitropropane was also added to cyclohexenone to yield (52%) the unsaturated nitro alcohol (**5**), a type of compound not available by any other nitroaldol-forming method (eq 2).[8]

(4)

(1)

(5)

(2)

The 1,4-adduct of BuLi to 1-nitro-1-butene can be further lithiated in situ to form a doubly lithiated reagent (**6**) which is acylated by methyl 2-methylpropanoate, with formation after aqueous workup of the nitro ketone (**7**) in an overall yield of 30% (eq 3).[8] An application of nitroalkane *C*-acylation[2,5,8,13] to the synthesis of *rac*-amino acids is exemplified with the aminoheptanoic ester (**8**), prepared in two steps (50% yield)[13] from nitrohexane and methyl chlorocarbonate (eq 4).

Dilithionitronates Bearing Additional Functional Groups.

The doubly lithiated nitroalkanes can also be generated from precursors containing additional functional groups. For instance, 1-nitro-2-propene gives a reagent (**9**), which was added to benzophenone to give the otherwise not accessible nitroaldol adduct (**10**) in 53% yield (eq 5).[8] More surprising is the fact that nitroalkanes with β-leaving groups, such as trifluoronitroethane,[11,12] can also be doubly lithiated to give rather stable reagents of type (**11**). These may be used for the reactions with various electrophiles mentioned above. Thus the trifluoromethyl-substituted nitroaldol (**12**) with a tertiary hydroxy group could be prepared in 60% yield (eq 6).[12] *Retro*-nitroaldol cleavage occurs readily during bulb-to-bulb distillation (90 °C/10 mmHg).

(6)

(11) **(12)**

Nitroaldol additions of doubly lithiated alkoxyl-substituted nitroalkanes can be highly diastereoselective, as demonstrated by the addition of THP-protected 2-nitroethanol to cyclohexanecarbaldehyde to form (**13**) (64%) (eq 7).[5] Another example is the preferential formation of the (*S*,*S*)-diastereoisomer (**14**) in the allylation of a glyceraldehyde-derived nitro compound (68% yield; dr = 82:18) (eq 8).[6]

O,O-Dilithio-1-nitropropene[1]

[-] · $C_3H_5Li_2NO_2$ · *O,O*-Dilithio-1-nitropropene · (MW 100.96)

(reacts with electrophiles at the β-position; electrophiles may be alkyl halides, aldehydes, ketones, α,β-unsaturated aldehydes and ketones, esters, and nitroalkenes[1-10])

Alternate Name: N,N-[bis(lithioxy)]-1-propenylamine.

Preparative Methods: generated by α,β-double deprotonation of nitroalkanes with BuLi or LDA.

Generation of Reagents (1) from Suitable Nitroalkanes.

Treatment of nitroalkanes with excess strong base may lead to α,α- or α,β-double deprotonation (eq 1). With simple nitroalkanes (**2**) (R = H or alkyl) the isomeric dilithio derivatives (**1**) and (**3**) can be generated selectively by reversing the mode of addition of the reagents. The lithium lithionitronate (**3**) is formed when 2 equiv ***n-Butyllithium*** are added to a solution of the nitroalkane in THF/HMPA or ***N,N´-Dimethylpropyleneurea*** (DMPU) at -90 °C,[6,11] while the bis(lithioxy)enamine (**1**) is generated when the nitroalkane is added to the solution of 2 equiv BuLi under otherwise identical conditions (eq 2).[10] With nitroalkanes (**4**) bearing an additional acidifying group R^2 in the β-position, such as vinyl[4] or aryl[2,3,5] or methoxycarbonyl,[3,6,7] the base (BuLi[2-5] or ***Lithium Diisopropylamide***[3,6,7]) can be added to the nitroalkane solution for the α,β-double deprotonation. If there is just one α-nitro CH proton in (**4**) (R^1 &neq; H), only α,β-deprotonation can occur; in this case, 1 equiv of BuLi is used for the first deprotonation, followed by 1 equiv of ***t-Butyllithium*** for the second deprotonation.[8,9] In Table 1 the conditions for different nitroalkanes are listed. The solutions of reagents (**1**) are all colored from light yellow to deep red; they are stable for some hours at temperatures below -50 °C. The structure of reagents (**1**) is unknown; thus in the formulae used herein they are shown with both lithiums at oxygen, because of the known affinity of lithium for oxygen.

(1) (2) (3) (1)

Table 1 Conditions for Generation of Dianion Derivatives

Substitution pattern of nitroethane moiety (4) R^1	R^2	Conditions for a,b-double deprotonation
H	H or alkyl	inverse addition of nitroalkane to 2 equiv BuLi
H	vinyl or aryl	2 equiv BuLi added
H	CO_2Me	2 equiv LDA added
alkyl or	H $(CH_2)_n$	1 equiv BuLi, then 1 equiv *t*-BuLi

Reactions of α,β-Doubly Deprotonated Nitroalkanes with Electrophiles.

The chemistry of doubly lithiated methyl 3-nitropropanoate (**1**) (R = CO_2Me) is covered in the article on ***Methyl 3-Nitropropanoate***. The reagents (**1**) are formally enamines with two LiO substituents on nitrogen; they are *much* more reactive nucleophiles than normal enamines and have been called super-enamines.[2] These reagents are also, formally, doubly reduced nitroalkenes (other reagents are formally doubly reduced unsaturated carbonyl compounds;[1c,1d,12] we have occasionally called such systems LUMO-filled π-systems[1c]). As outlined in eq 3, they provide nucleophilic reactivity in the β-position of a nitro group. Nitroalkenes, on the other hand, are highly reactive electrophiles, so that the reactivity of the dilithio derivatives (**1**) constitutes an umpolung[13] of nitroalkene reactivity (eq 3).

(3)

An example of the preparation of a homo-nitroaldol from a simple nitropropane is shown in eq 4.[10] The nitroalcohol (**5**) is isolated in 77% yield, with essentially no isomeric ordinary nitroaldol being formed; the diastereomer ratio (dr) is poor (2.6:1).

(4)

(5)

More complex nitroalcohols of this type are produced when nitrocyclopentane and nitrocyclohexane are doubly lithiated and added to benzaldehydes to give (**6**) (40% yield, dr = 4:1) and (**7**) (32% yield, dr > 20:1),[8] or when 1,1,1-trifluoro-2-nitropropane is employed (see (**8**) in eq 5) (20% yield, dr = 3:1).[9] A special demonstration of the reactivity umpolung is the preparation of an unsymmetrical 2,3-diaryl-1,4-dinitrobutane (**9**) from 2-phenylnitroethane and a 2-arylnitroethylene (65% yield) (eq 6).[5]

(6)

(7)

(5)

(8)

(6)

(9)

Finally, in eq 7 the reactivity of the butadiene derivative (**10**) is outlined; from the bright red solutions of this reagent and electrophiles the isomeric 2-vinylnitroalkanes and 1-nitro-2-alkenes are obtained in varying ratios.[4] Remarkably, only the regioisomer resulting from reaction at the 4-position is formed in the Michael addition to cyclic (five- through seven-membered ring) and open-chain α,β-enones.[4,14] The product (**11**), isolated in ~50% yield with cyclohexenone, has been converted to the 1,7-dicarbonyl derivative (**12**) by Nef reaction[4,14] carried out under the McMurry conditions.[15]

1,5-Dilithiopentane[1]

[2223-58-7] · $C_5H_{10}Li_2$ · 1,5-Dilithiopentane · (MW 84.02)

(constructing block agent: transformations of carboxyl groups and metal halides into cyclohexane and metallacyclohexane synthetic intermediates, and α,o-bifunctional compounds; in presence of Cu^I ion, the reagent is transformed into an organobiscuprate)

Alternate Name: 1,5-pentanediyldilithium.

Solubility: sol ether, THF, hydrocarbons.

Form Supplied in: prepared in ether and used in solutions which usually range from 0.5 to 1.2 M.

Analysis of Reagent Purity: titration;[2] ^{1}H NMR α-CH_2 signal δ -0.81 (t, *J* = 9 Hz);[3] quenching with chlorotrimethylsilane;[3,4] GLC.[5]

Preparative Methods: was first prepared by direct reaction of 1,5-dibromopentane with ***Lithium*** metal at 0 °C in anhydrous ether.[4,8] This method was later improved by using lithium metal (4 equiv) containing 1% Na with 1,5-dichloropentane (1 equiv).[5] The optimum procedure[9] uses a 12.5% excess of lithium and maintains the temperature at 0 °C (eq 1). Yields up to 90% can be obtained by this method, which may also serve to prepare lower analogs.

The Barbier procedure, under ultrasonic irradiation, may also be used. In a particular case, 1,5-dibromopentane (2 equiv), methyl *R*(-)-2-methyloctanoate (1 equiv) and lithium (8 equiv) were reacted in THF at -25 °C for 25 min (see eq 3).[10]

1,5-Dilithiopentane can also be prepared by lithium-iodine exchange between ***t-Butyllithium*** and 1,5-diiodopentane (eq 2).[3] This method requires a temperature of -78 °C and 4 equiv of *t*-BuLi.[2] The excess of reagent is important, as a stoichiometric amount leads to the corresponding cycloalkane almost quantitatively.

The procedure also generates, in excellent yields, lithio compounds from homoallylic-type iodides. Alkyl bromides and secondary iodides may also be used, but yields are lower.

Handling, Storage, and Precautions: solutions are highly flammable; must be stored and handled in the absence of proton sources, carbon acids, and oxygen. Flasks and Schlenk tubes should be flushed with dry Ar or N_2. At -20 °C, ether solutions have a useful life of one to four months.[5,6] At higher temperature (~30 °C), organolithiums react readily with ethers.[7]

Synthetic Applications.

1,5-Dilithiopentane converts various electrophiles and bis(electrophiles) into cyclohexane and spirobicyclic compounds. It is also useful for the preparation of α,o-bifunctional compounds and other organobimetallic reagents.

Cyclohexane Derivatives.

1,5-Dilithiopentane reacts as a bis(nucleophile) with geminal bis(electrophile), providing cyclohexane derivatives, as is exemplified in eq 3, with a chiral ester as substrate.[10]

Cyclohexanone can also be prepared in modest yield from 1,5-dilithiopentane and ***Carbon Monoxide***.[11]

Unlike smaller rings, six-membered metallacycles are not available through cycloaddition reactions. They are formed by the reaction of metal dihalides with appropriate organobismetallic reagents such as 1,5-dilithiopentane.[12] The deuterated 1,5-dilithiopentane in eq 4 was used in a mechanistic study of the thermal decomposition of metallacycles.[13]

α,o-Bifunctional Compounds.

1,5-Dilithiopentane reacts readily with ***Chlorotrimethylsilane*** to produce 1,5-bis(trimethylsilyl)pentane. This reaction has been used to titrate the reagent (eq 5).[3,4] 1,5-Bis(trimethylstannyl)pentane was produced in a like manner (80%) from ***Chlorotrimethylstannane***.[3]

1,5-Dilithiopentane is less prone to cyclization than 1,4-dilithiobutane, as is shown by the reactions of the two compounds with ***Chlorotriphenylsilane***.[14] Thus 1,5-dilithiopentane gives mainly (75%) 1,5-bis(triphenylsilyl)pentane (eq 6) while the parent compound, under the same conditions, furnishes 1,4-bis(triphenylsilyl)butane in only 19%, the main product of the reaction being the cyclic product 1,1-diphenyl-1-silacyclopentane (see also ***1,4-Dilithiobutane***).

α,o-Diketones can be easily produced by the reaction of an organobiscuprate with an acyl chloride.[15] Thus 1,5-dilithiopentane, in the presence of ***Phenylthiocopper(I)***,[16] reacts with benzoyl chloride to give 1,7-diphenylheptane-1,7-dione (eq 7).[17]

(7)

The yield of open chain products resulting from the addition of 1,*n*-dilithioalkane to at least 2 equiv of substrate may be optimized by performing the reaction in dilute solution.[18]

Heterobimetallic zinc and copper reagents have been prepared from 1,5-diiodopentane.[19] The interesting point with this reagent is that the two organometallic moieties have quite different reactivities. It is thus possible to prepare bis(functionalized) compounds by successively reacting the reagent with two different electrophiles. Very good yields (60-80%) have been obtained with various substrates (eq 8) (see also ***1,4-Dilithiobutane***).

(8)

Spiroannulation.

The first published reaction of 1,5-dilithiopentane involved a cyclization. Thus the preparation of 6-silaspiro[5.5]undecane was realized from 1,5-dilithiopentane and 1,1-dichloro-1-silacyclohexane (eq 9).[8]

(9)

1,5-Dilithiopentane and parent dilithio compounds such as 1-lithio-3-(2-lithiophenyl)propane and 1,5-dilithiohex-5-ene can also be used in their bis(heterocuprate) form. In this manner, various spiroketones have been obtained in good to excellent yields.[6,15] For example, spiro[5.5]undecan-2-one was synthesized with a 74% yield from 3-chlorocyclohex-2-en-1-one and the bis(heterocuprate) prepared by adding, at -78 °C, a THF solution of 1,5-dilithiopentane to phenylthiocopper, also in THF (eq 10) (see also ***1,4-Dilithiobutane***).

The direct and stereoselective synthesis of a known key intermediate of the sesquiterpenes β-vetivane, hinesol, and epihinesol was achieved using this methodology.[20] The desired *cis* stereochemistry was obtained, as expected, based on related work (eq 11).[21]

Related Reagents.

1,4-Bis(bromomagnesio)butane; ***1,5-Bis(bromomagnesio)pentane***; ***1,4-Dilithiobutane***.

1,3-Dilithiopropyne[1]

[58335-31-2] · $C_3H_2Li_2$ · 1,3-Dilithiopropyne · (MW 51.93)

(anionic propargyl coupling reagent[2,3])

Preparative Methods: from allene via dilithiation;[3,4] from propyne via dilithiation;[2,5,6] from 1-bromopropyne via polylithiation.[7]

Handling, Storage, and Precautions: solutions of the reagent are stable at 20 °C and should be handled in the usual way (argon).

Propargylation.

The introduction of a propargylic group as a nucleophile formally requires the protection of the terminal alkyne, e.g. as the trialkylsilylated derivative.[8] An efficient alternative is provided by 1,3-dilithiopropyne, readily available via dilithiation of either propyne or ***Allene***.[2-6] In particular, the dilithio derivative circumvents the general problem of propargyl and allenyl metal derivatives which equilibrate in solution and often give mixtures of alkenes and alkynes on reaction with electrophiles.[9,10]

As a rule, 1,3-dilithiopropyne, originating from propyne, reacts preferentially at the 3-position with various electrophiles, including ***Chlorotrimethylsilane***, epoxides, and alkyl halides (eq 1).[2,5] Poor regiochemical control has been reported when allyl halides are involved.[11] Reaction with carbonyl derivatives leads to the β-alkynyl alcohol (eq 2).[12]

The reagent also undergoes efficient sequential 1,3-dialkylation. After introduction of the first group at the 3-position, subsequent reaction with a variety of electrophiles (***Iodine***, ***Formaldehyde***, RX, epoxide) occurs at the terminal alkynic position (eq 3).[2,6] Dilithio derivatives of 3-substituted propyne also react preferentially at the propargylic carbon site with electrophiles.[5,7,11,13]

(3)

Controlled lithiation of allene produces an active species which also behaves as a propargyl dianion.[14] The presence of hexane was found necessary to obtain pure alkynic derivatives upon alkylation with alkyl halides, including allylic ones (eq 4).[3,15] In the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** or in THF, a 1:3 ratio of allenic/alkynic derivatives results.[3]

(4)

The dilithio derivative, obtained from allene at -55 °C with 2 equiv of ***n-Butyllithium*** in THF, reacts with the lithium salt of carboxylic acids, leading to conjugated allenyl ketones (eq 5).[16,17]

(5)

The general reactivity of 1,3-dilithiopropyne is in line with the propargylide structure.[18] An acetylide structure with a bridging lithium has been calculated for $C_3H_2Li_2$.[19,20]

Related Reactions.

High regiocontrol in favor of propargyl products is also shown by the dilithium reagents prepared from phenyl propargyl sulfide[11] (eq 6) and selenide.[21]

Related Reagents.

Allenyllithium; ***3-Lithio-1-triisopropylsilyl-1-propyne***; ***1-Lithio-3-trimethylsilyl-1-propyne***; ***Propynyllithium***; ***Propynylmagnesium Bromide***.

Dilithium Acetylide[1]

[1070-75-3] · C_2Li_2 · Dilithium Acetylide · (MW 37.90)

(as dianion and as bistrimethylsilyl derivative finds use in the synthesis of variously substituted alkynes,[7] alkenes,[5] γ-diketones,[4] etc.; preferred over its sodium counterpart in reactions with enolizable carbonyls)

Alternate Name: dilithioacetylene.

Physical Data: white crystalline solid; *d* 1.65 g cm^{-3}.

Solubility: insol; used as suspension in THF, Et_2O, liq NH_3, or a hydrocarbon.

Form Supplied in: freshly prepared sample is recommended for good results, although commercially available.

Preparative Methods: from ***Acetylene***:[2] THF (250 mL) is added to ***n-Butyllithium*** (2.0 mol) in ether (1250 mL) maintained at -20 °C and dry acetylene gas bubbled through the solution for 2-3 h to obtain a copious white precipitate. The resulting mixture is boiled under reflux for 12 h to ensure disproportionation of any ***Lithium Acetylide***.

From ***Trichloroethylene***:[3] to 100 mL of 1:1 mixture of anhydrous ether and THF is added 0.6 mol BuLi, cooled to -78 °C, and 0.2 mol ***Trichloroethylene*** in 50 mL of ether is added dropwise over 20 min. The mixture is stirred for 2 h at rt, by which time the flask is full of white solid.

Trichloroethylene as a source is claimed to yield superior results in obtaining dilithioacetylene, as shown by silylating the dianion.

Handling, Storage, and Precautions: highly moisture sensitive; very short exposure to air under good ventilation allowed. Use of freshly prepared solution advised. Use in a fume hood.

γ-Diketone Synthesis.[4]

This is a convenient reagent for preparing synthetically useful γ-diketones not generally accessible by other methods. Dilithium acetylide adds to two moles of aldehyde to give alkynic glycols, which upon catalytic reduction followed by oxidation using Sarett's procedure give 1,4-diketones in moderate to good yields (eq 1).

This approach to γ-diketones is superior to the complementary bis-dithiane route, especially with secondary and tertiary aldehydes.

Substituted Alkenes.[5]

Dilithioacetylene with trialkylboranes gives dilithium ethynylbis(trialkylborates), which on treatment with ***Iodine*** followed by hydrolysis or oxidation give alkenes or ketones. Alkenes thus obtained are a mixture of (*E*) and (*Z*) isomers. However, an alternate methodology using equimolar amounts of ***Cyanogen Bromide*** and ***Sodium Methoxide*** to treat the borate offers a convenient route to obtain (*E*)-alkenes exclusively. If 3 equivs of BrCN to 1 equiv of NaOMe are used, tri- and tetrasubstituted alkenes are formed (eq 2).

The yield for the disubstituted alkene drops considerably if the R group is not primary.

Arylpropargyl Amines.[6]

Therapeutically useful aryl propargylamines are obtainable in virtually quantitative yield by the reaction of dilithium acetylide with *N*-(methoxymethyl)aniline (eq 3). The product propargyl aniline can be further transformed by the same approach to symmetric and unsymmetric aryl diamines. This method is superior to the traditional *N*-alkylation method or the Mannich reaction in terms of yields and simplicity.

Bistrimethylsilylacetylene.[7]

Although alkynide anions are excellent nucleophiles and readily undergo acylation and alkylation with appropriate electrophiles, reactions with tertiary alkyl halides are not synthetically useful because of the competing elimination reaction. However, tertiary alkylation of alkynic carbon is possible via bis-silylalkynes under Lewis acid catalysis in high yields (eq 4).

Bis(1-adamantyl)acetylene is also prepared by this route. This reaction fails with primary or secondary alkyl halides.

Bis(trimethylsilyl)acetylene finds use, inter alia, as a dienophile,[8] and in making iodoethynyltrimethylsilane[9] which, with arylcopper reagents, is used to make arylalkynes.[10]

Dilithium Cyanobis(dimethylphenylsilyl)cuprate

$(Me_2PhSi)_2Cu(CN)Li_2$

[110769-32-9] · $C_{17}H_{22}CuLi_2NSi_2$ · Dilithium Cyanobis(dimethylphenylsilyl)cuprate · (MW 373.97)

(higher-order copper reagent for transfer of a dimethylphenylsilyl group to enones, allenes, alkynes, epoxides, and alkyl halides)

Physical Data: relatively stable reagent at rt; usually prepared in situ at 0 °C.

Solubility: sol THF (-78 °C and above).

Preparative Methods: prepared[1] by adding 0.5 equiv of dry ***Copper(I) Cyanide*** to dimethylphenylsilyllithium in THF (eq 1), which in turn is generated from ***Chlorodimethylphenylsilane*** and ***Lithium*** metal. Analogous bis(trimethylsilyl)cyanocuprates are prepared in a similar manner.

$$2\ Me_2PhSi\text{-}Li \xrightarrow[\text{THF, 0 °C}]{\text{CuCN}} \underset{\textbf{(1)}}{(Me_2PhSi)_2Cu(CN)Li_2} \qquad (1)$$

Handling, Storage, and Precautions: cannot be stored or isolated. Care must be taken to avoid oxygen and moisture in the reaction system. Use in a fume hood.

Structure and Properties of the Reagent.

Low-temperature ^{29}Si, ^{13}C, and ^{1}H NMR spectroscopic techniques have been used to probe the nature of these higher-order cuprates.[2] These studies showed conclusively the facile dissociation-reassociation of ligands on copper. In the presence of ***Methyllithium***, dimethylphenylsilyllithium, and copper(I) cyanide, a mixed metallocuprate is formed (eq 2). The metallocuprate (**2**) preferentially transfers the dimethylphenylsilyl group to enones and 1-alkynes.

$$(Me_2PhSi)_2Cu(CN)Li_2 + MeLi \rightleftharpoons \underset{\textbf{(2)}}{(Me_2PhSi)(Me)Cu(CN)Li_2} \qquad (2)$$

Conjugate Additions to Enones.

In general, the reactivities of lower-order and higher-order cyano silylcuprates are very similar toward α,β-unsaturated ketones in ether (eq 3).[2] In some cases, as with alkynic esters, a higher-order reagent gives higher yields and greater stereoselectivity at -78 °C. When the bis(trimethylsilyl)cyanocuprate (**3**) was added to ethyl 2-butynoate, a high yield of only the (*E*)-isomer was obtained (eq 4).[3]

(3)

(4)

With cyclohexenone, the corresponding lower-order cuprate gave a 58% product yield and, in the case of eq 4, a mixture of (*E*/*Z*) adducts was observed with the corresponding lower-order cuprate. Interestingly, the mixed (dimethylphenylsilyl)(methyl)cyanocuprate (**2**) gave the highest yield (94%) of adduct with cyclohexenone.

Silylcupration of Alkynes.

Higher-order silyl cuprates such as (**1**) add regioselectively to terminal alkynes in a *cis* fashion, and the intermediate vinylcopper species (**4**) may be trapped with electrophiles to give 2,2-disubstituted vinylsilanes (**5**) (eq 5).[1,2] Corresponding reactions with the lower-order cuprate of reagent (**1**) give low yields of regioisomeric vinylsilanes upon protonation.[4]

(5)

Typical electrophiles (E^+) that have been employed are ammonium chloride for protonation (94% yield), ***Iodomethane*** (71%), cyclohexenone (54%), and ***Propylene Oxide*** (89%). An example of trapping a vinylcopper species with an ethyl

acrylate precursor is shown in eq 6 for the synthesis of the vinylsilane (**6**).[4,5]

Silylcupration of Allenes.

As a type of activated alkene, allenes undergo silylcupration with reagent (**1**) to give either vinyl- or allylsilanes.[6] Simple alkylallenes react quickly at -78 °C to give allylsilanes cleanly (eq 7). In this case the silyl group is transferred to the less substituted carbon of the allene.

With allene itself or terminal allenes the regioselectivity is reversed and vinylsilanes are the major products.[7,8] In these cases an intermediate allylcuprate (**7**) is generated which can be quenched with electrophiles such as ***Chlorine***, ***Acetyl Chloride***, or a proton to give products (**8**), (**9**), and (**10**), respectively (eq 8).

(8)

Intermediate (**7**) (R = H) behaves abnormally when reacted with cyclohexenone and iodine. In the former case, 1,2-addition, and not conjugate addition, prevails; in the latter case, an unusual rearrangement occurs to form the 2-iodoallylsilane (**11**) (eq 9).

(9)

Previously, the reactions of reagents (**1**) and (**3**) with 3,3-dimethylallene were reported to give the allylsilane adduct (**12**) initially which, upon trapping with cyclohexenone and acetyl chloride, produced the expected adducts (**13**) and (**14**), respectively (eq 10).[9]

(10)

Silylcuprations of Strained Alkenes.

The reactions between oxabicyclo[3.2.1]octenones and reagent (**1**) and its lower-order analog have been studied.[10] Silylcupration of 8-oxabicyclo[3.2.1]oct-6-en-3-one (**15**) with (**1**) is rapid and is followed by a slower step involving trapping onto the carbonyl group at C-3 to give a ring-closed cyclobutanol product (**16**) along with some of the protonated ketone (**17**) (eq 11).

(11)

Silylcupration of α-methyl substituted derivatives of (**15**) produced intermediates (**18**) which undergo such slow ring closure onto the ketone that (**18**) could be trapped with electrophiles (MeI or H^+). In an unusual oxidation process, treatment of intermediate (**18**) (R^1 = R^2 = Me) with dry silica gel produced the β-hydroxysilane (**19**) in quantitative yield (eq 12). Product (**19**) easily undergoes a base-catalyzed Peterson alkenation to the starting alkene.

In summary, the higher-order silyl cuprates (**1**) and (**3**) tend to be more reactive and more nucleophilic than their lower-order counterparts in silylcuprations and S_N2-like displacements. Both classes of reagents are fairly stable up to ambient temperatures.

Dilithium Pentamethyltricuprate[1]

$Li_2Cu_3Me_5$

[61701-36-8] · $C_5H_{15}Cu_3Li_2$ · Dilithium Pentamethyltricuprate · (MW 279.69)

(highly regiospecific organometallic methylating agent for conjugate addition to enones[2] and enals,[3,4] and for displacement of allylic acetates,[5] carbamates,[5] and lactones[6])

Solubility: sol diethyl ether to -78 °C.

Analysis of Reagent Purity: low temperature NMR spectroscopy in ether indicates a reagent of discrete Me(5):Cu(3) stoichiometry as a structurally complex aggregate.[7]

Preparative Method: to ***Copper(I) Iodide*** (2.0 mmol) in 5.0 mL ether at -78 °C is added a 0.95 M solution of ***Methyllithium*** (3.3 mmol). Insoluble MeCu is initially produced with 1 equiv of MeLi:CuI; subsequent addition of MeLi dissolves most MeCu; a small amount of MeCu remains after complete addition.

Handling, Storage, and Precautions: use immediately following preparation, in a fume hood.

α,β-Unsaturated Ketones.

$Li_2Cu_3Me_5$, formed as an aggregate in ether when the MeLi:MeCu ratio is at least 0.66:1, is a more highly regiospecific conjugate methylating agent for α,β-unsaturated ketones than ***Lithium Dimethylcuprate*** or ***Dilithium Trimethylcuprate***. Rates of reaction for $Li_2Cu_3Me_5$ with enones are comparable to $LiCuMe_2$ and Li_2CuMe_3, even in hindered systems (eq 1).[2]

RM =		
	$LiCuMe_2$	82: 1:17
	Li_2CuMe_3	19:79:2
	$Li_2Cu_3Me_5$	96: 0:4

α,β-Unsaturated Aldehydes.

$Li_2Cu_3Me_5$ is more effective than $LiCuMe_2$ for the conjugate methylation of enals (eq 2). The use of ether-pentane as solvent was found to increase the ratio of 1,4-methylation to 1,2-methylation by $Li_2Cu_3Me_5$ (eq 3).[3,4]

(2)

RM =			
	$LiCuMe_2$	91.5:8.5	90%
	$Li_2Cu_3Me_5$	>99.5:<0.5	90%

(3)

RM =		
	$LiCuMe_2$ (Et_2O, 86%)	36.0:64.0
	$Li_2Cu_3Me_5$ (Et_2O, 85%)	77.5:22.5
	$Li_2Cu_3Me_5$ (Et_2O-pentane, 88%)	95.1:4.9

Allylic Acetates, Carbamates, and Lactones.

The addition of $Li_2Cu_3Me_5$ to allylic carbamates results in exclusively *syn*,δ-methylation, while $LiCuMe_2$ exhibits depressed regio- and stereochemical control (eq 4). The methylation of allylic acetates occurs with similar regio- and stereospecificity using either $LiCuMe_2$ or $Li_2Cu_3Me_5$; however, the displacement of allylic acetates with Li_2CuMe_3 or

$LiCuMe_2$ generally proceeds with less regio- and stereospecificity than the displacement of the corresponding allylic carbamates (eq 4).[5]

a) $R^1 = CONHPh$

$R^2M = LiCuMe_2$	(79%)	57:27:16
$Li_2Cu_3Me_5$	(92%)	>99:<1:0

b) $R^1 = COMe$

$R^2M = LiCuMe_2$	(89%)	0:65:35
$Li_2Cu_3Me_5$	(87%)	<1:66:33

A detailed study of the methylation of various gibberellin allylic lactones by $Li_2Cu_3Me_5$, $(LiCuMe_2)_2$ and $(LiCu_2Me_3)_2$ revealed the following trends (eq 5): (1) attack at the tertiary position C-10 is possible only by an S_N2' pathway; (2) attack at the secondary carbon C-2 is the most favored reaction, whether by S_N2 or S_N2' attack; and (3) the usual S_N2' *anti* displacement[8] by organocuprates can be suppressed and S_N2' *syn* attack at C-2 can be induced by increasing the steric bulk surrounding C-3. Under these steric constraints, S_N2' *syn* attack at a secondary site is a more favorable reaction than S_N2 displacement at the tertiary carbon C-10.[6]

Dilithium Tetrabromonickelate(II)

Li_2NiBr_4

[13826-95-4] · Br_4Li_2Ni · Dilithium Tetrabromonickelate(II) · (MW 392.19)

(source of soft nucleophilic bromide, reacting with epoxides[1] and functionalized aziridines[2] regiospecifically)

Solubility: sol THF.

Form Supplied in: prepared from commercially available LiBr and $NiBr_2$.

Preparative Method: anhydrous ***Lithium Bromide*** (6.96 g, 0.08 mol) and ***Nickel(II) Bromide*** (8.72 g, 0.04 mol) are stirred in dry THF (95 mL) at 25 °C. After 48 h, the stirring is stopped and undissolved solids are allowed to settle. The resulting clear dark blue solution is about 0.4M in Li_2NiBr_4. In reactions, 1.6 equiv of the reagent are typically added per equiv of substrate and allowed to stir at the requisite temperature until completion.[1,3]

Handling, Storage, and Precautions: the reagent should be generated in a dry, inert atmosphere and used directly.

Bromohydrins.

Dilithium tetrabromonickelate was initially developed as a source of soft bromide for use in reactions with epoxides.[1a] It was reasoned that tetrabromonickelate as a source of bromide, along with the presence of a hard but mild electrophile (Li^+), would facilitate ring opening in the presence of other acid sensitive groups. Examples below show that epoxides undergo regioselective ring opening to give bromohydrins in which the bromine adds preferentially to the less-hindered position of the epoxide (eqs 1 and 2).

(1)

In certain acid or base sensitive compounds, other methods, such as the use of alkali metal salts in the presence of dipolar aprotic solvents, are clearly not satisfactory, in that the resultant bromide ion is somewhat hard and can thus function as a base as well as a nucleophile. The consequences of this are seen in eq 3, where cyclization of the product occurs when LiBr in DMF is used, as opposed to clean epoxide opening without secondary cyclization with Li_2NiBr_4/THF.

In a synthetic route to α-enol aldehydes, reaction of α-cyano-α-hydroxymethyl epoxides with Li_2NiBr_4, followed by treatment of the mixture of the two intermediate compounds with pyridine/THF, led to the desired aldehyde (eq 4).[3]

(4)

Aziridine Opening.

Suitably protected and functionalized chiral bis-aziridines, prepared from D-mannitol, were allowed to react with Li_2NiBr_4 in THF. Depending on the protecting group, either chiral polysubstituted piperidines or bis-α-bromoamines were formed (eq 5).[2]

Dilithium Tetrachlorocuprate(II)[1,2]

Li_2CuCl_4

[15489-27-7] · Cl_4CuLi_2 · Dilithium Tetrachlorocuprate(II) · (MW 219.24)

(organic soluble copper catalyst[1] used in catalytic quantities to improve the efficiency of halide[2] and allylic acetate[3] displacements with Grignard reagents; it is used in stoichiometric amounts to open epoxides[4] and aziridines[5a])

Physical Data: d 0.910 g cm^{-3}.

Solubility: sol up to concentrations of 0.5 M in THF.

Form Supplied in: commercially available as a 0.1 M solution in THF.[2a]

Preparative Methods: prepared in THF solution by reaction of ***Lithium Chloride*** (0.2 mol) and ***Copper(II) Chloride*** (0.1 mol).[5b]

Handling, Storage, and Precautions: moisture and oxygen sensitive.

Introduction.

The addition of two or more equivalents of lithium chloride to copper(II) chloride will result in a dark red THF soluble solution of dilithium tetrachlorocuprate.[1,2] Dilithium tetrachlorocuprate has been used most frequently to enhance the efficiency of halide displacements with a Grignard reagent. The reagent is used catalytically in amounts less than 10 mol % and typically it will increase the displacement yield.

Halide Displacements with Grignard Reagents.

The first report describing the use of dilithium tetrachlorocuprate was by Kochi and Tamura in 1971.[2] They described the coupling of *n*-butylmagnesium bromide with *n*-hexyl bromide using Li_2CuCl_4 to afford decane in 78% yield. This report was followed by the use of more complex substrates, including Grignard reagents containing protected ethers, unsaturation, and strained rings with homoallylic halides (eqs 1-3).[6-8] It is noteworthy that displacement predominated over dehydrohalogenation in these cases.

(1)

(2)

(3)

Sterically hindered Grignard reagents were coupled with toluenesulfonates to afford sterols with modified side chains (eq 4)[9] and with benzylic halides resulting in neopentyl derivatives of naphthalenes (eq 5).[10] In this example the copper catalyst reduced homodimer formation (i.e. 1,2-bisnaphthylethane formation).

The benzylic type Grignard reagent derived from 3-chloromethylfuran would not displace an allylic halide unless dilithium tetrachlorocuprate was employed (eq 6).[11]

Functionalized Grignard reagents were efficiently coupled with halides containing an ester (eq 7)[12] or carboxylic acid salt (eq 8).[13] In both cases there was little reaction at the carboxyl termini. The alkenic product from eq 8 was of interest for use in ultra thin-layer photoresists. High purity alkene in which double bond isomers were not present was obtained with Li_2CuCl_4 catalysis.

A vinylic type Grignard reagent was coupled with *n*-octyl iodide to afford 2-substituted 1,3-dienes in high yields. In this example, CuI was not an effective coupling catalyst (eq 9).[14]

(9)

A double displacement was reported by Schlosser using 1 mol % of the copper catalyst (eq 10).[15]

(10)

A cyclic α-halo ether was displaced with the aid of dilithium tetrachlorocuprate. The copper catalyst increased the yield and stereoselectivity for the displacement (eq 11).[16]

(11)

without Li_2CuCl_4	78%	*trans*:*cis* = 40:1
with Li_2CuCl_4	88%	*trans*:*cis* = 90:1

Allylic Acetate and Quaternary Ammonium Salt Displacements.

The first report using dilithium tetrachlorocuprate in allylic acetate displacements was by Schlosser in which *trans*-crotyl acetate was converted into *trans*-2-octene (eq 12).[3] The reaction was reported to be regio- and stereoselective. In

addition to the desired coupling product, the reaction also produced 10% of the carbonyl addition product 5-methyl-5-nonanol. The level of carbonyl addition product could be reduced using stoichiometric amounts of ***Copper(I) Iodide***. The coupling of a (*Z*)-trisubstituted allylic acetate also proceeded with 100% regio- and stereocontrol (eq 13).[17] In this latter example, nerol derivatives containing an allylic acetate were compared with those containing a bromide, sulfonium salt, ammonium salt, and a carbonate. The acetate was superior, both in terms of maintaining alkene geometry and regiocontrol (α- vs. γ-attack).

(12)

(13)

The regiocontrol was rationalized by Backvall, who observed drastic changes in regiochemistry with changes in reaction conditions. Rapid addition of the Grignard reagent resulted in α-attack (eq 14).[18] A slow Grignard addition in the presence of higher catalyst loadings (5 mol % vs. 2 mol %) completely reversed the regiochemistry of the displacement.

(14)

These results were explained by assuming the presence of a monoalkylcopper complex (**1**) and a dialkylcopper complex

(**2**) (eq 15). With rapid addition, there is a buildup of the dialkylcopper species which favors the α-product. Support for this was provided by reacting preformed *n*-Bu_2CuLi with the acetate to afford a 96:4 mixture of regioisomers. A slow addition, on the other hand, will result in predominant reaction via the monoalkylcopper species, which favors γ-attack.

The displacement of allylic acetates was extended to diene systems. A study of all four stereoisomers of 2,4-heptadienyl acetate showed that only the (*E*,*E*) isomer was 100% stereospecific (eq 16).[19] The (2*Z*,4*E*) isomer was the least stereospecific, resulting in a 2:1 ratio of diene isomers (eq 17).

The displacement reported by Roush in which an (*E*,*E*)-diene afforded a mixture of regioisomers may have been improved using the rapid addition technique or by using a preformed copper reagent (eq 18).[20]

(18)

An allylic quaternary ammonium salt was also a good substrate for displacement under dilithium tetrachlorocuprate catalysis (eq 19).[21]

(19)

Epoxide and Aziridine Opening.

When used in excess of stoichiometric quantities, the reagent will open epoxides[4] and activated aziridines.[5a] The epoxide of cyclohexene was opened at rt to afford a *trans*-chlorohydrin in near quantitative yield (eq 20).[4] The opening usually occurs at the least hindered site; however, styrene oxide produced a mixture of chlorohydrins with the secondary chloride predominating. The opening of strained rings was extended to aziridines which are activated as the toluenesulfonamide (eq 21).[5]

(20)

(21)

Cross-Coupling Reactions.

There are only a few reports describing the use of dilithium tetrachlorocuprate as a catalyst for coupling Grignard reagents with vinylic and aryl iodides.[14,22-24] In one report, one of two iodides was replaced using Li_2CuCl_4 (eq 22).[23] An example using a 1,3-diene indicates that palladium catalysis may be more effective for these types of transformations (eq 23).[14]

(22)

R = allyl (84%), Bu (51%)
vinyl (88%)

(23)

with Li_2CuCl_4 45%
with $Pd(PPh_3)_4$ 75%

There is one report in which a carbonylative cyclization was observed, presumably by intramolecular trapping of an acylmetal derivative (eq 24).[24]

Dilithium Tetrachloropalladate(II)[1]

Li_2PdCl_4

[15525-45-8] · Cl_4Li_2Pd · Dilithium Tetrachloropalladate(II) · (MW 262.11) (hydrate)

[123334-21-4]

(catalyst for coupling of aryl- and vinylmercurials with alkenes[2] and carbon monoxide;[3] can cyclopalladate many compounds;[4] can oxidize alkenes[5])

Solubility: sol H_2O, polar organic solvents.

Form Supplied in: commercially available as a hydrate, $Li_2PdCl_4.xH_2O$; red purple solid. *Drying:* at 100 °C and 0.1 mmHg for 24 h.

Preparative Method: very often prepared in situ from 1 equiv of ***Palladium(II) Chloride*** and 2 equiv of ***Lithium Chloride*** in the appropriate solvent (MeOH, EtOH, $MeCO_2H$, THF).

Handling, Storage, and Precautions: is hygroscopic and should be stored in the absence of moisture. Toxicity data are not available.

Coupling of Mercury Derivatives.

Various arylmercurials undergo transmetalation with Li_2PdCl_4 in methanol, ethanol, acetic acid, or THF to form arylpalladium salts. In the presence of alkenes these produce arylated alkenes (eq 1).[6] The reaction is usually stoichiometric in Li_2PdCl_4; however, a catalytic version with ***Copper(II) Chloride*** as a cooxidant has been reported.[7]

(1)

Similarly, organopalladium intermediates derived in situ from 5-mercurated pyrimidine nucleosides and Li_2PdCl_4 in

MeOH react with alkenes and disulfides to produce nucleosides substituted at the C-5 position by carbon[8] or sulfur (eq 2).[9]

(2)

Vinylmercury(II) chlorides, acyclic alkenes, and Li_2PdCl_4 generate halide-bridged dimeric (π-allyl)palladium complexes in high yield.[10] The analogous reaction of monocyclic alkenes affords either (π-allyl)palladium complexes or 1,4-dienes, depending on the reaction conditions employed (eq 3).[2] (π-Allyl)palladium complexes can be prepared by the reaction of Li_2PdCl_4 with bicyclic alkenes,[11] dienes,[12] vinyl- and methylenecyclopropanes[13], vinyl- and methylenecyclobutanes,[14] and dienolsilyl ethers.[15] These π-allyl complexes are electrophilic in character and undergo reaction with a variety of nucleophiles.[16]

(3)

Aryl- and vinylmercurials readily react with ***Carbon Monoxide*** in the presence of Li_2PdCl_4 at atmospheric pressure. α,β-Unsaturated acids are formed in high yields in aqueous THF or acetic acid.[3] Analogous reaction in the presence of alcohols affords α,β-unsaturated esters (eq 4).[17]

(4)

Addition of vinyl- and arylmercurials to vinyl epoxides gives allylic alcohols.[18]

Cyclopalladation.

Tertiary benzylamines,[19] benzalimines,[20] aromatic azo compounds,[21] and substituted furans[22] undergo coordination with Li_2PdCl_4, followed by electrophilic attack of the metal on the *ortho*-position of the benzene/furan ring, to give a cyclopalladated five-membered ring. Cyclopalladation reactions have been extensively reviewed.[4] The system Li_2PdCl_4/NaOAc is most commonly used, acetate acting as a base to facilitate the C-H bond cleavage. The palladation can be performed in methanol, ethanol, acetone, dioxane, and chloroform, as well as in binary water-organic mixtures. As a rule, palladation occurs at ambient temperature. However, heating is required in certain cases. These palladacycles can react with alkenes (eq 5), carbon monoxide, carbon dioxide, halogens, organolithium and Grignard reagents, acid chlorides, and alkyl chlorides.[23]

(5)

Allylic[24] and homoallylic[25] amines and sulfides undergo regiospecific carbopalladation in the presence of stabilized enolates and Li_2PdCl_4 to provide stable five-membered palladacycles (eq 6). This reaction has also been performed

intramolecularly.[26] Pd in these cycles can be replaced by carboxylate[26] (CO, MeOH), hydrogen[24] (H_2 or ***Sodium Borohydride***), or by a substituted vinyl group[26] (***Methyl Vinyl Ketone***, ***Triethylamine***).

(6)

Oxidation of Alkenes.

Alkenes can be oxidized by Li_2PdCl_4 to aldehydes or ketones (Wacker reaction).[5] Because the reagent is expensive, the reaction is usually carried out with a cooxidant, most often $CuCl_2$. In the presence of alcohols, acetals and vinyl ethers may be formed (eq 7).[5b] Intramolecular versions of oxypalladation are known to produce unsaturated lactones. Carboxylic acids with $\Delta^{3,4}$, $\Delta^{4,5}$, and $\Delta^{5,6}$ unsaturation undergo this reaction in aqueous solution.[25,27,28] Cyclization of 2-hydroxychalcones gives flavones (eq 8).[29]

(7)

(8)

Vinylation.

N-Phenylhydroxamic acids can be vinylated in the presence of Li_2PdCl_4 to give derivatives that readily undergo [3,3]-sigmatropic rearrangement to form indoles (eq 9).[30]

Dilithium Tributylcuprate

Li_2CuBu_3

[61288-01-5] · $C_{12}H_{27}CuLi_2$ · Dilithium Tributylcuprate · (MW 248.77)

(organometallic butylating agent for ketones,[1] enol ethers,[2] and organomercurials[3])

Physical Data: in ether, ^1H NMR spectra have shown[4] that Li_2CuBu_3 is not an actual species, but a more complex mixture that can be more accurately represented as a BuLi to BuCu ratio. In pentane, however, Li_2CuBu_3 exists in equilibrium with BuLi and $LiCuBu_2$ (see ***Dilithium Trimethylcuprate***).

Solubility: sol ether, THF, and pentane to -80 °C.

Preparative Method: ***n-Butyllithium*** (3.3 mmol) is added to ***Copper(I) Iodide*** (1.0 mmol) in ether at -40 °C.

Handling, Storage, and Precautions: Li_2CuBu_3 should be used as soon as possible following preparation. Use in a fume hood.

Addition to Ketones and Enol Ethers.

Li_2CuBu_3 behaves similarly to Li_2CuMe_3[5] in enhancing the yield and stereoselectivity in reactions with ketones (eq 1)[2] (see ***Dilithium Trimethylcuprate***). Notable in additions to hindered ketones is a depression of carbonyl reductions with Li_2CuBu_3 compared to the alkyllithium reagent.

(1)

RM =	BuLi, 5 °C, 93%	73:27
	BuLi, -78 °C, 98%	86:14
	Li_2CuBu_3, -78 °C, >99%	97:3

Li_2CuBu_3 undergoes reaction with 2,3-dihydrofuran to yield 3-octen-1-ol in 75% yield.[2] The optimal conditions for reaction use 5.0 equiv of butyllithium per 1.0 equiv CuI. This result raises the possibility that the reactive agent may be a cuprate species possessing a Bu:Cu ratio that is >3 (eq 2).[4,6]

(2)

RM =	$LiCuBu_2$	15%
	Li_2CuBu_3	75%

Alkylation of Organomercurials.

Butylation of alkenyl-, phenyl-, and alkylmercurials with Li_2CuBu_3 proceeds only in moderate yield (40-60%), but nonetheless exhibits an almost tenfold enhancement in yield over that obtained with $LiCuBu_2$.[3]

Dilithium Trimethylcuprate[1]

Li_2CuMe_3

[61278-42-0] · $C_3H_9CuLi_2$ · Dilithium Trimethylcuprate · (MW 122.53)

(organometallic methylating agent for ketones,[2] enones,[3,4] halides,[5] and hydrazones[6] and for cross-coupling reactions with mercury(II) chlorides[7])

Physical Data: in Et_2O, Li_2CuMe_3 exists in equilibrium with MeLi and $LiCuMe_2$.[8] In THF, however, it has been shown by ^7Li NMR that Li_2CuMe_3 is not a discrete species, but an equilibrium mixture of more complex organocuprates which may be more accurately represented as a MeLi-to-MeCu ratio.[9] In this article, Li_2CuMe_3 is employed to represent a 3:1 ratio of MeLi to CuI. It is additionally important to recognize that the varied modes of reaction of Li_2CuMe_3 suggest that different species or mechanisms of reaction may occur under specific conditions with certain reactants. In some cases the course of reaction indicates an initial metal ion-oxygen complexation followed by the addition of MeLi, while in others the reaction of a higher order cuprate appears likely.

Solubility: sol ether and THF to -100 °C.

Preparative Method: to ***Copper(I) Iodide*** (30 mmol) suspended in 100 mL anhydrous ether or THF at 0 °C is added ***Methyllithium*** (90 mmol, 2 M in THF or ether) and the light tan solution is stirred for 10 min before cooling and use.

Handling, Storage, and Precautions: Li_2CuMe_3 should be used immediately following preparation to obtain optimal yields.

Addition to Ketones.

The addition of an organolithium or Grignard reagent to an unhindered cyclohexanone generally leads to the predominant formation of the axial alcohol.[10] However, the 3:2 mixture of $LiCuMe_2$ and MeLi to form the Li_2CuMe_3 complex adds to 4-*t*-butylcyclohexanone to give 94% *trans*-4-*t*-butyl-1-methylcyclohexanol in 91% yield (eq 1).[2] Similar results have been observed with 4a-methyl-*trans*-2-decalone and 2-methylcyclohexanone (eq 2), as well as with various C(3)-substituted cyclohexanones (eq 3).[11]

(1)

RM =	MeMgI, 5 °C	51:49

t-Bu	Li_2CuMe_3	3
H	MeLi	21
H	Li_2CuMe_3	6

Comparable stereoselectivity resulted from the slow addition of MeLi to a solution of ketone and $LiCuMe_2$ and the use of ***Lithium Perchlorate*** and ***Lithium Bromide*** in solution with MeLi.[12] These results suggest a complexation of the ketone by $LiCuMe_2$ followed by rapid addition by MeLi from the least hindered face. Interestingly, Li_2CuMe_3 showed no stereochemical advantage over MeLi in the reaction with 2-methylcyclopentanone.[2] However, methylation of racemic 2-methyl-2-phenyl-1-indanone gave addition predominantly from the least hindered face (eq 4).[13]

(4)

RM =	MeMgBr	78:22
	MeLi	15:85
	Li_2CuMe_3	18:82

Addition to Enones.

Li_2CuMe_3 provides exclusive 1,4-addition to α,β-unsaturated carbonyl compounds.[3,4] While the Li_2CuMe_3 complex has a similar reaction rate to $LiCuMe_2$ for conjugate addition to β-monosubstituted enones in THF, Li_2CuMe_3 yields mostly 1,2-addition for sterically hindered β-disubstituted enones. This regioselectivity is presumably due to the more rapid 1,2-addition by MeLi relative to the sterically demanding 1,4-addition by Li_2CuMe_3. The use of ether as solvent results in an increase in the overall rate of reaction at the cost of a decrease in regioselectivity. This loss of selectivity is presumably a result of 1,2-addition by MeLi (eq 5).[4]

(5)

RM =	$LiCuMe_2$, THF, 3 h	95:0 :5

The reaction of Li_2CuMe_3 with (*Z*)-hexenolide in ether at 0 °C gave a mixture of 4-alkenoic acid and 4-methyl 5-hexenoic acid in 89% total yield (eq 6).[14]

(6)

RM = $LiCuMe_2$ (92%) 88:12
Li_2CuMe_3 (89%) 85:15

Substitution of Halides.

Li_2CuMe_3 generally shows higher reactivity and enhanced yields compared with $LiCuMe_2$ and $Li_2Cu_3Me_5$ in the substitution of alkyl, allylic, vinylic, and aryl halides (eqs 7 and 8).[5]

(7)

RM = $LiCuMe_2$ 21%:14%
Li_2CuMe_3 93%:5%

(8)

RM = $LiCuMe_2$ 0%
Li_2CuMe_3 quantitative

The rate of halogen reactivity was I > Br > Cl > F; THF proved to be the most efficacious solvent investigated, except for substitution of fluorine in which ether was proven to be more effective. Notable exceptions to this generally successful reaction are bromo- and chlorocyclohexane, chloro- and fluorobenzene, and *p*-chloroanisole. These compounds showed either no reaction with any cuprate investigated or halogen-metal exchange which resulted in reduction.

The reaction of 6-substituted 1-heptenes with Li_2CuMe_3 led to varied products, depending on the leaving group, implicating a complex reaction mechanism for this displacement reaction (eq 9).[15] The 6-iodo-substituted compounds produced a reaction profile of products which supports the possibility that the displacement of iodide by Li_2CuMe_3 may proceed through an electron transfer mechanism, while leaving group displacement in the other 6-substituted electrophiles occurs via an apparent S_N2 mechanism.

Li_2CuMe_3	intractable mixture
$MeLi + BF_3 \cdot Et_2O$ then $LiCuMe_2$	78%

Activation of C-N.

It has been shown that Li_2CuMe_3 provides a source of Cu^I which activates C-N bonds in hydrazones toward nucleophilic attack by MeLi in ether.[6] The reaction fails in THF due to the preferential complexation of Cu^I by THF. The final result is a *gem*-dialkylated product. In a subsequent publication,[17] it was shown that addition of Li_2CuMe_3 to aldehyde tosylhydrazones resulted in the formation of hindered cuprates which react smoothly with alkyl halides in the normal cuprate fashion (eq 11).

(11)

The reaction of tosylhydrazones from secondary or tertiary aldehydes give acceptable yields, while unbranched tosylhydrazones result in low yields. The reaction proceeds through an initial 1,2-addition to the C-N bond, followed by selective secondary or tertiary ligand transfer.

Cross-Coupling Reactions with Organomercurials.

The addition of 5 equiv of Li_2CuMe_3 to aryl mercury(II) chlorides in ether followed by quenching with MeLi and oxygen resulted in effective methylation (eq 12).[7,18] In addition, organomercurials produced via oxymercuration of alkenes react readily with Li_2CuMe_3 (eq 13). A compilation of all the reaction types revealed the order of reaction efficiency to be aryl- > vinyl- > primary alkyl- > secondary alkylmercurial. The reactions are proposed to proceed via an initial mercury-copper transmetalation to generate a mixed diorganocopper species which then undergoes a thermal or oxidative elimination to produce the cross-coupled product. The highly stereoselective nature of the reaction is inconsistent with a radical anion chain mechanism for the cross coupling.

Dilithium (Trimethylstannyl)(2-thienyl)cyanocuprate

[112621-93-9] · $C_8H_{12}CuLi_2NSSn$ · Dilithium (Trimethylstannyl)(2-thienyl)cyanocuprate · (MW 350.37)

(reagent for transfer of the Me_3Sn moiety to the β-carbon of α,β-unsaturated carbonyl compounds[1,2])

Solubility: sol THF.

Preparative Method: the higher-order cuprate $(Me_3Sn)(2\text{-Th})Cu(CN)Li_2$ (**1**) (Th = thienyl) can be prepared by the treatment of a solution of ***Hexamethyldistannane*** and thiophene in dry THF with ***Methyllithium***, followed by addition of solid ***Copper(I) Cyanide*** (eq 1).[1] Although the actual structure of the reagent is not known, formula (**1**) is used for convenience and to show stoichiometry. Analogous formulations have been employed for higher-order alkylcuprates.[4] A solution of the reagent in THF is bright yellow in color.

Handling, Storage, and Precautions: the reagent should be prepared using dry THF under an inert atmosphere. Since organotin[3] and cyanide compounds are toxic, work-up of reactions employing the reagent should be carried out in a fume hood.

Reaction with α,β-Unsaturated Carbonyl Compounds.

Reagent (**1**) effects efficient conjugate addition of the Me_3Sn function to α,β-unsaturated ketones, aldehydes, and esters (eqs 2 and 3).[1] In this type of reaction, (**1**) appears to be less reactive than Me_3SnLi[5,6] but more reactive than the lower-order cuprate $Me_3SnCu(SPh)Li$ (**6**) (see ***Lithium Phenylthio(trimethylstannyl)cuprate***). Thus Me_3SnLi converts (**4**) into (**5**) under conditions[5] much milder than those indicated in eq 3, while reagent (**6**) fails to react with (**4**).[6]

(2)

(3)

(2) R = H
(4) R = OEt

(3) R = H, 62%
(5) R = OEt, 91%

Reaction with α,β-Alkynic Esters.

Reagent (**1**) is useful for the stereoselective conversion of α,β-alkynic esters into alkyl (*Z*)-3-trimethylstannyl-2-alkenoates.[1] Although the lower-order cuprate (**6**) also effects this type of transformation,[7] reactions of (**6**) with substrates containing an ether function on the γ-carbon produce mainly the products of PhS transfer.[7] This difficulty is avoided by utilization of reagent (**1**) (eq 4).[1,8] Interestingly, the intermediate derived from the reaction of (**7**) with (**1**) can be trapped with reactive alkylating agents (eq 5).[1] An intramolecular version of this process has also been achieved (eq 6).[1]

(4)

(5)

(6)

Related Reagents.

A number of higher-order mixed (trialkylstannyl)cyanocuprates related in structure to (**1**) have been reported. These reagents, which include the (trimethylstannyl)cuprates $(Me_3Sn)(R)Cu(CN)Li_2$ (**8**) (R = Me)[9] and (**9**) (R = Bu)[9,10] and the (tributylstannyl)cuprates $(Bu_3Sn)(R)Cu(CN)Li_2$ (**10**) (R = 2-Th),[2,11] (**11**) (R = Me),[12,13] and (**12**) (R = Bu),[14-16] have been prepared via a variety of interesting methods[9-14] and have been shown to be excellent sources of the Me_3Sn and Bu_3Sn moieties in reactions with an impressive array of electrophilic substrates. Representative examples are given in eqs 7-11.[9,10,13,14,16]

Dilithium Tris(1-pentynyl)cuprate

[58384-88-6] · $C_{15}H_{21}CuLi_2$ · Dilithium Tris(1-pentynyl)cuprate · (MW 278.79)

(organometallic alkynylating agent for α,β-unsaturated ketones[1] and for displacement of electrophilic amines[2])

Solubility: sol ether to -78 °C.

Preparative Method: to purified ***Copper(I) Iodide*** (10.5 mmol) suspended in ether at 0 °C is added 1-pentynyllithium (30 mmol; prepared from ***n-Butyllithium*** and 1-pentyne).[3]

Handling, Storage, and Precautions: should be used immediately following preparation.

Addition to α,β-Unsaturated Cyclic Ketones.

$Li_2Cu(1\text{-pentynyl})_3$, in ether with HMPA as cosolvent, adds regiospecifically to cyclic enones to produce 1,2-alkylation products in high (85-95%) yield (eq 1).[1] $Li_2Cu(1\text{-pentynyl})_3$, as well as other dilithium trialkynylcuprates, failed to give 1,2- or 1,4-addition products in ether alone.[3,4]

(1)

Synthesis of 1-Alkynylamines.

1-Pentynylamines are formed by displacement of electrophilic amines with $Li_2Cu(1\text{-pentynyl})_3$ in 69-87% yield (eq 2) depending on the amine substrate and the conditions used in the preparation of $Li_2Cu(1\text{-pentynyl})_3$.[2] For example, formation of $Li_2Cu(1\text{-pentynyl})_3$ from 3 equiv of 1-pentynyllithium and 1 equiv of ***Copper(I) Cyanide*** resulted in a 69% yield, while forming $Li_2Cu(1\text{-pentynyl})_3$ from 3 equiv of 1-pentynyllithium and 1 equiv of CuBr.DMS (see ***Copper(I) Bromide***) gave an 87% yield using the same electrophilic amine.

Dilongifolylborane[1]

[77882-24-7] · $C_{30}H_{51}B$ · Dilongifolylborane · (MW 422.55)

(reagent for asymmetric hydroboration of prochiral alkenes[1,2])

Alternate Name: Lgf_2BH.

Physical Data: mp 160-161 °C (sealed evacuated capillary).

Solubility: sparingly sol common organic solvents, i.e. THF, CCl_4, CH_2Cl_2, $CHCl_3$. The suspended material is active.

Form Supplied in: white solid, mp 161-163 °C.

Preparative Method: although now commercially available, the reagent is readily prepared by hydroboration of (+)-longifolene with ***Borane-Dimethyl Sulfide*** ($BH_3.SMe_2$) in a 2:1 ratio (eq 1).

Handling, Storage, and Precautions: guidelines for handling air- and moisture-sensitive reagents should be followed.[1c] The pure reagent is described as an irritant.

Asymmetric Hydroboration.[2]

Dilongifolylborane (Lgf_2BH) is a chiral dialkylborane intermediate in steric requirement between the two widely investigated chiral organoboranes derived from α-pinene: ***Monoisopinocampheylborane*** ($IpcBH_2$)[3] and ***Diisopinocampheylborane*** (Ipc_2BH).[4]

Due to the hindered *exo* face environment of the longifolene double bond, the addition of borane proceeds exclusively from the *endo* face. Even in the presence of excess longifolene, hydroboration stops cleanly at the dialkylborane stage.

The reported levels of asymmetric induction achieved with this reagent in the hydroboration-oxidation of representative alkenes are in the range of 59-78% ee for *cis* and 45-75% ee for trisubstituted alkenes. The highest levels of asymmetric induction have been recorded for *cis*-2-butene (eq 2) and 2-methyl-2-pentene (eq 3).[2]

(2)

(3)

Trisubstituted alkenes such as 2,4,4-trimethyl-2-pentene and 1-phenylcyclopentene, which apparently exceed the steric requirements of Lgf_2BH, fail to react after 4 days at 35 °C.

Although the ready availability of only the (+)-longifolene enantiomer potentially limits the use of Lgf_2BH as a reagent for natural product synthesis, this form proved appropriate for the preparation of an optically enriched intermediate in a synthesis of the naturally occurring enantiomer of verrucarinic acid (eq 4).[5]

(4)

(+)-Longifolene of >99% ee can be liberated from Lgf_2BH which has been diastereomerically enriched by recrystallization from THF at 0 °C (eq 5).[6]

Dimesitylborane[1]

[51458-06-1] · $C_{18}H_{23}B$ · Dimesitylborane · (MW 250.19)

(very selective hydroborating reagent for alkenes and alkynes;[2] preparation of boron-stabilized alkyl and vinyl carbanions[2,3])

Alternate Names: bis(2,4,6-trimethylphenyl)borane; Mes_2BH.

Physical Data: mp 162-164 °C.

Solubility: moderate sol THF (37.5 g L^{-1}).

Form Supplied in: white solid.

Preparative Methods: from Mes_2BF and $LiAlH_4$;[1,2a] Mes_2BH_2Li (Mes_2BF + 2 LiH) and benzyl chloride[2a] or MeI;[2b] Mes_2BF and LiH.[2c]

Purification: recrystallization from 1,2-dimethoxyethane.[1,2a]

Handling, Storage, and Precautions: solid stable in air and in THF but reacts with moisture and protic solvents. Best stored under an inert atmosphere. Use in a fume hood.

Hydroboration of Alkenes.

Mes_2BH is a highly selective reagent for the hydroboration of alkenes.[2a] In general, suspensions of the reagent in THF react slowly with mono- (**1**) and 1,2-disubstituted (**2**) alkenes (8-25 h, 25-65 °C) and reactions are very sensitive to steric factors. The air-stable (and often crystalline) dimesitylboranes which result may be oxidized to alcohols with alkaline ***Hydrogen Peroxide*** (eq 1). Geminally disubstituted alkenes and cycloalkenes react very slowly with Mes_2BH.

(1) (2)

(1)

Alkyl dimesitylboranes of the type produced by these hydroboration reactions also have been found to be useful in the preparation of boron-stabilized carbanions which may be alkylated[3] (eq 2) or converted into alkenes,[4] glycols,[5] or ketones[6] upon reaction with carbonyl compounds. The bulky dimesitylboryl group not only imparts stability to its derivatives but sterically promotes the C_γ-alkylation of allylic carbanions.[7]

(2)

Hydroboration of Alkynes.

Generally, Mes_2BH reacts rapidly (within minutes) with alkynes, giving aldehydes and ketones upon oxidation of resulting vinylboranes (eq 3).[2a] The slow rate of reaction of Mes_2BH with cyclohexanone[2c] suggests that such relatively rapid hydroborations could be conducted in the presence of many common nonacidic functional groups. Compatability with halides,[8] phosphines, and ferrocene[9] has been demonstrated. Unprecedented regioselectivity was observed in the hydroboration-oxidation of 2-hexyne (**3**) where isomeric 2- and 3-hexanone were produced in a ratio of 90:10 (cf. 60:40 with ***Diborane*** and 78:22 with ***9-Borabicyclo[3.3.1]nonane***), making this the most selective hydroborating agent of unsymmetrical alkynes known (see also **4**).[2a]

(3) **(4)**

The directing influence of silyl and stannyl groups has been used regioselectively to prepare α-metallovinylboranes which are precursors of boron-stabilized vinyl carbanions (eq 4).[2b]

The resistance to boron ate-complex formation imparted by the mesityl groups to certain vinyl dimesitylboranes has been shown to enable metal-halogen exchange-initiated nucleophilic addition reactions to the boron-activated double bond (eq 5).[8]

Related Reagents.

9-Borabicyclo[3.3.1]nonane; ***Borane-Dimethyl Sulfide***; ***Borane-Tetrahydrofuran***; ***Dicyclohexylborane***; ***Disiamylborane***.

3,4-Dimethoxybenzyl Bromide

[21852-32-4] · $C_9H_{11}BrO_2$ · 3,4-Dimethoxybenzyl Bromide · (MW 231.09)

(reagent for introduction of 3,4-dimethoxybenzyl protecting group, which can be cleaved selectively under conditions of benzylic oxidation[1])

Alternate Name: DMBBr.

Physical Data: mp 52-53 °C.

Solubility: reactions are usually carried out in polar solvents such as THF or DMF.

Preparative Methods: synthesized from commercially available 3,4-dimethoxybenzyl alcohol and PBr_3[2] or HBr.[3]

Purification: recrystallization from absolute ethanol.[2]

Handling, Storage, and Precautions: the reagent is quite unstable and is best prepared fresh or stored at low temperature under nitrogen. It is a lachrymator.

3,4-Dimethoxybenzyl Ethers (DMB Ethers).

The benzyl group is a frequently used protecting group[4] in organic synthesis due to its acid and base stability, and its facile removal by catalytic hydrogenation or with sodium in liquid ammonia. The group is most commonly used to protect alcohol functions; however, it may not be generally applied to substrates which have other functional groups susceptible to the reductive conditions. To overcome this problem and generally to extend the range of protecting groups available, methoxy-substituted benzyl ethers have been prepared (e.g. the 3,4-dimethoxy[1] and 4-methoxybenzyl[5] (PMB) ethers). DMB ethers are made using the benzyl bromide (or chloride), alcohol, and base,[1] or

with base sensitive substrates using the trichloroacetimidate[6] (see ***Benzyl 2,2,2-Trichloroacetimidate***). PMB ethers can also made in similar fashion under either basic[5] or acidic[7] conditions. DMB ethers can be removed oxidatively using ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** (DDQ)[1,5] or trityl tetrafluoroborate,[5b,c,6,7a] and PMB ethers have also been cleaved with a variety of other methods.[4,8] The products obtained are the methoxy substituted benzaldehyde and the parent alcohol (eq 1), although with an allylic alcohol there is a risk of over oxidation to give the enone (eq 2).[9] Methoxybenzyl ethers with free α- or β-hydroxy groups can be converted to acid cleavable acetals with DDQ oxidation under anhydrous conditions, and further oxidized to base cleavable benzoates.[10] Simple benzyl ethers and many other protecting and functional groups remain unaffected under these conditions.[1,5]

(1)

(2)

Each substituted benzyl ether has a different oxidation potential (1.45 V for the DMB-OR, and 1.78 V for the PMB-OR), so each methoxy substitution pattern results in different rates of ether cleavage.[1,11] This means that the DMB group can be removed in the presence of a PMB ether with high selectivity (eq 3).[1] It has also been shown that other methoxybenzyl ethers react at widely differing rates.[11] For example, the reaction time for the DMB ether was <20 min (86% yield of alcohol), and the 2,6-dimethoxy isomer required 27.5 h (80% yield) (eq 4).[11] Other substitution patterns give reaction times between these two extremes.

(3)

PMB and DMB ethers are less readily cleaved than simple benzyl ethers using catalytic hydrogenation.[12] W-4 ***Raney Nickel*** gave the best selectivities (eq 5), but deprotection using ***Sodium-Ammonia*** showed no discrimination at all.[12]

The versatility of a combination of the substituted and unsubstituted benzyl ethers as protecting groups has been shown in the multi-step syntheses of 16-membered macrolides[13] and other natural products.[14,15] The DMB group alone has also been used as an alcohol protecting group in molecules ranging from the relatively simple[16] to complex oligoribonucleotides,[6,7a] and occasionally for protection of nitrogen-containing groups.[8,17]

3,5-Dimethoxybenzyl 4-Nitrophenyl Carbonate

[6453-62-9] · $C_{16}H_{15}NO_7$ · 3,5-Dimethoxybenzyl 4-Nitrophenyl Carbonate · (MW 333.30)

(amino-protecting group used in peptide synthesis[1])

Physical Data: mp 114-15 °C.

Solubility: sol chloroform, THF.

Preparative Method: by reduction of 3,5-dimethoxybenzoic acid with ***Lithium Aluminum Hydride*** and then acylation of the resulting 3,5-dimethoxybenzyl alcohol with 4-nitrophenyl chloroformate.[1]

N-Protection of Amino Acids.

Reaction of amino acids with the reagent (**1**) in aqueous THF in the presence of ***Sodium Hydroxide*** affords 3,5-dimethoxybenzyloxycarbonyl derivatives in 55-76% yields (eq 1).[1] This protecting group can be cleaved by irradiation with a high-pressure mercury lamp for 1.5 h in aqueous dioxane (42-85% yields). The advantage is provided in that acidic, basic, or reductive reaction conditions can be avoided.

(ambident electrophiles;[1,2] alkylation of S-,[3,4] N-,[5] and O-nucleophiles;[6,7] acylation of C-nucleophiles[8])

Physical Data: mp: (**1**) 20 °C; (**4**) 72 °C; (**6**) 20 °C; (**8**) 151-152 °C; (**10**) 55 °C; (**14**) 88-90 °C; (**15**) dec; (**16**) 89-91 °C.

Solubility: freely sol liquid sulfur dioxide and arsenic trifluoride.[9b,c] When prepared in situ, halogenated solvents such as dichloromethane or 1,1,2-trichlorotrifluoroethane are most commonly used.[2,5b,6a,b,8e,f] With these solvents, however, the reagents are only slightly soluble and usually exist as a slurry at -30 °C. Refer to Olah et al.,[9a] where solubilities follow the trend phosphates > antimonates > borates.

Form Supplied in: the reagents are prepared in situ. They exist as colorless solids when isolated.[6d] Stability of the carbenium ions varies considerably, especially in the substituted analogs.[6,8e,8f]

Preparative Methods: each reagent is conveniently prepared by introduction of the desired Lewis acid such as ***Boron Trifluoride Etherate***, ***Antimony(III) Chloride***, or phosphorus pentafluoride to a cooled solution containing the appropriate orthoformate (or orthoester, R^2 &neq; H).[2] For dimethoxycarbenium bromide, the use of sulfur dioxide at -30 °C is required.[9b] For isolation techniques using a specially designed apparatus, see Pindur and Flo.[10]

Purification: since the reagents are prepared in situ, they are commonly used without further purification. When isolable, the reagents are purified by recrystallization.

Handling, Storage, and Precautions: dialkoxycarbenium salts are hygroscopic and should therefore be kept under an inert atmosphere (Ar or N_2). For optimal results, reaction vessels should be flame dried and purged with argon using anhydrous solvents in all instances.[6a] If isolable, storage in a dry box or a tightly sealed vessel under an inert atmosphere is recommended. Olah et al.[9a] describe the phosphate series to be stable under an inert atmosphere at rt without refrigeration. The borate and antimonate series are generally stable for weeks under an inert atmosphere at 0 °C. All dialkoxycarbenium salts are powerful acylating/alkylating

agents; therefore skin and eyes should be protected when handling the solutions and especially the isolated salts. Use in a fume hood.

Introduction.

Dialkoxycarbenium salts exhibit an interesting dichotomy in reactivity.[2g] These ambident electrophiles are powerful acylating and alkylating agents. The mode of reactivity can be altered depending upon the nucleophile, the reagent, the reaction temperature, the reaction time, and the solvent. Prepared in situ, these salts surpass in reactivity other common alkylating agents such as Meerwein's salt, alkyl triflates, and alkyl halides.[2,6,8] Each cationic component serves as a versatile electrophile which has proven to be an efficient formylating or alkylating reagent. All of the dialkoxycarbenium salts are accessible by judicious choice of orthoester and Lewis acid. Limitations include solubility and stability, which make the commercially available trialkyloxonium tetrafluoroborates attractive (see ***Triethyloxonium Tetrafluoroborate***, ***Trimethyloxonium Tetrafluoroborate***).[7a] However, dialkoxycarbenium salts provide a means for efficient acylation or alkylation of weak nucleophiles not accessible from their parent counterparts.

Alkylation of Sulfur Nucleophiles.

Dimethoxycarbenium tetrafluoroborate has been extensively used in the conversion of numerous thiacyclophanes to polycyclic aromatic compounds.[3c] This method efficiently transforms sulfide linkages into carbon-carbon double bonds via a Stevens rearrangement followed by an elimination step. Using this sequence, dimethyldihydropyrene[3c,d] was synthesized in five steps, two of which involved the formation of a bis(sulfonium)cyclophane intermediate with dimethoxycarbenium tetrafluoroborate (eq 1).

Formation of other bis(sulfonium) salts using dimethoxycarbenium tetrafluoroborate was successfully applied toward the synthesis of other pyrene derivatives such as [2.2]metaparacyclophene-1,9-diene,[3e] [7],[7.7]circulene,[3f] [2.2](2,6)pyridinophene-1,9-diene,[3g] and [2.2.2](1,3,5)cyclophane-1,9,17-triene.[3h] Another example of sulfur activation employing both dimethoxycarbenium tetrafluoroborate as well as hexafluorophosphate has been applied to the synthesis of various organic charge-transfer complexes.[4a,b] Critical for the success of these syntheses is the conversion of various thione derivatives to the corresponding selenone derivatives. Treatment of thieno[3,4-*d*]-1,3-dithiole-2-thione with dimethoxycarbenium hexafluorophosphate afforded the desired thionium hexafluorophosphate, which was subsequently transformed to the selenone analog in the presence of ***Hydrogen Selenide*** (eq 2).

(2)

Activation of the carbon-sulfur double bond with dialkoxycarbenium salts has led to the preparative synthesis of similar analogs. Thioimidates can be prepared by the selective alkylation of thioamides using either dimethoxy- or diethoxycarbenium tetrafluoroborate (eq 3).[4c,d] The products isolated are used as key intermediates in the synthesis of β-lactams. Meerwein's salt also carries out the transformation shown in eq 3. Other examples include the formation of hexachloroantimonate salts via ethylation of dithiolodithione dimers (eq 4).[4e] Lastly, heterolysis of disulfide bonds has been achieved by treatment of a diaryl disulfide with diethoxycarbenium tetrafluoroborate (eq 5).[4f]

(3)

(4)

(5)

Alkylation of Nitrogen Nucleophiles.

Dialkoxycarbenium tetrafluoroborates provide an efficient means for the production of secondary amines through nitrilium salt intermediates.[5b] *N*-Alkylnitrilium salts other than *N*-methyl or *N*-ethyl are not readily accessible using the trialkyloxonium tetrafluoroborates. Treatment of a series of dialkoxycarbenium salts with benzonitrile furnished, after reductive workup, the desired substituted benzylamines (eq 6). Higher analogs such as *n*-propyl did not provide the desired *n*-propylbenzylamine but rather isopropylbenzylamine. This rearrangement does limit applications of other higher-order dialkoxycarbenium salts.

Formation of nitrilium salts has also been applied to the field of organometallic chemistry.[5c] In these examples the reductive workup of the intermediate iminoester with sodium borohydride is eliminated. Diethoxycarbenium tetrafluoroborate is used to perform two nitrogen-based alkylations (eq 7). The resulting complex is isolated and purified by recrystallization.

Another example of activation/reduction is illustrated in the preparation of 1-alkyl-2,1-benzisoxazoline derivatives.[5d] Treatment of 2,1-benzisoxazoles with dialkoxycarbenium hexachloroantimonate affords the desired 1-alkyl-2,1-benzisoxazolium salts, which are subsequently treated with a variety of nucleophilic reagents (eq 8). The following transformation is catalyzed by in situ preparation of either dimethoxy- or diethoxycarbenium salts as well as the related trialkyloxonium tetrafluoroborates. Nucleophilic reagents employed include Grignards, cyanides, malonates, morpholines, and other amine derivatives. The end products were obtained in good yields without appreciable amounts of ring-opened byproducts.

(8)

X = H; R = Me, 89%
X = Cl; R = Ph, 94%

A final example of nitrogen activation of weak organic bases is in the alkylation of *N*,*N*-disubstituted sulfonamides.[5e] The reagent of choice is dialkoxycarbenium hexachloroantimonate because sulfonamides are inert toward Meerwein's salt. Shown in eq 9 is the formation of two hexachloroantimonates from the corresponding *N*,*N*-disubstituted sulfonamides. Subsequent treatment of these salts with aqueous acid effectively cleaves the N-S bond into corresponding amine and sulfonic acid derivatives.

(9)

R = Me, 60%
R = -(CH2)4-, 80%

Alkylation of Oxygen Nucleophiles.

Dialkoxycarbenium hexachloroantimonates are versatile reagents in the alkylation of a variety of oxygen-containing substrates.[6a] Even weak nucleophiles which are inert to trialkyloxonium salts are cleanly and rapidly alkylated. Treatment of diethoxycarbenium hexachloroantimonate with sulfoxides (eq 10),[6a] aldehydes, ketones, esters (eq 11),[6c] and amides (eq 12)[6a] yield alkylated products which can either be isolated as antimonate salts or their subsequent transformation products.

(10)

(11)

(12)

Dimethoxycarbenium tetrafluoroborates are stronger alkylating agents than their parent trialkyloxonium tetrafluoroborates. Interestingly, the preparation of methyl or ethyl Meerwein's salt can be accomplished by treatment of the appropriate dialkoxycarbenium salt with either dimethyl or diethyl ether (eq 13).[7] This procedure has been reported to yield the desired trialkyloxonium salt in very high purity.

(13)

Aryl-substituted dimethoxycarbenium tetrafluoroborates, although sluggish in reactivity due to the steric conjestion about the carbenium center, will alkylate at oxygen.[6b] Treatment of 2,6-dimethyl-4-pyrone with an aryl-substituted tetrafluoroborate salt affords the desired 4-methoxy-2,6-dimethylpyrylium tetrafluoroborate in good yield (eq 14).

(14)

Ar = Ph or 2,4,6-$Me_3C_6H_2$

Acylation of Carbon Nucleophiles.

The foregoing examples illustrate the use of dialkoxycarbenium salts for the selective alkylation of weakly nucleophilic heteroatoms.[2g] In these examples, reaction conditions of thermodynamic control were generally employed. However, when dialkoxycarbenium salts are used under conditions of kinetic control a different type of product is obtained. Under the latter reaction conditions, carbocyclic or aromatic conjugated cyclic and acyclic ketones are converted into protected derivatives of formyl ketones.[8b] Employing diethoxycarbenium tetrafluoroborate prepared in situ with a variety of cyclic (eq 15) and acyclic (eq 16) ketones in the presence of ***Diisopropylethylamine*** at low temperatures in a methylene chloride solution affords the corresponding β-keto acetals.[8c] Other functional groups such as halide, nitrile, alkene, arene, and ester functionalities are compatible with this method. Regioselectivity is governed by steric effects; therefore reaction generally takes place at the less substituted α-position.

(15)

R = H	$n = 1$	45%
R = H	$n = 2$	87%
R = Me	$n = 2$	11%

(16)

R = Me	76%
R = $Me_2C{=}CH$	58%
R = $EtO_2CCH_2CH_2$	59%

This method has been extended to the preparation of α,β-unsaturated aldehydes via β-keto acetals (eq 17)[8c] and some

aryl-substituted bicyclo[3.3.1]nonadienones through an acid-catalyzed cyclization of the α-(diethoxymethyl) ketones (eq 18).[8d]

(17)

(18)

High levels of regioselectivity are observed when reactions between electron-rich heterocycles and dialkoxycarbenium tetrafluoroborates are carried out. From 2-methylindole, several 3-acylated indoles are produced without *N*-alkylation

(eq 19).[8e] Conversion to the desired aldehyde or ketone after initial acylation is observed upon aqueous workup.

(19)

Treatment of 2,3-substituted indoles with diethoxycarbenium tetrafluoroborates results in selective acylation on the nitrogen.[8f] Interestingly, however, upon switching to the dimethoxy derivative, alkylation on nitrogen predominates even in the 2-methylindole series. As the steric size of the carbenium ion increases, for example when switching from dialkoxycarbenium salts to dialkoxyalkylcarbenium salts, one observes a shift from acylation to alkylation as well as a decrease in overall reactivity.

Another interesting variation in the electrophilic reactivity of these ambident reagents exists in the area of anionic acylations. Treatment of dimethoxycarbenium tetrafluoroborate, predominately an alkylating agent, with either lithium cyclononatetraenide[8g] or potassium cyclopentadienylirondicarbonyl[8h] results in the formation of the desired acylated derivatives.

1,1-Dimethoxyethane

[534-15-6] · $C_4H_{10}O_2$ · 1,1-Dimethoxyethane · (MW 90.12)

(reagent for diol protection[1] and condensation reactions[8])

Alternate Name: acetaldehyde dimethyl acetal.

Physical Data: mp -113.2 °C; bp 64.5 °C; *d* 0.850 g cm^{-3}.

Solubility: sol most organic solvents.

Handling, Storage, and Precautions: flammable liquid.

Diol Protection.

1,1-Dimethoxyethane used for the protection of diols as acetals of acetaldehyde can offer advantages over the more commonly employed acetonide protection using ***2,2-Dimethoxypropane*** or ***Acetone***. The acetonides tend to prefer the formation of five-membered rings and thus offer some selectivity for 1,2-diol over 1,3-diol protection. This selectivity is switched for the *O*-ethylidene derivatives. This is believed to result from an elimination of an axial methyl group in the chair conformations of the *O*-ethylidene compounds.[1] This is illustrated in the ethylidenation (eq 1) of L-sorbose. The use of acetaldehyde for this transformation is ineffective.[2] The product of the acetonation of L-sorbose is shown for comparison purposes. Similar selectivity has been observed in the protection of steganone (eq 2).[3] Although a new stereocenter is created and there is the possibility of generating a mixture of stereoisomers, the one with the equatorial methyl group is usually preferred.

Mixed acetals of acetaldehyde can be prepared by reaction of 1,1-dimethoxyethane with another alcohol under acid catalysis. If the alcohol is a tertiary allylic one (eq 3), the mixed acetal loses methanol to form the enol ether which then undergoes a Claisen rearrangement.[4]

The reaction of the bis(trimethylsilyloxy)pyrimidine (eq 4) in the presence of ***Titanium(IV) Chloride*** and the acetal produces the α-methoxyethyluracil in 62% yield.[5]

(4)

Cyanotrimethylsilane reacts with 1,1-dimethoxyethane (eq 5) to afford 2-methoxypropanenitrile in 73% yield if catalyzed by ***Boron Trifluoride Etherate***[6] and in 63% yield if catalyzed by ***Zinc Iodide***.[7]

(5)

Condensation Reactions.

The dimethyl acetal of acetaldehyde serves as a useful surrogate for ***Acetaldehyde*** in a number of Lewis acid mediated condensation reactions.[8] Vinyl ethers are especially receptive partners in these reactions. Methyl vinyl ether reacts to produce the 3-methoxy acetal (eq 6) in 60% yield. This product is also accompanied by 18% of an addition product derived from further reaction of the vinyl ether with the methoxy acetal. The relative reactivity of this acetal as well as a number of other acetals has been reported.[9]

(6)

Trimethylsilyl enol ethers couple with the acetal in an aldol-type reaction to afford β-methoxy carbonyl compounds. These reactions can be effected by the use of a number of different Lewis acids. Some of the Lewis acids that have been employed are $TiCl_4$, ***Tin(IV) Chloride***, ***Zinc Bromide***, ***Triphenylmethyl Perchlorate*** or hexachloroantimonate, and ***Trimethylsilyl Trifluoromethanesulfonate***. The silyloxy diene (eq 7) on treatment with the acetal in the presence of either $SnCl_4$ or $ZnBr_2$ provides the aldol product in 62% and 63% yield, respectively.[10] The bis(thiomethyl)silyloxy diene (eq 8) when treated with trityl perchlorate condenses with 1,1-dimethoxyethane to provide the β-methoxy ketone in 61% yield.[11]

(7)

(8)

Stereoselectivity.

A $TiCl_4$-catalyzed reaction of the silyloxy diene (eq 9) with the acetal results in a 57:43 (*E*):(*Z*) mixture of products in 51% yield. These products are derived from attack at the γ-position of the carbonyl system.[12]

(9)

(E):*(Z)* = 57:43

The reaction of the silyl enol ether of *t*-butyl acetoacetate, trimethylsilyl triflate, and the dimethyl acetal (eq 10) affords a 1:1 mixture of stereoisomers in 90% yield.[13]

(10)

The enol ether derived from (*R*)-hexahydromandelic acid (eq 11) produces the aldol product in good yield. The products were reduced with ***Lithium Aluminum Hydride*** for the determination of the enantiomeric excesses. If the reaction is catalyzed by Me_3SiOTf, the product after reduction has an ee of 60% and an *erythro*:*threo* ratio of 9:1. Catalysis by Ph_3CSbCl_6 results in an increase in the ee to 98%, but the *erythro*:*threo* ratio drops to 4:1.[14]

(11)

Allylic and allenic stannanes also couple with 1,1-dimethoxyethane. Treatment of the tributylallenylstannane with $TiCl_4$ and the acetal (eq 12) yields a 56:44 mixture of *threo*:*erythro* isomers in 67% yield.[15] An aqueous-mediated condensation of the cyclohexenylstannane (eq 13) furnishes an 85% yield of *erythro* and *threo* stereoisomers in a 62:38 ratio.[16]

(12)

(13)

Pictet-Spengler condensations of tryptophan derivatives lead to the formation of *cis*/*trans* mixtures of tetrahydro-β-carbolines. The ratio of products depends on the nature of the substituent on the nitrogen. *N*-(Hydroxy)tryptophan ethyl ester on reaction with 1,1-dimethoxyethane (eq 14) and ***Trifluoroacetic Acid*** in CH_2Cl_2 produces a 2:1 (*cis*/*trans*) mixture of diastereomers.[17] The *N*-benzyl derivative under the same conditions gives an 84:16 (*trans*/*cis*) mixture.[18]

(14)

meso-Tetramethylporphyrinogen is produced in 28% yield by the reaction of pyrrole and the dimethyl acetal of acetaldehyde (eq 15) in CCl_4 in the presence of CF_3CO_2H.[19]

(15)

Miscellaneous.

Calculations[20] and NMR investigations[21] of the conformations of 1,1-dimethoxyethane have been reported. The acetal can be used to prepare the methoxy(phenylseleno) acetal of acetaldehyde using ***Diisobutylaluminum Phenyl Selenide***,[22] and selenoacetaldehyde employing bis(dimethylaluminum) selenide.[23]

Related Reagents.

Dimethoxymethane; ***2,2-Dimethoxypropane***; ***Triethyl Orthoformate***.

Dimethoxymethane

[109-87-5] · $C_3H_8O_2$ · Dimethoxymethane · (MW 76.10)

(widely used OH-protecting reagent, applicable to alkanols, phenols, and carboxylic acids; stable above pH 4; resistant to bases; resistant to nucleophiles; resistant to organometallic reagents; resistant to catalytic hydrogenation; resistant to hydride reduction; labile with Lewis acids; resistant to most oxidants; convenient reagent for the chloromethylation of arenes; applicable to the C-6 methylenation of steroids; useful solvent for the preparation of Grignard reagents and organolithium derivatives)

Physical Data: bp 41-42 °C; mp -104.8 °C; *d* 0.863 g cm^{-3}; fp -17 °C.

Solubility: sol water (24% at 16 °C), chloroform, 1,2-dichloroethane, dichloromethane, THF.

Methoxymethylation of Alcohols and Related Compounds.

Dimethoxymethane is a convenient reagent for the protection of alcohols as their methoxymethyl (MOM) ethers. The MOM protecting group is superior to such common alternatives as the tetrahydropyranyl (THP) group in that it avoids the complication of introducing additional chirality during its installation. This is particularly important when the alcohol to be protected is chiral and hence the introduction of a second asymmetric center during the protection would generate a diastereomeric mixture, complicating purification, assignment of NMR signals, etc.

The MOM protecting group has been widely applied in synthesis. Classically it has been installed under basic conditions using ***Chloromethyl Methyl Ether***.[1] Application of this procedure is therefore limited to species stable to basic conditions and nucleophiles. Additionally, the use of chloromethyl methyl ether has been sharply curtailed since it has been shown to be a potent carcinogen.[2] Conversely, dimethoxymethane is comparatively nontoxic. *O*-Methoxymethylation using dimethoxymethane under acidic conditions has greatly expanded the applicability of this protecting group. Treatment of alcohols with a large excess of dimethoxymethane, and ***Phosphorus(V) Oxide*** at rt, affords the corresponding methoxymethyl ethers (94-99%) (eq 1). In most cases, no further purification is required.[3]

(1)

MOM ethers can be formed via acid-catalyzed acetal exchange effected with ***p-Toluenesulfonic Acid***. The reaction can be driven to completion by the removal of the methanol formed with molecular sieves or by azeotropic distillation with

methylene chloride cosolvent. This method advantageously avoids the use of the very large excesses of phosphorus pentoxide usually required, which complicates the workup of large scale preparations of alkanolic or phenolic methoxymethyl ethers. Preparation of 10-20 kg quantities of material has been demonstrated.[4]

A general methodology for the preparation of methoxymethyl derivatives, using the methoxymethyl cation generated from $Zn^0/BrCH_2CO_2Et$/dimethoxymethane, has also been described. Methoxymethyl derivatives of phenols, thiols, imides, alkyl carboxylates, aryl carboxylates, and alkynes can be prepared in good to high yields (45-88%). In addition, esterification of acid chlorides can be effected using dimethoxymethane and anhydrous ***Zinc Bromide*** (eq 2).[5]

(2)

Methoxymethyl ethers of primary alcohols may be conveniently prepared, in high yields, using ***Nafion-H*** catalyst ($MeOCH_2OMe$, 41 °C, 10-24 h). Reaction of secondary alcohols requires elevated temperatures. The solid catalyst is separated by filtration and the product purified by chromatography. Tertiary alcohols yield alkenic dehydration products. Bridgehead tertiary alcohols yield methyl ethers.[6]

Iodotrimethylsilane also catalyzes the acetal exchange with dimethoxymethane to yield methoxymethyl ethers of primary and secondary alcohols under mild reaction conditions (25 °C, 1-6 h, 76-95%). In the low yielding examples (76-80%), the remaining starting materials are recovered. Tertiary alcohols yield the corresponding alkyl iodides rather than MOM ethers. The reaction can also be carried out using in situ generated iodotrimethylsilane (***Allyltrimethylsilane-Iodine***).[7]

The treatment of primary and secondary alcohols with dimethoxymethane in the presence of catalytic amounts of ***Lithium Bromide*** and *p*-toluenesulfonic acid at rt affords the corresponding dimethoxymethyl derivatives (25 °C, 15 min to 2 h, 71-100%), under particularly mild conditions. Examples include allylic, propargylic, cyclic, and neopentyl alcohols. Tertiary alcohols are not completely protected even after 24 h at reflux temperature. 1,3-Diols yield cyclic acetals.[8]

Cleavage of Methoxymethyl Derivatives.

Cleavage of methoxymethyl ethers to expose the parent alcohols is conventionally carried out under protic acid conditions: 2 N HOAc (90 °C, 40 h),[9] HCl (aq) (MeOH, 62 °C, 15 min),[10] 6 M HCl (THF-H_2O, 50-55 °C, 6-8 h),[11] CF_3CO_2H (H_2O-THF),[12] HCl (g) (MeCN).[13] Alternatively, the deprotection may be carried out using Lewis acids under anhydrous conditions: $PhSH/BF_3.Et_2O$,[14] Me_3SiCl/Et_4NBr (0 °C)[15] (selective cleavage of MOM ether in the presence of acetonide), $Me_3SiBr/n\text{-}Bu_4NBr$ (0 °C, 25 min to 12 h).[16] Selective cleavage of MOM esters in the presence of MOM ethers under mild conditions can be effected with Bu_3SiBr (trace MeOH).[17] More recently, nonacidic and aprotic conditions for the cleavage of MOM ethers have been developed. The reaction has been carried out with very high yields: Me_2BBr (-78 °C, 1 h, 90-93%).[18] Similarly, MOM ethers of 1,2- or 1,3-diols are cleaved in high yields under mild conditions using $(i\text{-PrS})_2BBr$ (-78 °C). Protic or Lewis acids yield cyclic diol formals with these substrates.[19] Activation of MOM ethers via hydride abstraction to facilitate cleavage can be effected with $TrBF_4$ (25 °C).[20]

Chloromethylation of Arenes.

Dimethoxymethane reacts under Friedel-Crafts conditions to accomplish the chloromethylation of aryls. Chloromethylation of thioanisole using dimethoxymethane/$AlCl_3$ affords *p*-methylthiobenzyl chloride (74%), contaminated with a trace of *o*-methylthiobenzyl chloride (150:1) (eq 3).[21]

Alternative procedures employing chloromethyl methyl ether in acetic acid[22] or aqueous formaldehyde and hydrochloric acid[23] show inferior selectivity and yield. Similarly, *p*-nitrophenol can be chloromethylated (69%) using dimethoxymethane and HCl (eq 4).[24]

6-Methylenation of 3-Oxo-Δ^4-steroids.

A simple, single step, 6-methylenation of 3-oxo-Δ^4-steroids using dimethoxymethane has been described (eq 5). The protocol replaces a multi-step series of reactions.

A number of Lewis or protic acids are effective: $POCl_3$, *p*-TsOH, H_2SO_4, $HClO_4$, HX, Amberlyst H-15, P_4O_{10}/silica

gel, PCl_5, $EtOP(O)Cl_2$. Of these, ***Phosphorus Oxychloride*** is the most suitable. The reaction can also be carried out using diethoxyethane and other formaldehyde acetals. Of these, diethoxymethane and dimethoxymethane yield superior results.[25]

Solvent for Preparation of Grignard and Organolithium Reagents.

Dimethoxymethane has been utilized as a solvent for the preparation of Grignard reagents from chloromethyl methyl ether (eq 6). While the reaction can be carried out in more common solvents, such as THF, dimethoxymethane is the solvent of choice owing to enhanced stability of the Grignard reagent in this medium.[26]

(6)

Methoxymethyllithium can be prepared from chloromethyl methyl ether in dimethoxymethane solvent (eq 7).[27] The reaction is unsuccessful in more common solvents, such as diethyl ether or THF.

(7)

Related Reagents.

Chloromethyl Methyl Ether.

2,2-Dimethoxypropane

[77-76-9] · $C_5H_{12}O_2$ · 2,2-Dimethoxypropane · (MW 104.15)

(reagent used in the preparation of acetals,[1,2] acetonides,[3] isopropylidene derivatives of sugars[4-6] and nucleosides,[7] methyl esters of amino acids,[8] and enol ethers;[9] undergoes the aldol condensation with enol silyl ethers;[10] used in the preparation of hypophosphite esters[11] and dimethylboronate esters[12])

Physical Data: bp 83 °C; *d* 0.847 g cm^{-3}.

Form Supplied in: liquid; widely available.

Handling, Storage, and Precautions: flammable liquid; irritant.

Formation of Acetals.

The reagent can be used to prepare a variety of acetals via transacetalization. This involves interchanging the alkoxy or ketone groups in an acidic medium. Both symmetrical [$R^1R^2C(OR^3)_2$] and mixed [$R^1R^2C(OR^3)OR^4$] acetals can be obtained, depending upon the choice of conditions.[1]

The three equilibria shown in eqs 1-3 are established when 2,2-dimethoxypropane, an alcohol, and a catalytic amount of acid are mixed. Distillation of the methanol formed shifts the equilibrium far in the direction of the new acetals. Methanol and 2,2-dimethoxypropane form a binary azeotrope; however, this can be broken by the addition of a hydrocarbon solvent such as hexane or benzene.

(3)

Methyl acetals of other ketones can be obtained by acidifying a mixture of the ketone, methanol, and 2,2-dimethoxypropane and removing the acetone formed by distillation. In this case, the function of the 2,2-dimethoxypropane is to react with the water formed to give methanol and acetone (eqs 4 and 5). This is evidenced by the fact that the reaction is very slow in the absence of alcohol or water, but fast when methanol is present. The rate of the reaction is also directly related to the alcohol concentration.[1]

(4)

(5)

One undesirable side reaction is the formation of enol ethers via the acid-catalyzed loss of one molecule of alcohol from the acetal. This occurs even at relatively low temperatures (50 °C). In order to suppress this reaction, the procedure was modified to include a neutralization with base prior to workup.

A recent example of the use of 2,2-dimethoxypropane in the above capacity involves the reaction of an aldehyde or ketone with ***o-Nitrobenzyl Alcohol*** to afford the bis-*o*-nitrobenzyl acetal derivative.[2] This protecting group has the advantage that it is photoremovable in high yield by irradiation at 350 nm.

Acetonide Formation.

The reagent has been used to great advantage as a protecting group for the labile dihydroxyacetone side chain of the corticosteroids. Cyclic acetal formation between the 17α,21-diol grouping of the prednisolone side chain and 2,2-dimethoxypropane in an acid-catalyzed exchange reaction gives 17α,21-isopropylidenedioxypregnane in good yield (eq 6).[3]

(6)

The base stability of the isopropylidenedioxy function makes it useful for the preparation of C-21 modified cortical hormones whose formation requires strongly basic conditions. The acetonide is easily cleaved with aqueous acetic or formic acid in the presence of heat.

Isopropylidene Derivatives of Sugars and Nucleosides.

A mixture of 2,2-dimethoxypropane, DMF, and a catalytic amount of ***p-Toluenesulfonic Acid*** constitutes an efficient acetonating agent capable of protecting vicinal, *trans*-diequatorial hydroxy groups and of forming *N*-acetyl-2,2-dimethyloxazolidines from vicinal hydroxy and acetamido groups.[4] Reaction of methyl α-D-glucopyranoside under the above conditions gives recovered starting material, methyl 4,6-*O*-isopropylidene-α-D-glucoside, and a trace amount of the diisopropylidene glucoside (eq 7). Similarly, deoxyinosamine, upon treatment with the same reagent mixture, affords as the major product the diisopropylidene derivative (eq 8).

(7)

(8)

A further improvement to the existing procedure involves the substitution of ***Tin(II) Chloride*** for the *p*-toluenesulfonic acid and 1,2-dimethoxyethane for DMF.[5a] Studies involving D-mannitol have shown that the tin(II) chloride does not act as a Lewis acid catalyst or as a source of HCl (by reaction with the hydroxy groups) since the use of zinc chloride under identical conditions gives no reaction. In this particular case, it was subsequently demonstrated that no catalyst is required and that isopropylidenation occurs under completely neutral conditions, presumably via acetal exchange.[5b] Tin(II) chloride has been used to catalyze isopropylidene formation in other carbohydrate systems.[6]

The ability of 2,2-dimethoxypropane to act as a water scavenger has resulted in its use (in conjunction with acetone and an acid catalyst) in the protection of the 2´,3´-hydroxy groups of purine and pyrimidine nucleosides.[7] Here again, the formation of acetone and methanol serves to drive the equilibrium towards the product.

Esterification of Amino Acids.

Methyl ester hydrochlorides of amino acids have been prepared in which 2,2-dimethoxypropane has been used as the source of the methoxy group, the reaction solvent, and the reagent for the removal of the water formed by virtue of the hydrolysis of the acetal to methanol and acetone.[8a] This procedure has also been used to prepare the methyl esters of fatty acids.[8b]

Enol Ethers.

Treatment of testosterone acetate with 2,2-dimethoxypropane/DMF/TsOH converts this material into the enol ether (eq 9).[9] In this case, enol ether formation is attributed to loss of water directly from the unsaturated hemiacetal.

(9)

Aldol Condensation with Enol Silyl Ethers.

The first example of an aldol condensation between an unactivated enolate and an electrophilically activated carbonyl substrate was accomplished using enol silyl ethers and acetals or orthoesters in conjunction with a catalytic amount of ***Trimethylsilyl Trifluoromethanesulfonate***. The reaction proceeds very readily at -78 °C and affords the *erythro*-aldol product with high stereoselectivity.[10] The use of 2,2-dimethoxypropane in this reaction affords β-methoxy ketones (eq 10).

(10)

Hypophosphite Esters.

Methyl hypophosphite has been prepared by the reaction between ***Hypophosphorous Acid*** and 2,2-dimethoxypropane (eq 11).[11] However, the product reacts further with the acetone formed to give 1-hydroxy-1,1-dimethylmethylphosphinate (eq 12).

Dimethyl Boronate Esters.

Dimethyl esters of arylboronic acids have been prepared by heating a mixture of the acid, 2,2-dimethoxypropane, and ***Zinc Chloride*** (catalyst).[12]

(Diels-Alder diene;[1] steroid synthesis;[2] cyclopentanones;[3] norbornadienone[4])

Physical Data: yellow liquid with sweet odor; bp 108-110 °C/11 mmHg; d_4^{20} 1.50 g cm^{-3}.

Preparative Method: dechlorination of hexachlorocyclopentadiene in methanolic potassium hydroxide solution (eq 1).[5]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: do not inhale the vapor; can cause dizziness. This reagent should only be used in a fume hood.

5,5-Dimethoxy-1,2,3,4-tetrachlorocyclopentadiene (**1**) is an excellent diene for Diels-Alder reactions. It undergoes cycloaddition reactions with ***Ethylene*** and subsequent reductive dechlorinations using Na/*t*-BuOH/THF to give 7,7-dimethoxynorbornene (eq 2).

(2)

A wide range of alkenes undergo [4 + 2] cycloaddition reactions with (**1**). The adducts can be used in the preparation of cyclopentane moieties. Reductive dechlorination of adducts followed by ***Potassium Permanganate*** oxidation yields cyclopentanone units (eq 3).

(3)

The bicyclic enone (**2**), which is useful for steroid synthesis, can be synthesized by Diels-Alder reaction with (**1**), followed by three subsequent steps. When (**2**) is treated with ***Vinylmagnesium Bromide*** followed by ***Potassium Hydride***, (**3**) is obtained, which can be converted to steroids (eq 4).

(4)

The reaction of (**1**) with cyclic dienophiles can be used in the preparation of *cis*-fused bicyclo[4.*n*.0]dienes (eq 5).

(5)

Diels-Alder reactions of (**1**) with 3,3-dimethylcyclopropene followed by reductive dechlorination and acidic hydrolysis gives 7,7-dimethylcycloheptatriene (eq 6).

Norbornadienone can be synthesized from (**1**). Diels-Alder reaction of (**1**) with 1,2-dibromoethylene followed by a sequence of steps gives norbornadienone (eq 7).

Highly complex molecules like hexacyclo[6.5.1.0.^{2,7}.0.^{4,9}.0^{10,14}]tetradeca-5,12-diene can be synthesized by Diels-Alder reaction with (**1**) (eq 8).

2,5-Dimethoxytetrahydrofuran

(R = Me)

[696-59-3] · $C_6H_{12}O_3$ · 2,5-Dimethoxytetrahydrofuran · (MW 132.16) (R = Et)

[3320-90-9] · $C_8H_{16}O_3$ · 2,5-Diethoxytetrahydrofuran · (MW 160.21)

(1,4-butanedial equivalents; useful for constructing heterocycles; the methoxy derivative is more commonly used)

Alternate Name: DMTHF.

Physical Data: R = Me: bp 145-147 °C; *d* 1.020 g cm^{-3}. R = Et: bp 167-174 °C; *d* 0.967 g cm^{-3}.

Solubility: practically insol H_2O; sol MeOH, Et_2O, THF.

Form Supplied in: colorless liquids; commercially available as a mixture of *cis* and *trans* isomers.

Preparative Method: by catalytic hydrogenation of 2,5-dialkoxy-2,5-dihydrofurans.[1]

Handling, Storage, and Precautions: flammable liquids; must be stored in a cool ventilated place. Noxious by inhalation, ingestion, or by contact with skin. Use in a fume hood.

Synthesis of Pyrroles, Pyrrolidines, Carbazoles, and Dihydropyridazines.

2,5-Dimethoxytetrahydrofuran[1] is a stable compound which liberates 1,4-butanedial (***Succindialdehyde***) in acid medium. The latter reacts with primary amines and hydrazines to give pyrrole derivatives according to the Paal-Knorr reaction of 1,4-dicarbonyl compounds (eq 1).[2]

(1)

Thus a large variety of polyfunctionalized aliphatic, aromatic, or heterocyclic derivatives bearing a primary amine function give pyrroles by heating in acetic acid[3] in the presence of DMTHF. Interestingly, the same reaction performed in refluxing benzene affords 9-substituted carbazoles[4] in a one-pot synthesis (eq 2).

(2)

When the reaction with unsubstituted hydrazines is conducted in a saturated solution of HCl in ethanol, formation of either pyrrole (X = NO_2) or dihydropyridazine (X = H) (eq 3) occurs.[5] A mixture of both heterocyclic compounds[6] has also been observed.

(3)

The Robinson-Schopf condensation of DMTHF with *R*-(-)-phenylglycinol in the presence of ***Potassium Cyanide*** affords 2-cyano-5-oxazolopyrrolidine (eq 4).[7] This synthon constitutes the basis of a general method for the synthesis of

enantiomerically pure pyrrolidine[8] and pyrrolizidine[9] alkaloids.

Substituted Furans.

Either 2- or 2,5-substituted tetrahydrofuran derivatives can be formed by nucleophilic addition of benzotriazole,[10] ***Chlorodiphenylphosphine***,[11] silyl ethers,[12] or ***Cyanotrimethylsilane***[13] (eq 5). However, halotrimethylsilanes induce acetal cleavage to give 1,4-dihalo-1,4-dimethoxybutane and not 2,5-dibromotetrahydrofuran (eq 6).[14]

Acyclic Derivatives.

DMTHF also reacts as a dialdehyde in the presence of acid, without recyclization to a five-membered ring system. Thus condensation with dithiols affords bisdithioacetals,[15] reaction with β-naphthol leads to dibenzoxanthene derivatives (eq 7),[16] and aldolization reaction with aromatic aldehydes gives diaryl-2,3-diformylbutadienes.[17]

(7)

Related Reagents.

2,5-Dihydro-2,5-dimethoxyfuran; ***Furan***; ***Glutaraldehyde***; ***Succindialdehyde***; ***2-Trimethylsilyloxyfuran***.

1,1-Dimethoxy-3-trimethylsilyloxy-1,3-butadiene

[61539-61-5] · $C_9H_{18}O_3Si$ · 1,1-Dimethoxy-3-trimethylsilyloxy-1,3-butadiene · (MW 202.32)

(diene in Diels-Alder reactions)

Physical Data: bp 84-87 °C/10 mmHg; *n*23D 1.4640.

Analysis of Reagent Purity: ^{1}H NMR (60 MHz, neat) δ 4.39 (s, 1 H), 4.07 (d, *J* = 1.0 Hz, 1 H), 3.99 (d, *J* = 1.0 Hz, 1 H), 3.61 (s, 3 H), 3.52 (s, 3 H), 0.14 (s, 9 H); IR (film) 1657, 1272, 1251, 850 cm^{-1}.

Preparative Method: enol silylation of 4,4-dimethoxy-3-buten-2-one, which is prepared from 4,4-dichloro-3-buten-2-one.[1]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; should be handled in a well-ventilated fume hood.

Diels-Alder Reactions.

This diene is more powerful than Danishefsky's diene in Diels-Alder reactions with electron-deficient dienophiles.[2] The enhanced nucleophilic character of the diene apparently overrides the steric difficulties associated with the (*Z*)-methoxy group.

There are many examples of Diels-Alder reactions of the diene with quinones as the dienophile.[1a,3] While halogen substituents on the quinone have been used to direct the regiochemistry of the addition, haloquinones are not always easy to prepare. Sulfinylquinones are a convenient alternative (eq 1).[3d]

(1)

The Diels-Alder reaction with methyl *trans*-β-nitroacrylate, an alkyne equivalent, allows access to substitution patterns that are otherwise difficult to synthesize (eq 2).[4] Comparison of eq 2 with the corresponding reaction using methyl propiolate (eq 3) indicates that this represents an umpolung of Diels-Alder reactivity.[2] When the alkyne is substituted as shown in eq 4, more drastic conditions are necessary (xylene, 140 °C, 18 h).[5] Allenes have also been used in Diels-Alder reactions with the diene.[1b,2,6]

(2)

(3)

(4)

The key step in one approach to the natural product griseofulvin and its analogs involves a Diels-Alder reaction with the diene.[7] For example, a tetrasubstituted dienophile was used to form three contiguous quaternary centers in the cycloaddition step shown in eq 5.[7d]

(5)

Seven-membered carbocycles such as heptafulvenes[8] and tropones[9] (eq 6) have been successfully prepared by Diels-Alder reactions of the diene with triafulvenes or cyclopropenes, respectively.

(6)

Hetero Diels-Alder Reactions.

Carbonyl compounds and the diene react in the presence of the mild Lewis acid $Eu(fod)_3$ (eq 7)[10] or ***Zinc Chloride***[11] as catalysts to give dihydropyrones in high yields. Under similar conditions, transoid dienes such as 1,1,4-trimethoxybutadiene or 1,1-dimethoxybutadiene undergo polymerization. The higher reactivity of the diene has been ascribed to its preference for the cisoid conformation.[11]

(7)

Related Reagents.

1,3-Dimethoxy-1-trimethylsilyloxy-1,3-butadiene; ***1-Methoxy-1,3-bis(trimethylsilyloxy)-1,3-butadiene***.

1,3-Dimethoxy-1-trimethylsilyloxy-1,3-butadiene

[106875-55-2] · $C_9H_{18}O_3Si$ · 1,3-Dimethoxy-1-trimethylsilyloxy-1,3-butadiene · (MW 202.32) (*E*)

[74272-66-5] (*Z*)

[90857-62-8]

(diene in Diels-Alder reactions; nucleophile)

Physical Data: bp 54 °C/0.5 mmHg.

Analysis of Reagent Purity: IR (film) 1660, 1270, 1255, 845 cm^{-1}; ^1H NMR (199.5 MHz, $CDCl_3$) δ 4.32 (d, *J* = 1 Hz, 1 H), 4.00 (dd, 2 H), 3.53 (d, 6 H), 0.28 (s, 9 H); ^{13}C NMR (50.10 MHz, $CDCl_3$) δ 157.9, 89.6, 77.8, 74.9, 54.1, 53.1, -0.6. The stereochemistry of the diene has been determined to be (*Z*) by NOE experiments.[1]

Preparative Method: enol silylation of methyl (*E*)-3-methoxy-2-butenoate, which is prepared from methyl acetoacetate and trimethyl orthoformate.[2]

Purification: the diene should be distilled at the lowest possible temperature to avoid intramolecular silyl migration which occurs above 80 °C.

Handling, Storage, and Precautions: stable in an inert atmosphere under anhydrous conditions when stored at 5 °C for several months. Use in a fume hood.

Diels-Alder Reactions.

Diels-Alder reactions of quinones with a variety of polarized dienes is an efficient method for the synthesis of highly substituted anthraquinones. The regioselectivity of the reaction is controlled by hydroxy,[3] halo (eq 1),[4] and sulfonyl[5] directing groups on the dienophile. In most cases, methanol is lost in preference to TMSOH during aromatization.[6]

(1)

In the presence of Lewis acids the diene condenses with aldehydes and unactivated ketones in a regiospecific manner to provide δ-lactones in good yield.[7] The diene has also been used to trap photochemically generated thioformaldeyde.[8] While $Eu(hfc)_3$[7] and oxovanadium(IV) complex[9] catalysts have been reported to induce asymmetry in cycloadditions with Danishefsky's diene, zero or very poor optical yields have been obtained with this diene under the same conditions. This suggests that substituents at the 1-position of the diene make a critical contribution to the asymmetric induction.[7,9]

Diastereoselective hetero Diels-Alder reactions have been successful in $Eu(hfc)_3$ catalyzed condensations of the diene with α-alkoxy[7,10] and α-amino aldehydes (eq 2).[11] Cycloaddition with α-alkoxy imines requires a strong Lewis acid such as ***Diethylaluminum Chloride*** to ensure rapid reaction and to suppress polymerization of the diene.[12] The degree of diastereoselectivity is dependent on the alkyl side chain and the alkoxy or amine protecting group. Amino acid esters have been used as chiral auxiliary groups in reactions of the diene and imines with $EtAlCl_2$ as catalyst (eq 3).[13]

(2)

Alkylation.

Nucleophilic attack by the diene on 2,3,5-tri-*O*-benzyl-D-ribofuranosyl acetate in the presence of ***Trimethylsilyl Trifluoromethanesulfonate*** occurs at the carbonyl carbon of the 2-benzyloxy group instead of at the C-1 carbon of the in situ generated oxonium ion (eq 4).[14]

1,2-Dimethoxyvinyllithium[1]

[59648-89-4] · $C_4H_7LiO_2$ · 1,2-Dimethoxyvinyllithium · (MW 94.04)

(reacts with aldehydes and ketones to form allylic alcohols;[1] the functionally equivalent reagent, 2-lithio-1,4-dioxene, reacts with aldehydes, ketones, and methyl halides[2,3] to form allylic alcohols and methylated alkenes)

Form Supplied in: prepared in situ and used directly.

Preparative Method: prepared in situ under nitrogen by the reaction of 1,2-dimethoxyvinyl bromide in anhydrous ether at -70 °C with ***n-Butyllithium*** in hexane. 1,2-Dimethoxyvinyl bromide is obtained from the reaction at 0 °C of aqueous ***Glyoxal*** in methanol (2 equiv)/dichloromethane with ***Hydrogen Bromide*** gas, followed by dehydrohalogenation with sodium *t*-butoxide (1 equiv).[1]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (N_2 or Ar) to exclude oxygen and moisture.

Additions to Aldehydes and Ketones.

1,2-Dimethoxyvinyllithium adds to aldehydes and ketones to yield allylic alcohols. The alcohols, when dissolved in THF and 6 N hydrochloric acid, rearrange to α-methoxy-α,β-unsaturated aldehydes.[1] With aromatic aldehydes, α-methoxycinnamaldehydes are obtained in isolated yields of 51-76% (eq 1). Cyclohexanone is converted to the unsaturated aldehyde in 86% yield (eq 2).

(1)

(2)

Pentacarbonyl [(*Z*)-1,2-dimethoxyvinyl]carbene complexes can be prepared by the addition of the reagent to ***Hexacarbonylchromium*** and ***Hexacarbonyltungsten*** followed by protonation or alkylation, respectively.[4] Synthesis of simple aldehydes from 1,2-dimethoxyvinyllithium and trialkylboranes has been reported.[5]

Functionally Equivalent Reagents.

2-Lithio-1,4-dioxene is prepared by the addition of ***n-Butyllithium*** in hexane to 1,4-dioxene cooled in an ice/water bath[2] or by the addition of ***t-Butyllithium*** to the dioxene.[2,3] The reagent has been identified by its ^{13}C NMR spectrum[2] and is stable even at rt. Addition of the reagent to aldehydes and ketones yields secondary and tertiary allylic alcohols (eq 3), which can be converted into α-hydroxy ketones,[3] α,α´-dihydroxy ketones,[3] and 2-oxaalkanal 1-dithioacetals.[5] 2-Lithio-1,4-dioxene may also be methylated.[2]

(3)

4-Lithio-2,2-dimethyl-1,3-dioxole, prepared as in eq 4, reacts with aldehydes and ketones to form allylic alcohols, which subsequently afford α-keto aldehydes.[6,7]

(4)

Related Reagents.

1-Ethoxyvinyllithium; ***1-Methoxyallenyllithium***; ***1-Methoxyvinyllithium***.

(Eschenmoser-Claisen rearrangements;[2] monoacylation of diols;[3] triazine synthesis[4])

Physical Data: mixture of (**1**) and (**2**) bp 105-110 °C; *d* 0.911 g cm^{-3}. Mixture of (**3**) and (**4**) bp 126-129 °C. (**2**) bp 104-105 °C. (**4**) bp 126 °C.

Solubility: sol benzene, toluene, xylene, DMF, chloroform.

Form Supplied in: amide acetal (**1**) is commercially available, usually as a mixture of (**1**) and (**2**). The commercial mixture is 85-95% pure; methanol (5-10%) may be present as a stabilizer.

Preparative Methods: O-methylation of *N,N*-dimethylacetamide with ***Dimethyl Sulfate*** (or diethyl sulfate), followed by reaction with ***Sodium Methoxide*** (or ethoxide). Fractional distillation affords mixtures of (**1**) and (**2**) (or **3** and **4**). Treatment with calcium metal and redistillation gives the ketene *O,N*-acetals (**2**) (58%) (or **4**; 74%).[5]

Introduction.

Amide acetal reagent (**1**) is in equilibrium with its enamine (eq 1).[5] The stabilized carbenium ion, which is an intermediate in this equilibrium, adds to nucleophiles under neutral conditions.

Eschenmoser-Claisen Rearrangement.

Condensation of (**1**) with allylic alcohols followed by loss of a second equivalent of methanol gives ketene *N,O*-acetals, which undergo 3,3-sigmatropic rearrangement to afford γ,δ-unsaturated amides (eq 2).

In a general procedure, the allylic alcohol and dimethylacetamide dimethyl acetal are heated at reflux in a high boiling solvent such as xylene or DMF with simultaneous distillation of methanol. Other suitable solvents include diglyme, dioxane, toluene, and benzene. Several papers indicate that the Eschenmoser-Claisen reaction proceeds at lower temperatures with higher yields and shorter reaction times than the classical Claisen and the orthoester Claisen rearrangements.[6] However, it suffers the disadvantage that the product is a disubstituted amide, a functional group which is not always easily converted to other groups.[7] Several examples of transformations of disubstituted amides to other functional groups are included in the discussion below.

Eschenmoser and co-workers demonstrated that the amide acetal rearrangement of cyclohexenols is stereospecific, i.e. the *cis*-4-substituted cyclohexenol gives a single stereoisomer of the cyclohexeneacetamide product (eq 3), whereas the *trans*-cyclohexenol affords its stereoisomer (eq 4).[8]

(4)

Benzyl alcohols rearrange to *o*-methylbenzeneacetamides (eq 5).

(5)

The amide acetal rearrangement, like the Claisen rearrangement, generally proceeds through a chairlike transition state with all substituents in equatorial positions, an arrangement which leads to *trans* geometry of the double bond in the product and chirality transfer (eq 6).[9]

(6)

The products of the Eschenmoser-Claisen rearrangement with 3-(trimethylsilyl)allyl alcohols (eq 7) undergo protonolysis and desilylation with ***Hydrogen Fluoride*** to give β,γ-unsaturated amides which can be converted into the corresponding esters.[10]

The Eschenmoser-Claisen method was used for the rearrangement of an allyl alcohol bearing two organometallic groups because of its nearly neutral conditions (eq 8). The product, obtained in 74% yield with 90% chirality transfer, was reduced with ***Lithium Triethylborohydride*** to the primary homoallylic alcohol.[11]

Parker and co-workers found that terminal propargyl alcohols condense with dimethylacetamide diethyl acetal (**3**) to form an intermediate which undergoes amine migration. This enamine subsequently rearranges through an orthoester Claisen rearrangement (eq 9).[12] A side product is the enol ether, which is formed from the enol derived from the enamine. Hydrolysis of the products gives a γ-keto ester.

(9)

Substituted propargyl alcohols undergo the simple Claisen-type rearrangement to give allenic amides (eq 10).

(10)

Amide acetal Claisen rearrangements have been used in the synthesis of *C*-glycopyranosides,[6] pyranosides,[13] sugars,[14,15] and indole alkaloids.[7,16] In Corey's synthesis of thromboxane B_2, an amide product is transformed to a lactone by iodolactonization followed by deiodination with ***Tri-n-butylstannane*** (eq 11).[14]

(11)

Monoacylation of Diols.

Vicinal diols form (dimethylamino)ethylidene acetals, which can be cleaved with aqueous acetic acid to give monoacylated products.[3] In unsymmetrical diols, the less hindered hydroxy group is selectively protected. For example, with this method 1,2-*O*-isopropylidene-α-D-glucofuranose is selectively acylated at the C-6 hydroxy group.

Heterocycle Synthesis.

N,*N*-Dimethylaminomethylenehydrazones are formed by addition of this reagent to α-ketohydrazones.[4] Subsequent heating with ammonium acetate in acetic acid causes cyclization to give 1,2,4-triazines (eq 12).

(12)

1,2,4-Triazoles and 1,2,4-oxadiazoles can be synthesized in high yields in a two-step procedure with this reagent. First the dimethyl acetal condenses with an amide to give an *N*-acylamidine. Subsequently, reaction with acetic acid and hydrazine gives triazoles, whereas addition of hydroxylamines gives oxadiazoles (eq 13).[17]

(13)

Another method for the synthesis of 1,2,4-oxadiazoles is condensation of the amide acetal with an amidoxime (eq 14).[18] Fused amino pyridines have been formed through the cyclocondensation of an amide acetal with an amino ketone.[19]

(14)

Related Reagents.

Dimethyl 1,3-Acetonedicarboxylate[1]

(**1**; R = Me)

[1830-54-2] · $C_7H_{10}O_5$ · Dimethyl 1,3-Acetonedicarboxylate · (MW 174.15) (**2**; R = Et)

[105-50-0] · $C_9H_{14}O_5$ · Diethyl 1,3-Acetonedicarboxylate · (MW 202.21) (**3**; R = H)

[542-05-2] · $C_5H_6O_5$ · 1,3-Acetonedicarboxylic Acid · (MW 146.10)

(acidic β-keto esters, which undergo 2:1 condensations with α-dicarbonyl compounds to form bicyclo[3.3.0]octane-3,7-diones;[1-6] Robinson-Schöpf condensation to form piperidones;[7] α,α- and α,α´-dialkylation with 1,*n*-dibromoalkanes; aldol and Claisen condensations with 1,3-dicarbonyl compounds;[13] various heterocyclizations with nitriles and aldehydes;[16] α,α´-aldol annulations with 1,2-enedials, producing tropone derivatives[20 -22])

Physical Data: (**1**) bp 150 °C/25 mmHg; *d* 1.185 g cm^{-3}. (**2**) bp 250 °C/760 mmHg; bp 140 °C/12 mmHg; *d* 1.113 g cm^{-3}. (**3**) decomposes upon heating.

Solubility: sol ethanol, methanol.

Form Supplied in: colorless liquid.

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: can be stored in the refrigerator. Does not appear to be toxic.

Dimethyl and diethyl 1,3-acetonedicarboxylates (**1** and **2**) have been extensively used in the Weiss-Cook condensation reaction with various 1,2-dicarbonyl compounds, either at acidic or alkaline pH to form *cis*-bicyclo[3.3.0]octane-3,7-dione derivatives, as well as [*n*.3.3]propellanes in a single step (eqs 1 -4).[1 -6] These tetraesters are isolated in the *anti* bisenol form. They have been employed in the synthesis of several natural and nonnatural products.[1,2]

(4)

The diacid (**3**) undergoes the Robinson-Schöpf condensation with β-ethoxyglutaraldehyde and ammonium chloride to produce 7-ethoxy-9-azabicyclo[3.3.1]nonan-3-one (eq 5).[7]

(5)

Dimethyl 1,3-acetonedicarboxylate (**1**), upon heating with acenaphthenequinone in the presence of glycine (catalyst) in norbornadiene as the solvent, affords dimethyl 7,10-fluoranthenedicarboxylate, a key intermediate in the synthesis of corannulene (eq 6).[8] Diethyl 1,3-acetonedicarboxylate (**2**) in the presence of ***Manganese(III) Acetate*** in acetic acid adds to the exocyclic enol lactone to provide an oxaspirolactone (eq 7).[9] Condensation of (**1**) (excess) with 1,3-cyclohexanedione in citrate phosphate buffer at pH 6.8 affords 5,6,7,8-tetrahydro-5-oxocoumarin-4-ylacetate (eq 8)[10] in good yield.

(6)

Alkylation of (**2**) with 1,3-dibromopropane and ***1,4-Dibromobutane***, individually, provides the cyclohexanone and cyclopentyl bis-esters, respectively (eqs 9 and 10).[11]

Reaction of (**1**) with α,α´-***Dibromo-o-xylene*** under phase-transfer conditions yields bicyclo[4.4.1]undecan-11-one (eq 11).[12] The related naphthyl derivatives have also been prepared.

(11)

Condensation of (**2**) with ***Diethyl Malonate*** in the presence of ***Sodium Ethoxide*** gives diethyl 2,4,6-trihydroxybenzene-1,3-dicarboxylate (eq 12),[13] while condensation of either (**1**) or (**2**) with an aldehyde and an amine in a 1:2:1 ratio provides the corresponding piperidones (eq 13).[14]

(12)

(13)

Condensation of (**3**) with 3,4-dihydro-β-carboline in aqueous methanol gives an amino acid intermediate which after esterification and treatment with aqueous ammonia cyclizes to the keto lactam illustrated in eq 14.[15]

Reaction of (**1**) with trifluoroacetonitrile in the presence of ***Potassium t-Butoxide*** in THF produces methyl 4,6-dihydroxy-2-trifluoromethyl-3-pyridinecarboxylate (eq 15).[16]

Reaction of (**2**) with ***Malononitrile*** and ***Sulfur*** in the presence of diethylamine as a catalyst affords ethyl 2-amino-3-cyano-5-(ethoxycarbonyl)thiophene-4-acetate (eq 16).[17] Diester (**1**) undergoes condensation with salicylaldehyde derivatives in the presence of piperidine to form the corresponding bis-coumarins represented in eq 17.[18] Condensation of (**2**) with *N*-methylaminoacetaldehyde at pH 9-10 produces ethyl 3-(ethoxycarbonyl)-1-methylpyrrole-2-acetate and 3-(ethoxycarbonyl)-1-methylpyrrole-2-acetic acid (eq 18).[19]

(17)

(18)

Diester (**1**) undergoes condensation with pyrrole-, *N*-methylindole- and 2,3-indenedicarbaldehydes to provide tropone derivatives (eqs 19-21).[20-22]

Dimethyl Acetylenedicarboxylate

[762-42-5] · $C_6H_6O_4$ · Dimethyl Acetylenedicarboxylate · (MW 142.11)

(an electron deficient symmetrical alkynic diester useful as a dienophile and dipolarophile in cycloaddition reactions;[1] can undergo [2 + 2] cycloaddition;[2] Michael acceptor;[3] synthesis of phthalic acid derivatives[4] and heteroaromatics[5])

Alternate Name: DMAD.

Physical Data: bp 195-198 °C; bp 98 °C/20 mmHg; *d* 1.1564 g cm^{-3}.

Solubility: sol common organic solvents, e.g. diethyl ether, ethyl alcohol, carbon tetrachloride.

Form Supplied in: commercially available liquid.

Handling, Storage, and Precautions: lachrymator and vesicant; avoid inhalation and contact with skin or eyes. Use in a fume hood.

As a Dienophile in the Diels-Alder Cycloaddition.

DMAD is a ubiquitous dienophile capable of facile cycloadditions with a wide variety of dienes. Much effort has been devoted to the development of dienes which retain additional functionality in the Diels-Alder adduct. New dienes are often reacted with DMAD in order to test their efficacy as a diene in the Diels-Alder reaction.[6] DMAD is a liquid with a high boiling point and can be used as the Diels-Alder solvent. The number of possible stereoisomers is limited. Due to the symmetry of DMAD there are no regio or *endo*/*exo* isomers with respect to the dienophile. For this reason, DMAD is not useful for determining any regioselective biases of a diene. The triple bond gives rise to a double bond in which the product methyl esters are necessarily *cis*. A maximum of two stereoisomers are possible only if the two faces of the diene are either electronically[7] or sterically[8] nonequivalent, otherwise one isomer is produced. The two esters make the triple bond electron poor, and therefore well suited for normal electron demand Diels-Alder cycloadditions. A comparison of relative Diels-Alder reaction rates of common dienophiles, including DMAD, has been performed.[9]

Diels-Alder adducts from DMAD are 1,4-cyclohexadienes, which are prone to aromatization. In fact, the Diels-Alder/aromatization sequence constitutes a powerful protocol for the synthesis of phthalate derivatives (see below). Aromatization is facile when loss of a small molecule is possible. In many cases a benzenoid compound, not the initial Diels-Alder adduct, is directly isolated. Loss of an alcohol is common (eq 1).[10]

(1)

If loss of a small molecule is not possible, the diene adduct can be treated with oxidizing agents such as ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone***.[11] In the case of cyclic dienes, the initial adduct can undergo a retro-Diels-Alder reaction, extruding carbon dioxide,[12] carbon monoxide,[13] or ethylene[14] to produce aromatic products (eqs 2-4).

(2)

(3)

(4)

Adducts possessing a [2.2.1] ring system, obtained from five-membered cyclic dienes such as furans[15] and pyrroles,[16] may fragment to gain aromaticity. DMAD has been exceedingly useful for the synthesis of a number of heteroaromatics such as indoles[17] and furans.[18] Electron deficient alkynes are well suited for the synthesis of pyrimidines from 1,3-diazabutadienes (eq 5).[19]

(5)

The cycloaddition of DMAD with anthracene[20] has been used for the synthesis of an interesting new iodate phosphorolytic agent.[21] DMAD has been used extensively in the development of *o*-quinodimethane equivalents (eq 6).[22]

(6)

Examples of higher order cycloadditions with DMAD are abundant. Extended conjugated cycloalkenes such as heptafulvene,[23] fulvenes,[24] azulenes,[25] and indolizines[26] have furnished higher order cycloadducts on treatment with DMAD.

As a Dipolarophile.

Not surprisingly, DMAD also undergoes cycloadditions with 1,3-dipoles. Cycloadditions with common 1,3-dipoles such as azides,[27] diazo alkanes,[28] nitrile imines,[29] nitrile ylides,[30] nitrile oxides,[31] azomethine imines,[32] azoxy compounds,[33] azomethine ylides,[34] and nitrones[35] have been reported. As in the case of the Diels-Alder reaction, the number of stereoisomers obtained is limited (see above). When the faces of the dipole are not equivalent, DMAD can add stereoselectively.[36] Two recent synthetically interesting examples of cycloaddition of DMAD with carbonyl ylides[37] and azomethine ylides[38] are illustrated (eqs 7 and 8).

(7)

(8)

Due to the unsaturation remaining in the [3 + 2] adducts obtained with DMAD, aromatization and sigmatropic rearrangements are common. Adducts from α-diazo ketones tend to undergo 1,5-acyl sigmatropic rearrangements (eq 9).[39]

(9)

Simple fragmentations of the [3 + 2] adducts are also common. Reaction of DMAD with quinoxaline 4-oxide gives a pyrrole compound (eq 10).[40] The initial [3 + 2] adduct fragments and incorporates a second molecule of DMAD.

(10)

Cyclization with extended dipoles is known. Benzothiazole undergoes Michael addition with DMAD to form a 1,4-

dipole intermediate which subsequently cyclizes with a second molecule of DMAD (eq 11).[41] 1,4-Thiazepines have been constructed via cyclization of DMAD with a 1,5-dipole (eq 12).[42]

(11)

(12)

[2 + 2] Cycloaddition.

DMAD readily undergoes [2 + 2] cycloadditions with enamines, often at ambient temperatures, to form cyclobutene compounds.[43] In many cases these compounds are not isolated and tend to fragment to form 1,3-dienamines.[44] When the enamine is cyclic the ring is enlarged by two carbon atoms (eq 13).[45] This chemistry has successfully been carried out on a range of enamine substrates including indoles,[46] quinolines,[47] and vinylogous imides (enamino lactams).[48] The cycloaddition with enamines is compatible with a wide range of functionalities (eq 14).[49]

(13)

(14)

1,1-Dimethoxyalkenes,[50] enol ethers,[51] and silyl enol ethers[52] undergo Lewis acid mediated [2 + 2] cycloaddition with DMAD to afford cyclobutene compounds. In the case of silyl enol ethers the [2 + 2] adducts can generate fragmentation products analogous to the enamine substrates. The common isolation of simple Michael adducts and strong solvent dependency on yield is solid evidence for a stepwise mechanism involving dipolar intermediates.[53]

As a Michael Acceptor.

A wide variety of nucleophiles undergo 1,4-addition with DMAD. There are examples where carbon,[54] oxygen,[55] nitrogen,[56] and halogen[57] nucleophiles undergo simple Michael addition, thus making DMAD useful for the synthesis of a great number of substituted alkenes. A predominance of the (*Z*)-isomer (methyl esters *trans*) is most common.[58] Frequently, the initial Michael adducts cyclize; this presents a facile route to heterocycles and especially heteroaromatics. With amine nucleophiles the resultant enamines (or vinylogous urethanes) often cyclize onto nearby electrophilic centers. The process is especially efficient when a five- or six-membered ring can be formed. Thus vinylogous amides yield pyridines on treatment with DMAD, whereas α-amino ketones give pyrroles (eqs 15 and 16).[59]

(15)

(16)

Alternatively, a nearby nucleophile in the Michael adduct may attack the ester moiety of DMAD. This process is facile when five- or six-membered rings can be formed (eq 17).[60]

(17)

If there are no proton sources to quench the enolate formed by the Michael addition, cyclization onto a nearby electrophilic center is possible. Thus treatment of the benzyl anion of 5-pyrimidinecarboxylate with DMAD affords a quinazoline (eq 18).[61]

(18)

Alternatively, the enolate could undergo another Michael addition, incorporating a second molecule of DMAD which then cyclizes (see dipolar reactions, eq 11). DMAD reacts with *p*-toluenethiosulfonate at rt to form tetramethyl thiophenetetracarboxylate in good yield (eq 19).[62] Interestingly, phenylacetylene, diphenylacetylene, or 3-phenyl-2-propynoate did not give any thiophenes. Apparently only alkynes with two electron-withdrawing groups will work.

(19)

1,4-Addition of radicals to DMAD are also known.[63] Michael addition of the *t*-butoxy radical,[64] selenyl radicals,[65] and the isopropyl radical[66] (eq 20) have recently been studied.

(20)

DMAD has been used in a palladium-catalyzed annulation with aryl halides.[67]

Related Reagents.

Methyl Propiolate.

(α,α-Dimethylallyl)trimethylsilane[1]

[67707-64-6] · $C_8H_{18}Si$ · (α,α-Dimethylallyl)trimethylsilane · (MW 142.32)

(regiospecific prenylation of acetals;[2] precursor of substituted tetrahydrofurans via reactions with carbonyl compounds[2])

Solubility: sol common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Preparative Methods: treatment of ***Trichlorosilane*** with 3-methylbut-2-en-1-ylmagnesium chloride followed by ***Methylmagnesium Bromide*** (2 equiv) provides (α,α-dimethylallyl)dimethylsilane (bp 108 °C) in 76% yield with 99% isomeric purity. The hydrosilane is converted to the ethoxysilane quantitatively by the reaction with ethanol catalyzed by ***Hydrogen Hexachloroplatinate(IV)***, and then fluorinated in situ with ***Tetrafluoroboric Acid*** to give the fluorosilane in 87% yield. The latter is methylated with a small excess of ***Methyllithium*** to give (α,α-dimethylallyl)trimethylsilane in 96% yield.[2] Alternatively, (α,α-dimethylallyl)trimethylsilane can be prepared from 3-methylbut-1-yn-3-ol in six steps.[3]

Purification: distillation.

Handling, Storage, and Precautions: can be stored in a glass bottle.

Prenylation of Acetals.

(α,α-Dimethylallyl)trimethylsilane reacts with acetals in the presence of a Lewis acid to give the corresponding homoallyl alcohols with complete regioselectivity (eqs 1 and 2). The reaction with carbonyl compounds often leads to the formation of tetrahydrofuran derivatives (eq 3), presumably through the formation of chloride.[2]

Cycloaddition with Silyl Shift.

The reaction of (α,α-dimethylallyl)trimethylsilane with ***4-Phenyl-1,2,4-triazoline-3,5-dione*** gives a cycloaddition

product where the trimethylsilyl group undergoes a 1,2-shift (eq 4).[4]

Photochemical Prenylation.

Photolysis of (α,α-dimethylallyl)trimethylsilane in the presence of 1-methyl-2-phenyl-1-pyrrolinium perchlorate leads to the formation of a (3,3-dimethylprop-2-en-1-yl)pyrrolidine as the sole regioisomer (eq 5).[5]

Isomerization.

(α,α-Dimethylallyl)trimethylsilane can undergo isomerization to (γ,γ-dimethylallyl)trimethylsilane with fluoride ion catalysis.[6]

[54159-47-6] · $C_{13}H_{28}AlN$ · Diethylaluminum 2,2,6,6-Tetramethylpiperidide · (MW 225.35)

(mild, nonbasic amine transfer reagents, compatible with many functional groups[1])

Physical Data: dialkylaluminum amides[2] are commonly prepared in situ. Dimethylaluminum amide exists as a six-membered ring trimer in the solid state.[2c]

Solubility: sol dichloromethane, benzene, toluene, xylene.

Preparative Methods: dialkylaluminum amides are conveniently prepared in situ from the appropriate trialkylaluminum and amine[3] or amine hydrochloride.[4]

Handling, Storage, and Precautions: dialkylaluminum amides are hydrolytically unstable. 1 M stock solutions can be prepared and stored in the freezer, although best results are usually obtained with freshly prepared reagents.[3,5]

Preparation of Dialkylaluminum Amides.

Although in early studies dialkylaluminum amides were isolated,[6] in practice the reagents are either made in situ from

primary and secondary amines or ammonia and a trialkylaluminum, or stock solutions are prepared and stored.[3,5] Diethylaluminum amides often show reduced reactivity compared to dimethylaluminum amides,[3] which are less reactive than dialkylhaloaluminum-amine complexes.[4b,6d,7] Dialkylaluminum amides that have been used in organic synthesis include dimethylaluminum amide, dimethylaluminum anilide, dimethylaluminum *o*-bromoanilide, dimethylaluminum 2-(diethylamino)ethylamide, dimethylaluminum *N*-methoxy-*N*-methylamide, diethylaluminum diethylamide, diethylaluminum *n*-propylamide, diethylaluminum 2,2,6,6-tetramethylpiperidide (DATMP), diethylaluminum *N*-methylanilide, and dimethylaluminum *N*-methyl-*N*-trimethylsilylamide.

Conversion of Esters to Amides.

The reaction of dimethylaluminum amides with a variety of esters to produce amides in high yields has been widely used (eq 1).[1,3]

$$Me_2AlNR^1R^2 + R^3CO_2R^4 \xrightarrow[25\text{-}41\ ^\circ C]{CH_2Cl_2} R^3CONR^1R^2 \qquad (1)$$

$$R^1, R^2 = H, \text{alkyl, aryl}$$

In general, aminolysis of esters requires high temperatures and/or long reaction times,[8] and the strong alkali metal catalysts sometimes used[9] are often not compatible with sensitive functionality. The use of dimethylaluminum amides has the advantages of low temperatures and moderate reaction times. The aluminum amides are conveniently prepared in situ and appear to be mild, nonbasic reagents, compatible with many functional groups. The isolation of the product is simple, since hydrolysis of the aluminum reagents and products affords only methane and acid-soluble aluminum salts. For example, this procedure has been used to prepare the oxindole portion of gelsemine (eq 2).[10]

This method has also been used to prepare *N*-substituted 4-(1*H*-imidazol-2-yl)benzamides from the corresponding

methyl ester and *N*-substituted amine in the presence of ***Trimethylaluminum*** (eq 3).[11]

(3)

Lactones undergo acyl-oxygen bond cleavage when treated with dialkylaluminum amides to produce hydroxy amides upon hydrolysis.[3,6a] A hindered lactone was converted to the corresponding hydroxy amide upon treatment with dimethylaluminum amide (eq 4). Sodium amide in liquid ammonia was unsuccessful at performing the same transformation.[3]

(4)

The aluminum amide reagent derived from *N,O*-dimethylhydroxylamine (see also ***N,O-Dimethylhydroxylamine***) was used to achieve lactone ring-opening in the total syntheses of (+)-actinobolin and (-)-bactobolin (eq 5).[12]

P = *p*-$MeC_6H_4CH_2SO_2$-

An alternative procedure involves the use of ***Dimethylaluminum Chloride***-amine complexes in the same transformations. These reagents, prepared from the reactions of trimethylaluminum with conveniently handled, readily available amine hydrochloride salts, provide efficient means for the aminolysis of esters (eq 6).[4,13]

The use of these alternative aluminum reagents avoids the necessity of having to condense and measure volatile low molecular weight amines and ammonia. In a diastereospecific synthesis of the C-20-C-34 segment of the immunosuppressant FK-506, a lactone is converted to the hydroxy amide when subjected to the complex from trimethylaluminum and ***N,O-Dimethylhydroxylamine*** hydrochloride (eq 7).[14]

(7)

This type of reaction can also be done intramolecularly, affording lactams (eq 8).[15] β-Lactams can also be synthesized, as in Woodward's synthesis of cephalosporin C (eq 9).[16]

(8)

(9)

Bifunctional units such as 1,2-diaminoethane are effectively coupled with trimethylaluminum to produce reagents that can be treated with esters to give 2-imidazolines and benzimidazoles directly (eq 10).[17]

(10)

Transaminations can also be achieved using dialkylaluminum amides. For example, Schreiber used dimethylaluminum *N*-methoxy-*N*-methylamide to convert an oxazolidone auxiliary to the *N*-methyl-*N*-methoxy amide (eq 11).[18] This transformation gives a key intermediate corresponding to the C-22-C-28 segment of rapamycin in a form suitable for

alkylative coupling.

Conversion of Esters to Nitriles.

Esters are converted to nitriles in a one-pot procedure when heated with 2 equiv of dimethylaluminum amide in refluxing xylene (eq 12).[5] This reaction, which is thought to proceed through a carboxamide or aluminum derivative of a carboxamide as an intermediate, is the first direct conversion of an ester to a nitrile.

In studies toward the total synthesis of tetronomycin, Yoshii and co-workers used this procedure to directly convert a lactone to a hydroxy nitrile (eq 13).[19]

Conversion of Nitriles to Amidines.

Often methods used for amidine synthesis are moderate to poor yielding, multistep processes.[20] In early studies, dimeric aluminum amidine derivatives resulting from the addition of diethylaluminum dimethylamide to benzonitriles were isolated for spectroscopic study,[6b,c] but the synthetic scope of the reaction in preparing amidines was not demonstrated. However, it was recently found that the addition of a dimethylchloroaluminum-amine complex[4] to a nitrile produces the corresponding amidine directly (eq 14).[7]

(14)

Dialkylaluminum amides react sluggishly with nitriles compared to the corresponding dialkylchloroaluminum-amine complexes.[4b,6d,7] Alkyl, benzyl, and aryl amidines are prepared in high yield (78-96%) from the corresponding nitriles using this method. Mono- and disubstituted amidines are obtained from *N*-substituted amine complexes. This transformation can also be achieved intramolecularly. By generating the dimethylchloroaluminum-amine complex in situ from 6-aminocapronitrile hydrochloride and trimethylaluminum, caprolactamidine was prepared (eq 15).

(15)

Additionally, guanidines can be prepared from the corresponding *N*-substituted cyanamide (eq 16).[7]

(16)

Epoxide and Oxetane Cleavage.

Diethylaluminum amides react stoichiometrically with epoxides at rt to give, after hydrolysis, β-amino alcohols in good yield (eq 17).[21] The classical method of reacting epoxides directly with amines is limited by the poor reactivity of nonnucleophilic or bulky amines and the high temperatures often necessary. This procedure avoids these problems.

(17)

The reaction of 1-hexene oxide with diethylaluminum diethylamide occurs exclusively at the terminal carbon (eq 18). In contrast, the reaction of isoprene oxide with diethylaluminum *n*-propylamide gives a mixture of products in which the tertiary carbinyl amine predominates (eq 19). This can be compared to the direct reaction of isoprene oxide with *n*-propylamine, which gives the tertiary allylic alcohol.[22]

(18)

(19)

$Et_2NAlNHPr$	72:17:11
$PrNH_2$	0:100:0

Epoxides can be converted to allylic alcohols using ***Diethylaluminum 2,2,6,6-Tetramethylpiperidide*** (DATMP),[23] which is readily prepared from diethylaluminum chloride and the corresponding lithium amide.[24] On reaction with DATMP in benzene, (*E*)-cyclododecene oxide is converted quantitatively in 1 h at 0 °C into (*E*)-2-cyclododecen-1-ol (eq 20).[23] In contrast, under the same reaction conditions, the (*Z*)-isomer affords only 8% of the alcohol. DATMP seems virtually unreactive toward all *cis*-2,3-disubstituted epoxides.

(20)

DATMP is very reactive towards 2,2,3-trisubstituted epoxides (eqs 21 and 22).[24] The observed selectivity is consistent with a cyclic *syn*-elimination mechanism, in which the organoaluminum compound adds to the epoxide preferentially on the same side as hydrogen at C-3. The proton required for elimination is supplied by the alkyl group on C-2 which is *cis* to the hydrogen atom on C-3.[23] The resulting double bond generally prefers the (*E*) configuration.

(21)

(22)

Similarly, homoallylic alcohols can be made by rearrangement of oxetane rings using an organoaluminum amide. Reaction of oxetanes with diethylaluminum methylanilide in boiling benzene gives the corresponding homoallylic alcohols in high yields (eqs 23 and 24).[25] Again the (*E*) configuration of the product is preferred.

(23)

(24)

Substitution of Allylic Phosphates.

Nucleophilic substitution of allylic phosphates can be accomplished using dialkylaluminum amides. For example, the reaction of *cis*- or *trans*-5-isopropenyl-2-methyl-2-cyclohexenyl diethyl phosphate with dimethylaluminum phenylamide results in the corresponding allylic amines (eq 25).[26] Substitution occurs with predominant inversion of configuration.[27]

(25)

	yield (%)	*cis*:*trans*
a = OPO(OEt)$_2$, b = H	70	12:88
a = H, b = OPO(OEt)$_2$	87	99:1

Conversion of Ketones to *N*-Methyl Imines.

N-Methyl imines[28] can be formed from the reaction between ketones and (trimethylsilyl)(dimethylalumino)methylamine (eq 26).[29] Imine yields are fair using this method. The aluminum reagent is prepared by treating the corresponding trimethylsilylalkylamine with trimethylaluminum in benzene.

Dimethylaluminum Chloride[1]

Me_2AlCl

[1184-58-3] · C_2H_6AlCl · Dimethylaluminum Chloride · (MW 92.51)

(strong Lewis acid that can also act as a proton scavenger; reacts with HX to give methane and MeAlClX)

Alternate Name: chlorodimethylaluminum.

Physical Data: mp -21 °C; bp 126-127 °C; *d* 0.996 g cm^{-3}.

Solubility: sol most organic solvents; stable in alkanes or arenes.

Form Supplied in: commercially available neat or as solutions in hexane or toluene.

Analysis of Reagent Purity: solutions are reasonably stable but may be titrated before use by one of the standard methods.[1e]

Handling, Storage, and Precautions: must be transferred under inert gas (Ar or N_2) to exclude oxygen and water. Use in a fume hood.

Introduction.

The general properties of alkylaluminum halides as Lewis acids are discussed in the entry for ***Ethylaluminum Dichloride***. Dialkylaluminum halides are less acidic than alkylaluminum dihalides. Me_2AlCl is more expensive than ***Diethylaluminum Chloride***, but the methyl group of Me_2AlCl is much less nucleophilic than the ethyl group of Et_2AlCl. Much higher yields will generally be obtained by use of Me_2AlCl in the ene reactions of carbonyl compounds. In other cases, such as the Diels-Alder reactions of α,β-unsaturated esters, comparable yields will be obtained with either Lewis acid.

Catalysis of Diels-Alder Reactions.

Me_2AlCl has been used as a Lewis acid catalyst for inter- and intramolecular Diels-Alder reactions with a wide variety of dienophiles. High diastereoselectivity is obtained from chiral α,β-unsaturated *N*-acyloxazolidinones with more than 1 equiv of Me_2AlCl.[2] Use of Me_2AlCl as a catalyst affords high yields in inter- and intramolecular Diels-Alder reactions of α,β-unsaturated ketones (eq 1),[3,4] and intramolecular Diels-Alder reactions of α,β-unsaturated

aldehydes.[4,5] Me_2AlCl-catalyzed Diels-Alder reactions of α,β-unsaturated *N*-acylsultams (eq 2)[6] and 1-mesityl-2,2,2-trifluoroethyl acrylate (eq 3)[7] proceed in high yield with excellent asymmetric induction. Methylaluminum sesquichloride, prepared from Me_2AlCl and ***Methylaluminum Dichloride***, catalyzes an intramolecular Diels-Alder reaction with an aldehyde as the dienophile to afford a dihydropyran.[8]

(1)

(2)

(3)

Catalysis of Ene Reactions.[9]

A wide variety of Lewis acids will catalyze the ene reactions of formaldehyde with electron-rich alkenes. Electron-deficient aldehydes, such as chloral and glyoxylate esters, also undergo ene reactions with a variety of Lewis acid catalysts. Ene reactions of aliphatic and aromatic aldehydes with alkenes that can form a tertiary cation, and of formaldehyde with mono- and 1,2-disubstituted alkenes, are best carried out with 1 or more equiv of Me_2AlCl. The alcohol-Me_2AlCl complex produced in the ene reaction decomposes rapidly to give methane and a nonbasic aluminum alkoxide that does not react further (eq 4). This prevents solvolysis of the alcohol-Lewis acid complex or protonation of double bonds. Good to excellent yields of ene adducts are obtained from aliphatic and aromatic aldehydes and 1,1-di- and trisubstituted alkenes. ***Formaldehyde*** is more versatile and gives good yields of ene adducts with all classes of alkenes.[10] When less than 1 equiv of Me_2AlCl is used, γ-chloro alcohols are formed, resulting from the stereospecifically *cis* addition of the hydroxymethyl and chloride groups to the double bond (eq 5). The chloro alcohols are converted to ene-type adducts in the presence of excess Me_2AlCl. Formaldehyde undergoes Me_2AlCl-induced reactions with terminal alkynes to give a 2:3 mixture of the ene adduct allenic alcohol and the (*Z*)-3-chloro allylic alcohol in 50-75% yield (eq 6).[11]

(4)

(5)

1 equiv	20%	39%
1.5 equiv	73%	2%

(6)

Me_2AlCl catalyzes the ene reactions of a variety of aldehydes with (*Z*)-3β-acetoxy-5,17(20)-pregnadiene at -78 °C.[12] The stereoselectivity with aliphatic aldehydes is >10:1 in favor of the 22α-isomer, while aromatic aldehydes produce predominantly the 22β-isomer (eq 7). Me_2AlCl is also the Lewis acid of choice for ene reactions of α-halo aldehydes (eq 8).[13] Ene reactions of vinyl sulfides to produce enol silyl ethers are also catalyzed by Me_2AlCl (eq 9).[14]

(7)

(8)

(9)

Type-I intramolecular ene reactions of aldehydes, such as citronellal, that contain electron-rich trisubstituted double bonds proceed readily thermally or with a variety of Lewis acids. Intramolecular ene reactions with less nucleophilic 1,2-disubstituted double bonds proceed efficiently with Me_2AlCl as the Lewis acid catalyst (eqs 10 and 11).[15,16]

(10)

(11)

Type-II intramolecular ene reactions of aldehydes and ketones proceed readily with Me_2AlCl as the Lewis acid.[17-19] Unsaturated aldehydes and ketones can be generated in situ by Me_2AlCl-catalyzed reaction of ***Acrolein*** and ***Methyl Vinyl Ketone*** with alkylidenecycloalkanes at low temperatures (eq 12).[17] The monocyclic aldehyde reacts further under these conditions. The monocyclic ketone can be isolated at low temperature but undergoes a second ene reaction at rt to give the bicyclic alcohol. β-Keto esters form tertiary alcohols in intramolecular ene reactions. The products are stable because they are converted to the aluminum alkoxide (eq 13).[18] Intramolecular Me_2AlCl-catalyzed ene reactions have been used for the preparation of the bicyclic mevinolin ring system (eq 14).[19]

(12)

(13)

(14)

Generation of Electrophilic Cations.

Me_2AlCl in dichloromethane cleaves THP ethers without deprotecting *t*-butyldimethylsilyl ethers.[20] Azido enol silyl ethers undergo Me_2AlCl-catalyzed reactions with ***Allyltributylstannane*** and enol ethers, giving conjugate addition-type products that are isolated as the silyl enol ethers (eq 15).[21] Me_2AlCl will open norbornane epoxide to the rearranged chlorohydrin.[22]

(15)

Formation and Reaction of Aluminum Enolates.

Aluminum enolates prepared from esters react with imines to give a β-lactam resulting from aldol-type addition followed by ring closure (eq 16).[23]

(16)

Formation and Reaction of Alkynylaluminum Reagents.

Lithium acetylides react with Me_2AlCl to give dimethylaluminum acetylides that react analogously to the more commonly used diethylaluminum acetylides (see ***Diethylaluminum Ethoxyacetylide***). Addition of the aluminum acetylide to propiolactone results in an S_N2 reaction to give an alkynic acid (eq 17).[24]

(17)

Reaction as a Nucleophile.

Me_2AlCl will react analogously to MeMgBr and transfer a methyl group to many nucleophiles. Since ***Methylmagnesium Bromide*** and ***Methyllithium*** are readily available, use of Me_2AlCl to deliver a methyl group is needed only when the stereochemistry of addition is an important issue. High levels of asymmetric induction are obtained in the conjugate addition of Me_2AlCl to unsaturated acyloxazolidinones with carbohydrate-derived chiral auxiliaries (eq 18).[25] Me_2AlCl differs from higher dialkylaluminum chlorides in that methyl addition is a radical process that requires photochemical or radical initiation. Me_2AlCl will convert acid chlorides to methyl ketones.[26]

Dimethylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide

[86803-85-2] · $C_{17}H_{29}AlO$ · Dimethylaluminum 2,6-Di-*t*-butyl-4-methylphenoxide · (MW 276.44)

(designer Lewis acid for amphiphilic alkylation,[1] amphiphilic reduction,[2] stereoselective Diels-Alder reaction;[3] oxidative methylation[4])

Alternate Name: DAD.

Solubility: sol CH_2Cl_2, toluene, hexane.

Preparative Method: by reaction of a 1-2 M hexane solution of ***Trimethylaluminum*** with 1 equiv of 2,6-di-*t*-butyl-4-methylphenol in toluene or CH_2Cl_2 at room temperature for 1 h.[1,2]

Handling, Storage, and Precautions: the concentrated reagent and solutions are highly flammable and must be handled in the absence of oxygen and moisture. Solutions should be used as prepared for best results.

Amphiphilic Alkylation.

DAD is a bulky, oxygenophilic organoaluminum reagent which, like ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD), has been utilized for stereoselective activation of carbonyl groups. The combination of DAD with Grignard reagents or organolithium reagents generates an amphiphilic alkylation system which reacts with substituted cyclohexanones to afford equatorial alcohols, frequently the minor product with other organometallics (eq 1).[1] In general, MAD gives more reliable results in this amphiphilic alkylation than DAD (eq 2).

Al reagent:	none	79:21	
	Me_3Al	76:24	
	i-Bu_3Al	64:36	
	Me_2AlOPh	72:28	
	DAD	5:95	81%
	MAD	1:99	84%

Al reagent:	none		92:8
	DAD	80%	58:42
	MAD	84%	14:86

Amphiphilic Reduction.

When a bulky nucleophile such as ***t-Butylmagnesium Chloride*** is employed for the amphiphilic reaction system using DAD, substituted cyclohexanones afford equatorial alcohols almost exclusively as reduction products with high selectivity (eq 3).[2]

Stereoselective Diels-Alder Reaction.

The steric effect of DAD on the stereoselectivity in Diels-Alder reactions of cyclic dienes and α,β-unsaturated aldehydes has been studied.[3] For example, the ***Boron Trifluoride Etherate*** catalyzed Diels-Alder reaction of cyclopentadiene with acrolein gives a mixture of *endo*- and *exo*-adducts in a ratio of 9:1. The *endo* selectivity is improved by use of trimethylaluminum. Introduction of a more bulky 2,6-di-*t*-butyl-4-methylphenoxy group on aluminum by use of DAD results in a further enhancement in *endo* selectivity (eq 4). However, use of the even more hindered MAD catalyst lowers the *endo* selectivity.

$BF_3 \cdot OEt_2$	9:1	46%
Me_3Al	24:5	57%
DAD	32:1	52%
MAD	12:1	56%

In contrast, both DAD and MAD enhance *exo* selectivity in the Diels-Alder reaction of cyclopentadiene with methacrolein. This is due to steric repulsion between the bulky catalyst and cyclopentadiene, rather than an electronic effect involving the carbonyl group of the dienophile, as observed in the cycloaddition with acrolein (eq 5).

(5)

heat	1:5	
Me_3Al	1:15	64%
DAD	1:24	67%
MAD	1:48	76%

Oxidative Methylation.

A novel and direct transformation of aromatic aldehydes to the corresponding methyl ketones has been accomplished using a DAD/ether complex in toluene at rt (eq 6).[4]

Dimethylaluminum Iodide

Me_2AlI

[2938-72-9] · C_2H_6AlI · Dimethylaluminum Iodide · (MW 183.96)

(methylating agent; catalyst)

Alternate Name: dimethyliodoaluminum.

Physical Data: bp 111 °C/50 mmHg.[1]

Solubility: sol toluene, benzene.

Form Supplied in: must be prepared.[2]

Handling, Storage, and Precautions: although little is reported in general compilations of safety, normal precautions should prevail. Assume that this reagent behaves like ***Diethylaluminum Iodide***: moisture-sensitive and pyrophoric. Reacts with water to form an explosive and flammable gas. Extremely harmful if vapors are inhaled. The reagent is absorbed through skin. Wear gloves. Corrosive. Air-sensitive; must be stored under inert atmosphere. Use in a fume hood.

Alkylating Agent: Addition to a Carbonyl Group.

When Me_2AlI is used to deliver a methyl group to a carbonyl, there appears to be a powerful solvent effect that directs attack on cyclohexanones (eq 1).[2] Although the reaction specificity is notable, the reaction is of minimal value because most starting material is recovered, often in the range of 90%.

A preference was also noted for 1,4-attack over 1,2-attack (eq 2). As comparison, reaction with ***Trimethylaluminum*** gave exclusive 1,2-attack.

Related Reagents.

Diethylaluminum Chloride; ***Diethylaluminum Iodide***; ***Ethylaluminum Dichloride***; ***Methylaluminum Dichloride***.

Dimethylaluminum Methylselenolate[1]

$Me_2AlSeMe$

[67132-62-1] · C_3H_9AlSe · Dimethylaluminum Methylselenolate · (MW 151.04)

(preparation of methyl selenoesters; aldol condensation of enones)

Solubility: reaction are typically run in toluene.

Preparative Methods: conveniently prepared by heating a toluene solution of ***Trimethylaluminum*** with powdered ***Selenium*** for 2 h at reflux.[2] The yellow-colored supernatant was transferred to a septum-capped argon-filled Erlenmeyer flask.

Handling, Storage, and Precautions: the reagent was found to retain its activity for approximately one month at rt. Selenium reagents are toxic and should be handled with caution, in a fume hood.

Methyl Selenoesters.

Methyl and ethyl carboxylates and lactones are converted into methyl selenoesters in almost quantitative yields (eq 1).[2,3] While δ-valerolactone and *trans*-2-hydroxycyclohexane acetic acid γ-lactone were converted cleanly to hydroxy selenoesters, γ-butyrolactone was recovered unchanged. Acetals and isolated double bonds were not affected. Thionoesters are also converted to thionoselenoesters in similar yields.[4,5]

(1)

Methyl *cis*- and *trans*-cyclohexanedicarboxylates are converted to the corresponding selenoesters without enolization (eq 2).[6] The conversion seems to be sensitive to steric factors, allowing selective transformation of one ester group in the presence of others (eqs 3 and 4).[6] *t*-Butyl and trimethylsilyl esters are unreactive.

(2)

(3)

(4)

Selenoesters react with various nucleophiles to afford acids (water), esters (alcohols), and amides (amines).[3] Ketones,

including enones, were prepared in excellent yields from selenoesters and organocuprates.[6,7] Selenoesters gave slightly higher yields compared to corresponding acid chlorides.[7] While organomanganese and organoboronates were also effective, organocadmium and organomercury compounds were not effective.

Selenoesters afford 2-unsubstituted oxazoles upon reaction with various isocyanides in the presence of copper(I) salts and ***Triethylamine*** or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.[3] They are also mild acyl electrophiles in Friedel-Crafts reactions with ***Copper(I) Trifluoromethanesulfonate*** as catalyst (eq 5).[3] Benzene was not acylated and toluene was acylated in low yield.

(5)

Aldol Condensation of Enones.

This reagent adds methylselenol to enones in 1,4-fashion. The intermediate, an aluminum enolate, undergoes aldol condensation with aldehydes (see ***Diethylaluminum Thiophenoxide***) (eq 6).[8,9] This reagent also converts δ-alkylidene-δ-lactones to 1,3-cyclohexanediones, probably via an aluminum enolate.[10]

(6)

Beckmann Rearrangement.

Beckmann rearrangements of cyclododecanone and acetophenone oxime mesylates have been accomplished to afford an imino selenoether with 2 equiv of the title reagent (eq 7).[11]

(7)

This reagent can also open up oxiranes in preference to selenoester formation.[2,3]

Dimethylaluminum Trifluoromethanesulfonate

Me_2AlOTf

[107259-64-3] · $C_3H_6AlF_3O_3S$ · Dimethylaluminum Trifluoromethanesulfonate · (MW 206.12)

(Lewis acid[1-3])

Solubility: sol dichloromethane, hexane.

Preparative Methods: to a solution of ***Trimethylaluminum*** in dichloromethane at -78 °C was added 1 equiv of ***Trifluoromethanesulfonic Acid***. The resulting mixture was stirred at -78 °C for 30 min and 0 °C for 30 min under N_2.[1]

Handling, Storage, and Precautions: generated in situ and used directly.

Dimethylaluminum trifluoromethanesulfonate is used as a Lewis acid for alkenic cyclizations (eq 1),[1] cationic rearrangements (eq 2),[2] and epoxide-initiated cation-alkene cyclizations (eq 3).[3]

4-(Dimethylamino)benzaldehyde[1]

[28602-27-9] · $C_9H_{11}NO$ · 4-(Dimethylamino)benzaldehyde · (MW 149.19)

(preparation of aldehydes from Grignard reagents;[2] color test reagent for pyrroles,[3] primary amines,[4] and hydrazines[5])

Physical Data: mp 74 °C; bp 176-177 °C/17 mmHg.

Form Supplied in: light yellow solid.

Handling, Storage, and Precautions: upon exposure to light, solid will turn pink.

Formylation Reagent.

The reagent reacts with Grignard reagents to give *p*-dimethylaminophenyl carbinols, which upon treatment with diazonium salts undergo cleavage to the aldehyde (eq 1).[2b] Use of diazotized sulfanilic acid at pH 5-6 (0-5 °C) as the cleaving agent is advantageous, as the ether-insoluble methyl orange byproduct is readily separated from the aldehyde. Yields for both steps are generally moderate, being 50-75% for the Grignard addition, and 60-82% for the cleavage reaction.[2a] This method purportedly is advantageous to ethoxymethyleneaniline or ethyl orthoformate in that it provides aldehydes of high purity directly from the ether extracts, and works equally well for the synthesis of aliphatic or aromatic aldehydes (as does the alternative reagent ***Pentacarbonyliron***[6]).

Related Reagents.

N,N-Dimethylformamide; ***N-Ethoxymethyleneaniline***; ***N-Methyl-N-(2-pyridyl)formamide***.

(lithiation gives ambident anions for nucleophilic acylation (acrolein C-1 anion) and for use as ester homoenolate equivalents; synthesis of α-cyano enamines, α´-hydroxy-α,β-enones, γ-lactones, and, by Grignard alkylation, allylic amines)

Physical Data: (**3**) bp 94 °C/10 mmHg; *d* 0.981 g cm^{-3}. (**4**) bp 64-65 °C/10.5 mmHg; *d* 0.876 g cm^{-3}. (**7**) bp 51 °C/0.015 mmHg. (**8**) bp 55 °C/0.015 mmHg.

Metalation.

Deprotonation of either β,γ- or α,β-unsaturated α-(dialkylamino)nitriles with ***Lithium Diisopropylamide*** or ***n-Butyllithium*** at low temperatures generates ambident nitrile-stabilized carbanions.[2-6]

Alkylation.

Alkylation of the nitrile-stabilized carbanions from β,γ- and α,β-unsaturated α-(dialkylamino)nitriles with various electrophiles occurs regioselectively at the γ-position to give α-cyano enamines (α-amino acrylonitriles) (eq 1).[2-6] Substitution at the β-position of these substrates does not change the regioselectivity for γ-alkylation; however, a combination of increased steric hindrance at the β-position *and* diminished size of the α-dialkylamino group leads to mixtures of α- and γ-alkylation products (eq 1; $NR^1R^2 = NMe_2$).[6] In contrast, the β,γ-unsaturated α-(morpholino)nitriles show high α-regioselectivity in alkylations.[7]

$R^1, R^2 = Me$, 75%, α:γ = 27:73; $R^1 = Me$, $R^2 = Cy$, 64%, α:γ = 0:100

Addition of the nitrile-stabilized anions derived from these unsaturated α-(dialkylamino)nitriles to aromatic[3,4,6] and aliphatic[4] aldehydes occurs at the γ-carbon. However, the corresponding reaction with ketones provides either the kinetic α-alkylation product or the thermodynamic γ-alkylation product depending on conditions. In the former case, hydrolysis of the α-adducts affords α´-hydroxy-α,β-unsaturated ketones (eq 2),[5] whereas in the latter case, hydrolysis of the δ-hydroxy-α-cyano enamines gives rise to γ-lactones (eq 3).[3-5] The addition of an equivalent of anhydrous ***Zinc Chloride*** to these reactions reduces competing aldol condensations.[5] The reaction of the anions of unsaturated α-(dialkylamino)nitriles with α,β-unsaturated ketones generally results in alkylation at the γ-carbon of the nitrile and 1,4-addition to the α,β-unsaturated ketone. With β-substituents on the α,β-unsaturated ketone the kinetic 1,2-γ-product is favored at low temperatures and the thermodynamic 1,4-γ-product is formed at 25 °C.[2]

2-(Dimethylamino)-3-butenenitrile

Cyano Group Substitution by Grignard Reagents (Bruylant's Reaction).

The reaction of primary and secondary aliphatic, aromatic, or vinylic Grignard reagents with α-dialkylamino-β,γ-unsaturated nitriles leads to α-substituted allylic amines (eq 4).[8]

4-Dimethylamino-3-butyn-2-one

[20568-22-3] · C_6H_9NO · 4-Dimethylamino-3-butyn-2-one · (MW 111.14)

(activates carboxylic acids)

Physical Data: bp 40 °C/10^{-4} mmHg.

Solubility: sol THF.

Preparative Methods: bromination of 4-(dimethylamino)but-3-en-2-one leads essentially in quantitative yield to the hydrobromide which is treated with ***Triethylamine***. Further treatment with ***Potassium t-Butoxide*** leads to the title reagent.[1,2]

Purification: distillation at 40 °C/10^{-4} mmHg.

Handling, Storage, and Precautions: thermally unstable and is best stored at below -50 °C if kept for a prolonged period.

Introduction.

4-Dimethylamino-3-butyn-2-one is used to prepare activated enol esters,[3] which are then reacted further. Aryl carboxylic acids, e.g. benzoic acid, undergo addition to 4-dimethylamino-3-butyn-2-one in THF at -60 °C in the presence of methanol, ethanol, 2-propanol, or *t*-butyl alcohol to give the enol ester (**1**) in high yield (eq 1).

No competing addition of alcohols is observed under these conditions. A diverse range of other carboxylic acids, including those incorporating phenolic, amino and thiol functions have been utilised in this reaction where only products of type (**1**) are seen.

Synthesis of Thiol and Selenol Esters.

Reaction of enol esters with Li, Na, and K salts of primary, secondary, and tertiary thiolates and enolates occurs at 0 °C to give the corresponding thiol and selenol esters (**2**) and (**3**), respectively, in good yields (eq 2).[3]

Synthesis of Carboxylic Acid Esters.

Alcohols react with (**1**) in the presence of protic or Lewis acids to give esters (eq 3);[5] this esterification procedure has also been applied to the generation of large ring lactones (eq 4).[4]

X = H, Y = MEMO; Y = H, X = MEMO

Synthesis of Amide and Peptide Linkages.

Enol ester (**1**) reacts with amines to give amides (eq 5).[6] 4-Dimethylamino-3-butyn-2-one can also be used to achieve carboxyl activation of *N*-protected amino acids suitable for further coupling reactions with carboxyl-protected amino acids to give peptides.[7,8] The amount of racemization observed in this process is low. Serine, tyrosine, 4-hydroxyproline, cysteine, and histidine can be linked to form a dipeptide without protection of the second functional

group (OH, SH, NH).

[119477-31-5] · $C_{41}H_{43}FeN_2P_2$ · (*R*)-*N*-[2-(*N*,*N*-Dimethylamino)ethyl]-*N*-methyl-1-[(*S*)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine · (MW 682.62)

(chiral ligand for asymmetric synthesis;[1] gold(I)-catalyzed asymmetric aldol reaction;[2] silver(I)-catalyzed asymmetric aldol reaction;[3] enantioselective synthesis of β-hydroxy-α-aminophosphonates;[4] asymmetric allylic alkylation;[5] asymmetric allylic aminations;[6] asymmetric hydrogenations;[7] asymmetric [3 + 2] cycloaddition reactions[8])

Physical Data: viscous liquid, [α]25D +313° (*c* = 0.3, $CHCl_3$).

Solubility: sol dichloromethane, 1,2-dichloroethane, toluene, diethyl ether.

Preparative Methods: can be prepared[9] in two steps from commercially available (-)-(*R*)-*N*,*N*-dimethyl-1-[(*S*)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine.

Handling, Storage, and Precautions: although air stable at rt, storage under anhydrous conditions under an inert atmosphere is recommended both to prevent the slow air oxidation of the phosphorus(III) ligating groups and absorption of atmospheric moisture.

Chiral Ferrocenylamine Ligands.

Chiral ferrocenylamine ligands typified by the title reagent (**1**) have played a key role in the development of both

methodology and ligand design[10] for asymmetric synthesis, particularly for the enantioselective formation of C-C bonds using catalytic quantities of chiral transition-metal catalysts. In the following discussion, both (**1**) and close analogs will be discussed and compared because small structural modifications of the alkyl side-chain of (**1**) can lead to significant increases in stereoselectivity.[11]

Gold(I)-Catalyzed Aldol Reaction.

In 1986 an elegant enantioselective and diastereoselective synthesis of dihydrooxazolines was reported, using the aldol reaction of an aldehyde with an α-isocyanoacetate ester (formally a Knoevenagel reaction) using a cationic gold(I) complex of (**1**) (eq 1).[2]

(1)

The gold(I) complex is prepared in situ by the reaction of (**1**) with bis(cyclohexyl isocyanide)gold(I) tetrafluoroborate (**2**),[12] typically in anhydrous dichloromethane. The dihydrooxazolines obtained provide a ready access to enantiomerically pure β-hydroxy-α-amino acid derivatives. High diastereo- and enantioselectivity are generally maintained with a wide variety of substituted aldehydes,[2,13,14] and α-isocyanoacetate esters.[15-17] *N*,*N*-Dimethyl-α-isocyanoacetamides[18] and α-keto esters[19] have been substituted for the α-isocyanoacetate ester and aldehyde component, respectively, sometimes with improved stereoselectivity. The effect of both the central and planar chirality of (**1**) on the diastereo- and enantioselectivity of the gold(I)-catalyzed aldol reaction has been studied.[20] The modification of the terminal dialkylamino group of (**1**) can lead to improvements in the stereoselectivity of the reaction, which in certain cases can be dramatic (eq 2).[11,21] The utility of the gold(I)-catalyzed aldol reaction in the synthesis of natural products has been demonstrated.[22,23] The gold(I)-catalyzed reaction of an α-isocyanomethylphosphonate ester with an aldehyde provides an enantioselective synthesis of β-hydroxy-α-aminophosphonic acid derivatives.[24-26]

Ligand	R	% *trans*	% ee	% Yield
(R)-*(S)*-**(1)**	NMe_2	78	37	94
(R)-*(S)*-**(3)**	NEt_2	84	72	100
(R)-*(S)*-**(4)**		85	85	100
(R)-*(S)*-**(5)**		89	89	99

Silver(I)-Catalyzed Aldol Reaction.

In 1991 the silver(I)-catalyzed aldol reaction of an aldehyde with an α-isocyanoacetate ester was reported, analogous to the above mentioned gold(I)-catalyzed reaction.[3] The catalyst was prepared in situ from (**2**) and ***Silver(I) Perchlorate***. The stereoselectivity of the silver(I)-catalyzed reaction was shown to be temperature dependent, which was attributed to the variation of the degree of metal coordination with temperature. Slow addition of the α-isocyanoacetate ester to a mixture of the aldehyde and catalyst, which favored the preferred tricoordinate Ag^{I}, gave high diastereo- and enantioselectivity (eq 3).

Earlier workers reported the silver(I)-catalyzed reaction of an aldehyde with ***p-Tolylsulfonylmethyl Isocyanide*** (eq 4).[27] The (*R*)-(*R*)-dihydrooxazolines formed can be reduced with ***Lithium Aluminum Hydride*** to provide a facile route to α-alkyl-β-(*N*-methylamino)ethanols in good to excellent yield.

Asymmetric Allylations.

The asymmetric allylation of β-diketones with π-allyl Pd^{II} complexes using the chiral ligand (**1**) was reported to proceed with low stereoselectivity.[5] Modification of the alkyl side-chain of (**1**) led to significant improvements in enantioselectivity (eq 5).[5,28-31]

(5)

(6)

Ligand	Yield (%)	ee *(R)* (%)
(1)	57	22
(6)	92	75

The in situ formed Pd^{II} catalyst system prepared with the hydroxyalkyl-substituted ferrocenylamine (**7**) led to the opposite absolute configuration at the carbon stereocenter (eq 6).[28] A similar inversion of stereochemistry is observed with ferrocenylamine ligands containing a free hydroxyl substituent in the gold(I)-catalyzed aldol reaction.[21b] Although asymmetric allylic aminations can be achieved using the chiral ligand (**7**), significantly improved enantioselectivity is obtained with the bis(hydroxyalkyl)-substituted ligand (**8**) (eq 7).[6]

(6)

(7) R = CH_2CH_2OH
(8) R = $CH(CH_2OH)_2$

(R)-N-[2-(N,N-Dimethylamino)ethyl]-N-methyl-1-[(S)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine

An interesting intramolecular variation of this reaction provides oxazolidones, which may be hydrolyzed to synthetically useful optically active 2-amino-3-butenols (eq 8).[32] The absolute stereochemistry of the stereocenter formed is dependent upon the geometry about the double bond of the 2-butenylene dicarbamate substrate. A related Pd^{II}-promoted [3 + 2] cycloaddition of an activated alkene with a 2-(sulfonylmethyl)-2-propenyl carbonate, using the bis(hydroxyalkyl)-substituted ligand (**8**), gave methylenecyclopentane derivatives with high asymmetric induction.[8]

Asymmetric Hydrogenations.

Catalytic asymmetric hydrogenations of β-disubstituted-α-phenylacrylic acids have been achieved using the Rh^{I} complex of (**4**) (eq 9).[7,33] Asymmetric hydrogenation of unsymmetrically substituted trisubstituted acrylic acids leads to the formation of two stereocenters in high ee.[7] The variation of the terminal dialkylamino substituents has little effect on enantioselectivity.[33] A study of a Ru^{II} complex of (**1**) was reported as a model for understanding the stereoselective transition state of asymmetric hydrogenations.[34]

(2-Dimethylaminoethyl)triphenylphosphonium Bromide

[21331-80-6] · $C_{22}H_{25}BrNP$ · (2-Dimethylaminoethyl)triphenylphosphonium Bromide · (MW 414.33)

(precursor to dimethylaminoethylidenetriphenylphosphorane, which condenses with aldehydes and ketones to give allylic amines[1])

Physical Data: mp 201 °C.

Form Supplied in: white solid; widely commercially available.

Preparative Methods: this reagent and analogous *N*,*N*-dialkylaminoethyltriphenylphosphonium bromides are prepared by condensation of the corresponding β-amino alcohols with ***Triphenylphosphine*** in the presence of ***Hydrogen Bromide***.[1]

Purification: recrystallization from acetic acid-chloroform.

Handling, Storage, and Precautions: should be dried in vacuo for best results.

Reaction with Aldehydes and Ketones.

The ylide derived from deprotonation of (2-dimethylaminoethyl)triphenylphosphonium bromide with ***n-Butyllithium*** reacts with a wide variety of aldehydes and ketones in a modified Wittig reaction to yield the homologated unsaturated amine (eq 1).

(1)

The stereoselectivity of this reaction with aromatic aldehydes has been investigated and conditions have been described for the selective formation of either alkene isomer (eqs 2 and 3).[1,2]

The ylide reacts readily with both unactivated and hindered ketones to give products such as (**1**)-(**3**) and, in the case of unsymmetrical ketones, can show impressive levels of stereoselectivity.[1,3,4]

(1)

(2)

(3)

Related Reagents.

Attempts to extend this reaction by using the analogous ylide generated from (2-methylaminoethyl)triphenylphosphonium bromide (**4**) are plagued by low chemical yields.[1] In contrast, treatment of the phosphonium salt (**4**) with two equivalents of BuLi generates the dianion that reacts with aldehydes to give the

secondary allylic amines in high chemical yields with a modest preference for the (*E*) alkene isomer.[5]

(4)

(5)

The phosphine oxide (**5**) has also been developed for the stereoselective synthesis of allylic amines.[6] Condensation of the lithium anion of this reagent with ketones gives an equal mixture of the *syn* and *anti* addition products which can typically be separated by chromatography or distillation. The individual diastereomers are then subjected to a *syn* elimination protocol to provide the individual (*E*) and (*Z*) allylic amines in good overall chemical yields.

6-Dimethylaminofulvene[1]

[696-68-4] · $C_8H_{11}N$ · 6-Dimethylaminofulvene · (MW 121.18)

(synthesis of azulenes[2])

Physical Data: mp 67-68 °C.

Form Supplied in: yellow crystals; commercially available.

Preparative Methods: may be conveniently prepared by the reaction of cyclopentadienylsodium with ***N,N-Dimethylformamide-Dimethyl Sulfate***.[3,4] Alternatively, cyclopentadiene has been condensed with ***N,N-Dimethylformamide Diethyl Acetal***.[5,6]

Purification: recrystallization from petroleum ether or cyclohexane.

Handling, Storage, and Precautions: should be protected from light during storage.

Synthesis of Azulenes.

6-Dimethylaminofulvene undergoes [6 + 4] cycloadditions with thiophene 1,1-dioxides (**1**) to yield substituted azulenes (**3**). The reaction is believed to proceed via the indicated intermediate (**2**), although it has not been directly observed. Subsequent extrusion of sulfur dioxide and elimination of dimethylamine yields the azulene product (eq 1). 3,4-Dichlorothiophene 1,1-dioxide is significantly more reactive than the unsubstituted heterocycle.[7,8] Azulenes have also been obtained in low yield from related reactions of 6-dimethylaminofulvene with 5-alkoxycarbonyl-2-pyrones.[9]

6-Dimethylaminofulvene has been used in short synthetic routes to the hydroazulene sesquiterpene degradation products guaiazulene and chamazulene. The [6 + 4] cycloaddition reaction of 6-dimethylaminofulvene with 2-ethyl-5-methylthiophene 1,1-dioxide (**4**) produced a mixture of regioisomers favoring the desired product (eq 2). The major isomer (**5**) was converted into chamazulene in two additional steps.[2]

[[[(Dimethylamino)methylene]amino]methylene]dimethylammonium Chloride[1]

[20353-93-9] · $C_6H_{14}ClN_3$ · [[[(Dimethylamino)methylene]amino]methylene]dimethylammonium Chloride · (MW 163.65)

(β-dimethylaminomethylenating agent for ketones and amines;[2] yields enamino derivatives of esters and lactones;[3] converts Grignard reagents to aldehydes[4])

Alternate Name: Gold's reagent.

Physical Data: mp 100-102 °C.

Solubility: sol water, chloroform; insol nonpolar organic solvents.

Form Supplied in: tan to dark brown solid; commercially available.

Preparative Methods: [5] a 1 L, one-necked, round-bottomed flask is equipped with a Claisen adapter, mechanical stirrer, reflux condenser, and mineral oil bubbler. The flask is charged with cyanuric chloride (73.8 g, 0.4 mol) (*Caution*: cyanuric chloride is a lachrymator and causes burns on contact with the skin), ***N,N-Dimethylformamide*** (175.4 g, 2.4 mol) and 1,4-dioxane (100 mL). The resulting solution is stirred and heated at 85 °C for 2-3 h while a considerable amount of carbon dioxide is evolved. When gas evolution is minimal, the reaction mixture is allowed to cool to room temperature; the product rapidly solidifies (eq 1). The flask which contains the solid product is connected to an isopropyl alcohol/dry ice trap and the solvent is removed by evacuating the system to approximately 0.05 mmHg. The crude product weighs 186-187 g (95% yield). Another method of isolating the product is by rapid filtration and washing with acetone.

(1)

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 3.27 (s, 6H, two CH_3), 3.43 (s, 6H, two CH_3), 9.57 (s, 2H, -CH=N).

Handling, Storage, and Precautions: Gold's reagent is very hygroscopic and should be handled under a moisture-free environment. If kept dry, it has a substantial

shelf-life. Store in desiccator over anhydrous calcium sulfate.

Reaction with Mononucleophiles.

Gold's reagent (GR) is a general β-dimethylaminomethylenating agent which reacts successfully with anions derived from ketones (eq 2)[2] to produce enaminones, and with amides (eq 3)[2] to produce acylamidines. The stoichiometry of the reactions involves using 1 equiv of Gold's reagent and 1 equiv of base which was prepared by a reaction of the appropriate alcohol with sodium metal.

(2)

(3)

Gold's reagent also reacts with amines (eq 4)[2] to produce amidines. This reaction has been utilized in the preparation of a chiral formamidine from L-valinol *t*-butyl ether. Reports of the use of this chiral auxiliary in the asymmetric syntheses of indole,[6,7] isoquinoline,[8-10] and pyrrolidine[11] alkaloids have appeared.

(4)

The reaction with anions derived from unsymmetrical ketones (eq 5)[12] proceeds with complete regioselectivity to produce the least substituted enaminone. Use of other similar reagents result in mixtures.[13]

(5)

The reaction with anions derived from esters (eq 6) and lactones (eq 7)[3] also result in β-dimethylaminomethylenation. These reactions are interesting in that enamino lactones can be converted to α-methylene lactones.[14,15]

(6)

(7)

Reaction of Gold's reagent with the anion of *o,p*-nitrotoluenes (eq 8)[3] results in the formation of phenyl enamines. It has been shown that *o*-nitrophenyl enamines can be converted to indoles.[16]

(8)

Other effective β-dimethylaminomethylenating agents include the formamide acetals,[17] some of which are also commercially available. They are, however, expensive, moisture and heat sensitive, and require potent, mutagenic alkylating agents for their preparation. Under some circumstances they also necessitate high reaction temperatures and long reaction times. Alternatively, Gold's reagent is prepared in a single step, and in nearly quantitative yield, without purification, from inexpensive raw materials. The reaction of Gold's reagent with an amine or other substrate can be carried out at relatively low temperatures (65-90 °C) and moderate reaction times (12-24 h).

Reaction with Grignard Reagents.

The reaction of Gold's reagent with Grignard reagents (eq 9)[4] produced one-carbon homologated aldehydes upon acid hydrolysis of the intermediates. This is general for aromatic, benzylic, and aliphatic Grignard reagents. This is an advantage over a method using 2-oxazolines,[18] which only works for aromatic and benzylic Grignard reagents. Another reagent used in formylating Grignard reagents is ***N-Methyl-N-(2-pyridyl)formamide***,[19] which was developed by Meyers. This reagent, however, is somewhat expensive and is prepared in two steps in 80% overall yield and usually involves recovery of a byproduct.

(9)

Reaction with Dinucleophiles.

The reaction of Gold's reagent with 1,2- and 1,3-dinucleophiles incorporates a CH=N-CH unit into a ring. Upon reaction with ***Phenylhydrazine*** (eq 10) and ***Guanidine*** (eq 11),[20] the corresponding triazole and triazine are produced. The mechanism can be viewed as the two nucleophilic sites displacing the two dimethylamino groups. In the reaction with 2-(cyanomethyl)pyrrole (eq 12),[21] a 6-azaindolizine is formed. An alternative mechanism for cyclization was postulated involving a [1,5]-sigmatropic hydrogen shift followed by a 6π-electrocyclic ring closure.

(10)

(11)

(12)

Gold's reagent also reacts with 1,4- and 1,5-dinucleophiles. In the reaction with *o*-aminophenols (eq 13) and *o*-hydroxyacetophenones (eq 14),[22] it serves as a one-atom linchpin to form the corresponding oxazoles and pyranones. Gold's reagent reacts initially to form a β-dimethylaminomethylene derivative, which undergoes intramolecular cyclization to form the fused ring. In the case of anthranilic acid (eq 15),[23] Gold's reagent serves as a two-atom linchpin. The resulting azalactone reacts with *N*,*N*-dimethylformamidine, which is produced in the initial reaction with Gold's reagent. The final product is a quinazolinone.

(13)

(14)

(15)

There are other reagents such as DMF acetals[24] and ***Dimethylchloromethyleneammonium Chloride***[25] which (in some cases) accomplish similar functions. Gold's reagent has some distinct advantages over these compounds. It is a well defined, stable, and preformed salt which reacts cleanly with a variety of nucleophiles under basic conditions with significant regioselective control. It is also an efficient, economical and clean alternative to analogous reagents.

Related Reagents.

t-Butoxybis(dimethylamino)methane; ***N,N-Dimethylformamide Diethyl Acetal***; ***N-Formylpiperidine***; ***N-Methylformanilide***.

Dimethylaminomethyllithium

Me_2NCH_2Li

[26285-58-5] · C_3H_8LiN · Dimethylaminomethyllithium · (MW 65.06)

(agent for nucleophilic dialkylaminomethylation; regioselective preparation of 2-dialkylamino alcohols)

Physical Data: the X-ray structure of the ether-complexed dimer of *N*,*N*-dimethylaminobenzyllithium[1a] and its structure in solution (^{1}H, ^{13}C NMR)[1b] have been reported. The pK_a of its potassium salt has been determined to be 41.1.[1c]

Solubility: sol THF and ether.

Form Supplied in: prepared in situ by the methods described below and used directly.

Handling, Storage, and Precautions: must be prepared and handled under inert gas (Ar) to exclude oxygen and moisture.

General Discussion.

The direct preparation of *N*,*N*-dialkylaminomethyllithium (**2**) by deprotonation of tertiary aliphatic methylamines (**1**) with alkyllithium bases is normally not possible. Thus dimethyldodecylamine is deprotonated by ***t-Butyllithium*** only to the extent of 7%.[2a] The slow deprotonation rate of (**1**) and the thermal instability of (**2**) prevent further enrichment in (**2**). To solve this problem, acceleration of metalation by activation of the base or the amine has been used.

With the stronger basic system ***s-Butyllithium*/*Potassium t-Butoxide*** the direct preparation of the potassium salts (**4**) from (**1**) is possible when excess amine is used as solvent (e.g. ***Triethylamine***, *N*-methylpiperidine, *N*-methylpyrrolidine) (eq 1).[2b] The potassium salts can be alkylated but are strongly basic. Enolizable carbonyl compounds are only deprotonated. When the potassium salts are treated with ***Lithium Bromide*** in ether, the more nucleophilic lithium salts (**2**) are formed and hydroxyalkylation to give 2-amino alcohols (**3**) is possible even with acidic carbonyl compounds such as cyclohexenone.

The easiest way to activate the amines consists of complexation with ***Boron Trifluoride*** prior to metalation to give, after deprotonation with *s*-butyllithium, a sort of dipole-stabilized[3] anion (**6**), as demonstrated for *N*-methylpyrrolidine and *N*-methylpiperidine.[4] After quenching with benzaldehyde, benzophenone, or cyclohexanone the corresponding 2-amino alcohols (**3**) have been obtained in good yields (eq 2). Alkylation with ***Iodomethane*** (51%), oxidation with ***Iodine*** to give the 1,2-diamine (65%), and acylation with benzonitrile (50%) or ***Methyl Acrylate*** (69%) are also reported.

To avoid the difficulties of direct deprotonation, the very fast method of tin-lithium exchange can be used. From α-stannylated amines (**7**) the α-lithioamines (**2**) are available immediately with ***n-Butyllithium*** in hexane (e.g. trimethylamine, *N*-methylpiperidine, *N*,*N*-dimethylaniline, *N*-methyldiphenylamine) and can be trapped with benzaldehyde to give the amino alcohols (**8**) in high yields (eq 3).[5] The only exception observed has been with *N*-lithiomethylmorpholine, which decomposed rapidly.

(3)

The method has been extended to other *N*-methylamines, of which *N*-benzyldimethylamine is the most interesting, since after electrophilic reaction the benzyl group can be removed reductively to give formally the product of α-lithiodimethylamine. After reaction at -65 °C with ***Chlorotrimethylsilane***, the silylated amine is obtained in 87% yield. However, after warming to rt for 1 h, only the product of a Wittig rearrangement is found.[6] For comparison of the three methods see Table 1.

Table 1 Comparison of Preparation of 2-Amino Alcohols (**3**) by the Different Methods Described

R^1	R^2	R^3	R^4	Eq	Yield (%)
$(CH_2)_5$		H	Ph	(1)	73
$(CH_2)_5$		H	Ph	(2)	79

Me	Me	H	Ph	(3)	81
Me	Ph	H	Ph	(3)	81

Some further synthetic applications are given in eqs 4 and 5.[7,8]

The α-stannylated amines (**7**) are best prepared by addition of ***Tri-n-butylstannyllithium*** to *S,N*-acetals (50-75%)[5,6] or tributylstannylmagnesium chloride to *O,N*-acetals (65-89%)[7] or immonium salts (75-89%).[8]

Another way to accelerate metalation is through intramolecular complexation:[9] ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA)[10] or ***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine*** (PMDTA)[11] can be deprotonated at the methyl group with alkyllithiums in alkanes to give the corresponding aminoalkyllithiums; the latter can be trapped with ***Chlorotrimethylstannane*** or benzaldehyde. Lithiated PMDTA has been characterized by NMR methods and shown to be monomeric in solution.[12]

All reactions described so far are restricted to the generation of dialkylaminomethyllithiums and failed to generate homologous dialkylaminoalkyllithiums. This limitation can be overcome by acceleration of the tin-lithium exchange reaction by built-in complexing ligands, as for the generation of lithiated and configurationally stable aziridine reagents.[13] The method has been exploited for the preparation of enantiomerically enriched aminoalkyllithium compounds to study their configurational stability (eq 6).[14]

More generally, secondary and even tertiary dialkylaminoalkyllithium reagents can be generated by reductive metalation of *S*,*N*-acetals with ***Lithium 4,4´-Di-t-butylbiphenylide*** (LiDBB) (eq 7).[15]

Related Reagents.

N-t-Butoxycarbonyl-N-methylaminomethyllithium; ***N´-t-Butyl-N-methyl-N-trimethylsilylmethylformamidine***; ***N-Nitrosodimethylamine***.

(Dimethylamino)methyl Methyl Ether[1]

(**1**; R = Me)

[62393-45-7] · $C_4H_{11}NO$ · (Dimethylamino)methyl Methyl Ether · (MW 89.14) (**2**; R = Bu)

[56275-84-4] · $C_7H_{17}NO$ · Butyl (Dimethylamino)methyl Ether · (MW 131.22)

(precursor for *N*,*N*-dimethyl(methylene)ammonium salts;[2,3] useful for the in situ dimethylaminomethylation of silyl enol ethers to produce β-(*N*,*N*-dimethylamino) ketones (Mannich bases)[4,5])

Physical Data: (**1**) bp 67 °C/760 mmHg; (**2**) bp 128 °C/756 mmHg.

Solubility: sol H_2O, acetonitrile.

Preparative Methods: amino ethers (**1**)[3] and (**2**)[6] are prepared from a mixture of dimethylamine (0.5 mol), alcohol (1 mol), and ***Potassium Carbonate*** (0.6 mol) at 0 °C. ***Paraformaldehyde*** is added after a few min, and the mixture is stirred overnight at room temperature. The product is purified by filtration followed by distillation to give a colorless liquid.

Handling, Storage, and Precautions: handle with gloves in a well-ventilated fume hood. Incompatible with acids and acid chlorides. Readily decomposes in water in the presence of acid.

General Discussion.

The mechanism of the acid-catalyzed hydrolysis of (**2**), which involves the formation of an iminium intermediate, has been studied in detail.[6] *N*,*N*-Dimethyl(methylene)ammonium salts are readily obtained by the reaction of (**1**) with acid halides (eq 1) or ***Methyltrichlorosilane*** (eq 2).[3] The latter method may be used in situ for dimethylaminomethylation of silyl enol ethers to give β-(*N*,*N*-dimethylamino) ketones in good yield (eq 3).[4]

In a similar manner, (**2**) reacts with silyl enol ethers in the presence of either ***Iodotrimethylsilane*** or ***Trimethylsilyl Trifluoromethanesulfonate*** to provide the Mannich reaction product (eq 4).[5] However, in the reaction of (**2**) with ***Chlorotrimethylsilane*** the effective intermediate is believed to be an oxonium salt as there is no evidence of the formation of an iminium salt. It is interesting to note that the use of ***Bis(dimethylamino)methane*** in the place of (**2**) in the above reaction does not proceed smoothly.

Terminal alkynes have also been converted in excellent yields into Mannich bases by reaction with (**2**) instead of formaldehyde and dimethylamine (eq 5).[7]

Related Reagents.

Bis(dimethylamino)methane; ***t-Butoxybis(dimethylamino)methane***; ***Dimethyl(methylene)ammonium Iodide***; ***Formaldehyde-Dimethylamine***; ***(Methoxymethyl)bis(trimethylsilyl)amine***; ***N-(Methylthiomethyl)piperidine***.

(2-Dimethylaminomethylphenyl)phenylsilane

[129552-42-7] · $C_{15}H_{19}NSi$ · (2-Dimethylaminomethylphenyl)phenylsilane · (MW 241.41)

(hydrosilylating agent; selective reducing agent for carbonyls, acyl chlorides, carboxylic acids, and heterocumulenes under neutral conditions)

Physical Data: bp 115 °C/0.05 mmHg.

Solubility: sol ether, THF, alkanes, aromatics, chlorinated solvents.

Preparative Methods: to 67 g (0.5 mol) of *N*,*N*-dimethylbenzylamine in 300 mL of anhydrous ether are added dropwise under nitrogen 200 mL (0.5 mol) of ***n-Butyllithium*** (2.5 M in hexane). After being stirred for 48 h at 25 °C, the yellow suspension is transferred into a dropping funnel and added at 0 °C to 54 g (0.5 mol) of phenylsilane in 200 mL of ether. The mixture is stirred for 16 h, then filtered over celite. Solvents are removed under vacuum, and the residue is diluted in pentane, filtered again and fractionally distilled to give 82 g (68%) of 2-(dimethylaminomethylphenyl)phenylsilane (**1**).[1]

Related aminoarylsilanes are similarly prepared[2] from 1-(dimethylaminomethyl)naphthalene and 1-(dimethylamino)naphthalene, giving [8-(dimethylaminomethyl)-1-naphthyl]phenylsilane (**2**) and [8-(dimethylamino-1-naphthyl]phenylsilane (**3**), respectively.

General Discussion.

The reducing properties of silicon hydrides are enhanced by intramolecular pentacoordination.[1,3] Solvolysis is observed with alcohols and phenols, and addition to carbonyls occurs without the requirement of external catalysts. Some previous reports concerned the reduction of aroyl chlorides to aldehydes using organosilanes under catalytic conditions with Pd/C[4] or tributyltin hydride with catalytic Pd^0,[5] but incompatible functional groups on the substrate must be avoided. Such problems are overcome with organosilicon hydrides activated by intramolecular coordination of an aminoaryl group. These reagents react with acyl chlorides in carbon tetrachloride, affording chlorosilanes and aldehydes (eq 1).[6] The reactions are fast and quantitative. The aldehydes are either isolated by direct distillation from

the crude product mixture, or trapped after filtration over wet silica. The organosilanes can be recycled after separation and treatment with ***Lithium Aluminum Hydride***. Halogen, methoxy, and nitroaryl substituents, heteroaryl groups, and alkenes remain unchanged. The method is also suitable for the conversion of dicarboxylic acid chlorides into dialdehydes.

Hydrosilylation of isocyanates and isothiocyanates (eq 2) is readily achieved under mild conditions. Treatment of the adducts through the one-pot addition of acyl chlorides gives *N*-acylformamides and *N*-acylthioformamides.[7] *N,N´*-Dialkyl *C*-acylamidines result from the acylation[8] of *C*-silylamidines, obtained (eq 3) by hydrosilylation of alkylcarbodiimides with (**2**).

Pentacoordinated hydrosilanes react with excess aryl isocyanates to give isocyanurates.[9] Carboxylic acids are directly reduced to aldehydes in a one-pot process[10] through the thermal decomposition of pentacoordinated silyl carboxylates (eq 4). The aldehydes are extracted from the crude product mixture by distillation, or separated from the trisiloxane by column chromatography over Florisil. The reaction is selective, since fluoro, nitro, cyano, methoxy and heteroaryl substituents do not react with the silane. The present method also permits the reduction of α,β-unsaturated acids. The efficiency follows the order (**2**) > (**1**) > (**3**).

(4)

Related Reagents.

Triethylsilane; ***Triethylsilane-Trifluoroacetic Acid***.

[2403-55-6] · $C_8H_{15}NO$ · 1-Morpholino-2-methyl-1-propene · (MW 141.24) (**4**; R,R = $-(CH_2)_5-$)

[673-33-6] · $C_9H_{17}N$ · 1-Piperidino-2-methyl-1-propene · (MW 139.27) (**5**; R,R = $-(CH_2)_6-$)

[94167-75-6] · $C_{10}H_{19}N$ · 1-Perhydroazepino-2-methyl-1-propene · (MW 153.30)

(either the enamine nitrogen or its β-carbon atom is nucleophilic, undergoing substitution or conjugate addition;[1] can take part in 1,2- or 1,4-cycloaddition[1])

Physical Data: (**1**) bp 89-90 °C; *n*20D 1.4221; $IR_{C=C}$ 1680 cm^{-1}. (**2**) bp 50 °C/14 mmHg; *n*20D 1.4739; $IR_{C=C}$ 1674 cm^{-1}. (**3**) bp 59-60 °C/17 mmHg; *n*20D 1.4676; $IR_{C=C}$ 1675 cm^{-1}. (**4**) bp 65-67 °C/12 mmHg; *n*20D 1.4676; $IR_{C=C}$ 1675 cm^{-1}. (**5**) bp 85-86 °C/12 mmHg; *n*20D 1.4845; $IR_{C=C}$ 1667.

Preparative Methods: the usual method of preparation for these enamines is the condensation of a secondary amine with isobutyraldehyde (2-methylpropanal) (eq 1).[2]

Handling, Storage, and Precautions: colorless liquid; readily reacts with water or atmospheric oxygen. Should be stored under dry nitrogen.

Alkylation.

Enamines derived from β-disubstituted aldehydes are alkylated on nitrogen by alkyl halides. Activated alkyl halides provide easier access to *C*-alkylated products, but the increased activity also results in greater amounts of dialkylation products. Allyl, benzyl, and propargyl halides give *C*-alkylated products with these enamines. However, in some cases (e.g. crotyl bromide, eq 2),[3] *N*-alkylation may occur initially, followed by isomerization to the *C*-alkyl isomer (e.g. via [3,3]-sigmatropic rearrangement). High dielectric solvents favor *C*-alkylation in these reactions. Ternary iminium ions can alkylate acyclic enamines (eq 3).[4]

(2)

(3)

Acylation.

Addition of ***Acetyl Chloride*** to the morpholine enamine of isobutyraldehyde gives normal *C*-acylation which upon hydrolysis produces a keto aldehyde (eq 4).[5]

(4)

Cycloaddition.

The initial product formed when an electrophilic alkene such as ***Methyl Vinyl Ketone*** is allowed to react with an acyclic enamine is a dihydropyran (eq 5).[6]

[2 + 2] Cycloaddition takes place to form thermally stable cyclobutane products when acyclic enamines with no β-hydrogens are treated with dimethylketene,[7] ***Methyl Acrylate***,[2b] fumaronitrile,[2c] and ***Dimethyl Fumarate*** or diethyl fumarate.[2c,8] The thermal and the photochemical fumarate reactions give different stereoisomeric products (eqs 6 and 7).[8]

Acid-catalyzed hydrolysis effects aldol cyclization to give 4,4-dimethyl-2-cyclohexenone.[6b]

Related Reagents.

1-(Dimethylamino)-2-nitroethylene[1]

[1190-92-7] · $C_4H_8N_2O_2$ · 1-(Dimethylamino)-2-nitroethylene · (MW 116.14)

(synthetic reagent for nitroalkenes and nitroaromatics;[1] can undergo addition-elimination reaction with nucleophiles;[1] can effect inverse electron demand Diels-Alder reaction[2])

Physical Data: mp 104 °C.

Solubility: sol alcohols, ethers, chloroform, acetone; slightly sol *n*-hexane.

Preparative Methods: by reaction of ***N,N-Dimethylformamide Diethyl Acetal*** (85% yield)[3] or ***N,N-Dimethylformamide-Dimethyl Sulfate*** complex (60%)[4] with ***Nitromethane***; condensation of ***Triethyl Orthoformate*** with $MeNO_2$ in the presence of DMF (52%),[5] or addition-elimination reaction of ***1-Nitro-2-phenylthioethylene*** with Me_2NH (74%).[6]

Preparation of Nitroalkenes.

1-Dimethylamino-2-nitroethylene can be converted into synthetically useful nitroalkenes by addition-elimination reactions with nucleophiles such as organometallic reagents (eq 1),[7] enolates (eq 2),[8] indoles (eq 3),[9] polyalkoxybenzenes (eq 4),[9] a certain pyrimidine derivative (eq 5),[10] and the anion of fluorene (eq 6).[11]

4-Dimethylaminopyridine[1]

[1122-58-3] · $C_7H_{10}N_2$ · 4-Dimethylaminopyridine · (MW 122.19)

(catalyst for acylation of alcohols or amines,[1-11] especially for acylations of tertiary or hindered alcohols or phenols[12] and for macrolactonizations;[13-15] catalyst for direct esterification of carboxylic acids and alcohols in the presence of dicyclohexylcarbodiimide (Steglich-Hassner esterification);[5] catalyst for silylation or tritylation of alcohols,[9,10] and for the Dakin-West reaction[20])

Alternate Name: DMAP.

Physical Data: colorless solid; mp 108-110 °C; pK_a 9.7.

Solubility: sol MeOH, $CHCl_3$, CH_2Cl_2, acetone, THF, pyridine, HOAc, EtOAc; partly sol cold hexane or water.

Form Supplied in: colorless solid; commercially available.

Preparative Methods: prepared by heating 4-pyridone with HMPA at 220 °C, or from a number of 4-substituted (Cl, OPh, SO_3H, $OSiMe_3$) pyridines by heating with DMA.[2] Prepared commercially from the 4-pyridylpyridinium salt (obtained from pyridine and $SOCl_2$) by heating with DMF at 155 °C.[1,2]

Purification: can be recrystallized from EtOAc.

Handling, Storage, and Precautions: skin irritant; corrosive, toxic solid.

Acylation of Alcohols.

Several 4-aminopyridines speed up esterification of hindered alcohols with acid anhydrides by as much as 10 000 fold; of these, DMAP is the most commonly used but 4-pyrrolidinopyridine (PPY) and 4-tetramethylguanidinopyridine are somewhat more effective.[11] DMAP is usually employed in 0.05-0.2 mol equiv amounts.

DMAP catalyzes the acetylation of hindered 11β- or 12α-hydroxy steroids. The alkynic tertiary alcohol acetal in eq 1 is acetylated at rt within 20 min in the presence of excess DMAP.[3]

Esterifications mediated by ***2-Chloro-1-methylpyridinium Iodide*** also benefit from the presence of DMAP.[22]

DMAP acts as an efficient acyl transfer agent, so that alcohols resistant to acetylation by ***Acetic Anhydride-Pyridine*** usually react well in the presence of DMAP.[4a] Sterically hindered phenols can be converted into salicylaldehydes via a benzofurandione prepared by DMAP catalysis (eq 2).[4b]

Direct Esterification of Alcohols and Carboxylic Acids.

Instead of using acid anhydrides for the esterification of alcohols, it is possible to carry out the reaction in one pot at rt by employing a carboxylic acid, an alcohol, ***1,3-Dicyclohexylcarbodiimide***, and DMAP.[5,6] In this manner, *N*-protected amino acids and even hindered carboxylic acids can be directly esterified at rt using DCC and DMAP or 4-pyrrolidinopyridine (eq 3).[5]

(3)

DCC-DMAP has been used in the synthesis of depsipeptides.[6b] Macrocyclic lactones have been prepared by cyclization of hydroxy carboxylic acids with DCC-DMAP. The presence of salts of DMAP,[13a] such as its trifluoroacetate, is beneficial in such cyclizations, as shown for the synthesis of a (9*S*)-dihydroerythronolide.[13b] Other macrolactonizations have been achieved using ***2,4,6-Trichlorobenzoyl Chloride*** and DMAP in ***Triethylamine*** at rt[14] or ***Di-2-pyridyl Carbonate*** (6 equiv) with 2 equiv of DMAP at 73 °C.[15]

Acylation of Amines.

Acylation of amines is also faster in the presence of DMAP,[7] as is acylation of indoles,[8a] phosphorylation of amines or hydrazines,[2,8] and conversion of carboxylic acids into anilides by means of ***Phenyl Isocyanate***.[1] β-Lactam formation from β-amino acids has been carried out with DCC-DMAP, but epimerization occurs.[8b]

Silylation, Tritylation, and Sulfinylation of Alcohols.

Tritylation, including selective tritylation of a primary alcohol in the presence of a secondary one,[9] silylation of tertiary alcohols, selective silylation to *t*-butyldimethylsilyl ethers,[6] and sulfonylation or sulfinylation[10] of alcohols proceed more readily in the presence of DMAP. Silylation of β-hydroxy ketones with ***Chlorodiisopropylsilane*** in the presence of DMAP followed by treatment with a Lewis acid gives diols (eq 4).[16]

(4)

Miscellaneous Reactions.

Alcohols, including tertiary ones, can be converted to their acetoacetates by reaction with ***Diketene*** in the presence of DMAP at rt.[17] Decarboxylation of β-keto esters has been carried out at pH 5-7 using 1 equiv of DMAP in refluxing wet

toluene (eq 5).[18]

(5)

Elimination of water from a *t*-alcohol in a β-hydroxy aldehyde was carried out using an excess of ***Methanesulfonyl Chloride***-DMAP-H_2O at 25 °C.[23]

Glycosidic or allylic alcohols (even when *s*-) can be converted in a 80-95% yield to alkyl chlorides by means of ***p-Toluenesulfonyl Chloride***-DMAP. Simply primary alcohols react slower and secondary ones are converted to tosylates.[24]

Aldehydes and some ketones can be converted to enol acetates by heating in the presence of TEA, Ac_2O, and DMAP.[2] DMAP catalyzes condensation of malonic acid monoesters with unsaturated aldehydes at 60 °C to afford dienoic esters (eq 6).[19]

(6)

The conversion of α-amino acids into α-amino ketones by means of acid anhydrides (Dakin-West reaction)[20] also proceeds faster in the presence of DMAP (eq 7).

(7)

Ketoximes can be converted to nitrimines which react with Ac_2O-DMAP to provide alkynes (eq 8).[21]

For the catalysis by DMAP of the *t*-butoxylcarbonylation of alcohols, amides, carbamates, NH-pyrroles, etc., see ***Di-t-butyl Dicarbonate***.

Alfred Hassner

4-(Dimethylamino)pyridinium Chlorochromate

[81121-61-1] · $C_7H_{11}ClCrN_2O_3$ · 4-(Dimethylamino)pyridinium Chlorochromate · (MW 258.65)

(mild chromium oxidant, selective for the oxidation of benzylic, allylic, and sterically hindered alcohols to the corresponding aldehydes or ketones)

Alternate Name: DMAPCC.

Physical Data: mp 92-94 °C.

Solubility: sol H_2O; sl sol dichloromethane, chloroform.

Form Supplied in: yellow powder; commercially available.

Analysis of Reagent Purity: elemental analysis.

Preparative Method: by addition of ***4-Dimethylaminopyridine*** to a cooled solution of ***Chromium(VI) Oxide*** oxide in aqueous HCl.[1]

Handling, Storage, and Precautions: nonhygroscopic, shelf stable at rt indefinitely; slightly light sensitive over a period of days; preferably should be stored for long periods in a brown glass container. Treat as a typical chromium(VI)-amine reagent: oxidizer and cancer suspect agent. The reagent is most conveniently used as a suspension in CH_2Cl_2 or $CHCl_3$.

Selective Oxidant for Benzylic and Allylic Alcohols.

DMAPCC was developed in an investigation of the effects of varying the amine ligand on chlorochromate oxidations

of alcohols.[1] Compared to other pyridinium ligands, the (dimethylamino)pyridinium species oxidizes primary alcohols only very slowly. For example, when *n*-heptanol is treated with 4.0 equiv of DMAPCC in dichloromethane for 4 h, 94% of the starting alcohol is recovered (5% oxidation to heptanal).

In contrast to these results, DMAPCC is a useful reagent for the oxidation of allylic and benzylic alcohols to the corresponding aldehydes or ketones (eqs 1-3).[1] Like ***Pyridinium Chlorochromate***, the reagent is acidic enough to isomerize initially formed (*Z*)-unsaturated aldehydes to the corresponding (*E*)-isomers (eq 4). The benzylic selectivity is illustrated in the oxidation of 3-[4-(hydroxymethyl)phenyl]propanol using DMAPCC (eq 5). Treatment of this diol with excess reagent affords the benzaldehyde derivative in 62% yield. Less than 2% dialdehyde is obtained under these conditions. In contrast, oxidation of this diol using PCC under analogous conditions affords a mixture of mono- and dialdehyde in 45% and 32% yield, respectively.[1]

(1)

(2)

(3)

(4)

Other Selective Oxidations of Alcohol Functions.

In the attempted selective oxidation of the reduction product of andrenosterone with 3 equiv of DMAPCC under normal conditions, 11-oxotestosterone was obtained in 49% yield (eq 6). Less than 3% andrenosterone was obtained under these conditions.[1] Similarly, treatment of the triol in eq 7 with 4 equiv of the reagent for 3 h affords the more hindered monoketone in 36% yield.[2] Allowing the reaction to proceed for 22 h affords the tricarbonyl compound in 23% yield. It is likely that these observed selectivities are due to differential breakdown of the initially formed, more sterically hindered, secondary chromate ester.

(7)

Limitations.

As with most amine-modified chromium(VI) reagents, attempted oxidations of unprotonated basic nitrogen-containing molecules with DMAPCC are generally unsuccessful.[3] In the attempted oxidation of 2-pyridylcarbinol with this reagent, no aldehyde is observed, nor can starting alcohol be recovered from the reaction mixture. 4-(Dimethylamino)pyridine is the only organic product isolated from the reaction.[3]

Alternative Reagents for Related Selective Oxidations.

Manganese Dioxide has been widely used for the selective oxidations of allylic and benzylic alcohols; however, the reagent is most effective when freshly prepared, large excesses of the reagent must be used, and long reaction times are generally necessary for successful oxidations.[4] ***Barium Manganate*** has also proved to be an effective reagent for similar oxidations.[5] A number of amine-modified chromium(VI) reagents have also been reported to display allylic and benzylic oxidation selectivity.[3]

4-(Dimethylamino)pyridinium Chlorosulfite Chloride

[86128-91-8] · $C_7H_{10}Cl_2N_2OS$ · 4-(Dimethylamino)pyridinium Chlorosulfite Chloride · (MW 241.16)

(synthesis of esters and amides from carboxylic acids; dehydration of aldoximes; synthesis of chlorosilanes)

Physical Data: mp 155-157 °C.

Solubility: sol CH_2Cl_2.

Preparative Methods: generated by reaction of ***4-Dimethylaminopyridine*** with ***Thionyl Chloride*** in CH_2Cl_2 at -20 °C and isolated as a solid. The reagent is most commonly prepared and used in situ.[1]

Purification: need not be isolated; no methods have been described for its purification.

Handling, Storage, and Precautions: must be assumed to be moisture sensitive; precautions should be taken in accordance with those advised for both DMAP and $SOCl_2$.

Carboxyl Activation: Synthesis of Esters and Amides from Carboxylic Acids.

4-(Dimethylamino)pyridinium chlorosulfite chloride is more reactive than either ***Thionyl Chloride*** or thionyl chloride/pyridine for carboxyl activation. Aliphatic and aromatic, as well as amino acids (in racemic form), undergo activation (via the acyl halide) and subsequent esterification by reaction with an alcohol at -20 °C (eq 1).[1] The esterification step requires the addition of a second equivalent of DMAP and this method has been applied to a range of functionalized carboxylic acids.

High yields of esters are obtained from both acid-sensitive (cyanoacetic acid) and base-sensitive carboxylic acids (3-phenylpropionic acid and trichloroacetic acid) and, in these latter cases, use of 4-(dimethylamino)pyridinium chlorosulfite chloride is much more effective than use of thionyl chloride alone. The esterification process has been claimed to be independent of the steric environment of the carboxyl function, though this reagent may be of more limited value with heavily substituted benzoic acids.[2]

Carboxyl activation, in the presence of a primary amine, leads to the corresponding amide in excellent yield (eq 2).[3] In both the esterification and amidation processes and the oxime dehydration reaction discussed below, recovery of DMAP is straightforward.

Dehydration of Aldoximes.

A range of alkyl, aryl, and heteroaryl aldoximes undergo smooth dehydration with 4-(dimethylamino)pyridinium chlorosulfite chloride at -10 to +10 °C to give the corresponding nitriles in 70-100% yield (eq 3).[4]

Synthesis of Chlorosilanes.

t-Butyldiphenylsilanol has been converted to the corresponding chlorosilane in quantitative yield using 4-(dimethylamino)pyridinium chlorosulfite chloride (eq 4).[5] The use of oxalyl chloride/DMAP (see ***Oxalyl Chloride***) is also highly effective for this transformation, but a number of other reagents (concentrated HCl; MeCOCl; $SOCl_2$; *o*-phenylene cyclohexylphosphorochlorimidate/SO_2Cl_2) either fail completely or give inferior yields of product.

(chiral alkyltitanium reagent for asymmetric alkylation reaction;[1] chiral Lewis acid for asymmetric Diels-Alder reaction, [2 + 2] cycloaddition reaction, and intramolecular ene reaction;[2] reagent for asymmetric hydrocyanation of aldehydes and for kinetic resolution of α-aryl carboxylic acid derivatives[2])

Preparative Methods: chiral titanates are usually prepared by mixing dichlorodiisopropoxytitanium and a chiral 1,4-diol in toluene. Other solvents such as ether and dichloromethane can also be employed. The alcohol exchange reaction takes place immediately at rt. Wherever necessary, liberated isopropyl alcohol is

removed by azeotropic removal with toluene.[3] The chiral 1,4-diols are prepared from dimethyl (or diethyl) tartrate by a two-step procedure comprising acetalization followed by the addition of an aryl Grignard reagent.[4,5]

Handling, Storage, and Precautions: chiral titanates are usually prepared just before use under argon atmosphere. Care should be taken to avoid moisture, especially when a catalytic amount of the reagent is used.

Chiral Alkylating Reagent.

The chiral methyltitanium reagent prepared from (**1**) and ***Methyllithium*** or methyl Grignard reagent adds to various aldehydes with moderate to good enantioselectivity (eq 1).[6] Furthermore, the ate complex prepared from the chiral tetraalkoxytitanium (**2**) and methyllithium adds to aromatic aldehydes with more than 90% ee (eq 2).[7] The chiral allyltitanium reagent (**3**) having a cyclopentadienyl group on titanium adds to various aldehydes to give the corresponding allylated products with high optical purity (eq 3).[8]

(1)

(2)

Chiral titanates can be employed as catalysts for the alkylation of aldehydes using dialkylzinc reagents. For example, by the use of a catalytic amount of the chiral titanium reagent (**4**), addition of ***Diethylzinc*** to various aldehydes occurs with high enantioselectivity in the presence of ***Titanium Tetraisopropoxide*** (eq 4).[9] Furthermore, by using the chiral tetraalkoxytitanium (**2**), the alkylation reaction can be carried out in ether, which enables the use of various dialkylzinc reagents prepared in situ from the corresponding Grignard reagents and ***Zinc Chloride*** (eq 5).[10]

Chiral Lewis Acid.

These chiral titanium reagents are widely used as chiral Lewis acid catalysts. The Diels-Alder reaction of methyl acrylate and cyclopentadiene affords the *endo* adduct in moderate enantioselectivity when a stoichiometric amount of the chiral titanium reagent (**5**) is employed (eq 6).[6] Use of 3-(2-alkenoyl)-1,3-oxazolidin-2-ones as dienophiles greatly improves the optical purity of the cycloadduct when the 2-phenyl-2-methyl-1,3-dioxolane derivative (**6**) is used as a chiral ligand. Most importantly, the reaction proceeds with the same high enantioselectivity for the combination of various dienophiles and dienes even when 5-10 mol % of the chiral titanium reagent is employed in the presence of molecular sieves 4A (eqs 7 and 8).[11]

(7)

80-94% ee

(8)

The origin of the high enantioselectivity is found to lie in an attractive π-π interaction between the aryl group of the diol moiety and the dienophiles. Replacement of the phenyl group by a 3,5-dimethylphenyl group (as shown in **7**), which has higher π-basicity than a phenyl group, affords improved enantioselectivities in some cases (eq 9).[12]

(9)

The chiral titanium reagent (**6**) also catalyzes the [2 + 2] cycloaddition reaction of 1,3-oxazolidin-2-one derivatives of

α,β-unsaturated carboxylic acids and ketene dithioacetals in the presence of MS 4A to give cyclobutanone dithioacetal derivatives with high optical purity (eq 10).[13] Vinyl sulfides, alkynyl sulfides, and 1,2-propadienyl sulfides can also be employed in this reaction to give the corresponding cyclobutanes, cyclobutenes and methylenecyclobutane derivatives with high optical purity (eqs 11 and 12).[13-15]

(10)

(11)

(12)

By using a stoichiometric amount of the chiral titanium reagent prepared by mixing chiral diol, ***Titanium(IV) Chloride***, and titanium tetraisopropoxide, the asymmetric [2 + 2] cycloaddition reaction of 1,4-benzoquinones and styrenes gives the corresponding cyclobutane derivatives with high optical purity. These rearrange to 2,3-dihydrobenzofuran

derivatives on mild acid treatment (eq 13).[16]

The asymmetric intramolecular ene reaction of 1,3-oxazolidin-2-one derivatives of a diene carboxylic acid is also promoted by a stoichiometric amount of the chiral titanium reagent (**6**) to give cyclopentane or cyclohexane derivatives with high optical purity (eq 14).[17]

Other Reactions.

Chiral titanates can be employed in several other asymmetric reactions. For example, the chiral titanate (**6**) promotes hydrocyanation of aryl aldehydes by ***Cyanotrimethylsilane*** at low temperature (-65 °C) to give the corresponding cyanohydrins with high optical purity (eq 15).[18] Alkyl aldehydes are also converted into their cyanohydrins in high optical purity by employing the chiral titanium dicyanide species prepared in situ from the chiral titanate (**6**) and TMSCN at rt (eq 16).[18]

(4R,5R)-2,2-Dimethyl-4,5-bis(hydroxydiphenylmethyl)-1,3-dioxolane-Titanium(IV) Chloride

(16)

In the presence of a catalytic amount of the chiral titanium reagent (**8**) prepared from titanium tetraisopropoxide and the (*R*)-1,4-diol, kinetic resolution of *S*-(2-pyridyl) thioesters of α-aryl carboxylic acids is achieved with high relative rate of both the enantiomers to give the (*R*)-isopropyl esters with high optical purity (eq 17).[19]

(17)

The enantioselective iodolactonization of α-hydroxy carboxylic acid derivatives is achieved by using a stoichiometric amount of the chiral titanium reagent (**8**) (eq 18).[20]

Related Reagents.

Chloro(η^5-cyclopentadienyl)[(4R,trans)-2,2-dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolato(2-)-O^{α},O$^{α´}$]titanium; ***Dichlorotitanium Diisopropoxide***; ***2,2-Dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolatotitanium Diisopropoxide***.

N-[(Dimethylamino)-1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-ylmethylene]-*N*-methylmethanaminium Hexafluorophosphate *N*-Oxide

[148893-10-1] · $C_{10}H_{15}F_6N_6OP$ · *N*-[(Dimethylamino)-1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-ylmethylene]-*N*-methylmethanaminium Hexafluorophosphate *N*-Oxide · (MW 380.28)

(coupling reagent for peptide synthesis[1-4])

Alternate Name: HATU.

Physical Data: mp: sample decomposes at temperatures above 180 °C.

Solubility: sol DMF (0.6 mol L^{-1}).

Form Supplied in: white solid; commercially available.

Purification: by crystallization from a mixture of MeCN and CH_2Cl_2.

Handling, Storage, and Precautions: is very stable, not hygroscopic, and can be stored indefinitely at 0 °C. HATU solutions in DMF (0.5 M) can be stored in an inert atmosphere for weeks (after 4 weeks, purity is 85 %). Syntheses of peptides carried out with freshly prepared and 3-week old solutions show crude products of similar quality.[5] Violent decomposition can occur when dried at elevated temperature.

General Considerations.

HATU is the 7-azabenzotriazolyl analog of ***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate*** (HBTU).[6] X-ray structure determinations of both HATU and HBTU have revealed that the solid-state structures differ from the formulations commonly presented in the literature.[7] The solid-state structure is not the *N,N,N´,N´*-tetramethyluronium salt but rather the guanidinium *N*-oxide.

HATU and its pyrrolidinium derivative, 1-(1-pyrrolidinyl-1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-ylmethylene)pyrrolidinium hexafluorophosphate *N*-oxide (HAPyU), have been used as condensing reagents for the preparation of peptides by both solution and solid-phase techniques.[1-3] In solution, reaction of α-amino protected amino acids or dipeptides with equimolar amounts of α-carboxyl protected amino acid hydrochlorides or amino amides, and base (2 equiv) [***Diisopropylethylamine*** (DIPEA), *N*-methylmorpholine (NMM), ***2,4,6-Collidine***, or ***1,8-Bis(dimethylamino)naphthalene*** (Proton Sponge, PS)] in DMF proceeds cleanly, yielding the corresponding peptides in good yields. The level of epimerization in HATU-mediated couplings was reduced compared to HBTU-promoted acylations (eq 1) (Table 1).[1,4,8]

$$RCO_2H + R'NH_2 \xrightarrow[\text{DIPEA}]{\text{HATU}} RCONHR' \qquad (1)$$

Table 1 Racemization during HATU/HBTU Couplings in Solution

Entry	RCOOH	R¢NH$_2$ or R¢NH$_2$·HCl	Conditions	DL-isomer (%)
1	Z Phg OH	H Val OMe·HCl	HATU, PS- (3 equiv), 7 h	<1 2
2	Z Phg OH	H Val OMe·HCl	HBTU, PS- (3 equiv), 7 h	4.0
3	Bn Val OH	H Val OMe·HCl	HATU, NMM- (3 equiv), 3 h	28.3
4	Bn Val OH	H Val OMe·HCl	HBTU, NMM- (3 equiv), 3.5 h	46.8
5	Z Phe Val OH	H Val OMe·HCl	HATU, DIPEA- (3 equiv), 3.5 h	<1 2
6	Z Phe Val OH	H Val OMe·HCl	HBTU, DIPEA- (3 equiv), 4 h	4.1
7	Z Gly Phe OH	H Pro NH$_2$	HATU, DIPEA- (2 equiv)	1.6

							(2 equiv)	
8	Z	Gly	Phe	OH	H	Pro	NH_2	HATU, collidine-(2 equiv)	0.8
9	Z	Gly	Phe	OH	H	Pro	NH_2	HBTU, DIPEA-(2 equiv)	3.9
10	Z	Gly	Phe	OH	H	Pro	NH_2	HAPyU, DIPEA-(2 equiv)	1.3
11	Z	Gly	Phe	OH	H	Pro	NH_2	HAPyU, collidine-(2 equiv)	0.8
12	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HATU, DIPEA-(2 equiv), 3 h	4.0
13	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HBTU, DIPEA-(2 equiv), 3 h	17
14	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HATU, collidine-(2 equiv), 3 h	<0.1
15	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HBTU, collidine-(2 equiv), 3 h	12
16	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HAPyU, DIPEA-(2 equiv), 3 h	5.0
17	Fmoc	Phe	Ser-(*t*-Bu)	OH	H	Pro	NH_2	HAPyU, collidine-(2 equiv), 3 h	<0.1

The results, collected in Table 1, clearly indicated that (i) HATU is superior to HBTU (entries 1 vs. 2, 3 vs. 4, 5 vs. 6, 7 vs. 9, and 12 vs. 13); (ii) HAPyU is similar to HATU, although in some cases HAPyU can give slightly better results (entries 7 vs. 10); and (iii) the use of collidine considerably reduces the level of epimerization (entries 7 vs. 8, 12 vs. 14, 13 vs. 15, and 16 vs. 17).

HATU activation has been adapted for automated stepwise solid-phase peptide synthesis for both fluorenylmethyloxycarbonyl (Fmoc) and *t*-butyloxycarbonyl (Boc) strategies. For the former, the fragment 65-74 (H-Val-Gln-Ala-Ala-Ile-Asp-Tyr-Ile-Asn-Gly-NH_2) of the acyl carrier protein was chosen as a model to compare the performance of HATU and HBTU. Results from these studies indicated that uronium salt coupling is superior to carbodiimide and pentafluorophenyl ester-mediated methods, and the aza derivatives are more efficient than HBTU.[3]

HATU has shown special utility for the synthesis of peptides containing hindered amino acids. Thus the solid-phase assembly of the model pentapeptide H-Tyr-Aib-Aib-Phe-Leu-NH_2 was compared via three different coupling methods, HATU, HBTU, and Fmoc-amino acid fluorides, the last named being known as one of the most efficient reagents for

couplings involving consecutive Aib units.[9] After 2 h coupling using 4 equiv of both Fmoc-Aib-OH and Fmoc-Tyr(*t*-Bu)-OH, as well as HXTU plus 8 equiv of DIPEA (all remaining couplings were carried out for 30 min), the pentapeptide was obtained with a purity of 94% for the HATU synthesis, and only 43% for HBTU. The synthesis conducted under similar conditions with Fmoc-Aib-F gave a purity of 96%, indicating that the reactivity of HATU is much closer to that of fluorides than to that of HBTU.[3]

The use of HATU for the solid-phase coupling of *N*-methyl amino acids has also been shown to be beneficial if compared with HBTU, as found during the syntheses of fragments of cyclosporin (CsA): H-Val-MeLeu-Ala-NH_2 (HATU, >99%; HBTU, 87%);[10] H-MeLeu-MeLeu-Ala-NH_2 (HATU, >99% HBTU, 34%);[10] H-D-Ala-MeLeu-MeLeu-MeVal-Phe-Val-OH (HATU, 85%; HBTU, 8%).[3]

Various protected peptide segments have been coupled by solid-phase techniques using HATU-mediated coupling methods.[11] Thus the synthesis of the *N*-terminal domain of γ-zein protein has been reported in good yield by eight successive segment couplings of the same protected hexapeptide to give the desired sequence using HATU and ***3-Hydroxy-3H-1,2,3-triazolo[4,5-b]pyridine*** (HOAt) in the presence of DIPEA.[12]

Less racemization is observed for solid-phase segment condensations in the presence of HATU relative to HBTU. The coupling of Fmoc-Phe-Ser(*t*-Bu)-OH onto H-Pro-resin was accompanied by 5% and 15% racemization, respectively, with HATU and HBTU in the presence of DIPEA. Replacement of DIPEA with collidine reduced the racemization level to 3%, confirming the effects observed for coupling reactions carried out in solution.[4]

HATU and HAPyU have been used for the cyclization of linear peptides in both solution and solid-phase modes. Cyclization in solution with HAPyU of a linear hexapeptide constructed exclusively from L-amino acids gave a better yield and less racemization at the *C*-terminal residue compared to other uronium or phosphonium salts.[13] HATU has also been shown to be the method of choice for cyclizations conducted while the peptide still remains anchored to the polymeric support. In the preparation of a library of 1296 cyclic pentapeptides, cyclization was complete after 1 h as judged by the ninhydrin test.[14]

In the absence of the carboxylic component, HATU, as is the case for HBTU, reacts with amino groups leading to the formation of tetramethylguanidinium derivatives.[5,15] In syntheses conducted in solution, an excess of either HATU or amino component should be avoided. In both solution and solid-phase strategies, the order of addition of reagents is critical. HATU should be delivered to the carboxylic component for preactivation prior to addition of the amine.

In addition, formation of the guanidinium derivative can also occur during slow reactions, such as the preparation of cyclic peptides, where both amino and carboxylic components are of necessity present together in equimolar amounts. An excess of the uronium salt can block the amino group.[16] For the synthesis of cyclic peptides, the phosphonium derivatives 7-azabenzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyAOP) and 7-azabenzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate (AOP), which are also commercially available, may be more useful.

Dimethyl Bis(methylthio)methylphosphonate[1]

[61779-87-1] · $C_5H_{13}O_3PS_2$ · Dimethyl Bis(methylthio)methylphosphonate · (MW 216.29)

(treatment with base gives a carbanion that reacts with aldehydes and ketones[1-5])

Alternate Name: O,O-dimethyl formylphosphonate *S,S*-dimethyl thioacetal.

Physical Data: bp 72 °C/0.05 mmHg.

Solubility: sol THF, DME.

Form Supplied in: not commercially available.

Preparative Methods: $(MeO)_2P(O)CH(SMe)_2$[6] and related *S,S*-thioacetals of formylphosphonates[6,7] are readily prepared in high yields by the Arbuzov reaction of trialkyl phosphites with chloro dithioacetals (eq 1).[1,8] Other syntheses of thiophosphonates are known.[9]

Reactions with Aldehydes and Ketones.

The carbanion derived from the treatment of $(MeO)_2P(O)CH(SMe)_2$ with a base reacts with cyclic and acyclic, aliphatic and aromatic aldehydes and ketones in a Horner-Wadsworth-Emmons reaction to give ketene *S,S*-thioacetals in high yields[1-5] (eq 2[2,3]). The carbanion is generated using either ***n-Butyllithium*** in THF at -78 °C[2,3] or, less commonly, ***Sodium Hydride*** in DME.[2] Alternatively, with aromatic aldehydes the reaction may be performed under two-phase

conditions using ***Benzyltriethylammonium Chloride*** (TEBA) as a phase-transfer catalyst.[2]

(2)

Product	Conditions	Yield (%)	Ref
$H_2C{=}CH(SMe)_2$	BuLi, THF, -78 °C	96	2
$Me_2C{=}CH(SMe)_2$	BuLi, THF, -78 °C	80	2
$PhHC{=}CH(SMe)_2$	BuLi, THF, -78 °C	90	2
	NaH, DME	75	
	50% NaOH, THF, 5% TEBA	88	
	BuLi, THF, -78 °C	82	2
	BuLi, THF, -78 °C	60	3

Ketene *S*,*S*-thioacetals are key synthetic intermediates, susceptible to nucleophilic and electrophilic attack.[1,2b,10] Hydrolysis and alcoholysis of ketene *S*,*S*-thioacetals yields carboxylic acids and esters, respectively. Other transformations of ketene *S*,*S*-thioacetals allow homologation of the precursor carbonyl compound and polyfunctional ketene *S*,*S*-thioacetals provide access to heterocycles (e.g. eq 3).[11]

(3)

Alternative methods for the preparation of ketene *S*,*S*-thioacetals from carbonyl compounds include the Wittig reaction with phosphite ylides and the Peterson reaction with lithium derivatives of trimethylsilyl dithioacetals (eq 4).[1] The Wittig preparation is limited to aldehydes and is further restricted by the availability of the phosphite ylides. Also,

whereas the phosphate ester byproduct of the Horner-Wadsworth-Emmons reaction is water soluble and therefore easily separated from the ketene *S,S*-thioacetal, the phosphine oxide byproduct of the Wittig reaction is usually of a solubility similar to the product. The Peterson alkenation is a general synthesis, but suffers long reaction times and low yields with sterically hindered ketones.

(4)

Related Systems.

The carbanions of related *S,S*-thioacetals of formylphosphonates also react with aldehydes and ketones, including α,β-unsaturated aldehydes and ketones, to give the corresponding ketene *S,S*-thioacetals[2,4,5,12] (e.g. eq 5[2,12]). Horner-Wadsworth-Emmons reactions of carbonyl compounds with *O,S*-thioacetals of formylphosphonates[2a,5] [e.g. $(MeO)_2P(O)CH(SMe)OMe$] and mono(thio)phosphonates[4,13] [e.g. $(MeO)_2P(O)CH_2SMe$] are also known.

(*R,R*)-2,5-Dimethylborolane[1]

[97011-90-0] · $C_6H_{13}B$ · (*R,R*)-2,5-Dimethylborolane · (MW 96.00)

(reagent for asymmetric hydroboration;[2] also used as an auxiliary for asymmetric ketone reduction,[3] aldol,[4] and crotylboration[5] reactions; derived reagents are used in double asymmetric syntheses[6])

Physical Data: the most stable precursor is a complex with (*S*)-(+)-prolinol: mp 225-226 °C; [α]21D +23.2° (*c* 1.28, $CHCl_3$).

Solubility: sol pentane, Et_2O, THF.

Analysis of Reagent Purity: optical purity is assayed by oxidation (NaOMe, H_2O_2) to give 2,5-hexanediol, which has a maximum published rotation $[\alpha]^{23}_D$ -35.6° (*c* 8.29, $CHCl_3$). Derivitization of the diol as the bis-MTPA ester followed by HPLC analysis gives the relative amounts of (*R,R*)-, (*R,S*)-, and (*S,S*)-diols present.

Preparative Methods: a ca. 1:1 mixture of *cis*- and *trans*-*B*-methoxy-2,5-dimethylborolanes is first obtained by reaction of the Grignard reagent derived from 2,5-dibromohexane with diethylaminodichloroborane, followed by acidic methanolysis (eq 1).[2]

The *cis* isomer is then selectively complexed with *N,N*-dimethylaminoethanol, and the resolvable *trans* isomer is isolated by vacuum transfer (eq 2).

Reagent (**1**) is obtained by treatment of the racemic *trans* isomer with 0.45 equiv of (*S*)-prolinol, followed by vacuum transfer of the volatile fraction containing mostly (*S,S*)-2,5-dimethyl-*B*-methoxyborolane (eq 3). Through similar manipulation, (**2**) is obtained (eq 4).

Handling, Storage, and Precautions: (*R,R*)-2,5-dimethylborolane is stored as an air- and moisture-stable

complex (**1**) with (*S*)-(+)-prolinol. The (*S*,*S*)-isomer is stored as a stable complex with either (*R*)-(-)-prolinol or as a complex (**2**) with (*S*)-(+)-valinol, which is more readily available. The reagent and many of its derivatives are extremely air- and moisture-sensitive, and may ignite when exposed to air. Precautions for the handling of such materials should be rigorously followed.[7]

Asymmetric Hydroboration.[2]

For reaction with a prochiral alkene, (*R*,*R*)-2,5-dimethyl-*B*-methoxyborolane is liberated from (**1**) and a standard solution of the corresponding lithium dihydridoborate in ether is prepared (eq 5). Hydroboration is effected by addition of ***Iodomethane*** to the solution of dihydridoborate and alkene (eq 6). After oxidation, chiral secondary alcohols of high enantiomeric purity and predictable configuration are obtained from *cis*, *trans*, and trisubstituted alkenes. As is the case with other known asymmetric hydroborating agents,[8] 2-methyl-1-alkenes react with low asymmetric induction.

(5)

(6)

Asymmetric Reduction of Ketones.[3a,b]

A reagent system consisting of (*R*,*R*)-2,5-dimethylborolane (1.0 equiv) and the corresponding borolanyl mesylate (0.2 equiv) reduces a variety of prochiral ketones with asymmetric induction in the range of 80-100% ee. The reagent system is prepared in situ by addition of 1.4 equiv of ***Methanesulfonic Acid*** to a solution of the lithium dihydridoborate, prepared as in eq 5 above (eq 7).

(7)

Kinetic and molecular modeling studies support the view that asymmetric ketone reduction proceeds through reaction of the borolane with a complex formed by coordination of the borolanyl mesylate *syn* to the smaller alkyl group (R^1) of the

ketone (eq 8).[3b] After reaction is complete, the chiral borolane moiety is recovered as a crystalline complex with 2-amino-2-methyl-1-propanol (eq 9).

Asymmetric Aldol Reactions.[4]

For use in asymmetric aldol reactions, the dihydridoborate (eq 5) is converted to the borolanyl triflate (eq 10). The derived boron enolates of 1,1-diethylpropyl propanethioate (R = Me) and ethanethioate (R = H) react with representative aldehydes to give β-hydroxythioates with good to excellent enantioselectivity (eq 11). In the propanethioate series (R = Me), the observed 2,3-*anti* selectivity (*anti*:*syn* &egt; 30:1) is related to the preponderance of *E*(O)-geometry in the enolate.[9] The 1,1-diethylpropyl group of the thioate was selected to maximize the *E*(O):*Z*(O) ratio. Due to their intrinsically high enantioselectivity, the above enolates undergo highly diastereoselective aldol reactions with chiral aldehydes.[10] These double asymmetric[6] reactions have been employed in natural product syntheses.[11]

The borolanyl triflate (eq 10) has also been employed to form the chiral boron enolates of methyl ketones which have additional chiral centers present in their carbon framework. Reaction of these enolates with chiral aldehydes constitutes a triple asymmetric synthesis, in which the approximate multiplicativity of the three diastereofacial selectivities appears to be valid.[12]

Asymmetric Crotylboration.[5]

Reagents for crotylboration are prepared from 2,5-dimethyl-*B*-methoxyborolane (eq 5) by addition of (*Z*)- or (*E*)-crotylpotassium under standard conditions. Reactions with representative achiral aldehydes are 93-96% diastereoselective and 86-97% enantioselective for the major diastereomer (eqs 12 and 13). Results with chiral aldehydes conform to the rule of double asymmetric synthesis.[6]

(12)

(13)

Related Reagents.

Diisopinocampheylborane; ***Dilongifolylborane***; ***Monoisopinocampheylborane***.

Dimethyl 3-Bromo-2-ethoxy-1-propenylphosphonate[1]

[73542-48-0] · $C_7H_{14}BrO_4P$ · Dimethyl 3-Bromo-2-ethoxy-1-propenylphosphonate · (MW 273.08) (*E*)

[87278-14-6] (*Z*)

[119226-85-6]

(reagent for effecting cyclopentenone annulations[2,3])

Physical Data: colorless liquid; distillation temperature (bulb-to-bulb) 110 °C/0.05 mmHg.

Solubility: sol THF, $CHCl_3$, EtOAc, and other common organic solvents.

Preparative Method: is readily prepared in two steps from the commerically available keto phosphonate (**1**).[2b] Reaction of (**1**) with ***Triethyl Orthoformate*** in the presence of $FeCl_3.6H_2O$, followed by allylic bromination of the resultant enol ether (**2**), provides the title reagent (**3**) in 71% overall yield (eq 1).

Handling, Storage, and Precautions: should be used shortly after its preparation and should be handled only in a well-ventilated fume hood.

Cyclopentenone Annulations.

The use of (**3**) for the synthesis of 2-cyclopentenones involves three steps, as shown in general terms in eq 2. Alkylation of carbonyl substrates (**4**) with reagent (**3**),[4] followed by mild acid hydrolysis of the resultant products (**5**), affords the diketo phosphonates (**6**). Subjection of the latter substances to intramolecular Horner-Emmons processes[5] provides the annulation products (**7**).

A variety of functionalized ketones have been alkylated successfully with reagent (**3**).[2,6-10] In those cases in which this process is sluggish or inefficient, the use of the iodo reagent (**8**) is beneficial.[11-14]

(**8**)

Conversion of (**5**) into (**6**) (eq 2) is typically accomplished by treatment of (**5**) with dilute aqueous HCl in acetone at rt.[2,6-14] Under these conditions, groups that are potentially acid sensitive (acetals,[2,8] esters,[2,10,11] conjugated diene system[12]) are (normally) stable, although cleavage of a primary TBDMS ether has been noted.[13]

The intramolecular Horner-Emmons reaction (eq 2) has been effected via a variety of procedures, including the use of ***Sodium Hydride*** in DME,[2,6,13-18] THF,[8,15] or DMF[11] at various temperatures, ***Potassium Carbonate*** in the presence of

18-Crown-6 in benzene[7,9] or toluene,[19] phase-transfer conditions employing ***Tetra-n-butylammonium Hydroxide***-water in benzene[20] or toluene,[10] and $MeSOCH_2Na$ in THF.[12] While the use of NaH as base is usually satisfactory, this protocol fails to convert (**9**) into bicyclo[3.3.0]oct-1-en-3-one (**10**).[16] This transformation is readily achieved, however, as shown in eq 3.[20]

(3)

Compared with other procedures for effecting cyclopentenone annulations,[3] the method under discussion (eq 2) has several advantages. The overall process is convergent in nature, is generally efficient, and, importantly, the final step (internal Horner-Emmons reaction) can be achieved under conditions that do not isomerize the initially formed product (**7**). The synthetic utility of this method is illustrated by the examples given in eqs 4 and 5.[9,14]

Dimethyl Bromomalonate

(**1**; R = Me)

[868-26-8] · $C_5H_7BrO_4$ · Dimethyl Bromomalonate · (MW 211.02) (**2**; R = Et)

[685-87-0] · $C_7H_{11}BrO_4$ · Diethyl Bromomalonate · (MW 239.08) (**3**; R = *t*-Bu)

[15960-79-9] · $C_{11}H_{19}BrO_4$ · Di-*t*-Butyl Bromomalonate · (MW 295.20)

(cyclopropanation of Michael acceptors;[1,2] synthesis of vinylogous urethanes from thioamides via the Eschenmoser sulfide contraction[3-5])

Physical Data: (**1**) bp 112.5-113 °C/15 mmHg.[6] (**2**) bp 150-152 °C/25 mmHg.[6] (**3**) bp 120-125 °C/11 mmHg.[7]

Form Supplied in: (**1**) technical grade, ~90% purity; (**2**) technical grade, 85-95% purity, contains varying amounts of diethyl malonate and diethyl dibromomalonate.

Analysis of Reagent Purity: (**1**) ^{1}H NMR ($CDCl_3$) δ 3.85 (6H, s), 4.87 (1H, s);[8] (**2**) ^{1}H NMR (CCl_4) δ 1.34 (6H, t, *J* = 7 Hz), 4.28 (4H, q, *J* = 7 Hz), 4.72 (1H, s); IR (CCl_4) 1750 cm^{-1}; (**3**) ^{1}H NMR ($CDCl_3$) δ 1.45 (18H, s), 4.6 (1H, s);[9] ^{13}C NMR ($CDCl_3$) δ 27.4, 45.4, 83.5, 163.3;[9] IR (KBr) 1756 cm^{-1};[9] IR (CCl_4) 1765, 1740 cm^{-1};[10] IR (film) 1735 cm^{-1}.[4]

Preparative Methods: (**1**): by treatment of ***Malonic Acid*** with ***Bromine*** in diethyl ether followed by esterification with HCl in methanol;[11] by electrolytic bromination of dimethyl malonate with ***Magnesium Bromide*** or ***Copper(II) Bromide*** and ***Sodium Methoxide*** in acetonitrile-water at 2-3 °C.[12] (**2**): by light-induced bromination of ***Diethyl Malonate*** with bromine in carbon tetrachloride;[13] by treatment of diethyl malonate with bromotrichloromethane and ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** in benzene at 0 °C.[14] (**3**): by bromination of ***Malonic Acid*** with bromine in diethyl ether at rt followed by sulfuric acid catalyzed esterification with ***Isobutene*** in diethyl ether at rt;[7] by bromination of di-*t*-butyl malonate with bromine and ***Calcium Carbonate*** in chloroform at rt followed by reflux;[7] by lithiation of di-*t*-butyl malonate with ***n-Butyllithium*** in THF at -78 °C followed by addition of bromine and allowing reaction to warm to rt;[10] by lithiation of di-*t*-butyl malonate with *n*-butyllithium in THF at -78 °C, addition of ***Chlorotrimethylsilane***, warming to rt, and treatment of the resulting trimethylsilyl ketene acetal solution with bromine in carbon

tetrachloride.[4]

Cyclopropanation.

Bromomalonates react with Michael acceptors (α,β-unsaturated aldehydes, ketones, esters, and nitriles) under basic conditions to yield cyclopropane-1,1-dicarboxylic esters (eqs 1 and 2). Sodium[1,15] or potassium alkoxides,[10] ***1,1,3,3-Tetramethylguanidine***,[10] ***Potassium Carbonate***,[16] ***Diisopropylethylamine***,[2] and ***Cesium Fluoride*** or ***Potassium Fluoride***[17] have been used as bases in this reaction.

(1)

(2)

Eschenmoser Sulfide Contraction.

Thioamides react with bromomalonates under mild conditions to give vinylogous urethanes (eq 3).[3,4,5] In some cases, the addition of a phosphine is unnecessary because the intermediates spontaneously extrude sulfur.[3,5] The Battersby group has made extensive use of this process, followed by ester hydrolysis and decarboxylation, as a method for introduction of a methyl group in studies of vitamin B_{12} biosynthesis.[4,18] Use of 2-^{13}C labeled di-*t*-butyl bromomalonate (prepared from $^{13}CH_3CO_2H$) allows introduction of a ^{13}C-labeled methyl group.[18d]

N-, *O*-, and *S*-Alkylation.

Amino-, aryloxy-, and thiomalonates can be prepared by alkylation of amines,[7,8,11,19] phenols,[6,20] and thiols,[21] respectively, with bromomalonates (eq 4).

Other Applications.

Mn^{III}-promoted radical additions of dimethyl bromomalonate to alkenes give (β-bromoalkyl)malonates (eq 5).[22] A Wittig-type alkenation of aldehydes can be accomplished with ***Tri-n-butylstibine*** and bromomalonates (eq 6).[23] Bromomalonates can also serve as oxidizing agents, probably by acting as Br^+ donors (eq 7).[24]

Dimethylbromomethyleneammonium Bromide

(**1**; X = Br)

[24774-61-6] · $C_3H_7Br_2N$ · Dimethylbromomethyleneammonium Bromide · (MW 216.91) (**2**; X = $POBr_2$)

[-] · $C_3H_7Br_3NOP$ · Dimethylbromomethyleneammonium Dibromophosphate · (MW 343.77)

(conversion of primary, secondary, and tertiary aliphatic alcohols,[1] including those in sugars and nucleosides,[2] into the corresponding bromides; preparation of β-bromovinyl aldehydes,[3] and β-bromo-α,β-unsaturated ketones[4])

Physical Data: (**1**) mp 156-158 °C.

Form Supplied in: prepared in situ.

Preparative Methods: reagent (**1**) can be prepared by dropwise addition of ***Thionyl Bromide*** to DMF in a chlorinated solvent; after the addition is complete, the mixture is heated at 40 °C to remove any remaining sulfur dioxide (eq 1).[1]

An alternative preparation of this reagent from ***Triphenylphosphine***, ***Bromine***, and ***N,N-Dimethylformamide*** is claimed to be easier to perform.[1] A third route involves passing gaseous ***Hydrogen Bromide*** through a solution of ***Dimethylchloromethyleneammonium Chloride***.[1,2]

Reagent (**2**) can be prepared by adding ***Phosphorus(III) Bromide*** slowly to DMF in chloroform.[2] Reagent (**2**) is more reactive than the bromide salt (**1**), which has been accounted for by a rapid exchange of the bromide and dibromophosphate anions (eq 2).

Handling, Storage, and Precautions: the reagents are corrosive, air-sensitive, and lachrymatory, and must be treated with caution. Avoid skin contact. Reagents (**1**) and (**2**) must be generated prior to the reaction under anhydrous conditions. An explosion of a flask containing a β-bromovinyl aldehyde has been reported.[5] Use in a fume hood.

Conversion of Alcohols into Bromides.

Alcohols have been converted into the corresponding bromides in high yields using reagent (**1**) (eq 3).[1] Hydroxy groups of nucleosides are converted into bromides using similar conditions.[3] Thus, yields (%) for the following compounds were obtained: R^1/R^2 = $Me(CH_2)_3CH_2/H$ (89); $CyCH_2$ (82); PrMeCH (83); Et_2CH (82).

The reagent derived from DMF-***Triphenylphosphine Dibromide*** converts primary alcohols into bromides, but converts secondary alcohols into formate esters. Where primary and secondary alcohol functions are present, they are respectively converted into bromide and formate (eq 4).[4]

Reaction with 1,3-Diketones.

Mewshaw[5] reported that cyclic 1,3-diketones can be converted into β-bromo-α,β-unsaturated ketones in high yields

using reagent (**1**) (eq 5). The corresponding β-chloro-α,β-unsaturated ketones have been synthesized using dimethylchloromethyleneammonium chloride. Complexes derived from DMF and ***Phosphorus Oxychloride*** can give bis(β-chlorovinyl aldehydes) (eq 6).[6]

(5)

(6)

Preparation of β-Bromovinyl Aldehydes.

Reagents (**1**) and (**2**) react with methyl or methylene ketones to give β-bromovinyl aldehydes (β-BVAs) (eq 7).[2,7,8] Steroidal systems containing a ketone function also undergo this reaction.[9]

(7)

$$X = Y = Br;\ X = Br,\ Y = POBr_2$$

β-BVAs have been used as synthetic intermediates. The bromide group is easily displaced[7,9,11] and the aldehyde group is readily converted into other functionalities (eqs 8 and 9).[7,10-12] β-BVAs have not received the same level of attention as β-chlorovinyl aldehydes,[6,10,13] probably owing to the comparative instability of the former compounds.

(8)

(9)

Related Reagents.

Dimethylchloromethyleneammonium Chloride; ***N,N-Dimethylformamide***; ***Phosphorus(III) Bromide***.

[90482-06-7]

(chiral auxiliary for derivatization, directed lithiation, and asymmetric alkylation adjacent to nitrogen of benzylic or allylic secondary amines by formamidine exchange, metalation, alkylation, and hydrolysis[1,2])

Physical Data: bp 55-65 °C/0.05 mmHg; $[\alpha]_D$ -59.6° (*c* 3.5, EtOH).[2]

Preparative Methods: easily prepared from (*S*)-valinol in a high yielding four-step procedure (eq 1).[2] Other chiral formamidines can be prepared and used successfully in the methodology outlined here (eq 2).[2,3]

Handling, Storage, and Precautions: store under argon at rt; use in a fume hood.

Introduction.

In the equations, VBE will be used to depict the valinol *t*-butyl ether portion of the formamidine, while the *t*-leucinol methyl ether portion will be abbreviated LME.

Upon heating the title formamidine with a secondary amine, dimethylamine is extruded, affording a chiral formamidine derivative of the original amine (eq 3).[4a]

(S)-N,N-Dimethyl-N´-(1-t-butoxy-3-methyl-2-butyl)formamidine

Deprotonation and alkylation followed by formamidine removal allows entry to a host of isoquinoline alkaloids (eq 4).[3b,4]

This protocol has also been an avenue to a variety of indole alkaloids (eq 5).[5]

(S)-N,N-Dimethyl-N´-(1-t-butoxy-3-methyl-2-butyl)formamidine

Chiral 1-alkyl-2-benzazepines can be formed by utilization of the same method (eq 6).[3a]

This strategy also works well for the asymmetric alkylation of 3-pyrrolines (eq 7)[6] and tetrahydropyridines (eq 8).[7]

(7)

(S)-N,N-Dimethyl-N´-(1-t-butoxy-3-methyl-2-butyl)formamidine

The mechanistic process of these asymmetric alkylations and the configurational stability of the chiral lithioformamidines have been investigated.[8] A limitation of this strategy is that saturated, cyclic, secondary amines (e.g. pyrrolidines and piperidines) cannot be successfully alkylated in an asymmetric fashion.

Related Reagents.

N-t-Butoxycarbonyl-N-methylaminomethyllithium; ***N´-t-Butyl-N,N-dimethylformamidine***; ***N´-t-Butyl-N-methyl-N-trimethylsilylmethylformamidine***; ***N,N-Dimethylformamide Diethyl Acetal***; ***(R)-Methyl 2-t-Butyl-3(2H)-oxazolecarboxylate***; ***N-Nitrosodimethylamine***.

3,3-Dimethyl-1-butynylcopper(I)

[40575-23-3] · C_6H_9Cu · 3,3-Dimethyl-1-butynylcopper(I) · (MW 144.70)

(used in preparation of mixed cuprates; acts as weak nucleophile)

Alternate Names: *t*-butylethynylcopper(I); copper(I) *t*-butylacetylide.

Physical Data: orange solid; mp 80-150 °C (dec).

Solubility: sol ether, saturated hydrocarbons.

Preparative Methods: most conveniently prepared in situ by treatment of 3,3-dimethyl-1-butyne with ***n-Butyllithium***, followed by addition of ***Copper(I) Iodide*** or the $Me_2S.CuBr$ complex (see ***Copper(I) Bromide***).[1,2] 3,3-Dimethyl-1-butynylcopper(I) (**1**) can be isolated as a solid by addition of 3,3-dimethyl-1-butyne to a premixed solution of ***Copper(II) Sulfate*** and ***Hydroxylamine*** hydrochloride in aqueous ammonia. The aqueous layer is decanted and the precipitate is extracted with pentane. After workup, (**1**) is collected upon concentration of the solvent. Alternatively, (**1**) has been prepared by photoreduction of ***Copper(II) Acetylacetonate*** in the presence of 3,3-dimethyl-1-butyne.[3]

Handling, Storage, and Precautions: air and moisture sensitive. Use in a fume hood.

Weak Nucleophile.

Alkynyl organocopper reagents are weak nucleophiles; however, (**1**) will react with pivaloyl chloride to give 2,2,6,6-tetramethyl-4-heptyn-3-one (**2**) in 69% yield (eq 1).[4] The more reactive higher-order cuprate (**3**), formed from (**1**) and 2 equiv of lithium *t*-butylacetylide, transfers a *t*-butylacetylene group to phosphonoamine (**4**), affording alkynylamine (**5**) in 60% yield (eq 2).[5]

(1)

Other attempts at electrophilic transfer of a *t*-butylacetylene group are not as successful. Treatment of (**1**) with ***Cyanogen Bromide*** does not produce the desired nitrile (**6**); instead, bis-alkyne (**7**) is the only product isolated (eq 3).[6] The cuprate prepared from (**1**) and butylmagnesium bromide reacts slowly with benzoyl chloride, affording only a moderate yield (28%) of ketone (**8**) (eq 4).[7]

Mixed Organocuprates.

The title reagent is most commonly used for the in situ preparation of mixed cuprates. Alkynes bind tightly to copper, allowing selective transfer of a synthetically valuable primary, secondary, or vinylogous lithium reagent.[1,8] The *t*-butylacetylene ligand offers several advantages, including good solubility in ether and THF, thermal stability allowing reactions to be run at 0 °C, and volatile, easily removed byproducts. The first examples demonstrated the transfer of methyl and vinyl substituents to isophorone (**9**) (eq 5).[1] More complex groups include the α-acrolein anion equivalent (**12**), which adds in 1,4-fashion to enones in excellent yields (eq 6).[9,10]

(5)

(9)

(10) R = Me, 76%
(11) R = vinyl, 52%

(6)

(12) **(13)**

Mixed cuprates derived from (**1**) have been used in natural product total synthesis. 1,4-Addition of the cyclopropylcuprate (**14**) to 2-cyclohexen-1-one provided adducts (**15**) and (**16**) in a 3.1:1 ratio in 45% yield (eq 7). The *threo* adduct (**15**) can then be converted to (±)-*threo*-juvabione (**17**) in several steps.[11] The 1-heptenyl cuprate (**19**) reacts with primary iodide (**18**) to give alkene (**20**), with complete retention of the *cis* stereochemistry, in 36% yield with a 25% recovery of (**18**). Intermediate (**20**) can then be taken forward in a synthesis of LTB_4 (**21**) (eq 8).[12]

(17) (±)-*threo*-Juvabione

(21) LTB_4

Dimethylcarbamoyl Chloride

(**1**; X = Cl)

[79-44-7] · C_3H_6ClNO · Dimethylcarbamoyl Chloride · (MW 107.55) (**2**; X = F)

[431-14-1] · C_3H_6FNO · Dimethylcarbamoyl Fluoride · (MW 91.10)

(convenient source of the dimethylaminocarbonyl unit; introduction of carbamates as directing groups)

Alternate Names: DMC-Cl; dimethylcarbamic chloride; dimethylcarbamyl chloride; *N,N*-dimethylaminocarbonyl chloride.

Physical Data: (**1**) bp 165-167 °C; bp 55-57 °C/11 mmHg; *d* 1.678 g cm^{-3}. (**2**) bp 54-56 °C/51 mmHg.

Form Supplied in: both halides are colorless liquids; the chloride is widely available; the fluoride is not commercially available.

Handling, Storage, and Precautions: the liquid chloride decomposes on exposure to moist air or water and is usually kept under argon or nitrogen. Distillation at reduced pressure is recommended to prevent decomposition. It is a powerful lachrymator and a confirmed carcinogen and mutagen. Extreme care should be taken to avoid inhalation or skin contact. When heated to decomposition, toxic fumes containing CO, HCl, and NO_x are emitted. Use in a fume hood.

Source of the Dimethylaminocarbonyl Unit.

The chemistry of dimethylcarbamoyl chloride (DMC-Cl) parallels that of acid chlorides in that the chloride can be replaced by other nucleophiles.[1,2] However, these reactions are generally not as facile as their acid halide counterparts. Some reactions proceed via a trace equilibrium component, the more reactive dimethylaminoacylium ion (Me_2+N=C=O Cl^-). As a consequence, DMC-Cl is both less reactive and less selective than acid halides when reacted with substrates containing more than one nucleophilic site.[3,4] Reaction of DMC-Cl with alcohols (phenols), amines, and thiols affords the respective carbamates, ureas, and thiocarbamates (eq 1), which classically exhibit significant bioactivities.[5] Thus many important pharmaceuticals and especially agricultural biocides contain the DMC unit.[5,6] In these acylations, pyridine often is the preferred acid scavenger.[7] Like acid chlorides, DMC-Cl activates imine functions

in the synthesis of heterocycles (eq 2).[8]

(1)

Z = OR, OAr, NR_2, SR, etc.

(2)

R = OMe

Dimethylamides are available by heating DMC-Cl with alkali carboxylates.[9] Presumably an intermediate carbamic carboxylic anhydride loses CO_2. Aryl carboxamides also have been made from DMC-Cl by Friedel-Crafts acylation of arenes.[10] By including a hydrolysis step, this is a general route to aromatic carboxylic acids. Alkynylamides are available by a palladium-catalyzed condensation of terminal alkynes with DMC-Cl (eq 3).[11] Conjugated aldehydes react with carbamoyl chlorides to form dienyl carbamates (eq 4), which have been used as dienes in the Diels-Alder reaction.[4,12] After formation of the Diels-Alder adduct, the carbamate can be converted to the allylic alcohol by ***Lithium Aluminum Hydride*** reduction.[12]

(3)

(4)

Eliminations.

The reagent also has been used to dehydrate primary amides to nitriles.[13] Tetramethylformamidinium chloride is

formed by the condensation of DMF with DMC-Cl.[14] This is the key intermediate in the synthesis of ***Tris(dimethylamino)methane***,[15] a reagent used to introduce enamine functions in compounds containing activated methylene groups (eq 5).[16]

Carbamates as Directing Groups.

Deprotonation of aryl and many heteroaromatic carbamates with RLi/TMEDA occurs regioselectively at the *ortho* site. Subsequent treatment of the lithiated intermediates with electrophiles has yielded an enormous variety of *ortho*-substituted products in excellent yield (eq 6).[17] In an extension of this reaction the product is treated with a Grignard reagent in the presence of Ni^0 catalyst to replace the carbamate function. This latter reaction also works well without the prior *ortho* substitution step (eq 7).[18] Allylic and benzylic carbamates undergo similar substitution (eq 8)[19] and α-lithiation of *O*-vinyl carbamates recently has been demonstrated (eq 9).[20] In these processes, *N*,*N*-diethyl- and *N*,*N*-diisopropylcarbamates generally react more cleanly (also, in eq 8, the ratio of α to γ products is 5:95 with the NEt_2 reactant).[17-20] With lithioallyl *N*,*N*-diisopropylcarbamates, regio- and stereoselective homoaldol type additions have even been achieved via titanates.[19]

(8)

(9)

The DMC-Cl derived carbamates of cyclic allylic and homoallylic alcohols are epoxidized with ***m-Chloroperbenzoic Acid*** with high *syn* stereoselectivity (eq 10).[21] The carbamate function has also been used to direct the stereochemical course of Grignard additions to ketones by a chelation control mechanism (eq 11).[12] In the reaction depicted the diastereofacial selectivity is 100%; the product (R^2 = -$(CH_2)_2CH{=}CMe_2$) is an intermediate on the route[12] to the sesquiterpene hernandulcin, which is over 1000 times sweeter than sucrose.[22]

(10)

Dimethylcarbamoyl Fluoride.

The reagent is prepared directly from DMC-Cl by halide exchange; IR (CCl_4) 1800 cm^{-1}; ^1H NMR ($CDCl_3$) δ 2.95 (s). While an equilibrium process is involved, the thermodynamics overwhelmingly favor the acyl fluoride. Many fluoride sources have been utilized.[23] However, in the most efficient preparation (95% yield), DMC-Cl is stirred neat with ***Potassium Fluoride*** activated by 4 mol % ***18-Crown-6*** at rt (reaction monitored by IR).[24] Alternatively, an acetonitrile suspension of DMC-Cl and KF-CaF_2 is stirred at 50 °C for 24 h.[25]

There normally is little advantage in using DMC-F in place of the chloride as an acylating agent. An exception is the reaction of trimethylsilyl (TMS) protected anions which undergo electrophilic carbodesilyations in the presence of a catalytic amount of naked F^-. This scheme has been used to stereospecifically convert enol silyl ethers to vinyl carbamates (eq 12).[26] The *O*-acylation is catalyzed by $PhCH_2$+NBu_3 F^- (BTAF) and has been performed with enol silyl ethers from aldehydes and aliphatic, aromatic, and conjugated ketones.[26] A similar process has been utilized to obtain the hindered pyrazolecarboxylic acid from 1-methylpyrazole (eq 13).[27] The greater acidity of HC(5) accounts for the success of the first step of this synthesis (for H/D exchange in NaOMe/MeOD at 139 °C, the relative rate constants (k_2´) are HC(3) = 1, HC(4) = 2, HC(5) = 1500).[28]

Dimethylchloromethyleneammonium Chloride

(**1**; X = Cl)

[3724-43-4] · $C_3H_7Cl_2N$ · Dimethylchloromethyleneammonium Chloride · (MW 128.01) (**2**; X = PO_2Cl_2)

[21382-90-1] · $C_3H_7Cl_3NO_2P$ · Dimethylchloromethyleneammonium Dichlorophosphate · (MW 226.43)

(formylation of arenes,[1-3] heterocycles,[1-3] and alkenes;[2,3] conversion of alcohols into chlorides,[4] and carboxylic acids into acid chlorides;[5] preparation of β-chlorovinyl aldehydes,[3,6] cyclic β-chloro-α,β-unsaturated ketones,[7] and the conversion of acyclic precursors into ring systems[8])

Alternate Names: Vilsmeier reagent; Arnold's reagent.

Physical Data: (**1**) mp 132 °C (dec).

Solubility: fairly sol polar solvents.

Form Supplied in: the chloride (**1**) is a white hygroscopic powder and is commercially available. The dichlorophosphate (**2**) is made in situ.

Preparative Methods: ***Thionyl Chloride***,[4b] ***Oxalyl Chloride***,[5] or ***Phosgene*** is added slowly to ***N,N-Dimethylformamide***, with cooling, to give the chloride (**1**) (eq 1). A solvent (typically dichloromethane,[5] chloroform, or 1,1,2-trichloroethylene)[9] may be used, and is advisable for large scale preparations.

The most commonly used Vilsmeier reagent is that formed by adding ***Phosphorus Oxychloride*** to DMF, to give dimethylchloromethyleneammonium dichlorophosphate (**2**).[9] Reagent (**2**) is more reactive than reagent (**1**). Recent reports suggest that DMF-***Pyrophosphoryl Chloride*** ($P_2O_3Cl_4$) gives an even more reactive iminium intermediate (eq 2) than either salt (**1**) or salt (**2**).[10]

Handling, Storage, and Precautions: the chloride (**1**) is hygroscopic. DMF is an irritant and is harmful by skin absorption. The halogenating agents (thionyl chloride, phosgene, phosphorus oxychloride, etc.) are all corrosive and lachrymatory. Use in a fume hood.

Conversion of Alcohols into Chlorides.

Reagent (**1**) has been used to convert alcohols into chlorides in moderate to high yields.[4] An alternative Vilsmeier reagent derived from *N*,*N*-diphenylbenzamide-oxalyl chloride has been used for the same transformation. Sensitive groups, such as acetals, are not affected by the reaction conditions (eq 3) and the yields are high.[11]

Conversion of Carboxylic Acids to Acid Chlorides.

Reagent (**1**) has been used to convert a wide variety of carboxylic acids into acid chlorides.[5] A catalytic quantity of DMF may be used; thus isobutyric acid is converted into isobutyroyl chloride (89%) upon treatment with DMF (3 mol %) and phosgene.[5c]

Formylation of Arenes and Heterocyclic Systems.

Reagent (**2**) is the most commonly used Vilsmeier reagent for formylation of arenes and heterocycles. The subject has been extensively reviewed.[1-3] The formylation process is general for all activated aromatic systems (e.g. pyrene, anthracene, azulene, ferrocene, and *N*,*N*-dimethylaniline)[12a] and electron-rich heterocyclic systems (e.g. thiophenes, indoles,[12b] furans, and pyrroles (eq 4)).[12c] Formylations continue to be regularly reported in the literature.[13] However, simple aromatic hydrocarbons such as benzene and toluene do not react with Vilsmeier reagents, although the adduct formed from DMF-***Trifluoroacetic Anhydride*** has been used to formylate some unactivated aromatic hydrocarbons, e.g. naphthalene (50%) and 1,3,5-trimethylbenzene (60%).[14] DMF-$P_2O_3Cl_4$ has been reported to be a good formylating agent.[10] The time and temperature of the reaction, and the stoichiometry of the reagent, can be crucial to the outcome of

the reaction.

(4)

Formylation of Alkenes.

Activated alkenes, e.g. styrene, undergo formylation by DMF-$POCl_3$, usually giving α,β-unsaturated aldehydes in high yields.[3,15] 1-Aryl-1,3-butadienes are similarly formylated.[16] Simple alkenes can give complex products as a result of a series of reactions. Thus isobutene affords a trimethinium salt after repeated iminoalkylation (eq 5).[17] However, by using *N*-formylmorpholine (NFM)-$POCl_3$, alkenes have been successfully monoformylated (eqs 6 and 7).[18]

(5)

(6)

(7)

Depending upon the reaction conditions and the structure of the alkene, isomerization of the carbon-carbon double bond may occur prior to formylation (eq 8).[19]

Silyl enol ethers react with DMF-$POCl_3$ to give α-formyl carboxylic esters.[20]

Reaction of Carbonyl Compounds with DMF-$POCl_3$.

This subject has been extensively reviewed.[21] Methyl and methylene ketones are the most studied classes of compound; they afford β-chlorovinyl aldehydes (β-CVAs) when allowed to react with DMF-$POCl_3$ (eq 9). Acyclic, cyclic, heterocyclic, and benzo-fused ketones all give β-CVAs, which have proved to be useful intermediates in organic synthesis.[3] The chlorine atom is readily displaced by nucleophiles and the aldehyde can then be transformed by means of condensations, reaction with Grignard reagents, or Wittig reagents. Condensations involving the aldehyde group, followed by base-catalyzed cyclization, allows the formation of a wide variety of heterocycles, e.g. thiophenes, isoxazoles (eq 10), pyrimidines (eq 10), and pyrazoles.[3,22] More than 50 different ring systems have been synthesized using Vilsmeier methodology.[22]

β-CVAs can be hydrogenated to give saturated aldehydes, allowing the introduction of an aldehyde β with respect to the original ketone function (eq 11).[23]

β-CVAs have been used as dienophiles in Diels-Alder reactions.[24] Treatment of β-CVAs with strong aqueous base affords alkynes.[25] The chlorine atom can be removed using ***Zinc*** in ethanol,[26a] or hydrogen over ***Palladium on Carbon*** in the presence of ***Triethylamine***,[26b] giving α,β-unsaturated aldehydes.

Reaction of 1,3-Diketones.

Salt (**1**) reacts with cyclic 1,3-diketones, giving β-chloro-α,β-unsaturated ketones.[7] Cyclic 1,3-diketones can give bis-β-CVAs upon treatment with reagent (**2**).[27] 2,4-Pentanedione gave 2,4-dichlorobenzaldehyde on reaction with DMF-$POCl_3$ (eq 12),[28] and 2,4-dichloro-1,3-benzene dicarbaldehyde on reaction with the adduct from NFM-$POCl_3$ (eq 13).[27b]

Epoxidation of Alkenes.

When reagent (**1**) is treated with ***Hydrogen Peroxide*** the reagent (**3**) is formed, which is capable of epoxidizing alkenes.[29] However, the selectivity of reagent (**3**) is poor, and chlorinated products are also obtained. The yields and selectivity are improved by reacting alkenes with the intermediate (**4**), obtained from *N*-methylpyrrolidine-$POCl_3$ and H_2O_2.[30] Little chlorination of the alkene was noted and no Baeyer-Villiger products were identified from ketone-containing substrates. Acetals are not cleaved under the reaction conditions. Epoxidation occurs at the most substituted carbon-carbon double bond (eq 14).[30]

(3)

(14)

Cyclizations under Vilsmeier Conditions.

A large number of substrates undergo cyclization in the presence of DMF-$POCl_3$ and other Vilsmeier reagents.[8] The outcome of the reaction often depends upon the reaction time and temperature, and the nature of the Vilsmeier species. For example, benzylacetamides give quinolines and related systems; the nature of the product depends upon the conditions used (eq 15).[31]

2-Hydroxyacetophenones give 3-formylchromones.[32] Aryl benzyl ketones have been converted into 2-aryl-1,3-dichloroindenes.[33] Alkylidenemalononitriles give 2-chloro-3-cyanopyridines.[34] Unsaturated alcohols may undergo dehydration prior to formylation and cyclization (eq 16).[35]

Dimethyl Chlorophosphite

[3743-07-5] · $C_2H_6ClO_2P$ · Dimethyl Chlorophosphite · (MW 128.50)

(reactive phosphitylating agent for secondary alcohols; oxidation of the resulting phosphites provides phosphates)

Alternate Names: dimethyl phosphorochloridate; dimethyl chlorophosphonite; dimethoxychlorophosphine.

Preparative Method: obtained by reaction of ***Trimethyl Phosphite*** with ***Phosphorus(III) Chloride*** in HMPA.[1]

Inositol Phosphates.[2]

Phosphorylation of inositol derivatives is complicated by the relative unreactivity of phosphorus(V) reagents towards the secondary alcohol groups of inositol, and the tendency of the resulting phosphate triester intermediates to undergo cyclization and migration to neighboring hydroxy groups. Phosphitylation using the more reactive dimethyl chlorophosphite has avoided these problems while adding new selectivity features. For example, exhaustive phosphitylation of 1,4-dibenzoyl-*myo*-inositol (**1**) with excess dimethyl chlorophosphite[3] and ***Diisopropylethylamine*** yields the tetrakis(dimethyl phosphate) (**2a**) after ***Hydrogen Peroxide*** oxidation of the intermediate phosphite ester (eq 1).

(1)

This suggests that it is possible to convert all the free hydroxy groups in any appropriately protected inositol to phosphate esters, including bisphosphorylation of a *cis*-vicinal diol. However, if less than the stoichiometric amount of dimethyl chlorophosphite (3.3 equiv) is used, partial phosphitylation of (**1**) is effected yielding the tris(dimethyl phosphate) (**2b**) after acetylation and oxidation. Only the more reactive equatorial 3-, 5-, and 6-hydroxy groups on (**1**) are phosphorylated.

The use of other phosphorus(III) reagents has recently been suggested for the synthesis of inositol phosphates. These include ***Dibenzyl N,N-Diisopropylphosphoramidite*** (**3**),[4] and *o*-xylylene *N*,*N*-diethylphosphoramidite (**4**).[5]

(3) (4)

The indirect method of phosphorylation using a phosphorochloridite followed by oxidation to the phosphate has also been applied in the synthesis of monophosphate esters from hindered alcohols. This has been reported using diallyl chlorophosphite, $(CH_2{=}CHCH_2O)_2PCl$,[6] and ***Diethyl Chlorophosphite***, $(EtO)_2PCl$.[7]

Dimethyl Diazomalonate[1]

[6773-29-1] · $C_5H_6N_2O_4$ · Dimethyl Diazomalonate · (MW 158.13)

(carbene or carbenoid precursor;[1] cyclopropanation;[2] synthesis of oxazoles[3] and furans;[4] ring expansion;[5] deoxygenation of epoxides;[6] alkenation;[7] *C*-glycosidation;[8] etherification[9])

Physical Data: bp 60-61 °C/2 mmHg.

Solubility: sol ether, THF, halocarbon and hydrocarbon solvents.

Form Supplied in: not commercially available.

Preparative Methods: diazomalonates are generally prepared by diazo transfer reaction of malonates and sulfonyl azides.[10a] A recent modification employs polystyrene-supported trialkylammonium azide (generated in situ) under phase-transfer catalysis conditions and allows for facile isolation.[10b]

Handling, Storage, and Precautions: dimethyl diazomalonate has been utilized more extensively than has diethyl diazomalonate due to the explosion hazard of the latter. Nonetheless, care should be taken in preparation and handling of dimethyl diazomalonate. Storage at low temperature is recommended. The decomposition of dimethyl diazomalonate evolves nitrogen and can result in high pressures.

Cyclopropanation.

Decomposition of dimethyl diazomalonate by direct photolysis or by transition metal catalysis in the presence of alkenes leads to cyclopropanation (eq 1).[2a] The use of alkynes to trap the carbenoid species affords cyclopropenes (eq 2).[2b] Rhodium(II) acetate-catalyzed reaction with allenes allows ready access to methylenecyclopropanes, which form the basis for a methylenecyclopentane annulation protocol (eq 3).[2c]

(1)

(2)

(3)

Synthesis of Oxazoles and Furans.

Dimethyl diazomalonate reacts with a variety of nitriles in the presence of rhodium(II) acetate to afford 2-substituted 5-methoxy-4-methoxycarbonyl-1,3-oxazoles (eq 4).[3] This reaction is fairly general in scope, although cyclopropanation and insertion can be competing processes.

(4)

In contrast to the direct photolytic cyclopropanation of alkynes with dimethyl diazomalonate, benzophenone-sensitized photolysis in the presence of alkynes affords furans as the major products in moderate yields (eq 5).[4a]

(5)

An alternative furan synthesis is based upon allylic C-H insertion upon reaction with a ketone-derived enol ether.[4b] Reduction and hydrolysis affords the furan (eq 6). With aldehyde-derived enol ethers, copper(I) induced reaction with dimethyl diazomalonate yields an alkoxycyclopropane diester, whose reduction, hydrolysis, and oxidation affords a spiro-β-methylene-γ-lactone (eq 7).

(6)

(7)

Ring Expansion.

Sulfonium ylides can be prepared from sulfides and dimethyl diazomalonate under rhodium(II) or copper catalysis. Subsequent [2,3] or [1,2] rearrangement of the ylides derived from cyclic sulfides allows for ring expansion. Examples include the synthesis of *cis*-thiacyclooctene (eq 8),[5a] dihydrothiazinones (eq 9),[5b] and homocephems (eq 10).[5c]

(8)

(9)

(10)

Deoxygenation of Epoxides.

In the presence of catalytic rhodium(II) acetate, dimethyl diazomalonate deoxygenates epoxides under neutral conditions (eq 11).[6] This reaction tolerates functionality such as ketones, esters, alkyl and silyl ethers and halogen substituents, although alcohols and aldehydes undergo competing insertion reactions.

(11)

Alkenation.

Alkenation of thiolactones can be achieved by rhodium(II) acetate-catalyzed reaction with dimethyl diazomalonate (eq 12).[7a] Recently, an efficient alternative alkenation protocol has been demonstrated to be applicable to a variety of ketones and aldehydes by reaction with ***Tri-n-butylstibine*** and dimethyl diazomalonate in the presence of ***Copper(I) Bromide*** (eq 13).[7b] This process is proposed to occur via tributylstibonium bis(methoxycarbonyl)methylide.

(12)

(13)

C-Glycosidation.

Reaction of phenyl thioglycosides with dimethyl diazomalonate in the presence of rhodium(II) acetate allows for the construction of *C*-glycosyl linkages in moderate yields under neutral conditions (eq 14).[8a] The methodology is applicable to both thiofuranosides and thiopyranosides. A related insertion process allows for a mild carbon extension of 4-phenylthioazetidinones (eq 15).[8b]

(14)

(15)

Etherification.

Rhodium(II) acetate-catalyzed O-H insertion of dimethyl diazomalonate is exceedingly facile, resulting in an efficient, neutral etherification in the presence of other sensitive functionality (eq 16).[9]

Dimethyl Diazomethylphosphonate

(R = Me)

[27491-70-9] · $C_3H_7N_2O_3P$ · Dimethyl Diazomethylphosphonate · (MW 150.09) (R = Et)

[25411-73-8] · $C_5H_{11}N_2O_3P$ · Diethyl Diazomethylphosphonate · (MW 178.15)

(bifunctional reagents capable of Horner-Wadsworth-Emmons and carbene chemistry;[6] conversion of aldehydes to terminal alkynes;[6a] preparation of vinyl ethers[10] and enamines;[11] cyclopropanation of alkenes;[20] cycloaddition to furnish heterocycles[21])

Alternate Name: DAMP.

Physical Data: (R = Me) bp 59 °C/0.1 mmHg; *n*25D 1.4585. (R = Et) bp 86-88 °C/0.2 mmHg; *n*25D 1.4503.

Solubility: insol H_2O; sol MeOH, THF, toluene.

Preparative Methods: for the most part, the reagents have been prepared by the method of Seyferth,[1] a convenient three-step sequence beginning with commercially available *N*-(bromomethyl)phthalimide. More recently, two alternatives have been detailed, both of which appear to offer synthetic utility.[2]

Handling, Storage, and Precautions: stable indefinitely when stored at 4 °C under argon. *Caution*: All distillations should be carried out behind a blast shield.

Preparation of Diazo Phosphonates.

Diethyl (diazomethyl)phosphonate is readily lithiated (***n-Butyllithium***, THF, -100 °C) and the resulting lithio derivative can be acylated (PhCOBr, 33%) (eq 1) or silylated (poor yield).[3] The corresponding silver derivative, formed by treatment with ***Silver(I) Oxide***, can be alkylated with reactive allylic halides.[3] α-Diazo-β-hydroxy phosphonates result when the lithio derivative is treated with aryl aldehydes; alternatively they can be prepared by direct reaction of DAMP with aldehydes in the presence of ***Triethylamine*** (eq 2).[4]

(1)

(2)

Insertion Reactions.

The reagents, with Lewis acid catalysis, insert smoothly into readily fissile bonds. Thus aldehydes are converted into β-keto phosphonates[5] on treatment with the reagents and ***Tin(II) Chloride*** (eq 3).

(3)

Tandem Horner-Wadsworth-Emmons Carbene Reactions.

Carbonyl groups, on treatment with the anion of the reagents, are smoothly converted into intermediate vinyl carbene species.[6,9] In the case of ketones, one of three pathways is then followed. The first is a [1,2]-aryl shift which may occur to form an internal alkyne (eq 4).[6a,7] Reports indicate that, for the most part, this shift does not occur with transfer of an alkyl group.[8] The second possibility occurs when an abstractable hydrogen is available, into which bond the carbene inserts.[9] Examples of this chemistry abound; the method is useful for furnishing vinyl ethers (eq 5),[2b,6b,10] enamines (eq 5),[6b,11] cyclic alkenes (eq 6),[9,12,13] furans,[14] and other heterocycles (eq 7).[15] A recent example describes possible limitations of this technology, however; use of ***Trimethylsilyldiazomethane*** offers some improvement.[12b] Here, the alkenation sequence is provided by a Peterson alkenation reaction. Finally, the intermediate vinylcarbene species may be intercepted by alkenes, to yield methylenecyclopropanes.[2a,16]

(4)

(5)

R = Me, 58%
R = *t*-Bu, 56%

(6)

(7)

With aldehydes, treatment with dialkyl diazomethylphosphonate leads exclusively to terminal alkynes (eq 8).[2b,6a] This has proven useful, and is compatible with adjacent chirality (eqs 9 and 10).[17,18] The method provides a useful alternative to the Corey-Fuchs protocol, which could prove troublesome in some circumstances.[19]

(8)

(9)

R = Me, *i*-Pr, Bn, *i*-Bu, 4-$CH_2C_6H_4OBn$, -$(CH_2)_4NHCbz$

(10)

Cyclopropanation.

The reagents furnish cyclopropylphosphonates on exposure to alkenes in the presence of a metal or metal salt (eq 11).[1,20]

(11)

Cycloadditions.

The dipolar nature of the reagent has been exploited in the synthesis of pyrazolines,[1] 1,2,4-diazaphospholes (eq 12),[21]

dihydropyridazines,[18] pyridazines,[22] and pyrazoles.[23] On installation of a dipolarophilic group α to the diazo moiety, intramolecular cycloadditions are possible, and have been extensively investigated (eq 13).[24]

(12)

(13)

Related Reagents.

Methylenecyclopropane.

(-)-(*S*,*S*)-α,α´-Dimethyldibenzylamine

[56210-72-1] · $C_{16}H_{19}N$ · (-)-(*S*,*S*)-α,α´-Dimethyldibenzylamine · (MW 225.36)

(starting material for the formation of chiral amide reagents; useful in the stereospecific deprotonation of prochiral ketones, and as a chirality transfer agent in the reactions of prochiral enolates; stereoselective conjugate addition of organometallic reagents to unsaturated carbonyl systems[1])

Physical Data: (free base): bp 103-105 °C/0.5 mmHg;[2] $[\alpha]_D$ -157° (*c* 2.4, EtOH);[1a] -197.3° (*c* 3.65, benzene);[1b] -187.9° (*c* 6.87, benzene);[3] -171.6° (*c* 6.71, chloroform).[4] (HCl salt): mp >300 °C; $[\alpha]_D$ -84.1° (*c* 3, EtOH);[1a] -72.1° (*c* 2.94, EtOH).[1b]

Solubility: readily sol common organic solvents (ether, THF, chloroform, etc.); insol H_2O.

Form Supplied in: available commercially.

Analysis of Reagent Purity: diastereomeric purity can be assessed by the ^1H NMR chemical shift of the methyl groups,[1a] and by GC analysis.[5] Optical purity can be assessed by derivatization with (*R*)-(-)-1-(1-naphthyl)ethyl isocyanate and ^1H NMR analysis of the product.[4]

Preparative Methods: minor improvements to the original catalytic hydrogenation procedure[6] have been described (eq 1).[1a] This method provides (*S*,*S*)-(-)-(**1**) with an optical purity of only 70%. Enantiomerically pure (*S*,*S*)-(-)-(**1**) can be obtained by recrystallization of the hydrochloride salt of this enriched material from water[1b] or the benzoate salt from isopropanol.[3] A chemical reduction procedure has also been described that yields optically active (*S*,*S*)-(**1**) with 74% enantiomeric excess (eq 2).[2] A significant improvement to the former procedures is the diastereoselective hydrogenation of imines catalyzed by rhodium/chiral diphosphines, which yields (*S*,*S*)-(**1**) with an optical purity of 99.4% (eq 3).[5]

(1)

(2)

(3)

Purification: the free base can be distilled. The HCl salt can be recrystallized from water, which removes diastereomeric impurities. The benzoate salt can be recrystallized from isopropanol.

Handling, Storage, and Precautions: no special precautions have been noted in the literature. The free base is a clear distillable liquid that should be stored under an inert atmosphere to prevent air oxidation. Long term storage may lead to some coloration of the material.

Introduction.

In most cases the (*R*,*R*) and (*S*,*S*) enantiomers of (**1**) possess similar synthetic applications. References to both enantiomers have been incorporated into this article, under the heading of (*S*,*S*). The equations depict the actual enantiomer used in each publication.

Asymmetric Deprotonation/Protonation of Ketones.

Lithium amides of chiral amines have been used for performing asymmetric deprotonations of symmetrically substituted (prochiral) ketones.[7,8] The resulting optically active enols or enol derivatives (most frequently enol silanes) are highly versatile synthetic intermediates. Particularly useful for this purpose are chiral amines possessing C_2

symmetry, such as (**1**). For example, reaction of 4-*t*-butylcyclohexanone with the lithium amide of (*R*,*R*)-(**1**) (readily prepared in situ by treatment of (**1**) with ***n-Butyllithium***) is highly stereoselective; the resulting enol silyl ether possesses an 88% ee (eq 4).[9]

The most predictable results are obtained with conformationally rigid systems, such as those represented in eqs 5 and 6, which possess axially oriented α-protons.[10,11] This minimizes complications resulting from the presence of diastereotopic α-protons, although unexpected modes of deprotonation have been described with related chiral amides, which may involve boat conformations.[12] To prevent enolate equilibration (with the resulting loss of stereoselectivity), Corey's internal quench method for enolate trapping with silyl chlorides is frequently used.[13] The stereospecificity of this deprotonation is highly dependent on solvent and temperature conditions. Best results are obtained at -100 °C or lower temperatures, with THF as the solvent.

The lithium amide of (*S*,*S*)-(**1**) has been used to convert racemic α-substituted ketones into optically active ketones via

sequential deprotonation/asymmetric protonation of rigid prochiral enolates. Enantiomeric enrichment may occur during the protonation step as a result of the tight coordination between the enolate and the lithium amide in the form of diastereomeric complexes (eq 7).[14]

(7)

Alternatively, the enantiomeric enrichment derives from kinetic differences in the rate of deprotonation of the two ketone enantiomers (eq 8).[15] Ether is the best solvent for these reactions.

(8)

The lithium amide of (**1**) has also been used to perform the kinetic resolution of racemic lactams by selective kinetic deprotonation of one of the enantiomers, followed by reaction of the partially formed enolates with an electrophile.[16] These procedures have not proven to be particularly useful yet, since high enantiomeric purity is only achieved at low conversions of the starting materials (eq 9).[17]

(9)

Stereoselective Alkylation of Prochiral Enolates.

A limited amount of work has demonstrated the potential use of chiral amines in inducing stereoselectivity in the alkylation/carboxylation of prochiral enolates. The selectivity of these reactions, like those described above, is highly dependent on solvent and temperature conditions. The use of ether at -196 °C provides optimal results in a particular system (eq 10).[18]

(10)

Asymmetric Induction in Organometallic Reactions.

A number of chiral amines have been used as nontransferable ligands for the enantioselective conjugate addition of organocopper reagents, with optical yields as high as 95%.[19-22] (*R*,*R*)-(**1**) has also been used for this purpose, effecting the conjugate addition of organocopper reagents to enones with moderate to high enantioselectivity (eq 11).[23,24] The use of dimethyl sulfide as the solvent for this transformation is critical, since ether solvents produce products of low optical activity.

(11)

Although (**1**) itself has not been shown to be useful in the stereospecific 1,2-addition of organometallic reagents to carbonyl compounds, closely related amines, such as (*R*)-(α-methoxymethylbenzyl)-(*S*)-(α-methylbenzyl)amine, have been used to direct the addition of organolithium reagents to benzaldehyde with up to 95% stereoselectivity (eq 12).[25]

(12)

Enantioselective Conjugate Additions.

(*R*,*R*)-(**1**) has been used in the synthesis of (*R*)-β-aminobutanoic acid. The conjugate addition of the lithium amide of (*R*,*R*)-(**1**) to (*E*)-methyl crotonate proceeds with complete diastereoselectivity. Catalytic reduction of the benzyl groups results in the formal stereospecific 1,4-addition of an amino group to an unsaturated ester (eq 13).[26] Although (**1**) has not been used extensively for this type of transformation, a variety of other chiral amines have been used for similar purposes.[8,27,28]

(-)-(S,S)-alpha,alpha´-Dimethyldibenzylamine

Chiral Auxiliary.

(*R*,*R*)-(**1**) has been used as a chiral auxiliary to direct the stereochemistry of addition of a nucleophile to an acrylate moiety. Almost complete stereoselectivity is achieved in the addition of cyclopentanecarboxylic acid lithium dianion to the α-substituted acrylate substrate (eq 14).[29] This methodology allows stereochemical control at the α-position of a β-amino ester and thus complements the methodology described above[26] for the stereoselective formation of β-substituted β-amino esters.

Other Enantioselective Reactions.

Enantioselective epoxide elimination by chiral bases has been demonstrated.[30] More recently, the enantioselective [2,3]-Wittig rearrangement of a 13-membered propargylic allylic ether has been performed using the lithium amide of (*R*,*R*)-

(**1**) as the base for deprotonation (eq 15).[4] For this particular substrate, THF is a better solvent than ether, although pentane produces better results in a related transformation (eq 16).[4] In fact, a change in solvent in this type of reaction has been shown to lead to a reversal of the stereoselectivity of the transformation.[4]

N,N-Dimethyl Dichlorophosphoramide

[677-43-0] · $C_2H_6Cl_2NOP$ · *N,N*-Dimethyl Dichlorophosphoramide · (MW 161.96)

(electrophilic phosphorylating reagent used to convert vicinal diols to alkenes[2,3] and to activate carboxylic acids and alcohols towards nucleophiles)

Alternate Names: (dimethylamido)phosphoryl dichloride; dimethylphosphoramidic dichloride; *N,N*-dimethylamidophosphorodichloridate.

Physical Data: bp 194-195 °C/760 mmHg; *d* 1.369 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid.

Preparative Method: obtained by treatment of ***Phosphorus Oxychloride*** with dimethylamine.[1]

Purification: fractional distillation.

Handling, Storage, and Precautions: very reactive towards water, alcohols, and amines.

Diol Elimination.

N,N-Dimethyl dichlorophosphoramide efficiently converts vicinal diols into cyclic phosphoramides. These cyclic phosphoramides, when treated with ***Lithium*** in ammonia, afford alkenes resulting primarily via *syn* elimination.[2,3] The process occurs in high yield with cyclic diols to afford *cis*-alkenes contaminated with ~10% of the *trans*-isomer (eq 1). Yields, however, are typically much lower with cyclic *trans*-diols which afford *trans*-alkenes in 10- and 12-membered rings (eq 2); for a complete discussion on alternative methods, consult Block.[4]

Carboxylic Acid Activation.

Dimethyl dichlorophosphoramide readily phosphorylates carboxylic acids to give a mixed anhydride which reacts at carbon with a variety of nucleophiles. Upon heating the mixed anhydride, the dimethylamino group is transferred to produce tertiary amides.[5] Alternatively, alcohols or thiols can be added to produce esters[6] or thiol esters[7] at 0-25 °C (eq 3).

Applications of this method in the synthesis of β-lactams have been reported via the closure of β-amino alcohols[8] in high yield (eq 4) and the coupling of acetic acids with imines[9] in low to moderate yields (eq 5).

(4)

(5)

Although yields are often quite good (eqs 1-5) these methods are rarely used instead of acid chloride or ***1,3-Dicyclohexylcarbodiimide*** couplings.

Alcohol Activation.

Dimethyl dichlorophosphoramide also readily phosphorylates alcohols to produce an activated alcohol which undergoes displacement and elimination reactions. Primary, secondary, and tertiary alcohols are phosphorylated at rt. Upon heating the activated alcohol at ~80 °C for several hours, primary alcohols produce alkyl chlorides by an S_N2 process, tertiary alcohols produce alkenes by elimination (*trans* elimination is slightly more facile than *cis*), and secondary alcohols produce mixtures of alkyl chlorides and alkenes (eq 6).[10]

(6)

The phosphorylated alcohols may be treated at rt with dimethylamine to produce a tetramethylphosphorodiamidate derivative. These derivatives can be treated with lithium/ethylamine to reductively cleave the carbon-oxygen bond and produce deoxygenation products (eq 7).[11]

Dimethyl dichlorophosphoramide phosphorylates a broad range of alcohols, but the production of alkenes and alkyl chlorides is of somewhat limited utility since the two processes are competitive with secondary alcohols and since *trans* and *cis* eliminations occur at comparable rates. The reductive deoxygenation, on the other hand, is quite efficient with a broad range of substrates.

2,2-Dimethyl-1,3-dioxane-4,6-dione[1]

[2033-24-1] · $C_6H_8O_4$ · 2,2-Dimethyl-1,3-dioxane-4,6-dione · (MW 144.12)

(substitute for malonic esters as a two- or three-carbon nucleophile)

Alternate Name: Meldrum's acid.

Physical Data: mp 94-95 °C (dec); pK_a 4.8 in water, 7.3 in DMSO.[2]

Form Supplied in: colorless crystals; commercially available.

Purification: recrystallization from acetone and water.

Introduction.

Meldrum's acid (**1**) is not just a simple substitute for malonic esters but rather a unique reagent in its own right for the following reasons. Firstly, the acidity of Meldrum's acid is comparable to that of acetic acid,[2] and its stable enolate anion (**2**) is susceptible to the attack of various electrophiles even under nearly neutral conditions. Arnett[2a] has shown that the anomalously high acidity of (**1**) relative to dimethyl malonate and dimedone is the result of restricted rotation of the ester bonds in the bislactone structure. Subsequently, Houk[2c] and Wiberg[2d] have completed computational studies that provide an explanation of the acidity enhancement of (**1**), i.e. loss of a proton from the (*E*) rotamer (**3**) is easier than from the (*Z*) rotamer (**4**). Secondly, Meldrum's acid is susceptible to nucleophilic attack at the carbonyl groups, which results in ring cleavage, forming acetone and malonic acid derivatives (eq 1). Among the reactions of Meldrum's acid derivatives, the four described in the following sections have been the most frequently used for organic synthesis.[1b]

Ring Opening Reactions Initiated by Nucleophiles.

Under solvolytic conditions, Meldrum's acid derivatives generally form malonyl monoesters (eq 1). When ethanolysis is conducted in the presence of pyridine and ***Copper*** powder, subsequent decarboxylation occurs, giving monocarboxylates (eq 2)[3]. Amines cleave the dioxane ring in a similar manner, giving amides. In the reaction shown in eq 3, the 5-alkyl intermediate formed via Michael addition of (**1**) to the α,β-unsaturated ketone undergoes intramolecular attack by the amine nitrogen to form a tetrahydropyridone ring.[4] β-Keto esters can be readily prepared by the reaction of 5-acyl Meldrum's acids with alcohols (eq 4).[5] This reaction has been the most widely used application of Meldrum's acid, and it figures as a key step in many organic syntheses.[1b] Steps in the syntheses of tricyclic bimane,[6] a thiol analytical agent for proteins, and didemnin,[7] a cytotoxic cyclic peptide, are representative examples, which are illustrated in eqs 5 and 6, respectively. A chiral dienophile has been prepared by this method (eq 7).[8]

Conjugate Addition.

5-Methylene Meldrum's acids, which are easily prepared by a variety of methods[1] (in particular by the Knoevenagel reaction of (**1**) with carbonyl compounds), undergo conjugate additions with various nucleophiles, such as hydride (eq 8),[9] organometallic reagents (eq 9),[10] and phenols (eq 10).[11] Polyacylated alkenes are susceptible to conjugate addition of enolates, leading to a variety of products (eq 11).[12] Analogously, homoconjugate addition of nucleophiles to spiro-cyclopropyl derivatives takes place resulting in cyclopropyl ring opening (eq 12).[13]

Cycloaddition.

The C=C double bond of 5-methylene Meldrum's acid is usually an active dienophile (eq 13),[14] but the derivatives also act as reactive heterodienes both in inter- (eq 14)[15] and intramolecular (eqs 15 and 16)[16,17] Diels-Alder reactions.

Pyrolysis.

5-Methylene Meldrum's acid loses acetone and carbon dioxide at elevated temperatures giving methyleneketenes which further lose carbon monoxide thereby generating alkylidenecarbenes (eq 17).[1b] A wide variety of reactive species such as benzyne, cyclohexyne and hydroxyacetylene has been detected.[18] Various heterocycles (eq 18)[19] have been synthesized by intramolecular trapping of these chemical species.[1b]

(17)

(18)

Other Applications.

Recently, the applications of Meldrum's acid have been extended to the syntheses of a macrocyclic β-keto lactone (eq 19),[20] 4-pyridyl-substituted heterocycles (eq 20),[21] and 2-substituted indoles (eq 21).[22] The structures of Meldrum acid derivatives[23] and the kinetics of nitrosation of (**1**)[24] have been studied by NMR and X-ray methods.

6,6-Dimethyl-5,7-dioxaspiro[2.5]octane-4,8-dione

[5617-70-9] · $C_8H_{10}O_4$ · 6,6-Dimethyl-5,7-dioxaspiro[2.5]octane-4,8-dione · (MW 170.18)

(reagent for electrophilic four-carbon homologation by homo-Michael reactions and for preparation of five- and six-membered heterocycles)

Physical Data: mp 58-60 °C;[1] for MS and NMR spectral data, see Maquestiau and Helferty.[2]

Solubility: sol ether, THF, DME, DMF; insol H_2O.

Preparative Method: the preparation of this compound has been described (eq 1).[1]

Handling, Storage, and Precautions: use in a fume hood.

Nucleophilic Ring Opening Reactions.

This derivative of Meldrum's acid (***2,2-Dimethyl-1,3-dioxane-4,6-dione***) exhibits enhanced reactivity in nucleophilic ring opening reactions compared to the corresponding diester of 1,1-cyclopropanedicarboxylate. For example, (**1**) undergoes ring opening with piperidine to give the zwitterion (**2**) (eq 2).[3] The facility of these homo-Michael reactions is attributable to the enhanced overlap of the carbonyl group double bonds with the adjacent cyclopropane ring bonds and to the stability of the

6,6-Dimethyl-5,7-dioxaspiro[2.5]octane-4,8-dione

1,3-dioxane-4,6-dione anion leaving group.

Similarly a number of carbon, sulfur, nitrogen, and oxygen nucleophiles react with this substrate under very mild conditions (eq 3).[3,4]

The norcarane analog of (**1**) has been prepared from bicyclo[4.1.0]heptane-7,7-dicarboxylic acid (eq 4). Hydrolytic ring

cleavage occurs in refluxing aqueous acetone with inversion of stereochemistry to give, after fragmentation of the dioxane ring and lactonization, the *trans*-fused γ-butyrolactone-α-carboxylic acid. Conversion to the α-methylene lactone is accomplished by a Mannich reaction.[5]

Reaction of (**1**) with aniline at rt results in opening of the cyclopropane ring and cyclization to give 2-oxo-1-phenyl-3-pyrrolidine carboxylic acid (eq 5).[3]

A number of amino esters,[6] pyrroles,[7] and other heterocyclic derivatives[8] have been used to effect nucleophilic ring opening of (**1**). However, due to the poor nucleophilicity of pyrrole, the reaction is carried out using ***Sodium Hydride*** as base (eq 6).

Reaction of (**1**) with alkyl- and arylhydrazines gives 1-substituted 1,4,5,6-tetrahydro-3(2*H*)-pyridazinones (eq 7).[9]

Lewis acid-catalyzed ring opening of (**1**) using ***Ethylaluminum Dichloride*** and ***Allyltrimethylsilane*** has also been reported (eq 8).[10]

The spiro-activated vinylcyclopropane 6,6-dimethyl-1-vinyl-5,7-dioxaspiro[2.5]octane-4,8-dione reacts with nucleophiles exclusively on the cyclopropane ring position bearing the vinyl group (eq 9).[11]

Nu: = piperidine, NaSPh, $NaCH(CO_2Me)_2$

Ketene Formation.

Pyrolysis of (**1**) at 500 °C/0.5 mmHg gives carbonylcyclopropane which dimerizes at rt or which can be trapped using aniline to give a cyclopropanecarboxamide (eq 10).[12]

Related Reagents.

Cyclopropanone; ***Cyclopropenone 1,3-Propanediyl Acetal***; ***Diethyl Malonate***; ***Diethyl Methylenemalonate***; ***2,2-Dimethyl-1,3-dioxane-4,6-dione***; ***[1-(Ethoxycarbonyl)cyclopropyl]triphenylphosphonium Tetrafluoroborate***; ***1-Ethoxycyclopropanol***.

Dimethyldioxirane[1]

[74087-85-7] · $C_3H_6O_2$ · Dimethyldioxirane · (MW 74.09)

(selective, reactive oxidizing agent capable of epoxidation of alkenes and arenes,[11] oxyfunctionalization of alkanes,[19] and oxidation of alcohols,[23] ethers,[21] amines, imines,[32] and sulfides[35])

Alternate Name: DDO.

Physical Data: known only in the form of a dilute solution.

Solubility: sol acetone and CH_2Cl_2; sol most other organic solvents, but reacts slowly with many of them.

Form Supplied in: dilute solutions of the reagent in acetone are prepared from Oxone and acetone, as described below.

Analysis of Reagent Purity: the concentrations of the reagent can be determined by classical iodometric titration or by reaction with an excess of an organosulfide and determination of the amount of sulfoxide formed by NMR or gas chromatography.

Preparative Methods: the discovery of a convenient method for the preparation of dimethyldioxirane has stimulated important advances in oxidation technology.[1] The observation[2] that ketones enhance the decomposition of the monoperoxysulfate anion prompted mechanistic studies that implicated dioxiranes as intermediates.[3] Ultimately, these investigations led to the isolation of dilute solutions of several dioxiranes.[4] DDO is by far the most convenient of the dioxiranes to prepare and use (eq 1). Several experimental set-ups for the preparation of DDO have been described,[4-6] but reproducible generation of high concentration solutions of DDO (ca 0.1M) is aided by a well-formulated protocol.[6] The procedure involves the portionwise addition of solid Oxone (***Potassium Monoperoxysulfate***) to a vigorously stirred solution of $NaHCO_3$ in a mixture of reagent grade ***Acetone*** and distilled water at 5-10 °C. The appearance of a yellow color signals the formation of DDO, at which point the cooling bath is removed and the DDO-acetone solution is distilled into a cooled (-78 °C) receiving flask under reduced pressure (80-100 Torr). After preliminary drying over reagent grade anhydrous $MgSO_4$ in the cold, solutions of DDO are stored over molecular sieves in the freezer of a refrigerator at -10 to -20 °C. In instances where the concentration of DDO is crucial, analysis is typically based on reaction with an excess of an organosulfide monitored by NMR.[4,7,8]

Handling, Storage, and Precautions: solutions of the reagent can be kept in the freezer of a refrigerator (-10 to -20 °C) for as long as a week. The concentration of the reagent decreases relatively slowly, provided solutions are kept from light and traces of heavy metals. These dilute solutions are not known to decompose violently, but the usual precautions for handling peroxides should be applied, including the use of a shield. All reactions should be performed in a fume hood to avoid exposure to the volatile oxidant.

Introduction.

Reactions with DDO are typically performed by adding the cold reagent solution to a cold solution of a reactant in acetone or some other solvent. CH_2Cl_2 is a convenient solvent which facilitates reaction in a number of cases. After the reactant has been consumed, as monitored by TLC, etc., the solvent and excess reagent are simply removed to provide a nearly pure product. An excess of DDO is often used to facilitate conversion, provided further oxidation is not a problem. Where the product is especially sensitive to acid, the reaction can be run in the presence of solid ***Potassium Carbonate*** as an acid scavenger and drying agent. When it is important to minimize water content, the use of powdered molecular sieves in the reaction mixture is recommended. Reactions can be run from ambient temperatures down to -78 °C.

Dimethyldioxirane is a powerful oxidant, but shows substantial selectivity in its reactions. It has been particularly valuable for the preparation of highly reactive products, since DDO can be employed under neutral, nonnucleophilic conditions which facilitate the isolation of such species. Whereas DDO performs the general conversions of more classic reagents like ***m-Chloroperbenzoic Acid***, it generates only an innocuous molecule of acetone as a byproduct. This is to be contrasted with peracids whose acidic side-products can induce rearrangements and nucleophilic attack on products. Although several other dioxiranes have been prepared, these usually offer no advantage over DDO. An important exception is ***Methyl(trifluoromethyl)dioxirane***, whose greater reactivity is advantageous in situations where DDO reacts sluggishly, as in the oxyfunctionalization of alkanes.

The need to prepare DDO solutions beforehand, the low yield of the reagent based on ***Potassium Monoperoxysulfate*** (Oxone) (ca. 5%),[6] and the inconvenience of making DDO for large-scale reactions are drawbacks that can be avoided when the product has good stability. In these instances, an in situ method for DDO oxidations is recommended.

Oxidation of Alkenes and Other Unsaturated Hydrocarbons.

The epoxidation of double bonds has been the major area for the application of DDO methodology and a wide range of alkenes are effectively converted to epoxides by solutions of DDO.[4,7] Epoxidation is stereospecific with retention of alkene stereochemistry, as shown by the reactions of geometrical isomers; for example, (*Z*)-1-phenylpropene gives the *cis*-epoxide cleanly (eq 2), whereas the (*E*) isomer yields the corresponding *trans*-epoxide. Rate studies indicate

that this reagent is electrophilic in nature and that alkyl substitution on the double bond enhances reactivity.[7] Interestingly, *cis*-disubstituted alkenes react 7-9 times faster than the *trans* isomers, an observation that has been interpreted in terms of a spiro transition state.[9]

(2)

From a preparative viewpoint, the use of DDO solutions, while efficient and easy to perform, are generally not needed for simple alkenes that give stable epoxides. Rather, in situ methodology is suggested. However, the extraordinary value of isolated DDO has been amply demonstrated for the generation of unstable epoxides that would not survive most epoxidation conditions.[1] A good example of this sort of application is the epoxidation of precocenes, as exemplified in eq 3.[10] A number of impressive epoxidations have been reported for oxygen-substituted alkenes, including enol ethers, silyl enol ethers, enol carboxylates, etc.[1] Examples include a number of 1,2-anhydro derivatives of monosaccharides.[11] Steric features often result in significant stereoselection in the epoxidation, as illustrated in eq 4.[11] Conversions of alkenes with two alkoxy substituents have also been achieved (eq 5), even when the epoxides are not stable at rt.[12]

(3)

(4)

(5)

Although reactions are much slower with conjugated carbonyl compounds, DDO is still effective for the epoxidation of these electron-deficient double bonds (eq 6).[13] Alkoxy-substitution on such conjugated alkenes can also be

tolerated (eq 7).[14]

(6)

(7)

Allenes react with DDO by sequential epoxidation of the two double bonds to give the previously inaccessible, highly reactive allene diepoxides.[15] In the case of the *t*-butyl-substituted allene shown in eq 8, a single diastereomer of the diepoxide is generated, owing to steric control of the *t*-butyl group on reagent attack.

(8)

Certain polycyclic aromatic hydrocarbons can be converted to their epoxides, as typified by the reaction of phenanthrene with DDO (eq 9).[4] Aromatic heterocycles like furans and benzofurans also give epoxides, although these products are quite susceptible to rearrangement, even at subambient temperatures (eq 10).[16] The oxidation of heavily substituted phenols by DDO leads to quinones, as shown in eq 11, which illustrates the formation of an orthoquinone.[17] The corresponding hydroquinones are intermediates in these reactions, but undergo ready oxidation to the quinones.

(9)

(10)

(11)

Finally, preformed lithium enolates are converted to α-hydroxy ketones by addition to a cold solution of DDO (eq 12).[18]

(12)

Oxidation of Saturated Hydrocarbons, Ethers, and Alcohols.

Surely the most striking reaction of dioxiranes is their ability to functionalize unactivated C-H bonds by the insertion of an oxygen atom into this σ-bond. This has opened up an important new area of oxidation chemistry.[1] While DDO has been used in a number of useful transformations outlined below, the more reactive ***Methyl(trifluoromethyl)dioxirane*** is often a better reagent for this type of conversion, despite its greater cost and difficulty of preparation.

The discrimination of DDO for tertiary > secondary > primary C-H bonds of alkanes is more pronounced than that of the *t*-butoxide radical.[19] Good yields of tertiary alcohols can be secured in favorable cases, as in the DDO oxidation of adamantane to 1-adamantanol, which occurs with only minor reaction at C-2 (eq 13). Of major significance is the observation that these reactions are stereospecific with high retention of configuration, as illustrated by the oxidation of *cis*-dimethylcyclohexane shown in eq 14; the *trans* isomer gives exclusively the diastereomeric alcohol. This and other data have been interpreted in terms of an oxenoid mechanism for the insertion into the C-H bond. Several

interesting applications in the steroid field involve significant site selectivity as well.[20] The slower reactions of DDO with hydrocarbons without tertiary hydrogens are less useful and lead to ketones owing to a rapid further oxidation of the initially formed secondary alcohol. For example, cyclododecane is converted to cyclododecanone.

(13)

(14)

Ethers and acetals are slowly converted by DDO to carbonyl compounds. This serves as a nontraditional method for deprotection of these derivatives, an example of which is shown in eq 15.[21,22] Hemiacetals are presumed intermediates in these transformations.

(15)

While DDO has been little used for the oxidation of simple alcohols, it has found application in useful conversions of vicinal diols. The oxidation of tertiary-secondary diols to α-hydroxy ketones occurs without the usual problem of oxidative cleavage between the two functions (eq 16).[23] DDO has also been used to convert appropriate optically active diols selectively into α-hydroxy ketones of high optical purity; for example, see eq 17.[24]

(16)

(17)

Finally, the Si-H bond of silanes suffers analogous oxidation to silanols upon reaction with DDO. This reaction takes place with retention of configuration and is, as expected, more facile than C-H oxidations.[25]

Oxidation of Nitrogen Functional Groups.

Selective oxidations of nitrogen compounds are often difficult to achieve, but DDO methodology has been shown to be very useful in a number of instances. For example, one of the first applications of this reagent was in the conversion of primary amines to the corresponding nitro compounds (eq 18).[26] This process probably proceeds by successive oxidation steps via hydroxylamine and nitroso intermediates. Complications arise with unhindered primary aliphatic amines, owing to dimerization of the intermediate nitrosoalkanes and their tautomerization to oximes.[27] In oxidations of amino sugar and amino acid derivatives, it is possible to isolate the initially formed hydroxylamines (eq 19).[28]

(18)

(19)

The oxidation of secondary amines to hydroxylamines is readily achieved with 1 equiv of DDO (eq 20).[29] The use of 2 equiv of DDO results in further oxidation, the nature of which depends on the structure of the amine. Thus cyclic secondary amines which do not possess α-hydrogens are converted to nitroxides,[30] as illustrated in eq 21. Secondary benzylamines give nitrones (eq 22).[31]

$$(PhCH_2)_2NH \xrightarrow[\text{0 °C, 15 min, 98\%}]{\text{1 equiv DDO in acetone}} (PhCH_2)_2NOH \qquad (20)$$

(21)

$$PhCH_2NH\text{-}t\text{-}Bu \xrightarrow[\text{0 °C, 10 min, 96\%}]{\text{2 equiv DDO in acetone}} PhCH{=}N(O)\text{-}t\text{-}Bu \qquad (22)$$

A related transformation is the oxidation of imines to nitrones by DDO (eq 23).[32] It is interesting that the isomeric oxaziridines are not produced here, given that peracids favor these heterocycles.

$$C_6Me_5CH{=}NMe \xrightarrow[\text{CH}_2\text{Cl}_2\text{, 0 °C, 2 h, 71\%}]{\text{1.1 equiv DDO in acetone}} C_6Me_5CH{=}N(O)Me \qquad (23)$$

Reaction of α-diazo ketones with DDO leads to α-keto aldehyde hydrates (eq 24).[33] Oximes are converted to the free ketones by DDO.[34]

(24)

Oxidation of Sulfur Functional Groups.

Dimethyldioxirane rapidly oxidizes sulfides to sulfoxides and converts sulfoxides to sulfones (eq 25).[4,35] The partial oxidation of sulfides to sulfoxides can be controlled by limiting the quantity of DDO. Since Oxone is one of the many reagents that can perform these reactions, the extra effort involved in preparing DDO solutions is often not warranted. An exception involves the transformation of thiophenes to the corresponding sulfones (eq 26).[36] A similar procedure gives α-oxo sulfones by DDO oxidation of thiol esters (eq 27).[37]

Alkanethiols are selectively oxidized to alkanesulfinic acids by DDO (eq 28).[38] Air oxidation of an intermediate species appears to be important in this transformation.

N,N-Dimethyl-*O*-(diphenylphosphinyl)hydroxylamine[1]

[83575-89-7] · $C_{14}H_{16}NO_2P$ · *N,N*-Dimethyl-*O*-(diphenylphosphinyl)hydroxylamine · (MW 261.28)

(electrophilic aminations)

Physical Data: mp 129-131 °C.[2]

Solubility: slightly sol THF, diethyl ether; sol $CHCl_3$, CH_2Cl_2.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$, ppm): 2.78 (s, 6 H, Me_2N), 7.36-8.18 (m, 10 H, phenyl).

Preparative Methods: (1) to 9.67 g (100 mmol) *N,N*-dimethylhydroxylamine suspended in 80 mL CH_2Cl_2 are added dropwise at -20 °C under stirring 20.3 g (200 mmol) triethylamine. Then 23.7 g (100 mmol) diphenylphosphinyl chloride dissolved in 80 mL CH_2Cl_2 are added within 1 h. After extraction of the salts with ice water (2-3 times) the solution is dried ($MgSO_4$), and the solvent removed. Recrystallization from diethyl ether affords 17.7 g (68%) colorless crystals of *N,N*-dimethyl-*O*-(diphenylphosphinyl)hydroxylamine (**1**).[2,3]

(2) To a solution of 2.00 g (4.60 mmol) bis(diphenylphosphinyl) peroxide in 50 mL CH_2Cl_2, cooled to -60 °C, is added under stirring within 1 h 10.8 mL of a 0.86 M solution of dimethylamine in CH_2Cl_2 (9.20 mmol dimethylamine). The reaction is continued overnight under warming to 0 °C. Then the organic layer is washed 4 times with cold water, dried, and the solvent removed. After crystallization from diethyl ether, 1.18 g (98%) (**1**) are isolated. This is a general procedure which allows the preparation of other *N,N*-di- as well as *N*-alkyl-*O*-(phosphinyl)hydroxylamines.[4]

Handling, Storage, and Precautions: stable for more than a year if stored at -30 °C.

Electrophilic Aminations.

N,N-Dimethylaminocyclopentadiene and *N,N*-Dimethylaminocyclopentadienyllithium.

Reaction of cyclopentadienyllithium (**2**) with (**1**) leads to an equilibrium dominated by *N,N*-dimethylaminocyclopentadiene (**3b**) (eq 1).[3] Aminocyclopentadienes are not easily accessible by methodologies other than electrophilic amination. For this amination reaction, ***N,N-Dimethyl-O-(methylsulfonyl)hydroxylamine***[3] and *N,N*-dimethyl-*O*-(diphenoxyphosphoryl)hydroxylamine[3] can also be used.

Reaction of (**3**) with ***n-Butyllithium*** affords *N,N*-dimethylaminocyclopentadienyllithium (**4**), which is a precursor for the preparation of the corresponding metallocenes, e.g. (**5**) (eq 2),[3] and others.[5]

Amination of Lithiated Trimethylsilyl Cyanides: A Mild Oxidation of Aromatic Aldehydes to Amides.

(**1**) aminates lithiated *O*-(trimethylsilyl) aldehyde cyanohydrins (**8**) (eq 4), derived from aromatic aldehydes (**6**) and ***Cyanotrimethylsilane*** via the corresponding cyanohydrins (**7**) (eq 3).[6]

Since (**9**) (which is not isolated) is easily hydrolyzed (2 N HCl) to the amides (**10**), the reaction sequence (**6**) -> (**10**) amounts to a mild and selective oxidation of an aromatic aldehyde to an amide.

Alkynylcuprates to Ynamines.

(**1**) (or its amination equivalent *N*,*N*-dimethyl-*O*-(methylsulfonyl)hydroxylamine) reacts with metallated alkynes.[7] Although the reactions with RC&tbond;CLi and RC&tbond;CMgX do not lead to ynamines, the cuprates (**11**), prepared by one of three methods (eqs 5-7), do give ynamines.

(**11**) transfers only two R groups onto (**1**) (eq 8). The R groups can be Ph, *n*-Pr, *n*-Bu, *n*-C_6H_{13}, Cy, *t*-Bu, Me_3Si, or PhS, for example. The yields of the ynamines are usually in the range of 60-70%.

Dimethyl Disulfide

MeSSMe

[624-92-0] · $C_2H_6S_2$ · Dimethyl Disulfide · (MW 94.22)

(electrophilic trap for carbanions to prepare methyl sulfides; undergoes homolytic substitution at sulfur with radicals)

Physical Data: mp -85 °C; bp 110 °C; *d* 1.063 g cm^{-3}.

Solubility: insol H_2O; sol alcohol and ether.

Form Supplied in: liquid, widely available.

Purification: passage through neutral alumina.

Handling, Storage, and Precautions: use in a fume hood.

Electrophilic Carbanion Trap.

Dimethyl disulfide undergoes electrophilic attack by carbanions, with cleavage of the weak S-S bond to yield methyl sulfides. Aryllithiums have been most widely used; generation by *ortho*-lithiation (eq 1),[1] metal-halogen exchange (eq 2),[2] and intramolecular benzyne trapping (eq 3)[3] has been demonstrated. Aryl Grignard reagents[4] can also be used. Vinyllithiums effectively trap dimethyl disulfide, providing vinyl sulfides,[5] which can be converted into the corresponding ketones. This procedure can be used to effect a 1,2 keto transposition (eq 4).[6] Vinyl sulfides have also been prepared via lithiated diphenylphosphine oxide trapping of dimethyl disulfide followed by alkenation with aldehydes or ketones (eq 5).[7]

(4)

(5)

Dithioketene acetals can be prepared by metalation of geminal vinyl diiodides (eq 6);[8] allenyl enol ethers can also be sulfenated (eq 7).[9] Alkyllithiums are effectively sulfenylated (eq 8).[10] Less reactive carbanions are also easily trapped by dimethyl disulfide; allyllithiums react to give allylmethyl sulfides (eq 9),[11] and benzyllithiums provide benzyl sulfides.[12]

(6)

(7)

(8)

(9)

Sulfenylation α to carbonyl groups is accomplished via the respective enolates.[13] Oxidation and subsequent thermally induced elimination provides a route to α,β-unsaturated carbonyls;[14] however, this method has been largely supplanted by the corresponding selenenylation sequence[15] in which the selenoxide elimination occurs at or below ambient temperature. The advantages of the sulfur variant are the lower cost and lower toxicity of the reagent. Sulfenylation α to carboxylic acids followed by oxidation by ***N-Chlorosuccinimide*** or ***Sodium Periodate*** effects oxidative decarboxylation[16] via a putative Pummerer-like intermediate (eq 10). Introduction of a methyl sulfide group α to benzylic nitriles is best accomplished with the coaddition of ***Iodomethane*** (eq 11).[17] Lithiated 1,3-dithianes (see ***2-Lithio-1,3-dithiane***) react readily to provide orthothioformates.[18] Addition of an excess of ***Silver(I) Trifluoromethanesulfonate*** results in the um polung formation of dithiin carbocations (eq 12),[19] whereas ***Mercury(II) Chloride*** alcoholysis provides a route to esters.[20]

(10)

(11)

(12)

Activated Electrophilic Forms of Dimethyl Disulfide.

Electrophilic attack on dimethyl disulfide by non-anionic carbon nucleophiles is best accomplished by the addition of a Lewis acid or a methylating agent to enhance the electrophilicity of the sulfur trap. Electron-rich aromatics and indoles[21] are sulfenylated with dimethyl disulfide in the presence of Lewis acids. A combination of dimethyl disulfide and ***Sulfuryl Chloride*** can also be used, probably forming sulfenyl chloride in situ as the actual trapping agent (eq 13).[22]

(13)

A number of preformed electrophilic salt derivatives have been developed; the most popular is

Dimethyl(methylthio)sulfonium Tetrafluoroborate (DMTSF),[23] although sulfonate counterions[24] are sometimes used. These reagents react with alkenes to give intermediate episulfonium ions which can be intercepted by nucleophiles such as azide,[25] amines,[26] acetate, carboxylate, DMSO, cyano,[27] ***Triphenylphosphine***,[28] and alkynylaluminates (eq 14).[29]

(14)

Disulfenylation of alkenes using a premixed combination of ***Trifluoromethanesulfonic Acid*** and ***Iodosylbenzene*** with dimethyl disulfide is also effective.[30] Reaction of dithioacetals with DMTSF results in thionium ions which can be trapped with allylstannanes (eq 15),[31] vinylsilanes, and silyl enol ethers.[32] Orthothioesters can be similarly ionized upon treatment with DMTSF.[33]

(15)

Higher order sulfenating reagents (see ***Methylbis(methylthio)sulfonium Hexachloroantimonate***)[34] have been developed to generate episulfonium intermediates from alkenes. In these cases, the byproduct dimethyl disulfide is less nucleophilic than the dimethyl sulfide present with DMTSF reactions (eq 16).

(16)

Preparation of Isolable Sulfenylation or Sulfoxylation Reagents.

Dimethyl disulfide is used in the preparation of ***Methanesulfenyl Chloride***,[35] methanesulfinyl chloride,[36] and methyl methanesulfinate.[37]

Thiol Radical Source and Radical Trap Undergoing S_H2 Reaction.

Photolysis of dimethyl disulfide and other disulfides causes homolytic cleavage of the disulfide bond, resulting in formation of thiol radicals, which can be observed by ESR via nitroxyl spin traps.[38] Aryl,[39] alkyl,[40] and perfluoro[41] radicals react with dimethyl disulfide in an S_H2 displacement to yield the corresponding sulfides (eq 17). Distonic radical cations behave similarly, whereas conventional radical cations do not abstract the methyl sulfide group.[42] Dialkyl and diaryl disulfides add to terminal alkenes by a radical mechanism (eq 18).[43] The addition of dimethyl disulfide across the cyclopropyl bond of a [3.1.1]propellane is believed to occur by thiol radical attack followed by methyl sulfide abstraction (eq 19).[44]

(17)

Related Reagents.

Diphenyl Disulfide; ***2,2´-Dipyridyl Disulfide***.

Dimethyl Dithiobis(thioformate)[1]

[1468-37-7] · $C_4H_6O_2S_4$ · Dimethyl Dithiobis(thioformate) · (MW 214.38)

(oxidizing reagent for conversion of thiols to disulfides;[2] electrophilic sulfurization reagent[3])

Physical Data: mp 23-23.5 °C; bp 90-94 °C/0.1 mmHg.

Solubility: readily sol common organic solvents.

Form Supplied in: colorless crystals or yellow oil.

Analysis of Reagent Purity: ^{1}H NMR: δ 4.30 (6H, s, OCH_3); TLC, R_f 0.3 (silica gel, hexane).

Preparative Method: [1,2] oxidation of potassium *O*-methyl dithiocarbonate (prepared from potassium methoxide and carbon disulfide) with ***Nitric Acid*** or ***Chloramine-T***.

Purification: recrystallization from ethanol.

Handling, Storage, and Precautions: decomposes at temperatures over 140 °C to yield *O,S*-dimethyl dithiocarbonate;[1] stable for several months storage at rt. Handle in a fume hood.

Oxidation of Thiols to Disulfides.[2]

Most thiols are readily oxidized with this reagent in the presence of ***Pyridine*** as a catalyst to give the corresponding disulfides in excellent yields (eqs 1 and 2) (Table 1). In particular, this reagent is a clean and highly chemoselective oxidant for the conversion of thiols to disulfides without overoxidation to thiosulfinates, sulfinic acids, etc. The reactions are complete in a few minutes at rt. After evaporation of methanol and carbon disulfide (byproducts, eq 3) and pyridine (catalyst), most disulfides can readily be purified by recrystallization from the reaction mixture without chromatography.

Table 1 Preparation of Disulfides from Thiols

Thiol	Yield of disulfide (%)
PhSH	100
p-ClC_6H_4SH	100
$HSCH_2CH(NH_2)CO_2H$	89
$HSCH_2CH_2SH$	71[a]
p-HOC_6H_4SH	92
$HSCH_2CH_2CO_2H$	100

[a] Product is poly(ethylene disulfide).

Stereoselective α-Alkylidenation of γ-Butyrolactone.[3]

In the presence of 2 equiv of ***Lithium Diisopropylamide***, treatment of γ-***Butyrolactone*** with this reagent and aldehydes in

THF at -78 °C produces α-alkylidene-γ-butyrolactones (eq 4) (Table 2), the (*E*)-isomer being produced with high stereoselectivity. As shown in eq 5, the reaction proceeds via sulfurization of the lactone enolate, aldol condensation with the aldehyde, and final desulfurization of a thiirane.[4,5] When a metal halide such as ***Zinc Chloride*** or ***Copper(I) Iodide*** is added to the reaction mixture, the (*Z*)-isomer becomes the predominant product. The excellent stereoselectivity observed in this reaction has been attributed to repulsion between the β-methylene of the lactone and the aldehyde substitutent in the transition state for aldol addition, the transition state being different in the presence or absence of an added metal halide (eqs 6-9). This procedure has advantages for the stereoselective preparation of either the (*E*)- or (*Z*)-isomer of 2-alkylidene carbonyl compounds.

(4)

Table 2 Stereoselective Synthesis of a-Alkylidene-g-butyrolactone

N,N-Dimethyldithiocarbamoylacetonitrile[1]

[61540-35-0] · $C_5H_8N_2S_2$ · *N,N*-Dimethyldithiocarbamoylacetonitrile · (MW 160.29)

(alkylation;[2] arylation;[3] transformation to other functional groups;[2,4] reductive desulfurization[3,5])

Physical Data: mp 73-74 °C.

Solubility: insol H_2O; sol THF, dichloromethane, DMF; slightly sol alcohol.

Form Supplied in: white crystalline solid.

Preparative Method: quantitatively prepared from ***Chloroacetonitrile*** and sodium *N,N*-dimethyldithiocarbamate at rt in methanol.

Purification: recrystallized from ethanol.

Handling, Storage, and Precautions: can be used and be stored at rt under air. Use in a fume hood.

Nucleophilic Substitutions.

N,N-Dimethyldithiocarbamoylacetonitrile (**1**) serves as an active methylene compound, because its carbanion is stabilized by sulfur and cyano groups. It can be alkylated stepwise in aqueous sodium hydroxide under phase transfer catalysis (eq 1).[2] The anion undergoes nucleophilic aromatic substitution to give nitroarenes, with elimination of the dithiocarbamate group (eq 2).[3] Nucleophilic addition of (**1**) to phenyl isothiocyanate also occurs readily.[6]

Transformations.

Dialkylated *N,N*-dimethyldithiocarbamoylacetonitriles are transformed into ketones by ***N-Bromosuccinimide*** bromination or by basic hydrolysis (eq 3),[2] and they are hydrolyzed in acidic ethanol to produce α-mercapto carboxylates.[4] Bromination of (**1**) in methanol leads to the formation of 1,3-dithietan-2-ylium ion.[7] Alkylated *N,N*-dimethyldithiocarbamoylacetonitriles are reductively desulfurized to α-branched nitriles with ***Tri-n-butylstannane*** in the presence of a catalytic amount of ***Azobisisobutyronitrile*** (eq 4).[5]

Related Reagents.

N,N-Diethylaminoacetonitrile; ***2-(2,6-Dimethylpiperidino)acetonitrile***; ***Lithioacetonitrile***; ***Methoxyacetonitrile***.

N,N-Dimethylformamide[1]

[68-12-2] · C_3H_7NO · *N,N*-Dimethylformamide · (MW 73.11)

(formylating agent for certain organometallics[2-5]; used in combination with $POCl_3$ or acid halides to form the reactive Vilsmeier reagent[8,9])

Alternate Name: DMF.

Physical Data: mp -61 °C; bp 153 °C; *d* 0.944 g cm^{-3}; fp 57 °C.

Solubility: miscible with water and most organic solvents.

Form Supplied in: clear liquid; both d_7 and ^{13}C forms are available commercially; widely available.

Purification: decomposes slightly at its normal boiling point to give small quantities of of dimethylamine and carbon monoxide. The decomposition is catalyzed by acidic or basic materials so that even at rt DMF is appreciably decomposed if allowed to stand for several hours with solid KOH, NaOH, or CaH_2. Drying agents suitable for DMF are $CaSO_4$, $MgSO_4$, silica gel, and 4Å molecular sieves. After drying, distillation under reduced pressure will give reasonably dry DMF adequate for most laboratory purposes. Anhydrous DMF can be prepared by using certain desiccants.[1b]

Handling, Storage, and Precautions: anhydrous DMF should be stored under a nitrogen atmosphere in sure seal bottles or metallic cylinders; vapors are harmful, irritating to skin, eyes, and mucous membranes; it is suspected to be a carcinogen; use in a fume hood.

Reaction with Organometallics.

DMF is a good formylating agent for certain organometallic compounds. Even though formylation of some alkyllithium or Grignard reagents with DMF does not always give good yields of products due to side reactions,[1] sonication of a mixture of alkyl or aryl halide, lithium, and DMF substantially increases the rate of organometallic formation and yield of the formylated product.[2] Allenyl and vinyl organolithiums undergo formylation with DMF to

produce good yields of unsaturated aldehydes.[3] DMF can be added to the dianion of cyclohexanone oxime to give an isoxazole in good yield (eq 1).[4] Many organometallic compounds have been formylated on reaction with DMF.[5]

(1)

Alkali metal reduction of arylalkenes in the presence of DMF results in α-hydroxy amides in high yield (eq 2).[6] Through a novel three-component alkene formation involving DMF, an organolithium reagent, and a Wittig reagent, alkenes can be synthesized in high yield (eq 3).[7]

(2)

(3)

Vilsmeier Reaction.

A Vilsmeier reagent is generated when DMF is treated with ***Phosphorus Oxychloride*** or other acid chlorides; this reagent has found extensive use as a formylating, halogenating, and dehydroxylating agent (see also ***Dimethylchloromethyleneammonium Chloride***).[8]

Formylation.

Formylation can be achieved using the Vilsmeier reagent generated by treating DMF with an acid chloride. Indoles substituted at C-3 react with DMF-$POCl_3$ at 100 °C to give 2-formylindoles (eq 4).[9a] Similarly, 1,2-dihydropyridines[9b-d] and 1,4-dihydropyridines[9d] have been regioselectively formylated using DMF-$POCl_3$.

(4)

Alcohols undergo *O*-formylation when treated with DMF and benzoyl chloride, providing good yields of formates (eq 5).[10]

(5)

A similar transformation can be achieved by treating an amine with ***Chlorotrimethylsilane*** and ***Imidazole*** in DMF.[11] In contrast, primary amines form the formamidine on treatment with DMF-$POCl_3$ (eq 6).[12] Phthalimides undergo a one-pot deprotection and *N*-formylation on reaction with DMF and hydrazine.[13]

(6)

Reaction with Alcohols.

Alkyl halides can be easily synthesized on reaction of an alcohol with DMF and ***Phosgene***.[14] In an analogous manner, 1-triptycyl carbinols undergo a deoxygenative rearrangement and halogenation on treatment with ***Thionyl Chloride***-DMF.[15]

Reaction with Enolizable Ketones.

Both acyclic and cyclic enolizable ketones react with DMF-$POCl_3$ to form the β-chloro-α,β-unsaturated aldehydes. The regioselectivity of this reaction in substituted cyclohexanones is dependent on steric effects (eq 7).[16]

(7)

10:90

Several unsaturated alkenones have been converted to chlorobenzene mono-, di-, and tricarbaldehydes.[8] An illustrative example is the conversion of 2-hexen-4-one to 5-methyl-4-chloro-1,3-benzenedicarbaldehyde using DMF-$POCl_3$ (eq 8).[17]

(8)

Benzofurans result on reaction of α-phenoxyacetophenones with DMF-$POCl_3$ (eq 9).[18]

(9)

$R^1 = R^2 = OMe$

$R^1 = H,\ R^2 = OMe,\ OEt,\ NEt_2$

Tetrahydro-4*H*-thiopyran-1-one and tetrahydro-4*H*-pyran-4-one are converted to the respective chlorovinyl aldehydes on treatment with DMF-$POCl_3$ at ambient temperature.[19] Thiachroman-4-one affords the β-chlorovinyl aldehyde on treatment with DMF-$POCl_3$ below 50 °C, but at 100 °C 3-formylthiachromone is formed in modest yield (eq 10).[19]

(10)

Certain ketones can be converted to chloroalkenes on reaction with the Vilsmeier reagent. 3-Halo-2-cyclopenten-1-one has been prepared in excellent yield by reaction of cyclopentene-1,3-dione with DMF and ***Oxalyl Chloride*** or ***Oxalyl Bromide***.[20] In contrast, cyclohexane-1,3-diones afford cross-conjugated dialdehydes on treatment with DMF-$POCl_3$ (eq 11).[21]

(11)

In a similar manner, 2,3-dihydro-4-pyridones have been converted to 4-chloro-1,2-dihydropyridines on treatment with DMF-$POCl_3$ (eq 12).[22]

Reaction with Amides.

Quinoline-3-carbaldehydes can be prepared by reaction of acylanilides with DMF-$POCl_3$ (eq 13).[23]

In an analogous manner, dihydroisoquinolin-3-ones can be treated with DMF-$POCl_3$ followed by oxidation to give 3-chloro-4-formylisoquinolines.[24] Pyridines and related systems can be prepared using the reaction of the DMF-acid chloride adduct with carboxamides.[8]

Reaction with Acids.

The adduct generated from DMF and oxalyl chloride easily converts a carboxylic acid to its acid chloride.[25] The same adduct in combination with a hydride reagent can be used to reduce acids to aldehydes.[26] DMF and $SOCl_2$ convert a carboxylic acid to an acyl azide in the presence of ***Sodium Azide***, pyridine, and tetrabutylammonium chloride as a catalyst.[27] Using the dehydrating ability of the DMF-$SOCl_2$ adduct, β-lactams can be synthesized from an imine and a carboxylic acid in the presence of ***Triethylamine*** (eq 14).[27] Generally a mixture of *cis*- and *trans*-azetidinones is formed.

(14)

1,4-Dihydrobenzoic acids react with DMF-$POCl_3$ to give benzene mono-, di-, and tricarbaldehydes. This procedure also affords naphthalenedicarbaldehyde (eq 15).[28]

(15)

Reaction with Esters and Lactonic Carbonyl Groups.

Esters are normally inert to DMF-$POCl_3$ in the presence of other reactive groups.[29] The reaction of coumarone and DMF-$POCl_3$ gives a mixture of products.[30] 1,3-Oxazin-6-ones can be obtained by reaction of isoxazolin-5-ones with DMF-$POCl_3$ (eq 16).[31]

(16)

In contrast, 3-phenyl-5-isoxazolinone reacts with DMF-$POCl_3$ to give different products depending on conditions (eq 17).[32]

(17)

Miscellaneous Reactions.

DMF reacts with α-bromopropionamides in presence of ***Sodium Hydride*** or ***Silver(I) Oxide*** to form oxazolidinones, where the carbonyl group of DMF becomes incorporated (eq 18).[33]

(18)

Formylation of secondary amines can be achieved on reaction with DMF and 2,3-dihydro-1,4-phthalazinedione.[34] The combination of DMF and $SOCl_2$ can dehydrate oximes to nitriles.[27] Trifluoromethylsulfonylalkynes react with DMF to form enamides.[35] *N,N*-Bis(trimethylsilyl)enamines give azabutadienes on reaction with ***Sodium Methoxide*** in DMF.[36] α,α-Dichlorination of ketones can be achieved with ***Chlorine*** using DMF as solvent or as catalyst at 80-100 °C.[37] Reaction of an α-bromo ketone with ***Lithium Bromide*** and ***Lithium Carbonate*** in DMF at 140 °C results in a cyclic ether (eq 19).[38]

(19)

Related Reagents.

Acetic Formic Anhydride; ***Dimethylbromomethyleneammonium Bromide***; ***Dimethylchloromethyleneammonium Chloride***; ***Formyl Chloride***; ***N-Formylpiperidine***; ***N-Methylformanilide***; ***Methyl Formate***; ***N-Methyl-N-phenyl(chloromethylene)ammonium Phosphorochloridate***; ***N-Methyl-N-(2-pyridyl)formamide***.

N,N-Dimethylformamide Diethyl Acetal

(**1**; R^1 = Et, R^2 = Me)

[1188-33-6] · $C_7H_{17}NO_2$ · *N,N*-Dimethylformamide Diethyl Acetal · (MW 147.25) (**2**; R^1 = Me, R^2 = Me)

[4637-24-5] · $C_5H_{13}NO_2$ · *N,N*-Dimethylformamide Dimethyl Acetal · (MW 119.19) (**3**; R^1 = $PhCH_2$, R^2 = Me)

[2016-04-8] · $C_{17}H_{21}NO_2$ · *N,N*-Dimethylformamide Dibenzyl Acetal · (MW 271.39) (**4**; R^1 = Et, R^2 = Et)

[22630-13-3] · $C_9H_{21}NO_2$ · *N,N*-Diethylformamide Diethyl Acetal · (MW 175.31)

(mild and selective reagents for alkylation, formylation, and aminomethylenation[1])

Alternate Name: DMF diethyl acetal.

Physical Data: (**1**) bp 134-136 °C/760 mmHg; pK_b 6.2.[5] (**2**) bp 102-104 °C/720 mmHg; pK_b 6.25.[5] (**3**) bp 138-140 °C/0.5 mmHg; pK_b 6.2.[5] (**4**) bp 57-58 °C/20 mmHg; pK_b 6.4.[5]

Solubility: sol a variety of inert solvents.

Form Supplied in: pure liquid.

Preparative Methods: (1) a solution of sodium alkoxide (1 mol) and the secondary amine (1.1 mol) in 200-300 mL of the respective alcohol is refluxed as chloroform (39.5 g, 0.33 mol) is added. The mixture is refluxed for 2 h and the filtrate obtained is distilled in vacuo. For example, *N,N*-diethylformamide diethyl acetal is obtained in 32% yield.[7] (2) A solution of *N,N*-dialkyl(chloromethylene)ammonium chloride (Vilsmeier reagent, 1 mol) in 640-500 mL of chloroform is stirred while sodium alkoxide (2.1 mol) in 1 L of the respective alcohol is added. After 1 h at 20 °C the sodium chloride is separated and the mixture is distilled in vacuo. For example, the yield of DMF dimethyl acetal is 55%.[2]

Handling, Storage, and Precautions: most of the known orthoamide derivatives are colorless, distillable liquids with an amine-like smell. If moisture and presence of acids and high temperature are avoided, most of the reagents can be stored almost indefinitely. No significant toxicity has been reported.

Reactions and Synthetic Applications: General.

The formamide acetals enter into two main categories of reactions, namely alkylation and formylation, mostly via generation of aza-oxo-stabilized carbenium ions (eq 1).[1-7] As alkylation reagents they have been used in the synthesis of esters from acids, in the synthesis of ethers and thioethers from phenols and aromatic and heterocyclic thiols, and in the alkylation of CH-active methines. As formylating agents, formamide acetals are useful in the synthesis of enamines from active methylene compounds and amidines from amines and amides, as well as in the formation and modification of many types of heterocyclic compounds. They can be used for the dehydrative decarboxylation of β-hydroxy carboxylic acids to alkenes, and for the cyclization of *trans* vicinal diols to epoxides.[1] From the numerous literature reports on applications of these reagents,[1-7] some representative reactions are discussed in the following sections.

(1)

Alkylation Reactions.

DMF dialkyl acetals undergo a variety of reactions with 1,2-diols.[1] For example, the reaction of *trans*-cyclohexane-1,2-diol with DMF dimethyl acetal leads to the formation of cyclohexane epoxide (eq 2)[8] with inversion of configuration. Similarly, *meso*-1,2-diphenyl-1,2-ethanediol gives *trans*-stilbene epoxide stereospecifically (eq 3).[8,9a] This method has also been applied in the synthesis of cholestane epoxide from vicinal diols.[8] If the intermediate 2-dimethylamino-1,3-dioxolane is treated with ***Acetic Anhydride***, reductive elimination to the alkene occurs with retention of stereochemistry (eq 4).[9b]

(2)

(3)

(4)

DMF dimethyl acetal is an effective methylating reagent. For example, heterocyclic thiols are transformed to *S*-methyl heterocycles in high yields (76-86%).[10] DMF dibenzyl acetal is an interesting reagent for selective protection of nucleosides. For example, uridine and guanosine are selectively blocked at the -CONH function (eq 5).[11]

(5)

In a very simple procedure, carboxylic acids can be esterified under mild conditions with DMF dialkyl acetals. Some interesting uses are the conversion of carboxylic acids to ethyl and benzyl esters with DMF diethyl and dibenzyl acetals (yield 64-75%).[12] The dibenzyl acetal has been widely used as protecting group reagent for the carboxyl end group in peptides.[13] In several cases, DMF bis(4-dodecylbenzyl) acetal has also been used.[13,14] Some examples are given in Table 1.

Table 1 Esterification of Amino Acid and Peptide Derivatives with DMF Dibenzyl Acetal (**3**) and DMF Bis(4-dodecylbenzyl) Acetal (**5**)

RCO_2H[a]	Acetal	Reaction conditions	Yield (%)
N-DOBC-L-Val	(**3**)	C_6H_6, 80 °C, 1.5 h	97[13,14]

N-DOBC-L-Phe-L-Ala	(**5**)	CH_2Cl_2, 20 °C, 120 h	75[13]

[a] DOBC = 4-decyloxybenzyloxycarbonyl; Boc = *t*-butoxycarbonyl.

DMF dineopentyl acetal has been used as a reagent for dehydrative decarboxylation in order to avoid the possibility of competing *O*-alkylation of the carboxyl group.[15] This conversion of β-hydroxy carboxylic acids to alkenes by reaction with a DMF acetal involves an *anti* elimination, and it is thus complementary to the *syn* elimination of these hydroxy acids via the β-lactone. These reactions have been used to obtain both (*E*)- and (*Z*)-1-alkoxy-1,3-butadienes (eq 6).[15] For additional examples of alkenes obtained from β-hydroxy acids with DMF acetals, see Scheeren et al.[7]

(6)

Formylation Reactions.

DMF dialkyl acetals exhibit reactivity as a formyl cation synthon by introducing a C_1 unit at many nucleophilic centers (e.g. at N, S, O, or CH). For example, DMF dimethyl acetal can be used instead of formic acid for conversion of *o*-disubstituted aromatic systems into annulated heterocycles (eq 7).[16]

(7)

A nonacidic and regioselective route to Mannich bases from ketones and esters involves reaction with DMF acetals at a high temperature to form enamino ketones which are readily reduced by ***Lithium Aluminum Hydride*** to the Mannich bases (eq 8).[17]

(8)

CH-acidic groups (including methyl) react with DMF acetals via carbon-carbon bond formation and subsequent elimination of the respective alkanols to form enamines (aminomethylenation). Thus 2,4,7-trimethyl-1,3-dithia-5,6-diazepine reacts with DMF dialkyl acetals to give mono- or bis-aminomethylenated products depending on the amount of reagent and the reaction conditions (eq 9).[18a] The same reagents convert the more nucleophilic 2,5-dimethyl-1,3,4-thiadiazolium salts to the monoenamines (eq 10).[18a] Similarly, 1,2-dimethyl-3-cyano-5-nitroindole condenses with DMF diethyl acetal to give the (*E*)-indol-2-yl enamine (eq 11).[18b]

(9)

(10)

R^1	R^2	R^3	X	Yield (%)
Me	Me	Me	$MeSO_4$	93
Bz	Me	Me	Br	85
C_8H_{17}	Me	Me	I	85

(11)

A general indole synthesis involves reaction of an *o*-nitrotoluene derivative with DMF dimethyl acetal in refluxing DMF (eq 12).[19,20] The initially formed *o*-nitroaryl-substituted (*E*)-*N*,*N*-dimethylenamine is submitted to catalytic hydrogenation to give the indole by spontaneous cyclization. According to a variation of this methodology,[20] 2-arylindoles are readily available by reaction of *o*-nitrotoluene with DMF diethyl acetal and *o*-halobenzoyl chloride. This reaction proceeds via benzoylation of the respective enamine.

(12)

4-Dimethylamino-2-azabutadienes are readily accessible by the reaction of azomethines (imines) with DMF diethyl acetal (eq 13).[21] 1-Dimethylamino-1,3-butadienes can be synthesized in the same manner.[21] Reactions of 2-azavinamidinium

salts with DMF diethyl acetal give rise to 2-aza- and 2,4-diazapentamethinium salts (eq 14).[22]

(13)

R^1	R^2	R^3	Yield (%)
CO_2Me	H	Ph	83
CO_2Me	H	*p*-ClC_6H_4	70
CO_2Me	H	*p*-Tol	82

X = CH, N

(14)

Miscellaneous Reactions.

DMF acetals catalyze rearrangement reactions of allylic alcohols to β,γ-unsaturated amides.[23] This reaction, which involves a [2,3]-sigmatropic rearrangement, occurs with complete transfer of chirality. Thus the reaction of the (*R*,*Z*)-allylic alcohol (eq 15) with DMF dimethyl acetal gives the enantiomerically pure (*R*,*E*)-β,γ-unsaturated amide as the only product. The (*S*,*E*)-isomer also rearranges mainly to the (*R*,*E*)-amide, with only a trace of the (*S*,*Z*)-isomer. It has been suggested that both rearrangements proceed via a five-membered cyclic transition state with a carbene-like function.[23]

Enol acetates of oxo nucleosides are readily accessible by reaction of the nucleoside with DMF acetal and then with acetic anhydride (eq 16).[24] However, this method is limited to compounds with an oxo group in the 4´-position and with a free CO-NH group in the pyrimidine ring. This reaction is the first synthesis of oxo nucleoside enol acetates by direct enolization. Previous methods of enol formation fail with oxo nucleosides because of their instability in alkaline media.

6,6-Dimethylfulvene[1]

[2175-91-9] · C_8H_{10} · 6,6-Dimethylfulvene · (MW 106.18)

(hydroazulene synthesis;[2] alkene protection[3])

Physical Data: bp 40-43 °C/8 mmHg.[4]

Form Supplied in: liquid; commercially available.

Preparative Method: by reaction of cyclopentadiene with acetone under basic conditions.[4-7] The condensation has also been accomplished using pyrrolidine.[8]

Purification: distillation; chromatography on silica gel.

Handling, Storage, and Precautions: reported to undergo autoxidation to form an insoluble peroxide ($C_8H_{10}O_4$) which explodes upon heating to 130 °C. Mixing the peroxide with ether in a mortar has resulted in ignition.[9] Addition of hydroquinone is reported to suppress formation of this peroxide.[10] Sensitized photooxygenation of 6,6-dimethylfulvene at -70 °C yields a crystalline endoperoxide which explodes at -10 °C upon attempted isolation.[11]

Hydroazulene Synthesis.

Fulvenes can react as a 2π-, 4π-, or 6π-electron system in cycloaddition reactions.[1] 6,6-Dimethylfulvene serves as a 6π-addend in a cycloaddition route to hydroazulene derivatives. Treatment of 1-diethylaminobutadiene (**1**) with 3 equiv of 6,6-dimethylfulvene at rt for 2 days yields a hydroazulene product (**2**) in 65% yield (eq 1). The isolated material is the product of a [6 + 4] cycloaddition followed by elimination of diethylamine.[2,12]

(1)

Alkene Protection.

The reaction of 2-hydroxymethyl-1,4-benzoquinone (**3**) with 6,6-dimethylfulvene results in the formation of a 1:1 Diels-Alder adduct. The [4 + 2] cycloaddition product (**4**) is isolated after subsequent alkene epoxidation. Following ketone reduction and hydroxy protection, a retro-Diels-Alder reaction is accomplished by heating in diglyme (eq 2). The conditions for this retro-cycloaddition are milder than those required for cyclopentadiene Diels-Alder adducts. Analogous reactions have been used in syntheses of DL-senepoxide and DL-crotepoxide.[3,13,14]

(2)

Substituted Fulvenes.

Reaction of the lithium anion of 6,6-dimethylfulvene with aldehydes at low temperature results in functionalization at

the 7-position (eq 3).[15] Regioselective allylation at the 7-position may be accomplished in the presence of a palladium(0) catalyst (eq 4).[16]

Dimethyl Fumarate

[624-49-7] · $C_6H_8O_4$ · Dimethyl Fumarate · (MW 144.14)

(reactive dienophile; dipolarophile; radical acceptor)

Physical Data: mp 103-104 °C; bp 192-193 °C; *d* 1.37 g cm^{-3}.

Solubility: sol acetone, chloroform, methanol.

Form Supplied in: white solid.

Purification: recrystallized from benzene.

Handling, Storage, and Precautions: mutagen.

Cycloadditions.

Dimethyl fumarate has frequently been employed as a dienophile in Diels-Alder reactions. Dialkyl fumarates undergo Diels-Alder cycloadditions with aromatic dienes such as anthracene and dihydroquinone (eq 1).[1] Dienophiles which are more reactive than dialkyl fumarates include ***Tetracyanoethylene***, *N*-methylmaleimide, fumaronitrile, and maleonitrile. The [4 + 2] cycloaddition reaction of dimethyl fumarate with a diene is a stereospecific reaction and has been used to determine the geometry and stereoselectivity of Diels-Alder reactions of substituted *o*-quinodimethanes (eqs 2 and 3).[2] High diastereoselectivity has been observed in the organoaluminum catalyzed Diels-Alder reaction of (-)-dimenthyl fumarate with a variety of dienes (eq 4).[3] A diastereoselective Diels-Alder addition of the bis-lacate fumarate to an α-hydroxyorthoquinodimethane has also been reported.[4]

(4)

A range of 1,3-dipoles have been trapped by dimethyl and related dialkyl fumarates. Dimethyl fumarate and maleate have been used in experiments which examine the concertedness of cycloadditions through examination of the stereoselectivity of the cycloaddition process. Dipoles which have been trapped with dimethyl fumarate include nitrile (eq 5), azomethine,[5] carbonyl, and thiocarbonyl ylides.[6,7] Also nitrile oxides, nitrones,[8] and nitronates have been trapped by dimethyl fumarate.

Electron rich alkenes such as ketene dithioacetals and enamines react thermally with dimethyl fumarate to yield substituted cyclobutanes.[9] Asymmetric [2 + 2] cycloadditions have been developed which employ oxazolidone derivatives in combination with chiral titanium catalyst generated in situ from dichlorodiisopropoxytitanium and a tartrate-derived chiral diol (eq 6).[10] Dimethyl fumarate traps carbenoids generated photochemically and thermally (eq 7).[11,12]

(7)

Miscellaneous.

Dimethyl fumarate serves as an excellent radical trap (eq 8).[13] Asymmetric dihydroxylation of dimethyl fumarate provides dimethyl tartrate of good optical purity.[14]

(8)

Related Reagents.

Dimethyl Maleate; ***Maleic Anhydride***; ***N-Phenylmaleimide***; ***Tetracyanoethylene***.

[85611-60-5] · $CH_3F_6O_2SSb$ · Methoxysulfoxonium Hexafluoroantimonate · (MW 314.86)

(powerful methylating agents[1])

Physical Data: $Me_2I^+ SbF_6^-$ dec. 153-157 °C. $Me_2Br^+ Sb_2F_{11}^-$ dec. 74-79 °C. $Me_2Cl^+ Sb_2F_{11}^-$ mp 108-113 °C, dec. 116 °C.[2] IR and Raman spectra indicate that R_2X^+ have C_{2v} geometry and are sp^3 hybridized.[1] Most reactions of these species have been monitored by NMR.[1] In ^1H and ^{13}C NMR spectra, the shielding order is as expected, F < Cl < Br < I. δ_H: d, 5.68 ($MeF.SbF_5/SO_2F_2$); s, 5.63 ($MeOSOClF^+/SO_2ClF$); s, 5.50 ($MeOSO^+/SO_2$); s, 4.20

(Me_2Cl^+/SO_2); s, 4.13 (Me_2Br^+/SO_2); s, 3.60 (Me_2I^+/SO_2). δ_C: 96.8 ($MeF.SbF_5/SO_2F_2$); 81.9 ($MeOSOClF^+/SO_2ClF$); 74.9 ($MeOSO^+/SO_2$); 48.9 (Me_2Cl^+/SO_2); 37.6 (Me_2Br^+/SO_2); 9.5 (Me_2I^+/SO_2).

Solubility: sol SO_2, SO_2ClF, etc. React with protic and heteroorganic solvents.

Preparative Methods: $MeF.SbF_5$ and related reagents: the Me_2F^+ ion does not exist in solution, and the $MeF.SbF_5$ complex is only obtained in SO_2F_2 and CH_2F_2 solution.[3] When MeF and SbF_5 are mixed in other solvents, solvent-derived species are obtained. For example, addition of MeF in SO_2 to SbF_5 in SO_2 at -78 °C gives the $MeOSO^+$ ion.[3] The reaction of MeOSOCl with $SOCl_2.SbCl_5$ at -78 °C also generates the $MeOSO^+$ ion and has the advantage of using the cheaper and safer $SbCl_5$ and MeOSOCl (conveniently prepared from $MeOH/SOCl_2$).[4] Solutions of $MeF.SbF_5$, etc. are not stable: on warming to 0 °C $MeOSO^+$ SbF_6^- ($MeF.SbF_5/SO_2$) forms $FS(OMe)_2^+$ slowly,[3] whereas $MeOSO^+$ $SbCl_6^-$ decomposes to MeCl and SO_2.[4]

Me_2X^+ salts (X = Cl, Br, I): there are a large number of methods of preparing the Me_2X^+ ions, usually as perfluoro- or halofluoroantimonate salts. The four principal methods involve the addition of the appropriate MeX to an SO_2 solution of (i) SbF_5, (ii) $HSbF_6$, (iii) $AgSbF_6$, or (iv) $MeF.SbF_5$ at -78 to -68 °C.[1] Method (i) is generally preferred, since this leads to fewer impurities and side products. New methods to generate Me_2X^+ have been reported recently.[5,6]

Handling, Storage, and Precautions: these reagents should all be regarded as extremely hazardous, but no data on toxicity have been reported. Me_2X^+ (X = Cl, Br, I) can be isolated as crystalline, highly deliquescent salts,[1,2] and are stable at rt under dry N_2. The $MeF.SbF_5$ complex can only be obtained in SO_2F_2 and CH_2F_2 solution,[3] but $MeOSO^+$ salts can be isolated by evaporation of SO_2 solutions.[3] Use in a fume hood.

Reactivity.

The general reactivity order is $MeF.SbF_5$ >> Me_2Cl^+ > Me_2Br^+ > Me_2I^+; $MeF.SbF_5$ is the strongest methylating agent known. The ability of $MeF.SbF_5$ solutions to *O*-methylate the solvent (SO_2, SO_2F_2, SO_2ClF) has already been mentioned. At the other extreme, Me_2I^+ will not effect the same methylations as the other halonium ions below 0 °C, and often reacts less quickly than ***Methyl Trifluoromethanesulfonate*** (MeOTf) towards n-donors (heteroatoms).

σ-Donors (i.e. *C*-alkylation).

Neat $MeF.SbF_5$ rapidly self-condenses at rt to *t*-Bu^+ with concomitant formation of HF.[7] $MeF.SbF_5.SO_2ClF$ reacts with alkanes slowly at -78 °C.[8] The major product is always CH_4 via hydrogen transfer. Propane and higher straight-chained hydrocarbons also form straight and branched higher homologs. The reactions are thought to proceed via 2-electron-3-center bound carbenium ions and hydrogen abstraction.

π-Donors (i.e. *C*-alkylation): Arenes.[9]

Friedel-Crafts-type methylation of benzene and toluene has been studied in SO_2ClF at low temperatures. $MeF.SbF_5$ reacts at -78 °C in <1 min, forming benzenium ions.[10] Me_2X^+ (X = Cl, Br) reacts quickly at -50 °C, whereas Me_2I^+ requires temperatures above 0 °C.[2] Quenching yields the methylation product. The *o*:*m*:*p* ratios for methylation of toluene with all the ions are similar to those obtained from $MeOSO_2F/SbF_5$ or conventional Friedel-Crafts reagents at higher temperatures.[2]

π-Donors: Alkenes.

Methylation of alkenes in SO_2 with any of these reagents leads initially to carbenium ion formation. The reaction of $MeF.SbF_5.SO_2$ with highly substituted alkenes gives stable carbenium ions, whereas mono- or 1,2-dialkyl-substituted alkenes react further, resulting in polymerization and fluorination.[10] In contrast, Me_2X^+ ions (e.g. Me_2Br^+)[2,11] cause rapid polymerization under the reaction conditions studied.

n-Donors.

Reaction of Me_2X^+ (X = Cl, Br)[2,12] and $MeF.SbF_5$[10] with a range of heteroorganic compounds in SO_2 or SO_2ClF at -78 °C is rapid and quantitative. Methylation with Me_2I^+ usually requires temperatures >0 °C. In addition to methylations effected by MeOTf (often at higher temperatures), Me_2X^+ species also methylate RNO_2, R_2SO_2, RCO_2H, $R^1CO_2R^2$, and enolizable aldehydes and ketones. The greater reactivity of $MeF.SbF_5$ is exemplified by the formation of $MeOSO_2F$ from $MeF.SbF_5$ and SO_3.[10] $MeF.SbF_5$ has also been reported to effect *Cl*-, *Br*-, *I*-, *N*-, *O*-, *P*-, and *S*-methylations with a large variety of heteroorganic and inorganic substrates.[10,13]

Other Uses.

Dimethylhalonium ions (X = Br, I) have been used as lactone polymerization catalysts.[14] 1-Alkyl-2-methyleneaziridines have been successfully *N*-methylated with Me_2Cl^+ at -78 °C, whereas reaction with $MeOSO_2F$ in $CHCl_3$ (-60 °C) results in polymerization.[15] $MeF.SbF_5/SO_2$ (i.e. $MeOSO^+$) has been reported to undergo the ene reaction with vinyl halides at -65 °C to yield β,γ-unsaturated methyl sulfinates after the addition of MeOH (70-80%).[16] The reaction is reversed by the addition of base.

Related Reagents.

Dimethoxycarbenium Tetrafluoroborate; ***O-Methyldibenzofuranium Tetrafluoroborate***; ***Methyl Trifluoromethanesulfonate***; ***Triethyloxonium Tetrafluoroborate***.

N,N-Dimethylhydrazine

H_2NNMe_2

[57-14-7] · $C_2H_8N_2$ · *N,N*-Dimethylhydrazine · (MW 60.1)

(useful reagent for the preparation of *N,N*-dimethylhydrazones;[1-8] metalated derivatives are useful for stereoselective alkylations;[9-11] useful nucleophile for electrophiles other than aldehydes and ketones;[13-15] useful reagent for the formation of functionalized Wittig reagents[16])

Physical Data: bp 63 °C; *d* 0.786 g cm^{-3}.

Solubility: sol polar aprotic and nonpolar solvents.

Form Supplied in: colorless liquid, widely available.

Handling, Storage, and Precautions: highly toxic and is a cancer suspect agent. A well-ventilated fume hood should be used when handling this compound. Adequate skin and eye protection should also be worn.

Formation and Reactions of *N,N*-Dimethylhydrazones.

Hydrazones are easily prepared from carbonyl compounds and are susceptible to nucleophilic attack at the hydrazone carbon. Several recent examples are illustrative of this approach. For instance, treatment of hydrocinnamaldehyde with *N,N*-dimethylhydrazine afforded (*E*)-3-phenylpropanal *N,N*-dimethylhydrazone in 95% yield as a single isomer (eq 1).[1] Subsequent addition of a variety of alkylcerium, alkyllithium, and Grignard reagents afforded the nucleophilic addition products. Treatment of (α*R*,2*S*,3*S*,5*S*)-1-(1-oxopropyl)-*N*-methoxy-*N*,3,5-trimethyl-α-ethyltetrahydro-2-furanacetamide with *N,N*-dimethylhydrazine afforded the hydrazone (α*R*,2*S*,3*S*,5*S*)-5-[1-(*N,N*-dimethylhydrazono)propyl]-*N*-methoxy-*N*,3,5-trimethyl-α-ethyltetrahydro-2-furanacetamide in 92% yield (eq 2), which was then used in the construction of the C(10)-C(23) synthon for the natural product ferensimycin B.[2] Finally, reaction of ***Glyoxal*** with *N,N*-dimethylhydrazine afforded the monohydrazone, which was then treated with chiral 1,2-diamines to afford the chiral aminals (eq 3).[3] Addition of organolithium reagents to these aminals afforded the nucleophilic addition products with high diastereomeric purity.

(1)

(2)

(3)

N,*N*-Dimethylhydrazones participate in a variety of cyclization reactions. For example, dimethylhydrazones derived from aldehydes and ketones undergo an efficient thermal [2 + 2] cyclization with phenoxyketene to afford β-lactams in

good yields (eq 4).[4] 3,4-Dihydro-6-methoxy-2-(2-methyl-1-oxocyclopent-2-enyl)naphthalene-1-carbaldehyde *N*,*N*-dimethylhydrazone undergoes cycloaddition in refluxing bromobenzene to form 10,11-dihydro-2-methoxy-7-methyl-7*H*-benzo[*h*]cyclopent[*c*]isoquinolin-7-ol in 38% yield (eq 5).[5] An efficient synthesis of piperidines was achieved through treatment of *N*,*N*-dimethylhydrazine with ***Glutaraldehyde*** and 2 equiv of benzotriazole (eq 6).[6] The intermediate 2,6-bis(benzotriazolyl)piperidine was converted to dimethylaminopiperidine upon treatment with ***Sodium Borohydride*** in THF. Finally, the trifluoromethylated dimethylhydrazones derived from aryl aldehydes and *N*,*N*-dimethylhydrazine undergo cyclization to 4-trifluoroimidazoles upon refluxing in toluene (eq 7).[7] Several other cyclization reactions involving *N*,*N*-dimethylhydrazones have been reported.[8]

(4)

(5)

(6)

(7)

Metaloenamines derived from dimethylhydrazones can be alkylated with alkyl halides. For example, treatment of acetone dimethylhydrazone with ***n-Butyllithium***, followed by addition of 1,10-dibromodecane (0.5 equiv), afforded 2,15-hexadecanedione in 66% yield, after hydrolysis of the dihydrazone (eq 8).[9] The dimethylhydrazone of 3-methylcyclohexanone was alkylated with 2-(2-bromoethyl)-1,3-dioxolane (BED) to afford two monoalkylated regioisomers (eq 9).[10] Subsequent cyclization afforded two isomeric tetrahydroquinolines in an 8:92 ratio and 48% overall yield from 3-methylcyclohexanone. It is noteworthy that metalated Schiff base derivatives of conformationally locked cyclohexanones often display axial alkylation preferences exceeding 98%.[11]

(8)

Aldehydes can be converted to the corresponding nitriles by oxidation of the aldehyde dimethylhydrazones. For example, treatment of 2-naphthaldehyde *N*,*N*-dimethylhydrazone with aqueous ***Hydrogen Peroxide*** and a catalytic amount of ***Selenium(IV) Oxide*** afforded 2-cyanonaphthalene in 95% yield (eq 10).[12] ***m-Chloroperbenzoic Acid*** could also be used to transform the dimethylhydrazone to the nitrile.

Nucleophilic Attack by *N,N*-Dimethylhydrazine.

N,*N*-Dimethylhydrazine is a useful nucleophile for electrophiles other than aldehydes and ketones. 1,4,2-Dithiazolium salts react with *N*,*N*-dimethylhydrazine to form two products (eq 11).[13] The major 5-imino-1,4,2-dithiazole is formed by nucleophilic displacement of the dimethylamino group by the *N*,*N*-dimethylhydrazine. The minor thiourea

derivative is formed by spontaneous fragmentation of the dithiazole ring; benzonitrile and sulfur are also produced. Treatment of 2-chloro-9-(4-hydroxy-3-hydroxymethylbutyl)hypoxanthine with *N*,*N*-dimethylhydrazine affords a mixture of 2-*N*-amino-9-(4-hydroxy-3-hydroxymethylbutyl)-2-*N*-methylguanine (12%) and 9-(4-hydroxy-3-hydroxymethylbutyl)-2-*N*-dimethylguanine (11% yield; eq 12.[14] Treatment of 4,4-disubstituted thiazolidine-2,5-dithiones with *N*,*N*-dimethylhydrazine in ethanol affords the 5,5-disubstituted 3-dialkylaminoimidazolidine-2,4-dithiones in 67-98% yields (eq 13).[15] Finally, *N*,*N*-dimethyl-2,4-bis(trifluoroacetyl)-1-naphthylamine undergoes a nucleophilic aromatic N-N exchange reaction with *N*,*N*-dimethylhydrazine to afford *N*,*N*-dimethyl-*N*´-[2,4-bis(trifluoroacetyl)-1-naphthyl]hydrazine in quantitative yield (eq 14).[16] This product underwent an acid-promoted cyclization to afford the 2*H*-benz[*g*]indazole derivative upon refluxing in xylenes.

(12)

(13)

(14)

Formation of Functionalized Wittig Reagents.

Treatment of 1,2-vinylenebis(triphenylphosphonium) bromide with *N*,*N*-dimethylhydrazine afforded the functionalized

phosphonium salt, along with triphenylphosphine (eq 15).[17] The Wittig derivative was obtained by treatment with ***Potassium t-Butoxide***, and addition of a variety of aldehydes and ketones afforded the α,β-unsaturated hydrazones in 8-82% yields.

N,O-Dimethylhydroxylamine[1]

[1117-97-1] · C_2H_7NO · *N,O*-Dimethylhydroxylamine · (MW 61.10) (.HCl)

[6638-79-5] · C_2H_8ClNO · *N,O*-Dimethylhydroxylamine Hydrochloride · (MW 97.56)

(used extensively in the formation of *N*-methoxy-*N*-methylamides[2] and ureas,[3] which are valuable acylating agents)

Physical Data: mp -97 °C; bp 43.2 °C. .HCl salt, mp 115-116 °C.

Form Supplied in: commercially available as the HCl salt.

Handling, Storage, and Precautions: the free amine decomposes readily. However, the HCl salt is stable indefinitely.

Formation.

N,O-Dimethylhydroxylamine hydrochloride, although commercially available, can be generated from ***Ethyl Chloroformate*** and ***Hydroxylamine*** in excellent yield (eq 1).[4] The hydrochloride salt can be converted to the distillable free amine by reaction with strong base (eq 2),[5] but is generally formed in situ for most reactions.

(1)

Preparation of *N*-Methoxy-*N*-methylamides.

The widest use of the title compound is in the synthesis of *N*-methoxy-*N*-methylamides, which can be prepared from acid chlorides in good to excellent yield (eq 3).[6] The amides can also be prepared from carboxylic acids via anhydrides (eq 4)[7,8] or by using peptide coupling reagents such as ***1,3-Dicyclohexylcarbodiimide*** (eq 5)[9] and others.[10] A mild method for the generation of *N*-methoxy-*N*-methylamides from carboxylic acids using ***Carbon Tetrabromide*** and ***Triphenylphosphine*** has been published (eq 6).[11] *N,O*-Dimethylhydroxylamine reacts with cyclic anhydrides to produce amide acids (eq 7).[12] Esters can also be converted to their corresponding amides via dialkylaluminum amides, formed by the reaction of *N,O*-dimethylhydroxylamine or the hydrochloride with trialkylaluminum reagents (eq 8)[13] (see also ***Dimethylaluminum Amide***).

(5)

(6)

(7)

(8)

R = H, alkyl, aryl

Alkylation of *N*-Methoxy-*N*-methylamides.

N-Methoxy-*N*-methylamides have advantages over *N*,*N*-dialkylamides in that they give fewer side products in nucleophilic addition reactions, with little or no overaddition. Addition of a nucleophile to an *N*-methoxy-*N*-methylamide results in the formation of a stable chelated tetrahedral intermediate that is not susceptible to additional nucleophilic attack. Thus even in the presence of a large excess of a nucleophile, only monoalkylation occurs. The general reaction works well with alkyllithiums and Grignard reagents at low temperatures (eq 9).[2] Many nucleophiles have been used with these amides to produce symmetrical and unsymmetrical ketones,[2,14] α-amino ketones,[15] β-dicarbonyl compounds (eq 10),[16] and 1,4- and 1,5-dicarbonyl compounds (eq 11).[17,18] It has also been shown that *N*,*N*´-dimethoxy-*N*,*N*´-dimethylethanediamides, formed from ***Oxalyl Chloride***, undergo monoalkylation with alkyllithium or Grignard reagents to form α-keto amides (eq 12), which can subsequently be converted to 1,2-diketones.[19]

(9)

R^1	R^2M (equiv)	Isolatable yields (%)
Ph	MeMgBr (1.1)	93
Ph	PhC≡CLi (1.1)	90
$C_{17}H_{35}$	MeMgBr (2.0)	94
$MeCO_2(CH_2)_3$-	PhMgBr (6.0)	98

(10)

R^1	R^2	R^3	Yield (%)
C_5H_{11}	H	Et	82
Ph	Me	Et	84
4-MeC_6H_4	H	*t*-Bu	73

4-ClC_6H_4Li (4.0)	66	9

Acylation of the enolates of di-, tri-, and tetraketones with *N*-methoxy-*N*-methylamides results in high yield of the desired product (eq 13),[20] in contrast to acylations using esters which give lower yields and are generally problematic.

The dianions of β-keto esters react with α,β-unsaturated *N*-methoxy-*N*-methylamides to give the β,δ-diketo ester in moderate yields, with no trace of conjugate addition (eq 14).[21]

(14)

R = *t*-Bu, 49%; Et, 49%; Me, 57%

N-Methoxy-*N*-methylamides have recently been used to prepare regiocontrolled cross-aldol products, by using ***Zinc*** powder and ***Chlorotrimethylsilane*** to generate the intermediate β-siloxyamides, followed by reaction with a Grignard reagent. This reaction works with both enolizable and nonenolizable carbonyl compounds (eq 15).[22]

(15)

Reductions of *N*-Methoxy-*N*-methylamides.

Reduction of *N*-methoxy-*N*-methylamides occurs under mild conditions to give high yields of aldehydes, in contrast to *N*,*N*-dialkylamides which tend to give considerable quantities of amine and alcohol side products (eqs 16 and 17).[2] One area of recent interest involves the formation of *N*-protected α-amino aldehydes from the corresponding *N*-methoxy-*N*-methylamides in high yields without racemization (eq 18).[23]

(16)

(17)

(18)

Preparation and Uses of *N*-Methoxy-*N*-methylureas.

N,*O*-Dimethylhydroxylamine has also been used in the preparation of ureas by reaction with the appropriate carbonyl compound (eqs 19 and 20).[3]

(19)

(20)

The resultant ureas have been used as carbon dioxide equivalents in the formation of a variety of symmetrical and unsymmetrical ketones (eqs 21-23).[3]

1,3-Dimethyl-2-imidazolidinone

[80-73-9] · $C_5H_{10}N_2O$ · 1,3-Dimethyl-2-imidazolidinone · (MW 114.17)

(dipolar aprotic solvent[1] with characteristics between THF and HMPA; solvent of choice for many types of organic reactions, especially organometallic reactions[2])

Alternate Name: DMI.

Physical Data: bp 221-223 °C; *d* 1.044 g cm^{-3}.

Solubility: sol water, DMF, and THF.

Form Supplied in: clear, colorless liquid; commercially available.

Analysis of Reagent Purity: bp, NMR.

Purification: distillation over calcium hydride under reduced pressure.

Handling, Storage, and Precautions: for best results, this solvent should be stored under an inert atmosphere over 4Å molecular sieves. Handle in a fume hood.

Synthesis of Homoallylic Alcohols.

DMI is the solvent of choice for palladium-catalyzed carbonyl allylation of allylic alcohols (eq 1).[3] Allylation of ketones requires higher temperatures (eq 2). Preferential reaction of an aldehyde in the presence of a ketone can be achieved (eq 3). Allylic iodides can also be reacted with aldehydes and ketones in the presence of ***Tin(II) Fluoride***[4] to form homoallylic alcohols in good yield without the use of Lewis acids as additives (eq 4).

(1)

(2)

(3)

(4)

Synthesis of α-Methylene-γ-butyrolactones.

Palladium-catalyzed allylation of aldehydes and ketones with ethyl α-(hydroxymethyl)acrylate in the presence of ***Tin(II) Chloride*** in DMI/water provides α-methylene-γ-butyrolactones (eq 5).[5] *Syn* selectivity has been achieved when the reactions are run using a substituted hydroxymethylacrylate.

Preparation of Trimethylsilylsodium, Trimethylsilylpotassium, and Trimethylsilyllithium.

DMI is the solvent of choice for the preparation of TMSNa, ***Trimethylsilylpotassium***, and ***Trimethylsilyllithium*** (eq 6).[6] Other polar aprotic solvents such as DMF, DMSO, and tetramethylurea (TMU) are not suitable due to their reactivity toward strong base and alkali metals. Reactions of these species are also run in DMI (eqs 7 and 8).[2]

Dehydrations and Dehydrohalogenation Reactions.

DMI can be used as an alternative for HMPA[7] in dehydration and dehydrohalogenation reactions using ***Methyltriphenoxyphosphonium Iodide*** (MTPI) (eq 9).

(9)

Ullmann Ether Synthesis.

Preparation of *m*-phenoxybenzyl alcohol by condensation of *m*-hydroxybenzyl alcohol with chlorobenzene works best in DMI (eq 10).[8] Lower yields result when the reaction is run using DMSO or DMF.

(10)

Synthesis of α-Hydroxyallenes.

Reactions of propargyl iodides with aldehydes in the presence of $SnCl_2$ in DMI/DMF yield a mixture of α-hydroxylallenes and β-hydroxyalkynes[9] (eq 11).

(11)

Wittig-Horner Reactions.

High *syn* selectivity is achieved in Wittig-Horner reactions between aldehydes and diphenylphosphonates when run in THF/DMI at low temperature.[10] Subsequent stereospecific elimination yields *cis*-alkenes (eq 12).

Dimethyl Maleate

[624-48-6] · $C_6H_8O_4$ · Dimethyl Maleate · (MW 144.14)

(useful as a dienophile; dipolarophile; Michael acceptor; radical acceptor)

Physical Data: bp 204-205 °C; *d* 1.152 g cm^{-3}.

Solubility: sol most ethers and methanol.

Form Supplied in: colorless liquid; <=4% impurity of dimethyl fumarate.

Purification: distilled under reduced pressure.

Handling, Storage, and Precautions: toxic, irritant. Store in a brown bottle; avoid exposure to light.

Cycloadditions.

Dimethyl maleate is a doubly activated dienophile which reacts stereospecifically with a variety of dienes (see also ***Dimethyl Fumarate***). Dimethyl maleate has been utilized in examining the stereoselectivity in the Diels-Alder reaction of substituted *o*-quinodimethanes (eq 1).[1] The [4 + 2] cycloaddition between dimethyl maleate and a 1-amino-2-azadiene produces a dihydropyridine (eq 2).[2] Dimethyl maleate is an excellent dipolarophile which may be used to probe the concertedness of a cycloaddition process. However, caution needs to be exercised in drawing conclusions regarding the concertedness of a reaction based upon the stereoselectivity since maleate has been observed to isomerize quantitatively to fumarate by basic catalysis prior to cycloaddition.[3] The [3 + 2] cycloaddition of a variety of dipoles including trimethylenemethane (eq 3),[4] azomethine ylide (eq 4),[5] and nitrone (eq 5)[6] proceed *endo* stereoselectively with retention of alkene geometry.

(5)

The photochemical[7] and thermal[8] cycloadditions of dimethyl maleate to alkenes have been examined. Thermal reactions require the use of electron-rich alkenes such as ketene dithioacetals or enamines (eq 6). As expected, the alkene geometry is not retained in either thermal or photochemical [2 + 2] cycloadditions of dimethyl maleate. The photochemical addition of dimethyl maleate proceeds in low chemical yield with poor stereoselectivity.

Miscellaneous.

Higher homologs of carbohydrates have been prepared through ***Tri-n-butylstannane-Azobisisobutyronitrile*** induced radical addition to dimethyl maleate (eq 7) (see also ***N-Phenylmaleimide*** and ***Dimethyl Fumarate***).[9] Other electron-deficient alkenes which have been utilized as radical acceptors include ***Acrylonitrile***, ***Methyl Acrylate***, ***Methyl Vinyl Ketone***, and *N*-ethylmaleimide.

(7)

A useful phosphonate for the preparation of a variety of alkylidenesuccinates by an Emmons-Wadsworth-Horner reaction is prepared by refluxing a mixture of ***Trimethyl Phosphite*** and dimethyl maleate in phenol (eq 8).[10]

Dimethyl(methylene)ammonium Iodide[1]

(**1**; X = I^-)

[36627-00-6] · C_3H_8IN · Dimethyl(methylene)ammonium Iodide · (MW 185.02) (**2**; X = Cl^-)

[30438-74-5] · C_3H_8ClN · Dimethyl(methylene)ammonium Chloride · (MW 93.57) (**3**; X = $CF_3CO_2^-$)

[85413-84-9] · $C_5H_8F_3NO_2$ · Dimethyl(methylene)ammonium Trifluoroacetate · (MW 171.14)

(electrophilic aminomethylation (Mannich reaction) agent which condenses with active methylene compounds,[1] organometallic reagents,[2] and electron-rich aromatics and heteroaromatics[3] to produce tertiary amines; useful for the synthesis of α,β-unsaturated carbonyl compounds by elimination of the dimethylamino group[1])

Alternate Names: (**1**) Eschenmoser's salt; (**2**) Böhme's salt.

Physical Data: (**1**) mp 219 °C (dec). (**2**) mp 116 °C. (**3**) bp 100 °C/14 mmHg.

Solubility: sol DMF; partially sol[4] MeCN, CH_2Cl_2, THF (reactions in these solvents occur even though the reagent is not completely soluble).

Form Supplied in: salts (**1**) and (**2**) are widely available as solids.

Preparative Methods: salt (**1**) is prepared by thermolysis of (iodomethyl)trimethylammonium iodide[5] or cleavage of *N,N,N´,N´*-tetramethylmethanediamine by TMSI.[6] It is purified by recrystallization from tetrahydrothiophene dioxide or by sublimation at 120 °C/0.05 mmHg.[5] Salt (**2**) is prepared by cleavage of *N,N,N´,N´*-tetramethylmethanediamine by AcCl[7] or cleavage of methyl dimethylaminomethyl ether by TMSCl.[8] Salt (**3**), a liquid, is prepared by Polonovksi reaction of trimethylamine oxide with TFAA or cleavage of *N,N,N´,N´*-tetramethylmethanediamine with TFA. It is purified by distillation.[9]

Handling, Storage, and Precautions: salts (**1**)-(**3**) are very hygroscopic and must be used under anhydrous conditions to preserve their reactivity.

Dimethyl(methylene)ammonium Salts.

These reagents comprise a special family of preformed iminium salts which have been widely utilized in condensation reactions with active methylene compounds and arenes in a variant of the Mannich reaction. They have their origins in the work of Böhme,[10] who prepared the first dimethyl(methylene)ammonium salt (**2**).[11] Higher concentrations of iminium salts are achieved using salts such as (**1**)-(**3**) than under the conditions of the classical Mannich reaction in which the iminium salt is generated reversibly; hence reactions are faster, proceed under milder conditions, and are more compatible with sensitive functionality. Preformed iminium salts are sufficiently soluble in many aprotic solvents, enabling the use of highly reactive nucleophiles which would ordinarily decompose under the protic conditions of the classical Mannich reaction. Moreover, salts (**1**)-(**3**) have special applications as one-carbon synthons for an *exo* methylene group, owing to the leaving group ability of the dimethylamino group on subsequent quaternization. In addition to the iodide salt (**1**), the chloride (**2**) and trifluoroacetate (**3**) have been increasingly utilized in recent years and are essentially equivalent Mannich reagents. In choosing a particular counterion form, factors such as solubility, ease of preparation and purification, and moisture sensitivity should be considered. A comparison study of the three reagents[12a] favors the trifluoroacetate (**3**) because it is the most soluble and can be transferred by syringe, although it is more tedious to prepare. Several other counterion forms have been prepared by anion exchange of the chloride but have had minimal synthetic applications.[10,13]

Reactions with Active Methylene Compounds and their Derivatives.

Active methylene compounds with acidity comparable to or greater than that of a simple ketone or aldehyde condense directly and without prior activation with salts (**1**)-(**3**) in aprotic solvents to produce Mannich bases. Reaction conditions vary depending on the acidity of the substrate and may employ elevated temperatures and base additives to promote enolization. A comparison study finds that ketone Mannich bases are obtained in generally higher yields using salt (**2**) than under the conditions of the classical Mannich reaction, especially in the case of sterically crowded and α,β-unsaturated ketones.[7] For example, α-methylpropiophenone reacts with (**2**) to produce the corresponding Mannich base in 53% yield (eq 1), whereas under the classical conditions the yield is only 6%. Other ketone substrates reported to react with salts (**1**)-(**3**) in a superior manner to the classical Mannich reaction include chromanones,[14] thiochromanones,[14] and 1*H*-pyrido[3,2,1-*k*]phenothiazin-3(2*H*)-ones.[15] The regiochemistry of the reactions of unsymmetrical methyl ketones with salt (**3**) in TFA has been studied.[16] Under kinetic control, attack at the more substituted enol predominates in parallel to the classical Mannich reaction[17] to give the more substituted Mannich base, while under thermodynamic control reversibility favors the less substituted Mannich base (eq 2).[18] In addition to simple ketones and aldehydes, other classes of active methylene compounds known to react in this variant of the Mannich reaction include 2*H*-benzo[*b*]furan-3-ones,[19] 2*H*-benzo[*b*]thiophen-3-ones,[19] 1,3-dithian-5-ones,[20] α-methylene-β-diketones,[21] β-diketones,[22] malonates,[6,23-25] α-diazo ketones,[26] and *N*,*N*-diphenylglycinate esters.[27] These reactions have been used in the modification of natural products such as steroids,[9] hydrocodone,[28] oxycodone,[28] and spectinomycin.[26]

Temp		
72 °C	77%	16%
145 °C	-	55%

Preformed kinetic enolates undergo alkylation with salts (**1**)-(**3**), extending the scope of the Mannich reaction to weakly acidic active methylene components such as esters (eq 3),[12b,29,30] lactones,[12b,29,31-34] unsaturated lactones,[35] carboxylic acids,[12b] and nitriles.[36] Because of their enhanced nucleophilicity, enolates are able to add under extremely mild conditions (-78 °C to rt). Moreover, in the case of unsymmetrical ketones, predictable regiocontrol can be achieved if the enolate is prepared regiospecifically. Enolates used in these reactions have generally been prepared by deprotonation with strong bases such as ***Lithium Diisopropylamide***[29-35] or ***Potassium Hydride***,[12,29] cleavage of silyl enol ethers[12b] or enol carbonates[37] with ***Methyllithium***, or by decomposition of α-diazo ketones in the presence of trialkylboranes to generate the corresponding boron enolate.[38] The latter method, which reliably generates ketone enolates regiospecifically, is excellent for the regiospecific synthesis of Mannich bases derived from simple unsymmetrical ketones (eq 4). Also, ester enolates generated by cleavage of cyclopropyl esters in the presence of ***Trimethylsilyl Trifluoromethanesulfonate*** add to salt (**2**).[39]

Trimethylsilyl enol ethers derived from ketones and aldehydes add to salts (**1**)-(**3**) in a complementary fashion to enolates.[12a,32] The reaction proceeds via a silyloxonium ion which hydrolyzes on aqueous workup (eq 5). This method has been used for the synthesis of the two regioisomeric Mannich bases of 2-methylcyclohexanone starting from the individual silyl enol ethers[40] and for the synthesis of the *exo* Mannich base of (+)-camphor,[41] which does not undergo aminomethylation under the conditions of the classical Mannich reaction. Chromanone[42] and enone[40,43] trimethylsilyl enol ethers also react. In situ methods for the generation of salt (**1**), involving cleavage of *N*,*N*,*N*´,*N*´-tetramethylmethanediamine by ***Chloroiodomethane***[44] or cleavage of *n*-butyldimethylaminomethyl ether[45] by ***Iodotrimethylsilane***, are also compatible with these reactions and avoid handling the moisture-sensitive reagent (eq 6). In a minor variant of this reaction employing more stable *t*-butyldimethyl silyl enol ethers, the product retains the silyl enol ether following workup with retention or migration of the original position of the enol ether double bond, depending on the substrate (eq 7).[46]

(6)

(7)

Reactions with Organometallic Reagents.

In analogy to enolate anion additions, organometallic reagents such as alkyl bromomagnesium and lithium reagents,[2] vinyl and aromatic bromomagnesium reagents,[6] vinylcuprates,[47] and cyclopropyllithiums[48] add to salt (**1**) to produce *N*,*N*-dimethylamines (eq 8). Salt (**1**) is also capable of condensing directly with less nucleophilic organometallic reagents such as 1,4-bis(trimethylstannyl)-2-butyne to afford 2,3-bis(dimethylamino)methyl-1,3-butadiene.[49]

(8)

Synthesis of α,β-Unsaturated Carbonyl Compounds and Terminal Alkenes.

Salts (**1**)-(**3**) serve as excellent one-carbon units for an α-methylene group, since the dimethylamino group of the derived Mannich base can be easily eliminated by quaternization with ***Iodomethane*** followed by treatment with base (eq 9). Active methylene compounds that have been converted to their α-methylene derivatives by this method include esters,[27,29,30,39] lactones,[29,32-34,50] and ketones.[37,51] Similarly, γ-methylene enones,[40] and γ-methylene butenolides[35] have been prepared from their respective Mannich bases. Quaternary ammonium salts from Mannich bases of α-alkoxymalonates[23,52] and α-alkoxy-α-methoxycarbonyl lactones[24] undergo base or thermal fragmentation to provide enolpyruvates for the synthesis of chorismic acid and related natural products (eq 10). Mannich base hydrochlorides derived from β-diketones and salt (**2**) undergo spontaneous elimination by addition of water to give enediones.[22] Tertiary amines derived from the addition of organometallic reagents to salts (**1**)-(**3**) can also be converted to terminal alkenes by thermolysis of the corresponding *N*-oxides.[2]

(9)

(10)

Reactions with Aromatic Compounds.

Several electron-rich aromatic and heteroaromatic systems have been shown to undergo condensation reactions with salts (**1**)-(**3**) with improved yields and regiocontrol over the conventional method. Monosubstituted phenols, which typically give mixtures of *ortho*, *para*, and diaminomethylated products under conventional conditions, react with salt (**1**) or (**2**) in the presence of ***Potassium Carbonate*** to afford the corresponding *ortho*-substituted Mannich base in high yield (eq 11).[53] An ion pair interaction between the phenoxide anion and the iminium salt is believed to be responsible for the directing effect. This reaction is also successful with deactivating groups in the *para* position. 2,3-Dimethylphenol,[54] 1-naphthol,[55] and 2-methyl-1-naphthol[56] also react in a superior manner with respect to yield and regiospecificity by simple treatment with salts (**1**) or (**2**) in aprotic solvents. In the case of 1-naphthol derivatives, 4-substituted Mannich bases mainly result. The reaction has been exploited for the preparation of aminomethylated derivatives of papulacandin A, a resorcinol-containing antibiotic,[57] and 4,4´- and 3,3´-dihydroxy-α,β-diethylstilbenes.[58] Among heterocyclic systems, salt (**2**) has been used to effect aminomethylation at the 2-position of furan[59] and thiophene,[60] the 3-position of 4-substituted indoles,[61-63] the 8-position of a 2,3-dihydro-5(1*H*)-indolizinone derivative,[64] and the 5-position of a 1,4-dihydropyridine derivative.[65] The cases of furan and thiophene are noteworthy, since they fail or condense poorly in the classical Mannich reaction. In situ methods for the generation of dimethyl(methylene)ammonium species involving cleavage of *N*,*N*,*N´*,*N´*-tetramethylmethanediamine by ***Sulfur***

Dioxide[66] and by chlorosilanes[67] has been investigated in the Mannich reactions of *N*-methylpyrrole, indole, and *N*-methylindole (eq 12). Evidence suggests, however, that free iminium species are not involved in these reactions. An unusual out-of-ring aminomethylation reaction catalyzed by ***Acetyl Chloride*** occurs at the 1-methyl of a 1-methyl-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine derivative using salt (**2**), generated in situ by cleavage of *N*,*N*,*N*´,*N*´-tetramethylmethanediamine with excess AcCl.[68] In an interesting variant of the Mannich reaction, aryl- and heteroarylstannanes react with salt (**2**) to produce Mannich bases obtained by *ipso*-substitution of the stannyl group.[69] The directing effect of tin allows for the preparation of Mannich bases with substitution patterns not ordinarily obtained in the Mannich reaction, as in the case of 3-(*N*,*N*-dimethylaminomethyl)thiophene (eq 13).

(11)

(12)

(13)

Heteroatom Addition.

Salt (**2**) undergoes heteroatom addition to amides,[70] phosphoramides,[71] hydrazines,[72] oximes,[73] and secondary phosphines and arsines.[4]

Related Reagents.

(Methylene)ammonium salts containing different *N*-alkyl substitution have been synthesized and undergo similar reactions to those of dimethyl(methylene)ammonium salts.[1,3,10]

(*S,S*)-2,2´-(Dimethylmethylene)bis(4-*t*-butyl-2-oxazoline)[1]

[131833-93-7] · $C_{17}H_{30}N_2O_2$ · (*S,S*)-2,2´-(Dimethylmethylene)bis(4-*t*-butyl-2-oxazoline) · (MW 294.49)

(versatile chiral ligands for enantiocontrol of metal-catalyzed reactions such as copper-catalyzed cyclopropanation[2-5] and aziridination of alkenes,[6] addition of cyanotrimethylsilane to aldehydes,[7] or Lewis acid-catalyzed Diels-Alder reactions[8,9])

Physical Data: mp 88-89 °C; $[\alpha]_D$ -108°; $[\alpha]_{365}$ -394° (*c* 0.97, CH_2Cl_2).

Solubility: insol H_2O; sol all common organic solvents.

Preparative Methods: ligand (**1**) and related C_2-symmetric bisoxazolines are readily prepared from chiral β-amino alcohols using standard methods for the synthesis of 2-oxazolines.[1] This is exemplified by the simple three-step procedure shown in eq 1, involving amide formation, conversion of the resulting bis(2-hydroxyalkyl)amide to the corresponding bis(2-chloroalkyl)amide, and subsequent base-induced cyclization.[3a,4,8a,10,11]

There are several other convenient one- and two-step syntheses leading to enantiomerically pure bisoxazolines, e.g. condensation of amino alcohols with dicarboxylic acids,[2,7] dinitriles,[10a,12] or diimino esters[4,10,13] (cf. eq 2),[4,10a] or acid-catalyzed cyclization of (2-hydroxyalkyl)amides.[8b] By these methods, various types of differently substituted bisoxazoline ligands are readily available in both enantiomeric forms, often in high overall yield.

Purification: (**1**) can be purified by column chromatography (silica gel, hexane/EtOAc 7:3) and by recrystallization from pentane.

Handling, Storage, and Precautions: as a crystalline solid, (**1**) is stable at ambient temperature; for longer periods, storage at -20 °C is recommended.

C_2-Symmetric Bisoxazolines as Ligands in Asymmetric Catalysis.

Methylenebis(oxazolines) such as (**1**), (**3**), and (**5**) are patterned after the semicorrins,[1] which have been successfully employed as ligands in enantioselective Cu-catalyzed cyclopropanations and other reactions (see ***(1S,9S)-1,9-Bis{[(t-butyl)dimethylsilyloxy]methyl}-5-cyanosemicorrin***). The potential of bisoxazoline ligands of this type, which has been recognized independently by a number of research groups,[1-11,13-15] is demonstrated by a remarkable variety of different applications in asymmetric catalysis.

(1) R = *t*-Bu
(2) R = Ph

(3)

(4)

(5)

The short and simple syntheses of these compounds and the ease of modifying their structures make them ideal ligands for the stereocontrol of metal-catalyzed reactions. Using different amino alcohols and dicarboxylic acid derivatives as precursors, the steric and electronic properties, as well as the coordination geometry, can be adjusted to the specific requirements of a particular application. The neutral methylenebis(oxazoline) ligands (**1**) and (**2**), which form six-membered chelate rings, the bioxazolines (**4**), a class of neutral ligands with π-acceptor properties forming five-membered chelate rings, and the anionic methylenebis(oxazolines) of type (**3**) and (**5**) are representative examples.

Enantioselective Cyclopropanation of Alkenes.

Cationic Cu^{I} complexes of methylenebis(oxazolines) such as (**1**), which have been developed by Evans and co-workers,[3] are remarkably efficient catalysts for the cyclopropanation of terminal alkenes with diazoacetates. The reaction of styrene with ethyl diazoacetate in the presence of 1 mol % of catalyst, generated in situ from ***Copper(I) Trifluoromethanesulfonate*** and ligand (**1**), affords the *trans*-2-phenylcyclopropanecarboxylate in good yield and with 99% ee (eq 3). As with other catalysts, only moderate *trans*/*cis* selectivity is observed. Higher *trans*/*cis* selectivities can be obtained with more bulky esters such as 2,6-di-*t*-butyl-4-methylphenyl[3] or dicyclohexylmethyl diazoacetate[5] (94:6 and 95:5, respectively). The efficiency of this catalyst system is illustrated by the cyclopropanation of isobutene, which has been carried out on a 0.3 molar scale using 0.1 mol % of catalyst derived from the (*R*,*R*)-enantiomer of ligand (**1**) (eq 4).[3] The remarkable selectivity of >99% ee exceeds that of Aratani's catalyst[16] which is used in this reaction on an industrial scale.

(3)

(4)

For the cyclopropanation of terminal mono- and disubstituted alkenes, the cationic Cu^I complex derived from ligand (**1**) is clearly the most efficient catalyst available today, giving consistently higher enantiomeric excesses than related neutral semicorrin[1,17] or bisoxazoline Cu^I complexes of type (**3**),[1,2,4] which can induce enantiomeric excesses of up to 92% ee in the cyclopropanation of styrene with ethyl diazoacetate. High enantioselectivities, ranging between the selectivities of the Evans catalyst (eq 3) and complex (**3**) (M = Cu^I, R = *t*-Bu), have also been observed with cationic Cu^I complexes of azasemicorrins.[1,10a,18]

For analogous cyclopropanation reactions of trisubstituted and 1,2-disubstituted (*Z*)-alkenes, ligand (**1**) is less well suited. In these cases, better results have been obtained with the bisoxazoline ligand (**6**).[5] This is illustrated by the enantioselective cyclopropanation of 1,5-dimethyl-2,4-hexadiene, leading to chrysanthemates (eq 5).[5] The enantioselectivity in this reaction is comparable to the best results reported for Aratani's catalyst.[16] Ligand (**6**) has also been reported to induce high enantiomeric excesses in the cyclopropanation of (*Z*)-4,4-dimethyl-2-pentene, (*Z*)-1-phenylpropene, and 1,1-dichloro-4-methyl-1,3-pentadiene with (-)-menthyl diazoacetate (92-95% ee).[5] A mechanistic model rationalizing the stereoselectivity of Cu catalysts of this type has been published;[17] a comparison of different cyclopropanation catalysts is also available.[19]

(5)

Enantioselective Aziridination of Alkenes.

Copper complexes with neutral methylenebis(oxazoline) ligands (**1**) and (**2**) have also been employed as enantioselective catalysts for the reaction of alkenes with (*N*-tosylimino)phenyliodinane, leading to *N*-tosylaziridines.[6] The best results have been reported for cinnamate esters as substrates, using 5 mol % of catalyst prepared from CuOTf and the phenyl-substituted ligand (**2**) (eq 6). The highest enantiomeric excesses are obtained in benzene, whereas in more polar and Lewis basic solvents, such as acetonitrile, the selectivities are markedly lower. The chemical yield can be substantially improved by addition of 4Å molecular sieves. Both Cu^{I}- and Cu^{II}-bisoxazoline complexes, prepared from Cu^{I} or Cu^{II} triflate, respectively, are active catalysts, giving similar results. In contrast to the Cu-catalyzed cyclopropanation reactions discussed above, in which only Cu^{I} complexes are catalytically active, here Cu^{II} complexes are postulated as the actual catalysts.[6]

(6)

Analogous naphthylacrylates also react with excellent enantioselectivity under these conditions. Styrene and (*E*)-β-methylstyrene afford the corresponding *N*-tosylaziridines with 63 and 70% ee, respectively. For these two substrates, the *t*-butyl-substituted bisoxazoline (**1**) rather than (**2**) proved to be the most effective ligand.

Similarly high enantioselectivities in aziridination reactions of this type have been reported for Cu catalysts with C_2-symmetric diimine ligands, derived from 1,2-diaminocyclohexane and aromatic aldehydes.[20] The best results in this case have been obtained with 7-cyano-2,2-dimethylchromene as substrate (>98% ee). At present, it is difficult to compare the diimine-based with the bisoxazoline-based catalysts because different substrates were examined in these studies, with the exception of styrene which gave very similar results with the two catalysts (66 and 63% ee, respectively).[20,6] Thus further work will be necessary to establish the full scope of these promising catalyst systems.

Enantioselective Diels-Alder Reactions.

Methylenebis(oxazoline) complexes of Fe^{III}, Mg^{II}, and more recently also Cu^{II}, have been successfully employed as enantioselective Lewis acid catalysts in Diels-Alder reactions.[8,9] The most promising results have been obtained with Cu^{II} catalysts prepared from ligand (**1**) and ***Copper(II) Trifluoromethanesulfonate*** (eq 7).[9] In the presence of 10 mol % of catalyst in CH_2Cl_2 at -78 °C, acrylimide (**7a**) smoothly reacts with cyclopentadiene to afford the Diels-Alder product (**8a**) in 86% yield with excellent enantio and *endo*/*exo* selectivity. The crotonate derivative (**7b**) is less reactive, but at higher temperature also undergoes highly selective cycloaddition with cyclopentadiene. The fumarate (**7c**) gives similar results. In terms of selectivity and efficiency, this catalyst system can compete against the most effective chiral Lewis acid catalysts developed so far.[21]

(7) (8)

(a) R = H	-78 °C	>98% ee	*endo*:*exo* = 98:2
(b) R = Me	-15 °C	97% ee	*endo*:*exo* = 96:4
(c) R = CO_2Et	-55 °C	95% ee	*endo*:*exo* = 94:6

The thiazolidine-2-thione analogs of (**7b**) and (**7c**) are more reactive dienophiles and, therefore, the cycloaddition can be carried out at lower temperature. However, the selectivities and yields are similar as with (**7b**) and (**7c**).[9] The corresponding cinnamate derivative (**7**) (R = Ph), on the other hand, reacts with substantially lower enantioselectivity than the corresponding thiazolidine-2-thione analog (90% vs. 97% ee).

The stereochemical course of these reactions has been rationalized assuming a chelate complex between the (bisoxazoline)Cu catalyst and the dienophile as the reactive intermediate, with square planar coordination geometry of the Cu^{II} ion.[9]

Enantioselective Cyanohydrin Formation.

Magnesium complexes formed with the anionic semicorrin-type ligand (**5**) catalyze the addition of ***Cyanotrimethylsilane*** to aldehydes, leading to optically active trimethylsilyl-protected cyanohydrins.[7] In the presence of 20 mol % of the chloromagnesium complex (**9**), prepared from equimolar amounts of (**5**) and BuMgCl, cyclohexanecarbaldehyde is smoothly converted to the corresponding cyanohydrin derivative with 65% ee. Addition of 12 mol % of the bisoxazoline (**10**) results in a dramatic increase of enantioselectivity to 94% ee (eq 8). Replacement of (**10**) by its enantiomer reduces the selectivity to 38% ee. This remarkable effect has been proposed to arise from hydrogen-bond formation between the bisoxazoline (**10**) and HCN, which is generated in small amounts by hydrolysis of Me_3SiCN due to traces of water present

(S,S)-2,2´-(Dimethylmethylene)bis(4-t-butyl-2-oxazoline)

in the reaction mixture. The chiral [(**10**)&dotbond;HCN] aggregate is postulated as the reactive species undergoing nucleophilic addition to the aldehyde which, at the same time, is activated by coordination with the chiral magnesium complex (**9**).

(9)

(10)

(8)

(a) R = C_6H_{13} 95% ee
(b) R = Et_2CH 91% ee
(c) R = Cy 94% ee

Heptanal, 2-ethylbutanal, and pivalaldehyde react with similarly high enantioselectivities, whereas benzaldehyde (52% ee) and certain α,β-unsaturated aldehydes such as geranial (63% ee) afford considerably lower enantiomeric excesses. Most other catalysts used for the addition of HCN or Me_3SiCN to aldehydes usually exhibit higher enantioselectivities with aromatic or α,β-unsaturated aldehydes than with alkyl carbaldehydes.[22]

Enantioselective Allylic Alkylation.

Most ligands that have been employed in enantioselective Pd-catalyzed allylic substitutions are chiral diphosphines.[23] Recently, it has been found that chiral nitrogen ligands can also induce high enantioselectivities in such reactions.[1,18,24] The best results have been obtained with neutral azasemicorrin and methylenebis(oxazoline) ligands. In the presence of 1-2 mol % of catalyst, generated in situ from ***Bis(allyl)di-μ-chlorodipalladium*** and ligand (**11**), and a mixture of ***N,O-Bis(trimethylsilyl)acetamide*** (BSA) and catalytic amounts of KOAc in an apolar solvent like CH_2Cl_2 or toluene, racemic 1,3-diphenyl-2-propenyl acetate smoothly reacts with dimethyl malonate to afford the corresponding substitution product in high yield and with excellent enantioselectivity (eq 9).

(11)

(9)

More recently, even higher selectivities of up to 99% ee have been achieved in this reaction with chiral phosphinooxazolines (see ***(S)-2-[2-(Diphenylphosphino)phenyl]-4-phenyloxazoline***).[24-26] The application range of (bisoxazoline)Pd catalysts is limited to relatively reactive substrates such as aryl-substituted allylic acetates.[24] Analogous reactions of 1,3-dialkyl-2-propenyl acetates, for example, are impracticably slow and unselective. In this case, phosphinooxazolines have proved to be the ligands of choice.[24,25]

The crystal structures of some (allyl)Pd^{II}-bisoxazoline complexes have been determined by X-ray analysis.[1] The structural data of these complexes provide some clues about how the chiral ligand controls the stereochemical course of eq 9.

Other Applications.

In the reactions discussed so far, methylenebis(oxazolines) were found to be superior to bioxazolines of type (**4**). However, there are some enantioselective metal-catalyzed processes for which the bioxazolines (**4**) are better suited than neutral or anionic methylenebis(oxazolines). Two examples, the Ir-catalyzed transfer hydrogenation of aryl alkyl ketones[4] and the Rh-catalyzed hydrosilylation of acetophenone,[11] are given in eqs 10 and 11.

(S,S)-2,2´-(Dimethylmethylene)bis(4-t-butyl-2-oxazoline)

Using 1 mol % of catalyst generated in situ from ***Di-μ-chlorobis(1,5-cyclooctadiene)diiridium(I)*** and the bioxazoline (**12**) in refluxing isopropanol, various aryl alkyl ketones have been reduced in good yield with enantioselectivities ranging between 50-90% ee (eq 10).[10b] Dialkyl ketones are unreactive under these conditions. The highest enantiomeric excesses are obtained with phenyl isopropyl ketone (91% ee at 70% conversion, 88% ee at 93% conversion). Although these results compare favorably with the enantioselectivities reported for other Ir catalysts,[27] at present, (bioxazoline)Ir complexes cannot compete with the most efficient catalysts available for the enantioselective reduction of ketones[28] (see ***Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole***). Recently, high enantioselectivities in the transfer hydrogenation of certain aryl alkyl ketones have been achieved with chiral samarium catalysts.[29]

The dibenzylbioxazoline derivative (**13**) has been found to induce up to 84% ee in the Rh-catalyzed hydrosilylation of acetophenone with diphenylsilane (eq 11).[11] A large excess of ligand relative to [Rh] is necessary for optimal selectivity. Analogous bithiazoline derivatives were also investigated, but gave lower selectivities. In this case too, there are more selective catalysts available which afford high enantiomeric excesses in the hydrolsilylation of a wide range of ketones.[30]

Bioxazolines have also been employed in the enantioselective dihydroxylation of alkenes with ***Osmium Tetroxide***.[15] The best results have been obtained in the dihydroxylation of 1-phenylcyclohexene with a complex, formed between OsO_4 and the diisobutylbioxazoline (**4**) (R = CH_2CHMe_2), as a stoichiometric reagent (70% ee). Styrene and *trans*-stilbene afford enantioselectivities below 20% ee under these conditions (for highly enantioselective dihydroxylation catalysts,[31] see ***Dihydroquinine Acetate*** and ***Osmium Tetroxide***).

Related Reagents.

Dimethyl Methylphosphonate[1]

[756-79-6] · $C_3H_9O_3P$ · Dimethyl Methylphosphonate · (MW 124.09)

(treatment with BuLi gives a carbanion that reacts with aldehydes,[1] ketones,[1,2] esters,[1,3] acid chlorides,[4] enol lactones[5] and other electrophiles[6-11])

Alternate Names: dimethyl methylphosphate; dimethyl methanephosphate.

Physical Data: bp 180-181 °C; *d* 1.145 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: flammable; irritant; stench. Store under N_2.

Reactions with Aldehydes and Ketones.

$(MeO)_2P(O)Me$ in THF (or less commonly Et_2O, DME, DMF, or MeCN) is deprotonated by ***n-Butyllithium***[1] or ***Lithium Diisopropylamide***,[2,11] at -78 °C, to give $(MeO)_2P(O)CH_2Li$. Unlike the carbanions of phosphonate esters which possess a charge-stabilizing electron withdrawing group (see discussion on ***Triethyl Phosphonoacetate*** and ***Trimethyl Phosphonoacetate***), $(MeO)_2P(O)CH_2Li$ does not react directly with aldehydes or ketones to give an alkene.[1] Rather, the reaction gives a β-hydroxyalkylphosphonate which has a low efficiency of cycloelimination (eq 1).[1a,12,13] Cycloelimination, and hence alkene formation, is induced by treating the β-hydroxyalkylphosphonate with ***Cesium Fluoride*** in DMF (eq 1).[12] Thioalkylated acetophenones react directly with $(MeO)_2P(O)CH_2Li$ to give 2-aryl-1-thioalkyl-2-propenes (eq 2).[14] α-Lithio derivatives of alkylphosphonothioates [$(MeO)_2P(S)Me$] react directly with aldehydes and ketones to give 1,1-disubstituted, trisubstituted, and tetrasubstituted alkenes.[1a,15] Ligand exchanged derivatives of $(MeO)_2P(O)Me$ such as alkylphosphonic diamides, alkylphosphonothioates, alkyldiphenylphosphine oxides, and alkyldiphenylphosphinothioic amides also form alkenes directly.[12]

(1)

(2)

β-Hydroxyalkylphosphonates are precursors to copper β-metalated alkylphosphonates (eq 3).[16] These versatile d^2 reagents react in excellent yields in with a range of electrophiles such as acyl chlorides, aldehydes, enones, alkynic esters, allylic and alkynyl halides, trialkyltin halides and nitroalkenes (eq 3).[16]

(3)

Reactions with Esters.

The reaction of $(MeO)_2P(O)CH_2Li$ with an ester[3a,b] (eq 4)[3b] or a lactone[3c] gives a β-ketophosphonate. The condensation has been carried out in the presence of a number of functional groups.[3a] For example, $(MeO)_2P(O)CH_2Li$

reacts preferentially with a methyl ester in the presence of a phenylethyl ester (eq 5, entry 1)[17a] and a Weinreb amide in the presence of a methyl ester (eq 5, entry 2).[17b] Some problems were encountered with β-elimination and retro-aldol reactions.[3a,17] The condensation of an ester or equivalent with $(MeO)_2P(O)CH_2Li$ has also been carried out in the presence of an acid[3a,b,18] (eq 5, entry 3[18] and 4[3a]), ketone (eq 6),[19] and an acetal.[3c,20] An acid chloride reacts with $(MeO)_2P(O)CH_2Li$ to give a β-ketophosphonate.[4] Anhydrous ***Magnesium Bromide*** promotes the preferential reaction of $(MeO)_2P(O)CH_2Li$ with an acid chloride in the presence of an ester (eq 7).[4] β-Ketophosphonates have also been prepared by oxidation of a β-hydroxyphosphonate obtained from the reaction of $(MeO)_2P(O)CH_2Li$ with an aldehyde.[13]

(4)

(5)

$R^1 = OMe$, $R^2 = CHMePh$	34%
$R^1 = N(OMe)Me$, $R^2 = Me$	82%
$R^1 = N(OMe)Me$, $R^2 = H$	>77%
$R^1 = OMe$, $R^2 = 1\text{-}AdNH_2$ salt	>78%

The β-ketophosphonates are versatile synthetic intermediates and react with aldehydes to give α,β-unsaturated esters under Roush-Masamune[18,21] and other basic conditions[13,18,22] (also see discussion on Horner-Emmons reactions of ***Triethyl Phosphonoacetate*** and ***Trimethyl Phosphonoacetate***). β-Ketophosphonates also react intramolecularly with ketones to give cyclohexenones and cyclopentenones[19,20,23] (eq 6[19]). In some cases the ketone is protected as an acetal prior to the preparation of the β-ketophosphonate.[20,23] Higher esters of phosphonic acids are prepared by α-alkylation of the ***Sodium Hydride***-generated carbanion of β-ketophosphonates.[20a,24] The corresponding dianion, generated by the sequential addition of NaH and BuLi to a β-ketophosphonate, undergoes γ-alkylation.[20a,25]

Reactions with Enol Lactones.

An enol lactone reacts with $(MeO)_2P(O)CH_2Li$, at low temperatures, to give an α,β-unsaturated ketone[5,10] (eq 8[5c]). The reaction does not proceed with α-unsubstituted five-membered endocyclic enol lactones.[20a] Perhydroazulenones have also been prepared from a lactam and $(MeO)_2P(O)CH_2Li$ in a related reaction (eq 9).[26] The analogous Wittig reaction of enol lactones proceeds with nonstabilized ylides[5a,27] but not readily with stabilized ylides.[27,28]

(8)

(9)

Reactions with 1,3-Diketones.

The reaction of 2,2-disubstituted 1,3-cyclohexanediones with $(MeO)_2P(O)CH_2Li$ in the presence of ***Chlorotrimethylsilane*** gives 3-substituted 2-cyclohexanones in good yields (22-93%) (eq 10).[2] The reaction proceeds by a retro-aldol cleavage followed by a Horner-Emmons reaction.[2] The use of BuLi rather than LDA to generate $(MeO)_2P(O)CH_2Li$ results in reduced yields.[2]

(10)

Other Reactions.

Dimethyl (alkylthio)methylphosphonates, $(MeO)_2P(O)CH_2SR$, are prepared by sulfenylation of $(MeO)_2P(O)CH_2Li$ with alkyl and aryl benzenethiosulfonates.[6] Treatment of $(MeO)_2P(O)CH_2Li$ with ***Copper(I) Iodide*** gives the corresponding 1-copper derivative, $(MeO)_2P(O)CH_2Cu$. Dimethyl 1-(trimethylsilyl)- and 1-(trimethylstannyl) methanephosphonates are prepared by subsequent reaction of $(MeO)_2P(O)CH_2Cu$ with Me_3SiCl (eq 11, entry 1)[7a,c] and ***Chlorotrimethylstannane*** (eq 11, entry 2),[7a] respectively. The reaction of $(MeO)_2P(O)CH_2Cu$ with *O*-alkyl carbonochloridothioates gives a phosphorylthiocarbonyl compound (eq 11, entry 3), a precursor to α-unsubstituted

thiono esters.[7b,d,e]

Me_3SnCl, -30 to 22 °C	Me_3Sn	68%
ROC(S)Cl, -70 °C to rt	ROC=S	54-59%

Treatment of $(MeO)_2P(O)Me$ with ***Triphenylphosphine Dichloride*** gives a single ester linkage replacement by a chloride (eq 12, entry 1).[8a] An analogous reaction with ***Phosphorus(V) Chloride*** gives the dichloride (eq 12, entry 2).[8b] $(MeO)_2P(O)CH_2Li$ *N*-methylates purines,[9] is alkylated by an alkyl iodide,[10] and also undergoes a Michael addition with 4-chloro-β-nitrostyrenes.[11]

N,N-Dimethyl-*O*-(methylsulfonyl)hydroxylamine[1]

[75812-61-2] · $C_3H_9NO_3S$ · *N,N*-Dimethyl-*O*-(methylsulfonyl)hydroxylamine · (MW 139.20)

(reagent for electrophilic aminations, Me_2N transfers to nucleophiles)

Physical Data: mp 33-35 °C.[2]

Solubility: sol THF, diethyl ether; very sol $CHCl_3$, CH_2Cl_2.[2]

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) (ppm) 2.90 (s, 6 H, Me_2N), 3.08 (s, 3 H, $MeSO_2$).[2]

Preparative Methods: to a solution of 29.3 g (300 mmol) *N,N*-dimethylhydroxylamine hydrochloride and 35.6 g (300 mmol) ***Methanesulfonyl Chloride*** in 360 mL CH_2Cl_2 is added dropwise under stirring at -20 °C a solution of 60.7 g (600 mmol) ***Triethylamine*** in 240 mL CH_2Cl_2. After stirring for 30 min at 0 °C the reaction mixture is poured into ice water, the organic phase is extracted another two times with ice water and then dried over $MgSO_4$ at 0 °C. After removal of the solvent at 0 °C the noncrystalline residue is dissolved in 60 mL diethyl ether. On standing at -30 °C, *N,N*-dimethyl-*O*-(methylsulfonyl)hydroxylamine (**1**) crystallizes in colorless needles which are separated in a cooled frit. After one (or two) recrystallization(s) from diethyl ether between 21.9 and 26.4 g (53-63%) (**1**) are isolated.[3,4] In a similar fashion the following compounds have been prepared and used in electrophilic amination reactions: *N,N*-dimethyl-*O*-(phenylsulfonyl)hydroxylamine, mp 18-19 °C;[2b,3] *N,N*-diethyl-*O*-(mesitylsulfonyl)hydroxylamine, mp 103-104 °C;[2b,3] *N,N*-diethyl-*O*-(phenylsulfonyl)hydroxylamine, mp 46-47 °C;[2b] *N,N*-diethyl-*O*-(mesitylsulfonyl)hydroxylamine, mp 68-69 °C;[2b,3] *N*-(*O*-phenylsulfonyl)hydroxypiperidine, mp 57-58 °C;[2b] *N*-(*O*-mesitylsulfonyl)hydroxypiperidine, mp 50-51 °C;[2b] *N*-(*O*-mesitylsulfonyl)hydroxypyrrolidine, mp 23-24 °C.[2b]

Handling, Storage, and Precautions: reagents for electrophilic aminations with *N,N*-dimethyl(dialkyl) functionality like (**1**) are much more stable than their NH_2 analogs. Thus the pure compound (**1**) can be stored at -30 °C for at least 1 year.[2,3] Impure (**1**) (and related compounds), however, may decompose at rt,[2,3] as also reported for *N,N*-diethyl-*O*-(mesitylsulfonyl)hydroxylamine.[5]

Electrophilic Aminations.

N,*N*-Dimethyl-*O*-(methylsulfonyl)hydroxylamine (**1**) reacts with organometallic compounds RM to give *N*,*N*-dimethylamines (**2**) (eq 1). *N*,*N*-Dimethylamines prepared via eq 1 from RM and (**1**) together with a specification of RM are shown in (**3**)-(**19**).

(18) 69% (RLi)

(19) 67% (RLi)

As can be seen from the structures shown, *N*,*N*-dimethyl-*O*-(methylsulfonyl)hydroxylamine (**1**) aminates alkyl Grignard compounds (to give **3**) and aryl Grignard compounds (to give **4**) with moderate yields. The same is true for benzylic anion type carbon atoms (**5**-**9**). Compounds (**10**) and (**11**) are formed from the corresponding malonates, while (**12**)-(**16**) are derived from (ester)enolates, although with aryl-stabilized anionic carbon atoms. Metalated cyanides lead to (**17**)-(**19**).

Related amination reactions of organometallic compounds RM have been performed with *N*,*N*-dimethyl-*O*-(mesitylsulfonyl)hydroxylamine (**20**),[3] *N*,*N*-dimethyl-*O*-(phenylsulfonyl)hydroxylamine (**21**),[3] and *N*,*N*-dimethyl-*O*-(*p*-tolylsulfonyl)hydroxylamine (**22**).[4a] Structures (**23**)-(**26**) provide examples of *N*,*N*-dimethylamines formed by reactions of RM with the mesitylsulfonyl species (**20**).[3,6]

(20)

(25) 57% (RLi)

(26) 69% (RLi)

N,*N*-Dimethylamines of strained hydrocarbons like (**23**) and especially (**24**) are otherwise not easily accessible. The same is true for the cyclononatetraenylamine (**26**).[6] *N*,*N*-Dimethyl-*O*-(*p*-tolylsulfonyl)hydroxylamine (**22**) is reported to react with ***Phenylmagnesium Bromide*** and cyclohexylmagnesium bromide to give the corresponding *N*,*N*-dimethylamines in 54% and 14% yield, respectively.[4a] For further and comparable electrophilic amination reactions with transfer of a Me_2N group to give, for example, (**27**)-(**29**), see ***N,N-Dimethyl-O-(diphenylphosphinyl)hydroxylamine***.

(27)

(28)

(29)

Disadvantages.

Normal enolates are not aminated by (**1**), (**20**), (**21**), or (**22**), probably because of a β-elimination of $MeSO_3H$ initiated by deprotonation at one of the *N*-methyl groups.[4a] α-Lithiated sulfones like (**30**) are aminated to give (**31**) (eq 2); however, the reaction does not stop there. Rather, the α-aminosulfone (**31**) leads with unreacted (**30**) to the β-aminosulfone (**32**) (eq 3). Without the phenyl substituent at the anionic carbon atom, only the cuprate (**33**) gives (**34**) (eq 4).[2b]

(2)

(3)

(4)

The corresponding Li compound deprotonates (**1**) (or **20-22**). With the dibenzylamine reagent (**35**), amination of RLi is not observed because of the comparatively fast β-elimination to give (**36**) due to the rather acidic benzylic hydrogen atoms (eq 5).[4b]

(5)

Reactions with organometallic compounds in which iodide I^- is present (e.g. in Grignard reagents of the type RMgI) should be avoided because I^- reduces (**1**); a similar reaction is not observed with Cl^- and Br^- containing organometallic compounds.

Dimethyl(methylthio)sulfonium Tetrafluoroborate[1]

[5799-67-7] · $C_3H_9BF_4S_2$ · Dimethyl(methylthio)sulfonium Tetrafluoroborate · (MW 196.07)

(electrophilic sulfenylation reagent capable of reacting with nucleophilic atoms;[2] reacts with electron-rich alkenes to promote addition reactions,[3] cyclizations;[4] activates dithioacetals,[5] trithioorthoesters,[6] and thioglycosides[7] for carbon-carbon or carbon-heteroatom bond forming reactions)

Alternate Name: DMTSF.

Physical Data: mp 89-92 °C.

Solubility: sol MeCN, $MeNO_2$; insol in ether, pet ether; reacts with H_2O and other protic solvents.

Form Supplied in: cream-colored to white solid; available from various suppliers.

Preparative Method: DMTSF can be conveniently prepared from ***Dimethyl Disulfide*** and ***Trimethyloxonium Tetrafluoroborate*** (Me_3O^+ BF_4^-) in MeCN.[8] Precipitation of the product results after addition of ether and isolation requires filtration under anhydrous conditions.

Handling, Storage, and Precautions: DMTSF must be stored under anhydrous conditions, preferably in a well sealed bottle under nitrogen. Exposure to moisture results in a stench and the reagent is corrosive. Use in a fume hood.

Methylsulfenylation of Nucleophilic Atoms.

DMTSF reacts with ***Potassium Cyanide*** to yield MeSCN and with ***Phenylmagnesium Bromide*** to yield thioanisole.[8] Extensive investigations addressed the reactivity of DMTSF with nucleophilic agents.[9] DMTSF does not react with phenol at rt, but reacts slowly at 60 °C to yield the methylthiophenols (*ortho*/*para* = 0.22). The reaction with anisole also requires a temperature of 60 °C and results in *p*-methylthioanisole and *p*-methylthiophenol, a consequence of ether cleavage under the reaction conditions. Unlike phenol, dimethylaniline reacts rapidly with DMTSF at rt, yielding *p*-methylthio-*N*,*N*-dimethylaniline in 60% yield (eq 1). Despite the presence of an electron-withdrawing group, *p*-nitro-

N,*N*-dimethylaniline also reacts rapidly with DMTSF to yield *p*-nitro-*N*,*N*-dimethyl-*N*-methylthioanilinium tetrafluoroborate.

(1)

DMTSF reacts rapidly at rt with pyridine to yield the hydrolytically unstable methylthiopyridinium ion, which failed to methylate the MeSMe byproduct. When 4-cyanopyridine was used, an equilibrium mixture was detected by NMR.

Triphenyl Phosphite reacts rapidly with DMTSF at rt to yield the methylthiophosphonium salt which, unlike the pyridinium analog, methylates the MeSMe byproduct to yield $Me_3S^+ BF_4^-$. This salt is removed by precipitation with ether and chromatography provides triphenyl thionophosphate in an 86% yield (eq 2). This technique complements other methods of thionophosphate synthesis from phosphites.[10]

(2)

Synthesis of mixed disulfides involving a methylthio unit may utilize DMTSF. Thiols and thiolates react rapidly with the reagent to yield mixed disulfides. Unfortunately, disproportionation occurs, resulting in a mixture of products.[9] Subsequent investigations suggest that the addition of a sterically hindered base (eq 3),[11] or the use of a 2-(trimethylsilyl)ethanethiol derived component (eq 4),[12] permit high yields of unsymmetrical disulfides.

(3)

(4)

In systems having a tertiary amine and a sulfide unit, DMTSF demonstrates a chemoselectivity for sulfur (eq 5).[13]

(5)

Allylic sulfides react with DMTSF chemoselectively at the sulfur atom, generating thiosulfonium ions. This ion formation is reversible and the allylic thiosulfonium ion is capable of a [2,3]-sigmatropic rearrangement before subsequent electrophilic addition to the alkene.[14]

Methylsulfenylation of Alkenes.

A key application of DMTSF in organic synthesis involves electrophilic addition to alkenes and subsequent addition of a nucleophile to the bridged sulfonium ion. Support for this mechanism is provided by the *anti* addition products observed.[15]

Carbon Nucleophiles.

Most nucleophilic carbon sources are too basic for application to these reaction conditions. Alkynylalane ate complexes demonstrate an exception (eq 6).[16]

(6)

Nitrogen Nucleophiles.

Nitrogen nucleophiles, specifically NH_3, amines, azide, and nitrite, resulted in high yields of alkene addition products (eq 7).[15a] In the absence of additional nucleophiles, the resulting sulfonium salt reacted with a tertiary amine to yield the demethylated product or the ammonium salt with a retention of configuration (eq 8).[15b]

(7)

(8)

Oxygen Nucleophiles.

Successful application of oxygen nucleophiles includes anhydrous KOAc (anti-Markovnikov product), $H_2O/CaCO_3$ (Markovnikov product), and DMSO which, upon treatment with ***Diisopropylethylamine***, yields α-methyl thioketones (eq 9).[17]

(9)

Electrophilic ring closure demonstrates another utility of DMTSF. Examples of sulfenyl etherification and sulfenyl lactonization have been reported (eq 10).[18]

(10)

Phosphorus Nucleophiles.

Triphenylphosphine is an effective nucleophile for reacting with the bridged sulfonium ion in high yield. The phosphonium salts generated eliminate MeSH upon reaction with base, such as ***1,8-Diazabicyclo[5.4.0]undec-7-ene***, resulting in a synthesis of vinylphosphonium salts. If NaOH is used, a vinylphosphine oxide is generated.[19]

Other Nucleophiles.

DMTSF and $Et_3N.3HF$ react with alkenes to yield products formally of a MeSF addition. Yields are in excess of 80% and the reaction proceeds rapidly.[20] Homoallylic sulfides cyclized in the presence of DMTSF. The resulting sulfonium salt was successfully demethylated with Me_3N to yield 3-methylthiotetrahydrothiophenes.[21]

Dithioacetal, Trithioorthoester, and Thioglycoside Activation.

DMTSF provides a chemoselective reagent for dithioacetal activation in the presence of electron-rich alkenes.[22] This bond-forming procedure complements the $TiCl_4$ mediated reaction between acetals and silyl enol ethers demonstrated by Mukaiyama (see also ***Titanium(IV) Chloride*** and ***Trimethylsilyl Trifluoromethanesulfonate***). The generation of ketone precursors through dithioacetal carbanion (acyl anion equivalents) chemistry further amplifies the significance of DMTSF activation.

Dithioacetal Activation.

DMTSF chemoselectively reacts with dithioacetals in the presence of a vinylsilane[22] and in the presence of a silyl enol ether (eq 11), resulting in cyclization.[23]

(11)

Many carbon nucleophiles tend to be too basic for successful addition to the carbocationic center provided by DMTSF activation of dithioacetals and usually result in vinyl sulfide formation. In addition, the Me_2S generated competes for the electrophilic center. Allylstannanes overcome these constraints and successfully generate new carbon-carbon bonds (eq 12).[24] DMTSF activation of a thioacetal resulted in an electrophilic cyclization at the 3-position of a 3-substituted indole.[25]

(12)

Trithioorthoester Activation.

Electron-rich aromatic rings undergo electrophilic aromatic substitution with ***Tris(phenylthio)methane*** in the presence of DMTSF. Subsequent hydrolysis results in an aldehyde and a net electrophilic formylation.[6] Intramolecular reaction between a tris(phenylthio)methane unit and an alcohol represents an approach to lactone formation which utilizes the chemoselectivity of DMTSF.[26]

Thioglycoside Activation.

A thioglycoside was successfully converted into a glycosyl fluoride with DMTSF.[7]

Dimethyl (*E*)-4-Oxo-2-pentenedioate

[78939-37-4] · $C_7H_8O_5$ · Dimethyl (*E*)-4-Oxo-2-pentenedioate · (MW 172.15)

(useful reagent for Doebner-von Miller-type annulations, quinoline synthesis; a potential dienophile)

Alternate Name: dimethyl 2-oxoglutaconate.

Physical Data: mp 61-62 °C.

Preparative Methods: dimethyl 2-oxoglutaconate (**1**) has been known since 1946, when it was prepared in low yield by the oxidation of dimethyl glutaconate.[1] Although the preparation by this route was recently improved,[2] the following procedure, as previously described, has been shown to be a more efficient synthesis.[3] A solution of bromine in dry methylene chloride (1.01 equiv) is added dropwise to a solution of dimethyl 2-oxoglutarate in the same solvent at reflux, followed by removal of solvent (and HBr) in vacuo. The resulting α-bromo ketone is treated with ***Triethylamine*** (TEA, 1 equiv) in ether at 25 °C for 20 min followed by filtration, passing the filtrate through a pad of silica gel, and concentration in vacuo to provide (**1**).

Handling, Storage, and Precautions: the enone functional group is remarkably reactive with amines at rt. Care should be exercised to avoid addition of excess TEA in its preparation. Handle in a fume hood.

Annulation Reactions.

The applications of (**1**) have been primarily as a synthon in the Doebner-von Miller-type synthesis of elaborated quinolines. Aryl amines with a free *ortho* position are excellent candidates for annulations with (**1**). In its original application, the reaction of (**1**) with aminoindole (**2**) provided in a one-pot preparation an advanced intermediate in the synthesis of the oxidative enzyme cofactor PQQ.[3] The first step in such annulations involves the conjugate addition of the amino group, followed by cyclization to a tetrahydroquinolinol intermediate. Addition of an acid catalyst (HCl, TsOH, or $BF_3.Et_2O$) promotes dehydration and aromatization to give, in the example cited, the pyrroloquinoline (**3**) (eq 1).

(1)

Cyclization with substituted anilines can occur with high regioselectivity. For example, there are two available sites *ortho* to the amine of (**4**); however, no product of the cyclization to the 5-position was observed.[4] The exclusive formation of (**5**) as a result of cyclization at the 7-position was anticipated due to the bond fixation of indoles (eq 2).

(2)

As a consequence of the facile one-step annulations with a variety of aniline derivatives, the reagent has been invaluable in the preparation of several biologically significant quinolines,[5,6] benzoquinolines,[7] and pyrroloquinolines.[8,9] In this capacity the reagent affords easy access to the quinoline dicarboxylates. Other alkyl esters can be obtained by starting with the corresponding alkyl 2-oxoglutaconate as evidenced in an example utilizing a didecyl ester derivative.[10]

The potential utility of reagent (**1**) as a dienophile in Diels-Alder cycloadditions has been recognized in one report.[2]

Related Reagents.

Dimethyl 2,3-Pentadienedioate

[1712-36-3] · $C_7H_8O_4$ · Dimethyl 2,3-Pentadienedioate · (MW 156.15)

(reactive in Diels-Alder cycloadditions that yield homophthalate diesters[1] and six-membered heterocycles,[2] in dipolar cycloadditions that yield five-membered heterocycles,[3] and in tandem conjugate addition-cyclization reactions to yield various heterocyclic systems[4])

Alternate Name: 1,3-dimethoxycarbonylallene.

Physical Data: bp 58 °C/0.02 mmHg.

Solubility: sol THF, benzene, acetonitrile, DME, MeOH.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 3.81 (s, 6H), 6.10 (s, 2H). IR (film) cm^{-1} 1970, 1720, 1440.

Preparative Methods: although not commercially available, dimethyl 2,3-pentadienedioate can be prepared by the route outlined in eq 1[5] to give approximately 13 g of the reagent per run.

Purification: vacuum distillation.

Handling, Storage, and Precautions: dimethyl 2,3-pentadienedioate (**1**) polymerizes during distillation, necessitating that purification by this method be carried out in small batches. Upon standing, even overnight at refrigerator temperature, (**1**) becomes yellow and then orange and viscous. Preparation of amounts of (**1**) that will be immediately consumed, or storage of the vinyl chloride precursor and conversion to (**1**) as

needed, appear to be warranted. This reagent should be handled in a fume hood.

Homophthalate Diester Synthesis through Diels-Alder Cycloadditions.

By reaction with suitable dienes, especially reactive oxygenated examples, and subsequent aromatization, (**1**) serves as a building block for the synthesis of substituted homophthalate esters. In the example shown (eq 2),[1a] aromatization occurs by loss of methanol from the primary cycloadduct.

(2)

Alternatively, loss of carbon dioxide (eq 3)[6] or ethylene[7] from appropriate primary cycloadducts give homophthalate esters.

(3)

Six-Membered Heterocycle Synthesis through Hetero-Diels-Alder Cycloadditions.

Reagent (**1**) has been shown to engage certain heterodienes[2,8] in [4 + 2] cycloadditions to yield six-membered heterocyclic systems (eq 4).

(4)

Five-Membered Heterocycle Synthesis through Dipolar Cycloadditions.

Reagent (**1**) also enters into dipolar cycloadditions, examples involving nitrones (eq 5)[3a] and azides[3b] being well documented.

(5)

Heterocycle Synthesis through Tandem Conjugate Addition-Cyclization Reactions.

A number of applications of this reagent in transformations that are best characterized as tandem conjugate addition-cyclization reactions have been reported. These processes may combine conjugate addition of a carbon nucleophile with acylation of a heteroatom, as in eq 6,[4a] or conjugate addition of a heteroatom and acylation at carbon, as in eq 7.[4b] However, most often, heteroatoms play both nucleophilic roles (eqs 8 and 9).[4c-e]

(8)

(9)

Alternatively, heteroatom conjugate additions in tandem with aldol (eq 10)[8] and Dieckmann (eq 11)[4c] condensations allow (**1**) to give rise to heterocyclic structures in which both reagent-derived carboxyl groups appear as substituents.

cis-3-[*N*-(3,5-Dimethylphenyl)benzenesulfonamido]borneol[1]

(1*R*) (*endo,endo*)

[87360-02-9] · $C_{24}H_{31}NO_3S$ · *cis*-3-[*N*-(3,5-Dimethylphenyl)benzenesulfonamido]borneol · (MW 413.63)

(chiral auxiliary; ester enolate derivatives undergo stereoselective alkylations[2] and enantioselective *anti*-aldol reactions;[3] enoate derivatives undergo stereoselective 1,4-conjugate additions of organocopper reagents[4])

Alternate Name: *N*-(3,5-dimethylphenyl)-*N*-(3-hydroxy-4,7,7-trimethylbicyclo[2.2.1]hept-2-yl)benzenesulfonamide.

Physical Data: (1*R*) (*endo,endo*): mp 147-150 °C; [α]20D -26.0° (*c* = 4.0, $CHCl_3$).

Handling, Storage, and Precautions: the auxiliary is stable indefinitely at ambient temperatures in a sealed container.

Introduction.

One of several auxiliaries that exploit the asymmetry of naturally occurring (+)-camphor, the 3-(*N*-(3,5-dimethylphenyl)benzenesulfonamido)borneol auxiliary has proven significant utility in the π-facial differentiation of ester enolates and enoate derivatives. The *endo* orientation of the C(2) and C(3) substituents places the reactive functionality within the concave pocket created by the bornane skeleton as well as the shielding ability of the *N*-arylbenzenesulfonamide.

Preparation of the Auxiliary.

A synthesis of the (1*R*) auxiliary has been reported starting from (+)-camphor (eq 1). ***Zinc*** reduction of the intermediate

imine (**2**) followed by sulfonylation and ketone reduction with $Ca(BH_4)_2$ afforded the *cis,endo* product in 70-75% overall yield from camphorquinone (**1**).

Preparation of Derivatives.

Enoate derivatives were prepared by Horner-Wittig reactions between aldehydes and the ethyl phosphonate derived from the chloroacetyl ester of (**3**) in high (*E*) selectivity (97:3).[4b] Ester derivatives were obtained by treating alcohol (**3**) with the corresponding carboxylic acid chloride.[5]

α-Alkylation of Ester Derivatives.[2]

Alkylation of ester enolate derivatives, prepared by metalation with lithium cyclohexylisopropylamide (LICA), proceeds with high stereoselectivity. The configuration of the product is dependent on the solvent employed (eqs 2 and 3). When performed in THF with the addition of HMPA the product with the (*S*) configuration was formed preferentially; however, without HMPA the (*R*) configuration predominated. Silyl chloride trapping studies suggest that in the presence of HMPA the (*E*)-ester enolate is stereoselectively formed, as opposed to the (*Z*)-ester enolate in THF alone.[2b] The stereochemical outcome has been explained by alkylation of the corresponding enolate π-face opposite to the shielding 3,5-dimethylphenyl moiety. *O*-Benzylglycolates have also been employed in stereoselective alkylations, affording diastereomeric excesses of 88-95%.[2c] In this case the solvent-dependent stereochemical reversal does not occur and the (*E*)-ester enolate is stereoselectively formed in both cases.

Aldol Reactions of Ester Derivatives.[3]

The ***Titanium(IV) Chloride***-catalyzed addition of aldehydes to *O*-silyl ketene acetals derived from acetate and propionate esters proceeds with high stereoselectivity. Formation of the silyl ketene acetal was found to be essential for high diastereoselectivity. Treatment of the silyl ketene acetal, derived from deprotonation of the acetate ester with LICA in THF and silyl trapping, with a corresponding aldehyde in the presence of $TiCl_4$ (1.1 equiv) afforded the addition products in 93:7 diastereoselectivity and moderate yield (51-67%). Similarly, the propionate ester provides the *anti*-aldol product in high *anti*/*syn* selectivity (14:1) and facial selectivity (eq 4).

1,4-Conjugate Additions to Enoate Derivatives.[4]

High diastereoselectivity has been observed for ***Boron Trifluoride***-promoted addition of alkyl and aryl organocopper reagents to enoate derivatives (eq 5).[4b] When the organocopper reagent was prepared from alkyl- or aryllithiums, diethyl ether was found to be the solvent of choice; however, with Grignard reagents, THF was superior. The addition of boron trifluoride exhibited little influence on reactivity of the copper reagent but did enhance the stereoselectivity of the addition. It is believed that the enoate adopts an *s-trans* conformation and the observed stereochemical preference results from approach of the organocopper reagent to the less sterically hindered face opposite the aryl moiety.

Nondestructive Removal of the Auxiliary.

Primary alcohols are obtained by ***Lithium Aluminum Hydride*** reduction of the corresponding chiral esters. Also, hydrolysis of the auxiliary under basic conditions, 2N KOH in methanol,[4b] provides the carboxylic acid and recovered alcohol (**3**).

Related Reagents.

3-Hydroxyisoborneol; ***(1R,2S)-N-Methylephedrine***.

1,3-Dimethyl-2-phenylbenzimidazoline

[3652-92-4] · $C_{15}H_{16}N_2$ · 1,3-Dimethyl-2-phenylbenzimidazoline · (MW 224.33)

(heterocycle capable of reducing α-halo ketones, α,β-unsaturated carbonyl compounds, and α-nitro sulfones)

Alternate Name: DMBI.

Physical Data: mp 94 °C.

Preparative Method: N^1,N^2-dimethyl-*o*-phenylenediamine is condensed with benzaldehyde in methanol-acetic acid. The product is purified by recrystallization from petroleum ether.[1] The spent reagent may be recovered and reactivated by ***Sodium Borohydride*** in methanol.[5]

DMBI has been found to dehalogenate α-halo ketones and halogenated benzophenones without affecting the carbonyl group (eq 1) (see also ***Tri-n-butylstannane***). The mechanism was identified as a radical chain process containing a SET-hydrogen atom abstraction/propagation sequence.[2] The reaction typically requires initiation, e.g. by ***Azobisisobutyronitrile*** (AIBN) or ***Di-t-butyl Peroxyoxalate*** (DBPO). Thiophenol may be used to catalyze the transformation, for sluggish tertiary halo ketones, by facilitating the hydrogen atom transfer step.[3]

(1)

DMBI was reported to reduce α,β-unsaturated ketones to the corresponding saturated ketones in the presence of a Lewis acid (eq 2). ***Aluminum Chloride*** was found to be the acid of choice, with stoichiometric quantities being required.[4] The reaction failed for α,β-unsaturated aldehydes and in the absence of a Lewis acid.

(2)

α-Nitro sulfones were desulfurized when exposed to DMBI (eq 3).[5] The mechanism was found to be a radical chain process which typically requires initiation. More well-known desulfurization reagents, such as ***Raney Nickel*** or catalytic hydrogenation, would not be expected to leave the nitro group intact. DMBI was also superior to *N*-benzyl-1,4-dihydronicotinamide for this transformation.

(3)

DMBI is conveniently prepared from available starting materials. The reagent may be recovered and recycled. The reagent is most often used in mechanistic studies. No preparative (i.e. 0.1 mol) uses are available in the current literature.

2,6-Dimethylphenyl Propionate[1]

[51233-80-8] · $C_{11}H_{14}O_2$ · 2,6-Dimethylphenyl Propionate · (MW 178.25)

(lithium, titanium, and zirconium enolates used in the stereoselective synthesis of *anti*[2] or *syn*[4] β-hydroxy acid derivatives)

Physical Data: bp 60-65 °C/0.05 mmHg.

Preparative Methods: the reagent is prepared in excellent yield by the reaction of the sodium or lithium salt of 2,6-dimethylphenol with propionyl chloride.[2a,2b]

Stereoselection in Reactions of Lithium Enolates.

The (*E*)-lithium enolate (**2**) obtained from reaction of 2,6-dimethylphenyl propionate (**1**) with ***Lithium Diisopropylamide*** reacts with aldehydes to afford the *anti*-β-hydroxy ester (**3**) in a highly selective or specific manner (eq 1).[2-4] Table 1 illustrates the level of diastereoselection possible with a variety of structurally simple aldehydes. In general, reaction with aromatic and straight-chain aliphatic aldehydes results in lower degrees of diastereoselection than reaction with aldehydes containing branching at the α-carbon. The β-hydroxy esters are hydrolyzed to the corresponding *anti*-β-hydroxy acid under mild reaction conditions.

Ar = 2,6-dimethylphenyl (*E*)-(**2**)

(1)

(**3**) *anti* (**4**) *syn*

Table 1 Ratios of Diastereomeric b-Hydroxy Esters (**3**):(**4**) from the Reaction of the (*E*)-Lithium Enolate of (**1**) with Various Aldehydes (RCHO)

[a] A lower ratio of (**3**):(**4**) (13:1) was reported by another author.[4]
[b] A lower ratio of (**3**):(**4**) (8:1) was reported by another author.[4]

Condensations of the enolate (**2**) with more complex aldehydes (i.e. **5**-**20**) containing additional functional groups and stereocenters have been reported.[2b,5-12] Excellent levels of diastereocontrol are observed in formation of the 2,3-*anti*-β-hydroxy esters in all instances except the reaction with the α-alkoxy aldehydes.[6] With aldehydes that contain resident

stereocenters, the facial selectivity in the attack of enolate (**2**) on the aldehyde varies widely. Aldehydes (**5**)-(**7**) react with modest degrees of stereoselection (2-4:1) in favor of formation of the product predicted by Cram's rule (i.e. *syn* relationship between C-3 and C-4 in the β-hydroxy ester).[2,11] The aldehydes possessing a phenylthio group at the α-position (**8-13**) yield β-hydroxy esters in which the hydroxy groups and phenylthio groups are *anti* with a high degree of selectivity.[7] Aldehydes (**14**)-(**19**) appear to follow Cram's rule exclusively or highly selectively.[8,9] Facial selectivity in reaction of lithium enolate (**2**) with aldehyde (**20**) is modest (approximately 2:1).[12]

Lithium enolates derived from propionate esters of other highly hindered phenols (e.g. 2,6-di-*t*-butyl-4-methylphenol (BHT) and 2,6-di-*t*-butyl-4-hydroxyanisole (DBHA)) are known to be more selective than (**2**) in condensation reactions with aldehydes to yield *anti*-β-hydroxy esters.[2] However, these esters cannot be removed by simple hydrolytic procedures without complications from retro-aldol reactions. Removal of the BHT or DBHA group in these *anti*-β-hydroxy esters requires reduction to the corresponding 1,3-diol with ***Lithium Aluminum Hydride*** or conversion to the corresponding *anti*-β-hydroxy acids under oxidative conditions (e.g. ***Cerium(IV) Ammonium Nitrate***).[2b,c] Yields in the latter process are highly variable.[2a] The oxidations are often performed on the acetate esters of the *anti*-β-hydroxy esters in an attempt to produce reliable yields.[2b] Lithium enolates derived from other esters of 2,6-dimethylphenol are reported to be highly *anti* selective in condensations with aldehydes.[2]

Reactions of Titanium Enolates.

In contrast to reactions of (*E*)-lithium enolate (**2**), (*E*)-titanium enolates (**21**) are reported to afford the *syn*-β-hydroxy ester predominantly (eq 2).[4] The (*E*)-titanium enolates (**21**) are prepared by transmetalation of the corresponding (*E*)-lithium enolate. Achiral (*E*)-enolates (**21a**) yield predominantly *syn*-β-hydroxy esters in reactions with aldehydes (Table 2). The yield and degree of stereoselection are excellent in all cases except in reaction with pivaldehyde. With (*E*)-titanium enolates bearing chiral ligands (i.e. (**21b**) R = diacetoneglucose (DAG)), the *syn*-β-hydroxy ester of (*R*) configuration at C(2) is formed with high optical purity.

[a] DAG = diacetoneglucose.

The (*E*)-titanium enolates (**21**) can be equilibrated to a mixture of (*E*)- and (*Z*)-enolates in which the (*Z*)-enolate (**22**) predominates by standing at -30 °C for several hours.[4] The degree of diastereoselection in reaction of the equilibrated enolate mixture with aldehydes is not as consistently high as it is in the case of the reaction with the (*E*)-enolate (Table 3); however, the *anti*-β-hydroxy ester is usually the major product. The optical purity of the *anti*-isomer is very high in all cases.

Dimethyl(phenyl)silane

$PhMe_2SiH$

[766-77-8] · $C_8H_{12}Si$ · Dimethyl(phenyl)silane · (MW 136.29)

(hydrosilylating reagent; reductant in combination with acid or F^-)

Physical Data: bp 157 °C/744 mmHg; *d* 0.889 g cm^{-3}.

Solubility: sol common organic solvent such as chloroform, 1,2-dichloroethane, benzene, ether, acetone, dioxane, THF; insol H_2O.

Form Supplied in: oil, commercially available.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$-Me_4Si) δ 7.6-7.4 (m, 2 H), 7.4-7.2 (m, 3 H), 4.42 (septet, *J* = 3.6 Hz, 1 H), 0.34 (d, *J* = 3.6 Hz, 6 H). ^{13}C and ^{29}Si NMR have also been reported.[2]

Preparative Method: see Benkeser and Foster.[1]

Purification: distillation.

Handling, Storage, and Precautions: moisture sensitive; evolves H_2 when added to wet piperidine.

Diastereoselective Reduction of Carbonyl Compounds.[3]

Dimethyl(phenyl)silane reduces aldehyde and ketone carbonyls with the aid of fluoride ion or acid. α-Acylpropionamides, 1-aminoethyl ketones, and 1-alkoxyethyl ketones are readily converted into the corresponding β-hydroxy amides, α-amino alcohols, and α-alkoxy alcohols, respectively. The stereoselectivity is complementary and generally high: *erythro* (or *syn*) isomers are obtained with ***Trifluoroacetic Acid*** (TFA), whereas *threo* (or *anti*) isomers are obtained with fluoride ion activator (eq 1). The *erythro* selectivity in the acid-promoted carbonyl reduction is ascribed to a proton-bridged Cram's cyclic transition state. On the other hand, the *threo* selectivity in the fluoride-mediated reduction is explained in terms of the Felkin-Anh type model, wherein a penta- or hexacoordinated fluorosilicate is involved. No epimerization at the chiral center is observed during the reaction.

(1)

Hydrosilylation.[4]

With a transition metal catalyst, the hydrosilane adds to carbon-carbon double or triple bonds to give alkylsilanes or alkenylsilanes. Hydrosilylation of deoxydiisopropylidene-*arabino*-hexenopyranose (**1**) catalyzed by $[Rh(norbornadiene)Cl]_2$ (***Bis(bicyclo[2.2.1]hepta-2,5-diene)dichlorodirhodium***) gives 6-deoxy-6-phenyldimethylsilyldiisopropylidenealtrose (**2**), which is desilylated by ***Tetra-n-butylammonium Fluoride*** to yield 6-deoxydiisopropylidenealtrose (**3**) (eq 2).[5]

In the presence of a Pt complex like bis(η-divinyltetramethyldisiloxane)tri-*t*-butylphosphineplatinum(0) (**4**), phenyldimethylsilane reacts with 1-butyn-3-ol to give an 8:1 mixture of alkenylsilanes (**5** and **6**) (eq 3). The major product 1-dimethylphenylsilyl-1-buten-3-ol (**5**) is separated and resolved by lipase-catalyzed esterification.[6]

Hydrosilylation of 1,4-bis(trimethylsilyl)-1,3-butadiyne (**7**) gives 1,4-bis(trimethylsilyl)-1,3-bis(dimethylphenylsilyl)-1,2-butadiene (**8**) (***Chlorotris(triphenylphosphine)rhodium(I)***, 100 °C) or 1,4-bis(trimethylsilyl)-2-(dimethylphenylsilyl)-1-buten-3-yne (**9**) ($Pt(PPh_3)_4$, 100 °C) (eq 4) depending on the catalyst.[7] The enyne (**9**) is considered to be a precursor of the allene (**8**).

(4)

Transition metal-catalyzed hydrosilylation of α,β-unsaturated ketones and aldehydes with $PhMe_2SiH$ proceeds in a 1,4-fashion to give silyl vinyl ethers, which are hydrolyzed to give ketones and aldehydes. Asymmetric 1,4-reduction has been studied using a chiral transition metal catalyst, but with little success (eq 5).[8]

(5)

chiral cat = $[Rh\{(R)\text{-}PMePhCH_2Ph\}H_2S_2]^+ ClO_4^-$

Dimethyl (*Z*,*Z*)-2,4-hexadienedioate is hydrosilylated with $PhMe_2SiH/RhCl(PPh_3)_3$ to give the 1,6-hydrosilylation product, methyl (3*E*)-6-methoxy-6-(phenyldimethylsilyloxy)-3,5-hexadienoate (eq 6).[9]

(6)

Formylsilylation.

Under a ***Carbon Monoxide*** atmosphere (1-4 MPa), silylformylation of alkynes occurs in the reaction of alkynes and $PhMe_2SiH$ to give β-silyl enals in the presence of a rhodium catalyst (eq 7).[10] Terminal alkynes exclusively give products having the $SiMe_2Ph$ group at the terminal carbon. Depending on the structure of the alkyne, the isomer ratio (*E*/*Z*) varies from 0:100 to 100:0. Hydroxyl groups survive these conditions; however, in the presence of a tertiary amine, alkynols are converted into α-(dimethylphenylsilylmethylene) β-lactones (eq 8).[11]

(7)

(8)

Silylformylation of *N*-propargyl tosylamides gives normal β-silyl enal products, whereas the same reaction in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** or ***Triethylamine*** affords α-(dimethylphenylsilyl)methylene β-lactams (eq 9).[12] Propargylamines are transformed to 2-(dimethylphenylsilyl)methyl-2-propenals (eq 10).[13]

Dimethylphenylsilyllithium[1]

$PhMe_2SiLi$

[3839-31-4] · $C_8H_{11}LiSi$ · Dimethylphenylsilyllithium · (MW 142.22)

(reagent for addition to carbonyl compounds;[2] deoxygenation reactions;[3,4] in presence of copper(I) salts, an effective reagent for conjugate addition to α,β-unsaturated compounds,[5] conjugate displacement of tertiary allylic acetates,[6,7] and silylcupration of alkynes[8] and allenes[9])

Physical Data: NMR studies have shown the reagent is monomeric in ether.[10c]

Solubility: sol THF, Et_2O.

Preparative Methods: readily prepared from the reaction of $PhMe_2SiCl$ with 2 equiv of Li metal in THF or from the reaction of $PhMe_2SiSiMe_2Ph$ with Li metal in THF.[10a,b] Typical reaction procedure involves stirring ***Chlorodimethylphenylsilane*** with ***Lithium*** in THF at -8 °C under N_2 for 36 h.[8a] The supernatant reagent solution is calibrated using standard methods and used without further purification for reactions.[8a] It is advantageous to activate the Li metal prior to use by ultrasound irradiation of a hexane suspension,[11a] and to use argon as the inert gas to prevent formation of lithium nitrides.[11b]

Handling, Storage, and Precautions: the reagent solution in THF can be stored under argon or nitrogen at -20 °C for several weeks without significant degradation.[8a] Lithium is a highly flammable solid and must be handled and stored in an inert atmosphere (preferably argon).

Addition to Carbonyl Compounds.

$PhMe_2SiLi$ in THF undergoes addition to aldehydes and ketones under mild conditions to afford α-silyl alcohols upon aqueous workup. The α-silyl alcohols are versatile synthetic intermediates which can be readily manipulated into a variety of products. Consequently, these reactions have been widely utilized in organic syntheses,[12-15] for example in the synthesis of cytochalasin D cycloundecanone ring system (eq 1),[12] and in the synthesis of (±)-pregn-4-en-20-one.[13] Enones react with $PhMe_2SiLi$ predominantly via 1,2-addition to afford α-silyl alcohols which can be converted to silyl enol ethers via Brook rearrangement (eq 2).[15]

Addition of $PhMe_2SiLi$ to α-phenylthio ketones directly affords silyl enol ethers with very high (*Z*)-stereoselectivity (eq 3).[16]

Addition of $PhMe_2SiLi$ to aldehydes and subsequent *O*-sulfonylation of the generated alkoxides with ***p-Toluenesulfonyl Chloride*** affords α-silyl tosylates in good yields.[2] Conversion of these intermediates into α-silyl selenocyanates followed by fluoride-induced cyanide elimination reaction permitted the synthesis and study of reactivity of previously unknown selenoaldehydes (eq 4).[2]

(4)

Deoxygenation Reactions.

$PhMe_2SiLi$ reacts with oxabicyclo[2.2.1]heptenes in Et_2O at 0 °C to afford 1,3-cyclohexadienes (eq 5).[3] 6-8 equiv of $PhMe_2SiLi$ are required for complete consumption of the starting bicyclic compound. The excess stoichiometry sometimes leads to further reaction of the 1,3-cyclohexadiene product with the unreacted reagent. Use of the silylcuprate reagent $PhMe_2SiCu.LiCN$ in THF at 0 °C alleviates this problem.[3]

(5)

Epoxides are stereospecifically deoxygenated to alkenes with inversion of stereochemistry upon treatment with $PhMe_2SiLi$ in THF.[4] *trans*-Stilbene is obtained in 83% yield and >99% stereoselectivity from the reaction of oxide of *cis*-stilbene with $PhMe_2SiLi$. Similarly, *trans*-stilbene oxide is converted to *cis*-stilbene.

Reactions via Cuprates.

Dimethylphenylsilylcuprates [$(PhMe_2Si)_2CuLi.LiX$] (X = CN or halide), generated in situ from the reaction of 2 equiv of $PhMe_2SiLi$ with copper(I) salts (***Copper(I) Cyanide***, ***Copper(I) Iodide***), are popular reagents for the incorporation of $PhMe_2Si$ unit into organic molecules.[5-9,17] In general, these reagents react with substrates under milder conditions and tolerate polar functional groups better than $PhMe_2SiLi$. However, these reagents suffer from one major drawback in that not all the Si anions bound to copper are transferred to the substrate. Consequently, reaction workup affords nonvolatile byproducts which complicate product isolation.[5-9] This problem can be avoided by using the mixed cuprate $(PhMe_2Si)MeCuLi$, prepared from the reaction of 1 equiv of $PhMe_2SiLi$ and 1 equiv of MeLi with CuCN.[18] The mixed cuprate specifically transfers the silyl group (not the methyl group) to the substrate and exhibits reactivity comparable to that of ***Lithium Bis[dimethyl(phenyl)silyl]cuprate***. Synthetically useful reactions of dimethylphenylsilylcuprates include addition to saturated aldehydes, 1,4-addition to α,β-unsaturated enones, conjugate displacement of tertiary allylic acetates, and silylcupration of alkynes and allenes.

The addition of $(PhMe_2Si)_2CuLi$ to aldehydes has been utilized in the elegant synthesis of isocarbacyclin (eq 6).[19]

$(PhMe_2Si)_2CuLi$ undergoes 1,4- (conjugate) addition to a variety of cyclic and acyclic α,β-unsaturated enones to afford saturated β-silyl carbonyl compounds (eq 7).[5,20-22] In acyclic systems, enones can be regenerated from the β-silyl carbonyl compounds by bromination (***Bromine***-CCl_4) followed by desilylbromination (***Sodium Fluoride***-EtOH).[22] In cyclic systems, treatment of the β-silyl carbonyl compounds with ***Copper(II) Bromide*** affords the enones directly (eq 7).[20] This overall silylation-desilylation protocol not only represents a method for the protection of α,β-unsaturation but can also be used advantageously by alkylating the intermediate enolate of conjugate silyl addition prior to desilylation (eq 7). This methodology has been successfully applied in the synthesis of carvone and dihydrojasmone.[5a] The alkylation of intermediate enolates is highly diastereoselective, favoring the isomer in which the silyl group and the alkyl group are in *anti* orientation (eq 8). The silyl functionality of the β-silyl carbonyl compounds also can be converted into a hydroxy group with retention of configuration (eq 8).[5b]

(7)

(8)

$(PhMe_2Si)_2CuLi$ reacts with allylic acetates via stereospecific (*anti*) conjugate displacement of the acetate group to afford allylsilanes in excellent yields.[7,23] Similar stereospecificity is observed in reactions with propargyl acetates.[7a]

$(PhMe_2Si)_2CuLi$ reacts with alkynes via *syn* addition of the silyl group and copper to the carbon-carbon triple bond.[8] In reactions with terminal alkynes, the silyl group becomes attached predominantly to the terminal carbon. The acidic hydrogen of terminal alkynes does not get abstracted under the reaction conditions. The vinylcuprate intermediates react with electrophiles including alkyl/acyl halides, iodine, epoxides, and enones to regio/stereoselectively afford a variety of vinylsilanes.[8]

Silylcupration of allene with $(PhMe_2Si)_2CuLi$ followed by treatment of the intermediate cuprate with H^+, carbon electrophiles, and Cl_2 affords the corresponding vinylsilanes (eq 9).[9] However, reaction of the intermediate cuprate with I_2 affords an allylsilane, from which other more highly substituted allylsilanes are readily obtainable (eq 9). In reaction with substituted allenes, the product ratio (vinylsilane vs. allylsilane) is dependent upon the degree of substitution.[9]

Related Reactions.

In contrast to $PhMe_2SiLi$, related R_3SiLi reagents either are appreciably less stable, may require generation in toxic solvents (***Hexamethylphosphoric Triamide***), and can be less nucleophilic, favoring deprotonation or electron transfer reactions. Nevertheless, complementary synthetic organic transformations have been described for these reagents,[24] for example the 1,4-addition of ***Trimethylsilyllithium*** to enones[25] and the reduction of isocyanates to isocyanides with *t*-$BuPh_2SiLi$.[26] The wide synthetic utility of $PhMe_2SiLi$ and $(PhMe_2Si)_2CuLi$ in organic synthesis has also encouraged the development and use of related $PhMe_2Si^-$ derivatives of Al,[27] Mg,[28] Mn,[28] and Zn.[27a,29]

Related Reagents.

Dimethylphenylsilyl(methyl)magnesium; ***Lithium Bis[dimethyl(phenyl)silyl]cuprate***; ***Trimethylsilylcopper***; ***Trimethylsilyllithium***.

Dimethylphenylsilyl(methyl)magnesium

$PhMe_2SiMgMe$

[87436-97-3] · $C_9H_{14}MgSi$ · Dimethylphenylsilyl(methyl)magnesium · (MW 174.63)

(silyl magnesiation of alkynes; synthesis of vinylsilanes; disilylation of alkynes)

Solubility: sol ethereal solvents (ether, THF, DME, etc.).

Form Supplied in: not commercially available. The reagent is best prepared and used immediately.

Analysis of Reagent Purity: a suitable analytical method is not available. The reagent must be prepared immediately after titration of dimethylphenylsilyllithium and methylmagnesium iodide.

Preparative Method: an ethereal solution of methylmagnesium iodide (1.0 equiv) is added to a THF solution of ***Dimethylphenylsilyllithium***[1] (1.0 equiv) at 0 °C under an argon atmosphere. The mixture is stirred for 15 min and the resulting dimethylphenylsilyl(methyl)magnesium is used directly for further reactions.

Handling, Storage, and Precautions: the reagent is sensitive to moisture and should be handled under a dry, inert atmosphere. The reagent must be used immediately after preparation.

Silylmagnesiation of Alkynic Compounds.

Platinum- or copper-catalyzed silylmagnesiation[2,3] of 1-dodecyne followed by aqueous workup provides (*E*)-1-dimethylphenylsilyl-1-dodecene (eq 1), which has also been produced by stoichiometric silylcupration[4] or silyltitanation.[5] Electrophiles such as iodine, methyl iodide, and valeraldehyde react with the intermediate derived from $PtCl_2(P\text{-}n\text{-}Bu_3)_2$-catalyzed silylmagnesiation of 1-dodecyne to give the corresponding functionalized alkenylsilanes (eq 2).

(1)

Silylmagnesiation of 1,2-alkadienes in the presence of a ***Copper(I) Iodide*** catalyst, followed by aqueous workup, produces exclusively 1-(dimethylphenylsilyl)-1-cycloalkenes in which a $PhMe_2Si$ group is attached to the central carbon of the allene (eq 3).[6] The initial adducts can undergo an intramolecular cyclization when the R group is substituted at the terminal position by a leaving group, to provide cycloalkanes with a dimethylphenylsilylmethylene substituent (eqs 4 and 5).[7]

(5)

Synthesis of Vinylsilanes.

In the presence of a Pd catalyst, $PhMe_2SiMgMe$ converts enol phosphates into vinylsilanes (eq 6).[8] The reagent, which is believed to be $(PhMe_2Si)_3MnMgMe$ (prepared in situ from 3 equiv of $PhMe_2SiMgMe$ and ***Manganese(II) Chloride***), also transforms alkenyl halides, alkenyl sulfides, or enol phosphates into vinylsilanes (eq 7).[9]

(6)

(7)

Disilylation of Alkynes.

Addition of 1-alkynes to the reagent $(PhMe_2Si)_3MnMgMe$ affords (*E*,*Z*) mixtures of 1,2-bis(dimethylphenylsilyl)-1-alkenes (eq 8).[10] Trimethylsilyl(methyl)magnesium in place of $PhMe_2SiMgMe$ gives the corresponding disilylation product. The reaction can be successfully applied to the synthesis of highly strained tetrakis(trimethylsilyl)ethylene (eq 9).

N,S-Dimethyl-*S*-phenylsulfoximine[1]

(±)

[30004-67-2] · $C_8H_{11}NOS$ · *N,S*-Dimethyl-*S*-phenylsulfoximine · (MW 169.27) (*R*)-(-)

[80482-67-3] (*S*)-(+)

[33993-53-2]

(chiral sulfone analog useful in methylenation of carbonyl compounds[1,2] and resolution of ketones[1,3])

Physical Data: oil; $[\alpha]_D$ 184° (*c* 3, acetone); pK_a (DMSO) ~32.[1]

Solubility: sparingly sol water; sol dil acid, aq Cu^{II}; highly sol THF, alcohols, etc.

Preparative Methods: methyl phenyl sulfoxide is treated with ***Hydrazoic Acid*** (generated by addition of sulfuric acid to a slurry of sodium azide) in chloroform maintained at 45 °C to produce *S*-methyl-*S*-phenylsulfoximine.[4,5] The latter can be readily resolved using ***10-Camphorsulfonic Acid***; from the (+)-acid the salt of (+)-(*S*)-*S*-methyl-*S*-phenylsulfoximine is obtained pure by recrystallization.[6,7] The Clarke-Eschweiler procedure using ***Formaldehyde*** and ***Formic Acid*** provides an effective method for conversion of the N-H sulfoximine to the title compound.[7]

Handling, Storage, and Precautions: due care should be taken in the synthetic step using hydrazoic acid. *N,S*-Dimethyl-*S*-phenylsulfoximine is apparently of low toxicity. The compound, which is stable to acids and bases, as well as to most oxidizing and reducing conditions, maintains chemical and enantiopurity on long term storage.

N,S-Dimethyl-*S*-phenylsulfoximine is rapidly deprotonated with ***n-Butyllithium*** in THF at 0 °C; the deprotonation can be conveniently monitored by use of a trace of Ph_3CH as an indicator. The lithio reagent is an excellent nucleophile, particularly with respect to addition to carbonyl compounds (eq 1). Addition occurs in high yields with a wide range of carbonyl compounds in the temperature range of -78 to 25 °C. The reaction is often reversible in the cases of hindered carbonyl compounds. The major side reaction is enolization. Both the enolization and reversibility problems can be circumvented by conducting the addition and subsequent quenching at low temperatures; in this manner, β-

hydroxysulfoximines are obtained in high yield.[3] β-Hydroxysulfoximines are thermally unstable and revert to starting carbonyl compounds and sulfoximine in the temperature range 80-120 °C; the reversion is the basis for a ketone resolution method. The addition of optically pure sulfoximine (as its lithio derivative) to (±)-ketones which exhibit very high or complete diastereofacial selectivity results in the formation of two diastereomers which are generally responsive to separation by silica gel chromatography. Thermolysis of the separated diastereomers results in resolution of the ketone (eq 2).[3] Treatment of the separated diastereomers with ***Raney Nickel*** results in optically pure methyl carbinols (at the expense of destruction of the chiral *S* center).[8] The ketone resolution technique has reciprocity and a number of optically pure ketones, particularly (-)-menthone, have been found useful to resolve *N,S*-dimethyl-*S*-phenylsulfoximine.[3]

β-Hydroxysulfoximines undergo reductive elimination to yield alkenes upon treatment with ***Aluminum Amalgam*** in a mixture of THF, water, and acetic acid. In the case of conjugated enones and dienones the addition of the lithiosulfoximine occurs at the carbonyl; when the resulting adducts are reduced, dienes and trienes, respectively, are produced (eq 3).[9] The sulfoximine method often works where methylenation with triphenylphosphonium methylide fails[10] (eq 4).[11]

(4)

The combination of the chromatographic separation of enantiopure β-hydroxysulfoximine diastereomers and reductive elimination results in a method of ketone methylenation with optical resolution. The technique is illustrated in the synthesis of the ginseng sesquiterpene (-)-β-panasinsene and its enantiomer (eq 5).[12] The addition of the enantiopure lithiosulfoximine to prochiral enones or the diastereoface selective addition to racemic enones results in the formation of two diastereomeric adducts. The hydroxy group in these adducts can be used to direct the Simmons-Smith cyclopropanation (eqs 6 and 7).[13] Catalytic osmylation of such adducts is directed by the *anti* effect of the hydroxy augmented by chelation by the methylimino group (eq 7).[14]

(5)

(6)

Ylides derived from the salts obtained by *N,N*-dialkylation of sulfoximines and anions derived from *N*-tosylsulfoximines are useful reagents for the synthesis of epoxides or cyclopropanes from aldehydes and ketones or enones.[1]

Related Reagents.

Dibromomethane-Zinc-Titanium(IV) Chloride; ***Methylenetriphenylphosphorane***.

[13865-52-6] · $C_{11}H_{17}NS$ · Diethyl(phenylthiomethyl)amine · (MW 195.36)

(sources of the $R_2NCH_2^+$ synthon for reactions with many organometallics;[6] phenylthiomethylation reagents for enamines;[12] a modified Sommelet-Hauser rearrangement route[15] from benzyl bromides to *o*-tolualdehydes)

Physical Data: (**1**) bp 112-116 °C/9-11 mmHg. (**2**) bp 110-112 °C/5-6 mmHg; *d* 0.9878 g cm^{-3}; *n*25D 1.5500.

Preparative Methods: PhSH + R_2NH + CH_2O (71%);[1] PhSH + CH_2=+NMe_2 I^- (80%).[2]

Dialkylaminomethylation of Nucleophiles.

The dialkyl(phenylthiomethyl)amines are good sources of the $R_2NCH_2^+$ synthon for reactions with alkyl,[3] allyl (eq 1),[4] and aryl[5] Grignards, and alkenyl[6] copper reagents (eq 2); these C-C couplings give alkyl,[3] homoallylic,[4] benzylic,[5] and allylic[6] tertiary amines, respectively. Silyl-[7] and germyllithiums[8] give the corresponding dialkylaminomethylsilanes and -germanes. An alternative route to Me_2NCH_2-R (or -Ar) type tertiary amines from Grignards and other organometallics involves the use of methylene immonium salts[9] (Eschenmoser salt, CH_2=+NMe_2 Cl^-, is a commercial reagent; see ***Dimethyl(methylene)ammonium Iodide***), and benzotriazole-derived aminals[10] or amine *N*-oxides[11] can be used as sources of the $R_2NCH_2^+$ synthon in general. The above procedures are particularly valuable for the synthesis of tertiary benzylic amines where the usual Mannich conditions do not work owing to insufficient nucleophilicity of the starting aromatic reactant.

(1)

(2)

Phenylthiomethylation of Nucleophiles.

Under acidic conditions, the dialkylamino moiety becomes the leaving group and $PhSCH_2^+$ is thus delivered to a nucleophile. β-Phenylthio ketones are obtained from enamines (eq 3)[12] in a procedure that avoids the use of the obnoxious alternative ***Chloromethyl Phenyl Sulfide***.[13] However, good yields are only reported with enamines derived from MeCOR (or MeCOAr), and those derived from α-branched carbonyl compounds do not react at all (the chloromethyl sulfide alternative[12] is more versatile). Highly reactive aromatics[14] (indole, 2-naphthol; eq 4) are phenylthiomethylated in good yield, in contrast to simple phenols and aryl amines, halides, and ethers.

(3)

(4)

Modified Sommelet-Hauser Rearrangement.

The quaternary ammonium salts from dimethyl(phenylthiomethyl)amine and benzyl bromides give *o*-tolualdehydes in good yield.[15] This reaction was used in two different syntheses,[16,17] of juncusol (eq 5; R = H, 87%; R = CO_2Me, 54%).[16] The product from benzyl bromide and pyrrolidinoacetonitrile[18] undergoes an analogous reaction to give *o*-tolualdehyde in 85% yield. The classical alternatives, such as a reduction of the bromide or its precursor aldehyde to methyl, followed by formylation, cannot compete with these highly expedient synthetic routes.

Dimethylphosphinothioyl Chloride

[993-12-4] · C_2H_6ClPS · Dimethylphosphinothioyl Chloride · (MW 128.57)

(reagent for protection in peptide[1,2] and carbohydrate[3,4] synthesis)

Alternate Name: Mpt-Cl.

Physical Data: mp 24-25 °C; bp 107-107.5 °C/16 mmHg; bp 69-70 °C/11 mmHg;[5] n_D^{20} 1.546.

Form Supplied in: liquid; commercially available.

Preparative Method: chlorination of tetramethyldiphosphine disulfide[7] with ***Sulfuryl Chloride***.[1,6]

Handling, Storage, and Precautions: stable for several months in a refrigerator.[1] Should be handled in the fume hood.

Peptide Synthesis.

The dimethylphosphinothioyl (Mpt) group has been used to protect *N*-amino acids. It is more readily removed than *t*-butoxycarbonyl group, making it a convenient reagent for solid phase synthesis (eq 1).[1]

(1)

This method has been effectively demonstrated in the synthesis of the opioid agonist L-Leu-enkaphalin (L-Tyr-Gly-Gly-L-Phe-L-Leu).

Mpt-Cl also reacts rapidly with *N*-protected amino acids in the presence of ***Triethylamine*** to afford Mpt mixed anhydrides (Mpt-MA). These mixed anhydrides can be isolated by silica-gel column chromatography and stored without decomposition in a freezer. Cbz-Ser-Mpt-MA has been isolated in 17% yield, without protection of the side-

chain hydroxy group (eq 2).[8,9] As a consequence, these active Mpt-MAs have been used for peptide synthesis in methanol or ethanol rather than the usual dipolar aprotic solvents (HMPA, DMF, or DMSO). Synthesis of a heptapeptide (**1**) has been completed by this method.[2]

Cbz-Tyr-Leu-Asn-Ser-Ile-Asn-NH_2

(1)

Carbohydrate Protection/Synthesis.

Hydroxy groups of carbohydrates can be protected using Mpt-Cl in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** and catalytic amounts of ***4-Dimethylaminopyridine***. The Mpt group is stable to acidic hydrolysis conditions that cleave trityl and isopropylidene (acetonide) groups, DBU/MeOH, Bu_4NF, Bu_3SnH, Grignard reagents, and cat. NaOMe/MeOH. The Mpt group does not migrate as do acyl groups (carboxylate esters) under acidic and basic conditions.[4]

Mpt-Cl has been used in the stereoselective synthesis of B-glucopyranomides.[3]

2-(2,6-Dimethylpiperidino)acetonitrile

[825-28-5] · $C_9H_{16}N_2$ · 2-(2,6-Dimethylpiperidino)acetonitrile · (MW 152.27)

(α-lithiation affords a formyl anion equivalent)

Physical Data: bp 99-102 °C/15 mmHg.[1]

Preparative Method: by the condensation of 2,6-dimethylpiperidine and ***Chloroacetonitrile***.[1]

One-Carbon Homologation of Alkyl Halides to Aldehydes.

Following deprotonation, this latent formyl anion equivalent -CHO can be alkylated with alkyl halides and then hydrolyzed to the homologous aldehyde or ethanolyzed to the acetal (eq 1).[2]

2-(2,6-Dimethylpiperidino)acetonitrile

Synthesis of Aromatic Compounds.

Alkyl halides containing an electron-rich aromatic ring undergo subsequent cyclization via an iminium intermediate (eq 2).[2]

Formylation of α,β-Unsaturated Ketones.

Michael addition to 2-cyclohexen-1-one followed by reduction and methanolysis yields a hydroxy acetal derivative (eq 3).[3]

Physical Data: mp 123-127 °C.[1]

Solubility: sol H_2O, chloroform, benzene; very sol ethyl alcohol, diethyl ether.[2]

Form Supplied in: white crystals.

Handling, Storage, and Precautions: skin irritant; hygroscopic; store in cool dry place.[1]

Cyclic Acetals.

2,2-Dimethyl-1,3-propanediol (**1**) has been used effectively as a protecting group for ketones and aldehydes. The formation of the cyclic acetal can be accomplished in many ways. The most common is to reflux the ketone and diol (**1**) with a catalytic amount of acid and force the reaction to completion by removing H_2O, usually with a Dean-Stark trap (eq 1).[3] Other methods involve treating the ketone-diol mixture with ***Chlorotrimethylsilane*** (eq 2)[4] or ***Boron Trifluoride Etherate*** (eq 3).[5]

The advantages of diol (**1**) compared to other diols depend on the compound being protected. In the formation of β-halo acetals, for example, reagent (**1**) was found to be more effective than ***Ethylene Glycol*** because of easier separation and a longer shelf life of the product.[6] Diol (**1**) was also considered to be superior to ethylene glycol when Grignard reagents were prepared from β-halo acetals (eq 4).[7]

(4)

In comparing rates of acid hydrolysis of different cyclic acetals formed from a variety of diols, the following order was discovered; 1,3-propanediol >> (**1**) > ethylene glycol > 2,2-diethyl-1,3-propanediol > 2,2-diisopropyl-1,3-propanediol.[8] This has been attributed to the *gem*-dialkyl effect which serves to stabilize the cyclic acetal. Cleavage of the protecting group formed from diol (**1**) is easily accomplished via acidic hydrolysis using acids such as H_2SO_4, HCl, or TsOH.

Reagent (**1**) has been used in a variety of syntheses where its merits have not been elucidated. The following reactions show some of these transformations (eqs 5-7).[9-11]

(5)

(6)

(7)

Use as a Boron Ligand.

This diol has been used to complex boron.[12] For example, diol (**1**) was employed to remove the phenylboronic acid template from a Diels-Alder adduct under neutral conditions (eq 8).[13]

(8)

Related Reagents.

3-Bromo-1,2-propanediol; ***2,3-Butanediol***; ***Ethylene Glycol***; ***(2R,4R)-2,4-Pentanediol***; ***1,3-Propanediol***.

N,N-Dimethylpropionamide Dimethyl Acetal[1]

(**1**)

[19429-86-8] · $C_7H_{17}NO_2$ · *N,N*-Dimethylpropionamide Dimethyl Acetal · (MW 147.25) (**2**)

[816-05-7] · $C_6H_{13}NO$ · *N,N*-Dimethylpropionamide Dimethyl Acetal · (MW 115.20)

(reagents for stereoselective Eschenmoser-Claisen rearrangements[2] to give γ,δ-unsaturated amides, or, via subsequent protodesilation, to give β,γ-unsaturated amides)

Physical Data: (**1**) and (**2**) mixture: bp 117-120 °C. (**2**): bp 117-118 °C.

Solubility: sol benzene and xylene.

Preparative Methods: a mixture of (**1**) and (**2**) is prepared by *O*-methylation of *N,N*-dimethylpropionamide with ***Dimethyl Sulfate***, followed by reaction with ***Sodium Methoxide*** in methanol.[3] Fractional distillation affords a mixture of (**1**) and (**2**). Treatment with calcium metal and distillation gives the *N,O*-ketene acetal (**2**) (57%). Either a mixture of (**1**) and (**2**) or pure (**2**) may be used in sigmatropic rearrangements.

Handling, Storage, and Precautions: the reagents are potentially toxic and flammable. They should be handled in a fume hood.

Eschenmoser-Claisen Rearrangement.

Reagents (**1** + **2**) or (**2**) condense with allyl alcohols to produce *N,O*-ketene acetal intermediates that undergo [3,3]-sigmatropic rearrangements to afford γ,δ-unsaturated amides. Studies performed by Sucrow and Richter show that the overall transformation of the allylic alcohol is highly stereoselective, with the *trans* allylic alcohol affording the *erythro* product and the *cis* allylic alcohol affording the *threo* product (eq 1).[4]

(1)

trans — *erythro*:*threo* = 95:5
cis — *threo*:*erythro* = 97:3

This result has been rationalized in terms of a chair-like transition state in which the methyl group from the acetal occupies the axial position *anti* to the bulky dialkyl amino group (eq 2).

(2)

An X-ray structure of a cyclic *N*,*O*-ketene acetal derived from reagent (**1**) showed that the methyl substituent occupied the position *trans* to the nitrogen (eq 3).[5]

(3)

trans β,γ-Unsaturated carboxylic acid derivatives were prepared by amide acetal rearrangement of 3-(trimethylsilyl)allyl alcohols and subsequent desilylation with allylic rearrangement (eq 4).[6]

(4)

The propionamide acetal rearrangement was used to establish the *threo* stereochemistry in intermediates for prostaglandin H analog synthesis (eq 5).[7]

(5)

Other Applications.

The reaction of the reagent with an amide oxime gives 5-ethyl-1,2,4-oxadiazoles (eq 6).[8]

(6)

Related Reagents.

1,1-Dimethoxypropene, ***N,N-Dimethylacetamide Dimethyl Acetal***; ***N,N-Dimethylformamide Diethyl Acetal***; ***Dimethyl Sulfate***; ***Methylketene Dimethyl Acetal***; ***Triethyl Orthoacetate***.

N,N´-Dimethylpropyleneurea[1,2]

[7226-23-5] · $C_6H_{12}N_2O$ · *N,N´*-Dimethylpropyleneurea · (MW 128.18)

(dipolar aprotic solvent and cosolvent with properties very similar to those of HMPA; usually a somewhat larger amount is required in order to observe the same cosolvent effect as with HMPA; unlike HMPA, it was found to be nonmutagenic in a comparative investigation[1])

Alternate Names: DMPU; 1,3-dimethyltetrahydro-2(1*H*)-pyrimidone.

Physical Data: bp 110 °C/10 mmHg; mp ca. -20 °C; *d* 1.064 g cm^{-3}; ε$_r$ = 36.

Solubility: miscible with most organic solvents, and with water; a ca. 25% solution in THF can be cooled to dry-ice temperature without crystallization or phase separation.[3]

Form Supplied in: colorless, hygroscopic liquid; commercially available.

Purification: predry over KOH (only necessary with rather wet material), and distill from CaH_2 in vacuo.

Handling, Storage, and Precautions: store at rt in a bottle with a three-way stop cock and a serum cap, over freshly activated molecular sieve (4 Å) and under an inert atmosphere; if stored as indicated, DMPU is stable and ready for use for many months; samples should be withdrawn by syringe technique.

Like HMPA,[4] the cyclic urea DMPU is the prototype of a dipolar aprotic solvent (cf. DMSO, DMF, NMP). As a solvent and cosolvent, DMPU causes increased basicity and nucleophilicity of reagents. It was found to be especially useful for reactions of polyanionic species. Surprisingly, it may have a stabilizing effect on anionic systems that have a tendency to undergo fragmentation. A crystal structure of a Li enolate solvated by DMPU has been described.[5] The lower homolog ***1,3-Dimethyl-2-imidazolidinone*** (DMI) has also been recommended, but it is less useful for low-temperature work due to its greater tendency to crystallize.[6] Although DMPU is a carbonyl compound, it may be used as a cosolvent under the most vigorous metallating conditions (BuLi), at least at low temperatures. The similarity of effects observed with DMPU and the mutagenic HMPA is striking in many cases. (The effects of HMPA on the structure of Li compounds and Li enolates have been thoroughly investigated.[7]) For a detailed discussion of the many uses of HMPA in organic synthesis see ***Hexamethylphosphoric Triamide***. For safety reasons it is recommended that

DMPU is tested as a substitute for HMPA in each case, even in research laboratories; large-scale industrial applications of HMPA have been banned.

The reactions discussed in the following paragraphs are taken from work in which HMPA and DMPU have been compared. In an increasing number of publications on DMPU applications, no comparison is mentioned; some of these are included in the list of references.

Chiral DMPU derivatives have been synthesized; the best induction with one of them gave an aldol of 15% ee.[8]

Generation and Stereoselective Reactions of Lithium Enolates.

Bulky Li amide bases deprotonate ketones and esters to *trans* Li enolates (the trivial *cis*/*trans* nomenclature is used in order to avoid unnecessarily cumbersome language). This has been proved by the X-ray crystal structure analysis of several ester Li enolate derivatives[9] and by numerous NMR investigations of the silyl enol ethers, the trapping products of Li enolates with chlorosilanes. In connection with studies on the Ireland-Claisen rearrangement it was discovered[10] that the *cis* Li enolates are formed when the reaction is carried out in the presence of HMPA, under otherwise identical conditions. As can be seen from eq 1[3] and eq 2,[11] this cosolvent effect can be fully reproduced with DMPU; a review about the careful optimization of this enolate formation includes all details.[11] The diastereoselectivity of most enolate reactions is determined by the geometry of the enolate double bond, and therefore the DMPU effect outlined in eqs 1 and 2 is most important in organic synthesis.[12]

HMPA (23%)	85:15
DMPU (30%)	98: 2

Another useful application of the dipolar cosolvent is shown in eq 3[3] and eq 4.[13] The Li enolates from dimethyl tartrate acetonide (**1**) and from the threonine-derived oxazoline (**2**) have a tendency to undergo destructive β-elimination which can be suppressed to some extent by the presence of DMPU, allowing these enolates to be alkylated in reasonable to excellent yields. It is remarkable that a cosolvent which most chemists would expect to remove cations from their counterions (i.e. to generate naked anions) stabilizes species in which a migration of negative charge (i.e. elimination/fragmentation) leads to decomposition (cf. the use of the novel phosphazene bases (see ***Phosphazene Base P_4-t-Bu***)[14,15] for the same purpose[14a]); notice that the alkylation of the tartrate derivative (**1**) occurs from the face *cis* to the CO_2Me group.[13]

Generation and Reactions of Polylithiated Derivatives.

The reactivity of strong bases as necessary for double and polylithiations is often enhanced in the presence of DMPU, and at the same time the resulting species become more reactive. Some examples of such species are the peptide Li_3 enolate (**3**),[16] ***Methyl Dilithioacetoacetate*** (**4**),[17] the Li_2 nitronate-enolate (**5**)[3] (see ***Methyl 3-Nitropropanoate***), the lithio lithium nitronate (**6**)[3,18] (see ***O,O-Dilithio-1-nitropropene***), and the doubly lithiated iminonitrocyclohexane (**7**)[19] and ergolinylurea (**8**).[20] (We are aware of only one case in which HMPA could not be replaced at all by DMPU: the double lithiation of 1,1,1-trifluoro-2-nitropropane.[18])

(3)

(4)

(5)

(6)

(7)

(8)

For four of these intermediates the corresponding DMPU effects are specified in eqs 5-8. Thus the nitropropionate is not doubly lithiated at all in the absence of cosolvent, and HMPA and DMPU have the same effect on the yields of products (**9**) formed with various electrophiles (eq 5).[3] The addition of doubly lithiated nitropropane to benzaldehyde is not diastereoselective in THF alone, and gives the nitroaldol of (*l*) configuration preferentially in the presence of DMPU (eq 6);[3] this means that the intermediate nitronate-alkoxide is protonated diastereoselectively upon quenching the reaction mixture in the presence of cosolvent.[21] (see ***Trimethylsilyl Methanenitronate***). The chiral imine of 2-nitrocyclohexanone shown in eq 7 is doubly lithiated to a solution containing (**7**) and ***Lithium Diisopropylamide*** (since ***Diisopropylamine*** forms complexes with lithiated species, which are responsible for poor yields, the amine is converted to LDA for better results),[22] and allylation gives best yields of product (**10**) and highest diastereoselectivity in the presence of DMPU.[19] Finally, the conversion delineated in eq 8 shows a reversal of the stereochemical course of a benzylic lithiation/methylation in THF as compared to THF/DMPU (see epimers (**11a**) and (**11b**) in eq 8).[20] This case also exemplifies the compatibility of DMPU with a large excess of ***t-Butyllithium*** at -75 °C.

Nucleophilicity Enhancement in the Presence of DMPU.

Very often, nucleophilic substitutions of the S_N2 type are greatly accelerated by HMPA.[4] Again this effect is fully reproduced by DMPU. Thus sluggish alkylations of Li dithianes can be accelerated as shown in eq 9 for a reaction which is part of a ca. 50-step total syntheses[23] of myxovirescine A_1 and M_2.[24] Epoxide ring opening by acetylides is a classical case of a reaction which requires a boost, and this may be supplied by DMPU, being not quite as effective as HMPA (eq 10);[3] alkylations of acetylides by alkyl bromides and iodides have also been shown to give better yields in the presence of DMPU.[25,26] An interesting solvent effect is shown in eq 11: the ***Tetra-n-butylammonium Fluoride***-mediated addition of a silane to an aldehyde at room temperature occurs only at a reasonable rate in a dipolar aprotic solvent, and HMPA or DMPU win![27]

Solvent	CH_2Cl_2	THF	DMF	HMPA	DMPU
Yield (%)	1	9	56	91	89

A different type of effect on the nucleophilicity of a reagent is exhibited in the addition of ***2-Lithio-1,3-dithiane*** to cyclohexenone. Under standard conditions (THF, dry-ice temperature), 1,2-addition occurs almost exclusively;[28] in the presence of HMPA[29] or DMPU,[3] 1,4-addition takes place (eq 12). Again, this is a remarkable effect, because hard nucleophilic centers should prefer attack at the harder center of the enone, which is the carbonyl carbon (charge control), and soft centers should combine with the softer β-carbon (in fact, lithiated thioacetals bearing Si or Sn on the

carbanionoid center add to enones in a 1,4-fashion[30]); thus the polar cosolvent renders the lithio dithiane C(2) carbon softer! (It was shown that the Li alkoxide of (**12**) does not rearrange to the Li enolate of (**13**) even after 24 h at rt[29]).

Cosolvent	
-	98: 2
HMPA (2 equiv)	5:95
DMPU (4 equiv)	8:92

Transition Metal and Lanthanide Chemistry.

In an increasing number of publications, DMPU is described as a solvent or cosolvent in redox and radical reactions. Two examples are presented here. The spectacular, highly diastereoselective radical cyclization of the cyclopentene (**14**) to the tricyclic compound (**15**) in eq 13 is very slow in THF even at reflux temperature, while the addition of a tiny amount of DMPU accelerates it to such an extent that a respectable yield of 60% of the desired product is obtained at 0 °C (the authors call it a titration).[31] Other ***Samarium(II) Iodide*** reductive coupling reactions (for instance, of α,β-unsaturated esters to 3,4-disubstituted adipic esters)[32] and reductions (of ketones to alcohols and of enones to ketones)[33] are also improved in the presence of DMPU cosolvent.

(13)

(14) **(15)**

Cosolvent	°C	Yield (%)
-	64	<11
HMPA (5%)	0	67 (as free ketone)
DMPU (5%)	0	69 (as free ketone)

Finally, a complex of MoO_5 with pyridine and DMPU can be used instead of the corresponding HMPA complex ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** for hydroxylations of Li enolates (eq 14).[34] Even the crystal structures of the two complexes are similar.[35] In this case, switching from HMPA to DMPU does not remove all hazards: MoO_5.py.DMPU has been reported to be explosive, so must be handled behind appropriate safety equipment.[36]

(14)

$MoO_5 \cdot py \cdot HMPA$	63%	72%	74%
$MoO_5 \cdot py \cdot DMPU$	72%	72%	43%

trans-2,5-Dimethylpyrrolidine

(racemate)

[62617-69-0; 39713-72-9] · $C_6H_{13}N$ · *trans*-2,5-Dimethylpyrrolidine · (MW 99.18) (2*S*,5*S*)

[117968-50-0] (2*R*,5*R*)

[62617-70-3] (.HCl, racemate) · $C_6H_{14}ClN$ · *trans*-2,5-Dimethylpyrrolidine Hydrochloride · (MW 135.64)

[114143-75-8; 4832-49-9] (.HCl, 2*S*,5*S*)

[138133-34-3] (.HCl, 2*R*,5*R*)

[70144-18-2]

(C_2 symmetric chiral pyrrolidine,[1] useful in optically active form as a chiral auxiliary in a variety of asymmetric reactions)

Physical Data: free amine: bp 102-103 °C; (2*S*,5*S*) [α]25D +10.6° (*c* 1.0, EtOH);[2] (2*R*,5*R*) [α]25D -11.5° (*c* 1.0, EtOH).[2] Hydrochloride: racemate mp 187-189 °C;[3] (2*S*,5*S*) mp 200-201 °C,[4] [α]25D -5.63° (*c* 0.67, CH_2Cl_2);[4] (2*R*,5*R*) mp 200-203 °C,[5] [α]25D +5.57° (*c* 1.18, CH_2Cl_2).[5]

Form Supplied in: colorless oil; commercially available as a mixture of (±)-*trans* and *cis* isomers (the mixture is not easily separated).[6]

Purification: the free amine can be purified by fractional distillation; the hydrochloride salt can be recrystallized from absolute ethanol and diethyl ether.

Handling, Storage, and Precautions: irritant; flammable. Use in a fume hood.

Synthesis.

Several routes are available for the synthesis of *trans*-2,5-dimethylpyrrolidine.[2-9,22] Discussed below are preparative

scale procedures for the synthesis of the pure *trans* compound in racemic and enantiomerically pure form.

The racemic hydrochloride salt can be prepared in four steps and 70% overall yield (eq 1).[3] The synthesis is carried out on 2 mmol scale and starts with commercially available 5-hexen-2-one. The key step involves a mercury-catalyzed intramolecular amidomercuration to form the pyrrolidine ring. If desired, the racemate can be resolved via the salts of ***Mandelic Acid***.[2]

Alternatively, an efficient synthesis of either antipode starting from D- or L-alanine has been reported (eq 2).[9] The asymmetric synthesis conducted on 10 mmol scale involves a six-step sequence which incorporates the amidomercuration method.[3] The enantiomerically pure product is isolated as its hydrochloride salt in 44% overall yield. Furthermore, an optimization of the capricious cuprate reaction which improves both the yield and reproducibility has been described.[4]

More recently, a four-step synthetic sequence which provides expedient access to the (-)-(*R*,*R*)-enantiomer in 42% overall yield has been reported.[5] This route is convenient for large-scale preparation (0.2 mol scale), and is highlighted by an asymmetric ***Baker's Yeast*** reduction of 2,5-hexanedione. Subsequent mesylation, *N*,*N*-dialkylation, and deprotection provides the enantiomerically pure free pyrrolidine (eq 3). Alternatively, either enantiomer of the chiral pyrrolidine can be obtained in 15% overall yield from an isomeric mixture of 2,5-hexanediol, via a similar sequence in which (***S***)-α-methylbenzylamine is used as a chiral auxiliary.[22] Also, an enantioselective route to either (2*S*,5*S*)- or (2*R*,5*R*)-hexanediol has been reported.[23]

Asymmetric Alkylations and Michael Additions.

Asymmetric alkylation of the cyclohexanone enamine derived from (+)-*trans*-2,5-dimethylpyrrolidine has been studied (eq 4).[2] Alkylation with ***Iodomethane***, *n*-propyl bromide, and ***Allyl Bromide*** afforded the corresponding 2-*n*-alkylcyclohexanones in yields of 50-80% and with enantiomeric purities of 66, 86, and 64%, respectively.

The lithium enolates from tetronic acid-derived vinylogous urethanes have been generated and their reactivity investigated with a variety of electrophiles (eq 5).[10,11] The reactions proceed with excellent regio- and diastereoselectivity and a variety of alkylating agents can be utilized.

In the total synthesis of (-)-secodaphniphylline an asymmetric [1,4]-conjugate addition was used to establish relative and absolute stereocontrol.[12] The lithium enolate of a *trans*-2,5-dimethylpyrrolidine-derived amide adds in a Michael fashion to a cyclic α,β-unsaturated ester, with subsequent enolate trapping, to afford the desired product in 64% yield and 92:8 diastereoselection (eq 6).

Asymmetric Radical Reactions.

Several reports have documented the utility of nonracemic *trans*-2,5-dimethylpyrrolidine as a chiral auxiliary in asymmetric radical reactions.[13] For example, the addition of *n*-hexyl, cyclohexyl, and *t*-butyl radicals to the chiral

acrylamide of 4-oxopentenoic acid provided four diastereomeric products resulting from α- and β-addition (eq 7).[14] The isomers resulting from β-addition were formed with no diastereoselectivity; however, the isomers resulting from α-addition were formed in ratios of 16:1, 24:1, and 49:1. Unfortunately, the application of this chemistry is limited due to the poor regioselectivity in the addition and difficulty in removal of the chiral auxiliary.

R =	C_6H_{13}	16:16:1
	Cy	25:24:1
	t-Bu	50:49:1

Similar results have been achieved in the addition of chiral amide radicals to activated alkenes.[13] For instance, a chiral amide radical, derived from (-)-*trans*-2,5-dimethylpyrrolidine, adds in a 1,4-fashion to ethyl acrylate in 35% yield and with 12:1 diastereoselectivity (eq 8).[15] Unfortunately, substantial amounts of higher oligomers are also formed. The radical telomerization of chiral acrylamides to afford nonracemic lower-order telomers (n = 1-5) has also been described.[16]

(8)

Asymmetric Pericyclic Reactions.

Several reports illustrate the utility of *trans*-2,5-dimethylpyrrolidine as a chiral auxiliary in asymmetric Claisen-type rearrangements,[17] [4 + 2],[18,19] and [2 + 2] cycloaddition reactions.[20] The enantioselective Claisen-type rearrangement of *N*,*O*-ketene acetals derived from *trans*-2,5-dimethylpyrrolidine has been studied.[17] For example, the rearrangement of the *N*,*O*-ketene acetal, formed in situ by the reaction of *N*-propionyl-*trans*-(2*S*,5*S*)-dimethylpyrrolidine with (*E*)-crotyl alcohol, affords the [3,3]-rearrangement product in 50% yield and 10:1 diastereoselectivity (eq 9).

(9)

Carbamoyl nitroso dienophiles, derived from chiral pyrrolidines, have been generated and their reactivity with cyclohexadiene investigated.[18] Using (-)-*trans*-2,5-dimethylpyrrolidine as the auxiliary, the [4 + 2] cycloadduct is isolated in 82% yield and with 98% diastereomeric excess (eq 10). Similarly, chiral ynamine dienophiles have been utilized in asymmetric [4 + 2] cycloadditions with α,β-unsaturated nitroalkenes to afford cyclic nitronic esters.[19] The resulting esters subsequently undergo a rapid [1,3]-rearrangement to afford chiral cyclic nitrones in moderate yield and high diastereoselectivity (eq 11).

(10)

(11)

> 95% de

An asymmetric, thermal [2 + 2] cycloaddition of keteniminium salts derived from *trans*-2,5-dimethylpyrrolidine has been employed in the synthesis of prostaglandins.[20] An intramolecular [2 + 2] cycloaddition affords a *cis*-fused bicyclic system which is then further transformed into a common prostaglandin intermediate (eq 12).

Miscellaneous.

trans-2,5-Dimethylpyrrolidine has been utilized as a chiral auxiliary for an asymmetric iodolactonization in the total synthesis of (±)-pleurotin and (±)-dihydropleurotin.[21] The reaction affords the desired lactone in 47% yield and only 30% enantiomeric excess.

Related Reagents.

trans-2,5-Bis(methoxymethyl)pyrrolidine.

Dimethyl Selenoxide

[4371-90-8] · C_2H_6OSe · Dimethyl Selenoxide · (MW 125.03)

(mild oxidizing agent;[1,2] electrophilic reagent for oxyselenation of alkenes;[3] electrophile for aromatic substitutions[4,5])

Physical Data: mp 94 °C.

Solubility: sol water, ethanol, acetone, chloroform.

Preparative Methods: readily obtained by oxidation of dimethyl selenide with 30% aqueous ***Hydrogen Peroxide*** at -10 °C, or with ***Ozone*** in chloroform at -50 °C; also prepared by treating dimethylselenium dibromide with ***Silver(II) Oxide*** in methanol.

Purification: recrystallization from benzene gives the pure material as colorless needles.

Handling, Storage, and Precautions: hygroscopic; decomposes in ether, acetonitrile, THF, and CS_2; since the reactions of dimethyl selenoxide often produce volatile organoselenium derivatives having a highly unpleasant odor, use in a well-ventilated fume hood.

Oxidation.

Several selenoxides, such as dimethyl selenoxide,[1,2] dibenzyl selenoxide,[6] diphenyl selenoxide,[7] and bis(*p*-methoxyphenyl) selenoxide,[8] are mild and selective agents for the oxidation of various functional groups. Dimethyl selenoxide oxidizes trivalent phosphorus compounds and thio- and selenophosphonyl compounds to their oxygenated analogs more effectively than ***Dimethyl Sulfoxide***.[1] The reactions for the acyclic derivatives occur with nearly complete inversion of configuration (eq 1) and for cyclic derivatives with almost full retention (eq 2). The reagent also oxidizes thioureas and thiouracils to the corresponding carbonyl compounds in high yields. This reaction is useful for selective modifications of the 4-thiouracil group in transfer ribonucleic acids (eq 3).

(1)

(2)

(3)

The oxidation of halomethylarenes with dimethyl selenoxide in refluxing 1,2-dichloroethane gives polysubstituted aromatic aldehydes bearing substituents reactive toward acids, bases, or water (eq 4).[2]

(4)

Oxyselenation of Alkenes.

The reagent reacts with alkenes in AcOH-$CHCl_3$ at 60 °C to give 2-acetoxyalkyl methyl selenides (eqs 5 and 6).[3] This addition reaction is regioselective and *trans* stereospecific. Presumably MeSeOAc is the reactive species.

(5)

(6)

Electrophilic Aromatic Substitution Reactions.

Dimethyl selenoxide effects electrophilic substitution of phenols in the presence of hydrogen chloride at 0-20 °C to give dimethyl(hydroxyphenyl)selenonium chlorides, whose pyrolyses in refluxing toluene afford methyl hydroxyphenyl selenides in high yields (eq 7).[4]

(7)

The substitution reaction of 5-(trimethylsilyl)cyclopentadiene with dimethyl selenoxide forms the selenoniocyclopentadienide in an excellent yield (eq 8).[5] Similar reactions of pentafulvene, indole, and pyrrole give the corresponding selenonium salts.

Dimethylsuccinimidosulfonium Tetrafluoroborate

[54884-50-3] · $C_6H_{10}BF_4NO_2S$ · Dimethylsuccinimidosulfonium Tetrafluoroborate · (MW 247.02)

(stable sulfonium salt for the mild oxidation of alcohols and catechols in the presence of a tertiary amine; also used for the introduction of a methylthiomethylene substituent in the *ortho* position of simple phenols, or the transfer of a dimethylsulfonium group to nucleophiles)

Alternate Name: succinimidodimethylsulfonium tetrafluoroborate.

Physical Data: mp 169-171 °C

Solubility: very sol methylene chloride, acetonitrile; insol ether.

Form Supplied in: colorless solid; not commercially available.

Analysis of Reagent Purity: mp, ^{1}H NMR, or elemental analysis.

Preparative Method: an acetonitrile solution of ***N-Chlorosuccinimide*** and ***Dimethyl Sulfide*** produces the unstable dimethylsuccinimidosulfonium chloride at -25 °C, which is then treated with ***Triethyloxonium Tetrafluoroborate*** (eq 1).

Handling, Storage, and Precautions: hygroscopic, but thermally and air stable; can be stored indefinitely under N_2 in sealed flasks in the absence of moisture.

Introduction.

The general class of dimethylsuccinimidosulfonium salts are reagents useful for the transfer of the dimethylsulfonium moiety to nucleophilic species.[1] The main variation in this group of reagents is the nature of the counteranion (Cl, Br, BF_4). The title reagent incorporating the tetrafluoroborate anion is a thermally stable and isolable salt of this series. Both the chloride and bromide are generally generated in situ for the purpose of oxidations of alcohols[2] or the sulfonium aminations of anilines.[3]

Experimental Procedure.

NCS (22.7 g, 0.17 mol) was dissolved in freshly distilled acetonitrile under a nitrogen atmosphere. The solution was cooled to -25 °C with stirring while 10 mL (0.2 mol) of DMS was added dropwise. After stirring for 15 min, the reaction mixture was cooled to -50 °C until crystals formed. A solution of 25 g (0.17 mol) of triethyloxonium tetrafluoroborate in 100 mL of acetonitrile was added dropwise to the reaction mixture. After addition was complete (about 1 h), the flask was cooled to -78 °C until the solution solidified. The solid mass was slowly brought to rt over a period of 4 h; then 500 mL of anhyd ether was added slowly to precipitate the dimethylsuccinimidosulfonium tetrafluoroborate as a white solid. Recrystallization from acetonitrile/ether gave 33.6 g (80%) of the product as white needles (mp 169-171 °C).

Oxidation Reactions.

The advantage of the stable tetrafluoroborate reagent lies in its stoichiometric use in a variety of solvents under controlled reaction conditions in the absence of a nucleophilic anion. A particularly mild and selective oxidation of catechols to *o*-quinones can be effected with the title reagent and 1 equiv of ***Triethylamine*** in acetonitrile below 0 °C (eq 2).

These oxidations can be carried out between -20 and -50 °C in order to extend the lifetime of the sensitive and very reactive *o*-quinones.[4] The mechanism of this oxidation process involves the intermediacy of an aryloxysulfonium cation which undergoes base-promoted elimination of dimethyl sulfide (eq 3). The merits of this procedure include the absence of deleterious byproducts which could react with the quinone product and the lack of opportunity for overoxidation.

The title reagent is also effective for the oxidation of *p*-hydroquinones to *p*-quinones in quantitative yields (eq 4). The employment of an amine base is essential for this oxidation process.

Nucleophilic Additions to Succinimidosulfonium Cations.

The title reagent can also be considered as a source of the dimethylsulfonium cation through reaction with nucleophiles. Thus the nucleophilic addition of a phenolic oxygen atom to the reagent leads to an intermediate aryloxysulfonium species, which rapidly gives up a proton to generate a sulfonium ylide.[5] This latter intermediate undergoes a facile [2,3]-sigmatropic rearrangement to produce cyclohexadienones with 2,6-disubstituted phenols (eq 5).[6] In the case of unsubstituted phenols, the sigmatropic rearrangement takes place and the dienone rearomatizes to give the *ortho*-methylthiomethylene phenol.[7]

(5)

Other heteroatoms such as nitrogen and sulfur behave as good nucleophiles in reactions with the title reagent and related salts.[8] Stabilized carbanions such as substituted α-cyanoacetates react readily with the succinimidosulfonium reagent to give several rearangement products.[8] The initial combination of the reagent with the cyanoacetate anion is thought to generate a σ-sulfurane intermediate which could ionize to form the succinimido anion and a sulfonium cation (eq 6). In the presence of a weak base, the sulfonium cation is deprotonated to an ylide which can undergo a [1,2]-rearrangement to a methylthiomethylene derivative of the starting carbanion or, alternatively, the ylide may undergo a [2,3]-sigmatropic rearrangement to yield a substituted ketenimine (eq 7). In most cases, the ketenimine is the major product.

Dimethyl Sulfate[1]

[77-78-1] · $C_2H_6O_4S$ · Dimethyl Sulfate · (MW 126.13)

(effective methylating reagent[1])

Physical Data: bp 188 °C; mp -32 °C; *d* 1.333 g cm^{-3}; fp 83 °C.

Form Supplied in: water-white liquid; widely available.

Handling, Storage, and Precautions: extremely toxic and carcinogenic; use in a fume hood with adequate protection.[2]

O-Alkylation.

Dimethyl sulfate is a powerful alkylating agent and has been used for the methylation of almost every imaginable nucleophile over the years.[1] The variety of oxygen nucleophiles include carboxylic acids,[3] alcohols,[4] phenols,[5] lactams,[6] oximes,[7] pyridine *N*-oxides,[8] hydroxylamines,[9] hydroxamic acids,[10] and hydroperoxides.[11]

Carboxylic acids react with dimethyl sulfate in the presence of ***Dicyclohexyl(ethyl)amine*** (DICE) to afford methyl esters in high yield.[3] The method is reported to be facile and particularly useful when ester formation using ***Diazomethane*** or strongly acidic conditions is not possible. For example, β-9,10,12-trihydroxyoctadecanoic acid is readily converted to its methyl ester in 97% yield using this procedure (eq 1). Another example of this type of esterification was demonstrated with the preparation of bile acid methyl esters (eq 2).[12] These steroidal carboxylic acids were methylated using ***Potassium Carbonate*** as a base in refluxing acetone. Both of the aforementioned procedures avoid significant side reactions such as dehydration or ether formation resulting from competing alkylation of free hydroxy groups.

(1)

(2)

Syntheses of aryl and alkyl methyl ethers using dimethyl sulfate have also been reported. Simple alcohols and phenols may be alkylated using dimethyl sulfate in slightly hydrated solid/liquid heterogeneous media with 1,4-dioxane or triglyme/potassium hydroxide and small amounts of water to give the corresponding methyl ethers in excellent yield.[4] For example, *t*-butyl alcohol is converted to *t*-butyl methyl ether in nearly quantitative yield (eq 3). The procedure calls for the use of only a stoichiometric amount of dimethyl sulfate, which reduces problems associated in the workup and the potential toxicity of remaining dimethyl sulfate. In addition, methylation of alcohols using dimethyl sulfate and ***Alumina*** as a solid adsorbent reaction medium affords excellent yields of the corresponding alkyl alcohols.[13] Phenols and carboxylic acids, however, gave lower yields of methylated product using this procedure. A second example involves the stereospecific formation of highly substituted tetrahydrofurans. Treatment of a 2,5-dihydroxy-4-phenyl

sulfide with dimethyl sulfate in dichloromethane at 0 °C cleanly afforded the substituted tetrahydrofuran in excellent yield (eq 4).[14] It has been suggested that the reaction proceeds via methylation of a free hydroxy group followed by solvolysis of methanol assisted by the neighboring thiophenyl group. Subsequent cyclization gave the tetrahydrofuran as a single stereoisomer.

(3)

(4)

Several methods have been described for preparing aryl methyl ethers from phenols using dimethyl sulfate. For example, defucogilvocarcin M was completed by methylating a sterically hindered C-12 hydroxyl group using dimethyl sulfate and potassium carbonate (eq 5).[5] In addition, the synthesis of a carbazole alkaloid was completed via the selective alkylation of a 5-indolyl alcohol using dimethyl sulfate and ***Sodium Hydride*** to give 4-deoxycarbazomycin B in 96% yield (eq 6).[15]

(5)

(6)

The *O*-methylation of lactams to afford *O*-alkylimino ethers has also been reported. For example, the large-scale preparation of *O*-methylcaprolactim proceeds in good yield using caprolactam and 1 equiv of dimethyl sulfate in benzene (eq 7).[6] The treatment of caprolactam with excess dimethyl sulfate gives *N*-methyllactam as the major product.

(7)

Other alkylation processes include the *O*-methylation of oximes, *N*-oxides, hydroxylamines, and hydroxamic acids. The preparation of oxime ethers using dimethyl sulfate has proven an effective methodology for the construction of sidechains designed for new cephalosporin antibiotics. Treatment of α-oxime esters with dimethyl sulfate afforded the α-methoximino esters, which were subsequently hydrolyzed to the acid and used as sidechains via acylation chemistry (eq 8).[7]

(8)

The methylation of pyridine, quinoline, and isoquinoline *N*-oxides to afford *N*-methoxy salts has also been investigated. For example, treatment of quinoline *N*-oxide with dimethyl sulfate provides the *N*-methoxy methylsulfate salt in excellent yield (eq 9).[8] The resulting salts were subsequently treated with cyanide ion to afford cyanopyridines in a mild overall process.

(9)

A new route to 2-substituted indoles derived from 1-methoxyindole was recently described. Dimethyl sulfate proved to be the reagent of choice for the methylation of the unstable 1-hydroxyindole to give 1-methoxyindole in 51% yield (eq 10).[9] The resulting methoxyindole undergoes *O*-lithiation at the 2-position using ***n-Butyllithium***, and can be trapped with appropriate electrophiles. It should be noted that methylation of 1-hydroxyindole using ***Iodomethane*** afforded only very low yields of the desired methoxyindole.

(10)

Finally, a convenient synthesis of ***N,O-Dimethylhydroxylamine***, a reagent used to prepare aldehydes from *N*-methoxy-*N*-methylamides, has been reported. It includes a key dimethylation of an intermediate ethyl hydroxycarbamate using dimethyl sulfate and sodium hydroxide (eq 11).[10]

MeNHOMe · HCl (11)
200 g

N-Alkylation.

Dimethyl sulfate has also been a useful reagent for the preparation of *N*-methyl alkyl- and aryl-substituted amines, amides, and quaternary ammonium salts. Simple primary amines can be selectively methylated to afford secondary amines by first protecting the amine as a Schiff base or amidine ester,[16] amide,[17] or carbamate,[18] followed by alkylation using dimethyl sulfate and hydrolysis of the resulting amide or iminium ion. For example, the methylation of amidines has been employed in a route to *N*-alkyl amino acids. The amidine of phenylalanine methyl ester was prepared from the amino ester using dimethylformamide dimethyl acetal (see ***N,N-Dimethylformamide Diethyl Acetal***), followed by methylation and hydrolysis to afford the corresponding *N*-methylphenylalanine in good yield without racemization (eq 12).[16] Certain substrates such as phenylglycine methyl ester required the use of ***Methyl Trifluoromethanesulfonate*** as the alkylating agent and lower reaction temperatures to retain optical purity throughout the process. The selective synthesis of substituted *N*-monoalkylaromatic amines has also been reported. For example, 2-nitroacetanilide is cleanly converted to 2-nitro-*N*-methylaniline in one pot using phase-transfer conditions (eq 13).[17]

(12)

(13)

Tertiary alkyl and aromatic amines are also conveniently quaternized using dimethyl sulfate. For example, a series of thioquinanthrenediinium salts for use as potential antibiotics were prepared via methylation of their quinoline precursors using dimethyl sulfate (eq 14).[19]

(14)

S-Alkylation.

The methylation of sulfur-containing compounds using dimethyl sulfate to afford sulfides and sulfonium ions has also been explored. For example, trimethylsulfonium methyl sulfate has been prepared on a large scale via methylation of

dimethyl sulfide.[20] This salt has been subsequently used as a precursor of ***Dimethylsulfonium Methylide***, a popular reagent for the preparation of epoxides from ketones (eq 15). *O*-Alkyl *S*-methyl dithiocarbamates have also been prepared via condensation of an alkoxide with ***Carbon Disulfide***, followed by methylation using dimethyl sulfate (eq 16).[21] The resulting dithiocarbamates can then be reduced via radical chemistry to afford the alkane.

(15)

(16)

C-Alkylation.

Several processes involving the formation of C-C bonds via methylation of organometallics using dimethyl sulfate have been reported. For example, a series of 2-methylbutyrolactones and -valerolactones were prepared via asymmetric alkylation using chiral oxazolines and ***Lithium Diisopropylamide*** followed by treatment with dimethyl sulfate (eq 17).[22] The resulting oxazoline was then hydrolyzed to afford the optically active lactone. Aryllithium species also undergo rapid alkylation using dimethyl sulfate as the electrophile. For example, 3,4-bis(tributylstannyl)furan undergoes a single tin-lithium exchange and upon treatment with dimethyl sulfate and ***N,N´-Dimethylpropyleneurea***

(DMPU) affords the monomethylated product (eq 18).[23] The resulting compounds were then subjected to various palladium-mediated cross-coupling reactions to give 3,4-disubstituted unsymmetrical furans. Dimethyl sulfate was found to be superior to methyl iodide for this particular application.

Dimethyl Sulfide

[75-18-3] · C_2H_6S · Dimethyl Sulfide · (MW 62.13)

(reducing reagent; methylation; sulfide complex; ylide formation)

Alternate Names: DMS; methyl sulfide.

Physical Data: mp -98 °C; bp 38 °C; *d* 0.85 g cm^{-3}.

Solubility: insol water; sol ethanol, diethyl ether.

Handling, Storage, and Precautions: disagreeable odor; use in a fume hood.

Reduction of Ozonides and Sulfoxides.

Diacetals are obtained in high yields when the ozonolysis products of alkenes are treated with dimethyl sulfide and trimethyl orthoformate (see ***Triethyl Orthoformate***) (eq 1).[1] Hydrolysis to the diacetals is performed by heating in water containing tartaric acid. Ozonolysis (see ***Ozone***) of maleic acid followed by reduction with dimethyl sulfide gives ***Glyoxylic Acid*** (eq 2).[2]

(1)

(2)

Methyl phenyl sulfoxide is quantitatively reduced to the corresponding sulfide by treatment with dimethyl sulfide (2 equiv) and ***Trifluoroacetic Anhydride*** at 0 °C in CH_2Cl_2 (eq 3).[3] Trifluoroacetic anhydride can be replaced by acetyl trifluoroacetate or ***Thionyl Chloride***.

(3)

ortho-Alkylation.

Aromatic and heteroaromatic amines are methylated at the *o*-position via *N*-chloro derivatives. Aniline is treated with ***t-Butyl Hypochlorite*** or ***N-Chlorosuccinimide*** (1 equiv) in CH_2Cl_2 at -65 °C, and dimethyl sulfide (3 equiv) is added, followed by sodium methoxide (1.2 equiv) in methanol. 2-(Methylthiomethyl)aniline is obtained in 90% yield; its desulfurization by ***Raney Nickel*** gives *o*-toluidine (eq 4).[4] 2-Amino-3-methylpyridine is obtained in 50% overall yield by a similar sequence of reactions starting from 2-aminopyridine (eq 5).[5]

(4)

(5)

The above *o*-methylation can be successfully extended to *o*-alkylation[4] and also to the synthesis of indoles and hetero analogs. Use of methylthio-2-propanone (**1**), methylthioethanal (**2**), or methylthioethanal dimethyl acetal (**3**) instead of dimethyl sulfide, in similar processes using aniline and 2-aminopyridine, provides an elegant entry to indoles and hetero analogs (**4**)-(**7**).[6]

Dimethyl Sulfide Complexes.

Dimethyl sulfide rapidly reacts with ***Chlorine*** (1 equiv) in carbon tetrachloride at 0 °C to give the complex (**8**) as an insoluble solid. This complex (***Dimethyl Sulfide-Chlorine***; Corey-Kim reagent) is useful for oxidation of primary and secondary alcohols. Treatment of 4-*t*-butylcyclohexanol with (**8**) at -25 °C and then with ***Triethylamine*** gives 4-*t*-butylcyclohexanone (eq 6).[7] For the oxidation of primary alcohols, e.g. cyclohexanemethanol, ***N-Chlorosuccinimide-Dimethyl Sulfide*** (**9**)[8] is superior.

(6)

(8) **(9)**

Allylic and benzylic alcohols are not oxidized with the complex (**8**), but instead are converted into the corresponding chlorides. Of particular interest is the chemoselective chlorination of (*Z*)-3-methyl-2-pentene-1,5-diol, which bears allylic and homoallylic alcohol moieties in the same molecule (eq 7).[9] The allylic chloride is the only product obtained.

(7)

The ***Borane-Dimethyl Sulfide*** complex is a useful substitute for diborane and has been widely used for hydroborations and reductions, although it is a little less reactive than diborane itself.[10]

Sulphonium Ylides.

Heating of α-bromo esters with dimethyl sulfide leads to methyl sulfides. Subsequent *S*-methylation with ***Trimethyloxonium Tetrafluoroborate*** followed by α-deprotonation provides dimethylsulfonium ylides (eq 8).[11] These ylides undergo smooth reactions with electron-deficient alkenes, producing cyclopropanes. In the case shown in eq 8, a better yield (90%) of cyclopropane formation results when the ylide is generated in situ by treatment with ***Sodium Hydride*** rather than when the isolated ylide is used.

Related Reagents.

Boron Trifluoride-Dimethyl Sulfide; ***N-Bromosuccinimide-Dimethyl Sulfide***; ***Chloro(thexyl)borane-Dimethyl Sulfide***; ***Dibromoborane-Dimethyl Sulfide***; ***Dichloroborane-Dimethyl Sulfide***; ***Monochloroborane-Dimethyl Sulfide***; ***Trimethylstannylcopper-Dimethyl Sulfide***.

Dimethyl Sulfide-Chlorine[1]

Me_2S-Cl_2

(DMS)

[75-18-3] · C_2H_6S · Dimethyl Sulfide-Chlorine · (MW 62.15) (Cl_2)

[7782-50-5] · Cl_2 · Dimethyl Sulfide-Chlorine · (MW 70.90)

(mild oxidizing agent for primary and secondary alcohols[2] and vicinal diols;[3] chlorinating agent for phenols, phenol ethers, and anilines;[4] reagent for synthesis of methylthiomethyl esters,[5] for dehydration of aldoximes to nitriles,[6] and for synthesis of α-chloro ketones[7])

Alternate Name: chlorodimethylsulfonium chloride

Solubility: sol CH_2Cl_2, CCl_4, toluene, acetonitrile.

Preparative Method: prepared in situ by slow addition of a solution of ***Dimethyl Sulfide*** (1.25 equiv) in CH_2Cl_2 to a solution of ***Chlorine*** (1 equiv) in CH_2Cl_2 at -25 °C under an inert atmosphere;[4] typical scale is 3 mmol in 10 mL CH_2Cl_2.

Handling, Storage, and Precautions: chlorine gas is toxic and corrosive; when introducing the gas to CH_2Cl_2, ensure that the apparatus is properly trapped and vented in a fume hood to avoid escape of chlorine and overpressurization of the reaction vessel.

Oxidation of Alcohols to Aldehydes or Ketones.

Dimethyl sulfide-chlorine (DMS-Cl_2) and its derivatives (e.g. chlorine-methyl phenyl sulfide) have shown excellent utility as oxidizing agents for primary and secondary alcohols.[2] This reagent system is part of a family of halosulfonium salt reagents (see ***Dimethyl Sulfoxide-Oxalyl Chloride***, ***Dimethyl Sulfoxide-Dicyclohexylcarbodiimide***, ***Dimethyl Sulfoxide-Trifluoroacetic Anhydride***, ***Dimethyl Sulfoxide-Phosphorus Pentoxide***)[1b] and is closely related in its oxidizing properties to ***N-Chlorosuccinimide-Dimethyl Sulfide*** (DMS-NCS). The oxidation proceeds through a sulfoxonium ion complex (**2**), which is converted to the carbonyl by addition of ***Triethylamine*** (eq 1).[2]

The oxidation of vicinal diols has been problematic with some oxidizing agents.[3] Carbon-carbon bond cleavage occurs with certain of these reagents (***Chromic Acid***, ***Pyridinium Chlorochromate***, ***Pyridinium Dichromate***, ***Silver(I) Carbonate***). DMS-Cl_2 oxidizes *s*,*t*-1,2-diols to α-hydroxy ketones as illustrated in eq 2[3] and eq 3.[6] The yields are moderate; in eq 2 they can be improved to 85% by substituting methyl phenyl sulfide for dimethyl sulfide. In some instances methyl phenyl sulfide has been found to be superior to dimethyl sulfide.[3,9,10] Two good alternative reagents to DMS-Cl_2 are ***Dimethyl Sulfoxide-Chlorine***[3] and DMS-NCS, which also give good to excellent yields of keto alcohols without C-C cleavage. The oxidation shown in eq 3 was attempted with silver carbonate but gave only a 12% yield of hydroxy ketone.[8]

Another advantage of DMS-Cl_2 is its potential use in large-scale processes. The reagent is very inexpensive and the reaction byproducts are dimethyl sulfide (which can be recycled) and HCl.

Chlorination of Activated Aromatic Compounds.

DMS-Cl_2 regioselectively *p*-chlorinates activated aromatic compounds such as phenol, anisole, and *N*,*N*-dimethylaniline in good to excellent yields.[4] Eq 4 shows three general examples of this reaction. The reaction is complete in 5 min at -25 °C.

(4)

R = OH, 84%; OMe, 80%; NMe_2, 75%

Synthesis of Methylthiomethyl Esters.

Methythiomethyl esters can be synthesized by reaction of the triethylamine salt of a carboxylic acid with freshly prepared DMS-Cl_2 at -70 °C to rt (e.g. eq 5).[5] Yields for simple alkyl and aryl carboxylates range from 80 to 85%.

(5)

Dehydration of Aldoximes to Nitriles.

DMS-Cl_2 rapidly dehydrates aldoximes at low temperature.[6] Excess DMS-Cl_2 is formed at -78 °C in acetonitrile and treated with an aldoxime. Warming to -25 °C and addition of triethylamine affords the nitrile in excellent yield (eq 6).

(6)

Synthesis of α-Chloro Ketones.

α-Chloro ketones can be synthesized by treatment of an epoxide with DMS-Cl_2 in CH_2Cl_2 at low temperature.[7] Triethylamine is required to decompose the intermediate sulfonium salt to the α-chloro ketone (eq 7). Yields are greater than 80% but in some cases there is no control of regiochemistry.

Dimethyl Sulfone

[67-71-0] · $C_2H_6O_2S$ · Dimethyl Sulfone · (MW 94.15)

((methanesulfonyl)methylation agent; may be used as a dipolar aprotic solvent)

Physical Data: mp 108-110 °C; bp 238 °C; *d* 1.1707 g cm^{-3} (110 °C); pK_a 31.1 (DMSO) and 23 (water).

Solubility: sol in hot H_2O, EtOH, benzene.

Form Supplied in: white solid; commercially available.

Purification: recrystallized from $CHCl_3$ or H_2O and then dried over P_2O_5.

Handling, Storage, and Precautions: stable indefinitely at rt.

As a Solvent.

Because of its high boiling point, dimethyl sulfone is a convenient solvent for high-temperature reactions, e.g. treatment of 2-chloropyridine with ***Potassium Fluoride*** in dimethyl sulfone at 110 °C for 21 days results in the displacement of the chlorine by fluorine.[1]

Reactivity and Applications.

Dimethyl sulfone can be deprotonated by organolithium compounds, Grignard reagents, or alkali metal alkoxides,[2] amides,[3,4] or hydrides[5] to give (methanesulfonyl)methyllithium or (methanesulfonyl)methyldilithium, depending upon the amount of base added.[3] The choice of the solvent (THF, DMSO, or liquid ammonia) is dictated by the nature of the base. The resultant carbanions react with halides, aldehydes,[4] ketones, esters, nitriles,[3] or amides. Under phase transfer catalysis, condensation of dimethyl sulfone with aldehydes occurs without dehydration to give the corresponding β-hydroxysulfones.[6] The acidity of dimethyl sulfone (pK_a = 31) is greatly enhanced by forming ***Trifluoromethanesulfonylmethyl Methyl Sulfone*** (pK_a = 4) via reaction of (methanesulfonyl)methylmagnesium bromide with trifluoromethanesulfonyl fluoride or ***Trifluoromethanesulfonic Anhydride***. The trifluoromethanesulfonyl group serves the dual role of acidity enhancer and leaving group in a Ramberg-Bäcklund reaction, leading to a synthesis of alkenes.[7] The principles are illustrated in a synthesis of the cyclopentenone ring of

dihydrojasmone (eq 1).[8]

Related Reagents.

Methyl Phenyl Sulfone; ***Trifluoromethanesulfonylmethyl Methyl Sulfone***.

Dimethylsulfonium Methylide

[6814-64-8] · C_3H_8S · Dimethylsulfonium Methylide · (MW 76.18)

(exceedingly selective methylene transfer reagent capable of converting carbonyl compounds into oxiranes,[1] and imines into aziridines[2])

Form Supplied in: reactive intermediate generated in situ.

Preparative Methods: Method A.[1a,b] A solution of dimethylsulfonium methylide is readily prepared by addition of a solution of ***Trimethylsulfonium Iodide*** in ***Dimethyl Sulfoxide*** (800 mL per mol of sulfonium salt) with stirring (below 5 °C, because of the marked thermal instability of the methylide) to an equivalent molar amount of a 1.5-2 M solution of methylsulfinyl carbanion,[3] which is prepared by treatment of dry DMSO with ***Sodium Hydride*** under nitrogen followed by dilution with an equal amount of dry THF (to prevent solidification).

Method B.[1b] Alternatively, a solution of ***n-Butyllithium*** (11 mmol) in 8 mL of pentane may be added dropwise to a stirred suspension of 2.45 g (12 mmol) of powdered trimethylsulfonium iodide in 30 mL of dry THF under nitrogen at 0 °C.

Method C.[4] To a solution of ***Dimethyl Sulfate*** (189.2 g, 1.50 mol) in acetonitrile (700 mL) is added a solution of ***Dimethyl Sulfide*** (102.5 g, 1.65 mol) in acetonitrile (300 mL) with stirring at rt. After standing overnight, ***Sodium Methoxide*** (89.1 g, 1.65 mol) is added to the mixture at rt to give a solution of dimethylsulfonium methylide, which is successfully applied to the preparation of oxiranes from various kinds of carbonyl compound. In comparison with the former methods, this process is more favorable for preparing oxiranes on a large scale under mild conditions without using expensive alkylating agents and intractable solvents.

Method D.[1d] To a mixture of 0.1 mol of aldehyde (or ketone) and 22 g (0.14 mol) of trimethylsulfonium bromide dissolved in 60 mL of DMSO is added a solution of 14 g of ***Potassium t-Butoxide*** in 60 mL of DMSO with stirring and cooling under nitrogen over 30-45 min. After workup, the expected oxiranes can be separated and purified by distillation or recrystallization. In this method, ***Sodium Amide*** or sodium hydride can be used as a base instead of potassium *t*-butoxide, and DMF may be used as solvent. Benzalaniline may be converted by this method into the corresponding aziridine.

Method E.[5] Dimethylsulfonium methylide can also be obtained by phase-transfer catalysis. Thus trimethylsulfonium iodide does not react with benzaldehyde in the system CH_2Cl_2-NaOH, but on addition of

1-5 mol % of ***Tetra-n-butylammonium Iodide***, 2-phenyloxirane is obtained in >90% yield via the intermediate sulfonium methylide. Yields of oxiranes are rather low (20-35%) when ketones are used in this procedure.

Formation of Oxiranes.

Dimethylsulfonium methylide reacts with a variety of aldehydes and ketones by net methylene transfer to form oxiranes. Thus several compounds, including benzophenone, benzaldehyde, and cycloheptanone were converted into the corresponding oxiranes by selective addition of methylene to the carbonyl group (eqs 1-3).[1b]

(1)

(2)

(3)

It should be noted that dimethylsulfonium methylide prefers addition to the carbonyl group of α,β-unsaturated carbonyl compounds while ***Dimethylsulfoxonium Methylide***, which is a closely related reagent for methylene transfer to unsaturated compounds, tends to attack the α,β-double bond. For example, carvone was converted to the corresponding oxirane by treatment with the sulfonium ylide, whereas the sulfoxonium ylide reacts with carvone to give the cyclopropyl ketone (eq 4).[1b]

(4)

Similarly, selective oxirane formation was achieved in the cases of other α,β-unsaturated ketones such as eucarvone (93%), benzalacetone (87%), and pulegone (90%).[1b]

Epoxidation of β-ionone can also be achieved by the treatment of a mixture of trimethylsulfonium chloride (24 g), β-ionone (38.4 g), CH_2Cl_2 (100 mL), and ***Benzyltriethylammonium Chloride*** (1 g) with aqueous NaOH (18 M, 125 mL) at rt (eq 5).[6]

(5)

No epoxide is obtained, however, by reaction of β-ionone with dimethylsulfonium methylide generated by the conventional methods using other trimethylsulfonium halides[5,7] or trimethylsulfonium methylsulfate[4] as a precursor.

Dimethylsulfonium methylide undergoes stereoselective addition of two methylene units to 9,10-anthraquinone to afford the corresponding *trans*-bisepoxide (eq 6).[8]

(6)

Asymmetric Oxirane Synthesis.

A striking asymmetric synthesis of 2-phenyloxirane can be achieved by the reaction of benzaldehyde and dimethylsulfonium methylide generated from trimethylsulfonium iodide in 50% NaOH with the chiral phase-transfer catalyst (-)-*N*,*N*-dimethylephedrinium bromide (0.2 equiv) (eq 7).[9]

(7)

The optical yield of oxirane in eq 7 is 67%. If the asymmetric salt derived from ψ-ephedrine is used, the enantiomeric oxirane is formed preferentially. In this system the choice of the solvent is important. Little asymmetric induction is observed with THF or acetonitrile as solvent, while the use of benzene results in a high degree of induction.

Synthesis of Butenolides.

The reaction of a cyclic α-keto ketene dithioacetal with dimethylsulfonium methylide followed by acid hydrolysis produced the corresponding butenolide in high yield (eq 8).[10]

(8)

The reaction of dimethylsulfonium methylide with acyclic α-keto ketene dithioacetals also provides a simple synthesis of dihydrofurans, which can be converted into various furans and butenolides (eqs 9 and 10).[11]

(9)

(10)

Cyclopropanation via Methylene Transfer to Carbon-Carbon Double Bonds.

In contrast to α,β-unsaturated ketones, ethyl cinnamate, an α,β-unsaturated carboxylic acid ester, was transformed into 2-phenyl-1-cyclopropane carboxylate (eq 11).[1d]

(11)

Since dimethylsulfonium methylide is a far more powerful methylene transfer reagent than dimethylsulfoxonium methylide, it can convert 1,1-diphenylethylene into 1,1-diphenylcyclopropane in 60% yield though it is necessary to use an excess amount of methylide (5 equiv) (eq 12).[1b] However, dimethylsulfonium methylide is inactive toward tolan or *trans*-stilbene, and unreactive toward nonconjugated carbon-carbon double bond compounds.

(12)

Methylation of Aromatic Rings.

Dimethylsulfonium methylide reacts with acenaphthylene in DMSO-THF to give 3-methylacenaphthylene together with some 5-methylacenaphthylene (eq 13).[12] Similarly, fluoranthrene gives a mixture of 1- and 3-methylfluoranthrenes upon treatment with dimethylsulfonium methylide (eq 14).[12]

N-Methylation of Indoles.

Indoles can be selectively *N*-methylated by dimethylsulfonium methylide in THF at rt (eq 15).[13]

Aziridine Formation.

Dimethylsulfonium methylide reacts smoothly with imines. For example, benzalaniline can be converted to the

corresponding aziridine in 91% yield (eq 16).[1b,d]

(16)

Using this methodology, the first known heterocyclic analog of bicyclobutane, 3-phenyl-1-azabicyclo[1.1.0]butane, has been obtained by the reaction of 3-phenyl-2*H*-azirine with dimethylsulfonium methylide in dry THF at -10 °C (eq 17).[2]

(17)

Alkene Formation.

Dimethylsulfonium methylide reacts with benzyl chloride in the presence of excess amount of base to give styrene (eq 18).[1d]

(18)

Related Reagents.

Dimethylsulfoxonium Methylide.

Dimethyl Sulfoxide[1]

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide · (MW 78.13)

(polar aprotic solvent: acidity scale;[2] displacement reactions;[3-11] dealkoxycarbonylations;[12-21] oxidations[22-31])

Alternate Name: DMSO.

Physical Data: mp 18.4 °C; bp 189 °C; *d* 0.917 g cm^{-3}.

Solubility: miscible with water and numerous organic solvents in all proportions.

Form Supplied in: colorless, odorless liquid; widely available. *Drying:* anhyd material available by vacuum distillation from calcium hydride.

Handling, Storage, and Precautions: is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with ***Potassium Permanganate*** solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C.

Solvent.

Acidity Scale.

Equilibrium acidities for numerous compounds in DMSO (pK_a = 35.1) as the solvent have been determined. These acidities provide fundamental data for the evaluation of electronic and steric effects which occur on structural modification in organic molecules. The comparison of structural effects of acidities in DMSO with those found in the gas-phase are important in understanding solvation effects.[2]

Displacement Reactions.

Regiospecific displacement reactions are fundamental synthetic procedures for functional group interconversions. Although the rates of nucleophilic displacement reactions are dependent on solvent, substrate structure, nucleofuge, and nucleophile, the particular property of DMSO (and other polar aprotic solvents) is partially based on its ability to solvate cationic species. In effect, this leads to a less solvent-encumbered and more nucleophilic anion than in protic media.[3] The order of anion nucleophilicity can be reversed in the change from a protic solvent ($I^- > F^-$) to DMSO ($F^- > I^-$). Numerous nucleophiles such as acetylides, azide, cyanide, halides, carboxylates, hydroxide, and alkoxides have been used in DMSO for displacement reactions. Hydroxide and alkoxide anions exhibit a dramatic enhancement in basicity in DMSO relative to protic media.

Representative displacements (S_N2) are the conversion of the ditosylate to the dichloride (eq 1)[4] and the formation of large-ring macrocycles by intramolecular cyclizations of o-bromocarboxylic acids (eq 2).[5]

(1)

(2)

$n = 10$, 79-83%
$n = 14$, 95%
$n = 16$, 95%

Monosubstituted aryl fluorides can be prepared via S_NAr displacements of chloride from activated aryl chlorides (eq 3).[6]

(3)

R = H, Cl, CO_2Me, COPh, CN

The N-benzylation of indole was readily accomplished by treatment with ***Benzyl Bromide*** in the presence of ***Potassium Hydroxide*** in DMSO at rt.[7]

Since the cyanide group is a synthon for a carboxyl group and related derivatives, cyanations in DMSO are valuable synthetic transformations for the conversions of appropriate alkyl halides or tosylates to nitriles.[8] The conversion of a chiral propyl tosylate to a chiral nitrile has been reported (eq 4).[9]

(4)

Neutral nucleophiles such as amines in DMSO effect faster displacements than in comparable reactions performed in protic media.[10] Treatment of an α-bromo ester with ***Ammonia*** in DMSO at rt yielded the α-amino ester (eq 5).

(5)

Sodium Borohydride in DMSO is an effective source of hydride anion for reductive displacements of halide or sulfonate groups.[11] The selective removal of halide in the presence of an ester functionality was shown in the reduction of ethyl 2-bromohexanoate to ethyl hexanoate (86% yield, $NaBH_4$, DMSO, 15 °C, 0.75 h).

Dealkoxycarbonylations.

Activated substrates such as malonate esters (see ***Ethyl Malonate***), β-keto esters (see ***Ethyl Acetoacetate***), and α-cyano esters (see ***Ethyl Cyanoacetate***) find extensive utility in synthesis. The presence of these types of functionality lowers the pK_a of the adjacent C-H bond, and deprotonation can be effected by relatively weak and inexpensive bases. The regioselective C-alkylation (or treatment with other electrophilic agents) of these enolates leads to the incorporation of a new C-C bond. The regiospecific substitution of the alkoxycarbonyl group by hydrogen (or other groups such as alkyl) is then desirable. Traditionally, this transformation has been performed via a basic or acidic hydrolysis of the substrate followed by thermolysis of the resultant diacid or acid. In commencing from malonate esters, a reesterification is then necessary to obtain the monoester. Substrates which bear other acidic or base-sensitive groups cannot be utilized in the hydrol ysis-decarboxylation procedure.

A useful methodology for the dealkoxycarbonylations of malonate esters, β-keto esters, α-cyano esters and α-alkyl- or arylsulfonyl esters to prepare esters, ketones, nitrile, and sulfonyl analogs, respectively, has recently been developed.[12] This preparative procedure simply involves heating the substrate with water, or with water with added salts in a polar aprotic solvent such as DMSO (other aprotic solvents such as ***N,N-Dimethylformamide*** or ***Hexamethylphosphoric Triamide*** have found some use). Many salts have been utilized including sodium chloride, ***Lithium Chloride***, ***Sodium Cyanide***, and magnesium chloride.[12] The mechanistic pathways for the dealkoxycarbonations are highly dependent on substrate structure.

Some monosubstituted malonate esters and β-keto esters undergo dealkoxycarbonylation in water-DMSO (eq 6). Selective dealkoxycarbonylations have been found for mixed malonate esters.[12b]

(6)

(a) R = Et
(b) R = *t*-Bu

(a) DMSO, H_2O, LiCl; 60%
no LiCl; 10%
(b) R = DMSO, H_2O, 60%

The synthetic utility of the DMSO/salt/water dealkoxycarbonylations can be illustrated by some recent applications. In a total synthesis of racemic β-vetivone, the chemoselective demethoxycarbonylation of a β-keto ester in the presence of another ester functionality was readily accomplished (eq 7).[13] The silyl protective group was stable to the reaction conditions.

(7)

The demethoxycarbonylation of a β-keto ester led to racemic β-vetivone and epi-β-vetivone, from which pure racemic β-vetivone could be obtained by chromatography (eq 8).

In synthetic pathways to chiral α- and β-cuparenones, the demethoxycarbonylation of a β-keto ester in the presence of a benzyl ester was performed using ***Sodium Iodide*** in DMSO (eq 9).[14]

In a synthetic route leading to carbovir, the deethoxycarbonylation of a substituted α-nitro acetate analog was successful (eq 10).[15]

(10)

In a route to furanoid terpenes (eq 11)[16] and in a synthetic step leading to the pheromone of the monarch butterfly (eq 12)[17], substituted malonate esters have been readily demethoxycarbonylated.

(11)

(12)

The chemoselective removal of the malonate ester from a triester has been reported (eq 13).[18]

(13)

The demethoxycarbonylation of a phenyl sulfoxide substituted cyclopropyl malonate ester was reported to occur with 100% (*E*) diastereoselectivity (eq 14).[19]

(14)

In a pathway to erythrina alkaloids, a β-keto ester was deethoxycarbonylated with magnesium chloride in DMSO (eq 15).[20]

(15)

The deethoxycarbonylation of an α-cyano ester was also readily accomplished (eq 16).[21]

(16)

Oxidations.

The conversions of alkyl halides or tosylates to the corresponding aldehydes or ketones using DMSO as the oxidizing agent has found some synthetic application.[22] Reactive halides or tosylates react with DMSO, initially forming the *O*-alkyl analogs which generally rearrange to the more stable oxosulfonium salts. If the *O*-alkyl intermediates undergo a facile elimination of dimethyl sulfide, carbonyl compounds are formed. This methodology was discovered by Kornblum and co-workers, who reported that α-bromo ketones were transformed into α-keto aldehydes by treatment with DMSO at rt.[23] Other investigators reported similar transformations.[24]

Benzyl halides are readily converted on heating in DMSO into the corresponding aldehydes (eq 17).[25]

(17)

Benzylic tosylates can be converted to the corresponding aldehydes by treatment with DMSO in the presence of sodium bicarbonate at 100 °C for 5 min. Saturated primary halides can be converted to the tosylates and then oxidized by treatment with DMSO at 150 °C for a short period.[23b]

Although simple alkyl chlorides or bromides are inert to DMSO even at high temperatures, the conversion of 3-bromonortricyclene to nortricyclanone (69%) was accomplished by treatment with ***Silver(I) Tetrafluoroborate*** in DMSO for 1 h at rt followed by addition of ***Triethylamine***.[26] This silver-assisted DMSO oxidation procedure was studied more extensively and is a useful procedure for the synthesis of aldehydes and some ketones.[27] The conversion of 1-bromobutane to butanal (83%) can be effected by a solution of $AgBF_4$ in DMSO at room temperature.

Since the direct oxidation of aliphatic iodides can be accomplished using DMSO and sodium bicarbonate at 150 °C,[28] the oxidation of alkyl chlorides or bromides with DMSO has been performed in the presence of ***Sodium Iodide***.[29] For example, treatment of 1-chloro- or 1-bromooctane with DMSO in the presence of sodium bicarbonate and NaI and heating the mixture at 105-115 °C for 1-2 h leads to octanal (73 and 60%, respectively).

Benzylamine hydrobromides and benzyl trialkyl quaternary salts can be oxidized to the corresponding aldehydes by DMSO.[30] The oxidation of benzylamine hydrobromide with DMSO at 100-160 °C yielded benzaldehyde (95%).

The oxidation of aryl- or alkyl-substituted oxiranes by DMSO in the presence of molecular sieves and a catalytic amount of ***Trifluoroacetic Acid*** leads to α-hydroxy ketones (eq 18).[31]

A. Paul Krapcho

Dimethyl Sulfoxide-Acetic Anhydride[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Acetic Anhydride · (MW 78.13) (Ac_2O)

[108-24-7] · $C_4H_6O_3$ · Dimethyl Sulfoxide-Acetic Anhydride · (MW 102.09)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields with variable amounts of byproduct methylthiomethyl ethers)

Alternate Name: Albright-Goldman reagent.

Physical Data: DMSO mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. Ac_2O: mp -78 °C; bp 138-140 °C; *d* 1.082 g cm^{-3}.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. Ac_2O: sol ether, acetone, CH_2Cl_2.

Form Supplied in: colorless liquids; widely available, including anhydrous grades of DMSO packed under N_2.

Preparative Method: the active reagent, presumably Me_2+SOAc, forms slowly from a mixture of the coreactants over a period of hours at rt and reacts with the alcohol in situ.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves. Ac_2O: distillation from aluminum chloride or calcium carbide.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] ***Acetic Anhydride*** is a corrosive lachrymator.

The title reagent is useful for the oxidation of primary or secondary alcohols to aldehydes and ketones, respectively, at rt without added base. The reagents are inexpensive and the procedure is adaptable to large-scale reactions, such as the oxidation of yohimbine on a 2.5 mol scale.[3] The mechanism of this reaction appears to involve formation of activated DMSO by the rather slow reaction of DMSO with Ac_2O at rt to form the acyloxysulfonium ion (**1**); this then reacts with the alcohol to give the alkoxysulfonium ion (**2**) (eq 1). By analogy to other DMSO-based oxidations, (**2**) undergoes deprotonation to (**3**), which forms the oxidation product intramolecularly (eq 2).[1a,b] A common side reaction of alcohols ROH with activated DMSO is formation of methylthiomethyl ethers $ROCH_2SMe$ (**4**), which probably arise from dissociation of (**3**) or some other activated form of DMSO to form (**5**) due to the operational temperature of 25 °C and the long reaction times (12-24 h) (eq 3). Alternatively, (**5**) could be formed by an intramolecular proton abstraction in (**1**) via a six-membered transition state. The effect of pressure on the reaction has been examined, and the large negative entropy of activation is consistent with an associative mechanism.[4] The reaction is also greatly accelerated by pressure when carried out on a preparative scale.[4] Some examples of the procedure are shown in eqs 4-6.[5a,b,c]

$$Me_2SO + Ac_2O \longrightarrow \underset{(1)}{Me_2\overset{+}{S}O_2CMe} \xrightarrow{R^1R^2CHOH} \underset{(2)}{R^1R^2CHO\overset{+}{S}Me_2} \qquad (1)$$

$$(2) \xrightarrow{base} \underset{(3)}{R^1R^2CHO\overset{+}{S}MeCH_2^-} \longrightarrow R^1R^2CO + Me_2S \qquad (2)$$

$$(3) \longrightarrow \underset{(5)}{MeSCH_2^+} \xrightarrow{ROH} \underset{(4)}{ROCH_2SMe} \qquad (3)$$

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Dicyclohexylcarbodiimide · (MW 78.13) (DCC)

[538-75-0] · $C_{13}H_{22}N_2$ · Dimethyl Sulfoxide-Dicyclohexylcarbodiimide · (MW 206.33)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields with variable amounts of byproduct methylthiomethyl ethers)

Alternate Name: DMSO-DCC; Pfitzner-Moffatt reagent.

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. DCC: mp 34-35 °C; bp 122-124 °C/6 mmHg.

Solubility: DMSO: sol H_2O, alcohol, acetone, CH_2Cl_2, THF.

Form Supplied in: DMSO is a colorless liquid that is widely available, including anhydrous grades of 99%+ purity and <0.005% H_2O under N_2; DCC is a low-melting but crystalline solid that is widely available.

Preparative Method: the active oxidant, $CyNHC(O{+}SMe_2)NCy$, is generated in the presence of the alcohol substrate by the reaction of DCC, an acid, and pyridine, and reacts with the alcohol in situ.

Purification: DMSO: distillation from CaH_2 at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3&AAring; molecular sieves. DCC: distillation at reduced pressure.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] ***1,3-Dicyclohexylcarbodiimide*** is moisture sensitive and should be dry, crystalline material, otherwise it can be

distilled at 140 °C/5 mmHg;[4a] it is toxic and corrosive and should be handled with gloves in a fume hood.

The title reagent was the first of the activated DMSO reagents to be developed,[3] and offers the advantage not shared by many oxidizing methods of giving rapid oxidation at rt, without problems of overoxidation to give carboxylic acids. The disadvantages of the reagent are that the yields, though good, are not excellent, methylthiomethyl ethers occur as byproducts, and removal of the byproduct dicyclohexylurea can be a problem. The reaction mechanism has subtle differences from those of other DMSO-based oxidations and has been thoroughly documented by isotopic studies.[1a,g] The first step involves catalysis by acids such as ***Phosphoric Acid*** or ***Trifluoroacetic Acid*** in the presence of ***Pyridine*** (eq 1). Intramolecular proton abstraction via (**2**) is unique to this process, providing the ylide (**3**) (eq 2) common to all DMSO-based alcohol oxidations, which gives the carbonyl product by an intramolecular process (eq 3). In addition to previously summarized mechanistic studies, the effect of pressure on this reaction has also been examined, and the negative activation volume is consistent with an associative process.[2d]

$$CyNHC(O\overset{+}{S}Me_2)=NCy \quad (1)$$

$$CyNHCONHCy + Me\overset{+}{S}(OCHR^1R^2)CH_2^- \quad (2)$$

(3)

(3)

Some typical examples of this process are shown in eqs 4 and 5.[4] Water-soluble[4c] and polymeric[4d] carbodiimides have also been utilized to assist in the separation of the product from the product urea. Other recent examples shown include oxidation of a nucleoside (eq 6),[4e] formation of an α-hydroxy ketone (eq 7),[4f] and formation of a diketone (eq 8).[4g] Elimination occurs in substrates sensitive to the acidic conditions (eq 9).[4h]

(5)

In the procedure of eq 10 the crude aldehyde from the first step was subjected directly to allylboration with (*E*)-crotyldiisopinocampheylborane (see ***B-Crotyldiisopinocampheylborane***) to give the product in 70% yield for the two steps.[5a] The product aldehydes have also been used in Wittig homologations; prior isolation of the aldehydes is required.[5b,c]

Dimethyl Sulfoxide-Iodine

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Iodine · (MW 78.13) (I_2)

[7553-56-2] · I_2 · Dimethyl Sulfoxide-Iodine · (MW 253.81)

(oxidant with diverse applicability, including the conversion of benzoyl methylene groups to di- and triketones, thioacetals to carbonyl compounds, and ketones to α,β-unsaturated ketones)

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. I_2: mp 113 °C; bp 184 °C; *d* 4.930 g cm^{-3}.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. I_2: sol ether, $CHCl_3$, CS_2, aq soln HI.

Form Supplied in: DMSO is a colorless liquid; widely available, including anhydrous grades of 99%+ DMSO packed under N_2. I_2 is a widely available crystalline solid.

Preparative Methods: the actual reagent may differ from one reaction to another, and the specific procedures also differ.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg[1a] or 83-85 °C/17 mmHg;[1b] storage over 3Å molecular sieves. I_2: sublimation.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[1c] ***Iodine*** is corrosive and toxic.

The formation of dicarbonyl compounds by this reagent is a variation of the Kornblum oxidation[2] and presumably involves acid-catalyzed iodination of the carbonyl compound (**1**) to give an α-iodo ketone (**2**) which undergoes displacement by DMSO to give an alkoxysulfonium ion (**3**); this gives a dicarbonyl compound (**4**) in a 1,2-elimination with assistance by base (eq 1).[3a]

Reaction of the flavanone (**5**) to give (**6**) presumably involves an α-iodo ketone which undergoes elimination (eq 2).[3b] The ethylene thioacetal of cyclohexanone gives cyclohexanone (eq 3),[3c] and phosphine sulfides and selenides give the oxo analogs (eq 4).[3d]

Dimethyl Sulfoxide-Methanesulfonic Anhydride[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Methanesulfonic Anhydride · (MW 78.13) (Ms_2O)

[7143-01-3] · $C_2H_6O_5S_2$ · Dimethyl Sulfoxide-Methanesulfonic Anhydride · (MW 174.20)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields with minimal amounts of byproduct methylthiomethyl ethers)

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. Ms_2O: mp 69-70 °C; bp 125 °C/4 mmHg.

Solubility: DMSO: sol H_2O, alcohol, acetone, CH_2Cl_2, THF. Ms_2O: reacts H_2O; sol CH_2CH_2, THF.

Form Supplied in: DMSO is a colorless liquid that is widely available, including anhydrous grades of 99+% purity packed under N_2; Ms_2O is a crystalline solid that is widely available.

Preparative Method: the active oxidant is presumably Me_2+SOMs, and is generated in situ by adding Ms_2O to the alcohol in DMSO-HMPA.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg,[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] ***Methanesulfonic Anhydride*** is corrosive and moisture-sensitive.

DMSO-Ms_2O is occasionally used for the oxidation of primary and secondary alcohols to aldehydes and ketones,

respectively, and gives good yields of products with minimal formation of byproducts (eq 1).[3a,b] The use of the toxic ***Hexamethylphosphoric Triamide*** in some procedures is a disadvantage.[3a,b]

Reaction of the L-tryptophan derivative (**1**) with DMSO-Ms_2O gave (**2**) (eq 2).[3c]

Dimethyl Sulfoxide-Oxalyl Chloride[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Oxalyl Chloride · (MW 78.13) ($(COCl)_2$)

[79-37-8] · $C_2Cl_2O_2$ · Dimethyl Sulfoxide-Oxalyl Chloride · (MW 126.93)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields with minimal amounts of byproduct methylthiomethyl ethers)

Alternate Name: Swern reagent.

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. $(COCl)_2$: bp 63-64 °C/763 mmHg; *d* 1.455 g cm^{-3}.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. $(COCl)_2$: reacts H_2O; sol CH_2Cl_2, THF.

Form Supplied in: colorless liquids; widely available, including anhydrous grades of 99%+ DMSO packed under N_2, and 2M $(COCl)_2$ in CH_2Cl_2 under N_2.

Preparative Method: the active reagent, Me_2+SCl, is formed rapidly from DMSO-$(COCl)_2$ at -78 °C in CH_2Cl_2.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves. $(COCl)_2$: distillation under N_2.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] ***Oxalyl Chloride*** is corrosive and moisture-sensitive, and is said to react explosively with DMSO at rt.

DMSO-oxalyl chloride is the most widely used of the DMSO-based reagents for the oxidation of primary and secondary alcohols to aldehydes and ketones, respectively, and usually gives excellent yields with short reaction times and minimal formation of byproducts.[3] The active reagent (**1**) is generated in situ at low temperature by the addition of DMSO to $(COCl)_2$ in a solvent such as CH_2Cl_2, ether, or THF (eq 1). Addition of the alcohol to (**1**) gives the alkoxysulfonium ion (**2**) (eq 2), which on addition of an amine base is deprotonated to (**3**); the latter forms the carbonyl product (**4**) by intramolecular proton abstraction (eq 3).

$$Me_2S{=}O + (COCl)_2 \longrightarrow \underset{\textbf{(1)}}{Me_2\overset{+}{S}Cl\ Cl^-} + CO + CO_2 \qquad (1)$$

$$\textbf{(1)} + RR^1CHOH \longrightarrow \underset{\textbf{(2)}}{RR^1CHO\overset{+}{S}Me_2} \qquad (2)$$

$$\textbf{(2)} + \text{base} \longrightarrow \underset{\textbf{(3)}}{RR^1CHO\overset{+}{S}(Me)CH_2^-} \longrightarrow \underset{\textbf{(4)}}{RR^1C{=}O} + Me_2S \qquad (3)$$

In a typical procedure using ***Triethylamine*** as base, DMSO (2.4 equiv) is added to $(COCl)_2$ (1.2 equiv) in CH_2Cl_2 cooled to -50 to -60 °C, and then geraniol (**5**) (1.0 equiv) is added, followed by Et_3N (5 equiv). Washing and distillation give geranial (**6**) in 94% yield (eq 4).[4a] The sensitive alcohol (**7**) is oxidized to the aldehyde (**8**) in 83% yield, with less than 8% racemization (eq 5).[4b] The use of ***Diisopropylethylamine*** (DIPEA) as the base helps prevent epimerization (eq 6).[4c] This procedure has been applied on a 1 mol scale in a conversion that gave only a 40% yield with ***Chromium(VI) Oxide*** and H_2SO_4 (eq 7).[4d]

(5) (6) (4)

(5)

PMBOM = 4-MeOC$_6$H$_4$CH$_2$OCH$_2$

(6)

(7)

Diols are efficiently oxidized by this procedure (eqs 8 and 9),[4e,f] and selectivity for oxidation of less crowded hydroxy groups can be achieved (eq 10).[4g,h] Isolation of the ketoaldehyde (**10**) from oxidation of (**9**) proved difficult, so oxidation using the stronger base ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** was employed to give (**11**) directly from (**9**) (eq 11).[4i] Aryl dimethanols are oxidized to *ortho*-phthalaldehydes.[4j]

(10)

DMSO activated by $(COCl)_2$ without the addition of base has also been used for the conversion of β-triketides such as (**12**) to γ-pyrones (**13**) (eq 12).[5] A mechanism was proposed in which DMSO was regenerated (eq 13). In the presence of Et_3N the formation of (**14**) (30%) along with (**13**) (33%) was attributed to the intermediate (**15**) (eq 14).[5]

(15) **(14)** 30%

Examples of oxidation of alcohols to carbonyl compounds by DMSO-$(COCl)_2$ followed by in situ reaction of the product with another reagent include the use of alkynyllithiums (eq 15),[6a] Wittig reagents (eq 16),[6b] and Mannich reagents (eq 17).[6c] Extraction of the crude product followed by reaction with ***Hydroxylamine*** gives oximes (eq 18),[6d] and oxidation in the presence of MeOH gave an ester (eq 19).[6e]

(17)

(18)

(19)

The sequence of eqs 20 and 21 illustrates the use of consecutive Swern oxidations and further conversions.[6f] Reaction of trimethylsilylallyl alcohol on a 0.3 mol scale gave the ketone in 78% yield (eq 22).[6g]

Trimethylsilyl and triethylsilyl ethers are oxidized to carbonyl products by DMSO-$(COCl)_2$, but *t*-butyldimethylsilyl, *t*-

butyldiphenylsilyl, and *t*-butoxydiphenylsilyl ethers are not (eq 23).[7a-d] Chloride attack on silicon is thought to assist the reaction.[7b] Primary triethylsilyl ethers are selectively oxidized by DMSO-$(COCl)_2$ in the presence of tertiary triethylsilyl ethers (eq 24).[7e] This subject has been reviewed.[7f]

(23)

(24)

Elimination can occur from the carbonyl products resulting from oxidation of sensitive substrates (eq 25).[8]

(25)

Allylic alcohols can be converted to chlorides by treatment with DMSO-$(COCl)_2$ without the use of added base, presumably by chloride displacement of DMSO from the alkoxysulfonium ion (eq 26).[9a,b] DMSO-$(COCl)_2$ also acts as an electrophilic chlorinating reagent toward ketones (eq 27).[9c] Oxidation to the nonchlorinated ketone was achieved with ***Dimethyl Sulfoxide-Acetic Anhydride***.[9c]

(26)

Oxidation of diaziridines with DMSO-$(COCl)_2$ gives diazirines (eq 28),[10a] and dibenzylamine gives partial conversion to an imine (eq 29).[10b]

A related reagent for the activation of DMSO for oxidation of alcohols is ***Phenyl Dichlorophosphate*** ($PhOP(O)Cl_2$),[11a-c] which is more effective than DMSO-$(COCl)_2$ in the oxidation of benzyl alcohol (eq 30).[11a] Cyanuric chloride also activates DMSO for oxidation of alcohols.[11d]

Dimethyl Sulfoxide-Phosgene[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Phosgene · (MW 78.13) ($COCl_2$)

[75-44-5] · CCl_2O · Dimethyl Sulfoxide-Phosgene · (MW 98.92)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; because of the high toxicity of phosgene and the absence of any clear advantages, the use of this procedure is not recommended)

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. $COCl_2$: bp 8.2 °C/760 mmHg; *d* 1.432 g cm^{-3} (4 °C).

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. $COCl_2$: reacts slowly H_2O; sol CH_2Cl_2, THF, benzene.

Form Supplied in: DMSO is a colorless liquid; widely available, including anhydrous grades of DMSO packed under N_2; $COCl_2$ is a gas available in cylinders.

Preparative Method: the active reagent is proposed[2] to be $(CH_3)_2{+}SOCO_2CHRR^1$, formed from the reaction with DMSO of the chloroformate RR^1CHO_2CCl separately generated from phosgene and the alcohol.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg,[3a] or 83-85 °C/17 mmHg;[3b] storage over 3Å molecular sieves. $COCl_2$: distillation.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[3c] ***Phosgene***, also known as carbonic dichloride, is corrosive, moisture sensitive, and highly toxic, and

should only be used with extreme caution.

In this procedure, chloroformates are generated from $COCl_2$ and the alcohols are proposed to react with DMSO to form dimethylsulfonium salts (**2**) via decarboxylation of the intermediates (**1**) (eqs 1 and 2). This procedure has been used in the oxidation of various alcohols, including steroids, in 20-80% yields.[2] The use of 1,2-epoxypropane as an acid scavenger in the process has been suggested.[2b] This procedure is inconvenient and dangerous, and offers no apparent advantages.

Dimethyl Sulfoxide-Phosphorus Pentoxide[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Phosphorus Pentoxide · (MW 78.13) (P_2O_5)

[1314-56-3] · O_5P_2 · Dimethyl Sulfoxide-Phosphorus Pentoxide · (MW 141.95)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; modified procedure gives very good yields with short reaction times at 0 °C with minimal formation of byproducts; inexpensive).

Alternate Name: Onodera reagent.

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. P_2O_5: sublimes 360 °C/760 mmHg.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. P_2O_5: sol H_2O.

Form Supplied in: DMSO is a colorless liquid; widely available, including anhydrous grades of DMSO packed under N_2; P_2O_5 (more accurately P_4O_{10}) is a white crystalline solid; widely available.

Preparative Method: the active oxidant, formulated as $Me_2{+}SO(P_2O_5)^-$, is generated in situ from the reaction of DMSO and P_2O_5 in the presence of the alcohol.

Purification: DMSO: distillation from CaH_2 at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves. P_2O_5: sublimation.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] ***Phosphorus(V) Oxide*** is corrosive and a strong desiccant.

DMSO-P_2O_5 has long been used,[3a] but the early procedures involved elevated temperatures with no added base, and required long reaction times, as in the example of eq 1.[3b] This procedure has been used in conjunction with a reduction step for the inversion of hydroxy group configuration (eq 2).[3c] More recently the addition of ***Triethylamine*** base permits shorter reaction times and lower temperatures, but dry ice temperatures are not required, and this can be an advantage relative to the use of ***Dimethyl Sulfoxide-Oxalyl Chloride*** (eq 3).[4] The DMSO and P_2O_5 react to form $Me_2{+}SO(P_2O_5)^-$, which reacts in situ with the alcohol ROH to give the alkoxysulfonium ion $Me_2{+}SOR$ common to most oxidations by activated DMSO.

Dimethyl Sulfoxide-Silver Tetrafluoroborate

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Silver Tetrafluoroborate · (MW 78.13) ($AgBF_4$)

[14104-20-2] · $AgBF_4$ · Dimethyl Sulfoxide-Silver Tetrafluoroborate · (MW 194.68)

(reagent for conversion of alkyl halides to aldehydes and ketones)

Physical Data: DMSO: mp 18.55 °C; bp 189 °C/760 mmHg; 76 °C/16 mmHg; *d* (25 °C) 1.0958 g cm^{-3}; dielectric constant (25 °C) 46.7. $AgBF_4$: mp 200 °C.

Solubility: DMSO: miscible with water and most organic solvents. $AgBF_4$: sol water, ether, toluene, nitromethane, DMSO; moderately sol benzene and cyclohexane.

Form Supplied in: DMSO: clear anhyd liquid, widely available. $AgBF_4$: crystalline white solid, widely available. *Drying:* DMSO: generally quite dry when freshly opened, but very hygroscopic; distill from CaH_2 under reduced pressure. $AgBF_4$: very hygroscopic; dry in vacuo at 80 °C.

Handling, Storage, and Precautions: see ***Dimethyl Sulfoxide*** and ***Silver(I) Tetrafluoroborate***.

Silver-assisted nucleophilic displacement of halide to form an alkoxysulfonium ion, followed by deprotonation, most commonly by ***Triethylamine***,[1] effectively converts benzylic and allylic halides and some primary[1b] and secondary alkyl halides[1a,b,f,5] to the corresponding aldehydes or ketones at room temperature (eq 1,[1d] eq 2,[1e] eq 3,[1f] and eq 4[1j]). While avoiding the higher temperatures generally required by the Kornblum method[2] ($NaHCO_3$ (+NaI[3]), DMSO, 100-150 °C), the silver-assisted reaction has the disadvantage of higher cost. Most oxidations have been accomplished with silver tetrafluoroborate; however, there are successful examples which used ***Silver(I) Nitrate***[4] or hexafluorophosphate.[5] The same type of conversion has been accomplished with trialkylamine oxides,[6] ion-exchange polymer-bound chromate ion,[7] the classical Sommelet reaction,[8] and other methods.[9] Oxidation of the corresponding alcohols is the obvious alternative.[1e,k] On the other hand, bromination of an allylic or benzylic methyl group with ***N-Bromosuccinimide*** followed by DMSO-$AgBF_4$ oxidation[1h,i,j] is a useful substitute for direct oxidation of the

hydrocarbon.[10]

Typically, a solution of 1 mmol of halide (usually bromide or iodide) and 1.1-2.0 mmol of silver salt in 1-5 mL of DMSO is stirred at rt for 10 min to 24 h. Excess triethylamine is then added, the mixture is stirred for an additional 15 min and diluted with water. The product is isolated in the usual fashion. Several examples are given in Table 1.[1a,1b]

Table 1 Syntheses Employing DMSO-$AgBF_4$

Halide	Product	Yield (%)
		83 (0) [1b]
		80 [1b]
		90 [1b]
		69 [1a]

Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine · (MW 78.13) (SO_3)

[7446-11-9] · O_3S · Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine · (MW 80.06) (SO_3/pyridine)

[26412-87-3] · $C_5H_5NO_3S$ · Dimethyl Sulfoxide-Sulfur Trioxide/Pyridine · (MW 159.16)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; gives very good yields with short reaction times near rt with minimal formation of byproducts)

Alternate Name: Parikh-Doering reagent.

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. SO_3: mp 16.8 °C; bp 44.7 °C; *d* 1.970 g cm^{-3}. SO_3/pyridine: mp 175 °C.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. SO_3: reacts with H_2O. SO_3/pyridine: sol DMSO; reacts with H_2O.

Form Supplied in: DMSO is a colorless liquid; SO_3 is a low-boiling liquid, and the SO_3/pyridine complex is a crystalline solid; widely available, including SO_3/pyridine complex and anhydrous grades of DMSO packed under N_2. For the preparation of SO_3/pyridine complex see ***Sulfur Trioxide-Pyridine***.

Preparative Method: the active oxidant, formulated as $Me_2{+}SOSO_3^-$,[2d] is generated in situ by mixing DMSO and the SO_3/pyridine complex.

Purification: DMSO: distillation from CaH_2 at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; ***Sulfur Trioxide*** and SO_3/pyridine are toxic and corrosive, and react strongly with H_2O; reactions with DMSO form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide and dimethyl sulfone above 90 °C.[2c]

DMSO-SO_3/pyridine[3a] is a convenient oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively. The complex $Me_2{+}SOSO_3^-$ evidently forms on mixing DMSO and SO_3/pyridine, and upon addition of the alcohol and ***Triethylamine*** this forms the $RO{+}SMe_2$ species common to most DMSO oxidations; this alkoxysulfonium ion then reacts with added Et_3N, leading to the carbonyl product. This procedure involves operation near rt, which can be an advantage relative to the use of ***Dimethyl Sulfoxide-Oxalyl Chloride*** and usually gives fast reactions and good yields with minimal formation of byproducts. Some examples are shown in eqs 1 and 2.[3b,c] Oxidation with DMSO-SO_3/pyridine avoids the side reaction of chlorination of a pyrrole nucleus encountered with DMSO/$(COCl)_2$, but it was found necessary to add the SO_3/pyridine complex as a solid and not as a DMSO solution to the alcohol in DMSO-Et_3N-THF for oxidation to occur.[3d]

(1)

(2)

In the procedure of eq 3, Et_3N and SO_3/py were added to 0.1 mol of (**1**) at 0 °C, and after stirring the solution was diluted with EtOAc, extracted, and evaporated, and the crude product was dissolved in THF and added to Wittig reagent to give (**2**).[4]

Dimethyl Sulfoxide-Trifluoroacetic Anhydride[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Trifluoroacetic Anhydride · (MW 78.13) (TFAA)

[407-25-0] · $C_4F_6O_3$ · Dimethyl Sulfoxide-Trifluoroacetic Anhydride · (MW 210.03)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields with only small amounts of byproduct methylthiomethyl ethers but alcohols can be converted to trifluoroacetate esters, particularly at higher temperatures; also used for the conversion of primary amines to sulfilimines)

Alternate Name: Swern reagent.

Physical Data: DMSO: mp 18.4 °C; bp 189 °C *d* 1.101 g cm^{-3}. TFAA: mp -65 °C; bp 39.5-40 °C; *d* 1.487 g cm^{-3}.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. TFAA: sol CH_2Cl_2, ether, THF.
Drying: DMSO: distillation from CaH_2 at 56-57 °C/5 mmHg[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves. TFAA: distillation.

Form Supplied in: colorless liquids; widely available, including anhydrous grades of DMSO packed under N_2, and 99%+ TFAA.

Preparative Method: The active reagent $Me_2{+}SO_2CCF_3$ is formed rapidly on the addition of TFAA to DMSO in CH_2Cl_2 at -78 °C, and is used in situ.

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; reactions with DMSO form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C on distillation at atmospheric pressure;[2c] ***Trifluoroacetic Anhydride*** is toxic, corrosive, and water-sensitive, and reacts

violently with DMSO at rt.

DMSO-TFAA is commonly used for the oxidation of primary and secondary alcohols to aldehydes and ketones, respectively, and usually gives excellent yields with short reaction times and minimal formation of byproducts. The active reagent (**1**) is generated in situ at low temperature by the addition of TFAA to DMSO in a solvent such as CH_2Cl_2 (eq 1).[3a-c] Addition of the alcohol to (**1**) gives the alkoxysulfonium ion (**2**) (eq 2), which on addition of an amine base is deprotonated to (**3**); the latter forms the carbonyl product (**4**) by intramolecular proton abstraction (eq 3). Trifluoroacetates are sometimes byproducts in these reactions, but the use of ***Trichloroacetic Anhydride*** instead of TFAA prevents this problem.[3d]

$$Me_2S{=}O + (CF_3CO)_2O \longrightarrow \underset{\textbf{(1)}}{Me_2\overset{+}{S}O_2CCF_3\ CF_3CO_2^-} \qquad (1)$$

$$\textbf{(1)} + RR^1CHOH \longrightarrow \underset{\textbf{(2)}}{RR^1CHO\overset{+}{S}Me_2} \qquad (2)$$

$$\textbf{(2)} \xrightarrow{\text{base}} \underset{\textbf{(3)}}{RR^1CHO\overset{+}{S}MeCH_2^-} \longrightarrow \underset{\textbf{(4)}}{RR^1C{=}O} + Me_2S \qquad (3)$$

The examples shown in eq 4[4a] and eq 5[4b] illustrate the preparation of ketones in good yield with this reagent, while eq 6,[4c] eq 7,[4d] and eq 8[4e] show the oxidation of diols. The example of eq 6 gave only a 25% yield with ***Oxalyl Chloride*** activation.[4c] In the reaction of eq 8, ring opening and elimination of HBr also occurs.[4e] The addition of 2-propanol has been used to quench excess oxidant in this procedure.[4f]

(4)

(5)

(6)

(7)

(8)

The title reagent can react with electron-rich aromatic compounds to give aryldimethylsulfonium salts (eq 9).[5a] DMSO and ***Trifluoroacetic Acid*** (TFA) oxidize sulfides to disulfides, and the activation of the DMSO in this case was proposed to occur by protonation of the DMSO (eq 10).[5b] Oxidations with DMSO-TFAA followed by ***Triethylamine*** can result in formation of the byproduct (**5**), which is suggested to arise by a single electron transfer process (eq 11).[4c] Activation of DMSO by TFAA for oxidation of a dithiane avoids the problem of dithiane monosulfoxide formation encountered with $(COCl)_2$ activation.[5c] Sulfilimines are formed by reaction of DMSO-TFAA with primary amines (eq 12).[1e,5d]

Dimethyl Sulfoxide-Triphosgene[1]

(DMSO)

[67-68-5] · C_2H_6OS · Dimethyl Sulfoxide-Triphosgene · (MW 78.13) ($(CCl_3O)_2CO$)

[32315-10-9] · $C_3Cl_6O_3$ · Dimethyl Sulfoxide-Triphosgene · (MW 296.75)

(oxidant for the conversion of primary and secondary alcohols to aldehydes and ketones, respectively; avoids overoxidation to carboxylic acids; suitable for large-scale oxidation; gives good yields of high-purity products; more convenient than the use of phosgene)

Physical Data: DMSO: mp 18.4 °C; bp 189 °C; *d* 1.101 g cm^{-3}. $(CCl_3O)_2CO$: bp 203-206 °C; mp 79-83 °C.

Solubility: DMSO: sol H_2O, alcohol, acetone, THF, CH_2Cl_2. $(CCl_3O)_2CO$: reacts H_2O; sol CH_2Cl_2, THF, *o*-dichlorobenzene.

Form Supplied in: DMSO: colorless liquid; widely available, including anhydrous grades of DMSO packed under N_2. $(CCl_3O)_2CO$: crystalline solid, widely available.

Preparative Method: the active reagent is not known, but may be $Me_2{+}SCl$, formed from DMSO and triphosgene at -78 °C in CH_2Cl_2, or may be $Me_2{+}SOCO_2CHRR^1$, generated after addition of the alcohol, as in the case of phosgene.

Purification: DMSO: distillation from calcium hydride at 56-57 °C/5 mmHg,[2a] or 83-85 °C/17 mmHg;[2b] storage over 3Å molecular sieves. $(CCl_3O)_2CO$: drying at 0.1 mmHg.[3a]

Handling, Storage, and Precautions: ***Dimethyl Sulfoxide*** is readily absorbed through the skin and should always be handled with gloves in a fume hood; its reactions form foul-smelling byproducts and should be carried out with good ventilation, and the waste byproducts and liquids used for washing should be treated with $KMnO_4$ solution to oxidize volatile sulfur compounds; DMSO undergoes appreciable disproportionation to dimethyl sulfide (stench!) and dimethyl sulfone above 90 °C;[2c] $(CCl_3O)_2CO$ is a lachrymator, is moisture sensitive, and decomposes to ***Phosgene***; it therefore should be used with the same precautions as used for phosgene, which is highly toxic;[3b] use in a fume hood.

Triphosgene, or ***Bis(trichloromethyl) Carbonate***, is a solid reagent that is easier to handle than phosgene,[3c] and that can be used as a phosgene substitute in many applications.[3] However, triphosgene forms highly toxic phosgene on heating and should be used with due precautions.[3b] DMSO-triphosgene has been used in the oxidation of alcohols on a 0.1 M scale (eqs 1, 2).[4] The reactions are carried out by adding DMSO to triphosgene in CH_2Cl_2 at -78 °C, followed by addition of the alcohol and then ***Triethylamine***. Presumably the alkoxysulfonium ion Me_2+SOR common to most DMSO base oxidations is formed, but the mechanism has not been studied.

Thomas T. Tidwell

Dimethylsulfoxonium Methylide[1]

[6814-64-8] · C_3H_8OS · Dimethylsulfoxonium Methylide · (MW 92.16)

(widely used methylene transfer reagent; used for the epoxidation of ketones and aldehydes,[1] cyclopropanation of α,β-unsaturated carbonyl compounds[1] and also as a methylation reagent[2])

Physical Data: pK_a of sulfoxonium ion (Me_3+S(O)) at 25 °C in DMSO is 18.2;[3] mp 9-10 °C, bp 41-43 °C/0.1 mmHg.[4]

Solubility: sol THF, DMSO, 1,4-dioxane, DMF.

Preparative Method: usually generated in situ by the reaction of trimethylsulfoxonium iodide or chloride with strong base in a appropriate solvent without drying or further purification; not commercially available.

Analysis of Reagent Purity: determined by adding a small quantity of the reagent to water and titrating with standard acid using phenolphthalein as indicator.[5]

Handling, Storage, and Precautions: reactions using this nucleophilic reagent should be carried out under an inert atmosphere; it is more stable than ***Dimethylsulfonium Methylide*** and can be stored in solution under N_2 at 0 °C for months without appreciable decomposition.

Preparation.

Dimethylsulfoxonium methylide is a stabilized ylide which is generally prepared and used at rt.[1,6,7] Typically, the reagent is obtained by the reaction of finely powdered ***Trimethylsulfoxonium Iodide*** (or trimethylsulfoxonium chloride) with a strong base such as ***Sodium Hydride*** or ***n-Butyllithium*** under nitrogen in a suitable solvent. A variety of anhydrous solvents such as DMSO, THF, DMF, and 1,4-dioxane are reported to work well for this reaction. When NaH is used as the base, after hydrogen evolution has completed, the resulting ylide is ready for further reaction.[8]

Recently, a less hazardous modification for large-scale production has been reported. This method involves the reaction of ***Potassium t-Butoxide*** with trimethylsulfoxonium iodide in DMSO. Use of potassium *t*-butoxide eliminates the hazards of handling sodium hydride on a large scale, and also eliminates problems with the isolation of products which may be contaminated with the mineral oil from sodium hydride dispersions.[9] Preparation of dimethylsulfoxonium

methylide can also be achieved by using *t*-BuOK in *t*-butanol.[10] Alternatively, dimethylsulfoxonium methylide is accessible via a desilylation process.[11]

Preparations of sulfur ylides under phase-transfer catalyzed conditions have also been reported. One such system involved the use of CH_2Cl_2, ***Tetra-n-butylammonium Iodide*** (TBAI), NaOH, and trimethylsulfoxonium iodide.[12] *N*-Benzyl-*N*,*N*,*N*-trimethylammonium chloride has also been reported as an efficient catalyst for this reaction.[13] An alternative system using trimethylsulfoxonium iodide, cetrimide (cetyltrimethylammonium bromide), aqueous NaOH, and 1,1,1-trichloroethane has also been reported.[14] Usually, the phase-transfer catalyzed reactions are performed at elevated temperatures from 50 to 75 °C.

Epoxidation.

Dimethylsulfoxonium methylide is commonly used for epoxide preparation by reaction with a variety of compounds which contain an aldehyde or a ketone group (eqs 1-5).[1,3,7,8,15-19] Normally very high yields and purities of the desired epoxides are obtained. Use of trimethylsulfoxonium iodide instead of trimethylsulfonium iodide eliminates the need for removal of the noxious byproduct Me_2S. The byproduct DMSO generated from dimethylsulfoxonium methylide preparation can be readily removed by using standard organic/aqueous extractions. The reaction involves initial nucleophilic addition (dimethylsulfoxonium methylide) to the carbonyl group and subsequent elimination of DMSO and epoxide formation. Enolization usually does not compete with nucleophilic addition to the carbonyl group.[3]

(1)

(2)

(3)

(4)

(5)

Instead of using strong base in an anhydrous media, epoxides have also been prepared under phase-transfer catalysis conditions with a sulfur ylide.[12-14,20,21] Activated ***Barium Hydroxide*** was reported to catalyze the oxirane formation in interfacial solid-liquid conditions.[22,23] These reactions were performed in MeCN in the presence of $Ba(OH)_2$ with a small amount of H_2O.

The condensation of 1-tetralone with dimethylsulfoxonium methylide affords the corresponding oxirane in 75% yield.[24,25] However, if this parent ketone possesses an aromatic electron-releasing substituent such as a methoxy group, the resulting spiro-oxirane may not be stable and may readily rearrange to give ring-opened compounds.

Dimethylsulfoxonium methylide has also been employed in nucleoside preparations.[26] The reagent has been used to introduce the spiro epoxy group at the C-2´ position of 2´-keto-β-L-nucleosides. In this case, better yields of oxiranes are obtained with the use of trimethylsulfoxonium chloride instead of trimethylsulfoxonium iodide. Variation of the base used has a major effect on the course of the reaction. Only 2-L-galacto-spiro-epoxynucleoside is obtained if the dimethylsulfoxonium methylide is prepared from BuLi (eq 6).[27]

(6)

R = thyminyl, theophyllinyl

In some examples, selective epoxidations were observed in the reaction of dimethylsulfoxonium methylide with dicarbonyl compounds. Selective condensation (83% yield) of dimethylsulfoxonium methylide with the six-membered-

ring carbonyl group of *trans*-1,6-dimethylbicyclo[4.3.0]nonane-2,7-dione was observed, while the cyclopentanone remained unreacted (eq 7).[28]

(7)

The further transformation of the product epoxides to other functionalities by treatment with nucleophiles or Lewis acids has been widely reported. Epoxidation of quadricyclanone and adamantanone with dimethylsulfoxonium methylide provided spiro-oxirane products in good yields.[29,30] In the case of adamantanone, the product oxirane was further converted to the rearranged acid by reaction with ***Boron Trifluoride Etherate*** followed by oxidation with Jones' reagent (eq 8). Similarly, reaction of dimethylsulfoxonium methylide with methylheptenone followed by treatment of $BF_3.OEt_2$ provided the rearranged 2-isopropyl-5-methylcyclopentanone (eq 9).[17]

(8)

Reactions of hydroxybenzopyranones, hydroxyphenylalkanones, and 2-(*o*-hydroxyphenyl)alkyl ketones with dimethylsulfoxonium methylide provide an efficient route to oxygen heterocycles (eq 10).[31-33] The mechanism involves an intramolecular ring opening of the oxirane intermediate.

Stereoselective Epoxide Synthesis.

Dimethylsulfoxonium methylide has been reported to show higher stereoselectivity in reactions with aldehydes and ketones than its sulfonium analog. Reaction of 4-*t*-butylcyclohexanone with dimethylsulfoxonium methylide gave exclusively the *cis*-oxirane, while reaction with ***Dimethylsulfonium Methylide*** gave products with a ratio of 17:83 of the *trans* and *cis* isomers (eq 11).[1,34] Presumably the sulfoxonium ylide provided the kinetically controlled product, while the smaller sulfonium ylide gave a mixture of the kinetically and thermodynamically favored products. Similarly, epoxidation of 4-protoadamantanone with dimethylsulfoxonium methylide gave almost exclusively the *exo* isomer (*exo*:*endo* = 15:1), while the dimethylsulfonium methylide provided a mixture of the *exo* and *endo* isomers in a 3:2 ratio (eq 12).[35]

Several examples of conversion of chiral ketones and aldehydes to epoxides with high diastereomeric purity have been reported.[36-38] Stereoselective reaction of the nucleoside 2´-keto-3´,5´-*O*-(tetraisopropyldisiloxane-1,3-diyl)uridine with dimethylsulfoxonium methylide at 0 °C afforded only one isomer of the product epoxide in 63% yield.[39] Reaction of the heterocyclic carbonyl compounds with dimethylsulfoxonium methylide also provided the corresponding oxiranes, such as 1-oxa-6-heterospiro[2,5]octanes, in good yields and isomeric purities.[40,41] One example showed that dimethylsulfoxonium methylide reacted chemoselectively with the five-membered ketone ring in the presence of the six-membered carbonyl function to give the monoepoxide in good yield (eq 13).

(13)

In some cases, solvent appears to affect the stereoselectivity of the oxirane formation. Reaction of 3α,18-dihydroxy-17-noraphidicolan-16-one with dimethylsulfoxonium methylide in THF gives a 1:1 mixture of epoxides. When THF is replaced by DMSO as the solvent, the isomeric ratio is improved to 1:3. In the mixed solvent DMSO/DMI system, the ratio is further improved to 1:4.[42]

Generation of New Sulfur Ylides.

Treatment of cyclic β-chloro-substituted enones and chloropyrimidines with dimethylsulfoxonium methylide results in the formation of new sulfoxonium ylides.[43-47] Dimethylsulfoxonium methylide also reacts with acid anhydride,[48] acid chloride,[49] isocyanate,[50] and other activated carbonyl groups[51,52] to generate new sulfur ylides for further reactions. This method has been used to prepare acylated stable ylides[53] which can be converted to other products or further reacted with a second mole of the α,β-unsaturated carbonyl compounds (eqs 14-16).

(14)

(15)

(16)

Methylation.

Dimethylsulfoxonium methylide is a useful methylation reagent for the conversion of acids,[54] oximes,[55] N-heterocycles,[56] and aromatic hydrocarbons[57] to the corresponding methylated products. For example, nitrobenzene and 6-benzyladenine were methylated with dimethylsulfoxonium methylide in 67% and 63% yields (eqs 17 and 18).[2]

(17)

(18)

Preparation of Azetidine Derivatives.

N-Arylsulfonyl-2-phenylazetidines can be prepared by reaction of dimethylsulfoxonium methylide with *N*-arylsulfonyl-2-phenylaziridines in 51-72% yield.[58] Stereospecific conversion of *N*-arylsulfonylaziridines to *N*-arylsulfonylazetidines has also been reported. Reactions with *cis*-aziridines give *trans*-azetidines, and reactions with *trans*-aziridines produce the *cis*-azetidines. Presumably an S_N2 1,4-elimination mechanism is involved (eq 19).[59] Although several 2- and 2,3-substituted *N*-arylsulfonylazetidines have also been synthesized in good yields from reactions with dimethylsulfoxonium methylide, the fused azetidines could not be prepared by this procedure.[60] Dimethylsulfoxonium methylide also converts *N*-arylsulfonyloxaziridines to azetidines via a methylene transfer reaction. Similar reactions with *N*-alkyloxaziridines give only the deoxygenated product.[61]

(19)

Preparation of Oxetanes.

Dimethylsulfoxonium methylide is an efficient methylene transfer reagent in reactions with terminal epoxides to provide the corresponding oxetanes (eq 20).[10,62,63] The oxetanes can also be prepared from ketones or aldehydes with dimethylsulfoxonium methylide via double methylene transfer reactions.

(20)

Cyclopropanation.

Cyclopropanation using the Simmons-Smith conditions (see ***Iodomethylzinc Iodide***) does not work well for α,β-unsaturated carbonyl compounds. This difficulty has been overcome by the use of dimethylsulfoxonium methylide as the methylene transfer reagent. This method has been successfully applied to unsaturated ketones,[64-66] esters,[67-70] lactones,[71] amides,[72] nitriles,[73] and nitro compounds.[74,75] Dimethylsulfoxonium methylide appears to work better than the corresponding sulfonium analog in these reactions. Reaction of the sulfonium methylide with α,β-unsaturated carbonyl compounds gives the kinetically controlled 1,2-addition oxirane product,[1,66] while reaction with dimethylsulfoxonium methylide gives the 1,4-addition cyclopropane derivatives in synthetically useful yields (eqs 21-23).[64,70]

(21)

(22)

The mechanism of cyclopropanation involves an initial reversible conjugate addition of dimethylsulfoxonium methylide to the α,β-unsaturated carbonyl compound, followed by an irreversible ring closure; if excess dimethylsulfoxonium methylide is used in the reaction, epoxidation of carbonyl group may follow the cyclopropanation (eq 24).[76] Usually, the reaction is carried out in DMSO over a wide range of temperatures under an inert atmosphere. Cyclopropanation using TBAI as phase-transfer catalyst in an aqueous system was also reported.[12] Reaction of dimethylsulfoxonium methylide with fluorine-containing α,β-unsaturated ketones can result in products from different reaction pathways.[38,77,78] Reaction of dimethylsulfoxonium methylide with α-fluoro-substituted enones gives the corresponding fluoro-epoxides only.[79]

The cyclopropanated carbonyl compounds can readily be further transformed to other functionalities.[72,80,81] For example, a substituted vinyl phenyl ketone was converted to the cyclopropane intermediate with dimethylsulfoxonium methylide and the product was further transformed to a 1-tetralone derivative by acid-catalyzed cyclization.[80] The cyclopropyl amide which is derived from reaction of an α,β-unsaturated amide with dimethylsulfoxonium methylide can be further converted to a ketone or an acid derivative by reaction with an organometallic nucleophile or an anhydrous base.[72]

Cyclopropanation with dimethylsulfoxonium methylide in multifunctional compounds can be chemoselective.[66,82,83] Dimethylsulfoxonium methylide reacts preferentially with the less sterically hindered α,β-unsaturated carbonyl function to give the corresponding cyclopropane (eq 25).[65,84,85] On the other hand, reaction of dimethylsulfoxonium methylide with bifunctional cyclic enediones affords the oxirane product instead of generating the cyclopropyl derivative (eq 26).[85]

Chemoselective reaction of a methoxy-substituted dienone with dimethylsulfoxonium methylide results in cyclopropanation of the unsubstituted double bond.[83] Reaction of dimethylsulfoxonium methylide with the conjugated dienone 2,3-benzotropone gives a 1.1:1 mixture of the mono- and dicyclopropanated products.[86] One conjugated dienone, however, gave only the 1,6-addition product (eq 27).[82]

Stereoselectivity of Cyclopropanation.

Cyclopropanation of α,β-unsaturated carbonyl compounds with dimethylsulfoxonium methylide can be highly

stereoselective. Reaction of methyl 2-(4-oxo-2-cyclohexenyl)acetate with dimethylsulfoxonium methylide gave the corresponding *anti*- and *syn*-cyclopropane derivatives in a 85:15 ratio; the favored *anti* isomer results from the nucleophilic addition of the dimethylsulfoxonium methylide to the less hindered side of the α,β-unsaturated ketone (eq 28).[87] This steric effect was also observed in the cyclopropanation of 3β-acetoxy-16α,17α-methylene-5-pregnen-20-one.[88] Stereoselective cyclopropanation of a ten-membered enone with dimethylsulfoxonium methylide gives the bicyclohumulenone in 90% yield, with none of the *cis* isomer observed. Peripheral addition of oxysulfurane proceeds through the lower-energy conformation which leads to the most likely enolate intermediate. Subsequent ring closure gives the *trans* cyclopropane.[89] A recently reported asymmetric cyclopropanation of a chiral vinyl sulfoxide with dimethylsulfoxonium methylide gave high yield and stereoselectivity ((*R*,*S*):(*S*,*S*) = 5.9:1) (eq 29).[90]

(28)

(29)

Cyclopropanation of α,β-unsaturated bicyclic lactams with dimethylsulfoxonium methylide also proceeds with high diastereoselectivity. In these cases, a change of the angular substituent in the bicyclic lactam leads to a complete reversal in *endo-exo* selectivity (eq 30).[91]

Reaction with Other Functional Groups.

Reaction of α-halo carbonyl compounds with dimethylsulfoxonium methylide provides the α-cyclopropyl carbonyl derivatives rather than the oxirane.[92] Presumably the mechanism involves a double methylene transfer with the dimethylsulfoxonium methylide. Dimethylsulfoxonium methylide has also been reported to react with 1,3-dipolar compounds for the preparation of heterocyclic products (eq 31).[93]

Methylene transfer onto the triple bond of α,β-alkynyl ketones by reaction with dimethylsulfoxonium methylide has not been observed. Reaction of 1,3-diphenyl-2-propyn-1-one with dimethylsulfoxonium methylide gives only the Michael addition complex 1-methyl-3,5-diphenylthiabenzene 1-oxide.[94,95] Reaction of dimethylsulfoxonium methylide with thiobenzophenone gives 1,1-diphenylethylene sulfide in 71% yield.[96] Treatment of 4-dimethylamino-1-thia-3-azabutadienes with dimethylsulfoxonium methylide provided thiazol-2-ine derivatives. The mechanism involves regioselective ylide addition to the amidine group, followed by cyclization with elimination of DMSO (eq 32).[97]

Methylene transfer of dimethylsulfoxonium methylide to imines results in aziridine derivatives.[98] A facile procedure for the preparation of 3-amino-2,3-dihydrobenzofuran from dimethylsulfoxonium methylide and *o*-hydroxybenzylideneaniline has been reported. The mechanism involves a ring opening of the initial aziridine intermediate (eq 33).[99,100]

(33)

Reaction with Organometallics.

Dimethylsulfoxonium methylide has been reported to react with transition metal organometallic compounds as simple terminal ligands, bridging groups, or chelating moieties.[101-106] For example, the reaction of two equivalents of dimethylsulfoxonium methylide with the metal-functionalized 1,3-diphospha-2-propanone $Fe_2(CO)_6[(i\text{-Pr})_2N\text{-}PC(O)P\text{-}N(i\text{-Pr})_2]$ affords the 1,5-diphospha-3-pentanone derivative, a product resulting from the insertion of a CH_2 group into the P-(CO) bond.[107]

Dimethyl L-Tartrate[1]

[608-68-4] · $C_6H_{10}O_6$ · Dimethyl L-Tartrate · (MW 178.14)

(synthon for chiral auxiliary/ligand preparation; chiral ligand for asymmetric catalysis)

Physical Data: mp 57-60 °C (dec); bp 163 °C/23 mmHg; *d* 1.238 g cm^{-3}; $[\alpha]^{23}$ +21° (*c* = 2.5, H_2O).

Solubility: sol most organic solvents, water.

Form Supplied in: moist white crystals.

Handling, Storage, and Precautions: may cause irritation; store in a cool, dry place.

Synthon for Chiral Auxiliary/Ligand Preparation.

(*R,R*)-Dimethyl L-tartrate, a derivative of natural L-tartaric acid, is readily transformed into useful chiral auxiliaries and ligands for asymmetric synthesis.[1] Many of these transformations involve initial acetalization of the 2,3-vicinal hydroxy groups.[2-6] Thus α,α,α´,α´-tetraaryl-1,3-dioxolane-4,5-dimethanols (TADDOLs) are prepared from the corresponding acetals of dimethyl L-tartrate (eq 1) and, as the Ti^{IV} complexes (see ***2,2-Dimethyl-α,α,α´,α´-tetraphenyl-1,3-dioxolane-4,5-dimethanolatotitanium Diisopropoxide***), are useful catalysts for enantioselective additions of dialkylzinc reagents to aldehydes,[5] Diels-Alder reactions,[6,7] asymmetric hydrocyanations of aldehydes,[8] and others.[9] The enolate of the acetonide of dimethyl L-tartrate alkylates with good selectivity to give, after acetonide hydrolysis, allyl- or benzylated derivatives (eq 2).[10] Orthoesters are also prepared from dimethyl tartrate, and acylate silyl enol ethers in good yield and selectivity to give monoprotected 1,3-diketones (eq 3).[11]

(1)

94% ee (82:18, *threo*)

(2)

(3)

78% de

In an industrial asymmetric synthesis en route to the antiinflammatory agent naproxen, the dimethyl L-tartrate acetals of ethyl aryl ketones are brominated in high yield and selectivity to give the corresponding α-bromo derivatives.[12,13] Subsequent stereospecific Ag^{I}-promoted 1,2-aryl migration provides the 2-alkyl-2-arylacetic acid after hydrolysis of the tartrate auxiliary, which is recovered (e.g. eq 4).

The vicinal diol cyclic sulfate from dimethyl tartrate undergoes nucleophilic opening to give substituted malate esters.[14,15] However, for this application diethyl and diisopropyl L-tartrates give superior yields and selectivities. The asymmetric cyclopropanation of the 1-alkenylboronic ester derived from dimethyl L-tartrate (eq 5) is another example where other tartaric acid derivatives surpass the performance of dimethyl tartrate.[16]

Chiral Ligand for Asymmetric Catalysis.

Dimethyl L-tartrate is a demonstrated chiral ligand for the Ti^{IV}-catalyzed asymmetric epoxidation of allylic alcohols (Sharpless epoxidation),[17] and the Zn^{II}-mediated asymmetric cyclopropanation of allylic alcohols (Simmons-Smith reaction), see ***Iodomethylzinc Iodide***.[18] Enantioselectivities in these reactions are, however, better with the use of diethyl L-tartrate as the chiral modifier.

(chiral auxiliaries and Lewis acids for stoichiometric and catalytic enantioselective transformations)

Alternate Name: Ti-TADDOLates.

Introduction.

Ti-TADDOLates are α,α,α´,α´-tetraaryl-2,2-disubstituted 1,3-dioxolane-4,5-dimethanolatotitanium derivatives. The most common substituents are R^1, R^2 = Me/Me and Ph/Me, Ar = Ph and 2-naphthyl, X, Y = Cl/Cl, *i*-PrO/Cl, Cp/Cl, and *i*-PrO/*i*-PrO. The corresponding TADDOLs (**2**) are available in both enantiomeric forms from tartrate esters which are acetalized (R^1R^2CO) and allowed to react with aryl Grignard reagents.[1a,g,2] The reactions performed in the presence of Ti-TADDOLates or with Ti-TADDOLate derivatives include: nucleophilic additions to aldehydes[1a,b,f,g,j,2a,3-5] and nitroalkenes[6] of alkyl,[1a,b,g,2a,3-5] aryl,[5] and allylic[1d,f] groups; aldol additions;[1d,f] hydrophosphonylations[7] and cyanohydrin reactions[1j] of aldehydes; inter- and intramolecular Diels-Alder additions;[1e,h,i,2a,8,9] [2 + 2] cycloadditions;[1e,h,i,10] intra-[1e,h,i] and intermolecular[11] ene reactions; iodolactonizations;[12] and transesterifications.[1h,i] Analogous compounds of other metals, and TADDOL derivatives containing one or two amino,[13] phosphinic, phosphonic, and/or phosphite groups,[13,14] have also been made and used for various reactions such as: $LiAlH_4$ reductions;[15] Grignard additions to ketones;[16] Li enolate additions to nitroalkenes;[17] hydrosilylations of ketones;[14a] Pd-catalyzed allylations;[14b] and metathesis reactions.[18] Finally, the TADDOLs themselves have been proved to be useful as NMR shift reagents;[2c,19] as components for enantioselective formation of host-guest complexes;[20,21] and for enantioselective solid-state reactions.[22] (*R*,*R*)-Ti-TADDOLates and (*P*)-Ti-BINOLates often give the same products in enantioselective reactions.[9]

(2)

Preparation of Ti-TADDOLate Solutions.

Five different procedures have been mostly used for the preparation of TADDOLates (**1**).

- 1)TADDOLate (**1f**) can be obtained from ***Trichloro(cyclopentadienyl)titanium*** and TADDOL (**2**), with removal of HCl (eq 1).[1d,f]
- 2)TADDOLates (**1b**) and (**1e**) are prepared from (**2**) and ***Dichlorotitanium Diisopropoxide***, without removal of the *i*-PrOH formed (eq 2). They are typically used in the presence of 4 Å molecular sieves.[1e,h,i,8b,c,9,10]
- 3)Diisopropoxy Ti-TADDOLates (**1a**) and (**1d**) are conveniently made from (**2**) and ***Titanium Tetraisopropoxide*** with removal of *i*-PrOH by evaporation under reduced pressure or by azeotropic distillation (eq 3).[1a,b,g,2a,3e]
- 4)TADDOLate (**1a**) can be synthesized alcohol-free from spirotitanate (**3**) and $(i\text{-PrO})_4$Ti (eq 4).
- 5)Likewise, TADDOLate (**1b**) can be prepared from (**3**) and ***Titanium(IV) Chloride*** (eq 5).

An additional procedure leading from a titanate (**1**) (X = Y = *i*-PrO) to the corresponding dichloride (X = Y = Cl) is to treat the former with ***Tetrachlorosilane*** and pump off $(i\text{-PrO})_2SiCl_2$.[8a] A method in which the Ti-TADDOLate is present together with another Lewis acid (***Lithium Chloride***) is to treat a TADDOL (**2**) with 2 equiv ***n-Butyllithium***, followed by $TiCl_4$.[9]

Spirotitanate (**3**) was obtained by reacting TADDOL and 0.5 equiv $(EtO)_4$Ti or $(i\text{-PrO})_4$Ti, with azeotropic removal of the alcohol in refluxing toluene (eq 6). In the solid state it is rather stable to air (storage form);[3a,d,e] its crystal structure has been determined.[1g] Numerous TADDOLates of type (**1**) have been prepared and identified by NMR spectroscopy.[1g,3e,8a,23] Normally, they are used in situ in solvents such as toluene, petroleum ethers, CH_2Cl_2, Et_2O, or THF between -75 and +20 °C.

$$\text{CpTiCl}_3 + \mathbf{(2)} \xrightarrow{\text{-HCl}} \mathbf{(1f)} \qquad (1)$$

$$\mathbf{(2)} + (i\text{-PrO})_2\text{TiCl}_2 \longrightarrow \mathbf{(1b)}\ \text{or}\ \mathbf{(1e)} + 2\ i\text{-PrOH} \qquad (2)$$

$$\mathbf{(2)} + (i\text{-PrO})_4\text{Ti} \xrightarrow{\text{-}i\text{-PrOH}} \mathbf{(1a)}\ \text{or}\ \mathbf{(1d)} \qquad (3)$$

$$\mathbf{(3)} + (i\text{-PrO})_4\text{Ti} \longrightarrow \mathbf{(1a)} \qquad (4)$$

$$\mathbf{(3)} + \text{TiCl}_4 \longrightarrow \mathbf{(1b)} \qquad (5)$$

(3)

Nucleophilic Additions of Polar Organometallic Compounds to Aldehydes.

Ti-TADDOLates (**1**) have been used for both stoichiometric and catalytic nucleophilic additions to aldehydes. Thus the alcohols (**4**), (**9**), and (**10**) (eq 7) were obtained with the corresponding R_2Zn reagents[3d] in the presence of 0.2 equiv of (**1d**)[3c,e] or *ent*-(**1d**) and 1.2 equiv $(i\text{-PrO})_4Ti$. Alcohol (**5**) results from acetaldehyde and $(i\text{-PrO})_3TiPh$ mediated by 0.2 equiv of (**1a**).[5] (*R*)-Cyanohydrins such as (**6**) are formed from equimolar amounts of aldehydes, ***Cyanotrimethylsilane***, and (**1e**).[1e,h-j,24] Alcohol (**7**) and threonine derivative (**8**) are the result of additions to aldehydes of the CpTi-TADDOLates prepared in situ from (**1f**) and crotyl Grignard reagent[1f,25] or a glycine Li enolate derivative.[1f] As can be seen, highly diastereoselective (dr = diastereomer ratio) and enantioselective (er = enantiomer ratio) conversions can be achieved. A number of examples have been reported in the literature.[1-7] (*R*,*R*)-TADDOL derivatives (**1**) always give rise to *Si* addition (rel. topicity *unlike*);[26] the mechanism of these reactions has been discussed.[1g,9]

Cycloadditions and Ene Reactions.

These reactions were mostly studied with the Cl_2Ti-TADDOLate (**1e**) as prepared by the procedure shown in eq 2. In all cases, conditions are critical. There are numerous examples in the literature,[1c,e,h,i] including the Diels-Alder addition of 3-crotonyl-1,2-oxazolidin-2-one to cyclopentadiene[8a,27] (leading to (**11**) (X = 1,3-oxazolidin-2-on-3-yl) in (**11**), (**12**), (**14**), and (**16**)) and to open-chain dienes,[27] as well as the intramolecular version of this reaction (see, for instance, (**12**)[1i]). It was shown that the Diels-Alder reaction leading to (**11**) can be done with (**1**), (Ar = 2-naphthyl, $R^1 = R^2$ = Me, X = Y = Cl) with almost the same results as with (**1e**); with the analogous 1-naphthyl derivative the stereochemical course of the reaction reverses.[9] All these reactions are highly enantioselective and require ca. 10 mol % of the chiral catalyst. Some of these reactions have been carried out on a 45 mmolar scale.[9b,27] Other dienophiles such as methoxyquinones can also be employed. For the reactions leading to (**13**) and (**15**), somewhat different procedures were used.[8b,10b] Thus (**13**) was obtained

with excellent enantioselectivity using stoichiometric amounts of a Ti-TADDOLate (**1e**).[8b] Likewise, [2 + 2] cycloadditions, again with the acyloxazolidinone (see the cyclobutene **14**)[10a] or with methoxyquinone (see **15**, a precursor to benzodihydrofurans),[10b] have been studied and occur with high regio-, diastereo-, and enantioselectivities; the nucleophilic components of these cycloadditions are electron-rich alkenes, allenes, or alkynes (cation-stabilizing substituents on the double or triple bond) such as o-methylstyrenes,[10b] thioenol ethers,[1i] allenyl thioethers,[28] ketene dithioacetals,[28] or sulfenylated alkynes.[10a,28] The acyloxazolidinones derived from α,β-unsaturated carboxylic acids also lend themselves for intramolecular ene reactions. For instance, cyclopentane derivative (**16**) was formed from the corresponding open-chain 2,7-nonadienoic acid derivative.[29]

As in other applications of *N*-acyl-1,3-oxazolidin-2-ones,[30] -2-thiones, and -thiazolidine-2-thiones,[31] chelation of the Lewis acid center for restricted rotation is considered decisive for the reactions occurring under the influence of the Ti-TADDOLates. Generally, the attack of the nucleophilic component (diene or ene) on the chelated electrophile occurs from the bottom face if the chelate ring is drawn as shown in structures (**17**) and (**18**),[8a,9,27] (**19**),[8b,f] and (**20**).[8d,e] For the oxazolidinones, this means that the trigonal α-carbonyl center is approached from the (*Re*)-face when an (*R,R*)-Ti-TADDOLate is used (rel. topicity *like*);[26] the mechanism of this reaction has been discussed.[1g,9]

(20)

Other Enantioselective Transformations Mediated by Ti-TADDOLates.

The iodolactonization of 2-allyl-2-hydroxy-4-pentenoic acid shown in eq 8 gives (**21**) in a 67% yield (after cyclization of some iodo isopropyl ester formed as a side product),[12] the iodolactone is a single (-)-diastereoisomer with a 5:1 (*S*,*S*)/(*R*,*R*) ratio. The TADDOLate generated in situ was employed in stoichiometric amount. The two enantiomers of 2-pyridyl 2-phenylthiobutyrate react with a rate difference of 39:1 with excess isopropanol in the presence of 0.1 equiv of a Ti-TADDOLate under the conditions specified in eq 9. This leads to the isopropyl ester (**22**) containing 96% of the (*R*)-enantiomer in a 69% yield.[32] Thus the complex (**23**) reacts much faster than the (*R*,*R*)/(*S*) isomer in the S/O transesterification.

(8)

(9)

(23)

Use of TADDOLate Ligands on Other Metal Centers.

Of the many possible and actually studied applications of the readily available TADDOLs, only two may be mentioned here: enantioselective reduction and Grignard addition to aryl ketones. A chiral ***Lithium Aluminum Hydride*** derivative prepared from (**2**) reduces aryl ketones in THF to the corresponding alcohols of (*S*)-configuration with an enantioselectivity of ca. 20:1 (eq 10).[15]

(10)

This procedure works with a smaller reagent excess and at higher temperatures than the analogous procedure using ***(R)-1,1´-Bi-2,2´-naphthol*** for similar results.[33] There is an added benefit in that the enantiomer excess of the alcohols formed in the reduction may sometimes be increased by a clathrating effect during the workup and isolation step (cf. the reviews).[20] Another useful application of the TADDOL (**2**) (Ar = Ph, $R^1 = R^2$ = Me) is the highly enantioselective Grignard addition to aryl ketones. The procedure involves in situ reaction of 3 equiv RMgX with the TADDOL, followed by addition of the ketone at -100 °C in THF (eq 11).[16]

Dimethyl 1,2,4,5-Tetrazine-3,6-dicarboxylate[1]

[2166-14-5] · $C_6H_6N_4O_4$ · Dimethyl 1,2,4,5-Tetrazine-3,6-dicarboxylate · (MW 198.138)

(reactive heteroaromatic azadiene for inverse electron demand Diels-Alder reactions with a wide range of dienophiles and heterodienophiles; used to prepare substituted 1,2-diazines, 1,2,4-triazines, pyrroles, pyridines, indolines, and related condensed heterocycles)

Alternate Name: bis(methoxycarbonyl)-*s*-tetrazine.

Physical Data: mp 175-177 °C.

Solubility: sol dioxane, CH_2Cl_2, THF, C_6H_6; insol H_2O.

Form Supplied in: bright red crystalline solid.

Preparative Method: ***Ethyl Diazoacetate*** (0.90 mol) is added dropwise to a stirred solution of NaOH (4.0 mol) in 250 mL of H_2O at such a rate so as to maintain the temperature of the reaction between 60 and 80 °C. After cooling to 25 °C, the reaction slurry is poured onto 1 L of 95% EtOH, mixed well, and the liquid decanted. This washing procedure is repeated 5 times before the precipitate is collected by filtration, washed with absolute EtOH (0.5 L) and Et_2O (0.5 L) sequentially, and air-dried to afford disodium dihydro-1,2,4,5-tetrazine-3,6-dicarboxylate (**2**) (85-97%).

A stirred slurry of (**2**) (0.39 mol) in 200 mL of ice-water at 0 °C is treated dropwise with 1.95 equiv of concentrated HCl. The yellow solid formed is immediately collected by suction filtration, washed with cold H_2O (50 mL) and Et_2O (50 mL) sequentially, and dried at 60 °C overnight to afford dihydro-1,2,4,5-tetrazine-3,6-dicarboxylic acid (**3**) (72-74%).

The solid (**3**) (0.16 mol) is added in small portions over 20 min to a stirred solution of $SOCl_2$ (27.5 mL) in dry MeOH (375 mL) at -30 °C. After completion of the addition, the reaction mixture is allowed to warm to 25 °C over 2 h, and then concentrated under reduced pressure. Extraction of the residue with CH_2Cl_2 (400 mL × 5) from H_2O (400 mL) followed by removal of the solvent from the organic phase in vacuo affords dimethyl dihydro-1,2,4,5-tetrazine-3,6-dicarboxylate (**4**) (44-51%).

Nitrous gases generated by dropwise addition of a 6 N $NaNO_2$ solution (200 mL) to 125 mL of concentrated HCl

are bubbled into a stirred slurry of (**4**) (0.1 mol) in CH_2Cl_2 (800 mL) at 0 °C using a N_2 stream until the addition of $NaNO_2$ solution is complete. The solvent and excess nitrous gases are removed in vacuo to afford dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (**1**) (99%).[2]

Handling, Storage, and Precautions: dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate is a very reactive diene which is unstable to acid, base, H_2O, or protic solvents and should be stored moisture-free and refrigerated.

Cycloaddition Reactions.

Dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (**1**) is one of the most reactive heteroaromatic azadienes examined to date and it reacts with a wide range of dienophiles and heterodienophiles including electron-rich, neutral, strained, or electron-deficient alkenes, alkynes, dienes, enol ethers and acetates, enamines, ynamines, ketene acetals, enolates, benzynes, selected aromatics and heteroaromatics, imidates, thioimidates, aldehyde *N*,*N*-dimethylhydrazones, imines, azirines, and cyanamides. Extensive reviews have summarized[1] and compiled[1a] the results of such studies. Cycloaddition reactions occur exclusively across C-3/C-6 of the 1,2,4,5-tetrazine nucleus and is accompanied by a retro Diels-Alder reaction with extrusion of N_2 to afford substituted dihydro-1,2-diazines (dihydropyridazines) (eq 1),[3] or substituted 1,2-diazines (pyridazines) when the dienophiles are alkynes (eq 2),[4] or contain leaving groups capable of elimination with aromatization (eqs 3, 4 and 8).[3,5] Imines, imidates, and thioimidates prefer to react through their more reactive tautomeric enamine and ketene acetal forms, respectively (eq 5),[6] although cycloaddition of the C=N double bond may take place when such tautomerization is blocked (eq 6).[7] In selected instances, a preference for C&tbond;N triple bond addition over C=N double bond has been observed (eq 7).[8] Recent studies have illustrated the use of selenophene, oxazole, *N*-methylpyrazole,[9] 2-vinylindoles,[10] and naphthalenes[11] as dienophiles and an extensive and complete compilation of relative dienophile reactivities toward dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (Table 1)[12] has been described.

Table 1 Relative Dienophile Reactivity Toward Tetrazine **(1)**

Indoline Synthesis.

The 1,2-diazine (pyridazine) products obtained from the Diels-Alder reactions of dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate (**1**) are poor dienes for further Diels-Alder reactions.[13] However, the entropic assistance provided in intramolecular reactions has been utilized to promote their participation in Diels-Alder reactions with unactivated alkynes.[14] Thus a general 1,2,4,5-tetrazine -> 1,2-diazine -> indoline strategy based on sequential inverse electron demand Diels-Alder reactions of (**1**) has been developed and applied to the total synthesis of PDE-I and PDE-II (eq 9),[15,16] (+)-CC-1065 (**5**),[17] and related agents.[18]

(9)

R = $CONH_2$, PDE-I methyl ester
R = COMe, PDE-II methyl ester

(5) (+)-CC-1065

Pyrrole Synthesis.

A novel reductive ring contraction reaction of dimethyl 1,2-diazine-3,6-dicarboxylates to provide dimethyl pyrrole-2,5-dicarboxylates[19] has been developed and provides an attractive 1,2,4,5-tetrazine -> 1,2-diazine -> pyrrole synthetic strategy (eq 10).[20] Successful applications of this strategy in the total syntheses of octamethylporphyrin (**6**),[20] prodigiosin (**7**) (eq 11),[21] and isochrysohermidin (**8**) (eq 12)[22] have been reported.

(6) Octamethylporphyrin (OMP)

(7) Prodigiosin

(8) Isochrysohermidin

(11)

(12)

Pyridine Synthesis.

The triazine products derived from the [4 + 2] cycloaddition reactions of (**1**) with aryl imidates or aryl thioimidates are themselves electron-deficient heteroaromatic azadienes capable of participation in further regioselective inverse electron demand Diels-Alder reactions. Such triazines have proven useful in the preparation of substituted pyridines (see also ***Triethyl 1,2,4-Triazine-3,5,6-tricarboxylate*** and ***1,2,4-Triazine***). Consequently, a 1,2,4,5-tetrazine -> 1,2,4-triazine -> pyridine synthetic strategy has been developed based on two consecutive [4 + 2] cycloaddition reactions and successfully

applied in the total synthesis of streptonigrin (**9**) (eq 13).[23]

(9) Streptonigrin

Dimethylthiocarbamoyl Chloride[1]

[16420-13-6] · C_3H_6ClNS · Dimethylthiocarbamoyl Chloride · (MW 123.62)

(conversion of phenols to thiophenols;[2] and, through subsequent desulfurization, for deoxygenation of phenols;[2] conversion of allylic alcohols to 1,3-rearranged *S*-allyl dimethylthiocarbamates[3] which can be hydrolyzed to the thiols or further oxidized to α,β-unsaturated carbonyl compounds;[4] conversion of α-hydroxy-α,β-unsaturated ketones (diosphenols) to α-chloro- and α-bromo-α,β-unsaturated ketones;[5a,b] deoxygenation of diosphenols to α,β-unsaturated ketones;[5c] deoxygenation of pyridine *N*-oxides;[6] dehydration of primary and secondary alcohols[7])

Physical Data: mp 42-44 °C; bp 90-95 °C/0.5 mmHg; 62-65 °C/0.2 mmHg.

Solubility: very sol chloroform, THF; reacts (slowly) with protic solvents.

Form Supplied in: large lumps; commercially available.

Preparative Methods: treatment of tetramethylthiuram disulfide with ***Chlorine***[7] or ***Sulfuryl Chloride***.[8]

Purification: vacuum distillation.

Handling, Storage, and Precautions: stable for years at 0 °C.

Conversion of Phenols to Thiophenols.

O-Aryl dimethylthiocarbamates (**1**), prepared by sequential treatment of phenols with base (usually ***Sodium Hydride*** in DMF) and dimethylthiocarbamoyl chloride, rearrange to *S*-aryl dimethylthiocarbamates (**2**) when heated at typically 200-300 °C (the Newman-Kwart rearrangement) (eq 1).[2] For the purpose of preparing aryl-sulfur compounds, this process is a significant improvement over the pyrolysis of di-*O*-aryl thiocarbonates (the Schönberg rearrangement),[9] where only one of the two aryl groups becomes connected to sulfur.

The product (**2**) may be transformed to the corresponding thiophenol by hydrolysis, or by reduction with ***Lithium Aluminum Hydride***[10a] or ***Sodium-Ammonia***.[10b] Alternatively, (**2**) may be oxidized with ***Hydrogen Peroxide***/***Formic Acid*** to the arenesulfonic acid,[11a] oxidized with ***Chlorine***/***Acetic Acid*** to the arenesulfonyl chloride,[11b,c] or desulfurized with ***Raney Nickel***.[12] Derivatization of phenols with the analog diethylthiocarbamoyl chloride sets the stage for *ortho*-deprotonation and alkylation with various electrophiles prior to effecting *O*-aryl -> *S*-aryl rearrangement.[13] A wide variety of phenols has been successfully utilized in these processes; consequently the Newman-Kwart reaction is one of the most important methods for preparing aryl-sulfur compounds. Applications of the rearrangement can be found in medicinal chemistry,[14] molecular recognition and supramolecular chemistry,[15] and inorganic chemistry.[16]

Phenols bearing an electron-withdrawing group at the *ortho* or *para* position rearrange most readily (2-nitrophenol requires 20 min at 170 °C), consistent with the intermediacy of (**4**) (eq 2);[2,9b] this mechanism is supported by the correlation of rearrangement rates with σ-values.[17]

If two *o*,*p*-electron-withdrawing groups are present, as in (**6**) (eq 3),[18] or if an aza-aromatic system can be activated through protonation, as in (**8**) (eq 4),[2a] rearrangements occur much more readily. Conversely, electron-donating groups retard the reaction (e.g. 4-dimethylaminophenol requires 20 min at 295 °C).

Large alkyl or aryl groups at *ortho* positions slow the reaction[2a,19a] and, in general, cause lower yields.[2a,14a,16b,c] In some cases the preparation of dimethylthiocarbamates from hindered phenols is attended by thioacylation of the aromatic ring.[19b] Reactive functional groups at *ortho* positions can divert the course of the reaction (e.g. eq 5);[19c] in some cases these difficulties can be minimized by careful selection of reaction conditions.[20]

X = Cl gives normal Newman-Kwart rearrangement

Whereas rearrangement fails in the case of 1-naphthol,[21a] exemplary results are obtained with 2-naphthol,[2a,21b] 6-nitro-2-naphthol,[21c] and 3-phenanthrol.[2a] The enantiomerically pure bis(dimethylthiocarbamate) (**13**) undergoes rearrangement without racemization (eq 6).[15e] *O*-Thioacylation of 2-azulenol and 6-azulenol is complicated by concurrent *C*-thioacylation; use of the 1,3-bis(methoxycarbonyl) analogs, followed by hydrolysis/decarboxylation, circumvents this problem.[22a] There is only one hydroxythiophene example in the literature,[22b] and no examples involving hydroxyfurans or hydroxypyrroles.

A nice application of the Newman-Kwart rearrangement is seen in the preparation of the otherwise difficult to access 5-hydroxyisoflavone (**19**) from the easily accessible 5,7-dihydroxyisoflavone (**16**) (eq 7).[12]

Conversion of Allylic Alcohols to 1,3-Rearranged *S*-Allyl Dimethylthiocarbamates.

Allylic dimethylthiocarbamates (from reaction of allylic alcoholates with dimethylthiocarbamoyl chloride) undergo [3,3]-sigmatropic rearrangement when heated at 100-130 °C.[3] The products may be hydrolyzed with base or (better) reduced with lithium aluminum hydride to the allylic thiols (note: tertiary allylic thiols undergo allylic equilibration during aqueous hydrolysis). Although the rearrangement is somewhat slower[3b] than the more familiar rearrangement of allylic xanthates,[23] the products lend themselves to deprotonation and alkylation with electrophiles. This sequence has been used by Nakai, et al. for the synthesis of several acyclic terpenes such as the ant pheromone manicone (**24**) (eq 8).[4]

Conversion of α-Hydroxy-α,β-Unsaturated Ketones (Diosphenols) to α-X-α,β-Unsaturated Ketones (X = H, Cl or Br).

The hydroxy group of diosphenols may be activated towards substitution by conversion to the dimethylthiocarbamate. These derivatives, irrespective of substitution pattern in the diosphenol, are deoxygenated in near-quantitative yield to α,β-unsaturated ketones by ***Lithium Iodide*** in hot acetic acid.[5c] Dimethylthiocarbamates of diosphenols whose β-carbon atom is unhindered react with ***Lithium Chloride*** or ***Lithium Bromide*** in acetic acid to furnish the corresponding halo compounds;[5a] if the β-carbon atom is substituted, a variety of products is obtained.[5b] Evidence is provided for the intermediacy of cyclized compounds like (**27**) in these reactions (eq 9).[5]

(9)

Deoxygenation of Pyridine *N*-Oxides and Related Compounds.

Treatment of pyridine *N*-oxides with dimethylthiocarbamoyl chloride and lithium iodide in acetonitrile at rt or below gives chemoselective deoxygenation (eq 10).[6] Neither oxalyl chloride nor tosyl chloride can be used as activating agents, and it is speculated that the reaction proceeds through an intermediate like (**30**), analogous to (**27**).

(10)

Dehydration of Primary and Secondary Alcohols.

Dimethylthiocarbamates of primary and secondary alcohols bearing a β-hydrogen give alkenes when heated at 180-200 °C.[7] This procedure has some advantages over xanthate pyrolysis:[24] (a) one-step preparation of derivatives; (b) yields of elimination products are often better; and (c) no thiol is produced upon pyrolysis. This latter consideration is important in the dehydration-aromatization of (**33**) (eq 11).[25]

N,N-Dimethylthioformamide[1]

[758-16-7] · C_3H_7NS · *N,N*-Dimethylthioformamide · (MW 89.18)

(Vilsmeier reagent for formylation of aliphatic, aromatic, and heteroaromatic systems; acyl anion equivalent; thiolysis of alkyl, aryl, and acyl halides; conversion of oximes into nitriles; reduction of sulfoxides; formation of some sulfur heterocycles and formamidines)

Alternate Name: TDMF.

Physical Data: bp 58-60 °C/1 mmHg; *d* 1.047 g cm^{-3}; n_D^{20} 1.5760; fp 99 °C.

Solubility: sol THF, ethyl acetate, toluene, DMF; may react with some halogenated solvents.

Form Supplied in: yellow to colorless liquid.

Analysis of Reagent Purity: characterized by ^1H and ^{13}C NMR spectroscopy.[2]

Preparative Methods: various methods have been reported[3] for the preparation of TDMF. As with other thioamides, it is best obtained by treatment of the parent amide with a suitable thionating reagent (see also ***2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide***) (eq 1).[3d] More recently, efficient conversion has been effected using ***Phosphorus(V) Sulfide*** that has been activated using solid ***Sodium Carbonate*** (eq 2).[3a]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: can be stored for long periods of time at rt if kept sealed under inert atmosphere and out of direct contact with light; use in a fume hood.

Acyl Anion Equivalent.[1c-e]

TDMF can be readily deprotonated at low temperature to give a nucleophilic acylating reagent directly, and thus it serves as an acyl anion equivalent.[4] However, due to the thermal instability of the anion, very low temperatures and rapid trapping of the incipient anion are required. Moderate to good yields have been obtained in this manner in reactions where ketones or aldehydes serve as electrophiles (eq 3).[4e] Recent protocols alleviate the need for precise low temperature control and provide for comparable yields by requiring admixing of the TDMF and electrophile followed by slow addition of the mixture to a chilled solution of ***Lithium Diisopropylamide*** (-78 °C).[4a,b]

Formylation.

TDMF is a very effective formylating reagent[5] (see also ***Dimethylchloromethyleneammonium Chloride***), providing intermediate enamines in good yields in situations where other more traditional reagent combinations, such as DMF/acetic anhydride, fail (eq 4).[5c]

(4)

R^1R^2 = Benzo 93%
$R^1 = R^2 = H$ 85%

Recently, TDMF has shown potential as a formylating reagent, yielding enaminones using a modified protocol of the Eschenmoser coupling of thioamides (eq 5).[5a,1b]

(5)

Preparation of Thiols.

Thiols can be obtained in excellent yield from the methanolysis of the adduct formed between an organic halide and TDMF (eq 6).[6]

(6)

Thiopyran Generation.

TDMF undergoes a Diels-Alder reaction with an electron-deficient diene with concomitant loss of the dimethylamino group to yield a 2*H*-thiopyran (eq 7).[7]

(7)

Thiirane Generation.

Thiiranes can be obtained in good to excellent yields from treatment of the corresponding epoxides with TDMF in the presence of a strong acid (eq 8).[8]

(8)

Reduction of Sulfoxides.

Thioformamidium ions, formed from the combination of TDMF and an alkyl halide, serve as excellent reagents for the reduction of sulfoxides (eq 9).[9]

(9)

Preparation of Nitriles.

Thioformamidium ions have also been used to convert oximes to nitriles (eq 10).[10]

(10)

Reaction with Amines.

TDMF reacts with primary amines (aryl and alkyl) to yield formamidines (eq 11),[11] whereas upon heating TDMF in the presence of a secondary amine, the dimethylamino group is readily displaced by an amines of higher molecular weight, thereby leading to alternative thioformamide derivatives.[4c,12]

(11)

Related Reagents.

Acetic Anhydride; ***N,N-Dimethylformamide***; ***Potassium Thiocyanate***; ***Thiourea***; ***Tris(methylthio)methane***.

Dichlorodimethyltitanium[1]

Me_2TiCl_2

[35739-70-9] · $C_2H_6Cl_2Ti$ · Dichlorodimethyltitanium · (MW 148.86)

(Lewis acidic reagent[2] capable of geminal dimethylation of ketones[3] and aromatic aldehydes,[4] substitution reactions of tertiary alkyl halides and alcohols,[5] and stereoselective Grignard-type additions to aldehydes and ketones[6-9])

Physical Data: reliable data not available; dark violet in crystalline form (dec. at -10 °C); yellow in hydrocarbon solvents; violet in diethyl ether.

Preparative Methods: several methylmetal reagents such as ***Methyllithium***, ***Methylmagnesium Bromide***, Me_2Zn, and ***Trimethylaluminum*** react stoichiometrically with ***Titanium(IV) Chloride*** to form Me_2TiCl_2.[1-3] In the presence of ether, the Lewis acidic compound forms etherates. For a number of synthetic organic applications, ether-free solutions of Me_2TiCl_2 are required.[1,3,5] In these cases, the preparation of choice is the reaction of Me_2Zn with $TiCl_4$ in dry CH_2Cl_2 (eq 1).[3,5] *Caution*: Although Me_2Zn is highly pyrophoric, CH_2Cl_2 solutions are less so and are easy to handle.[3]

$$Me_2Zn + TiCl_4 \longrightarrow Me_2TiCl_2 \qquad (1)$$

Handling, Storage, and Precautions: although Me_2TiCl_2 can be crystallized, it is best not to isolate the compound (due to its thermal lability and light sensitivity). In situ reaction modes under an inert gas atmosphere (e.g. argon) in the absence of direct sunlight are recommended.

Methylation of Carbonyl Groups.

The most important synthetic applications of Me_2TiCl_2 pertain to carbonyl addition and S_N1 substitution reactions, sometimes in a one-pot tandem process, as in the geminal dimethylation of ketones (eq 2).[3] A two-fold excess of reagent is required which ensures Grignard-type reaction to a tertiary titanium alcoholate which then interacts with more Me_2TiCl_2 to form the final product via tertiary carbocations. The reactions need to be performed in nonethereal solvents such as CH_2Cl_2 at -30 to 0 °C (1-4 h).[3] $Me_3Al/TiCl_4$ can also be employed.[3] These reactions are milder and much more efficient than the previously reported reactions of ketones with an excess of Me_3Al at 120-180 °C.[10]

(2)

A fairly wide range of ketones is amenable to such geminal dimethylation, but the yields are drastically lowered when sterically hindered ketones are used.[3] The intermediacy of tertiary carbocations means that in relevant cases rearrangements may occur,[3] as in the case of (+)-cuparenone which affords racemic (±)-cuparene.[11]

Another restriction concerns the use of highly functionalized substrates which bind the reagent and do not undergo geminal dimethylation. However, for simple systems, Me_2TiCl_2 is ideally suited[3,5,12] and is to be preferred over multistep procedures such as Wittig alkenation of the ketone followed by Simmons-Smith cyclopropanation and ring-opening hydrogenation.[13] Furthermore, aromatic (but not aliphatic) aldehydes are also geminal dimethylated.[4]

Ketones can be reacted with ether-free alkyllithium reagents in pentane or hexane, and the resulting insoluble tertiary lithium alcoholates treated with Me_2TiCl_2 to form the mixed geminal dialkylated products.[14] This protocol allows for a simple access to synthetic tetrahydrocannabinoids (eq 3).[14]

R^1	R^2	Yield
Me	Et	77%
Me	Bu	80%
Bu	Bu	68%

Methylation of Tertiary Halides and Alcohols.

Me_2TiCl_2 prepared from $Me_2Zn/TiCl_4$ has also been used to methylate tertiary alkyl halides and tertiary alcohols.[5] In the former case, Me_2Zn and catalytic amounts of $TiCl_4$ can also be employed.[15] This method is also applicable to substitution reactions of chiral β-chloro sulfides which react with intermediate Me_2TiCl_2 stereospecifically with retention of configuration due to neighboring group participation.[15c]

Grignard-Type Additions to Carbonyl Compounds.

The above reactions all involve S_N1 ionization, which means that a Lewis acidic medium is required, including nonethereal solvents. This precludes the use of MeLi or MeMgX because these reagents always contain ether. In the case of Grignard-type carbonyl addition reactions of Me_2TiCl_2, ether can usually be tolerated. This means that MeLi or MeMgX can be transmetalated with $TiCl_4$ and the intermediate Me_2TiCl_2/etherate reacted with aldehydes or ketones. Interesting degrees of diastereoselectivities have been observed,[1,7] as in the stereocontrolled reactions of chiral α-keto

amides (eq 4).[8] Nevertheless, Me_2TiCl_2/etherate has not been used often in the general area of stereoselective carbonyl addition reactions. Usually 1 equiv of MeLi or MeMgX per one part of $TiCl_4$ has been employed, generating $MeTiCl_3$/etherate which is a nonbasic, chemo- and stereoselective Grignard analog.[16] Like MeLi/$CeCl_3$, it is useful in addition reactions of enolizable ketones.[17] Since carbonyl reactivity increases in the series $MeTiCl_3 < Me_2TiCl_2 < Me_4Ti$, the combination 2 MeLi/$TiCl_4$ in ether is a viable alternative.[1]

S,S-Dimethyl-*N*-(*p*-toluenesulfonyl)sulfilimine[1,2]

(**1**; R = *p*-$MeC_6H_4SO_2$)

[13150-75-9] · $C_9H_{13}NO_2S_2$ · *S,S*-Dimethyl-*N*-(*p*-toluenesulfonyl)sulfilimine · (MW 231.37) (**2**; R = 2,4-$(NO_2)_2C_6H_3$)

[37873-98-6] · $C_8H_9N_3O_4S$ · *S,S*-Dimethyl-*N*-(2,4-dinitrophenyl)sulfilimine · (MW 243.27)

(reagents for α-*S,S*-dimethylsulfuranylation of active methylene compounds,[2] and *ortho*-methylation of phenols;[3,4] (**1**) is a methylene transfer agent which converts carbonyl compounds into epoxides[5])

Alternate Names: (**1**) DMTS; (**2**) DMDNS.

Physical Data: (**1**) mp 154-155 °C; (**2**) mp 175-176 °C (dec).

Solubility: insol H_2O; sol ethyl and methyl alcohols, acetone, chloroform, and other common polar organic solvents.

Form Supplied in: (**1**) white solid; (**2**) orange solid.

Preparative Methods: (**1**) is conveniently prepared by adding a slight excess of ***Dimethyl Sulfide*** to an aqueous solution of ***Chloramine-T***, and collecting the deposited crystals by filtration and recrystallization from ethanol.[1] The yield of white crystalline solid is >95% based on chloramine T.

For preparation of (**2**), ***Phosphorus(V) Oxide*** (60 mmol) is added with stirring to 25 mL of DMF at 0 °C. After 30 min, ***Dimethyl Sulfoxide*** (60 mmol) is added. After stirring for 1 h, 20 mmol of 2,4-dinitroaniline in 25 mL of DMF is added dropwise at 0 °C with continued stirring. After 3 h, 180 mmol of ***Triethylamine*** is added at 0-5 °C, and stirring is continued for 3 h. The deposited crystals are collected by filtration and recrystallized from THF. The yield of orange crystalline material is 96% based on 2,4-dinitroaniline.[2,3]

Handling, Storage, and Precautions: stable at rt in a sealed bottle, but storage at lower temperature is recommended for (**2**). Use in a fume hood.

Reagent (**2**) reacts with *p*-toluenesulfonamide (at 90 °C for 7 h in DMF) to give (**1**) (58%), in an ylide exchange reaction.

Reactions of (**1**) and (**2**) with active methylene compounds in DMF give the corresponding sulfuranes (eq 1). Reagent (**2**), which is more basic than (**1**), gives higher yields of sulfuranes. Furthermore, the yields of the ylide exchange reactions depend on the pK_a value of the active methylene compounds, as shown in Table 1. The lower the pK_a value, the higher the yield of sulfurane.[2,3]

$$Me_2S{=}NR + CH_2R^1R^2 \xrightarrow[90\ °C,\ 7\ h]{DMF} Me_2S{=}CR^1R^2 + H_2NR \quad (1)$$

$$R = Tos,\ 2,4\text{-}(NO_2)_2C_6H_3$$

Table 1 Results of the Reactions of Sulfilimines (**1**) and (**2**) with Active Methylene Compounds in DMF at 90 °C for 9 h

Sulfilimine	Active methylene compound R^1	Active methylene compound R^2	pK_a	Sulfurane yield (%)
(**2**)	COMe	COMe	8.94	94
(**2**)	COMe	CO_2Et	10.7	80
(**2**)	CN	CN	11.2	98
(**1**)	CN	CN	11.2	12.5
(**2**)	CO_2Me	CO_2Me		58
(**2**)	CO_2Et	CO_2Et	13.3	48
(**2**)	Ph	Ph	34.1	0

Reactions of (**1**) and (**2**) with phenols give *o*-methylthiomethylated phenols (eq 2).[3,4] Mixtures of the phenols and 0.5 equiv of (**1**) or (**2**) are heated without solvent at 120-130 °C for 3-7 h. 2-Methylthiomethylphenols are obtained from 2- and 4-methyl, 2,5- and 3,5-dimethyl-, 2,3,5-trimethyl-, and 2-methoxyphenols in 55-95% yield (Table 2). In some case, significant amounts of bis(methylthiomethyl) products are also formed. The yields using (**2**) are higher than those using (**1**).

R = Tos, 2,4-$(NO_2)_2C_6H_3$

Table 2 Methylthiomethylation of Phenols with the Sulfilimines (**1**) and (**2**) at 120 130 °C for 3 7 h

Sulfilimine	Phenol	Yield (%)[a]	Sulfilimine	Phenol	Yield (%)[a]
(**2**)	2-MeO	82	(**1**)	2-MeO	78
(**2**)	2-Me	95	(**1**)	2-Me	73
(**2**)	4-Me	55 (24)[b]	(**1**)	2,5-Me_2	96
(**2**)	H	41	(**1**)	3,5-Me_2	58 (35)[b]
(**2**)	4-NO_2	0	(**1**)	2,3,5-Me_3	64

[a] Yields based on reacted sulfilimine. [b] Data in parentheses show the yields of bis(methylthiomethyl)phenols.

Like ***S,S-Dimethyl-N-(p-toluenesulfonyl)sulfoximine***[6] and (dimethylamino)dimethyloxosulfonium tetrafluoroborate,[7] the *N*-tosylsulfilimine (**1**) reacts as a methylene transfer reagent, converting aldehydes and ketones to epoxides (eq 3). Thus (**1**) is heated at 80-90 °C for 0.5 h in DMSO in the presence of ***Sodium Hydride***, and the resulting anion is allowed to react with carbonyl compounds to give 1-mono- and 1,1-disubstituted oxiranes in 46-56% yields.[5]

(3)

$R^1 = Ph$, $R^2 = H$, Me; $R^1R^2 = (CH_2)_6$

Related Reagents.

N,S-Dimethyl-S-phenylsulfoximine; ***Dimethylsulfonium Methylide***; ***Dimethylsulfoxonium Methylide***; ***S,S-Dimethyl-N-(p-toluenesulfonyl)sulfoximine***; ***S,S-Diphenylsulfilimine***.

(conversion of aldehydes and ketones to oxiranes,[1,2] ketones or oxiranes to oxetanes,[3] imines to aziridines,[1,2] and electrophilic alkenes to cyclopropanes[1,2])

Alternate Name: S,S-dimethyl-*N*-tosylsulfoximine.

Physical Data: (**1**) mp 167-169 °C, 170 °C (from ethanol);[2,4] (**2**) mp 89-91 °C; (**3**) mp 75-77 °C; (**4**) mp 107-109 °C; (**5**) mp 143-144 °C; (**6**) mp 145-146 °C; (**7**) mp 148-149 °C.

Solubility: moderately sol EtOH, THF, DMSO.

Form Supplied in: (**1**) white solid; commercially available.

Preparative Methods: excess DMSO containing ***Copper(II) Chloride*** (or another copper catalyst)[2,4] is treated with ***Chloramine-T*** trihydrate. (**1**) is obtained in 90% yield after aqueous EDTA workup and recrystallization from ethanol.

The other *N*-tosylsulfoximines can be prepared by the tosylation of N-H sulfoximines with ***p-Toluenesulfonyl Chloride*** in the presence of base,[2] but the two most useful and general methods are the oxidation of *N*-tosylsulfilimines with basic ***Hydrogen Peroxide***,[5] ***m-Chloroperbenzoic Acid*** anion,[6] ***Sodium Hypochlorite***,[8] or ***Ruthenium(VIII) Oxide***/sodium metaperiodate[7] and the copper powder-promoted reaction of sulfoxides with ***p-Toluenesulfonyl Azide***.[2,9]

Handling, Storage, and Precautions: (**1**) is a highly crystalline compound with no known toxicity and unlimited shelf life.

The generation of *N*-*p*-toluenesulfonyl-sulfonimidoyl-stabilized carbanions is best accomplished by stirring a slurry of *N*-tosylsulfoximine, e.g. (**1**), and ***Sodium Hydride*** in DMSO at rt until hydrogen evolution ceases (2-4 h). THF solutions of the lithium salts of *N*-tosylsulfoximines can be prepared by deprotonation with ***n-Butyllithium***. These anions, which are quite stable at room or slightly elevated temperatures, form a class of nucleophilic alkylidene transfer reagents. The mechanism of these transfer reactions is similar to that of sulfonium ylide reactions but the leaving groups are water-soluble anions rather than neutral molecules (eq 1). The nucleophilic transfer chemistry of sodium *N*-tosylmethanesulfonimidoylmethide (**8**) is similar to that of dimethylsulfoxonium methylide[10] in regard to regio- and stereochemical selectivity in that the products reflect thermodynamic control.[11] Anion (**8**) has been reported to be superior to dimethylsulfonium and dimethylsulfoxonium methylides for reactions in which enolate formation is a serious problem.[12]

These salts have been used to prepare oxiranes from aldehydes and ketones (eqs 2 and 3),[2] cyclopropanes from enones (eq 4),[2] and aziridines from imines (eq 5).[2] Alkylidene groups which have been transferred using reagents in this series include methylene, ethylidene, isopropylidene, benzylidene, cyclopentylidene, and cyclohexylidene. Optically active

versions of these reagents have been studied, but enantiomeric excesses of the resulting alkylidene transfer products have only been modest.[2] The reaction of carbanion (**8**) with epoxides results in the expansion of the ring by one carbon (eq 2). This unique oxetane synthesis, which can be carried out in one step by simply treating the ketone with 3 equiv of (**8**), is quite general and illustrates the use of (**1**) as a [$^{-}CH_2CH_2^{+}$] synthon.[3]

(2)

(3)

(4)

(5)

Reagent (**1**) can also be converted to an ethylene transfer reagent by condensation with benzonitrile, followed by reduction of the ketosulfoximine and dehydration (eq 6). The resulting *S*-vinyl-*N*-tosylsulfoximine reacts with stabilized anions to give cyclopropanes.[13] The *N*-tosyl group in *N*-tosylsulfoximines can be cleaved reductively using ***Sodium Anthracenide***.[14]

Related Reagents.

N,S-Dimethyl-S-phenylsulfoximine; ***Dimethylsulfonium Methylide***; ***Dimethylsulfoxonium Methylide***; ***Diphenylsulfonium Methylide***; ***Isopropyldiphenylsulfonium Tetrafluoroborate***.

N,N-Dimethyl-2-(trimethylsilyl)acetamide

[23184-28-3] · $C_7H_{17}NOSi$ · *N,N*-Dimethyl-2-(trimethylsilyl)acetamide · (MW 159.34)

(preparation of α,β-unsaturated amides,[1] β-enamino amides,[2] and γ-trimethylsiloxy amides[3])

Physical Data: bp 67-69 °C/4 mmHg; 47-49 °C/0.2 mmHg.

Preparative Methods: although the direct trimethylsilylation of the lithium enolate of *N,N*-dimethylacetamide[3a] is the most straightforward approach to the title reagent, other α-silyl amides have been prepared by amidation of the corresponding esters.[4] The reaction of aminosilanes with ketene gives the *O*-trimethylsilylated isomer, which thermally rearranges to the α-trimethylsilylamide.[5] In reactions of chlorosilanes with the lithium enolates of amides, larger silyl groups such as the *t*-butyldimethylsilyl group tend towards *O*-silylation, and smaller groups on nitrogen lead to *C*-silylation.[3a] Thermal isomerization leads to the *C*-silylated tautomer as the major product (eq 1). The direct *C*-dimethylphenylsilylation of the lithium enolate of *N*-methyl-δ-valerolactam has been reported (eq 2).[6]

Preparation of α,β-Unsaturated Amides.

Reaction of *N,N*-dimethyl-2-(trimethylsilyl)acetamide with either ***Lithium Diisopropylamide*** or ***n-Butyllithium*** in THF

at 0 °C provides the lithium enolate, which is stable at rt for several days. This enolate reacts with aldehydes and ketones to produce α,β-unsaturated amides via the condensation-Peterson elimination sequence (eq 3). This reaction was employed in an approach to (±) cherylline (eq 4).[7]

(3)

(4)

The reaction of the lithium enolate of *N*,*N*-dimethyl-2-(trimethylsilyl)acetamide with aromatic nitrones gives α-aryl-α,β-unsaturated amides in modest yields (eq 5).[8] The reaction of the lithium enolate with amides yields β-amino-α,β-unsaturated amides (eq 6),[2] and the reaction with propene oxide leads to *N*,*N*-dimethyl-4-(trimethylsiloxy)pentanamide (eq 7).[1]

(5)

(6)

(7)

Other Applications.

The direct α-trimethylsilylation of β-lactams and the intermediates used in the synthesis of this important class of compounds have been reported.[9]

Related Reagents.

t-Butyl Trimethylsilylacetate; ***Ethyl 2-(Methyldiphenylsilyl)propanoate***; ***Ethyl Trimethylsilylacetate***; ***Trimethylsilylacetic Acid***; ***Trimethylsilylacetone***.

Dinitratocerium(IV) Chromate Dihydrate[1]

$[Ce(NO_3)_2]CrO_4.2H_2O$

[92989-80-5] · $CeCrH_4N_2O_{12}$ · Dinitratocerium(IV) Chromate Dihydrate · (MW 416.18)

(mild oxidizing reagent for the transformation of several functional groups in dry benzene[2])

Alternate Name: DCCD.

Solubility: sol DMF, DMSO; moderately sol H_2O; insol MeCN, EtOH, PhH.

Form Supplied in: orange-red solid; readily available.

Preparative Method: to a hot solution of ***Potassium Dichromate*** (0.1 mol) a solution of ***Cerium(IV) Ammonium Nitrate*** (0.1 mol) is added. After cooling, the precipitate is washed with H_2O and acetone and dried in the air (79%).[2]

Handling, Storage, and Precautions: stable >220 °C, and at rt for months. Chromium is a cancer suspect agent and inhalation of this reagent should be avoided.

Oxidations.

Oxidations with this reagent proceed heterogeneously in dry benzene at reflux. Evaporation of the solvent followed by chromatography gives pure product(s). Drawbacks encountered with Ce^{IV} oxidations[1,3] are not observed when using DCCD.[2]

The reagent effects the oxidation of benzylic alcohols to the corresponding aldehydes in high yield (eq 1).[2] Deactivated benzyl and allylic alcohols are not easily oxidized. Oxidation of arylethylene glycols is accompanied by carbon-carbon bond cleavage and produces the degraded aldehydes in high yields (eq 2).[2] α-Hydroxy carboxylic acids are similarly converted to aldehydes efficiently (eq 3).[2]

(1)

(2)

(3)

Primary benzylamines are easily transformed to the corresponding aldehydes in quantitative yields (eq 4).[2] Disulfides are produced in good yields by the oxidation of thiols (eq 5).[2] The reagent oxidizes hydroquinones to quinones in high yields (eq 6).[2] Benzoins are not oxidized efficiently.

(4)

(5)

(6)

A brief comparison between DCCD, ***Cerium(IV) Ammonium Nitrate*** (CAN),[1a,3,4] ***Barium Manganate*** (BM),[5] and ***Bis(pyridine)silver(I) Permanganate*** (BPSP)[6] is given in Table 1.

Table 1 Comparison of Yields Achieved by Various Oxidizing Agents

Substrate	Product	DCCD	CAN	BM	BPSP
		85	-	80	95
Hydroquinone	p-Benzoquinone	100	83	75	90
Benzylamine	Benzaldehyde	100	-	95	95
Cinnamyl alcohol	Cinnamaldehyde	20	-	100	-
Furoin	Furil	30	5	-	-
Benzyl alcohol	Benzaldehyde	100	94	90	100

2,4-Dinitrobenzeneseleninic Acid

[65252-77-9] · $C_6H_4N_2O_6Se$ · 2,4-Dinitrobenzeneseleninic Acid · (MW 279.07)

(catalyst with hydrogen peroxide for the epoxidation of alkenes[1,2] and the Baeyer-Villiger oxidation of aromatic aldehydes and ketones[3])

Physical Data: mp 140-143 °C (dec).

Solubility: slightly sol water; sol dioxane, ethyl acetate.

Preparative Methods: obtained from the oxidation of bis(2,4-dinitrophenyl) diselenide with 85% ***Hydrogen Peroxide***[4] or fuming ***Nitric Acid***.[5] Bis(2,4-dinitrophenyl) diselenide is prepared from the reaction of ***Lithium Diselenide*** with 2,4-dinitrochlorobenzene[6] or from the base hydrolysis of 2,4-dinitrophenyl selenocyanate.[5]

Handling, Storage, and Precautions: both 2,4-dinitrobenzeneseleninic acid and bis(2,4-dinitrophenyl) diselenide are stable indefinitely at rt. Selenium compounds are potentially toxic and should be handled in a fume hood.

2,4-Dinitrobenzeneseleninic acid, conveniently generated in situ from bis(2,4-dinitrophenyl) diselenide (**1**), catalyzes the epoxidation of alkenes in CH_2Cl_2 under two-phase reaction conditions with 30% H_2O_2 (eq 1).[1,2] The addition of anhydrous $MgSO_4$ removes excess water, enhancing the reaction rate[1] and inhibiting diol formation.[7] Catalyst levels of 0.5-5% are effective for epoxidizing di-, tri-, and tetrasubstituted alkenes in high yields. With less reactive terminal alkenes, such as styrene, the addition of 30% H_2O_2 in portions over 14 h and the presence of radical inhibitor are needed to achieve good yields of epoxide.[8] Allylic alcohols exhibit little, if any, stereoselectivity (eq 2) or regioselectivity (eq 3), in contrast to epoxidations with peroxycarboxylic acids or with alkyl hydroperoxides in the presence of vanadium and molybdenum catalysts.[1]

(1)

(2)

(3)

The use of safe and inexpensive 30% H_2O_2, the ease of product isolation (mild base extraction removes the traces of catalyst from the CH_2Cl_2 layer), and the potential for catalyst recycle[3] make the in situ generation of 2,4-dinitroperoxybenzeneseleninic acid (eq 4)[9] an attractive alternative to the stoichiometric use of peroxycarboxylic acids for Baeyer-Villiger oxidations.

(4)

Phenols are obtained from aromatic aldehydes via their corresponding aryl formates in high yield with 30% H_2O_2 (eq 5), while 90% H_2O_2 is needed to convert polymethoxyacetophenones to phenols in moderate yields. α,β-Unsaturated aldehydes react similarly to aromatic aldehydes to give vinyl formates (see also ***o-Nitrobenzeneseleninic Acid***).[10]

(5)

A variety of other seleninic acids (see also ***Benzeneseleninic Acid*** and ***o-Nitrobenzeneseleninic Acid***) and diselenides have been studied using the two-phase oxidation conditions. However, from an activity standpoint, 2,4-dinitrobenzeneseleninic acid is the catalyst of choice for large scale syntheses, particularly epoxidations.[1,8]

2,4-Dinitrobenzenesulfenyl Chloride

[528-76-7] · $C_6H_3ClN_2O_4S$ · 2,4-Dinitrobenzenesulfenyl Chloride · (MW 234.63)

(sulfenylation agent used in electrophilic additions,[1,2] diene synthesis,[12] protection of nucleosides,[13] and preparation of propargyl alcohol synthons for use in cycloaddition chemistry[15])

Alternate Name: 2,4-dinitrophenylsulfenyl chloride.

Physical Data: mp 94-97 °C.

Solubility: sol most common organic solvents.

Form Supplied in: commercially available as a solid (96% pure).

Handling, Storage, and Precautions: corrosive; lachrymator. This reagent should be handled in a fume hood.

Electrophilic Additions.

The most common use of 2,4-dinitrobenzenesulfenyl chloride is in electrophilic additions. The reagent reacts with a variety of nucleophiles by displacement of the chlorine atom (eq 1).[1] The electrophilic addition of this reagent to alkenes (eq 2),[2] alkynes,[3] and allenes[4] has been extensively studied. The addition occurs in a *trans* stereospecific fashion. Additives to the reaction, such as ***Lithium Perchlorate*** and ***Formic Acid***, reportedly increase the electrophilicity of the reagent.[5,6] Mechanistic aspects, along with stereo- and regioselectivity, have been reported.[2b,7-11]

Diene Synthesis.

The 1,4-dehydration of allylic alcohols using 2,4-dinitrobenzenesulfenyl chloride and ***Triethylamine*** provides 1,3-dienes in good yields (eq 3).[12] The reaction involves a 2,3-sigmatropic rearrangement of the sulfenate ester, followed by a thermal *syn* elimination. Selenenate esters can also be converted to the 1,3-dienes, but the conditions are more severe and the reaction is less general than with this reagent.

Protection of Nucleosides.

The 2,4-dinitrobenzenesulfenyl group serves as a protecting group for both the hydroxy functionalities and the base in nucleosides (eq 4).[13,14] Dinitrobenzenesulfenic esters are stable to pyridine solutions of ***Acetic Anhydride*** or ***p-***

Toluenesulfonyl Chloride. ***1,3-Dicyclohexylcarbodiimide*** conditions for forming oligonucleosides also do not affect this protecting group. Deprotection is readily accomplished with nucleophilic reagents such as ***Sodium Thiosulfate***, ***Thiophenol***, or ***Potassium Cyanide***.

(4)

Propargyl Alcohol Synthons in Cycloadditions.

Allenic sulfoxides can serve as propargyl alcohol equivalents in 1,3-dipolar cycloaddition reactions.[15] Treatment of propargyl alcohol with 2,4-dinitrobenzenesulfenyl chloride and triethylamine gives the transient sulfenate ester that spontaneously rearranges to the allenic sulfoxide. The (2,4-dinitrophenyl)sulfinyl-substituted allene reacts smoothly with a variety of nitrones. The initially formed cycloadduct undergoes a 2,3-sigmatropic rearrangement to produce sulfenate esters of isoxazolidines (eq 5).

3,5-Dinitrobenzenesulfonyl Chloride

[31206-25-4] · $C_6H_3ClN_2O_6S$ · 3,5-Dinitrobenzenesulfonyl Chloride · (MW 266.63)

(sulfonylating agent for the preparation of crystalline sulfonamides and sulfonate esters; 3,5-dinitrobenzenesulfonate esters exhibit high reactivity in solvolysis reactions[1,2])

Physical Data: mp 98.5 °C.

Solubility: sol AcOH, pyridine; insol diethyl ether.

Form Supplied in: not commercially available; easily prepared.

Preparative Method: by a modified Sandmeyer reaction.[3,4] Diazotization of 3,5-dinitroaniline (0.25 mol) at -15 °C in aqueous acetic acid/conc HCl followed by addition to a saturated solution of SO_2 in acetic acid gives the product, which is precipitated by the addition of water, washed with water then diethyl ether, and dried under vacuum (81% yield).

Handling, Storage, and Precautions: reactive sulfonylating agent: avoid contact with skin and mucous membranes. Can be stored at rt for prolonged periods when dried and kept free of moisture.

General Reactions.

Arenesulfonyl chlorides are vital precursors for the preparation of a wide variety of functional groups including sulfonate esters, sulfonamides, and sulfones. A variety of substituted arenesulfonyl chlorides can be used to derivatize alcohols and primary and secondary amines forming sulfonate esters and sulfonamides, respectively. Substituted arenesulfonate esters exhibit varying rates of S_N1 and S_N2 reactions which are dependent on the aryl substituents.[2]

Solvolysis of 3,5-Dinitrobenzenesulfonates.

Solvolysis of the crystalline 3,5-dinitrobenzenesulfonate of 3-pentyn-1-ol in CF_3CO_2H-CF_3CO_2Na gives 2-

methylcyclobutanone[1] in 73% yield (eq 1). The yield of 2-methylcyclobutanone was reduced when the *p*-toluene- and *m*-nitrobenzenesulfonates were used. Cyclobutanone[5] and other alkyl-substituted cyclobutanones[6] have also been prepared via this participation of an alkynic bond during solvolysis of homopropargylic sulfonate esters, but the former requires the use of the more reactive trifluoromethanesulfonate.

Related Reagents.

p-Anisolesulfonyl Chloride; ***Benzenesulfonyl Chloride***; ***4-Bromobenzenesulfonyl Chloride***; ***Methanesulfonyl Chloride***; ***p-Toluenesulfonyl Chloride***; ***Trifluoromethanesulfonyl Chloride***.

2,4-Dinitrobenzenesulfonylhydrazide

[53777-75-6] · $C_6H_6N_4O_6S$ · 2,4-Dinitrobenzenesulfonylhydrazide · (MW 262.23)

(an effective reagent for preparing propargyl ketones and aldehydes via the Eschenmoser fragmentation[2])

Alternate Name: DNSH.

Physical Data: mp 120 °C.

Solubility: sol most organic solvents.

Analysis of Reagent Purity: IR, NMR.

Preparative Method: by treatment of 2,4-dinitrobenzenesulfonyl chloride with 95% hydrazine in THF and crystallized from EtOH/THF.[1]

Handling, Storage, and Precautions: thermally labile; should be stored in a freezer. It is a toxic and potentially flammable solid that should be handled with gloves under inert atmosphere and freshly prepared as needed.

Eschenmoser Fragmentation.

Despite reports of the superiority of 2,4-dinitrobenzenesulfonyl hydrazide (DNSH) in the Eschenmoser fragmentation, this reagent has received very little attention as a mild alternative to ***p-Toluenesulfonylhydrazide*** and *N*-aminoaziridines.[2,3] Condensation of DNSH with α,β-epoxy ketones in THF or dichloromethane gives smooth cleavage to alkynones and alkynals between 0 °C and rt (eqs 1-3) when treated with catalytic amounts of base (pyridine, sodium bicarbonate, or sodium carbonate). Yields are good to excellent. The fragmentation shown in eq 2 cannot be effected with ***p-Toluenesulfonylhydrazide***, and *N*-aminoaziridines give low, irreproducible yields.[1]

R = H, 62%; Me, 62%

(2)

(3)

Use of this reagent for synthesis of selenosulfonates has also been briefly examined, but ***Mesitylenesulfonylhydrazide*** is more efficient.[4,5]

3,5-Dinitrobenzoyl Chloride

[99-33-2] · $C_7H_3ClN_2O_5$ · 3,5-Dinitrobenzoyl Chloride · (MW 230.57)

(activation of hydroxy groups by conversion to the corresponding ester;[1] preparation of 3,5-dinitrobenzoates and 3,5-dinitrobenzamides for characterization purposes[3])

Physical Data: mp 69-71 °C; bp 196 °C/11 mmHg.

Solubility: sol ether; reacts with water and protic solvents.

Form Supplied in: 98% pure form as yellow solid (2% impurity as carboxylate); widely available.

Purification: recrystallization from carbon tetrachloride/petroleum ether (40-60 °C) or from benzene.

Handling, Storage, and Precautions: lachrymator; corrosive and moisture sensitive. Avoid inhalation. Store in sealed tube or under petroleum ether.

Preparation of 3,5-Dinitrobenzoates.

3,5-Dinitrobenzoates, prepared by the acylation of a hydroxy group with 3,5-dinitrobenzoyl chloride, have been utilized in solvolysis studies,[1] S_N2' displacement of propargylic alcohols,[2] and derivatization of alcohols for characterization purposes.[3,4] A variety of functional groups are stable under the benzoylation conditions (eqs 1 and 2). An alternative preparation of 3,5-dinitrobenzoates entails the direct coupling of 3,5-dinitrobenzoic acid and an alcohol using an activating reagent such as ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride*** (eq 3).[2b]

(2)

The 3,5-dinitrobenzoate esters of alcohols are often crystalline derivatives and have been used for characterization purposes.[3] For example, selective benzoylation of the secondary hydroxy group of an isomer of 25-hydroxyvitamin D_3 affords the corresponding crystalline 3,5-dinitrobenzoate derivative (eq 4).[3b]

(4)

The chromatographic separation of the enantiomers of alcohols, using a chiral stationary phase, is enhanced by the preparation of the corresponding 3,5-dinitrobenzoate derivatives.[4]

Benzoylation of Amino Groups.

3,5-Dinitrobenzamides are useful derivatives of amines for characterization purposes (eqs 5 and 6). The 3,5-dinitrobenzamides of amines have been particularly useful for the chromatographic separation of amines, amino acids, and amino alcohols using chiral stationary phases.[4,5]

2,4-Dinitrophenylhydrazine

[119-26-6] · $C_6H_6N_4O_4$ · 2,4-Dinitrophenylhydrazine · (MW 198.16)

(readily forms derivatives with aldehydes and ketones;[1,2] synthesis of heterocycles;[3-5] reduction of carbonyls[6])

Alternate Name: $DNPH_2$.

Physical Data: mp 194 °C (198 °C dec).

Solubility: sol DMF, DMSO, aniline, hot EtOAc; mod sol hot EtOH; slightly sol Et_2O, $CHCl_3$, benzene, CS_2.

Form Supplied in: moist, orange-red solid (contains 20-35% H_2O).

Preparative Method: from 2,4-dinitrochlorobenzene and hydrazine in 81-85% yield.[7]

Handling, Storage, and Precautions: toxic; irritant; flammable solid.

Derivatives of Aldehydes and Ketones.

The reaction of 2,4-dinitrophenylhydrazine with aldehydes and ketones represents an extensively studied qualitative test and usually leads to the formation of yellow to orange crystals of the corresponding 2,4-dinitrophenylhydrazone (DNP) derivatives (eq 1).[1] Some long-chain aliphatic ketones (e.g. 2-decanone and 6-undecanone) fail to provide solid DNP derivatives.[2] Further caution needs to be exercised in interpreting the results since primary and secondary alcohols containing two or more vinyl or aromatic substituents can be oxidized to the carbonyls which then form the corresponding hydrazones in low yields.[8] Tertiary alcohols tend to undergo condensation reactions with $DNPH_2$ (eq 2).[9]

(1)

+ H_2O (2)

Formation of Heterocycles.

The reactivity of $DNPH_2$ has also been utilized in the syntheses of nitrogen-containing heterocycles.[3] Imino ester hydrochlorides, generated from nitriles, react with $DNPH_2$ to provide amidazones, which are converted in situ to 1,3,5-substituted triazoles by reaction with acid chlorides (eq 3).[4] Treatment of acyldimedone derivatives with $DNPH_2$ provides indole derivatives (eq 4).[5]

(3)

(4)

Reduction.

Catalytic hydrogenolysis of DNP derivatives of alkyl aryl or diaryl ketones leads to the formation of corresponding methylene derivatives and represents a useful alternative to Wolff-Kishner and Clemmenson reductions (eq 5).[6] In the steroid series, where ordinary methods fail to induce unsaturation in α-bromo ketones, $DNPH_2$ has been used to effect dehydrohalogenation.[10]

(5)

Carbonyl Regeneration.

DNP derivatives can be cleaved to regenerate the carbonyl functionality. Efficient techniques for affecting this transformation include DNP exchange with pyruvate,[10a] Amberlyst 15 catalyst,[11] clay-supported iron(III) nitrate,[12] and aqueous titanium(III) ion.[13]

Related Reagents.

N,N-Dimethylhydrazine; ***O-2,4-Dinitrophenylhydroxylamine***; ***Phenylhydrazine***.
