
[17508-17-7] · $C_6H_5N_3O_5$ · *O*-2,4-Dinitrophenylhydroxylamine · (MW 199.14)

(widely applicable electrophilic amination reagent; converts aldoximes to cyanides and benzofurans)

Alternate Names: DNPHA; NH_2ODNP.

Physical Data: pale yellow needles, mp 112-113 °C. A rapid active-site-directed inhibitor of D-amino acid oxidase.[1]

Preparative Methods: can be generated economically from the reaction of 2,4-dinitrochlorobenzene and ethyl *N*-hydroxyacetimidate with subsequent hydrolysis.[2] *t*-Butyl *N*-hydroxycarbamate[3] and *N*-hydroxy-5-norbornene-2,3-dicarboximide[4] can be used in place of ethyl *N*-hydroxyacetimidate.

Handling, Storage, and Precautions: an otherwise stable, crystalline solid, DNPHA has been known to detonate when combined with ***Potassium Hydride*** and therefore direct combination of these two reagents should be avoided.[5] 2,4-Dinitrophenol, a byproduct of amination reactions involving DNPHA, is a highly toxic, flammable solid. Use in a fume hood.

Conversion of Aldoximes to Cyanides and Benzofurans.

The title compound has been used in a convenient, high-yield conversion of aldehydes to nitriles via oximes.[6] Oximes derived from a variety of aldehydes and ketones have also been used in the formation of 5,7-dinitrobenzofurans via the Fischer reaction (eq 1).[7]

Preparation of Dialkylamines.

A number of reagents exist for the preparation of primary,[8] secondary,[9] and tertiary amines[10] from organoboranes; a common feature of all these reagents is the lone leaving group on nitrogen. Consequently, these reagents are suitable for transferring only one alkyl group from the organoborane; transfer of two alkyl groups from the organoborane to the same nitrogen requires two leaving groups on the nitrogen. This dual transfer can be achieved with the use of *N*-chloro-*O*-(2,4-dinitrophenyl)hydroxylamine generated in situ from DNPHA. In the following example, reaction of DNPHA with ***t-Butyl Hypochlorite*** followed by addition of perhydroboraphenalene and subsequent peroxide oxidation gives the amino alcohol (eq 2).[11]

Amination Reactions.

Electrophilic amination constitutes the major use of DNPHA in synthesis; attack on the amine nitrogen of DNPHA readily occurs in an S_N2 fashion. The stability of DNPHA relative to the corresponding *O*-arylsulfonylhydroxylamines,[7c] which also have been used for these transformations, and the good leaving-group ability of the 2,4-dinitrophenolate anion both enhance its usefulness. The primary substrates for amination by DNPHA are nitrogen-containing compounds in the form of heterocycles or disubstituted amino derivatives. Many species have been *N*-aminated, including pyrroles,[3] pyridines,[12] nucleosides,[13-16] carbamates,[17-19] amides,[18] phthalimides,[3,20] sulfonamides,[3] thiazolidines,[21] and triazin-5(2*H*)-ones;[22-24] an example of a sulfonamide is given in eq 3.[3] In the case of guanine[14] and 2-amido- and 2-carbamoylthiophenes,[18] however, other amination reagents have proven more efficacious; furthermore, nucleosides are aminated at the most basic *endo* nitrogen position.[13] Primary[25] and tertiary[26] amines have also been *N*-aminated by this method.

(3)

DNPHA has been used to aminate other heteroatoms as well. Phenol derivatives[27] (including hydroxycoumarins),[28] thiophenol derivatives,[11] and phosphines[11] have all been successfully converted to their *O*- *S*-, and *P*-amino derivatives by this reagent. In addition, aliphatic compounds such as malonates[5] and aromatic compounds such as fluorene derivatives[3] have been aminated at the active carbon center. An interesting reaction involving a boraalkane has also been reported.[29]

The kinetics of DNPHA addition are first-order with respect to both substrate and nucleophile and are second-order overall.[11]

1,3,2-Dioxathiolane 2,2-Dioxide[1]

($R^1 = R^2 = H$)

[1072-53-3] · $C_2H_4O_4S$ · 1,3,2-Dioxathiolane 2,2-Dioxide · (MW 124.13) ($R^1 = R^2 =$ *n*-Bu)

[127901-92-3] · $C_{10}H_{20}O_4S$ · 4,5-Dibutyl-1,3,2-Dioxathiolane 2,2-Dioxide · (MW 236.37)

(display epoxide-like reactivity;[2,3] nucleophilic displacement of both oxygen functions is feasible[4-6])

Alternate Names: ethylene sulfate; cyclic sulfates.

Preparative Methods: cyclic sulfates of 1,2-diols (1,3,2-dioxathiolane 2,2-dioxides) are most easily prepared in a two-step procedure (eq 1).[2] Reaction of a 1,2-diol with ***Thionyl Chloride*** leads to a cyclic sulfite which is then oxidized to the corresponding cyclic sulfate (**1**). Direct conversion of a 1,2-diol to a cyclic sulfate using ***Sulfuryl Chloride*** is generally less efficient.[2,3]

(1)

Handling, Storage, and Precautions: the structural similarity between cyclic sulfates and ***Dimethyl Sulfate*** must be recognized. Dimethyl sulfate, and to a lesser extent ethylene sulfate, are carcinogenic and potent alkylating agents that are toxic by inhalation and ingestion.[1] **Cyclic sulfates must, as a result, be treated with extreme care**.

Cyclic sulfates of 1,2-diols are an important group of reagents and recent advances in the asymmetric dihydroxylation

of alkenes (see ***Osmium Tetroxide***) will serve to increase further their synthetic potential.[7] Cyclic sulfates display reactivity towards nucleophiles that is closely related to that of epoxides and react in a regioselective fashion with hydride (eq 2)[2] and a wide range of heteroatoms (eqs 3-5)[2,3,8,9] and carbon-based nucleophiles (eq 6).[2,5,6]

The reactivity of nitrogen nucleophiles towards cyclic sulfates has attracted considerable interest and provides an efficient entry into 1,2-amino alcohols (eq 7).[4,10]

(7)

It is, however, important to appreciate the additional scope offered by cyclic sulfates over epoxides as electrophilic components in displacement processes. Following nucleophilic ring-opening, the intermediate β-sulfate, e.g. (**2**), functions as a leaving group and can undergo a second displacement.[2] This provides a direct access to aziridines (including *N*-unsubstituted variants) (eq 8),[4,10] to 1,2-diamines (eq 9),[11] and, with activated carbon nucleophiles, to cyclopropanes (eq 10).[5,6]

(8)

(9)

(10)

In cyclic sulfates derived from α,β-unsaturated esters, regioselective nucleophilic attack has been observed (eq 11);[2] the corresponding epoxide undergoes ring opening with a lower level of regioselectivity.

(11)

Cyclic sulfates are stable towards L-selectride (***Lithium Tri-s-butylborohydride***)[12] and are also compatible with acid (and the sulfate cleaved in the presence of acid-labile protecting groups, e.g. OTBDMS, acetonide).[13]

4*H*-1,3-Dioxin

[290-13-1] · $C_4H_6O_2$ · 4*H*-1,3-Dioxin · (MW 86.10)

(precursor to a β-formylvinyl anion equivalent;[1] useful for the preparation of β-substituted acroleins,[1-3] *syn*-1,3-diols,[4] and *anti,anti*-1,2,3-triols[4])

Physical Data: bp 97-99 °C.

Solubility: sol THF, ether, hexanes.

Preparative Methods: by elimination of 5-tosyloxy-1,3-dioxane in DMSO using ***Potassium t-Butoxide***[5] or $KOCMe_2C_6H_{13}$[6] as the base. A more convenient procedure employs triethylene glycol as the solvent and ***Potassium Hydroxide*** as the base.[2]

Handling, Storage, and Precautions: thermally labile. A rapid distillation is required in order to prevent decomposition via retrocycloaddition to acrolein and formaldehyde.

β-Formylvinyl Anion Equivalent.

4*H*-1,3-Dioxin undergoes rapid metalation upon treatment with ***s-Butyllithium*** or ***t-Butyllithium*** to provide the allylic anion (**1**).[1] A variety of electrophiles such as alkyl halides, epoxides, aldehydes, and ketones can be employed in subsequent alkylation reactions to afford 4-substituted dioxins which smoothly undergo bis-hetero retrocycloaddition reactions upon refluxing in toluene (4-12 h) to provide (*E*)-α,β-unsaturated aldehydes, presumably through a boat-like transition state with the alkyl substituent in a pseudoequatorial position (eq 1).[1] Moreover, the thermal generation of β-substituted acroleins has been exploited in a one-pot retrocycloaddition-cycloaddition sequence (eq 2).[1]

(1)

(2)

Numerous β-formylvinyl anion equivalents have been previously reported. However, the use of all of these equivalents requires at least one reagent-mediated step to unravel the α,β-unsaturated aldehyde after the alkylation step, e.g.: (**2**) $HgCl_2$, MeCN, H_2O, 50 °C;[7] (**3**) H_2O_2;[8] (**4**) H_3O^+;[9] (**5**) H_3O^+;[10] (**6**) 1 H_3O^+, 2 NEt_3;[11] and (**7**) 1 Pt, e^-, 2 NEt_3.[12]

(2)

(3)

(4)

(5)

(6)

(7)

syn-1,3-Dihydroxy- and *anti,anti*-1,2,3-Trihydroxypropanediyl 1,3-Dianion Equivalents.

4-Alkyl-1,3-dioxins, such as the one shown in eq 1, can be further metalated and alkylated with excellent regioselectivity to provide 4,6-dialkyl-1,3-dioxins (eq 3). Hydroboration reactions of 4,6-dialkyl-1,3-dioxins proceed with complete stereoselectivity from the face opposite the 6-alkyl substituent to provide, after oxidative workup, a single 5-hydroxy-substituted dioxin which can be hydrolyzed to an *anti,anti*-1,2,3-triol (eq 4). Excellent diastereofacial discrimination is similarly observed in the hydrogenation reactions of 4,6-dialkyl-1,3-dioxins to provide only a *syn*-1,3-diol after hydrolysis (eq 5).

(3)

(4)

(5)

β-Formylvinyl Cation Equivalent.

4*H*-1,3-Dioxin participates in Heck reactions with a variety of aryl halides and aryl triflates to afford 4-aryl-substituted dioxins which, upon thermolysis in refluxing toluene, are transformed to 3-arylacroleins (eq 6).[3]

Related Reagents.

1,3-Dibutoxy-1-lithio-1-propene.

(1,3-Dioxolan-2-ylmethyl)triphenylphosphonium Bromide

[52509-14-5] · $C_{22}H_{22}BrO_2P$ · (1,3-Dioxolan-2-ylmethyl)triphenylphosphonium Bromide · (MW 429.31)

(generation of the nonstabilized ylide (1,3-dioxolan-2-ylmethylene)triphenylphosphorane for Wittig alkenation; synthesis of masked α,β-unsaturated aldehydes from aldehydes; reagent for two-carbon chain homologation[1])

Physical Data: mp 193-195 °C.

Form Supplied in: white solid, 98%.

Preparative Method: from 2-bromomethyl-1,3-dioxolane and triphenylphosphine at 100 °C (36 h).[2]

Purification: recrystallized from methylene chloride/ether.[2]

α,β-Unsaturated Aldehydes.

This phosphonium salt reacts with base to give (1,3-dioxolan-2-ylmethylene)triphenylphosphorane, which is used in situ. Wittig reaction of this nonstabilized phosphorus ylide with aldehydes affords α,β-unsaturated acetals; acidic hydrolysis then provides the corresponding aldehydes. The alkene stereochemistry obtained is highly dependent on the base or solvent used. (*E*)-Alkenes are predominant with lithium methoxide or potassium carbonate in DMF (e.g. eq 1).[2-6] Reactions of the ylide with ketones are generally poor.

(1)

Fraser-Reid and co-workers studied the stereoselectivity of this reagent in reactions with benzaldehyde involving different bases. When the phosphorane was prepared in THF with ***n-Butyllithium***, only the (*E*)-alkene is formed. With dimsylsodium (***Sodium Methylsulfinylmethylide***) in DMSO a 3:1 ratio of (*Z*)- to (*E*)-isomers is obtained, while addition of THF to the DMSO reaction results in a 8:1 preference for the (*Z*)-isomer.[7] These reaction conditions have been applied to ansamycin precursors (eq 2).[7-9]

(2)

Also, whereas α-alkoxy aldehydes usually furnish (*E*)-alkenes almost exclusively with ***Formylmethylenetriphenylphosphorane***, Sakai et al. found that (1,3-dioxolan-2-ylmethylene)triphenylphosphorane, generated from the phosphonium reagent by using ***Sodium Hydride*** in THF-HMPA, gives mainly (*Z*)-alkenes (eq 3).[10] Replacing the THF with DMF reduces this preference to ca. 75:25.

(3)

The Bestmann protocol with formylmethylenetriphenylphosphorane, which involves treatment with EtBr and NaOEt to form a diethyl acetal intermediate, offers a similar means for elaboration of aldehydes into α,β-unsaturated aldehydes chain-extended by two carbons, with high (*Z*) stereoselectivity.[11,12] Related ylide reagents have also been used for such two-carbon homologations.[13]

Diphenylacetylene

[501-65-5] · $C_{14}H_{10}$ · Diphenylacetylene · (MW 178.24)

(precursor to substituted stilbenes[1,2] and benzil;[3] participant in cycloaddition chemistry;[4] symmetrical π-acidic ligand used widely in organometallic chemistry[5])

Physical Data: mp 62.5 °C; bp 90-97 °C/0.3 mmHg; *d* 0.990 g cm^{-3}.

Solubility: sol ether, hot alcohol.

Form Supplied in: colorless solid; widely available.

Handling, Storage, and Precautions: low oral toxicity; possible danger from absorption through skin.

Introduction.

Due to the symmetry and high degree of planarity of diphenylacetylene, it has enjoyed enormous success as a highly Lewis acidic and sterically accessible alkyne for use in various areas of organic chemistry, as well as in organometallic chemistry where it serves as an excellent ligand of varying hapticity.

Oxidation and Reduction.

The oxidation of diphenylacetylene is reported to proceed under a variety of conditions. Its cleavage to benzoic acid has been accomplished by molybdenum(VI) and tungsten(VI) polyoxometalates,[6] as well as by [bis(trifluoroacetoxy)iodo]pentafluorobenzene.[7] Chromium-based complexes,[3] zinc/chromium,[8] electrooxidation,[9] and ***Barium Manganate***,[10] among others,[11] have been successfully utilized in the oxidation of diphenylacetylene to benzil. However, methods for its oxidation to the monoketone are scarce.[12]

The reduced states of diphenylacetylene are attainable via several efficient methods. (*E*)-Stilbene is produced in 80% yield with the aid of $NiCl_2.4PPh_3$.[1] Hydrogenation over a ruthenium catalyst[2] provides (*Z*)-stilbene, as does the use of $CoCl_2.4PPh_3/SmI_2/AcOH$[13] or zinc in combination with Pd/C.[14] Reduction of the alkyne bond to the alkane level is achieved with the use of hydrogen and a montmorillonite-(diphenylphosphine)palladium(II) complex,[15] or zinc in combination with Pd/C.[14]

Addition of X-Y Across the Alkyne π-Bond.

Addition across the alkynic bond occurs with a number of reagents. Formal addition of RS-Cl (eq 1),[16] PhSe-F,[17] Me_3Sn-PPh_2, PhS-F, PhS-SPh,[18] and ClHg-OAc[19] proceeds in *trans* fashion in each instance. However, similar addition of Bu_3Sn-H (eq 2),[20] RNH-H,[21] and HO_2C-H[22] leads to the formation of *cis*-stilbene derivatives. H-CN,[23] TMS-CN,[24] X_2 (X = halogen),[25] Et-$AlEt_2$,[26] and Al-H[27] additions to diphenylacetylene have also been reported.

(1)

(2)

Susceptibility to Carbene Addition.

Diphenylacetylene undergoes addition with chromium, tungsten, and cobalt[28] carbenes. Chromium Fischer-type carbenes react with diphenylacetylene to form cyclopentenones (eq 3).[29] Pyrrolinones are accessed when nitrogen is present in the chromium carbene reagent (eqs 4 and 5).[30] Tungsten carbenes of the Fischer class respond differently in that they form seven-membered rings (eq 6).[31] Diphenylacetylene has also demonstrated an ability to undergo facile cycloaddition with *ortho*-manganated aryl ketones to afford inden-1-ols (eq 7).[32]

(3)

Interaction with Various Metals.

The response of diphenylacetylene to palladium in coupling[33] and annulation (eq 8)[34] transformations is well documented. Spiroannulation has been effected with the aid of nickel (eq 9),[35] and insertion into zirconium complexes has been shown to provide a variety of unsaturated molecules.[36] Finally, diphenylacetylene has exhibited a general propensity for ligating to organometallic complexes[37] and clusters,[38] and to be capable of engaging in metathesis reactions.[39]

(8)

(9)

Ring Formation and Cycloaddition.

Incorporation of a vicinal diphenyl group into rings of various types has been demonstrated repeatedly. Oxazoles,[40] benzothiophenes,[41] indoles,[42] pyrroles,[43] and furan-2(5*H*)-ones[44] among others[45] containing this arrangement have been reported. Ring construction that involves the diphenylacetylene moiety has been accomplished in various ways. Diphenylacetylene undergoes cycloaddition to ketenes of several types, with subsequent fragmentation and rearrangement (eqs 10 and 11).[46]

(10)

(11)

Diphenylacetylene participates satisfactorily in Pauson-Khand reactions.[47] Furthermore, [3 + 3] cycloaddition with azomethine ylides provides the respective pyrrole in good yield (eq 12).[48] Examples of [4 + 2],[49] [2 + 2],[50] 1,3-dipolar,[51] and other cycloadditions[52] have been widely reported.

(12)

Related Reagents.

Dimethyl Acetylenedicarboxylate.

Diphenylacetyl Chloride

[1871-76-7] · $C_{14}H_{11}ClO$ · Diphenylacetyl Chloride · (MW 230.70)

(preparation of diphenylketene[1])

Physical Data: mp 49-53 °C; bp 175-176 °C/17 mmHg.

Form Supplied in: 90% technical grade.

Preparative Method: by the action of ***Thionyl Chloride*** on diphenylacetic acid.[2]

Handling, Storage, and Precautions: corrosive; a lachrymator. Use in a fume hood.

Diphenylacetyl chloride is used as the principal reagent in the preparation of diphenylketene.[1] Diphenylacetyl chloride reacts with ***Triethylamine*** in an inert solvent such as ether or benzene, at rt, to give 53-57% yield of diphenylketene (eq 1). The ketene may be isolated for subsequent use (eq 2).[2] More frequently, diphenylketene is generated in situ (eq 3).[3]

(1)

Diphenylacetyl chloride has been used in the synthesis of thiol esters via thiolate ions supported on the anion exchanger Amberlyst A-26. Many acid chlorides have been reacted in this manner (eq 4).[4]

Regina Zibuck

(Diphenylarsinyl)methyllithium[1]

$Ph_2As(O)CH_2Li$

[61024-99-5] · $C_{13}H_{12}AsLiO$ · (Diphenylarsinyl)methyllithium · (MW 266.11)

(indirect nucleophilic halomethylation[2] and haloalkylation[3] of aldehydes, ketones, alkyl halides, and epoxides; synthesis of 2-hydroxy-1,2λ^5-oxarsolanes,[1,4] 1,2-bis(diphenylarsinyl)ethane, 1,2-bis(diphenylarsino)ethane (diars), and 1-diphenylarsino-2-(diphenylarsinyl)ethane[5])

Solubility: sol THF.

Preparative Method: quantitatively formed as a yellow solution in THF by treating the easily accessible (diphenylarsinyl)methane[6] with LDA at -40 °C (eq 1).

Handling, Storage, and Precautions: handle and store the THF solution of $Ph_2As(O)CH_2Li$ under N_2 or Ar; $Ph_2As(O)Me$ (mp 153-154 °C) is stable in air but toxic. Use in a fume hood.

Indirect Nucleophilic Halomethylation and α-Haloalkylation.

$HalCH_2Li$ and HalCH(Alk)Li would be interesting reagents for nucleophilic halomethylation and α-haloalkylation, but they are quite unstable due to carbene formation. Ph_2AsCH_2Li[7] is an attractive synthetic equivalent for $HalCH_2Li$, but $Ph_2As(O)CH_2Li$ is more accessible and more reactive. Treatment of this reagent with electrophiles (aldehydes, ketones, alkyl halides) followed by ***Lithium Aluminum Hydride*** and then with halogen (Br_2, I_2) or ***Thionyl Chloride*** affords halogen compounds (e.g. β-hydroxy alkyl halides) in preparatively useful yields (eq 2; R = H).[2] The yield determining step is the reaction with the electrophile, according to eqs 3 and 4.

Like $Ph_2As(O)Me$, the higher homologs (prepared as in eq 3) can be lithiated at the methylene group α to the As atom by ***Lithium Diisopropylamide***. The resulting compounds provide entry to functionalized hydrocarbons according to eq 2 (R = Alkyl).[3] ***Sulfuryl Chloride*** is particularly useful as a reagent for replacing the diphenylarsino group by chlorine. Also the methine group of *s*-butyldiphenylarsine oxide is lithiated by LDA (80%). α-Lithiated alkyldiphenylarsine oxides react extremely diastereoselectively with benzaldehyde or acetophenone.[3b]

Synthesis of 2,2-Diphenyl-2-hydroxy-1,2λ^5-oxarsolanes.

The treatment of terminal epoxides with $Ph_2As(O)CH_2Li$ and subsequently with H_2O leads to 2,2-diphenyl-2-hydroxy-1,2λ^5-oxarsolanes (eq 5), which are smoothly reduced by $LiAlH_4$ to γ-hydroxy alkyl arsines. These undergo halogenolysis to give γ-hydroxy alkyl halides.[1,4]

Coupling.

$Ph_2As(O)CH_2Li$ reacts with ***Copper(II) Chloride*** to give 1,2-bis(diphenylarsinyl)ethane (64%), which is quantitatively reduced by $LiAlH_4$ to 1,2-bis(diphenylarsino)ethane, the important ligand diars for transition metals (eq 6). ***Sodium Borohydride*** can be used to obtain the corresponding monooxide (88%).[5]

1,1-Diphenyl-2-azaallyllithium[1]

(**1**; R^1 = Ph, R^2 = H)

[64042-43-9] · $C_{14}H_{12}LiN$ · 1,1-Diphenyl-2-azaallyllithium · (MW 201.21) (**2**; R^1 = H, R^2 = Ph)

[37019-83-3]

(agents for the nucleophilic aminomethylation of ketones and alkyl halides;[2] react with C=C, C=N, C=S, and N=N double bonds as well as with C&tbond;C and C&tbond;N triple bonds by [3 + 2] cycloaddition with high regioselectivity and stereospecificity;[3] corresponding cycloadditions with *N*-benzylidenebenzylamine[1])

Solubility: sol THF; slightly sol Et_2O.

Preparative Methods: 1,1-diphenyl- (**1**) and 1,3-diphenyl-2-azaallyllithium (**2**)[4] are prepared by deprotonation of *N*-(diphenylmethylene)methylamine or *N*-benzylidenebenzylamine, respectively, with ***Lithium Diisopropylamide*** in THF or Et_2O/THF at ca. -60 °C. Solutions thus prepared contain diisopropylamine. Amine-free solutions of *cis,trans*-(**2**) are obtained by thermal conrotatory ring opening of *N*-lithio-*cis*-2,3-diphenylaziridine in THF.[4] *cis,trans*-(**2**) is labile[4] and isomerizes readily at 20 °C[1] to give *trans,trans*-(**2**); 1-phenyl-2-azaallyllithium is prepared similarly.[1] Aliphatic substituted 2-azaallyllithium reagents are prepared by stannyl-lithium exchange.[5]

Handling, Storage, and Precautions: solutions of (**1**) and *trans,trans*-(**2**) in THF are stable at -30 °C under N_2 or Ar for days. No special precautions are necessary.

Indirect Nucleophilic Aminomethylation and Synthesis of 2-Azabutadienes.

Reaction of (**1**) with ketones yields hydroxy azomethines which are of preparative interest since they provide β-amino alcohols on hydrolytic cleavage with acids (eq 1).[2] Dehydration of the hydroxy azomethines with ***Thionyl Chloride***/***Pyridine*** provides an entry to 2-azabutadienes.[2c] Nucleophilic aminomethylation of alkyl bromides is also

possible (eq 2).[2a,c] With a chiral, optically active derivative of (**2**), a highly enantioselective amine synthesis has been developed (eq 3).[6] In addition, from the 3-cyano analog a synthesis of α-amino acids (eq 4) has been developed,[7] and the 3-vinyl analog is known.[8]

Stoichiometric 1,3-Anionic Cycloaddition.

(**1**) and (**2**) react with C=C, C=N, N=N, and C=S double bonds as well as with C&tbond;C and C&tbond;N triple bonds by [3 + 2] cycloadditions. In contrast to unstrained isolated C=C double bonds, one of the strained isolated C=C double bonds of norbornadiene undergoes 1,3-anionic cycloaddition with (**1**) or (**2**) to give pyrrolidines.[1] Compounds

with an alkenic double bond conjugated with an aromatic system[3,9] or an organoelement group[10] (PhS-, PhSe-, Ph_2P-, Ph_2As-, Ph_3Ge-, $Ph_2(O)P$-, $Ph_2(O)As$-; not PhTe-, Ph_2Sb-, Ph_3Sn-, Ph_3Pb-) are better 1,3-anionophiles. The cycloadditions with (**1**) can occur with high regioselectivity (e.g. eq 5) with aryl alkenes.[4] In addition, the cycloaddition of *cis,trans*-(**2**) with *trans*-stilbene (eq 6) or of *trans,trans*-(**2**) with *trans*-stilbene (eq 7) or with *cis*-stilbene occurs stereospecifically with respect to the alkene and the 2-azaallyl component (*cis* addition in each case).[4,11]

(5)

(6)

(7)

Cycloaddition of the 1,3-diphenyl-2-azaallyl anion (generated by a phase transfer technique) to cyclohex-2-enone derivatives yields bicyclic pyrrolidine derivatives (eq 8).[12] An intramolecular 2-azaallyl anion [3 + 2] cycloaddition has also been reported (eq 9).[5]

(8)

(9)

(**1**) and (**2**) react with 1,3-dienes[13] to afford pyrrolidines (e.g. eq 10); seven-membered cycloadducts cannot be detected.

(10)

(**2**) undergoes cycloaddition to aromatic azomethines and azo compounds (e.g. eq 11).[14] In contrast, (**1**) (which is generally more prone to form open-chain adducts than **2**) gives the expected cycloadduct only with *p,p´*-azotoluene, but with azobenzene and azomethines open-chain adducts are formed.[1]

(11)

(**2**) reacts with ***Phenyl Isocyanate*** and ***Phenyl Isothiocyanate*** according to eq 12.[15] (**2**) also reacts with phenylallenes[16] to produce methylenepyrrolidines. The use of diphenylcarbodiimide and CS_2 as substrates generates cycloadducts to which a secondary reaction occurs (e.g. eq 13), whereas CO_2 gives an open-chain product.

(12)

(13)

It has proved impossible to effect cycloaddition of (**1**) and (**2**) with terminal alkynes or with aliphatic nitriles having a hydrogen in the α-position to the cyano group. Internal alkynes and nitriles[1,17] normally react with (**1**) to give a cycloaddition product (e.g. eq 14). However, with (**2**), the corresponding aromatic ring system is generated instead of the cycloadduct (e.g. eq 15).

(14)

(15)

Catalytic 1,3-Anionic Cycloaddition with LDA as Catalyst.

Whereas, for unknown reasons, the use of *N*-(diphenylmethylene)methylamine (educt of **1**) in such reactions has

produced satisfactory results only in two cases, the yields of the cycloadducts obtained with benzylidenebenzylamine (educt of **2**) are generally good, and both *trans,trans*-(**2**) and *cis,trans*-(**2**) participate in cycloaddition.[1] Eq 16 shows the LDA-catalyzed polymerization of a vinyl derivative of *N*-benzylidenebenzylamine.[1]

Thomas Kauffmann

Diphenylbis(1,1,1,3,3,3-hexafluoro-2-phenyl-2-propoxy)sulfurane[1]

[32133-82-7] · $C_{30}H_{20}F_{12}O_2S$ · Diphenylbis(1,1,1,3,3,3-hexafluoro-2-phenyl-2-propoxy)sulfurane · (MW 672.57)

(dehydration of alcohols;[2] synthesis of epoxides and cyclic ethers;[3] cleavage of amides;[5] oxidation of amines[6])

Physical Data: mp 107-109 °C.

Solubility: sol ether, benzene, acetone, alcohols.

Form Supplied in: white crystals.

Analysis of Reagent Purity: NMR, IR.

Preparative Method: by the reaction of the potassium salt of 1,1,1,3,3,3-hexafluoro-2-phenylisopropanol with diphenyl sulfide in the presence of chlorine in ether at -78 °C.[1a]

Handling, Storage, and Precautions: avoid moisture; readily hydrolyzed; stable at rt; decomposes slowly at rt in solution.

Dehydration of Alcohols.

The title reagent (**1**) is useful for the dehydration of alcohols. In general, tertiary alcohols are dehydrated

instantaneously at rt. Some secondary alcohols are dehydrated. In cyclohexane rings, a *trans*-diaxial orientation of the leaving groups significantly increases the rate of elimination (eq 1). Primary alcohols do not yield products of dehydration unless the β-proton is sufficiently acidic. In most cases, the ether [$(CF_3)_2PhCOR$] is obtained.[2]

(1)

Epoxides.

Vicinal diols, capable of attaining an antiperiplanar relationship, can be converted to epoxides (eq 2). The reaction requires 1-2 equiv of (**1**) in chloroform, ether, or carbon tetrachloride and takes place at rt. The reaction is postulated to take place via ligand exchange with the sulfone followed by decomposition to the epoxide, diphenyl sulfoxide, and 1,1,1,3,3,3-hexafluoro-2-phenylisopropanol.

Other cyclic ethers have been prepared, but yields are highly dependent on product ring size. The following transformations are representative: 2,2-dimethyl-1,3-propanediol to 3,3-dimethyloxetane (86%), 1,4-butanediol to tetrahydrofuran (72%), 1,5-pentanediol to tetrahydropyran (39%), and diethylene glycol to dioxane (40%). Longer chain diols yield ethers [$(CF_3)_2PhCO(CH_2)_nOCPh(CF_3)_2$].[3]

Eschenmoser used this method to convert (5*R*,6*R*)-5,6-dihydro-β,β-carotene-5,6-diol to its epoxide (eq 3). This reagent is more effective than other reagents due to the unique solubility profile of the dihydrocarotenediol.[4]

Cleavage of Amides.

Secondary amides can be converted to esters with (**1**). The rate is sensitive to steric constraints at the nitrogen and the acyl carbon. In most cases the amine portion is trapped as the sulfilimine and/or the imidate, which are easily converted back to the amine (eq 4). The dual nature of this reaction affords a mild conversion of amides to esters as well as a simple method for deprotection of *N*-acylated amines.[5]

Oxidation of Amines.

In a related reaction, (**1**) reacts with primary amines (as well as amides and sulfonamides) to give sulfilimines (eq 5). Secondary amines are converted to imines on reaction with (**1**) whereas benzylamine is converted to benzonitrile (89%) with 2 equiv of (**1**).[6]

Diphenylboryl Trifluoromethanesulfonate

$Ph_2B\text{-}OSO_2CF_3$

[100696-94-4] · $C_{13}H_{10}BF_3O_3S$ · Diphenylboryl Trifluoromethanesulfonate · (MW 314.11)

(Lewis acid utilized for the preparation of homoallyl alcohols and ethers;[1,2] catalyst for asymmetric esterification of cyclic *meso*[3] and racemic dicarboxylic acid anhydrides;[4] catalyst for Friedel-Crafts acylation of acid anhydrides and acid chlorides[5])

Alternate Name: diphenylboryl triflate.

Solubility: sol common inert organic solvents such as CH_2Cl_2 and toluene.

Preparative Method: generated in situ from equimolar amounts of ***Silver(I) Trifluoromethanesulfonate*** and diphenylchloroborane. The reactants are mixed in toluene at 0 °C and stirred for 1 h. The reagent is then used immediately.

Handling, Storage, and Precautions: solutions are moisture and air sensitive and therefore they should be used under a dry inert atmosphere.

Allylation.

Ph_2BOTf is a mild and effective catalyst for the addition of allylsilanes to acetals to afford the corresponding homoallyl ethers. These reactions proceed at -78 °C in good yield, and with modest diastereoselectivity when a substituted allylsilane is utilized (eq 1). The allylation reaction of acetals is not catalyzed by either Ph_2BCl or AgOTf, nor is it catalyzed by Bu_2BOTf. Thus it has been postulated that stabilization of the boryl triflate by the two phenyl groups yields a boron atom with significant cationic character and it is this property that allows Ph_2BOTf to serve as the activator of the reaction.[1]

R	Diastereomer ratio	Yield
H	-	71%
Me	76:24	69%
Ph	82:18	73%

Ph_2BOTf has been utilized for the one-pot asymmetric allylation of aldehydes utilizing enantiomerically pure 1-phenylethyl trimethylsilyl ether as a coreactant and source of asymmetric induction (eq 2). The highest diastereomeric product ratios are typically observed with reactions run at -78 °C in toluene. The protecting group on the resulting homoallylic ethers can be easily removed via catalytic hydrogenation or by treatment with ***Iodotrimethylsilane***.[2]

R		
$Ph(CH_2)_2$	96:4	71%
Cy	93:7	74%
Ph	74:26	77%

Asymmetric Esterification.

Ph_2BOTf is a very efficient catalyst for the asymmetric esterification of cyclic *meso* and racemic dicarboxylic anhydrides. Various enantiomerically pure derivatives of mandelic acid have been utilized in reactions with anhydrides

of cyclic *meso*-dicarboxylic acids with good to excellent degrees of asymmetric induction. The best results are achieved when the reaction is run with 2 equiv of the diphenylborate of a single enantiomer of 2-methoxy-1-phenylethanol as the nucleophilic species. When (*R*)-2-methoxy-1-phenylethanol is used, the (1*S*, 2*R*) diastereomer predominates, as shown for *meso*-1,2-cyclohexanedicarboxylic anhydride in eq 3.[3] This method has been extended to the ring opening of racemic cyclic dicarboxylic anhydrides as well. In these cases the best results are achieved when >2 equiv of the anhydride per equivalent of nucleophile are used. Yields for the reported examples average approximately 75%, a typical example being shown in eq 4.[4]

(3)

(4)

Friedel-Crafts Acylation.

Ph_2BOTf has been reported to be an effective catalyst for the acylation of aromatic compounds with acid chlorides or acid anhydrides under mild conditions (eq 5).[5]

Diphenylcarbamoyl Chloride

[83-01-2] · $C_{13}H_{10}ClNO$ · Diphenylcarbamoyl Chloride · (MW 231.69)

(acylating agent in Friedel-Crafts reactions;[1] acylating agent for amines,[2] amino acids,[3] thiols,[2] phenols,[4] and carboxylic acid salts;[5] protecting group in oligonucleotide synthesis[6])

Alternate Name: DPC-Cl.

Physical Data: mp 85 °C.

Solubility: sol most common solvents.

Form Supplied in: white to off-white powder; widely available.

Handling, Storage, and Precautions: incompatible with strong oxidizing agents and strong bases; corrosive; moisture sensitive. Unlike dimethyl-, diethyl-, and methylphenylcarbamoyl chloride, it is not carcinogenic.

Acylating Agent in Friedel-Crafts Reactions.[1]

Diphenylcarbamoyl chloride can be used to introduce a carboxylic group into an aromatic compound. Friedel-Crafts acylation in ethylene chloride in the presence of ***Aluminum Chloride*** as catalyst gives a diphenylamide. Alkyl- or alkoxy-substituted benzenes are readily acylated, whereas fluoro or chloro derivatives are unreactive. With the exception of the sterically hindered amides obtained from mesitylene, durene, and pentamethylbenzene, the resultant diphenylamides are readily hydrolyzed by alkali (NaOH in 85% aq. EtOH or DMSO) to the parent carboxylic acids (eq 1).[7]

Acylating Agent for Amines, Amino Acids, Thiols, Phenols, and Carboxylic Acid Salts.

DPC-Cl reacts readily with primary and secondary aliphatic or cyclic amines,[2] and with the α-amino group of a wide variety of amino acids,[3] to give tri- or tetrasubstituted ureas (eq 2). In the case of amino acids, some racemization takes place on longer exposure to the basic conditions.[3]

Reactions with thiols[2] can be carried out in aq. EtOH under basic conditions ($NaHCO_3$), to give good yields of *N*,*N*-diphenylthiocarbamates. Other carbamoyl derivatives such as dimethyl- and dibutylcarbamoyl chloride are not as useful because they are too unstable to basic conditions in water.[2] Imidazole in acetone or EtOH can be converted into its DPC derivative using an excess of imidazole as the base.[2] O-Methylhydroxylamine reacts readily with DPC-Cl in THF to give *N*´-methoxy-*N*,*N*-diphenylurea in 62% yield.[8] The reaction of 5-methylene-1,3-thiazolidine-2-thione with DPC-Cl traps only the aromatic thiazole tautomer, giving the *S*-substitution product (eq 3).[9]

(3)

Phenols can be acylated by DPC-Cl in acetone[4] in the presence of ***Potassium Carbonate*** or in pyridine to give *N*,*N*-diphenylcarbamates.[10] Carboxylic *N*,*N*-diphenylcarbamic anhydrides have been isolated from the reaction of carboxylate salts with 1-(*N*,*N*-diphenylcarbamoyl)pyridinium chloride, prepared from DPC-Cl and pyridine, in aqueous or ethanolic solutions. In the presence of amino groups the reaction under these conditions is chemoselective and no carbamate is formed. These mixed anhydrides are stable, crystalline derivatives and are very reactive in acylation reactions (eq 4).[5]

(4)

The DPC group has been introduced in many pharmaceutical products. Hence the toxicity and tumor affinity of 5-fluorouracil have been modified by reacting it with DPC-Cl in DMA in the presence of ***Sodium Hydride*** to give the 1-DPC derivative (eq 5).[11] When excess DPC-Cl is employed in the presence of K_2CO_3, the 1,3-disubstituted derivative is also produced. Treatment of an 85/15 *endo*/*exo* mixture of bicyclo[2.2.1]hept-5-en-2-ylmethylamine obtained by Diels-Alder reaction with DPC-Cl, followed by crystallization, gives a 74% yield of pure *endo* product. This product can then be condensed with a sulfonamide to give a sulfamylurea, which is a highly potent hypoglycemic agent (eq 6).[12]

(5)

endo:*exo* = 85:15

endo 100%

(6)

Protecting Group in Oligonucleotide Synthesis.

The lactam function of the guanine residue is subject to side-reaction during oligonucleotide synthesis. It can be protected according to a widely used procedure originally devised by Kamimura et al.[5,13] Treatment of the amino-protected oligonucleotide with DPC-Cl in dry pyridine containing ***Triethylamine*** or ***Diisopropylethylamine*** gives, after silica gel chromatography, the corresponding O^6-(diphenylcarbamoyl)guanosine in excellent yield (eq 7).[5] DPC-Cl is superior to dimethyl- and dimethylthiocarbamoyl chloride for this purpose. In addition to the successful protection of the guanine residue, introduction of DPC improves the solubility and chromatographic properties of the resultant derivatives. Deprotection occurs in conc. ammonia-MeOH (9:1, v/v) over 3 h at 60 °C, which are the conventional conditions for deprotection of the *exo*-amino acyl groups of other nucleoside bases.[5] Modified deoxyguanosines[14] are protected in the same way. Stannylation of the guanosine followed by electrophilic attack of the DPC-Cl at the stannyl intermediate has been reported.[15] In the case of 2-aza-2´-inosine, N^1-acylation instead of O^6-acylation occurs.[16]

Diphenyl Cyanocarbonimidate

[79463-77-7] · $C_{14}H_{10}N_2O_2$ · Diphenyl Cyanocarbonimidate · (MW 238.26)

(preparation of heterocycles,[1,2] 1,2,4-triazoles,[1] 4-oxa-1,3-diazoles,[2] benzimidazoles,[1] hexahydropyrimidines,[3] and hydroquinazolines;[3] synthesis of *O*-phenylisoureas,[1] *N*-cyanoguanidines,[2] and guanidines;[4] modification of peptides;[5] reverse electron demand Diels-Alder heterodieneophile[6])

Alternate Names: DPCC; diphenoxymethylenecyanamide; diphenyl *N*-cyanoimidocarbonate.

Physical Data: mp 156-158 °C,[1] 161-163 °C (Aldrich).

Solubility: sol THF, propan-2-ol.

Form Supplied in: commercially available in ca. 97% purity.

Preparative Method: from diphenyl carbonate by treatment with PCl_5 followed by cyanamide.[1]

Handling, Storage, and Precautions: harmful if swallowed and irritating to the eyes and respiratory system. Care should be taken not to inhale the powder nor to allow it to come in contact with the skin. It is sensitive to moisture. It should be disposed of by dissolving in a solvent and burning the solution in an approved incinerator. Use in a fume hood.

Synthesis of Heterocycles.

Diphenyl cyanocarbonimidate was originally described as a synthon for heterocyclic synthesis by Webb and Labaw.[1] With *o*-phenylenediamine in boiling propan-2-ol, 2-cyanoaminobenzimidazole is formed. At rt the *O*-phenylisourea, the product of a single displacement, can be isolated and converted to the benzimidazole on warming (eq 1). The sequential displacement of the two phenoxide ions illustrates a major advantage of DPCC as a reagent. Sequential reaction of aniline followed by ***Hydrazine*** gives 5-phenylamino-3-amino-1,2,4-triazole (eq 1). A variety of 1,2,4-triazoles have been prepared by this method.[7]

(1)

Treatment of the *O*-phenylisourea with ***Hydroxylamine*** gives two isomeric oxadiazoles, the predominant isomer arising from initial nucleophilic attack by the hydroxylamine nitrogen (eq 2).[2] Cyclization to give six-membered rings also occurs, forming substituted hydropyrimidines (eq 3).[8] Imidazole ring formation to give a tricyclic structure has been accomplished by reaction of DPCC with a diamine (eq 4).[9]

(2)

Oxadiazole ring formation occurs with a hydrazide in the presence of ***Triethylamine***, presumably involving the enol in the second nucleophilic displacement (eq 5).[10] Reaction of DPCC with 2-aminobenzyl alcohol gives a six-membered benzoazine.[11]

An alternative mode of ring formation involves sequential substitution with two different nitrogen nucleophiles, followed by ring closure between one nitrogen and a reactive center on the other nucleophile. Thus β-alanine methyl ester gives an *O*-phenylisourea, which on treatment with benzylamine gives a hexahydropyrimidine (eq 6).[3]

If two modes of ring closure are possible then the five-membered ring is favored,[12] and this can only partially be reversed by discriminating between the ester functions (eq 7).[13] Rearrangement of the five-membered imidazolone to the corresponding acid of the hexahydropyrimidine takes place under mild base treatment, but racemization occurs.[14]

A combination of these two modes of cyclization occurs in the reaction of hydrazine with certain *O*-phenylisoureas to give 1,2,4,6-tetraazabicyclo[3.3.0]octanes (eq 8).[15]

(8)

Synthesis of *N*-Cyanoguanidines and Guanidines.

The *N*-cyanoguanidine drug cimetidine was prepared by Webb and Labaw from the sequential reaction of two different amines, and was their original reason for preparing DPCC (eq 9).[2] Guanidines can be prepared from the *N*-cyanoguanidines by acid hydrolysis.[16] Treatment of the *N*-cyanoguanidines with ***Trifluoroacetic Acid*** gives *N*-trifluoroacetates or, in the presence of water, the corresponding ureas.[5,11,17]

(9)

Modification of Peptides.

The o-amino function of lysine in peptides has been modified by treatment with DPCC to give the isourea, followed by an amine to give the *N*-cyanoguanidine (eq 10).[5] Capsaicin analogs containing *N*-cyanoguanidine groups have been prepared,[18] and methods have been described to prepare various *N*-guanidino-modified arginines.[19]

(10)

Diels-Alder Reaction.

The cyano group of DPCC acts as a heterodienophile in a reverse electron-demand Diels-Alder reaction with 3,6-bis(methoxycarbonyl)-1,2,4,5-tetraazabenzene to give a 1,2,4-triazabenzene derivative (eq 11).[6]

(11)

Related Reagents.

Alternate Name: (*R,R*)-stilbenediamine *N,N´*-bis-3,5-bis(trifluoromethyl)benzenesulfonamide.

Physical Data: (**1**) mp 155-156 °C; α_D +83.7° (*c* = 1, $CHCl_3$). (**2**) mp 213-214 °C; α_D +6.6° (*c* = 1.4, $CHCl_3$). (**3**) mp 213-214 °C; α_D +43.9° (*c* = 1.74, $CHCl_3$). (**4**) mp 243 °C (dec); α_D 122° (*c* = 0.107, acetone).

Solubility: except for the nitro derivative, the sulfonamides are sol CH_2Cl_2.

Preparative Methods: the most convenient preparation of (*R,R*)-stilbenediamine is described in *Organic Syntheses*.[7] Condensation of benzil and cyclohexanone in the presence of ammonium acetate and acetic acid (eq 1) produces a spirocyclic 2*H*-imidazole (mp 105-106 °C). Reduction with ***Lithium*** in THF/NH_3 followed

by an ethanol quench and hydrolysis with aqueous HCl (eq 2) affords the racemic diamine as a pale yellow solid (mp 81-82 °C). Resolution is achieved by multiple recrystallizations of the tartaric acid salts from water/ethanol. The sulfonamides are prepared by reaction of the enantiomerically pure diamine with the appropriate anhydride[1b] or sulfonyl chloride[2a] in CH_2Cl_2 in the presence of ***Triethylamine*** and a catalytic amount of ***4-Dimethylaminopyridine*** (eq 3).

Handling, Storage, and Precautions: the sulfonamides are all stable, crystalline compounds that do not require any special precautions for storage or handling.

Diels-Alder Reactions.

Reaction of the bis(triflamide) (**2**) with ***Diisobutylaluminum Hydride*** or ***Trimethylaluminum*** affords chiral Lewis acids that catalyze Diels-Alder reactions of acryloyl or crotonoyl derivatives with cyclopentadienes (eq 4).[1] The aluminum complex must be crystallized before use to remove traces of trimethylaluminum. High diastereo- and enantioselectivities are achieved with as little as 0.1 equiv of the Lewis acid, and the chiral sulfonamide is recoverable.

Asymmetric Aldol Reactions.

Reaction of (**1**) with ***Boron Tribromide*** in CH_2Cl_2 affords, after removal of solvent and HBr, a complex (**5**) useful for the preparation of chiral enolates (eq 5).[1a] Complex (**5**) is moisture sensitive and is generally prepared immediately before use. For propionate derivatives, either *syn* or, less selectively, *anti* aldol adducts may be obtained by selection of the appropriate ester derivative and conditions.[2a] Thus reaction of *t*-butyl propionate with (**5**) and triethylamine produces the corresponding *E*(O) enolate, leading to formation of *anti* aldol adducts upon addition to an aldehyde (eq 6). Selectivities may be enhanced by substitution of the *t*-butyl ester with the (+)-menthyl ester. Conversely, reaction of *S*-phenyl thiopropionate with (**5**) and ***Diisopropylethylamine*** affords the corresponding *Z*(O) enolates and *syn* aldol products (eq 7).[2a,c]

(R,R)-1,2-Diphenyl-1,2-diaminoethane N,N´-Bis[3,5-bis(trifluoromethyl)benzenesulfonamide]

R = Cy 86% 98:2 ds 91% ee

(7)

Products with low enantiomeric purity are obtained by direct application of this chemistry to unsubstituted acetate

esters. However, aldol reactions of *t*-butyl bromoacetate mediated by (**5**) afford synthetically useful bromohydrins (**6**) with high selectivities (eq 8).[2b] These may be reductively dehalogenated or converted to a variety of compounds by way of the derived epoxides.

Asymmetric Ireland-Claisen Rearrangements.

Chiral enolates derived from the boron complex (**5**) and allyl esters rearrange with excellent selectivity upon warming to -20 °C for a period of 1-2 weeks (eqs 9 and 10).[3] As discussed above, the geometry of the intermediate enolate can be controlled by appropriate choice of base and solvent, thus allowing access to either *syn* or *anti* configuration in the product. The reaction can be completed in 2-4 days with little erosion in selectivity when run at 4 °C.

(9)

75%, 99:1 ds, >97% ee

Ester-Mannich Additions.

The *E*(O) enolate (**7**) reacts with *N*-allyl or *N*-benzyl aldimines to afford chiral β-amino esters (eq 11).[4] As with the aldol reactions, best selectivities are achieved with imines derived from aromatic or unsaturated aldehydes. The method appears to have good potential for the synthesis of useful β-lactams if extended to other enolates.

Carbonyl Allylation and Propargylation.

(R,R)-1,2-Diphenyl-1,2-diaminoethane N,N´-Bis[3,5-bis(trifluoromethyl)benzenesulfonamide]

Boron complex (**8**), derived from the bis(tosylamide) compound (**3**), transmetalates allylstannanes to form allylboranes (eq 12). The allylboranes can be combined without isolation with aldehydes at -78 °C to afford homoallylic alcohols with high enantioselectivity (eq 13).[5] On the basis of a single reported example, reagent control might be expected to overcome substrate control in additions to aldehydes containing an adjacent asymmetric center. The sulfonamide can be recovered by precipitation with diethyl ether during aqueous workup. Ease of preparation and recovery of the chiral controller makes this method one of the more useful available for allylation reactions.

R = cyclohexyl	93% ee
R = hexyl	90% ee

In the same way, reaction of (**8**) with allenyl- or propargylstannanes affords intermediate borane derivatives which, upon reaction with aldehydes, produce the expected adducts with high selectivities (eqs 14 and 15).[6]

(14)

Other Applications.

Other (*R,R*)-stilbenediamine derivatives have been used to direct the stereochemical course of alkene dihydroxylation[8] (with stoichiometric quantities of ***Osmium Tetroxide*** and epoxidation of simple alkenes with ***Sodium Hypochlorite*** and manganese(III) complexes.[9]

Diphenyldiazomethane[1]

[883-40-9] · $C_{13}H_{10}N_2$ · Diphenyldiazomethane · (MW 194.25)

(alkylating agent for carboxylic acids; reagent for the synthesis of diphenylcyclopropanes from alkenes[1])

Physical Data: red solid, mp 29-32 °C.

Solubility: sol most organic solvents including ether, dichloromethane, petroleum ether, ethanol.

Preparative Methods: most commonly prepared by the oxidation of benzophenone hydrazone. The oxidants that are most frequently used are ***Mercury(II) Oxide***[2] and ***Nickel(II) Peroxide***,[3] though the use of ***Manganese Dioxide***,[4] ***Silver(II) Oxide***,[5] and ***Peracetic Acid***[6] have been reported. Typical reaction conditions involve addition of the oxidant to a solution of the hydrazone in a suitable solvent at rt. The oxidation requires 1-6 h to complete, depending on the conditions employed. Solvents that have been used are petroleum ether, diethyl ether and other ethereal solvents, and dichloromethane. When mercury(II) oxide is used, the addition of a basic ethanol solution speeds up the reaction and allows the oxidation to occur at a lower temperature. The reagent is typically not stored and is synthesized immediately prior to use. If the reagent is to be used for the esterification of a carboxylic acid, then an in situ oxidation can be employed using phenyliodine(III) diacetate (***(Diacetoxyiodo)benzene***)[7] or peracetic acid with a trace of iodine.[8] Interestingly, phenyliodine(III) diacetate provides a low yield of diphenyldiazomethane when used in the absence of a carboxylic acid, this has led the authors to suggest that the active alkylating agent is a species other than diphenyldiazomethane.

Handling, Storage, and Precautions: diphenyldiazomethane is potentially explosive. For this reason, extreme care must be observed in the synthesis and use of this compound with all operations being conducted behind a blast shield in a fume hood. There are also health related hazards that must be considered. Diazo compounds, as a class, are toxic and irritating and can be sensitizers. For a description of the hazards associated with this class of compounds, see the handling and storage precautions listed for ***Diazomethane***.

Alkylation of Carboxylic Acids.

Diphenyldiazomethane is an effective reagent for the alkylation of carboxylic acids. As with other diazoalkanes, the reaction occurs upon addition to a carboxylic acid. The only byproduct is N_2, thus reducing the workup to simple

removal of the solvent. The reaction requires the protonation of the diazoalkane on carbon by the carboxylic acid to give the corresponding diphenylmethyl diazonium salt. This then undergoes nucleophilic attack by the carboxylate to give the diphenylmethyl ester and N_2. This method has been used to protect carboxylic acids as their diphenylmethyl esters. Liberation of the acid can be accomplished by acid-catalyzed hydrolysis, or hydrogenolysis, making this a useful method for the protection of carboxylic acids which are base sensitive and cannot tolerate saponification. This reagent has been used for the esterification of free amino acids. Treatment of amino acids with diphenyldiazomethane does not lead to a reaction, due to the low acidity of the zwitterionic amino acid. However, the addition of a strong acid protonates the amino acid and thereby provides a reagent which will undergo alkylation with diphenyldiazomethane (eq 1).[9] Both serine and cysteine provide high yields of the desired ester in this reaction, indicating that hydroxyl and thiol groups do not interfere with this reagent. If the free amino group is converted to an amide or a urethane, then the reaction will proceed without the addition of an equivalent of acid. Thus *N*-protected amino acids have been esterified by the in situ conversion of benzophenone hydrazone to diphenyldiazomethane using phenyliodine(III) diacetate.[7] Common nitrogen protecting groups such as Boc, Cbz, Fmoc, and Troc are all effective in this reaction (eq 2). A wide range of substrates have been esterified with diphenyldiazomethane, including carbohydrates (eq 3)[10] and β-lactam derivatives (eq 4).[8] In the case of the β-lactam esterification, the diphenyldiazomethane was produced in situ by oxidation with peracetic acid. Interestingly, the acetic acid that is present as a contaminant in peracetic acid does not compete effectively for the diazo compound and a near stoichiometric amount of oxidant can be employed.

(1)

(2)

(3)

(4)

Cycloadditions.[11]

Diphenyldiazomethane undergoes cycloadditions with electron deficient alkenes to provide the corresponding diphenylpyrazolines. In the presence of a trace of acid the pyrazolines so obtained spontaneously undergo loss of N_2 to provide the corresponding cyclopropane.[12] This reaction is so sensitive to acid that base-washed glassware must be used in order to isolate the pyrazoline with certain substrates such as methyl acrylate (eq 5). If no acid is present, or if a mild base such as ***Triethylamine*** is added, then the pyrazolines must be heated in order to extrude N_2. Thus treatment of the azlactone derivative shown in eq 6 with diphenyldiazomethane and triethylamine at 80 °C provides the diphenylcyclopropane derivative in good yield. Interestingly, in this case, reaction in the absence of base provides none of the cycloadduct. The reaction can also be promoted by photolysis (eq 7).[13] The evidence suggests that this reaction proceeds by the extrusion of N_2 to provide diphenylcarbene, which then undergoes addition to the alkene.

(5)

(6)

(7)

Formation of cyclopropanes with diphenyldiazomethane and transition metal catalysts has also been studied. Various transition metals can be used, including Cu, Pd, and Rh. The chemoselectivity of the reaction depends on the metal complex used. Thus cyclopropanation of the norbornene derivative shown in eq 8 with diphenyldiazomethane under ***Palladium(II) Chloride*** catalysis provides the cyclopropane derived from the internal alkene, whereas the same reaction with $Rh_2(OAc)_2$ provides the cyclopropane derived from the exocyclic alkene.[14] Cyclopropanation of enamines with ***Copper(II) Acetylacetonate*** has also been reported (eq 9).[15] This catalyst is less active and will not cyclopropanate ethyl vinyl ether or cyclohexene.

(8)

(9)

Acetal Formation.

Treatment of diphenyldiazomethane with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** and an alcohol (or thiol) produces the corresponding benzophenone acetal (or thioacetal) (eq 10).[16] If the starting alcohol component is a diol, the reaction produces a cyclic acetal. Macrocyclic crown ether acetals have been synthesized by this method in moderate to high yields (eq 11).[17]

Diphenyl Diselenide[1]

[1666-13-3] · $C_{12}H_{10}Se_2$ · Diphenyl Diselenide · (MW 312.14)

(source of phenylseleno functionality, reactive with wide variety of organic nucleophiles,[2-13] electrophiles,[14-24] and radicals;[25-27] source of phenylseleno radicals[28-31])

Physical Data: mp 63-64 °C.

Solubility: sol MeOH, EtOH, ether, THF, toluene, and most common organic solvents; insol water.

Form Supplied in: yellow powder; widely available.

Preparative Methods: synthesized by reaction of ***Phenylmagnesium Bromide*** with ***Selenium***, followed by treatment with ***Bromine***.[32] This method is superior to older methods[33] in that it does not generate the toxic byproducts H_2Se and PhSeH.

Handling, Storage, and Precautions: is air stable, has a faint odor, and is not appreciably hygroscopic. Organoselenides are reputed to be highly toxic, although not as toxic as inorganic selenium compounds such as H_2Se or SeO_2.[1b] Use in a fume hood.

Introduction.

Diphenyl diselenide is most frequently used as a reagent for incorporation of the phenylseleno functionality into molecules. The phenylseleno group provides useful functionality arising from the variety of reactions in which it can be subsequently involved. The most noted reaction of organoselenides is their oxidative elimination, which generates alkenes from phenyl selenides under mild, neutral conditions.[34] Phenyl selenides can also undergo radical reduction[35] and certain radical alkylation reactions.[36] Other potentially valuable synthetic uses of phenyl selenides include reductive lithiation[37] and α-deprotonation.[38]

Incorporation of Nucleophilic Phenylseleno Reagents.

Diphenyl diselenide and ***Benzeneselenol*** are the most popular reagents for the generation of nucleophilic phenyl selenide. Diphenyl diselenide is usually the preferred precursor due to its greater ease in handling. Selenolate anions are potent, soft nucleophiles.[2]

There are many popular and generally applicable procedures for the generation of benzeneselenolate anions from PhSeSePh. Treatment of PhSeSePh with ***Sodium Borohydride*** provides a very convenient method for the generation of the benzeneselenolate anion.[3] The nucleophilicity of the anion thus formed is apparently decreased due to complexation with borane.[4] Uncomplexed sodium benzeneselenolate can be generated upon reduction of PhSeSePh with ***Sodium Hydride***[5] or ***Sodium*** metal.[4] Generation of sodium benzeneselenolate upon treatment of PhSeSePh with Rongalite (***Sodium Hydroxymethanesulfinate***) has been mentioned as being particularly amenable to large scale preparations, due to the absence of H_2 evolution.[6]

The benzeneselenolate anion is reactive with a variety of carbon electrophiles. It is reactive with benzyl (eq 1) and alkyl halides,[8] leading to the formation of simple alkyl phenyl selenides. The benzeneselenolate anion is also useful in the nucleophilic ring opening of oxiranes (eq 2).[3] This method can be of limited value with unsymmetrical oxiranes, as regioselectivity is often poor. While the borane-complexed benzeneselenolate anion generated from treatment of PhSeSePh with $NaBH_4$ is not a reactive enough nucleophile to cleave esters,[4,9] a variety of more reactive benzeneselenolate anions are quite effective in this regard (eq 3).[4,9,10] A particularly reactive form can be formed by reaction of PhSeSePh with ***Lithium Aluminum Hydride***. This species is capable of reaction with oxetanes and oxolanes, cleaving the ethereal carbon-oxygen bond (eq 4).[11]

(1)

(2)

(3)

(4)

The benzeneselenolate anion also adds in a conjugate fashion to unsaturated carbonyl compounds. Addition to α-methylene lactones proceeds quite readily (eq 5). Given the facility with which subsequent oxidative elimination of the phenylseleno group can be carried out, thus regenerating unsaturation, an effective means of protecting a labile α-methylene lactone is available.[12] The benzeneselenolate anion can also be generated electrochemically and added to

unsaturated ketones and esters in a conjugate fashion (eq 6).[13]

(5)

(6)

Incorporation of Electrophilic Phenylseleno Reagents.

A variety of carbanion nucleophiles react with PhSeSePh to generate the corresponding phenylseleno-substituted product. While PhSeSePh is not as electrophilic as other organoselenium reagents, such as ***Benzeneselenenyl Chloride***, ***Benzeneselenenyl Bromide***, or ***N-Phenylselenophthalimide***, there are numerous situations where it can be used to supply electrophilic phenyl selenide.

Diphenyl diselenide reacts readily with many organometallic species (eq 7).[14] Similar reactivity has also been observed with ester and lactone enolates (eq 8)[15] and nitrile-stabilized carbanions.[16] The reaction of ketone enolates with PhSeSePh usually fails due to an unfavorable equilibrium constant (eq 9).[17] However, this unfavorable equilibrium can be driven to completion upon addition of O_2,[18] which converts the $PhSe^-$ formed in the reaction to PhSeSePh.

(7)

(8)

Methods involving the reaction of less reactive nucleophiles with PhSeSePh usually involve in situ generation of the phenylselenium cation, or some other highly reactive phenyl selenide species. A variety of dialkyl ketones, aliphatic aldehydes, and even β-keto esters or β-diketones react with PhSeSePh in the presence of ***Selenium(IV) Oxide*** and a trace of H_2SO_4 (eq 10).[19] Enol acetates react with PhSeSePh upon electrochemical anodic oxidation in the presence of $Et_4N^+Br^-$ (eq 11).[20] It has been proposed that this method involves the in situ generation of PhSeBr. Phenyl selenoacetate is probably generated in situ upon reaction of PhSeSePh with ***Copper(II) Acetate*** or ***Lead(IV) Acetate***.[21] This reagent effects the *trans*-acetoxyselenation of alkenes. The phenylselenium cation has been generated from PhSeSePh upon photolysis in the presence of DCN, proceeding through a mechanism involving photoinduced electron transfer (eq 12),[22] or upon treatment of PhSeSePh with $(NH_4)_2S_2O_8$.[23] The phenylselenium cation thus generated induces selenolactonization and selenoetherification. Stereospecific selenoamination, proceeding through the possible intermediacy of a selenonium ion, has been reported upon reaction of cyclohexene with PhSeSePh in the presence of ***Chloramine-T*** (eq 13).[24]

(13)

Uses in Radical Reactions.

Diphenyl diselenide has been used as a source of phenylseleno radicals and as a radical trap, allowing for the introduction of phenylseleno functionality via radical reactions. Whereas photolysis of PhSeSePh has been shown to generate phenylseleno radicals reversibly, products arising from addition to simple alkenes have not been observed due to the reversible nature of this addition.[28] This reversible addition has, however, been used to isomerize alkenes, as exemplified in the photochemical isomerization of vitamin D_2 to 5,6-*trans*-vitamin D_2 in the presence of PhSeSePh, which proceeds in 57% yield (eq 14).[29] This isomerization only proceeds in 20-40% yield in the presence of ***Iodine***.[39]

(14)

The addition of PhSeSePh to alkynes, however, has been observed under thermal (eq 15)[30] or photochemical[31] conditions, leading to predominantly (*E*) products.

(15)

Diphenyl diselenide can also be used as an effective radical trap. Generation of the 5-hexenyl radical from a suitable alkylmercury(II) chloride in the presence of PhSeSePh generates both a cyclized and uncyclized alkyl phenyl selenide (eq 16). By analysis of the product ratios under various reaction conditions, and the known rate of the hexenyl radical cyclization, a rate constant of 2.6×10^7 L mol^{-1} s^{-1} at 45 °C was obtained for the S_H2 reaction of a primary alkyl radical with PhSeSePh.[25] Diphenyl diselenide has also been used to trap radicals generated from a variety of other

sources,[26] including those generated photochemically from thiohydroxamate esters (eq 17).[27]

(16)

(17)

Other Uses.

Diphenyl diselenide can catalyze the allylic chlorination of alkenes with ***N-Chlorosuccinimide***. The major product is usually a rearranged allylic chloride. This reaction is not believed to proceed through a radical mechanism, in contrast with most procedures for allylic chlorination (eq 18).[40] Phenylselenoalkynes are formed in good yield upon reaction of terminal alkynes with ***(Diacetoxyiodo)benzene*** and PhSeSePh (eq 19).[41]

(18)

(19)

The carbene or carbenoid species generated from ***Diazomethane***,[42] α-diazo esters,[43] or 6-diazopenicillinates[44] will insert in the Se-Se bond of PhSeSePh to generate bis(phenylseleno) acetals (eq 20).

(20)

Terminal alkenes can be converted to α-phenylseleno ketones upon reaction with PhSeSePh, ***Bis(tri-n-butyltin) Oxide***, and Br_2 (eq 21).[45] The initially formed reagent in this procedure is thought to be $PhSeOSnBu_3$.

(21)

Related Reagents.

Diphenyl Disulfide; ***Diphenyl Ditelluride***; ***2,2´-Dipyridyl Diselenide***.

Diphenyl Disulfide[1]

[882-33-7] · $C_{12}H_{10}S_2$ · Diphenyl Disulfide · (MW 218.36)

(source of phenylthio functionality, reactive with wide variety of organic nucleophiles,[2-12] radicals;[13-18] source of phenylthio radicals;[19-27] incorporates phenylthio functionality with deoxygenation when used in conjunction with Bu_3P[28-30])

Alternate Name: phenyl disulfide.

Physical Data: mp 61-62 °C.

Solubility: sol EtOH, ether, THF, benzene, CS_2; insol water.

Form Supplied in: white crystals; widely available in high purity.

Handling, Storage, and Precautions: air-stable; usually used as supplied. The odor of PhSSPh, while disagreeable, is not nearly as objectionable as that of the corresponding SH compound, thiophenol. Use in a fume hood. It has been reported that repeated skin contact with disulfides may cause irritation.[31]

Introduction.

Diphenyl disulfide is most frequently used as a reagent for incorporation of a phenylthio functionality into molecules. The phenylthio group is a useful functionality because of the variety of reactions in which it can be subsequently used. For example, phenyl sulfides undergo oxidative elimination, generating alkenes under relatively mild, neutral conditions.[2,32] Certain allylic phenyl sulfides undergo [2,3]-sigmatropic shifts upon oxidation to sulfoxides, leading to allylic alcohols.[33] Phenyl sulfides can also serve as a source of carbon-centered radicals in radical reactions, although they are usually not as reactive as alkyl halides and organoselenides in this regard.[34] Other valuable synthetic uses of phenyl sulfides include reductive lithiation[35] and α-deprotonation.[36]

Reactions of Diphenyl Disulfide with Carbon Nucleophiles.

The most common use of PhSSPh in organic synthesis is as an electrophilic source of the phenylthio functionality. Other related, and somewhat more reactive sulfenylating agents derived from PhSSPh include ***Benzenesulfenyl Chloride*** (PhSCl) and ***Phenyl Benzenethiosulfonate*** ($PhSO_2SPh$).[37] Phenyl benzenethiosulfonate is prepared from

PhSSPh by a wide variety of oxidizing agents.[38] While PhSCl is much more electrophilic than PhSSPh, it must be generated in situ from PhSSPh, and is therefore less convenient.

Ketone[2,3] (eq 1) and ester[2] (eq 2) enolates react readily with PhSSPh to generate the corresponding α-phenylthio carbonyl compound. Lactone[4] enolates also react with PhSSPh, leading to synthetic intermediates which have been carried on to form α-methylene lactones (eq 3). Ketoester dianions have been successfully sulfenylated to generate α-phenylthio ketones (eq 4).[5]

(1)

(2)

(3)

(4)

Aldehydes have been converted to α-phenylthio aldehydes by sulfenylation of an *N*-cyclohexyl imine (eq 5).[6] Modest enantiomeric excesses have been obtained when the imine generated from *R*-(+)-α-phenylethylamine is employed.[7]

(5)

Reaction of spirocyclobutanones with an excess of PhSSPh in the presence of ***Sodium Methoxide*** leads initially to α-bis(phenylthio) ketones, which can undergo in situ ring opening arising from nucleophilic attack of methoxide at the cyclobutanone carbonyl, to form γ-bis(phenylthio) esters (eq 6).[8]

(6)

Cyclohexanones undergo dehydrogenative sulfenylation upon reaction with PhSSPh in methanolic NaOMe to give *o*-phenylthio phenols (eq 7).[9] This reaction is interesting, in that the PhSSPh appears to behave both as a source of electrophilic phenylthio functionality and as an oxidizing agent in the course of the transformation.

(7)

The reaction of strongly nucleophilic organometallic reagents such as Grignard and organolithium species with PhSSPh, leading to the corresponding phenyl sulfide, is quite general. This type of reaction has seen extensive use in the chemistry of heterocycles as a method for incorporating the phenylthio functionality. Several illustrations of this mode of reaction are shown here.

A phenylthio group can be introduced at the 5-position of 2-alkylfurans (eq 8).[10] This serves to block subsequent additions at C-5 and activate C-4 towards electrophilic attack. 3-Phenylthioindoles have been synthesized by metalation of indoles, with subsequent anion quenching by PhSSPh (eq 9).[11] Lithiation of pyridyl phenyl sulfoxides with ***Lithium Diisopropylamide***, followed by quenching with PhSSPh yields the corresponding phenylthio derivatives

(eq 10).[12]

(8)

(9)

(10)

Reactions of Diphenyl Disulfide with Alkenes.

Diphenyl disulfide adds cleanly to many alkenes and dienes upon catalysis by $BF_3.OMe_2$.[39] The trifluoroacetoxysulfenylation of unsaturated esters, carboxylic acids, nitriles, and amides has recently been described (eq 11).[40] In this versatile addition reaction, the PhSSPh is oxidized to the phenylthio cation by ***Manganese(III) Acetate***. The electrophilic sulfur species is believed to add to the alkene, activating it towards nucleophilic attack by ***Trifluoroacetic Acid***. Mild aqueous hydrolysis leads to β-hydroxyalkyl phenyl sulfides in good yield and high regioselectivity.

Other Reactions of (Formally) Electrophilic Diphenyl Disulfide.

While PhSSPh is not electrophilic enough to react with alkynyltrimethylsilanes, a more reactive phenylthio electrophile is generated upon addition of ***Copper(I) Trifluoromethanesulfonate*** and ***Calcium Carbonate*** to the mixture. This reagent combination effects the conversion of alkynyltrimethylsilanes to alkynyl phenyl sulfides (eq 12).[41]

The coupling of 5-(chloromercurio)-2-deoxyuridine with PhSSPh, as well as with other diaryl and dialkyl disulfides, has been observed, leading to the corresponding phenylthio derivative (eq 13).[42]

Diphenyl Disulfide as a Source of Thiiyl Radicals.

Thiiyl radicals can be generated from PhSSPh upon photolysis, or thermolysis, or in the presence of radical initiators. The radicals thus generated add reversibly to alkenes[19] and alkynes,[20] generating β-phenylthio alkyl and vinyl radicals, respectively. Diphenyl disulfide adds to alkynes irreversibly to generate bis(phenylthio)alkenes only under forcing conditions (eq 14).[21] The aniline and *n*-pentyl nitrite used in this example serve to generate phenyl radicals which initiate the radical chain process. The major product obtained is a substituted benzothiophene upon reaction with phenyl and *t*-butyl alkynes.[21,22]

(14)

The reversible addition of PhSSPh to alkenes under photolytic conditions has been used extensively for the isomerization of alkenes[23] as illustrated in the synthesis of humulene (eq 15).[23b]

(15)

The reversible addition of a thiiyl radical arising from catalytic PhSSPh has been recently used in more complex radical processes. In eq 16,[24] the addition of a thiiyl radical initiates a cascade of radical processes leading to carbocyclization via an epoxide fragmentation, which terminates with expulsion of the initially added radical. Thiiyl radical-induced ring opening of a vinylcyclopropane, followed by intermolecular addition to an acrylate ester and subsequent cyclopentane formation, is illustrated in eq 17.[25] This transformation can also be accomplished upon addition of ***Trimethylaluminum***. A mechanistically analogous process involving addition of O_2 to vinylcyclopropanes, leading to formation of five-membered endoperoxides, has also been described.[26]

(16)

(17)

Thiiyl radicals have been incorporated into molecules via radical addition-elimination processes. Diphenyl disulfide reacts with β-tributylstannylacrylates upon photolysis to generate the corresponding β-phenylthioacrylate (eq 18).[27]

(18)

Diphenyl Disulfide as a Radical Trapping Agent.

Diphenyl disulfide is an effective radical trapping reagent, leading to formation of phenyl sulfides. Reactions of this

type may proceed through an S_H2 mechanism, or possibly through the intermediacy of a trivalent sulfuranyl radical species.[13] Photolysis of 5-hexenylmercury(II) chloride in the presence of varying concentrations of PhSSPh leads to mixtures of uncyclized 5-hexenyl phenyl sulfide and cyclized product (eq 19). Upon analysis of these product ratios, a rate constant of 7.6×10^4 sec^{-1} was obtained for the reaction of the hexenyl radical with PhSSPh.[14] Radicals generated from benzoylmethylmercury(II) chlorides add to alkenes prior to termination by attack at PhSSPh, leading to more synthetically interesting products (eq 20).[15]

(19)

(20)

The carbon-centered radicals generated upon heating thiohydroxamate esters can react with PhSSPh to generate the corresponding phenyl sulfide (eq 21).[16] Diphenyl disulfide has also been used to trap radicals generated upon homolyses of organocobalt species.[17] The alkyl radicals generated from trialkylboranes upon photolysis or exposure to O_2 have also been trapped by PhSSPh in synthetically useful yields.[18]

(21)

Diphenyl Disulfide/Tributylphosphine.

The mixture of PhSSPh and ***Tri-n-butylphosphine*** has proven to be of use for a variety of transformations. Aldehydes can be readily converted to diphenyl thioacetals upon treatment with these reagents (eq 22), while ketones are converted to diphenyl thioacetals only in poor yield.[28] The thioacetals thus formed are of synthetic interest due to their potential use as acyl anion synthons. Similar conditions convert oxiranes to vicinal diphenyl thioethers (eq 23).[28] The PhSSPh/Bu_3P reagent is also useful for the conversion of carboxylic acids to phenyl thioesters[29] and the related conversion of alcohols to phenyl thioethers (eq 24).[30]

(22)

(23)

(24)

The reduction of nitro[43] and oxime[44] functionality to imines has been accomplished by this reagent system. The PhSSPh used in this reaction is also reduced to thiophenol. In several examples, the imine thus formed has been trapped intramolecularly to generate a pyrrole (eq 25). In each of these examples the phosphine serves as a deoxygenating agent through its conversion to Bu_3PO.

(25)

Related Reagents.

Dimethyl Disulfide; ***Diphenyl Disulfide***; ***2,2´-Dipyridyl Disulfide***.

Diphenyl Ditelluride[1]

[32294-60-3] · $C_{12}H_{10}Te_2$ · Diphenyl Ditelluride · (MW 409.42)

(parent member of the diaryl ditellurides, useful reagents for the formation of alkyl, aryl, and vinyl tellurides by either nucleophilic, electrophilic, or radical pathways; alkyl and vinyl tellurides and especially alkyl 2-thienyl tellurides undergo very clean transmetalation reactions, providing alkyl and vinyl metal reagents;[1] alkyl aryl tellurides give alkyl radicals with tributyltin hydride[1])

Physical Data: mp 66-67 °C; *d* 2.23 g cm^{-3}.

Solubility: sol acetone, chloroform, tetrachloromethane; moderately sol ether; slightly sol ethanol.

Form Supplied in: nonvolatile, orange crystals.

Preparative Methods: diaryl ditellurides are prepared by the action of aryllithium or arylmagnesium halides on tellurium powder followed by oxidation with air or with aqueous potassium ferricyanide.[2] Electron-rich diaryl ditellurides (e.g. bis(2,4-dimethoxyphenyl) ditelluride[3]) are prepared by reaction of the arene with tellurium tetrachloride to give the aryltellurium trichloride followed by reduction with $Na_2S_2O_5$.

Purification: crystallization from ethanol.

Handling, Storage, and Precautions: air stable; unknown toxicity. Use in a fume hood.

Arenetellurolates.

Diaryl ditellurides are reduced with ***Sodium*** wire in THF/DMF, ***Samarium(II) Iodide*** in THF/HMPA, or ***Sodium Borohydride*** in ethanol to give the powerfully nucleophilic arenetellurolates which take part in substitution reactions with alkyl, aryl, and benzyl halides (eq 1).[4] PhTeTePh may also be reduced electrochemically or with sodium in liquid ammonia and the resulting PhTeNa used as an effective nucleophile in the $S_{RN}1$ substitution of haloarenes.[5] Substitution of iodoarenes to give mixed diaryl tellurides also takes place, with catalysis by ***Copper(I) Iodide***, with benzenetellurolate formed from PhTeTePh and $NaBH_4$ in HMPA.[6] Acyl chlorides react with benzenetellurolate derived from $NaBH_4$ and PhTeTePh in THF/EtOH to give acyl aryl tellurides, which are effective precursors of acyl radicals[7] and acyl lithiums.[8] Trapping with ***Chlorotrimethylsilane*** gives $PhTeSiMe_3$ which, in the presence of ***Zinc Iodide***, reacts with lactones to give Me_3Si esters of o-phenyltelluro acids and with cyclic ethers to give o-phenyltelluro

alcohols as their Me_3Si ethers.[9]

(1)

Reduction with ***Diisobutylaluminum Hydride*** gives PhTeAl(i-Bu)$_2$ (see also ***Diisobutylaluminum Phenyl Selenide***), which undergoes conjugate addition to α,β-unsaturated carbonyl compounds. The intermediate aluminum enolates react with aldehydes to give aldols. Subsequent treatment with ***m-Chloroperbenzoic Acid*** gives α-alkylidene aldols (eq 2).[10] PhTeAl(i-Bu)$_2$ is also an excellent nucleophile toward acetals, alkyl sulfonates, and oxiranes.[11]

(2)

Electrophilic Species.

Diaryl ditellurides react with Grignard and organolithium reagents to give alkyl aryl tellurides. The reaction has been used to titrate these organometallics.[12] Activation of PhTeTePh with ***Bromine*** and ***t-Butyl Hydroperoxide*** (TBHP) in alcohols provides electrophilic reagents for alkoxytelluration of alkenes.[13] PhTeTePh readily takes part in telluro-cycloetherifications and lactonizations of hydroxy and carboxy alkenes on activation with ***p-Nitrobenzenesulfonyl Peroxide*** (NBSP) (eq 3).[14]

(3)

Radical Reactions.

Diaryl ditellurides are very efficient traps for alkyl radicals generated by a variety of means, as in eq 4.[15] PhTeTePh adds across alkynes on initiation with ***Azobisisobutyronitrile*** (AIBN) to give 1,2-bis(phenyltelluro)-alkenes.[16] Vinyl-, allyl- and alkylmercurials undergo photostimulated radical substitution with PhTeTePh to give the corresponding phenyl tellurides.[17]

$$Ph_2B(CH_2)_{15}Me \xrightarrow[O_2,\ THF]{(PhTe)_2} \underset{64\%}{PhTe(CH_2)_{15}Me} + \underset{33\%}{TePh_2} \qquad (4)$$

Reductions.[1]

1,2-Dibromides are converted to alkenes with a catalytic amount of ditelluride and $NaBH_4$.[18] A variation is the generation of *o*-quinodimethane from α,α´-dibromo-*o*-xylene with PhTeNa.[19] $NaBH_4$ reduces nitrobenzene to azoxybenzene in aqueous methanolic NaOH at rt with a catalytic amount of PhTeTePh. At reflux the product is azobenzene.[20]

Related Reagents.

Diphenyl Diselenide; ***Diphenyl Disulfide***.

Diphenyliodonium Carboxylate

[1488-42-2] · $C_{13}H_9IO_2$ · Diphenyliodonium Carboxylate · (MW 324.12)

(starting point for the synthesis of *N*-substituted anthranilic acids;[4] useful benzyne precursor[7])

Alternate Name: (carboxyphenyl)phenyliodonium hydroxide inner salt.

Physical Data: $C_{13}H_9IO_2.H_2O$: mp 220-222 °C (dec). $C_{13}H_9IO_2$: mp 215-216 °C (dec).

Solubility: sol dichloromethane, hot water.

Preparative Method: by oxidation of 2-iodobenzoic acid with potassium persulfate in H_2SO_4, followed by addition of benzene. It is isolated as colorless prisms of the monohydrate. Anhydrous material can be obtained in quantitative yield by extraction of the monohydrate with dichloromethane and evaporation of the solvent.[1]

Handling, Storage, and Precautions: described as a stable, easy to handle, safe, crystalline compound.[1]

Structure.

Although diphenyliodonium carboxylate is usually represented as an acyclic iodonium salt (**1**), NMR[2] and X-ray diffraction[3] studies indicate a cyclic structure (**2**).

(1)

(2)

Synthesis of Anthranilic Acid Derivatives.

Ullmann-type reaction of diphenyliodonium carboxylate with amines yields anthranilic acid derivatives. Diphenyliodonium carboxylate reacts with anilines in the presence of ***Copper(II) Acetate*** to afford the corresponding anthranilic acids (eq 1).[4]

(1)

A protocol for the synthesis of 9-oxoacridan-4-carboxylic acids has also been developed (eq 2).[5] This Ullmann-type coupling has been applied to the synthesis of several products of pharmacological interest.[6]

(2)

Generation of Benzyne.[7]

When a solution of diphenyliodonium carboxylate is heated to 160 °C, decomposition to benzyne, CO_2, and iodobenzene takes place (eq 3). This reaction is usually carried out in diglyme (160 °C), although butyrolactone (205 °C) and triglyme (220 °C) have been used in some cases.[8]

(3)

This procedure uses neither basic nor oxidative reagents. The high temperature that is required for decomposition of diphenyliodonium carboxylate leads in some cases to lower yields than alternative procedures, particularly if a thermally unstable reaction partner is used. However, diphenyliodonium carboxylate might be a convenient benzyne precursor for use with substrates of low reactivity; a comparative study of the reactivity of benzyne generated from several precursors (and therefore under a variety of conditions) with the weakly reactive diene thiophene showed that best yields of cycloadduct were obtained using high temperature generation from diphenyliodonium carboxylate.[9]

Benzyne generated from this precursor has been trapped as a Diels-Alder adduct by several dienes. Trapping efficiency increases in the order anthracene < 1,3-diphenylisobenzofuran < 2,3,4,5-tetraphenylcyclopentadienone (tetracyclone) < 2,5-bis(*p*-dimethylaminophenyl)-3,4-diphenylcyclopentadienone < 2,5-di-*p*-anisyl-3,4-diphenylcyclopentadienone.[8] When the last of these dienes is used, the adduct is isolated in 79% yield (eq 4).

(4)

Benzyne generated by decomposition of diphenyliodonium carboxylate undergoes 1,3-dipolar cycloaddition with pyridinium dicyanomethylide to afford 6-cyanobenz[*a*]indolizine (eq 5).[10]

(5)

1,4-Diphenyl-1,2,4-triazolium-3-olate does not react with benzyne generated by oxidation of 1-aminobenzotriazole, but if diphenyliodonium carboxylate is used as the benzyne precursor, 2-phenylindazole is obtained by cycloaddition-extrusion reactions (eq 6).[11]

(6)

Disulfides, ditellurides, diselenides, and related compounds undergo insertion of benzyne (eq 7).[12,13]

Diphenyliodonium Chloride[1]

$Ph_2I^+ Cl^-$

[1483-72-3] · $C_{12}H_{10}ClI$ · Diphenyliodonium Chloride · (MW 316.57)

(phenylation of carbanions,[2-8] oxygen anions,[9-16] nitrogen[17-22] and sulfur groups,[23-29] inorganic anions[30-32])

Physical Data: mp 233-235 °C (subl).

Solubility: sol H_2O, MeOH, *t*-BuOH, DMF/EtOH.

Form Supplied in: white solid; commercially available.

Handling, Storage, and Precautions: stable; can be stored at rt without decomposition.

Introduction.

A general observation concerning diphenyliodonium chloride is that other salts can be formed by anion metathesis in H_2O, 90% HCO_2H, or MeOH (eq 1). In most synthetic applications, Ph_2ICl is equivalent to Ph_2IBr.

$$Ph_2I^+ \ Cl^- \xrightarrow{M^+ \ X^-} Ph_2I^+ \ X^- \qquad (1)$$

$$X^- = F^-, Br^-, HSO_4^-, SO_4^{2-}, RCO_2^-, CF_3CO_2^-, IO_3^-, ClO_4^-, BF_4^-$$
$$Ph_4B^-, ArSO_3^-, PF_6^-, AsF_6^-, OH^-, HgCl_3^-, NO_3^-$$

Nucleophilic Displacement Resulting in Phenylation.

A major reaction of Ph_2ICl is nucleophilic displacement according to the overall reaction in eq 2. The nucleophile may be carbon, oxygen, nitrogen, or sulfur based systems, as well as phosphorus, selenium, and tellurium.

$$Ph_2I^+ \ Cl^- + Z^- \longrightarrow Ph\text{-}Z + PhI + Cl^- \qquad (2)$$

Phenylation of Carbanions.

The following reactions of carbanions using *t*-butyl alcohol as solvent are representative (eqs 3-12). Among the better substrates are 1,3-dicarbonyl compounds (eqs 3, 4, 8, and 9),[2,3,5] α-cyano ketones (eq 6),[4] aromatic ketones (eqs 5 and 7),[4] acetone enolates (eq 10),[6] and nitronate ions (eqs 11 and 12).[7,8]

		70[16]

Phenylation at Nitrogen.

Phenylation at nitrogen is not generally useful for aliphatic and aromatic amines. However, the reaction is valuable for hydroxamic acid derivatives, imides, sulfonamides, and certain other nitrogen heterocycles, as shown in Table 2.[17-22]

Table 2 Phenylation of Nitrogen with Diphenyliodonium Salts

-[19]

39-45[20]

88[17]

-[21]

61[22]

Phenylation at Sulfur.

Phenylation at sulfur is most effective for the formation of various sulfonium salts from diaryl or dialkyl sulfides (eqs 13-15).[23-25]

(13)

(14)

$$Ph_2S \xrightarrow{Ph_2I^+ Cl^-} Ph_3S^+ Cl^- \qquad (15)$$

S-Phenylation of bis(4-methoxyphenyl)-2-arylthiopyrimidines has been used in the syntheses of nonsteroidal anti-inflammatory drugs (eq 16).[26]

Other substrates which undergo *S*-phenylation are *p*-$TolSO_2^-Na^+$,[18] $EtOCSS^-Na^+$,[27] $ArCSS^-Na^+$,[28] and $R_2NCSS^-Na^+$.[23] Elemental tellurium can be phenylated with Ph_2IBr to yield Ph_2Te,[33] while Ph_2Se yields $Ph_3Se^+Br^-$ and Ph_3P yields $Ph_4P^+Br^-$.[34]

Phenylation of Inorganic Anions.

The phenylation of inorganic anions is a useful synthetic method. The examples collected in Table 3 include nitrite,[30] azide,[9] cyanide,[18] thiocyanate,[18] fluoride,[31] and sulfite.[32]

Table 3 Phenylation of Inorganic Anions

1,3-Diphenylisobenzofuran[1]

[5471-63-6] · $C_{20}H_{14}O$ · 1,3-Diphenylisobenzofuran · (MW 270.34)

(highly reactive diene,[1] suitable for the trapping of unstable or transient dienophiles as their Diels-Alder adducts; standard reagent for the determination of singlet oxygen; useful reagent in the synthesis of polyaromatic species)

Physical Data: yellow crystalline needles, mp 128-130 °C.

Solubility: sol acetonitrile, benzene, chloroform, dichloromethane, DMSO, THF, toluene.

Handling, Storage, and Precautions: air sensitive; light sensitive.

Properties.

The majority of isobenzofurans should only be viewed as reactive intermediates. 1,3-Diphenylisobenzofuran (**1**) is a moderately stable compound and is commercially available. On the other hand, isobenzofuran (**2**) has only been isolated at low temperatures.[2] The reactivity of these species is confined to the furanoid ring. Isobenzofurans have been described as the most reactive Diels-Alder dienes known.[3] The reactivity is attributable to the extra resonance energy gained by formation of an aromatic ring during the cycloaddition.

Synthesis.

Owing to the extensive interest in isobenzofurans in recent years, numerous technologies for their preparation have been forwarded, and these have been amply reviewed.[4] Synthesis from phthalan precursors is most popular and useful (eq 1).[5]

(1)

(1)

In a convenient protocol, 3,6-di-2´-pyridyl-*s*-tetrazine and 1,4-dihydro-1,4-endoxynaphthalene react in two steps to yield isobenzofuran, which can subsequently react with the dienophile of interest (eq 2).[6]

(2)

(2)

Trapping of Unstable Dienophiles as Diels-Alder Adducts.

Cycloaddition reactions of 1,3-diphenylisobenzofuran have been extensively exploited for trapping unstable dienophiles. The Diels-Alder cycloaddition of the parent isobenzofuran is some 11 times faster than of the 1,3-diphenyl analog,[7] and hence this species is often used in instances where the highest level of reactivity is required. Exceedingly unstable species, such as Dewar furan, can be generated and trapped in this manner (eq 3).[8]

The isobenzofuran must, however, itself be generated immediately prior to carrying out the reaction.[9] The more stable 1,3-diphenylisobenzofuran is an excellent trapping agent for reactive or unstable alkenes and alkynes and has extensively been exploited in this application. Adducts with species such as arynes, cycloalkenes, and cycloalkynes are commonly prepared. For example, 3,4-pyridynes readily form cycloadducts with 1,3-diphenylisobenzofuran (eq 4).[10]

A highly strained polycyclic alkyne, 4-homoadamantyne, has been generated and trapped as a cycloadduct with 1,3-diphenylisobenzofuran (eq 5).[11] Similarly, a highly strained cyclopropene, tricyclo[3.2.1.0^{2,4}]oct-2(4)-ene, has been synthesized and trapped in this manner (eq 6).[12] The related species 5,6-dimethyl-1,3-diphenylisobenzofuran is purported to be more stable and yield more easily characterized adducts.[13]

The Diels-Alder reaction of 1,3-diphenylisobenzofuran can be accelerated by catalysis with Lewis acids, such as ***Boron Trifluoride Etherate***. Cycloaddition with diethyl vinylphosphonate yields a mixture of two isomers in high yields (75%) (eq 7).[14]

Diels-Alder additions of isobenzofurans with alkenic dienophiles normally yield mixtures of *exo* and *endo* adducts. Reversible cycloadditions tend to favour *exo* isomers, presumably on thermodynamic grounds.

Higher Order Cycloadditions.

Isobenzofurans are frequently utilized as 4π components in cycloaddition reactions. These can be Diels-Alder $[4_\pi + 2_\pi]$ or higher order $[4_\pi + 4_\pi]$ and $[4_\pi + 6_\pi]$ cycloadditions. Tropone yields the $[\pi_4 + \pi_6]$ thermal cycloadduct (eq 8).[15]

(8)

Synthesis of Polyaryl Systems.

Cycloaddition of isobenzofurans followed by deoxygenation of the cycloadducts constitutes a powerful methodology for the synthesis of polyaromatic species (eq 9).[16]

(9)

Reaction with Singlet Oxygen.

1,3-Diphenylisobenzofuran reacts rapidly with singlet oxygen to yield an unstable endoperoxide[17] which subsequently decomposes to *o*-dibenzoylbenzene (eq 10), although the details of this reaction are controversial.[18] The quenching reaction has become a standard in the field of singlet oxygen chemistry.[19] Disappearance of 1,3-diphenylisobenzofuran can be monitored by measurement of absorbance at 415 nm or by loss of fluorescence emission at 458 nm.[20]

(10)

Lithiation of Isobenzofuran.

Deprotonation of isobenzofuran occurs readily to yield the 1-lithio species. In practice, the phthalan precursor is lithiated (0.05 equiv diisopropylamine/2.1 equiv MeLi/0 °C), yielding 1-lithioisobenzofuran, which reacts smoothly with electrophiles (eq 11).[21]

(11)

Photochemistry.

1,3-Diphenylisobenzofuran[22] and isobenzofuran[23] photodimerize to form head-to-head [$8_\pi + 8_\pi$] adducts (eq 12). The latter adduct has been determined to have *anti* stereochemistry. The reaction is reversible for the 1,3-diphenylisobenzofuran adduct. Thermolysis returns the starting material.[24] This head-to-head dimer can also be generated thermally[25] and is encountered in the product mixture of cycloaddition reactions.[26]

BASF Corporation, Wyandotte, MI, USA

Diphenylketene[1]

[525-06-4] · $C_{14}H_{10}O$ · Diphenylketene · (MW 194.24)

(acylation of carboxylic acids to give mixed anhydrides;[2] cycloaddition with a variety of unsaturated compounds;[3] synthetic source of diphenylallenes[4])

Physical Data: bp 118-120 °C/1 mmHg.

Solubility: sol benzene, THF.

Form Supplied in: not commercially available.

Preparative Methods: originally prepared by zinc reduction of α-chlorodiphenylacetyl chloride;[5] oxidation of benzil monohydrazone with yellow ***Mercury(II) Oxide*** followed by thermal rearrangement of the α-diazo ketone;[6] dehydrohalogenation of diphenylacetyl chloride with ***Triethylamine***;[7] debromination of α-bromodiphenylacetyl bromide by the action of ***Triphenylphosphine***.[8]

Purification: vacuum distillation at 118-120 °C/1 mmHg.

Handling, Storage, and Precautions: material stored in a tightly stoppered bottle at 0 °C is stable for several weeks. Trace amounts of hydroquinone and storage under nitrogen inhibit polymerization and lead to increased stability. Given the reactivity of diphenylketene with amino acids, care should be taken to avoid skin contact.

Acylation of Carboxylic Acids.

Diphenylketene provides a neutral method for the conversion of carboxylic acids into mixed anhydrides.[2] Amino acids can be transformed into activated esters through the intermediacy of these mixed anhydrides without racemization (eq 1).[9]

(1)

Cyclization Reactions.

Diphenylketene undergoes most of the cyclization reactions that are characteristic of ketenes.[1] For example, cyclization with hexafluoroacetone leads to a β-lactone (eq 2).[10] Reaction with simple alkenes leads to cyclobutanones (eq 3),[11] although many of these reactions are prohibitively slow.[12] Cyclizations have also been observed with numerous other functionalities, including allenes,[13] alkynes,[14] azides,[15] diimides,[16] imines,[17] phosphinimides,[18] phosphaalkynes,[19] and 1,3-dipoles.[20]

(2)

(3)

Miscellaneous Reactions.

Wittig reaction of diphenylketene leads to the synthesis of allenes (eq 4).[4] In fact, tetraphenylallene can be made upon heating diphenylketene in the presence of HMPA.[21] Amines also react with diphenylketene; for example, reaction of 2-azabicyclo[2.2.1]hept-5-enes leads to the formation of 2-piperidinones (eq 5).[22] Epoxides and oxetanes can be opened with diphenylketene and tetraphenylantimony iodide to generate γ- and δ-lactones in good yield (eq 6).[23]

(4)

(5)

(6)

Related Reagents.

Dichloroketene.

Diphenylmercury

Ph_2Hg

[587-85-9] · $C_{12}H_{10}Hg$ · Diphenylmercury · (MW 354.81)

(mild reagent for the incorporation of the phenyl group into organic substrates;[1] transmetalation processes[2])

Physical Data: mp 128-129 °C; d_4^{20} 2.30 g cm^{-3}.

Solubility: sol diethyl ether, dichloromethane.

Form Supplied in: commercially available as a white solid; widely available.

Handling, Storage, and Precautions: harmful if swallowed, inhaled, or absorbed through the skin. Inhalation may be fatal as a result of spasm, inflammation and edema of the larynx and bronchi, chemical pneumonitis, and pulmonary edema. Use in a fume hood.

Phenylation of Organic Substrates.

In general, the reaction of diphenylmercury with haloalkanes is unsuccessful. However, it has been reported that diphenylbromomethane reacts with diphenylmercury to afford triphenylmethane (eq 1).[3]

(1)

Heck has demonstrated the use of diphenylmercury as a coupling partner in palladium-promoted and -catalyzed phenylation of alkenes.[1] Thus treatment of an alkene with diphenylmercury in the presence of a stoichiometric amount of a palladium salt affords the phenyl-substituted alkene (eq 2). The results of this reaction are summarized in Table 1.[1]

(2)

Table 1 Phenylation of Alkenes with Ph_2Hg

Starting alkene	Product	Yield (%)
		63[1a]
		49 (*E*), 10 (*Z*)[1a]
		60[1a]
		64[1a]
		88[1a]
		52[1b]

To some extent, this reaction has been superseded by the more conventional Heck reaction using aryl iodides as the coupling partner.[4] However, a palladium-catalyzed procedure has also been reported, where a reoxidant is added to regenerate the palladium catalyst.[1] Diphenylmercury reacts with acid chlorides in the presence of sodium iodide and a palladium catalyst. For example, under these conditions, cinnamoyl chloride can be converted into chalcone (eq 3).[5]

(3)

The palladium- and rhodium-catalyzed carbonylation of diphenylmercury is also possible. The reaction of diphenylmercury with ***Carbon Monoxide*** in the presence of a rhodium catalyst affords benzophenone (eq 4).[6] The carbonylation of diphenylmercury and related compounds by ***Octacarbonyldicobalt*** has also been reported.[7]

(4)

Radical Reactions.

Diphenylmercury undergoes radical reactions. Treatment of a tetrachloromethane solution of diphenylmercury in the presence of ***Dibenzoyl Peroxide*** catalyst affords the products of radical reaction (eq 5).[8] The reaction of diphenylmercury with a fluoroxy compound affords the product of electrophilic fluorination, fluorobenzene (eq 6).[9] Treatment of diphenylmercury with ***Thiocyanogen*** affords phenyl thiocyanate and phenylmercury thiocyanate (eq 7).[10]

(5)

(6)

(7)

Transmetalation Reactions.

Diphenylmercury has been widely exploited for the preparation of other organometallic reagents by transmetalation processes.[2] While a simple method for the preparation of diphenylmercury is from the Grignard reagent phenylmagnesium bromide,[11] there has nevertheless been an interest in the preparation of diphenylmagnesium from diphenylmercury. Thus treatment of diphenylmercury in THF with ***Magnesium*** metal affords a solution of diphenylmagnesium (eq 8).[12]

(8)

Diphenylzinc has been prepared by treatment of diphenylmercury with ***Zinc*** metal (eq 9) which afforded the product with sufficient quality that, after crystallization, an X-ray crystal structure determination could be carried out. The fact that the diphenylzinc can be obtained under salt-free conditions is useful.[13]

$$Ph_2Hg \xrightarrow{Zn,\ Et_2O} Ph_2Zn \qquad (9)$$

The reaction between a trichlorotin complex and diphenylmercury results in ligand exchange of one of the chlorides for a phenyl group (eq 10).[14] Reaction of an osmium hydrido complex with diphenylmercury results in the formation of a coordinatively unsaturated σ-aryl osmium complex (eq 11).[15] Similar reactions have also been reported for ruthenium complexes and, independently, rhodium complexes.[16]

The transmetalation of diphenylmercury can lead to other phenylmetal species which can be used synthetically in situ. For example, the reaction between diphenylmercury and ***Lead(IV) Acetate*** affords phenyllead triacetate,[17] which reacts with nucleophiles. In the presence of ***2-Nitropropane***, 2-phenyl-2-nitropropane is produced in 63% yield (eq 12).[18]

Diphenylmercury has been converted into the corresponding bis(chromium tricarbonyl) adduct. The reaction with 2 equiv of ***n-Butyllithium*** affords the aryllithium, which can be trapped with a variety of electrophiles including ***Carbon Dioxide*** (eq 13).[19]

The reaction of diphenylmercury with excess ***Borane-Tetrahydrofuran*** affords an intermediate arylboron species, which upon oxidative workup affords a good yield of phenol (eq 14).[20]

Other metals (or their complexes) which have been phenylated by diphenylmercury include cadmium,[2] antimony,[2] silicon,[2] arsenic,[2] ytterbium,[21] palladium,[22] and tellurium.[23]

Diphenyl(methoxymethyl)phosphine

Ph_2PCH_2OMe

[43139-94-2] · $C_{14}H_{15}OP$ · Diphenyl(methoxymethyl)phosphine · (MW 230.26)

(one-carbon homologation of hindered ketones to the corresponding aldehydes via the methyl enol ethers[1])

Physical Data: bp 134-135 °C/0.25 mmHg);[2] *n*20D 1.6085;[3] ^{1}H NMR ($CDCl_3$) δ 7.70-7.20 (m), 4.14 (d, *J* = 8 Hz), 3.38 (s).[2]

Solubility: sol THF, ether.

Preparative Methods: from the reduction of diphenyl(methoxymethyl)phosphine oxide with ***Hexachlorodisilane*** (50% yield)[2] or ***Lithium Aluminum Hydride*** (ca. 50% yield).[7] Nucleophilic addition of methoxymethylmagnesium chloride to diphenylchlorophosphine[3] furnishes the reagent (**1**) in 80% yield. An alternative synthesis (eq 1), which is suitable for large scale preparation, involves reductive lithiation of diphenylchlorophosphine with 2.2 equiv of ***Lithium*** in liquid ammonia, followed by trapping of the phosphide anion at low temperature with ***Chloromethyl Methyl Ether*** (**caution: carcinogen**).[1] Workup of the reaction is performed under argon.

Handling, Storage, and Precautions: stench. Undergoes oxidation to the phosphine oxide on standing in air.

Ketone Homologation.

The conversion of hindered or enolizable ketones to the corresponding one-carbon homologous aldehydes is often an inefficient process because of competing enolization. The common Wittig reagent for carrying out this reaction, ***Methoxymethylenetriphenylphosphorane*** (**2**),[4] often fails to provide acceptable yields of the intermediate enol ethers.[5] The lithio anion (**3**) of diphenylmethoxymethylphosphine oxide is more effective;[6] however, it is not satisfactory for all applications. For example (eq 2), spiroketone (**4**) affords approximately equal amounts of enol ether (**5**) and starting ketone from the reaction with (**3**).[1] The design of diphenyl(methoxymethyl)phosphine (**1**) as an improved reagent was predicated on the assumption that it would have both a smaller steric requirement than (**2**) or (**3**), and that for electronic

reasons it would be a more aggressive nucleophile.

(2) **(3)**

(2)

(4) **(5)**

The anion of (**1**) is prepared by deprotonation at -95 °C in THF with ***s-Butyllithium***. Addition of a THF solution of the ketone to the lithio anion of (**1**) followed by warming to 25 °C affords a β-hydroxy phosphine. Subsequent addition of methanol and excess ***Iodomethane*** leads to the methyl enol ether which undergoes hydrolysis to the aldehyde in the presence of ***Trichloroacetic Acid*** in dichloromethane. The reaction sequence has been applied successfully to the total synthesis of warburganal (eq 3),[8] and in somewhat lower yield to phyllanthocin (eq 4).[9] Spiroketone (**4**) is converted completely to the methyl enol ether.[1] Fenchone, an extraordinarily hindered ketone, undergoes homologation to the aldehyde in 79% yield.[1]

(3)

(4)

A limitation of the reagent is seen in its failure to add to propellane (**6**).[10] The reaction of lithio-(**1**) with camphor proceeds only to the extent of 10%.[1] Contrast this with the behavior of diethyl (α-lithioisocyanomethyl)phosphonate,[11] which reacts with camphor to produce the homologous aldehyde in 97% yield, thus suggesting the superiority of the phosphonate for some applications.

N-(Diphenylmethylene)aminoacetonitrile

[70591-20-7] · $C_{15}H_{12}N_2$ · *N*-(Diphenylmethylene)aminoacetonitrile · (MW 220.29)

(glycine anion equivalent for amino acid synthesis by phase transfer catalysis)

Alternate Names: aminoacetonitrile benzophenone imine; O'Donnell's Schiff base.

Physical Data: mp 81-82 °C; pK_a (DMSO) = 17.8.[1]

Form Supplied in: commercially available.

Preparative Method: by transimination of benzophenone imine with aminoacetonitrile hydrochloride.[2,3] The crude product can often be used as it is or it can be recrystallized (Et_2O/hexane or CCl_4).

Handling, Storage, and Precautions: stable to flash chromatography and stable at rt. It is best stored under argon to avoid contact with moisture. The hydrolysis product, benzophenone, can be detected either by TLC (EtOAc/hexane) or by NMR.

Amino Acid Synthesis by Alkylation using Phase Transfer Catalysis.

The benzophenone imine of aminoacetonitrile is a versatile glycine anion equivalent[4] for the synthesis of higher amino acid derivatives by alkylation of a variety of alkyl halides (methyl, benzylic, allylic, primary, secondary) under phase transfer catalysis (PTC) conditions.[5] The PTC method involves a simple reaction procedure, mild conditions, inexpensive and safe reagents and solvents, and the ability to easily scale-up the reaction. Typically the substrate is stirred at rt in a two-phase system (liquid-liquid (with aqueous base)[5] or solid-liquid (with solid base)[6] PTC) in the presence of the alkyl halide and the phase transfer catalyst, a tetraalkylammonium salt. The monoalkylated product is readily hydrolyzed to the racemic higher amino acid (eq 1).[7,8] Combination with enzymatic resolution provides optically active amino acids.[9] Labeled amino acids for various biochemical studies are prepared from deuterio-substituted alkyl halides[10-12] or by α-deuteration with 50% aq. NaOD.[13] Boronation of the propargylated derivative and hydrolysis leads to *o*-carboranylalanine (eq 2), a boron-containing amino acid of use in the treatment of melanoma by boron neutron capture therapy (BNCT).[14] Palladium-catalyzed allylation leads to γ,δ-unsaturated amino acids.[15]

1-Aminocyclopropane-1-carboxylic acid (ACC), the biosynthetic precursor of ethylene in plants, can be prepared by PTC alkylation with ***1,2-Dibromoethane*** followed by hydrolysis (eq 3).[16] Reduction of the initial alkylation product gives 1-amino-1-(aminomethyl)cyclopropane, which can be differentially protected.[17] Alkylation with 1,3-dibromopropane and modified stoichiometry yields 2,6-diaminopimelic acid (DAP), a key structural component of bacterial cell walls.[16]

Other Reactions.

Michael addition to phenyl vinyl sulfoxide under solid-liquid PTC conditions in the absence of solvent followed by thermolysis gives the α,β-dehydroamino acid derivative by double bond migration.[18] Reaction with aromatic aldehydes results in 1,2-carbonyl addition followed by elimination of water,[19] while reaction with imines gives the 1,2-adduct.[20] Arylation by nucleophilic aromatic substitution occurs with either (halobenzene)tricarbonylchromium complexes[21] or cationic arenetricarbonylmanganese complexes.[22]

N-(Diphenylmethylene)methanamine

(R = H)

[13280-16-5] · $C_{14}H_{13}N$ · *N*-(Diphenylmethylene)methanamine · (MW 195.28) (R = Li)

[64042-43-9] · $C_{14}H_{12}LiN$ · 1,1-Diphenyl-2-azaallyllithium · (MW 201.21)

(lithiation produces an α-amino carbanion equivalent)

Alternate Names: benzophenone *N*-methylimine; *N*-(diphenylmethylene)methylamine.

Preparative Methods: prepared by condensation of benzophenone with methylamine in the presence of $TiCl_4$[1] or by various other methods.[2,3]

Amine Synthesis by Reaction of 2-Azaallyl Anions with Electrophiles.[4,5]

The benzophenone imine of methylamine is deprotonated to a 2-azaallyl anion which reacts with electrophiles (alkyl halides, epoxides, aldehydes, and ketones)[6-9] at the methylene terminus. Hydrolysis yields nucleophilic aminomethylation products derived from a synthetic equivalent of the α-carbanion of a primary amine (eq 1).

Interesting derivatives of silicon, germanium, and tin ($Ph_2C{=}N\text{-}CH_2SiR_3$, $Ph_2C{=}N\text{-}CH_2GeR_3$, and $Ph_2C{=}N\text{-}CH_2SnR_3$) have been prepared by lithium-metal exchange.[10] Reaction with cyclic carbamates followed by hydrolysis has been reported (eq 2).[11,12]

Other Reactions.

Various cycloaddition reactions ([2 + 2];[13-16] [2 + 2 + 2];[13-15] [3 + 2];[17,18] [4 + 2];[19] [6 + 3$^-$][20]) of either the neutral parent or anionic derivative have been reported. Reaction with the chromium carbene complex [$(CO)_5Cr{=}C(OMe)Me$] under photochemical conditions gives a β-lactam by a formal [2 + 2] cycloaddition.[21]

The parent Schiff base has also served as the electrophile for reaction with ***n-Butyllithium***[22] or an active methylene compound.[23] Orthometalation by reaction with ***Tin(IV) Chloride***,[24] as well as oxidation to either oxaziridine or nitrone,[25-27] has been reported.

Related Reagents.

Benzophenone Imine; ***N-t-Butoxycarbonyl-N-methylaminomethyllithium***; ***Dimethylaminomethyllithium***; ***N-***

(Diphenylmethylene)aminoacetonitrile; ***Ethyl N-(Diphenylmethylene)glycinate***; ***N´-t-Butyl-N-methyl-N-trimethylsilylmethylformamidine***; ***Nitromethane***; ***N-Nitrosodimethylamine***.

(*S*)-Diphenyl(1-methylpyrrolidin-2-yl)methanol[1]

[110529-22-1] · $C_{18}H_{21}NO$ · (*S*)-Diphenyl(1-methylpyrrolidin-2-yl)methanol · (MW 267.40)

(chiral ligand for the enantioselective addition of dialkylzincs,[2] alkynylzinc,[3b] and cyanomethylzinc bromide[4] to aldehydes; chiral ligand for the enantioselective Reformatsky reaction;[5] chiral ligand for the enantioselective Diels-Alder reaction;[6] chiral auxiliary for asymmetric polymerization[7])

Alternate Name: DPMPM.

Physical Data: mp 68.5-68.9 °C; [α]23D + 57.0° (*c* 1.0, $CHCl_3$).

Solubility: sol hexane, benzene, toluene, Et_2O, cyclohexane, dichloromethane.

Form Supplied in: colorless crystals; available in either enantiomeric form.

Preparative Method: reaction of ***Phenylmagnesium Bromide*** with (*S*)-*N*-[(benzyloxy)carbonyl]proline methyl ester and subsequent reduction with ***Lithium Aluminum Hydride*** affords the title compound in 83% overall yield.[2b]

Catalytic Enantioselective Addition of Dialkylzincs to Aldehydes.

DPMPM (**1**) is a chiral amino alcohol which is a precursor to a chiral catalyst for the enantioselective addition of dialkylzincs to aldehydes.[2] In the presence of 2 mol % of (*S*)-(**1**), optically active alcohols of up to 100% ee are obtained from the enantioselective addition of dialkylzincs to aldehydes (eq 1, Table 1). When benzaldehyde is allowed to react with ***Diethylzinc*** using (*S*)-(**1**) (2 mol %), (*S*)-1-phenylpropan-1-ol with 97% ee is obtained in quantitative yield (entry 1). When the lithium alkoxide of (*S*)-(**1**) (5 mol %) is employed as a chiral ligand in the addition to aromatic aldehydes, ee's of the alcohols obtained increase to 99.5-100% ee (entries 4 and 5). Amino alcohol (**1**) is also effective in the enantioselective addition of Et_2Zn to the aliphatic aldehyde heptanal, and (*S*)-nonan-3-ol with 91% ee is obtained (entry 2). In the addition to aromatic aldehydes, enantioselectivities using DPMPM are comparable with those obtained with 3-*exo*-(dimethylamino)isoborneol (DAIB).[8] In the addition to heptanal, DPMPM (**1**) is more enantioselective than DAIB (61%

ee). However, in the addition to aliphatic aldehydes of wider range, *N*,*N*-dibutylnorephedrine[9] is more enantioselective than (**1**).

Table 1 Enantioselective Addition of Dialkylzincs to Aldehydes Using (**1**) or (**2**) as Chiral Catalysts

Entry	R^1	R^2	Catalyst	Yield (%)	ee (%)	Config.
1.[2b]	Ph	Et	(*S*)-(**1**)	100	97	(*S*)
2.[2b]	*n*-Hexyl	Et	(*S*)-(**1**)	96	91	(*S*)
3.[2b]	Ph	Et	(*S*)-(**2**)	100	100	(*R*)
4.[2b]	Ph	Et	Li-(*S*)-(**1**)	100	99.5	(*S*)
5.[2b]	4-$MeOC_6H_4$	Et	Li-(*S*)-(**1**)	96	100	(*S*)
6.[10]	4-$CF_3C_6H_4$	Et	(Li-*S*)-(**1**)	80	91	(*S*)
7.[11]	PhCDO	Et	(*S*)-(**1**)	86	91	(*S*)
8.[2a]	PhCH=CH	Et	(*S*)-(**1**)	91	97	(*S*)
9.[2b]	PhCH=CH	Me	(Li-*S*)-(**1**)	47	89	(*S*)
10.[3]	$Me_3SiC^{o}C$	Et	(*S*)-(**1**)	67	78	

The sense of the asymmetric induction is dependent on the structure of the catalyst. (1*R*,2´*S*)-Phenyl(1-neopentylpyrrolidin-2-yl)methanol (**2**) mediates the addition of Et_2Zn to aldehydes to afford (*R*)-alcohols in up to 100% ee (entry 3).[2b] By using (**1**) as a chiral ligand, optically active fluorine-containing alcohols[10] and deuterio alcohols[11] of high optical purities have been synthesized (entries 6 and 7). The enantioselective addition to α,β-unsaturated aldehydes (e.g. cinnamaldehyde) using (**1**) affords optically active allylic alcohols with 89-97% ee (entries 8 and 9).[2] Enantioselective addition of dialkylzincs to alkynyl aldehydes and furyl aldehydes using (**1**) as a chiral catalyst affords optically active alkynyl alcohols (78% ee, entry

10)[3] and furyl alcohols (88-94% ee).[12] When terephthalaldehyde is allowed to react with Et_2Zn using (**1**) as a chiral ligand, the corresponding optically pure diol is obtained.[13]

Unlike alkyllithium and Grignard reagents, dialkylzinc does not add to ketones even in the presence of (**1**). Thus the chemo- and enantioselective alkylation of a keto aldehyde (4-benzoylbenzaldehyde) with Et_2Zn using (*S*)-(**1**) affords the corresponding optically active hydroxy ketone with 93% ee in 99% yield.[14]

Enantioselective Addition of Cyanomethylzinc Bromide, Reformatsky Reagent, and Alkynylzinc Reagents to Aldehydes.

The enantioselective additions of cyanomethylzinc bromide,[4] Reformatsky reagent (see ***Ethyl Bromozincacetate***),[5] and alkynylzinc[3b] reagent to aldehydes using (**1**) as chiral catalyst or ligand afford optically active β-hydroxy nitrile (93% ee),[4] β-hydroxy ester (78% ee) (eq 2),[5] and alkynyl alcohol (43% ee).[3b]

(2)

$R^1 = Ph$, $R^2 = CN$, 76%, 93% ee; $R^1 = 2$-naphthyl, $R^2 = CO_2$-*t*-Bu, 82%, 78% ee

Catalytic Asymmetric Diels-Alder Reaction.

Amino alcohol (**1**) combined with ***Boron Tribromide*** generates a chiral catalyst for the asymmetric Diels-Alder reaction (97% ee) of unsaturated aldehydes and dienes.[6]

Asymmetric Polymerization.

Polymerization of methacrylate derived from (**1**) affords optically active polymer of helical conformation of single screw sense.[7]

Diphenyl 2-Oxo-3-oxazolinylphosphonate

[78605-38-6] · $C_{15}H_{12}NO_5P$ · Diphenyl 2-Oxo-3-oxazolinylphosphonate · (MW 317.25)

(activation of carboxylic acids; formation of amides, β-lactams, and thiol esters; phosphorylation of alcohols)

Alternate Name: DPPOx.

Physical Data: colorless solid, mp 51 °C (*n*-hexane); bp 150-160 °C/0.03 mmHg.

Solubility: sol acetonitrile, THF, DMF, CH_2Cl_2.

Preparative Method: by reacting equimolar quantities of ***Diphenyl Phosphorochloridate*** and 2-oxazolone together with ***Triethylamine*** in CH_2Cl_2 at rt.[1,2] The product is isolated in 96% yield by filtration of the triethylamine hydrochloride salts, concentration in vacuo below 30 °C, and chromatography of the residue on silica gel.

Analysis of Reagent Purity: ^{1}H NMR: 6.74 (dd, *J* = 2.4 and 2.5 Hz, 1H), 6.81 (dd, *J* = 1.7 and 2.4 Hz, 1H), 7.32 (bs, 10H).

Handling, Storage, and Precautions: stable at rt, protected from moisture (over anhydrous silica gel), for several years. Complete hydrolysis occurs within 24 h in 50% aqueous THF at rt.

Activation of Carboxylic Acids.[1,2]

Reaction of diphenyl 2-oxo-3-oxazolinylphosphonate with alkyl, aryl, and unsaturated carboxylic acids yields the corresponding 3-acyl oxazolides under mild neutral conditions (eq 1). Alkoxycarbonyl-protected amino acids are amenable to the reaction conditions, except in cases where elimination is competitive, e.g. *N*-Cbz-serine. Sterically hindered 2,4,6-trimethylbenzoic acid failed to form the oxazolide, but instead gave the acid anhydride. 3-Acyl oxazolides of chiral acids, formed in this way, have been used in the synthesis of chiral amino alcohols,[3] amino sugars,[4] and hydroxy amino acids.[5] The carboxyl group of the 3-acyl oxazolides is activated toward nucleophilic

attack.

(1)

Amide Formation.[1,2]

Acyl oxazolides undergo facile aminolysis, leading to amides. Diphenyl 2-oxo-3-oxazolinylphosphonate reacts very slowly with amines. Thus the coupling can be achieved in one step by mixing an amine and a carboxylic acid in acetonitrile at rt with 1.2 equiv of DPPOx. This reaction has been successfully applied to peptide formation using Cbz and *t*-Boc protected amino acids and amino acid ethyl esters (eq 2) without racemization.

(2)

β-Lactam Formation.[6]

Treatment of β-amino carboxylic acids with diphenyl 2-oxo-3-oxazolinylphosphonate and triethylamine in refluxing acetonitrile (eq 3) gives good yields of monocyclic β-lactams (50-89%).

(3)

DPPOx was unsuccessful in cyclizing 2-thiazolidineacetic acid; however, the related tris(2-oxo-3-oxazolinyl)phosphine oxide (eq 4) gives the bicyclic β-lactam in 57% yield.

(4)

Thiol Ester Formation.[7]

Thiol esters are formed in 68-96% yield by reaction of thiols with carboxylic acids, DPPOx, and triethylamine in acetonitrile at rt (eq 5). Sterically hindered thiols require longer reaction times for comparable yields.

(5)

Phosphorylation of Alcohols.[8]

DPPOx reacts very sluggishly with alcohols at rt. However, the reaction is greatly accelerated by ***Cesium Fluoride*** and transition metal acetylacetone complexes to give mixed phosphates in good yields (eq 6). The catalytic ability of the complexes is in the activity order $Zr^{IV} > Ce^{III} > Zn^{II} > Mn^{III} > Mn^{II}$.

Diphenylphosphine

Ph_2PH

[829-85-6] · $C_{12}H_{11}P$ · Diphenylphosphine · (MW 186.20)

(readily deprotonated to give diphenylphosphide;[1a] useful for the synthesis of phosphorus-based alkenation reagents;[2] source of phosphorus-centered radical[3])

Physical Data: bp 280 °C; *d* 1.070 g cm^{-3}.

Solubility: sol ethanol, ether, benzene, concd HCl; insol H_2O.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: ^1H NMR (P-H) δ 5.14; ^{31}P NMR (P-H, 85% H_3PO_4) δ +40.7.[4]

Preparative Methods: from Ph_3P,[1b] Ph_2PCl_3,[5] or Ph_2POCl.[5]

Purification: distillation.[1b]

Handling, Storage, and Precautions: foul-smelling liquid. Very easily oxidized in air; pyrophoric; light-sensitive.

Alkylation.

The alkylation of diphenylphosphine has been used extensively for the preparation of novel phosphine ligands, Wittig-Horner reagents, and phosphonium salts. Deprotonation of diphenylphosphine with ***n-Butyllithium*** gives the characteristically orange solution of lithium diphenylphosphide,[1] providing access to the desired tertiary phosphines via an S_N2 or S_N2' displacement.[2] Phosphonium salts are also readily available by direct reaction of an appropriate alkylating agent and diphenylphosphine.[6] Optically active bis(diphenylphosphino) ligands can be prepared through tosylate displacement/epoxide ring opening. In some cases, complete regio- and stereoselectivity can be achieved (eq 1).[7] Elaborate diphenylphosphine oxide-based alkenation reagents can be synthesized by alkylation, followed by direct oxidation to provide advanced precursors of complex natural products (eq 2).[2]

During the preparation of many phosphines, due care must be taken to avoid phosphorus oxidation. The use of the diphenylphosphine-borane complex circumvents the problem of phosphine oxidation. The diphenylphosphine-borane complex is not only protected from oxidation, but is also activated so that it can be reacted under mild conditions (methanolic KOH, 0 °C) with a variety of electrophiles (eq 3). The desired tertiary phosphine can be obtained by decomplexation with a large excess of a secondary amine.[8]

(3)

Addition to Alkenes and Alkynes.

The addition of diphenylphosphine to unsaturated systems under radical conditions provides access to a variety of functionalized phosphines.[9] Phosphorus-centered radicals can be formed under standard (***Azobisisobutyronitrile***, refluxing benzene) or photochemical conditions in a manner similar to silicon-, tin-, and selenium-based radicals. Highly functionalized phosphines are obtained upon radical cyclization of dienes or enynes (eq 4).[3] Tin- and silicon-substituted phosphines are available from the corresponding vinylstannane[10] or -silane.[11] Phosphine radical addition to diketene provides access to phosphine-substituted lactones.[12]

(4)

Michael addition of diphenylphosphine to activated alkenes provides products useful for the construction of phosphine ligands. These reactions can be carried out under neutral,[13] acidic,[14] or basic conditions,[15] or via the preformed diphenylphosphide.[16] Diastereoselective addition of lithium diphenylphosphide to lactone (**1**) provides a good yield of the *trans* adduct (eq 5).[16] Double addition to bromomaleic anhydride provides useful yields of the bis(diphenylphosphino) adduct as the *trans* isomer (eq 6).[14]

(5)

(6)

Addition to C=X Bonds.

The nucleophilic nature of diphenylphosphine (and diphenylphosphide) can be utilized in the addition to carbon-heteroatom double bonds. The 1,2-addition to aldehydes,[17] ketones,[18] imines,[19] isocyanates, isothiocyanates, carbodiimides,[20] cyclic carbonates,[21] and 2-halo heterocycles[22] provide a host of interesting phosphines. Addition of diphenylphosphine to aromatic aldehydes in alcoholic media or dilute acid gives α-alkoxy[17] or α-hydroxy[18a] benzylphosphines, respectively. Alternatively, employment of a typical Lewis acid in aprotic media also leads to α-hydroxy phosphines, which air oxidize to the α-hydroxy phosphine oxides. However, addition to aldehydes in the presence of a Lewis acid and a catalytic amount of niobium(V) chloride provides phosphine oxides (eq 7).[18b,c] The use of concentrated protic acid media also provides a simple, high-yielding synthesis of unsymmetrical phosphine oxides (eq 8).[18a]

(7)

(8)

Other Applications.

Lithium diphenylphosphide can be used to effect a number of functional group interconversions, such as the dealkylation of alkyl aryl ethers,[23,1b] or the dehydroxylation of α-hydroxy ketones.[24] In some cases, 1,2-dibromoalkenes can be converted into alkynes by treatment with lithium diphenylphosphide in refluxing THF.[25] Treatment of epoxides with lithium diphenylphosphide followed by phosphine oxidation,[26] or conversion into the phosphonium salt[27] ultimately provides a method for alkene inversion (eq 9).

Diphenylphosphine Oxide

[4559-70-0] · $C_{12}H_{11}OP$ · Diphenylphosphine Oxide · (MW 202.20)

(preparation of triarylphosphine oxides,[1] important as asymmetric catalysts; preparation of alkenyldiphenylphosphine oxides[3,4] and Horner-Wittig reagents[5])

Physical Data: mp 56-57 °C.

Form Supplied in: white solid; widely commercially available.

Handling, Storage, and Precautions: moisture sensitive; irritant.

Palladium-Catalyzed Coupling with Aryl Triflates.

In the synthesis of P-N chelating ligands for asymmetric catalysis,[1] aryl triflates are coupled with $Ph_2P(O)H$ under Pd catalysis, with subsequent reduction of the resulting phosphine oxides to the aryldiphenylphosphines (eq 1). (*R*)-(-)-1,1´-Binaphthol triflate provides the monophosphorylation product[2] in good yield with maintainance of enantiomeric purity (eq 2).

(1)

Preparation of Diphenylvinylphosphine Oxides.

Treatment of α-keto tosylates with diphenylphosphine oxide gives epoxyphosphine oxides, which provide vinylphosphine oxides via deoxygenation with ***Diphosphorus Tetraiodide*** (eq 3).[3] Alternatively, alkenyl bromides react with diphenylphosphine oxide under palladium catalysis to yield vinylphosphine oxides (eq 4).[4]

Reaction with Chlorodifluoromethane.

Difluoromethyldiphenylphosphine oxide, synthesized from diphenylphosphine oxide and chlorodifluoromethane, reacts with aldehydes and ketones to yield 1,1-difluoroalkenes (eq 5).[5] Alkenation proceeds in increasing (12-81%) yields over a range of more to less electron-deficient carbonyl compounds.

Diphenylphosphinic Chloride

[1499-21-4] · $C_{12}H_{10}ClOP$ · Diphenylphosphinic Chloride · (MW 236.64)

(agent for acid activation,[1] alkylphosphine oxide formation,[2] and amine protection[3])

Alternate Name: chlorodiphenylphosphine oxide.

Physical Data: bp 222 °C/16 mmHg; *d* 1.240 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: handle only in a chemical fume hood, wear chemical-resistant gloves and safety goggles, do not breathe vapor, and avoid contact with eyes or skin. Store in a flammable storage cabinet under nitrogen. Contact with water generates hydrogen chloride gas.

Acid Activation.

Chlorodiphenylphosphine oxide has been utilized for the activation of acids via in situ formation of the diphenylphosphinic (DPP) mixed anhydrides. These anhydrides are superior to carbon-based mixed anhydrides because they do not suffer from disproportionation to symmetrical anhydrides.[1] Also, nucleophiles prefer to attack at carbon rather than phosphorus, solving the regioselectivity problem associated with carbon-based mixed anhydrides.[4] Additionally, diphenylphosphinic mixed anhydrides are more electrophilic. Finally, diphenylphosphinic mixed anhydrides form rapidly allowing shorter activation times.

Diphenylphosphinic mixed anhydrides have been utilized to form peptide bonds.[5] Peptides are easier to isolate by this method than by employing ***1,3-Dicyclohexylcarbodiimide***. These anhydrides are the method of choice for the formation of amides of 2-alkenoic acids (eq 1).[6] Carbodiimide and acyl carbonate methods proved to be inferior. Primary amines result in better yields than secondary amines. This activation protocol can be employed to form thiol esters.[7] β-Amino acids are readily converted to β-lactams with chlorodiphenylphosphine oxide (eq 2).[8] Secondary amines work best. This activation protocol has been utilized to convert acids to amines via a Curtius rearrangement (eq 3).[9] Phenols have been generated from diene acids, presumably via base-induced elimination of diphenylphosphinic acid from the mixed anhydrides to form ketenes which spontaneously cyclize (eq 4).[10] Acids have been converted to ketones via activation followed by reaction with organometallic reagents (eq 5).[11]

Phosphine Oxides.

This reagent reacts with organometallic reagents to form phosphine oxides.[2] Alkyl phosphonates have been converted to diphenylvinylphosphine oxides via trapping of the α-lithioalkylphosphonate with diphenylchlorophosphine oxide, deprotonation, and reaction with aldehydes (eq 6).[12] Organometallic reagents have been converted to 1,3-dienes utilizing $Ph_2P(O)Cl$ and carbonyl compounds (eq 7).[13]

Thiol Esters and Ketones.

The Dpp mixed anhydrides react with thiols to yield thiol esters (eq 8)[7] and undergo carbon-acylation reactions with

both Grignard reagents and diethyl sodiomalonate in good yields (eq 9).[14]

Protection of Amino Groups.

In the presence of *N*-methylmorpholine, Ph_2POCl reacts with amino acid esters in CH_2Cl_2 at 0 °C in 1.5-2 h to give *N*-diphenylphosphinyl (Dpp) amino acid esters (65-80%), which are then hydrolyzed under mild alkaline conditions to give *N*-Dpp amino acids (eq 10).[3,4] Since Ph_2POCl hydrolyzes extremely quickly under aqueous conditions, it is not possible to prepare *N*-Dpp amino acids directly.

The Dpp derivatives are slightly more acid-labile than the Boc derivatives and are cleaved by HOAc-HCOOH-H_2O (7:1:2) (24 h), 1 M HCl in H_2O-dioxane (2:1) (3 h), TFA-CH_2Cl_2 (1:1) (40 min), and 95% TFA (10 min). Selective cleavage of the Dpp group in the presence of a *t*-butyl ester and a phenyl ester is possible.

Amination.

Ph_2POCl reacts with ***Hydroxylamine*** to yield *O*-(diphenylphosphinyl)hydroxylamine.[15] This reagent aminates stabilized carbanions and Grignard reagents in moderate yields (eq 11).[16] Electrophilic *N*-amination of imide sodium salts is also possible using this reagent (eq 12).[17]

(11)

(12)

60%

Diphenylphosphinamide[18] and 1-diphenylphosphinyl-2,2-dimethylaziridine,[19] which are derived from Ph_2POCl, react with Grignard reagents to give high yields of primary amines and moderate yields of α,α-dimethylarylalkylamines, respectively.

(*R*)-*N*,*N*-Dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethylamine

(*R*)-(*S*)-PPFA

[55700-44-2] · $C_{26}H_{28}FeNP$ · (*R*)-*N*,*N*-Dimethyl-1-[(*S*)-2-(diphenylphosphino)ferrocenyl]ethylamine · (MW 441.37) (*S*)-(*R*)-PPFA

[55650-58-3]

(effective chiral phosphine ligand[1] for nickel- or palladium-catalyzed asymmetric cross coupling of organomagnesium or -zinc reagents with alkenyl bromides,[2-4] and for palladium-catalyzed asymmetric hydrosilylation of 1,3-dienes[5])

Alternate Name: (*R*)-(*S*)-PPFA.

Physical Data: mp 139 °C; [α]25D -361° (*c* 0.6, ethanol).[1a]

Purification: recrystallization from ethanol.[1a]

Handling, Storage, and Precautions: stable in air for years, but best kept sealed in a refrigerator.

Asymmetric Cross Coupling.

In the presence of a nickel catalyst, generated in situ from ***Nickel(II) Chloride*** and (*R*)-(*S*)-PPFA, secondary alkyl Grignard reagents, represented by 1-phenylethylmagnesium chloride, react with alkenyl halides to give optically active alkenes of up to 68% ee (eq 1). The isolated palladium complex, $PdCl_2$[(*R*)-(*S*)-PPFA], can be also used for the cross coupling.[2] Use of a zinc reagent in place of the Grignard reagent increases the enantioselectivity to 86% ee.[3]

(1)

M = Mg, Zn

$PdCl_2$[(*R*)-(*S*)-PPFA]

The stereoselectivity obtained with the PPFA ligand is generally higher than that obtained with ***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane*** (DIOP) (7-16% ee), 1,2-bis(diphenylphosphino)propane (prophos) (0% ee), and 2,2´-bis(diphenylphosphinomethyl)-1,1´-binaphthyl (NAPHOS) (11% ee).

The asymmetric cross coupling with the chiral ferrocenylphosphine-palladium catalyst has been successfully applied to the synthesis of optically active allylsilanes (eq 2).[4] The reaction of α-(trimethylsilyl)benzylmagnesium bromide with vinyl bromide and (*E*)-β-bromostyrene catalyzed by 0.5 mol % of $PdCl_2$[(*R*)-(*S*)-PPFA] gives a quantitative yield of the corresponding allylsilanes of 95% ee. High enantioselectivity is also observed in the cross coupling of 1-(triethylsilyl)ethylmagnesium chloride with (*E*)-β-bromostyrene.

(2)

Asymmetric Hydrosilylation of Alkenes.

The palladium complex $PdCl_2$[(*R*)-(*S*)-PPFA] catalyzes the asymmetric hydrosilylation of norbornene, styrene, and 1,3-dienes (eq 3).[5] The hydrosilylation of 1-phenyl-1,3-butadiene with ***Trichlorosilane*** proceeds regioselectively in a 1,4-fashion to give (*Z*)-1-phenyl-1-silyl-2-butene of 64% ee.

(3)

Optically active ferrocenylbisphosphines, (*R*)-*N*,*N*-dimethyl-1-[(*S*)-1´,2-bis(diphenylphosphino)ferrocenyl]ethylamine [(*R*)-(*S*)-BPPFA] and its derivatives, are efficient chiral bisphosphine ligands for rhodium-catalyzed asymmetric hydrogenation, palladium-catalyzed asymmetric allylic substitution reactions, and gold-catalyzed asymmetric aldol-type reactions of α-isocyano carboxylates.[1,6]

Synthesis of Chiral Phosphorane.

(*S*)-(*R*)-PPFA has been converted to an enantiomerically pure ferrocenylphosphonium salt (**1**) in two steps in 54% yield (eq 4). The chiral phosphorane (**2**), generated in situ from (**1**) by ***n-Butyllithium*** in THF, reacts with aldehydes in the presence of a Lewis acid, ***Diethylaluminum Ethoxide*** to give vinylation products (**3**) (eq 5) with variable enantiomeric excess (up to 70%).[7]

(*S*)-2-[2-(Diphenylphosphino)phenyl]-4-phenyloxazoline

(**1**; R = Ph)

[148461-15-8] · $C_{27}H_{22}NOP$ · (*S*)-2-[2-(Diphenylphosphino)phenyl]-4-phenyloxazoline · (MW 407.47)
(**2**; R = *i*-Pr)

[148461-14-7] · $C_{24}H_{24}NOP$ · (*S*)-2-[2-(Diphenylphosphino)phenyl]-4-isopropyloxazoline · (MW 373.46)
(**3**; R = *t*-Bu)

[148461-16-9] · $C_{25}H_{26}NOP$ · (*S*)-2-[2-(Diphenylphosphino)phenyl]-4-*t*-butyloxazoline · (MW 387.49)

(readily available chiral ligands for enantiocontrol of palladium-catalyzed allylic substitution reactions[1,2])

Physical Data: (**1**) amorphous solid; $[\alpha]_D$ +30.8° (*c* = 1.0, $CHCl_3$). (**2**) amorphous solid; $[\alpha]_D$ -44.9° (*c* = 1.4, $CHCl_3$). (**3**) mp 105 °C; $[\alpha]_D$ 58.2° (*c* = 1.2, $CHCl_3$).

Solubility: insol H_2O; sol most organic solvents.

Preparative Methods: chiral phosphinoaryloxazolines, a class of ligands developed independently in three different laboratories,[1,3,4] are readily prepared in enantiomerically pure form starting from chiral amino alcohols and aromatic carboxylic acids or nitriles. Several short, convenient syntheses from 2-bromobenzonitrile (eq 1),[1,5] 2-bromobenzoic acid (eq 2),[3] or 2-fluorobenzonitrile (eq 3)[4] have been described. Alternatively, derivatives such as (**2**), which do not contain any reactive groups in the oxazoline ring that are attacked by BuLi, can be prepared from aryloxazolines by orthometalation and subsequent reaction with Ph_2PCl (eq 4).[1] Phosphino-oxazolines with an additional stereogenic center at the phosphorus atom, such as (**4**), and phosphinomethyl oxazolines of type (**5**) have also been reported.[3] The different synthetic routes allow for a wide range of structural modifications at the oxazoline ring, the phosphine group, and the ligand backbone.

Purification: impurities such as phosphine oxides, formed by air oxidation, can be removed by column chromatography on silica gel or, for crystalline derivatives, by recrystallization.

Handling, Storage, and Precautions: Phosphino oxazolines of this type are sufficiently stable to be handled in air. For longer periods of time, they should be stored at -20 °C under argon.

Palladium-Catalyzed Allylic Substitution.

Palladium complexes of chiral phosphino oxazolines are highly effective catalysts for enantioselective allylic substitution reactions.[1-4] The catalysts are usually prepared in situ from ***Bis(allyl)di-μ-chlorodipalladium*** and the corresponding ligands. In the presence of 1-2 mol % of catalyst and a mixture of ***N,O-Bis(trimethylsilyl)acetamide*** (BSA) and catalytic amounts of KOAc as a base, racemic 1,3-diphenyl-2-propenyl acetate reacts smoothly at rt with dimethyl malonate to afford the substitution product in essentially quantitative yield and with excellent enantioselectivity (eq 5). For this substrate, the phenyloxazoline (**1**) is the optimal ligand.[1] The observed ee of 99% exceeds the selectivities previously obtained with other ligands such as ferrocenyl phosphines,[6] chiraphos,[7] BINAP,[7] 5-azasemicorrins,[8] or bis(oxazolines).[8,9] The corresponding isopropyl- and *t*-butyl-oxazolines (**2**) and (**3**) afford slightly lower en antiomeric excesses (98 and 95% ee, respectively).[1,3] Acetylacetonate[1] and diethyl acetaminomalonate,[1] as well as *N*-nucleophiles such as benzylamine, *p*-toluenesulfonamide, benzoylhydrazine, and $(Boc)_2NNa$,[10] also react with excellent enantioselectivity (eq 6).

(5)

(6)

Moderate to high selectivities have been observed in allylic alkylations of 1,3-dialkyl-2-propenyl acetates.[1] Here, the *t*-butyloxazoline derivative (**3**) is the ligand of choice. Under standard conditions, *n*-alkyl-substituted allylic acetates smoothly react at rt with selectivities of 70-80% ee (eq 7). Similar results have been obtained with various *N*-nucleophiles.[10] The corresponding diisopropylallyl acetate is much less reactive, but under more vigorous conditions with $NaCH(CO_2Me)_2$ in DMF at 65 °C the reaction proceeds in good yield with high enantioselectivity (eq 8).[1] Analogous reactions of this substrate with *N*-nucleophiles are impracticably slow. In this case, the corresponding diethyl phosphate gives much better results (eq 9).[10]

O-(Diphenylphosphinyl)hydroxylamine[1,2]

[72804-96-7] · $C_{12}H_{12}NO_2P$ · *O*-(Diphenylphosphinyl)hydroxylamine · (MW 233.22)

(reagent for electrophilic aminations; H_2N transfers to nucleophiles)

Physical Data: mp 133-134 °C.[1]

Solubility: very low in aprotic organic solvents.

Analysis of Reagent Purity: IR (cm^{-1}): 3270, 3170, 1210.[3]

Preparative Methods: [1-7] ***Triethylamine*** (12.4 g, 120 mmol) in methylene chloride (20 mL) is added with stirring to a mixture of ***Hydroxylamine*** hydrochloride (3.82 g, 55.0 mmol) in methylene chloride (100 mL) at -20 °C. After stirring at -20 °C for 1.5 h, ***Diphenylphosphinic Chloride*** (11.6 g, 49.0 mmol) in methylene chloride (20 mL) is added with stirring and cooling to maintain the temperature at -20 °C. The solution is stirred for another 1.5 h. During this time the reaction mixture attains 25 °C and a precipitate is formed, composed of triethylamine hydrochloride and *O*-(diphenylphosphinyl)hydroxylamine (**1**). To this mixture, water (100 mL) is added to dissolve the triethylamine hydrochloride salts, and the remaining (**1**) is filtered. This product is washed with anhydrous ether, and dried over phosphorus pentoxide at 25 °C/10 mmHg overnight to yield 6.81 g (60%) (**1**).

Handling, Storage, and Precautions: in contrast to *O*-(mesitylsulfonyl)hydroxylamine, an explosion with (**1**) has never been observed. (**1**) decomposes if heated above the melting point (~140 °C). It is stable for a year if stored below 0 °C.[3]

Reactions with the NH group of Imidazoles and Xanthines.

The *N*-amination of the imidazole and xanthine NH groups in (**2**) and isolation of the products (**3**) is achieved via deprotonation, amination, and imine crystallization (eqs 1-3). The amination occurs at the N-1(7) (R^3) position of the imidazole ring if this position is unsubstituted (examples **a-d**), and at the N-1 position of the pyrimidine ring in xanthines if the N-7 position is substituted (example **e**).

(1)

(2)

(2)

(3)

(3)

(a) $R^1 = R^2 = R^3 = R^4 = H$

(b) $R^1 = R^2 = R^3 = H;\ R^4 = NO_2$

(c) $R^1 = R^3 = H;\ R^2 = NO_2;\ R^4 = Me$

(d) 
(e) 
The yields of (**3**) are usually better than 70%.[2,7] In a similar fashion, indole and carbazole have been *N*-aminated to give (**4**) and (**5**) in 52-62% yields.[2,7]

(4)

(5)

The *N*-amination of pyridine (and related compounds), although possible,[2,7] is more successful with ***O-(Mesitylsulfonyl)hydroxylamine***. Amination of a tertiary amine has been also reported.[8] Aminations at phosphorus and sulfur have been observed, (one example in each case);[4] again, *O*-(mesitylsulfonyl)hydroxylamine is the reagent of choice.

Reactions with Carbanions.

(**1**) aminates many types of carbanions RM to give primary amines, although the yields are low to moderate.[1,5,6,9,10] With *O*-(mesitylsulfonyl)hydroxylamine, only more stabilized carbanions are aminated; in this case, deprotonation of the aminating reagent is more likely to occur. The amines (**6**)-(**9**) are some examples of primary amines prepared using (**1**).[6]

(6) 30% (RLi)
51% (RMgBr)
70% (RMgCl)

(7) 37% (RLi)

(8) $R^1 = H$, 30% (RLi)
$R^1 = CO_2Me$, 47% (RLi)
$R^1 = CO_2$-*t*-Bu, 78% (RLi)

(9) 67% (RLi)

If the alkynylcuprate (**10**) is aminated with (**1**), the nitrile (**12**) is formed via the unstable primary ynamine (**11**) (eq 4).[6]

$$\underset{\textbf{(10)}}{(Ph\text{-}C{\equiv}C)_2CuLi} \xrightarrow{\textbf{(1)}} \underset{\textbf{(11)}}{[Ph\text{-}C{\equiv}C\text{-}NH_2]} \xrightarrow{-O} \underset{\textbf{(12)}}{PhCH_2\text{-}C{\equiv}N} \qquad (4)$$

Carbanions RM can also be aminated with (**13**)[10,11] and (**14**),[12] which receive their high electrophilicity only after lithiation. (**13**) and, especially, (**14**) are less prone to deprotonation by RM than are (**1**) and, especially, *O*-(mesitylsulfonyl)hydroxylamine. There is an excellent review on the amination of carbanions.[10]

Diphenyl Phosphonate[1]

[4712-55-4] · $C_{12}H_{11}O_3P$ · Diphenyl Phosphonate · (MW 234.20)

(mild coupling agent for synthesis of esters and amides)

Alternate Name: diphenyl phosphite.

Physical Data: mp 12 °C (25 °C);[1a] bp 100 °C/0.008 mmHg, 218-219 °C/26 mmHg; *n*25D 1.5564-1.5570; δ ^{31}P 1.9 ($^1J_{PH}$ 756 Hz).

Solubility: misc most organic solvents; hydrolyzes readily to the monoester, δ ^{31}P 4.0 ($^1J_{PH}$ 719).

Form Supplied in: colorless liquid, widely available, containing up to 15% of phenol.

Purification: distillation.[2] Best done in small batches since decomposition frequently occurs. Phenol can be substantially removed by heating at 150 °C at water pump vacuum.

Handling, Storage, and Precautions: no toxicity data have been reported but the invariable presence of phenol and its ready hydrolysis by atmospheric moisture makes the commerical material corrosive.

In the presence of tertiary amines, preferably ***Pyridine*** or ***Imidazole***, the ester acts as an efficient coupling agent in the formation of peptides (eq 1).[1,3] Ureas and thioureas may be similarly prepared from ***Carbon Dioxide*** or ***Carbon Disulfide*** (eq 2).[4]

The diester undergoes easy transesterification in two distinct stages, allowing the preparation of unsymmetrical diesters (eq 3).[5]

The use of stronger bases than pyridine, e.g. ***Triethylamine***, causes rapid disproportionation to $(PhO)_3P$ and $PhOPHO_2^-$.[2c,5]

Diphenyl Phosphorazidate

[26386-88-9] · $C_{12}H_{10}N_3O_3P$ · Diphenyl Phosphorazidate · (MW 275.22)

(peptide synthesis;[1] synthesis of α-aryl carboxylic acids;[4] synthesis of thiol esters;[7,8] stereospecific conversion of alcohols to azides;[9] ring contraction of cycloalkanones;[13] decarbonylation of aldehydes[26])

Alternate Names: DPPA; *O,O*-diphenylphosphoryl azide.

Physical Data: bp 157 °C/0.17 mmHg; *d* 1.277 g cm^{-3}; fp >110 °C.

Solubility: sol toluene, THF, DMF, *t*-butyl alcohol.

Form Supplied in: colorless liquid; commercially available in kilogram quantities.

Preparative Method: by the reaction of ***Diphenyl Phosphorochloridate*** with a slight excess of ***Sodium Azide*** in acetone at rt (85-90% yield).[1]

Purification: vacuum distillation (bath temp <200 °C, dec >200 °C)

Handling, Storage, and Precautions: handle and store under nitrogen. Refrigerate. Decomposes at >200 °C and may produce toxic fumes of phosphorus oxides and/or phosphine. Toxic, irritant. Harmful if swallowed, inhaled, or absorbed through the skin. Use in fume hood. Incompatible with oxidizing agents and acids. Hazardous combustion or decomposition products include carbon monoxide, carbon dioxide, and nitrogen oxides. Prolonged contact with moisture may produce explosive hydrogen azide (HN_3).

General.

Diphenyl phosphorazidate is a readily available, nonexplosive, and relatively stable azide widely used as a reagent in peptide synthesis,[1-3] and as a versatile reagent in a wide array of organic transformations. DPPA has been successfully utilized in the synthesis of α-amino acids[4] and α-aryl carboxylic acids;[5,6] direct preparation of thiol esters from carboxylic acids and thiols;[7,8] the stereospecific preparation of alkyl azides;[9] and the phosphorylation of alcohols and amines.[10] The application of DPPA in a modified Curtius[11] reaction permits a simple one-step conversion of

carboxylic acids to urethanes under mild reaction conditions. DPPA acts as a nitrene source,[12] and can undergo 1,3-dipolar cycloaddition reactions.[5,13] The Curtius degradation[14] of carboxylic acids in the presence of *t*-butanol gives the Boc-protected amine directly (eq 1).

(1)

DPPA has been utilized in the synthesis of 1,4-dinitrocubane by Eaton and co-workers.[15] Refluxing cubane-1,4-dicarboxylic acid with DPPA and ***Triethylamine*** in *t*-butanol forms the intermediate *t*-butyl carbamate in nearly quantitative yield. This method avoids the formation of the explosive diacyl azide.

Peptide Synthesis.

Urethanes are readily prepared by refluxing equimolar mixtures of DPPA, a carboxylic acid, an alcohol, and triethylamine. The reaction involves transfer of the azide group from DPPA to the carboxylic acid. The resulting acyl azide subsequently undergoes a Curtius rearrangement. This reaction has been successfully applied in the area of peptide synthesis.[1] The coupling of acylamino acids or peptides with amino acid esters or peptide esters in the presence of base proceeds in high yields without racemization, and is compatible with a variety of functional groups. The reaction of malonic acid half-esters results in the corresponding α-amino acid derivatives[4] (eq 2). It should be noted that addition of the alcohol at the beginning of the reaction results in esterification.

(2)

α-Aryl Carboxylic Acids.

Alkyl aryl ketones are converted into the corresponding α-aryl alkanoic acids[4] via a three-step sequence. Yields of >90% are possible if the synthesis is carried out in a one-flask procedure. The sequence includes a 1,3-dipolar cycloaddition of DPPA to the corresponding enamines (eq 3). Although ***Thallium(III) Nitrate*** has also been used in similar oxidative rearrangements,[16] the DPPA method exhibits higher functional specificity, uses less toxic reagents, and gives preparatively useful yields. Naproxen, a nonsterodial anti-inflammatory therapeutic, has been prepared by this route.[6]

Stereospecific Conversion of Alcohols to Azides.

Reaction of an alcohol with DPPA, ***Triphenylphosphine***, and ***Diethyl Azodicarboxylate*** forms the corresponding azides in 60-90% yields.[9] The stereospecific nature of this reaction permits the conversion of Δ^5-sterols such as 3β-cholestanol exclusively to the 3α-cholestanyl azide in 75% yield. This synthesis is clearly superior to the alcohol -> tosylate -> azide route which is longer and also prone to competing elimination reactions.

Ring Contraction Reactions.

DPPA undergoes 1,3-dipolar cycloadditions to the enamines of cyclic ketones.[13] The resulting Δ^2-triazolines, which are not isolated, undergo loss of nitrogen to form ring-contracted products, which, on hydrolysis, yield cycloalkanoic acids. In the case of six- to eight-membered cycloalkanones, overall yields as high as 75% have been reported (eq 4).

Amination of Aromatic and Heteroaromatic Organometallics.

Reaction of organic azides with Grignard and lithium compounds gives 1,3-disubstituted triazenes,[17] which are readily converted to amines by reductive[18,19] or hydrolytic[20,21] workup. These methods are limited to either the aromatic Grignard[18,20] or lithium[21] compounds, and have not been very successful with heteroaromatic organometallics. Aromatic and heteroaromatic organometallics (Grignard and lithium compounds) are aminated in good yields in a one-pot process by treatment with DPPA and reduction of the resulting phosphoryltriazenes with ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (eq 5).[22]

Metal-Catalyzed Decarbonylation of Primary Aldehydes.

The decarbonylation of primary aldehydes under catalytic conditions is difficult, requiring high temperatures or involving radical mechanisms;[23] the rt decarbonylations[24,25] using stoichiometric ***Chlorotris(triphenylphosphine)rhodium(I)*** have had limited practicality due to the high cost of the reagent. Recently, a high-yielding, rt decarbonylation of primary aldehydes using catalytic amounts (5 mol %) of $Rh(PPh_3)_3Cl$ and stoichiometric amounts of DPPA, with minimal formation of alkene byproducts, has been developed[26] (eq 6).

Synthesis of Macrocyclic Lactams.

Macrocyclic lactams are conventionally prepared by the reaction of dicarboxylic acid chlorides with diamines, a method which is effective with simple acyl chlorides. Activation of the carboxylic groups in order to overcome the drawbacks of high dilution and the low yields and purity encountered with larger acyl chlorides has seen only limited success.[27] The superior activating ability of DPPA has recently been demonstrated.[28] The reactions of dicarboxylic acids and diamines in the presence of DPPA form macrobicyclic lactams in yields as high as 82%. By comparison, in a control experiment using conventional high-dilution techniques, the corresponding acyl chlorides cyclized with the diamine to form the lactam in only 24% yield.

DPPA has been used for the direct *C*-acylation of methyl isocyanoacetate with carboxylic acids to give 4-methoxycarbonyloxazoles.[29] L-Daunosamine, the glycone component of anticancer anthracycline antibiotics, has been synthesized from L-lactic acid in 9 steps with a 24% overall yield,[30] where a key step in the sequence is the direct *C*-acylation of methyl isocyanoacetate with the lithium salt of the lactate ester using diphenyl phosphorazidate (eq 7).

Diphenyl Phosphorochloridate

[2524-64-3] · $C_{12}H_{10}ClO_3P$ · Diphenyl Phosphorochloridate · (MW 268.64)

(phosphorylation;[1] synthesis of α-substituted β-lactams;[14] synthesis of anhydrides, esters, and thioesters;[18] conversion of aldoximes to nitriles;[22] preparation and reaction of enol phosphates[25,26,29])

Alternate Names: diphenyl chlorophosphate; diphenylphosphoryl chloride.

Physical Data: bp 314-316 °C/272 mmHg; *d* 1.296 g cm^{-3}; fp >110 °C.

Solubility: sol dichloromethane, THF.

Form Supplied in: viscous colorless liquid; commercially available.

Preparative Methods: by heating a mixture of 1.1 equiv phosphoryl chloride and 2 equiv of phenol to 180 °C, and distilling the product.[1] Prepared in situ by the reaction of diphenyl hydrogen phosphonate and carbon tetrachloride.

Purification: vacuum distillation.

Handling, Storage, and Precautions: moisture sensitive; handle and store under nitrogen. Store in a cool place. Harmful liquid and fumes; inhalation may be fatal. Use in a fume hood. Extremely corrosive; causes burns. Incompatible with strong bases and oxidizing agents. Combustion or decomposition products include carbon monoxide, hydrogen chloride gas, phosphorus oxides, and/or phosphine.

General.

As first demonstrated by Brigl and Müller[1] in the synthesis of glucose and fructose phosphates, diphenyl phosphorochloridate is an excellent reagent for the synthesis of monoalkyl phosphates. The reagent has been used to block the amino group in amino sugar and nucleoside synthesis,[2] and in the synthesis of glycosyl phosphates,[3] key intermediates in the synthesis of nucleotide sugars. The reagent has been used in peptide synthesis,[4] one-pot syntheses of sulfinates, sulfinamides, and thiosulfinates,[5] and as an intermediate in the synthesis of ***Diphenyl Phosphorazidate***[6,7]

and diphenyl phosphoroisothiocyanatidate.[8] The reagent has been utilized in the study of the β-(phosphonooxy)alkyl radical rearrangements,[9] involving the 1,2-migration of phosphate esters.

α-Substituted β-Lactams.

Azidoacetyl Chloride, a valuable reagent for β-lactam synthesis[10-12] by Sheehan's acid chloride-imine method,[13] tends to decompose explosively unless rigorous precautions are observed. The application of phosphorylating reagents provides a safe and viable alternative to this reaction. The reaction of a Schiff base and carboxylic acid in the presence of diphenyl phosphorochloridate and ***Triethylamine*** (eq 1) results in substituted β-lactams in 50-70% yield.[14]

Synthesis of Anhydrides, Esters, and Thioesters.

Phosphorus reagents such as diphenyl phosphorazidate[15] and diphenyl phosphorochloridate[16] have been used for carboxy group activation through the respective mixed phosphoric acid anhydrides. These have been found suitable for the one-pot preparation of carboxylic acid anhydrides, esters, and thioesters.[17] The hydroxy acid (eq 2) does not undergo lactonization under conventional conditions. Activation with diphenyl phosphorochloridate, however, and treatment with ***4-Dimethylaminopyridine***, results in cyclization to the lactone and a dimer in 32% yield and 25% yield, respectively.[18] The diol is generated in quantitative yield with ***Trifluoroacetic Acid*** in aqueous acetonitrile.

Reaction with Amide Enolates.

The synthesis of 3-amino-2*H*-azirines is generally accomplished by the reaction of α-chloro enamines with sodium azide.[19] The less stable 2-monosubstituted 3-amino-2*H*-azirines require a modified synthesis and difficult experimental conditions.[20] A new and simpler route to these compounds involves the reaction of diphenyl phosphorochloridate with amide enolates,[21] followed by reaction with ***Sodium Azide*** to give moderate yields of 2-monosubstituted 3-amino-2*H*-azirines (eq 3).

These 2-substituted aminoazirines react with carboxylic and thiocarboxylic acids to form the respective amides and thioamides (eq 4).

Conversion of Aldoximes to Nitriles.

The reaction of aldoximes with dialkyl hydrogen phosphonates (R = Ph, Me, *n*-Bu), carbon tetrachloride, and triethylamine at ambient temperatures results in the formation of nitriles in high yields.[22] Diphenyl hydrogen phosphonate gives the best yields (85-95%). The reaction proceeds via the in situ generation of diphenyl phosphorochloridate (eq 5),[23] followed by the esterification of the aldoxime, and subsequent Beckmann fragmentation (eq 6).

Synthesis and Reactions of Enol (Vinyl) Phosphates.

A general method for the preparation of enol phosphates involves the reaction of lithium enolates with dialkyl phosphorochloridates.[24] Enol phosphates have been prepared by a novel cycloaddition reaction. Reaction of the enolate of methyl vinyl ketone with diphenyl phosphorochloridate yields the phosphate diene, which then undergoes [4 + 2] cycloaddition (eq 7) to form the Diels-Alder adduct in 90% yield.[25] With relatively poor dienophiles like cyclohexenone, Lewis acid catalysts such as ***Aluminum Chloride*** may be required.

Enol phosphates are versatile intermediates which undergo many synthetically useful transformations. The coupling of enol phosphates with lithium dialkylcuprates provides alkyl-substituted alkenes in good yields (eq 8).[26]

The Pd^0-catalyzed cross coupling of organometallics and organic halides has generally been limited to aryl and alkenyl halides.[27,28] Thus the palladium-catalyzed cross coupling of vinyl phosphates and organoaluminum compounds, reported by Oshima and co-workers,[29] provides an effective tool for the transformation of enolizable ketones into alkyl-, alkenyl-, and alkynyl-substituted alkenes (eq 9).

α,α-Diphenyl-2-pyrrolidinemethanol[1]

(*S*)

[112068-01-6] · $C_{17}H_{19}NO$ · α,α-Diphenyl-2-pyrrolidinemethanol · (MW 253.37) (*R*)

[22348-32-9] ((*S*) .HCl)

[16226-54-3] · $C_{17}H_{20}ClNO$ · α,α-Diphenyl-2-pyrrolidinemethanol Hydrochloride · (MW 289.83)

(precursor to several chiral oxazaborolidine catalysts[1] used for the enantioselective reduction of prochiral ketones[2,3])

Alternate Name: diphenylprolinol.

Physical Data: mp 79-79.5 °C (hexane); 80-82 °C (EtOH). $[\alpha]_{589}$ -54.3° (*c* 0.261, MeOH); -68.1° (*c* 3.17, $CHCl_3$) for the (*S*)-enantiomer.

Solubility: very sol THF, CH_2Cl_2, MeOH, toluene.

Preparative Methods: addition of ***Phenylmagnesium Bromide*** to (*S*)-proline-*N*-carboxyanhydride (73% overall from proline).[4] Addition of *N*-benzyl-(*S*)-proline ethyl ester to phenylmagnesium chloride followed by catalytic hydrogenolysis (49% overall from proline).[5] Addition of *N*-(benzyloxycarbonyl)-(*S*)-proline methyl ester to phenylmagnesium chloride (50% overall yield from proline).[3a,c] Addition of phenylmagnesium bromide to *N*-(ethyloxycarbonyl)-(*S*)-proline methyl ester followed by alkaline hydrolysis (65% overall yield from proline).[6] Addition of (*S*)-proline ethyl ester hydrochloride to phenylmagnesium chloride (20-26% overall yield from proline, ca. 80% ee).[7] Enantioselective deprotonation of *N*-Boc-pyrrolidine with ***s-Butyllithium/(-)-Sparteine*** followed by reaction with benzophenone to give (*R*)-diphenylprolinol (63% yield from pyrrolidine).[8] Add ition of phenylmagnesium chloride to methyl pyroglutamate followed by reduction with borane to give racemic diphenylprolinol (51% yield) which can be resolved as its *O*-acetylmandelate salt to give the (*R*)- and (*S*)-enantiomers (30% yield from the racemate).[3b] Addition of lithiated *N*-nitrosopyrrolidine to benzophenone to give racemic diphenylprolinol (58-60% yield based on benzophenone).[9]

Purification: recrystallization from hexane, ethanol, or methanol/water.

Handling, Storage, and Precautions: no special information available. In general, however, it is advisable that

all reactions with this reagent be conducted in a well ventilated fume hood. Care should be exercised to avoid contact of this reagent and the derived oxazaborolidine catalyst with the eyes and skin.

Enantioselective Ketone Reduction.

Following Itsuno's lead for enantioselective reductions using diphenylvalinol,[10] Kraatz was the first to describe the use of a 1:2 mixture of (*S*)-diphenylprolinol (**1**) and ***Borane-Tetrahydrofuran*** for the stoichiometric enantioselective reduction of ketone (**2**) to obtain the plant growth regulator triapenthenol (**3**) (eq 1).[2] Although not characterized at the time, the species responsible for the enantioselectivity observed was presumed to be an oxazaborolidine-borane complex.[10b]

(1)

Diphenylprolinol (**1**) and borane-THF react in a multistep process to give the unsubstituted oxazaborolidine-borane complex (**7**) (eq 2). Formation of amine-borane complex (**4**) is exothermic, and this intermediate can be isolated as a stable crystalline solid.[4b] Subsequent conversion to oxazaborolidine (**6**) requires heating the THF solution under pressure (1.7 bar) at 70-75 °C for 48-72 h. Corey isolated and characterized free oxazaborolidine (**6**) as a solid (mp 107-124 °C), which was reported to be a mixture of monomer and dimer (NMR).[3a] Finally, addition of borane-THF to a solution of oxazaborolidine (**6**) affords oxazaborolidine-borane complex (**7**) which was not isolated and was identified based on ^{11}B NMR evidence.

Corey demonstrated that oxazaborolidine (**6**) can be used catalytically (2.5-100 mol %) with excess borane (60-200 mol %) for the enantioselective reduction of prochiral ketones (eq 3 Table 1).[3a,c]

(3)

Table 1 Catalytic Enantioselective Reduction of Ketones using Oxazaborolidine (*S*)-(**6**)

Ketone	$H_3B{\cdot}THF$ (mol %)	Catalyst (*S*)-(**6**) (mol %)	Enantio-meric purity[a]	Absolute configuration
PhCOMe	100	10	97%	(*R*)
PhCOEt	60	5	90%	(*R*)
t-BuCOMe	60	10	92%	(*R*)
1-Tetralone	60	5	89%	(*R*)
$PhCOCH_2Cl$	60	5	97%	(*S*)

[a] Enantiomeric purities determined by capillary GC analysis of the (-)-menthyloxycarbonyl derivative, and have been corrected by adding 1% to the experimentally observed values to correspond to values for optically pure catalyst.[3a]

The following catalytic cycle was proposed to explain the behavior of the oxazaborolidine catalyst (eq 4).[3a,11] Oxazaborolidine (**6**) reacts with borane to give oxazaborolidine-borane complex (**7**). Coordination between the Lewis acidic ring boron and the carbonyl oxygen activates the ketone toward reduction. Intramolecular hydride transfer from the BH_3 coordinated to the ring nitrogen then occurs via a six-membered ring chair transition state.[12] Following hydride transfer, the alkoxy-BH_2 dissociates, and oxazaborolidine (**6**) is free to begin the cycle again. For a more detailed discussion, see the entry for ***Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole***.

(4)

Problems with the preparation and stability of oxazaborolidine (**6**) led to the development of a series of *B*-substituted oxazaborolidines derived from diphenylprolinol. The *B*-methyl substituted oxazaborolidine (**9a**) was first prepared (eq 5) by reaction of diphenylprolinol (**1**) with methylboronic acid under dehydrating conditions (toluene at 23 °C in the presence of 4 Å molecular sieves or toluene at reflux using a Dean-Stark trap) followed by vacuum distillation (0.1 mmHg, 170 °C)[3a,c] Based on NMR evidence, the product (mp 74-87 °C) was reported to be a mixture of monomer and dimer.[3a] The corresponding *B*-butyloxazaborolidine (**9c**), prepared in a similar manner from *n*-butylboronic acid, was also reported to be a mixture of monomer and dimer.[13] Subsequent investigations demonstrated that the reported dimers were in fact the intermediate (**8**) and the more stable disproportionation product (**10**) (eq 6).[4] Furthermore, the presence of (**8**) or (**10**) was demonstrated to be deleterious to the enantioselectivity of the catalyst.[14]

(5)

(6)

A small-scale procedure, based on the reaction of bis(trifluoroethyl) alkylboronates with diphenylprolinol (eq 7) was reported for the preparation of the *B*-ethyl- (**9b**) and *B*-butyl- (**9c**) oxazaborolidines.[15] The bis(trifluoroethyl) alkylboronates were prepared from the disproportionation of tris(trifluoroethyl) borate and the corresponding trialkylborane. Since trimethylborane is not commercially available, this procedure is not applicable for the preparation of *B*-methyloxazaborolidine (**9a**).

(7)

A practical large-scale process for the synthesis of *B*-methyloxazaborolidine (**9a**) was developed using commercially available trimethylboroxine (eq 8), which affords the product as an analytically pure, colorless crystalline solid (mp 79-81 °C).[4,16] The *B*-ethyl- (**9b**), *B*-butyl- (**9c**), and *B*-phenyloxazaborolidines (**9d**) were also prepared from the corresponding triethyl-, tributyl-, or triphenylboroxine. The free oxazaborolidines, thus prepared, are stable if rigorously protected from moisture.

A significantly more stable form of the catalyst is the crystalline oxazaborolidine-borane complex (**11**).[4b,16,17] This borane complex is readily prepared from oxazaborolidine (**9a**) and ***Borane-Dimethyl Sulfide*** complex (BMS) (eq 9).

The enantioselectivities reported for the reduction of acetophenone and α-tetralone using the different catalysts (5-10 mol %) and borane-THF or BMS are summarized in Table 2. The best results are obtained by slowly adding the substrate (neat or as a solution in dichloromethane) to a solution of borane complex (**11**) (5 mol %) and BMS (0.6-1.0 mol equiv) in dichloromethane at -20 °C.[16]

Table 2 Enantioselective Reduction of Acetophenone and a-Tetralone

Catalyst	Prep.	mol %	Aceto-phenone	a-Tetralone
(**9a**) (R = Me)	eq 5	10	96.5% ee	83.3% ee
(**9a**) (R = Me)	eq 8	10	98% ee	94% ee
(**9b**) (R = Et)	eq 7	10	96% ee	
(**9c**) (R = Bu)	eq 7	10	96% ee	
(**9d**) (R = Ph)	eq 8	10	72% ee	94% ee
(**11**)	eqs 8 and 9	5	97.6% ee	99.2% ee
(**11**)	eqs 8 and 9	100	>99.8% ee	99.2% ee

In addition to these simple examples, oxazaborolidines derived from diphenylprolinol have been used as enantioselective catalysts for the preparation of prostaglandins,[3a] PAF antagonists,[3a] a key intermediate of ginkgolide B,[18] a key intermediate of forskolin,[19] (*R*)- and (*S*)-fluoxetine,[20] (*R*)- and (*S*)-isopreterenol,[21] vitamin D analogs,[22] the carbonic anhydrase inhibitor MK-0417,[14] the dopamine D1 agonist A-77636,[23] taxol,[24] the LTD_4 antagonists L-695,499 and L-699,392,[25] the β-adenergic agonist CL 316,243,[26] and MK-0499.[27] Recently, Bringmann employed oxazaborolidines (**9a**) and (**9c**) to catalyze the atropo-enantioselective ring opening of achiral biaryl lactones (eq 10).[28]

Diphenylselenium Bis(trifluoroacetate)

[42572-21-4] · $C_{16}H_{10}F_6O_4Se$ · Diphenylselenium Bis(trifluoroacetate) · (MW 459.22)

(two-electron oxidant for phenolic compounds and amines under nonaqueous conditions; source of diphenylselenonium cations in reactions with certain phenols)

Physical Data: mp 175-176 °C.

Solubility: very sol dimethoxyethane, methylene chloride; reacts with protic or nucleophilic solvents.

Form Supplied in: colorless solid; not commercially available.

Analysis of Reagent Purity: mp, IR, and elemental analysis.

Preparative Method: predried diphenyl selenoxide (0.001 mol) is dissolved in 10 mL of dry dimethoxyethane and 0.15 mL (0.001 mol) of freshly distilled ***Trifluoroacetic Anhydride*** is added by syringe. After the reaction mixture has been stirred for 15 min at 0 °C, the solvent is removed in vacuo to give a white solid (eq 1).[1]

Handling, Storage, and Precautions: thermally stable, but very hygroscopic. While the reagent may be isolated in an inert atmosphere, it is most conveniently used by generating it in situ. This reagent should be handled in a fume hood.

Structure and Properties of the Reagent.

By analogy to other tetrasubstituted sulfuranes and selenuranes,[2] the diphenylselenium bis(trifluoroacetate) reagent is believed to exist in a trigonal bipyramidal geometry in which the trifluoroacetoxy groups assume the apical positions.[3]

The covalent and symmetrical selenurane structure is confirmed by the normal IR absorption for the acyl groups (1738, 1718 cm^{-1}) and the singlet ^{19}F NMR absorption at 2.0 ppm downfield from an external trifluoroacetic acid standard. While the reagent is highly hygroscopic, it can easily be handled to obtain an elemental analysis.

Oxidations of Phenolic Compounds.

The title reagent serves as a mild two-electron oxidant for phenols and catechols. The presence of the two trifluoroacetates as leaving groups in the reagent provide a facile exchange mechanism for the incorporation of nucleophiles. There are three modes of oxidation observed for phenols with this reagent: phenolic coupling, benzylic oxidation, and hydroxylation. Some of the prime advantages of this reagent over the more traditional metal oxidants for oxidations of phenols include the homogeneous nature of the reagent in organic solvents, the stoichiometric control of oxidation, and the selectivity found for the oxidation sites. As a typical oxidation process for phenols, 2,6-dimethylphenol undergoes a clean *para-para* oxidative coupling with subsequent oxidation of the hydroquinone with 2 equiv of the reagent at rt (eq 2).[1]

(2)

The coupling reaction (eq 2) occurs exclusively when the oxidizing reagent is added to the phenol. In contrast, when the phenol is added to a solution of the oxidant at rt, the major oxidation pathway involves *para*-hydroxylation and subsequent oxidation to yield 2,6-dimethylbenzoquinone (eq 3). This process involves a unique nucleophilic addition of trifluoroacetate to an aromatic ring.

(3)

The mechanistic interpretation of these reactions involves the initial ligand exchange of a trifluoroacetate for the phenol. The newly formed aryloxyselenurane is an activated aromatic ring susceptible to nucleophilic attack either by another phenol (eq 2) or the trifluoroacetate anion (eq 3). The latter process is accentuated by an increase of the *p*-benzoquinone product when additional lithium trifluoroacetate is added to the reaction solution (eq 4).[1]

Other phenols that undergo the *para*-oxidation to form benzoquinones include thymol (eq 5) and 3,5-dimethylphenol (eq 6).

Intramolecular phenolic coupling reactions are also possible with the title reagent. At low temperatures the diphenolic compound in eq 7 undergoes oxidative coupling to produce the spirodienone product.

(7)

Applications of the diphenylselenium bis(trifluoroacetate) reagent to the synthesis of tetrahydrobenzylisoquinoline alkaloids have revealed some very selective and clean benzylic oxidative processes. In the tetrahydroisoquinoline system of eq 8, the benzylic carbon *para* to the free phenol is initially oxidized to the *para*-quinone methide which rapidly isomerizes to the dihydroisoquinoline system.[1]

(8)

Oxidations of Heterocyclic Amines.

The diphenylselenium bis(trifluoroacetate) reagent is a powerful two-electron oxidant for primary, secondary, and tertiary amines. In the tetrahydroisoquinoline system, the major oxidation products are the imines (eq 9).[4] In some cases (R = Me), a minor reaction product is the fully oxidized quinoline (10%). Thus the controlled oxidation of a secondary amine to an imine can be effected under very mild conditions.[5] When tertiary amines are oxidized with the reagent, regiospecific iminium ions are formed under nonaqueous conditions. Workup of this reaction with cyanide salts gives rise to the well-known Reissert compounds (eq 10).[4]

(9)

R = H	x = 2 equiv	80%
R = Me	x = 3 equiv	81%
R = CO_2H	x = 2 equiv	100%

(10)

Transfer of Diphenylselenonium Cations.

In systems where phenolic coupling, benzylic oxidation, or hydroxylation processes are restricted, reactions of the reagent with certain phenols yield selenonium phenoxides or rearrangement products. For example, estrone is converted to its *ortho*-diphenylselenonium zwitterion with 1 equiv of the reagent (eq 11).[1]

(11)

A similar *ortho*-selenonium phenoxide was observed in the reaction of the trisubstituted phenol shown in eq 12, accompanied by an unusual rearrangement product of the zwitterion.[6] The phenoxide zwitterion is a precursor to the diaryl ether.

Diphenylsilane-Cesium Fluoride

Ph_2SiH_2-CsF

Ph_2SiH_2

[775-12-2] · $C_{12}H_{12}Si$ · Diphenylsilane-Cesium Fluoride · (MW 184.33) CsF

[13400-13-0] · CsF · Diphenylsilane-Cesium Fluoride · (MW 151.91)

(reagent for the reduction of aldehydes,[1,2] ketones,[1,2] and esters;[3] selective 1,2-reduction of enones[2,4] and enals[2,4])

Physical Data: Ph_2SiH_2: bp 95-97 °C; *d* 0.993 g cm^{-3}. CsF: mp 683 °C.

Solubility: Ph_2SiH_2: sol THF. CsF: sol H_2O; slightly sol THF, MeCN.

Form Supplied in: Ph_2SiH_2: clear liquid; widely available. CsF: white solid; widely available.
Drying: anhydrous CsF is prepared by flame drying under vacuum, taking care not to fuse the salt.

Handling, Storage, and Precautions: Ph_2SiH_2 should be used in a fume hood.

Carbonyl Reduction.

The Ph_2SiH_2-CsF reagent can reduce neat aldehydes and ketones to alcohols at 25 °C in <30 min[1,2] (eq 1), though ***Triethoxysilane*** activated with either ***Cesium Fluoride*** or ***Potassium Fluoride*** is generally a better reagent for these solvent-free reductions.[4]

Esters can be reduced to alcohols with Ph_2SiH_2-CsF at elevated temperatures in 65-90% yield; however, the more reactive silane $(EtO)_3SiH$ with CsF activation will do the reduction at 25 °C.[3] Several enones and enals undergo selective 1,2-reduction with Ph_2SiH_2-CsF[2,4] (eq 2), although cyclohexenone reduction is not as selective and there is a tendency for overreduction to cyclohexanol to occur.[2]

Related Reagents.

Phenylsilane-Cesium Fluoride; ***Triethoxysilane***; ***Triethylsilane***.

Diphenylsilane-Tetrakis(triphenylphosphine)palladium(0)-Zinc Chloride[1]

Ph_2SiH_2-$(Ph_3P)_4Pd$-$ZnCl_2$

(Ph_2SiH_2)

[775-12-2] · $C_{12}H_{12}Si$ · Diphenylsilane-Tetrakis(triphenylphosphine)palladium(0)-Zinc Chloride · (MW 184.33) ($(Ph_3P)_4Pd$)

[14221-01-3] · $C_{72}H_{60}P_4Pd$ · Diphenylsilane-Tetrakis(triphenylphosphine)palladium(0)-Zinc Chloride · (MW 1155.62) ($ZnCl_2$)

[7646-85-7] · Cl_2Zn · Diphenylsilane-Tetrakis(triphenylphosphine)palladium(0)-Zinc Chloride · (MW 136.29)

(mild reducing agent for the reduction of α,β-unsaturated systems[2] and allylic hetero substituents[7])

Physical Data: Ph_2SiH_2: bp 95-97 °C/13 mmHg; *d* 0.993 g cm^{-3}.

Solubility: Ph_2SiH_2: sol usual organic solvents; insol H_2O.

Form Supplied in: Ph_2SiH_2: liquid; widely available.

Handling, Storage, and Precautions: Ph_2SiH_2: irritant; avoid inhalation, ingestion, or skin contact. Use in a fume hood.

1,4-Reduction of α,β-Unsaturated Aldehydes and Ketones.[2]

α,β-Unsaturated aldehydes and ketones are readily reduced using a combination of diphenylsilane, ***Tetrakis(triphenylphosphine)palladium(0)***, and ***Zinc Chloride*** in chloroform at ambient temperature.[3] The reduction is highly chemoselective, occurring in a 1,4-fashion (eqs 1 and 2).[4] Although α,β-unsaturated esters, amides, and nitriles are reduced under these conditions, the reaction is much slower, allowing the possibility of selective reduction

of unsaturated aldehydes or ketones (eq 3).

(1)

(2)

(3)

Typical reaction conditions employ a slight excess of diphenylsilane, 1-2% of the palladium catalyst, and 10-50% of zinc chloride. No special precautions such as dry or oxygen free conditions are required; this allows commercial solvents and wet zinc chloride to be used as supplied without purification. Anhydrous conditions have in fact been found to result in slower reaction rates.

The stereoselectivity of the reduction has been examined by the use of diphenyldideuteriosilane, which has shown that

deuterium is introduced from the least hindered face of the enone (eq 4).[2,5]

(4)

A variation on the above conditions involving the inclusion of a catalytic quantity of ***Copper(II) Chloride*** has been used by an Australian group to selectively reduce an α,β-unsaturated ketone in the presence of a vinylic phosphine oxide (eq 5).[6]

(5)

Allylic Reductions.

The reduction of allylic heterosubstituents can readily be achieved using the diphenylsilane-tetrakis(triphenylphosphine)palladium-zinc chloride system in THF (eq 6).[7] Reduction also occurs with diphenylsilane and tetrakis(triphenylphosphine)palladium alone, conditions that will not reduce α,β-unsaturated ketones. This provides a complementary chemoselectivity to that of the corresponding ***Tri-n-butylstannane*** system which favors reduction of the enone (eq 7).[8] The allylic displacement occurs with absolute inversion of configuration, consistent with a mechanism of palladium complexation from the opposite side to the leaving group followed by transfer of hydride to the ligand from palladium. An apparent exception to this was found when tri-*O*-acetylglucal was reduced under these conditions with retention of configuration. This has been explained by a neighboring group participation by the 4-acetoxy substituent.[9]

(6)

(7)

Related Reagents.

Palladium(II) Hydroxide; ***Tri-n-butylstannane***.

S,S-Diphenylsulfilimine[1]

$Ph_2S{=}NH.H_2O$

(monohydrate)

[68837-61-6] · $C_{12}H_{13}NOS$ · *S,S*-Diphenylsulfilimine · (MW 219.33) (anhydrous)

[36744-90-8] · $C_{12}H_{11}NS$ · *S,S*-Diphenylsulfilimine · (MW 201.31)

(nucleophilic imino transfer reagent;[2-5] one-step conversion of aldehydes to nitriles;[6,7] synthesis of nitrogen compounds from *N*-substituted diphenylsulfilimines;[8-11] synthetic intermediate for organic sulfur compounds[12-17])

Physical Data: mp 70-71 °C; pK_a 8.56.[2]

Solubility: slightly sol H_2O, hexane; sol alcohol, benzene, THF, chloroform, acetone.

Form Supplied in: white needles; commercially available.

Analysis of Reagent Purity: IR: S=N 940 cm^{-1} (monohydrate), 910 cm^{-1} (anhydrous); titration.

Purification: the sulfilimine is dissolved in 3% aqueous sulfuric acid. The aq solution is treated with charcoal and then made alkaline under ice-cooling to precipitate the sulfilimine, which is recrystallized from benzene or benzene-hexane.

Handling, Storage, and Precautions: for most purposes the monohydrate is utilized without dehydration; store in the dark; storage at rt for several months causes a smell of diphenyl sulfide; decomposes at 100 °C without solvent; anhydrous sulfilimine is hygroscopic; use in a fume hood.

Nucleophilic Imino Transfer Reagent.

Conjugate addition of Ph_2SNH to β-substituted α,β-unsaturated ketones gives the imino transfer products, *N*-unsubstituted 2-acylaziridines or 2-acyl-1-aminoethylenes (enamines) or both compounds (eqs 1-3).[2-5] Optically active 2-acylaziridines can be synthesized using optically active *S*-(*o*-methoxyphenyl)-*S*-phenylsulfilimine by asymmetric induction.[2]

S,*S*-Diphenyl-*N*-(2-benzoylethenyl)sulfilimines, obtained from addition with benzoylalkynes, undergo pyrolysis to afford 3-substituted 5-phenylisoxazoles in good yields (eq 4).[3]

One-Step Synthesis of Nitriles.

Treatment of Ph_2SNH with aliphatic and aromatic mono- and dialdehydes affords the corresponding nitriles in high yields (eq 5).[6,7]

$$RCHO + Ph_2SNH \xrightarrow[80\ ^\circ C]{C_6H_6} RCN + H_2O + PhSPh \qquad (5)$$

R = Ph, *p*-Tol, *p*-ClC_6H_4, *p*-$MeOC_6H_4$, *p*-HOC_6H_4, 3-py, *t*-Bu, C_7H_{15}, C_8H_{17}, $PhCH{=}CH_2$

N-Substituted Diphenylsulfilimines.

By alkylation[8] and acylation,[1,3] Ph_2SNH can readily be converted to the corresponding *N*-substituted sulfilimines, which have been further utilized for synthesis of various nitrogen-containing compounds[3] by pyrolysis and reactions with other electrophilic reagents (eqs 6-9).[8-11]

(6)

(7)

$RN{=}{\cdot}{=}O$ (8)

(9)

Synthetic Intermediate for Organic Sulfur Compounds.

N-Unsubstituted diarylsulfilimines are the most convenient reagents for the synthesis of diarylsulfoximines and sulfonediimines, which are aza analogs of sulfones and have interesting pharmacological properties. Treatment of the sulfilimines with ***Sodium Hypochlorite*** in aqueous methanol and then with aqueous ***Sodium Hydroxide*** results in the formation of the corresponding sulfoximines in high yields (eq 10).[12] Synthesis of *N*-tosylsulfonediimines can only be performed by the reaction of the sulfilimine with dry ***Chloramine-T*** and the dry sodium salt of tosylamide in dry MeCN (eq 11).[12,13] *N*-Unsubstituted sulfonediimines are prepared directly from the sulfilimines with ***t-Butyl Hypochlorite*** and liquid NH_3 via *N*-halosulfilimines[15] (eq 12).[14]

(10)

(11)

(12)

The alkaline hydrolysis of *N*-halosulfilimines[15] in aqueous MeOH forms an unusual type of organic sulfur compound, *S*,*S*-diphenyl-*S*-methoxythiazyne, which is readily converted to the sulfoximine upon treatment with aqueous acid (eq 13).[16] With ***Tetra-n-butylammonium Fluoride*** the *N*-bromosulfilimine is also converted to *S*,*S*-diphenyl-*S*-

fluorothiazyne, which is further converted to the corresponding *S*-alkoxythiazynes by sodium alkoxides and to *S*-aminothiazynes by cyclic secondary amines.[17]

Diphenylsulfonium Methylide[1]

Ph_2SR

(R = $=CH_2$)

[40411-90-3] · $C_{13}H_{12}S$ · Diphenylsulfonium Methylide · (MW 200.32) (R = $-Me^+BF_4^-$)

[10504-60-6] · $C_{13}H_{13}BF_4S$ · Methyldiphenylsulfonium Tetrafluoroborate · (MW 288.14)

(methylene transfer reagent[1,3])

Physical Data: $Ph_2SMe^+BF_4^-$: white powder, mp 63-66 °C; positive SIMS (secondary ion mass spectra) in glycerol have been reported.[4]

Solubility: $Ph_2SMe^+BF_4^-$: sol CH_2Cl_2, THF, DMF, DMSO, alcohols, H_2O.

Form Supplied in: $Ph_2SMe^+BF_4^-$: white powder; commercially available.

Analysis of Reagent Purity: the purity of $Ph_2SMe^+BF_4^-$ can be determined by HPLC analysis using a Hypersil 5 SAS column with 80/20 acetonitrile/low UV PIC B8 + 0.1% triethylamine as a mobile phase (document of analysis provided by Lancaster).

Preparative Methods: $Ph_2SMe^+BF_4^-$ is usually prepared by direct methylation of diphenyl sulfide.[2] Concentrated H_2SO_4 is added slowly to a mixture of MeOH (which serves as solvent as well as reactant) and Ph_2S. After 18 h at 80 °C, the solution is cooled to 0 °C and washed with Et_2O. After phase separation, tetrafluoroboric acid is then introduced to the reaction mixture at rt followed by addition of H_2O. The reaction mixture is extracted with CH_2Cl_2. The combined organic layer is then washed with saturated $NaHCO_3$, dried over $MgSO_4$ and concentrated to give the crude product which is purified by recrystallization from MeOH/Et_2O in 65% yield.[2] $Ph_2SMe^+BF_4^-$ can also be prepared by the reaction of diphenyl sulfide with excess methyl iodide in nitromethane at rt in the absence of light. Silver tetrafluoroborate is then added to precipitate the iodide ion. After the reaction is complete, the silver iodide salt is removed by filtration.[5-9] The filtrate is then condensed to give the crude product as a pale yellow oil. Stirring of the oily residue in Et_2O overnight provides a white powder. After filtration and drying under vacuum, diphenylmethylsulfonium tetrafluoroborate is isolated in 71% yield. Diphenylsulfonium methylide is generated by treatment of $Ph_2SMe^+BF_4^-$ with a strong base such as NaH, LDA, *n*-BuLi, or *t*-BuLi[1,10] under an inert atmosphere. Solvents such as DME and THF are generally used in the reaction to generate the ylide. Alternatively, $Ph_2S{=}CH_2$ can be prepared in situ by the reaction of benzyne with PhSMe.[11] $Ph_2S{=}CH_2$ is usually prepared and used immediately without purification.

Handling, Storage, and Precautions: $Ph_2SMe^+BF_4^-$ can be stored in a desiccator at rt for months or stored in closed vessels in a dry place away from sources of heat. It is incompatible with strong oxidizing agents.

Introduction.

Like ***Dimethylsulfonium Methylide*** and ***Dimethylsulfoxonium Methylide***, diphenylsulfonium methylide is a methylene transfer reagent. Although it has not been as commonly used as dimethylsulfonium and dimethylsulfoxonium methylide in the preparation of epoxides and cyclopropanes, it has been reported to offer the advantage of avoiding sulfur-containing byproducts resulting from the Sommelet rearrangement.[12]

Epoxidation.

Treatment of 2 equiv of diphenylsulfonium methylide with a heterocycle possessing a leaving group produces a new sulfonium ylide which can be subsequently reacted with a ketone or aldehyde to generate an epoxide. The resultant epoxide can be converted to an acyl derivative by reacting with ***Lithium Diethylamide*** (eq 1).[3]

Het = quinoline, quinazoline, quinoxaline, benzoxazole; X = Cl, methylsulfonyl; R^1R^2CO = acetaldehyde, acetone, benzaldehyde, cyclohexanone, propionaldehyde

Cyclopropanation of Double Bonds.

Unlike many other sulfur ylides, diphenylsulfonium methylide can react directly with unactivated alkenes to produce cyclopropane derivatives. ***Copper(II) Acetylacetonate*** catalyzed cyclopropanation of alkenes with diphenylsulfonium methylide was reported in 1974. This transition metal induced methylene transfer might involve an intermediate metal-carbene complex.[1] Better yields of cyclopropanes are achieved when copper bis(η-3-pentylacetylacetonate) is used instead of $Cu(acac)_2$ in the methylenation of alkenes (eq 2).[13]

(2)

Cyclopropanation of Enones.

Diphenylsulfonium methylide is not commonly used in the cyclopropanation of enones. Reaction of diphenylsulfonium methylide with the enedione resulting from benzoquinone-cyclopentadiene Diels-Alder addition gives the corresponding cyclopropane derivative in only 9% yield.[14]

Methylation.

Diphenylmethylsulfonium tetrafluoroborate is a powerful alkylation reagent. Alkylation of $PhCO_2K$ with diphenylmethylsulfonium tetrafluoroborate in acetonitrile at 20 °C for 7 h provides the corresponding methyl ester in 66% yield.[15] Methyl transfer to pyridine-d_5 by diphenylmethylsulfonium tetrafluoroborate is reported to be 1300 times faster than that using σ-ammoniomethylsulfurane.[16] Diphenylmethylsulfonium tetrafluoroborate has also been used in the methylation of nitrogen heterocyclic compounds such as indole, benzimidazole, thymine, and uracil. These reactions are carried out in CH_2Cl_2 or DMF with bases such as aqueous NaOH, aqueous KOH, or powdered KOH (eq 3).[2]

(3)

O-Methylation of amides such as DMF, DMA, and caprolactam can readily be accomplished with diphenylmethylsulfonium tetrafluoroborate in excellent yields.[17] Alkylation of β-keto esters with diphenylmethylsulfonium tetrafluoroborate is also reported to provide the *C*-alkylated products in excellent yields under aprotic conditions.[18]

Other Applications.

Diphenylmethylsulfonium tetrafluoroborate has been utilized in the presence of ***Aluminum Chloride*** to prepare a low temperature molten salt electrolyte.[19,20] It has also been used as a cationic photoinitiator in polymer chemistry.[21]

3,6-Diphenyl-1,2,4,5-tetrazine[1]

[6830-78-0] · $C_{14}H_{10}N_4$ · 3,6-Diphenyl-1,2,4,5-tetrazine · (MW 234.28)

(an electron-deficient heteroaromatic azadiene capable of participation in inverse electron demand cycloaddition reactions with a wide range of dienophiles[1])

Alternate Name: diphenyl-*s*-tetrazine.

Physical Data: mp 195 °C.

Solubility: sol toluene, CH_2Cl_2, MeOH; insol H_2O.

Form Supplied in: carmine-red needles.

Preparative Method: [2] a mixture of benzonitrile (84 mmol) and 95% hydrazine (100 mL) is heated at 100 °C for 72 h. The resulting orange-yellow solid is broken up, washed with H_2O, air dried, ground to a fine powder, and added to 100 mL of 10% acetic acid. Small portions of sodium nitrite are added to this solution while warming at 100 °C for 1 h. The red solid thus produced is collected, washed with H_2O, and recrystallized from EtOH.

Handling, Storage, and Precautions: stable at rt.

Cycloaddition Reactions.

3,6-Diphenyl-1,2,4,5-tetrazine (**1**) is one of the oldest and most extensively studied electron-deficient heteroaromatic azadienes capable of participation in inverse electron demand Diels-Alder reactions with a wide range of dienophiles and heterodienophiles including electron-rich, neutral, strained, and electron-deficient alkenes, alkynes, dienes, enol ethers, enamines, ynamines, ketene acetals, enolates, benzynes, amidines, imines, and azirines.[1] These cycloaddition reactions occur exclusively across C-3/C-6 of the 1,2,4,5-tetrazine nucleus and are accompanied by a retro Diels-Alder reaction with extrusion of N_2 to afford substituted 4,5-dihydro-1,2-diazines (eq 1),[3] their 1,4-dihydro tautomers (when possible) (eq 2),[4] or substituted 1,2-diazines (pyridazines) when the dienophiles are alkynes (eq 3)[4] or contain leaving groups capable of elimination with aromatization (eqs 4 and 5).[5,6] Aromatization of the dihydro-1,2-diazines may also

be effected by subsequent oxidation of the alkene [4 + 2] cycloadducts for dienophiles which lack a built-in leaving group (eq 6).[7]

(4)

(5)

(6)

Imines and amidines often cycloadd to 3,6-diphenyl-1,2,4,5-tetrazine through their more reactive tautomeric enamine and *N*,*N*-ketene aminal forms, respectively (eqs 7 and 9).[8,9] Cycloaddition of imines and amidines with (**1**) with reaction of the C=N double bond takes place when such tautomerization is not accessible (eqs 8 and 10).[8,10] Cycloadditions with azirines result in ring-expanded products derived from [3,3]-sigmatropic rearrangement of a dihydro-1,2-diazine intermediate followed by [1,5]-hydrogen shift (eq 11).[11] Ring expansion has also been observed with other strained dienophiles (eqs 12 and 13).[12] In addition, the 4π participation of 3,6-diphenyl-1,2,4,5-tetrazine in [4 + 1] and [6 + 4] cycloaddition reactions has also been described.[13]

Despite the extensive studies with 3,6-diphenyl-1,2,4,5-tetrazine and its broad range of reactivity toward a wide spectrum of dienophiles, synthetic applications of this reagent are limited due to the presence of the phenyl substituents which are incompatible with many synthetic targets. However, a large number of 1,2,4,5-tetrazines with a range of substituents are available[1b,14] and many are amenable to further synthetic manipulations for specific applications. One notable example is the development of a general approach to the preparation of substituted indoles and indolines through use of the sequential [4 + 2] cycloaddition reactions of 3,6-bis(methylthio)-1,2,4,5-tetrazine.[15] The application of a 1,2,4,5-tetrazine -> 1,2-diazine -> indole synthetic strategy based on the use of 3,6-bis(methylthio)-1,2,4,5-tetrazine in the total synthesis of *cis*- and *trans*-trikentrin A (**2**) and (**3**) has been detailed (eq 14).[16]

4,6-Diphenylthieno[3,4-*d*]dioxol-2-one 5,5-Dioxide[1]

[54714-11-3] · $C_{17}H_{10}O_5S$ · 4,6-Diphenylthieno[3,4-*d*]dioxol-2-one 5,5-Dioxide · (MW 326.34)

(acylating agent in peptide synthesis;[1] synthesis of substituted ureas and isocyanates;[6] acylating agent in Friedel-Crafts reaction)

Physical Data: mp 230-290 °C.

Solubility: sol THF, CH_2Cl_2, dioxane.

Form Supplied in: yellow powder, 95%.

Preparative Method: by reaction of 4-hydroxy-3-oxo-2,5-diphenyl-2,3-dihydrothiophene 1,1-dioxide[2] with ***Phosgene*** (eq 1).[1]

Handling, Storage, and Precautions: irritant; chemical, physical, and toxicological properties have not been thoroughly investigated.

Acylating Agent in Peptide Synthesis.

The reagent (**2**) reacts smoothly with carboxylic acids and pyridine in anhydrous aprotic solvents to give active esters (**3**) (eq 2), which are easily crystallizable, stable compounds. Compound (**3**) is an excellent acyl transfer agent. Reaction of (**3**) with amines readily affords amides (eq 2)[1] under mild conditions in high yield. In several experiments it has been demonstrated that these esters are more effective acyl transferring agents than the *p*- and *o*-nitrophenyl esters commonly employed in peptide synthesis.

Synthesis of Boc-Amino Acid Esters.

The reagent (**2**) can be employed in a one-pot preparation of activated Boc-amino acid esters when used for both activation of the Boc-amino acid and for introduction of the Boc group (eq 3).[3] The reagent (**2**) has been successfully utilized in peptide synthesis[4] and in the formation of activated matrices for HPLC that require formation of an amide bond.[5]

Di- and Trisubstituted Ureas and Urethanes.

Similar to Boc activation, reaction of (**2**) with amines forms an intermediate carbamate (eq 4), which upon heating in dichlorobenzene gives the corresponding isocyanate or upon treatment with another molecule of amine gives the corresponding urea derivative.[6] The products are obtained in 78-92% yield.

Active Ester in Friedel-Crafts Acylation Reactions.

A variety of active esters have been prepared from the reaction of (**2**) and carboxylic acids (eq 5). This product is an active agent in Friedel-Crafts acylation of aromatic substrates.[7] The method can be applied under milder conditions than the methods that use corresponding acid anhydrides or acyl chlorides, and fewer byproducts are formed.

Diphenylstannane[1]

Ph_2SnH_2

[1011-95-6] · $C_{12}H_{12}Sn$ · Diphenylstannane · (MW 274.95)

(hydrostannylation of alkenes and alkynes; reduction of aldehydes and ketones; hydride transfer reactions with other organometallic reagents)

Alternate Name: diphenyltin dihydride.

Physical Data: colorless oil; bp 89-93 °C/0.3 mmHg, 74 °C/0.001 mmHg; mp -17 °C; *d* 1.39 g cm^{-3}; *n*20D 1.5951.

Solubility: sol most organic solvents. Many polar aprotic solvents catalyze the decomposition to diphenyltin oligomer and hydrogen (e.g. MeOH, Et_2NH, pyridine, morpholine, DMF, DMSO). Diphenylstannane reacts (exothermically) with all protic solvents.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: ^{119}Sn NMR recommended (δ -234 ppm, $^1J(^{119}Sn\text{-}^1H)$ 1928 Hz).[4]

Preparative Methods: from Ph_2SnCl_2 and $LiAlH_4$[2] or Et_2AlH[3] in diethyl ether; yield 70-89%. The ***Lithium Aluminum Hydride*** method is recommended.

Handling, Storage, and Precautions: must be stored in the absence of oxygen, moisture, and light (preferably under argon). Use in a fume hood.

Introduction.

All aspects of the preparation, spectroscopic properties, and chemical reactions of diphenylstannane are discussed in the Gmelin Handbuch volume dealing with organotin hydrides (literature covered up to the end of 1974),[1a] while more general aspects of the preparation and chemistry of organotin hydrides (and deuterides) are reviewed in the Houben-Weyl volume on organotin compounds (literature coverage up to 1977).[1b]

Hydrostannylation.

The hydrostannylation of monoalkenes (e.g. acrylonitrile, methyl acrylate, methyl methacrylate) or monoalkynes affords monomeric products (eq 1).[5] Dialkenes (e.g. 1,4-divinylbenzene) or dialkynes (e.g. 1,4-diethynylbenzene), in contrast, yield polymeric materials.[6] In some cases (e.g. 1,2-divinylbenzene, 1,2-diethynylbenzene) a mixture of polymeric and monomeric products is formed (eq 2).[7]

$$Ph_2SnH_2 + 2\,H_2C{=}CHCN \xrightarrow{70\ ^\circ C} Ph_2Sn(CH_2CH_2CN)_2 \quad (1)$$

(2)

Reduction of Aldehydes and Ketones.

Aldehydes and ketones are reduced by diphenylstannane to primary and secondary alcohols, respectively. This reaction is of preparative interest in the case of α,β-unsaturated ketones, since here only the carbonyl group is normally reduced, the alkenic double bond remaining unaffected (eq 3).[8] Some cases are known, however, in which the double bond is reduced while the carbonyl group remains intact.[9]

$$Ph_2SnH_2 + H_2C{=}CHCOMe \longrightarrow 1/n\,(Ph_2Sn)_n + H_2C{=}CHCH(OH)Me \quad (3)$$

Hydride Transfer Reactions.

Diphenylstannane undergoes reversible exchange reactions with diphenyltin dihalides to afford halodiphenylstannanes,[10] which in turn can be used as reducing agents. Many other ligand exchange reactions are known, but these have not so far been shown to be of interest for synthetic organic chemistry.

Virtually no synthetic work has been published since 1974. The reason for this is likely to be the fact that, in general, diphenylstannane has no notable advantage over the dimethyltin or dibutyltin analogs. Its disadvantage lies in the high boiling points of diphenyltin compounds, which make it difficult to remove tin-containing residues completely from reaction products. Its one potential advantage lies in the fact that such compounds are in some cases solids at rt. However, even these generally have a residual solubility in organic compounds. It will indeed not generally be necessary to resort to the use of tin dihydrides in order to carry out chemistry of the nature described above, except when polymeric or cyclic organotin products are required. The monohydrides are chemically very versatile and in addition much more stable (see in particular ***Trimethylstannane*** and ***Tri-n-butylstannane***). The problem of the toxicity of organotin compounds and their interaction with the environment or their effect on animals has been dealt with in some detail in the literature; relevant work on triphenyltin compounds has resulted in the detection of diphenyltin species, as reported in several publications.[11]

Related Reagents.

Tri-n-butylstannane; ***Triphenylstannane***.

University of Dortmund, Germany

Diphenyl(vinyl)phosphine Oxide[1]

[2096-78-8] · $C_{14}H_{13}OP$ · Diphenyl(vinyl)phosphine Oxide · (MW 228.24)

(Horner-Wittig[2] reagent for the preparation of allylic amines; undergoes a variety of cycloaddition[3] and conjugate addition reactions[4])

Physical Data: mp 115-117 °C; bp 180-210 °C/1 mmHg.

Solubility: sol THF, CH_2Cl_2, toluene; insol H_2O.

Preparative Methods: can be prepared (eq 1) by four methods: (a) dehydrohalogenation of a haloethyldiphenylphosphine oxide,[5,6] (b) reaction of diphenylphosphinic chloride and vinylmagnesium bromide,[7] (c) palladium-catalyzed coupling of vinyl bromide and diphenylphosphine oxide,[8] (d) oxidation of commercially available diphenyl(vinyl)phosphine.[9]

Handling, Storage, and Precautions: the toxicological properties of the reagent are unknown; however, by analogy with other Michael acceptors it should be assumed to be toxic. While radical polymerization is sluggish, diphenyl(vinyl)phosphine oxide readily undergoes anionic polymerization in the presence of Grignard reagents.[5]

Conjugate Additions.

Diphenyl(vinyl)phosphine oxide readily undergoes conjugate addition with carbon,[4] nitrogen,[4,10,11] oxygen,[4,12] and sulfur[4,13] nucleophiles. Of particular interest is the addition of chiral amines (eq 2)[11] and alcohols (eq 3),[12] which provide precursors of chiral phosphines, potentially useful ligands for various transition metal catalyzed processes.

(2)

(3)

Alkylation of the pyrrolidine enamine of cyclohexanone, followed by a Baeyer-Villiger oxidation and acyl transfer, leads to a two-carbon ring expansion (eq 4).[14]

(4)

Horner-Wittig Reactions.

Simple amines such as ***Morpholine***, ***Piperidine***, and ***Pyrrolidine*** add to the vinylphosphine oxide to furnish adducts[11] which can be used in the regio and stereospecific Horner-Wittig synthesis of allylic tertiary amines (eq 5).[2] The anions, generated with ***n-Butyllithium*** in THF at 0 °C, react with aldehydes and ketones (including enolizable ones) at -78 °C to give isolable β-hydroxyphosphine oxides. Completion of the Horner-Wittig reaction (***Sodium Hydride***, DMF, 30 °C) gives allylamines in high yield. In the cases where R^1 &neq; R^2 the diastereoisomeric β-hydroxyphosphine oxides can be separated by chromatography or fractional crystallization. Stereospecific *syn* elimination of $Ph_2PO_2^-$ then enables isolation of both the (*Z*)- and (*E*)-alkenes. In contrast, the conventional Wittig reaction often gives inseparable mixtures of geometric isomers.

(5)

NR = morpholine, piperidine, pyrrolidine

Cycloaddition Reactions.

Diphenyl(vinyl)phosphine oxide undergoes 1,3-dipolar cycloaddition reactions with a variety of nitrones, giving mixtures of regioisomeric isoxazolidines.[3] The regiochemistry of the cycloaddition is very sensitive to minor structural changes in the nitrone (eqs 6-8). The chemistry has been extended to chiral nitrones.[15]

(6)

(7)

(8)

Lewis acid catalyzed Diels-Alder reactions with ***Cyclopentadiene*** giving predominantly *endo* selectivity have been described (eq 9).[16]

Diphosphorus Tetraiodide[1,2]

[13455-00-0] · I_4P_2 · Diphosphorus Tetraiodide · (MW 569.54)

(exhibits a high affinity for oxygen and acts as a unique reagent able to promote substitution, dehydration, and reduction reactions)

Physical Data: mp 124 °C (from CS_2);[3] X-ray;[4] ^{31}P NMR.[5]

Solubility: sol CS_2; partly sol CH_2Cl_2.

Form Supplied in: bright orange solid; commercially available.

Handling, Storage, and Precautions: can be weighed out rapidly in air into vials flushed with nitrogen. Store under nitrogen in the absence of moisture. This reagent should be handled in a fume hood.

Introduction.

Diphosphorus tetraiodide is a bright orange solid which fumes in air, probably due to the presence of trace amounts of white phosphorus. It is most conveniently prepared by mixing, at rt, stoichiometric amounts of white phosphorus and iodine in CS_2,[3] or by reaction of phosphorus trichloride with potassium iodide in ether (3 equiv KI, reflux, 12 h, 75%).[6] Diphosphorus tetraiodide often exhibits similar reactivity to ***Phosphorus(III) Iodide***. P_2I_4 exhibits a high affinity for oxygen and acts as a unique reagent able to promote substitution and dehydration, as well as reduction, reactions. In the last case, a mixture of phosphorus acids (including hypophosphorous acid) and iodine is formed. The characteristic reactivity of P_2I_4 was disclosed very early by Berthelot in 1855, when he described the synthesis of allyl iodide from glycerol and P_2I_4.[7] In this transformation, H_2O_2 is formally removed and one hydroxy group is substituted by an iodide ion.

P_2I_4 was first used in the early 1920s by Kuhn[8,9] and later by Inhoffen[10] for the reduction of unsaturated diols to *trans*-polyenes or enepolyynes (eq 1).

Reactions of P_2I_4 Involving Substitutions with Iodide Ion.

P_2I_4 reacts with alcohols (CS_2, 20 °C, 0.5-24 h) to form alkyl iodides in good to very good yields (eq 2).[3] The reaction is quite general and occurs with primary, secondary, and tertiary alcohols,[3,11] as well as with benzyl[3] and allyl alcohols.[12] The reaction is very fast (<0.5 h) with *t*-alkyl, benzyl, and allyl alcohols, but quite slow (24 h for completion) with primary and secondary alcohols, especially with neopentyl derivatives (144 h). It has also been successfully carried out in special cases (i.e. for the preparation of [^{11}C]methyl iodide (99.5% purity, 3.4 Ci μmol^{-1})[13] and [^{11}C]allyl iodide[3]), under vacuum (10^{-2} mmHg), in the gas phase, and on solid supports (VGSR).

R^1, R^2, R^3 = H, Me, Hex	24 h	70%	0%
R^1, R^2, R^3 = H, H, Pr	0.1 h	33%	55%
R^1, R^2, R^3 = Me, Me, Bu	0.5 h	82%	0%
R^1, R^2, R^3 = Me, Me, Ph	0.5 h	90%	0%

Rearrangement does not usually occur[3] except with allyl alcohols[12] and only in rare cases are elimination reactions observed (for example from *cis*-4-*t*-butyl-1-cyclohexanol and a little from its *trans* stereoisomer).[3] The reaction is stereoselective with secondary alkyl halides and occurs by net inversion of configuration.[3] The reaction takes another course (i) when carried out on primary and secondary alcohols if it is rapidly quenched by water (after 0.1 h instead of 24 h), where it mainly produces dialkyl phosphites (eq 2),[3] and (ii) when carried out on benzyl alcohols bearing electron-withdrawing groups (or whose benzylic carbon is quite hindered by a *t*-butyl group or by two methyl groups in 2,6-positions on the aromatic ring), which undergo reduction in refluxing benzene to form the parent hydrocarbons in good to moderate yields.[14] Under the same conditions, but in the presence of disulfides, benzyl alcohols afford the corresponding benzyl sulfides (0.5 equiv P_2I_4, benzene, reflux 4-10 h, 6-90% yield).[15]

α,o-Diols, with the exception of 1,2-glycols (see below), produce the corresponding diiodides on reaction with 0.5 equiv of P_2I_4[3] and form monoiodides if half the amount of P_2I_4 is used instead.[16] Selective transformation of primary over secondary carbinols has been achieved. Cyclopropyl carbinols which do not bear a fully alkyl substituted carbinol carbon produce the corresponding iodides in good yield (70%), in addition to trace amounts of 3-alkenyl iodides resulting from cyclopropane ring opening (eq 3).[17] However, these cleavage products are formed as predominant products[17] (i) from alcohols where the carbinol carbon is fully alkyl substituted, (ii) from cyclopropyl carbinols bearing a silyl substituent on the cyclopropane ring (eq 3), and (iii) from seleno analogs which possess hydroxy groups at an allylic position.[17]

X = TMS	R^1 = H	R^2 = Dec	0 °C, 1 h	0%	73%

β-Aminoalkyl carbinols are cyclized to aziridines (P_2I_4, benzene, 20 °C, 24 h, 45-75% yield).[18]

The high oxygenophilicity of the phosphorus atom of P_2I_4 coupled with the high nucleophilicity of iodide ion allows the ring opening of cyclopropyl ketones to γ-iodo ketones,[17] oxetanes,[19] tetrahydrofurans,[19] and tetrahydropyrans[19] to the corresponding o-diiodides (60, 50, and 15% yield, respectively, reaction carried out at 20 °C) and of γ-butyrolactone (90 °C, 24 h) to 4-iodobutyric acid or to methyl butyrate, depending upon the reagent (H_2O or methanol) used to quench the reaction.[1])

P_2I_4 can be employed for the deprotection of α,α-bis(methoxy)- and α,α-bis(ethoxy)alkanes, leading to the corresponding aldehydes or ketones together with methyl or ethyl iodide. The reaction is particularly easy with α,α-bis(methoxy)alkanes (20 °C, 0.2 h), but does not occur with dioxolanes even under drastic conditions.[20] This reaction has been successfully used[21] for the cleavage of alkoxymethyl aryl ethers to give hydroxyarenes and has been applied to the synthesis of the antibiotic ascofuranone.[21]

P_2I_4 also reacts with thioacetals, orthothioesters, and their seleno analogs to produce vinyl sulfides, ketene thioacetals, vinyl selenides, and ketene selenoacetals, respectively.[22]

Reactions of P_2I_4 Involving Reduction.

P_2I_4 reacts differently with glycols (eq 1) or related α,δ-diols whose β,γ-carbons are both sp^2, sp, or part of a cyclopropane ring. These substrates lose two hydroxy groups and are converted to alkenes,[8-10] 1,3-dienes,[10] 1,2,3-trienes,[6] or 1,4-dienes,[23] respectively. β-Thioalkyl carbinols[24] and β-selenoalkyl carbinols[1,17] also behave differently from β-aminoalkyl carbinols (see above) and afford alkenes. The reaction is best achieved in the presence of ***Triethylamine***, occurs in a few hours at rt, is more efficient with methylseleno than with methylthio, phenylseleno, or phenylthio derivatives (which are the least reactive), and allows the regioselective synthesis of terminal, di-, tri-, and tetrasubstituted alkenes. The synthesis of alkylidenecyclopropanes[17] and allenes[25] via this approach can only be achieved from β-hydroxyalkyl methyl selenides. The elimination is in general antistereospecific,[1,17] except with β-hydroxyalkyl phenyl sulfides[24] which are the least reactive compounds and probably react via the intermediate formation of a thiiranium or a seleniranium ion (eq 4). Since β-hydroxyalkyl selenides can be synthesized from α-selenoalkyllithiums and carbonyl compounds, even hindered and/or enolizable ones such as 2,2,6-trimethylcyclohexanone or deoxybenzoin,[26] this set of reactions allows the synthesis of the corresponding alkenes which are not available via the Wittig reaction (eq 5).[27-29]

(4)

X = SeMe, SePh, SMe de > 94%
X = SPh de = 50%

(5)

P_2I_4 also reduces epoxides (eq 6)[1,19,30] and thiiranes[31] to alkenes. The reduction of epoxides takes place at rt in methylene chloride in the presence of a base such as triethylamine or pyridine.[19] The reduction of thiiranes requires more drastic conditions (DMF, 80 °C).[31] Both reactions are regioselective and highly stereoselective, allowing the synthesis of a variety of alkenes (terminal, di-, tri-, and tetrasubstituted)[19,30,31] whose stereochemistry is derived from that of the starting epoxides or thiiranes (eq 6).[19,30,31]

(6)

This reaction allows the synthesis of polyfunctionalized alkenes such as enones,[19,30] diphenylvinylphosphine oxides,[32] vinylcyclopropanes,[30] and 1,3-dienes[19,30] from the corresponding epoxides. The ethylidene derivative shown in eq 6 is produced in modest yield as the pure (*E*) stereoisomer.[33] Other reagents able to deoxygenate epoxides, such as ***Tungsten(VI) Chloride-n-Butyllithium*** and [*n*-Bu_3SnAlMe]Li, result in considerable scrambling of alkene stereochemistry.[33]

P_2I_4 is a valuable reducing agent, able to reduce under mild conditions iodo,[34] bromo,[34] and seleno ketones,[17] including cyclic ones (0.5 equiv, 25 °C, 1-7 h, 54-97% yield; eq 7). Sequential reaction of terminal epoxides with ***Iodotrimethylsilane***, Jones reagent, and P_2I_4 allows the one-pot chemoselective synthesis of the corresponding methyl ketone resulting from the reduction of the iodomethyl ketone intermediate (eq 7).[34]

(7)

P_2I_4 also reduces, under mild conditions, aminoxides,[35] sulfoxides,[36,37] and selenoxides[36] to amines, sulfides, and selenides, respectively (eq 8). These conditions are sufficiently mild so that the very easy selenoxide elimination leading to alkenes does not compete.

(8)

P_2I_4 reduces ozonides very rapidly at -78 °C;[17] promotes, under unusually mild conditions, the reduction of nitroalkanes to nitriles (eq 9);[36] and transforms, in boiling acetonitrile, arenesulfonic acids, their salts, their chlorides, and their esters to diaryl disulfides.[38] Arenesulfonamides are stable towards P_2I_4 in boiling acetonitrile, but are successfully reduced at much higher temperature and under neat conditions to give diaryl disulfides as the sole products.[38]

(9)

Reactions of P_2I_4 Involving Dehydration or Related Reactions.

P_2I_4 has proved to be a valuable dehydrating agent. Thus 2-amino alcohols are transformed to aziridines (see above);[18] aldoximes[30,39] and amides[40] are smoothly transformed to nitriles, and thioamides behave similarly.[41] P_2I_4 also allows the dehydrative condensation of carboxylic acids with amines.[42] The latter reaction seems to be attractive for converting weak or hindered amines into amides and has been used for the synthesis of a few peptides.[42]

Related Reagents.

Lithium Aluminum Hydride-Diphosphorus Tetraiodide.

(2*R*,3*R*)-Dipivaloyltartaric Acid

[65259-81-6] · $C_{14}H_{22}O_8$ · (2*R*,3*R*)-Dipivaloyltartaric Acid · (MW 318.36)

(chiral auxiliary for enantioselective protonation (deracemization) and asymmetric transformation; starting material for synthesis of chiral succinimides and polyhydroxy compounds)

Alternate Name: (2*R*,3*R*)-DPTA.

Physical Data: mp 135 °C; [α]25D -24.2° (1.7, dioxane).[1]

Solubility: sol Et_2O, THF, aq $NaHCO_3$ solution; insol cold H_2O.

Preparative Method: hydrolysis of the corresponding anhydride obtained by heating (2*R*,3*R*)-tartaric acid and pivaloyl chloride at 120-140 °C for 4 h.[1] *Drying:* over P_2O_5 in vacuo, controlled by ^1H NMR and optical rotations.

Handling, Storage, and Precautions: the anhydrous solid can be stored at rt in the absence of moisture. It is retrievable from its basic solution (10 % aq $NaHCO_3$), after acidification (HCl), with a quantitative yield.[2] On heating it transforms into an anhydride with elimination of one molecule of water.

Chiral Auxiliary Used for Enantioselective Protonation (Kinetic Control).

(2*R*,3*R*)-Dipivaloyltartaric acid has been essentially used for enantioselective protonations.[3] Surprisingly, for the creation of the chirality during the formation of the C-H linkage, this type of reaction has received attention only recently, unlike enantioselective hydrogenations or enantioselective reductions with hydride anion, widely used in asymmetric syntheses. (2*R*,3*R*)-DPTA was the first protonating reagent leading to appreciable enantioselections (up to 80 %) when applied to

different classes of substrates such as enamines,[4] enolates of functionalized esters,[5] and carbonyl compounds.[4] At the present time, high enantioselectivities have also been reached with other protonating agents,[6] but often limited to one target molecule.

The first reported experiments concerned the protonation of enamines with (2*R*,3*R*)-DPTA leading, after hydrolysis of the iminium salts formed in situ, to optically active carbonyl compounds.[7] Starting from the (*Z*)- and (*E*)-morpholino enamines of 2-phenylpropanal, it was possible to establish, in spite of modest results (ee 13-18%), that the protonation step was kinetically controlled: the (*Z*)- and (*E*)-isomers led to 2-phenylpropanal with a reverse configuration, excluding an equilibrium of the intermediate diastereoisomeric salts (eq 1).[7]

(1)

The protonation of lithium enolates of Schiff bases of racemic α-amino esters leads, after the workup, to α-amino acids of (*S*) configuration with ee as high as 70% (eq 2).[2,5,8,9]

A first set of experiments, the study of the protonation of enolates obtained from benzaldehyde Schiff bases and ***Lithium Diisopropylamide***, showed that the asymmetric induction was not significantly affected by the size of the R moiety of the amino acid (R = Me, Et, *i*-Pr, *n*-Bu, *t*-Bu, Ph; ee = 44-56%).[2,9] The two main factors improving the enantioselection were the Ar substituent of the Schiff base and the lithium amide used for the deprotonation.[5,8,10] The following results (Table 1) indicate clearly that the enantioselectivity increases with the electron-donating power of substituents *para* to the Schiff base (eq 3),[5] leading to 70% ee with the Schiff base of *p*-methoxybenzaldehyde derived from phenylglycine.[9]

Table 1 Influence of the *para*-Substituent

X	ee (%)	X	ee (%)
NC	12	Me	53
Cl	31	MeO	57 (70)[a]
H	50	Me_2N	61

[a] Protonation carried out at - 105 °C.

The favorable effect of electron-donating substituents X, interpreted as the structure of the enolate becomes more rigid due to the increase of the coordination between the lithium and the nitrogen atoms, was confirmed on a series of α-amino acids.[9]

The enantioselectivity was dramatically affected by the structure of the lithium amide used for the deprotonation, indicating that the secondary amine liberated during the metalation step participates in the protonation step.[3,8,10] The utilization of chiral lithium amides allowed higher enantioselections than with classical LDA (eq 4) (Table 2).[8,10]

(4)

Table 2 Influence of the Lithium Amide used for Deprotonation

Lithium amide	ee (%)	Lithium amide	ee (%)
$LiN(i\text{-}Pr)_2$	50		70
$LiNEt_2$	28		60
	22		

The crucial role of the secondary liberated amine was also reported in experiments involving deprotonation with lithium (*R*)-*N*-ethyl(1-phenylethyl)amide and reprotonation at -70 °C with 2*R*,3*R*, racemic, and *meso*-DPTA, yielding, respectively, 70, 39, and 24% ee of the (*S*)-enantiomer. In the two last cases, significant inductions were obtained with the sole secondary chiral amine as chiral inductor in the medium.[8] Since these first results, chiral lithium amides have been widely used for asymmetric synthesis.

Owing to the importance of the amine, probably acting as a ligand of lithium or a proton carrier [ammonium salt of (2*R*,3*R*)-DPTA],[3,10] a process was proposed allowing the introduction of different amines and consequently a modification of the selectivity of the protonation: after deprotonation of a Schiff base of methyl valinate with ***Lithium Hexamethyldisilazide*** (LHMDS), the liberated HMDS was replaced by a more basic primary, secondary, or tertiary amine prior to the addition of (2*R*,3*R*)-DPTA (eq 5) (Table 3). In some cases, higher ee were observed compared to the classical procedure with LHMDS (34% ee) or LDA (47% ee).[10]

(5)

Table 3 Influence of the Added Amine

Added amine	ee (%)	Added amine	ee (%)
-	34		50
Et_2NH	44	$EtNH_2$	55
i-Pr_2NH	47		64

Enantioselective protonation of lithium dienolates obtained from Schiff bases of methyl α-aminobutenoates was carried out using (2*R*,3*R*)-DPTA, in order to synthesize vinylglycine by deconjugation (ee 36%).[9] Protonation of a cyclic lithium enolate derived from mandelic acid with (2*R*,3*R*)-DPTA was reported to occur with a low ee.[6b]

The potassium (*Z*)-enediolate obtained from racemic benzoin and ***Potassium Hydride*** when treated with (2*R*,3*R*)-DPTA affords (*S*)-benzoin with 80% ee (optically pure after one recrystallization in methanol).[11] In the reaction conditions, the enediolate is first *O*-protonated, then the resulting enediol slowly tautomerizes at low temperature into optically active benzoin with a high enantioselectivity. In the cases of incomplete tautomerization the residual enediol was immediately oxidized to benzil by the oxygen of the air during the workup. It was shown that the tautomerization of the enediol was hindered by the presence of an excess of (2*R*,3*R*)-DPTA (eq 6).[11]

Finally, the configuration of the protonation product is predictable using the L Rule. The prochiral substrate is represented according to the letter L, where the vertical line represents the C=C bond and the horizontal line the C-X bond (X = nucleophilic atom). In such a case, protonation with (2*R*,3*R*)-DPTA is favored on the L-face, i.e. on the side of the reader. As an example, the protonation of a lithium enolate of a Schiff base of an α-amino ester, leading to the (*S*)-enantiomer, is given in eq 7.[3]

In enantioselective protonations, the final optically active product is generally chemically identical to the starting racemic material, precursor of the prochiral substrate on which the protonation is carried out. That is why the term deracemization was proposed for this type of process.[3,4,12] In a deracemization, the protonation step is kinetically controlled. Therefore a deracemization differs from an asymmetric transformation in which the reactions are thermodynamically controlled.[3,4]

Chiral Auxiliary Used for Asymmetric Transformations (Thermodynamic Control).

Racemic *N*-benzyl-*N*-methyl-α-amino propiophenone mixed with (2*R*,3*R*)-DPTA in acetone or dichloromethane leads with 90% yield to the corresponding salt of the (*S*)-amino ketone, which was reduced over ***Palladium on Carbon*** to a mixture of ephedrine (80%) and pseudo-ephedrine (20%) (eq 8).[13]

Starting Material for Asymmetric Syntheses.

(3*R*,4*R*)-Dipivaloyltartaric anhydride, the direct precursor of (2*R*,3*R*)-DPTA, has been used as starting material for the synthesis of (3*R*,4*R*)-dipivaloyltartrimide,[14] its *N*-chloro and *N*-bromo derivatives (eq 9)[15], and epimeric (3*R*,4*R*)-dipivaloyl-5-alkyl lactones (eq 10), which are valuable intermediates for access to optically active polyhydroxy compounds.[16]

Dipotassium Acetylide[1]

KC&tbond;CK

[22754-96-7] · C_2K_2 · Dipotassium Acetylide · (MW 102.22)

(useful C_2 nucleophile for preparation of ethynyl steroids[2-5] and 1,4-dicarbonyl compounds[6])

Alternate Names: 1,2-ethynediyldipotassium; potassium acetylide; potassium carbide.

Solubility: low sol THF at 25 °C.[3]

Preparative Methods: dipotassium acetylide is prepared in situ and has not been isolated. Preparative routes include treatment of acetylene with potassium hydroxide in 1,2-dimethoxyethane or acetal solvents at temperatures between -10 °C and 20 °C,[1] addition of acetylene to a solution of potassium *t*-pentoxide,[2] and addition of 1 equiv of acetylene to 2 equiv of potassium *t*-butoxide in THF at 25 °C.[3] Solutions produced by the above methods are then used immediately. The reaction of dipotassium acetylide with ***N,O-Bis(trimethylsilyl)acetamide*** affords bis(trimethylsilyl)acetylene (eq 1), which confirms the nature of the reactive species. Because dipotassium acetylide has not been isolated, there is little physical data that is available for it.

Preparation of Ethynyl Steroids.

Treatment of androsta-4,9(11)-diene-3,17-dione with dipotassium acetylide (prepared from ***Acetylene*** (1 equiv) and ***Potassium t-Butoxide*** (2 equiv) in THF) afforded the propargyl alcohol derived from exclusive attack at C-17 (eq 2).[3] Trapping experiments using ***Chlorotrimethylsilane*** revealed that the C-3 ketone was completely enolized, whereas the C-17 was only partially ionized. Apparently, the C-17 ketone was sufficiently ketonic at equilibrium to allow acetylide addition to proceed to completion.

In a related study, treatment of androsta-1,4-diene-3,17-dione with dipotassium acetylide afforded 17α-ethynyl-17β-hydroxyandrosta-1,4-dien-3-one (97%; eq 3). Again, the C-3 ketone was not alkylated.

Treatment of 9α-hydroxyandrost-4-ene-3,17-dione with dipotassium acetylide did not afford the desired 9α,17β-dihydroxy-17α-ethynylandrost-4-en-3-one, but rather gave a mixture of the rearranged steroids 4-methyl-19-norandrosta-4,9-diene-1,17-dione, 4ε-methyl-19-norandrosta-5(10),9(11)-diene-1,17-dione, the two corresponding C-17 hydroxyethynylated products, and the two C-10 diastereomers of 17α-ethynyl-17β-hydroxy-9,10-secoandrost-4-ene-3,9-dione (eq 4). Yields were not reported. The desired 9α,17β-dihydroxy-17α-ethynylandrost-4-en-3-one was prepared by treatment of 9α-hydroxy-3-methoxyandrosta-3,5-dien-17-one with ***Lithium Acetylide-1,2-Diaminoethane*** in dry THF, followed by acidic workup (eq 5).

(4)

(5)

Preparation of 1,4-Dicarbonyl Compounds.

Treatment of pivalaldehyde with dipotassium acetylide in *p*-dioxane/diethyl ether afforded the corresponding alkynic glycol after acidic workup (22%; eq 6). Hydrogenation of the alkynic glycol, followed by oxidation of the alcohols, afforded 2,2,7,7-tetramethyloctane-3,6-dione in 82% yield. In the same study, comparison was made with the dimetalloacetylides acetylenebismagnesium bromide and dilithium acetylide. Both of these acetylides afforded moderate yields of alkynic glycols upon condensation with aliphatic and aromatic aldehydes. In a direct comparison, treatment of acetylenebismagnesium bromide with pivalaldehyde afforded 2,2,7,7-tetramethyloctane-3,6-diol in 36% yield, while reaction of dipotassium acetylide with pivalaldehyde afforded the same diol in 22% yield.

Dipotassium Tetrachloroplatinate(II)[1]

K_2PtCl_4

[10025-99-7] · Cl_4K_2Pt · Dipotassium Tetrachloroplatinate(II) · (MW 415.08)

(homogeneous hydrogen isotope exchange catalyst;[2] selective oxidative functionalization of alkane C-H bonds;[3] used for the synthesis of various platinum complexes)

Physical Data: dark red crystals; *d* 3.38 g cm^{-3}.

Solubility: sol H_2O (0.93 g/100 mL at 15 °C, 5.3 g/100 mL at 100 °C); insol ethanol, acetone.

Form Supplied in: solid; widely available. *Drying:* at 120 °C/0.1 mmHg for 24 h.

Handling, Storage, and Precautions: should be stored in the absence of moisture; irritating to skin, eyes, and respiratory organs; corrosive.

Hydrogen Isotope Exchange Catalyst.

Aromatic and aliphatic compounds undergo exchange of isotopic hydrogen with a catalytic amount of this reagent. This system is valuable for labeling compounds with deuterium and/or tritium in one step and constitutes the homogeneous equivalent of the well-known heterogeneous platinum technique. A wide range of compounds, including alkanes,[4] cycloalkanes,[5] saturated carboxylic acids,[6] benzoic acid,[7] benzyl alcohol,[8] β-phenylpropionic acid,[9] phenylalanine, phenylglycine,[10] and tyrosine[11] have been D and/or T labeled using this technique (see also ***Disodium Tetrachloroplatinate(II)***).

Functionalization of Saturated Hydrocarbons.

K_2PtCl_4 or the combination K_2PtCl_4/K_2PtCl_6 in aqueous medium is often used for the selective oxidation of isolated C-H bonds of saturated hydrocarbons (see also ***Disodium Tetrachloroplatinate(II)***). Ethane can be selectively oxidized to acetic or glycolic acid.[12] Tetrahydrofuran is oxidized to γ-butyrolactone (eq 1),[13] and isovaleric acid to γ-valerolactone (eq 2).[14]

(1)

(2)

Complexes.

The reaction of 1,2-diamines and similar ligands with K_2PtCl_4 is widely used for the synthesis of cisplatin analogs, powerful antitumor agents (eq 3).[15]

(3)

Alkenes,[16] including ethylene,[17] and dienes,[18] readily coordinate with K_2PtCl_4, forming complexes (eq 4). These complexes readily undergo displacement reactions with free alkene in the solution.[19]

(4)

A number of aromatic and heteroaromatic compounds, substituted with suitable donor ligands, undergo cycloplatination reactions when treated with K_2PtCl_4 (eq 5).[20]

Dipropenylmercury

[2097-71-4] · $C_6H_{10}Hg$ · Dipropenylmercury · (MW 282.75)

(transmetalation reactions by tin[2] and lithium;[3] metallo-ene reactions;[4] interaction with sulfur-containing compounds[5,6])

Physical Data: liquid; bp 90-92 °C/6.5 mmHg, 58-58.5 °C/1.5 mmHg; *n*20D 1.6309, *d*204 2.3180 g cm^{-3}.

Solubility: sol diethyl ether.

Preparative Methods: there have been several reports of the synthesis of dipropenylmercury.[7] The most straightforward synthesis is probably that reported by Borisov and co-workers.[1] ***Allylmagnesium Bromide***, prepared in ether, is reacted with mercury(II) bromide in THF at 5 °C. After 1 h, the reaction is quenched with saturated ammonium chloride. Evaporation and then distillation affords dipropenylmercury.

Handling, Storage, and Precautions: reported to be an unstable material, and is best used immediately after preparation. Despite the lack of specific toxicity data, it is reasonable to assume that as with all mercury compounds, care should be taken in handling these toxic reagents. Use in a fume hood.

The use of dipropenylmercury as a reagent in organic synthesis is not extensive, although this compound has been studied by IR[8] and NMR spectroscopy[9] and polarography[10] in some depth.

The use of dipropenylmercury, as well as other mercury-containing reagents, has been explored in the reaction with ***Trimethylstannane***.[2] Trimethylpropenylstannane is formed as the product (eq 1).

The use of dipropenylmercury as a precursor to a trianion has been described.[3] Thus treatment of dipropenylmercury with aniline and ***Mercury(II) Acetate***, followed by acetate/bromide exchange with potassium bromide, affords an aminomercurial. Treatment of this aminomercurial with ***Phenyllithium*** and then ***Lithium*** powder affords the trianion derivative, which was characterized by quenching with D_2O and then aqueous hydrochloric acid to afford the corresponding dideuterio compound (eq 2). A variety of other electrophiles were also employed.

The Hg-C bonds in dipropenylmercury are sensitive to homolysis.[10] Thus in the reaction between dipropenylmercury and oxygen in the presence of tetraphenylporphyrin (TPP), the expected ene product is observed as a minor product, whereas acrolein is formed as the major product (eq 3), which, it was suggested, arises from oxidation of the propenyl radical formed upon homolysis of the Hg-C bond. However, other allylmercury reagents successfully undergo ene reactions with alternative ene coupling partners (which do not require photosensitization), and so there appears to be further scope for metallo-ene reactions of allylmercury reagents.

Treatment of dipropenylmercury with ***Thiophenol*** gives an exothermic reaction which results in the formation of mercury bis(thiophenolate), phenyl(propenyl)sulfide, and mercury metal.[5] The reaction of dipropenylmercury with the sulfur-containing thianthrene cation radical has also been reported.[6]

Dipyridine Chromium(VI) Oxide[1]

[26412-88-4] · $C_{10}H_{10}CrN_2O_3$ · Dipyridine Chromium(VI) Oxide · (MW 258.22)

(reagent for oxidizing alcohols to carbonyl compounds)

Alternate Names: Collins reagent; chromium(VI) oxide-pyridine.

Solubility: sol CH_2Cl_2; (*Z*)-1,2-dichloroethylene; pyridine; $CHCl_3$.

Form Supplied in: red crystals; not commercially available.

Preparative Methods: prepared in 85-91% yield from ***Chromium(VI) Oxide*** and ***Pyridine***.[2,3] Caution: the reaction is extremely exothermic. The chromium(VI) oxide should be added to dry pyridine at such a rate that the temperature does not exceed 20 °C and in such a way that the oxide mixes rapidly with pyridine. Other chromium(VI) oxide-pyridine complexes are known. These include the Ratcliffe reagent (dipyridine chromium(VI) oxide prepared in situ in CH_2Cl_2),[4,5] and the Sarett reagent ($CrO_3.(C_5H_5N)_2$ in pyridine).[6] The preparation and workup of the Sarett reagent is sometimes tedious. The hygroscopic nature of the Collins reagent and its propensity to inflame may be avoided by the in situ preparation of the complex according to the Ratcliffe procedure.

Handling, Storage, and Precautions: Caution: the Collins reagent is extremely hygroscopic; exposure to moisture rapidly converts it to the yellow dipyridinium dichromate. The reagent should be stored at 0 °C under nitrogen or argon in a sealed container, protected from light. All chromium(VI) reagents must be handled with care; their mutagenicity is well documented.[7] This reagent should be prepared and handled in a fume hood.

Allylic Oxidation to Form α,β-Unsaturated Ketones.

Although a solution of chromium(VI) oxide in pyridine is not very useful for allylic oxidation, the isolated dry chromium(VI) oxide-dipyridine complex in dichloromethane oxidizes allylic methylene groups to enones at rt in good to excellent yields. Δ^5-Androsten-7-one-3β,17β-diol diacetate is thus obtained (82%) from the oxidation of Δ^5-androstene-3β,17β-diacetate.[8] Attack at an allylic methine position yields the isomeric enone when possible; for

example, 3-(4-fluorophenyl)cyclohexenol is oxidized to the isomeric enone (eq 1).[8] Similar rearrangements occur in methylene systems with steric hindrance.[8] If more than one allylic methylene group is present in a conformationally flexible molecule, isomeric enones resulting from attack at both positions are formed (eq 2).[8] Selectivity is observed in conformationally rigid molecules.[8] Methyl groups are not easily oxidized. In general, the Collins reagent gives higher yields and less overoxidation than ***Di-t-butyl Chromate*** or ***Chromium(VI) Oxide*** in acetic acid.

(1)

(2)

Alkynes are oxidized to conjugated alkynic ketones (ynones) by the Collins reagent.[9] The Collins reagent oxidizes 4-octyne to 4-octyn-3-one (eq 3). Oxidation of alkynes by ***t-Butyl Hydroperoxide*** and catalytic amounts of ***Selenium(IV) Oxide***[10] effects oxidation at both centers adjacent to a triple bond. A catalytic amount of chromium(VI) oxide in benzene and *t*-butyl hydroperoxide selectively oxidizes alkynes to ynones in about 50% yield.[11]

(3)

Oxidation of Primary Alcohols to Aldehydes.

The oxidation of alcohols is generally performed in dichloromethane with a sixfold excess of the Collins reagent. The

Collins reagent[3] gives higher yields than the Sarett reagent[6] and comparable yields to the Ratcliffe reagent.[5] The Collins reagent oxidizes 1-heptanol to 1-heptanal in 70-84% yield[3] and the Ratcliffe reagent oxidizes 1-decanol to 1-decanal in 83% yield.[4,5] The Collins reagent oxidizes the primary allylic alcohols geraniol (eq 4) and nerol (eq 5) to geranial and neral, respectively, without isomerization.[12] The Ratcliffe reagent oxidizes cinnamyl alcohol to cinnamaldehyde in 96% yield.[5] The Collins reagent has been used to oxidize primary hydroxy groups of sugars to aldehydes in 50-75% yield.[13] Although the Sarett reagent is useful for the conversion of primary allylic and benzylic alcohols to their corresponding aldehydes, its use for primary saturated alcohols (with the exception of some steroidal ones) is less effective than the Collins or Ratcliffe reagent.

(4)

(5)

The oxidation of allylic alcohols to aldehydes is facilitated by use of Celite-supported Collins reagent (eq 6).[14,15] This method has been used to prepare intermediates in the synthesis of bulnesol[14] and guaiol.[15] A modified Ratcliffe reagent, CrO_3.2py in acetonitrile on Celite, was used to oxidize primary alcohols to aldehydes.[16]

(6)

The (*S*)-alcohol (**1**) is oxidized by the Collins reagent to the aldehyde (**2**) with no more than 5% racemization (eq 7).[17]

(7)

Primary alcohols are converted to the corresponding *t*-butyl esters by Collins reagent in CH_2Cl_2/DMF/Ac_2O and a large excess of *t*-butyl alcohol (eq 8).[18] This conversion is probably general except for aromatic aldehydes.

(8)

Oxidation of Secondary Alcohols to Ketones.

The Collins reagent (eq 9),[19] the Ratcliffe reagent,[5] and the Sarett reagent[20,21] are effective in oxidizing secondary alcohols to ketones. Generally, acid sensitive functional groups such as acetals, double bonds, oxiranes, and thioethers are not affected, although there are exceptions. The Collins reagent oxidizes *exo*-7-hydroxybicyclo[4.3.1]deca-2,4,8-triene to bicyclo[4.4.1]deca-2,4,8-triene-7-one (64%).[22] Collins reagent oxidizes the secondary alcohol functional groups in β-hydroxy-(*Z*)-*O*-alkyloximes to the corresponding β-keto-*O*-alkyloximes.[23]

(9)

A number of alternative reagents are available for the oxidation of primary and secondary alcohols to aldehydes and ketones. Related chromium-based reagents include ***Chromium(VI) Oxide-3,5-Dimethylpyrazole***, ***Chromium(VI) Oxide-Quinoline***, ***Pyridinium Chlorochromate***, and ***Pyridinium Dichromate***.

Oxidation of Tertiary Allylic Alcohols to Epoxy Aldehydes.

The Collins reagent oxidizes tertiary allylic alcohols to epoxy aldehydes (eq 10).[24]

Oxidation of Carbohydrates.

Addition of acetic anhydride to the Collins reagent increases the yields (>90%) for the oxidation of secondary hydroxy groups to carbonyl groups in carbohydrates.[13,25,26]

Oxidation of β-Hydroxy Ketones to 1,3-Diketones.

Collins reagent oxidizes β-hydroxy ketones to 1,3-diketones (eq 11).[26,27] Higher yields are generally obtained with ***Dimethyl Sulfoxide-Oxalyl Chloride*** (Swern reagent).

Oxidation of β-Hydroxy Esters to β-Keto Esters.

Collins reagent oxidizes β-hydroxy esters to β-keto esters (eq 12).[27]

Oxidative Cyclization of 5,6-Dihydroxyalkenes.

Collins reagent oxidizes the unsaturated diols (**3**) to the corresponding *cis*-tetrahydrofurandiols (**4**) (eq 13).[28]

Oxidation of 1,4-Dienes.

Oxidation of the 1,4-diene (**5**) with Collins reagent or ***Di-t-butyl Chromate*** yields dienones (**6**) and (**7**) in the ratio of 1:3 (~65% total yield) (eq 14).[29] Complementary regioselectivity (**6**)/(**7**) = 9:1 (~70% total yield) is obtained with ***Pyridinium Chlorochromate*** (PCC).

Other Applications.

Collins reagent, Jones' reagent, and chromic acid in 50% acetic acid oxidatively deoximate ketoximes to the corresponding carbonyl compounds.[30]

Secondary alkylstannanes are converted into the corresponding carbonyl compounds by oxidation with Collins reagent (eq 15).[31,32] Mixtures of alcohols and dehydration products are obtained from tertiary alkylstannanes.

(15)

Collins reagent oxidizes trimethylsiloxy-substituted 1,4-cyclohexadienes to phenols (eq 16).[32]

(16)

Collins reagent oxidizes steroidal tertiary amines to *N*-formyl derivatives (eq 17).[3]

Di-2-pyridyl Carbonate[1]

[1659-31-0] · $C_{11}H_8N_2O_3$ · Di-2-pyridyl Carbonate · (MW 216.21)

(dehydration agent; preparation of esters,[3] amides,[4] nitriles;[5] alkoxycarbonylation[6] or protection[7] of amines; carbonyl transfer[8])

Alternate Name: 2-DPC.

Physical Data: mp 76-78 °C.

Solubility: sol CH_2Cl_2.

Form Supplied in: white solid.

Preparative Methods: from ***Phosgene*** and ***2-Hydroxypyridine*** in the presence of ***Pyridine*** in THF[9] or ***Triethylamine*** in CH_2Cl_2 (eq 1).[3,7] Phosgene can also be replaced with triphosgene (***Bis(trichloromethyl) Carbonate***).[2] The usual yield is about 80%.

Handling, Storage, and Precautions: quite stable and can be stored under nitrogen at rt for several months without any noticeable decomposition.

Introduction.

The advantages of using 2-DPC are the following: 2-hydroxypyridine is a neutral compound and can be removed completely from the reaction mixture by the usual aqueous workup. The 2-pyridyl esters are also highly reactive.[10]

As a Dehydrating Agent.

2-DPC can be used for the direct esterification of carboxylic acids in good yield and under mild conditions.[1,3] The reaction can be carried out with equimolar amounts of acids, alcohols, and 2-DPC in the presence of 0.1 equiv ***4-Dimethylaminopyridine*** (DMAP) in CH_2Cl_2 at rt. The reaction of diphenylacetic acid and benzyl alcohol gave the corresponding ester in 90% yield (eq 2).

(2)

Typical yields are as follows: methyl diphenylacetate, 95%; benzyl octanoate, 94%; isopropyl phenylacetate, 90%. With aromatic acids and hindered carboxylic acids the esterification is not very satisfactory. The yields drop to 68% for ethyl benzoate or 42% for benzyl pivalate. In these cases the corresponding 2-pyridyl benzoate and pivalate are isolated.

For the preparation of amides a stepwise procedure must be used.[4,11] Formation of activated pyridyl esters and subsequent treatment with amines provide the carboxylic amides. This reaction gave benzyloctanamide in 80% and cyclohexylbenzamide in 85% yield.[1]

2-DPC can also be used to form nitriles via dehydration of the corresponding aldoximes. The reaction was carried out in refluxing toluene or in presence of 0.1 equiv of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** in CH_2Cl_2 at rt.[5] The last procedure gave benzonitrile in 83% yield.

Alkoxycarbonylation of Amines.

2-DPC is useful for the *N*-protection of amino acids via an activated carbonate.[7] The mixed carbonate is obtained by the reaction of 2-DPC with an equimolar amount of *t*-butyl alcohol in the presence of 0.1 equiv DMAP in CH_2Cl_2. The isolated carbonate obtained in 80% yield was added to a solution of L-proline and ***Triethylamine*** in DMF-water (eq 3). After crystallization the yield of *N*-Boc-proline was 98%. Some other typical yields were as follows: *N*-Boc-Ala, 84%; *N*-Boc-Leu, 95%.

The same strategy was used to synthesize functionalized carbamates.[2] The reaction between (+)-menthol and 2-DPC in the presence of triethylamine (CH_2Cl_2) gave the mixed carbonate which was used directly, after classical workup. The reaction of this carbonate and the amine gave the carbamate in 81% yield (eq 4). Amines produced in situ by reduction of the azide can also be transformed into the corresponding carbamate.[6]

Carbonyl Transfer Reaction.

2-DPC is useful for the preparation of cyclic carbonates or 2-oxazolidones.[1,8] The reaction with diols is carried out in refluxing toluene. The reaction of ethylene glycol gave an 85% yield of the corresponding carbonate. In the presence of DMAP in CH_2Cl_2 at rt, 1,3-butanediol gave the cyclic carbonate in 85% yield. The reaction of 2-DPC with β-amino alcohols in CH_2Cl_2 at rt gave good yields of the corresponding 2-oxazolidone: 1-aminopropan-2-ol, 87%; 1-phenyl-2-aminoethanol, 93%; 2-amino-4-nitrophenol, 96% (eq 5).

(5)

Related Reagents.

1-(t-Butoxycarbonyl)imidazole; ***1-N-(t-Butoxycarbonyl)-1H-benzotriazole 3-N-Oxide***; ***2-(t-Butoxycarbonyloxyimino)-2-phenylacetonitrile***; ***t-Butyl Chloroformate***; ***Di-t-butyl Dicarbonate***.

2,2´-Dipyridyl Diselenide

[59957-75-4] · $C_{10}H_8N_2Se_2$ · 2,2´-Dipyridyl Diselenide · (MW 314.12)

(selenoxide elimination to afford alkenes;[1] can mediate the formation of chiral oxazolines;[2,3] a coupling reagent of nucleosides;[4] can catalyze allylic oxidation[5])

Physical Data: mp 50 °C.

Solubility: sol THF, acetonitrile, dichloromethane, methanol.

Preparative Methods: by reaction of 2-bromopyridine with ***Sodium Hydrogen Selenide*** (prepared from ***Selenium*** and ***Sodium Borohydride***) in ethanol followed by oxidation[1,4] or with ***Lithium Diselenide*** (prepared from selenium and ***Lithium*** in the presence of ***Diphenylacetylene*** as catalyst) in THF-HMPA.[6]

Purification: column chromatography on silica gel using hexane-ethyl acetate (2:1) or light petroleum ether-ethyl ether (1:1) as eluent. Recrystallization from petroleum ether (30-70 °C) or diisopropyl ether-ethyl acetate.

Handling, Storage, and Precautions: the reaction of sodium hydrogen selenide should be carried out in a well-ventilated hood (H_2, containing H_2Se, is produced). Selenium is reputed to be toxic. 2,2´-Dipyridyl diselenide should be stored in the dark.

Selenoxide Elimination.

In the selenoxide elimination reactions to afford alkenes, the 2-pyridineseleninyl group has been reported to be a better leaving group than the benzeneseleninyl group. Typical examples are the formation of cyclooctenone[1] and monosubstituted terminal alkenes.[7] 2,2´-Dipyridyl diselenide was used in the preparation of starting selenides, for example 2-(2-pyridylseleno)cyclooctanone, by reaction with the lithium enolate of cyclooctanone (eq 1). In another method, 2,2´-dipyridyl diselenide was treated with sodium borohydride to afford sodium 2-pyridineselenolate, which was used in the subsequent nucleophilic substitution reactions (eq 2).

Neighboring Group Participation.

In the Ritter-type substitution of a hydroxy group by nitriles through the anchimeric assistance of the areneselenenyl group onto the chiral carbon, chiral amides were obtained without loss of optical purity by the use of the 2-pyridineselenenyl group (eq 3), whereas racemic amides were obtained by the use of the benzeneselenenyl group. Subsequent oxidation of the selenides to selenones and treatment with base induces the intramolecular substitution of the 2-pyridineselenonyl group by the oxygen atom of the amide to afford chiral oxazolines (eq 4).[3]

(4)

Coupling Reagent of Nucleosides.

A combination of 2,2´-dipyridyl diselenide and ***Triphenyl Phosphite*** has been utilized in the synthesis of oligonucleotides (eq 5).[4] This reagent has been reported to be superior to sulfur analogs such as ***2,2´-Dipyridyl Disulfide*** and ***Triphenylphosphine***[8] in that the reaction using this combination is free from undesirable byproducts. A combination of 2,2´-dipyridyl diselenide and triphenylphosphine has also been used in the selective phosphorylation of 5´-hydroxy group of oligoribonucleotides.[9]

(5)

Allylic Oxidation.

2,2´-Dipyridyl diselenide catalyzes the oxidation of alkenes to unsaturated ketones by ***Iodylbenzene*** (eq 6).[5] The reactive species is considered to be 2-pyridineseleninic anhydride, which is much more reactive to alkenes than

benzeneseleninic anhydride.

(6)

Related Reagents.

Diphenyl Diselenide; ***Diphenyl Disulfide***; ***2-Pyridineselenenyl Bromide***.

2,2´-Dipyridyl Disulfide[1]

[2127-03-9] · $C_{10}H_8N_2S_2$ · 2,2´-Dipyridyl Disulfide · (MW 220.34)

(macrolactonization of o-hydroxy acids,[6] acylation of pyrroles,[22] couplings at anomeric centers[27])

Alternate Names: 2,2´-dithiopyridine.

Physical Data: mp 57-58 °C.

Solubility: benzene, THF, CH_2Cl_2, MeCN, DMF.

Form Supplied in: white (colorless) crystalline solid.

Preparative Methods: although 2,2´-dipyridyl disulfide is commercially available, it can be readily prepared from 2-pyridinethione by oxidation with a number of reagents.[2]

Purification: recrystallization from hexane at 30 mL g^{-1} concentration.[3]

Handling, Storage, and Precautions: the solid is irritating to eyes, mucus membranes, and respiratory tract, and physical contact should be avoided. Combustion produces toxic byproducts including nitrogen oxides. Cold storage in air-tight containers is recommended. Use in a fume hood.

Macrolactonization.[4]

When a carboxylic acid is treated with 2,2´-dipyridyl disulfide in the presence of ***Triphenylphosphine***, the corresponding 2-pyridinethiol ester is formed.[5] Corey and Nicolaou have developed an efficient method for the synthesis of macrocyclic lactones based on these 2-pyridinethiol esters.[6] When an o-hydroxy thiolester is heated in refluxing xylene under high dilution conditions (10^{-5} M, typically accomplished with syringe pump techniques), macrolactonization occurs, liberating triphenylphosphine oxide and pyridinethione. The reaction is quite general and is believed to proceed by a double activation mechanism in which the basic 2-pyridinethiol ester simultaneously activates

both the hydroxy and the carboxylic acid moieties with a single proton transfer. It has been shown that the cyclization rate is not affected by the presence of acids, bases, or any of the possible reaction contaminants.[7]

This method is mild, highly efficient for the preparation of medium to large rings (7-16,[6] 12-21[7]), and has been applied to the synthesis of a number of important macrocyclic targets including monensin,[8] brefeldin A (eq 1) and erythronolide B,[9] (±)-11-hydroxy-*trans*-8-dodecenoic acid lactone,[10] (±)-vermiculine,[11] enterobactin,[12] and prostaglandins.[8,13]

(1)

In an effort to develop an even milder lactonization protocol, other diaryl disulfides were explored, the most promising being imidazole derivatives (**1**) and (**2**).[14] The formation of dilides (dimers of macrocyclic lactones) is occasionally a problem, necessitating the use of other cyclization methods.[4,15] A variation of Corey's method using silver salts has been developed.[3,16]

(1) R = Me
(2) R = *i*-Pr

If an o-aminopyridinethiol ester is used, macrolactamization occurs.[17] A method for the synthesis of β-lactams from β-amino acids has also been developed where the use of MeCN has been found to be critical (eq 2).[18] The intermolecular version of this reaction is a powerful peptide coupling method.[19,20]

(2)

Related Reactions of 2-Pyridinethiol Esters.

In the absence of an internal nucleophile, the thiopyridyl esters generated by the reaction of carboxylic acids with 2,2´-dipyridyl disulfide and triphenylphosphine exhibit other reactivities. Thiolesters are potent acylating agents, reacting with Grignard reagents to yield ketones instead of tertiary alcohols.[21,22] This activity has been exploited for the synthesis of 2-acylpyrroles using pyrrylmagnesium salts as the nucleophilic species. Nicolaou and co-workers have exploited 2-pyridinethiol esters in the synthesis of a number of complex 2-acylpyrroles (eq 3).[23] In certain troublesome cases, the use of stoichiometric ***Copper(I) Iodide*** has been found to significantly improve yields.[24]

(3)

2-Pyridinethiol esters are readily reduced with ***Sodium Borohydride*** in the presence of isopropanol.[25] Activation of 2-pyridinethiol esters with ***Iodomethane*** allows for mild trapping with alcohols or benzenethiol, yielding esters or thiolesters.[26] In these cases the use of iodomethane avoids the need for thiophilic silver or mercury salts and allows for transthiolesterification.

Disaccharide Formation.

Treatment of glycoside (**3**) with 2,2´-dipyridyl disulfide and ***Tri-n-butylphosphine*** in CH_2Cl_2 rapidly yields thiopyridyl derivative (**4**) as a mixture of anomers. Activation of (**4**) with iodomethane, followed by treatment with glycoside acceptor (**5**), affords the disaccharide fragment of avermectin (**6**),[27] exclusively α-linked in 78% yield (eq 4).[28] Although other methods are available, this protocol offers advantages in practicality and stereoselectivity.

Carbon-carbon bonds can be similarly formed at the anomeric center of carbohydrates. Oxonium ions, formed by the treatment of 1-(2´-thiopyridyl)glycosides with ***Silver(I) Trifluoromethanesulfonate***, can be trapped with silyl enol ethers, silyl ketene acetals, and reactive aromatic compounds, where the stereoselectivity of the addition is determined by solvent and nucleophile choice.[29] The intramolecular version of this process has also been examined (eq 5).[30] Similarly, bicyclic piperazinediones are available by the intramolecular trapping of iminium ions, generated from the appropriate thiopyridyl derivatives with $PhHgClO_4$ (eq 6).[31]

(5)

(6)

Alkene Formation.

The elimination of pyridinethione or 2-pyridylsulfenic acid forms the basis of a number of alkene syntheses. For example, treatment of dithioacetal anions with 2,2´-dipyridyl disulfide affords the α-thiopyridyl derivative, which undergoes elimination at below room temperature to give ketene dithioacetals.[32] Ester enolates have been similarly treated, although ***m-Chloroperbenzoic Acid*** is first used to generate the sulfoxide which reacts further to yield an α,β-unsaturated ester.[33] This methodology has been applied to the synthesis of methyl dehydrojasmonate (**7**) (eq 7).[34]

Other Reactions.

Treatment of an active hydroxy compound with 2,2´-dipyridyl disulfide and *n*-Bu_3P yields the corresponding thiopyridyl derivative. This methodology has been applied to the preparation of 5-arylthio-5´-deoxyribonucleosides (eq 8).[35] Monophosphate esters [$ROP(O)(OH)_2$] will react similarly to form the activated triphenylphosphonium adduct, which, in the absence of an added external nucleophile, dimerizes yielding a pyrophosphate.[36] *N*-Methylimidazole has been found to catalyze this transformation. The addition of alcohols or amines, however, traps the phosphoryloxyphosphonium salt as the mixed diphosphate ester or mixed ester/amide, respectively (eq 9).[37] ***Chlorotrimethylsilane*** and $(pyS)_2$ have also been reported to facilitate the oxidation of phosphites to phosphates.[38]

General Reactions of Diaryl Disulfides.[1]

2,2´-Dipyridyl disulfide reacts with a variety of carbon nucleophiles, yielding the corresponding thiopyridyl derivatives. These include phosphonate stabilized anions,[39] bromouridine derivatives,[40] indole anions,[41] and heterocyclic stabilized anions.[42]

Dirhodium(II) Tetraacetamide

$Rh_2(NHCOMe)_4$

[87985-40-8] · $C_8H_{16}N_4O_4Rh_2$ · Dirhodium(II) Tetraacetamide · (MW 438.10)

(catalyst for selective carbenoid reactions of diazo compounds[1])

Physical Data: UV/vis (MeCN) 500 (2.2), 345 (shoulder) nm.[2] NMR (CD_3CN): δ 2.20 (s).[3]

Solubility: sol MeOH, MeCN, pyridine, DMSO; insol CH_2Cl_2, toluene.

Form Supplied in: blue solid for anhydrous form; purple solid as hydrate.

Preparative Method: by ligand substitution from $Rh_2(OAc)_4$.[3]

Handling, Storage, and Precautions: air stable, weakly hygroscopic; stored in desiccator.

Introduction.

Dirhodium(II) tetraacetamide, $Rh_2(acam)_4$, was first prepared from ***Dirhodium(II) Tetraacetate*** in a melt of acetamide.[4] However, this method gave a mixture of $Rh_2(OAc)_{4-n}(acam)_n$, of which $Rh_2(acam)_4$ was the dominant product but could not be conveniently separated. The preferred procedure is to treat $Rh_2(OAc)_4$ with acetamide in refluxing chlorobenzene under conditions where acetic acid is trapped by sodium carbonate in a Soxhlet extraction apparatus (eq 1).[3] Four acetamidates are ligated to one dirhodium(II) nucleus, and each rhodium is bound to two nitrogen and two oxygen donor atoms arranged in a *cis* geometry.[5] Incomplete substitution, when only three acetamides have replaced acetate, yielding $Rh_2(acam)_3(OAc)$, produced a catalyst whose selectivity is not optimum.

Metal Carbene Transformations.

Although insoluble in the solvents in which catalytic metal carbene transformations are performed, $Rh_2(acam)_4$ enters solution after addition of the diazo compound. The principal advantage of this catalyst is its selectivity for product formation from reactions with diazocarbonyl compounds, but its reactivity towards dinitrogen extrusion is less than that of dirhodium(II) tetra(carboxylates).

Stereoselectivity in Cyclopropanation Reactions.

Use of $Rh_2(acam)_4$ for intermolecular cyclopropanation of alkenes results in higher *trans* (*anti*) selectivity which, when the diazo compound is 2,6-di-*t*-butyl-4-methylphenyl diazoacetate (BDA), is exceptional (e.g. eq 2: 98% *trans*).[3] Product yields are high (75-96%), and byproducts are often minimal. Relative reactivities are also enhanced by $Rh_2(acam)_4$, which has made possible highly regioselective cyclopropanation of selected dienes (e.g. eq 3).[3] However, $Rh_2(acam)_4$ is unsuitable, relative to ***Dirhodium(II) Tetraacetate***, for intermolecular cyclopropanation of styrene by the pantolactone ester of *trans*-2-diazo-4-phenyl-3-butenoate.[6] Substitution of $Rh_2(acam)_4$ by the more soluble ***Dirhodium(II) Tetra(caprolactam)***, $RH_2(cap)_4$, does not provide any obvious advantage in reactivity or selectivity for cyclopropanation.

Carbon-Hydrogen Insertion Reactions.

Use of $Rh_2(acam)_4$ provides an increase in regioselectivity for competitive insertion into carbon-hydrogen bonds (tertiary > secondary > primary) that result in the formation of five-membered ring carbonyl compounds (e.g. eq 4; pfb = perfluorobutyrate).[7,8]

Both diazoacetoacetates and diazoacetates show exceptional selectivity enhancement with $Rh_2(acam)_4$. However, the same degree of control is not evident in the competition from diazoacetoacetamides for β-lactam versus γ-lactam formation.[9-11] The use of $Rh_2(cap)_4$ in place of $Rh_2(acam)_4$ does not provide any obvious advantage in regioselectivity for carbon-hydrogen insertion.

Chemoselectivity.

Few comparisons have been made with $Rh_2(acam)_4$ and $Rh_2(cap)_4$, but those that have suggest that $Rh_2(cap)_4$ holds an advantage.[11] *N*-(2-Arylethyl)-*N*-*t*-butyldiazoacetamides, for example, exhibit competition between aromatic cycloaddition and carbon-hydrogen insertion (e.g. eq 5), and chemoselectivity for C-H insertion with $Rh_2(cap)_4$ is greater than with $Rh_2(acam)_4$, but both are more selective than is $Rh_2(OAc)_4$.

$Rh_2(acam)_4$	23%	77%
$Rh_2(cap)_4$	3%	97%

Dirhodium(II) Tetraacetate

$Rh_2(O_2CMe)_4$

[15956-28-2] · $C_8H_{12}O_8Rh_2$ · Dirhodium(II) Tetraacetate · (MW 442.02)

(catalyst for carbenoid reactions of diazo compounds,[1] hydroboration of alkenes and alkynes,[2] hydrocarbon oxidation[3])

Physical Data: λ 590 nm, ε 210 (EtOH); λ 552 nm, ε 235 (MeCN).[4] IR -ν (CO_2) 1585 cm^{-1}.[5]

Solubility: sol MeOH, acetic acid, MeCN, acetone; slightly sol toluene; insol Et_2O, 1,2-dichloroethane, CH_2Cl_2.

Form Supplied in: emerald-green solid for anhydrous form.

Preparative Method: prepared from $RhCl_3.xH_2O$.[6]

Handling, Storage, and Precautions: air stable, moderately hygroscopic; stored in desiccator. Removal of axially coordinated solvent can be achieved in vacuum oven at 60-80 °C.

Metal Carbene Transformations.

When used in amounts as low as 0.05 mol %,[7] $Rh_2(OAc)_4$ serves as a highly effective and efficient catalyst for dinitrogen extrusion from diazo carbonyl compounds and subsequent metal carbene directed alkene[1,8] and alkyne[9] addition reactions, σ-bond insertion reactions,[1,10] ylide generation,[1,11] and carbene coupling processes,[12] among others. With diazoacetates and diazo ketones, catalytic reactions are generally performed in dichloromethane at rt. The diazo compound is added at such a rate so as to minimize its concentration in the reaction solution.[6] The less reactive α-diazo-β-carbonyl alkanoates, including diazomalonates and diazoacetoacetates, and related diazo dicarbonyl compounds require refluxing 1,2-dichloroethane or refluxing benzene for efficient catalyst turnovers. In laboratory scale reactions, $Rh_2(OAc)_4$ is removed from the reaction solution by filtering through a short column of silica or alumina, or the product(s) are distilled directly from the catalyst-containing mixture. (Rhodium acetate undergoes thermal decomposition at temperatures near 250 °C.)

Cyclopropanation/Cyclopropenation.

Its catalytic uses for intermolecular cyclopropanation and cyclopropenation reactions, discovered only recently by

Teyssié and co-workers,[9,13] have been the standard through which mechanistic[14] and synthetic (selectivity)[8,15] understanding of metal carbene addition reactions have been derived.[1] Intermolecular addition reactions of diazoacetates with alkenes occur at 25 °C in high yield. Their stereoselectivities and regioselectivities[16] are lower than those achieved with the use of ***Dirhodium(II) Tetraacetamide***,[8] but high selectivities are observed with vinylcarbenoid addition (eq 1)[17] and nitrocarbenoid addition[18] to alkenes. Cyclopropene formation occurs with a broad selection of alkynes (eq 2),[19a] but not phenylacetylene.[9,19] Neither cyclopropanation nor cyclopropenation occurs readily with α,β-unsaturated carbonyl compounds or nitriles.[20]

Intramolecular analogs of these reactions suggest the overall viability of $Rh_2(OAc)_4$ catalysis (eqs 3 and 4),[21-23] although for alkyne addition the presumed cyclopropene intermediate is unstable and undergoes reactions characteristic of vinylcarbenoid species,[22,23] of which the most frequently encountered involve rearrangement to furans. The intramolecular Büchner reaction of aryl diazoketones (eq 5)[24] is, formally, cyclopropanation of an aromatic ring, for which $Rh_2(OAc)_4$ is especially suitable;[24] the diazoamide analog of this transformation is particularly facile.[25]

(4)

(5)

Carbon-Hydrogen Insertion.

The utility of $Rh_2(OAc)_4$ as a catalyst for metal carbene transformations is most evident in its ability to effect insertion into unactivated carbon-hydrogen bonds.[1,10] Preference for the formation of five-membered rings is pronounced (eq 6),[26] and selectivity for insertion into tertiary C-H bonds is usually greater than for insertion into secondary C-H bonds, and primary C-H bonds are the least reactive.[27] Although these controlling influences are pervasive, an increasing number of examples suggest that the factors which control regioselectivity in these reactions are complex (e.g. eq 7).[28]

(6)

(7)

Heteroatom activation of adjacent C-H bonds[29] has made possible the construction of β-lactam derivatives from diazoacetoacetamides (eq 8)[30] and of β-lactones from selected diazomalonates.[31] With *N*-benzyl derivatives, the presence or absence of an acyl group uniquely defines the course of the catalytic reaction (eq 9; R = *t*-Bu; S = H, Me, OMe, Br).[32] Both electronic and conformational (steric) effects are responsible for the selectivity in these reactions.

(8)

(9

Intermolecular variants of carbon-hydrogen insertion reactions are generally of limited value because of lower reactivity and selectivity.[1] Insertion into vinylic or alkynic C-H bonds is not competitive with cyclopropanation or cyclopropenation under ordinary circumstances. The so-called allylic C-H insertion reaction, commonly observed in copper-catalyzed reactions of diazomalonates or β-diazo-α-keto esters,[33] is not common with $Rh_2(OAc)_4$ catalysis.[14b]

In contrast to the paucity of examples for C-H insertion into vinylic or alkynic C-H bonds, intramolecular insertion into aromatic C-H bonds is well documented.[1] These reactions are most pronounced when the aromatic ring is activated for substitution by oxygen[34] or nitrogen[35] (e.g. eqs 10 and 11),[34,35a] and they are more suitably described as aromatic substitution reactions than as C-H insertion reactions. Aryl-substituted diazo ketones,[36] diazoacetates,[34] diazoacetoacetates,[34] and their corresponding amide derivatives[35] are all effective. The formation of a five-membered ring is preferred, but, with suitable structural demands in the diazo carbonyl reactant, six-membered ring formation occurs.[37]

(10)

(11)

Heteroatom-Hydrogen Insertion.

One of the most important applications of metal carbene chemistry has been in the syntheses of penems, exemplified in eq 12, which is key step in the total synthesis of the carbapenem thienamycin.[38] This reaction has become the method of choice for the synthesis of bicyclic β-lactams from 2-azetidinones substituted through the 4-position to a diazocarbonyl group.[39]

(12)

Oxygen-hydrogen insertion (with water) is a common undesirable side reaction in $Rh_2(OAc)_4$ catalyzed transformations, but its synthetic importance is evident in intramolecular processes. Cyclization via O-H insertion occurs readily and in high yield for five-, six-, and seven-membered ring formation (eq 13),[40] but C-H insertion becomes competitive in attempts to effect eight-membered ring formation. Intermolecular processes have also been examined,[41] but they have

more limited usefulness.

(13)

Thiol insertion also occurs in both intermolecular and intramolecular transformations,[42,43] but these reactions are more difficult to perform because of the facile coordination of thiols and sulfides with $Rh_2(OAc)_4$. Intermolecular silicon-hydrogen insertion provides a convenient methodology for the synthesis of α-silyl esters and ketones (eq 14).[44] Overall, $Rh_2(OAc)_4$ is generally suitable, and often the catalyst of choice, for heteroatom-hydrogen insertion reactions of diazo esters and ketones.[43]

(14)

Ylide Generation.

Metal carbenes produced by $Rh_2(OAc)_4$-catalyzed dinitrogen extrusion from diazo compounds are electrophilic.[1] Reactions of these reactive intermediates, which resemble metal-stabilized carbocations, with Lewis bases constitute a generally effective methodology for ylide generation (eq 15).[11] The relative reactivity of Lewis bases towards ylide generation follows the expected order of basicity for carbon-heteroatom compounds. Ylide products are further transformed by insertion, sigmatropic rearrangement, or dipolar addition reactions, dependent on the design of the ylide. Heteroatom-hydrogen insertion is reasonably regarded as an ylide transformation.

(15)

The relative reactivity for ylide generation, determined from subsequent [2,3]-sigmatropic rearrangement of the initially formed ylide in competition with cyclopropanation (eq 16),[45,46] shows that ylide formation increases in the order RI > RBr > RCl, R_3N > R_2O, and R_2S > R_2O. Allyl substituents facilitate ylide generation (eq 17),[46,47] and their

influences on relative reactivities suggest that the formation of the metal-stabilized ylide and metal dissociation (eq 15) are equilibrium processes.

(16)

Z	Yield (%)	
NMe_2	95	100:0
SMe	96	100:0
I	98	100:0
Br	76	28:72
Cl	95	5:95
OEt	88	10:90

(17)

R	Z		Yield (%)
H	H	10:90	88
Me	H	92:8	86
Ph	H	73:27	95
TMS	H	94:6	68
H	OMe	77:23	75

Rhodium(II) acetate has two axial coordination sites at which reactions with diazo compounds occur. Strongly coordinating compounds, either reactants or solvents, occupy these sites and inhibit electrophilic addition to diazo

compounds. Consequently, whereas reactions with diazo compounds that possess chloride, bromide, iodide, or ether functional groups take place at rt, those with sulfide or amine functional groups require higher temperatures for dinitrogen extrusion.

Stable sulfonium ylides have been produced by intermolecular reactions of thiophenes with dimethyl diazomalonate, catalyzed by $Rh_2(OAc)_4$ (eq 18),[48] as well as by intramolecular reactions (eq 19).[49] The formation of four- to seven-membered rings has been possible,[49,50] but C-H insertion is competitive with seven-membered ring ylide generation. The stability of the ylide is dependent on the sulfur substituent (Ph > $PhCH_2$ > allyl) as well as on ring size. Stable sulfoxonium ylides have also been formed in $Rh_2(OAc)_4$-catalyzed reactions.[51]

(18)

(19)

Use of the [2,3]-sigmatropic rearrangement of sulfonium ylides for ring enlargement has made possible the construction of medium ring compounds (eq 20).[47] β-Elimination is a competing process and becomes the favored transformation with the proper stereoelectronic arrangement in the reactant ylide (e.g. eq 21).[52] An intramolecular ring contraction methodology is also effectively promoted through sulfonium ylide generation with $Rh_2(OAc)_4$ catalysis (e.g. eq 22).[53] Sulfur ylides derived from $Rh_2(OAc)_4$-catalyzed reactions of diazo compounds have played important roles in β-lactam antibiotic syntheses.[54-56]

(20)

(21)

(22)

Nitrogen ylide formation is not reported as extensively as is sulfur ylide generation, but sufficient examples exist to

suggest its versatility. The synthesis of allenes by [2,3]-sigmatropic rearrangement (eq 23)[57] of prop-2-yn-1-yl-dimethylammonium ylides exemplifies the potential diversity of its applications. A general methodology for oxazole synthesis has been developed through the use of nitrile ylides (eq 24).[58] Additional examples that suggest the advantages of the catalytic route to ylide generation are reported elsewhere.[11]

Relative to cyclopropanation (of alkenes) or cyclopropenation (of alkynes), oxonium ylide formation is generally disfavored in $Rh_2(OAc)_4$-catalyzed reactions of diazo compounds. Notable exceptions include those described in eq 17 and in intramolecular transformations. Cyclobutanone formation is the outcome of $Rh_2(OAc)_4$-catalyzed dinitrogen extrusion from 4-alkoxydiazo ketones (eq 25).[59] Allyl ethers offer a pathway to [2,3]-sigmatropic rearrangement products, including those leading to medium ring ethers (eq 26),[60,61] and tetrahydrofuran-3-ones have been prepared by a carbon-oxygen insertion methodology involving ylide intermediates,[62] but few other successful demonstrations of oxonium ylide generation have been reported.

Dirhodium(II) tetraacetate has been shown to have superior capabilities for carbonyl ylide generation with diazo

ketones,[11] especially in intramolecular reactions. The carbonyl ylide, when generated in the presence of selected dipolarophiles, readily undergoes 1,3-dipolar addition (e.g. eqs 27 and 28)[63,64] either intermolecularly (***Dimethyl Acetylenedicarboxylate***, ***N-Phenylmaleimide***, diethyl fumarate, aldehydes) or intramolecularly. Regioselectivity is predictable by frontier molecular orbital interactions.[64b] Carbonyl ylide generation with carboxylate esters is rare,[30b] but with amides, carbamates, and imides, carbonyl ylide formation is well documented (e.g. eq 29).[11,65]

(27)

(28)

(29)

Selectivity in Metal Carbene Transformations.

The high reactivity of catalytically generated metal carbenes often limits their selectivity when more than one site for addition and/or insertion exists in a molecule. In this regard, $Rh_2(OAc)_4$ is often less selective for metal carbene transformations than is either ***Dirhodium(II) Tetrakis(perfluorobutyrate)*** or rhodium(II) carboxamides (either ***Dirhodium(II) Tetraacetamide*** or ***Dirhodium(II) Tetra(caprolactam)***).[8,28,66] In addition, use of $Rh_2(OAc)_4$ can lead to lower product yields than does use of alternative dirhodium(II) catalysts. Nevertheless, for most transformations where there is one preferred site for metal carbene reaction, $Rh_2(OAc)_4$ remains the catalyst of choice.

High diastereocontrol complements exceptional stereocontrol for geometrical isomer formation in the cyclopropanation of styrene with vinyldiazocarboxylates that possess the pantolactone chiral auxiliary (eq 30).[67] However, with pantolactone diazoacetate in the cyclopropanation of styrene, a 76:24 *trans*:*cis* product mixture forms in only 72% yield and 28-30% diastereomeric excess (de).[68] Similarly, in competitive reactions between cyclopropanation and C-H insertion, use of $Rh_2(OAc)_4$ provides very little selectivity (eq 31),[66] but dirhodium(II) tetrakis(perfluorobutyrate) promotes exclusive C-H insertion and use of dirhodium tetra(caprolactam) leads to exclusive cyclopropanation. A variety of examples of high and low selectivities has been reported for $Rh_2(OAc)_4$-catalyzed reactions,[1] and no simple explanation has emerged that will account for all of the results. Predictions are often empirical, but changing the ligands of the catalyst often provides a dirhodium(II) compound with the desired selectivity enhancement.

(30)

Catalytic Hydroboration of Alkenes and Alkynes.

The use of $Rh_2(OAc)_4$ to catalyze the hydroboration of alkenes and alkynes with ***Catecholborane*** represents a novel application of this transition metal compound.[2] In laboratory scale reactions, 0.5 mol % $Rh_2(OAc)_4$ is effective. Selectivity is dependent on the alkene (eq 32) and often differs from that found with ***Chlorotris(triphenylphosphine)rhodium(I)*** (Wilkinson's catalyst).[69]

The hydroboration of alkynes is also promoted by rhodium acetate. However, since $Rh_2(OAc)_4$ is transformed during hydroboration, the nature of the active catalyst is at present unknown. The combination of catecholborane and $Rh_2(OAc)_4$, both in catalytic amounts, catalyzes isomerization of terminal alkenes.[2]

Autooxidation of Alkenes.

In the presence of catalytic amounts of $Rh_2(OAc)_4$, cyclohexadienes undergo aromatization (eq 33), and dienes undergo oxidative cleavage (eq 34),[3a] at atmospheric pressure. *p*-Cymene is also reported to be oxidized to the tertiary alcohol. Hydroperoxide decomposition to alcohol and dioxygen, catalyzed by $Rh_2(OAc)_4$, has been demonstrated.

Other Catalytic Reactions.

Hydrogenation activity for $Rh_2(OAc)_4$ has been reported,[70] but these results could not be repeated.[71] Hydrosilylation of alkenes is catalyzed by $Rh_2(OAc)_4$, but reactions are much less efficient than those catalyzed by dirhodium(II) tetrakis(perfluorobutyrate).[71] The same is true of silylcarbonylation reactions with alkynes,[72] and $Rh_2(OAc)_4$ is not a hydroformylation catalyst.

Dirhodium(II) Tetra(caprolactam)

[138984-26-1] · $C_{24}H_{44}N_4O_4Rh_2$ · Dirhodium(II) Tetra(caprolactam) · (MW 658.54)

(catalyst for selective carbenoid reactions of diazo compounds[1])

Solubility: sol MeOH, MeCN; slightly sol toluene, 1,2-dichloroethane, CH_2Cl_2.

Form Supplied in: blue solid for anhydrous form; purple solid as hydrate.

Preparative Method: prepared by ligand substitution from $Rh_2(OAc)_4$.[2]

Handling, Storage, and Precautions: air stable, weakly hygroscopic; stored in desiccator.

Introduction.

Dirhodium(II) tetra(caprolactam), $Rh_2(cap)_4$, which is much more soluble in organic solvents than is the corresponding acetamide,[3] is prepared by ligand substitution of acetate by caprolactam on ***Dirhodium(II) Tetraacetate*** (eq 1) in refluxing chlorobenzene. When performed in a Soxhlet extraction apparatus where the extractor thimble contains sodium carbonate, acetic acid is trapped and ligand substitution is forced to completion. Four caprolactam molecules ligate one dirhodium(II) nucleus, and each rhodium is bound to two nitrogen and two oxygen donor atoms arranged in a *cis* configuration.[4]

Metal Carbene Transformations.

The principal advantages of $Rh_2(cap)_4$ are its solubility and its selectivity for product formation in reactions with diazocarbonyl compounds, relative to dirhodium(II) tetra(carboxylates). Having lower Lewis acidity than dirhodium(II) tetra(carboxylates), $Rh_2(cap)_4$ is less reactive towards diazo compounds; reactions with diazoacetates, diazoacetamides, and diazo ketones usually occur in refluxing dichloromethane, and reactions with diazoacetoacetates and diazoacetoacetamides ordinarily occur at temperatures above 80 °C.

Regioselectivity in Carbon-Hydrogen Insertion Reactions.

The use of $Rh_2(cap)_4$ provides high levels of regiocontrol in carbon-hydrogen insertion reactions of diazoacetate and diazoacetoacetate esters.[2] Whereas 2,3,4-trimethyl-3-pentyl diazoacetate forms γ-lactone products from insertion into primary and tertiary C-H bonds in a statistical distribution with ***Dirhodium(II) Tetrakis(perfluorobutyrate)*** ($Rh_2(pfb)_4$), only tertiary C-H insertion is observed with $Rh_2(cap)_4$ (eq 2). Similarly, when competition for C-H insertion is between primary and secondary C-H bonds, $Rh_2(cap)_4$ directs insertion to the secondary C-H bond with high selectivity (eq 3). Nearly identical selectivities are observed with ***Dirhodium(II) Tetraacetamide*** so, by extrapolation, $Rh_2(cap)_4$ will also be the catalyst of choice for regioselective cyclopropanation reactions with dienes.[3]

$Rh_2(pfb)_4$	39%	61%
$Rh_2(OAc)_4$	90%	10%
$Rh_2(cap)_4$	>99%	<1%

Chemoselectivity in Metal Carbene Transformations.

When there are two reaction centers for intramolecular carbenoid reactions, the use of $Rh_2(cap)_4$ often leads to the production of only one product.[5,6] Cyclopropanation is favored over aromatic substitution (eq 4), over tertiary carbon-hydrogen insertion (eq 5), and over aromatic cycloaddition (eq 6). Product yields are high in each case. The order of reactivity for metal carbenes generated from $Rh_2(cap)_4$ is cyclopropanation > tertiary C-H insertion > secondary C-H insertion > aromatic cycloaddition,[6] and the rate differences between them are as much as 100-fold.

Carbonyl ylide generation is favored over aromatic cycloaddition with $Rh_2(cap)_4$ (eq 7),[7] but in competition with cyclopropanation both ylide generation and alkene cycloaddition occur with equivalent facility.[5,8] Except for ylide generation, these catalytic metal carbene transformations exhibit an overwhelming preference for five-membered ring formation,[9] but within this controlling limitation, both chemoselectivity and regioselectivity are greatly influenced by the ligand of dirhodium(II).

(7)

The selectivities achieved with changes in dirhodium(II) ligands are due, in part, to the degree of charge localization on the carbene carbon.[6] However, conformational restrictions from the carbene system that is bound to dirhodium(II) can also influence selectivity,[2] so broad generalizations regarding selectivity with $Rh_2(cap)_4$ are inappropriate.

Dirhodium(II) Tetrakis(methyl 2-pyrrolidone-5(*S*)-carboxylate)

[131766-06-8] · $C_{24}H_{36}N_4O_{12}Rh_2$ · Dirhodium(II) Tetrakis(methyl 2-pyrrolidone-5(*S*)-carboxylate) · (MW 778.46)

(highly enantioselective catalyst for carbenoid reactions of diazo compounds)[1-3]

Physical Data: λ 615 nm, ε 211 ($ClCH_2CH_2Cl$). ^1H NMR ($CDCl_3$) of Rh_2(5*S*-MEPY)$_4$(MeCN)$_2$: δ 4.32 (dd, *J* = 8.8, 3.0 Hz, 2H), 3.95 (dd, *J* = 8.6, 2.1 Hz, 2H), 3.70 (s, 6H), 3.68 (s, 6H), 2.70-2.55 (m, 4H), 2.26 (s, 6H), 1.8-2.4 (m, 12H). $[\alpha]_D^{23}$ = -259.5° (MeCN, *c* = 0.098).

Solubility: sol MeOH, MeCN, acetone; slightly sol CH_2Cl_2, $ClCH_2CH_2Cl$, toluene.

Form Supplied in: red crystals as the bis-acetonitrile complex; blue solid after removal of the axial nitrile ligands.

Preparative Method: from ***Dirhodium(II) Tetraacetate*** by ligand substitution with methyl 2-pyrrolidone-5(*S*)-carboxylate.[4,5]

Handling, Storage, and Precautions: air stable, weakly hygroscopic; stored in desiccator.

Introduction.

The preparation of the title reagent, Rh_2(5*S*-MEPY)$_4$, is the same as that used for ***Dirhodium(II) Tetraacetamide***[6] or ***Dirhodium(II) Tetra(caprolactam)***.[7] Ligand exchange occurs in refluxing chlorobenzene, and the acetic acid that is liberated is trapped in a Soxhlet extraction apparatus by sodium carbonate. Purification occurs by chromatography on a CN-capped silica column; recrystallization from acetonitrile-2-propanol (1:1) provides Rh_2(5*S*-MEPY)$_4$(MeCN)$_2$(*i*-PrOH). Four 2-pyrrolidone-5(*S*)-carboxylate molecules ligate one dirhodium(II) nucleus; each rhodium is bound to two nitrogen and two oxygen donor atoms arranged in a *cis* configuration.[4] The methyl carboxylate substituents are positioned with a counterclockwise orientation on each rhodium face.

Metal Carbene Transformations.

The effectiveness of $Rh_2(5S\text{-MEPY})_4$ and its 5*R*-form, $Rh_2(5R\text{-MEPY})_4$, is exceptional for highly enantioselective intramolecular cyclopropanation[8] and carbon-hydrogen insertion[9] reactions. Intermolecular cyclopropanation occurs with lower enantiomeric excesses[10] than with alternative chiral copper salicylaldimine[11] or C_2-symmetric semicorrin[12] or bis-oxazoline[13] copper catalysts, but intermolecular cyclopropenation exhibits higher enantiocontrol with $Rh_2(MEPY)_4$ catalysts.[14] The methyl carboxylate attachment of $Rh_2(5S\text{-MEPY})_4$ is far more effective than sterically similar benzyl or isopropyl attachments for enantioselective metal carbene transformations.[4] The significant enhancement in enantiocontrol is believed to be due to carboxylate carbonyl stabilization of the intermediate metal carbene and/or to dipolar influences on substrate approach to the carbene center.

Enantioselective Intramolecular Cyclopropanation Reactions.

The exceptional capabilities of the $Rh_2(5S\text{-MEPY})_4$ and $Rh_2(5R\text{-MEPY})_4$ catalysts for enantiocontrol are evident in results obtained with a series of allyl diazoacetates (eq 1).[5,8] Both high product yields and enantiomeric excess (ee's) are characteristic. Intramolecular cyclopropanation of (*Z*)-alkenes proceeds with a higher level of enantiocontrol than does intramolecular cyclopropanation of (*E*)-alkenes. In preparative scale reactions, less than 0.25 mol% of catalyst can be employed to achieve high yields of pure product.[5]

(1)

R^t	R^c	% ee
H	H	95
Me	Me	98
H	Ph, Et, Bn, Bu_3Sn	≥94
Pr	H	83
Ph	H	65

Similar success in enantiocontrol has been achieved for intramolecular cyclopropanation of homoallyl diazoacetates (eq 2).[15] With these substrates the enantiomeric excesses do not extend beyond 90%, but they are virtually independent of double bond substituents.

(2)

R^1	R^2	R^3	% ee
Me	Me	H	77
Et, Ph, Bn, TMS	H	H	80-90
H	Et, Ph	H	73-82
H	H	Me	79

Enantioselective Intermolecular Cyclopropenation Reactions.

The use of $Rh_2(MEPY)_4$ catalysts for intermolecular cyclopropenation of 1-alkynes results in moderate to high selectivity. With propargyl methyl ether (or acetate), for example, reactions with (-)-menthyl [(+)-(1*R*,2*S*,5*R*)-2-isopropyl-5-methyl-1-cyclohexyl] diazoacetate catalyzed by $Rh_2(5S\text{-MEPY})_4$ produces the corresponding cyclopropene product (eq 3) with 98% diastereomeric excess (de).[14,16]

(3)

These reactions are subject to significant double diastereoselection with (+)- and (-)-menthyl diazoacetates. With ethyl diazoacetate, enantiomeric excesses are moderate (54-69% ee), but they increase up to 78% ee with *t*-butyl diazoacetate.[14] These are the first examples of enantioselective catalytic cyclopropenation reactions.

Enantioselective Intramolecular Carbon-Hydrogen Insertion Reactions.

The suitability of $Rh_2(5S\text{-MEPY})_4$ and $Rh_2(5R\text{-MEPY})_4$ for enantioselective intramolecular C-H insertion reactions is evident in results with 2-alkoxyethyl diazoacetates (eq 4).[9] Both lactone enantiomers are available from a single diazo ester. Other examples have also been reported, especially those with highly branched diazo substrate structures.[9]

(4)

Diazoacetamides are robust diazo substrates, but they generally give lower enantioselection, and regioselectivity for γ-lactam formation is dependent on the substituents on carbon at which insertion occurs (e.g. eq 5).[17] With *N*-(*n*-butyl)-*N*-(*t*-butyl)diazoacetamide the ratio of γ:β-lactam is 88:12. A significant improvement in enantioselection (up to 78% ee) occurs with the use of the oxazolidinone analog of $Rh_2(5S\text{-MEPY})_4$.[17]

(5)

Polyethylene-Bound, Soluble, Recoverable Dirhodium(II) 2-Pyrrolidone-5(*S*)-carboxylate.

The homogeneous Rh_2(5*S*-MEPY)$_4$ catalyst has been attached to a polyethylene chain that is soluble in organic solvents at about 70 °C.[18] Ligand displacement of 2-pyrrolidone-5(*S*)-carboxylate from Rh_2(5*S*-MEPY)$_4$ by a soluble polyethylene-bound 2-pyrrolidone-5(*S*)-carboxylate produces a recoverable dirhodium(II) catalyst, PE-Rh_2(5*S*-PYCA)$_4$, in high yield. The effectiveness of this catalyst has been demonstrated by high enantioselection for intramolecular cyclopropanation of 3-methyl-2-buten-1-yl diazoacetate (see eq 1) in refluxing benzene solution (98% ee) and for intramolecular C-H insertion of 2-methoxyethyl diazoacetate (see eq 4) under the same conditions (72% ee). For both transformations, reactions catalyzed by Rh_2(5*S*-MEPY)$_4$ that occur at the same temperature give lower % ee values. Although diminished selectivity can occur with catalyst recovery and reuse under standard conditions, retention of catalyst effectiveness is achieved by using 2-3 mol % of the pyrrolidone ligand in up to seven subsequent runs with recovered, reused PE-Rh_2(5*S*-PYCA)$_4$.

Dirhodium(II) Tetrakis(perfluorobutyrate)

$Rh_2(O_2CC_3F_7)_4$

[73755-28-9] · $C_{16}F_{28}O_8Rh_2$ · Dirhodium(II) Tetrakis(perfluorobutyrate) · (MW 1057.98)

(catalyst for carbenoid reactions of diazo compounds,[1] hydrosilylation of alkenes and alkynes,[2] and silylcarbonylation of alkynes[3])

Physical Data: λ 626 nm, ε 248 (CH_2Cl_2).[4]

Solubility: sol MeCN, DMSO, pyridine, benzene, CH_2Cl_2, alkenes.

Form Supplied in: anhydrous form is green; hydrate is blue.

Preparative Methods: from ***Dirhodium(II) Tetraacetate*** by ligand displacement in refluxing perfluorobutyric acid containing perfluorobutyric anhydride.[5]

Handling, Storage, and Precautions: air stable, very hygroscopic; stored in desiccator.

Metal Carbene Transformations.

Alkene Coordination.

Dirhodium(II) tetrakis(perfluorobutyrate), $Rh_2(pfb)_4$, and ***Dirhodium(II) Tetrakis(trifluoroacetate)***, $Rh_2(tfa)_4$, are unique among dirhodium(II) carboxylates and carboxamides in their ability to form association complexes with alkenes and alkynes in solution.[2,4] Equilibrium constants range from 70 M^{-1} (styrene) to 932 M^{-1} (2-methoxypropene). However, alkene coordination with $Rh_2(pfb)_4$ has no effect on relative reactivity or selectivity in cyclopropanation reactions with ethyl diazoacetate. Being more soluble in weakly polar solvents than is $Rh_2(tfa)_4$, removal of $Rh_2(pfb)_4$ from reaction solutions by simple chromatography on silica is more difficult.

Stereoselectivity and Regioselectivity.

The strongly electron-withdrawing perfluorobutyrate ligands render $Rh_2(pfb)_4$ significantly more electrophilic than ***Dirhodium(II) Tetraacetate*** or ***Dirhodium(II) Tetraacetamide***. As a result, reactivity towards diazo compounds is substantially increased, relative to $Rh_2(OAc)_4$, and stereoselectivity and regioselectivity in cyclopropanation and

carbon-hydrogen insertion reactions are greatly diminished (e.g. eqs 1-3).[6] Regioselectivity for C-H insertion into primary and secondary carbon-hydrogen bonds (eq 3) is nearly statistical, demonstrating that relative reactivities for insertion are essentially equal.[7-11]

(1)

	anti:*syn*

$Rh_2(acam)_4$	7	93

	%	%
$Rh_2(pfb)_4$	34	66
$Rh_2(OAc)_4$	75	25
$Rh_2(acam)_4$	92	8

(3)

Chemoselectivity.

Dirhodium(II) perfluorobutyrate has proven to be highly selective in competitive intramolecular metal carbene transformations.[12] In contrast to results with ***Dirhodium(II) Tetra(caprolactam)***, the use of $Rh_2(pfb)_4$ favors aromatic substitution over cyclopropanation (eq 4),[13] insertion over cyclopropanation (eq 5),[13] and aromatic substitution over carbonyl ylide generation (eq 6).[14] Product yields are high in each case. The order of reactivity for metal carbenes generated from $Rh_2(pfb)_4$ is aromatic substitution > tertiary C-H insertion > cyclopropanation &AApprox; aromatic cycloaddition > secondary C-H insertion, and the rate differences between them are as much as 100-fold.[13]

(4)

Additional applications of $Rh_2(pfb)_4$ to metal carbene transformations include intramolecular O-H insertion (eq 7),[14] where intramolecular cyclopropanation would also be a viable pathway. For intramolecular cyclopropenation reactions of diazo ketones which undergo subsequent vinylcarbene formation, use of $Rh_2(pfb)_4$ leads to different products than those from dirhodium(II) octanoate.[15] In contrast to the use of rhodium(II) octanoate in pentane which effects exclusive cyclopropanation, $Rh_2(pfb)_4$ in CH_2Cl_2 promotes [3 + 2] annulation in reactions of a vinyldiazomethane with vinyl ethers (eq 8),[16] and this result further exemplifies the influence of the highly electrophilic $Rh_2(pfb)_4$ on selectivity.

Isomerizations of Cyclopropenes.

Cyclopropenes undergo facile rearrangements catalyzed by $Rh_2(pfb)_4$ to yield products that are structurally different from those obtained with the use of copper, platinum, or silver catalysts.[17] The selectivity achieved with $Rh_2(pfb)_4$ is remarkable (Scheme 1), and, as suggested by eq 9, the involvement of $Rh_2(pfb)_4$ is consistent with the generation of a vinylcarbene intermediate.

Scheme 1

(9)

Hydrosilylation of Alkenes and Alkynes.

Hydrosilylation of 1-alkenes is catalyzed by $Rh_2(pfb)_4$ under mild conditions.[18] The mode of addition determines the products that are formed. When the alkene is added to triethylsilane in the presence of $Rh_2(pfb)_4$, normal hydrosilylation (eq 10) occurs; reversed addition causes the formation of vinyl- or allylsilanes (eq 11). Alkene isomerization catalyzed by the combination of $Rh_2(pfb)_4$ with triethylsilanes has also been reported.[18]

(10)

(11)

Hydrosilylation of 1-alkynes catalyzed by $Rh_2(pfb)_4$ forms either vinylsilanes (*trans* addition) or allylsilanes in moderate to high isolated yields, dependent on the mode of addition.[19] Addition of triethylsilane to 1-alkynes in dichloromethane containing $Rh_2(pfb)_4$ results in the formation of vinylsilanes, whereas addition of the alkynes to triethylsilane produces allylsilanes (eq 12) in high yield. Product dependence on the mode of addition is associated with organosilane coordination with $Rh_2(pfb)_4$. Organosilane alcoholysis is also catalyzed by $Rh_2(pfb)_4$ (eq 13);[20] primary alcohols react with triethylsilane approximately five times faster than do secondary alcohols.

(12)

(13)

Silylcarbonylation of Alkynes.

$Rh_2(pfb)_4$ is a highly effective catalyst for silylation of terminal alkynes in reactions performed at atmospheric pressure or at 10 atm CO pressure and at or below rt.[3] At atmospheric CO pressure, addition of the alkyne to the organosilane is critical to the success of this transformation (eq 14), which is characterized by virtually complete regioselectivity and (*Z*/*E*) selectivity that is greater than 10:1, often reaching >30:1. ***Dirhodium(II) Tetraacetate*** is relatively ineffective as a catalyst for silylcarbonylation. The advantages of $Rh_2(pfb)_4$ as a catalyst for silylcarbonylation of alkynes lie in the mild conditions employed, high catalysts turnovers, and exceptional (*E*/*Z*) ratios.

Dirhodium(II) Tetrakis(trifluoroacetate)

$Rh_2(O_2CCF_3)_4$

[31126-95-1] · $C_8F_{12}O_8Rh_2$ · Dirhodium(II) Tetrakis(trifluoroacetate) · (MW 657.90)

(catalyst for carbenoid reactions of diazo compounds[1])

Physical Data: λ 610 nm, ε 210 (CH_2Cl_2).[2]

Solubility: sol MeCN, DMSO, pyridine; slightly sol dichloromethane, benzene.

Form Supplied in: anhydrous form is green; hydrate is blue.

Preparative Method: from ***Dirhodium(II) Tetraacetate*** by ligand displacement in refluxing trifluoroacetic acid containing trifluoroacetic anhydride.[3]

Handling, Storage, and Precautions: air stable, very hygroscopic; stored in desiccator.

Alkene Coordination.

Dirhodium(II) tetrakis(trifluoroacetate), $Rh_2(tfa)_4$, like the corresponding ***Dirhodium(II) Tetrakis(perfluorobutyrate)***, $Rh_2(pfb)_4$, forms π-complexes with alkenes.[2,4] Equilibrium constants for alkene coordination are 2-3 times less than those for $Rh_2(pfb)_4$, and they are relatively insensitive to steric influences. Coordination causes substantial changes in chemical shifts for vinyl protons.[4] A determination of chirality has been made through an axial bis-alkene complex of $Rh_2(tfa)_4$.[5] Nitroxide and phosphine complexes have also been characterized.[6,7]

Metal Carbene Transformations.

Fluoroalkanoate complexes of dirhodium(II) were first employed to effect intermolecular carbon-hydrogen insertion reactions (eq 1).[8,9] Although insertion product yields are relatively high, selectivity is low. A similar low level of selectivity occurs in intermolecular cyclopropanation of alkenes[10,11] and dienes.[12] However, relative to $Rh_2(tfa)_4$, $Rh_2(pfb)_4$ exhibits even lower levels of stereocontrol and regiocontrol in cyclopropanation reactions.

Both reactivity and solubility in weakly polar solvents render $Rh_2(pfb)_4$ superior to $Rh_2(tfa)_4$ for metal carbene transformations.

The cationic character of the intermediate metal carbene formed from a vinyldiazo compound is evident in the formation of the bicyclo[2.2.1]heptene system in eq 2.[13] Here, use of $Rh_2(tfa)_4$ favors this carbocation addition product even in pentane, whereas use of ***Dirhodium(II) Tetraacetate*** in pentane reduces the yield of this product to only 5%. Electrophilic substitution products have also been reported from $Rh_2(tfa)_4$-catalyzed reactions of vinyldiazomethane derivatives with *N*-(methoxycarbonyl)pyrrole.[14] Overall $Rh_2(tfa)_4$ is not as effective as $Rh_2(pfb)_4$, nor is its selectivity in reactions of metal carbenes significantly different.

$Rh_2(tfa)_4$, CH_2Cl_2	32%	68%
$Rh_2(tfa)_4$, pentane	46%	54%
$Rh_2(OAc)_4$, CH_2Cl_2	67%	33%
$Rh_2(OAc)_4$, pentane	95%	5%

Dirhodium(II) Tetraoctanoate

$Rh_2(O_2CC_7H_{15})_4$

[73482-96-9] · $C_{32}H_{60}O_8Rh_2$ · Dirhodium(II) Tetraoctanoate · (MW 778.74)

(nonpolar solvent-soluble catalyst for carbenoid reactions of diazo compounds)

Solubility: sol MeOH, MeCN, Et_2O, CH_2Cl_2, toluene, hexane, pentane.

Form Supplied in: green solid; commercially available.

Preparative Method: prepared by ligand substitution from $Rh_2(OAc)_4$.[1]

Handling, Storage, and Precautions: air stable, weakly hygroscopic; stored in desiccator.

Metal Carbene Transformations.

Because of its solubility in organic solvents, dirhodium(II) tetraoctanoate, $Rh_2(oct)_4$, has seen wide use as an alternative for ***Dirhodium(II) Tetraacetate*** as a catalyst for reactions of diazo compounds. However, although $Rh_2(oct)_4$ is initially soluble in relatively nonpolar organic solvents, whereas $Rh_2(OAc)_4$ is not, there are few other advantages to its use as a laboratory scale catalyst. Thus $Rh_2(OAc)_4$ can be chromatographically separated on silica or alumina from reaction products, but $Rh_2(oct)_4$ is often resistant to chromatographic separation.

Temperature Effects.

Uses of $Rh_2(oct)_4$ for catalytic reactions with diazo compounds parallel those of $Rh_2(OAc)_4$.[2,3] Although product yields are higher with $Rh_2(OAc)_4$, use of $Rh_2(oct)_4$ at 0 °C in dichloromethane causes exceptionally high diastereocontrol (97% de) for the intermolecular cyclopropanation of styrene by the (*R*)-(-)-pantolactone ester of *trans*-2-diazo-4-phenyl-3-butenoate (eq 1).[4] Here temperature seems to be important since in refluxing dichloromethane both $Rh_2(OAc)_4$ and $Rh_2(oct)_4$ gave this cyclopropane product with a diastereomeric excess of 88 ± 1%.

Temperature control in $Rh_2(oct)_4$-catalyzed reactions of a vinyldiazomethane (Scheme 1) in CH_2Cl_2 (0 and 40 °C) or benzene (80 °C) affords selective entry to intramolecular aromatic cycloaddition (0 °C), [3 + 4] annulation (40 °C), and [3 + 2] annulation (80 °C).[5]

Scheme 1

Solvent Effects.

Use of $Rh_2(oct)_4$ in pentane significantly influences product control in catalytic carbenoid reactions. Cyclopropanation occurs to the exclusion of [3 + 2] annulation in reactions of vinyldiazomethanes with vinyl ethers (eq 2); with $Rh_2(OAc)_4$ in dichloromethane, both products are formed.[6] Intramolecular reactions of diazo ketones show a similar solvent dependence with systems designed for tandem cyclopropenation/vinylcarbene formation/cyclopropenation versus hydrogen migration (eq 3).[7] In other cases the influence of solvent on selectivity is not as great,[8,9] but for the synthesis of tropanes the use of $Rh_2(oct)_4$ in pentane has advantages not demonstrated by $Rh_2(OAc)_4$ in dichloromethane (eq 4).[10] Solvent control of the reaction pathway is associated with the degree of charge development in the transition state for the carbenoid reaction.

$Rh_2(oct)_4$, pentane	0%	91%
$Rh_2(OAc)_4$, CH_2Cl_2	24%	37%

Disiamylborane[1]

[1069-54-1] · $C_{10}H_{23}B$ · Disiamylborane · (MW 154.14)

(hindered organoborane for chemo-[2] and regioselective[3] hydroboration and chemo-[4] and stereoselective[5] reduction; can be used to mediate couplings of alkenes[6] and alkynes[7])

Alternate Name: bis(1,2-dimethylpropyl)borane.

Physical Data: mp 35-40 °C; fp -17 °C.

Solubility: sol THF, ether, diglyme.

Form Supplied in: prepared in situ; kits are available.

Preparative Methods: generally prepared by reaction of ***Diborane*** with 2-methyl-2-butene in ethereal solvents at 0 °C;[8] alternatively by substituting borane-1,4-thioxane.[9]

Handling, Storage, and Precautions: flammable; very air- and moisture-sensitive. Generally prepared immediately prior to use. Handle in a fume hood.

Hydroboration of Alkenes.

Compounds containing double bonds react with disiamylborane (Sia_2BH) to give tertiary boranes of the form Sia_2BR (eq 1). These trialkylboranes are generally not isolated, but are submitted to further reactions to provide a variety of products. The reactions of disiamylborane adducts are typical of organoboranes. If the intermediate is quenched with acid, the borane is replaced with a proton (eq 2); the net result is a *syn* hydrogenation.[10]

(1)

(2)

The organoborane may also be oxidized with alkaline peroxide to give an alcohol which retains the position and configuration of the borane adduct. Thus, for example, Sia_2BH is the reagent of choice for anti-Markovnikov hydration of o-unsaturated esters due to its high selectivity for terminal hydroboration (eq 3).[11] Alternatively, direct oxidation of the intermediate resulting from hydroboration of a terminal alkene with ***Pyridinium Chlorochromate*** provides the aldehyde (eq 4).[12] Once again, Sia_2BH is the reagent of choice for this reaction because of its high selectivity for the alkenic terminus. Reaction of Sia_2BR with ***Iodine*** under basic conditions provides the corresponding iodide.[13] When R is primary, the formation of RI proceeds in high yield, because transfer of the siamyl groups occurs only slowly (eqs 5 and 6). A similar transformation may be accomplished using borane, but yields are generally lower because R_3B gives only partial conversion to RI.[14] This Sia_2BH-based approach was found to be clearly superior to a hydrozirconation route for the iodination of the (η^6-hexabutenylbenzene)(η^5-cyclopentadienyl)iron cationic complex illustrated in eq 7.[15]

(3)

(4)

(5)

(6)

(7)

Unlike diborane, disiamylborane exists as a dimer even in solution in THF.[16] This failure to dissociate in a coordinating solvent, presumably due to the steric bulk of the siamyl groups which disfavor the borane/ether complex, causes Sia_2BH to act as a highly hindered hydroborating agent. As a general rule, Sia_2BH reacts preferentially with less sterically hindered alkenes. An extensive comparative study has determined the relative rates of reaction of double bonds with a variety of substitution patterns.[17]

Reaction occurs to place the borane at the least encumbered position. These differences in reaction rate are often large enough to be synthetically useful; thus 1-hexene reacts at the terminal position with >99:1 selectivity (with diborane the selectivity for the 1-position is ~15:1).[18] Sia_2BH even responds to the bulk of the substituents on the double bond; 4-methyl-*trans*-2-pentene reacts slowly with the reagent (12 h at 0 °C) to give mainly the 2-alcohol (Scheme 1).[18]

Scheme 1

This high level of steric discrimination makes Sia_2BH a useful reagent for selective reaction with one double bond of a polyunsaturated compound; for example, hydroboration of limonene (eq 8) gives (after oxidative workup) a good yield of α-terpineol,[19] while the diene of eq 9 reacts selectively at one of the four possible alkenic positions.[20]

(8)

(9)

Sia_2BH-mediated hydroboration is a key step in a unique carbocyclization reaction (eq 10).[6] Thus dienyl iodide is selectively hydroborated at the less-substituted alkene; oxidative cyclization of this intermediate provides a cycloalkene. The borane route provides a useful alternative to methods involving palladium catalysis.

(10)

Hydroboration of Alkynes.

Sia_2BH is a valuable reagent for the chemo- and regioselective hydroboration of alkynes. The reagent is more selective for terminal hydroboration than diborane; it is also more selective for monoaddition.[8] Reaction of 1-hexyne with Sia_2BH gives a vinylborane as an intermediate. Hydrolysis gives 1-hexene as the product (eq 11). In the case of internal alkynes, this process results in a net *syn* hydrogenation to give a (*Z*)-alkene (eq 14).[21] Oxidative workup of the vinylborane provides an aldehyde (eq 12).[8] The intermediate can also be oxidized with copper salts in the presence of cyanide ion to give an α,β-unsaturated nitrile (eq 13).[22] Sia_2BH is superior to ***Dicyclohexylborane*** for this transformation, which provides an alternative to the hydroalumination/cyanogen sequence.[23]

(11)

(12)

(13)

The reaction of Sia_2BH with 1,4-dichloro-2-butyne, followed by treatment of the intermediate with a thiolate anion, provides a one-pot synthesis of 2-thioalkylbutadienes (eq 15).[24] A similar strategy, replacing the thiolate with an organolithium reagent, is unsuccessful for the synthesis of 2-alkylbutadienes, as the siamyl group migrates preferentially to primary alkyl.[25]

Sia_2BH adds regioselectively to a variety of asymmetrically substituted alkynes. Reaction with alkynyl sulfides occurs primarily α to sulfur; processing of the vinylborane intermediate by hydrolysis (of the corresponding ate complex) or oxidation leads to a vinyl sulfide (eq 17) or thiolester (eq 16), respectively.[26] Cyclohexylborane is more selective

(83:17) for α-boration than Sia_2BH (72:28) in this reaction. The reagent also reacts selectively at the 2-position of 1-chloro-2-heptyne; acid hydrolysis leads to a (*Z*)-allyl chloride (eq 18), while base treatment gives the terminal allene (eq 19).[27] Similarly, alkynyl acetals react with Sia_2BH to place the borane proximal to the heteroatom.[28]

(16)

(17)

(18)

(19)

Hydroboration of alkynes with Sia_2BH is more rapid than the corresponding reaction of alkenes, allowing for the selective conversion of enynes into dienes (eq 21)[2] or enones (eq 20).[29]

(20)

(21)

The enynes themselves can be prepared in Sia_2BH-mediated reactions. Hydroboration of diynes protected by bulky silyl groups occurs in a highly regioselective fashion; hydrolysis of the resultant organoboranes gives silylated enynes (eq 22).[30] Alternatively the vinylborane resulting from reaction of a terminal alkyne with Sia_2BH undergoes further reaction

with an alkynyllithium to give an ate complex, oxidation of which with iodine leads to carbon-carbon bond formation (eq 23).[7]

(23)

Functional Group Reductions.

An unusual mix of chemo- and stereoselectivity makes Sia_2BH a useful reducing agent for carbonyl compounds. While aldehydes and ketones are reduced rapidly, a variety of other functionalities including carboxylic and sulfonic acids, acid chlorides, and sulfones are inert.[4] Ketone reduction is often highly stereoselective, with the bulky reducing reagent delivering hydride from the less hindered face of the carbonyl (eqs 24 and 25).[5]

(24)

(25)

Sia_2BH is superior to ***Lithium Aluminum Hydride*** or borane for this transformation, but is generally less stereoselective than ***Diisopinocampheylborane***. While esters are unreactive, γ-lactones may be reduced to the corresponding lactols, a selectivity which has been used to advantage in carbohydrate synthesis (eq 26).[31] Amides also show a unique pattern of reactivity; while Sia_2BH fails to reduce primary amides, tertiary amides are converted to the corresponding aldehydes (eq 27).[31]

(26)

(27)

Sia_2BH also reacts with α,β-unsaturated ketones, with reduction occurring in a 1,4-sense.[32] The resultant boron enolate may be hydrolyzed to provide the saturated ketone (eq 28), or alternatively may be treated with an aldehyde to give *syn*-aldol products (eq 29).

(28)

(29)

Dicyclohexylborane, diisopinocampheylborane, and diisocaranylborane all accomplish a similar transformation; 9-BBN is inferior because it leads to significantly more 1,2-reduction.

Related Reagents.

Borane-Tetrahydrofuran; ***Diborane***; ***Dicyclohexylborane***.

Disodium Phenanthrenide

[84810-06-0] · $C_{14}H_{10}Na_2$ · Disodium Phenanthrenide · (MW 224.22)

(organohalide reducing agent)

Preparative Method: prepared in situ by reaction of parent hydrocarbon with ***Sodium*** in dimethyl ether.[1]

The first reference to the use of the disodio derivative of phenanthrene is a fleeting comment on the similarity of the parent hydrocarbon to naphthalene in the presence of sodium metal in dimethyl ether.[1] This tantalizing reference was exploited by Vogel et al. in the first efficient synthesis of bicyclo[4.2.0]octa-2,4,7-triene (**1**) (eq 1).[2] Disodium phenanthrenide was found to be superior to the previously examined methods for preparation of this elusive cyclooctatetraene tautomer.[3]

(1)

The main employment of sodium phenanthrenide has been in the preparation of exotic hydrocarbons such as that shown above. For instance, this reductive dehalogenating reagent was used in preparation of hemi-Dewar naphthalene, benzobicyclo[2.2.0]hexa-2,5-diene (**2**) (eq 2). Sodium phenanthrenide was the only reagent able to carry out the reduction used to prepare this sensitive substrate.[3,4]

(2)

Finally, 5 mol equiv of disodium phenanthrenide reductively dechlorinates tetrachloride (**3**) to give functionalized Dewar benzene (**4**) (eq 3).[5]

Disodium Tetracarbonylferrate(-II)[1]

$Na_2Fe(CO)_4$

($Na_2Fe(CO)_4$)

[14878-31-0] · $C_4FeNa_2O_4$ · Disodium Tetracarbonylferrate(-II) · (MW 213.87) ($Na_2Fe(CO)_4$.1.5(1,4-dioxane))

[59733-73-2] ($K_2Fe(CO)_4$)

[16182-63-1] · $C_4FeK_2O_4$ · Dipotassium Tetracarbonylferrate(-II) · (MW 246.09) ($[Fe(CO)_4]^{2-}$)

[22321-35-3] · C_4FeO_4 · Disodium Tetracarbonylferrate(-II) · (MW 167.89)

(carbonylating agent for halides, producing aldehydes and ketones;[1] hydroacylates Michael acceptors;[2] forms cyclic ketones from β- and γ-haloalkenes;[3] selectively reduces unsaturations α to a carbonyl;[4] catalyst for dismutation of aromatic aldehydes to esters;[5] produces [(η^4-diene)$Fe(CO)_3$] complexes via nucleophilic displacement[6])

Physical Data: mp (K^+_2 salt) 270-273 °C (dec).

Solubility: sol THF, DMF, *N*-methylpyrrolidone (NMP), EtOH.

Form Supplied in: colorless to red solid; commercially available as 1:1.5 complex with 1,4-dioxane.

Preparative Methods: preparations of the sodium salt-dioxane complex[7] and of the free sodium[8] and potassium[9] salts of tetracarbonylferrate have been published.

Handling, Storage, and Precautions: $Na_2Fe(CO)_4$ is very air sensitive and is pyrophoric. The solid is stable over moderately long periods of time under inert atmosphere at rt, if kept in the dark. The potassium salt is also air sensitive but is not pyrophoric. These materials are best stored and handled in a nitrogen or argon filled dry box. Tetracarbonylferrate is considered to be a neural, renal, and hepatic toxin and is a cancer suspect agent.

Carbonylation Reactions.

The tetracarbonylferrate dianion is a potent nucleophile. Its principal use is in the functionalization of halide compounds. Although $Na_2Fe(CO)_4$ does not enjoy the widespread popularity of its main group rival, the Grignard reagent, it does

have the advantage of usually adding a carbonyl group to the substrate. Tetracarbonylferrate typically reacts readily with alkyl halides or tosylates (RX) at rt to generate $RFe(CO)_4^-$, a useful synthetic intermediate. The reaction proceeds with stereochemical inversion and is typically carried out in THF. However, more polar solvents, such as NMP, DMF, or *N*,*N*-dimethylacetamide (DMA) are often used to help decrease $Na_2Fe(CO)_4$ ion-pairing and hence accelerate the rate of reaction with less reactive substrates, such as alkyl chlorides. The formation of the alkyltetracarbonylferrate has been shown to fail on occasion, however. For example, when a β-lactam functionality is present, reductive ring opening occurs.[10] Acylferrates, $RCOFe(CO)_3L^-$ (L = CO, PPh_3), may be prepared either by reaction of $Fe(CO)_4^{2-}$ with an acid halide or, more commonly, by migratory insertion through reaction of $Fe(CO)_4^{2-}$ with RX in the presence of CO or PPh_3. The chemistry of $RCOFe(CO)_3L^-$ in many cases is similar to that of $RFe(CO)_4^-$ (eq 1), since the latter is subject to carbonyl insertion. Both produce unsymmetrical ketones upon addition of a second alkyl halide reagent.[11-13]

(1)

The utility of this chemistry has been enhanced (eq 2) through the use of catalytic Pd^0. Aryl iodides oxidatively add to palladium and transmetalation occurs, opening a single-step route to aryl ketones.[14] Alkyl- or acylferrates, when treated with oxygen (eq 1) followed by acidic workup, are converted to acids, allowing the overall transformation of RX to RCO_2H.[15]

Similarly, the use of halogen gives acid halides, which are converted in situ to amides, esters, or acids. The acylferrates will react in situ with acid to produce aldehydes[12] and are subject to Cu^{I} coupling, giving symmetrical α-diketones, RCOCOR.[16] Tetracarbonylferrate may be used to produce cyclopentanones from δ-dibromides (eq 3).[17] However the formation of six- and seven-membered rings suffers from low yields.

Alkyl- and acyltetracarbonylferrates are susceptible to alkene insertion reactions. This phenomenon was initially recognized through the single-step preparation of alkyl ethyl ketones from RX, ethylene, and $Fe(CO)_4^{2-}$.[18] Later, reactions between these ferrates and various Michael acceptor alkenes were uncovered.[2] Precursors to jasmone and γ-jasmolactone have been produced (eq 4). Allenes insert into $RFe(CO)_4^-$ to give [(η^4-hydroxytrimethylenemethane)$Fe(CO)_3$] complexes, which thermally rearrange to [(η^4-enone)$Fe(CO)_3$] complexes.[19] ***Ethylene Oxide*** also inserts into the iron-acyl bond in $RCOFe(CO)_4^-$, giving an unisolated β-hydroxy ketone, which dehydrates to an α,β-unsaturated ketone.[20] Yields of 60-80% are found. Cyclizations may be accomplished via alkene insertion. Cyclopentanones and cyclohexanones are produced by the tetracarbonylferrate treatment of monosubstituted alkenes bearing a β- or γ-halide.[1,3,21,22] The less hindered product prevails. 5-Bromo-1,2-pentadiene cyclizes to 2-methylcyclopenten-3-one. These cyclization reactions, which are carried out in THF with an acid workup, generally give moderate yields (30-75%); nevertheless some of the higher yields are found for the synthesis of the spirocyclic ketones which are otherwise accessible only with difficulty.

Reduction Reactions.

Tetracarbonylferrate more commonly functions as a nucleophile than as a reducing agent. Nevertheless, several valuable transformations involving selective reduction have been demonstrated. The most desirable of these allows reduction of an unsaturated group α to a carbonyl. The key step in the synthesis of 9,10-dihydroretinal (the reduction of the conjugated 9,10-alkene) was accomplished (eq 5) with the use of $Fe(CO)_4^{2-}$.[4] However, as illustrated, there is some tendency toward simultaneous reduction of the carbonyl group. The ability to reduce carbonyls mildly is exploited in the synthesis of *cis*-caronaldehyde (eq 6).[23]

More typically acid anhydrides are reduced to aldehydes (or occasionally to acids) by $Na_2Fe(CO)_4$ in THF.[24] Intramolecular anhydrides produce aldehydic acids. Tetracarbonylferrate functions as a catalyst in the high yield dismutation of aromatic aldehydes.[5] A plausible mechanism is presented (eq 7). The complex resulting from nucleophilic attack of $Fe(CO)_4^{2-}$ on RCHO is apparently sufficiently nucleophilic itself to attack another molecule of aldehyde. The aldehyde complex can also be partially alkylated in a competitive stoichiometric process. However, this reaction does not appear to be efficient enough to be of synthetic value. Alkyl- or acyltetracarbonylferrates give reductive coupling products with nitroaromatics.[25] Upon reaction with nitrobenzene, they produce *N*-phenylamides.

Other Nucleophilic Substitutions.

The $Fe(CO)_4^{2-}$ anion forms *S*-bound complexes with nonenolizable thioketones.[26] These can be acylated at the sulfur to produce thioesters. However, thioketones bearing enolizable protons are deprotonated by $Fe(CO)_4^{2-}$. 1,1-Cyclopropanedicarboxylates are ring opened by tetracarbonylferrate to produce stabilized carbanions (eq 8).[27] Alkylation may then be carried out at both ends of the dianion. Tetracarbonylferrate will also displace chloride from $[(\eta^6\text{-}C_6H_5Cl)Cr(CO)_3]$.[28] A variety of $[(\eta^4\text{-1,3-diene})Fe(CO)_3]$ complexes are accessible through the reaction of 1-methylallylic halides or phosphates with $K_2Fe(CO)_4$.[6] Nevertheless, the direct synthesis of these complexes from the diene and ***Pentacarbonyliron*** or ***Nonacarbonyldiiron*** remains the preferred route.

Disodium Tetrachloropalladate(II)[1]

Na_2PdCl_4

[13820-53-6] · Cl_4Na_2Pd · Disodium Tetrachloropalladate(II) · (MW 294.20)

(can cyclopalladate aromatic and heteroaromatic compounds;[2] homogeneous catalyst for vinylation of imides and lactams;[3] homogeneous catalyst for carbonylation of allyl chlorides;[4] catalyst for oxidation of alkenes to ketones[5])

Solubility: very sol H_2O; slightly sol ethanol, acetone, acetic acid.

Form Supplied in: brown-red solid. *Drying:* at 100 °C/0.1 mmHg for 24 h.

Preparative Method: very often prepared in situ from 1 equiv of ***Palladium(II) Chloride*** and 2 equiv of ***Lithium Chloride*** in the appropriate solvent (MeOH, EtOH, $MeCO_2H$).

Handling, Storage, and Precautions: is hygroscopic and should be stored in the absence of moisture. The trihydrate is formed in aqueous solution. Toxicity data are not available.

Organopalladium Reagents.

Various aromatic and heteroaromatic compounds containing nitrogen and sulfur atoms undergo cyclopalladation upon treatment with Na_2PdCl_4 to form dimeric complexes (eq 1).[6] Similarly, oximes of α,α´-dialkyl ketones react with Na_2PdCl_4 to give five-membered ring palladacycles.[7] These complexes are readily oxidized to the β-acetoxy oximes (eq 2). Functionalized hexopyranosides can be prepared using this reaction.[8]

(1)

Alkenes react with Na_2PdCl_4 to give π-complexes,[9] π-allyl complexes,[10] or π-benzyl complexes,[11] depending on nature of the compound. π-Allyl complexes are readily available by coupling of arylmercurials with alkenes.[12] These complexes are electrophilic in character and react with a variety of nucleophiles.[13]

Vinylation and Carbonylation.

Imides and lactams are converted to *N*-vinyl derivatives when heated with ***Vinyl Acetate*** in the presence of Na_2PdCl_4 (eq 3).[3] Allylic halides can be carbonylated at atmospheric pressure in the presence of Na_2PdCl_4 to form either β,γ-unsaturated acids or esters (eq 4).[4] Aromatic aldehydes can be carbonylated in the presence of amines to afford α-keto amides.[14]

Oxidations.

Oxidations are usually with either ***t-Butyl Hydroperoxide*** or ***Hydrogen Peroxide*** in conjunction with Na_2PdCl_4 as a catalyst. Simple alkenes give mixtures of products by this method.[15] α,β-Unsaturated esters and ketones are oxidized to β-keto esters and β-diketones, respectively.[5] α,β-Unsaturated phosphonates give β-ketophosphonates (eq 5).[16]

Disodium Tetrachloroplatinate(II)[1]

Na_2PtCl_4

[10026-00-3] · Cl_4Na_2Pt · Disodium Tetrachloroplatinate(II) · (MW 382.86)

(homogeneous hydrogen isotope exchange catalyst;[2] selective oxidative functionalization of alkane C-H bonds;[3] isomerization of alkenes[4])

Solubility: sol H_2O (8 g/100 mL); slightly sol alcohol, acetone, acetic acid.

Form Supplied in: red-brown solid; available as a tetrahydrate $Na_2PtCl_4.4H_2O$. *Drying:* at 120 °C/0.1 mmHg for 24 h.

Handling, Storage, and Precautions: should be stored in the absence of moisture; irritating to skin, eyes, and respiratory organs; corrosive.

Hydrogen Isotope Exchange Catalyst.

Aromatic and aliphatic compounds undergo exchange of isotopic hydrogen with a catalytic amount of this reagent (see also ***Dipotassium Tetrachloroplatinate(II)***). This system is valuable for labeling compounds with deuterium and/or tritium in one step and constitutes the homogeneous equivalent of the well-known heterogeneous platinum technique. A wide range of compounds, including benzene and substituted benzenes,[5] polyphenyls,[6] polycyclic hydrocarbons,[7] and some steroids[8] undergo D and/or T exchange. Deuteration in the side chain of long-chain alkylbenzenes occurs predominately at the benzylic and the terminal carbons.[9] Aromatics are generally quite reactive, whereas aliphatics such as cyclohexane exchange very slowly.[10] Nitrobenzene has similar reactivity to toluene[11] and bromobenzene.[12] Exchange usually occurs only in the sterically unhindered *meta* and *para* positions (eq 1).[11] Aromatic α-hydroxy acids undergo oxidative decarboxylation during the Na_2PtCl_4-catalyzed homogeneous deuteration (eq 2).[13]

(1)

deuterium distribution (% per H) *ortho*, 12.5; *meta*, *para*, 82.7

(2)

23.1% D incorporation

Functionalization of Saturated Hydrocarbons.

Na_2PtCl_4 or the combination Na_2PtCl_4/Na_2PtCl_6 in aqueous solution can be used to functionalize saturated hydrocarbons (see also ***Dipotassium Tetrachloroplatinate(II)***). Unusual and often very high selectivity is observed for oxidation at what are more commonly the least reactive positions. The products from oxidation of alkanes are mainly alcohols together with chloroalkanes, ethers, and acids. Ethanol can be selectively converted to ethylene glycol.[14] The methyl group of *p*-toluenesulfonic acid is selectively oxidized to the corresponding alcohol and aldehyde.[15] In spite of the simplicity of these systems, there is little recent work on them that shows promise for the development of preparative-scale processes.

Alkene Isomerization.

α,β-Unsaturated ketones can be isomerized to β,γ-unsaturated ketones through the formation of a π-complex with Na_2PtCl_4 (eq 3).[4] Analogous reaction with Na_2PdCl_4 gives a stable π-allyl complex (eq 4) (see ***Disodium Tetrachloropalladate(II)***).[16]

Disodium Tetracyanonickelate(II)

$Na_2Ni(CN)_4$

[14038-85-8] · $C_4N_4Na_2Ni$ · Disodium Tetracyanonickelate(II) · (MW 208.75)

(catalyst for hydrocyanation of alkynes[1])

Physical Data: yellow solid.

Solubility: sol water, ethylene glycol.

Preparative Method: prepared by first precipitating and isolating nickel dicyanide from an aqueous nickel nitrate solution,[2] followed by dissolution with a stoichiometric quantity of aqueous sodium cyanide.[3] Yellow needle-like crystals of disodium tetracyanonickelate crystallize from water with three molecules of water of recrystallization. Anhydrous material can be prepared by drying at 100 °C.

Handling, Storage, and Precautions: cyanides are highly toxic and appropriate precautions should be taken.

Catalytic Hydrocyanation of Alkynes.

Treatment of alkynes with catalytic amounts of $Na_2Ni(CN)_4$ along with excess cyanide ion (in the form of ***Potassium Cyanide***) and either ***Sodium Borohydride*** (in ethylene glycol) or ***Zinc*** (in water) as the reducing agent leads to saturated secondary nitriles. The advantages of using this reagent is that it avoids the use of toxic HCN and can be performed under mild conditions (45 °C). Terminal alkynes give exclusively secondary nitriles in good yields (eq 1), while internal alkynes lead to mixtures of products (eq 2).[1]

(1)

Aromatic nitriles can also be prepared from aromatic amines by initial conversion to the corresponding diazonium tetrafluoroborates, followed by treatment with $Na_2Ni(CN)_4$ in the presence of ***Sodium Carbonate*** or sodium phosphate at a pH of around 10 (eq 3).[4]

N,N´-Disuccinimidyl Carbonate

[74124-79-1] · $C_9H_8N_2O_7$ · *N,N´*-Disuccinimidyl Carbonate · (MW 256.19)

(reagent for the preparation of (active) esters in peptide chemistry;[1] β-eliminations[2] and carbonyl insertions in heterocyclic and especially peptide chemistry;[3] useful in preparation of some carbamates, ureas, and nitrosoureas[4])

Alternate Name: DSC.

Physical Data: mp 211-215 °C (dec); prisms.[5]

Form Supplied in: white to off-white powder.

Preparative Methods: by treatment of ***N-Hydroxysuccinimide*** (HOSu) with ***Trichloromethyl Chloroformate*** (TCF, $Cl_3COCOCl$) or using trimethylsilylated *N*-hydroxysuccinimide and phosgene, both giving DSC in good yield (eq 1).[1]

Handling, Storage, and Precautions: moisture sensitive; stable under refrigeration; irritant.

Active Ester Preparation in Peptide Chemistry.

Eq 2 shows the method for activating acids for subsequent reaction with amines, to give peptide bonds.[1]

(2)

Di(N-succinimidyl) Oxalate (DSO) has also been used as an alternative to DSC in the preparation of esters.[8]

Carbamate Preparation.

DSC reacts with primary and secondary amines to give carbamates (eq 3),[4] in which the carbonyl group is activated by the electron withdrawal of the succinimidyl group. Further attack by the amino groups on the carbonyl of such active carbamates gives ureas. Such carbamates produced by DSC have been used in the preparation of chiral derivatizing agents for amino compounds[6] and in the preparation of nucleoside analogs.[7]

(3)

β-Eliminations.

β-Elimination of the hydroxy group of *N*-protected β-hydroxy-α-amino acids has been effected using DSC and ***Triethylamine***.[2] Reaction of Z-threonine with equimolar DSC/Et_3N in acetonitrile gave exclusively the (*Z*)-isomer of Z-DBut-OMe (eq 4). Similarly, use of a 1:2 molar ratio of DSC gave the (*Z*)-isomer of Boc-DBut-OSuc, which on treatment with the methyl ester of alanine gave Z-DBut-Ala-OMe (eq 5).

(4)

(5)

Carbonyl Insertions.

DSC has been used as a replacement for ***Phosgene*** in the cyclization of *N*-aralkyl α-amino acids to *N*-carboxyanhydrides (eq 6).[9] This method releases *N*-hydroxysuccinimide as a byproduct, which is only weakly acidic and so does not affect any acid sensitive groups, whereas phosgene releases 2 equiv of hydrogen chloride. Unlike in ester formation using carboxylates, where the central carbonyl group of DSC is released as CO_2, with better nucleophiles, such as secondary α-amino functions, incorporation of the carbonyl group occurs. This is assumed to be by *N*-substitution by R-CO-, followed by intramolecular anhydride formation by tertiary amine. Similar carbonyl insertions by ***N,N´-Carbonyldiimidazole*** (CDI) to give heterocycles[10,11] leads to racemization. Use of DSC as a carbonyl insertion reagent has led to its use in the preparation of ureas and various heterocycles.[3] Reaction with amines (to give ureas), 1,2-diamines (to give cyclic ureas), 1,2-aminothiols (to give cyclic thiocarbamates), and 1,2-hydroxyamines have all been observed. One simple example is the action of DSC on cyclohexylamine to give dicyclohexylurea. A series of (thio)carbamates used as muscle relaxants have also been prepared, e.g. chloroxazone (5-chloro-2-hydroxybenzoxazole) (eq 7). 3-(Benzoxazolyl, benzimidazolyl)pyrazole derivatives have also been made using DSC in MeCN.

Di(*N*-succinimidyl) Oxalate

[57296-03-4] · $C_{10}H_8N_2O_8$ · Di(*N*-succinimidyl) Oxalate · (MW 284.20)

(forms active ester with *N*-protected amino acids for peptide synthesis,[1] succinimide/glutarimide synthesis,[7] as activated carriers for analysis, enzyme immobilization, and chromatographic chiral stationary phases preparation;[8] curing agent in photographic sensitive materials[9])

Alternate Name: DSO.

Physical Data: mp 245-247 °C (dec).

Solubility: acetonitrile (5 g/100 mL suspension).

Form Supplied in: solid; 85-98%+, dependent on supplier.

Handling, Storage, and Precautions: moisture sensitive; irritating to eyes, respiratory system, and skin; harmful by inhalation, in contact with skin, and if swallowed.

Peptide Synthesis.[1]

Unlike ***N-Hydroxysuccinimide***, *N*-protected amino acids can be reacted directly with DSO to produce an ester and either gaseous or water-soluble byproducts. The ester can then be used to form peptides (Scheme 1).

Scheme 1

This reagent is part of a family of oxalates, all of which give similarly high yields.[1] They are more convenient than the standard ***1,3-Dicyclohexylcarbodiimide*** coupling method for active ester and peptide syntheses. They are also more economical than the related compounds ***N,N´-Disuccinimidyl Carbonate***[2] and *N*-succinimidyl diphenyl phosphate,[3] which have been used previously as active ester and peptide synthesis reagents.

Succinimide and Glutarimide Synthesis.

Conventional glutarimide syntheses proceed via the dehydration of either glutaric acids[4] or ammonium glutarates,[5] or by the pyrolysis of bisglutarimides.[6] All these methods give poor yields (10-40%), although corresponding succinimide syntheses do work better.[7] The use of DSO, however, provides a more general route to these and other cyclic systems and the yields are typically around 80% (eq 1).[7]

Disulfur Dichloride

ClS-SCl

[10025-67-9] · Cl_2S_2 · Disulfur Dichloride · (MW 135.04)

(synthesis of thioketones and thioaldehydes from hydrazones;[1] synthesis of dithiazoles[2] and episulfides[3])

Alternate Name: sulfur monochloride.

Physical Data: mp -77 °C; bp 138 °C; *d* 1.688 g cm^{-3}; n_D^{20} 1.6700.

Solubility: sol benzene, ether; readily sol CS_2.

Form Supplied in: golden yellow, oily liquid; pungent odor; fumes in moist air; impure sample can be reddish orange due to SCl_2; commercially available.

Purification: distillation of 500 g from 20 g of sulfur and 5 g of charcoal; fraction from 135 to 137 °C is collected.

Handling, Storage, and Precautions: refrigerate in dark bottle; air and moisture sensitive; incompatible with acids, bases, alcohols, and amines. Avoid contact with metals; harmful if swallowed; inhalation may be fatal. Use in a fume hood.

Synthesis of Thioketones and Thioaldehydes.

Based on the resulting tautomers from a synthesis of hindered *N*-thiosulfinylanilines (Ar-N=S=S) from anilines (eq 1),[4] a synthesis for thioketones and thioaldehydes has been worked out from hydrazone derivatives and S_2Cl_2.[5]

(1)

Hydrazone derivatives are treated with S_2Cl_2 to produce an *N*-thiosulfinylamine which undergoes cyclization, followed by molecular extrusion of N_2 (g) to give an *S*-thioxothioketone. The *S*-thioxothioketones ($R_2C{=}S{=}S$) are not isolable, as they decompose to the thioketones and sulfur (eq 2).[2,6] The yield of 2,2,4,4-tetramethylthiopentanone is the isolated yield; spectra showed near quantitative conversion.

(2)

2,4,6-Tri-*t*-butylthiobenzaldehyde was the first stable thiobenzaldehyde synthesized. It was prepared from the corresponding hydrazone in 40% yield using S_2Cl_2 in the presence of ***Triethylamine*** (eq 3). In the absence of oxygen, no decomposition was observed after 1 year at rt in the solid phase. In the presence of air, it is quantitatively converted to 2,4,6-tri-*t*-butylbenzaldehyde.[7]

(3)

Synthesis of Dithiazoles.

Treatment of unsaturated oxime derivatives with disulfur dichloride in the presence of Hünig's base gives high yields of cyclopenta-1,2,3-dithiazoles (eq 4).[3] Treatment of saturated oximes such as cyclopentanone oxime gives unsaturated, perchlorinated dithiazoles (eq 5) in significantly reduced yield.

(4)

(5)

Episulfides from Alkenes.

Disulfur dichloride adds to alkenes to form β-chloroalkyl mono-, di-, and trisulfides. The monosulfides, however, cannot be converted into episulfides. Their production is minimized by the addition of dichloropolysulfanes, S_xCl_2. The β-chloroalkyl sulfides are then reduced with ***Aluminum Amalgam*** or ***Sodium Sulfide*** to the episulfide (eq 6).[3b]

(6)

Miscellaneous.

Disulfur dichloride can also be used to synthesize *N*,*N*-dithiobissulfoximines,[7] to synthesize macrocyclic, polysulfur compounds,[8] and is part of an extremely powerful chlorinating agent for perchlorination of

aromatic systems (see also ***Aluminum Chloride*** and ***Sulfuryl Chloride***).[9] It is also a reagent for the synthesis of aranotins, a small group of sulfur-bridged diketopiperazines,[10] and it was tried in conjunction with sulfur dichloride for one-step episulfide synthesis.[11]

1,3-Dithiane[1]

[505-23-7] · $C_4H_8S_2$ · 1,3-Dithiane · (MW 120.26)

(functional group equivalent; umpolung; C-C bond formation)

Physical Data: mp 53-54 °C; fp 90 °C; bp 207-208 °C/760 mmHg, 60-62 °C/12 mmHg.

Solubility: very sol C_6H_6, ether, $CHCl_3$, THF; slightly sol H_2O.

Form Supplied in: slightly yellow needles; hygroscopic.

Analysis of Reagent Purity: mp, as well as by visual inspection; freshly sublimed reagent is snow white.

Purification: sublimes 45-48 °C (bath temp)/0.1-0.5 mmHg; recryst MeOH (0.5 g mL^{-1}).

Handling, Storage, and Precautions: IPR-MUS LD_{50}: 1500 mg/kg; RTECS No. J05070000. May be harmful by inhalation, ingestion, or skin absorption; may cause irritation; exposure can cause nausea, headache, and vomiting; toxicological properties have not been thoroughly investigated. Stench! Use in a well ventilated fume hood.

Synthesis of 1,3-Dithianes.

The standard procedure to prepare 1,3-dithianes involves the Lewis-acid catalyzed derivatization of aldehydes or acetals with ***1,3-Propanedithiol***[1c,2-4] or with a derivative of the dithiol with an oxophile.[5,6] The use of ketones,[3] acids,[7] or methyl ethers[8] as starting material has been reported. As an alternative, the thioacetal formation can be initiated by a Brønsted acid, e.g. the clay montmorillonite KSF.[9] Also, the reaction of 1,3-propanedithiol with *gem*-diiodoalkanes catalyzed by $Ph_2PCH_2PPh_2/Pt^{2+}$ gives access to 1,3-dithianes,[10] as does a double Michael addition reaction sequence on 2-ynone derivatives.[11]

1,3-Dithianes as Functional Group Equivalents.

R_2CO.

The use of the 1,3-dithiane functionality as a protecting group for a ketone or aldehyde (**1**) has been recognized for some time (Scheme 1).[3,4] The good stability of this dithioacetal and its compatibility with a wide variety of reagents are an advantage in this respect. There is a plethora of conditions reported in the literature for unmasking the carbonyl function,[1,4,12-14] spanning from oxidative,[15] alkylative,[16] and photochemical[17] to metal-catalyzed procedures.[18]

Scheme 1

R_2CH_2.

Reduction of 1,3-dithianes to the corresponding alkane (**2**) is a well-established transformation.[14b]

R_2CF_2.

gem-Difluoro compounds (**3**) can be prepared from ketones and aldehydes via the corresponding 1,3-dithiane in good yield.[19] In combination with the potential of 1,3-dithianes for reactivity umpolung, this sequence represents an interesting access to the CF_2^{2-} synthon.

1,3-Dithianes in Carbon-Carbon Bond Formation.

In addition to the exploitation of its metallated derivative as a versatile reagent for C-C bond formation (see ***2-Lithio-1,3-dithiane***), 1,3-dithianes have been used in transition metal-catalyzed alkenations to give (**4**) and *gem*-dialkylations to yield (**5**).[20] Amino pyridines and anilines can be *ortho*-formylated on treatment with 1,3-dithiane in the presence of pivaloyl chloride (***Trimethylacetyl Chloride***) and then base to give (**6**).[21,22] Another option in this category is to use the reagent's cationic counterpart (**7**), which reacts with enol ethers to give 1,3- or 1,5-dicarbonyl arrangements (see ***2-Chloro-1,3-dithiane***).[23]

1,3-Dithianes in Reactivity Umpolung.

The singular most important aspect in 1,3-dithiane chemistry is its use as a carbonyl equivalent which provides umpolung of the normal pattern of reactivity, e.g. acyl anion (**8**) chemistry.[1,24] A comprehensive view of this facet of the 1,3-dithiane reagent is covered under ***2-Lithio-1,3-dithiane***.

Related Reagents.

Bis(phenylthio)methane; ***Methoxy(phenylthio)methane***.

1,4-Dithiothreitol[1]

[27565-41-9] · $C_4H_{10}O_2S_2$ · 1,4-Dithiothreitol · (MW 154.28)

(reducing agent for disulfides;[1,2] protection of thiols and proteins containing free SH groups from air oxidation[3])

Alternate Names: DTT; *threo*-2,3-dihydroxybutane-1,4-dithiol.

Physical Data: mp 42-44 °C (racemate); redox potential -0.33 V, pH 7, varying -0.06 V per pH unit; p*K* 9.2 and 10.1.

Solubility: very sol water, alcohols.

Form Supplied in: white solid; widely available; normally supplied as the racemate, but chiral 1,4-dithio-L-threitol [*16096-97-2*],[4] mp 49-51 °C, is also available. The *erythro* isomer (1,4-dithioerythritol, DTE, [*6892-68-8*], mp 82-84 °C)[1] has redox properties similar to the *threo* isomer (*E*°´ is more positive by 0.004 V)[5] and is also available. The oxidized cyclic form (*trans*-1,2-dithiane-4,5-diol [*14193-38-5*], mp 130-132 °C)[1] is available; it has a UV spectrum (λ_{max} 283 nm; ε = 273). DTT and DTE are colorless above 260 nm, but both reduced and oxidized forms absorb below 240 nm.

Analysis of Reagent Purity: the presence of monothiols can be detected by addition of arsenite (which forms a tight tridentate complex with DTT),[6] followed by addition of 5,5´-dithiobis(2-nitrobenzoate).[7] Total thiol content is determined by omitting arsenite.

Handling, Storage, and Precautions: solid material should be stored under refrigeration in a closed bottle. Solutions will slowly oxidize in the presence of air to the cyclic disulfide, which is inert. The concentration of reduced material can be determined by assay with 5,5´-dithiobis(2-nitrobenzoate).[8]

Reduction of Disulfides.

DTT and DTE are the reagents of choice for reducing disulfide bonds, and protecting thiols and the thiol groups on proteins from air oxidation to disulfides.[1-3] DTT also reduces diselenides.[9] The equilibrium constant for reduction of

the disulfide of glutathione by DTT is 210 M.[10] DTT undergoes disulfide interchange to liberate the thiol with the lowest pK (eq 1). The mixed disulfide then cyclizes rapidly, releasing the other monothiol (eq 2).

The high equilibrium constant for this cyclization reaction produces the low redox potential for DTT. The hydroxy groups at C-2 and C-3 convey water solubility and reduce the stench (the solid has an odor, but only at very close range). Since the active form for disulfide interchange is the thiolate anion, these reactions go faster at higher pH. With the first p*K* at 9.2, however, there is sufficient thiolate even at pH 7 to give a reasonable rate.

The rates of reduction of disulfides by DTT show a normal dependence on the p*K* of the thiol being liberated,[11] and this fact has been used to determine the p*K*'s of SH groups on proteins. For example, the p*K* of the active site cysteine in papain was 4.1 at pH 6 and 8.4 at pH 9, with the change resulting from a group titrating with a p*K* of 7.5.[11b] The equation used in this work was: $\log k = 7.03 + 0.5\ pK_{nuc} - 0.27\ pK_c - 0.73\ pK_{1g}$, where k is the rate constant in $M^{-1}\ min^{-1}$ for reaction of the monoanion of DTT with the disulfide, and the subscripts nuc, c, and 1g refer to DTT, the center sulfur in the transition state, and the leaving thiol on the protein.

A series of other dithiols have been prepared as potential reducing agents, but none of them that are water soluble have lower redox potentials than DTT.[10,12] Two that have lower p*K*'s (7.6-7.8) and thus react faster at neutral pH have higher redox potentials of -0.27 V at pH 7 and are less effective reducing agents than DTT.[13] So far, none of these is commercially available.

Reagent for Studies of Protein Folding.

DTT and its oxidized form have found use in studying disulfide interchange reactions during protein folding and unfolding.[14] Mixtures of these provide a redox buffer that can be adjusted to match the redox potential of individual disulfide bonds.

Other Properties and Problems.

The low redox potential of dithiothreitol interferes with its use in the presence of certain reagents. While it gives full color yield in reactions with aromatic disulfides such as 5,5´-dithiobis(2-nitrobenzoate)[8] or 2,2´- or 4,4´-dipyridyl disulfide,[15] it gives only 4% the expected color in the nitroprusside assay for thiols,[1,16] presumably because it reduces the iron. It reduces Cr^{III} or Co^{III}, so inert complexes of nucleotides with these metal ions cannot be used in its presence. Dithiothreitol also undergoes transesterification with thioesters of coenzyme A.[17]

DTT and DTE chelate heavy metal ions tightly, which can be helpful at times, but deleterious with autooxidizable ions such as Fe^{II}. While they oxidize only slowly in air in the absence of heavy metal ions, DTT and DTE are readily oxidized in air in the presence of Fe^{II}, so solutions containing Fe^{II} and DTT must be kept anaerobic.[18]

Di-*p*-tolylcarbodiimide

[726-42-1] · $C_{15}H_{14}N_2$ · Di-*p*-tolylcarbodiimide · (MW 222.31)

(synthesis of nitrogen heterocycles)

Physical Data: bp 221-223 °C/20 mmHg, 114 °C/0.02 mmHg; mp 56-58 °C.

Solubility: sol diethyl ether, benzene, pyridine, *t*-butanol.

Form Supplied in: off-white crystalline solid.

Preparative Methods: although di-*p*-tolylcarbodiimide is commercially available, it is quite expensive. It can be conveniently prepared from di-*p*-tolylthiourea by oxidation with ***Mercury(II) Oxide***,[1] ***Triphenylphosphine*** in the presence of ***Diethyl Azodicarboxylate***,[2] or with mercury(II) benzamide.[3] A synthetic method dimerizing *p*-tolyl isocyanate has been reported.[4]

Purification: recrystallizations from diethyl ether and other solvents have been reported.[1]

Handling, Storage, and Precautions: harmful by inhalation, ingestion, or skin absorption and exposure causes strong eye and lung irritation. The solid is light- and moisture-sensitive and should be stored refrigerated in dark, well-sealed containers under an inert atmosphere. It should be used in a fume hood.

Heterocycle Synthesis.

Di-*p*-tolylcarbodiimide is a potent electrophile which reacts with a wide variety of nucleophiles to yield formamidine derivatives substituted at the central carbon. This reactivity has been exploited to prepare a large number of nitrogen heterocycles. Treatment of di-*p*-tolylcarbodiimide (**1**) with ethyl allophanate, for example, results in the formation of 2-substituted quinazolin-4(3*H*)-ones (eq 1).[5] β-Lactams can also be prepared by the reaction of carbodiimides with α-halo esters in a Reformatsky-type reaction (eq 2).[6]

(1)

(2)

The reaction of (**1**) with thiazolium ylides related to thiamine has been extensively studied by Takimazawa and co-workers. They have found that, depending upon reaction conditions and the substrate used, a wide variety of thiamine-annulated heterocycles can be prepared (eq 3).[7]

(3)

Treatment of (**1**) with amidrazones in MeCN at 80-90 °C yields 5-tolylamino-1,2,4-triazoles in good yields.[8] Similarly, Molina and co-workers have found that (**1**) reacts with a variety of *N*-amino heterocycles to yield triazoles from *N*-amino-2-thioxo-4-imidazolidinones (eq 4),[9] ring annulated [1,2,4]triazolo[4,3-*b*]triazoles from [1,2,4]triazoles,[10] and [1,2,4] triazolo[5,1-*c*][1,2,4]triazines from 3,4-diamino[1,2,4]triazine.[11] Related additions have also been reported for thiadiazolines.[12]

(4)

Other Reactions with Nucleophiles.

Di-*p*-tolylcarbodiimide reacts with sulfonic acids to afford the corresponding sulfonic anhydride (and di-*p*-tolylurea).[13] Treatment of (**1**) with an alcohol in the presence of base yields the corresponding *N,N´*-di-*p*-tolyl-*O*-alkyl pseudourea ethers. These ethers decompose in the presence of mono- and disubstituted hydrogen phosphates to afford tertiary phosphates in high yields (eq 5).[14] A variation of this methodology has been widely applied for the preparation of nucleoside phosphites.[15]

(5)

Other Reactions.

Di-*p*-tolylcarbodiimide is reduced with ***Sodium Borohydride*** in isopropanol to afford formamidines in good yields.[16] Diarylcarbodiimides have been found to help carboxylate active methylene compounds such as fluorene, where the diimide acts as model for biotin.[17]

Divinyl Ketone

[1890-28-4] · C_5H_6O · Divinyl Ketone · (MW 82.11)

(highly reactive, easily polymerized, polyfunctional annulation reagent; generally reacts by adding nucleophiles, dienes or radicals)

Alternate Name: 1,4-pentadien-3-one.

Physical Data: bp 38-40 °C/65 mmHg, 30 °C/16 mmHg.

Solubility: sol most common solvents.

Form Supplied in: unstable; prepare immediately before use as described below.

Preparative Methods: the title reagent has been prepared from the precursors listed in Table 1. For example, dehydrohalogenation of 1,5-dihalo-3-pentanones may be effected by distillation from anhydrous ***Sodium Carbonate*** (35-80%)[1] or from ***Quinoline*** (95%).[2] Under milder conditions (1.1 equiv Na_2CO_3 and lower temperature) the dichloro ketone gave 5-chloro-1-penten-3-one (37-80%).[1c,3] The dihalo ketone precursors are usually prepared by Friedel-Crafts acylation of ***Ethylene***,[1c,4] or from the methyl β-halopropionate via a novel titanium-catalyzed ethyl Grignard addition, followed by ***N-Bromosuccinimide*** oxidation of the resulting cyclopropanol.[1b] The Mannich base precursors in Table 1 have been prepared from 1-methyl-4-piperidone (**1**) by conversion to its *N*-methyl iodide salt,[5] by reaction of this salt with dimethylamine,[6] or by reaction of (**1**) with ***p-Toluenesulfonyl Chloride*** and amines.[7] These reagents are normally used for in situ generation of divinyl ketone.

Table 1 Divinyl Ketone Precursors

[a] Dihydrochloride salt, mp 191 192 °C. [b] Hydrochloride salt, mp 164 167 °C.

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: brief storage in solution (ether or hydrocarbon) at low temperature due to ease of polymerization. A toxic, flammable, lachrymatory liquid which must be used with care. As a dialkylating agent, it may be mutagenic. Wastes may be disposed of by treatment with ammonium hydroxide. Use in a fume hood.

Substituted Divinyl Ketones.

Since the late 1970s, a large number of substituted divinyl ketones (**2**) have been prepared, many as substrates for the Nazarov reaction.[8] Tables 2 and 3 list a few simple methyl-, phenyl-, silyl-, and halogen-substituted examples. Other examples have been cataloged.[9-20]

General Synthetic Methods.

A variety of synthetic methods have been applied to the preparation of substituted divinyl ketones. Among the most general and effective of these are: (a) acylation of alkenyl silanes,[9] stannanes,[10] and cuprates[11] with α,β-unsaturated acyl chlorides; (b) transition metal-catalyzed carbonylation of alkenyl stannanes[12] and mercurials;[13] (c) formation of dialkenyl secondary carbinols by organometallic addition to aldehydes, followed by oxidation with ***Chromic Acid***,[14] ***Dimethyl Sulfoxide***,[15] ***Manganese Dioxide***,[16] ***Nickel(II) Peroxide***,[17] or ***Barium Manganate***;[17b,18] (d) palladium-catalyzed coupling of metallated methoxyallenes with alkenyl halides (eq 1);[19] and (e) orthoester alkylation of trimethylsilyloxydienes,[20a] followed by β-elimination.

(1)

Many less general, but potentially useful, procedures have been reported. These include: (f) α,α´-dibromination of ketone acetals, followed by dehydrohalogenation and acetal hydrolysis;[21] (g) retro-ene reaction of substituted vinylcyclopropane derivatives (eq 2);[22] (h) pyrolysis of norbornenyl precursors;[23] and (i) isomerization of alkynones to dienones.[24]

(2)

Reactions of Divinyl Ketones.

As noted above, many divinyl ketones have been used as substrates for the Nazarov cyclization.[8] In addition, the polyfunctional nature of these compounds makes them versatile participants in a variety of other reactions.

Conjugate Addition of Heteronucleophiles.

Tetrahydro-4*H*-pyran-4-one,[4b,25] and its sulfur and selenium analogs,[1b,5,26] may be prepared by nucleophilic addition (or substitution) to divinyl ketone (or 1,5-dichloro-3-pentanone). Similar reactions have been used in synthetic approaches to alkaloids related to catharanthine[15b] and emetine[6b] (eq 3). In the latter example, subsequent Mannich alkylations culminate in bonding to four of the five carbon atoms in divinyl ketone.

Michael Addition of Carbon Nucleophiles.

The umpolung aldehyde intermediates generated by thiazolium salt catalysis have been used by Stetter et al. to prepare polyketones (eq 4).[1c,27] Carboannulations may be effected by sequential Michael reactions[28] or a combination of Michael and aldol reactions.[3] However, attempts to generate the tricyclo[5.3.1.0^{3,8}]undecane ring system by three sequential Michael reactions between divinyl ketone and cyclohexenone enolate failed.[29] The desired assembly was eventually achieved by an initial Diels-Alder cycloaddition, followed by a Michael reaction (eq 5),[2] and provided the foundation of a synthesis of seychellene.[2] A similar case, employing acid catalysis in the cycloaddition step, was interpreted as a threefold sequence of Michael reactions.[30]

Cycloadditions.

Unsaturated ketones are excellent dienophiles. An interesting study of sequential Diels-Alder reactions of conjugated tetraenes with dialkenyl ketones to give tricyclic products has been reported.[23a] Dimethylhydrazone derivatives of divinyl ketone react with strong dienophiles to give heterocyclic products.[31]

Other Reactions.

Addition of carbon radicals to divinyl ketone may yield useful polyfunctional products (eq 6).[32] 1,2-Carbonyl addition reactions are best accomplished with precursors (Table 1). In this manner, cross-conjugated allenes were prepared by ***Lithium Acetylide*** addition to 1,5-dichloro-3-pentanone, followed by organocuprate substitution.[33]

Divinyl Sulfone

[77-77-0] · $C_4H_6O_2S$ · Divinyl Sulfone · (MW 118.17)

(bifunctional Michael acceptor that gives six-membered ring heterocycles with primary amines[1] or analogous reagents;[2] furnishes γ-diketones in the reaction with aldehydes and a thiazolium salt (Stetter reaction);[3] reasonably powerful dienophile[4])

Physical Data: bp 233-234 °C; bp 90-92 °C/8mmHg; mp ca. -26 °C; *d* 1.177 g cm^{-3}.

Form Supplied in: colorless liquid; commonly stabilized with hydroquinone; widely available.

Preparative Methods: by dehydration of bis-β-hydroxyethyl sulfone with phosphoric acid at 280 °C or by pyrolysis of bis-β-acetoxyethyl sulfone at 500 °C.[5]

Handling, Storage, and Precautions: toxic, corrosive liquid; vesicant and mild lachrymator; to be handled with care; use in a fume hood.

Addition Reactions.

The two vinyl groups of the title reagent are activated towards nucleophilic additions, but they react also with electrophiles and radicals. Among the electrophilic additions is the reaction with aromatic diazonium salts (eq 1),[6] while for supposed radical additions, the reaction of ketene alkyl trimethylsilyl acetals promoted by ***Titanium(IV) Chloride*** is representative (eq 2).[7] The product of the latter reaction depends upon the substitution pattern at the α-carbon.

$$p\text{-}ClC_6H_4N_2 + (CH_2{=}CH)_2SO_2 \xrightarrow[\substack{CuCl_2,\ rt \\ 23\%}]{Me_2CO} (p\text{-}ClC_6H_4CH_2CHCl)_2SO_2 \quad (1)$$

(2)

Other nucleophilic additions include reactions with primary amines (eq 3),[1] phosphines (eq 4),[2] and sodium peroxide (eq 5).[8]

(3)

(4)

(5)

Of synthetic relevance is the Stetter reaction,[3] which provides a general route to polyfurans, polypyrroles, and polythiophenes,[9] as represented in eq 6 for a terpyrrole.[9b]

(6)

Cycloadditions.

Divinyl sulfone has been shown to react as both a dienophile and a dipolarophile. Examples of [4 + 2] cycloaddition[10] include the reaction with cyclopentadiene (eq 7)[4] and indole-2,3-quinodimethane (eq 8).[10a] In the former reaction the monoadduct can be isolated and reacted with another diene, while in the latter the first addition is followed by elimination of CO_2 and $CH_2{=}CHSO_2H$, with direct formation of the aromatic carbazole. Dipolar cycloadditions are represented in eqs 9 and 10.[11] In the latter example the 1,3-dipolar cycloaddition is preceded by a Michael addition.

(7)

(8)

(9)

(10)

Cycloaddition reactions of divinyl sulfone with benzyne (eq 11)[12a] and cobalt complexes of alkynes (eq 12)[12b] are also known.

Dodecacarbonyltetrarhodium[1]

$Rh_4(CO)_{12}$

[19584-30-6] · $C_{12}O_{12}Rh_4$ · Dodecacarbonyltetrarhodium · (MW 747.76)

(catalyst for hydrogenation, hydroformylation, silylformylation, hydroboration, aldol reactions)

Physical Data: mp 150 °C (dec);[2] IR (nujol) 2089, 2079, 2056, 2043, 2035, 1875 cm^{-1}.[3]

Solubility: sol hexane, benzene, toluene, acetone, dichloromethane.

Form Supplied in: dark red crystalline solid; commercially available.

Preparative Method: prepared from ***Tetracarbonyl(di-μ-chloro)dirhodium***[4]

Handling, Storage, and Precautions: air sensitive; should be handled under nitrogen or argon; water sensitive (decomposes to $Rh_6(CO)_{16}$ in the presence of water); heat sensitive; store in refrigerator under carbon monoxide. Use in a fume hood.

Catalytic Hydrogenation.

$Rh_4(CO)_{12}$, either in solution or bound to alumina, is an effective catalyst for the hydrogenation of alkenes to alkanes[5] in good yield. Asymmetric hydrogenations with enantioselectivities up to 70% have also been achieved by using $Rh_4(CO)_{12}$ in combination with chiral phosphines such as (**1**) and (**2**).[6]

(1)

(2)

Hydroformylation.

Alkenes are hydroformylated to aldehydes under mild conditions using $Rh_4(CO)_{12}$ as the catalyst,[7] while alkynes react under water-gas shift conditions to give furan-2(5*H*)-ones (eq 1) as a mixture of isomers when unsymmetrical alkynes are used.[8] Both mono- and disubstituted alkynes have also been found to undergo cross-hydroformylation with ethylene to give exclusively *trans*-α,β-unsaturated ketones in good yield.[9]

Silylformylation and Hydrosilylation.

The addition of trialkylsilanes and carbon monoxide across the carbon-carbon triple bond of alkynes (silylformylation) is catalyzed by $Rh_4(CO)_{12}$. β-Silylacrylaldehydes are formed in good yield with a high degree of stereocontrol for the (*Z*) isomer (eq 2) (see also ***Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide***).[10] In the presence of a base such as ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) and the highly hindered silane *t*-butyldimethylsilane, propargyl alcohols[11] and propargyl amines[12] can be cyclized to α-silylmethylene-β-lactones and lactams (eq 3; Z = O, NR^3) in good yield. The addition of hydrosilanes across the double bond of alkenes is also catalyzed by $Rh_4(CO)_{12}$.[13]

Preparation of (*Z*)-Allylic Boronates.

1,3-Dienes undergo hydroboration with ***Catecholborane*** in the presence of $Rh_4(CO)_{12}$ to give, exclusively, (*Z*)-allylic boronates in good yield.[14] These compounds react with aldehydes to give *erythro*-alcohols (eq 4).

Crossed Aldol Reactions with Enol Trimethylsilyl Ethers.

Crossed aldol reactions of enol trimethylsilyl ethers and aldehydes and ketones occur rapidly in the presence of a catalytic amount of $Rh_4(CO)_{12}$ to give β-trimethylsiloxyalkanones (eq 5), while the reaction of enol trimethylsilyl ethers with acetals yields β-methoxy ketones.[15]

Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide

$Rh_4(CO)_{12}$-$HSiMe_2Ph$-CO

($Rh_4(CO)_{12}$)

[19584-30-6] · $C_{12}O_{12}Rh_4$ · Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide · (MW 747.76) ($HSiMe_2Ph$)

[766-77-8] · $C_8H_{12}Si$ · Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide · (MW 136.29) (CO)

[630-08-0] · CO · Dodecacarbonyltetrarhodium-Dimethyl(phenyl)silane-Carbon Monoxide · (MW 28.01)

(silylformylation of alkynes,[1] aldehydes,[8] and oxiranes;[11] siloxymethylenation of enamines[10])

Physical Data: $Rh_4(CO)_{12}$: decomposes to $Rh_6(CO)_{16}$ at 130-140 °C under N_2. $HSiMe_2Ph$: bp 157 °C/744 mmHg; n_D^{20} 1.4995; d_4^{20} 0.889 g cm^{-3}.

Solubility: $Rh_4(CO)_{12}$: readily sol CH_2Cl_2, $CHCl_3$; sol THF, acetone, toluene, pentane; less sol MeOH, cyclohexane.

Form Supplied in: $Rh_4(CO)_{12}$: dark red when crystalline; orange when powdered. $HSiMe_2Ph$: colorless oil.

Purification: $Rh_4(CO)_{12}$: a typical impurity is a trace amount of $Rh_6(CO)_{16}$. A $Rh_6(CO)_{16}$-free product can be obtained by extraction, under CO with pentane, followed by crystallization at -70 °C, filtration at this temperature, and drying in a stream of CO.

Handling, Storage, and Precautions: $Rh_4(CO)_{12}$: stable in air, although on prolonged standing decomposition occurs; best stored under a CO atmosphere.

Silylformylation.

Silylformylation of alkynes with ***Dimethyl(phenyl)silane*** and ***Carbon Monoxide*** leading to β-silylacrylaldehydes is catalyzed by ***Dodecacarbonyltetrarhodium/Triethylamine*** (eq 1).[1] $Co_2Rh_2(CO)_{12}$[2] and ***Dirhodium(II) Tetrakis(perfluorobutyrate)***[3] are also effective for the silylformylation of alkynes. The reaction has been applied to the

formation of β-lactones from propargyl alcohols (eq 2).[4] The products in the reaction of propargyl amines depend on the nature of substituents on nitrogen (eqs 3 and 4).[5] The $Rh_4(CO)_{12}$/$HSiMe_2Ph$/CO combination acts on a diyne to afford a bicyclic ketone (eq 5).[6] Rh-catalyzed silylformylation of alkynes has also been applied to the synthesis of pyrrolizidine alkaloids.[7]

Di-μ-chlorobis(1,5-cyclooctadiene)dirhodium(I) is also an active catalyst for silylformylation of aldehydes, leading to α-siloxy aldehydes under mild reaction conditions (eq 6).[8] Hydrosilanes such as $HSiEt_3$ and $HSiPh_3$ are not effective reagents for Rh-catalyzed silylformylation of aldehydes and $HSiEt_3$ was recovered intact.

$[RhCl(CO)_2]_2$/$HSiEt_2Me$/CO.

This similar reaction system has been found to be effective for the incorporation of CO into the α-carbon atom of enamines to give α-(siloxymethylene)amines, which can be easily converted into α-siloxy ketones by hydrolysis (eq 7).[9] The system has also been utilized for the incorporation of CO into *N*,*N*-acetals (eq 8).[10] Ring-opening silylformylation of oxiranes is also catalyzed by ***Tetracarbonyl(di-μ-chloro)dirhodium*** (eq 9).[11] The use of $HSiMe_2Ph$ as the hydrosilane gives a higher product yield than with $HSiEt_2Me$.

Dodecacarbonyltriiron[1]

$Fe_3(CO)_{12}$

[17658-52-8] · $C_{12}Fe_3O_{12}$ · Dodecacarbonyltriiron · (MW 503.67)

(reduces $ArNO_2$ to $ArNH_2$;[1c,5,6] alkyne cyclotrimerization catalyst;[1d,1e,7] isomerizes alkenes;[1f,8] desulfurizes episulfides[1c,9])

Physical Data: mp 140 °C dec.[1]

Solubility: partially sol organic solvents.

Form Supplied in: black air-sensitive solid, stabilized with ~10% methanol which can be removed by leaving on a vacuum pump at 25 °C for at least 5 h.[2]

Analysis of Reagent Purity: IR, ^{13}C NMR.[3]

Purification: sublimation at 70 °C/0.1 mmHg.[1b]

Handling, Storage, and Precautions: store under an inert atmosphere in a freezer; old samples may ignite spontaneously upon exposure to air; emits acrid smoke and fumes when heated to decomposition.[1b,4] Use in a fume hood.

Reduction of Aromatic Nitro Groups to Amines.[1c]

Methanolic solutions of dodecacarbonyltriiron reduce aromatic nitro groups to primary aromatic amines while leaving a variety of functional groups unaffected (Table 1).[5a] Dienes are not reduced by this reagent, but do form a complex with an iron tricarbonyl fragment. These reactions occur under conditions which produce the hydridodecacarbonyltriferrate anion [$HFe_3(CO)_{11}^-$], which is probably the active reducing agent.

Table 1 Reduction of Aromatic Nitro Groups with Methanolic Dodecacarbonyltriion

R	Yield $ArNH_2$ (%)
H	77
p-Cl	86
o-Cl	83
m-NH_2	95
p-NH_2	63
p-OMe	84
p-OH	38
m-OH	66
p-NHCOMe	77

Imines are also reduced in reasonable to good yields under the same conditions. Interestingly, the reagent will reduce phthalazine selectively to 1,2-dihydrophthalazine, constituting one of a few methods to accomplish this selective transformation (eq 1).[5b]

(1)

A number of improvements have been made to the original dodecacarbonyltriiron reduction. A significant rate acceleration was accomplished under phase-transfer conditions in which hydroxide rather than methanol is responsible for the formation of hydridodecacarbonyltriferrate anion (Table 2).[6a] In a similar manner, use of ***18-Crown-6*** in conjunction with 1 N ***Potassium Hydroxide*** in a two-phase reaction medium also leads to short reaction times and good yields of aromatic amines.[6b] A very convenient method for performing these reductions involves stirring the aromatic substrate in hexane solution overnight with dodecacarbonyltriiron adsorbed on basic alumina. Yields obtained from this procedure are good, conditions are significantly milder than the homogeneous reaction, and the workup is quite simple.[6c]

Table 2 Reduction of Aromatic Nitro Groups with Dodecacarbonyltriiron under Phase Transfer Conditions

R	Time (h)	Yield $ArNH_2$ (%)
Me	2.0	85
OMe	2.0	92
Cl	0.75	88
COMe	2.0	60

Alkyne Cyclotrimerization.[1d,1e]

Dodecacarbonyltriiron has been reported to catalyze the cyclotrimerization of alkynes, forming substituted benzenes. For example, ***Diphenylacetylene*** forms hexaphenylbenzene upon heating with dodecacarbonyltriiron in a sealed tube (eq 2).[7a,7b] Hexacyclopropylbenzene has also been prepared in this manner from dicyclopropylacetylene in 20% yield with 2,3,4,5-tetracyclopropylcyclopentadienone being formed in ~30% yield as the major byproduct (eq 2).[7c] In fact, cyclopentadienones can be obtained using this reagent and they may be used as precursors to substituted benzenes (eq 3).[7b,7c]

(2)

Alkene Isomerization.[1f]

Many metal carbonyl complexes are known to isomerize alkenes, often giving thermodynamic mixtures of alkene isomers. Usually unconjugated dienes are brought into conjugation.[1f] This latter property has been exploited in the isomerization of the cyclopentene double bond of prostaglandin precursors. The free diene is obtained upon oxidation with excess Collins reagent (***Dipyridine Chromium(VI) Oxide***) (eq 4).[8a]

(4)

More recently, it has been shown that dodecacarbonyltriiron will photochemically catalyze the isomerization of allyl alcohols to ketones or aldehydes and allyl ethers and acetates to the corresponding enol ethers and acetates (eqs 5-8).[8b] These isomerization reactions apparently involve a π-allyl-iron hydride intermediate.[8c] The inaccessibility of the allylic hydrogen may account for the *exo*-alcohol's relative inertness to the reagent (eq 8).[8b]

(5)

(6)

(7)

(8)

Episulfide Desulfurization.[1c]

Episulfides are stereospecifically desulfurized by dodecacarbonyltriiron. Thus when heated at reflux in benzene with dodecacarbonyltriiron, *cis*- and *trans*-2-butene episulfide form *cis*- and *trans*-2-butene in 95:5 and 3:97 ratios, respectively.[9]

Related Reagents.

Octacarbonyldicobalt; ***Pentacarbonyliron***.

p-Dodecylbenzenesulfonyl Azide

[79791-38-1; 119652-78-7] · $C_{18}H_{29}N_3O_2S$ · *p*-Dodecylbenzenesulfonyl Azide · (MW 351.57)

(diazo-transfer reagent for activated methylene groups[1])

Alternate Name: *p*-DBSA.

Physical Data: liquid mixture of isomers without precise mp or bp.

Solubility: sol pentane, acetone, and most organic solvents.

Form Supplied in: viscous liquid.

Analysis of Reagent Purity: elemental analysis (C, H, N, S) and HPLC.

Preparative Method: prepared by addition of granular ***Sodium Azide*** (1.3 equiv) to a mixture of isomeric sulfonyl chlorides (from a commercial mixture of isomers of *p*-dodecylbenzenesulfonic acid) in acetone solution.[1]

Purification: elution through short column containing silica gel G with methylene chloride-hexane (1:4) as eluant.[1]

Handling, Storage, and Precautions: is the safest of the usual arenesulfonyl azides (tosyl azide, etc.) employed in diazo-transfer processes;[1] appropriate care should be taken, as with all azides. Use in a fume hood.

Reagent for Diazo-Function Transfer.

The title reagent has been called a safer diazo-transfer reagent, and is a mixture of 12 or more isomeric *p*-dodecylbenzenesulfonyl azides, ranging by HPLC from 24% to 1% in area and giving essentially a single spot

by TLC.[1]

The title reagent has been shown to be very useful for the synthesis of various crystalline diazocarbonyl compounds such as diazobarbituric and diazoisopropylidenemalonic acids,[1] derivatives and homologs of diazoacetoacetic acid,[1,2] and 9-diazoanthrone (eq 1).[1]

(1)

Formation of noncrystalline byproduct dodecylsulfonamides facilitates the workup procedure and isolation of the target crystalline diazo compounds from the reaction mixture.[1]

Vinyldiazomethanes containing two electron-withdrawing groups are readily available using *p*-DBSA in the presence of ***Triethylamine*** (eq 2).[3]

(2)

The process seems to be nonstereospecific. From a mixture of diethyl *cis*- and *trans*-glutaconates, exclusively the *trans*-diazo compound was isolated in high yield, indicating that equilibration occurs under the reaction conditions.[3]

The reagent is also effective in the case of allyl methyl ketone, which has a less acidic methylene group than the previous substrate (eq 3).[4]

(3)

The reaction is complete in a few minutes but a stronger base, ***1,8-Diazabicyclo[5.4.0]undec-7-ene***, is required

for initial anion formation.

Electrochemical Methods

Electrochemical methods have a long history in organic chemistry dating back (1849!) to the original Kolbe electrolytic dimerization of carboxylic acids. Unfortunately, most organic chemists have considered this an esoteric area as far as synthetic applications are concerned, even though useful selectivity principles have been delineated in considerable detail, and a large number of synthetic applications have been published. Economic advantages of electrochemical methods, in spite of the commercialization of the Monsanto process for the hydrodimerization of acrylonitrile, have not been fully appreciated. Publication of several highly readable books and articles that deal with experimental procedures and listing of equipment suppliers should prompt organic chemists to consider electrochemical methods in synthesis. A list of such references that deal with the practical aspects of electrochemical synthetic methods is given below.[1-9]

(1*R*,2*S*)-Ephedrine

[299-42-3] · $C_{10}H_{15}NO$ · (1*R*,2*S*)-Ephedrine · (MW 165.23)

(chiral auxiliary for the following: diastereoselective alkylation and reduction of chiral hydrazones; diastereoselective alkylation of chiral amides; diastereoselective conjugate addition of organometallic reagents to unsaturated amides and imidazolidinones; diastereoselective alkylation and cyclopropanation of oxazepinediones and oxazolidines; diastereoselective homoaldol addition of *N*-allylimidazolidinone, and asymmetric coupling reaction of Grignard reagents; chiral ligand for enantioselective conjugate addition of organometallic reagents to enones; chiral ligand for enantioselective addition of dialkylzincs to aldehydes)

Alternate Name: [*R*-(*R**,*S**)]-α-[1-(Methylamino)ethyl]benzenemethanol

Physical Data: mp 37-39 °C; bp 255 °C; [α]21D -41° (*c* 5, 1M HCl). Hydrochloride, mp 216-220 °C; [α]20D -34° (*c* 4, H_2O).

Solubility: sol alcohol, chloroform, ether, water.

Form Supplied in: waxy solid or crystals; also available as hydrochloride in either enantiomeric form.

General Features of Ephedrine.

Ephedrine is a chiral β-amino alcohol which is available in either enantiomeric form. It is often utilized as a chiral auxiliary in asymmetric synthesis. Via bond formation with the amino group of ephedrine, ephedrine can be derived into chiral hydrazones[2,3] and amides.[5,6] Highly diastereoselective asymmetric reactions are known using these chiral compounds. In reactions using organometallic reagents, the hydroxy groups of hydrazones and amides become metal alkoxides. Metal atoms of the alkoxide may chelate with nitrogen or oxygen atoms of chiral hydrazones and amides. This chelation may reduce the number of possible conformations of reactive species, and this may increase the diastereoselectivities.

On the other hand, by bond formation with amino and hydroxy groups of ephedrine, ephedrine can be converted into chiral ring systems such as imidazolidinones,[12,13] oxazepinediones,[14-18] and oxazolidines.[20,21] Diastereoselective reactions of derivatives of these chiral ring systems afford compounds with high de. The relatively rigid conformation of these ring systems is one of the reasons for high diastereoselectivities.

(1R,2S)-Ephedrine

Ephedrine becomes a chiral ligand of metal atoms by the deprotonation of the hydroxy group and by the presence of the nitrogen atom.[22-26] Highly enantioselective asymmetric reactions are known using chiral ephedrine-type ligands.

In addition, ephedrine is a chiral base catalyst because of the presence of the amine group.[29-32] A highly enantioselective base-catalyzed reaction is known.

Diastereoselective Alkylation and Reduction of Chiral Hydrazones Derived from Ephedrine.[2]

Methylmagnesium Bromide adds to the chiral hydrazone derived from *N*-aminoephedrine and benzaldehyde to afford the optically active chiral hydrazine in almost 100% de. Hydrogenolysis of the chiral hydrazine gives (*R*)-α-phenylethylamine with more than 97% ee (eq 1). Ephedrine is recovered in good yield and without any loss of optical purity.

On the other hand, the diastereoselective reduction of the chiral hydrazone derived from *N*-aminoephedrine and acetophenone and subsequent hydrogenolysis affords (*S*)-α-phenylethylamine with 30% ee.[3] Optically active α-phenylethylamine with high ee is obtained from the diastereoselective alkylation of chiral hydrazones derived from (*R*)- or (*S*)-1-amino-2-(methoxymethyl)pyrrolidine.[4a]

Diastereoselective Alkylation of Chiral Amides Derived from Ephedrine.

Chiral amides derived from ephedrine are converted to the corresponding dianion. The subsequent diastereoselective alkylation with alkyl iodides affords chiral α-substituted amides with >90% de.[5] Acid hydrolysis affords optically active α-substituted acids with 78% ee as a result of racemization in the cleavage step (eq 2).

(1R,2S)-Ephedrine

On the other hand, treatment with ***Methyllithium*** affords optically active methyl ketone in 44-74% ee, also as a result of racemization. α-Chiral ketones with higher ee (99% ee) are obtained from the diastereoselective alkylation of chiral hydrazones derived from (*R*)- or (*S*)-1-amino-2-methoxymethylproline.[4b]

Diastereoselective Conjugate Addition of Organometallic Reagents to Chiral α,β-Unsaturated Amides and Imidazolidinones Derived from Ephedrine.

Grignard reagents (2 equiv) add to chiral α,β-unsaturated amides derived from ephedrine in a 1,4-addition manner with high diastereoselectivities. Subsequent acidic hydrolysis affords optically active β-substituted carboxylic acids with 85-99% ee (eq 3).[6]

A seven-membered chelate intermediate is one of the reasons for the very high diastereoselectivities. The method is successfully applied to the asymmetric synthesis of malingolide.[7] Similar results are obtained in diastereoselective conjugate addition of Grignard reagents to unsaturated amides derived from (*S*)-2-(1-hydroxy-1-

methylethyl)pyrrolidine. The presence of a tertiary amine (e.g. ***1,8-Diazabicyclo[5.4.0]undec-7-ene***) increases the diastereoselectivity, and subsequent hydrolysis affords β-substituted carboxylic acids with up to 100% ee.[8] Conjugate additions of alkyllithium or Grignard reagents to chiral *N*-crotonoylproline,[9] imides,[10] and *N*-enoyl sultams[11] also afford β-substituted carboxylic acids with 60% ee, 96% ee, and 96% ee, respectively.

The chiral imidazolidinone[12] derived from urea and ephedrine hydrochloride is utilized in a diastereoselective conjugate methylation.[13] Subsequent hydrolysis affords optically pure (-)-citronellic acid (eq 4).

(4)

Diastereoselective Conjugate Additions to Chiral Oxazepinediones Derived from Ephedrine.

Ephedrine can form a chiral seven-membered relatively rigid oxazepinedione ring by condensation with malonic acid monoester. Alkylidene derivatives of chiral oxazepinediones undergo highly diastereoselective additions with nucleophilic reagents. Grignard reagents in the presence of a catalytic amount of ***Nickel(II) Chloride*** add to chiral alkylideneoxazepinediones. Acid hydrolysis affords optically active β-substituted acids with up to >99% ee (eq 5).[14] The method is applied to the diastereoselective synthesis of (-)-indolmycin with 93% ee.[15]

(1R,2S)-Ephedrine

(5)

Diastereoselective addition of sulfonium ylides affords enantiomerically pure cyclopropanedicarboxylic acid diesters after removal of the chiral auxiliary (eq 6).[16]

(6)

Diastereoselective addition of ***Phenylthiomethyllithium*** and subsequent treatment affords optically active lactones with >90% ee (eq 7).[17]

(1R,2S)-Ephedrine

(7)

In addition, a chiral oxazepinedione plays the role of a nucleophile in the reaction with nitroalkenes in the presence of ***Potassium t-Butoxide*** and crown ether (eq 8).[18]

(8)

Homoaldol Addition with Chiral *N*-Allylimidazolidinone Derived from Ephedrine.

The chiral allyltitanium compound derived from ephedrine reacts with carbonyl compounds with very high (>200:1) de. Subsequent hydrolysis and oxidation affords optically pure 4-substituted γ-lactones (eq 9).[12] 4-Substituted γ-lactones with 92% ee can also be synthesized by catalytic enantioselective alkylation of 3-formyl esters.[19]

(1R,2S)-Ephedrine

Diastereoselective Cyclopropanation and Alkylation of Chiral Oxazolidines Derived from Ephedrine.

Ephedrine forms oxazolidines upon reaction with aldehydes. Chiral unsaturated oxazolidines derived from ephedrine and unsaturated aldehydes are treated with diazomethane in the presence of ***Palladium(II) Acetate***. Hydrolysis of the oxazolidine ring affords optically active formylcyclopropanes with >90% ee (eq 10).[20]

Diastereoselective addition of cuprate reagents to unsaturated oxazolidines and subsequent hydrolysis affords 3-substituted aldehydes with up to 81% ee (eq 11).[21]

Asymmetric Coupling Reactions of Chiral Grignard Reagents Derived from Ephedrine Derivatives.

Asymmetric coupling reactions of ***Allyl Bromide*** and chiral Grignard reagents derived from ephedrine methyl ether in the presence of ***Copper(I) Iodide*** (10 mol %) followed by oxidation affords optically active homoallyl alcohols with 60% ee (eq 12).[22]

(12)

Enantioselective Conjugate Addition to Prochiral Enones of Organometallic Reagents Modified with Ephedrine.

Enantioselective conjugate addition to 2-cyclohexenone with chiral organo(alkoxo)cuprates [MCu(OR*)R] has been studied.[1a] When the cuprate is prepared from the lithium alkoxide of ephedrine, ***Phenyllithium***, and CuI, 3-phenylcyclohexanone with 50% ee is obtained.[23] The enantioselectivity reaches 92% ee in enantioselective ethylation when a chiral diamino alcohol derived from ephedrine is employed (eq 13).[24]

(1R,2S)-Ephedrine

(13)

On the other hand, enantioselective conjugate addition to 2-cyclohexenone with lithium dibutylcuprates (having a noncovalently bound chiral phosphorus ligand derived from ephedrine) affords 3-butylcyclohexanone with up to 76% ee (eq 14).[25]

(14)

Isopropylmagnesium chloride adds to 2-cyclohexenone in 17% ee in the presence of a catalytic amount of chiral alkoxyzinc chloride derived from ephedrine and ***Zinc Chloride*** (eq 15).[26]

(15)

Concerning the catalytic enantioselective conjugate addition reaction, conjugate addition of dialkylzinc to chalcone in

the presence of a catalytic amount of the chiral nickel complex derived from norephedrine affords β-substituted ketones with up to 90% ee (eq 16).[27]

(16)

Enantioselective Addition of Dialkylzincs to Aldehydes Using Chiral Amino Alcohols Derived from Ephedrine.

Nucleophilic addition of dialkylzinc to aldehydes is usually very slow. Amino alcohols facilitate the addition of ***Diethylzinc*** to benzaldehyde to afford 1-phenylpropanol.[1b,28] When chiral amino alcohols possessing the appropriate structure are used as a precatalyst, optically active secondary alcohols are obtained.[1b] Highly enantioselective chiral catalysts derived from ephedrine are known. (1*R*,2*S*)-*N*-Isopropylephedrine functions as a precatalyst for the enantioselective addition of diethylzinc to benzaldehyde to afford (*R*)-1-phenylpropanol with 80% ee in 72% yield.[29] The use of an excess amount of diethylzinc increases the enantioselectivity up to 97% ee (eq 17).[30]

(17)

The lithium salt of (1*R*,2*S*)-*N*-[2-(dimethylamino)ethyl]ephedrine acts as a precatalyst for the addition of diethylzinc to afford the alcohol with 90% ee (eq 18).[31]

(18)

The dilithium salt of a chiral diaminodiol derived from ephedrine mediates the enantioselective addition of dialkylzinc to aldehydes to afford (*R*)-1-phenylethanol with 85% ee (eq 19).[32]

(1R,2S)-Ephedrine

Ephedrine-borane[1]

[126874-38-2] · $C_{10}H_{14}BNO$ · Ephedrine-borane · (MW 175.04)

(chiral Lewis acid catalyst for carbonyl additions, reductions, and hydroborations[1])

Alternate Name: (4*S*,5*R*)-3,4-dimethyl-5-phenyl-1,3,2-oxazaborolidine.

Physical Data: [2,4] colorless liquid, bp 110-112 °C/20 mmHg, 45 °C (bath)/0.1 mmHg; [α]20D = -108° (*c* 1.0 $CHCl_3$). For the corresponding reagent prepared from pseudoephedrine (1*S*,2*S*), [α]20D = +59° (*c* 1.0 $CHCl_3$). Spectral data:[2a,3,4] ^{1}H NMR selected data δ ($CDCl_3$) 3.68 (m), 5.58 (d, *J* = 8.5 Hz); ^{1}H NMR δ (C_6D_6) 0.43 (d, *J* = 6.6 Hz), 2.50 (s), 3.28 (m), 5.41 (d, *J* = 8.6 Hz); ^{11}B NMR δ +29 ppm (d, *J* = 147 Hz); ^{13}C NMR δ (C_6D_6) 15.42, 30.25, 59.62, 83.58, 126.59, 127.32, 128.13, 140.02; IR_{B-H} 2562 cm^{-1}. For the corresponding reagent from pseudoephedrine (1*S*,2*S*): ^{1}H NMR selected data δ ($CDCl_3$) 3.30 (m), 4.90 (d, *J* = 7.0 Hz).

Solubility: sol THF.

Form Supplied in: not commercially available.

Preparative Methods: [2] a solution of (1*R*,2*S*)-(-)-ephedrine (8.25 g, 50 mmol) in anhydrous THF (50 ml) was treated with ***Borane-Dimethyl Sulfide*** complex (50 mmol, 5 mL of 10 M solution). The reaction mixture was stirred at 25 °C for 1 h, at which time one equivalent of hydrogen had evolved. The volatiles were removed in vacuo to furnish a white solid, ^{11}B NMR (δ ~8 ppm). The solid was gradually heated to 100 °C and maintained at that temperature until the second equivalent of hydrogen had evolved. The product was distilled under reduced pressure to provide the pure oxazaborolidine (86%). An alternative procedure is available.[3]

Handling, Storage, and Precautions: the reagent is sensitive to moisture and should be handled under a dry, inert atmosphere.

Enantioselective Addition of Diethylzinc to Aldehydes.

The reagent catalyzes the enantioselective addition of ***Diethylzinc*** to aldehydes (eq 1).[2]

Enantioselective Alkene Hydroboration.

Substituted styrene derivatives undergo rhodium-catalyzed hydroboration in the presence of a catalytic amount of the title reagent. However, optimal regio- as well as enantioselection is attained by using the corresponding reagent derived from pseudoephedrine (eq 2).[4]

If the *N*-isopropyl analog of the borane reagent is used in conjunction with bis(4-methoxystyrene)rhodium chloride dimer as catalyst, the corresponding (*E*)-vinylborane and 4-methoxyethylbenzene are obtained in equal proportions (eq 3).[5]

Enantioselective Carbonyl Reduction.

The title reagent reacts with borane through N->B coordination. This complexation enhances the Lewis acidity at the ring boron atom, thereby triggering dimerization of the adduct via hydride bridging.[6] This complex is capable of reducing acetophenone with good enantioselectivity (eq 4). The proposed reactive complex features *anti* coordination of acetophenone to the ring boron atom and *syn* to the coordinated BH_3.[7]

Several other 1,3,2-oxazaborolidines have been successfully used as chiral catalysts or reagents in borane-promoted reduction of ketones,[8] imines and oxime ethers,[9] and lactones[10] as well as in aldol condensations,[11] Diels-Alder cycloadditions,[12] and allylmetal additions to aldehydes.[13]

Related Reagents.

α,α-Diphenyl-2-pyrrolidinemethanol; ***Norephedrine-Borane***; ***Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c][1,3,2]oxazaborole***.

Epichlorohydrin[1]

[106-89-8] · C_3H_5ClO · Epichlorohydrin · (MW 92.53) (*R*)

[51594-55-9] (*S*)

[67843-74-7]

(readily available three-carbon unit functionalized on every carbon; convenient HCl or HBr trap; linker for various polymers)

Alternate Name: chloromethyloxirane.

Physical Data: mp -57 °C; bp 115-117 °C; *d* 1.183 g cm^{-3}.

Solubility: 6.6 wt% in water; sol alcohol, acetone, THF, toluene, *n*-heptane.

Form Supplied in: neat liquid; both enantiomers available.

Handling, Storage, and Precautions: should only be handled in a well ventilated fume hood because of its low permissible exposure limit of 2 ppm and reports of allergic skin reactions and lung, liver, and kidney damage. MSDSs are available from the two principal manufacturers (Dow and Shell). The material is not moisture or air sensitive.

Introduction.

Epichlorohydrin (**1**) is most widely used in polymer synthesis.[2] Other common uses include an in situ trapping agent for HCl, HBr,[3] or the alcohol generated during formation of Meerwein's reagent (eq 1).[4]

Reactions with Nucleophiles.

The epoxide is, by far, the more reactive site and a wide variety of nucleophiles have been used (eq 2) to open the ring at C-3 such as HCl (96%),[5] HOAc (>50%),[6] H_2S (65% as cyclized product 3-thietanol),[7] HCN (66%),[8] ethanol (90%),[9] *t*-butanol (86%),[10] phenyl or benzyl thiol (99% or 93%, respectively),[11] and phenyl selenide (generated in situ from the diselenide and sodium hydroxymethyl sulfite) (>55%).[12] If desired, the epoxide is easily formed from the chlorohydrin by treatment with excess KOH or Et_3N.

The epoxide is also opened at C-3 by various electrophilic reagents that fit into the generalized scheme in eq 3. Examples include ***Chlorotrimethylsilane*** (TMSCl) (85%),[13] TMSCl/NaBr (X = Br) (85%),[14] ***Cyanotrimethylsilane*** (91%),[15] ***Azidotrimethylsilane*** (83%),[16] ***Thionyl Chloride*** (70%),[17] H_2NCOCl (96%),[18] and MeCH=CHCOCl (80%).[19] The only report of unusual selectivity for opening the epoxide at C-2 was for ***Sulfuryl Chloride*** (eq 4).[20]

A number of special catalysts have been developed to facilitate ring opening and improve the regioselectivity for reaction at C-3. For example, Sn^{II} halides are useful in preparations of (**2**) (X = Cl, 70%; X = Br, 63%; X = I, 90%).[21] An equimolar mixture of ***Lithium Bromide*** and ***Copper(II) Bromide*** gave (**2**) (X = Br, 93%).[22] The ring can be opened selectively by anilines in the presence of other amines when ***Cobalt(II) Chloride*** is the catalyst.[23] $MgSO_4$ was found to catalyze the addition of 2 mol of CN^- to (**1**) to afford 3-hydroxyglutaronitrile.[24] CaF_2 supported on KF was used in the conversion of (**1**) to epifluorohydrin.[25] A catalyst composed of a 1:2 mole ratio of ***Di-n-butyltin Oxide***

and tributyl phosphate was developed for ring opening by alcohols.[26] Other catalysts shown to be of value for the examples given above include $FeCl_3$,[6] $LiClO_4$,[11] Et_3N,[11] CAN,[9] DDQ,[10] Ti(O-*i*-Pr)$_4$,[15b] $CoCl_2$,[13,19] $YbCl_3$,[15a] and Al(O-*i*-Pr)$_3$.[16]

A variety of carbon nucleophiles react at C-3 with high regioselectivity. Examples include Grignard reagents,[27] aryllithium,[28] alkynyllithium,[29] and others (eqs 5-8).[30-33]

(5)

(6)

(7)

(8)

Compound (**1**) can be chain extended by one carbon by a Co-catalyzed CO insertion followed by reduction (eq 9).[34] A whole class of medicinally important compounds called β-blockers are prepared from (**1**) as illustrated in eq 10 for the synthesis of a propranolol analog.[35]

(9)

(10)

Preparation of Heterocycles.

A wide array of heterocycles are available from (**1**). A few examples are shown in eqs 11-16).[36-41]

(11)

(12)

(13)

(14)

(15)

(16)

In some cases the reaction rate and yield are dramatically improved if the product can be trapped as the TMS ether (eq 17).[42] Also, (**1**) lends itself well to nucleophilic opening under phase transfer conditions (eq 18).[43]

(17)

(18)

The ready availability[44] of both enantiomers of (**1**) has greatly enhanced its value as a synthetic intermediate. The pheromone (*S*)-(-)-ipsenol (**2**), prepared[45] in 16% overall yield in four steps from (*R*)-(**1**), is just one of many examples of this utility. In practice, either isomer can sometimes be used by adjusting the order of addition of the groups at C-1 and C-3. The synthesis of (-)-anisomycin (**3**) illustrates this point.[46]

(2) (*S*)-(-)-Ipsenol

(3) (-)-Anisomycin

Erbium(III) Chloride[1]

$ErCl_3.6H_2O$

[10138-41-7] · Cl_3Er · Erbium(III) Chloride · (MW 381.73) (.$6H_2O$)

[10025-75-9]

(mild Lewis acid for selective acetalization;[2] used with $NaBH_4$ as a selective reducing agent;[3] catalyst for Friedel-Crafts-type reactions;[4] forms enolates from α-bromo ketones[5] and oxyallyl cations[6] from α,α´-dibromo ketones)

Physical Data: mp 774 °C; bp 1500 °C; *d* 4.1 g cm^{-3}.

Solubility: sol H_2O, methanol, ethanol; slightly sol 2-propanol, THF.

Form Supplied in: pink crystals, deliquescent. *Drying:* anhydrous erbium chloride is prepared from the hydrate by reflux in ***Thionyl Chloride***, or heating to 400 °C in the presence of a two-fold excess of ammonium chloride in a vacuum with intense mixing.

Handling, Storage, and Precautions: anhydrous $ErCl_3$ should be used after drying without delay. Erbium exhibits an oral toxicity of LD_{50} in rats 6.7 g kg^{-1}.

Selective Acetalization.

Erbium trichloride is an efficient catalyst for acetalization.[2] In methanol solution, $ErCl_3$ rapidly promotes an equilibrium between aldehydes and their acetals which is shifted to completion by the addition of trimethyl orthoformate as a water scavenger. High yields are obtained after short reaction times at room temperature with most substrates (eqs 1-3).

$$C_7H_{15}CHO \xrightarrow[\text{MeOH, rt}]{\substack{ErCl_3 \cdot 6H_2O \\ HC(OMe)_3}} C_7H_{15}CH(OMe)_2 \qquad (1)$$

10 min
100%

(2)

(3)

Acetalization of ketones is more difficult.[3] As a rule, conjugated ketones (i.e. aromatic and α,β-unsaturated) do not react (eq 4), but cycloalkanones give excellent yields (eq 5). The reaction is sensitive to steric hindrance, permitting selective reactions with dicarbonyl substrates (eq 6).

(4)

(5)

(6)

Selective Reductions of Carbonyl Compounds.

$ErCl_3$ induces regiospecific reduction of α,β-unsaturated ketones to allylic alcohols in the presence of ***Sodium Borohydride*** in a fashion similar to ***Cerium(III) Chloride***. The major use of $ErCl_3$ involves the selective reduction of dicarbonyl compounds which is based on the in situ acetalization of the more reactive carbonyl group by methanol.[3,7] The unprotected, less reactive group is thus reduced. The acetal need not necessarily be isolated, and the overall process can thus be run in one pot (eqs 7 and 8).

(7)

(8)

In aqueous ethanol the hydrate or hemiacetal rather than the acetal is formed, and these derivatives function as transient protecting groups. The deprotection step can thus be avoided, making the overall process shorter.[8,9]

Friedel-Crafts Alkylation Catalyst.

Benzyl halides react with benzene in the presence of catalytic amounts (0.3 equiv) of a series of lanthanide (including erbium) chlorides.[4] Yields of ~60% are obtained after 18 h at 75 °C. In this procedure the catalyst is easily recovered and reused (eq 9). Double alkylation is observed in the reaction of acetyl chloride and benzaldehyde in benzene or toluene (eq 10).[10] Chloromethylation has been reported using chloromethyl methyl ether.[10]

$$PhCH_2Cl + PhH \xrightarrow[\text{75 °C, 18 h; 63\%}]{ErCl_3} PhCH_2Ph \qquad (9)$$

Erbium Enolates from α-Bromo ketones.

α-Bromo ketones, treated with lanthanide chlorides and ***Sodium Iodide*** or ***Tin(II) Chloride***, yield the corresponding enolates which undergo cross-aldol reaction upon addition of a carbonyl compound.[5] $ErCl_3$-$SnCl_2$ gives a 76% yield of the aldol product (eq 11), lower than that obtained with La or Ce, but the stereoselectivity is higher.

Oxyallyl Cations from α,α´-Dibromo Ketones.

With lanthanide chlorides, including erbium, and $SnCl_2$, α,α´-dibromo ketones furnish oxyallyl cations, which can be trapped with various dienes.[6] The corresponding [3 + 2] cycloadducts are isolated in good yield (eq 12) although comparable or better yields are obtained with the corresponding cerium salt.

Esterases

(enzymes of the class of hydrolases, which catalyze the hydrolysis of carboxylic acid esters[1])

Solubility: insol cold and warm H_2O.

Form Supplied in: available from various sources (microorganisms and mammalian) as powders or water suspensions.

Handling, Storage, and Precautions: stable at a pH range 6-10; can be stored at 0-4 °C for months.

Esterase-Catalyzed Hydrolysis.

Hydrolytic enzymes have been accepted in organic synthesis as valuable biocatalysts, since they are commercially available at relatively low price and possess a broad substrate specificity, without necessitating use of expensive cofactors.[2] Esterases are such useful enzymes and have been widely used for the preparation of enantiomerically pure chiral compounds, by hydrolytic resolution of racemic esters or asymmetrization of prochiral substrates.[3] Well defined experimental procedures for a pig liver esterase-catalyzed saponification have been documented.[4] Generally, the enzymatic hydrolysis is carried out in an aqueous buffer, sometimes containing cosolvents,[5] at pH 7-9 and keeping the temperature at 20-25 °C. Generally, the molar equivalent NaOH for the hydrolysis is added maintaining the pH constant with an automatic titrator and, after acidification, the product is extracted with organic solvents. Esterases are commercially available from various sources, either microbial or mammalian, and in some instances also crude acetone powders can be used for the same purpose.

Pig Liver Esterase (PLE).

This is the more used carboxylesterase (carboxylic-ester hydrolase, EC 3.1.1.1, *CAS 9016-18-6*) which physiologically catalyzes the hydrolysis of carboxylic acid esters to the free acid anion and alcohol.[1] PLE is a serine hydrolase which has been widely used for the preparation of chiral synthons and these applications have been fully reviewed.[6] An active-site model for interpreting and predicting the specificity of the enzyme has been published.[7] In the pioneering studies of the enzyme applications field, PLE was used for the chiral synthesis of mevalonolactone.[8] Prochiral 3-substituted glutaric acid diesters are well suited for a PLE-catalyzed asymmetrization, which leads to optically active monoesters (eq 1).[9]

(1)

The asymmetrization of prochiral disubstituted malonates has been enantioselectively realized in the presence of PLE (eq 2).[10]

(2)

The asymmetric hydrolysis of several cyclic *meso*-diesters has been accomplished and optically pure monoesters have been obtained.[11] A classical example is the hydrolysis of dimethyl *cis*-4-cyclohexene-1,2-dicarboxylate, which affords the corresponding nearly optically pure half ester, a versatile synthon for various chiral cyclohexane derivatives (eq 3).[12]

(3)

The PLE-catalyzed asymmetric hydrolysis of *meso*-1,3-*cis*-3,5-*cis*-1,3-diacetoxy-5-benzyloxycyclohexane afforded (1*S*,3*S*,5*R*)-1-acetoxy-5-benzyloxycyclohexan-3-ol, which could be used as chiral building block for the synthesis of the compactin lactone moiety and quinic acid (eq 4).[13]

(4)

Organometallic *meso*-diesters can be asymmetrized as well to the corresponding half ester, as shown for an (arene)tricarbonylchromium diester (eq 5).[14]

(5)

The resolution of racemic esters is catalyzed by PLE in a highly enantioselective fashion.[3,6] Several interesting applications of this method are available. The hydrolysis of *trans*-bicyclo[2.2.1]heptane diesters has been studied to ascertain the structural requirements for the PLE hydrolysis.[15] A bulky tricyclodecadienone ester can be resolved by an highly enantioselective reaction (eq 6).[16]

(6)

The resolution procedure applies to racemic organometallic esters[17] and to the esters of a thianucleoside, for the preparation of pure enantiomers of an antiviral agent (2´,3´-dideoxy-5-fluoro-3´-thiacytidine) (eq 7).[18]

PLE has usually been applied to the enantioselective preparation of optically active compounds, but its use can be extended to chemo- or regioselective hydrolyses. A continuous process for the separation of a *cis*/*trans* unsaturated ester was realized using immobilized PLE (eq 8).[19]

The chemoselective hydrolysis of an acetoxy group in the presence of a γ-lactone ring has been reported in the presence of PLE (eq 9).[20] In a benzylpenicillin, PLE catalyzes the chemoselective hydrolytic opening of the β-lactam ring, the methoxycarbonyl moiety remaining uneffected (eq 10).[21]

(9)

(10)

Dimethyl malate presents two ester functions α and β with respect to a hydroxy group, and PLE is able to regioselectively discriminate between these two moieties.[22]

Acetone Powder Containing Esterase Activity.

The main advantage in using crude homogenates or acetone powders of organs such as liver is to have a cheap source of different enzymes. If one of these is desired for a specific substrate, the crude enzymatic mixture can be used with some advantage, compared to the purified enzymes. Pig liver acetone powder (PLAP), together with other extracts, is commercially available or can be prepared from fresh pig liver.[23] PLAP has been used for the enantioselective hydrolysis of the racemic acetate of *trans*-2-phenylcyclohexanol (eq 11).[24]

(11)

The acetates of 1-arylalkan-1-ols were successfully resolved by acetone powders (PLAP and goat liver acetone powder, GLAP) containing esterase activity (eq 12).[25]

(12)

An interesting application of the esterase activity of horse liver acetone powder (HLE) has been the enantioselective hydrolysis of racemic lactones. The powder proved to be more effective than PLE in this hydrolysis, from which the unreacted lactone was recovered with high enantiomeric excess. The process seems more effective for δ and medium size lactones (eq 13).[26]

(13)

R = Pr; $n = 1$	72% ee
R = C_5H_{11}; $n = 2$	78% ee

R = Me; $n = 6$	>95% ee

Cholesterol Esterase.

This enzyme (EC 3.1.1.13; *CAS 9026-00-0*) physiologically catalyzes the hydrolysis of cholesterol esters, monoacylglycerols, and vitamin esters.[27] It has also been used for several cyclic and noncyclic substrates with variable enantioselectivity.[28] The resolution of racemic esters has been reported[29] and an interesting example is the application to the racemic acetate of an hemiacetal (eq 14).[30]

(14)

(±) (-) >97% ee

Acyl Cholinesterases.

Acetylcholinesterase (AChE; EC 3.1.1.7; *CAS 9000-81-1*) is the serine esterase which catalyzes the hydrolysis of acetylcholine and possesses an esteratic site,[31] and which is responsible for unspecific hydrolyses of several substrates. Also, butyrylcholinesterase (EC 3.1.1.8; *CAS 9001-08-5*) has been sometimes used for asymmetric hydrolysis of esters.[32] Acetylcholinesterase has been used for the hydrolysis of noncyclic substrates and the results have shown satisfactory enantioselectivity.[32a,33] The enzyme from electric eel seems especially well suited to the hydrolysis of cyclic diols.[34] The asymmetrization of *cis*-3,5-diacetoxycyclopent-1-ene to (3*R*)-acetoxy-(5*S*)-hydroxycyclopent-1-ene (eq 15)[35] and the preparation of an optically active triol monoacetate starting from the triacetate of 1,3,6-trihydroxycyclohept-4-ene (eq 16)[36] are good examples of successful reactions catalyzed by acetylcholinesterase.

(15)

(16)

Other Esterases.

Other less common esterases have been sometimes used for biocatalytic applications in organic synthesis.[37] The enzymatic approach can be the method of choice for the preparation of optically pure drugs, although sometimes special enzymes have to be prepared for this aim. By cloning a carboxylesterase into a microorganism, high level production of the esterase is made possible for the production of 2-(aryloxy)propionates and (*S*)-naproxen.[38] The esterase activity of rabbit plasma has been used for a chemoselective hydrolysis of a methylthiomethyl ester.[39] An esterase from *Candida lypolitica* has been used for the resolution of a tertiary α-substituted carboxylic acid ester.[40] Recently, a carboxyl esterase of molecular weight 30 000 (Esterase 30 000) has been introduced for the asymmetric hydrolysis of diesters. A cyclopropyl malonate has been hydrolyzed by the esterase and the unreacted diester was recovered nearly optically pure (eq 17).[41] Diethyl 3-hydroxyglutarate, a substrate which is asymmetrized with modest enantioselectivity with PLE or other enzymes,[9e,f] has been enantioselectively hydrolyzed in the presence of Esterase 30 000 (eq 18).[42]

1,2-Ethanedithiol[1]

[540-63-6] · $C_2H_6S_2$ · 1,2-Ethanedithiol · (MW 94.20)

(1,3-dithiolane formation; ether cleavage; reduction (carbonyl to methylene; sulfoxide to thioether); *gem*-difluoride formation; dithiolenium ion formation)

Physical Data: d 1.123 g cm^{-3} (23.5 °C); bp 146 °C/760 mmHg; 63 °C/46 mmHg.

Solubility: slightly sol water; miscible with many organic solvents.

Form Supplied in: widely available.

Handling, Storage, and Precautions: stench! Inhalation can cause chest pain, headache, nausea, pulmonary edema; LD_{50} (oral, mouse) 342 mg kg^{-1}; see ***1,3-Propanedithiol***. Use in a fume hood.

1,3-Dithiolane Formation.

1,2-Ethanedithiol (**1**) condenses with aldehydes, ketones, and acetals to afford 1,3-dithiolanes,[1,2] useful for carbonyl protection (eqs 1 and 2).[3a,b] Stability, condensation selectivity, and conditions for carbonyl regeneration parallel those discussed for ***1,3-Propanedithiol***.[4] Esters and lactones can be protected as ketene dithioacetals and/or dithioortholactones, resistant to nucleophilic attack, using the bis(dimethylalanyl) derivative of (**1**).[5]

(1)

(2)

Ether Cleavage.

An acetonide can be cleaved in the presence of a nearby *t*-butyldiphenylsilyl ether with (**1**).[6a] Under more vigorous conditions, aliphatic methyl ethers are cleaved (eq 3).[6b]

(3)

Reduction.

Raney Nickel desulfurization of 1,3-dithiolanes effects overall reduction of C=O to CH_2, as does ***Sodium-Ammonia*** in THF (eqs 4 and 5).[7a,b] Na/hydrazine is an alternative reagent (eq 6).[10a] Peptidic sulfoxides are reduced to thioethers with (**1**) and an electrophilic catalyst.[11a]

(4)

(5)

(6)

(resolved)

gem-Difluoride Formation.

1,3-Dithiolanes yield geminal difluorides on treatment with ***Pyridinium Poly(hydrogen fluoride)*** and a mild oxidant (eq 7).[8a,b] 1,3-Dithianes react more slowly and give lower yields.[8a]

(7)

Dithiolenium Ion Formation.

Acid chlorides, anhydrides, esters, and orthoesters, upon treatment with (**1**) and a Lewis acid, can produce electrophilic 1,3-dithiolenium cations which react with a variety of carbon nucleophiles.[9] Selective indole formylation in the presence of a primary carboxamide could thus be achieved (eq 8).[9a]

(8)

Miscellaneous.

Racemic ketones have been resolved by condensation with (*R*,*R*)- or (*S*,*S*)-2,3-butanedithiol, then reduced as above to give resolved deoxy compounds (eq 6).[10a,b] Oxidation of prochiral 1,3-dithiolanes under modified Katsuki-Sharpless conditions yields monosulfoxides of high ee.[10c] In peptide synthesis, (**1**) is frequently used as a cation scavenger during deprotection.[11a,b] Transition metal cations are strongly chelated by (**1**), as exemplified by demetalation of Cu^{II} and Ni^{II} metalloporphyrins.[11c]

Ethanethiol

EtSH

[75-08-1] · C_2H_6S · Ethanethiol · (MW 62.13)

(thioacetal formation; nucleophilic reagent;[1-4] cation scavenger and hydrogen donor)

Physical Data: bp 35 °C; *d* 0.839 g cm^{-3}.

Solubility: sol alcohols, ether, acetone.

Form Supplied in: colorless liquid; widely available.

Purification: dissolve in aqueous 20% NaOH, extract with benzene, steam distill until clear. Cool, acidify with 15% H_2SO_4, distill ethanethiol. Dry with $CaSO_4$, $CaCl_2$, or 4Å sieves followed by fractional distillation under nitrogen.

Handling, Storage, and Precautions: stench; irritant and flammable liquid. Keep in cool place in a tightly sealed bottle. Refrigerate before opening due to possible pressure build-up. Use only in a well-ventilated fume hood.

Nucleophilic Reagent.

Ethanethiol undergoes reactions typical of a nucleophilic species, including displacement at saturated carbon, addition to electron-deficient alkenes and alkynes, epoxides, and acylations (eqs 1-3).[1-4]

(1)

(2)

(3)

A useful reaction is the formation of dithioacetals by the acid-catalyzed condensation of carbonyl compounds and ethanethiol (see also ***1,2-Ethanedithiol*** and ***1,3-Propanedithiol***).[5,6] Acid catalysts used include ***Boron Trifluoride***, ***Zinc Chloride***, ***Lanthanum(III) Chloride***, ***Tetrachlorosilane***, ***Chlorotrimethylsilane***, and ***Tellurium(IV) Chloride*** (eq 4).[7] Acid-catalyzed thioacetalization of lactols produces the corresponding acyclic thioacetal (eq 5).[8]

(4)

(5)

Ethylthiosilane is a useful reagent for effecting nucleophilic additions to carbonyl compounds.[9] Ethylthiosilane is most readily prepared by heating a mixture of ethanethiol, ***Hexamethyldisilazane***, and a trace of chlorotrimethylsilane.[9a] Both the thermal and catalyzed carbonyl addition reactions of ethylthiosilane have been investigated.[10,11] The combination of alkylthiosilanes and Lewis acids have proven useful in the preparation of thioacetals and hemithioacetals under buffered conditions (eq 6). Small amounts of tetrabutylammonium cyanide, ***Tetra-n-butylammonium Fluoride***, or ***Potassium Cyanide-18-Crown-6*** complex effect anionic-initiated addition of ethylthiosilane to carbonyl compounds. Under these reaction conditions, saturated aldehydes produce hemithioacetals,

the product of 1,2-addition (eq 7). Unsaturated ketones and aldehydes yields exclusively silyl enol ethers via the 1,4-addition reaction pathway (eq 8). The 1,4-addition pathway has been used advantageously to generate enol ethers which then undergo stereoselective aldol reaction (eq 9).[12]

(6)

(7)

(8)

Ethanethiol is weakly acidic (pK_a ~10-11) and upon deprotonation generates ethanethiolate.[1a,13] The metal salts of ethanethiolate are highly nucleophilic and relatively nonbasic. The combination of these two properties has led to the development of sodium thiolate, and other metal salts of alkanethiolates, as useful reagents in organic synthesis. For example, the cleavage of methyl aryl ethers is accomplished using sodium ethanethiolate in refluxing DMF (eqs 10 and 11).[14-16] Sodium ethanethiolate is generated in situ by the deprotonation of ethanethiol with sodium hydroxide under an inert atmosphere.

Alternative nucleophiles for inducing cleavage of aryl methyl ethers include sodium thiophenoxide, sodium benzylselenide, sodium thiocresolate, ***Sodium Cyanide***, ***Lithium Iodide***, and ***Iodotrimethylsilane***. Metal thiolates, such as sodium ethanethiolate, in dipolar aprotic medium have also been used to cleave alkyl esters.[17-20] The use of metal thiolates in HMPA is one of the mildest methods devised for effecting cleavage of alkyl esters through an S_N2

mechanism (eq 12).[19,20] The dealkylation of methyl esters via metal thiolates is particularly useful in cases of hindered ester groups. Ethanethiol also reportedly cleaves aryl methyl ethers and alkyl esters in combination with Lewis acids (eqs 13 and 14).[21,22]

(12)

(13)

(14)

Cation Scavenger.

Thiols, such as ethanethiol, have been used to scavenge liberated cations in organic reactions. For example, protic cleavage of the *t*-butyl carbamate protecting group used in peptide synthesis liberates *t*-butyl cations and may alkylate methionine or tryptophan.[23,24] ***Thiophenol*** is most commonly used to scavenge cations. In a similar fashion, protodesilylation utilizes ethanethiol to scavenge the silyl cation (eq 15).[25]

(15)

Hydrogen Atom Donor.

The sulfur-hydrogen bond of ethanethiol is prone to homolytic cleavage by either the intervention of a radical or photolytic cleavage. Ethanethiol has been utilized as a hydrogen atom donor in radical reactions (eq 16).[26] The photoaddition of thiols to a carbon-carbon double bond has also been examined (eq 17).[1b]

Ethanolamine

[141-43-5] · C_2H_7NO · Ethanolamine · (MW 61.08)

(synthesis of oxazolidines,[1] oxazolidinones,[2] 2-oxazolines;[3] hydroboration workup[4])

Alternate Names: 2-aminoethanol; monoethanolamine; MEA.

Physical Data: viscous liquid; bp 170 °C; 58 °C/5 mmHg; mp 10.3 °C; *d* 1.018 g cm^{-3}; pH = 12.1 (25 w/w % aqueous solution); pK_a = 9.4 (25 °C).

Solubility: sol H_2O, alcohol, $CHCl_3$; slightly sol ether, benzene; insol hydrocarbons.

Preparative Methods: large-scale preparation by ammonolysis of ***Ethylene Oxide***.[5]

Purification: azeotrope with benzene followed by fractional distillation under reduced pressure.

Handling, Storage, and Precautions: hygroscopic; absorbs CO_2 from atmosphere; corrosive.

N-Arylation and Alkylation.

MEA can be used to introduce β-hydroxyethylamino functionality onto aromatics containing electron-withdrawing groups (eq 1)[6] or heterocycles (eq 2)[7] by nucleophilic substitution. *N*-Alkyl or *N*,*N*-dialkylated derivatives of MEA can be obtained in good yields under mild conditions by alkylation (e.g. ***Benzyl Chloride***, ***Sodium Hydroxide***; mono, 68%; di, 72%)[8] or reductive amination (e.g. ***Acetone***, ***Platinum(IV) Oxide***, 95%;[9] ***Acetaldehyde***, ***Sodium Borohydride***, 76%[1c]). MEA derives its versatility by conversion to derivatives that serve in other transformations. Substituted ethanolamines are used in many asymmetric reactions.

(1)

(2)

Reactions with Carbonyls.

MEA condenses with aldehydes and ketones to give oxazolidines (**1**),[1] carbonates to give oxazolidinones (**2**),[2] acids to give oxazolines (**3**),[3] and standard acylating agents (eq 3). These heterocycles are used as intermediates in natural product and polymer synthesis. It selectively deacylates acyl glycosides[10] and replaces hydrazine for cleavage of Gabriel synthesis intermediates.[11]

Hydroborations.

MEA aids hydroboration reaction workup by transesterifying the borate ester to give the product alcohol and a borinate precipitate (eq 4).[4] MEA has also been used to increase optical purities by crystallization of the resulting MEA esters.[12]

Heterocycle Synthesis.

Besides the heterocyclic systems shown in eq 3, different ring systems are obtained on reaction of MEA with CO_2, CS_2, isocyanates, nitriles, α-diketones [(**4**) and (**5**) depending on the reaction conditions],[13] and with 1,4-butenediol to give (**6**).[14]

(4) **(5)** **(6)**

MEA is converted into a dienophile that has been used to prepare vicinal *cis*-amino alcohols (eq 5).[15]

(5)

Quaternary Amine Dealkylation.

MEA dealkylates quaternary ammonium salts (methyl groups) prepared during exhaustive methylation of amines (eq 6).[15]

Ethoxyacetylene[1]

[927-80-0] · C_4H_6O · Ethoxyacetylene · (MW 79.09)

(preparation of alkenylcuprates,[2] anhydrides,[3] ketenes,[4,5] lactones;[6] reacts with allylboranes[7])

Alternate Name: ethyl ethynyl ether.

Physical Data: bp 48-50 °C; *d* 0.800 g cm^{-3} (0.745 g cm^{-3} in hexane).

Solubility: sol alcohol, ether, benzene, hexane.

Preparative Methods: from chloroacetaldehyde diethyl acetal (70%).[8,9]

Form Supplied in: 50 w/w % solution in hexane(s).

Handling, Storage, and Precautions: moisture sensitive; potential fire hazard with certain metal salts.[8] Use in a fume hood.

Cycloaddition Reactions.

Ethoxyacetylene (**1**) participates in [2 + 2], [4 + 2], and 1,3-dipolar cycloaddition reactions. Diels-Alder reactions with oxazinones give substituted 3,5-disubstituted 2,6-dichloropyrimidines (eq 1).[10] 1,3-Dipolar cycloaddition reactions with aldoximes (eq 2)[11] and with nitrile oxides[12] give isoxazoles.

Ethoxyacetylene and its derivatives thermally decompose to generate ketenes[4,5,13] which either add to themselves or undergo further cycloaddition reactions. In addition, other ketenes, such as dimethylketene, add to (**1**) to give cyclobutanone derivatives (eq 3).[14]

Ethoxyacetylene gives pyrazoles with ***Diazomethane***, triazoles with aryl and substituted alkyl azides, 2-quinolines with aryl isocyanates, and *o*-ethoxyphenylacetylene with benzyne.[1] Phospholes may be prepared in a [2 + 2 + 1] cycloaddition of a terminal phosphinidene complex with (**1**).[15] Organometallic reagents add to ethoxyacetylene to give 1,4-naphthoquinone-cobalt[16] and 2*H*-pyrrole-tungsten complexes,[17] and phenols.[18]

Nucleophilic Additions to Ethoxyacetylene.

Vinyl anions can be generated by nucleophilic addition to ethoxyacetylene. Alkyl cuprates tend to transfer only one group while (*Z*)-alkenyl cuprates transfer both groups to give (*E*)-α,β-unsaturated ketones after hydrolysis of the initial enol ethers (eq 4).[19] These vinylcopper reagents have been coupled, condensed with alkyl and vinyl iodides, acid chlorides, vinylogous acid chlorides, and iodine to give a variety of derivatives.[2]

(4)

Trimethylsilylmethylcopper adds to ethoxyacetylene with *cis* addition to give allylic silane (**2**) that, when quenched with electrophiles, gives (*E*)-3-substituted 2-alkoxy-2-alkenylsilanes (eq 5).[20]

E	yield (%)
H	95
Cl	90
I	95
$CH_2{=}CHCH_2$	98
CO_2Me	70

(5)

Arylcopper reagents extend this chemistry. Thus, by coupling a Grignard reaction with a Wacker oxidation, 1,4-diketones can be prepared (eq 6).[21]

Nucleophilic Reactions of Ethoxyacetylene.

Anions derived from ethoxyacetylene, generated as the Grignard reagent,[22] or lithium[8,23] or aluminum[24] salts, add to alkyl halides,[25] aldehydes, ketones, and epoxides[22] to give precursors of α-hydroxy ketones,[26] aldehydes, acids, or α,β-unsaturated esters. Cyclohexene epoxide and ethoxyacetylene give a lactone upon treatment of the intermediate alcohol with acid. Conversion to the alane is necessary as no ring opening occurs with lithium ethoxyacetylide (eq 7). This methodology is superior to that which uses lithium *t*-butylacetate (Rathke's salt), which fails to react with hindered epoxides.[24]

Ethoxyacetylene reacts with aldehydes and ketones in the presence of ***Boron Trifluoride*** to give α,β-unsaturated esters.[27]

Acylation Reactions.

Amines can be acylated by ethoxyacetylene to give carboxylic acid derivatives in good yields.[13] 1-Ethoxyvinyl esters, which are useful as acylating agents, have been prepared from carboxylic acids and ethoxyacetylene in a Ru^{II}-catalyzed reaction.[28] Cyclic anhydrides have been formed by dehydrating diacids with (**1**) (eqs 8 and 9).[3,29] Weakly nucleophilic 2-fluoro-2,2-dinitroethanol yields bis(2-fluoro-2,2-dinitroethyl)ethoxy ethyl orthoester in a 95% yield in a Hg^{II}-catalyzed reaction with ethoxyacetylene.[30]

(8)

(9)

Lactones have been prepared by thermolysis of adducts formed from lithium ethoxyacetylide and hydroxy ketones (eq 10). Higher reaction temperatures increase conversion and lower reaction times. Good yields are reported for five-, six-, and seven-membered rings. Larger macrocycles (9-, 10-, 15-membered) require Bu_3N as a catalyst to get respectable yields and to minimize oligomeric products (see also ***2-Chloro-1-methylpyridinium Iodide***).[6]

Insertion Reactions.

Allyl(dialkyl)boranes react with ethoxyacetylene to give dialkyl(alkoxypentadienyl)boranes which may be converted to 2-alkoxy-1,4-pentadienes[7] or methyl allyl ketone[31] on protonolysis. In a one-pot reaction, triallylboranes and ethoxyacetylene give 1,4-pentenynes as shown in eq 11.[7] Similar chemistry is observed with tribenzylboranes.[31] The ethoxyacetylene/(iodo-9-BBN) adduct reacts with acyclic α,β-unsaturated ketones to give δ-keto esters (74-95%)[32] and with aryl aldehydes to give cinnamic esters (89% yield, 99% (*E*)).[33] Unlike Wittig chemistry, this methodology tolerates base-sensitive functional groups. In a ***Mercury(II) Acetate*** catalyzed reaction, ethoxyacetylene, diphenylboronic acid, and alkyl or aryl aldehydes give β-hydroxy and β-acetoxy esters.[34]

Transition Metal Catalyzed Reactions.

Zirconium reagents catalyze a one-pot addition of ethoxyacetylene to aryl iodides or bromides to give (*E*)-β-ethoxyalkene derivatives (eq 12). A variety of functional groups are tolerated on the aryl halide (Cl, OMe, CN, CO_2Me).[35] This chemistry has been extended to indoles.[36] Ethoxyacetylene gives pyrones with CO_2 and ***Bis(1,5-cyclooctadiene)nickel(0)***,[37] and indenols with acetophenone and $PhCH_2Mn(CO)_5$.[38]

(12)

Miscellaneous Synthetic Transformations.

Ethoxyacetylene has been used to prepare substituted acylketenes,[39] (alkoxyethynyl)phosphonites,[40] and alkoxy metal carbenes.[41]

[78906-20-4]

(mono- and bifunctional three-carbon electrophile in carbonyl reactions, vinylogous acylations[2] and various cyclocondensation reactions[1,3])

Alternate Name: 3-ethoxy-2-propenal.

Physical Data: (**1**) bp 68-72 °C/11 mmHg; *d* 0.9835 g cm^{-3}; *n*20D 1.473-1.474. (**2**) bp 78-81 °C/14 mmHg; *d* 0.957-0.960 g cm^{-3}; *n*20D 1.474-1.479. (**3**) mp 25 °C; bp 36-37 °C/1.5 mmHg; *d* 1.0306 g cm^{-3}; *n*20D 1.481-1.482.

Form Supplied in: colorless liquid(s); 3-ethoxy-2-methylacrolein (**2**) is commercially available.

Preparative Methods: 3-ethoxyacrolein (**1**) and its 2-alkyl analogs (**4**) are obtained by mild hydrolysis of malonic dialdehyde bisacetals,[4a,b] and the former also by decarboxylation of β-acroleinyl carbonate.[4c] 3-Methoxyacrolein (**3**) is prepared via the carbonate[5a,b] or by methylation of malonic dialdehyde sodium salt.[5c]

Handling, Storage, and Precautions: to avoid polymerization the ethoxyacroleins should be stored in a refrigerator, and the 2-unsubstituted compound kept in a freezer. They are slight lachrymators. Use in a fume hood.

Cyclization with Amino Compounds.

3-Alkoxyacroleins are vinylogous formates. As bifunctional electrophiles they cyclize with amino compounds to give a variety of nitrogen heterocycles. They can replace unstable malonic dialdehydes and the less reactive tetraacetals. Related are 3-aminoacroleins, which can be used for the synthesis of pyridines.[6] Amidines cyclocondense with 2-alkyl-3-ethoxyacroleins (**2**) and (**4**) to give 2,5-dialkylpyrimidines in better yield than with malonic dialdehyde tetraacetals (eq 1).[3] Reaction with ***Urea***, ***Thiourea***, or ***Guanidine*** affords 2-hydroxypyrimidines, 2-pyrimidinethiones, or 2-aminopyrimidines, respectively.[3]

$R^1 = C_1\text{-}C_5$ alkyl

(1)

$R^2 = Me$ 50-70%

$R^2 = X = OH, SH, NR_2$ 25-90% $X = O, S$

The reaction of (**2**) or (**4**) with heterocyclic enamines such as 5-aminopyrazoles, -isoxazoles, or -isothiazoles (eq 2) yields 1*H*-pyrazolo[3,4-*b*]-,[7a] isoxazolo[5,4-*b*],[7b] or isothiazolo[5,4-*b*]pyridines.[7c] Intermediate heterocyclic aminoacroleins can be isolated. Vinylogous amidation of (**2**) and (**4**) with L-proline ester and cyclization of the aminoacroleins give 2,3-dihydro-1*H*-pyrrolizines.[8]

The macrocyclic 1,8-dihydro-1,4,8,11-tetraaza[14]annulenes are formed from 3-ethoxyacroleins and enediamines such as diaminomaleodinitrile (eq 3).[9a] Improvement of yields is achieved by the metal template effect, in which a metal cation coordinates the enediamine.[9b]

Reaction with Carbon Nucleophiles.

Alkylmagnesium halides add to (**2**) or (**4**) regioselectively in a 1,2-addition.[10] Hydrolysis of the intermediate γ-hydroxyenol ethers affords α,β-unsaturated aldehydes, resulting in the oxopropenylation of the Grignard reagent (eq 4).[2] The methoxy analog (**3**)[5b] and the reactive 3-trimethylsilyloxyacroleins[11] have also been used. Vinylic Grignard reagents afford conjugated polyenes.[12]

Nitrogen heterocycles with a lithiable α-methylimino group, such as 2-methylpyridine, and (**2**) or (**4**) yield labile heterocyclic γ-hydroxyenol ethers which cyclize with acids to compounds with a bridgehead nitrogen, such as 3-alkylquinolizinium salts (eq 5).[13] Substituted dihydroindolizinium and dihydrothiazolo[3,2-*a*]-pyridinium are obtained similarly.[14]

2-Alkyl-1-ethoxy-1,3-butadienes are obtained by Wittig alkenylation of (**2**) or (**4**)[15] (or (**3**)[5c]). Vinylogous transesterification of (**2**) with chiral 1-arylethanols and methenylation yields 3-aryloxy-1,3-dienes (ee 85-91%).[16a] These undergo Diels-Alder reactions with electron-deficient dienophiles. Addition to ***Isoprene*** (eq 6)[16a,b] gives an optically active terpene alcohol.

Related Reagents.

(Z)*-β-*Aminoacrolein; ***3-Ethoxyacrylonitrile***; ***Ethyl 3-Ethoxyacrylate***; ***Ethyl Hydroxymethyleneacetate, Sodium Salt***; ***Malondialdehyde***; ***Methyl Diformylacetate***; ***Propargyl Aldehyde***.

3-Ethoxyacrylonitrile

[61310-53-0] · C_5H_7NO · 3-Ethoxyacrylonitrile · (MW 97.12) (*E*)

[58243-08-6]

(bifunctional three-carbon electrophile; C_3N building block in various condensation reactions/cytosine synthesis;[1,2] polarized alkene for cycloaddition reactions[3])

Alternate Name: 3-ethoxy-2-propenenitrile.

Physical Data: bp 188-190 °C, 90-91 °C/19 mmHg; *d* 0.944-0.947 g cm^{-3}; *n*20D 1.454.

Form Supplied in: colorless liquid; commercially available.

Handling, Storage, and Precautions: keep cold; 3-ethoxyacrylonitrile is a lachrymator. Use in a fume hood.

Cyclocondensations.

One important condensation reaction of 3-ethoxyacrylonitrile involves a base-catalyzed cyclization with ***Urea*** to give cytosine (eq 1).[1] 3-Ethoxyacrylonitrile is obtained by fragmentation of isoxazole and subsequent ethylation.

No catalyst is needed when 3-ethoxyacrylonitrile is condensed with aromatic (or aliphatic) amidines, affording 2-amino-2-arylpyrimidines.[2,4] The alternate ***2-Chloroacrylonitrile*** gives lower yields.[2]

The introduction of substituents in position 5 of the cytosine ring can be achieved by metalation of 3-

ethoxyacrylonitrile and subsequent alkylation.[5] Metalation with ***n-Butyllithium*** takes place regioselectively at the α-position.[6] The 2-lithio derivative reacts with activated primary bromides (***Allyl Bromide*** or ***Benzyl Bromide***) or straight chain primary alkyl iodides. Condensation with urea affords 5-alkylcytosines in moderate yields (eq 2).[5]

Other Cyclizations.

A benzimidazolium *N*-ylide undergoes 1,3-dipolar cycloaddition with 3-ethoxyacrylonitrile to give a benzopyrrolo[1,2-*a*]pyrazine derivative (eq 3).[7]

In a formal [3 + 2] cycloaddition, acylcarbenes add to conjugated nitriles. The acylcarbenes are produced from α-diazoaldehyde esters and can react, e.g. with 3-ethoxyacrylonitrile in the presence of catalytic amounts of

Dirhodium(II) Tetraacetate, to give a 2-substituted 4-ethoxycarbonyl-1,3-oxazole (eq 4).[8]

(4)

Photocycloadditions.

Ortho photocycloaddition with 4-cyanoanisole as the arene component and 3-substituted acrylonitriles are regiospecific. (*E*)-3-Ethoxyacrylonitrile yields predominantly a 1:1 adduct, a bicyclo[4.2.0]octa-2,4-diene derivative, after 24 h irradiation with 4-cyanoanisole in acetonitrile (eq 5).[3] No azocine is formed.

(5)

Ethylenes undergo photocycloadditions to 1,4-benzoquinone, yielding spiro-oxetanes (Paterno-Büchi reaction). Investigations were made with a variety of alkenes and electron-donor and -acceptor dienes.[9] While electron-donor dienes such as ***Ethyl Vinyl Ether*** give only very small yields of oxetane, the captodative alkene (*E*)-3-ethoxyacrylonitrile adds to 1,4-benzoquinone in 30% yield (equal amounts of the *cis* and *trans* isomer) (eq 6).

(6)

trans	*cis*
$R^1 = R^4 = H$	$R^1 = R^3 = H$
$R^2 = OEt$	$R^2 = OEt$
$R^3 = CN$	$R^4 = CN$

1:1

Similar photocycloaddition of (*E*)-3-ethoxyacrylonitrile to 1,4-naphthoquinone affords both *cis* and *trans* adducts and a small amount of a second *cis* isomer.[10]

Other Addition Reactions.

3-Ethoxyacrylonitrile can be used as the starting material for the synthesis of glyoxal mono(diethyl acetal). The nitrile is brominated to the bromo acetal with ***N-Bromosuccinimide***, which is converted into the cyano ester and the glyoxal acetal (eq 7).[11]

(7)

Related Reagents.

3-Ethoxyacrolein; ***Ethoxymethylenemalonitrile***; ***Ethyl 3-Ethoxyacrylate***; ***Ethyl Ethoxymethylenecyanoacetate***.

2-Ethoxyallyl Acetate

[76524-71-5] · $C_7H_{12}O_3$ · 2-Ethoxyallyl Acetate · (MW 144.17)

(preparation of enol ethers via the corresponding allylpalladium complexes;[1] cyclopentenone annulation[1])

Alternate Name: 3-acetoxy-2-ethoxy-1-propene.

Preparative Methods: by reaction of α-lithioethyl vinyl ether with ***Paraformaldehyde*** (40-50%) followed by acetylation (***Acetic Anhydride***, ***Pyridine***).[1]

Handling, Storage, and Precautions: use in a fume hood.

Preparation of Enol Ethers.

2-Ethoxyallyl acetate (**1**) is a useful reagent for the preparation of enol ethers by way of palladium-catalyzed allylic alkylations. Reaction of the π-allylpalladium intermediate generated from (**1**) with several types of nucleophiles has been studied. Aryl,[2] vinyl,[2] and enol stannanes[2,3] all give satisfactory reactions (eqs 1-3).

(1)

(2)

(3)

For enol stannanes where regioisomers are possible, the product obtained is that arising from reaction of the more stable enolate (cf. eqs 4 and 5).[3] Active methylene compounds, such as β-diketones or β-keto esters, can be alkylated in the presence of a base (eqs 6 and 7).[1]

(4)

(5)

(6)

(7)

Cyclopentenone Annulation.[4]

The enol ethers arising from palladium-catalyzed allylic alkylations can be transformed into cyclopentenones. Several methods for cyclization have been developed. For simple ketones, acidic hydrolysis of the enol ether followed by base-promoted aldol condensation provides the annulated product (eq 8).[3] More complex ketones require the use of an intramolecular Wittig reaction to effect cyclization (eqs 9 and 10).[1] In the event, enol ether hydrolysis with ***N-Bromosuccinimide*** and H_2O provides the α-bromo ketone. Reaction with ***Triphenylphosphine*** yields a phosphonium salt which, upon treatment with base, undergoes cyclization. A useful application of this method is seen in the synthesis of several analogs of the Wieland-Miescher ketone (eq 9).[1]

(8)

(9)

(10)

Related Reagents.

Bromoacetone; ***2,3-Dibromopropene***; ***2,3-Dichloropropene***; ***Ethyl Chloroformate***; ***2-Methoxyallyl Bromide***; ***2-Nitro-1-propene***; ***Tetrakis(triphenylphosphine)palladium(0)***.

2-Ethoxycarbonylallyltrimethylsilane[1]

[74976-84-4] · $C_9H_{18}O_2Si$ · 2-Ethoxycarbonylallyltrimethylsilane · (MW 186.33)

(2-ethoxycarbonylallylation of aldehydes and acetals; the allylation products are useful precursors to α-methylene-γ-butyrolactones;[2] precursor of allyl cation equivalents for [3 + 2] and [3 + 4] cycloadditions[7,8])

Alternate Name: ethyl 2-(trimethylsilylmethyl)acrylate.

Physical Data: bp 35-40 °C/2 mmHg.

Solubility: sol common organic solvents.

Analysis of Reagent Purity: ^{1}H NMR.

Purification: by distillation.

Preparative Methods: a three-step synthesis from ***Diethyl Malonate*** has been reported.[2] *t*-Butyl and trimethylsilyl esters are also prepared by this method. Syntheses from ethyl diethylphosphonoacetate[3] and ethyl α-bromoacrylate[4] also have been reported, but the simplest procedure involves the reaction of ethoxalyl chloride with two equivalents of ***Trimethylsilylmethylmagnesium Chloride*** followed by treatment with ***Thionyl Chloride*** (53% yield).[5] The Ce^{III}-mediated reaction of trimethylsilylmethylmagnesium chloride with ***Diethyl Oxalate*** is also reported to give 2-ethoxycarbonylallyltrimethylsilane in 45% yield.[6]

Handling, Storage, and Precautions: the reagent can be stored in a glass bottle.

Reaction with Acetals.

The reaction of 2-ethoxycarbonylallyltrimethylsilane (**1**) with acetals proceeds smoothly in the presence of a Lewis acid such as ***Titanium(IV) Chloride*** to afford the corresponding ethoxycarbonylallylation products in good yield (eq 1).[2]

The resulting homoallyl ethers can be converted to the corresponding α-methylene-γ-butyrolactones by dealkylation with ***Iodotrimethylsilane*** (eq 2).

Reaction with Aldehydes.

The reaction with aldehydes in the presence of $TiCl_4$ leads to the formation of α-methylene-γ-butyrolactones directly but in low yield (eq 3).[2]

Preparation of 1-Acetoxy-2-trimethylsilylmethyl-2-propene.

Reduction of (**1**) with ***Lithium Aluminum Hydride*** gives 2-trimethylsilylmethylallyl alcohol, which is converted to 1-acetoxy-2-trimethylsilylmethyl-2-propene. When $LiAlD_4$ is used, the dideuterated compound is prepared (eq 4).[7] These acetates are used for the palladium-catalyzed cycloaddition with electron-deficient alkenes.

Preparation of Substituted 1-Trimethylsilylmethylallyl Alcohol.

The reaction of (**1**) with ***Methyllithium*** gives 1,1-dimethyl-2-trimethylsilylmethylallyl alcohol (eq 5). The trifluoroacetate derivative is useful for the generation of the 2-trimethylsilylmethylallyl cation (by reaction with ***Zinc Chloride***), which undergoes cycloaddition reactions with dienes.[8] The reaction of (**1**) with the di-Grignard reagent from 1,4-dibromobutane leads to cyclopentanol derivatives that also undergo cyclization reactions with dienes.[9]

Chain Elongation of Aldonolactones.

2-Ethoxycarbonylallyltrimethylsilane is successfully applied to the chain elongation reactions of monosaccharides.[10] The *t*-butyl ester,[2] instead of the ethyl ester, is also used in the reaction (eq 6).

Related Reagents.

3-Acetoxy-2-trimethylsilylmethyl-1-propene; ***Allyltrimethylsilane***; ***3-Iodo-2-trimethylsilylmethyl-1-propene***.

[1-(Ethoxycarbonyl)cyclopropyl]triphenylphosphonium Tetrafluoroborate

[52186-89-7] · $C_{24}H_{24}BF_4O_2P$ · [1-(Ethoxycarbonyl)cyclopropyl]triphenylphosphonium Tetrafluoroborate · (MW 462.24)

(used in annulation reactions with nucleophile-carbonyl pairs such as anions derived from β-dicarbonyls and imides)

Physical Data: mp 179-181 °C.

Solubility: sol chloroform; slightly sol DMSO, DMF, HMPT; insol diethyl ether.

Form Supplied in: white, nonhygroscopic crystalline solid.

Preparative Methods: prepared in 80% yield by treating commercially available ***Cyclopropyltriphenylphosphonium Bromide*** sequentially with ***Lithium Diisopropylamide*** and ***Ethyl Chloroformate***, followed by counterion exchange using sodium fluoroborate.[1]

Purification: recrystallization from chloroform-ether.

Carbocycle Synthesis.

The title reagent (**1**) is a geminally activated cyclopropane which reacts with a variety of carbonyl-containing carbon nucleophiles to afford carbocyclic products. This annulation process has been accomplished using anions derived from 1,3-diketones (eq 1),[1] β-keto esters (eq 2),[1,2] β-keto aldehydes (eq 3),[3] and β-keto phosphonates[4] to afford perhydroindans, spiranes, and cyclopentene-1-carboxylates. These reactions are most commonly conducted at 25 °C in HMPA but examples using DMSO (25 °C), DMF (25 °C), and THF (65 °C) as solvent have also been reported. The reactions involve ring opening of the cyclopropane followed by an intramolecular Wittig reaction of the resulting intermediate-stabilized phosphorane. The Wittig reaction occurs at the most reactive carbonyl group when dicarbonyl compounds are used (eqs 2, 3).

(1)

(2)

(3)

This annulation procedure has been used to prepare terpenoid materials, including spirovetivanes, steroids, and insect growth regulators.[3-5]

Heterocycle Synthesis.

Anions derived from imides (eq 4)[6-8] and carboxylic acids (eq 5)[9] react with (**1**) to afford dihydropyrroles and dihydrofurans. These processes have been used in the synthesis of pyrrolizidine and furoquinoline alkaloids.[6,9] Monothioimides give mixtures of products derived from Wittig reaction at both the carbonyl and thiocarbonyl groups.[6]

(4)

(5)

Heterocycles such as (**2**)-(**4**) have also been prepared from (**1**) and the appropriate nitrogen-, oxygen-, or sulfur-centered anions.[1,10] Intermediate stabilized phosphoranes have been characterized in several instances.[8,10]

(2) 92%

(3) 50%

(4) 35%

Related Reagents.

[1-(Methoxycarbonyl)cyclopropyl]triphenylphosphonium tetrafluoroborate [*52186-91-1*][1] has seen little use and gave inferior yields in reactions with imide anions.[8] [1-(Ethoxycarbonyl)cyclobutyl]triphenylphosphonium tetrafluoroborate fails to give annulation products with the sodium salt of ethyl acetoacetate.[1] [1-(Phenylthio)cyclopropyl]triphenylphosphonium tetrafluoroborate [*58992-26-0*] has been shown to undergo some annulation reactions related to those reported for (**1**).[11] One example is shown in eq 6.[6]

Ethoxycarbonyl Isothiocyanate[1]

EtO_2C-NCS

[16182-04-0] · $C_4H_5NO_2S$ · Ethoxycarbonyl Isothiocyanate · (MW 131.49)

(highly reactive isothiocyanate for condensation and cyclization reactions to form thioamides, thioureas, and heterocycles[1])

Physical Data: bp 44-46 °C/10 mm Hg; *d* 1.160 g cm^{-3}.

Solubility: freely miscible in most organic solvents.

Form Supplied in: colorless to pale brown liquid.

Purification: distillation in vacuo.

Handling, Storage, and Precautions: exceedingly pungent odor, irritating to eyes and nose; store at 0 °C; slowly decomposed by water; reacts exothermically with alcohols and amines. This reagents should only be handled in a fume hood.

Thiourea Synthesis.

Ethoxycarbonyl isothiocyanate reacts with stoichiometric amounts of ammonia, primary, and secondary amines to afford the expected thioureas in high yield (eq 1).[1]

(1)

Synthesis of Thioamides.

Friedel-Crafts thioacylation of aromatics with ethoxycarbonyl isocyanate mediated by ***Aluminum Chloride*** gives moderate to good yields of arylthioamides or *N*-ethoxycarbonylthioamides, dependent on reaction conditions (eq 2).[2]

(2)

The thioamides synthesized by the reaction of cyclic or acyclic enamines with ethoxycarbonyl isothiocyanate can be isolated or carried on further to 4-thiouracils upon treatment with an additional primary amine (eq 3).[3,4]

(3)

Synthesis of Heterocycles.

Ethoxycarbonyl isothiocyanate is sufficiently reactive for functionalization of urea nitrogens. Treatment of *N*,*N*´-disubstituted ureas with ethoxycarbonyl isothiocyanate followed by base-catalyzed ring closure and *S*-methylation provides a convenient synthesis of 1,3,5-triazine-2,4-diones (eq 4).[5]

(4)

Ethoxycarbonyl isothiocyanate was used as a key starting point in a convenient and multigram synthesis of 1,2,4-oxadiazolidine-3,5-dione (eq 5), a bioisostere for the carboxylic acid group.[6]

(5)

The synthesis of 5-amino-1,2,3-thiadiazoles can be achieved through [3 + 2] cycloaddition of ethoxycarbonyl

isothiocyanate with diazo ketones (eq 6).[7]

(6)

The reaction of 2-alkylamino[8] and 2-alkylhydrazino[9] aza-heterocycles with ethoxycarbonyl isothiocyanate has been used to generate interesting mesoionic species.

Ethoxycarbonylmethylcopper[1]

EtO_2CCH_2Cu

[35756-99-1] · $C_4H_7CuO_2$ · Ethoxycarbonylmethylcopper · (MW 150.65)

(reagent for improved yields of allylation of ethyl acetate[2])

Preparative Methods: by the reaction of ***Ethyl Lithioacetate*** and ***Copper(I) Iodide*** in THF as a heterogeneous pale yellow solution at -110 °C or as a light brown homogeneous solution at -30 °C.

Handling, Storage, and Precautions: unstable above -30 °C; decomposes readily upon exposure to air or moisture. Use in a fume hood.

Characteristics.

Kuwajima and Doi[2] reported the preparation of ethoxycarbonylmethylcopper by the reaction of the lithium enolate of ethyl acetate with copper iodide in THF at -110 °C. Upon warming the mixture to -30 °C a light brown homogeneous solution was obtained. Oxidative dimerization of the ethoxycarbonylmethylcopper resulted in the formation of diethyl succinate in 73% yield. The copper enolate did not react with butyl bromide or tosylate and did not add to pentanal; however, reaction with cyclohexenyl bromide resulted in a 69% yield of the alkylated product (eq 1).

(1)

Amos and Katzenellenbogen[3] reported formation of a pale yellow heterogeneous reagent upon reaction of the lithium enolate of ethyl acetate and copper iodide at -78 °C, which turned dark brown upon warming to -30 °C. Oxidative coupling of the reagent prepared in this fashion also gave diethyl succinate, but in lower yield (29%). The nature of the species produced by reaction of the lithium enolate with copper iodide is not completely defined; however, the copper enolate exhibits dramatically different reactivity than the corresponding lithium enolate. The copper enolate appears to be a much softer nucleophile.

Reactions.

In the synthesis of sulfonium ion mimics of cationic intermediates involved in the squalene synthetase-catalyzed rearrangement of farnesyl pyrophosphate, alkylation of the lithium enolate of ethyl acetate with a thiosulfonate gave poor yields due to competing condensation reactions. Reaction of ethoxycarbonylmethylcopper and the thiosulfonate provided the desired product in reasonable yield (eq 2).[4] Selective displacement of the allylic halide of ***2,3-Dibromopropene*** has also been accomplished using the softer copper nucleophile (eq 3).[5]

(2)

(3)

Reaction of ethoxycarbonylmethylcopper with propargylic mesylates resulted in the formation of the allene ester product by an S_N2' reaction while the corresponding lithium enolate provided only the alkynic product or did not react (eq 4).[3] In contrast to the reaction with the propargylic electrophile, reaction with most allylic electrophiles generally proceeds by direct substitution without allylic transposition. The synthesis of 4′, 8′, and 12′ nor analogs of geranylgeraniol was accomplished by direct displacement of allyl bromides with ethoxycarbonylmethylcopper.[6] Reaction of ethoxycarbonylmethylcopper with farnesyl bromide provided the ester in 97% yield; allyl chlorides may also be employed in the alkylation reaction. The synthesis of the sex pheromone of *Phtorimaea operculella* was achieved without any indication of competing S_N2' alkylation (eq 5).[7]

(4)

Regioselective 1,4-addition of ethoxycarbonylmethylcopper to cyclopentadiene monoepoxide has also been reported (eq 6).[8] There has been an exception to the predominant mode of α alkylation of allylic electrophiles. A general method for the regioselective synthesis of 2-alkenenitriles by the γ alkylation of 3-buten-2-one cyanohydrin diethyl phosphate included ethoxycarbonylmethylcopper as one of the nucleophiles.[9] A more reactive, stabilized copper derivative is produced from iododifluoroacetate and copper powder.[10] Ethoxycarbonyldifluoromethylcopper reacts with allyl, benzyl, alkenyl, alkynyl, and aryl halides.

Related Reagents.

Cyanomethylcopper.

Russell J. Linderman

Ethyl 2-Methyl-4-oxo-2-cyclohexene-1-carboxylate

[487-51-4] · $C_{10}H_{14}O_3$ · Ethyl 2-Methyl-4-oxo-2-cyclohexene-1-carboxylate · (MW 182.22)

(a useful building block in natural product synthesis;[1-5] often alkylated in the 3-position[6])

Alternate Names: Hagemann's ester; 4-ethoxycarbonyl-3-methyl-2-cyclohexenone.

Physical Data: bp 268-272 °C; *d* 1.078 g cm^{-3}.

Form Supplied in: 90% technical grade liquid commercially available.

Preparative Methods: ethyl 2-methyl-4-oxo-2-cyclohexene-1-carboxylate[7] is typically prepared by the condensation of 2 equiv of ethyl acetoacetate with 1 equiv of formaldehyde in the presence of catalytic piperidine.[8] Aldehydes other than formaldehyde have been used to prepare 6-substituted compounds (eq 1).[9]

Cyclization of diketo esters proceeds in 50-75% yield using catalytic pyrrolidine and acetic acid (eq 2).[10]

(2)

Natural Product Syntheses.

The title reagent (Hagemann's ester) serves, for example, as a starting material in the synthesis of (±)-α- and (±)-β-pinene,[1] yohimbine congeners,[2] vermiculine,[3] and other natural products.[4]

The 6-methyl derivative was employed in a total synthesis of (±)-agarospirol (epihinesol).[5] ***Lithium Aluminum Hydride*** reduction of its ethylene acetal followed by hydrolysis and concomitant dehydration afforded 3,5-dimethyl-4-methylene-2-cyclohexenone which underwent a 1,6-Michael addition with ***Diethyl Malonate***.

Alkylation of Hagemann's ester occurs predominantly at the 3-position, with a small amount of alkylation at the 1-position (eqs 3 and 4).[6]

(3)

(4)

Reaction of Hagemann's ester with Michael acceptors such as ***Methyl Vinyl Ketone*** leads to C-1 and C-3 Michael adducts.[11]

Functionalization at C-1 is best achieved via the dienol ether or ester.[12] The ethyl dienol ether was prepared by treatment of Hagemann's ester with 2 equiv of diethyl sulfate and sodium hydride (eq 5).

(5)

The ethyl dienol ether can be alkylated by a variety of electrophiles upon deprotonation with ***Lithium Diisopropylamide*** (eq 6). Other electrophiles used include ***Formaldehyde***, Michael acceptors, and ***Methyl Chloroformate***. All proceed in good to excellent yields.

(6)

A regiospecific synthesis of substituted 1,3-cyclohexadienes uses Hagemann's ester and its derivatives as

starting material.[13] Borohydride reduction or Grignard reaction of the ketone carbonyl followed by saponification and dehydrative decarboxylation with *N*,*N*-dimethylformamide dineopentyl acetal gives various substituted 1,3-cyclohexadienes.

Related Reagents.

Ethyl Acetoacetate; ***Formaldehyde***; ***Iodomethane***; ***Methyl 6-Oxo-1-cyclohexenecarboxylate***; ***Methyl 3-Oxo-4-pentenoate***; ***Methyl Vinyl Ketone***.

(Ethoxycarbonylmethylene)triphenylphosphorane[1]

$Ph_3P{=}CHCO_2Et$

[1099-45-2] · $C_{22}H_{21}O_2P$ · (Ethoxycarbonylmethylene)triphenylphosphorane · (MW 348.38)

(stabilized phosphorane reagent useful for Wittig alkenation reactions to give α,β-unsaturated ethyl esters on reaction with carbonyl compounds;[1] heterocyclic ring construction;[2-4] synthesis of cyclopropanes from epoxides[5])

Physical Data: mp 128-130 °C.

Solubility: sol EtOH (42 g 100 mL^{-1}), THF (13 g 100 mL^{-1}), and $CHCl_3$ (29 g 100 mL^{-1}); insol water (<0.5 g 100 mL^{-1}).

Form Supplied in: white crystalline powder.

Handling, Storage, and Precautions: no special handling or storage requirements are necessary. The use of carefully dried reagents leads to a lower rate of Wittig alkenation reaction.[6] The compound is stable in water (>3 h), and >99% stable in 0.5 N NaOH in MeOH-water (1:1) for at least 3 h.

Weakly Basic Phosphorus Ylide.

This phosphorane is readily prepared by deprotonation of ***(Ethoxycarbonylmethyl)triphenylphosphonium Bromide*** (pK_a 8.95-9.2), typically with ***Sodium Ethoxide*** or ***Sodium Hydroxide***.[7] Deprotonation of the phosphonium bromide produces a phosphorane in which the negative charge on the α-carbon is stabilized by d_π-p_π bonding to the phosphorus and also by the adjacent ethoxycarbonyl group. Additionally, NMR studies have shown that this reagent exists as a ca. 3:1 mixture of *cis*:*trans* ylide/enolates as shown in eq 1, with a barrier to rotation estimated at ca. 10 kcal mol^{-1} for the methyl ester.[6,8] The high proportion of negative charge on the oxygen is reflected in *O*-ethylation with ***Triethyloxonium Tetrafluoroborate*** at -78 °C to give a 3:1 mixture of *cis*:*trans* ethyl vinyl ethers.[6] The presence of small amounts of water or other proton sources facilitate the reaction of the phosphorane, presumably by reversibly protonating the α-carbon and lowering the barrier to rotation, allowing for more reactive ylide forms with single bond character between the α- and β-carbons (viz. *cis*- and *trans*-ylide structures).[6] For this reason, it is counterproductive to be overly concerned with removing traces of moisture in standard reactions involving this phosphorane.

(1)

Wittig Alkenation Reactions.

This reagent is among those typically referred to as stabilized Wittig reagents, because of the extra negative charge stabilization by the ester functionality (see also ***(Methoxycarbonylmethylene)triphenylphosphorane***). As such, its basicity and reactivity is moderated relative to the nonstabilized alkylidenephosphoranes. If more reactive reagents are required, phosphonates such as $(EtO)_2P(O)CH_2CO_2Et$ can be employed in the Horner-Wadsworth-Emmons (HWE) alkenation procedure.[1] The phosphonate reagents have the added advantage that the phosphates obtained as side-products are easier to remove than triphenylphosphine oxide, the phosphorus-containing product of the phosphorane reactions. Although intermediates have not been observed in reactions of stabilized phosphoranes by spectroscopic techniques, the reaction mechanism would be expected to include a four-membered oxaphosphetane immediately prior to elimination to the alkene and triphenylphosphine oxide.[1a]

(Ethoxycarbonylmethylene)triphenylphosphorane reacts with the carbonyl groups of aldehydes,[9-26] ketones,[27-34] ketenes,[35-37] anhydrides,[39] imides,[40] and certain amides[41a,42] and esters[4,41] to insert the α,β-unsaturated ethyl ester (ethyl acrylate) functionality. The reaction has wide generality and has been extensively employed, especially en route to intermediates for further synthetic manipulation. Where the newly established double bond has stereochemistry, such as in reactions with aldehydes and unsymmetrical ketones, it is generally *trans* (*E*) in nature, although the (*E*:*Z*) ratio is influenced by a variety of factors, such as the nature of the aldehyde, solvent, and additives.

Reactions with Aldehydes.

There are numerous instances in which this reaction has been carried out in organic synthesis, and only a few representative examples are given here. In the synthesis of rapamycin, the aldehyde group was converted to the expected (*E*) ester, without significant epimerization or elimination of the α-mesyloxy or β-benzyloxy substituents, respectively (eq 2).[10a] The relatively low basicity of the phosphorane allows for mild transformations of this type, without affecting base-sensitive groups.

(2)

There are occasions when these mild conditions are preferred to the more basic conditions attendant to the HWE phosphonate reagent $(EtO)_2P(O)CHCO_2Et^-\ Na^+$. For example, in the preparation of a substrate for a quinolizine synthesis, the phosphorane produced the

desired acrylate ester, whereas use of the HWE reagent resulted in considerable amounts of premature ring closure to give a piperidine side product (eq 3).[10b]

(3)

The alkenation reaction can be carried out by the in-situ generation of the phosphorane reagent by the use of ethylene oxide (eq 4).[11] The bromide counterion of the phosphonium salt opens the ethylene oxide, and the alkoxide which then forms deprotonates the α-carbon.

(4)

When the phenyl ligands on the phosphorus atom are replaced with alkyl groups, the relative proportion of (*E*) isomer increases.[12] For example, in reactions with benzaldehyde under the same conditions, $Ph_3P{=}CHCO_2Et$ and $Bu_3P{=}CHCO_2Et$ gave (*E*:*Z*) ratios of 89:11 and 95:5, respectively.[12] The placement of ferrocenyl ligands on the phosphorus also resulted in the same degree of (*E*) stereoselectivity,[13] but 2-furyl ligands produced more of the (*Z*) isomer in ethanol.[14] Rate studies on phosphoranes of type $(p\text{-}XC_6H_4)_3P{=}CHCO_2Et$ gave ρ values in the area of +2.5-3.0.[15] Bridged phosphorane species in which two of the phenyl ligands are attached via a divinyl spacer react slowly to give more (*Z*) isomer (24%) than use of the standard reagent (11%).[16]

Greater (*E*) selectivity is observed when the α-carbon is alkylated, such as in reactions of $Ph_3P{=}C(Me)CO_2Et$.[1,17] However, α-halogenation of the phosphorane and its use to prepare vinyl halides is less (*E*) selective (eq 5).[18]

(Ethoxycarbonylmethylene)triphenylphosphorane

Generally, the formation of the (*E*) isomer is favored by the use of aprotic solvents in the absence of lithium salts,[1a] and the influence of solvent can often be remarkable. For example, reaction of the phosphorane with a sugar-derived aldehyde gave the corresponding acrylates with (*E*:*Z*) mixtures that varied from 86:14 (DMF) to 8:92 (MeOH; eq 6).[19]

The high amounts of the (*Z*)-acrylate observed in eq 6 under certain conditions is characteristic of the reactions of α-alkoxy aldehydes, particularly in the presence of an additional β-alkoxy group and in an anhydrous alcoholic solvent.[1a] For example, treatment of isopropylideneglyceraldehyde with the phosphorane reagent in methanol at 0 °C[20] or 25 °C[21] gave the expected acrylates with an (*E*:*Z*) ratio of ca. 10:90. This effect has been observed repeatedly in reactions with carbohydrate-based aldehydes, as they bear multiple oxygenated sites. In the reaction of a fucose-derived hemiacetal (reacting in the aldehyde form) a ca. 1:2 mixture of (*E*:*Z*)

(Ethoxycarbonylmethylene)triphenylphosphorane

isomers formed (eq 7),[22] whereas reaction of 2-deoxyribose derivatives (lacking an α-alkoxy group) gave solely (*E*) acrylates.[23]

The reaction of sugar-derived hemiacetals with stabilized phosphoranes has provided an important starting point for the synthesis of key natural products such as the leukotrienes.[1c] Additionally, the hydroxyl group that remains from the hemiacetal can attack the β-carbon of the acrylate in a Michael fashion to form *C*-glycosides, useful as important synthetic intermediates, such as in the reaction of diisopropylideneallofuranose shown in eq 8.[24] The alkene product of the Wittig reaction can be isolated directly in some cases or the Michael closure can be so fast that only the *C*-glycoside products are detected. In certain circumstances, diene products formed by further elimination reactions are observed.[25] The nature of the ester group and the presence of free or masked hydroxyls on the sugar substrate are important determinants in whether cyclized or open chain products are isolated in these systems.[26]

Reactions with Ketones.

Ketones can be unreactive partners in condensations with stabilized phosphoranes. These reactions can be enhanced by reaction at 9 kbar.[27] For example, alkenation with benzophenone gave an 82% yield of product at 50 °C after 35 h, whereas refluxing in xylene after 1 d at 1 bar resulted in only 10% product. In addition, the reaction with ketones can be facilitated by prolonged heating or mixing the two reactants together at high temperature without the use of solvent.[28] In other cases, the addition of small amounts of an acid catalyst (e.g. benzoic acid) increases the yield of reactions with hindered carbonyls (eq 9).[29] The acid may be acting by increasing the electrophilicity of the carbonyl or by enhancing the rate of exchange of the various ylide forms as discussed above.

(Ethoxycarbonylmethylene)triphenylphosphorane

Keto sugars typically react very nicely with the phosphorane, often producing unexpected stereochemical outcomes. For example, the choice of a silyloxy or benzyl ether protecting group led to dramatically different mixtures of acrylates as shown in eq 10.[30] Alkoxy or hydroxy substituted ketones may actually react faster than their deoxy counterparts.[31]

The use of a chiral carboxylic acid in reaction of the phosphorane and 4-methylcyclohexanone resulted in the expected ethyl acrylate with an enantiomeric excess (ee) of <10%.[32] However, the presence of a chiral host in the same sequence afforded the expected acrylate with an ee of 42% (eq 11).[33] There are only a few reported enantioselective Wittig alkenations, such as the use of bicyclic phosphonamide reagents, in which case as much as 90% ee is observed.[34]

(Ethoxycarbonylmethylene)triphenylphosphorane

(11)

Reactions with Ketenes.

Reaction of an acyl halide with the phosphorane in the presence of 1 mol equiv of ***Triethylamine*** affords allenic esters via in-situ generation of a ketene from the acid halide, followed by a standard Wittig reaction (eq 12).[35] In a similar fashion, carboxylic acids, activated by triethylamine and ***2-Chloro-1-methylpyridinium Iodide***, generate ketenes which can be reacted with the stabilized phosphoranes to afford allenic carboxylate esters.[36] The reaction of silicon- and germanium-substituted ketenes ($Me_3MCH{=}C{=}O$) with the phosphorane also gives allenic esters, which rearrange to the alkynes Me_3MC&tbond;CCH_2CO_2Et upon distillation.[37]

(12)

Allenes are also formed by the use of $Ph_3P{=}C{=}C(OEt)_2$, produced by treatment of $Ph_3P{=}CHCO_2Et$ with ***Triethyloxonium Tetrafluoroborate*** followed by base treatment.[38] Reaction with fluorenone gave the expected allene product, which dimerized immediately to a spirofluorene adduct.[38]

Reactions with Anhydrides and Imides.

Stabilized phosphoranes condense with anhydrides to yield enol lactones (see ***(Methoxycarbonylmethylene)triphenylphosphorane***).[39] Both the (*E*) and (*Z*) isomers can be obtained depending on the substrate, and also regioisomers are produced if the anhydride is unsymmetrical. There is predominant reaction at a site with weak steric hindrance (e.g. α-methyl) which changes to the less hindered carbonyl with added hindrance (α,α-dimethyl).[39] Imides also react to give *N*-vinyl amides in a similar manner.[40]

Reactions with Amides and Esters.

Certain reactive or suitably disposed esters[4,41] also react in a Wittig fashion to yield vinyl ethers, and some amides[41a,42] such as those in penicillin and clavulanic acid derivatives afford vinyl amines.

Alkylations, Acylations, and Related Processes.

Stabilized phosphoranes are sufficiently nucleophilic to be alkylated in order to construct more complicated reagents, particularly with reactive alkyl groups such as allyl, benzyl, and methyl.[1,43] Halogenation of the phosphorane leads to the α-halo derivatives, which give vinyl halides upon standard Wittig alkenations.[7c,44] The nucleophilic alkylation reaction of the phosphorane with a large

variety of substrates has been investigated, such as in the ring opening of *N*-methoxypyridinium salts[45] and the β-alkylation of alkyl propynoates.[46] Treatment of the phosphorane in the absence of an added electrophile leads to phosphaketene $Ph_3P{=}C{=}C{=}O$.[47] The phosphorane coordinates with organometallics to form stable complexes, and can occasionally participate in subsequent reactions of the organometallic complex.[48]

Acylation of the phosphorane provides diacylphosphoranes, which are often so highly stabilized and unreactive that they do not perform Wittig alkenations well.[1] However, flash vacuum pyrolysis (FVP) can afford either terminal alkynes or propargylic esters, depending on the conditions (eq 13).[49]

(13)

Heterocyclic Ring Formation.

Reaction of the phosphorane with azides gives phosphazenes, whereas similar treatment of $Ph_3P{=}C(Me)CO_2Et$ results in triazole formation via 1,3-dipolar cycloaddition of the azide to the enolate resonance form of the phosphorane (eq 14).[50] A similar cyclocondensation occurs with hydrazonyl chlorides to give 5-alkoxy substituted pyrazoles.[2]

(14)

The combination of Wittig alkenation followed by further reaction of the α,β-unsaturated ester has resulted in the efficient preparation of several heterocyclic ring systems. In addition to the *C*-glycoside synthesis discussed earlier, pyrrolidines can be prepared in a similar Wittig/Michael sequence starting from α-hydroxypyrrolidine carbamates.[51]

Reaction of *o*-hydroxybenzaldehydes with the phosphorane is followed by condensation of the ester with the phenyl hydroxyl in a synthesis of coumarins (eq 15).[3,43,52]

(Ethoxycarbonylmethylene)triphenylphosphorane

(15)

Nucleophilic Epoxide Opening.

Under rigorous conditions, oxiranes react with the phosphorane to give ethoxycarbonylcyclopropanes (eq 16).[5] The mechanism proceeds via nucleophilic opening of the epoxide, followed by attack of the alkoxide on the phosphorus, cleavage of the alkyl-phosphorus bond, and backside displacement of triphenylphosphine oxide. Normal Wittig alkenations of aldehydes with the phosphorane are sufficiently mild so as to not react with the epoxide functionality.

(16)

Oxidation.

Oxidation of the phosphorane yields symmetrical alkenes, or cyclic alkenes if bisylides are employed. This reaction was carried out originally using ***Triphenyl Phosphite-Ozone***;[53] however, a newer procedure using oxaziridines is a more general method.[54]

Formation of Thio- and Selenoaldehydes.

Treatment of the phosphorane with sulfur,[55] episulfides,[56] or selenium[57] results in formation of $Ph_3P{=}S$ or $Ph_3P{=}Se$ and $S{=}CHCO_2Et$ or $Se{=}CHCO_2Et$. These unstable thio- or selenoaldehydes can be trapped as their Diels-Alder adducts. In reaction with elemental sulfur or episulfides,[55,56] the symmetrical alkene ($EtO_2CCH{=}CHCO_2Et$) was formed by decomposition of the thioaldehyde. Treatment of thioaldehyde $S{=}CHCO_2Et$ with amines (e.g. ***Morpholine***) led to good yields of thioamides $R^1R^2NC(=S)CO_2Et$.[55a]

Ethoxycarbonylmethyl Trifluoromethanesulfonate

[61836-02-0] · $C_5H_7F_3O_5S$ · Ethoxycarbonylmethyl Trifluoromethanesulfonate · (MW 236.13)

(alkylation of sulfides,[1,3] amines,[2] and other nucleophiles;[3,4] in situ generation of ester-stabilized ylides via onium salt deprotonation[1,2,5-8])

Alternate Name: ethyl (2-trifluoromethylsulfonyloxy)acetate.

Physical Data: mp 22-23 °C.

Solubility: freely miscible with common organic solvents.

Form Supplied in: large colorless needles, refrigerator temperature; colorless liquid, room temperature.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$, δ) 1.35 (3 H, t, *J* = 7.0 Hz) 4.34 (2 H, q, *J* = 7.0 Hz) 4.98 (2 H, s).

Preparative Methods: from ***Ethyl Diazoacetate*** and ***Trifluoromethanesulfonic Acid***, or from ethyl glycolate and ***Trifluoromethanesulfonic Anhydride/Pyridine***.[3]

Purification: recrystallization from hexane at freezer temperatures.[3]

Handling, Storage, and Precautions: the reagent is a lachrymator. Like other moderately active alkylating agents, it should be treated as a potentially toxic agent. It can be stored for months under anhydrous conditions in the freezer as the frozen solid.

Onium Salt Formation.

The title reagent is used for the alkylation of sulfur or nitrogen compounds. It has an ca. 100-fold reactivity advantage over ethyl bromoacetate, and is a less potent lachrymator. It also has the advantage of the nonnucleophilic triflate counterion. The resulting ammonium or sulfonium salts are resistant to S_N2 dealkylation by the anion, a problem that

is often encountered with sulfonium bromides.[1] The initially formed onium salts are usually generated in situ and are treated with base to form the corresponding sulfonium or ammonium ylides. Synthetic applications focus on subsequent ylide fragmentation or rearrangement reactions.

Five-Center Ylide Fragmentation to Alkenes.

Alkylation of aminonitriles followed by deprotonation of the ammonium salt with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** results in the formation of unsaturated nitriles (eq 1).[2,5] The intermediate ammonium ylide (**1**) undergoes concerted α,α´-fragmentation. Good yields are obtained with aldehyde-derived aminonitriles (R^1 = H), but more highly substituted ylides (R^1 = alkyl) undergo competing homolytic C-N cleavage (Stevens rearrangement). Conversion of 2-dimethylaminocyclohexanone into cyclohexenone (68%) can be performed in the same way,[2] but fragmentation does not occur cleanly starting with unactivated amines $RCH_2CH_2NMe_2$. The five-center fragmentation is more facile using sulfides as starting materials (eq 2).[1,5] An activating group is not essential, but the five-center fragmentation is faster if an electron-withdrawing group is present at the α-carbon.[1]

2,3-Sigmatropic Ring Expansion of Ylides.[6]

Medium ring sulfides or amines can be prepared from cyclic sulfides or amines having α-alkenyl or α-alkynyl substituents (eq 3).[6a] The intermediate onium salts are deprotonated with DBU, and the resulting ylides rearrange at room temperature or below. A similar ring expansion of a five-membered sulfide has been used in the early stages of a sulfur-based total synthesis of methynolide.[7].

Keto Ester Synthesis by Sulfide Contraction.[8]

Thioamides are alkylated by ethoxycarbonylmethyl trifluoromethanesulfonate to give the salts (**2**) (eq 4). Treatment with a basic thiophile (**3**) results in the formation of a conjugated enamine (**5**) via the episulfide (**4**). Enamine hydrolysis with methanolic HCl affords the keto ester (**6**) (85% overall). A similar yield is obtained in this case using ethyl bromoacetate. However, the triflate has an advantage over the bromide if the α-methyl derivative is used.

Miscellaneous Applications.

The title reagent has been used to alkylate imines.[4a,d,f] The reactivity advantage of the triflate by comparison with the α-bromo ester is increasingly important in more highly branched reagents such as $TfOCH(Me)CO_2R$.[4b,c,e] The latter can be used successfully in enolate alkylation reactions.

(Ethoxycarbonylmethyl)triphenylphosphonium Bromide[1]

$Ph_3{+}PCH_2CO_2Et\ Br^-$

[1530-45-6] · $C_{22}H_{22}BrO_2P$ · (Ethoxycarbonylmethyl)triphenylphosphonium Bromide · (MW 429.30)

(precursor to $Ph_3P{=}CHCO_2Et$, a widely-used stabilized phosphorane;[2,3] Wittig reagent for the formation of α,β-unsaturated ethyl esters[2-4])

Physical Data: mp 158 °C (dec).

Solubility: sol water (10 g 100 mL^{-1}), EtOH (35 g 100 mL^{-1}), and $CHCl_3$ (55 g 100 mL^{-1}); insol THF (<1 g 100 mL^{-1}).

Form Supplied in: white, crystalline solid which can adopt a light pink tinge from dissociation of small amounts of HBr.

Handling, Storage, and Precautions: the compound is a mild irritant, due to the partial dissociation of HBr. Drying is not required for most synthetic applications. Storage at room temperature is adequate. Stable in water, but decomposes to triphenylphosphine oxide in 1.0 N NaOH ($t_{1/2}$ ca. 15 min).

Weakly Acidic Phosphonium Salt.

This compound is easily prepared by reaction of ***Triphenylphosphine*** and ethyl bromoacetate,[2,3] and has been mainly used as a precursor for $Ph_3P{=}CHCO_2Et$, formed by treatment with base (eq 1); see ***(Ethoxycarbonylmethylene)triphenylphosphorane*** and ***(Methoxycarbonylmethylene)triphenylphosphorane***).[2] The phosphorane is stabilized by both the ethoxycarbonyl group and d_π-p_π bonding to the adjacent phosphorus atom, and is a commonly employed Wittig alkenation reagent. The phosphonium bromide is somewhat acidic and can be deprotonated under weakly basic conditions (pK_a = 8.95-9.2).[5,6] Common bases employed are sodium alkoxides in alcohols,[3,4] aqueous sodium hydroxide,[7] and tertiary amines.[8]

(1)

(Ethoxycarbonylmethylene)triphenylphosphorane has been generated in situ from the phosphonium bromide and utilized as

required, particularly during the first decade or so of general use of the Wittig reaction with aldehydes and ketones.[1-4] As an example, the phosphonium bromide was prepared from triphenylphosphine and ethyl bromoacetate and then treated with ***Sodium Ethoxide*** to form the phosphorane, which was reacted with α-fluoro ketones to afford α,β-unsaturated esters (eq 2).[4] The stereochemistry about the newly formed double bond in unsymmetrical alkenes is generally *trans* (*E*), as expected for reactions of stabilized phosphorus ylides, although there are many special conditions which enhance formation of the (*Z*) isomer.[1] (Ethoxycarbonylmethylene)triphenylphosphorane is now commercially available and can be stored without incident for prolonged periods, so that most chemists start with this reagent directly. The main advantage associated with the phosphonium bromide is that it is ca. 50% less expensive than the phosphorane on a molar basis. There is no special requirement for either the phosphonium bromide or the phosphorane to be absolutely dry when using them in Wittig alkenations, as trace amounts of water catalyze the reaction.[9] Large amounts of excess aqueous base hydrolyze the reagent, releasing triphenylphosphine oxide.

(2)

The phosphonium bromide can be prepared in situ and reacted directly with aldehydes in the presence of ***Ethylene Oxide*** (eq 3). The bromide counterion of the phosphonium salt opens ethylene oxide forming an alkoxide anion, which then deprotonates the α-carbon to form the phosphorane.[10]

(3)

In addition to Wittig alkenations, the phosphonium bromide can be expected to substitute for (ethoxycarbonylmethylene)triphenylphosphorane in any of the other applications of the phosphorane, by in situ treatment of the phosphonium bromide with base.

N-Ethoxycarbonylphthalimide

[22509-74-6] · $C_{11}H_9NO_4$ · *N*-Ethoxycarbonylphthalimide · (MW 219.20)

(phthaloylating agent selective for amines;[1] selective protection of amino acids[2] and amino alcohols[3])

Physical Data: mp 90-92 °C.

Solubility: sol DMF, benzene, THF, ether, chloroform; partially sol water, ethanol, isopropyl alcohol; insol petroleum ether.

Form Supplied in: crystalline (colorless).

Analysis of Reagent Purity: commercial material is >95% pure.

Preparative Methods: addition of ***Ethyl Chloroformate*** to a cold solution of ***Phthalimide*** and ***Triethylamine*** in DMF;[4] alkylation of potassium phthalimide with ethyl chloroformate.[5]

Purification: commercial product can be purified by recrystallization from ethanol, although some loss of material occurs due to ring opening. Synthetic material should be purified by the method of McArthur.[4] A 2 M solution of the crude material in chloroform is cooled overnight in a refrigerator and filtered to remove phthalimide. The solution is then concentrated to approximately 70% of the volume and an equal volume of petroleum ether is added. The crystals that form are collected and dried to give the desired *N*-ethoxycarbonylphthalimide.

Handling, Storage, and Precautions: no special handling conditions or precautions are required.

Phthaloylation of Amines.

The phthalimide protecting group has long been utilized for amines in organic synthesis.[6] While this group can be

introduced under a variety of conditions such as phthalic anhydride or ***Phthaloyl Dichloride***, these generally require drastic conditions and are not typically selective. The use of *N*-ethoxycarbonylphthalimide allows the phthaloylation of primary amines under mild conditions (eq 1).[7] Primary amines can be selectively protected in the presence of secondary amines (eq 2),[8] as well as amides and carbamates (eq 3).[9] The advantage of the phthalimido protecting group are its stability to both acid and mild base as well as the well known methods for selective removal with ***Hydrazine*** (eq 4)[10] or ***Phenylhydrazine*** (eq 5).[11]

(1)

(2)

(3)

(4)

(5)

Selective Phthaloylation of Amino Acids.

In his attempt to develop a method for the selective amine protection of amino acids, Nefkens introduced *N*-ethoxycarbonylphthalimide.[5] He reported the protection of a variety of amino acids without racemization (eq 6).[2] These phthaloyl derivatives are typically highly crystalline, thereby facilitating purification. The phthaloylation of hindered amino acids such as valine could be achieved by initial deprotonation followed by protection in ethyl acetate (eq 7).[12] Recently, McArthur has shown that the aqueous conditions initially developed by Nefkens lead to the formation of undesired side products.[4] Heating *N*-ethoxycarbonylphthalimide in ethanol generates the corresponding carbamate (eq 8).[4] He has developed an alternative method for the phthaloylation of amino acids in THF that occurs in exceptional yields without racemization (eq 9).[1] These protections can be performed on amino acids with a variety of sensitive functionalities such as hydroxyl groups (eq 10)[2] or halogens without reaction at these centers (eq 11).[13]

1-Ethoxycyclopropanol[1]

[13837-45-1] · $C_5H_{10}O_2$ · 1-Ethoxycyclopropanol · (MW 102.07)

(homoenolate formation, ring expansion to β-lactams and pyrrolines via 1-aminocyclopropanols, to cyclobutanones via 1-vinylcyclopropanols, and to cyclopentanones via 1-trimethylsiloxy-1-vinylcyclopropanes[1])

Physical Data: bp 60 °C/20 mmHg.

Solubility: sol usual organic solvents (ether, THF, CH_2Cl_2).

Preparative Methods: acyloin-type reaction of ethyl 3-halopropionates with highly dispersed ***Sodium*** (or ***Lithium***) in refluxing Et_2O in the presence of ***Chlorotrimethylsilane*** provides 1-ethoxy-1-trimethylsiloxycyclopropane in high yields.[2,3] Use of sonochemical activation simplifies the procedure.[4] Then, simple methanolysis (MeOH, $ClSiMe_3$) leads to the hemiacetal (eq 1).

Cyclization of optically pure β-halo esters gives enantiomerically pure cyclopropanes at C-2 and a 1:1 diastereomeric mixture at C-1.[5]

Handling, Storage, and Precautions: can be kept unaltered for several months at 0 °C. On heating at 100 °C, or on standing in acidic solvents, it undergoes ring opening to ethyl propionate.

Preparation and Reactions of Isolable Metal Homoenolates.

With metals (Ti, Hg, Zn, Sn, Bi, Sb, Te, Nb, etc.), siloxycyclopropanes afford reactive homoenolate species which are stable enough for isolation and characterization.[1b] For instance, an exothermic reaction occurred with ***Titanium(IV) Chloride*** to provide fine violet needles of a titanium species in 89% yield (eq 2).[1b]

Many examples of carbon-carbon bond formation from metal homoenolates with various electrophiles have been reported. Thus reaction of zinc homoenolates with acid chlorides in ethereal solvents containing 2 equiv of HMPA produces γ-keto esters in high yield (eq 3).[6] Palladium catalysis accelerates the reaction.[7]

In a polar solvent, treatment of zinc homoenolates with Me_3SiCl results in cyclopropane formation.[1b] Palladium homoenolates, from siloxycyclopropanes and ***Palladium(II) Chloride*** or its phosphine complex, can also serve as useful reaction intermediates.[8]

Reactivity and Synthetic Applications.

Ring expansion of properly activated cyclopropanes is now one of the major methods of forming cyclobutane derivatives.[1] Thus, addition of vinylmagnesium halides to the cyclopropanone hemiacetal provides 1-vinylcyclopropanols,[9] which on simple heating at 100 °C in liquid phase or by reaction with a variety of electrophilic reagents (HBr, $PhCO_3H$, *t*-BuOCl, etc.), undergo quantitative C_3 -> C_4 ring expansion to substituted cyclobutanones, thus providing convenient intermediates for the creation of a wide range of structural building blocks (eq 4).[1a,c] For instance, Baeyer-Villiger oxidation leads to γ-butyrolactones,[10] and reaction with sodium azide in buffered acetone provides γ-lactams.[9]

(4)

Conversely, *O*-silylation ($ClSiMe_3$, NEt_3, 5% DMSO)[11] affords 1-siloxy-1-vinylcyclopropanes, which undergo thermal vinylcyclopropane-cyclopentene rearrangement to 1-silyloxycyclopentenes exclusively (eq 5).[1]

(5)

Acid or basic hydrolysis gives 2-substituted cyclopentanones. Alternatively, the generation of corresponding lithium enolates (***Methyllithium*** in Et_2O) followed by α-alkylation produces α,β-disubstituted cyclopentanone derivatives, which constitute the basic framework of several natural products of biological importance.[12] For instance, the total synthesis of (±)-11-deoxyprostaglandin E_2 has been performed from the cyclopropanone hemiacetal, via the thermal C_3 -> C_5 ring expansion of a suitable 1-butadienyl-1-trimethylsiloxycyclopropane (eq 6).[13]

PGE_2 (6)

Reaction of enolates with the cyclopropanone hemiacetal magnesium salt led to substituted hydrazulenones.[14] β-Amino esters are formed on photolysis of ***Ethyl Azidoformate*** and 1-ethoxy-1-trimethylsiloxycyclopropane in MeCN.[15] Treatment of 1-alkoxy-1-siloxycyclopropane with a catalytic amount of palladium-phosphine complex in $CHCl_3$ under carbon monoxide atmosphere gives 4-ketopimelate.[8a] Arylation of siloxycyclopropanes by aryl triflates is effected by palladium catalysis.[8b] Inactivation of cytochrome P-450 by heteroatom-substituted cyclopropanes has been interpreted by the ring opening of a cyclopropanone hemiacetal to ethyl 3-hydroxypropionate.[16]

1-Vinylcyclopropyl sulfonates and allylically isomeric 2-cyclopropylidenethyl carbonate and acetate, which are readily available from the cyclopropanone hemiacetal, undergo regioselective palladium(0)-catalyzed nucleophilic substitutions. With stabilized anions Nu^1 (e.g. enolates of malonic esters or β-dicarbonyl compounds), the substitution

occurs *exclusively* at the terminal vinylic position providing cyclopropylidene derivatives; on the other hand, use of organometallic or hydride reagents Nu^2 (e.g. ***Phenylzinc Chloride***) entails tertiary substitution on the cyclopropane ring *exclusively* (eq 7).[17]

Related Reagents.

Cyclopropanone; ***Cyclopropenone 1,3-Propanediyl Acetal***; ***1-Ethoxy-1-(trimethylsilyloxy)cyclopropane***; ***1-(Tetrahydropyranyloxy)cyclopropanecarbaldehyde***.

2-Ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline

[16357-59-8] · $C_{14}H_{17}NO_3$ · 2-Ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline · (MW 247.29)

(activating agent used in peptide synthesis)

Alternate Names: ethyl 1,2-dihydro-2-ethoxy-1-quinolinecarboxylate; EEDQ.

Physical Data: mp 66-67 °C; bp 125-128 °C/0.1 mmHg.

Solubility: sol water, alcohol.

Form Supplied in: white powder; widely available and can be easily prepared.[1]

Peptide Synthesis.

In peptide synthesis, peptide bonds are created from the activated carboxylic group of a N^{α}-protected amino acid that is reacted with the nucleophilic free amino group of another amino acid (eq 1).

(1)

Activation of the carboxylic acid can be performed according to several strategies, leading mainly to two kinds of intermediates: active esters and acid anhydrides, which can be either symmetrical anhydrides or mixed anhydrides.

2-Ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline

EEDQ is a reagent used in peptide synthesis for the mixed carbonic anhydride strategy. It allows a slow formation of unsymmetrical anhydrides under very mild conditions (eq 2).[2]

Faster reaction of the mixed anhydride with nucleophilic species reduces the extent of side reactions that occur with high concentration of the anhydride (eq 3).[3]

The tendency to racemization is limited to a small extent. Nevertheless, wrong-side attack, leading to the formation of urethane, is not suppressed (eq 4).[4]

2-Ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline

As best results had been obtained with mixed anhydrides of ***Isobutyl Chloroformate***, probably because the isobutyl group decreases the amount of urethane products, IIDQ (**1**), an analog of EEDQ, has been proposed for use in peptide synthesis.[5,6]

(1)

As another alternative, EEDQ has been linked to a polymeric support, providing a supported coupling reagent in high yield (eq 5).[7]

(5)

Coupling reactions mediated by this reagent occur cleanly in high yield and with a low degree of racemization, comparable with that observed with EEDQ itself.[8] Nevertheless, the use of EEDQ in peptide synthesis is rather limited, other coupling reagents being very much more popular. Examples are: the carbodiimides, mainly ***1,3-Dicyclohexylcarbodiimide*** and diisopropylcarbodiimide; the family of BOP reagents such as ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate***; uroniums such as ***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate*** (HBTU), or urethane *N*-protected carbonic anhydrides (UNCA), and active esters.

3-(1-Ethoxyethoxy)propyllithium

[37494-03-4] · $C_7H_{15}LiO_2$ · 3-(1-Ethoxyethoxy)propyllithium · (MW 138.14)

(nucleophilic organolithium reagent used as synthetic equivalent of 3-hydroxypropyl anion)

Solubility: normally prepared in diethyl ether and used in situ.

Handling, Storage, and Precautions: organolithium reagent sensitive to moisture; normally used immediately, but filtered 1 M solutions may be stored for months at -30 °C.

Nucleophilic Additions.

This reagent (referred to below as EEOPrLi), like the analogous Grignard reagent, is normally used in synthetic chemistry as a synthon for the 3-hydroxypropyl anion. The reagent, developed by Eaton for this purpose and first reported in 1972,[1] is normally prepared in ca. 1 M ethereal solution by treatment of the bromide with ***Lithium*** wire or shot at ca. -5 to -15 °C after initiation at room temperature. The cloudy solution may be used immediately, or may be passed through a sintered glass funnel to give a crystal clear solution which may be stored at -30 °C for months. At room temperature, slow decomposition occurs to give cyclopropane, among other products. The 3-(1-ethoxyethoxy)propyl bromide starting material may be prepared on a large scale by the dichloroacetic acid catalyzed solvent-free addition of acid-free 3-bromopropanol to ***Ethyl Vinyl Ether***.

Addition of the prepared reagent, unlike its Grignard counterpart,[1] takes place readily to ketones and aldehydes at 0 °C or lower under typical conditions for organolithium reagents. Treatment with aqueous acid or ***Pyridinium p-Toluenesulfonate*** after simple workup readily induces hydrolysis to liberate the free alcohol together with the volatile byproducts ethanol and acetaldehyde and without affecting the newly introduced tertiary alcohol. Heating with acid causes cyclodehydration to produce the tetrahydrofuran, while simple oxidation, for example with ***Chromium(VI) Oxide***, generates the γ-lactone.[1,2] These transformations are illustrated for cyclohexanone (eq 1).

Eaton has used the addition to 2-octanone followed by hydrolysis and oxidation to the γ-lactone in his synthesis of dihydrojasmone (eq 2).[1]

The reagent has also been shown to add to lactones, addition to γ-caprolactone followed by hydrolysis with HCl leading to cyclization to spiroacetals (eq 3).[3]

Addition to substituted pyridines takes place to give the 2-(3-hydroxypropyl) derivatives, both in rearomatized form

after aerial oxidation (eq 4)[4] and as the dihydropyridine by trapping with ***Ethyl Chloroformate*** (eq 5).[5]

(4)

(5)

Epoxides are also successful electrophiles,[6] a reaction elegantly exemplified in a synthesis of brefeldin A in optically pure form. The synthesis involves addition of 3-(1-ethoxyethoxy)propyllithium to (*S*)-***Propylene Oxide*** and trapping of the alkoxide with ***Benzyl Bromide*** (eq 6).[7] Uncommonly for this reagent, the reaction is carried out in THF.

(6)

It is perhaps worth noting that 3-(1-ethoxyethoxy)propyllithium has also been used in the surface modification of poly(chlorotrifluoroethylene) films.[8] These authors comment that generation of the reagent in heptane solution is much more rapid than in ether.

The related dialkyl lithium cuprate reagent, also developed by Eaton,[1] undergoes efficient conjugate addition to α,β-unsaturated ketones at low temperature (e.g. eq 7).[9] Eaton has used this reaction to prepare a key intermediate in his synthesis of peristylane.[1,10] The cuprate reagent has also been shown to displace halide from primary alkyl iodides, as does the simple lithium reagent in the presence of catalytic quantities of Cu^{I}. This reaction was used to prepare gossyplure, the pink bollworm sex pheromone mixture (eq 8).[11]

3-(1-Ethoxyethoxy)propylmagnesium Bromide

[86551-76-0] · $C_7H_{15}BrMgO_2$ · 3-(1-Ethoxyethoxy)propylmagnesium Bromide · (MW 235.41)

(nucleophilic Grignard reagent used as synthetic equivalent of 3-hydroxypropyl anion)

Solubility: normally prepared in THF and used in situ.

Handling, Storage, and Precautions: Grignard reagent sensitive to moisture; must be prepared in the cold and used immediately; tends to rearrange even below room temperature.

Nucleophilic Additions.

This reagent (referred to below as EEOPrMgBr), like the analogous organolithium reagent, is normally used in synthetic chemistry as a synthon for the 3-hydroxypropyl anion. The reagent was first prepared by Eaton in ethereal solution for this purpose in 1972,[1] but was indicated by him to be much less useful than the corresponding organolithium reagent. Following a 1976 report by Ponaras concerning preparation of another sensitive Grignard reagent oxygenated at the 3-position,[2] the reagent is now normally prepared in THF solution by treatment of the bromide with an excess of ***Magnesium*** while maintaining the temperature strictly below 25-30 °C; ***1,2-Dibromoethane*** is used to initiate the reaction if necessary. At room temperature the reagent tends to rearrange and is normally used at around 0 °C. The 3-(1-ethoxyethoxy)propyl bromide starting material may be prepared on a large scale by the dichloroacetic acid-catalyzed solvent-free addition of acid-free 3-bromopropanol to ***Ethyl Vinyl Ether***.[1] The value of the ethoxyethoxy group over the possible alternative tetrahydropyran is readily seen: after reaction of the organometallic species, hydrolysis to liberate the free alcohol takes place more readily, and the byproducts ethanol and acetaldehyde are both volatile.

Unlike its organolithium counterpart,[1] the reagent is not reported to add readily to ketones. The displacement of halides from primary bromides is, however, useful: in a report actually antedating that of Ponaras, the Grignard reagent is prepared at 0 °C in THF solution in 65% yield. Copper-catalyzed addition to 1-bromononane and subsequent hydrolysis of the acetal group using aqueous ***Trichloroacetic Acid*** gave 1-dodecanol in 52% isolated yield (eq 1).[3] In a later example not requiring copper catalysis, Shea prepared a functionalized diene by displacement of bromide from 2-bromomethyl-1,3-butadiene in THF at -10 °C followed by hydrolysis using ***Pyridinium p-Toluenesulfonate*** (eq 2).[4]

(1)

(2)

The reagent is also reported to undergo efficient reaction with β-alkoxy-α,β-unsaturated ketones.[5,6] For example, addition to 3-ethoxy-2-cyclohexenone in benzene-THF solution took place below 10 °C (eq 3). The authors comment that the corresponding organolithium reagent gives unsatisfactory yields. Very careful hydrolysis of the acetal to give the hydroxy ketone was necessary in order to avoid spirocyclization.[5]

(3)

Particularly interesting is the addition of the reagent to an enantiomerically pure *N*-acylpyridinium salt to give the *N*-acylpyridone, subsequently used in an asymmetric synthesis of (+)-elaeokanines A and C (eq 4).[7]

N-Ethoxymethyleneaniline[1]

[6780-49-0] · $C_9H_{11}NO$ · *N*-Ethoxymethyleneaniline · (MW 149.19)

(preparation of aldehydes from Grignard reagents[2,3])

Alternate Name: ethyl *N*-phenylformimidate.

Physical Data: bp 87-88 °C/10 mmHg.

Form Supplied in: liquid, commercially available; best preparation is from ***Triethyl Orthoformate*** and aniline.[4]

Handling, Storage, and Precautions: store refrigerated under dry nitrogen.

Formylation Reagent.

Of the various older methods reviewed[1] for the synthesis of aldehydes from Grignard reagents, use of this imidate reagent was considered one of the best,[2] giving higher yields than ***Triethyl Orthoformate***.[1a] However, newer procedures have been developed that may yield superior results, e.g. treatment of Grignard reagents with ***Pentacarbonyliron***.[5] The reaction proceeds through the formation of the imine which is hydrolyzed to the aldehyde (eq 1).[2] Cyclohexane-1,3-dione also adds to the imidate, and upon hydrolysis of the intermediate 2-(phenylamino)methylene gives the 2-formylcyclohexane-1,3-dione.[6,7]

Formation of Ketones.

Recent reinvestigation of the above reaction has demonstrated that the reagent can also be utilized for the synthesis of a variety of ketones, by using 2 equiv of a Grignard reagent (80 °C) or alkyllithium (-30 °C).[8] This involves the addition of a second Grignard reagent or, preferably, an alkyllithium to the first-formed imine. Aqueous hydrolysis gives *N*-disubstituted methylaniline (ca. 100% yield) which is oxidized with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** to the Schiff's base; hydrolysis gives the ketone (eq 2).[8] This is not applicable to aliphatic ketones.

α,β-Unsaturated α-Substituted Aldehydes.

Condensation of ethoxymethyleneaniline with α-lithioalkylphosphonates gives, after treatment with ***Lithium Diisopropylamide***, lithio enaminoalkylphosphonates, which condense with aldehydes to give α,β-unsaturated α-

substituted aldehydes in moderate yield (eq 3).[9]

β-Lactams.

Treatment of α-substituted aliphatic acid chlorides with ethoxymethyleneaniline in the presence of ***Triethylamine*** generates only *trans* 1-phenyl-3-substituted 4-ethoxy-β-lactams in moderate to good yield.[10,11] The chromium carbene complex in eq 4 photochemically cyclizes with the imidate to give the same azetidinone (X = NBz_2) in good yield.[12]

Related Reagents.

N,N-Dimethylformamide; ***N-Methyl-N-(2-pyridyl)formamide***.

Ethoxymethylenemalonitrile[1]

[123-06-8] · $C_6H_6N_2O$ · Ethoxymethylenemalonitrile · (MW 122.13)

(Michael acceptor for addition/elimination reactions;[2] synthesis of substituted benzene rings[3] and other aromatic heterocycles;[4] dipolarophile[5])

Alternate Name: EMMN.

Physical Data: mp 64 °C; bp 160 °C/12 mmHg.

Solubility: sol alcohols, THF, DMF, $CHCl_3$, CH_2Cl_2.

Form Supplied in: colorless crystalline solid; commercially available.

Analysis of Reagent Purity: mp, ^{1}H NMR, ^{13}C NMR, IR.

Preparative Methods: can be synthesized by the condensation of ***Triethyl Orthoformate*** and ***Malononitrile*** in the presence of ***Acetic Anhydride***.[6] Likewise, ethoxy[^{2}H]methylenemalonitrile can be made using $DC(OEt)_3$.[7]

Purification: by distillation under reduced pressure.

Handling, Storage, and Precautions: is classified as a strong sensitizing agent and should be handled with gloves and goggles in a fume hood. Avoid contact with eyes, skin, and clothes. Also, ethoxymethlenemalonitrile is a combustible liquid with a flash point of 155 °C. It should be stored in a cool, dry place.

Use as a Michael Acceptor.

Ethoxymethylenemalonitrile has been used as a Michael acceptor for a wide variety of nucleophiles such as alcohols,[8] amines,[9] anilines,[2] enamines,[10] ester enolates,[11] hydrazines,[12] imines,[13] pyrroles,[14] stabilized carbanions,[15] thiazoles,[16] and thiols[17] to name only a few. Usually, the Michael addition is accompanied by β-elimination of the

ethoxy group to give substituted methylenemalonitrile derivatives (eq 1). Some highly conjugated dithiolylidenebutenes can be synthesized in this manner (eq 2).[18]

Treatment of EMMN with 2 equiv of ***Phenylmagnesium Bromide*** results in formation of the double Michael addition product (eq 3) following the customary addition/elimination sequence.[19]

Use in the Synthesis of Aromatic and Heteroaromatic Derivatives.

Since the nitriles themselves offer yet another electrophilic site for reactivity, the addition/elimination adducts are often not isolated but are converted directly to a variety of aromatic (eq 4)[3] and heteroaromatic derivatives including pyridones (eq 5),[15] pyrimidines (eq 6),[20] thiophenes (eq 7),[17] pyrazoles (eq 8),[21] pyrones (eq 9),[22] and heterocyclic annulenes (eq 10).[23]

(3-Ethoxy-3-oxopropyl)iodozinc

I-Zn-$(CH_2)_n$-R

(n = 2; R = CO_2Et)

[104089-16-9] · $C_5H_9IO_2Zn$ · (3-Ethoxy-3-oxopropyl)iodozinc · (MW 293.43)

(organozinc reagents functionalized with ester, ketone, nitrile, amide, or halide functionalities, capable of C-C bond formation with a variety of organic electrophiles, e.g arylation, vinylation, ethynylation, acylation, allylation, Michael-type addition, and addition to carbonyl CO bonds)

Alternate Name: Tamaru's reagent.

Physical Data: dark powder; reagent prepared in situ (see below).

Analysis of Reagent Purity: aliquots of reactions in process can be checked by VPC or TLC after addition of 1 N HCl.[1c]

Preparative Methods: organozincs (**1**)-(**5**), possessing electrophilic functionality (ester, ketone, nitrile, amide, halide) in the same molecule, can be prepared in high reproducibility in mmol to mol scales by the direct reaction of the corresponding iodides and zinc metal. Four kinds of procedures have been reported. *Method A*:[1] reaction of ***Zinc/Copper Couple*** with an iodide in benzene containing 1.5-2 equiv of DMF or DMA at 60 °C for several hours. For the preparation of zincio ketone (**3**), the use of HMPA in place of DMF or DMA is essential.[2] For the preparation of β-zincio esters (**1a-c**) and β-zincio nitriles (**2a-c**), THF also may be used as solvent in place of benzene-DMF or DMA. *Method B*:[3] reaction of zinc/copper couple with an iodide in benzene-DMA (2.7 equiv) under sonication at 20-35 °C for 30 min. This method is applied to the preparation of (**1d**), characteristically possessing an acidic amide proton. *Method C*:[4] reaction of ***Zinc*** powder or foil, activated with ***1,2-Dibromoethane*** (4-5%) and ***Chlorotrimethylsilane*** (3%) in THF, with a primary iodide at 35-40 °C and with a secondary iodide at 25-30 °C in the same solvent (ca. 12 h). *Method D*:[5] reaction of zinc metal, prepared by a slow addition of ***Lithium Naphthalenide*** (2 equiv) to a THF solution of ***Zinc Chloride***, with an alkyl bromide at rt. The zinc powders produced by this method are very reactive and react even with vinyl bromides and aryl bromides (e.g. ethyl *o*- and *p*-bromobenzoates).

Handling, Storage, and Precautions: the iodozinc reagents can be prepared and handled like Grignard reagents, and may be stored at rt for ca. one week; however, freshly prepared samples are recommended. All reactions should be conducted in a well-ventilated fume hood.

Introduction.

(3-Ethoxy-3-oxopropyl)iodozinc

The title reagent is an example of a lower homolog in a series of functionalized organozinc reagents with the general structure depicted above. See Table 1 for selected examples of reagents discussed in this entry.

Table 1 Selected Functionalized Organozinc Reagents $I\ Zn\ (CH_2)_n\ R$

	5	COPh	[*113274-37-6*]
(5)	4	Cl	[*112403-39-1*]

Reaction of Functionalized Organozincs.

As evident from their high functional group compatibility, organozincs show a very low reactivity toward most organic electrophiles. However, as discussed here, they can undergo C-C bond forming reactions with many electrophiles in the presence of an appropriate transition-metal catalyst or a Lewis acid. Some reactions of functionalized organocopper reagents,[6] derived from organozincs by transmetalation with a stoichiometric amount of CuCN.2LiCl (see ***Copper(I) Cyanide***) are discussed for comparison. For the reactions of bis(β-alkoxycarbonylethyl)zinc reagents, see Nakamura et al.[7]

Arylation, Vinylation, and Ethynylation.

Vinyl iodides, vinyl triflates, and aromatic iodides,[2,8] as well as aromatic bromides with electron-attracting substituents,[5] undergo coupling with organozincs in the presence of a catalytic amount of palladium (eqs 1-4). The vinylation (eq 3) proceeds with retention of configuration; the corresponding *trans*-iodide provides the *trans* coupling product exclusively in 71% yield.[8a] Arylation sometimes suffers from biaryl formation; for such cases, the use of the catalyst specified in eq 1 is recommended.[8a] The arylation tolerates an acidic amide proton (eq 2),[3,14c] and optically active phenylalanine derivatives are

obtained according to this procedure.[3] Organocopper reagents directly react with ethynyl iodides and bromides under mild conditions (eq 5).[9]

(1)

(2)

(3)

(4)

$n = 3$, 67%; $n = 6$, 74%

(3-Ethoxy-3-oxopropyl)iodozinc

(5)

Acylation.

Organozinc iodides are so unreactive that they do not react smoothly even with highly reactive acid chlorides, e.g. yielding butyrophenone in 20% yield by the reaction of *n*-propylzinc iodide with ***Benzoyl Chloride*** in benzene-DMF at 70 °C for 4 h.[10] The acylation is greatly accelerated by a palladium catalyst (eqs 6 and 7)[1,2] or a stoichiometric amount of CuCN.2LiCl (eq 8).[4a,5,11] The reactions in eqs 6 and 7, and the three-component connection reactions of allylic benzoates, ***Carbon Monoxide***, and organozincs (eq 9),[12] may proceed via acylpalladium intermediates.

(6)

(7)

(8)

(3-Ethoxy-3-oxopropyl)iodozinc

Addition to Activated Alkenes and Alkynes.

Conjugate addition of organozincs to α,β-unsaturated aldehydes, ketones, esters, and nitro compounds takes place smoothly in the presence of ***Chlorotrimethylsilane*** (2 equiv) and either a catalytic[13] or a stoichiometric amount of ***Copper(I) Cyanide***.[14] The retention of regiochemistry of the methyl substituent of (**1c**) (eq 11) is in contrast to the migration of the methyl group as observed for the reaction of (**1c**) with aldehydes (eq 18).[15] The reaction is not accompanied by racemization (eq 10)[13] and tolerates the acidic alkynic and amide protons (eq 12).[14c] Organozincs (e.g. **1a**, **1e**, **5**) nonselectively add to conjugated iminium salts in 1,2- and 1,4-fashion (eq 13),[16] while sorbaldehyde (2,4-hexadienal) undergoes a selective 1,4-addition reaction (vs. 1,2- and 1,6-additions) under the catalytic conditions shown in eq 10.[13]

(11)

(78% from **(1c)**) (70% from **(1b)**)

(12)

100% *E*

(13)

32:68

Allylation.

(3-Ethoxy-3-oxopropyl)iodozinc

Allylation of organozincs proceeds either catalytically (eqs 14 and 15)[17] or stoichiometrically (eqs 16 and 17)[14a] with respect to Cu^I salts. Generally, the stoichiometric reaction shows a higher regioselectivity (S_N2'/S_N2) and is applied to sequential double allylation reactions (eqs 16 and 17).[18,19]

(14)

(15)

(16)

(3-Ethoxy-3-oxopropyl)iodozinc

Addition to Carbonyls.

Functionalized organozincs react smoothly with aromatic aldehydes, but not with aliphatic aldehydes, in the presence of 2 equiv of chlorotrimethylsilane to give the alcohols in good yields (eqs 18 and 19).[15] Aliphatic aldehydes primarily provide the corresponding aldol products. Organocopper reagents may be sufficiently reactive toward both aromatic and aliphatic aldehydes in the presence of 2 equiv of ***Boron Trifluoride Etherate*** (eq 20).[20] Organotitanium reagents, prepared by the reaction of organozincs and ***Chlorotitanium Triisopropoxide***, are reactive toward aldehydes and ketones (eq 21).[21] Dialkylzincs (e.g. bis(γ-ethoxycarbonylpropyl)zinc) undergo an enantioselective addition to aldehydes in the presence of 2 equiv of ***Titanium Tetraisopropoxide*** and a catalytic amount of a chiral amide ligand.[22] In the presence of trialkylsilyl chloride and at elevated temperatures, β-zincio esters intramolecularly add to the ester carbonyl to provide allyloxysiloxycyclopropanes in moderate yields (eq 22).[23] These allyloxy derivatives are difficult to prepare according to Salaün's procedure.[24] The isomerization of (**1c**) to (**1b**) (eq 18) may involve cyclization similar to the one shown in eq 22.

Related Reagents.

[4696-25-7] (*E*)-(**2**; R = Me)

[4188-69-6] · C_4H_8O · 1-Methoxy-1-propene · (MW 72.12) (*Z*)-(**2**)

[4188-68-5]

(condensation with acetals to give α,β-unsaturated aldehydes;[3] acyl anion equivalent;[4] [4 + 2][5] and [2 + 2][6] cycloaddition reactions; transvinylation to prepare allyl vinyl ethers[7])

Physical Data: (**1**) bp 69-71 °C; *d* 0.778 g cm^{-3}. (*E*)-(**1**) bp 75 °C. (*Z*)-(**1**) bp 69 °C. (*E*)-(**2**) bp 48.5 °C. (*Z*)-(**2**) bp 45 °C.[2]

Solubility: sol most common organic solvents; slightly sol water.

Form Supplied in: colorless, extremely flammable liquids, obtained as a mixture of (*E*)/(*Z*) isomers by the pyrolysis of the corresponding acetals over pumice or $NaHSO_4$.[2b,c] The (*E*)/(*Z*) isomers have been separated by fractional distillation[2b,8] and by preparative-scale gas chromatography.[6a] Pure (>97%) (*E*) isomers of propenyl ethers have been prepared by H_2-activated ***(1,5-Cyclooctadiene)bis(methyldiphenylphosphine)iridium(I) Hexafluorophosphate*** catalyzed isomerization of allyl alkyl ethers.[9] 1-Ethoxy- but not 1-methoxy-1-propene is available commercially. 1-Ethoxy-1-propene is a skin irritant, moderately toxic by skin absorption, ingestion, and inhalation.[2c] Biological data on 1-methoxy-1-propene are unavailable. Use in a fume hood.

Condensation with Acetals.

Lewis acid-catalyzed condensations of 1-ethoxy-1-propene (**1**) with acetals give, after hydrolysis of the intermediate alkoxy acetals, α,β-unsaturated aldehydes and ketones.[3] Of the Lewis acids, ***Zinc Chloride*** and ***Boron Trifluoride Etherate*** are the most frequently used, although ***Montmorillonite K10*** can offer certain advantages, such as ease of workup.[10] In a study of the condensation of acetals with methyl vinyl ether in the presence of $BF_3.OEt_2$, the order of reactivity was found to be: acetals from α,β-unsaturated aldehydes > benzaldehyde acetals > methyl orthoformate > acetals from saturated aldehydes.[11] The enol ether-acetal condensation is exemplified by a synthesis of the C_{19} carotenal (**4**) from the C_{16} acetal (**3**) using (**1**) in the presence of $ZnCl_2$ (eq 1).[12]

(1)

Acyl Anion Equivalent.

Deprotonation of the α-H of (**1**) with ***t-Butyllithium*** at -74 °C, in THF or in *n*-pentane/TMEDA, generates the highly reactive α-alkoxy vinyl derivative (**5**) (eq 2), related lithio derivatives of which are known to react with a variety of electrophiles.[4]

(2)

Cycloaddition Reactions.

Thermal [4 + 2] Addition.

1-Ethoxy-1-propene participates in a variety of inverse-electron-demand Diels-Alder reactions to give cycloadducts with high *endo* selectivity and retention of the dienophile alkene geometry. The (*E*) isomer reacts faster than the (*Z*) isomer, and improved reaction conditions include the use of high pressure and Lewis acid catalysis.[5] The cycloaddition of (**1**) to enals,[5] enones,[5] and α,β-unsaturated esters[13] is regiospecific, giving dihydropyrans in excellent yields, often with very high stereospecificity (eq 3).[14] Similarly, the thermal or pressure-promoted cycloaddition of (**1**) to *N*-sulfonyl-1-aza-1,3-butadienes produces tetrahydropyridines, generally in a highly stereospecific manner with predominant *endo* selectivity (eq 4).[15] Cycloaddition of (**1**) yields dihydrooxazines from nitrosoalkenes[16] or from azomethines,[17] and chromanes from quinone methides.[18]

(3)

(4)

Thermal [2 + 2] Addition.

Electron-deficient alkenes react rapidly with (**1**) to give cyclobutane derivatives, with the (*Z*) isomer of (**1**) reacting faster than the corresponding (*E*) isomer. In general, stereoisomeric mixtures of products are obtained, which increase with solvent polarity (eq 5).[6] Ketenes give cyclobutanones (eq 6),[19,20] while *p*-tosyl isocyanate and *p*-tosyl isothiocyanate give *N*-tosyl azetidinone (eq 7)[20] and *N*-tosyl-2-thietaneimine (eq 8),[21] respectively, on cycloaddition with (**1**).

(5)

(6)

(7)

(8)

Photochemical Addition.

Photoaddition of vinyl ethers to α,β-enones produces alkoxycyclobutanes, and alkoxyoxetanes from aldehydes and ketones (see ***Ethyl Vinyl Ether***).[22] Although not with (**1**), extensive studies have been conducted on the cycloaddition of 1-methoxy-1-propene to acetone.[23]

Transvinylation.

In contrast to ethyl vinyl ether, (**1**) is rarely used in the transvinylation of alcohols. An example is the preparation of the aldehyde (**7**) in >51% yield by sequential transvinylation-Claisen rearrangement executed by heating an (*E*)/(*Z*) mixture of 1-ethoxy-1-propene with the allyl alcohol (**6**) in the presence of ***Mercury(II) Acetate*** (eq 9).[7]

(9)

Related Reagents.

(2-Ethoxy-1-propenyl)triphenylphosphonium Iodide

[62639-97-8] · $C_{23}H_{24}IOP$ · (2-Ethoxy-1-propenyl)triphenylphosphonium Iodide · (MW 474.29)

(precursor for 2-ethoxyallylidenetriphenylphosphorane, which is a three-carbon annulation reagent[1])

Physical Data: mp 163-165 °C.

Preparative Methods: by the condensation of ***Ethyl Iodide*** with 1-triphenylphosphoranylidene-2-propanone.[2]

Purification: recrystallization from methanol-ethyl acetate.

Handling, Storage, and Precautions: should be dried in vacuo for best results.

Annulation of Cyclohexanones.

Deprotonation of (2-ethoxy-1-propenyl)triphenylphosphonium iodide[1] with ***n-Butyllithium*** in hexanes gives 2-ethoxyallylidenetriphenylphosphorane (**1**) (eq 1).[2] This reagent has been used[2] to donate three carbon atoms in a [3 + 3] annulation of cyclohexenones onto enones for the construction of six-membered carbocyclic systems.[3]

(1)

(1)

Thus the in situ generated ylide (**1**) reacts in a tandem Michael addition Wittig reaction with a variety of α,β-unsaturated ketones (**2**) to provide the 2-ethoxy-1,3-cyclohexadienes (**3**). These intermediates are subsequently hydrolyzed on workup with 1 N HCl to give the cyclohexenones (**4**) in 26-61% overall chemical yield (eq 2).[4] This reaction sequence has been used for the construction of monocyclic, fused bicyclic, and spiro bicyclic ring systems.[2]

2-Ethoxypyridine 1-Oxide

[3445-09-8] · $C_7H_9NO_2$ · 2-Ethoxypyridine 1-Oxide · (MW 139.16)

(acyl activating agent for peptide synthesis;[1] catalyst for phosphotriester bond formation[2])

Physical Data: mp 72-74 °C.

Solubility: sol ethanol, acetic acid.

Preparative Methods: from 2-ethoxypyridine and ***Hydrogen Peroxide***[3] or 2-chloropyridine 1-oxide and ethanolic ***Sodium Ethoxide***.[4]

Peptide Synthesis.[1]

Reacts with acid chlorides to give activated esters which can be condensed with amino acids, giving 1-hydroxy-2(1*H*)-pyridone as a water-soluble byproduct (eq 1). This is an advantage over coupling using ***1,3-Dicyclohexylcarbodiimide*** because of the easier separation of byproducts.

Phosphotriester Bond Formation.[2]

One of a range of oxygen-nucleophilic catalysts for phosphotriester bond formation which gives few byproducts. 4-Ethoxypyridine 1-oxide is even faster.[2]

1-Ethoxy-4-tributylstannyl-1,3-butadiene[1]

[66876-05-9] · $C_{18}H_{27}OSn$ · 1-Ethoxy-4-tributylstannyl-1,3-butadiene · (MW 386.91)

(reagent for the four-carbon homologation of aldehydes and ketones to dienals)

Physical Data: bp 120-130 °C/0.3 mmHg.[2]

Solubility: sol THF.

Preparative Methods: prepared as a mixture of (*E*) and (*Z*) isomers by the hydrostannation of 1-ethoxy-1-buten-3-yne with one equivalent of ***Tri-n-butylstannane*** and catalytic ***Azobisisobutyronitrile***.[2]

Purification: purified by distillation.[2]

Handling, Storage, and Precautions: organostannane reagents are potentially toxic;[3] their preparation and use must therefore be conducted wearing appropriate protective clothing in a well ventilated hood. The reagent should be stored under an inert atmosphere and protected from light and moisture.

Transmetalation.

Transmetalation of 1-ethoxy-4-tributylstannyl-1,3-butadiene (**1**) with one equivalent of ***n-Butyllithium*** at -78 °C proceeds smoothly to afford 1-lithio-4-ethoxy-1,3-butadiene (**2**).[2] This reagent reacts with aldehydes and ketones to yield the expected 1,2-adducts. Treatment of the resulting enol ethers with catalytic acid promotes the rearrangement to afford dienal products[2,4] (eq 1).[4a] Substrates which are sensitive to acidic environments can be converted to dieneals by treatment of the corresponding allylic mesylate with ***Triethylamine*** (eq 2).[5] This overall procedure provides (*E*,*E*)-dieneals in high geometric purity from aldehydes. Condensation of (**2**) with ketones affords mixtures of (*E*,*E*) and (*E*,*Z*) products.[2] Consequently, this reagent is of less synthetic utility for the homologation of ketones to geometrically pure (*E*,*E*)-dienals.

The iterative condensation of (**2**) provides an efficient method for the preparation of (*E*)-polyenals with high isomeric purity.[6,7] This approach was found to be superior to either the Wittig-Horner or Corey's lithio-*N*,*N*-dimethylhydrazone homologation procedures for the construction of geometrically pure hexenal (**3**) (eq 3).[6,7]

Physical Data: bp 110 °C/0.3 mmHg.[3a]

Solubility: sol THF, DMF, MeCN.

Preparative Methods: prepared in high yield by the reductive hydrostannation of ***Ethoxyacetylene*** with ***Tri-n-butylstannane***.[2,3a]

Purification: by distillation.[3a]

Handling, Storage, and Precautions: organostannane reagents are potentially toxic;[4] their preparation and use must therefore be conducted wearing appropriate protective clothing in a well ventilated hood. The reagent should be stored under an inert atmosphere and protected from light and moisture.

Transmetalation.

Treatment of 1-ethoxy-2-tributylstannylethylene (**1**) with ***n-Butyllithium*** proceeds quantitatively to afford (*E*)-2-ethoxyvinyllithium.[3] This reagent exhibits reactivity typical of vinyllithium reagents, affording entry into a variety of substituted enol ethers which are readily hydrolyzed to the corresponding acetaldehyde derivative.[3] For further discussion of this chemistry, see ***1-Ethoxyvinyllithium***.

Cross-Coupling Reactions.

Stille et al. pioneered the palladium-catalyzed cross-coupling reaction of organostannanes with a variety of electrophilic partners. These reactions proceed under mild conditions which are often compatable with typically sensitive functional groups.[1]

Aromatic halides, with the exception of phenols and unsubstituted anilines, couple smoothly with (**1**) to afford the corresponding (*Z*)-enol ether (eq 1).[5] Heteroaromatic halides and triflates also react smoothly with (**1**).[5,6] In several cases, mixtures of (*E*)- and (*Z*)-enol ethers were obtained with electron-deficient heteroaromatic substrates.[5b,6]

Coupling of (**1**) with an *ortho* heterosubstituted aromatic substrate followed by hydrolysis to the acetaldehyde and cyclization is a convenient and flexible method for the preparation of functionalized heterocycles (eq 2).[5b] Benzofurans, indoles, isocoumarins, pyranopyridinones, and pyrrolopyridines have been prepared using this sequence.[5b]

(1)

(2)

Palladium-catalyzed carbonylative coupling of (**1**) with aromatic iodides affords (*E*)-3-ethoxy-1-phenyl-2-en-3-ones in moderate yield.[7] Under similar coupling conditions the corresponding aryl bromides yield none of the expected product. Electron-deficient aromatic systems are poor substrates for this reaction. In such cases the rate of direct insertion of (**1**) is competitive with the carbonylative coupling reaction. For example, carbonylative coupling of (**1**) with 4-nitroiodobenzene afforded (*E*)-3-ethoxy-1-(4-nitrophenyl)prop-2-en-1-one and (*Z*)-2-ethoxy-1-(4-nitrophenyl)ethylene in 25% and 40% yields, respectively. Chromones and 4(1*H*)-quinolones have been prepared from these intermediates (eq 3).[7]

Ethoxy(trimethylsilyl)acetylene

EtO-C&tbond;C-SiMe$_3$

[1000-62-0] · $C_7H_{14}OSi$ · Ethoxy(trimethylsilyl)acetylene · (MW 142.27)

(mild agent for conversion of carboxylic acids into carboxylic anhydrides;[1] dehydrative condensation agent for carboxylic acids and amines and alcohols;[2] trimethylsilylketene precursor;[3] 2π component in cycloaddition reactions[4])

Physical Data: bp 57 °C/34 mmHg; *d* 0.828 g cm^{-3}.

Solubility: insol H_2O; freely sol most common solvents.

Form Supplied in: colorless liquid; widely available.

Preparative Methods: by silylation of ***Ethoxyacetylene***.[1,3,5]

Handling, Storage, and Precautions: storable in a refrigerator for years without any polymerization or decomposition (one of the features that favors the use of this reagent over ethoxyacetylene for many applications).

Carboxylic Anhydrides.

Dehydration of carboxylic acids or dicarboxylic acids to the corresponding anhydrides is effected by using ethoxy(trimethylsilyl)acetylene (**1**). In general, a carboxylic acid is treated with 1.5 equiv of (**1**) in CH_2Cl_2, $ClCH_2CH_2Cl$, or MeCN at rt to 60 °C for 2 h to 1 d followed by concentration of the reaction mixture to give a pure anhydride in an almost quantitative yield (eq 1).[1] The only byproduct of this reaction is the neutral and volatile ethyl (trimethylsilyl)acetate. Use of ethoxyacetylene for this purpose has been limited because of its instability to heat, high volatility, and low reactivity with some carboxylic acids.[6] The reagent (**1**) resolves these problems and is especially effective for preparation of the carboxylic anhydrides with acid-sensitive functional groups such as (**2**)[1] and (**3**).[7] Suitably functionalized homophthalic anhydrides (**2**) and (**4**)[8] and their heteroaromatic derivatives (**5**)[9] are key intermediates for total synthesis of natural anthracyclines and their heteroaromatic analogs.

(2) 99%

(3) 100%

(4) 99%

(5) 100%

Dehydrative Condensation of Carboxylic Acids with Amines and Alcohols.

In the presence of a mercuric catalyst, (**1**) causes dehydrative condensation of carboxylic acids with H-acidic materials such as amines and alcohols to give the corresponding amides, esters, lactones, and peptides in high yields.[2]

Preparation of (Trimethylsilyl)ketene.

Heating of (**1**) at 120 °C is a convenient method for preparation of ***Trimethylsilylketene*** (**6**) (eq 2).[3] This ketene is an easy-handling, storable, and distillable monomeric liquid, and is useful for acylation of sterically hindered alcohols and amines (eq 3). Other useful applications of (**6**) are represented in the preparation of α-silyl acetates,[10] α-silyl ketones,[11] α,β-unsaturated esters,[12] and silylallenes.[17]

Cycloaddition Reactions.

Dichloroketene, *N*-sulfonylimines, ***Diazomethane***, and aroylketenes add to (**1**) to provide good yields of a cyclobutenone,[4] 2-azetines,[13] a pyrazole,[14] and 4-pyrones,[15] respectively. Cooligomerization of three molecules of (**1**) with one molecule of ***Carbon Dioxide*** proceeds in the presence of Ni^0 catalyst, giving a 2-pyrone derivative in 90% yield.[16]

1-Ethoxy-1-(trimethylsilyloxy)cyclopropane

[27374-25-0] · $C_8H_{18}O_2Si$ · 1-Ethoxy-1-(trimethylsilyloxy)cyclopropane · (MW 174.32)

(preparation of 3-metallopropionates;[1] metal homoenolate precursor[2])

Physical Data: bp 50-53 °C/22 mmHg.

Solubility: insol H_2O.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: GLC, NMR.

Preparative Methods: for the synthesis of the parent and the 2-monoalkyl-substituted compounds, reduction of ethyl 3-chloropropionate with ***Sodium-Potassium Alloy*** alloy in the presence of ***Chlorotrimethylsilane*** in ether.[3] A recent modification using ultrasound irradiation is much more convenient and more widely applicable.[4] Other substituted derivatives are prepared by cyclopropanation of alkyl silyl ketene acetals with the Furukawa reagent (***Diiodomethane***/***Diethylzinc***).[5]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: moisture sensitive, yet, once purified by distillation, is stable for a long period of time in a tightly capped bottle at room temperature.

Stoichiometric Precursor of Metal Homoenolates.

The reaction of 1-alkoxy-1-trimethylsilyloxycyclopropane with a variety of Lewis acidic metal chlorides affords the 3-metallated propionate esters in good to excellent yield (see below).[1,6,7] For instance, the reaction of 1-ethoxy-1-trimethylsilyloxycyclopropane with one equivalent of ***Tin(IV) Chloride*** gives a 3-stannylpropionate, which further reacts with another equivalent of the cyclopropane to give a dialkylated tin compound (eq 1).

The reaction of the siloxycyclopropane with ***Titanium(IV) Chloride*** produces the titanium homoenolate (3-titaniopropionate) in good yield; this, however, is relatively unreactive (eq 2).[8] Addition of one equivalent of $Ti(OR')_4$ generates a more reactive $RTiCl_2OR'$ species, which smoothly reacts with carbonyl compounds below room temperature.[9] The γ-hydroxy ester adducts are useful synthetic intermediates and serve as precursors to γ-lactones and cyclopropanecarboxylates.[10] A useful variation involves the use of the cyclopropanecarboxylate ester as a functionalized homoenolate precursor to obtain levulinic acid derivatives (eq 3).[11]

(2)

(3)

The zinc homoenolate prepared by the treatment of the siloxycyclopropane with ***Zinc Chloride*** is a versatile synthetic reagent (eq 4).[12] Reduction of 3-iodopropionate with activated ***Zinc*** also produces a zinc homoenolate species.[13]

(4)

Treatment of the silyloxycyclopropane with $ZnCl_2$ followed by addition of an enone, HMPA, THF, and a catalytic amount of a Cu^I salt results in quantitative formation of a conjugate adduct as an enol silyl ether (eq 4). The chlorosilane, a byproduct, is essential for the conjugate addition of the copper homoenolate.[14,15] ***Boron Trifluoride Etherate*** promotes the copper-catalyzed conjugate addition reaction with a different stereochemical outcome.[16] A useful application of the conjugate addition reaction is a [3 + 2] synthesis of cyclopentenones, wherein the homoenolate acts as a 1,3-dipole equivalent (eq 5).[17]

(5)

1-Ethoxy-1-(trimethylsilyloxy)cyclopropane

The zinc homoenolate undergoes copper-catalyzed allylation with allylic chlorides. The reaction is not only extremely S_N2' regioselective but stereoselective for δ-chiral allylic chlorides.[18] Arylation and vinylation of the zinc homoenolates proceed in the presence of a palladium-phosphine complex.[19] Similarly, palladium-catalyzed acylation reaction gives γ-keto esters (eq 6).

Catalytic Generation of Homoenolate Reactive Species.

Homoaldol reaction between the siloxycyclopropane and an aldehyde with a catalytic amount of ***Zinc Iodide*** in methylene chloride affords a γ silyloxy ester (eq 7).[18,20] Arylation[21] and acylation[22,23] of the silyloxycyclopropanes in the presence of a palladium catalyst take place via direct attack of an aryl- or acylpalladium intermediate on the C-C bond of the cyclopropane (eqs 8 and 9). The reaction is applicable not only to ester synthesis but also to ketone and aldehyde synthesis. Heating a chloroform solution of the silyloxycyclopropane in the presence of a palladium-phosphine catalyst under 1 atm ***Carbon Monoxide*** produces a γ-keto pimelate (eq 10).[24]

(7)

$R^1 = H, Me$

(8)

$R^2 = H$, alkoxy, alkyl, aryl

(9)

R = alkoxy, alkyl, aryl

(10)

Precursor of Lithiocyclopropane.

Bromination of the silyloxycyclopropane with ***Phosphorus(III) Bromide*** produces 1-bromo-1-ethoxycyclopropane. Successive treatment of the bromide with ***t-Butyllithium*** and an enal affords a cyclopropylcarbinol, which undergoes acid-catalyzed ring enlargement to give 2-vinylcyclobutanone (eq 11).[25]

(11)

Reactions with Azidoformates.

Photolysis of an acetonitrile solution of the cyclopropane and ***Ethyl Azidoformate*** at rt gives a C-H insertion product (eq 12).[26] However, thermolysis of the same mixture in DMSO gives a 3-aminopropionate by insertion of nitrene into the cyclopropane ring (eq 13).[27]

(12)

(13)

Cyclopropanone Hemiacetals and Their Use.

Mild alcoholysis of the silyloxycyclopropane gives a cyclopropanone hemiacetal. This compound serves as a stable equivalent of unstable cyclopropanones.[3] Treatment with two equivalents of alkynylmagnesium bromide gives a 1-ethynyl-1-hydroxycyclopropane (eq 14).[28]

(14)

The cyclopropanol also serves as a source of homoenolate radical species. Treatment of a mixture of the cyclopropanol and an enol silyl ether with manganese(III) 2-pyridinecarboxylate in DMF gives a 1,5-dicarbonyl compound (eq 15).[29]

1-Ethoxy-1-(trimethylsilyloxy)cyclopropane

(15)

Strecker amino acid synthesis starting with the cyclopropanone hemiacetal provides a enantioselective route to a cyclopropane amino acid (eq 16).[30]

(*Z*)-2-Ethoxyvinyllithium

[64724-28-3] · C_4H_7LiO · (*Z*)-2-Ethoxyvinyllithium · (MW 78.04)

(equivalent of the anion of acetaldehyde in aldol condensation and alkylation)

Preparative Methods: proceeds smoothly by reaction of (*Z*)-1-ethoxy-2-tri-*n*-butylstannylethylene, prepared by hydrostannation of the commercially available compound ***Ethoxyacetylene***, with 1.1 equiv of ***n-Butyllithium*** in THF at -78 °C for 1 hr.[1,2] (*Z*)-2-Ethoxyvinyllithium can also be prepared by halogen-metal exchange between (*Z*)-ethoxyvinyl bromide and butyllithium in diethyl ether at -80 °C.[3]

Handling, Storage, and Precautions: (*Z*)-ethoxyvinyllithium is stable in THF up to -45 °C, in an ethylene glycol dimethyl ether/THF mixture (1:1) up to -35 °C, and fairly stable up to -30 °C.[3] (*E*)-2-Ethoxyvinyllithium is unstable even at -80 °C.

Addition to Carbonyl Compounds.

(*Z*)-2-Ethoxyvinyllithium offers a highly efficient route to α,β-unsaturated aldehydes from carbonyl compounds. Thus it reacts with aldehydes and ketones at -78 °C to produce allylic alcohols in good yields. The intermediate allylic alcohols are converted into α,β-unsaturated aldehydes under nonacidic conditions. Chromatography of the resulting allylic alcohols on silica gel or Florisil is sufficient to cause complete allylic rearrangement to the α,β-unsaturated aldehydes (eqs 1 and 2).[4,5]

(1)

(2)

(*Z*)-2-Ethoxyvinyllithium can react with the hindered ketone (**1**), that is unreactive with either $(MeO)_2POCHLiCO_2Me$ or ***Ethyl Lithio(trimethylsilyl)acetate*** to form, after hydrolysis, an α,β-unsaturated aldehyde (eq 3).[6]

(1)

(3)

Addition of (*Z*)-1-ethoxyvinyllithium to the silyl ketone (**2**) and subsequent methylation provides the allenyl silyl ether (**3**) through C-O silyl migration and concomitant equilibration to allenyl anion (eq 4).[7]

(4)

Alkylation.[1]

(*Z*)-2-Ethoxyvinyllithium reacts with alkyl halides to accomplish a two-carbon chain extension of halides to aldehydes. Alkylation of (*Z*)-1-ethoxyvinyllithium with 1-iododecane in THF at -78 °C requires ***Hexamethylphosphoric Triamide*** as cosolvent (1 equiv) (eq 5). The allylic halide geranyl bromide is more reactive and is smoothly alkylated without HMPA as cosolvent (eq 6). The resulting enol ethers are converted by mild acid treatment (3:2:1 acetic acid-THF-water, 40 °C) to carbonyl compounds in 95% isolated yields.

(5)

(6)

Vinylcuprate Reagent.[1]

Reaction of ***Copper(I) Iodide*** and ***Dimethyl Sulfide*** in THF with (*Z*)-1-ethoxyvinyllithium at -78 °C produces a red-brown soluble cuprate. It undergoes both conjugate addition with α,β-unsaturated carbonyl compounds (eqs 7 and 8) and direct displacement reaction with activated halides (eq 9).

(7)

(8)

(9)

Related Reagents.

(*Z*)-[(Trimethylsiloxy)vinyl]lithium is prepared by halogen-metal exchange between (*Z*)-2-bromo-1-(trimethylsiloxy)ethylene and ***t-Butyllithium*** at -70 °C in ether. Condensation of (*Z*)-[(trimethylsiloxy)vinyl]lithium

with aldehydes and ketones occurs readily at -75 °C. Treatment of the products with dilute ***Hydrochloric Acid*** produces α,β-unsaturated aldehydes (eq 10).[8]

(10)

Transmetalation of the vinylstannane (**4**) (mixture of geometric isomers), available by treatment of 1-ethoxy-1-buten-3-yne with ***Tri-n-butylstannane*** and a catalytic amount of ***Azobisisobutyronitrile***, with *n*-butyllithium in THF at -78 °C proceeds smoothly. Condensation of the resulting lithium reagent with aldehydes and ketones produces dienols which transform into dienals by either silica gel chromatography or ***p-Toluenesulfonic Acid*** in aq THF (eq 11).[9]

(11)

See also ***1,2-Dimethoxyvinyllithium 1-Ethoxyvinyllithium 5-Lithio-2,3-dihydrofuran 6-Lithio-2,3-dihydro-4H-pyran 1-Methoxyvinyllithium***

1-Ethoxyvinyllithium[1]

[40207-59-8] · C_4H_7LiO · 1-Ethoxyvinyllithium · (MW 78.04)

(reacts with aldehydes and ketones to form allylic alcohols;[1,2] adds to the carbon-nitrogen double bond of isoquinolinium salts;[3] reacts with chlorosilanes;[4] can add to conjugated sulfones[5])

Physical Data: ^{13}C NMR solution studies in THF have been reported.[6]

Solubility: sol THF.

Form Supplied in: prepared in situ and used directly.

Preparative Methods: prepared in situ under nitrogen by the reaction of ***Ethyl Vinyl Ether*** in anhydrous THF with ***t-Butyllithium***.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture.

Additions to Aldehydes and Ketones.

1-Ethoxyvinyllithium adds to benzaldehyde to yield an allylic alcohol (eq 1) which, upon acid hydrolysis, forms the α-hydroxy methyl ketone.[2] Reaction also occurs with ketones (eq 2).[7]

(1)

(2)

γ-Ethoxy dienones have been synthesized in good yields via the intermediate produced by the reaction of 1-ethoxyvinyllithium with 3-ethoxy-2-cyclohexenones.[8]

Addition of the reagent to a 2-dialkylaminocyclohexanone has been reported (eq 3).[9]

(3)

The reagent adds to conjugated enones at the carbonyl group (eq 4).[10-12]

(4)

Addition of the reagent to an aldehyde in the total synthesis of nikkomycin B produced the vinyl ether, which was not isolated.[13] The reagent can also be used to prepare the corresponding cuprate, which adds 1,4 to enones.[14]

Addition to Carbon-Nitrogen Double Bonds.

The reagent adds cleanly to isoquinolinium salts (eq 5) to yield, after acid hydrolysis, the methyl ketone.[3]

(5)

Reaction with Chlorosilanes.

Chlorosilanes react with 1-ethoxyvinyllithium[4,15] to yield, after acid hydrolysis, acylsilanes with overall yields of 19-31% (eq 6).[4]

(6)

Addition to Conjugated Sulfones.

The reagent adds to conjugated sulfones at the β-carbon in good yields (eq 7).[5]

(7)

Related Reagents.

5-Lithio-2,3-dihydrofuran; ***6-Lithio-2,3-dihydro-4H-pyran***; ***1-Methoxyvinyllithium***.

Ethyl Acetoacetate[1]

(**1**; R^1 = Me, R^2 = Et)

[141-97-9] · $C_6H_{10}O_3$ · Ethyl Acetoacetate · (MW 130.16) (**2**; R^1 = R^2 = Me)

[105-45-3] · $C_5H_8O_3$ · Methyl Acetoacetate · (MW 116.13) (**3**; R^1 = Me, R^2 = *t*-Bu)

[1694-31-1] · $C_8H_{14}O_3$ · *t*-Butyl Acetoacetate · (MW 158.22) (**4**; R^1 = Ph, R^2 = Et)

[94-02-0] · $C_{13}H_{16}O_3$ · Ethyl Benzoylacetate · (MW 192.29)

(three- or four-carbon nucleophile in alkylations,[2] conjugate additions,[3] and various condensation reactions[4,5])

Physical Data: (**1**) bp 180-181 °C; *d* 1.025 g cm^{-3}. (**2**) bp 169-170 °C; *d* 1.076 g cm^{-3}. (**3**) bp 71-72 °C/11 mmHg; *d* 0.961 g cm^{-3}. (**4**) bp 266-270 °C; *d* 1.113 g cm^{-3}.

Preparative Methods: ethyl, methyl, and *t*-butyl acetoacetates and ethyl benzoyl acetate are commercially available. A wide variety of acetoacetic esters may be prepared via alcoholysis of diketene[6] and ester exchange reaction of *t*-butyl acetoacetate.[7]

Handling, Storage, and Precautions: use in a fume hood.

Alkylations.

Alkylation at the α-carbon of ethyl acetoacetate via an alkali metal enolate and subsequent removal of the ester group by sequential hydrolysis and decarboxylation provides a classical synthesis of methyl ketones (eq 1).[8] The ambident reactivity of the acetoacetate anion often causes competing *C*- and *O*-alkylations.[9] The extent of *C* vs. *O* alkylation depends on the nature of the leaving group, metal counterion, and solvent.[10,11] In general, heterogeneous reaction conditions, less electropositive metal cations, e.g. lithium, nonpolar or protic solvents, and polarizable alkylating agents such as alkyl iodides and allylic, propargylic, and benzylic halides favor *C*-alkylation. Highly dipolar aprotic solvents, e.g. HMPA, and highly reactive alkylating agents such as alkyl sulfonates and sulfates tend to favor *O*-alkylation. Use of phase-transfer catalysis,[12] heating crystalline thallium(I) enolates with alkyl iodides,[13] and alkylation in the presence of ***Tetra-n-butylammonium Fluoride*** base (eq 2)[14] are among the methods that successfully avoid or minimize *O*-alkylation. While primary and unhindered secondary halides give good yields of *C*-alkylated products, tertiary halides undergo elimination

under anionic alkylation conditions. In such cases, alkylation may be achieved via reaction of the enol with cationic species (eq 3).[15]

(1)

(2)

(3)

Metal coordinated alkenes react with acetoacetate anion, affording an alternative type of alkylation.[16] π-Allyl palladium species, catalytically generated by reaction of Pd^0 complexes with allylic acetates or halides, provide efficient *C*-allylation of the acetoacetate anion.[17] Alkylations with vinyl epoxides, allylic carbonates, and allylic carbamates via Pd^0 catalysis proceed without the need for an external base since the π-allylpalladium species in these systems are sufficiently basic to deprotonate acetoacetate in situ.[17] The regio- and stereoselectivities in alkylations with cyclic vinyl epoxides (eq 4)[18] are opposite to those observed under standard carbanion conditions.[19] A highly efficient Pd^0-catalyzed addition of methyl acetoacetate to 1,3-dienes can be achieved using ***1,3-Bis(diphenylphosphino)propane*** ligand (eq 5).[20]

(4)

(5)

Manganese(III) Acetate promotes the radical addition of ethyl acetoacetate to enol ethers and subsequent oxidative cyclization to 1-alkoxy-1,2-dihydrofurans, which may be hydrolyzed to alkylated acetoacetate derivatives (eq 6).[21] The corresponding reaction with simple alkenes is less general.[22]

(6)

α,γ-Dianions of acetoacetates (see ***Methyl Dilithioacetoacetate***) can be generated by treatment with 1 equiv of ***Sodium Hydride***, followed by 1 equiv of ***n-Butyllithium***, or 2 equiv of ***Lithium Diisopropylamide*** in THF.[23] Reaction of the dianion with a variety of alkylating agents including alkyl halides (eq 7)[23] and epoxides (eq 8)[24] results in regioselective γ-alkylation.

(7)

(8)

Acylations.

C-acylation at the α-carbon of ethyl acetoacetate may be achieved by reaction of the magnesio or sodio derivative with an acid chloride.[25] Acylation may also be performed efficiently in the presence of $MgCl_2$ and pyridine (eq 9).[26]

(9)

The dianions of acetoacetates undergo γ-*C*-acylation with esters.[27] Proton transfer occurs readily from product to the starting enolate. As a result, two equivalents of the dianion are needed to ensure complete conversion. This problem can be overcome by employing *N*-methoxy-*N*-methyl amides (see ***N-Methoxy-N-methylacetamide***) as acylating agents.[28] Addition of catalytic amounts of ***N,N,N´,N´-Tetramethylethylenediamine*** greatly improves the efficiency of acylation of dilithio ethyl acetoacetate (eq 10).[29] *N,N*-Dimethyl carboxamides can also be used as acylating agents in the presence of ***Boron Trifluoride Etherate***.[30]

(10)

Carbonyl Additions and Condensations.

Knoevenagel condensation of acetoacetates with carbonyl compounds may be carried out using a wide range of catalysts and reaction conditions.[4] A particularly mild and efficient procedure involves the use of ***Titanium(IV) Chloride*** and pyridine in THF at low temperatures, which allows the condensation of ethyl acetoacetate with aliphatic, aromatic, and heteroaromatic aldehydes to produce α-alkylideneacetoacetates (eq 11).[31] The condensation of *t*-butyl acetoacetate with

aldehydes and subsequent cleavage of the *t*-butyl ester by heating with catalytic ***p-Toluenesulfonic Acid*** provides a convenient synthesis of α,β-unsaturated methyl ketones.[32] α-Alkyl-substituted acetoacetates can add to aldehydes; however, the adducts often undergo acyl cleavage under the reaction conditions to give α,β-unsaturated esters (eq 12).[33] The dianion of methyl acetoacetate reacts with aldehydes and ketones in the γ-position to give aldol adducts (eq 13).[34]

(11)

(12)

(13)

Conjugate Additions and Annulation Reactions.

A wide variety of activated alkenes, alkynes, and allenes participate in conjugate additions or Michael reactions with acetoacetates. α,β-Unsaturated ketones, esters, nitriles, aldehydes, lactones, sulfoxides, sulfones, and nitro compounds are among the more commonly used alkene acceptors.[3] Although conventional procedures employ strongly basic catalysts, neutral reaction conditions (eq 14)[35,36] are often used to overcome side reactions such as bis additions and self condensations.

(14)

1,5-Diketones produced by the conjugate addition of acetoacetates to α,β-unsaturated ketones are useful in the synthesis of cyclohexenones via intramolecular aldol condensation.[37] A sequence of Knoevenagel condensation, Michael addition, aldol cyclization, and dealkoxycarbonylation may be carried in one pot using ethyl acetoacetate, an aliphatic aldehyde, and ***Piperidine*** catalyst (eq 15).[38] In general, however, annulation reactions of acetoacetates involve the Michael addition and the aldol cyclization as two separate steps (eq 16).[39]

(15)

(16)

Trimethylsilyl Enol Ethers.

Successive silylation of methyl acetoacetate with ***Chlorotrimethylsilane*** gives the mono- and the bis(trimethylsilyl) enol ethers (eq 17),[40] which are useful as synthetic equivalents of acetoacetate in reactions with a variety of electrophiles. Lewis acid-catalyzed reaction of the mono(trimethylsilyl) enol ether with *N*-acylimines,[41] oxonium ions,[42] thianium ions[43] and vinyl iminium ions (eq 18)[44] gives α-*C*-alkylated acetoacetate derivatives.

(17)

(18)

$TiCl_4$-catalyzed aldol addition of the bis(trimethylsilyl) enol ether of methyl acetoacetate to carbonyl compounds occurs exclusively in the γ-position.[45] Highly diastereoselective aldol additions can be achieved in reactions with α-alkoxy aldehydes (eq 19).[46] The bis(trimethylsilyl) enol ether may also be used as a 1,3-dianionic synthon for annulation with dicarbonyl electrophiles. Lewis acid-catalyzed annulation with α,α-dialkoxy ketones,[47] β,β-dialkoxy ketones,[40] and 1,4-keto aldehydes (eq 20)[48] allows the construction of five-, six-, and seven-membered ring systems, respectively.

Asymmetric Reduction.

Highly enantioselective asymmetric hydrogenation of acetoacetates can be achieved using ***2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl***-ruthenium complexes (eq 21).[49] The resulting 3-hydroxybutanoates (see ***Ethyl 3-Hydroxybutanoate***) are versatile auxiliaries and building blocks for the synthesis of enantiomerically pure products. Racemic α-substituted acetoacetates may also be hydrogenated in high stereoselectivity via dynamic kinetic resolution.[50]

Heterocyclic Synthesis.

A wide variety of five- and six-membered heterocyclic systems may be derived by the cyclocondensation of acetoacetates with 1,2- and 1,3-bifunctional reagents wherein one or both of the functionalities are heteroatomic (Table 1). The regioselectivity in these cyclizations can often be altered by replacing acetoacetates with their enol ether or enamine derivatives.

Table 1 Heterocyclic Synthesis via Cyclocondensation of Ethyl Acetoacetate (and Analogs) with 1,2- and 1,3-Bifunctional Reagents

Bifunctional reagent	Heterocyclic products
Hydrazines[51]	pyrazolones
Hydroxylamines[52]	isoxazolones
Hydroxamoyl chlorides[53]	isoxazoles
Hydrazidoyl chlorides[53]	pyrazoles
a-Amino ketones[54]	pyrroles
a-Halo ketones[55]	furans
a-Hydroxy carbonyl compounds[4]	furanones
b-Hydroxy carbonyl compounds[4]	pyranones
Salicylaldehydes[4]	coumarins
o-Aminobenzaldehydes and *o*-aminoacetophenones[4,56]	quinolines
Ureas, thioureas, amidines and guanidines[57]	pyrimidines

The classical synthesis of coumarins via the von Pechmann reaction[58] involves the condensation of acetoacetates with phenols under acid catalysis (eq 22).[59] Chromones are produced when the phenol contains a deactivating group or the acetoacetates are α-substituted. The condensation of acetoacetates with anilines can give either 2-hydroxy- or 4-hydroxyquinolines, depending upon the reaction temperature.[60] In the Hantzch synthesis of symmetrical dihydropyridines, two equivalents of acetoacetates are condensed with aldehydes in the presence of ***Ammonia*** (eq 23).[61] A variation of the Hantzch synthesis for the preparation of unsymmetrical dihydropyridines involves the condensation of α-(alkylidene)acetoacetates with 3-aminocrotonate.[62]

(22)

(23)

N-Ethylacetonitrilium Tetrafluoroborate

[462-35-1] · $C_4H_8BF_4N$ · *N*-Ethylacetonitrilium Tetrafluoroborate · (MW 156.91)

(reagent for the dehydration of aldoximes to nitriles[1])

Form Supplied in: needles; very unstable; not commercially available.

Preparative Methods: this salt can be prepared by *N*-alkylation of ***Acetonitrile*** with ***Triethyloxonium Tetrafluoroborate*** (eq 1),[2] or by *C*-alkylation of isocyanides.[1] The treatment of *O*,*O*,*O*-triethyl phosphorothioate with equimolar amounts of ***Nitrosonium Tetrafluoroborate*** in anhydrous acetonitrile gave the *N*-ethylacetonitrilium ion in moderate yield (eq 2).[3]

Handling, Storage, and Precautions: powerful alkylating agent similar to triethyloxonium tetrafluoroborate; treat with due caution.

Dehydration of Aldoximes.[1]

Nitrilium salts are very electrophilic and react readily with hydroxylic substances. They react with aldoximes (in MeCN for 8 h at 20 °C, 0.5 h at 80 °C) to give imino esters, which collapse to give the amide of the nitrilium ion and a nitrile (eq 3).[1] This reaction works well for a range of aromatic and alkyl R groups. The reagent compares favorably with the previous use of ***Trichloroacetonitrile*** for this transformation.[4]

Ethyl Acrylate[1]

[140-88-5] · $C_5H_8O_2$ · Ethyl Acrylate · (MW 100.13) (Me ester)

[96-33-3] · C_3H_6O · Methyl Acrylate · (MW 58.09)

(two- and three-carbon alkylating and annulating reagent commonly used in cycloadditions,[2] conjugate additions,[3] tandem vicinal dialkylation reactions,[4] and Heck reactions[5])

Physical Data: mp -71 °C; bp 98-100 °C; *d*204 0.924 g cm^{-3}; *n*20D 1.4049.

Solubility: 2 g 100 mL^{-1} H_2O (20 °C); forms 45% aqueous azeotrope, bp 81 °C; sol EtOH, ether; forms 57% ethanol azeotrope, bp 76 °C.

Form Supplied in: &egt;99%; typically stabilized with 15-200 ppm hydroquinone monomethyl ether; widely available.

Purification: [6] commercial material should be washed repeatedly with aq dil NaOH to free it from stabilizers; alternatively, stabilizers can be extracted using inhibitor removal columns (commercially available). Follow by washing with saturated aq $CaCl_2$. Dry using $CaCl_2$, and distill under reduced pressure. Store the purified ester tightly capped in an amber container, refrigerated below 0 °C.

Handling, Storage, and Precautions: the compound is a cancer suspect agent. A highly flammable irritant, it has an acrid, lachrymatory, penetrating odor. It polymerizes upon standing; polymerization is accelerated by heat, light, or peroxides. Additionally, polymerization occurs upon distillation at atmospheric pressure. Pure material can be stored below -10 °C without polymerization. This toxic reagent should be handled in a fume hood and skin contact should be scrupulously avoided.

Introduction.

The chemical reactivity of the alkyl acrylates is dominated by the electron-deficient nature of the carbon-carbon double bond. The lower alkyl acrylates readily polymerize, and the resulting polymers find commercial application in surface coatings, varnishes, and printing inks.[7]

Cycloaddition Reactions.

Alkyl acrylates probably rival maleic anhydride as the most common dienophiles in Diels-Alder chemistry.[2] They undergo [4 + 2] cycloadditions with a wide variety of dienes and 1,3-dipoles such as nitrones[8] and *S*-methylides,[9] providing entry to functionalized carbocyclic and heterocyclic systems. Eq 1 illustrates the use of methyl acrylate in a sequential Diels-Alder-decarboxylative retrocycloaddition-Diels-Alder preparation of a bornene diester intermediate, which can be converted to barrelene.[10] Certain bulky Lewis acids preferentially coordinate to alkyl acrylates with sterically undemanding alkyl groups, activating them towards reactions with dienes and substantially increasing the stereoselection of the reaction for *endo* adducts (eq 2).[11] Lewis acid-catalyzed ene reactions[2] of acrylates can be used in stereoselective, three-carbon chain homologations, such as in the synthesis of chenodeoxycholic acid (eq 3).[12]

(2)

(3)

Conjugate Addition Reactions.

A large number of carbon nucleophiles undergo conjugate additions with alkyl acrylates, including cyanide, enolates, nitro-, sulfinyl-, and sulfonyl-stabilized carbanions, organocopper reagents, Grignard reagents, enamines, amines, thiols, and radicals.[3a,13] Performed under protic conditions, monobasic nucleophiles such as ***2-Nitropropane*** provide high chemical yields of β-substituted propionates (eq 4).[14] If the nucleophile is dibasic, 1:2 nucleophile:acrylate adducts form efficiently:[15] 3-amino-1-propanol provides a 1:2 adduct with ethyl acrylate (eq 5) that can be used to prepare azetidine.[16]

(4)

(5)

In aprotic solvents the ester enolate formed upon conjugate addition can be alkylated in the α-position; a large number of these tandem vicinal dialkylation reactions are known.[4] Most such reactions are initiated by Michael addition of an enolate to the acrylate substrate; in contrast, organocopper reagents have been used relatively rarely. This may be because of a lack of reactivity with lithium dialkylcuprates: the situation is substantially improved when higher order cyanocuprates are employed.[17] With proper choice of nucleophile, both 1:1 and 1:2 conjugate adducts can participate in subsequent annulation reactions, illustrated by the [3 + 3] annulation synthesis of glutethimide (eq 6).[18] In aprotic media, these Michael-ring closure (MIRC)[4] reactions can afford cyclized products directly, as in the [1 + 2 + 3][19] cyclohexanone synthesis of eq 7,[20] or upon workup, illustrated by the [3 + 3] synthesis of 6-methoxytetralone (eq 8).[21]

(6)

(7)

(8)

Radical conjugate additions are relatively straightforward to perform;[3a,22] typically, ***Samarium(II) Iodide*** is used as a one-electron transfer reagent to form the radical conjugate donor.[23] A simple MIRC-type synthesis of γ-lactones is initiated by conjugate addition of various ketyls to ethyl acrylate (eq 9).[24]

(9)

Vinylations of Organohalogen Compounds.

The Heck reaction provides a convenient route to various substituted acrylate derivatives.[5] While the substituting reagent may simply be a second molecule of alkyl acrylate, resulting in tail-to-tail dimerization for formation of dialkyl (*E*)-2-hexenedioates,[25] sp^2- and sp-hybridized halides are more commonly used.[26] A rapid, two-step, stereospecific synthesis of pellitorine is indicative of the efficiency of the method (eq 10).[27] The process is reliable and quite general, although anomalous products can form: the reaction of methyl acrylate and 2-bromobenzaldehydes provides, in addition to the expected β-substituted acrylate, unusual doubly substituted products (eq 11).[28]

(10)

(11)

Other Reactions.

The carbon-carbon double bond of alkyl acrylates undergoes predictable electrophilic addition reactions:[29] the addition of ***Hydrogen Bromide*** to provide alkyl β-bromopropionates is typical (eq 12).[30] Transesterification[31] and hydrolysis[32] are accomplished via acid catalysis; concomitant polymerization can cause yields to be variable. Pyrolysis of ethyl acrylate at 590 °C yields ethylene and acrylic acid.[33]

Ethylaluminum Dichloride[1]

$EtAlCl_2$

[563-43-9] · $C_2H_5AlCl_2$ · Ethylaluminum Dichloride · (MW 126.95)

(strong Lewis acid that can also act as a proton scavenger; reacts with HX to give ethane and $AlCl_2X$)

Alternate Name: dichloroethylaluminum.

Physical Data: mp 32 °C; bp 115 °C/50 mmHg; *d* 1.207 g cm^{-3}.

Solubility: sol most organic solvents; stable in alkanes or arenes.

Analysis of Reagent Purity: solutions are reasonably stable but may be titrated before use by one of the standard methods.[1e]

Form Supplied in: commercially available neat or as solutions in hexane or toluene.

Handling, Storage, and Precautions: must be transferred under inert gas (Ar or N_2) to exclude oxygen and water. Use in a fume hood.

Alkylaluminum Halides.

Since the early 1980s, alkylaluminum halides have come into widespread use as Lewis acid catalysts. These strong Lewis acids offer many advantages over traditional metal halide Lewis acids such as ***Boron Trifluoride***, ***Aluminum Chloride***, ***Titanium(IV) Chloride***, and ***Tin(IV) Chloride***. Most importantly, the alkyl group on the aluminum will react with protons to give an alkane and a new Lewis acid. Alkylaluminum halides are therefore Brønsted bases, as well as Lewis acids. The alkyl groups are also nucleophilic, and this is the major disadvantage in the use of these compounds as Lewis acids.

Pure, anhydrous Lewis acids do not catalyze the polymerization of alkenes or the Friedel-Crafts alkylation of aromatics by alkenes. Cocatalysts, such as water or a protic acid, react with the Lewis acid to produce a very strong Brønsted acid that will protonate a double bond. Therefore, use of strictly anhydrous conditions should minimize side reactions in Lewis acid-catalyzed ene, Diels-Alder, and [2 + 2] cycloaddition reactions. Unfortunately, it is difficult to prepare anhydrous, proton-free $AlCl_3$, BF_3, etc. Alkylaluminum halides are easily prepared and stored in anhydrous form and, more importantly, scavenge any adventitious water, liberating an alkane and generating a new Lewis acid in the process.

Using alkylaluminum halides, Lewis acid-catalyzed reactions can now be carried out under aprotic conditions. This is of value when side reactions can be caused by the presence of adventitious protons; it is of special value when acidic protons are produced by the reaction. In these cases, use of the appropriate alkylaluminum halide in stoichiometric rather than catalytic amounts gives high yields of products not formed at all with other Lewis acids. The Me_2AlCl-catalyzed ene reactions of aliphatic aldehydes with alkenes, which give homoallylic alcohol-Me_2AlCl complexes that react further to give methane and the stable methylaluminum alkoxides, is an example of this type of reaction (eq 1).[1h,2] Loss of methane prevents the alcohol-Lewis acid complex from solvolyzing or protonating double bonds.

The alkylaluminum halides cover a wide range of acidity. Replacing chlorines with alkyl groups decreases Lewis acidity. $EtAlCl_2$ and ***Methylaluminum Dichloride*** are only slightly less acidic than $AlCl_3$. ***Diethylaluminum Chloride*** and ***Dimethylaluminum Chloride*** are substantially less acidic, and ***Trimethylaluminum***, Me_2AlOR, and $MeAl(OR)_2$ are even weaker Lewis acids. Alkylaluminum halides with fractional ratios of alkyl to chloride are also available. The sesquichlorides are commercially available. Other reagents can be prepared by mixing two reagents in the desired proportion. If no reaction occurs with the alkylaluminum halide, a stronger Lewis acid should be tried. If polymerization or other side reactions compete, a weaker Lewis acid should be used. The sequential ene and Prins reactions shown in eq 2 proceed cleanly with $Me_3Al_2Cl_3$.[3] Complex mixtures are obtained with the stronger Lewis acid $EtAlCl_2$ while the weaker Lewis acid Me_2AlCl reacts with ***Formaldehyde*** to give ethanol.

Use of more than one equivalent of Lewis acid will produce complexes that are formally 1:2 substrate Lewis acid complexes, but are more likely salts with a R_2Al-substrate cation and an aluminate anion.[4-6] This substrate in this salt is much more electrophilic and reactive than that in simple Lewis acid complexes.

These reagents are easier to use than typical inorganic Lewis acids. They are soluble in all organic solvents, including hexane and toluene, in which they are commercially available as standardized solutions. In general, alkane solvents are preferred since toluene can undergo Friedel-Crafts reactions. On a laboratory scale, these reagents are transferred by syringe like alkyllithiums and, unlike anhydrous solid Lewis acids, they do not require a glove bag or dry box for transfer.

While the Brønsted basicity of the alkyl group is advantageous, these alkyl groups are also nucleophilic. The addition of the alkyl group from the aluminum in the Lewis acid-reagent complex to the electrophilic center can be a serious side reaction. The ease of alkyl donation is $R_3Al > R_2AlCl > R_3Al_2Cl_3 > RAlCl_2$. When the nucleophilicity of the alkyl group is a problem, a Lewis acid with fewer alkyl groups should be examined. Addition of diethyl ether or another Lewis base may moderate the reaction if its greater acidity causes problems.

Ethylaluminum compounds are more nucleophilic than methylaluminum compounds and can donate a hydrogen as well as an ethyl group to the electrophilic center. Unfortunately, methylaluminum compounds must be prepared from ***Chloromethane***, while ethylaluminum compounds can be prepared much more cheaply from ***Ethylene***. Therefore ethylaluminum compounds are usually used unless the nucleophilicity of the alkyl group is a problem. Although the predominant use of alkylaluminum halides is as Lewis acids, they are occasionally used for the transfer of an alkyl group or hydride to an electrophilic center.

Eq 3 shows an unusual reaction in which the nature of the reaction depends on the amount, acidity, and alkyl group of the alkylaluminum halide.[6] Use of 1 equiv of Me_2AlCl leads to a concerted ene reaction with the side chains *cis*. Use of 2 equiv of Me_2AlCl produces a more electrophilic aldehyde complex that cyclizes to a zwitterion. Chloride transfer is the major process at -78 °C; at 0 °C, chloride transfer is reversible and a 1,5-proton transfer leads to an ene-type adduct with the side chains *trans*. Use of 2 equiv of $MeAlCl_2$ forms a cyclic zwitterion that undergoes two 1,2-hydride shifts to form the ketone. A similar zwitterion forms with $EtAlCl_2$, but β-hydride transfer leading to the saturated alcohol is faster than 1,2-hydride shifts.

Catalysis of Diels-Alder Reactions.

$EtAlCl_2$ is a useful Lewis acid catalyst for Diels-Alder reactions. It is reported to be more efficacious for the Diels-Alder reaction of ***Acrolein*** and butadiene than either $AlCl_3$ or Et_2AlCl.[7] It is a useful catalyst for intramolecular Diels-Alder reactions with α,β-unsaturated esters (eq 4)[8] and aldehydes[9] as dienophiles. It has also proven to be a very efficient catalyst for the inter-[10] and intramolecular[11] asymmetric Diels-Alder reaction of chiral α,β-unsaturated acyl sultams (eq 5) and has been used to catalyze a wide variety of Diels-Alder reactions.[12]

(5)

Catalysis of Ene Reactions.

Although $AlCl_3$ can be used as a Lewis acid catalyst for ene reactions of α,β-unsaturated esters,[13a] better results are obtained more reproducibly with $EtAlCl_2$. Ene reactions of ***Methyl Propiolate*** proceed in good yield with 1,1-di-, tri-, and tetrasubstituted alkenes (eq 6).[14] A precursor to 1,25-dihydroxycholesterol can be prepared by an ene reaction with methyl propiolate. Three equiv of $EtAlCl_2$ are needed since the acetate esters are more basic than methyl propiolate (eq 7).[15] *Endo* products are obtained stereospecifically with methyl α-haloacrylates (eq 8).[14] $EtAlCl_2$ has also been used to catalyze intramolecular ene reactions (eq 9).[16]

(6)

(7)

(8)

(9)

$EtAlCl_2$ is usually too strong a Lewis acid for ene reactions of carbonyl compounds.[13b,c] However, alkenes that contain basic sites that complex to the Lewis acid do not undergo Me_2AlCl-catalyzed ene reactions with formaldehyde. In these cases, $EtAlCl_2$ is the preferred catalyst.[17,18] The dienyl acetate shown in eq 10 reacts with excess ***Formaldehyde*** and $EtAlCl_2$ to provide the conjugated diene ene adduct that undergoes a quasi-intramolecular Diels-Alder reaction to afford a pseudomonic acid precursor. Me_2AlCl catalyzes the ene reaction of aliphatic aldehydes with 1,1-di-, tri-, and tetrasubstituted alkenes. Terminal alkenes are less nucleophilic, so the only reaction is addition of a methyl group to the aldehyde. $EtAlCl_2$, a stronger Lewis acid with a less nucleophilic alkyl group, catalyzes the reaction of aliphatic

aldehydes with terminal alkenes in CH_2Cl_2 at 0 °C to give 50-60% of the ene adduct.[18] Use of $EtAlCl_2$ as a catalyst affords the best diastereoselectivity in the ene reaction of dibenzylleucinal with ***Isobutene*** (eq 11).[19] $EtAlCl_2$ has also been used to catalyze intramolecular ene reactions of trifluoromethyl ketones.[20]

Catalysis of Intramolecular Sakurai Reactions.

$EtAlCl_2$ has been extensively used as a catalyst for intramolecular Sakurai additions. Enones (eqs 12 and 13)[21,22] have been most extensively explored. Different products are often obtained with fluoride or Lewis acid catalysis. $EtAlCl_2$ is the Lewis acid used most often although $TiCl_4$ and BF_3 have also been used. $EtAlCl_2$ also catalyzes intramolecular Sakurai reactions with ketones[23] and other electrophiles.[24] The cyclization of electrophilic centers onto alkylstannanes[25] and Prins-type additions to vinylsilanes[26] are also catalyzed by $EtAlCl_2$.

(13)

Catalysis of [2 + 2] Cycloadditions.

$EtAlCl_2$ catalyzes a wide variety of [2 + 2] cycloadditions. These include the addition of alkynes or allenes to alkenes to give cyclobutenes and alkylidenecyclobutanes (eq 14),[27] the addition of electron-deficient alkenes to allenyl sulfides (eq 15),[28] the addition of propiolate esters to monosubstituted and 1,2-disubstituted alkenes to form cyclobutene carboxylates (eq 16),[14b] and the addition of allenic esters to alkenes to form cyclobutanes.[29]

(14)

(15)

(16)

Generation of Electrophilic Cations.

$EtAlCl_2$ has proven to be a useful Lewis acid for inducing a wide variety of electrophilic reactions. It is particularly useful since an excess of the reagent can be used so that all nucleophiles are complexed to acid. Under these conditions, intermediates tend to collapse to give cyclobutanes or undergo hydride shifts to give neutral species. Reaction of the 1:2 ***Crotonaldehyde***-$EtAlCl_2$ complex with 2-methyl-2-butene at -80 °C affords a zwitterion that collapses to give mainly the cyclobutane. Closure of the zwitterion is reversible at 0 °C. Since there are no nucleophiles in solution, two 1,2-hydride shifts take place to give the enal (eq 17).[5] Intramolecular versions of these reactions are

also quite facile (eqs 18 and 19).[5,21] $EtAlCl_2$ promotes the ring enlargement of 1-acylbicyclo[4.2.0]oct-3-enes (eq 20).[30]

(17)

(18)

(19)

(20)

$EtAlCl_2$ catalyzes the Friedel-Crafts acylation of alkenes with acid chlorides,[31] the formal [3 + 2] cycloaddition of alkenes with cyclopropane-1,1-dicarboxylates (eq 21),[32] the Friedel-Crafts alkylation of anilines and indoles with α-aminoacrylate esters,[33] and the formation of allyl sulfoxides from sulfinyl chlorides and alkenes.[34] $EtAlCl_2$ induces the Beckmann rearrangement of oxime sulfonates. The cationic intermediates can be trapped with enol silyl ethers (eq 22).[35] $EtAlCl_2$ is the preferred catalyst for addition of the cation derived from an α-chloro sulfide to an alkene to give a cation which undergoes a Friedel-Crafts alkylation (eq 23).[36]

(21)

(22)

(23)

$EtAlCl_2$ reacts with aliphatic sulfones to generate an aluminum sulfinate and a cation that can be reduced to a

hydrocarbon by $EtAlCl_2$,[37] trapped with a nucleophile such as ***Allyltrimethylsilane***,[38] or undergo a pinacol-type rearrangement (eq 24).[39]

(24)

Elimination Reactions.

$EtAlCl_2$ induces elimination of two molecules of HBr from the dibromide to give the dihydropyridine (eq 25).[40] The usual base-catalyzed elimination is ineffective.

(25)

Nucleophilic Addition.

$EtAlCl_2$ has been used to activate conjugated systems toward attack of an external nucleophile or to transfer a hydride or ethyl group as a nucleophile. Addition of a cuprate to the chiral amide in the presence of $EtAlCl_2$ improves the diastereoselectivity, affording a >93:7 mixture of stereoisomers (eq 26).[41] Reaction of butyrolactones with $EtAlCl_2$ reduces the lactone to a carboxylic acid by opening to the cation and hydride delivery (eq 27).[42] Sulfonimidyl chlorides react with $EtAlCl_2$ at -78 °C to provide *S*-ethyl sulfoximines in 65-95% overall yield (eq 28).[43]

(26)

(27)

(28)

Modification of Carbanions.

Trimethylsilyl allylic carbanions react with aldehydes in the presence of $EtAlCl_2$ exclusively at the α-position to give *threo* adducts (eq 29).[44]

(29)

Related Reagents.

Diethylaluminum Chloride; ***Diethylaluminum Iodide***; ***Dimethylaluminum Chloride***; ***Dimethylaluminum Iodide***; ***Methylaluminum Dichloride***.

Ethyl Azidoformate[1]

[817-87-8] · $C_3H_5N_3O_2$ · Ethyl Azidoformate · (MW 115.09)

(electron-deficient azide; can undergo cycloadditions with alkenes to yield triazolines;[1] generates ethoxycarbonylnitrenes on thermolysis and photolysis[1])

Physical Data: bp 40 °C/30.5 mmHg.

Solubility: sol ether, methylene chloride.

Preparative Methods: as reported by Lwowski and Mattingly.[27]

Handling, Storage, and Precautions: is potentially explosive and care should be taken when distilling or heating solutions of this compound. It has been stored in the cold, protected from light, for up to 3 months without any apparent deterioration. However, ethyl azidoformate is eventually hydrolyzed in the presence of moisture, leading to the formation of HN_3. Such long-stored samples can explode on handling (due to the HN_3) and it is therefore recommended that ethyl azidoformate be used immediately after preparation. The vapors of this compound are also toxic. The original literature should be consulted before preparation and use of this compound.[27] This reagent should only be handled in a fume hood.

Introduction.

Ethyl azidoformate is usually prepared by the reaction of ***Ethyl Chloroformate*** with ***Sodium Azide***. It is principally used for two broad classes of reactions: (a) the cycloaddition of the azide moiety to an unsaturated functionality, and (b) as a source of ethoxycarbonylnitrene. This reagent has limited synthetic utility primarily because of its thermal instability. Ethyl azidoformate and other azidoformates begin to decompose above 60 °C.[1b] The related methyl azidoformate also displays similar reactivity and will also be discussed wherever relevant.

Cycloaddition Reactions.

The cycloaddition reactions of azides to alkenes are generally believed to be concerted. Ethyl azidoformate is considered an electron-poor azide and reacts readily with electron-rich alkenes. The product of these reactions are Δ^2-triazolines. The triazolines derived from electron-poor azides are usually not stable and can lose nitrogen readily to give

the aziridines and/or imines even at room temperature.[1c] However, many triazolines have been isolated in good yields. If the desired products are the triazolines themselves, the cycloaddition reactions are synthetically useful only if they proceed readily well below the decomposition temperature of the parent azide. At higher temperatures, ethyl azidoformate decomposes to give the corresponding nitrene which can react in a variety of pathways. Also, at higher temperatures, triazoline decomposition occurs readily. Strained and/or electron-rich alkenes undergo cycloaddition readily at room temperature or below. Norbornene,[2] substituted norbornenes,[3] and other strained bicyclic systems give triazolines in high yields (eqs 1 and 2). The presence of functional groups such as primary amines on the alkene are known to interfere with the cycloaddition reaction.[4]

Cycloadditions with norbornenes usually proceed from the *exo* face, even in the case of a 7-substituted azanorbornene (eq 3),[5] although exceptions have been reported.[6] Unsymmetrical norbornenes exhibit poor regioselectivity (eq 2). The products of triazoline fragmentation under thermal conditions are not always predictable and both aziridines and imines can result, although there are occasional examples of good product selectivity. Other rearrangement products have also been observed (eq 4).[7] However, photolysis of triazolines generally gives the aziridines in good yields, which are free of other side-products (eq 5).[3] In many cases this thermolysis/photolysis route to aziridines is superior to the direct photolysis of ethyl azidoformate in the presence of an alkene. If aziridines are the desired products, the poor regioselectivity in the cycloaddition step is not a drawback since both regioisomeric triazolines lead to the same aziridine.

(4)

(5)

Cycloadditions of ethyl azidoformate with electron-rich alkenes are also expected to proceed readily, although few examples are known. The cycloadducts from the reaction of ethyl azidoformate with optically active enamines were subject to photolysis.[8a] α-Amino ketones were isolated in moderate yields, presumably derived from the ring opening of the initially formed aziridine (eq 6). Reaction of enol silanes with ethyl azidoformate has also been reported to give *N*-substituted α-amino ketones.[8b] However, under these conditions it is possible that the reaction may proceed through a nitrene intermediate.

(6)

Cycloaddition of ethyl azidoformate to unactivated, unstrained alkenes usually requires elevated temperatures (70-120 °C). Under such conditions, nitrenes may be generated, leading to products derived from the fragmentation of triazolines. For example, reaction of ethyl azidoformate with tetramethylethylene (solvent) at 72 °C gave four products (eq 7).[9] The authors estimate that at least 60% of the aziridine was produced via the nitrene pathway.

Cycloadditions of ethyl azidoformate with alkynes and other triple bonds have also been attempted. The reaction with *N*,*N*-diaminopropyne, a ynamine, and ***Ethoxyacetylene*** has been reported to proceed at room temperature to give triazoles, although no yields were given.[10] Reaction of ethyl azidoformate with tetramethylallene at 130 °C gave a 38% yield of the triazoline along with the oxazoline.[11] The latter is probably derived from a nitrene intermediate. The reaction of ethyl azidoformate with stabilized phosphorus ylides has also been reported to give the corresponding triazoles in excellent yields.[12]

Generation and Reactions of Nitrenes.

Photolysis of ethyl azidoformate gives rise to ethoxycarbonylnitrene. Curtius rearrangement of azidoformates to give isocyanates under photolytic conditions (the photo-Curtius rearrangement) is a minor pathway. Depending on the conditions of photolysis, the nitrenes generated can react from either the singlet or the triplet state and the reactivity of the two species can be different. Nitrenes undergo two major reactions, insertion into single bonds and addition across double bonds. In many cases, both reactions occur, limiting the utility. Other side products can also be formed. The synthetic application of intermolecular C-H insertion of nitrenes is severely limited because of the poor selectivity of the nitrenes for different types of C-H bonds.[13] Even intramolecular insertions of substituted azidoformates usually give a mixture of the possible insertion products and have hence found only rare application in synthesis.[14] Insertion of nitrenes into aromatic and heteroaromatic rings has found some preparative value. Irradiation of ethyl azidoformate in benzene with UV light gives good yields of the azepine (eq 8),[15] in contrast to the thermal process which gives a 40% yield.[16]

The addition of nitrenes to double bonds under photolytic conditions has found wider use. Singlet nitrenes add across alkenes stereospecifically. This reaction is applicable to many types of alkenes. Thus methoxycarbonylnitrene reacts

with a strained alkene, ***Methylenecyclopropane***, to give the azaspiropentane (eq 9).[17] Reaction of ethoxycarbonylnitrene with an unactivated alkene, ***3-Sulfolene***, gives the aziridine which on thermal decomposition yields a divinyl carbamate (eq 10).[18] Ethoxycarbonylnitrene has also been added to activated alkenes such as dihydropyrans[19] and optically active silyl ketene acetals.[20] In the latter case, the isolated products were *N*-carbonylethoxy α-amino esters, presumably formed by ring opening of the initial aziridine. Modest levels of asymmetric induction were obtained. In many cases the photolysis can be done below room temperature to minimize undesirable side reactions.

(9)

(10)

Ethoxycarbonylnitrene can also be generated from ethyl azidoformate by thermolysis, producing singlet nitrenes. Reaction of ethoxycarbonylnitrene with an electron-deficient alkene gives the aziridine in good yield (eq 11).[21]

(11)

The reaction of ethoxycarbonylnitrene with ***Diphenylacetylene*** gives the corresponding oxazole in 33% yield (eq 12).[22] The mechanism of this reaction may proceed via a 1,3-dipole as shown or by a stepwise mechanism involving initial attack of the nitrene to produce a 1*H*-azirine. Aliphatic nitriles react in a similar manner under photolytic conditions to give the corresponding 5-ethoxyoxadiazoles.[23] The reaction of ethyl azidoformate with 1,1-dimethylallene under photolytic conditions has been reported to occur regioselectively at the more substituted double bond to give the the oxazoline.[11]

Photochemical addition of ethoxycarbonylnitrene to isocyanides leads to the corresponding carbodiimides in moderate yields, which on hydrolysis give ureas.[24] Addition of ethoxycarbonylnitrene to cobalt cyclopentadiene complexes has also been reported to give pyrroles, albeit in low yields.[25]

Other reagents such as ***p-Nitrobenzenesulfonyloxyurethane*** and *N*-ethoxycarbonyl-*N*,*O*-bis(trimethylsilyl)hydroxylamine[26] have also been used as a source of ethoxycarbonylnitrene. The article on the urethane reagent should be consulted for further applications of ethoxycarbonylnitrene in organic syntheses.

Related Reagents.

t-Butyl Azidoformate; ***p-Nitrobenzenesulfonyloxyurethane***.

N-Ethylbenzisoxazolium Tetrafluoroborate

[4611-62-5] · $C_9H_{10}BF_4NO$ · *N*-Ethylbenzisoxazolium Tetrafluoroborate · (MW 234.99)

(peptide-coupling reagent;[1] reacts with a wide range of nucleophiles to give *o*-hydroxy-*N*-ethylbenzamido derivatives[2])

Physical Data: mp 109.5-110.2 °C.

Solubility: sol acetonitrile; slightly sol dichloromethane; sol aqueous acid (unstable above pH 4).

Form Supplied in: crystalline solid; commercially available.

Preparative Methods: ethylation of benzisoxazole with purified ***Triethyloxonium Tetrafluoroborate***.[2]

Handling, Storage, and Precautions: the salt is reported not to be hygroscopic, although it etches glass on long exposure to moist air; should be protected from light; reported to be an irritant.

Peptide Coupling.

N-Ethylbenzisoxazolium tetrafluoroborate (EBF) is used to couple amines and carboxylic acids in a two-stage procedure. Firstly, EBF reacts with the carboxylic acid to form an active phenolic ester. Secondly, the active ester reacts with the amine to form the peptide linkage (eq 1).[3] The procedure for the formation of the active ester employs a carefully buffered aqueous solution of the Cbz-protected aminoacid (or oligopeptide), to which an equal volume of ethyl acetate or dichloromethane is added, followed by 1.1 equiv of finely powdered EBF. The acylsalicylamide ester is isolated from the organic solvent and may be recrystallized. This product is stable to storage. This procedure does not suffer when used with the sterically demanding valine or proline residues. The active ester cleanly reacts with peptide amines in dipolar aprotic solvents, yielding the amide and *N*-ethylsalicylamide, which can be removed with alkali or carbon tetrachloride. The second step is, however, very slow, taking ca. 48 h at room temperature (roughly 20 times slower than the rate of *p*-nitrophenyl ester couplings[4]), and suffers from unwanted side-reactions (Brenner rearrangements[5]) in the presence of strongly basic amines such as triethylamine. More seriously, significant amounts (up to 1-2%) of epimerization may occur.[6]

EBF has been used to prepare peptide cyclodimers in yields which compare favorably with other procedures.[1] For this method, intermediate Cbz-protected acylsalicylamide esters were hydrogenolyzed to form the free amines which then yielded the cyclodimers (eqs 2 and 3).

Peptide cyclotrimers have also been prepared in this manner.[7,8] After deblocking at nitrogen, a highly dilute solution of the resulting free amine in dry pyridine was stirred for 65 h at room temperature to give the cyclotrimer in an impressive 90% yield (eq 4).

Detailed mechanistic studies indicate that the *N*-ethylbenzisoxazolium cation readily undergoes base-catalyzed elimination to form a transitory *N*-ethylbenzoketoketenimine (eq 5).[9]

In the case of reactions with carboxylic acids (X = RCO_2), the initial addition product then rapidly rearranges to the active ester (eq 6).

Several hydroxy-,[10] nitro-,[3] and chloro-substituted[11] *N*-ethylbenzisoxazolium cations have been studied in attempts to vary the reactivity of the intermediate active ester (see ***2-Ethyl-7-hydroxybenzisoxazolium Tetrafluoroborate***).

Reactions with Nucleophiles.

The *N*-ethylbenzisoxazolium cation reacts rapidly in aqueous solution with a range of nucleophiles, yielding *o*-hydroxy-*N*-ethylbenzimido derivatives. Hydrolysis proceeds smoothly in mild acid, but at pH above 7, polymeric material is obtained (eq 7).[2]

(7)

Treatment of EBF with aqueous solutions of simple nucleophiles (HS^-, F^-, CN^-) or with methanolic methoxide gives high yields of the benzimido derivatives (eq 8).

(8)

Reaction of EBF with cyanate, thiocyanate, and thiourea generates initial adducts which can undergo internal rearrangements. For example, the adduct of cyanate to EBF yields a cyclic urethane (eq 9); reaction with thiocyanate yields the analogous thiourethane.[2]

Ethyl *N*-Benzylideneglycinate

[40682-54-0] · $C_{11}H_{13}NO_2$ · Ethyl *N*-Benzylideneglycinate · (MW 191.23)

(α-amino acid synthesis)

Alternate Name: ethyl glycinate benzalimine.

Physical Data: pale yellow liquid; bp 65-75 °C/0.001 mmHg;[1] IR spectrum.[1]

Solubility: very sol most organic solvents; insol hexane.

Preparative Methods: condensation of ethyl glycinate with benzaldehyde.[1,2]

Handling, Storage, and Precautions: unstable to hydrolysis so that chromatographic treatment on silica gel produces ethyl glycinate and benzaldehyde.

α-Alkylated α-Amino Acid Synthesis.

Ethyl *N*-benzylideneglycinate has two acidic hydrogens at the α-position which can be metalated and then alkylated to give α-alkylated α-amino acids.[2-5] Iteration of this procedure produces α,α-dialkylated α-amino acids. The use of α,o-dihaloalkanes as alkylating agents opens a good entry to cyclic α-amino acids after hydrolysis (eq 1).[6-8] Alkylations using sterically bulky *t*-butyl α-halo esters result in unusual γ-alkylation to give β-amino esters after hydrolysis (eq 2).[9]

(1)

(2)

Stereoselective Pyrrolidine Synthesis.

Ethyl *N*-benzylideneglycinate can be reversibly lithiated on treatment with ***Lithium Bromide-Triethylamine*** in THF at room temperature and the lithiated species then undergoes exclusively *endo* selective cycloadditions to α,β-unsaturated carbonyl compounds to give pyrrolidine esters (eq 3).[10,11] The reactions with ketene dithioacetals followed by the elimination of thiol produce pyrrole or 2-pyrone derivatives, depending upon the reaction conditions (eq 4).[12]

(3)

(4)

Glutamic Acid Synthesis.

Under catalyzed conditions, smooth Michael additions take place with α,β-unsaturated ester acceptors, offering a convenient and direct synthetic route to glutamic esters (eq 5).[13] Vinyl phosphonates can also serve as acceptor molecules.[14,15]

(5)

The C=N bond of ethyl *N*-benzylideneglycinate reacts with ketene or its equivalents to produce azetidinones.[1,16] When carboxylic acids are activated by interaction with trichlorocyanuric acid, azetidinones are formed (eq 6).[17] Stereoselective aldol reactions of the titanium (*Z*)-enolates of ethyl *N*-benzylideneglycinate are also known.[18]

(6)

Related Reagents.

Ethyl N-(Diphenylmethylene)glycinate.

Ethyl 3-Bromo-2-(hydroxyimino)propanoate

[73472-94-3] · $C_5H_8BrNO_3$ · Ethyl 3-Bromo-2-(hydroxyimino)propanoate · (MW 210.03)

(alkylating agent, especially useful for 3-substitution of indoles under mild conditions;[1] reacts with bases to give ethyl 2-nitrosopropenoate, an electron-deficient heterodiene[1,2])

Alternate Name: ethyl bromopyruvate oxime.

Physical Data: mp 78-79 °C.

Solubility: sol ether, dichloromethane, and most organic solvents.

Preparative Methods: reaction of ethyl 3-bromo-2-oxopropanoate (ethyl bromopyruvate) with hydroxylamine hydrochloride in methanol-chloroform gives the oxime (quantitative yield); it can be recrystallized from dichloromethane-hexane.[3,4] The compound has also been prepared using a two-phase system (water and chloroform).[5]

Handling, Storage, and Precautions: can be stored for several months in a refrigerator without deterioration. No specific toxicity data are available, but as a highly reactive alkylating agent it must be handled with appropriate precautions.

Alkylation of Indoles.

Indoles unsubstituted at the 3-position are alkylated by reaction with ethyl 3-bromo-2-(hydroxyimino)propanoate (**1**) and anhydrous ***Sodium Carbonate*** in dichloromethane at room temperature. The reaction has been carried out with a wide range of indoles, including indole-2-carbaldehyde and others with an electron-withdrawing substituent at the 2-position.[6] Adducts can usually be isolated in good yield when equimolar amounts of the indole and of the oxime are used. A side reaction which is sometimes troublesome is attack of a second mole of the alkylating agent at C-3 to give a 2:1 adduct, as in the example shown in eq 1.[7] This reaction can be suppressed by using the indole in excess.[8] Alkylation at other positions of the indole ring system is rare; minor products resulting from attack at the 2- and 5-positions have been observed with indoles bearing a dialkylamino substituent at C-4.[9]

The oximes produced in these reactions have the (*E*) configuration,[8] as required by a mechanism involving cycloaddition of a transient nitrosoester, ethyl 2-nitrosopropenoate, to the indole followed by ring opening. The cycloadduct with 1-methoxyindole has been detected in solution; it rearranges to the oxime under mild conditions.[10]

With indoles bearing an alkyl or other electron-donating substituent at C-3, attack still takes place at the 3-position to give cycloadducts which can usually be isolated in high yield.[5,11] 3-(Alkylthio)indoles are an exception in that the products isolated result from migration of the alkylthio substituent to C-2.[12]

Alkylation of Other Heterocycles.

Pyrrole and 1-methylpyrrole are alkylated at C-2 by (**1**). 2,5-Dimethylpyrrole is also attacked at C-2, the product being a cycloadduct (eq 2).[13] Furan and 2,5-dimethylfuran similarly form cycloadducts.[5,14] With the nucleophilic heterocycles imidazole, pyrazole, and 1,2,4-triazole, products of *N*-alkylation are isolated.[15]

Formation of 5,6-Dihydro-4*H*-1,2-oxazines with Nucleophilic Alkenes.

Ethyl 2-nitosopropenoate, generated in situ from (**1**) and sodium carbonate, is an electron-deficient heterodiene which reacts with a wide range of electron-rich alkenes (eq 3). Cycloadducts have been formed in good yield with enamines,[16,17] enol ethers,[16,18] silyl enol ethers,[19] and allylsilanes.[20] The cycloaddition is regioselective and stereoselective; diastereoselective addition to a chiral enol ether has also been observed.[21] Conjugated alkenes such as indene and cyclopentadiene also form cycloadducts, but with simple alkenes such as 1-octene the yields are low.[5] Addition to methoxyallene takes place in good yield at the substituted double bond.[22] An example of cycloaddition to a C=N bond, in *N*-methyl-*N*-phenylbenzamidine, has also been reported.[23] The cycloadducts can be reduced to pyrroles[16,18,19] and pyrrolidines[17,18,24] and there are several reports of one-pot cycloadditions and in situ reductions.

(3)

One special application of the reaction with enamines has been in the construction of the skeleton of *Vinca* alkaloids.[25]

Ethyl 2-(Bromomethyl)acrylate

(R = Et)

[17435-72-2] · $C_6H_9BrO_2$ · Ethyl 2-(Bromomethyl)acrylate · (MW 193.04) (R = *t*-Bu)

[53913-96-5] · $C_8H_{13}BrO_2$ · *t*-Butyl 2-(Bromomethyl)acrylate · (MW 221.09)

(powerful allylic alkylating reagent[1-3] employed as its organozinc derivative to prepare α-methylene lactones[4] and lactams;[5] important source of functional acrylic monomers for polymerization[6,7])

Alternate Name: ethyl 2-(bromomethyl)propenoate.

Physical Data: R = Et, bp 40-41 °C/0.1 mmHg; R = *t*-Bu, bp 60-61 °C/0.1 mmHg.

Solubility: insol H_2O; sol ether, acetone, alcohol, THF, chloroform.

Form Supplied in: colorless liquid.

Preparative Methods: many preparations of these compounds have been described,[8] for example dehydrobromination of β,β´-dibromoisobutyric esters[9-11] or acid, or bromination of *t*-butyl or ***Ethyl* α-*(Hydroxymethyl)acrylate*** with ***Phosphorus(III) Bromide***.[12]

Handling, Storage, and Precautions: reputed to be lachrymatory, vesicatory, and toxic. Usual precautions of storage in darkness between 0 and 5 °C and handling with gloves under a well ventilated hood are recommended.

Electrophilic Alkylating Reagent.

The electrophilic reactivity of the allylic bromide moiety is increased by the presence of the carboxylate group (Michael acceptor) and the reagent can thus act as a powerful allylic electrophile. It can be coupled with various organometallic reagents, *gem*-dimetallic reagents[2,3] or O-,[13,14], S-,[15-17], N-, and P-nucleophiles (eq 1).[18,19]

(1)

The alkylation with ***Cyanomethylcopper***[1] gave 89% yield of the corresponding 1-(3-cyanoethyl)acrylic ester, while π-2-(methoxyallyl)nickel bromide was tested as a source of 5-ethoxycarbonyl-5-hexen-2-one.[20] Palladium-catalyzed cross-coupling with vinyl- and aryltin[21] and vinylzirconium reagents[22] allowed the preparation of the corresponding 2-allyl- and 2-benzylacrylates. Coupling with functional zinc or zinc-copper organometallic derivatives[23-25] gives rise to various polyfunctional acrylic derivatives (eq 2).[26]

(2)

The allylation of other nucleophiles such as the enolates of cyclic 1,3-diketones[27] (or their enol ethers[28]), β-keto esters,[29] β-dimethylaminopropionates,[30] and bicyclic enolates[31] has been reported. Tandem alkylation-Michael addition with dienolates gives rise to cyclic or bicyclic compounds,[32] while tandem alkylation-Claisen condensations leads to the formation of functional α-methylenecyclopentanones (eq 3).[33]

(3)

Alkylation of enamines[34] has been proposed as the first step in the synthesis of potential antitumor α-methylene δ-valerolactones.

Unsymmetrical organic sulfides containing the methacrylic ester group are produced under nonbasic reaction conditions.[35] Thio-Claisen rearrangement[36] took place via *S*-allylation with ethyl 2-(bromomethyl)acrylate (eq 4).

N-Allylation by ethyl 2-(bromomethyl)acrylate has been developed as key steps in the synthesis of bioactive molecules such as α-methylene-β-alanine,[37] or analogs of Iboga alkaloids.[38]

Synthesis of α-Methylene Lactones and Lactams.

One of the most important applications of ethyl 2-(bromomethyl)acrylate was found in a pseudo-Reformatsky reaction. First described by Ohler et al.,[4] this reaction leads to the formation of potential antitumor α-methylene-γ-lactones,[39,40] via an organozinc intermediate (eq 5).

This reaction was extensively applied to various carbonyl compounds. 5-Mono- or 5,5-disubstituted α-methylene-γ-

lactones bearing a steroidal moiety,[41] nucleic acid bases,[42] furanose systems,[43] six-membered[44] or five-membered[45] heterocyclic groups, adamantyl groups,[46] and bornyl groups[47] have been prepared and evaluated as antineoplasic and allergenic[48,49] compounds. Bis-α-methylene-γ-lactones have been produced from dicarbonyl compounds.[50]

The Reformatsky reaction with imines leads to the corresponding less toxic α-methylene-γ-lactams.[5] Bis addition of the organozinc intermediate to acyl chlorides or nitriles before cyclization leads to the formation of new α-methylene-γ-lactones and lactams (eq 6).[51]

(6)

Attempts to improve the yield of the Reformatsky reaction included the use of ***Tin***,[52] tin-aluminum alloy,[53] ***Zinc*** dust in aqueous ammonium chloride solution,[54] or electrogenerated zinc.[55] Low valent metal halides (***Lithium Aluminum Hydride-Chromium(III) Chloride***)[56] and ***Tin(II) Chloride***[57] were found to undergo insertion into the carbon-bromine bond of 2-(bromomethyl)acrylates. Asymmetric induction from complex reagents made with $SnCl_2$, tartaric ester, and allylic bromides has been described.[58]

The preparation of intermediate organozinc derivatives of 2-(bromomethyl)acrylates[59] by direct action of zinc dust in THF (or DME) at controlled temperature allowed regio- and stereoselective condensations with polyfunctional electrophilic compounds without side reactions (eq 7).[60]

(7)

Their coupling with chiral imines, derived from α-amino esters[61] or β-amino alcohols,[62] leads to the formation of the corresponding α-methylene-γ-lactams (*R*,*R*) or (*S*,*S*) via a diastereoselective set of reactions (de > 95%).

Other organometallic reagents derived from ethyl 2-(bromomethyl)acrylate are known, such as organotin,[63] which allows palladium-promoted arylation, and organomercury,[64] for acylation reactions. Ethyl 2-(bromomethyl)acrylate/π-(allyl)nickel in DMF is a powerful selective nucleophilic reagent for haloaromatics[65] and iodoalkanes[66] (eq 8).

(8)

Polymer Chemistry.

Ethyl 2-(bromomethyl)acrylate also has an important place in polymer chemistry as a monomer[6] or as a source of functional monomers such as sulfur-containing acrylic compounds[67] or 6-*O*-methylallylgalactose intermediates for the preparation of poly(vinyl)saccharides.[7] It also has been employed as a chain-transfer agent.[68]

Ethyl Bromozincacetate[1]

[5764-82-9] · $C_4H_7BrO_2Zn$ · Ethyl Bromozincacetate · (MW 232.37)

(chemoselective ester enolate reagent[1])

Alternate Name: Reformatsky reagent.

Preparative Methods: see below.

Handling, Storage, and Precautions: α-halo esters and α-halo ketones used for the preparation of Reformatsky reagents are lacrymators and should be used in a well ventilated hood; solutions of the reagent in ethereal solvents are stable at low temperatures for a few days. The reagent is prone to hydrolysis and must be handled in anhydrous solvents under an inert atmosphere.

Introduction.

The Reformatsky reagent shown in the above title is the historically first[5] and most widely used zinc ester enolate prepared by zinc insertion into an α-halo ester. However, the Reformatsky reaction can be taken as subsuming all enolate formations by oxidative addition of a metal or a low-valent metal salt into an activated carbon-halogen bond.[1] It is this mode of enolate formation which distinguishes the Reformatsky reaction from other fields of metal-enolate chemistry.

The reagent is dimeric in solution except in the most polar solvents;[2] X-ray analysis of $BrZnCH_2CO_2$-*t*-Bu.THF shows a dimeric unit in the solid state with the metal being bound to an sp^3 carbon atom.[3] In contrast, zinc enolates of ketones are *O*-metalated species.[4]

Performance and Reagent Preparation.

Originally,[5] the reaction was performed in a one-step fashion by adding a mixture of the halo ester and the electrophile (usually a carbonyl compound) to a ***Zinc*** suspension in an ethereal or hydrocarbon solvent. However, enolate formation and its reaction with electrophiles can be done successively. This two-step procedure has contributed to the advancement of the Reformatsky reaction, as electrophiles which would quarternize upon mixing with α-halo esters (e.g. azomethines) can be used under these conditions without problems. Moreover, the zinc enolates may be transmetalated prior to use in order to adapt their reactivity to electrophiles beyond the scope of classical Reformatsky reactions.[1]

Difficulties in initiating the reaction are avoided by the use of activated zinc samples.[1a,6] As they promote the reaction even at very low temperatures (Table 1), their use results in generally high yields, the suppression of undesirable side reactions, and an increase in diastereoselectivity. Less reactive donors such as α-chloro esters are equally suited when highly reactive metals are employed.[7] The improved reliability recommends metal-activation techniques for applications to natural product synthesis. Among the zinc samples described so far, finely dispersed and readily prepared zinc/silver on graphite[7] (see also ***Potassium-Graphite***) and zinc obtained by reduction of ***Zinc Chloride*** with ***Potassium Naphthalenide***, ***Lithium Naphthalenide***, or alkali naphthalenides are most effective (Table 1).[8] For large-scale experiments, the application of ultrasound[9] or of electrochemical support[10] for Reformatsky reactions is recommended.

Table 1 Comparison of the Reactivity of Different Zinc Samples for the Preparation of Ethyl Bromozincacetate followed by reaction with Benzaldehyde (A) or Cyclohexanone (B)

Reagent	Carbonyl compound	Solvent	T(°C)	t(min)	Yield (%)
Zinc dust	A	Benzene	+80	720	61
Zinc dust	B	Benzene	+80	[a]	56
Zn/Cu couple	A	THF	+66	60	82
Zn/Cu couple	B	THF	+66	60	82
Rieke Zn	A	Et_2O	+25	60	98
Rieke Zn	B	Et_2O	+25	60	95
Zn ultrasound	A	1,4-Dioxane	+25	5 300	98
$ZnCl_2/Li$[b]	A	Et_2O	0	30	95
$ZnCl_2/Li$[b]	A	Et_2O	- 78	30	56
Zn/Ag graphite	B	THF	- 78	20	92

[a] Reaction time not reported. [b] Zinc sample obtained by reduction of $ZnCl_2$ with commercially available lithium dispersion in Et_2O.[8e]

In contrast to other metal enolates, Reformatsky reagents are reasonably stable over a wide temperature range (from -78 °C to above 80 °C for short periods of time) and can be prepared in solvents greatly differing in polarity (most commonly employed are THF, DME, Et_2O, 1,4-dioxane, benzene, toluene, dimethoxymethane, DMF, or mixtures thereof; scattered reports using hexane, acetonitrile, CH_2Cl_2, $B(OMe)_3$, DMSO, and HMPA may be found).[1] The major path for their decomposition is loss of EtOZnBr with formation of ketene which immediately acylates an intact zinc enolate, thus leading to β-keto esters.[11] Reformatsky reagents are therefore usually freshly prepared and used without delay, although solutions

of $BrZnCH_2CO_2$-*t*-Bu in a number of solvents were reported to exhibit virtually unchanged reactivity after 4-6 days.[2]

Reformatsky Donors.

Ethyl bromoacetate is the most widely used halogen compound for zinc insertion but other short-chain 2-bromo esters work equally well under standard conditions.[1] The alcohol part of the ester plays only a minor role, and by its proper choice (e.g. *t*-butyl, TMS, tetrahydropyranyl bromo esters)[12] β-hydroxy acids can be readily obtained by zinc-induced reaction of these donors with carbonyl compounds followed by hydrolysis of the respective β-hydroxy esters initially formed. Allyl bromo esters on treatment with zinc undergo Claisen rearrangements to 4-alkenoic acids (eq 1).[13] As the chain length of the 2-bromo ester increases, or upon switching to the less reactive 2-chloro ester, the use of highly activated zinc samples and/or more polar solvent systems becomes obligatory in order to accomplish zinc enolate formation.[1]

(1)

Bromo(chloro)difluoro esters and ketones show no peculiarities in their behavior and have found widespread applications in the synthesis of fluorinated natural product analogs (eq 2).[14] In contrast, dibromo-, dichloro-, and trichloroacetates tend to polymerize on reaction with zinc dust at reflux temperatures;[15] however, they can be selectively transformed with more appropriate reagent systems. Depending on the conditions used, they either afford glycidates (with Zn/Ag-graphite at -78 °C)[16] or 2-alkenoates (with Zn/***Diethylaluminum Chloride*** at 0 °C),[17] respectively, on reaction with carbonyl compounds (eq 3).

Haloacetonitriles and α-halo acetamides[1,18] are well suited as donors in Reformatsky reactions (eq 4). When *N*-methoxy-*N*-methylbromoacetamide is used (eq 5), the resulting products may be converted into β-hydroxy ketones by the Weinreb procedure.[19]

4-Bromo-2-butenoates as vinylogous bromo esters form ambident carbon nucleophiles upon treatment with zinc, which may either lead to α- or γ-substitution products on reaction with electrophiles. A set of conditions has been worked out that allows control of these pathways, with the polarity of the reaction medium and the temperature being the crucial parameters (eq 6).[20] The data suggest that kinetic control leads to α-products, whereas thermodynamic control affords the γ-substitution products.

2-Bromomethyl-2-alkenoates react readily under allylic rearrangement with carbonyl compounds in the presence of zinc to form α-methylene-γ-lactones.[21] Because of the high biological relevance of that structural unit, this reaction has found widespread use in natural product synthesis,[22] both in an inter- (eq 7)[23] and intramolecular fashion (eq 8).[24] With diastereotopic ketones the stereoselectivity of the C-C bond-forming step may be significantly enhanced by using highly reactive Zn/Ag-graphite as promotor at very low temperatures.[25]

The particular advantages of the Reformatsky reaction are nicely illustrated by a recent total synthesis of (+)-pilocarpine.[26] Zinc insertion provides a reliable and regioselective access to monoenolates of succinic acid diesters, a difficult task with other methods of enolate formation (eq 9). Although some optimization was necessary in order to avoid undesirable side reactions (eliminations), dimethyl (2*S*,3*S*)-2-bromo-3-ethyl-1,4-butandioate could be transformed into the key intermediate of the pilocarpine synthesis in a highly selective manner and in excellent yield.

Electrophiles.

Zinc enolates of esters or ketones show moderate reactivity compared to the respective of alkali metal enolates. Hence, they exhibit higher degrees of chemoselectivity upon treatment with different electrophiles. For a long time, aldehydes and ketones have been the only relevant group of substrates for these reagents and they are still widely used.[1] Examples of Reformatsky reactions with carbonyl compounds of almost any class of natural products can be found in the literature. Highly hindered ketones as well as readily enolizable carbonyl compounds and even acylsilanes (eq 10)[27] are prone to nucleophilic attack. α,β-Unsaturated carbonyl compounds react regioselectively in a 1,2-addition manner with only very few exceptions to this rule. The latter can easily be explained by steric hindrance (eq 11)[4b,28] or peculiar electronic properties of the acceptor molecule, as in aroyl ketene *S,N*-acetals (eq 12)[29] or 1,3-diaza-1,3-butadiene[30] derivatives.

(10)

(11)

(12)

However, other kinds of electrophiles are also good acceptors for Reformatsky reagents, such as nitriles (sometimes called

the Blaise reaction) (eq 13),[31,4b] azomethines (preferably via the two-step procedure giving rise to β-lactams) (eq 14),[32] and carboxylic acid chlorides (with assistance of catalytic amounts of Pd^0 complexes) (eq 15).[31c,33] Alkylation of zinc ester enolates, however, is troublesome and restricted to short-chain alkyl iodides, allyl and benzyl halides in aprotic dipolar solvents.[2,34] Under transition metal catalysis they also react with aryl and alkenyl halides or triflates.[35] *C*-Silylation of the zinc enolates by ***Chlorotrimethylsilane*** is essentially confined to bromoacetate (eq 16)[36] and haloacetonitrile.[37]

(13)

(14)

(15)

(16)

The slightly different reactivity of zinc enolates towards the aforementioned types of electrophiles allows chemoselective transformations of di- or polyfunctional substrates. Although in unsymmetrical diketones no differentiation among the carbonyl groups was reported, keto nitriles, keto amides, keto esters, or halogenated ketones may be attacked exclusively at the carbonyl group.[1]

Recent investigations show that 3-acyloxazolidin-2-ones or 3-acylthiazolidine-2-thiones constitute a promising group of acyl donors for zinc enolates (eq 17).[38] Different kinds of anhydrides (eq 18),[39] activated esters, and lactones,[40] including aldonolactones,[41] react smoothly with bromo esters under Reformatsky conditions. Particular emphasis is laid on the high

yield of β-amino esters by reaction of zinc enolates with different kinds of *N,O*-acetals and aminals (eq 19).[42] Oxocarbenium cations obtained by in situ activation of acetals with Lewis acids are equally suited as electrophiles in Reformatsky reactions (eqs 20 and 21).[43] A summary of reactions with electrophiles other than carbonyl compounds is given in the literature.[1]

Intramolecular Reformatsky Reactions.

As the site of enolate formation is determined by the halogen moiety, Reformatsky reactions are well suited for intramolecular aldolizations. This is a major advantage since regioselective enolate formation by proton abstraction in polycarbonyl systems is a rather difficult task. Thus a homologous series of o-(α-bromoacetoxy)aldehydes has been cyclized to β-hydroxy lactones of ring size 13-16,[44] but smaller rings can also be formed in moderate to good yields.[45] This technique has been used in natural product synthesis (eq 22),[46] with the formation of the 11-membered ring of cyctochalasan being the most impressive example (eq 23).[47] Less conventional electrophiles such as nitriles[48] or imides[49] are equally well suited acceptors in entropically favored intramolecular reactions (eq 24).

(22)

(23)

(24)

Samarium(II) Iodide as substitute for metallic zinc turned out to be highly advantageous in promoting such cyclizations with formation of normal-, medium-, and large-sized ring systems (eq 25).[50,51] Furthermore, high degrees of diastereocontrol may be exercised via the formation of rigid transition states with the strongly chelating Sm^{3+} counterion.[51]

(25)

Tandem Reaction.

Due to their high tolerance towards different functional groups, zinc enolates are predisposed for reaction sequences. The selective formation of either a carbocyclic or a heterocyclic ring from nitriles bearing an additional halo or sulfonyloxy group within the molecule is an illustrative example of how to impose control on such reaction tandems (eq 26).[52] In this specific case, the hard-soft acid-base (HSAB) principle determines whether the intermediate zinc enamides are *N*-alkylated (X = OSO_2Me) or *C*-alkylated (X = Br). Moreover, *O*-TMS cyanohydrins serve for lactone syntheses in a one-pot procedure.[31c]

(26)

Under the rather drastic conditions of conventional Reformatsky reactions (reflux in ethereal or hydrocarbon solvents), the β-hydroxy esters formed may suffer subsequent dehydration in an unselective way. The use of α-silylated Reformatsky donors or of α-silyl ketones shows how to control the regioselectivity of the elimination step.[16,27a] Thus sequences of Reformatsky reactions followed by (in part spontaneous) Peterson eliminations determine the regiochemistry of the newly formed double bond (eqs 27 and 28). When bromo(trimethylsilyl)acetonitrile is used as donor, high to complete (*Z*) selectivity for the α,β-unsaturated nitriles obtained was reported.[53]

(27)

(28)

A sequence of an intramolecular Reformatsky reaction with a 2,5-dibromopentanoate donor, followed by etherification of the intermediate zinc aldolate with the terminal bromo group in the presence of HMPA, was ingeniously used to build-up the tricyclic skeleton of daphnilactone and related molecules starting from rather simple precursors (eq 29).[54]

(29)

2-Oxoglycosyl bromides upon treatment with zinc give rise to carbohydrate intermediates with an umpoled anomeric center; the aldolate initially formed on reaction with excess ***Formaldehyde***, together with the residual ketone group on the sugar, trap a second aldehyde molecule with formation of a stable lactol ring (eq 30).[55]

(30)

Stereoselectivity.

A general method for highly diastereo- and enantioselective Reformatsky reactions is still missing. Some of the approaches described so far take advantage of the known propensity of zinc(II) to bind to nitrogen donor atoms which may be present in either one of the substrates or in a ligand added to the reaction mixture. With amino carbonyl compounds as electrophiles, for example, highly stereoselective additions are usually observed, and a direct relationship between the complexing ability of the amino group (location, basicity of the N atom) and the de values for the products obtained has been established.[56] A nice illustration of how uncommon electrophiles can be used to prepare enantiomerically enriched products is the ring-opening of enantiomerically pure oxazolidines by zinc ester enolates to β-amino esters, proceeding with inversion of the configuration at the *N*,*O*-acetal carbon atom (eq 31).[57]

(31)

A means to achieve excellent diastereoselectivity in reactions of *ortho*-substituted benzaldehyde derivatives is the π-face selective attack of a zinc ester enolate on the corresponding tricarbonylchromium complexes (eq 32).[58]

(32)

Preparatively useful degrees of diastereoselectivity have been observed with *N*-(α-bromoacyl)oxazolidinones[59] and/or with metals other than zinc exhibiting higher chelating abilities. For intramolecular reactions, SmI_2 served this purpose very well, because of the rigidity of a Sm^{3+}-chelated bicyclic transition state (eq 33).[51] An Evans-type auxiliary together with activated tin as promotor for the Reformatsky reaction have been employed in a diastereoselective approach to neooxazolomycin (eq 34).[60] With a few exceptions only, induction by chiral alcohol components in α-bromo esters is rather low[61] and until now hardly competitive with today's state of the art in aldol reactions.

(33)

(34)

In addition to some early reports with (-)-spartein as chiral ligand,[62] promising results of enantioselective zinc- or indium-induced reactions of haloacetates with carbonyl compounds in the presence of chiral amines or amino alcohols as ligands to the metal have been published recently (eq 35).[63]

(35)

Substitution of Zinc by Other Metals.

Oxidative addition into an activated carbon-halogen bond with formation of enolates is by no means restricted to metallic zinc.[1] Low-valent metal salts of adequate reduction potentials such as ***Samarium(II) Iodide***[41d,64,50,51] or ***Chromium(II) Chloride***[65] are equally suited. A great deal of work has been carried out with more or less activated forms of ***Magnesium***,[66] ***Tin***,[67] ***Nickel***,[68] ***Cerium***,[69] ***Indium***,[70] manganese,[71] and cadmium[72] as promotors for Reformatsky-type reactions. Although in specific cases advantages such as increased diastereoselectivity could be drawn from their use, only SmI_2 and to some extent cerium and indium (both are effective with the more reactive α-iodo esters) show reasonable scope. Some representative examples are compiled in Table 2.

Table 2 Reformatsky Reactions with Substitutes for Zinc

Donor	Electrophile	Metal	T(°C)	t(h)	Yield (%)

Ethyl 4-Chloroacetoacetate[1]

(**1a**; R = Et)

[638-07-3] · $C_6H_9ClO_3$ · Ethyl 4-Chloroacetoacetate · (MW 164.60) (**1b**; R = Me)

[32807-28-6] · $C_5H_7ClO_3$ · Methyl 4-Chloroacetoacetate · (MW 150.57) (**1c**; R = *i*-Pr)

[41051-20-1] · $C_7H_{11}ClO_3$ · Isopropyl 4-Chloroacetoacetate · (MW 178.63) (**1d**; R = *t*-Bu)

[74530-56-6] · $C_8H_{13}ClO_3$ · *t*-Butyl 4-Chloroacetoacetate · (MW 192.66)

(highly functionalized four-carbon building block for organic synthesis[1])

Physical Data: (**1a**) mp -8.5 °C; bp 95 °C/10 mmHg; fp 92 °C; *d* 1.212 g cm^{-3}. (**1b**) mp 14 °C; bp 50 °C/1 mmHg; fp 107 °C; *d* 1.287 g cm^{-3}. (**1c**) mp 10 °C; bp 64 °C/1.65 mmHg; fp 86 °C; *d* 1.152 g cm^{-3}. (**1d**) bp 101 °C/15 mmHg; fp 41 °C; *d* 1.130 g cm^{-3}.

Form Supplied in: the alkyl 4-chloroacetoacetates are colorless liquids.

Solubility: sol most organic solvents. The ethyl ester (**1a**) is 12% enolized in the pure liquid, and highly enolized (60% in CCl_4) in nonpolar solvents.[2]

Preparative Methods: the industrial production of the esters is made exclusively by chlorination of diketene followed by reaction of the intermediate acid chloride with the corresponding alcohol.[3]

Handling, Storage, and Precautions: these reagents are lachrymators of moderate toxicity; use in a fume hood.

Reactivity.

The 4-chloroacetoacetates with their four reactive carbon centers offer diverse synthetic possibilities, and their reactions may be subdivided into those occurring at the 1-, 2-, 3-, or 4-positions, and various combinations of these

with di- and trifunctional reagents to give ring formation.

Reactions at the 1-Position.

Reactions of nucleophiles at this position are of minor importance. Hydrolysis produces 4-chloroacetoacetic acid which on nitrosation gives 3-chloropyruvaldoxime, useful for the synthesis of 6-substituted pteridines.[4]

Reactions at the 2-Position.

Electrophiles readily react at position 2. Chlorination with ***Sulfuryl Chloride*** represents a good route for the synthesis of 3-chlorotetronic acid.[5] Nitrosation is best carried out under acidic conditions to form the (*Z*)-oxime (**2**). This may be isolated[6] or reacted directly in situ with thiourea to form the 2-aminothiazole (**3**) (eq 1),[7] which is an important intermediate for the side chain synthesis of many β-lactam antibiotics.

The combined effect of trimethyl orthoformate (see ***Triethyl Orthoformate***) and aniline results in the formation of the *N*-substituted methylene compound (**4**) (eq 2).[8]

In the reaction with fluorosulfonyl isocyanate (see ***Chlorosulfonyl Isocyanate***), initial attack occurs at the oxygen atom and then at higher temperatures the enol-carbamate intermediate rearranges to give the 2-substituted product (**5**). This on further heating decarboxylates to yield the acetoacetamide (**6**) (eq 3),[9] useful for the preparation of acesulpham sweetener analogs.

With less reactive electrophiles the enolate salt of (**1a**) is used (e.g. alkylation[10]). If deprotonation of (**1a**) (pK_a 9.7) is incomplete then dimerization occurs through intermolecular self-alkylation to give 2,5-dialkoxycarbonylcyclohexane-1,4-dione.[11] Aldehydes condense in the Knoevenagel reaction and the intermediate unsaturated ketones (**7**) are used in the Hantzsch synthesis of dihydropyridines (**8**) (eq 4).[12]

Reactions at the 3- and 4-Positions.

In general, soft nucleophiles react at position 4 and hard nucleophiles react at position 3. For selective reactions at position 4 it may be necessary to protect position 3.

Reactions at Position 4.

Aliphatic[13a] and aromatic[13b] thiolate anions and ***Potassium Thiocyanate***[13c] substitute readily, but with anionic oxygen nucleophiles the substitution is made on the acetoacetate enolate. The 4-*t*-butoxy derivative is used for the preparation of ethyl 4-*t*-butoxy-3-hydroxybutanoate (**9**), a versatile chiral building block (eq 5).[14]

Substitution with tertiary amines proceeds readily, and the reaction with ***Trimethylamine*** provides a synthetic route to carnitine.[15] Substitution with primary and secondary amines is best made after protection of the 3-position.

Reaction at Position 3.

Asymmetric reduction of the keto group is accomplished using the Noyori process,[16a] which allows synthesis of either the (*R*)- or (*S*)-4-chloro-3-hydroxybutanoate more efficiently than with biological methods.[16b] After formation of the acetal (**10**), selective substitution with hydroxylamine at the 1-position gives a synthetic route[17] to the isoxazole pantherine (**11**) (eq 6).

(6)

Acetal (**10**) can be directly converted to (*E*)-4-chloro-3-methoxy-2-butenoic acid ester (**12**). This compound is the reagent of choice for selective substitution at position 4.[18] With primary amines, cyclization to form tetramic acids (**13**) occurs (eq 7).

In contrast, the reaction of alkyl 4-chloroacetoacetates with weakly basic primary and secondary amines yields enamines;[19] the enamines from primary amines cyclize to give tetronic acids.[20] Enol ether (**12**) reacts with phosphites to produce Horner-Emmons reagents, useful for carbon chain extension after ylide generation with ***Sodium Hydride***.[18]

Ring-Closure Reactions.

When alkyl 4-chloroacetoacetates react with bifunctional reagents, various ring closures yielding heterocycles occur.

Retention of the Chloromethyl Group.

Cyclizations with hard dinucleophiles can occur between positions 1 and 3. Thus amidines yield pyrimidines[21] and carbamates give oxazinones.[23] In this category is the von Pechmann reaction with phenols, which produces coumarins.[22] Ring closure between positions 3 and 2 occurs with ***Chloroacetaldehyde*** under basic conditions to produce 3-alkoxycarbonyl-2-chloromethylfuran,[24] and the Hantzsch synthesis of dihydropyridines also falls in this category.

Loss of the Chloromethyl Group.

The reactions of alkyl 4-chloracetoacetate enolates with isocyanates and isothiocyanates give 2-aminofuranones[25] and 2-aminothiophenones,[26] respectively. Ring formation between the reactive 3- and 4-positions is well documented, whereby the soft nucleophilic center reacts at position 4. Amides, thioamides, and thiourea give the corresponding 4-oxazolyl- and 4-thiazolylacetic acid esters,[27] and 2-aminothiophenol produces a 3,4-dihydro-2*H*-1,4-benzothiazine.[28] Also, direct formation of an indole by reaction of an *N*-benzylaniline with (**1**) has been reported.[29]

Related Reagents.

Also available by bromination of diketene are the corresponding 4-bromoacetoacetates (methyl ester [*17790-81-7*]; ethyl ester [*13176-46-0*]), which find similar use in synthesis.[1] The 4-iodo- and 4-fluoroacetoacetates are known, but they are of minor importance. See also ***Acetoacetic Acid***; ***Diketene***; ***Ethyl Acetoacetate***; ***Ethyl 4-(Triphenylphosphoranylidene)acetoacetate***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

Ethyl Chloroformate[1]

[541-41-3] · $C_3H_5ClO_2$ · Ethyl Chloroformate · (MW 108.52)

(for ethoxycarbonylation of a wide variety of nucleophiles including anions of carboxylic acids[4] and esters,[5] nitriles,[7] dithianes,[9] ketones, enamines,[10] imines,[11] sulfones,[12] cuprates,[13] stannanes,[14] Grignards,[15] alanes,[18] furans,[17] alkynes;[19] acylation of alcohols,[20,22] carbonyls,[23,25] amines, and aziridines;[27] cleavage of tertiary amines;[32] formation of mixed anhydrides[38])

Physical Data: mp -81 °C; bp 95 °C; *d* 1.135 g cm^{-3}.

Solubility: miscible with benzene, chloroform, diethyl ether, ethanol; insol water.

Form Supplied in: colorless liquid; widely available.

Purification: the liquid is washed with water then distilled at atmospheric pressure using an efficient fractionating column and $CaCl_2$ guard tube.[2]

Handling, Storage, and Precautions: slowly hydrolyzed by water to CO_2 and HCl; store at cool temperatures: pressure may develop within bottle; thermal decomposition to CO_2 and EtCl occurs; highly flammable (fp 2 °C); toxic by inhalation and skin absorption; lachrymatory, irritant; use in a fume hood.

Ethoxycarbonylation of Active Methylene Compounds.

Ethyl chloroformate[3] reacts with a wide range of nucleophiles. Enolates derived by deprotonation of aliphatic and aromatic carboxylic acids bearing at least one α-hydrogen with two equivalents of ***Lithium Diisopropylamide*** at low temperature in THF are ethoxycarbonylated to give the monoesters of malonic acids (eq 1).[4] The yields are highest for alkyl carboxylic acids at -78 °C.[5] Although higher yielding than with ***Diethyl Carbonate***, treatment of the α-lithiated esters with ***Carbon Dioxide*** frequently gives better yields of the malonates.[4,6] Mixed malonates, especially those derived from bulky alkyl esters, can be similarly prepared (eq 2).[5]

(1)

(2)

α-Lithionitriles are ethoxycarbonylated in good yield.[7] Acetals[8] and 1,3-dithianes[9] are effectively ethoxycarbonylated (eq 3) if ethyl chloroformate is used as a cosolvent to prevent side reactions. Ethoxycarbonylation of ketones is achieved when enamines are treated with ethyl chloroformate, in some cases giving comparable yields to those obtained using metal enolates.[10]

(3)

Enantioselective ethoxycarbonylation has recently been attempted[11] via deprotonation of *N*-benzylidenebenzylamine with two equivalents of a chiral lithium amide base and quenching with ethyl chloroformate; levels of asymmetric induction were low but higher than those obtained using other chloroformates (eq 4).

(4)

Ethoxycarbonylation of Vinyl Anions.

α,β-Unsaturated sulfones are α-ethoxycarbonylated (eq 5) on deprotonation with ***n-Butyllithium*** in THF at -78 °C and quenching with this reagent.[12]

(5)

Vinyl cuprates under Pd^0 catalysis give α,β-alkenic esters (eq 6).[13] Aryl, vinyl, and heterocyclic stannanes[14] react smoothly under Pd^0 catalysis at 100 °C to give ethyl esters (eq 7) in good yields if the catalyst and chloroformate are added to the reaction mixture slowly. A wide variety of functionality on tin is tolerated but allylstannanes are generally low yielding. Use of isobutyl chloroformate improves the yields in these acylcarbonylations.

(6)

(7)

Ethyl esters are produced from Grignard reagents[15] if the organometallics are not present in excess. This is also the basis of the 5-ethoxycarbonylation of 2,4-dimethylpyrrole.[16] 2-Lithiofurans are ethoxycarbonylated in good yield (eq 8).[17]

(8)

Trans-α,β-unsaturated esters can be prepared by ethoxycarbonylation of vinylalanes derived from terminal alkynes bearing primary, secondary, or tertiary alkyl substituents without the necessity of forming an intermediate ate complex (eq 9).[18] *Cis*-α,β-unsaturated esters result from ethoxycarbonylation of lithiated alkynes (eq 10)[19] followed by reduction over Lindlar catalyst.

(9)

(10)

O-, *N*-, and *S*-Acylations.

O-Ethoxycarbonylation is observed in some instances. Aliphatic alcohols, phenols,[20] and cyanohydrins[21] react in the

presence of tertiary amines to give carbonates. Equatorial oriented steroid hydroxyls are selectively acylated in the presence of axial hydroxyl groups.[22] Enol carbonates (eq 11)[23] are readily derived from ketones by formation of the lithium enolate using ***Lithium 2,2,6,6-Tetramethylpiperidide*** in THF/HMPA at -78 °C followed by an ethyl chloroformate quench at room temperature. The use of HMPA prevents competitive *C*-acylation. LiTMP is necessary to avoid side reactions common with other amine-derived bases such as LDA. Sodium and potassium enolates are not useful, generally giving competitive *C*-acylation. This procedure avoids the use of classical methodology relying on the use of Hg^{II} salts.

(11)

Trans-1-(1,3-butadienyl) carbamates[24] and carbonates[25] are useful dienes in Diels-Alder chemistry. The carbonates are produced when ***Crotonaldehyde*** (and its congeners) are deprotonated and treated at -78 °C with ethyl chloroformate (eq 12). Use of higher temperatures results in loss of some of the (*Z*) geometry. Similar treatment of crotonaldehyde imines affords the carbamates.

(12)

O-Ethylation occurs when the sodium enolates of α-formyl γ- and δ-lactones are refluxed in THF with ethyl chloroformate.[26]

N-Ethoxycarbonylation forms the basis of a variety of reactions of nitrogenous compounds. Aziridines form *N*-ethoxycarbonylaziridines which are converted, on heating, to allylic amines (eq 13).[27]

(13)

Tertiary amines may be cleaved by ethyl chloroformate in certain circumstances. *N*-Demethylation has been noted. For example, tropine acetate (eq 14) is readily converted to nortropine hydrochloride[28] on refluxing with ethyl chloroformate and subsequent acid-mediated hydrolysis of the intermediate urethane.

Reductive C-N bond cleavage has been demonstrated in more complex systems using ethyl chloroformate as a solvent.[29] Chlorination of corticosteroid cyclic ethers has been observed.[30] Tertiary aliphatic and alicyclic amines can be dealkylated.[31] Phenyl chloroformate, however, is usually regarded as the reagent of choice. In summary, deamination, demethylation, debenzylation, and deallylation of tertiary amines can all occur on treatment with ethyl chloroformate but the regioselectivities of these reactions are difficult to predict.[32]

Imides (e.g. phthalimide) are ethoxycarbonylated if the potassium salt is treated with ethyl chloroformate at 5-10 °C. At elevated temperatures (60-110 °C) the lithium salts are *N*-ethylated in high yield. *N*-Alkylation also occurs with other imide systems such as barbiturates, hydantoins, and succinimides.[33] Thiols give the corresponding monothiocarbonates.[34] Thioamides form ethyl imidates[35] and cyclic iminoethers[36] are obtained from thiolactams on mild warming with ethyl chloroformate. Sulfinic and sulfonic acids yield their ethyl esters.[37]

Mixed Anhydrides.

The preparation of mixed anhydrides from ethyl chloroformate and carboxylic acids enables coupling of peptides and amino acids.[38] This coupling procedure has largely been superseded by more effective methods relying on the use of superior reagents; see ***1,3-Dicyclohexylcarbodiimide*** (DCC) and ***1-Hydroxybenzotriazole*** (HOBT).

Ethyl chloroformate enables the one-step cyclization of peptides (eq 15),[39] yields generally being superior to those obtained if ***Bis(2,4-dinitrophenyl) Carbonate*** is used. However, ***Isobutyl Chloroformate***/*N*-methylmorpholine is now the reagent of choice for many solution-phase anhydride couplings.[40]

(15)

N-Protected amino acids and peptides are rapidly converted to the corresponding amino alcohols in high yields with complete retention of optical purity via reduction of the mixed anhydride by cold ***Sodium Borohydride*** in THF with dropwise addition of methanol (eq 16).[41] The disulfide bridges of cystine, the methyl and benzyl esters of o-carboxyl-protected glutamic and aspartic acids of peptides, and *N*-Cbz and *N*-Boc protection are compatible with the methodology. The anhydrides derived from ethyl chloroformate are superior to isobutyl and benzyl carbonates both in terms of yield and retention of optical purity.

(16)

Carboxylic acid triethylamine salts yield mixed anhydrides which, when treated with ethoxymagnesiomalonic esters give the benzoylated malonate.[42] Alternatively, treatment of the mixed anhydrides with sodium tetracarbonylferrate(II) produces the aldehyde derived from the parent aliphatic or aromatic carboxylic acid in good yield.[43]

Formation of mixed anhydrides also provides the basis for the synthesis of acyl azides (eq 17)[44] and hence amines via the Curtius rearrangement. The azide ion is usually delivered to the most electrophilic carbonyl,[45] but steric considerations may be important. The method is applicable even to strained cyclopropyl- and cyclobutylcarboxylic acids.[46] ***Diisopropylethylamine*** (Hünig's base) has been mooted as a superior base for the formation of mixed anhydrides.[47]

(*Z*)-Ethylenic mixed anhydrides are easily prepared without isomerization and react with vinyl cuprates (and other organometallics) under Pd^0 catalysis with >99% stereochemical control to give unsymmetrical divinyl ketones (eq 18).[13] Alternative routes via (*Z*)-ethylenic acyl chlorides produce (*E*/*Z*) mixtures.

Miscellaneous.

β-Cyanoesters (eq 19)[48] are produced from β-amido acids providing that the acid and amide functionality are sufficiently close to enable formation of a cyclic intermediate.

Aromatics undergo Friedel-Crafts alkylation in the presence of ***Aluminum Chloride***, probably due to the formation of

EtCl in situ.[49]

Ethyl chloroformate has been used to moderate reactivity in polymerizations. For example, PVC with good thermal stability is prepared in the presence of this reagent.[50]

S-Ethyl Chlorothioformate

[2941-64-2] · C_3H_5ClOS · *S*-Ethyl Chlorothioformate · (MW 124.585)

(used in synthesis of carbothioate *S*-esters)

Physical Data: mp -60 °C; bp 132 °C; bp 39 °C/20 mmHg; *n*20D 1.4820; *d* 1.195 g cm^{-3}; fp 30 °C.

Solubility: sol DMF (17.9 g 100 mL^{-1}).

Form Supplied in: liquid; 95-98%, dependent on supplier.

Purification: two short-path distillations.

Handling, Storage, and Precautions: the liquid is flammable, moisture sensitive, harmful if swallowed and causes burns. It is also a lachrymator. Use in a fume hood.

Carbothioate *S*-Esters.

This reagent provides a superior procedure for the preparation of carbothioate *S*-esters. These are interesting synthetic intermediates, due to their activated carbonyl group,[1] and have, amongst other things, been used as a complexing reagent in some organometallic systems.[4] The previous method of Schotten-Baumann involves the reaction of a carboxylic acid with either ***Thionyl Chloride*** or ***Oxalyl Chloride*** followed by a thiol and base.[2] This has the disadvantage of introducing an acid chloride moiety into the substrate during the first step of the sequence with the consequent possibility of side reactions. The modified procedure involves the reaction of the sodium salt of the carboxylic acid with the reagent in DMF and pyridine, firstly at 0 °C and then at room temperature (eq 1).[3]

(1)

This reaction works considerably better if the *S*-phenyl ester is used instead (64%); with the same derivative, use of the lithium salt gave an improved yield over the sodium salt although no reaction of the *S*-ethyl ester with this cation was attempted.

Fungicidal carbanilates have have also been prepared using this method. Electron-donating *meta*-substituted phenyl(ethylthio-*N*-substituted amide)s were prepared, using a dichloromethane-pyridine solvent mixture.[5]

Tarbell et al. have studied the reaction of aromatic carboxylic acids with chlorothioformate *S*-esters to yield the corresponding mixed anhydrides.[6] Thermal decomposition of this gives the arenecarbothioate *S*-ester.

An alternative to forming carbothioate esters uses the *O*-ester isomer of ethyl chlorothioformate.[7] Treatment of dibutylethoxyphosphine in toluene with ethoxythiocarbonyl chloride gave 70-80% of the *S*-ethylcarboxydibutylphosphine oxide. This could then be reacted with benzylamine in isopropyl alcohol to give the benzylaminocarboxydibutylphosphine oxide.

α-Fluoro-β-thioester Esters.

An α-fluoro-β-thioester ester has been prepared in 57% yield using this reagent and some phosphorus chemistry.[8] ***Tri-n-butylphosphine*** and ethyl bromofluoroacetate were initially reacted in THF at rt; deprotonation with ***n-Butyllithium*** at -78 °C was followed by addition of the acid chloride; workup was with mild aqueous base to give $EtSC(O)CFHCO_2Et$.

α,β-Unsaturated Thiocarboxylates.[9]

Synthesis of α,β-unsaturated thiocarboxylates by Schaumann has been achieved by two different methods: *ipso* substitution of the silyl group in vinylsilanes or cyclopropylsilane by Lewis acid-activated *S*-ethyl chlorothiocarbonate;[10] and standard Horner-Emmons type alkenation.[11] With the former the best results were obtained with ***Aluminum Chloride***, rather than ***Titanium(IV) Chloride*** or ***Magnesium Bromide*** as catalysts, in dichloromethane at -60 °C and yields varied between 25% and 66% depending on the substrate. It is thus assumed that the reactive intermediate is the hard *S*-ethylcarbonyl cation; *S*-*t*-butyl, -

hexyl, and -cyclohexyl chlorothiocarbonates gave no substitution, due to cation breakdown, even with $AlCl_3$ at -78 °C, yielding instead the alkyl halide and carbonyl sulfide.[12] The workup was with saturated NH_4Cl (aq) followed by saturated $NaHCO_3$ (aq), brine, water, drying with $MgSO_4$ and distillation in vacuo, with added hydroquinone. More vigorous conditions were required with the cyclopropylsilane but no ring opening was observed. It appears that edge coordination of the cyclopropane to the electrophile is involved.[13]

The Horner-Emmons type reaction is a more general procedure and allows the use of the *S*-*t*-butyl, -hexyl, and -cyclohexyl chlorothiocarbonates, unlike the previously mentioned method. Yields for this one-pot reaction scheme were quite variable (21-81%). However, usually only the (*E*)isomer product was formed.

Other Reactions of *S*-Ethyl Chlorothioformate.

Bis(tributyltin) sulfide has been used as a sulfur transfer reagent under neutral and mild conditions with *S*-ethyl chlorothioformate; using 1 mol equiv in $CHCl_3$ at 110 °C for 12 h gave 97%, via GLC, of bis(*S*-ethylcarboxy) thioanhydride.[14]

A facile Rosenmund type reduction of acid chlorides, including the *S*-ethyl ester, with hypervalent silicon hydrides has been demonstrated.[15] Ethyl chlorothioformate was unreactive compared to most acid chlorides with this reaction, so a more efficient silane (**1**) had to be used; the yield of ethylthioformaldehyde was greater than 95% via NMR integration. In a continuation of this work, Corriu has also shown that reaction of the standard silane (**2**) with ***Phenyl Isocyanate*** yielded an adduct which, on addition of the reagent, gave the *N*-acylthioformamide EtSC(O)NPhCHO in 80% yield.[16] In addition the chlorosilane produced was readily recycled by reduction with ***Lithium Aluminum Hydride***. Only one paper previously existed on the preparation of *N*-acylthioformamides.[17]

Ethyl Crotonate[1]

(*E*)

[623-70-1] · $C_6H_{10}O_2$ · Ethyl Crotonate · (MW 114.16) (*Z*)

[6776-19-8] (Me ester)

[623-43-8] · $C_5H_8O_2$ · Methyl Crotonate · (MW 100.13)

(alkylating and annulating reagent commonly used in cycloadditions,[2] conjugate additions,[3] tandem vicinal dialkylation reactions,[4] and Heck reactions[5])

Physical Data: bp 142-143 °C; *d*204 0.916 g cm^{-3}; *n*20D 1.425.

Solubility: insol H_2O; sol EtOH, ether, most other polar solvents.

Form Supplied in: typically furnished predominantly as the (*E*)-isomer; purity &egt;96%; widely available.

Preparative Method: the (*Z*)-isomer can be prepared by semihydrogenation of ethyl tetrolate in excellent chemical yield.[6]

Purification: commercial material can be washed with 5% aq Na_2CO_3, followed by aq saturated $CaCl_2$. Drying with $CaCl_2$ and distillation at atmospheric or reduced pressure provides the pure ester.[7]

Handling, Storage, and Precautions: should be stored tightly capped in an amber container and preferably refrigerated. Crotonates are flammable and corrosive, usually with a lachrymatory odor. This toxic reagent should be handled in a fume hood.

The chemistry of alkyl crotonates parallels that of the alkyl acrylates (see ***Ethyl Acrylate***), particularly in their use as dienophiles in cycloadditions[8] and in their conjugate addition reactions.[9]

Ethyl Cyanoacetate

(R = Et)

[105-56-6] · $C_5H_7NO_2$ · Ethyl Cyanoacetate · (MW 113.13) (R = Me)

[105-34-0] · $C_4H_5NO_2$ · Methyl Cyanoacetate · (MW 99.10) (R = *t*-Bu)

[1116-98-9] · $C_7H_{11}NO_2$ · *t*-Butyl Cyanoacetate · (MW 141.19)

(reagent with a doubly activated methylene group for free radical cyclizations, for preparing heterocycles, for nucleophilic substitution reactions, for preparing α-alkylidene derivatives, and for carbocyclic ring formation)

Physical Data: R = Me, bp 204-207 °C; *d* 1.123 g cm^{-3}; R = Et, bp 208-210 °C; *d* 1.063 g cm^{-3}; R = *t*-Bu, bp 90 °C/10 mmHg.

Solubility: sol EtOH, ether.

Form Supplied in: liquid; widely available.

Preparative Method: ethyl and methyl cyanoacetate are conveniently prepared from cyanoacetic acid and the corresponding ***Triethyloxonium Tetrafluoroborate*** and trimethyloxonium fluoroborate.[1] *t*-Butyl cyanoacetate is prepared from cyanoacetyl chloride and *t*-butyl alcohol.[2]

Analysis of Reagent Purity: gas chromatography.

Handling, Storage, and Precautions: ethyl cyanoacetate is a lachrymator irritant. Methyl cyanoacetate is described as an irritant. Keep containers well closed. Inhalation should be avoided. Hydrogen cyanide or other low molecular weight cyano compounds may be liberated in event of overheating. Handle in a fume hood.

Condensation Reactions With Carbonyl Groups.

Ethyl cyanoacetate undergoes the Knoevenagel condensation[3] (or the Knoevenagel-Doebner modification) with aldehydes and ketones in the presence of β-alanine,[4] glycine,[5] ammonium acetate,[6,7] ***Piperidine***,[8] piperidine acetate,[8] bismuth trichloride,[9] ***Dihydridotetrakis(triphenylphosphine)ruthenium(II)***,[10] or weak bases.[11] The ammonium acetate-

catalyzed reaction of acetophenone and ethyl cyanoacetate affords ethyl (1-phenylethylidene)cyanoacetate (eq 1).[7] Condensation of ethyl cyanoacetate with propanal followed by reduction with hydrogen and palladium yielded ethyl butylcyanoacetate.[8] Ethyl cyanoacetate and other active hydrogen compounds can also be alkylated by alcohols in modest yields using the combination of ***Diethyl Azodicarboxylate*** and ***Triphenylphosphine***.[12]

(1)

Reactions with α,β-Unsaturated Carbonyl Compounds.

Activated nitriles such as ethyl cyanoacetate react with α,β-unsaturated carbonyl compounds in the presence of dihydridotetrakis(triphenylphosphine)ruthenium to afford Michael adducts which can undergo an aldol cyclization stereoselectively to afford cyclohexanes (eq 2).[10] Ethyl cyanoacetate reacts with *p*-benzoquinone to afford diethyl α,α´-dicyano-2,5-dihydroxy-*p*-benzenediacetate which is hydrolyzed to 2,5-dihydroxy-*p*-benzenediacetic acid (eq 3).[13] Methacrylamides react with ethyl cyanoacetate in the presence of ***Cesium Fluoride***-tetramethoxysilane to form dihydropyridinones (eq 4).[14]

(2)

(3)

(4)

Synthesis of Cyclopropanes and Cyclopentanes.

1-Cyanocyclopropanecarboxylic acid (eq 5)[15] or 1-cyanocyclopentane-1-carboxylate[16] can be prepared by cyclocondensation (double alkylation) of ethyl cyanoacetate and ***1,2-Dibromoethane*** or ***1,4-Dibromobutane*** under phase transfer conditions. Ethyl cyanoacetate reacts (2 equiv) with alkenes (1 equiv) in the presence of ***Copper(II) Chloride*** and ***Copper(II) Acetate*** in DMF to afford *endo*- and *exo*-cyclopropane derivatives (yields based on the alkene) (eq 6).[17] Cyclopropanes were obtained under similar conditions from 1-decene and styrene. Use of dimethyl malonate in place of ethyl cyanoacetate gave lower yields of cyclopropanes.

(5)

(6)

Alkylation Reactions.

Ethyl cyanoacetate undergoes nucleophilic aromatic substitution with hexafluorobenzene in DMF/***Potassium Carbonate*** to yield ethyl cyano(pentafluorophenyl)acetate which is converted to (pentafluorophenyl)acetonitrile.[18] Ethyl

cyanoacetate reacts with *o*,α-dichlorotoluene to afford ethyl 2-(*o*-chlorobenzyl)cyanoacetic acid which is an intermediate in the synthesis of 1-cyanobenzocyclobutene (bicyclo[4.2.0]octa-1,3,5-triene-7-carbonitrile).[19] The nucleophilic substitution reaction of ethyl and *t*-butyl cyanoacetate with 3-bromochromone (eq 7) or 6-bromofurochromone affords the respective 3-substituted derivative,[20] presumably by an addition-elimination mechanism.

Radical Cyclizations.

Ethyl cyanoacetate reacts with the tosylate of (*E*)-4-hexen-1-ol to afford ethyl (*E*)-2-cyano-6-octenoate which yields 1-cyano-2-methylcyclohexanecarboxylate on treatment with ***Dibenzoyl Peroxide*** (eq 8).[21] Similarly, oxidative free radical cyclization of ethyl (*4E*,8-nonadien-1-yl)cyanoacetate in the presence of the co-oxidants Mn^{III} and Cu^{II} acetate afforded ethyl 1-cyano-2-[1-(1,4-pentadienyl)]cyclopentanecarboxylate (35%).[22] In the absence of Cu^{II} acetate or with benzoyl peroxide alone in cyclohexane, a mixture of the stereoisomers of methylhydrindane is formed (eq 9). The Mitsunobo reactions of 1,*n*-diols with ethyl cyanoacetate in the presence of triphenylphosphine and diethyl azodicarboxylate afford 1-cyano-1-cycloalkanecarboxylates (eq 10).[23]

(9)

(10)

Synthesis of Heterocycles.

Reaction of 2-arylazirines and ***Hexacarbonylmolybdenum*** with ethyl cyanoacetate furnishes the *trans* disubstituted succinimides (eq 11).[24] Ethyl cyanoacetate condenses with butanone in the presence of ammonium acetate and ammonia to yield α,α´-dicyano-β-ethyl-β-methylglutarimide (70%), which can be converted to β-ethyl-β-methylglutaric acid.[25] Ethyl cyanoacetate reacts with aromatic and heterocyclic hydrazines to form 1-aryl-3-amino-5-pyrazolones (eq 12).[26]

(11)

(12)

Ethyl cyanoacetate condenses with urea to form 2,6-dihydroxy-5-aminouracil (eq 13), which is the first step in a synthesis of 5,6-diaminouracil hydrochloride.[27] Similarly, thiourea and ethyl ethoxymethylenecyanoacetate afford 2-mercapto-4-amino-5-ethoxycarbonylpyrimidine and 2-mercapto-4-hydroxy-5-cyanopyrimidine.[28] Guanidine condenses with ethyl cyanoacetate to produce 2,4-diamino-6-hydroxypyrimidine.[29]

(13)

Other Applications.

Novel carbon-carbon bond formation of nonactivated alkenes with ethyl cyanoacetate has been developed by anodic oxidation using Mn^{II} and Cu^{II} diacetates to give selectively either ethyl cyanoalkanecarboxylates or cyanoalkenecarboxylates (eq 14).[30,31] Preparation of cyanomethyl ketone derivatives of *N*-acetylphenylalanine and *N*-acetylleucylphenylalanine is accomplished by condensation of the corresponding activated carboxylic acids and the carbanion of *t*-butyl cyanoacetate.[32] ***Malononitrile***, benzoylacetonitrile, and nitroacetonitrile are also reactive. Reaction of ethyl cyanoacetate and butanone in the presence of ***Potassium Cyanide*** and ***Acetic Acid***, followed by acidic hydrolysis and heat, affords α-ethyl-α-methylsuccinic acid.[33]

(14)

Related Reagents.

Acetonitrile; ***Cyanoacetic Acid***; ***3-Ethoxyacrylonitrile***; ***Ethyl Ethoxymethylenecyanoacetate***; ***Lithioacetonitrile***; ***Malononitrile***.

Ethyl Diazoacetate[1]

[623-73-4] · $C_4H_6N_2O_2$ · Ethyl Diazoacetate · (MW 114.10)

(for synthesis of cyclopropane- and cyclopropenecarboxylic acid derivatives,[1-3] β-keto esters,[4] and 2-substituted 2-diazoacetic esters,[5,6] for homologation of ketones[7-9])

Alternate Name: EDA.

Physical Data: mp -22 °C; bp 42 °C/5 mmHg 73 °C/80 mmHg, 141 °C/720 mmHg; *d*17.64 1.0852, *d*244 1.083 g cm^{-3}; *n*17.6D 1.4588, *n*25D 1.4616; volatile with steam, ether and benzene vapors.

Solubility: sol alcohol, acetone, benzene, ether, ligroin; slightly sol water.

Form Supplied in: yellow oil; commercially available from many suppliers; typical impurities include ethyl chloroacetate and solvents (CH_2Cl_2, ether).

Preparative Method: by the reaction of ***Sodium Nitrite*** with glycine ethyl ester hydrochloride.[5,6]

Handling, Storage, and Precautions: explodes when heated, or on contact with concentrated H_2SO_4 or HCl; decomposes under irradiation. The reagent has to be stored in a dark cold place. It is toxic and reactions involving the formation or reaction of this substance should be performed in well-ventilated fume hood and behind a safety shield. The chemist should wear a suitable face shield.

Cyclopropanation of Unsaturated Compounds.

The most useful method of preparation of many cyclopropanecarboxylic acids is catalytic decomposition of ethyl diazoacetate in the presence of alkenes (eq 1).[1-3,10-12]

(1)

Addition of the transient ethoxycarbonyl carbenoid formed under catalytic decomposition of diazoacetate is *cis* stereospecific (eq 2).[1,13] The less sterically hindered cyclopropanecarboxylate usually predominates (eq 3).[1-3,11]

(2)

(3)

4.5:1

Decomposition of EDA with heterogeneous copper catalysts requires relatively high temperatures and gives moderate yields of cyclopropanecarboxylates.[1,2,14] Utilization of homogeneous catalysts such as ***Copper(I) Acetylacetonate*** increases the yields of cyclopropanes (eq 4). Rhodium(II) carboxylates (e.g. ***Dirhodium(II) Tetraacetate***) have been found to be even more effective, allowing the reaction to be carried out at room temperature or at even lower temperatures, with low concentrations of catalyst (0.5 mol %).[3,11] Rh^{II} complexes with chiral ligands have been used in stereocontrolled synthesis of chrysantemic and related acids.[2,15]

A wide variety of unsaturated compounds react with EDA in the presence of catalysts to give cyclopropanecarboxylates, for example polynuclear aromatic or heteroaromatic compounds,[1,2] enol ethers,[12] and ketene dialkyl acetals.[16] Catalytic cyclopropanation with EDA has also been used in the synthesis of bicyclobutanes,[1] triangulanes,[17] and other polycylic systems.[10,12]

Cyclopropene-3-carboxylate esters usually are prepared by rhodium-catalyzed decomposition of EDA and its analogs in the presence of alkynes. Target compounds can be obtained in a high yield even at room temperature from both terminal and disubstituted alkynes (eq 5).[1,18]

Copper catalysis requires a temperature of 90-140 °C and gives satisfactory yields of cyclopropene esters only in the case of disubstituted alkynes.[18] When double and triple bonds are both present in the same molecule, reaction takes place at both of them, a preference being shown for addition to the double bond.[1,6,19] Decomposition of EDA with chiral rhodium(II) compounds allows one to achieve high enantioselectivity in cyclopropene synthesis.[20]

Homologation of Ketones.

EDA is the most useful diazoalkane for homologation of cyclic and acyclic ketones without the formation of epoxides as byproducts. This reaction is catalyzed by ***Boron Trifluoride Etherate***,[7-9] ***Tin(IV) Chloride***,[21] or ***Triethyloxonium Tetrafluoroborate***.[2] The homologation is not regiospecific and usually gives a mixture of isomeric 2-keto esters, but insertion occurs preferentially at the less substituted side of the carbonyl group (eq 6).[8]

(6)

A procedure for regiospecific homologation of ketones was developed by using α-halo-substituted ketones. Treatment of the halo ketone with EDA is followed by removal of the halogen using ***Zinc*** followed by decarboxylation of the resulting β-keto ester (eq 7).[7,22]

(7)

α-Diketones can be converted to β-diketones by reaction with EDA in the presence of ***Zinc Chloride*** followed by hydrolysis (eq 8).[23]

(8)

Synthesis of 2-Substituted Acetic Esters.

EDA reacts with trialkylboranes,[24] dialkylchloroboranes,[25] or alkyl(aryl)dichloroboranes[26] with loss of nitrogen to give, after hydrolysis, the homologated ethyl ester in a moderate to high yield. β,γ-Unsaturated carboxylic esters have

been obtained using this procedure (eq 9).[25]

Homologated ethyl esters have also been prepared by insertion of ethoxycarbonylcarbene generated by catalytic decomposition of EDA in C-H,[12,27] C-O and C-S,[6] or Si-H bonds.[28] Ethyl 2-alkoxyacetates have been obtained in good yield by Rh^{II}-catalyzed decomposition of EDA in the presence of various alcohols.[29]

Ethyl Lithiodiazoacetate.

This reagent, which is stable only below -50 °C, can be prepared by treating EDA with ***n-Butyllithium*** in THF at -115 to -78 °C.[5] Reaction of ***Ethyl Diazolithioacetate*** with alkyl-, acyl-, and trialkylsilyl halides results in the formation of 2-substituted ethyl diazoesters (eq 10).[5,6,30]

This reagent also reacts with carbonyl compounds, forming 2-diazo-3-hydroxy esters (eq 11).[5,6]

Transmetalation of ethyl lithiodiazoacetate gives access to silver, mercury, and tin derivatives of EDA.[5,6]

Cycloheptatrienes.

Thermal or photochemical decomposition of EDA in benzene and its derivatives leads to the formation of cycloheptatriene esters in moderate yields.[1,2] ***Dirhodium(II) Tetrakis(trifluoroacetate)*** has been recently reported to be a very effective catalyst for this reaction and increased the yields of cycloheptatrienes (eq 12).[31]

(12)

β-Keto Esters from Aldehydes.

In addition to methods of β-keto ester synthesis described above, these compounds can be prepared by the addition of EDA to aldehydes in the presence of ***Tin(II) Chloride*** (eq 13).[4]

(13)

Ylide Rearrangements.

Catalytic decomposition of EDA in the presence of sulfides, tertiary amines, or iodides leads to formation of intermediate ylides which undergo Stevens rearrangement (eq 14).[2,3,6] Ylides bearing an allylic double bond give the products of a [2,3]-sigmatropic rearrangement (eq 15).[3,32]

(14)

(15)

Dirhodium(II) Tetraacetate has been shown to be the most useful catalyst for this transformation.[3]

Ethyl Diazolithioacetate[1]

[55718-77-9] · $C_4H_5LiN_2O_2$ · Ethyl Diazolithioacetate · (MW 120.05)

(nucleophilic diazo species for preparation of substituted diazo esters,[2-9] β-keto esters,[3,6,10-12] acylalkynes,[13] and for carrying out one-carbon ring expansion reactions[14-16])

Alternate Name: ethyl lithiodiazoacetate.

Solubility: sol ether solvents.

Preparative Methods: prepared in situ by lithiation of ***Ethyl Diazoacetate*** using ***n-Butyllithium*** or ***Lithium Diisopropylamide***, or by transmetalation of $Hg[C(N_2)CO_2Et]_2$.

Handling, Storage, and Precautions: stable in solution only below -50 °C. Use in a fume hood.

Preparation of Diazo Esters.

Ethyl diazoacetate can be readily converted into a range of diazo esters by way of its lithio derivative. The lithium derivative can be prepared by transmetalation of diethyl mercuriobis(diazoacetate) with butyllithium at -70 °C,[2] or, much more conveniently, by lithiation of commercially available ethyl diazoacetate using butyllithium[2,3] or LDA.[4,5] The lithio derivative reacts with a range of electrophiles (eq 1) to give substituted diazoesters (Table 1). With carbonyl compounds, better yields are often obtained if butyllithium is added to the mixture of ethyl diazoacetate and carbonyl compounds;[3] acrolein undergoes exclusive 1,2-addition.[5,6] Similar condensations between ethyl diazoacetate and aldehydes (or ketones) can also be carried out in the presence of potassium hydroxide.[7]

Table 1 Representative Examples of the Reaction of Ethyl Diazolithioacetate with Electrophiles

Electrophile	R	Yield (%)
Me_3SiCl[2]	Me_3Si	52
Bu_3SnCl[2]	Bu_3Sn	50
PhCOCl[2]	PhCO	45
PhCHO[2,3]	PhCH(OH)	41 (95)
$C_7H_{15}CHO$[4]	$C_7H_{15}CH(OH)$	68
$CH_2{=}CHCHO$[5,6]	$CH_2{=}CHCH(OH)$	87
PhCOMe[2,3]	PhCMe(OH)	50 (94)
MeCOMe[3]	$Me_2C(OH)$	93

Other carbonyl electrophiles such as six-membered lactones,[8] thiolactones,[9] and *N*-Boc lactams[8] also react with ethyl diazolithioacetate to give the corresponding diazo β-keto esters (eq 2), which in the case of the hydroxy and mercapto compounds can be recyclized to the corresponding seven-membered heterocycles by treatment with ***Dirhodium(II) Tetraacetate***.[8,9]

(2)

X = O 81%
X = S 58%
X = NBoc 60%

Preparation of β-Keto Esters and Related Compounds.

Addition of ethyl diazolithioacetate to aldehydes gives α-diazo-β-hydroxy esters (see above). Treatment of these with HCl,[3,10] rhodium(II) acetate,[11] or various other metal salts[12] results in loss of nitrogen and the formation of β-keto esters (eq 3). A variation on the reaction involves acetylation of the intermediate hydroxy diazo compound, followed by pyrolysis to give the enol acetate of the β-keto ester;[6] hydrogenation of the hydroxy diazo ester over palladium gives β-hydroxy esters (eq 3).[6]

(3)

Preparation of Acylalkynes.

In contrast to the above reactions of α-diazo-β-hydroxy esters (eq 3), reaction of these species with ***Boron Trifluoride Etherate*** gives alkynic esters (eq 4).[13]

(4)

Ring Expansion Reactions.

The conversion of α-diazo-β-hydroxy esters derived from aldehydes into β-keto esters involves H-migration (eq 3); an analogous reaction of α-diazo-β-hydroxy esters derived from cyclic ketones would therefore result in a one-carbon ring expansion reaction. This has been successfully used for simple cyclic ketones (eq 5),[3] and for chromanones and their thio derivatives (eq 6).[14,15] Thiopyrylium salts can be similarly ring expanded.[16]

(5)

Related Reagents.

Other metalated derivatives of ethyl diazoacetate are known,[1] e.g. the silver derivative is readily converted into substituted diazo esters by alkylation (eq 7).[17]

t-Butyl diazoacetate is also readily lithiated; quenching with lactones gives products entirely analogous to the ethyl ester (eq 2).[18]

Diazolithioacetone can be generated from ***Diazoacetone*** using butyllithium or LDA and participates in similar reactions to ethyl diazolithioacetate. Thus addition to aldehydes gives α-diazo-β-hydroxy ketones, treatment of which with rhodium(II) acetate gives β-diketones (eq 8),[19] or with boron trifluoride etherate to give acetylalkynes (cf. eq 4).[13]

Ethyl Dibromoacetate

Br_2CHCO_2Et

[617-33-4] · $C_4H_6Br_2O_2$ · Ethyl Dibromoacetate · (MW 245.90)

(used in preparation of α-bromo and α,α-dialkyl substituted esters;[1] undergoes Reformatsky/Darzens reactions with aldehydes and ketones[2])

Physical Data: bp 194 °C; 77 °C/12 mmHg; *d* 1.9025 g cm^{-3}.

Solubility: insol H_2O; sol hexane, ether, CH_2Cl_2, acetone, EtOAc, EtOH.

Form Supplied in: colorless to light yellow liquid; practical grade commercially available.

Handling, Storage, and Precautions: lachrymator; avoid inhalation of fumes. Handle in a fume hood.

Alkylation of Br_2CHCO_2Et with organoboranes in the presence of ***Potassium t-Butoxide*** or a hindered phenoxide base affords α-bromo esters or α,α-dialkyl substituted esters, depending upon the amounts of reagents employed and the reaction temperature (eq 1).[1] The phenoxide base (p*K* 11.7) minimizes self-condensation of both the starting material and the product. The procedure in eq 1 represents an attractive alternative to the classical malonic ester synthesis.[3]

(1)

Reformatsky-type addition of Br_2CHCO_2Et to aldehydes or ketones at low temperature in the presence of zinc/silver-graphite provides α-bromo-β-hydroxy esters in excellent yield (eq 2).[2] Mild base treatment then yields the expected glycidic esters, while other transformations of the initial adduct have also been reported (eq 2).[4] The use of Zn/Ag-graphite represents a major improvement over the classical Reformatsky conditions,[5] which required the use of Zn, Mg, or Ca amalgams with Br_2CHCO_2Et to avoid reductive loss of the bromo substituent.[5] The Zn/Ag-C reagent has also been utilized with aldonolactones.[6] Modification of the Reformatsky-type zinc reagent by the addition of ***Diethylaluminum Chloride*** allows the isolation of α,β-unsaturated esters in moderate yield (eq 3),[7] an alternative to the Wadsworth-Emmons reaction.[8]

(2)

(3)

The ***Triethylborane*** catalyzed radical addition of Br_2CHCO_2Et to ketene acetals affords unsaturated 1,4-diesters in fair yield (eq 4),[9] although the generality of the reaction has not been explored.

(4)

Under precisely controlled conditions (all reagents dispersed on sand), benzenethiolate displacement on Br_2CHCO_2Et provides the corresponding thioacetal (eq 5).[10] Further alkylation should provide a route to pyruvic acid derivatives.

(5)

The ethoxycarbonylcyclopropanation of both simple alkenes (eq 6)[11] and alkylidenemalonates (eq 7)[12] with Br_2CHCO_2Et in the presence of copper powder or zinc has also been reported.

(6)

(7)

Related Reagents.

Dichloroacetonitrile; ***Methyl Dichloroacetate***.

Ethyl 3,3-Diethoxyacrylate

[32002-24-7] · $C_9H_{16}O_4$ · Ethyl 3,3-Diethoxyacrylate · (MW 188.25)

(used in cycloaddition reactions with cyclopentenones, 1-aza-1,3-butadienes, and alkynylalkoxycarbene metal complexes to give carbocyclic and heterocyclic compounds; undergoes [3,3]-sigmatropic rearrangement with allylic alcohols to give substituted allylmalonates.)

Physical Data: bp 122-123 °C/10 mmHg; *n*25D 1.4597.[1]

Solubility: sol organic solvents.

Handling, Storage, and Precautions: keep away from moisture. Handle in a fume hood.

Ethyl 3,3-diethoxyacrylate (**1**) is prepared[1] from ***Ethyl Cyanoacetate*** by the Pinner reaction.[2] It has been used in a variety of cycloaddition reactions. Head-to-tail regioselectivity in the [$_\pi$2 + $_\pi$2] photocycloaddition of (**1**) with cyclopentenones (**2**) to give the bicyclo[3.2.0]heptanones (**3**) was significantly better than that observed with methyl β-acetoxyacrylate. Treatment of the cycloaddition products (**3**) with ***Sodium Borohydride*** followed by ***p-Toluenesulfonic Acid*** gave the lactones (**4**).[3]

(2) **(3)** **(4)**

$R^1, R^2 = H, H; Me, H; H, Me$

Cycloaddition of the alkynylalkoxycarbene metal complexes (**5**) with (**1**) provided (**8**), via (**7**) and, presumably, (**6**).

Oxidation of (**8**) with ***Dimethyl Sulfoxide*** gave the 6-ethoxy-2*H*-pyrones (**9**).[4]

(5) **(6)** **(7)**

R = Ph, *t*-Bu; M = Cr, W

(8) **(9)**

Reaction of (**1**) and the 1-aza-1,3-butadiene (**10**) in a [4 + 2] cycloaddition reaction at 13 kbar (1300 MPa) provided (**11**), which was converted to the pyridine (**12**) by treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.[5]

(10) **(11)** **(12)**

Raucher reported that the [3,3]-sigmatropic rearrangement of (**1**) with allylic alcohols (**13**) using a catalytic amount of ***2,4,6-Trimethylbenzoic Acid*** provides a convenient method for the regiospecific synthesis of substituted allylmalonate esters (**15**).[6] The alcohols examined were (**16**)-(**22**).

(13)

(14)

(15)

(16)

(17)

(18)

(19)

(20)

(21)

(22)

Trost reported that reaction of (**1**) and (**23**) with a catalytic amount of ***Pyridinium p-Toluenesulfonate*** at room temperature gave (**24**), an intermediate in a total synthesis of (-)-aspochalasin B.[7]

(23) R = $COCH_2SO_2Ph$

(24)

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl 3-Ethoxyacrylate***; ***Ketene Diethyl Acetal***; ***Methylketene Dimethyl Acetal***.

N-Ethyl(diethoxyphosphinyl)methylketenimine

[73473-51-5] · $C_9H_{18}NO_3P$ · *N*-Ethyl(diethoxyphosphinyl)methylketenimine · (MW 219.25)

(ketenimine functionalized with a diethoxyphosphinyl group;[1] reacts with nucleophiles to give various phosphonates; an annulation reagent for the synthesis of heterocycles)

Physical Data: bp 86-90 °C/1 mmHg.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: IR: $\nu_{C=C=N}$ 2030 cm^{-1}.

Preparative Method: synthesized in 82% yield by the dehydration of diethyl (*N*-ethylcarbamoylethyl)phosphonate, which is prepared from *N*-ethyl-α-chloropropionamide and diethyl sodiophosphite (eq 1).

Handling, Storage, and Precautions: use in a fume hood.

Reaction with Nucleophiles and Use as an Annulation Reagent.[2]

Nucleophilic addition of ethanol, diethylamine, or hydrazoic acid to the title ketenimine (**1**) gives the imidate, amidine, or tetrazole with a phosphonyl residue, respectively, showing typical reactivity of ketenimines (eq 2).

(2)

The reactions of (**1**) with sodium salts of salicylaldehyde, *o*-hydroxyacetophenone, α-formyl-β-naphthol, 2-formylpyrrole, and 2-acetylpyrrole in DMF give benzopyrans, naphthopyrans, and pyrrolizines with exocyclic imine groups (eqs 3 and 4). These annulation reactions occur via initial nucleophilic attack of the anionic species at the center carbon of the ketenimine followed by the intramolecular Horner-Emmons reaction as seen in the tandem Michael-Horner-Emmons reaction of vinylphosphonates.[3]

(3)

(4)

Related Reagents.

Trimethyl 2-Phosphonoacrylate; ***Tris(trimethylsilyl)ketenimine***.

Ethyl 3,3-Diethoxypropanoate

[10601-80-6] · $C_9H_{18}O_4$ · Ethyl 3,3-Diethoxypropanoate · (MW 190.27)

(synthesis of heterocycles; Pictet-Spengler reaction;[1] malonaldehyde monoacetal;[2] enantiomeric pure γ-amino-β-hydroxybutanoic acid[3])

Alternate Name: ethyl 3,3-diethoxypropionate.

Physical Data: bp 92-95 °C/15 mmHg; *d* 0.978 g cm^{-3}.

Solubility: sol water, diethyl ether.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: *n*20D = 1.4117.

Preparative Methods: can be obtained by treatment of 1,1,1-trichloro-4-ethoxy-3-buten-2-one with ethanol in the presence of catalytic amounts of ***Potassium Carbonate***. The trichloromethyl ketone is prepared from ***Ethyl Vinyl Ether*** and ***Trichloroacetyl Chloride***.[4]

Purification: fractional vacuum distillation through a short Vigreux column.

Handling, Storage, and Precautions: ethyl 3,3-diethoxypropanoate is the stable, protected derivative of the unstable 3-oxopropanoate. It can be stored at room temperature for several months without decomposition.

Ethyl 3,3-diethoxypropanoate is a useful starting material for the synthesis of heterocycles such as coumarins (eq 1),[5] isoxazoles,[6] pyrimidines,[7] porphyrins,[8] imidazolinones,[9] and thiadiazines (eq 2).[10] Also spermine metabolites,[11] steroids,[1] herbicides,[12] antihypertensives,[13] photographic sensitizers,[14] cephalosporins,[15] lycopodium alkaloids,[16] nucleic acids,[17] prostaglandin ($PGF_{2\alpha}$) precursor,[18] pentaerythriol[19] as well as related alcohols can be obtained from ethyl 3,3-diethoxypropanoate.

(1)

(2)

Ethyl 3,3-diethoxypropanoate can be used for Pictet-Spengler reactions (eq 3),[1] and various other condensation reactions.[5,8-10,20]

(3)

Different monoprotected malonaldehydes can be obtained from ethyl 3,3-diethoxypropanoate by transacetalization and reduction with ***Diisobutylaluminum Hydride***/Et_2O at -78 °C[2a,b] or with ***Lithium Aluminum Hydride*** followed by oxidation with ***Dimethyl Sulfoxide-Oxalyl Chloride***.[4] The malonaldehyde monoacetals were employed in the synthesis of dihydropyrans[21a] and secologanin derivatives[21b,c] by tandem Knoevenagel hetero-Diels-Alder reactions.[22] They can also be used in Wittig reactions with various phosphorus ylides, and in addition of Grignard reagents, carbanions generated from nitroalkanes, and other organometallic compounds.[2c] They are also valuable substrates for the synthesis of heterocycles such as pyrazoles, isoxazoles, and pyrimidines.[2c]

Ethyl 3,3-diethoxypropanoate is used for the total synthesis of both enantiomers of 3-amino-2-hydroxybutanoic acid (GABOB) by enzymatic kinetic resolution of its cyanohydrin acetate (eq 4).[3] As a substitute of ethyl 3,3-

diethoxypropanoate and the unstable 3-oxopropanoate, the stable 4,4,4-trichloro-3-oxobutanal may be used since the α,α,α-trichlorocarbonyl group can easily be transformed into an ester moiety with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** in the presence of an alcohol.[21a,b]

(4)

In addition, diformylacetates, which are useful educts for the synthesis of 1,4-dihydropyridines and NADH analogs as well as sugar derivatives (see ***Methyl Diformylacetate***), can be obtained from ethyl 3,3-diethoxypropanoate by formylation.

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***3-Ethoxyacrolein***; ***Ethyl Hydroxymethyleneacetate, Sodium Salt***; ***Malondialdehyde***; ***Methyl Diformylacetate***.

Ethyl Difluoroiodoacetate

(R = Et)

[7648-30-8] · $C_4H_5F_2IO_2$ · Ethyl Difluoroiodoacetate · (MW 249.94) (R = Me)

[109872-87-9] · $C_3H_3F_2IO_2$ · Methyl Difluoroiodoacetate · (MW 235.92)

(useful for introduction of a CF_2CO_2R group)

Physical Data: R = Et, bp 70-72 °C/70 mmHg;[1] bp 72-74 °C/70 mmHg.[2]

Preparative Methods: prepared by the reaction of $FSO_2OCF_2CO_2Et$ with NaI (93%) (eq 1);[2] oxidation of $CF_2ICH{=}CF_2$ followed by esterification with EtOH (overall, 21% (eq 2);[3] by the addition of ICl to EtOCF = CF_2 followed by hydrolysis (overall, 44%) (eq 3);[1] and by the iodination of $XZnCF_2CO_2Et$ generated from $BrCF_2CO_2Et$ (available commercially) and Zn (58-73%) (eq 4).[4]

$$FSO_2OCF_2CO_2Et \xrightarrow{NaI} ICF_2CO_2Et \qquad (1)$$

$$CF_2Br_2 \xrightarrow{F_2C{=}CH_2} CF_2BrCH_2CF_2Br \xrightarrow{NaOH}$$

$$CF_2BrCH{=}CF_2 \xrightarrow{NaI} CF_2ICH{=}CF_2 \xrightarrow[2.\ EtOH]{1.\ KMnO_4} ICF_2CO_2Et \qquad (2)$$

$$F_2C{=}CFOEt \xrightarrow{ICl} ICF_2CFClOEt \xrightarrow{H_2SO_4} ICF_2CO_2Et \qquad (3)$$

$$BrCF_2CO_2Et \xrightarrow[2.\ I_2]{1.\ Zn} ICF_2CO_2Et \qquad (4)$$

Handling, Storage, and Precautions: handle in a fume hood

Reformatsky Reaction.

Treatment of difluoroiodoacetates with ***Zinc*** and aldehydes or imines gives the corresponding β-hydroxy-α,α-difluoro esters (eq 5)[5] and α,α-difluoro β lactams,[6] respectively. Alternatively, $BrCF_2CO_2Et$ could also be utilized as a precursor for this transformation.[7] Difluoroiodoacetates are converted to the 2,2-difluoroketene silyl acetal by the reaction with Zn and ***Chlorotrimethylsilane***. Subsequently, the silyl acetal reacts with α,β-unsaturated compounds to form the 1,4-addition product or a mixture of 1,4-addition and 1,2-addition products.[8]

$$ICF_2CO_2Et + RCHO \xrightarrow{Zn} RCH(OH)CF_2CO_2Et \qquad (5)$$

Formation and Reactions of the $CuCF_2CO_2R$ Reagent.

The copper reagent $CuCF_2CO_2R$ is prepared by the reaction of difluoroiodoacetate and ***Copper***. This copper reagent couples with a variety of halides including vinyl bromides and iodides, aryl and alkyl iodides, and allyl and benzyl bromides (eq 6).[9]

$$ICF_2CO_2R + Cu + RX \longrightarrow RCF_2CO_2R \qquad (6)$$

Radical Addition to Alkenes.

Addition of difluoroiodoacetates to alkenes has been initiated by Cu,[4,10] peroxide, and metallo complexes[11] to give the corresponding ester adduct, which could be reduced by ***Zinc/Nickel(II) Chloride***[4] to form the iodine-free α,α-difluoro ester (eq 7). More conveniently, the α,α-difluoro ester could be prepared from difluoroiodoacetates and alkenes in the presence of $Zn/NiCl_2.6H_2O$.[12] In this process, $Zn/NiCl_2.6H_2O$ behaves both as the radical initiator and the reducing reagent (eqs 7 and 8).

$$ICF_2CO_2R + H_2C{=}CHR' \xrightarrow{Cu} R'CHICH_2CF_2CO_2R \xrightarrow[NiCl_2 \cdot 6H_2O]{Zn} R'CH_2CH_2CF_2CO_2R \qquad (7)$$

(8)

Related Reagents.

1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride[1]

[25952-53-8] · $C_8H_{18}ClN_3$ · 1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride · (MW 191.74) (base)

[1892-57-5] (.MeI)

[22572-40-3]

(peptide coupling reagent;[1b,2] amide formation;[3] ester formation;[4] protein modification;[5] mild oxidations of primary alcohols[6])

Alternate Name: 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide; water-soluble carbodiimide; EDC; EDCI.

Physical Data: free base is an oil, bp 47-48 °C/0.27 mmHg; HCl salt is a white powder, mp 111-113 °C; MeI salt mp 97-99 °C.

Solubility: sol H_2O, CH_2Cl_2, DMF, THF.

Form Supplied in: commercially available as HCl salt and as methiodide salt that are white solids. Reagents are >98% pure; main impurity is the urea that can form upon exposure to moisture.

Analysis of Reagent Purity: IR: 2150 cm^{-1} (N=C=N stretch); urea has C=O stretch near 1600-1700 cm^{-1}.

Purification: recrystallization from CH_2Cl_2/ether.

Handling, Storage, and Precautions: EDC is moisture-sensitive; store under N_2 in a cool dry place. It is incompatible with strong oxidizers and strong acids. EDC is a skin irritant and a contact allergen; therefore avoid exposure to skin and eyes.

Peptide Coupling Reagent.

This carbodiimide (EDC) reacts very similarly to ***1,3-Dicyclohexylcarbodiimide*** and other carbodiimides. The advantage EDC has over DCC is that the urea produced is water soluble and, therefore, is easily extracted. Dicyclohexylurea is only sparingly soluble in many solvents and is removed by filtration which may not be as effective as extraction. A typical example of EDC for peptide coupling is shown in (eq 1).[2]

The problems associated with carbodiimide couplings are mainly from the *O*-acylisourea intermediate (**1**) having poor selectivity for specific nucleophiles. This intermediate can rearrange to an *N*-acylurea (**2**), resulting in contamination of the product and low yields. Additionally it can rearrange to 5(4*H*)-oxazolones (**3**) that tautomerize readily, resulting in racemization. Using low dielectric solvents like CH_2Cl_2 or additives to trap (**1**) minimizes these side reactions by favoring intermolecular nucleophilic attack on (**1**).[1b]

(1) (2) (3)

R = carbodiimide chain; R^1 = amino acid; R^2 = amino acid side chain; R^3 = NH protecting group

When low dielectric constant solvents are used, the carboxylic acid tends to dimerize, thus promoting symmetrical anhydride formation. This intermediate is stable enough to give good yields of the desired product. High dielectric solvents such as DMF retard acylation of amino acids, and *N*-acylurea can be a major byproduct.[1b] Unfortunately, many starting materials require polar solvents for dissolution.

Addition of trapping agents such as ***N-Hydroxysuccinimide***[7] and ***1-Hydroxybenzotriazole*** (HOBt)[8] reduce the extent of many side reactions, especially *N*-acylurea formation. Also, racemization is suppressed when these additives are present. The latter reagent eliminates the intramolecular dehydration of o-amides of asparagine and glutamine that occurs with carbodiimides (eq 2).[8,9]

R = carbodiimide chain

(2)

With EDC the addition of ***Copper(II) Chloride*** suppresses racemization to <0.1% compared to 0.4% with HOBt under ideal conditions.[10] Combinations of HOBt and $CuCl_2$ are also useful.[10b] The suggested stoichiometry for the highest optical purity and yield is 2 equiv of HOBt and 0.25-0.5 equiv of $CuCl_2$ in DMF.

A practical example of EDC's utility is the solution synthesis of human epidermal growth factor, a 53-residue protein.[11] This included several couplings of fragments ranging from three to six residues in length. All couplings were performed with EDC/HOBt in DMF or NMP. At the completion of the synthesis, no racemized material could be detected by HPLC.

Amide Formation.

Formylated amino acids and peptides are prepared in high yields by forming the acid anhydride (eq 3).[3] These products are pure without requiring chromatography or recrystallization.

(3)

Another method for formylation of amines is with *p*-nitrophenyl formate, which usually gives products in high yield. However, removing the last traces of the *p*-nitrophenol is difficult.[12]

Treating carbon dioxide and amines with EDC gives symmetrical ureas (eq 4).[13] DCC with CO_2 at ambient pressure works equally well.

(4)

EDC facilitates the synthesis of xanthine analogs by condensing a diamine with water-soluble acids (eq 5).[14] The use of water as the solvent precludes the use of DCC in this case.

Ester Formation.

Esters of *N*-protected amino acids are prepared in high yield with EDC and ***4-Dimethylaminopyridine*** (eq 6).[4] DMAP causes extensive racemization if not used in a catalytic amount.[15] However, when esterifying the α-carboxyl of β- and γ-benzyl esters of aspartyl and glutamyl derivatives, extensive racemization was observed even with DMAP present in catalytic amounts. It is postulated that the side-chain esters contribute in some fashion to the lability of the α-H.

Carbodiimides including EDC are also useful in preparing active esters such as the *p*-nitrophenyl, pentafluorophenyl, and *N*-hydroxysuccinimide esters.[1b] Numerous additional methods have been reported.[16]

Protein Modification.

Carboxyl groups in proteins react with EDC, resulting in an activated group that can be trapped with a nucleophile such as glycine methyl ester.[5] The nucleophile can also be amino groups in the protein, causing cross-linking. Applications for carboxylate modification include determining which groups are buried versus exposed, and mechanistic studies for determining which carboxyl groups are essential for an enzyme's activity.

EDC is used extensively in cross-linking proteins to solid supports for affinity chromatography.[17]

Oxidation of Primary Alcohols.

One example of EDC substituting for DCC in the Pfitzner-Moffatt oxidation is shown in (eq 7).[6] The use of DCC in this example resulted in a difficult purification of the product and lower yields.

(7)

Miscellaneous Reactions.

EDC is a useful water scavenger as well. An example of this utility is given in (eq 8).[18] The carbodiimide is required in this reaction, but DCC does not work well in this transformation.

(8)

Another example of EDC having a marked improvement over DCC is the formation of cyanoguanidines (eq 9).[19] This was originally attempted with DCC, which gives poor yields even after extended reaction times. It is thought the positively charged nitrogen in EDC facilitates the C-S bond cleavage and since DCC lacks this atom the reaction goes slowly.

Pyrroles are formed when acetylenes undergo cycloadditions with *N*-acylamino acids in the presence of EDC.[20] An *N*-alkenylmunchnone azomethine ylide is generated in situ and is trapped by the dipolaraphile. Loss of CO_2 yields the pyrrole (eq 10).

Related Reagents.

Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate; ***N,N´-Carbonyldiimidazole***; ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide***; ***1,3-Dicyclohexylcarbodiimide***; ***Diphenyl Phosphorazidate***; ***Di-p-tolylcarbodiimide***; ***N-Ethyl-5-phenylisoxazolium-3´-sulfonate***; ***1-Hydroxybenzotriazole***; ***Isobutene***; ***Isobutyl Chloroformate***; ***1,1´-Thionylimidazole***.

Ethyl (Dimethylsulfuranylidene)acetate

[7380-81-6] · $C_6H_{12}O_2S$ · Ethyl (Dimethylsulfuranylidene)acetate · (MW 148.25)

(stabilized sulfonium ylide reagent capable of reacting with a variety of electrophiles to produce substituted cyclopropanes, epoxides, enamines, and stabilized ylides, as well as other products[1])

Alternate Name: EDSA.

Physical Data: d 1.52 g cm^{-3}.

Solubility: toluene, benzene, CH_2Cl_2, acetone, THF, EtOH

Form Supplied in: not available commercially.

Preparative Method: synthesized in two simple steps (85% overall yield). An equimolar combination of ethyl bromoacetate and ***Dimethyl Sulfide*** is stirred in acetone at rt for three days, after which the precipitated sulfonium salt is isolated by filtration. The salt is then converted to the ylide by treatment with K_2CO_3/NaOH in $CHCl_3$/water.[1b]

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 1.2 (t, 3H), 3.9 (q, 2H), 2.7-2.8 (br s, 7H).

Handling, Storage, and Precautions: although the reagent is subject to moisture-induced and thermal decomposition, no report of hazard has been found. The presence of water gives rise to ester hydrolysis and quenching of the ylide to form the zwitterionic sulfonium carboxylate $Me_2{+}SCH_2CO_2^-$. Significant instability has also been noted at slightly elevated temperatures (35% decomposition at 80 °C in 3 h). Successful storage (several weeks) can be accomplished at -10 °C under anhydrous conditions.[1b]

Cyclopropanations.

A variety of electron-deficient alkenes react with this reagent in aprotic solvents to produce good yields of ethoxycarbonyl-substituted cyclopropanes (eq 1). EtOH and presumably other protic solvents allow alternative reaction pathways which seem to be dependent on proton transfer.[1c] The mechanism can be thought of as 1,4-addition followed by intramolecular ring closure with loss of dimethyl sulfide. In general, the reaction succeeds for double bonds activated by one or two strong electron-withdrawing groups (EWG) which may include CHO, COR, CO_2R, CN, and CF_3 (Table 1).[1b,2-8] The reaction is

stereoselective in favor of the *trans* product but in certain cases the selectivity is only marginal.

Ethyl (Dimethylsulfuranylidene)acetate

100[6]

50[7]

Stabilized Sulfur Ylides.

Acid chlorides, anhydrides, and isocyanates acylate EDSA to generate good yields of stabilized sulfur ylides. In addition, alkynes conjugated with either ketones or esters react in a similar fashion (eq 2).[1e]

$R^1 = OEt, Me$

Epoxidations.

In contrast to ***Dimethylsulfonium Methylide***,[9] EDSA usually does not react with aldehydes or ketones in a 1,2-sense to generate epoxides. However, under certain conditions,[1e] electron-deficient carbonyls do undergo this reaction. Thus EDSA can be considered an alternative (albeit of limited scope) to α-haloacetic acid esters in the Darzens condensation (eq 3).[10]

(3)

$R = Me, R^1 = COMe, 50\%$
$R = Ph, R^1 = COPh, 92\%$
$R = Me, R^1 = CO_2Et, 42\%$
$R = H, R^1 = CCl_3, 22\%$

Interestingly, the carboxylate salt of EDSA has been reported to epoxidize unactivated ketones.[11]

Alternative Reagents.

While ***Ethyl Diazoacetate***[12] also reacts with alkenes to provide good yields of ethoxycarbonyl substituted cyclopropanes, it can be differentiated from EDSA in two ways. In the first place, EDSA, requiring an electron deficient double bond, can be considered more selective. Secondly, in large scale reactions, ethyl diazoacetate carries a risk of explosion which EDSA does not have. Ethyl chloroacetate (or ***Methyl Chloroacetate***) under basic conditions accomplishes the same transformation as EDSA.[13]

Related Reagents.

Two similar carbonyl-stabilized dimethylsulfonium methylides (**1** and **2**) have been reported to function as cyclopropanating reagents in a fashion analogous to EDSA.[14]

Ethyl *N*-(Diphenylmethylene)-2-acetoxyglycinate

(R = Et)

[97611-55-7] · $C_{19}H_{19}NO_4$ · Ethyl *N*-(Diphenylmethylene)-2-acetoxyglycinate · (MW 325.36)
(R = Me)

[130551-77-8] · $C_{18}H_{17}NO_4$ · Methyl *N*-(Diphenylmethylene)-2-acetoxyglycinate · (MW 311.34)
(R = Bn)

[130946-34-8] · $C_{24}H_{21}NO_4$ · Benzyl *N*-(Diphenylmethylene)-2-acetoxyglycinate · (MW 387.43)

(glycine cation equivalent for amino acid synthesis)

Alternate Names: ethyl α-acetoxyglycinate benzophenone imine; O'Donnell's Schiff base.

Physical Data: R = Me, mp 102-103 °C; R = Et, mp 62-65 °C; R = Bn, mp 63-64 °C.

Preparative Methods: by bromination of ethyl *N*-(diphenylmethylene)glycinate in the presence of acetate (NBS, NaOAc, DMF).[1] The crude product can be purified by recrystalization. (Et_2O/hexane).

Handling, Storage, and Precautions: although stable at room temperature, the compound is normally stored under argon in the freezer. The hydrolysis product, benzophenone, can be detected either by TLC (EtOAc/hexane) or by NMR.

Complementary Synthons for Amino Acid Chemistry.

The acetate Schiff base ester can react as a glycine cation equivalent with a variety of nucleophiles to replace the acetate group. The resulting products are often difficult to prepare using the complementary anionic glycine

equivalent (see ***Ethyl N-(Diphenylmethylene)glycinate***) (eq 1).

(1)

Reaction with Heteroatom Nucleophiles.

Reaction with alcohols (methyl, primary, secondary) or thiophenol replaces the acetoxy group with a new α-heteroatom group (eq 2). These products can themselves be used as cationic glycinates for further reaction with nucleophiles.[1]

(2)

Reaction with Carbon Nucleophiles.

Reaction with higher order mixed cuprates results in α,β carbon-carbon bond formation (eq 3). This provides preparations of aryl and heteroaryl glycine derivatives as well as α-monosubstituted amino acids containing a β-quaternary center (e.g. *t*-butylglycine).[2]

(3)

Neutral carbon nucleophiles such as activated aromatics or organosilicon reagents react in the presence of ***Titanium(IV) Chloride*** to yield aryl and heteroaryl glycines as well as γ,δ-unsaturated or γ-keto amino acid derivatives (eq 4).[3]

(4)

RG = ArH (active aromatics/heteroaromatics) or $CH_2{=}CHCH_2TMS$, $PhC({=}O)CH_2TMS$

Reaction with organoboranes allows for effective appendage of the amino acid substructure onto structures that can be converted into organoboranes (e.g. alkenes, organolithium reagents, aryl halides, hydrocarbons, etc.) (eq 5).[4]

(5)

R = RCH_2CH_2, Cy, Ar, $ArCH_2CH_2$, *t*-Bu

Reaction of the methyl ester acetate Schiff base with anions of active methylene compounds (soft nucleophiles) in the presence of a Pd^0 catalyst results in carbon-carbon bond formation (eq 6). The reaction likely occurs through a 2-aza-π-allyl palladium complex.[5]

(6)

Ethyl *N*-(Diphenylmethylene)glycinate[1-3]

(R = Et)

[69555-14-2] · $C_{17}H_{17}NO_2$ · Ethyl *N*-(Diphenylmethylene)glycinate · (MW 267.33) (R = Me)

[81167-39-7] · $C_{15}H_{15}NO_2$ · Methyl *N*-(Diphenylmethylene)glycinate · (MW 253.30) (R = Bn)

[81477-91-0] · $C_{22}H_{19}NO_2$ · Benzyl *N*-(Diphenylmethylene)glycinate · (MW 329.38) (R = *t*-Bu)

[81477-94-3] · $C_{19}H_{21}NO_2$ · *t*-Butyl *N*-(Diphenylmethylene)glycinate · (MW 295.38)

(glycine anion equivalent for amino acid synthesis by phase transfer catalysis and other methods)

Alternate Names: ethyl glycinate benzophenone imine; O'Donnell's Schiff base.

Physical Data: R = Et, mp 51-52 °C; pK_a (DMSO) 18.7;[4] R = Me, mp 42.5-43 °C; R = Bn, mp 86.5-87 °C; R = *t*-Bu, mp 111-112 °C.

Form Supplied in: several are commercially available.

Preparative Methods: by transimination of ***Benzophenone Imine*** with alkyl glycinate hydrochloride (room temperature/CH_2Cl_2).[5] The crude product can often be used or it can be purified by recrystallization or flash chromatography.

Handling, Storage, and Precautions: the compounds are stable at room temperature, but they should be protected from moisture and acidic conditions (stored under argon or nitrogen). The hydrolysis product, benzophenone, can be detected either by TLC (EtOAc/hexane) or by NMR.

Amino Acid Synthesis by Catalytic Enantioselective Alkylation using Phase Transfer Catalysis.

Optically active α-amino acids are prepared in up to 66% enantiomeric excess (83:17 mixture of enantiomers) by

alkylation of the benzophenone imine of glycine *t*-butyl ester (R = *t*-Bu) under phase transfer catalysis (PTC) conditions using chiral catalysts derived from the *Cinchona* alkaloids. The ability to scale the reaction up and the possibility of preparing α-amino acids in high optical purity were demonstrated by the synthesis of 6.5 g of optically pure nonnatural 4-chloro-D-phenylalanine (eq 1) using the *N*-benzylated derivative of cinchonine. The enantiomeric L-amino acids are prepared by simply changing to pseudoenantiomeric catalysts derived from cinchonidine.[1] Use of optically active crown ethers (29% ee)[6] or optically active *vic*-diols as cocatalysts (4% ee)[7] has been reported.

Other Preparations of Optically Active Amino Acid Derivatives.

Enzymatic resolution has been used to prepare optically pure α-amino acid derivatives following either enantioselective PTC alkylation[8] or racemic alkylation.[9-12]

Asymmetric synthesis involving alkylation of these and related Schiff base esters in the presence of either a chiral leaving group (up to 76% ee) or a chiral proton source (deracemization) (up to 70% ee) have been reported.[13]

Palladium Catalysis.

Pd^0 catalyzed alkylations of the anion of Schiff base esters leads to γ,δ-unsaturated,[14] γ-allenic,[15] cyclopropyl-containing,[16] or 1,3-diene-containing[17] amino acid derivatives. A catalytic, enantioselective allylation has been achieved in up to 68% ee by using chiral ligands in conjunction with Pd^0 catalysis (eq 2).[18,19]

(2)

Other Alkylation Chemistry.

The benzophenone imines of glycine alkyl esters can be alkylated by a variety of different classes of alkyl halides (methyl, benzylic, allylic, propargylic, α-halo ester, primary, secondary) using either PTC or anhydrous conditions (Table 1).[20-22]

Table 1 Types of Amino Acid Side-Chains Produced by Alkylation of *N*-(Diphenylmethylene)glycinate Anions

Side-chain contains	Side-chain contains
^{11}C[23,24]	Cyclopropyl[16,25,26]
Cyclooctatetraenyl[11]	Boron[27]
Nitrogen[10,25,28–32]	Metal-binding (bipy)[8,33]
Photoaffinity label[34]	Nitroxide radical[35,36]
Phosphorus[37–40]	Oxygen[9,10,26,29,31,40–47]
Sulfur[9,39]	Selenium[48]
Fluoroalkyl[49]	Fluoro[12,30,34,50,51]
Halo (Cl, Br)[10,12,29]	

Other Reactions.

Michael additions,[44,52-55] aldol type reactions (eq 3),[56-60] imine additions,[61,62] acylation (both *N*-acylation[63] and *C*-acylation[64]), reaction with difluorocarbene,[65] and monoarylation[66-68] have been reported.

Ethyl Diphenylphosphinite

[1733-57-9] · $C_{14}H_{15}OP$ · Ethyl Diphenylphosphinite · (MW 230.26)

(amide and peptide formation from azides and carboxylic acids; Staudinger reaction)

Alternate Name: ethoxydiphenylphosphine.

Physical Data: d 1.066 g cm^{-3}.

Solubility: sol chloroform (50 mg mL^{-1}).

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: irritant; moisture sensitive; stored under N_2; needs refrigeration.

Peptide Synthesis.

The preparation of carboxylic amides via activation of the amino fragment through the Staudinger reaction[1] has been reported independently by Garcia[2] and Roberts.[3] The strategy involves the electrophilic addition of an azide to a phosphorus(III) center (**1**) followed by elimination of N_2 giving the iminophosphorane (**2**) (also known as phosphazene). Phosphorane (**2**) reacts with carboxylic acids to form amides (eq 1). While ***Triphenylphosphine*** (**1a**) and ethyl diphenylphosphinite (**1b**) have been used as phosphorus reagents, the latter has proven more advantageous. First, coupling with the carboxylic acid takes place at lower temperatures. Second, during the workup the phosphine oxide byproduct is hydrolyzed to diphenylphosphinic acid which is subsequently extracted out of the reaction mixture.

(1a) $R^1 = R^2 = Ph$
(1b) $R^1 = Ph;\ R^2 = OEt$

(1)

More recently, an approach to amide/peptide synthesis that bypasses the use of nonpolar solvents has been developed. This is based on the reduction of an azide to the corresponding amine in situ and in the presence of a preformed activated carboxyl component.[4]

Phosphoramide Synthesis.

A homolog of phosphinite (**1b**), namely methyl diphenylphosphinite (**3**), has been used in the synthesis of phosphoramides (eq 2).[5]

Ethyldiphenylsulfonium Tetrafluoroborate[1]

[893-69-6] · $C_{14}H_{15}BF_4S$ · Ethyldiphenylsulfonium Tetrafluoroborate · (MW 302.17)

(transformation of carbonyl groups to oxiranes;[2] α,β-unsaturated systems to α-cyclopropyl ketones;[3] a very powerful alkylating agent[4])

Physical Data: mp 76-77 °C.

Form Supplied in: not commercially available.

Preparative Methods: there are two common methods of preparation. The first involves adding ***Silver(I) Tetrafluoroborate*** to a solution of Ph_2S and ***Ethyl Iodide*** (5 equiv), and stirring the mixture for several hours (eq 1).[5]

The second method is a relatively new and unique technique.[6] Under acidic conditions, the alkylation of aliphatic and aromatic sulfides has been carried out by using alcohols instead of alkyl halides (eq 2).

Carbonyl Additions to Form Oxiranes.

To a solution of ethyldiphenylsulfonium tetrafluoroborate in THF at -76 °C under nitrogen was added an appropriate alkyllithium, followed by 0.9 equiv of cyclohexanone. After stirring for 1 h and workup, the oxirane shown (eq 3) was obtained in good yield.[7]

(3)

Reactions with α,β-Unsaturated Carbonyl Groups.

If the carbonyl group is α,β-unsaturated, reaction takes place at the alkene to form substituted cyclopropanes.[8] Meyers et al. have taken advantage of this and used ethyldiphenylsulfonium tetrafluoroborate to form 1,2,3-trisubstituted cyclopropanes (eq 4).[3]

(4)

O-Alkylation of Carboxylates and Amides.

Ethyldiphenylsulfonium tetrafluoroborate acts as a very powerful alkylating agent and converts phosphoric diesters to phosphoric triesters (eq 5).[9] Ethyldiphenylsulfonium tetrafluoroborate also performs *O*-alkylation of amides[10] and carboxylate salts.[11]

Ethylene

$CH_2=CH_2$

[74-85-1] · C_2H_4 · Ethylene · (MW 28.06)

(used in photochemical and thermal cycloadditions, Friedel-Crafts and other alkylations, vinylation reactions, and as an alkene in electrophilic addition reactions)

Physical Data: mp -169 °C; bp -104 °C; vapor density 0.97; flammable gas.

Solubility: insol H_2O; sol THF, pet ether, benzene.

Form Supplied in: gas (lecture bottle); widely available.

Handling, Storage, and Precautions: store and use with adequate ventilation. Explosions involving ethylene have occurred: when mixed with aluminum chloride at 30-60 bar pressure in the presence of supported nickel catalysts, methyl chloride, or nitromethane; when mixed with trifluoromethyl hypofluorite without diluent; when reacted with chlorine, ozone, or nitrogen oxide; when passed through 5 Å molecular sieves.[1]

Photochemical Cycloadditions.

Ethylene has been utilized extensively in intermolecular [2 + 2] photocycloaddition reactions with enones.[2] Cyclohexenones (eq 1),[3] cyclopentenones (eq 2),[4] and functionalized enones (eqs 3 and 4)[5,6] undergo cycloaddition with ethylene in high yield.

(1)

(2)

(3)

(4)

Thermal Cycloadditions.

Ethylene is a relatively poor dienophile but can be used in the Diels-Alder reaction with active dienes or under forced conditions such as high pressure (eqs 5-8).[7-9] Nitrone cycloadditions can also be carried out with ethylene under high pressure (eq 9).[10]

(5)

(6)

(7)

(8)

(9)

Friedel-Crafts Reactions.

Ethylene alkylates a variety of aromatic systems in the presence of Lewis acids (eqs 10 and 11).[11] 2-Tetralones can be

prepared from aromatic acetyl chlorides and ethylene in the presence of ***Aluminum Chloride*** (eqs 12 and 13).[12]

(10)

(11)

(12)

(13)

Ethylene reacts with aromatic acid chlorides (eq 14),[13] aliphatic acid chlorides (eqs 15 and 16),[14] and anhydrides (eq 17)[15] under Lewis acid catalysis to produce α,β-unsaturated ketones and 3-chloroethyl ketones. Ethylene also condenses with haloalkanes to effect a formal ethylene insertion (eqs 18 and 19).[16]

(14)

Other Alkylation Reactions.

Alkylbenzenes containing at least one benzylic hydrogen may be alkylated with ethylene in the presence of catalysts such as sodium or ***Potassium-Graphite*** (eqs 20 and 21).[17] Ethylene can alkylate aromatic rings *ortho* to heteroatoms using aluminum catalysts (eqs 22 and 23).[18]

(20)

(21)

(22)

(23)

Organometallic Catalyzed Reactions and Heck Reactions.

Palladium-catalyzed oxidation of ethylene is an important industrial process. Ethylene is oxidized to vinyl acetate[19] by ***Palladium(II) Acetate*** in acetic acid and to acetaldehyde (the Wacker process).[20] In the presence of bis(acetonitrile)dichloropalladium(II), indoles are converted to vinyl indoles (eq 24).[21] Silyl enol ethers are alkylated by ethylene in the presence of ***Bis(benzonitrile)dichloropalladium(II)*** (eq 25).[22] Stabilized carbanions are also vinylated by ethylene with the assistance of $PdCl_2(MeCN)_2$ (eqs 26 and 27).[23] Substituted *o*-bromonitrobenzene derivatives react with ethylene to yield the corresponding indole derivative or vinyl derivative (eq 28).[24]

(24)

(25)

(26)

(27)

(28)

An efficient asymmetric hydrovinylation of cyclohexa-1,3-dienes catalyzed by nickel complexes in the presence of a chiral aminophosphine ligand has been reported (eq 29).[25] Acrylamides can be prepared through the reaction of isocyanates with ethylene in the presence of ***Bis(1,5-cyclooctadiene)nickel(0)*** (eq 30).[26] Bis(1,5-cyclooctadiene)nickel

also catalyzes the conversion of styrene to 5-phenyl-4-pentenoic acid (eq 31).[27]

(29)

(30)

(31)

Rhodium catalysts (e.g. ***Dodecacarbonyltetrarhodium***) have also been used for carbonylation-alkylation reactions of alkynes with ethylene to form ketones (eq 32) and lactones (eq 33).[28]

(32)

(33)

Other Organometallic Reactions.

Diallylic organozinc derivatives and allylic magnesium halides react with ethylene to afford the corresponding zinc or Grignard derivatives (eqs 34 and 35).[29] The conditions for the organozinc addition are milder than those needed for the Grignard addition. Secondary and tertiary alkyllithium reagents also add to ethylene to give primary alkyllithium reagents that are inert to further addition to ethylene (eq 36).[30] An example of an intramolecular addition of a lithium reagent generated from the addition to ethylene has also been reported (eq 37).[31] Ethylene can be deprotonated and added to benzaldehyde to obtain the allylic alcohol in high yield (eq 38).[32]

(34)

(35)

(36)

(37)

(38)

Alkene Polymerization.

Ethylene is used extensively in polymerization reactions (Ziegler-Natta). ***Titanium(IV) Chloride*** and ***Triethylaluminum*** catalyzed the conversion of ethylene to polyethylene (eq 39).[33]

(39)

Miscellaneous Reactions.

Ethylene has been used in cycloadditions with ***Chlorosulfonyl Isocyanate*** to form 2-(2-chloroethyl)-3-oxoisothiazolidine 1,1-dioxides (eq 40).[34] Compared to other alkenes, ethylene provides substituted cyclopentenones with modest results under Pauson-Khand reaction conditions (eqs 41 and 42).[35] Perchlorovinylcarbene (formed from the thermal ring opening of tetrachlorocyclopropene) adds efficiently to form 1-chloro-1-(trichloroethenyl)cyclopropane (eq 43).[36] Electrophilic addition of sulfenyl chlorides and chlorine sulfate to ethylene provides chloroethyl sulfides (eq 44)[37] and chloroalkyl sulfonate (eq 45).[38]

(*R,R*)-[Ethylene-1,2-bis(η^5-4,5,6,7-tetrahydro-1-indenyl)]titanium (*R*)-1,1´-Bi-2,2´-naphtholate

(*R,R,R*)

[143063-72-3] · $C_{40}H_{36}O_2Ti$ · (*R,R*)-[Ethylene-1,2-bis(η^5-4,5,6,7-tetrahydro-1-indenyl)]titanium (*R*)-1,1´-Bi-2,2´-naphtholate · (MW 596.64) (*S,S,S*)

[83417-93-0]

(precursor to a catalyst for the asymmetric reduction of unsaturated organic molecules[1])

Physical Data: mp 274.5-277 °C (dec); $[\alpha]_{578}$, -3700° (*c* = 0.45 mg cm^{-3} in $CHCl_3$).

Solubility: sol THF, benzene, toluene; slightly sol ether; very slightly sol hexane.

Preparative Methods: originally prepared and characterized by Brintzinger et al. from the corresponding dichloride derivative and ***(R)-1,1´-Bi-2,2´-naphthol***.[2] The dichloride is synthesized by reacting the dilithium salt of 1,2-bis(3-indenyl)ethane with ***Titanium(IV) Chloride*** followed by hydrogenation over ***Platinum(IV) Oxide***.[2] Since the original report, two improved procedures for its preparation have appeared.[3,1b]

Handling, Storage, and Precautions: the complex is air and moisture stable and can be stored indefinitely.

Catalyst Generation and Handling.

When complex (**1**) is allowed to react with 2 equiv of ***n-Butyllithium*** and 2.5-3 equiv of phenylsilane in THF under an inert atmosphere, an active reduction catalyst, complex (**2**), is formed (eq 1).

Complex (**2**) is believed to be a titanium(III) hydride and has not been isolated or characterized (no ^{1}H NMR signals for any titanium species are observable, probably as a result of the paramagnetic nature of the complex). This complex is extremely air sensitive and must be handled under rigorously oxygen-free conditions. Solutions of complex (**2**) are stable under inert atmosphere for at least 24 h and exhibit no sensitivity to light. For synthetic purposes it is most convenient to generate the active catalyst from complex (**1**) immediately prior to use.

Reduction of Unfunctionalized Alkenes.

The asymmetric reduction of trisubstituted alkenes with this system has recently been investigated.[4] It was shown that high ee's could be achieved in this reaction, although high pressures and long reaction times were necessary. As an example, *trans*-methylstilbene can be reduced at 2000 psi of hydrogen and 65 °C with excellent chemical and optical yield (eq 2). This represents the first catalyst system for the reduction of unfunctionalized, trisubstituted alkenes with good to excellent enantioselectivity.

(2)

Reduction of Imines.

This catalyst system is very effective for the asymmetric hydrogenation of imines.[1b] For example, *N*-(1-cyclohexyl)ethylidenebenzylamine (as a mixture of *anti* and *syn* isomers) can be reduced in excellent yield and good enantiomeric excess (eq 3). The reaction must be conducted at high pressures in order to achieve maximum enantioselectivity. This effect was found for several acyclic imines.

(3)

The reduction of cyclic imines with this system was found to proceed under much milder conditions.[5] For example, 2-phenylpyrroline was reduced at 80 psi of hydrogen to afford 2-phenylpyrrolidine in good yield and excellent enantiomeric excess (eq 4).

(4)

This reaction was found to be applicable to ring sizes of 5 to 7 (although more forcing conditions were required for six-membered rings) and was compatible with several functional groups. In all cases studied, ee's greater than 95% were observed. Among the functional groups investigated were acetals, silyl ethers, trisubstituted alkenes, and alcohols. Monosubstituted alkenes were completely reduced and disubstituted alkenes were partially reduced and isomerized under the standard conditions. The reaction has the practical advantage that the active catalyst can be generated in a Fisher-Porter bottle and the reaction can then be conducted in the same vessel. Thus no transfer of air-sensitive

materials is necessary.

(-)-[Ethylene-1,2-bis(η^5-4,5,6,7-tetrahydro-1-indenyl)]zirconium (*R*)-1,1´-Bi-2,2´-naphtholate[1]

[133868-91-4] · $C_{40}H_{36}O_2Zr$ · (-)-[Ethylene-1,2-bis(η^5-4,5,6,7-tetrahydro-1-indenyl)]zirconium (*R*)-1,1´-Bi-2,2´-naphtholate · (MW 639.98)

(in combination with methylaluminoxane it is an enantioselective hydrogenating[2] and cyclopolymerizing agent;[3] reagent for the resolution of racemic ethylenebis(tetrahydro-1-indenyl)]zirconium dichloride[4])

Physical Data: [α]25436 -1761° (*c* 1.1, $CHCl_3$).

Preparative Methods: this reagent is an intermediate for the preparation of optically pure ethylenebis(tetrahydro-1-indenyl)zirconium dichloride.[4] That is, according to the procedure described for the kinetic resolution of ethylenebis(tetrahydro-1-indenyl)titanium dichloride with (*R*,*R*)- or (*S*,*S*)-binaphtholate,[5] 1 equiv of racemic ethylenebis(tetrahydro-1-indenyl)zirconium dichloride[6] can be resolved with 0.5 equiv of (*R*,*R*)-binaphthol in the presence of sodium metal in toluene to yield the optically active (*S*,*S*)-ethylenebis(tetrahydro-1-indenyl)zirconium dichloride and the (-)-[ethylenebis(tetrahydro-1(*R*)-indenyl]zirconium (*R*)-binaphtholate. The separated optically pure (-)-[ethylenebis(tetrahydro-1(*R*)-indenyl]zirconium (*R*)-binaphtholate can be easily converted to the corresponding optically pure zirconocene dichloride upon treating with HCl gas.

Catalytic Hydrogenation and Cyclopolymerization.

This zirconium reagent constitutes a homogeneous catalytic system (Ziegler-Natta catalyst) with methylaluminoxane (MAO) for the purpose of enantioselective hydrogenation[2] of alkenes or cyclopolymerization[3] of alkenic compounds to optically active polymers. In the hydrogenations, terminal alkenes substituted in the 2- or 3-positions and internal alkenes are hydrogenated with 23-65% ee in good yields. In the catalytic deuteration of styrene with this reagent, the *re*-face of styrene is deuterated in 65% optical purity (eq 1). This enantioselectivity in hydrogenation is opposite to propylene oligomerization with the same catalytic system. 1,5-Hexadiene is polymerized with this catalytic system in 91% enantioface selectivity to give poly(methylene-1,3-cyclopentane) (PMCP), which is inductive of a highly isotactic microstructure (eq 2). The absolute configuration of the polymer is tentatively assigned on the basis of the sign of the optical rotation of the model compound *trans*-(1*R*,3*R*) 1,3-dimethylcyclopentane.[3]

(±)-1,1´-Ethylenebis(4,5,6,7-tetrahydro-1-indenyl)zirconium Dichloride

[112243-79-5] · $C_{20}H_{24}Cl_2Zr$ · (±)-1,1´-Ethylenebis(4,5,6,7-tetrahydro-1-indenyl)zirconium Dichloride · (MW 426.57)

(chiral metallocene complex for stereoselective alkene and silane polymerization;[1] asymmetric hydrogenation catalyst for alkenes;[2,3] reagent for the asymmetric synthesis of allylic amines;[4] asymmetric carbomagnesiation catalyst;[5] precursor to chiral Lewis acid catalysts[6])

Physical Data: d 1.616 g cm^{-3} (calc).

Solubility: insol hexanes, diethyl ether; sol CH_2Cl_2, $CHCl_3$, THF; slightly sol toluene.

Form Supplied in: crystalline white or pale yellow solid; not widely available.

Analysis of Reagent Purity: ^1H NMR and/or elemental analysis.

Preparative Methods: by hydrogenation of the corresponding racemic ethylenebis(η^5-indenyl)zirconium dichloride[7a] over PtO_2 or 5% Pt/C at 1000 or 50-500 psi, respectively. The indenyl precursor is generally prepared from 1,2-bis(3-indenyl)ethane and $ZrCl_4$ in THF solution via the dilithium[7b] or dipotassium salt[3] of the former compound. In the former case, racemic material can be obtained in pure form (40-50% yields),

whereas in the latter case the product (>70% crude) is contaminated with significant amounts of the *meso* isomer which can be removed by fractional crystallization from toluene. The racemate can be resolved on a gram scale by conversion to the (*S*)- or (*R*)-binaphtholate derivative.[4,8] Conversion, for example, of the (*S*,*S*)-binaphtholate derivative to the dimethylzirconocene derivative (MeLi, ether, or toluene) followed by treatment with either stoichiometric anhydrous dimethylamine hydrochloride (CH_2Cl_2) or anhydrous HCl (ether) provides optically pure material; $[\alpha]_{435}$ = +416°(*c* = 0.048 g 100 mL^{-1}, CH_2Cl_2).[8]

Purification: the racemate is best crystallized from hot toluene. Optically pure material, which is much more soluble, is best crystallized from hexanes/toluene.

Handling, Storage, and Precautions: the compound is air and moisture stable but is best stored for long periods of time (years) in a desiccator. No known toxic effects or safety hazards.

Introduction.

While primarily employed in the study of the stereoselective polymerization of alkenes and, to a lesser extent, dehydrogenative polymerization of silanes,[1] *rac*-$[CH_2(\eta^5\text{-}C_9H_{10})]_2ZrCl_2$ (**1**) has attracted increasing attention as a reagent and/or catalyst in organic synthesis.

Asymmetric Hydrogenation.[2,3]

In the presence of methylaluminoxane and hydrogen (or deuterium), the dimethyl derivative (**2**) of (*S*)-(+)-(**1**) effects the asymmetric hydrogenation or deuteration of alkenes in up to 65% ee (e.g. eq 1). While this level of asymmetric induction is modest, it should be noted that this is one of the few methods available for asymmetric hydrogenation of unfunctionalized alkenes. The sense of asymmetric induction is reversed from that observed in alkene polymerization; coordination and insertion of the alkenes occurs from the *re* enantioface.

The active intermediate in these transformations is a cationic zirconium hydride complex generated in situ. More recent work has established that preformed cationic hydride complexes are equally effective.[3]

Asymmetric Synthesis of Allylic Amines.[4]

Optically pure (*S*)-(+)-(**1**) can be converted to the methyl triflate complex (**3**) via the dimethyl derivative (**2**). Reaction of (**3**) with lithium aryl amides at elevated temperatures generates, in situ, zirconaziridine intermediates which undergo facile insertion of alkynes to generate, on acidic workup, allylic amines in high optical purity (eq 2). Although this process requires stoichiometric amounts of (**2**), optically pure (**1**) can be recovered following workup with HCl/ether and recycled. Other substrates include alkenes and aldehydes and furnish saturated amines and β-amino alcohols, respectively, in high optical purity.

Asymmetric Carbomagnesiation of Alkenes.[5]

Complex (*S*)-(+)-(**1**) in the presence of alkyl Grigard reagents effects the catalytic carbomagnesiation of allylic alcohols or ethers in both a diastereo- and enantioselective manner. A mechanism involving an in situ generated metallacyclopropane complex has been invoked to rationalize the sense of asymmetric induction. For example, cyclic allylic ethers undergo carbomagnesiation with excellent levels of stereocontrol (eq 3).

Asymmetric Lewis Acid Catalysts.[6]

Compound (**1**) has been transformed into the optically pure cationic alkoxide complex (**4**) via the intermediacy of the dimethyl derivative (**2**). Complex (**4**) is an effective catalyst for the Diels-Alder reaction of simple dienophiles with dienes (eq 4). With the dienophiles studied, the magnitude of the asymmetric induction is modest (<=55% ee) but the sense of asymmetry is consistent with a simple model for dienophile coordination to the metal center.

Ethylenebis(triphenylphosphine)nickel(0)[1]

[23777-40-4] · $C_{38}H_{34}NiP_2$ · Ethylenebis(triphenylphosphine)nickel(0) · (MW 611.34)

(catalyzes vinylcyclobutene-cyclohexadiene rearrangement;[2] mild synthesis of [2^n]-cyclophanes;[3] stereospecific alkene dimerization catalyst;[4,5] cyclopropanation;[6] alkene oligomerization catalyst[7])

Physical Data: mp. 108-110 °C (dec); ^{1}H NMR δ (C_6D_6) 2.55 ppm (C_2H_4).

Solubility: very sol benzene, toluene; sparingly sol ether, pentane.

Form Supplied in: yellow crystalline solid; not commercially available.

Preparative Methods: most readily prepared in 75% yield from ***Nickel(II) Acetylacetonate***, ***Diethylaluminum Ethoxide***, and ***Triphenylphosphine***. In the presence of ***Ethylene*** the yields can be raised to >95% (eq 1).[8] Alternatively, ***Triethylaluminum*** may be employed in an ethylene saturated solution, yielding 85% of the complex.[9]

The reagent has also been prepared from ***Dichlorobis(triphenylphosphine)nickel(II)***, ***Zinc***, and ethylene (eq 2) or ***Nickel(II) Chloride***, zinc, PPh_3, and ethylene in yields of 80% and 71%, respectively.[10]

$$Ni(MeCOCHCOMe)_2 \xrightarrow[\substack{PPh_3,\ C_6H_6 \\ 75\text{-}98\%}]{Et_2AlOEt} (Ph_3P)_2Ni(C_2H_4) \qquad (1)$$

$$(Ph_3P)_2NiCl_2 \xrightarrow[\substack{THF \\ 80\%}]{Zn,\ CH_2{=}CH_2} (Ph_3P)_2Ni(C_2H_4) \qquad (2)$$

Purification: can be recrystallized from methanol at reduced temperatures.

Handling, Storage, and Precautions: is very air sensitive and should be stored under inert atmosphere,

preferably in a dry box.

The relatively weak nature of the ethylene-nickel interaction allows for the facile replacement with other coordinating ligands. Much of the chemistry of the catalyst is therefore attributed to this fact. In addition, a number of other related catalysts differ only by the nature of the phosphine ligands, thereby modifying some of its properties.[1]

Vinylcyclobutene-Cyclohexadiene Rearrangements.

Ethylenebis(triphenylphosphine)nickel(0) has been used as an isomerization catalyst for the ring expansion of vinylcyclobutenes to cyclohexadienes.[2,11] It also promotes the dechlorination of 1,2-dichlorides to the corresponding cyclobutenes. The reactions can be carried out independently, or direct conversion of the dichloride to the cyclohexadiene is also possible (eq 3). Conditions under which these transformations are carried out include thermolysis followed by oxidation of the resulting Ni^0 alkene complex to Ni^I and subsequent ring expansion, or preoxidation of the catalyst to Ni^I. Yields range from 40-50%. The presence of electron-withdrawing substituents on the cyclobutene system are required, whereas substitution on the vinyl group effectively lowers yields.

(3)

Preparation of Cyclophanes.

The reaction of halomethyl benzene derivatives with the catalyst results in oxidative addition to nickel, yielding the corresponding Ni^I or Ni^{II} benzyl complexes that have properties similar to nucleophilic Grignard species.[12,13] Appropriately, use of di-, tri-, to oligosubstituted aromatics results in the production of a variety of [2^n]-cyclophanes. For example, two equivalents of 1,2-bis(bromomethyl)benzene react with one equivalent of the catalyst to furnish the corresponding cyclophane in 66% yield (eq 4).[14]

Other examples include the synthesis of [2^4](1,2,4,5)-cyclophane from 1,2,4,5-tetrabromomethylbenzene in 64% yield (eq 5).[14]

On a related note, the reaction of ethylenebis(triphenylphosphine)nickel(0) with 1,4-bis(chloromethyl)benzene in benzene at room temperature yields a variety of paracyclophanes including [2.2.2] (5%), [2.2.2.2] (20.3%), and [2.2.2.2.2] (8.1%).[3] These mild and efficient one-step preparations offer attractive alternatives to conventional syntheses that often employ reactive and corrosive alkali metals (Wurtz coupling) and/or multistep routes.[15]

Reaction with Alkenic and Allenic Compounds.

The catalyst can be utilized with a number of alkenes under either thermal or photochemical conditions to produce cyclobutane and other dimerized products. For example, irradiation of a toluene solution of 1,7-octadiene with ethylenebis(triphenylphosphine)nickel(0) followed by air oxidation yields stereospecifically *trans*-bicyclo[4.2.0]octane accompanied by oligomers (eq 6).[4] The reaction also works intermolecularly with monosubstituted alkenes, yielding the corresponding 1,2-*trans*-cyclobutanes (eq 7).

(6)

(7)

It is also possible to induce such alkene dimerizations thermally via well known nickelacyclopentane intermediates.[16] Treatment of such intermediates with a variety of reagents yields a number of useful organic products (eq 8).[5,17] Other catalytic ethylene dimerization systems include $(PPh_3)_2Ni(C_2H_4)$ embedded on an alumina surface.[18] A variety of cyclopropene systems can be cyclodimerized to the corresponding cyclobutane derivatives via oxidation of the intermediate nickelacyclopentane intermediates as well.[19,20]

(8)

It has been found that a catalyst prepared from ethylenebis(triphenylphosphine)nickel(0) and ***Chloromethyl Methyl***

Sulfide acts as a cyclopropanation reagent for cyclooctene (eq 9).[6]

Another cationic complex which is active towards styrene oligomerization is derived from ***Benzyl Chloride***. Treatment of the intermediate η^3-coordinated cationic complex (0.09 mol %) with styrene at rt for 2 h forms oligomers with M_n = 850 and 67% isotactic content (eq 10).[21]

Isomerization and skeletal rearrangements[22] of alkenes are also promoted by the catalyst. For example, allylbenzene is quantitatively converted into *trans*-1-phenylpropene by a catalyst derived from ethylenebis(triphenylphosphine)nickel(0) and HCl (eq 11).[7]

(11)

The catalyst (2.5 mol %) also reacts with allene at elevated temperatures to yield a mixture of the trimer, tetramer, pentamer, and higher oligomers (eq 12).[23] The related complex ***Bis(1,5-cyclooctadiene)nickel(0)*** also promotes a similar reaction.

20% 53% 10%

(12)

Reaction with Isocyanates.

Ethylenebis(triphenylphosphine)nickel(0) reacts with alkenes (ethylene and propene) and isocyanates, producing isolable azanickelacyclopentanes which can be further converted into a variety of useful intermediates depending upon the conditions employed. Thus reaction with ***Phenyl Isocyanate*** and ethylene can yield amides or carbamides (eq 13).[24] Reaction with propene yields a mixture of regiosiomers. Related catalysts that also induce the desired transformations include (TPP)Ni(CDT) and $Ni(cod)_2$.[24]

Ethylenebis(triphenylphosphine)platinum(0)[1]

[12120-15-9] · $C_{38}H_{34}P_2Pt$ · Ethylenebis(triphenylphosphine)platinum(0) · (MW 747.73)

(nucleophilic metal species that readily undergoes ligand exchange with alkenes[2] and alkynes;[3] acts as an efficient hydrosilation catalyst;[4] oxidatively adds to activated C-X bonds[5] and some C-C bonds, enabling rearrangement to occur[6])

Physical Data: white solid, mp 126-128 °C (dec).

Solubility: sol benzene, THF, dichloromethane; insol alcohols.

Form Supplied in: commercially available as a white solid.

Preparative Methods: can be prepared by the reduction of $[Pt(PPh_3)_2(CO)_3)]$.PhH with ***Sodium Borohydride*** in ethylene saturated EtOH.[7]

Handling, Storage, and Precautions: the complex can be briefly handled in air and stored indefinitely under nitrogen. Platinum is reported to be of low toxicity.

Complexation with Alkenes.

The title reagent readily undergoes alkene ligand exchange, possibly via the unsaturated L_2Pt (L = Ph_3P) as the active species. Numerous platinum alkene complexes have been synthesized by this procedure.[2,3,8] Electron-deficient multiple bonds are generally more strongly bound, leading to more stable complexes. In some instances, alkene complexation is a preliminary to rearrangement of the carbon framework via the intermediacy of a σ bound organoplatinum species (eqs 1 and 2).[6,9]

Hydrosilation.

The title reagent has been used to catalyze hydrosilation of a variety of functional groups, typically employing 2-4 mol % of catalyst.[10-14] In one example, a racemic silane and an alkyne provided a chiral vinylsilane.[10] Tanaka has used *o*-bis(dimethylsilyl)benzene to enable double silation of functional groups. The postulated intermediate formed from the catalyst and silane is a bis(silyl)platinum species (eq 3).[11] Aldehydes and ketones have been shown to add silicon across the C=O bond, whereas unsaturated carbonyl compounds undergo 1,2- or a 1,4-addition depending on the steric environment (eq 4).[12] Styrene reacts in a 1,1-fashion, presumably via a hydride shift, to afford the *gem*-disilyl derivative, whereas isoprene reacts in the more usual 1,2-mode (eq 5).[11] More recently, silicon polymers have been prepared by employing tetrakis(dimethylsilyl)benzene and diynes (eq 6).[3]

(5)

(6)

R = Hex, A = Ph, 78%
R = Ph, A = Fe(Cp)$_2$, 94%

Insertion into C-X Bonds.

Oxidative addition to alkyl,[13] allyl,[14] and alkenyl[15] C-X bonds (where X = leaving group) occurs readily. Inhibition of the insertions in the presence of radical scavengers suggests a radical mechanism.[13] The title reagent adds to *gem*-dihalomethanes to form stable complexes.[16] In the case of dichloromethane, photolysis is required before insertion occurs.[17] Addition to allylic C-X bonds occurs *anti* to the leaving group. This is postulated to be due, in part, to the electron-donating capacity of the triphenylphosphine ligands and the propensity of the complex to dissociate to form the more nucleophilic L_2Pt (eq 7).[14] An anomolous reaction is the insertion of platinum into the alkenyl C-Cl bond of 1,2-dichloropropene, as opposed to the expected insertion at the allylic position (eq 8).[18]

Ethylene Chloroboronate[1]

[1192-03-6] · $C_2H_4BClO_2$ · Ethylene Chloroboronate · (MW 106.32)

(mild Lewis acid, in combination with tertiary amines is a selective enolization reagent for ketones and thioesters;[2] the corresponding enolates show a high degree of regio- and stereocontrol in the aldol reaction[2])

Physical Data: viscous syrup at rt; bp 70-74 °C/1 mmHg; n_D^{20} 1.4640.

Solubility: insol *n*-pentane, diethyl ether; sol dichloromethane.

Analysis of Reagent Purity: (NMR) ^{11}B -31.20 ppm (monomer), -23.50 ppm (associated); ^{1}H 4.38 ppm; ^{13}C 65.79 ppm.

Preparative Methods: obtained by reaction of ***Ethylene Glycol*** with ***Boron Trichloride*** in CH_2Cl_2 (85% yield).[2a,3a,b]

Handling, Storage, and Precautions: should be used as prepared for best results. The viscous syrup should be handled under N_2 in the absence of moisture. 1.0 M Dichloromethane solutions of the reagent are stable for months when stored in the absence of moisture at -15 °C.

Regio- and Stereoselective Aldol Condensations.

Methyl, ethyl, and cyclic ketones react with ethylene chloroboronate (**1**) and ***Diisopropylethylamine*** at -78 °C to give the corresponding enolates (enolborates) with a high degree of regio- and stereocontrol.[2a-c] The selectivity is as follows: Me &egt; Et; Me > CH_2CH_2R; Me > CH_2CHR_2; Me >> CHR_2; Et >> CHR_2. Ethyl ketone derived enolborates are generated selectively with *Z*(O)-stereostructure (&egt;95%). An example is shown in (eq 1).

(1)

Reaction of enolborates with both aliphatic and aromatic aldehydes at -78 to -15 °C forms β-hydroxy ketones in good yield (60-90%) and with high *syn* diastereoselectivity (&egt;96:4) (eq 2).[1,2]

(2)

While *syn* selectivity from *Z*(O)-boron enolates is an expected result,[1b] much more surprising is the high *syn* selectivity observed with *E*(O)-enolborates, for example the enolate derived from cyclopentanone (eq 3).

(3)

To explain the *syn* selectivity for reactions of both *Z*(O)- and *E*(O)-enolates derived from (**1**), a chair transition state for *Z*(O)-enolates and a boat transition state for *E*(O)-enolates were suggested.[2c,d] Computational studies on aldol reactions using *Z*(O)- and *E*(O)-enolborates, as well as enolborinates (-O-BR_2), provided a set of data which is consistent with the experimental results and further corroborates the proposed mechanism.[4] The following main conclusions are drawn. (i) The ground state conformations of the enolates are important in determining the different reactivities of *Z*(O)-enolborates and *E*(O)-enolborates, the latter being much more reactive that the former. (ii) *Z*(O)-Enolborates prefer chair transition states, while *E*(O)-enolborates favor twist-boat transition states. Both transition states lead to the formation of *syn* aldol products. (iii) In contrast, when enolborinates are used, bulky ligands at boron disfavor the twist-boat for the *E*(O)-enolates, resulting in the formation of *anti* isomers.[4]

Pinacol chloroboronate-derived enolborates are also stereoconvergent, giving high yields of the *syn* diastereoisomers irrespective of the enolate geometry (eq 4).[5]

(4)

The enantioselective version of this reaction is also known, using chiral diols, but the ee's are modest (eq 5).[6]

(5)

Reaction of phenyl thiopropionate with (**1**) and diisopropylethylamine provides the corresponding enolate, whereas esters give unsatisfactory yields. Enolization at -78 °C results in a 70:30 *Z*(O):*E*(O) enolate mixture, whereas the reaction at 25 °C furnishes an 18:82 mixture. However, both enolates react with aldehydes with high *syn* distereoselectivity. The addition to chiral aldehydes has also been studied (eq 6).[2d]

4-Ethylenedioxybutyllithium

[129471-18-7] · $C_6H_{11}LiO_2$ · 4-Ethylenedioxybutyllithium · (MW 122.093)

(reagent used as a bis homoenolate equivalent for the production of aldehydes and lactones)

Preparative Method: solutions of the title compound can be obtained by treatment of a solution of chlorobutyraldehyde ethylene acetal (commercially available) in THF under inert gas with a solution of 2.4 equiv of ***Lithium Naphthalenide*** in THF at -78 °C for 7 h. Solutions are used directly.

Handling, Storage, and Precautions: the reagent is purported to be stable at -78 °C.

General Considerations.

This lithium reagent was reported for the first time in 1990 by Ramon and Yus[1] using the aromatic radical anion electron transfer technique (**1** -> **2**).[2] A variety of Grignard counterparts to the reagent are known and had seen extensive use prior to 1990. The advantage of the lithium reagent is its generation at low temperature because these reagents are quite basic and readily decompose at ambient temperatures.[3] However, the corresponding magnesium chloride can be prepared in high yield at room temperature in THF if the Grignard is prepared in high concentration (ca. 5 M).[4]

(1) (2) (1)

Reaction with Electrophiles.

The reagent (**2**) reacts with a variety of carbonyl-containing electrophiles at low temperature to provide adducts in moderate to good yield (eqs 2 and 3).

(2)

(3)

Reaction with aldehydes and ketones gives the corresponding alcohols while reaction with benzonitrile or the amides provides the protected keto aldehydes (eq 4). Reagent (**2**) also reacts with ***Phenyl Isothiocyanate*** and benzaldehyde phenylimine to give adducts. However, (**2**) does not react well with alkyl halides either by itself or in the presence of Cu^{I} salts. Further, reaction with nitriles and anhydrides results only in proton transfer, attesting to the basicity of the species.

(4)

Treatment of (**2**) with a catalytic amount of CuBr-dimethyl sulfide complex (see ***Copper(I) Bromide***) allows conjugate addition to 2-cyclohexen-1-one to occur, resulting in the 1,4-adduct in 61% yield (eq 5).

(5)

Synthesis of Tetrahydropyrans and δ-Lactones.[5]

Hydrolysis of the adducts of (**2**) and carbonyl compounds with acid affords cyclic hemiacetals. These can be oxidized with Cr^{VI} reagents to give δ-lactones in 30-60% overall yield from chloroacetal (**1**) (eq 6).

Synthesis of 6,8-Dioxabicyclo[3.2.1]octanes.

Reaction of (**2**) with α-trimethylsilyloxy aldehydes and ketones leads after hydrolysis to 6,8-dioxabicyclo[3.2.1]octanes, substructures found in the frontalin/brevicomin metabolite class (eq 7).[6]

Related Lithium Reagents.

3-Butenyllithium (**3**)[7] has been used as a masked aldehyde bishomoenolate equivalent. Due to the amount of unmasking involved, however, this is not preferable to (**2**).

(3)

Related Reagents.

2-(2-Bromoethyl)-1,3-dioxane; ***3-Butenyl-1-magnesium Bromide***; ***4-Ethylenedioxybutylmagnesium Bromide***.

4-Ethylenedioxybutylmagnesium Bromide

[91083-05-5] · $C_6H_{11}BrMgO_2$ · 4-Ethylenedioxybutylmagnesium Bromide · (MW 219.36)

(nucleophilic Grignard reagent used as a synthetic equivalent of the 4-oxobutyl anion)

Solubility: sol THF.

Handling, Storage, and Precautions: Grignard reagent sensitive to moisture; normally prepared in THF solution and used immediately.

Nucleophilic Additions.

This Grignard reagent and its magnesium chloride counterpart, like the analogous organolithium reagent, are employed in synthetic chemistry as synthons for the 4-oxobutyl anion; the Grignard reagents appear, however, to have been subject to much less widespread use than the organolithium reagent. They are normally used in THF as solvent. Both reagents are unstable under some circumstances, but the bromide may be readily prepared by stirring the bromoacetal precursor (ca. 2-3 M in THF) with crushed ***Magnesium*** turnings (1.5 equiv) at rt under a dry nitrogen atmosphere, with periodical external cooling.[1] For efficient formation, the chloride reagent is best prepared from a ca. 5 M solution of the chloroacetal in THF at below 30 °C.[2] Less concentrated solutions require higher temperatures, inevitably resulting in partial decomposition to the alkoxide of 2-cyclobutyloxyethanol.[2,3] The solutions of Grignard reagent are normally diluted with diethyl ether or THF before use.

Both reagents are effective nucleophiles. The bromide has been added to carbonyl groups, including those of α,β-unsaturated aldehydes,[4] and to cyanides without disruption of an adjacent aziridine unit (eq 1).[1] Copper-catalyzed conjugate addition to carboxymethyl alkynes also takes place; in this application the intermediate underwent Dieckmann-type cyclization, providing access to functionalized cyclopentenones (eq 2).[5] The more common chloride reagent undergoes acylation with anhydrides[6] and acid chlorides,[9] addition to carbonyl groups,[2] including those of α-chloro ketones,[7] and conjugate addition-elimination to β-alkoxy-α,β-unsaturated ketones.[8] Copper-catalyzed conjugate addition to α,β-unsaturated ketones is also reported,[9,10] hydrolysis and cyclization of the products leading to cyclohexenyl ketones (eq 3). The reagent is also reported to undergo addition to oxazolidines with concomitant ring cleavage (eq 4).[11]

Ethylene Glycol[1]

[107-21-1] · $C_2H_6O_2$ · Ethylene Glycol · (MW 62.08)

(formation of acetals;[1] stereoselective aldol reactions;[2] solvent for Diels-Alder reaction;[3] solvent for Fischer indole reaction;[4] preparation of tertiary alcohols from trialkylboranes[5])

Alternate Name: ethane-1,2-diol.

Physical Data: bp 197 °C; *d* 1.11 g cm^{-3}.

Solubility: completely sol H_2O, low MW alcohols, acetone; insol benzene, chlorinated hydrocarbons.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: harmful or fatal if swallowed. Prolonged or repeated breathing of vapor harmful. Causes eye irritation. May cause kidney and nervous system damage. Causes birth defects in laboratory animals. Use in a fume hood.

Acetal Formation.[1]

The dioxolane group is one of the most widely used protecting groups for carbonyl compounds. Dioxolanes are generally stable to bases, Grignard reagents, alkyl lithium reagents, metal hydrides, Na/NH_3, Wittig reagents, hydrogenation conditions, oxidants, and bromination and esterification reagents.[1] This wide range of stability has been especially useful in steroid synthesis.[6] The ease of formation of dioxolanes roughly follows the order: aldehydes > acyclic ketones and cyclohexanones > cyclopentanones > α,β-unsaturated ketones > α-mono- and disubstituted ketones >> aromatic ketones. Ketones generally require stronger acids than aldehydes, such as sulfuric, hydrochloric, or TsOH.[7-11] A typical protection procedure involves heating a benzene or toluene solution of the ketone and ***p-Toluenesulfonic Acid*** (eq 1).[9] Alternatively, a Lewis acid catalyst, such as ***Boron Trifluoride Etherate***[12-14] may be used (eqs 2 and 3).[13,14]

Water removal can be accomplished by using Dean-Stark distillation,[15] molecular sieves,[16] $CaSO_4$,[17] $CuSO_4$,[18] or water scavengers such as ***Triethyl Orthoformate***[19-21] or dialkyl sulfites (eq 4).[22]

Compounds that are stable under strongly acidic conditions can be derivatized using a mixture of ethylene glycol and HCl (eq 5).[23,24]

(5)

Many procedures have also been developed for acid-sensitive compounds. Use of either adipic[25] or ***Oxalic Acid***[26] gives good yields of sensitive steroid Δ^4-3-ethylene acetals. ***Selenium(IV) Oxide*** has also been used effectively for steroid acetalization (eq 6).[27]

(6)

Pyridinium salts are mild catalysts for ethylene acetal formation.[28-31] ***Pyridinium p-Toluenesulfonate*** (PPTS) catalyzes acetal formation with less than 4% epimerization, whereas use of TsOH led to 34% epimerization (eq 7).[30]

(7)

The use of a hindered pyridinium salt, such as ***2,4,6-Collidinium p-Toluenesulfonate*** (CTPS), allows acetalization of α,β-unsaturated ketones in the presence of saturated carbonyl systems (eq 8).[31]

(8)

N,N-Dimethylformamide/Dimethyl Sulfate is another mild acetalization catalyst.[32] Metal catalysts, such as Rh complexes[33] and ***Palladium on Carbon***[1a] have also been used effectively (eqs 9 and 10). Ion-exchange resins offer significant advantages for the preparation of sensitive steroid acetals (eq 11).[34] An especially convenient method involves running a solution of the ketone and ethylene glycol through a column of Amberlyst.[35] Zeolites have also been used to prepare acetals.[36]

(9)

(10)

(11)

Ketones that react slowly under normal acetalization conditions can be converted into dioxolanes at high pressure (eq 12).[37] A procedure has also been developed for the dioxolanation of ketones in the presence of aldehydes using a bis-silyl ether of ethylene glycol (eq 13).[38] The selective acetalization of aldehydes in the presence of ketones has been accomplished using ethylene glycol and alumina or silica gel.[39]

(12)

(13)

In addition to their use as protecting groups, dioxolanes have been employed as intermediates. One example is a ring expansion of cyclopentanones via Grob fragmentation of the acetal (eq 14).[40] A novel synthesis of glycerol from formaldehyde and ethylene glycol involves dioxolane intermediates.[41]

(14)

Dioxolane formation is not limited to aldehydes and ketones. Amide acetals have been prepared directly and by the alcohol interchange method (eq 15).[42]

(15)

The interchange of carbonyl protecting groups can be quite valuable in organic synthesis. For example, replacing a thioacetal with an acetal would allow a subsequent oxidation or hydrogenation which is not possible in the presence of a sensitive sulfur-containing group. Reacting the thioacetal with $MeOSO_2F$, followed by treatment with ethylene glycol, achieves this transformation under mild conditions.[43] ***Ethylene Chloroboronate***, prepared from BCl_3 and ethylene glycol, has been used for stereoselective aldol reactions with aliphatic and aromatic aldehydes (eq 16).[2]

(16)

Solvent Effects.[1d]

Ethylene glycol is an excellent solvent for many reactions and its high boiling point (197.6 °C) and low freezing point (-13 °C) permit a wide range of operating temperatures. Both NaOH and KOH are very soluble in ethylene glycol. Examples are the hydrolysis of *t*-butylurea,[44] the dehydrochlorination of monovinylacetylene,[45] and the Wolff-Kishner deoxygenation.[46] Dehydroxylations of (*R*,*R*)-tartrates with ***Samarium(II) Iodide*** are best accomplished in ethylene glycol.[47] The conversion of alkyl bromides to alkyl fluorides has been carried out in ethylene glycol.[48] Removal of the acetonide group can be accelerated by substituting ethylene glycol for H_2O.[49] The Fischer indole synthesis can be performed without the addition of an acid catalyst by heating a phenylhydrazone in ethylene glycol.[4,50] Ethylene glycol has also been used as a substrate for the synthesis of indoles and other heterocycles.[51] The Ru complex catalyzed reaction of substituted anilines and ethylene glycol offers an alternative route to the indoles under milder conditions than conventional methods (eq 17).[51a,b]

(17)

Ethylene glycol is superior to benzene, MeCN, DMSO, MeOH, and H_2O for the Diels-Alder reaction involving relatively hydrophobic dienes and dienophiles. The increased reaction rate in ethylene glycol is attributed to the improved aggregation of the diene and dienophile (eq 18).[3]

(18)

The synthesis of tertiary alcohols from trialkylboranes and CO at 100-150 °C has been improved in the presence of ethylene glycol[5,52-54] (eq 19).[54a] The purpose of the ethylene glycol is to trap the intermediate boronic anhydride, which can form a polymer that is difficult to oxidize.

W. Christopher Hoffman

Union Carbide, South Charleston, WV, USA

Ethylenimine[1]

[151-56-4] · C_2H_5N · Ethylenimine · (MW 43.08)

(aminoalkylating agent[1])

Alternate Name: aziridine

Physical Data: mp -74 °C; bp 56.7 °C; *d* 0.829 g cm^{-3}.

Solubility: miscible with H_2O and virtually all organic solvents.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: highly toxic; causes inhalation hazard and skin burns. Use a laboratory hood and wear goggles and gloves. Aziridine is also highly flammable (flash point -11.1 °C, similar to that of benzene). Stable at rt if acid impurities are excluded. Usually stored over solid sodium hydroxide.

Introduction.

Many reactions of aziridines are similar to other cyclic amines. However, the strain present (113 kJ mol^{-1}) results in much easier ring-opening reactions by cleavage of C-N and occasionally C-C bonds.

Aziridines form quaternary ammonium salts with protons and Lewis acids, but these salts are usually reactive towards nucleophiles present in the reaction mixture. They are isolable using weakly nucleophilic solvents (like H_2O) and counterions[2] (perchlorate,[2a] tetrafluoroborate,[2b] trinitrophenylsulfonate,[2c] hydrogen sulfate, etc.). Aziridinium salts were formed at low temperatures from salicylic, glycolic, formic, acetic, benzoic, and dichloroacetic acids, but decomposed within a very short time.[1] Stable salts are obtained from dicarboxylic acids (oxalic,[3a] adipic, terephthalic, isophthalic, tetrachlorophthalic[3b]).

Aziridine forms coordination compounds by the donation of the unshared pair of electrons on the nitrogen atom to molecules or metal ions capable of accepting such electron pairs. The complex with BMe_3 is stable at 100 °C for several hours.[4] ***Boron Trifluoride Etherate*** cleaves aziridine rings readily,[5] but adducts with ***Trimethyl Borate*** and $B(OPh)_3$ are reasonably stable.[6] Labile metal ion-aziridine complexes have been made with Cu^{II}, Hg^{II}, Mn^{II}, Co^{II}, and Ni^{II}.[7] Some salts like Cr^{III}, Co^{III}, Pd^{II}, Pt^{II}, Rh^{I}, and Rh^{III} give inert complexes with aziridine.[7]

Nucleophilic Attack of the Aziridine Nitrogen on Carbon.

Stable HBF_4 salts are formed when trialkyloxonium fluoroborates are used for alkylation of aziridine.[1a] Problems with ring cleavage arise in the reaction of aziridine with alkyl or aryl halides (alkylation) and formation of quaternary ammonium salts. Ring cleavage can be avoided or reduced by using an excess of aziridine over alkyl halide.

Nucleophilic addition to β-alkenic carbons depends on the presence of acceptor groups to stabilize the transient partial negative charge on the α-carbon in the transition state. The reaction of aziridine with activated vinylic chlorides proceeds with retention of configuration.[8,9] Addition to activated alkynes is stereoselective (eq 1).[8] Only esters of alkyne mono-[9] and dicarboxylic acids[10] yield an excess of (*E*)-isomer. Other acceptor groups prefer the formation of (*Z*)-isomer.

R = Y = CO_2Me	15:85
R = Y = CF_3	>95:<5

Ring Expansion of Aziridines.

Carbonylation gives β-lactams (eqs 2 and 3).[11] The insertion occurs with net retention of configuration and is quite regioselective. ***Carbon Monoxide*** inserts into either the more (catalyst ***Tetracarbonyl(di-μ-chloro)dirhodium***)[11a] or the less (catalyst ***Tetracarbonylnickel***)[11b] substituted C-N bond. The (*E*)-amidine formed by addition of aziridine to isocyanides (eq 4) rearranges to the imidazolines.[12]

(2)

(3)

(4)

Aziridine is an excellent starting material for the synthesis of various heterocycles: 1,3-oxazolidines,[13] 1,3-thiazolidines,[13] dihydro-1,4-thiazines,[14] bicyclic pyrrolidines,[15] Δ^1-pyrrolines.[16] Moreover, it is a building block for various alkaloids: crinine, sendaverine, corgoine, reframidine, α-dihydrocaranone, and γ-lycorane.[1c]

Other Reactions.

N-Chloroaziridine is prepared by gas/solid chlorination[17] and used to prepare azirine by dehydrohalogenation. The larger cyclic imines (4-6 membered) are more stable and obtained in higher yields (eq 5).[17b] Various aza macrocycles can be formed by using aziridine as a construction unit, either by ring cleavage,[18a] or with aziridine in the side chain.[18b]

Ethylene Oxide

[75-21-8] · C_2H_4O · Ethylene Oxide · (MW 44.05)

(electrophile; 2-hydroxyethyl equivalent)

Alternate Name: oxirane

Physical Data: bp 13.5 °C/746 mmHg; *d* 0.8824 g cm^{-3}.

Solubility: sol water and most organic solvents.

Form Supplied in: liquid, in 100 mL sealed tubes; gas, in 100 mL cylinders.

Handling, Storage, and Precautions: extremely flammable; vapors can detonate; possible carcinogen; use in a fume hood.

Nucleophilic Opening.

Ethylene oxide and epoxides in general have been the subject of extensive reviews.[1] Much of the chemistry involved with ethylene oxide revolves around the opening of the strained ring to form a 2-ethanol substituted moiety. The reagents employed have ranged from carbon nucleophiles, to alcohols and water, to amines.

Reaction with Organolithium Reagents.

The carbon nucleophiles can be classified by the type of organometallic reagent involved in the opening reaction of the epoxide. The reagent of choice for this transformation is an organolithium reagent.[2] Treatment of an ester lithium enolate with an excess of ethylene oxide affords a spirolactone (eq 1).[2a]

(1)

A lithio acetylide reacts with ethylene oxide in the presence of ***Boron Trifluoride Etherate*** (eq 2).[2c] While $BF_3.Et_2O$ has been used to increase the yields of epoxide openings with organolithium reagents,[3] the reaction solvent also plays an important role in obtaining high yields of ring-opened material with a lithio acetylide (eq 3).[2b] While ***t-Butyllithium*** readily metalates some epoxides, it only opens ethylene oxide.[4]

(2)

(3)

Reaction with Allylpotassium Reagents.

Isoprene has been metalated with ***Potassium Diisopropylamide*** (KDA). Employing this nonnucleophilic, strong base lessened polymerization and permitted the reaction of the allylpotassium reagent with ethylene oxide to form the homologated alcohol (eq 4).[5]

(4)

Reaction with Grignard Reagents.

Grignard reagents add with equal facility as organolithium reagents to ethylene oxide (eq 5).[6]

(5)

Reaction with Lithium Dialkylcuprates.

Lithium dialkylcuprates have long been known to react selectively and in high yield with oxiranes.[7] A number of more complex, modified cuprate reagents recently have been developed.[8] A vinylstannane was treated with the higher-order cuprate derived from ***Methyllithium*** and ***Copper(I) Cyanide*** and subsequent reaction with ethylene oxide afforded the homologated alcohol in 48% yield. The vinylstannane was also metalated with ***n-Butyllithium*** and reaction with 2-thienyl(cyano)copperlithium afforded the mixed higher-order vinyl cuprate that reacted with ethylene oxide in 38% yield. However, the authors found the easiest method for the formation of the homologated alcohol was to produce the mixed cuprate and treat it with ethylene oxide (eq 6).[8a]

Reaction with Vinylaluminum Reagents.

Vinylaluminum reagents react with ethylene oxide, but lithium alanates react in even higher yield (eq 7).[9]

Reaction of Ylides.

A new β-oxidobenzyl ylide was formed by reacting lithium diphenylphosphide with ethylene oxide followed by reaction with ***Benzyl Bromide***. The reaction of these ylides with aldehydes afforded (*E*)-alkenes with good stereoselectivity (eq 8).[10] Another ylide formed from ethylene oxide undergoes a Wittig reaction with an aldehyde derived from (*R*)-limonene. The resulting alkene retains the ethanol moiety derived from ethylene oxide (eq 9).[11]

(8)

(*E*):(*Z*) = 85:15

(9)

(*Z*):(*E*) = 67:33

Reaction with Amines.

Heteroatom-containing moieties add to ethylene oxide to form 2-substituted ethanol derivatives.[1] Amines add in this fashion to form 1,2-ethanolamines.[12] For instance, bubbling ethylene oxide through a solution of dimethylethylenediamine in methanol at 35 °C affords the corresponding alcohol (eq 10).[13]

Reaction with Me_3SiI.

By reacting ethylene oxide with ***Iodotrimethylsilane***, a simple derivative is formed that is also useful as a two-carbon synthon in the preparation of pheromone components (eq 11).[14]

Reaction with Aldehydes.

A very facile method for the formation of acetals under essentially neutral conditions involves the reaction of ethylene oxide with aldehydes in an autoclave at 110-220 °C (eq 12).[15]

Related Reagents.

1,3-Butadiene Monoxide; ***Glycidol***; ***Isoprene Epoxide***; ***Propylene Oxide***.

Ethylene Sulfide[1]

[420-12-2] · C_2H_4S · Ethylene Sulfide · (MW 60.13)

(mercaptoethylation reagent for primary and secondary amines[2])

Alternate Name: thiirane.

Physical Data: bp 55-56 °C; *d* 1.010 g cm^{-3}; n_D^{20} 1.4935.

Solubility: insol H_2O; sol most common organic solvents.

Form Supplied in: colorless liquid; commercially available, stabilized with 0.5% BuSH.

Analysis of Reagent Purity: by IR,[3a] ^1H NMR,[3b] and GLC.[4]

Preparative Methods: readily obtained from ethylene carbonate and ***Potassium Thiocyanate***.[5]

Handling, Storage, and Precautions: highly toxic,[6] flammable liquid; must be stored in a freezer to prevent gradual polymerization, which is promoted by mineral and organic acids, bases, aqueous ammonia, strong amines, and heavy metal salts. Stabilizers against polymerization: H_2S, alkyl and benzyl thiols, alkyl sulfides, and thioacetamide. Use in a fume hood.

Mercaptoethylation of Amines.

Ethylene sulfide is widely used for mercaptoethylation of primary and secondary amine groups in various organic compounds to obtain aminothiols themselves or to convert them into sulfur heterocycles. Aqueous ammonia causes only a rapid polymerization of ethylene sulfide and no cysteamine formation. The action of anhydrous ammonia has not been investigated. Efforts to obtain monomeric ethylene sulfide addition products to ***Hydrazine*** and ***Hydroxylamine*** failed.

Mercaptoethylation of amines by ethylene sulfide proceeds with opening of the episulfide ring by an S_N2 mechanism, the slow step being nucleophilic attack of the amine on the episulfide carbon atom followed by a rapid proton exchange between N and S atoms.[7] Strongly basic amines react more rapidly,[8] but high basicity promotes polymerization of ethylene sulfide as well.[9] The latter reaction may be suppressed by using nonpolar solvents (benzene, ether, THF,

dioxane) and an excess of the amine, which also prevents the formation of bis(mercaptoethyl) derivatives in the case of primary amines and further alkylation of product at sulfur (giving thioethers).[10] Heating favors the mercaptoethylation reaction and diminishes the polymerization.[11]

A substantial improvement of the earlier synthetic procedures is the gradual addition of the ethylene sulfide to a refluxing amine solution in benzene, which diminishes the polymerization to less than 1%.[2] This procedure with warm, but not refluxing, solution gives good yields even when stoichiometric amounts of reagents are used (eq 1).[12] Primary aliphatic amines may be mercaptoethylated near room temperature in aqueous media containing the amine-silver complex, which finally is decomposed by H_2S (eq 2).[13]

(1)

(2)

Weakly basic aryl amines,[8] esters of aminobenzoic acids,[14] and α-amino acids[15] require more drastic conditions (100-105 °C, sealed tube, alcoholic solutions or absence of solvent) for mercaptoethylation.

The preparation of bis(mercaptoethyl)amines by means of ethylene sulfide has been little investigated,[11,16] and reaction conditions have not been optimized. However, satisfactory yields of $HN(CH_2CH_2SH)_2$ (83%) and $N(CH_2CH_2SH)_3$ (72%) were obtained by slowly treating cysteamine with an excess of ethylene sulfide at rt in toluene followed by refluxing (24 and 36 h, respectively).[17]

Other Applications.

Other useful applications of ethylene sulfide for the synthesis of organosulfur compounds in excellent yields (>90%): $PhCH_2SCH_2CH_2Br$,[18] $PhSCH_2CH_2SH$,[19] $R_2AsSCH_2CH_2SCN$,[20] 1,4-dithiane,[21] 1,3-dithiolane-2-thione,[22] and a thiazolidine derivative of the C_{20} diterpenoid alkaloid lindheimerine by cyclocondensation of its N=C bond with ethylene sulfide.[23]

Related Reagents.

2-Mercaptoethanol.

Ethyl 3-Ethoxyacrylate[1]

[1001-26-9] · $C_7H_{12}O_3$ · Ethyl 3-Ethoxyacrylate · (MW 144.17) (*E*)

[5941-55-9] (*Z*)

[40648-44-0]

(mono- and bifunctional three-carbon electrophile in acylation reactions;[2] various condensation reactions;[3] building block for heterocycles[1] and nucleoside synthesis[4])

Alternate Name: 3-ethoxy-2-propenoic acid, ethyl ester.

Physical Data: bp 195-196 °C, 85.5-86.5 °C/19 mmHg; *d* 0.993-0.998 g cm^{-3}; n_D^{20} 1.444-1.448.

Form Supplied in: colorless, sweet-smelling liquid, stabilized with 0.01% hydroquinone monomethyl ether; commercially available.

Handling, Storage, and Precautions: should be stored at 0-4 °C. It is a slight lachrymator and irritant. Use in a fume hood.

Reactions at the Double Bond.

Transetherification.

Ethyl 3-ethoxyacrylate and 3,3-diethoxypropionate undergo reversible interconversion in the presence of some acidic-type catalysts.[5] Thus the acrylate is converted into the propionate in the presence of ***Boron Trifluoride Etherate***; the propionate distilled with ethanol and a catalytic amount of sodium bisulfate affords the acrylate. Replacing ethanol by less volatile alcohols yields ethyl 3-alkoxyacrylates or ethyl 3,3-dialkoxypropionates[5] (eq 1). Similarly, thiols[5] and thiophenols[6] undergo transetherification reactions with ethyl 3-ethoxyacrylate and sodium bisulfate to give alkylthioacrylates.

(1)

Addition.

Addition of allyl alcohols to ethyl 3-ethoxyacrylate using ***N-Bromosuccinimide*** as bromine donor yields ethyl 3-allyloxy-2-bromopropionates, which can be cyclized reductively to 3-ethoxycarbonyltetrahydrofurans with ***Chromium(II) Acetate*** (eq 2).[7]

(2)

Other Substitutions.

β-Ethoxycinnamates are obtained in moderate yields by cross-coupling reaction of iodobenzenes with ethyl 3-ethoxyacrylate in the presence of ***Palladium on Carbon*** (eq 3).[8] 3-Iodopyridine and 3-iodoquinoline react similarly.[8]

Carboxy Reactions and Subsequent Cyclization.

Ethyl 3-ethoxyacrylate is an important starting material in the synthesis of uracil nucleosides. In a three-step synthesis the ester is converted into the acid chloride, then to the acyl isocyanate which reacts with ammonia,[2a] aliphatic[2a] or aromatic amines[2a,9] to give β-ethoxyacryloylureas (cf. eq 4). These acylureas are cyclized in alkaline solution to the corresponding uracils. With acyl isothiocyanates, thiopyrimidones[2b] are obtained, while for the synthesis of thymines, 3-methoxy-2-methylacrylic acid is used.[2a] Carbocyclic analogs of uracil nucleosides are obtained when the amine component is a hydroxycyclopentylamine (eq 4).[4,10] The cyclization is catalyzed by acid.[4] Tetrahydroxycyclopentylamines may be also used.[11]

(4)

Other Cyclizations.

Aminoarabinose containing a 2´-amino-1,2-oxazoline ring reacts with ethyl 3-ethoxyacrylate directly to give the $O^{2,2'}$-anhydrouridine, although the yield is poor (24%).[12]

2-Substituted 4(3*H*)-pyrimidinones are obtained by reaction of ethyl 3-ethoxyacrylate with orthoesters and ammonia.[3] Ethoxyacrylate alone reacts with ammonia (mol ratio 2:1) to give ethyl 2(1*H*)-pyridone-5-carboxylate (eq 5);[3] excess of ammonia gives additional pyridine-3,5-dicarboxylate.

Condensation of 4,6-diamino-2-methylthiopyrimidine with ethyl 3-ethoxyacrylate in acetic acid yields 4-amino-2-methylthio-7-oxopyrido[2,3-*d*]pyrimidine, whereas a complex mixture is obtained with ethyl propiolate.[13]

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl Hydroxymethyleneacetate, Sodium Salt***; ***Methyl Diformylacetate***; ***Methyl Propiolate***.

Ethyl Ethoxymethyleneacetoacetate

[3788-94-1] · $C_9H_{14}O_4$ · Ethyl Ethoxymethyleneacetoacetate · (MW 186.21)

(mono-, bi-, and trifunctional three-carbon electrophile in carbonyl reactions, cyclizations;[1] β-keto ester equivalent)

Physical Data: bp 265-266 °C, 149-151 °C/16 mmHg; *d* 1.067 g cm^{-3}; *n*20D 1.472-1.473.

Form Supplied in: colorless, viscous liquid.

Preparative Methods: obtained by heating ***Ethyl Acetoacetate*** with ***Triethyl Orthoformate*** in ***Acetic Anhydride***.[2a,b]

Handling, Storage, and Precautions: may be kept for a few weeks at 0 °C in the dark with addition of hydroquinone. The enol ether hydrolyses slowly in contact with water. Use in a fume hood.

Cyclization with Amino Nucleophiles.

Ethyl ethoxymethyleneacetoacetate (**1**) has three types of carbonyl groups, the labile ethoxy group (a masked aldehyde) being the most reactive. It will be substituted first by nucleophiles such as amino compounds. Amidines give aminomethylene derivatives, which cyclize to a substituted pyrimidine ring with a bridgehead nitrogen. 2-Aminopyridines condense with (**1**), the intermediates yielding 3-acetyl-4-keto-4*H*-pyrido[1,2-*a*]pyrimidine (eq 1).[1a] 5-Amino-4-cyanopyrazole and (**1**) cyclocondense to 6-ethoxycarbonyl-3-cyano-7-methylpyrazolo[1,5-*a*]pyrimidine.[1b] In a modified Gould-Jacobs reaction of amino heterocycles and (**1**), cyclization takes place at a carbon atom: 1-substituted 5-aminopyrazoles give 5-acetyl-1*H*-pyrazolo[3,4-*b*]pyridine derivatives.[3a,b] Similarly, acetyl-substituted isoxazolo[4,5-*b*]pyridines,[3c] thieno[2,3-*b*]pyridines,[4] thieno[3,2-*b*]pyridines,[4] 5*H*-[1]benzopyrano[3,4-*b*]pyridinones,[5a] and 3*H*-pyrano[3,2-*f*]quinoline[5b] are obtained from 5-aminoisoxazole, 2- or 3-aminothiophene derivatives, 3-aminocoumarin, and 6-aminocoumarin, respectively. 1,1,1-Tris(aminomethyl)ethane and (**1**) condense to form a hexadentate ligand for Co^{III} and Fe^{III}.[6]

(1)

Reaction with Carbon Nucleophiles.

Compounds with acidic protons such as acetoacetate[7a] or malodinitrile[7b] behave as nucleophiles towards (**1**). 2-Methylpyridinium salts[8] and (**1**) give 1-alkyl-2-allylidenedihydropyridines (eq 2).

(2)

Dimethylsulfoxonium ylides as nucleophiles and (**1**) yield 4-ethoxycarbonyl-1,3-dimethylthiabenzene 1-oxide[9a] or a carbonylvinyl-stabilized sulfur ylide.[9b]

Related Reagents.

[71363-40-1]

(push-pull alkene;[1] N-heterocycle synthesis; 1,3-dipolar cycloaddition;[2] 1,4-addition-elimination (Ad_N-E)[3])

Physical Data: R = Et, mp 51-53 °C; bp 190-191 °C/30 mmHg; subl. 25 °C/0.02 mmHg. R = Me, mp 88 °C; bp 185 °C/25 mmHg.

Solubility: slightly sol water; sol ethanol, diethyl ether.

Form Supplied in: white solid; widely available.

Preparative Methods: can be prepared from ***Triethyl Orthoformate***, ***Ethyl Cyanoacetate***, and ***Acetic Anhydride*** in the presence of ***Zinc Chloride*** (catalyst).[4]

Purification: recrystallization from ethanol and sublimation.

Handling, Storage, and Precautions: use in a fume hood.

Ethyl ethoxymethylenecyanoacetate is a valuable reagent in the synthesis of N-heterocycles. Pyrimidines (eq 1),[6] pyridines,[7] pyrazoles,[8] indolizines,[9] quinolizones, and pyridones[10] can be obtained. It is also used in the synthesis of

pyrones (eq 2).[11]

The [3 + 2] cycloaddition of ethyl ethoxymethylenecyanoacetate with cyclopropenone acetals[2a] (see also ***Diethyl Ethoxymethylenemalonate*** and ***Diethyl Ethylidenemalonate***), benzonitrilium isopropylide (eq 3)[2d] or diazo compounds[2b,c,12] leads to cyclopentenones, pyrrolines, and pyrazolines, respectively. Benzonitrilium isopropylide is generated in situ from a photoinduced cleavage of the corresponding 2*H*-azirine (eq 3).

The ethoxy group of ethyl ethoxymethylenecyanoacetate can be substituted by various nucleophiles in an Ad_N-E mechanism. Malonates,[3f] enolates,[3b,c,g] quarternary salts of heterocyclic bases containing an active methylene group,[3d] amines,[3a,e] etc. were used as nucleophiles in this reaction.

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***3-Ethoxyacrolein***; ***3-Ethoxyacrylonitrile***; ***Ethoxymethylenemalonitrile***; ***Ethyl Cyanoacetate***; ***Ethyl 3-Ethoxyacrylate***; ***Ethyl Ethoxymethyleneacetoacetate***.

3-Ethyl-2-fluorobenzothiazolium Tetrafluoroborate[1]

[60150-69-3] · $C_9H_9BF_5NS$ · 3-Ethyl-2-fluorobenzothiazolium Tetrafluoroborate · (MW 269.04)

(transformation of alcohols to alkyl halides;[2] optical inversion of secondary alcohols;[3] esterification of carboxylic acids;[4] cyclization of alcohols[5])

Solubility: insol CH_2Cl_2; reacts with alcohols.

Preparative Methods: treatment of 2-fluorobenzothiazole with Meerwein's reagent (***Triethyloxonium Tetrafluoroborate***).[1]

Handling, Storage, and Precautions: hygroscopic salt; handle cautiously, the toxicity of this reagent has not been reported.

Alkyl Halides.

2-Halobenzothiazolium salts react readily with alcohols to form an alkoxybenzothiazolium salt. This intermediate reacts with alkali metal halides to form alkyl halides in good yield (eq 1).[2]

The general procedure is to suspend the benzothiazolium salt in CH_2Cl_2 and add the alcohol and ***Triethylamine*** dropwise. This is followed by addition of the alkali halide in acetone or DMF. Inverted alkyl halides are obtained with optically active secondary alcohols (eq 2).[2]

Alcohol config.	MX	Yield (%)
(*S*)	NaI	87 (*R*)
(*R*)	LiBr	64 (*S*)

There are a variety of ways to convert alcohols to halides. The most common is halogen acids HX or inorganic acid halides such as ***Thionyl Chloride***.[6] However, treatment of secondary alcohols with these reagents often gives rearranged products instead of the inverted alkyl halide.

A benzoxazolium salt (**1**) gives comparable yields with acyclic alcohols, and it gives good yields of the inverted halide

with cyclic alcohols (eq 3).[7] The benzothiazolium salt does not give satisfactory results for these types of alcohols (see also ***2-Chloro-3-ethylbenzoxazolium Tetrafluoroborate***).

Inversion of Secondary Alcohols.

Reaction of alkoxybenzothiazolium salts with ***Trichloroacetic Acid*** gives esters with an inverted stereocenter. These are saponified under mild conditions to give the inverted secondary alcohol in good yield (eq 4).[3]

Another method often used for inverting secondary alcohols is the Mitsunobu reaction involving treatment of the alcohol with ***Triphenylphosphine*** and ***Diethyl Azodicarboxylate***.[8]

Ester Formation.

2-Halobenzothiazolium salts have been used to synthesize esters from carboxylic acids and alcohols (eq 5).[4] This is similar to (eq 4) except a more stable ester is formed when the trichloro substitution is avoided.

(5)

There are many useful reagents for synthesizing esters from carboxylic acids. Many of them are commercially available and are more practical than the benzothiazolium salts (see ***N,N´-Carbonyldiimidazole***, ***1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide***, ***1,3-Dicyclohexylcarbodiimide***, ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride***, and ***1,1´-Thionylimidazole***).

Cyclization of Alcohols.

A similar 2-fluorobenzothiazolium salt (**2**) has been used in the dehydrative cyclization of sesquiterpene alcohols (eq 6).[5]

Presumably this would work similarly with the *N*-ethylbenzothiazolium salt. Yields of the desired products are lower when the reaction temperature is -78 °C. Compound (**2**) is the most effective reagent for this transformation. The benzoxazolium salt (**1**) gives about 45% of the desired products under similar conditions. The 2-fluoropyridinium salt (**3**) gives 58% of the desired products at -40 °C (see also ***2-Chloro-3-ethylbenzoxazolium Tetrafluoroborate***).

Ethyl Diethoxyacetate

(R = Et)

[6065-82-3] · $C_8H_{16}O_4$ · Ethyl Diethoxyacetate · (MW 176.24) (R = Me)

[89-91-8] · $C_5H_{10}O_4$ · Methyl Dimethoxyacetate · (MW 134.15)

(lithium derivatives act as nucleophiles;[1-9] useful reagents for synthesis of heterocyclic compounds[1,3,10])

Alternate Name: ethyl glyoxylate diethyl acetal.

Physical Data: R = Et, bp 86-88 °C/16 mmHg; *d* 0.985 g cm^{-3}. R = Me, bp 67 °C/18 mmHg; *d* 1.096 g cm^{-3}.

Handling, Storage, and Precautions: these liquid compounds are moisture sensitive. They should be stored at low temperature.

Reaction of Lithium Derivatives.

A key step in a high yield total synthesis of (±)-4-isoavenaciolide is the conjugate addition of the lithium derivative of ethyl diethoxyacetate to a butenolide (eq 1).[1] Conjugate addition also occurs with 3-methoxy-2-cyclohexenone[2] and phenyl vinyl sulfoxide (eq 2).[3] However, reactions with α,β-enones mainly give the 1,2-addition products in many cases; exclusive conjugate addition is observed in the case of a 16-methylene-17-oxo steroid for steric reasons.[4] Obviously reactions with saturated ketones give the expected 1,2-adducts.[5,6]

Alkylation with alkyl halides gives acetals of α-keto esters (eq 3).[7,8] The same reaction with 7-iodoheptanoic acid gives an intermediate for prostaglandins synthesis.[9]

Synthesis of Heterocyclic Compounds.

Alkyl dialkoxyacetates are widely used in heterocyclic chemistry.[1,3,10] For instance, reaction of a lithium derivative with an α-iminocarbonyl compound gives the carbonyl addition product, precursor of 4-benzoyl-β-lactams (eq 4).[10a]

(4)

Substitution of a methoxy group of the acetal function of methyl dimethoxyacetate by a bromine using ***Triphenylphosphine Dibromide*** leads to an interesting reagent for synthesis of tetrahydroisoquinolines.[10b] Synthesis of 1*H*-1,2,4-triazole-3,5-dicarbaldehyde occurs according to eq 5.[10c]

(5)

Reactions with Nucleophiles.

Tertiary alcohols are obtained by reactions with ***Ethynylmagnesium Bromide***[10d] and with ***Trimethylsilylmethylmagnesium Chloride*** and ***Cerium(III) Chloride***.[5] These alcohols are intermediates in syntheses of tin heterocycles[10d] and of 2-methylene-3-trimethylsilylpropionaldehyde (eq 6),[5] respectively. An organodimagnesium compound leads to the cyclic product (eq 7).[11]

Ester[10f,12] or ketone[10e] enolates are also effective as nucleophiles in Claisen reactions. A similar result is obtained from dimsylsodium (eq 8).[13] However, ammonia gives an amide which leads to an interesting intermediate for synthesis of a polyheterocyclic antibiotic.[10g]

Preparation of Thioacetals.

Thioacetals are obtained by reaction with thiols[10i] or dithiols[14] which leads to a convenient synthesis of α-keto esters (eq 9).[14]

Reaction of Ylides.

Reaction with phosphonium ylides leads to other ylides which react with aldehydes and yield α,β-unsaturated carbonyl compounds (eq 10).[15]

Formation of the Deacetalization Product.

Reactions with glyoxylic acid monohydrate lead to mixtures of hemiacetal and of alkyl glyoxylate hydrate. Dehydrations provide ethyl or methyl glyoxylate in a convenient way.[16]

Related Reagents.

1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene; ***Ethyl 3,3-Diethoxypropanoate***; ***Glyoxylic Acid Diethyl Dithioacetal***; ***Methyl Glyoxylate***.

2-Ethyl-7-hydroxybenzisoxazolium Tetrafluoroborate

[16859-20-4] · $C_9H_{10}BF_4NO_2$ · 2-Ethyl-7-hydroxybenzisoxazolium Tetrafluoroborate · (MW 251.00)

(reagent for the formation of activated esters in peptide synthesis[1-3])

Physical Data: mp 137-138 °C.

Solubility: sol dipolar aprotic solvents and water.

Preparative Methods: from 2,3-dihydroxybenzaldehyde and ***Hydroxylamine-O-sulfonic Acid***, followed by treatment with ***Triethyloxonium Tetrafluoroborate*** (78% yield for the two steps).[1,3]

Handling, Storage, and Precautions: the salt is not hygroscopic or light sensitive but releases HF when exposed to moist air.

Peptide Synthesis.

The 2-ethylbenzisoxazolium cation has been studied as a peptide coupling reagent.[1] A reagent which reacted rapidly and efficiently with carboxylic acids to produce a stable but activated ester was required. This ester must then react efficiently with peptide amines without competitive hydrolysis or racemization. 2-Ethyl-7-hydroxybenzisoxazolium tetrafluoroborate was found to be the most satisfactory derivative to fulfill these criteria. Treatment of a peptide carboxylate salt with the title reagent in pyridine-water at pH 4.5-5.0 gives excellent yields of the ester product (eq 1) with a half life of the reaction of ca. 1-2 min. This ester is formed by attack at the iminium cation before migration of the acyl group to give the more stable *meta*-acyloxy substituted product containing a strong intramolecular hydrogen bond.

Coupling of the active ester with amines occurs rapidly in the presence of ***1,1,3,3-Tetramethylguanidine*** (TMG) (eq 2).[2] Racemization is minimized at 0-10 °C and above 0.05 M concentration. Reaction times for 90% reaction in DMSO at 22 °C range from 15 to 90 min. Hindered amino acids react more slowly, e.g. Val + Val having a reaction time of 4 h. Proline reacts very slowly (9 h for 90% completion with ZGly). A wide range of peptide couplings can be successfully achieved with the title reagent, which compares favorably with ***1-Hydroxybenzotriazole/1,3-Dicyclohexylcarbodiimide*** for peptide synthesis, particularly for the synthesis of small peptides.[3]

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: NMR and optical rotation ($[\alpha]_D$).

Preparative Methods: reduction of ***Ethyl Acetoacetate*** with ***Baker's Yeast***[2,4-6] yields the (*S*)-(+) enantiomer; reduction with *Geotrichum candidum*[4,7] yields the (*R*)-(-) enantiomer. The (*R*)-(-) enantiomer was also prepared[1] by depolymerization of poly-(*R*)-3-hydroxybutyric acid (PHB). Both enantiomers can be prepared by chemical reduction using a ruthenium catalyst complexed with (*S*)- and (*R*)-BINAP, respectively.[8,9] The yeast reduction of ethyl acetoacetate has been varied: in petroleum ether (58%, 94% ee),[10] in the presence of ethyl chloroacetate (75%, 99% ee),[10,11] immobilized by magnesium alginate and under high concentration of Mg^{2+} ion (65%, 99% ee),[13] immobilized by calcium alginate in organic-water solvent system.[14]

Chemical reductions with ***Sodium Borohydride***-L-tartaric acid[15] ((*R*)-(-), 65%, 81% ee) and with a chiral oxazaphospholidine-borane complex[16] ((*R*)-(-), 80%, 99% ee) have been published.

Purification: the enrichment of the (*S*)-(+) enantiomer to 100% enantiomeric purity by means of the 3,5-

dinitrobenzoate has been described.[2,17]

Handling, Storage, and Precautions: should be stored in a refrigerator because of possible transesterification-oligomerization at room temperature.[2]

Dianion Alkylation.

β-Hydroxy carboxylates can be converted to their corresponding dianions through deprotonation of the hydroxy group and the α-carbon atom.[18,19] The so-formed double charged enolates are relatively stable species and can efficiently react with electrophiles in the α-position. The dianions of (3*R*)- and (3*S*)-ethyl 3-hydroxybutanoate were prepared[3,20] by lithiation with 2 equiv of ***Lithium Diisopropylamide*** in THF at -50 to -70 °C and 1 equiv of an alkyl halide was added, often in the presence of HMPA at -75 to 0 °C. The usual yield is 70-90%, and the stereoselectivity is generally better than 95:5 in favor of the *anti* isomer (eq 1).

Alkylations with ***Iodomethane***,[3,21-24] ***Allyl Bromide***,[3,20] ***Benzyl Bromide***,[3] *n*-butyl bromide,[20] dimethylallyl bromide,[25] ***Benzyl Chloromethyl Ether***,[26,27] (*S*)-2-methylbutyl iodide,[29] and (benzene)$Mn(CO)_3^+PF_6^-$ [29] have been reported.

The mechanistic explanation for the ~20:1 stereoselection is the formation of a chelate as depicted in (**1**), where the approach of the electrophile is more favorable *anti* to the sterically more demanding Me (or alkyl) group.

(1)

This method of dianion alkylation is an important and reliable preparative way to control the vicinal stereochemistry; the method is especially valuable, because both (*R*) and (*S*) starting materials are commercially available, although quite expensive, or may be easily prepared.

Dianion Amination.

The electrophilic amination has been carried out with the synthetic equivalent of [NH_2^+], i.e. ***Di-t-butyl Azodicarboxylate*** (TBAD) (eq 2).[30,31] The initially formed 94:6 mixture of the α-hydrazino-β-hydroxy ester was transformed into the α-amino-β-hydroxy derivative,[30] and was also used in the total synthesis of an amino sugar.[32]

(2)

Reaction of the Dianion with Imines: Formation of β-Lactams.

The dianions of (*R*)- and (*S*)-ethyl 3-hydroxybutyrate have been added to different imines, yielding in one step the β-lactam, a precursor for, e.g. thienamycin (eq 3).[33-37]

A very clean and highly stereoselective reaction has been achieved with the Zn/Li dianion and *N*-trimethylsilylphenylpropargylidene imine and the corresponding cinnamylidene imine (eq 4). Only one isomer was observed out of the four possible in yields of 85% and 78%, respectively.[38]

Other Esters and General Remarks.

The dianion chemistry of 3-hydroxy esters is of a very broad utility and synthetic importance.[39] Beside the cases above, a large variety of alkylations of 3-hydroxy ester dianions has been reported, e.g. (*S*)-dialkyl 2-hydroxysuccinate (malate)[40-42] and other examples.[3,43-45] It is of major importance to realize that a second alkylation allows the enantioselective preparation of a quaternary carbon center.[3,20,46-48] This is obviously also the case when cyclic analogs, such as (1*R*,2*S*)-ethyl 2-hydroxycyclohexanecarboxylates (eq 5), 95:5 de),[49] are alkylated by means of the dianion.[49-51]

Related Reagents.

(R)-2-t-Butyl-6-methyl-4H-1,3-dioxin-4-one; ***Di-t-butyl Azodicarboxylate***; ***Ethyl Acetoacetate***.

Ethyl α-(Hydroxymethyl)acrylate[1]

[10029-04-6] · $C_6H_{10}O_3$ · Ethyl α-(Hydroxymethyl)acrylate · (MW 130.16)

(important source of functionalized acrylic monomers for polymerization and copolymerization; intermediate in the preparation of α-(halomethyl)acrylates, methacrylates, and α-methylene lactones; powerful polyfunctional Michael acceptor)

Physical Data: bp 65-70 °C/1 mmHg; *n*20D = 1.4494.

Solubility: sol H_2O, ether, acetone, alcohol, THF, chloroform.

Preparative Methods: by hydroxymethylation of ***Ethyl Acrylate*** with aqueous ***Formaldehyde*** solution in the presence of tertiary amines (***Triethylamine***, ***1,4-Diazabicyclo[2.2.2]octane***),[3] under microwave radiation,[4] or by the Wittig-Horner reaction of ***Triethyl Phosphonoacetate*** with formaldehyde in the presence of aqueous ***Potassium Carbonate*** (eq 1).[5,6] Many side reactions have been found to occur with the first method and the mechanism involving the formation of ethers has been elucidated.[7] Carbonylation of propargyl alcohol to produce this reagent has also been described.[8]

Purification: by distillation at reduced pressure.

Analysis of Reagent Purity: by GLC analysis (e.g. 2 m silica capillary OV-1 column); ^{1}H NMR (CCl_4) 4.20 (2H), 5.80 and 6.15 (2H); ^{13}C NMR ($CDCl_3$) 60.9, 124.8, 140.2, and 166.5.

Handling, Storage, and Precautions: is lachrymatory, vesicatory, and toxic.[2] This reagent should be handled with gloves in a well ventilated hood. Storage at 0 °C in the dark is recommended.

Preparation of Polymers.

Ethyl α-(hydroxymethyl)acrylate has been fully studied for polymerization as the pure compound,[9,10] as its derivatives (chloride,[11] trityl,[12] acetoxy,[13] disilyloxy[14]), as difunctional and multifunctional monomers capable of cyclopolymerization[15] and copolymerization with 2-vinyl-4,4-dimethylazlactone,[16] or as crosslinking agents with biepoxides.[17] It has found employment for the impregnation and in-situ polymerization in the manufacture of wood-polymer composites.[18]

Preparation of α-(Halomethyl)acrylates.

The corresponding bromide and chloride[11] have been prepared by reaction of ethyl α-(hydroxymethyl)acrylate with ***Phosphorus(III) Bromide*** and ***Thionyl Chloride***,[5] while the fluoride and iodide have been obtained by halogen exchange.[5]

Synthesis of Methacrylates and α-Methylene-γ-lactones.

α-(Hydroxymethyl)acrylate can act as a Michael acceptor and, in this way, it can add magnesium organocuprates without subsequent elimination giving rise to α-(hydroxymethyl)alkanoic esters (eq 2). In contrast, reaction of the acetoxy derivative with Grignard reagents in the presence of a catalytic amount of Cu^{I} salt leads to the formation of α-substituted acrylic esters (eq 3).[19]

(2)

(3)

Palladium-catalyzed hydroxyalkylation of aldehydes and cyclohexanone by α-(hydroxymethyl)acrylate derivatives in the presence of ***Tin(II) Chloride*** and ***1,3-Dimethyl-2-imidazolidinone*** (DMI/H_2O) was shown to be a new route to α-methylene-γ-butyrolactones (eq 4).[20]

(4)

A new synthesis of α-(1-hydroxyalkyl)-β-lactams[21] by addition of primary amines to ethyl α-(hydroxymethyl)acrylate has been recently proposed (eq 5).

(5)

Bromine addition-dehydrobromination on ethyl α-(hydroxymethyl)acrylate resulted in the formation of α-(bromomethyl)glycidic ester (eq 6).[22]

(6)

Ethyl α-(hydroxymethyl)acrylate was also employed as allyloxycarbonyl protecting group for amino acids in peptide synthesis[23] and used as an intermediate in the total synthesis of (±)-heptelidic acid.[24]

Ethyl Hydroxymethyleneacetate, Sodium Salt

[58986-28-0] · $C_5H_7NaO_3$ · Ethyl Hydroxymethyleneacetate, Sodium Salt · (MW 138.11)

(a three-carbon β-dicarbonyl building block)

Alternate Name: ethyl formylacetate, sodium salt.

Solubility: sol H_2O and protic solvent; insol THF.

Preparative Methods: the material is usually prepared by the condensation of ethyl acetate and ethyl formate in the presence of a strong base such as ***Sodium Hydride***, sodium alkoxide, or ***Sodium*** metal (eq 1).[2-6]

(1)

The condensation is accompanied by side reactions, and the white solid obtained is generally about 70% pure. Preparation under carbon monoxide pressure has been suggested to improve the yield and purity.[6] The compound has also been prepared by the careful hydrolysis of ethyl β-chloroacrylate.[7] The free acid (malonic semialdehyde) is easily oxidized in air,[1] and the various parent esters[8-10] are all subject to polymerization, although the *t*-butyl ester can be stored at -80 °C without deterioration for a month.[10a]

Handling, Storage, and Precautions: salts and free acid have limited stability[1] and should be prepared as needed; use in a fume hood.

Synthons.

Because the parent compound and its salts are unstable, a number of synthons have been prepared and investigated. As suggested in the references above, the various esters increase in stability as the bulk of the alkyl group increases. The enolate salt has been trapped as ethyl β-trimethylsilyloxyacrylate[11] and further elaborated as an equivalent of the sodium enolate. In similar manner, benzhydryl *N*-benzylaminoacrylate[12] has been used in reactions typical of the enolate salt.

Reactions.

Perhaps the most frequent use of ethyl hydroxymethyleneacetate is for the preparation of various 4-pyrimidinols, wherein the reagent provides the three-carbon piece in the principal synthesis of pyrimidines (eq 2).[6,13]

(2)

Y = H, R, OR, NR_2; Z = H, R, Ar, NR_2, OR, SR

The enolate has been used for the synthesis of variously β-substituted acrylates (**1**)[11,14,15] which have applications as stable synthons of the enolate. They have also served as dienophiles in electrocyclic reactions.[14]

(1)

Y = OTMS, OAc, NR_2

1,1-Dialkylhydrazines yield the corresponding hydrazones.[16] The enolate can be alkylated on the central carbon to provide useful substituted building blocks. Condensation with acetone provides 4*H*-1,3-dioxin-4-ones, which have been brominated on C-6 (eq 3).[9] Xanthate formation on the central carbon provides an entry to 5-thiopyrazoles (eq 4).[17]

(3)

Reaction of substituted *t*-butyl esters with cysteine or penicillamine esters proceeds to thiazolidinylacetate esters. Subsequent Mukaiyama-Ohno cyclization diastereoselectively provides penam-3-carboxylic acid derivatives (eq 5)[8a,b] Oxapenams have been similarly prepared.[12]

Related Reagents.

Diethyl Ethoxymethylenemalonate; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl 3-Ethoxyacrylate***; ***Ethyl Ethoxymethyleneacetoacetate***; ***Malondialdehyde***; ***Methyl Diformylacetate***; ***2,2,6-Trimethyl-4H-1,3-dioxin-4-one***.

Ethyl Iodide[1]

[75-03-6] · C_2H_5I · Ethyl Iodide · (MW 155.97)

(esterification of carboxylic acids;[1] alkylation of amines,[6,8] alkoxides, thiolates[9] and enolates;[17,21] preparation of Grignard reagents[22])

Alternate Name: iodoethane.

Physical Data: mp -108 °C; bp 70-73 °C, *d* 1.941 g cm^{-3}.

Solubility: sol water (with decomposition), alcohol, most organic solvents.

Form Supplied in: heavy, clear, very refractive liquid; colorless when pure, becomes red on exposure to light and air due to iodine liberation; common impurities are ethanol and iodine.

Preparative Methods: prepared by reaction of ethanol and iodine in the presence of red phosphorus.

Purification: purified by shaking with dilute solution of sodium bisulfite or sodium thiosulfate until colorless; wash with water, dry ($CaCl_2$), and distill. May also be purified by passing through a column of silica gel or alumina followed by distillation.

Handling, Storage, and Precautions: store colorless solution over silver leaf or copper wire in brown bottle away from light. Avoid storing over mercury as ethylmercury(II) iodide, the byproduct of decomposition, is extremely poisonous. Harmful if swallowed, inhaled, or absorbed through the skin. Extremely harmful to mucous membranes, upper respiratory tract, eyes, and skin. Exposure can cause spasms, inflammation of contact area, coughing, nausea, and vomiting. Use in a fume hood.

Esterifications.

Ethyl iodide has seen widespread use as a reagent for conversion of carboxylic acids to ethyl esters.[1] The procedure involves treatment of a carboxylic acid with base followed by addition of ethyl iodide. The method is particularly useful with substrates containing acid-sensitive protecting groups. Conditions are varied: HMPA/NaOH (yields >95%),[2] DMSO/KOH (>90%),[3] $NaHCO_3$/DMF (>95%),[4] CsF/DMSO or DMF (92-100%).[5] The latter method was particularly useful in the direct conversion of organotin carboxylates, commonly employed to protect carboxylic acids in the presence of amines in peptide synthesis, to esters. The conversion proceeds in excellent yields (85-91%) at mild

temperatures with no racemization (eq 1).

(1)

Heteroatom Alkylation.

Various heteroatoms react with ethyl iodide. *N*-Ethylamines, hydrazines,[6] and amides have been prepared. Secondary *N*-ethylamines were prepared by Katritzky et al. in 55-65% yield via the reaction of (**1**) with ethyl iodide followed by treatment with NaOH/H_2O (eq 2).[7]

(2)

Pyrroles were *N*-ethylated (DMSO, KOH, 60% yield) during the synthesis of novel 2-azafulvenes.[8]

In a related reaction, thioethers were prepared in the presence of a Pt^{II} catalyst in 80-90% yield.[9] This reaction was developed as an alternative to the more traditional method demonstrated by Ono (DBU/benzene).[10] In a similar fashion, alcohols can be converted to the corresponding ethyl ethers.

C-Alkylations.

Alkylation of carbon nucleophiles with ethyl iodide is a convenient method for introducing an ethyl group at a carbon center. The substrates are treated with base (*t*-BuOK,[11] NaOEt,[12] *n*-BuLi,[13] NaHMDS,[14] LiHMDS,[15] LDA,[16] etc.) followed by quenching with ethyl iodide. The solvent is usually, but not limited to, THF or diethyl ether. Temperatures and reaction times vary depending on the specific substrate. Yields also vary but most appear to be good to excellent (>80%). A variety of compounds have been prepared including introduction of quaternary chiral centers at bridgehead positions (eq 3).[17]

Asymmetric alkylation reactions have also taken advantage of the versatility of this reagent. Such chiral enolate systems as oxazolidinones,[18] dihydropyrimidinones,[19] camphorsulfonamides,[20] and chiral lactams[21] have been alkylated in high chemical and optical yields. Meyers et al. utilized chiral lactams in a general preparation of cyclohexenones bearing a tertiary or quaternary chiral center at the C-4 position (eq 4).[21]

Grignard Reagent.

Conversion of ethyl iodide to its Grignard reagent proceeds easily (Mg, Et_2O, 0 °C). An example of the utilization of this reagent can be found in the synthesis of a debromoaplysin analog (eq 5).[22]

Ethyliodomethylzinc[1]

ICH_2ZnEt

[33598-72-0] · C_3H_7IZn · Ethyliodomethylzinc · (MW 235.39)

(cyclopropanation reagent[1])

Alternate Name: Sawada reagent.

Preparative Methods: obtained by the reaction of ***Ethylzinc Iodide*** with ***Diiodomethane*** in ether at 30-35 °C[1] or by the reaction of diiodomethane with ***Diethylzinc***.[2]

Handling, Storage, and Precautions: decomposes slowly at room temperature; should be handled under nitrogen and in the absence of moisture.

Cyclopropanation Reactions.

Ethyliodomethylzinc (Sawada reagent) is a useful cyclopropanation reagent which gives, in many cases, better yields than the Simmons-Smith reagent[2,3] (see ***Ethylzinc Iodide*** and eqs 1 and 2).[1] Although formulated as ethyliodomethylzinc, the actual reagent may well be ***Iodomethylzinc Iodide***.[1] The difference of reactivity with the Simmons-Smith reagent may be due to the presence of different zinc salts and to the slightly different reaction conditions used for their generation. Contrary to the Furukawa reagent (CH_2I_2 and Et_2Zn, see ***Diethylzinc***), the Sawada reagent (CH_2I_2 and EtZnI) does not react well with enol ethers[1] and gives moderate yields in the case of α,β-unsaturated esters (eq 3).[1]

(1)

X = Et, Furukawa reagent, 79%
X = I, Sawada reagent, 92%

(2)

X = Et, Furukawa reagent, 60%
X = I, Sawada reagent, 77%

(3)

Interestingly, the polycyclic ketone (**1**) is efficiently converted to the corresponding cyclopropane derivative (**2**) in high yield (eq 4).[4] The related aluminum reagent prepared by the reaction of ***Trimethylaluminum*** and CH_2I_2 has proven to be a powerful cyclopropanation reagent (eqs 5 and 6).[5] Finally, ethyl iodomethylzinc allows the methylation of various phenols at high temperature (eq 7).[6]

Ethyl Isocyanoacetate[1]

(R = Et)

[2999-46-4] · $C_5H_8NO_2$ · Ethyl Isocyanoacetate · (MW 113.14) (R = Me)

[39687-95-1] · $C_4H_6NO_2$ · Methyl Isocyanoacetate · (MW 99.11)

(heterocycle formation accompanied by cyclization onto the isocyano group;[1] forms stabilized carbanion for alkylations in amino acid synthesis;[1] α,α-additions to isocyano group and Passerini reactions[2])

Physical Data: ethyl ester, bp 89-91 °C/11 mmHg; methyl ester, bp 59-60 °C/3 mmHg.

Solubility: slightly sol H_2O; sol organic solvents.

Form Supplied in: yellow oils.

Preparative Methods: α-isocyanoacetate esters are most conveniently prepared by dehydration of the corresponding *N*-formylamino acid esters using ***Phosphorus Oxychloride*** in the presence of ***Triethylamine*** in CH_2Cl_2.[3]

Purification: by distillation.

Handling, Storage, and Precautions: isocyano compounds are generally quite sensitive to acids and immediately decompose to amine or formamide derivatives. They must be stored under N_2 at 0 to -20 °C. All operations should be performed in a well-ventilated fume hood because of the strong, disagreeable odor, and the equipment should be washed with acid after use.

Heterocycle Formation by Electrophiles.

Isocyanoacetates having hydrogen at the carbon flanked with two activating groups can easily form the carbanion. α-Metalated (anionic) isocyanoacetates, which are obtained by means of the usual bases in carbanion chemistry such as NaH, *t*-BuOK, *n*-BuLi, DBU, and Et_3N, permit attack of various electrophiles. The ambivalent nature of the isocyanide carbon atom allows nucleophilic cyclization to form heterocycles after addition to polar multiple bonds such as

carbonyl, imino, thioxo, nitrile, active alkene, etc. (eq 1).

Reaction of α-anions from isocyanoacetate with acylating agents gives oxazole-4-carboxylates via cyclization of the enol form onto the isocyano group (eq 2).[4] 3-Amino-4-hydroxycoumarins and 2(1*H*)-quinolinones are synthesized by reactions with acetyl or salicyloyl chlorides[5] and benzooxazinones[6] followed by acid hydrolysis in a straightforward reaction. The addition of an arylsulfenyl chloride to the carbenoid carbon of ethyl isocyanoacetate followed by treatment with ***Triethylamine*** affords 2-arylthio-5-ethoxyoxazoles in situ (eq 3).[7] Reaction with nitriles in the presence of ***Potassium Hydride*** in diglyme affords 5-substituted imidazole-4-carboxylates[8] and reactions with Schiff bases (imino compounds) form imidazolines.[9]

Ethyl isocyanoacetate reacts with ***Carbon Disulfide*** to give thiazolethiolates in the presence of ***Potassium t-Butoxide***, which provide 5-(methylthio)thiazole-4-carboxylates with ***Iodomethane*** (eq 4).[10]

The coupling reactions with arenediazonium ions give 1-aryl-1*H*-1,2,4-triazole-3-carboxylates via cyclization of hydrazone compounds in the presence of sodium acetate in aq MeOH.[11] Condensation with heteroallenes such as isocyanates and isothiocyanates generates oxazole and thiazole skeletons, but the reactions give complicated products under various reaction conditions.[12] Michael addition proceeds easily with C-C bond formation, while α,β-unsaturated carbonyl compounds on heating to 70-80 °C provide pyrrolines accompanying further cyclization by insertion of the anion into the isocyano group.[13] When a nitroalkene is the Michael acceptor, 3,4-disubstituted pyrrole-2-carboxylates are obtained by cyclization and elimination of the nitro group (eq 5).[14]

(5)

Reactions with Aldehydes and Ketones.

Reactions with carbonyl compounds as electrophiles afford many valuable products. For example, formylaminoacrylates are obtained in the presence of *t*-BuOK or NaH via isomerization of the oxazolinyl anion by proton shift from C-4 to C-2 followed by elimination (eq 6).[15] In the presence of NaCN in EtOH, *trans*-2-oxazoline-4-carboxylates are produced by protonation of the oxazolinyl anion.[16] The use of metal catalysts such as NiCl and Cu_2O also gives the oxazoline products. Especially, in the presence of a gold(I) complex (**1**) coordinated to a chiral ferrocenylphosphine ligand (**2**), oxazoline-4-carboxylates are formed with high enantio- and diastereoselectivity (eq 7).[17]

(6)

(1) **(2)**

Formamidine derivatives are also formed using pyrrolidine or piperidine as bases in MeOH by insertion of the bases into the isocyano group of α-isocyanoacrylate, which is proposed as an intermediate (eq 8).[18] The reaction with aldehydes in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** in THF affords pyrrole-2,4-dicarboxylates via Michael addition by another equivalent of methyl isocyanoacetate to the proposed intermediate, i.e. methyl isocyanoacrylates (eq 8).[19] Reaction with acetaldehyde in the presence of Et_3N in benzene affords methyl α-isocyano-β-hydroxybutyrate (eq 8).[20]

α-Activating Group for Amino Acids Synthesis.

Carbon-carbon bond formation at the α-carbon of α-isocyanoacetates by alkylation with carbon electrophiles provides a useful preparative method for the synthesis of various amino acid derivatives, since the isocyano group is easily converted to the amino group by acidification. Hence, isocyanoacetates are regarded as synthetic equivalents for α-activated amino acids (eq 9).[1]

Reactions of α-metalated α-isocyanopropionate with alkyl halides and Michael acceptors followed by hydrolysis give α-methyldopa,[21] α-methylhistidine,[21] and α-methylglutamic acid.[22] Palladium-catalyzed allylation of ethyl α-isocyanopropionate with allyl acetate in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** affords α-allylalanine ethyl ester after acidification.[23] Furthermore, 2-oxazoline-4-carboxylates, which are accessed readily by reaction with aldehydes and ketones as described in the above section, are easily converted to β-hydroxy-α-amino acid derivatives by acid hydrolysis.[1] In the same way, oxazole-4-carboxylates obtained by reaction with acylating agents are hydrolyzed to give *C*-acylamino acid esters.[4]

Insertion into the Isocyano Group.

α,α-Additions to the isocyano group are well known reactions in catalytic chemistry.[24] Furthermore, the Passerini reaction, which provides α-acyloxycarboxamide from isocyano compounds, ketones, and carboxylic acids,[25] and the Ugi reaction (four-component condensation: 4CC)[26] are unique peptide synthetic methods. As an application of the 4CC, the reaction of 3-aryloxy-4,5-dihydroxypyrrole, which is an intramolecular condensation product of the aldehyde and amine components, with ethyl isocyanoacetate and benzoic acid affords *N*-benzoyl-β-aryloxyprolylglycinate (eq 10).[27]

Related Reagents.

(2S,4S)-3-Benzoyl-2-t-butyl-4-methyl-1,3-oxazolidin-5-one; ***t-Butyl Isocyanide***; ***Diethyl Isocyanomethylphosphonate***; ***Ethyl N-(Diphenylmethylene)glycinate***; ***Phenyl Isocyanide***; ***1,1,3,3-Tetramethylbutyl Isocyanide***; ***p-Tolylthiomethyl Isocyanide***; ***p-Tolylsulfonylmethyl Isocyanide***.

(chiral pool reagent for synthesis; occasionally used as a chiral auxiliary)

Alternate Name: ethyl L-(-)-lactate.

Physical Data: (*S*)-(R = Et) bp 154 °C, 69 °C/36 mmHg, *d* 1.031 g cm^{-3};[20] (*R*)-(R = Et) bp 58 °C/20 mmHg, *d* 1.032 g cm^{-3};[20] (*S*)-(R = Me) bp 40 °C/11 mmHg, *d* 1.086 g cm^{-3};[25] (*R*)-(R = Me) bp 58 °C/19 mmHg, *d* 1.091 g cm^{-3};[20] (*R*)-(R = Bu) bp 77 °C/10 mmHg, *d* 0.974 g cm^{-3}.[27]

Solubility: sol water, alcohols, ethers, THF, and common organic solvents.

Form Supplied in: liquid; commercially available.

Use as a Chiral Pool Reagent.

(*S*)-Ethyl lactate has been extensively used as a chiral pool reagent, often via transformation into a diverse array of simple, enantiomerically pure analogs. Principal among these are a variety of *O*-protected (*S*)-2-hydroxypropanals (eq 1).

(1)

These have been prepared by various combinations of straightforward steps including ester to amide conversion, alcohol protection, direct reduction of the ester or amide to the aldehyde group, and reduction of the ester to the alcohol followed by reoxidation to the aldehyde. The sensitivity of the (*S*)-propanals to epimerization has been of paramount concern. One of the best procedures which avoids racemization and has been run on a preparative scale is noted (eq 2).[1]

(2)

Subsequent reduction also affords (*S*)-2-benzyloxypropanol in 89% yield. NMR assay of the (*R*)- and (*S*)-Mosher esters indicated no racemization over the sequence. Synthesis via oxidation of (*S*)-benzyloxypropanol (eq 3) provides the benzyloxypropanal with <8% racemization.[2]

(3)

Attempted formation of the benzyl ether of (*S*)-ethyl lactate with NaH/BnBr results in considerable racemization (50-75% ee). This racemization is obviated by use of the amide analog noted in eq 2. ***Diisobutylaluminum Hydride*** has been used to convert the ester directly to the aldehyde employing the methoxymethyl,[3,4] benzyl,[2,5] 2,6-dichlorobenzyl,[6] *t*-butyldiphenylsilyl,[7] benzyloxymethyl,[8] THP,[9] trityl[10] and TBDMS[11] protecting groups. Protected (*S*)-2-hydroxypropanals have been used in synthetic studies relating to sugars,[12-15] amino sugars,[16] thiotetronic acids,[17] antimycin-A_3,[18] rhodinose,[19] aplysiatoxin via the (*R*)-lactate,[20] (-)-sarracenin,[21] and for preparation of enantiomerically pure 1-methyl-2-alkenyl-*N*,*N*-diisopropylcarbamates from the (*R*)- and (*S*)-lactates.[22]

(*S*)-Ethyl lactate has also been used as a ready source of (*S*)-propane-1,2-diol and (*S*)-methyloxirane (eq 4).[23,24] These compounds have been used for preparation of numerous natural products including nonactin,[25] sulcatol,[26] recifeiolide,[27] methyl-1,6-dioxaspiro[4,5]decanes, the pheromone components of *Paravespula vulgaris*,[28] and the rhynchosporosides.[29] The (*S*)-oxirane has also been used in the synthesis of chiral macrocyclic poly(ether diester)ligands.[30] A convenient procedure for preparation of the (*R*)-methyloxirane via mesylate activation, reduction, and internal inversion has been reported.[31]

(4)

A variety of inverted analogs of (*S*)-ethyl lactate have been prepared by standard activation displacement procedures. Included are the (*R*)-propionyloxypropionate (mesylation/$EtCO_2Cs$-DMF);[32] azide (Mitsunobu conditions);[33,34] aryloxy ethers (mesylation/aryl oxide);[35] chloride ($SOCl_2$-DMF);[36] bromide (sulfonation/$MgBr_2$);[37] mercapto analogs (Mitsonobu conditions);[38,39] amino analogs (triflate/amine);[40] hydroxylamines;[41,42] and selenides.[43]

Protected (*S*)-ethyl lactate cleanly acylates methyllithium to afford the 2-butanone with essentially complete enantiomeric fidelity and in nearly quantitative yield. Various diastereoselective constructions were achieved by nucleophilic addition to the ketone (eq 5).[44] For example, addition of vinyllithiums, followed by acetal formation and Lewis acid-mediated rearrangement, provided a ready entry into the indicated 3-acyltetrahydrofurans.

(5)

(*S*)-Ethyl lactate has been used to prepare (*S*)-2-methyloxetane in modest yield with <0.5% racemization by a series of standard transformations (eq 6).[45]

(6)

Other small chiral molecules have also been prepared by straightforward transformations (eq 7).[46]

(*S*)-Ethyl lactate has also been used as a chiral fragment for numerous other studies. Included are synthetic efforts relating to salenomycin,[47] (-)-biopterin,[48] (+)-polyoxamic acid,[49] jaspamide,[50] the enantiomeric 2-pentanols,[51] pumilitoxin B,[52,53] D-ristosamine,[54] protomycinolide IV,[55] and tirandamycin.[56]

Use as a Chiral Auxiliary.

(*S*)-Ethyl lactate has been used as a chiral auxiliary in a variety of simple Diels-Alder reactions.[57-60] As the fumaric acid diester, the de employing cyclopentadiene can almost be completely reversed by addition of ***Titanium(IV) Chloride*** (eq 8).[61] In general, superior de values are achieved using ***(R)-Pantolactone*** in this context, and also for base-mediated addition to ketenes.[62]

(*S*)-Ethyl lactate was used for diastereocontrol and asymmetric transmission in a sequential 2,3-Wittig-oxy-Cope rearrangement, affording product in 91% ee (eq 9).[63,64] Excellent asymmetric induction has also been noted in the Lewis acid-mediated ene reaction of (*S*)-ethyl lactate-derived intermediates (eq 10).[65]

(c) KH, 18-crown-6, 25 °C, 75%

R = Et, Ph
$R^1 = C_6H_{13}$, aryl, styryl

(10)

86-97% ee

(*S*)-Ethyl lactate has been used to enantioselectively protonate the indicated enolate at -100 °C to afford the (*R*)-ketone in 73% yield and 73% ee (eq 11).[66]

(11)

Applications to Products of Commercial Interest.

(*S*)-Ethyl lactate has been incorporated in chiral syntheses of (*S*)-2-arylpropionic acids, an important class of nonsteroidal anti-inflammatory agents, including ibuprofen and naproxen (eq 12).[67 -69] These syntheses, though elegant in concept, are unlikely to compete with existing industrial methods for production of the (*S*) enantiomers of these drugs.

(12)

(*S*)-Ethyl lactate has also been used to synthesize the important 4-acetoxyazetidinone intermediate, crucial to numerous carbapenem syntheses. The key step in its use was the diketene addition to the (*S*)-lactaldehyde imine, which in the best case proceeded in 67% yield with a 10:1 ratio of diastereomers (eq 13).[70,71]

(13)

Other applications to β-lactam syntheses have been reported.[72-74]

Related Reagents.

Ethyl Mandelate; ***(R)-Pantolactone***.

Ethyl Lithioacetate

(R = Et)

[56267-15-3] · $C_4H_7LiO_2$ · Ethyl Lithioacetate · (MW 94.05) (R = Me)

[57570-85-1] · $C_3H_5LiO_2$ · Methyl Lithioacetate · (MW 80.02) (R = *t*-Bu)

[53503-61-0] · $C_6H_{11}LiO_2$ · *t*-Butyl Lithioacetate · (MW 122.11) (R = Bn)

[71010-30-5] · $C_9H_9LiO_2$ · Benzyl Lithioacetate · (MW 156.12)

(two-carbon nucleophile in ester enolate alkylation, condensation, conjugate addition, and transmetalation reactions)

Solubility: sol THF.

Form Supplied in: white solids.

Analysis of Reagent Purity: the ^1H and ^{13}C NMR spectra (C_6D_6/THF solutions) for *t*-butyl lithioacetate have been reported.[1]

Preparative Methods: solutions of lithioacetates are prepared by addition of the appropriate ester to a 1 M THF solution of ***Lithium Diisopropylamide*** maintained at -78 °C. Enolate formation is complete within 15 min and the solutions are normally used directly.[2] Enolization of *t*-butyl acetate in hexane produces a precipitate of amine-free enolate.[1,3] Solutions of the ester enolates are stable at -78 °C, but Claisen ester condensation products form rapidly at 25 °C, perhaps via a ketene intermediate.[4] This instability requires that reactions of the ester enolates be completed at as low a temperature as possible and is perhaps the major limitation to their use.

Alkylation Reactions.[5]

Alkylation of lithioacetates with primary organic halides generally occurs without significant problems of dialkylation or *O*-alkylation.[6] Typically, HMPA is added so that alkylation can be completed at low temperatures. Alkylation

procedures with α-chloroboronic esters,[7] α-halo esters,[8] triflates,[9] and halo epoxides[10] have been reported. In at least one case, alkylation with an epoxide has been achieved (eq 1).[11a] In the case of cyclohexene epoxide, the yield is improved by using the diethylaluminum derivative.[11b] Arylation or vinylation can be achieved by photostimulated reaction with aryl halides,[12] by means of a nickel catalyst,[13] and by reaction with arenetricarbonylchromium complexes (eq 2).[14]

Aldol Condensations.[2]

Aldol condensations of lithioacetates usually proceed rapidly and stable lithium aldolates are obtained with both aldehyde and ketone substrates at -78 °C. If reaction mixtures are allowed to warm prior to quenching, lower yields of β-hydroxy esters may be obtained.[15] Diastereoselective reactions with a variety of chiral aldehydes have been reported.[2,16] Relatively high selectivity (13:1) is obtained with epoxy aldehydes (eq 3).[16a] Condensation of lithioacetates with imine substrates has been used to prepare β-lactams.[17]

Acylation Reactions.[18]

The acylation of lithioacetates with a variety of acylating agents is possible, including esters,[19] acid chlorides,[20] acyl imidazoles,[21] anhydrides,[22] and thionolactones.[23] In most cases, yields are limited by proton exchange of the acidic β-keto ester product with the starting enolate. This is usually allowed for by using an excess of amide base,[20] or, more commonly, an excess of the lithioacetate (eq 4).[19a]

Conjugate Additions.[24]

Conjugate additions of lithioacetates to unsaturated esters,[25] thioamides,[26] acyl ylides,[27] sulfonium salts,[28] and ketones,[29] and to ketene thioacetal monoxides,[30] have been reported. Exceptionally bulky Lewis acids have been used to favor conjugate addition over carbonyl addition to unsaturated ketones.[31] The enolate product of conjugate addition reactions can be used for subsequent alkylation (eq 5)[32] or alkenation (eq 6)[25a] reactions.

Transmetalation Reactions.

Lithioacetates have been transmetalated by a variety of metal compounds including ***Cerium(III) Chloride***,[33] ***Tri-n-butylchlorostannane***,[34] titanium alkoxides,[35] ***Diethylaluminum Chloride***,[11b] and complexes of nickel and palladium.[36] Reaction of lithioacetates with ***Chlorotrimethylsilane*** gives a mixture of *C*-silylated and *O*-silylated products (eq 7).[6]

Ethyl Lithiopropiolate

(R = Et)

[72036-30-7] · $C_5H_5LiO_2$ · Ethyl Lithiopropiolate · (MW 104.04) (R = Me)

[72036-29-4] · $C_4H_3LiO_2$ · Methyl Lithiopropiolate · (MW 90.01) (R = *t*-Bu)

[-] · $C_7H_9LiO_2$ · *t*-Butyl Lithiopropiolate · (MW 132.10) (R = $CH_2CH{=}CH_2$)

[109907-88-2] · $C_6H_5LiO_2$ · Allyl Lithiopropiolate · (MW 116.05)

(used in synthesis of alkynic alcohols by addition to aldehydes, ketones,[1] or epoxides[2])

Preparative Methods: by treating the alkyl propiolate (e.g. ***Methyl Propiolate***) with ***n-Butyllithium*** at low temperature.[1] An alternative method uses ***Lithium Diisopropylamide*** (LDA).[2]

Handling, Storage, and Precautions: alkynyllithium reagents are air- and moisture-sensitive. These reagents decompose above -78 °C. The ethyl derivative seems to be slightly more stable than the methyl compound. Ethyl and methyl propiolate should be handled with caution.

Synthesis of Propargyl Alcohols.

The lithium reagent rapidly adds to a variety of aldehydes and ketones to give the alkynic alcohols (eqs 1 and 2).[1] These products may be converted into γ-butenolides and γ-lactones.[3] The use of ***Cerium(III) Chloride*** provides higher yields in some cases (eq 3).[4]

(1)

(2)

(3)

Synthesis of Homopropargyl Alcohols.

In the presence of ***Boron Trifluoride Etherate*** the reagent will open epoxides to provide homopropargyl alcohols (eq 4).[5] Allyl and *t*-butyl lithiopropiolates have been used in applications where an easily removable protecting group is required.[6]

(4)

Related Reagents.

3,3-Diethoxy-1-propene; ***Lithium Acetylide***; ***Propynyllithium***; ***3-Tetrahydropyranyloxy-1-propyne***.

Ethyl Lithio(trimethylsilyl)acetate[1]

[-] · $C_7H_{15}LiO_2Si$ · Ethyl Lithio(trimethylsilyl)acetate · (MW 166.25)

(reacts with carbonyl compounds to give α,β-unsaturated esters[2])

Solubility: sol ethereal solvents; reacts with protic solvents.

Preparative Methods: available by reaction of ethyl trimethylsilylacetate with ***Lithium Diisopropylamide***, lithium isopropylcyclohexylamide, or lithium dicyclohexylamide in THF at low temperature.[1b,2]

Handling, Storage, and Precautions: as with any other organometallic agent, the reagent should be used under an inert atmosphere.

Peterson Alkenation.

The use of a Peterson approach for the preparation of α,β-unsaturated esters can hold a number of advantages over a Wittig reaction or one of its derivatives.[2] In addition to an easily removed byproduct, hexamethyldisiloxane, silyl esters can provide the desired α,β-unsaturated esters in moderate to good yields when a Wittig approach fails.[1a,3] Stereoselection can also be observed. In some cases, this can be increased by use of a magnesium enolate and acidic workup.[1a,4] While the analogous Wittig approach requires the use of a stabilized ylide and, hence, usually results in the formation of just the (*E*) isomer (or the thermodynamically more stable isomer) of the α,β-unsaturated ester product, the Peterson reaction can either provide a mixture of the isomeric product alkenes, or the (*Z*) isomer if selection is seen.[5] The stereochemical differences can be interpreted in terms of the Wittig reaction being under thermodynamic control, while the Peterson method is kinetically controlled. Thus stereochemical control during the addition of the silicon reagent can result in stereoselective formation of the α,β-unsaturated ester (eq 1).[6]

(1)

Alkylations.

Alkylation of the title enolate (**1**) with alkyl iodides in the presence of HMPA allows for the preparation of higher α-silyl esters.[7]

Ester enolate (**1**) can be alkylated by vinyl halides in the presence of a nickel catalyst to afford α-trimethylsilyl-β,γ-unsaturated esters. These products react with a wide variety of electrophiles in the presence of a Lewis acid to provide γ-subsituted α,β-unsaturated esters (eq 2).[8]

(2)

Other Electrophiles.

In addition to carbonyl compounds, ester enolate (**1**) also reacts with other electrophiles. With nitrones, the product is dependent upon the structure of the nitrone: α,*N*-dialkyl nitrones provide alkenes, while α-aryl-*N*-alkyl nitrones or α,*N*-diaryl nitrones usually give aziridines.[9] With the phenylhydrazone of a 1,2-dicarbonyl compound, reaction with (**1**) provides a convenient preparation of 3(2*H*)-pyridazinones (eq 3).[10]

(3)

Analogs.

The ester enolates derived from methyl or *t*-butyl trimethylsilylacetate react in an analogous manner to ethyl ester (**1**) with carbonyl compounds.[1a,3,11] However, with the *t*-butyl ester the carbonyl reactant has to be an aldehyde as steric

problems result in enolization of ketonic substrates.[12] As with the ethyl ester, addition of the enolate to the carbonyl substrate may allow for stereochemical control of the resultant α,β-unsaturated ester geometry.[5c,13] In addition, the groups attached to silicon can be modified without substantial changes to the reactivity with carbonyl compounds.[14]

It is also possible to introduce additional functionality into the α-silyl ester. Thus *t*-butyl (trimethylsilyl)chloroacetate reacts with carbonyl compounds after ester enolate formation with LDA to form *t*-butyl α-chloro-α,β-unsaturated esters, although the elimination of the silyl moiety may have to be encouraged by the use of ***Thionyl Chloride***,[3,15] as it also is with the α-bromo analog.[16] A second silyl group, with its additional bulk, can allow for high stereoselection, although the outcome does depend on the metal counterion used in the enolate.[12,17]

Analogs of the ester enolate derived from higher carboxylic acids can also be prepared by the addition of an organometallic agent to ***Methyl 2-Trimethylsilylacrylate*** (**2**). The resultant ester enolate from the Michael addition can be used for a subsequent Peterson alkenation reaction when reacted with a carbonyl compound (eq 4).[18]

(4)

The sterically demanding *t*-butyl ester enolate reacts with acylimidazoles to provide β-keto esters (eq 5).[19]

(5)

The ester enolates derived from the methyl or *t*-butyl esters react with lactones to yield vinyl ethers as a mixture of isomers (eq 6).[20]

(6)

With cyclopentenone derivatives, 1,4-addition is observed for the ester enolates of methyl and *t*-butyl trimethylsilylacetate,[21] although 1,2-addition occurs with acyclic conjugated enals.[11,12] With a steroidal cyclopentenone substrate, both 1,2- and 1,4-addition were observed.[22] Conjugate addition is observed for the methyl ester with chiral vinyl sulfoxides. High enantioselectivity can be attained (eq 7).[23]

(7)

As with the ethyl ester, other ester derivatives can be alkylated through their lithium enolates.[24] Use of the menthyl ester provides a route to chiral silanes (eq 8).[25]

Related Reagents.

t-Butyl* α*-Lithiobis(trimethylsilyl)acetate; ***t-Butyl Trimethylsilylacetate***; ***Ethyl Bromozincacetate***; ***Ethyl Lithioacetate***; ***Ethyl Trimethylsilylacetate***; ***Ketene Bis(trimethylsilyl) Acetal***; ***Ketene t-Butyldimethylsilyl Methyl Acetal***; ***1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene***; Methyl (Methyldiphenylsilyl)acetate; ***Methyl 2-Trimethylsilylacrylate***; ***Triethyl Phosphonoacetate***; ***Trimethylsilylacetic Acid***.

Ethyllithium[1]

EtLi

[811-49-4] · C_2H_5Li · Ethyllithium · (MW 36.01)

(organometallic reagent used in 1,2-[2] and 1,4-additions;[2a,b,3] synthesis of various transition metal complexes;[4] used as a base in the preparation of 2-bromofuran,[5a] with phenylallene to form terminal alkynes,[5b] as a catalyst in conjunction with TMEDA in the alkylation of amines with alkenes;[5c] used for the in situ preparation of lithium diethylcuprate,[2a,3b,6] and EtCu(CN)Li.BF_3[6])

Physical Data: mp 95 °C; sublimes at 80 °C/10^{-3} mmHg.

Solubility: sol hydrocarbons, THF, Et_2O.

Form Supplied in: approx. 1 M light brown solution in benzene.

Preparative Methods: prepared from alkyl halides and elemental lithium.[8a-e]

Purification: recrystallized from hexane[8e] or cyclohexane[8c,d] under argon at 4 °C to give a white solid.

Handling, Storage, and Precautions: the dry solid is extremely pyrophoric on exposure to air. Solutions are flammable, corrosive and react violently with water and should be used immediately. Storage for as little as one week at low temperatures can lead to up to one-half of the reagent being converted to ethane, ethylene, and the enolate of acetaldehyde.[3a,8a,d,e]

Nucleophilic Addition.

Ethyllithium is known to add as a nucleophile to α,β-unsaturated ketones in both a 1,2- and 1,4-manner. Addition of ***Hexamethylphosphoric Triamide*** (HMPA) enhances selectivity of 1,4-addition, as illustrated in eq 1. This selectivity is also affected by coordinating ability of the solvent. A general order for increasing 1,4-selectivity is EtLi (pet. ether) <= EtLi (Et_2O) <= EtLi (1 equiv HMPA) <= EtLi (2 equiv HMPA).[2a] Similar results were obtained for reactions with MVK, 2-cyclohexen-1-one, and 2-cycloocten-1-one.

	1,2-addition, rearrangement	1,4-addition
EtLi	80%	20%
EtLi + HMPA (1 equiv)	24%	76%
EtLi + HMPA (2 equiv)	0%	100%

Ethyllithium undergoes nucleophilic addition with pyridine to afford exclusively the 1,2-adduct. When used in conjunction with diethylmagnesium, however, significant amounts of 1,4-adducts are observed (eq 2). This mixed organometallic system also provides enhanced 1,4-selectivity when reacted with 2-cyclohexen-1-one.[2b]

EtLi	100%	0%
mixed system	27%	54%

1,2-Addition of ethyllithium to triethyl phosphate is known to generate precursors for Horner reagents, as shown in eq 3.[2c,d]

Addition to benzoquinone is exclusively 1,2- with the second addition favoring the *cis* isomer by a 4:1 ratio.[2e] Also

noted is 1,2-addition to amides followed by dehydration of the resulting aminal.[2f] Ethyllithium acts first as a base and then as a nucleophile in its reaction with aldehyde-*O*-alkyloximes. Ethyl ketones are prepared by their reaction with ethyllithium followed by hydrolysis of the imine (eq 4).[2g]

(4)

Azophilic 1,2-addition has been observed for the addition of ethyl- and *n*-butyllithium to fluorenimines.[2h] Superior diastereoselectivity to titanium and copper reagents is exhibited by EtLi in its 1,2-addition to acrolein dimer during chelation-free formation of the dihydropyranols illustrated in eq 5. Complementary selectivity is possible when other reagents are employed.[2i]

(5)

Metal-mediated asymmetric 1,2-nucleophilic attack by ethyllithium at C-2 (eqs 6 and 7) occurs exclusively *exo* to the $Fe(CO)_3$ group of (vinylketenimine)tricarbonyliron(0) complexes to give chiral quaternary centers of high optical purity.[2j]

(6)

On the contrary, chelation-controlled 1,4-addition of ethyllithium to acylketene acetals with diastereoselective enolate trapping has been reported (eq 8).[3a,b]

Similarly, tandem 1,4-additions of alkyllithium reagents to chiral aromatic and unsaturated oxazolines followed by electrophilic trapping with ***Iodomethane*** proceed in good yield and with excellent diastereoselectivity (eq 9).[3c]

Synthesis of Organometallic Complexes.

Ethyllithium has been employed in the synthesis of ethylenic organometallic compounds,[4] including a Ziegler-Natta polymerization precursor complex that contains both an alkyl ligand and a coordinated alkene (eq 10),[4a] and a hydridobis(ethylene)rhenium(I) complex (eq 11).[4d]

$$HfCl_4 + 6\,EtLi + 2\,TMEDA \longrightarrow [Li(TMEDA)]_2[Hf(C_2H_4)Et_4] \quad (10)$$

(11)

Use as a Base.

A clean procedure for the preparation of 2-bromofuran involves the lithiation of furan in diethyl ether followed by treatment with elemental ***Bromine*** (eq 12).[5a] Solutions of other alkyllithium reagents are impractical for this procedure due to the necessity of removal of less volatile solvents prior to their subsequent replacement by Et_2O.

(12)

Reaction of phenylallene with two equivalents of ethyllithium followed by reaction with reactive electrophiles provides access to terminal alkynes (eq 13).[5b] The intermediate dianion readily undergoes alkylation exclusively at the sp^3 center.

(13)

Ethyllithium serves as catalytic base in the alkylation of amines with alkenes in the presence of TMEDA.[5c]

Preparation of Other Reagents.

The in situ preparations of ***Lithium Diethylcuprate***[2a,6] and $EtCu(CN)Li.BF_3$[7] are widely documented. A chiral mixed ethylcuprate was used to produce (*R*)-(+)-3-ethylcyclohexanone with high selectivity (ee >95%) only when freshly prepared and recrystallized ethyllithium was used to make the reagent. Trace alkoxide contamination lowered the ee to

9%.[6b]

Related Reagents.

Diethylzinc.

Ethylmagnesium Bromide

EtMgBr

[925-90-6] · C_2H_5BrMg · Ethylmagnesium Bromide · (MW 133.28)

(ethyl group introduction; used for preparation of other Grignard reagents)

Solubility: sol diethyl ether (6.8 M L^{-1}), dibutyl ether (5.4 M L^{-1}), diisopropyl ether (1.0 M L^{-1}), THF (1.5 M L^{-1}), anisole (0.28 M L^{-1}).

Form Supplied in: 3.0 M solutions in diethyl ether (*d* 1.020 g mL^{-1}), 1.0 M solution in THF (*d* 1.010 g mL^{-1}) and 1.0 M solution in *t*-butyl methyl ether (*d* 0.841 g mL^{-1}).

Preparative Methods: details for preparation and determination of concentration are available.[1]

Handling, Storage, and Precautions: for preparation and use of EtMgBr the usual requirements for Grignard reagents must be considered (anhydrous ***Magnesium*** turnings and solvents, inert atmosphere). Reaction apparatus and bottles for storage of EtMgBr should be flushed with N_2 and protected from moisture. At the end of the reaction the BrMg derivatives can be decomposed by adding dil acid. If the reaction product is sensitive to acid, hydrolysis can be done with a saturated NH_4Cl solution.[1]

Reactions with Carbonyl Compounds.

EtMgBr with aldehydes produces secondary alcohols. Various aliphatic,[2] aromatic,[3] and allylic[4] aldehydes are transformed into corresponding hydroxy derivatives in 50-100% yield. Stereoselectivity of EtMgBr addition to the terminal or secondary aldehyde group is low; the Cram and anti-Cram isomers are formed in ratio 2:1 to 4:1. Unexpected anti-Cram selectivity is achieved in the MAD- or MAT-mediated alkylation of nonchelating α-chiral aldehydes (MAD = ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)***; MAT = ***Methylaluminum Bis(2,4,6-tri-t-butylphenoxide)***).[5] The Cram selectivity is enhanced (9:1) with addition of crown reagents;[6] nevertheless, Et_2Mg gives Cram isomers with greater selectivity than EtMgBr.crown. ***Hexamethylphosphoric Triamide*** as cosolvent also affects the stereochemistry of addition.[7]

Addition of EtMgBr to ketones (including cyclobutanone and macrocyclic ketones[8]) produces tertiary alcohols. The addition of ***Cerium(III) Chloride*** suppresses side reactions of enolizable ketones.[9] Stereoselectivity of the addition depends on ketone structure, solvent, temperature,[10] and reagents for stereoselective activation (eqs 1-3).[5,11]

X	°C	Yield (%)	(2*S*):(2*R*)
I	-78	89	53:47
Br	-78	86	11:89
Br	0	94	3:97

Highly stereoselective (92:8) addition to 2-acetyl-1,3-oxazine derivatives (eq 2)[12] is controlled by chelation to the oxygen rather than the nitrogen atom of the ring. Addition opposite to the 2-substituent side with formation of *cis*-cyclohexanols is predominant for 2-substituted cyclohexanones (eq 3).[13] 3-Substituted *N*-alkylpiperidin-4-one derivatives[14] react in a similar stereoselective manner. Addition to 4-*t*-butylcyclohexanones is nonselective: equal amounts of both equatorial and axial cyclohexanols are produced. The organoaluminum compound MAD[5] can be used for stereoselective activation to produce equatorial cyclohexanols exclusively.

In general, esters with an excess of Grignard reagent produce tertiary alcohols[15] (secondary alcohols from formic acid esters). In contrast, the one-pot synthesis of secondary alcohols from esters and EtMgBr/***Lithium Borohydride*** results from a slow addition of EtMgBr to the ester to provide a ketone intermediate which is reduced rapidly with $LiBH_4$ to form a secondary alcohol (eq 4).

(4)

EtMgBr can be used for ester *O*-acyl bond cleavage and removal of common acyl groups[16] without affecting base-sensitive groups (silyl ether, halide, or phosphate) adjacent to the ester (eq 5). Debenzoylation of secondary alkyl esters requires excess of the reagent (up to 30 equiv). Interaction of alkyl esters with EtMgBr in the presence of ***Titanium Tetraisopropoxide*** results in hydroxy cyclopropane formation (eq 6). Ring opening produces an ethyl ketone.[17]

(5)

(6)

γ-Butyrolactone treated with EtMgBr in excess generates 4-ethylhexane-1,4-diol (eq 7).[18] α-Silylated derivatives of γ-butyro- and γ-valerolactone react with the Grignard reagent to give 2-substituted 4,5-dihydrofurans,[19] useful for the production of γ-keto acids (eq 8).

(7)

(8)

Halogenated 2-oxocoumarins react like γ-lactones, affording the ring-opening products and 4-ethyldihydrocoumarin derivatives (eq 9).[20] Lactone ring opening can be effected by EtMgBr in benzene, whereas in ether or THF the addition reaction is predominant.

The reaction of ***Diketene***[21] with EtMgBr in the presence of the $NiCl_2${bis(diphenylphosphino)propane} complex gives 3-methylenepentanoic acid (eq 10).

Acyl chlorides react with EtMgBr, affording ethyl ketones (eq 11). The reaction is applicable to acyl chlorides of high CH acidity.[22,23]

Cyclic anhydride reactions with EtMgBr can give products of anhydride ring opening[24] (eq 12), or the hydroxy acid formed may lactonize (eq 13).[25]

(13)

Interaction with C=C, C=N, and C&tbond;N Bonds.

The regioselectivity of EtMgBr addition to double bonds is determined by substrate structure. Regioselective 1,4-addition of EtMgBr to 2*H*-benzopyrans and 2-oxobenzopyran[26] is observed. Allenic[27] bonds and double bonds conjugated with azomethines[28] undergo 1,2-addition. Reactions with conjugated enynes[29] lead to both γ-alkynic (1,2-addition) and β-allenic (1,4-addition) compounds. Chiral zinc(II) complexes[30] catalyze the asymmetric 1,4-addition to α,β-unsaturated ketones. High stereoselectivity can be achieved in conjugate additions of γ-hydroxy enones[31] (eq 14). Preliminary complexation of EtMgBr with the alkoxide, followed by Et group transfer, results in formation of the *syn* product (*anti*:*syn* = 0:100).

(14)

Several removable chiral auxiliaries have been used to achieve diastereoselective conjugate addition (eq 15).[32,33]

(15)

Interaction of α,β-unsaturated ketones[34] with EtMgBr followed by addition of ***Chlorotrimethylsilane*** forms β-ethyl enol silyl ethers.

Reaction with 2-substituted methyl acrylates[35] results in dimerization by conjugate addition (eq 16). Successive addition of EtMgBr and aldehydes to α-alkyl acrylates affords δ-lactones.[36] The diastereoselectivity of the product

increases with the bulkiness of aldehyde employed (eq 17).

(16)

(17)

The copper-catalyzed reaction of EtMgBr with cyclic carbonates of vicinal diols[37] proceeds in S_N2' fashion and results in (*E*)-allylic alcohol formation with high diastereoselectivity (de >99%) (eq 18).

(18)

The interaction of EtMgBr with chiral *N*-enoylsultams[38] proceeds with Et group addition on the β-carbon in stereocontrolled fashion. Cross aldol condensation with the thioamide enolates forms predominantly the *threo* isomer (eq 19).[39]

Reaction of EtMgBr with the endocyclic C=N bond of benzothiazine[40] or BF_3-complexed thiazolines[41] proceeds by 1,2-addition.[42] 1,4-Addition of EtMgBr to chiral α,β-unsaturated aldimines provides an asymmetric synthesis of aldehydes (eq 20).[43]

Crotonaldehyde oxime[44] with EtMgBr gives *threo* aziridines. Diazadienes[45] with EtMgBr give enediamines and/or tautomeric β-aminoimines in polar solvents; in nonpolar solvents, *C*-alkylation products can also be isolated.

Reaction of pyridinium salts with EtMgBr produces 4-ethyl-1,4-dihydro- and 2-ethyl-1,2-dihydropyridines in variable ratios (eq 21).[46] The presence of ***Copper(I) Iodide*** (5 mol %) favors 4-addition. When the 4-position is blocked, a regiospecific synthesis of 1,2-dihydropyridine may be feasible. The similar addition to the unsubstituted electrophilic position of the quinoline[47] ring is observed.

(21)

Addition of EtMgBr to nitriles forms ketimine-magnesium derivatives; hydrolytic workup gives ethyl ketones. Ketones are obtained from *p*-substituted benzonitrile,[48] 4-cyanomethylisoxazole, and isothiazole derivatives.[49] Treatment of cyanohydrin OTMS derivatives[50] with EtMgBr followed by hydrolysis affords α-hydroxy ketones. For sterically hindered cyano compounds,[51] forcing conditions are required (5 kbar).

Ketimine anions, generated by the reaction of nitriles with EtMgBr, are dimerized to form symmetrical azines[52] by ***Copper(I) Iodide*** and *t*-butyl peroxybenzoate (eq 22).

(22)

Reaction with Lactols, Acetals, and Aminals.

Ethylmagnesium bromide reacts with lactols to form secondary and tertiary alcohols, or the products formed from them (eq 23).[53] Such reaction can show interesting solvent effects, and can be highly diastereoselective (eq 24).[54]

(23)

(24)

Reaction between EtMgBr and a mixed orthoester results in preferential substitution of a phenoxy group (eq 25).[55] The methoxy groups of *N*-dialkylformamide dimethyl acetal[56] can be easily substituted in a similar manner.

(25)

Dialkyl acetals derived from α,β-unsaturated aldehydes[57] afford the cross-coupling product with EtMgBr in the presence of ***Titanium(IV) Chloride*** (eq 26). The $TiCl_4$-catalyzed coupling of EtMgBr with cyclic chiral acetals[58] provide a convenient route for the preparation of chiral alcohols of high optical purity (eq 27).

(26)

Reaction of dithiolane[59] derived from benzophenone with EtMgBr in the presence of a Ni catalyst proceeds in an unusual manner, with ethylidene coupling product formation (eq 28).

EtMgBr reacts with perhydrobenzooxazine derivatives[60] to provide primary amines in good chemical yield and with high enantiomeric excess. Diastereoselective ring opening of oxazoline[61] or oxadiazine[62] derivatives by EtMgBr is also observed.

Reaction with Epoxides.

Interaction of EtMgBr with (*S*)-(+)-***Epichlorohydrin***[63] and *trans*-1,2-epoxy-1,3-bis(trimethylsilyl)propane[64] proceeds with stereoselective opening of the oxirane ring.

Substitution at the sp^2 Carbon Atom.

The substitution of halogens in vinyl iodides and 2-bromo-1,4-benzodioxin, and the substitution of alkoxy groups of enol ethers,[65] are catalyzed by $NiCl_2$(dppp) or ***Tetrakis(triphenylphosphine)palladium(0)*** and proceed with retention of configuration when alkene derivatives are used. During reaction of (*E*)-(1-halo-1-alkenyl)boron esters[66] with EtMgBr the halogen substituent is replaced by the Et group with complete inversion of configuration at the vinylic center.

Substitution of the R^1R^2N group[67] is observed in the reactions of EtMgBr with diethylaminodinitrobutadienes or (3-dimethylamino-2-propenoyl)ketene dithioacetals (eq 29).

(29)

Ethylmagnesium bromide can give *ipso* substitution products with arenes and azines. When EtMgBr reacts with 2-methylsulfonyl-6-chloropyridine[68] the SO_2Me group is replaced; the chlorine atom is unaffected. An SET mechanism is probably involved, since 4-phenylsulfonylpyridine under the same conditions gives 4,4´-bipyridine. The replacement of pyrimidine 4-chloro substituents[69] by EtMgBr occurs in the presence of $NiCl_2$(dppp). The same types of catalysts, $PdCl_2$(dppf) and $PdCl_2$(dppb), are effective in the preparation of selectively monoalkylated benzenes.[70]

Substitution at Heteroatoms.

Nucleophilic cleavage of the 1,2-dithiolane S-S bond[71] by EtMgBr is a facile and selective route to mono-5-substituted 1,3-propanedithiols (eq 30). In the reaction of (1-chlorovinyl)diphenylphosphine oxide[72] with EtMgBr the chlorovinyl moiety is the leaving group.

(30)

Ring opening of 1,2-propanediol cyclic sulfite[73] by EtMgBr affords a chiral sulfinate with high regio- and stereoselectivities (eq 31).

(31)

Ephedrine sulfinamides from oxathiazolidine derivatives[74] can be obtained in a similar way using Grignard reagents, but EtMgBr gives lower diastereoselectivity in the production of sulfinamides. Asymmetric synthesis of silicon compounds[75] is achieved by an EtMgBr substitution reaction at the Si atom.

Miscellaneous.

EtMgBr is used for the preparation of alkynic Grignard reagents[76] including γ-functional Grignard reagents[77] generated from propargylic alcohols (see ***Ethynylmagnesium Bromide***). Addition of EtMgBr in the presence of CuI to alkynic Grignard reagents affords vinylic magnesium reagents.[78]

EtMgBr is used for the preparation of 2-pyridylmagnesium bromide[79] and as a base[80] for carbanion generation. Highly regio- and stereoselective cycloaddition of reactive nitrones to magnesium alkoxides of allyl alcohols[81] is realized by use of EtMgBr (eq 32).

(32)

Trifluoroacetyltriphenylsilane reacts with EtMgBr to produce 2,2-difluoroenol silyl ether (eq 33).[82]

(33)

EtMgBr is also used for thione reduction[83] and preparation of alkyl isothiocyanates[84] and organozinc[85] compounds.

Related Reagents.

t-Butylmagnesium Chloride; ***Methylmagnesium Bromide***.

Ethylmagnesium Bromide-Copper(I) Iodide[1]

EtMgBr + CuI

(EtMgBr)

[925-90-6] · C_2H_5BrMg · Ethylmagnesium Bromide-Copper(I) Iodide · (MW 133.28) (CuI)

[7681-65-4] · CuI · Ethylmagnesium Bromide-Copper(I) Iodide · (MW 190.45)

(used for preparing allenic,[2] alkenic,[2] and allylic alcohols;[3] reduces alkynes to alkenes;[4] reduces alkenyl sulfoxides to alkenyl sulfides[5])

Preparative Methods: prepared in situ under anhydrous conditions by reacting ***Ethylmagnesium Bromide*** (**1**) and ***Copper(I) Iodide*** (**2**) in varying molar ratios.

Handling, Storage, and Precautions: use in a fume hood.

S_N2' Alkylations: Preparation of Allenic, Alkenic, and Allylic Alcohols.

Allenic and alkenic alcohols have been prepared by reacting methoxy-substituted alkynyl and alkenic alcohols, respectively, with a preformed solution of ethylmagnesium bromide-copper(I) iodide (eqs 1 and 2).[2]

(1)

(2)

Kang et al.[3] used (**1**) and catalytic (**2**) in the presence of ***Boron Trifluoride Etherate*** to prepare a chiral allylic alcohol from a cyclic carbonate (eq 3). This conversion represents a 1,3-chirality transfer method.

(3)

Reduction of Alkynes.

Alkynes are reduced to the corresponding *cis*-alkenes by treatment with excess (**1**) and (**2**) (2:1) at -30 °C in ether (eqs 4-6).[4]

(4)

(5)

(6)

Reduction of Alkenyl Sulfoxides.

Treatment of α,β-unsaturated sulfoxides with (**1**) in the presence of catalytic (**2**) in ether at 0 °C affords the corresponding alkenyl sulfides with the original configuration about the vinyl group (eq 7).[5]

(7)

Ethyl Malonate[1]

(R = Et)

[1071-46-1] · $C_5H_8O_4$ · Ethyl Malonate · (MW 132.13) (R = Me)

[16695-14-0] · $C_4H_6O_4$ · Methyl Malonate · (MW 118.10) (R = *t*-Bu)

[40052-13-9] · $C_7H_{12}O_4$ · *t*-Butyl Malonate · (MW 160.19) (R = Bn)

[40204-26-0] · $C_{10}H_{10}O_4$ · Benzyl Malonate · (MW 194.20)

(synthesis of β-keto esters[2,3] and esters[4])

Physical Data: R = Et, bp 110 °C/0.05 mmHg, *d* 1.189 g cm^{-3}. R = Me, bp 80 °C/0.15 mmHg, *d* 1.128 g cm^{-3}. R = *t*-Bu, bp 90 °C/2 mmHg. R = Bn, mp 49-52 °C.

Preparative Methods: ethyl malonate is commercially available, or it may be easily prepared[1] by acidification of the potassium salt of ethyl malonate, which is also commercially available or is readily obtained from ***Diethyl Malonate***.[1] Methyl and *t*-butyl malonates can be obtained from Meldrum's acid (***2,2-Dimethyl-1,3-dioxane-4,6-dione***) by treatment with the appropriate alcohol.[5,6] Methyl malonate has also been prepared from dimethyl malonate or from potassium methyl malonate.[7] Benzyl malonate has been prepared from ***Malonyl Chloride*** and benzyl alcohol,[8a] or from dibenzyl malonate.[8c,d]

Ethyl malonate (**1**) has been most widely utilized in the efficient one-step synthesis of β-keto esters.[3,9,10] Two different approaches have been taken in this regard, both of which take advantage of the facile decarboxylation which occurs when a *C*-acyl derivative of (**1**) is subjected to a mild acidic hydrolysis. In the first procedure, treatment of (**1**) with ***n-Butyllithium*** (2 equiv) results in the formation of the dianion (**2**), which readily undergoes *C*-acylation with various acid chlorides to provide β-keto esters in excellent yields following mild acidic workup (eq 1).[3a] This methodology has been applied in the synthesis of a variety of β-keto esters.[9] A related procedure involving a milder preparation of a dianion of (**1**) has also recently been reported.[10]

(1)

In a different approach, the neutral magnesium salt of methyl malonate (**3**), prepared from $Mg(OEt)_2$ and methyl malonate (2 equiv), adds smoothly to a variety of acylimidazoles, which are themselves obtained by prior derivatization of a carboxylic acid with ***N,N´-Carbonyldiimidazole*** (CDI) (eq 2).[3b] The β-keto ester is again obtained in a single step upon a mild acidic workup.

(2)

The corresponding magnesium salts of other malonate half-esters have been prepared and utilized extensively. The mildness and versatility of this procedure have made it the method of choice for the preparation of β-keto esters, as demonstrated by the numerous recent synthetic applications which have been reported.[11] For example, homologation of the acid (**4**) to keto ester (**6**), an important intermediate in the synthesis of thienamycin, was accomplished in 86% yield with the magnesium salt of *p*-nitrobenzyl malonate (**5**) (eq 3).[11a] This methodology has also been applied in the synthesis of β-keto esters from amino acids.[12]

In a one-step alternative to the classical malonic ester synthesis, the dianion (**2**) has been alkylated with a number of alkyl halides. Subsequent decarboxylation leads to various esters in moderate yield (eq 4).[4]

Ethyl malonate has been used in the preparation of cinnamic and acrylic acid derivatives under modified Doebner/Knoevenagel conditions.[13] Ethyl 2,4-pentadienoate has been prepared in a one-pot, high yielding application of this procedure (eq 5).[13a]

An intermolecular carbolactonization of alkenes with (**1**) in the presence of ***Manganese(III) Acetate*** has been employed in the preparation of various γ-lactones in good yields (eq 6).[14]

Activated derivatives of (**1**), such as the corresponding acid chloride or ***1-Hydroxybenzotriazole*** ester, have been utilized in the preparation of various mixed malonate esters or amides by reaction with alcohols or amines,

respectively.[8d,15]

Chiral monosubstituted[16] and disubstituted[17] derivatives of (**1**) are useful intermediates for the preparation of chiral synthons which have been applied in the synthesis of sesquiterpenes containing a quaternary chiral center (eq 7).[17a]

(1)

Mandelic acid esters are also useful chiral auxiliaries because both enantiomers are commercially available and inexpensive. For example, they serve as useful chiral auxiliaries in Diels-Alder reactions (de >95%) (eq 2)[3] and as precursors for chiral acetals.[7]

(2)

Optically active mandelic acid esters are also useful as derivatizing agents for NMR analyses of the enantiomeric purity of isotopically substituted carboxylic acids, alcohols, and amines through analysis of the corresponding derivatives using either the carboxyl group or the hydroxy group.[4]

Related Reagents.

Ethyl Metaphosphate[1]

[4697-37-4] · $C_2H_5O_3P$ · Ethyl Metaphosphate · (MW 108.04)

(reagent used for phosphorylation of nucleophiles when generated in situ and used as a monomer[1])

Monomeric Metaphosphates.

The chemistry of metaphosphates has been reviewed.[1] Monomeric metaphosphates are highly reactive species and are typically prepared in situ via various fragmentation processes and then trapped with appropriate nucleophiles. For example, ethyl metaphosphate has been generated by photolytic[2] and thermal[3] fragmentation of ethyloxaphosphabicyclo[2.2.2]octene. The resulting reactive ethyl metaphosphate monomer can then be trapped with various alcohols to afford phosphate derivatives (eq 1). Another preparation involves the fragmentation of alkyl α-(oximino)benzylphosphonates using anhydrous HCl in the presence of various hydroxylic trapping agents.[4] An application for this methodology was demonstrated with the modification of silica gel for potential development of new phosphorylated chromatographic materials (eq 2).[5]

Metaphosphates are highly electrophilic species and also react with various activated aromatic compounds to afford products of electrophilic aromatic substitution,[3] as well as with epoxides to afford dioxaphospholanes.[6] Due to the highly reactive nature of monomeric metaphosphates, however, the use of these reagents for organic synthesis remains limited in scope.

Cyclic Tetramer of Ethyl Metaphosphate.

While the monomeric form of ethyl metaphosphate has only limited synthetic utility, the polymeric form commonly known as ***Polyphosphate Ester*** (PPE) has been used for a number of valuable synthetic

transformations including dehydrations,[7] Beckmann rearrangements,[8] Fischer indole synthesis,[9] and *N*-alkylation.[10] A convenient large scale preparation of PPE has been described by Cava and co-workers.[11] Thus, to a mixture of 300 mL of anhydrous diethyl ether in 150 mL of chloroform is added 150 g of phosphorus pentoxide. The mixture is warmed under reflux for 4 days. The resulting solution is filtered and the filtrate concentrated in vacuo at 40 °C to afford PPE as a clear colorless oil. Polyphosphate ester, sometimes referred to as ethyl polyphosphate or polyphosphoric ester, exists as a complex mixture of polymeric cyclic and acyclic esters. (**1**) shows the structure of the cyclic tetramer [*801-24-1*] (MW 432.14). Some applications of PPE in organic synthesis are described below.

(1)

Dehydration Reactions.

PPE is commonly used to promote cyclodehydration reactions, such as the Bischler-Napieralski reaction. Thus, a key step in the synthesis of (±)-hernandine involves the cyclization of a secondary amide using PPE to afford the requisite dihydroisoquinoline (eq 3).[12] Another example of this reaction is the preparation of 5*H*-2-benzazepine analogs.[13] Polyphosphate ester is reported to be the reagent of choice for conversion of phenylpropylamines to the corresponding benzazepines (eq 4).

(3)

(4)

PPE has also been used for the preparation of 2-substituted benzimidazoles,[14] benzoxazoles, and benzothiazoles.[15] For example, condensation of *o*-aminophenol with acetic acid in the presence of PPE at 100 °C affords 2-methylbenzoxazole in 75% yield (eq 5).[15] Likewise, condensation of *o*-aminothiophenol with furan-2-carboxylic acid in the presence of PPE under refluxing chloroform gives 2-(2-furyl)benzothiazole in 64% yield (eq 6).[15] The preparation of the aforementioned benzazoles using PPE is reported to be superior to that using ***Polyphosphoric Acid*** (PPA). A general synthesis of 2,3-dihydro-4*H*-1,3-benzoxazin-4-ones based on the same protocol has also been reported. Thus condensation of a salicylamide with aldehydes or ketones using PPE affords good yields of the corresponding benzoxazinone (eq 7).[16]

(5)

(6)

(7)

Cyclization via Friedel-Crafts acylation using PPE has also been reported. For example, the ring closure of substituted 2-(2-methoxycarbonylphenylamino)benzoic acids affords the corresponding 9-oxoacridan-4-carboxylic acids in excellent yield (eq 8).[17] Other examples involving the PPE activation or dehydration of carboxylic acid moieties include the conversion of carboxylic acids to nitriles[18,19] and the preparation of thioesters from acids.[20]

(8)

Beckmann Rearrangement and Fischer Indole Synthesis.

The use of PPE to effect certain rearrangements has also been reported. For example, the oxime derived from adamantanone readily undergoes the Beckmann rearrangement to afford the corresponding lactam in 65% yield (eq 9).[8] The procedure is reported to be superior to standard procedures which give primarily second-order Beckmann fragmentation products. The preparation of indoles via Fischer indole synthesis using PPE has also been described. For example, cyclohexanone phenylhydrazone undergoes rearrangement to the indole under mild conditions (eq 10).[9]

(9)

(10)

N-Alkylation.

PPE is also an effective alkylating agent for primary and secondary amines as well as for certain nitrogen containing heterocycles. The reaction usually occurs at temperatures higher than those typically used for the previously described transformations. Thus 2-aminobenzophenone *N*-(2-hydroxyalkyl)imines are conveniently *N*-alkylated and cyclocondensed at 160 °C to afford good yields of the corresponding benzodiazepine derivatives (eq 11).[10]

Ethyl (Methyldiphenylsilyl)acetate[1]

(R = Et)

[13950-57-7] · $C_{17}H_{20}O_2Si$ · Ethyl (Methyldiphenylsilyl)acetate · (MW 284.46) (R = Me)

[89266-73-9] · $C_{16}H_{18}O_2Si$ · Methyl (Methyldiphenylsilyl)acetate · (MW 270.43) (R = *i*-Pr)

[87776-13-4] · $C_{18}H_{22}O_2Si$ · Isopropyl (Methyldiphenylsilyl)acetate · (MW 298.49) (R = *t*-Bu)

[77772-21-5] · $C_{19}H_{24}O_2Si$ · *t*-Butyl (Methyldiphenylsilyl)acetate · (MW 312.52)

(vinyl 1,1-dication synthetic equivalent in reactions with Grignard reagents;[2] reagent for Peterson synthesis of α,β-unsaturated esters[3])

Physical Data: clear to light yellow liquids. R = Et, *n*25D 1.5381; R = *i*-Pr, *n*26D 1.5398; R = *t*-Bu, *n*24D 1.5324.

Preparative Method: whereas the direct silylation of the lithium enolate of an ester normally results in the formation of a mixture of the α-silyl ester and the corresponding silyl ketene acetal, the same reaction with ***Methyldiphenylchlorosilane*** gives exclusively the α-methyldiphenylsilyl ester.[2d,4] This direct *C*-silylation is the best general route to α-silyl esters.

Purification: best purified by silica gel chromatography. The esters can be distilled through a suitable short path apparatus.

Handling, Storage, and Precautions: the esters desilylate in acid or alkaline medium. They desilylate very slowly with water or alcohols under neutral conditions.

Alkene Synthesis.

The first synthetically successful conversion of an α-silyl ester to an alkene was accomplished by the reaction of ethyl trimethylsilylacetate with 2 equiv of the Grignard reagent formed from high purity ***Magnesium*** and a primary or aryl halide, followed by elimination of the β-hydroxy silane formed (eq 1).[2a] Although the same reaction has never been

reported for ethyl α-(methyldiphenylsilyl)acetate, use has been made of the ready *C*-methyldiphenylsilylation of the lithium enolates of esters to form ethyl α-alkyl-α-(methyldiphenylsilyl)acetates.[4a] These α-silyl esters react with primary or aryl Grignard reagents to provide, after elimination, trisubstituted alkenes (eqs 2-5).[2c,d] Improved results are often obtained when the first addition is carried out with a Grignard reagent and the second with an organolithium reagent. The use of a Grignard reagent followed by an organolithium reagent allows the preparation of mixed trisubstituted alkenes (eq 5). The stereoselectivity is excellent when the elimination step is accomplished under basic conditions, but only moderate when carried out under acidic conditions.

(1)

(2)

(3)

(4)

Tetrasubstituted alkenes can be prepared in an analogous fashion from α,α-dialkyl-α-(methyldiphenylsilyl)acetate, prepared by alkylation of the corresponding α-alkyl-α-silyl ester (eqs 6 and 7).[4b] These reactions are, however, strongly influenced by the steric demands of the highly substituted α-carbon and therefore tend to give ketones even with an excess of the Grignard reagent. Alkenes are obtained only with the Grignard/organolithium reagent combination, and even this sequence sometimes succumbs to steric strain. No reports of the use of cerium reagents in these transformations have appeared.

Synthesis of α,β-Unsaturated Esters.

Yamamoto and co-workers[3c] and others[3d,e] have shown that α-trimethylsilyl acetates effect Peterson alkenation of ketones and aldehydes. The lithium enolates of α-(methyldiphenylsilyl) esters react similarly with ketones and aldehydes to give α,β-unsaturated esters (eq 8).[3a,b] In the case of α-silyl acetates, no particular advantage of either the trimethylsilyl or methyldiphenylsilyl group over the other is apparent. In the case of α-substituted α-silylacetates, the methyldiphenylsilyl group has the distinct advantage of being directly prepared by methyldiphenylsilylation of the lithium enolate of the ester.[1b] The (*E*)/(*Z*) stereoselectivity of the α,β-unsaturated ester synthesis shows no correlation

with the steric bulk of the alcohol portion of the α-(methyldiphenylsilyl)acetates. However, the (*E*)/(*Z*) ratio is affected by the temperature and mode of addition. It appears that the elimination step in the process leads to a mixture of diastereomeric alkenes.[3a,b]

(8)

R = Et, *i*-Pr, *i*-Bu, (-)-menthyl

A Michael addition of the silyl enolate was employed in a short synthesis of (±)-methyl jasmonate from cyclopentenone (eqs 9 and 10).[5] This convergent scheme was carried out in three steps: conjugate addition of methyl α-(methyldiphenylsilyl)lithioacetate to cyclopentenone, alkylation of the resulting enolate with (*Z*)-1-bromopent-2-ene, and desilylation with ***Potassium Fluoride***. (±)-Ethyl jasmonate was prepared in a similar fashion. In the conjugate addition step, the α-(methyldiphenylsilyl)ester gave superior results to those obtained with the α-trimethylsilyl esters.

Ethyl 2-(Methyldiphenylsilyl)propanoate[1]

[77772-22-6] · $C_{18}H_{22}O_2Si$ · Ethyl 2-(Methyldiphenylsilyl)propanoate · (MW 298.49)

(precursor to 1,1-disubstituted 1-propenes;[1c,2] reacts with primary Grignard reagents to give 2-(methyldiphenylsilyl)-3-alkanones,[3] which in turn lead to regioselectively derived methyldiphenylsilyl enol ethers[4] or to 3-alkanones; reagent for the synthesis of α-methyl-α,β-unsaturated esters[5])

Alternate Name: ethyl 2-(methyldiphenylsilyl)propionate.

Physical Data: clear to pale yellow liquid; *n*24D 1.5407.

Preparative Method: whereas the direct silylation of the lithium enolate of an ester normally results in the formation of a mixture of the α-silyl ester and the corresponding silyl ketene acetal, the reaction of lithium ester enolates with methyldiphenylchlorosilane gives exclusively the α-methyldiphenylsilyl ester.[1b,c] This direct *C*-silylation is the best general route to α-silyl esters.

Purification: can be purified by silica gel chromatography, eluting with ethyl acetate/hexane (2:98 v/v), or by short path distillation.

Handling, Storage, and Precautions: this compound and other α-silyl carbonyl compounds are hydrolyzed under acidic or basic conditions to give the parent desilylated esters.

1,1-Disubstituted 1-Propenes.

The reaction of ethyl (methyldiphenylsilyl)propanoate (**1**) with primary or aryl Grignard reagents results in the formation of the α-silyl ketone or a 1,1-disubstituted 1-propene.[1c,2] For example, the reaction with ***Phenylmagnesium Bromide*** in refluxing THF for several hours leads to 1,1-diphenyl-1-propene in good yield (eq 1). In general, the more sterically demanding the Grignard reagent, the lower the yield of the alkene. The synthesis of alkenes from other more sterically hindered α-(methyldiphenylsilyl) esters requires a sequential reaction of the ester with a Grignard reagent followed by an organolithium reagent (eq 2).

α-Silyl Ketones, Silyl Enol Ethers, and Ketones.

The reaction of (**1**) with Grignard reagents leads to the corresponding 2-(methyldiphenylsilyl)-3-alkanone (eq 3).[3] This reaction is favored when the acid portion of the ester is larger than propionyl. The reaction proceeds through formation of a magnesium enolate on the side of the α-silyl ketone opposite to that of the bulky methyldiphenylsilyl group (eq 4). The direct conversion of α-(methyldiphenylsilyl) esters to ketones can be accomplished by treatment of the ester with a Grignard reagent followed by protiodesilylation with ***Potassium Fluoride***/methanol (eq 5).

(5)

The α-(methyldiphenylsilyl) ketones isomerize to the corresponding silyl enol ether regioselectively simply by mild thermolysis at about 150 °C (eq 6). This reaction can also be done in a stereoselective fashion to give the (*Z*)-enol silyl ether when the thermolysis is carried out in acetonitrile (eq 7).[4]

(6)

(7)

α-Methyl-α,β-unsaturated Esters.

Deprotonation of (**1**) and related compounds followed by reaction of the resulting enolate with aldehydes provides α-methyl(alkyl)-α,β-unsaturated esters in good yields.[5] The (*Z*) diastereomer predominates, with (*Z*)/(*E*) ratios between 90:10 and 79:21. Acrolein reacts in a similar manner, undergoing 1,2-alkenation to give a 77:23 mixture of (*Z*)- and (*E*)-ethyl 2-methyl-2,4-pentadienoates (eq 8).

(8)

Related Reagents.

Ethyl (Methylthio)acetate

[4455-13-4] · $C_5H_{10}O_2S$ · Ethyl (Methylthio)acetate · (MW 134.22)

(addition to anilines; the chloride salt adds to anilines to give indolin-2-ones)

Physical Data: bp 70-72 °C/25 mmHg; *d* 0.905 g cm^{-3}.

Form Supplied in: oil; widely available.

Handling, Storage, and Precautions: water sensitive; protect from atmospheric moisture; stench.

Ethyl (methylthio)acetate can be treated with ***t-Butyl Hypochlorite*** in dichloromethane to give the methylsulfonium chloride[1] salt which reacts with anilines, via a Sommelet-Hauser type rearrangement of the intermediate azasulfonium salt, to afford *ortho* addition of ethyl (methylthio)acetate after treatment with ***Triethylamine*** and workup. This reaction is very mild and can be done in the presence of ketones, esters, and *N*-protected nitrogen groups. Treatment of the addition product with HCl gives 3-methylthioindolin-2-ones (eq 1).[2]

Oxidative removal of the methylthio group with ***N-Chlorosuccinimide*** in dichloromethane can be achieved to convert the methylthio group to a carbonyl group.[2] The reductive removal of the methylthio group is simply effected by the addition of commercially available ***Raney Nickel*** until the starting material has been consumed according to TLC analysis,[3] or by the use of ***Tin*** metal in ethanolic HCl.[4] Since alkylation of indolin-2-ones gives complex mixtures, ethyl (methylthio)acetate is also very useful for the preparation of 3-alkylindolin-2-ones. The methylthio group enables selective deprotonation with ***Sodium Hydride*** and quenching with reactive electrophiles,[3] such as ***Iodomethane*** and ***Benzyl Bromide***. Treatment with Raney nickel affords the alkylated indolin-2-ones (eq 2).

Ethyl Nitroacetate

[626-35-7] · $C_4H_7NO_4$ · Ethyl Nitroacetate · (MW 133.12)

(alkylations;[3,5,6] Michael additions;[4] amidoalkylations;[7] Knoevenagel condensations;[8-11] palladium-catalyzed allylations;[12-14] α-alkoxyallylation;[15] generation of alkyl nitronates;[16,17] generation of hydroxynitrilium ions for synthesis of (*E*)-oximes;[18] synthesis of 4-hydroxy-2-isoxazolines;[19] oxidant for alcohols;[20] synthesis of α-amino esters[21])

Physical Data: bp 194-195 °C; *d* 1.203 g cm^{-3}; *n*20D 1.425.

Solubility: sol ethanol, diethyl ether.

Form Supplied in: colorless liquid; widely available.

Preparative Methods: from ***Nitromethane*** by self-condensation to produce methazonic acid, followed by dehydration to nitroacetonitrile, hydrolysis, and esterification.[22] Alternatively, it is accessible from ***Ethyl Acetoacetate*** by nitration; the resultant ethyl nitroacetoacetate is decomposed with ethanol.[23]

Purification: fractional vacuum distillation.

Handling, Storage, and Precautions: stable for at least six months if stored in the refrigerator.

C-Alkylation.

Due to its strong acidity (pK_a (DMSO) = 9.2),[24] ethyl nitroacetate (**1**) can easily be deprotonated by a number of weak bases or electrochemically at the cathode.[1] The anion typically reacts with alkyl halides, enones, acetates, carbonates, amines, and alcohols or it can be condensed with aldehydes, ketones, or imines.[2] Thus the sodium salt of ethyl nitroacetate (**1**) is alkylated with ***Benzyl Bromide*** (**2**) (eq 1).[3]

(1)

In a Michael addition, (**1**) reacts with 2-acetyl-1,4-dihydroxyanthracene-9,10-dione (**3**) in the presence of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (eq 2).[4] Aromatization of the Michael adduct (**4**) is achieved either by elimination of nitric acid with DBU in an inert atmosphere to form ester (**5**), or by oxidation of the quinone moiety in an air atmosphere to afford ester (**6**) (eq 2).

(2)

(6)

Ethyl nitroacetate can be alkylated by gramine in refluxing toluene in quantitative yield (eq 3).[5] Heating of (**1**) with trityl alcohol (**7**) and trichloroacetic acid gives ethyl 3,3,3-triphenyl-2-nitropropanoate (**8**) in 41% yield (eq 4).[6]

(3)

(4)

(7) **(8)**

N-(1-Benzotriazol-1-ylalkyl)amides (**9**) react with (**1**) under mild conditions to give rise to the α-amidoalkylation products (**10**) (eq 5).[7]

(5)

(9) **(10)**

Ethyl nitroacetate (**1**) undergoes Knoevenagel condensations[8] with aldehydes, ketones, and imines. Acid-base combinations like ***Titanium(IV) Chloride*/*Pyridine***[9] or ***Acetic Acid*/*Piperidine***[10] are particularly good catalysts for this reaction. Iminophosphate (**11**) is converted to the Knoevenagel product (**12**) upon exposure to the sodium salt of ethyl nitroacetate (eq 6).[11]

Under palladium catalysis, ethyl nitroacetate (**1**) reacts with allylic carbonates, acetates, and phenoxides to give the allylated compounds.[12] Thus *C*-glycopyranosides (**14**) are accessible from 2,3-unsaturated glycals (**13**) (eq 7).[13] The key step in the synthesis of the carbocyclic nucleoside carbovir is a Pd^0-catalyzed addition of (**1**) to the carbonate (**15**) followed by a Krapcho-deethoxycarbonylation (eq 8).[14] Both reactions are completely regio- and stereoselective.

Ethyl nitroacetate (**1**) can be α-alkoxyallylated when treated with acetals (**16**) of α,β-enals.[15] The first step of the reaction is the formation of the Claisen system (**17**) which, when heated at 200 °C, undergoes the [3,3]-sigmatropic rearrangement, albeit in poor yield (eq 9).

(9)

O-Alkylation.

Under Mitsunobu conditions, ethyl nitroacetate (**1**) reacts with alcohols by way of exclusive *O*-alkylation to afford alkyl nitronates (**18**) (eq 10).[16] These have been shown to be reactive 1,3-dipoles in cycloadditions with alkenes, alkynes, and hetero dipolarophiles.[2] Versatile heterocycles like isoxazolines are accessible by this transformation.[17]

(10)

By the action of a strong acid like ***Trifluoromethanesulfonic Acid***, (**1**) is converted to the highly electrophilic hydroxynitrilium ion (**19**).[18] Aromatic compounds can easily add to (**19**) to furnish (*E*)-oximes (**20**) stereoselectively (eq 11).

(11)

Ethyl nitroacetate (**1**) condenses with α-bromo aldehydes (**21**) in the presence of ***Alumina*** in a synthesis of 4-hydroxy-2-isoxazolines (**22**) (eq 12).[19] This reaction can be analyzed in terms of a nitroaldol-cyclization sequence. The primarily formed oxides (**23**) are reduced to the desired isoxazolines (**22**) with ***Trimethyl Phosphite*** (eq 12).

Oxidation.

A combination of ***Diethyl Azodicarboxylate***, ***Triphenylphosphine***, and ethyl nitroacetate (**1**) is an effective system for the oxidation of primary and secondary alcohols (eq 13).[20] Aldehydes and ketones are formed under neutral conditions. An *aci*-nitro ester (**24**) is the intermediate of the reduction and decomposes slowly when heated in THF (eq 13).

Ethyl glycinate (**25**) can be obtained via reduction of ethyl nitroacetate (**1**) using ***Ammonium Formate*** as a catalytic hydrogen transfer agent in a ***Palladium on Carbon*** suspension in methanol (eq 14).[21]

Related Reagents.

Methyl 4-Nitrobutanoate; ***Methyl 3-Nitropropanoate***; ***Nitromethane***; ***Phenylsulfonylnitromethane***.

Solubility: sol chlorinated and dipolar aprotic solvents, and hydrocarbon solvents in some cases. Gradual hydrolysis in protic media.

Form Supplied in: colorless crystalline or waxy solids.

Preparative Methods: [3] to a solution of (1*R*,2*R*)-*N*,*N*´-dineopentyl-1,2-diaminocyclohexane (1.37 g, 5.40 mmol) and triethylamine (2.3 mL, 48.5 mmol) in 25 mL of benzene is added ethylphosphoryl dichloride (0.89 g, 6.06 mmol). The suspension is heated to reflux for 80 h, the salts are filtered, and the filtrate is washed successively with 10% aq HCl (2 × 10 mL), aq saturated $NaHCO_3$, and water. Drying, evaporation, and chromatographic separation (EtOAc) gives the title compound (1.1 g, 62%) as a crystalline solid, mp 110-111 °C (hexanes). Single crystal X-ray analysis confirmed the structure. For an alternative synthesis of related compounds, see Kueller and Spilling.[8] Other 2-alkyl derivatives can be similarly prepared.[1-4]

Handling, Storage, and Precautions: crystalline reagents are stable when stored under argon at 0 °C for several months.

Asymmetric Alkenation of Alkylcyclohexanones.[1-3]

Anions of the reagents (**1**), (**4**), (**6**), and (**7**) add to alkylcyclohexanones in THF solution at -78 °C to give intermediate β-hydroxyphosphonamide adducts, which can be isolated and purified by chromatography. Treatment of the adducts with aq acetic acid leads to the corresponding alkylidene alkylcyclohexanes in good to excellent enantiomeric or diastereomeric excesses. The alkenes can also be obtained directly from the original reaction mixtures (aq AcOH quench), without isolation of intermediates. Except in the case of reagent (**1**), using the reagents prepared from (*R*,*R*)-1,2-diaminocyclohexane gives the (a*R*)-alkenes with 4-substituted alkylcyclohexanones and the (*E*)-alkenes with other analogs, based on a transition state that favors equatorial attack of the least encumbered face of the anion on the cyclohexanone derivative. For steric reasons, the reverse is observed with reagent (**1**).[3] Eq 1 illustrates a typical reaction and other examples of products are listed in Table 1 (enantiomeric excesses >99:1).[2,3]

Kinetic Resolution.[2]

When the reacting partners allow for a high degree of stereodifferentiation in the transition state, it is possible to achieve asymmetric alkenation by kinetic resolution (eq 2). This is best done with α-alkyl substituted cyclohexanones and bulky anions such as that derived from (**4**). In a typical procedure, (±)-2-methylcyclohexanone (1 mmol) is treated with the anion of (**3**) (0.5 mmol, -78 °C, THF, 1 h; then AcOH, -> 25 °C, and workup), to give (*E*,2*S*)-(2-methylcyclohexylidene)benzene; [α]25D -86.4° (*c* 1, $CHCl_3$), and the (*Z*)-isomer (>98:2 by capillary GC; 63% based on the reagent).

(3aR,7aR)-2-Ethyloctahydro-1H-1,3-dineopentyl-1,3,2-benzodiazaphosphole Oxide

(2)

Sequential Asymmetric Alkenation and Ene Reactions.[3]

Treatment of a number of (alkylcyclohexylidene)ethane derivatives with chiral nonracemic α-benzyloxy aldehydes results in the formation of branched alkylcyclohexene derivatives via a highly stereocontrolled ene reaction. Based on a chelated transition state, it is possible to predict the disposition of the double bond and the chirality of two new stereogenic centers, as illustrated in eq 3. The newly created stereogenic center bearing a *C*-methyl group from the ene reaction leads to interesting substitution patterns in relation to the existing *C*-methyl group. Oxidative cleavage of the double bond leads to acyclic counterparts with predictable disposition and chirality (e.g. 1,6-dimethyl, 1,5-dimethyl, etc.).[3]

(3aR,7aR)-2-Ethyloctahydro-1H-1,3-dineopentyl-1,3,2-benzodiazaphosphole Oxide

α-Substituted α-Alkylphosphonic Acids.[4]

In general, α-substituted phosphonamides can be transformed into the corresponding α-alkyl derivatives of very high diastereomeric purity by alkylation of the anions at -78 °C or lower (eq 4, Table 2). In most cases the approach of the electrophile is favored from the least hindered side of the anion, leading to highly enriched diastereomers. These products can be subsequently hydrolyzed to the corresponding phosphonic acids. A typical procedure is as follows. To a solution of (**3**) (1 mmol) in THF, is added ***n-Butyllithium*** (1.40 mmol at -78 °C), the temperature is lowered to -100 °C, and ***Allyl Bromide*** (1.15 mmol) is added. After stirring for 15 min, the reaction mixture is quenched with MeOH, and the solution processed as usual. Chromatographic purification gives the expected product as a crystalline solid (X-ray), mp 87-88 °C, [α]25D -91.5° (*c* 1.0, $CHCl_3$).

α-Chloro-α-alkylphosphonic Acids.[4]

The reagent is prepared from α-chloromethylphosphonyl dichloride and (*R*,*R*)- or (*S*,*S*)-*N*,*N*′-dimethyl-1,2-diaminocyclohexane as described above. Alkylation is done as described above (BuLi, THF, -100 °C, followed by isolation, then hydrolysis, 0.1N HCl, 25 °C). Eq 5 and Table 3 illustrate some examples.[4]

α-Amino-α-alkylphosphonic Acids.[5]

Treatment of iminodithiolane derivatives (eq 6) with ***Potassium Hexamethyldisilazide*** in THF (-78 °C) generates the corresponding anions which, when treated with various alkyl halides, give the corresponding α-alkyl derivatives in high diastereomeric excess. Unlike other α-substituted phosphonamides discussed above, the alkylation of the (*R*,*R*)-α-iminodithiolane derivative gives products with the opposite orientation of the new alkyl chain, which are normally expected from the enantiomeric (*S*,*S*) series. This has been rationalized based on the intermediacy of a potassium chelate involving the phosphoryl oxygen and the imino nitrogen atoms, thus exposing the other face of the anion.[5] Eq 6 illustrates a typical sequence and Table 4 lists some examples of α-amino-α-alkylphosphonic acids prepared using this sequence.

α-Amino-β-aryl phosphonic acids are accessible from the addition of the anion of chloromethylphosphonamide (**8**) to *N*-arylimines, followed by hydrogenolysis of the aziridine derivative.[6]

Asymmetric Conjugate Addition of Allyl- and Crotylphosphonamides.[7]

The asymmetric *C*-allylation of α,β-unsaturated carbonyl compounds is a powerful tool for the functionalization of a carbonyl compound in the β-position. Since such a process normally leads to the corresponding enolate derivative when anionic reagents are used, there exists the possibility of trapping with an electrophile. Thus sequential addition and trapping can lead to vicinally substituted carbonyl compounds. Asymmetric allylation has been achieved previously with simple cycloalkenones using phosphorus[9] and sulfur[10] based reagents that must be prepared in diastereomerically pure form.

The anions of allyl- and crotylphosphonamides, (**2**) and (**5**) respectively, show excellent selectivity toward a variety of α,β-unsaturated compounds, affording the diastereomerically pure or enriched products. Quenching the enolates with various electrophiles gives vicinally substituted carbon centers. Oxidative cleavage of the phosphonamide moiety affords the equivalent of an acetaldehyde (α-methylacetaldehyde) anion 1,4-adduct to the original α,β-unsaturated carbonyl compound. Pertinent examples are shown in eq 7 and Table 5.

Conclusion.

The C_2 symmetry of (*R*,*R*)- and (*S*,*S*)-1,2-diaminocyclohexane, readily available from the racemic compound by resolution,[11] has served as a versatile chiral motif in the design of topologically unique stereodifferentiating reagents such as the phosphonamide anions described here. Several other applications of these reagents via anion chemistry, or simply based on the exploitation of other effects offered by their structures and heteroatom functionality, can be explored (catalytic processes, chiral ligands, etc.). The *N*,*N*′-disubstituted 1,2-diaminocyclohexane motif has also been remarkably versatile in other asymmetric processes such as the dihydroxylation of alkenes,[12] and a variety of other C-C bond-forming reactions.[13]

O-Ethylperoxycarbonic Acid

[70288-43-6] · $C_3H_6O_4$ · *O*-Ethylperoxycarbonic Acid · (MW 106.09)

(oxygen atom transfer reagent, useful for the epoxidation of alkenes)

Preparative Method: formed in situ by the reaction of aqueous ***Hydrogen Peroxide*** with ***Ethyl Chloroformate***.

Handling, Storage, and Precautions: generated in situ; not stable to storage.

Alkene Epoxidation.

The direct oxidation of an alkene to the corresponding epoxide is most typically accomplished by an organic peroxy acid or by metal-catalyzed oxygen atom transfer from a hydroperoxide.[1,2] Alternate methods based upon the utilization of hydrogen peroxide as the oxidant have also been developed, most notably by Payne.[3] Although H_2O_2 itself is not sufficiently reactive to epoxidize a nonconjugated alkene, its propensity for oxygen atom transfer can be markedly enhanced by placing the OOH moiety in conjugation with a multiple bond. Typical examples are peroxy acids (**1**) and peroxyimidic acids (**2**). The latter oxidant can be readily formed in situ by the addition of H_2O_2 to a nitrile. Acetonitrile,[3] benzonitrile,[3] and trichloroacetonitrile[4] have been employed as coreactants in the epoxidation of alkenes. ***Trichloroperoxyacetamidic Acid*** is a highly effective oxidant that is competitive with ***m-Chloroperbenzoic Acid*** on both a cost effective and reactivity basis. Acetoperoxyimidic acid has been scaled up for the synthesis of epoxides on a multimolar scale.[5]

(1)

(2)

(3)

O-Alkylperoxycarbonic acids (**3**) can be formed in situ by the reaction of H_2O_2 with alkyl chloroformates.[6] Although dialkyl esters of peroxycarbonic acid ($ROCO_3R'$)[7a] and peroxydicarbonates $(ROCOO)_2$[7b] are stable isolable

compounds, an *O*-alkylperoxycarbonic acid (**3**) must be generated in situ. *O*-Benzylperoxycarbonic acid has been prepared from dibenzyl peroxydicarbonate and alkaline H_2O_2 in methanol.[8] This peroxycarbonic acid (**3**; R = Bn) is considerably less stable than a peroxycarboxylic acid (**1**) and has a half-life of about 61 h at room temperature in benzene. However, it is an effective oxidizing reagent and exhibits a reactivity toward (*E*)-stilbene that is intermediate between that of ***Perbenzoic Acid*** and *m*-CPBA in benzene.

The current procedure utilizes a biphasic solvent system that allows one to utilize the cost and safety advantages of aqueous 30% H_2O_2 and CH_2Cl_2 as a second phase. This two-phase system is ideal since the rate of epoxidation of alkenes is maximized in nonpolar solvents like CH_2Cl_2. *O*-Ethylperoxycarbonic acid (**4**) is produced at the interface by the reaction of H_2O_2 with ethyl chloroformate (eq 1). The epoxidizing reagent should be formed in the presence of a buffer to neutralize the HCl produced since the decomposition of the $-CO_3H$ functional group is catalyzed by both acids and bases. When Na_2HPO_4 is used as a buffer, the reaction medium is slightly acidic and the pH decreases from 6.8 to 4.5 during the course of the reaction. Alternatively, if alkaline conditions are desired because of an acid-sensitive functional group, Na_3PO_4 may be used as the buffer and the pH maintained between 9.5 and 8.8.[6] It should be recalled that aqueous 30% H_2O_2 is typically stabilized by a strong acid (e.g. H_2SO_4) and the solution is acidic. *m*-CPBA has also been used under biphasic conditions.[9]

(1)

(4)

The overall procedure for alkene epoxidation with (**4**) is accompanied by the formation of two innocuous byproducts, carbon dioxide and ethanol (eq 2). Good to excellent yields of epoxides are obtained with a variety of alkenes, with the exception of 1-nonene. Terminal alkenes typically react more slowly with peroxy acids than more highly substituted double bonds.

(2)

This synthetic procedure offers the advantage of the in situ generation of a relatively inexpensive oxidant under either mildly acidic or basic conditions. Reaction times vary from 3-24 h at room temperature. The products of oxidation are not contaminated with residual byproducts.

N-Ethyl-5-phenylisoxazolium-3´-sulfonate[1]

[4156-16-5] · $C_{11}H_{11}NO_4S$ · *N*-Ethyl-5-phenylisoxazolium-3´-sulfonate · (MW 253.30)

(coupling reagent for peptide synthesis;[2] protein modification;[3] reduction of carboxylic acids into alcohols[4])

Alternate Names: Woodward's reagent K; NEPIS.

Physical Data: mp 206-208 °C (dec); UV λ_{max} (ε) 283 nm (22 500) in 0.1 N HCl.

Solubility: insol MeCN, $MeNO_2$, DMF, CH_2Cl_2; sol H_2O.

Form Supplied in: crystalline, anhydrous zwitterion; widely available as 95% pure that may contain some of the *para* sulfonate derivative.

Analysis of Reagent Purity: material that is sufficiently pure has mp 206-208 °C.

Purification: dissolve in aqueous 1 N HCl and reprecipitate by the slow addition of acetone. After filtration and drying the reagent is a fluffy solid.

Handling, Storage, and Precautions: stable to light and temperature and nonhygroscopic. No extra precautions need to be observed.

Peptide Coupling Reagent.

Woodward's reagent K reacts with an *N*-protected amino acid, under mild conditions, in the presence of a tertiary amine to form an enol ester intermediate, e.g. (**1**). This enol ester acylates an amino acid ester or peptide to afford the elongated peptide derivative (eq 1). The isoxazolium salt is not soluble in organic solvents, but as it reacts with a carboxyl group in the presence of a tertiary amine the reaction mixture clears.

Examples of di- and tripeptide couplings abound with yields typically >80%; minimal purification steps are required since the byproducts are water soluble (eq 2).[2]

The recommended coupling procedure is to activate the carboxyl group in $MeNO_2$ or MeCN with vigorous stirring for 10 min at rt or 1 h at 0 °C. Then the amino ester, dissolved in $MeNO_2$ or MeCN, is added and the coupling allowed to go at rt for several hours.

Good yields are obtained in coupling asparagine and glutamine. With some coupling reagents the carboxamide of these residues can undergo an intramolecular dehydration when the α-carboxylate is activated to give a nitrile residue (**2**) in the peptide.[5] However, this byproduct has not been observed with reagent K.

(2)

An additional advantage of reagent K is that when serine, threonine, etc., are activated their hydroxyl groups do not require protection.[6] For instance, the hydroxyproline tripeptide in eq 3 was obtained in good yield after crystallization.[2]

(3)

Several studies[7] on the extent of racemization with peptide coupling reagents have been published. This generally is a problem when performing a fragment condensation, but normally not a problem when the amino group is protected as a carbamate. For best control of the extent of racemization, accurate measurement of the tertiary amine is advised.[7b] The extent of racemization observed with reagent K is just a few percent for acylated amino acids,[7c] which is no worse than most coupling reagents except for the azide coupling procedure. There are some disadvantages of this reagent in peptide couplings. The most serious one is the limitation of solvents. Acetonitrile and nitromethane are the best for high yield, high optical purity products. However, many peptides are not readily soluble in these solvents. The next disadvantage is that the enol ester intermediate can rearrange to the imide side-product (**3**) which is difficult to remove.[1] Another problem with reagent K is its incompatibility with solid-phase peptide synthesis because of its poor solubility in organic solvents and relatively slow activation of carboxyl groups.[8]

(3)

A good comparison of reagent K with other reagents is in the synthesis of a protected derivative of oxytocin (eq 4).[9] This product was further elaborated to give oxytocin. The results are compared with those for ***1,3-Dicyclohexylcarbodiimide*** and ***N,N´-Carbonyldiimidazole*** in Table 1.

Cbz-Cys(Bn)-Tyr-Ile-Gln-Asn-Cys(Bn)-Pro-Leu-Gly-NH_2 (4)

Table 1 Comparison of Coupling Agents for Protected Oxytocin

Coupling method	Yield (%)	Mp (°C)	Biological activity[a]
DCC	80	225 230	81
CDI	70.5	225 230	50
Reagent K	85	240 242	134

[a] Units mg^{-1} in avian depressor activity for deprotected and oxidized nonapeptide.

An additional utility for reagent K is peptide cyclization.[10] The activation and cyclization steps are performed separately; therefore each can be carried out under the appropriate dilution conditions. This is advantageous when the carboxyl group activates slowly since it is in concentrated solution.

The isoxazolium salt has been used in the synthesis of other difficult peptide structures. A peptidoglycan has been obtained in good yield by this procedure (eq 5).[11]

(5)

Additionally, this reagent has been used repetitively in the synthesis of a steroid-peptide adduct with a free hydroxyl group (eq 6).[12] Deprotection and another coupling with Cbz-Arg(N^G-nitro) gave the dipeptide-steroid adduct in good yield. In both couplings the steroid hydroxyl group was not acylated.

(6)

Protein Modification.

Since this reagent is water soluble and is reactive under aqueous conditions below pH 4.75, it can specifically modify carboxyl groups in proteins.[3,13] This has proven useful in determining essential carboxyl groups in various enzymes. The enol ester is stable enough to isolate the modified protein and tag with a nucleophile for eventual identification of the modified amino acid. Other reagents such as the water-soluble carbodiimides are also used extensively in these mechanistic studies. However, an advantage with reagent K is that the enol ester formed has a UV absorbance at 340 nm (E_{340} = 7000 M^{-1} cm^{-1});[14] thus the number of carboxyl groups modified can be quantified.

Reduction of Carboxylic Acids to Alcohols.

The conversion of carboxylic acids to alcohols occurs in a two-step process under mild conditions using reagent K with yields for simple alcohols ranging from 50-100%.[4] The reduction of a dipeptide (eq 7) suggests a potential utility in modifying carboxyl groups in proteins.

(7)

Another method[15] to obtain alcohols is to reduce the mixed carbonic acid anhydride prepared with ***Ethyl Chloroformate*** with an excess of ***Sodium Borohydride***. This method uses less costly reagents; thus it is more useful for synthetic transformations.

Miscellaneous Reactions.

Pantothenic acid has been coupled to a long chain amine with reagent K (eq 8).[16] This is another example of the nonreactivity of hydroxyl groups with the enol ester intermediate. Attempts to prepare this amide through the mixed anhydride procedure give low yields.

(8)

Reagent K may have utility in sequencing peptides and proteins from the *C*-terminus (eq 9).[17] The 2-thiohydantoin produced is used to analyze a peptide sequence upon cleavage of the thiohydantoin from the peptide. This mild procedure gives good yields with amino acids that have sensitive side chains such as serine and lysine. The original ***Acetic Anhydride*** procedure[18] for *C*-terminal sequencing does not work well with these amino acids; therefore this procedure is an improvement. Another activation reagent, hydroxysuccinimide esters of Fmoc-amino acids, fails to give the thiohydantoin.[17]

(9)

R = variety of amino acid side chains

Ethyl (Phenylsulfinyl)acetate

[54882-04-1] · $C_{10}H_{12}O_3S$ · Ethyl (Phenylsulfinyl)acetate · (MW 221.27)

(addition to aldehydes followed by thermal elimination gives 3-keto esters;[1] addition to carbonyl compounds followed by desulfurization gives 3-hydroxy esters;[2] aldehyde Knoevenagel condensation products undergo thermal rearrangement to give (2*E*,4*E*)-dienoate esters or 4-hydroxy-(2*E*)-enoate esters[3,4])

Physical Data: colorless liquid.

Analysis of Reagent Purity: microanalysis; ^{1}H NMR[2,3] and ^{13}C NMR[5] spectroscopy.

Preparative Methods: sodium thiophenoxide in ethanol is treated with ethyl bromoacetate and refluxed for 1 h, giving ethyl (phenylthio)acetate after distillation (bp 101-104 °C/0.4 mmHg), which is oxidized with sodium periodate or preferably sodium perborate[6] in water/methanol to afford the title compound as a colorless liquid.[3] Another method is by treatment of the anion of methyl phenyl sulfoxide with diethyl carbonate.[2]

Addition to Aldehydes to give 3-Keto Esters[1] and 3-Hydroxy Esters.[2]

When deprotonated with bases containing the lithium or sodium counterion ethyl (phenylsulfinyl)acetate exhibits poor reactivity and fails to undergo alkylation or nucleophilic addition. However, deprotonation of ethyl (phenylsulfinyl)acetate with 1 equiv of ***Ethylmagnesium Bromide*** in diethyl ether at 0 °C gives the magnesium salt as a milky precipitate, and addition of aldehydes results in the formation of alkyl-2-phenylsulfinyl-3-hydroxy esters. Thermal *syn* elimination of benzenesulfinic acid affords an enol which tautomerizes to the 3-keto ester (eq 1). Desulfurization of the addition product with ***Raney Nickel*** gives 3-hydroxy esters, the result of a formal addition of ethyl acetate anion to an aldehyde.

Preparation of (2*E*,4*E*)-2,4-Dienoate Esters or 4-Hydroxy-(2*E*)-enoate Esters.[3,4]

Ethyl (2*E*)-2-phenylsulfinyl-2-alkenoates can be prepared by treatment of the aldehydes with ethyl (phenylsulfinyl)acetate and a catalytic amount of ***Piperidine*** in acetonitrile. The resultant vinyl sulfoxide is treated with anhydrous ***Potassium Carbonate*** in refluxing xylenes; after 4 h the *trans,trans* dienoate is isolated in 59% yield as a 91:9 mixture of the *trans,trans* isomer to other isomers, as determined by GLC. A 12% yield of the 4-hydroxy-(2*E*)-enoate ester, presumably resulting from hydrolysis of the intermediate sulfenate ester, is also obtained. The vinyl sulfoxide product of the Knovenagel condensation is proposed to undergo a base-catalyzed deconjugation followed by a thermally induced [2,3]-sigmatropic shift to give the sulfenate ester which can either hydrolyze to give the hydroxyenoate or undergo another [2,3]-sigmatropic shift, eliminating the sulfoxide to give the dienoate. Use of anhydrous conditions favors the formation of the diene (eq 2).

(2)

Treatment of an aldehyde with ethyl (phenylsulfinyl)acetate under prolonged Knoevenagel conditions using a catalytic amount of piperidine results in the formation, without isolation of intermediates of the hydroxy enoates.[7] This reaction has been used in the synthesis of (*R*)-patulolide (eq 3).[8]

Ethyl (Phenylsulfonyl)acetate

(R = Et)

[7605-30-3] · $C_{10}H_{12}O_4S$ · Ethyl (Phenylsulfonyl)acetate · (MW 228.27) (R = Me)

[34097-60-4] · $C_9H_{10}O_4S$ · Methyl Phenylsulfonylacetate · (MW 214.26)

(for introducing (ethoxycarbonyl)methyl and (phenylsulfonyl)methyl moieties)

Physical Data: R = Et, mp 41-42,[1] 42-43,[2] 45,[3] 47 °C;[4] bp 134-135 °C/0.01 mmHg. R = Me, bp 145 °C/0.01 mmHg.

Solubility: sol hot alcohol, benzene, diethyl ether; practically insol water.

Preparative Methods: prepared either by the substitution reaction of sodium benzenesulfinate[3] or Amberlyst A-26 benzenesulfinate[4] with ethyl chloroacetate or by reaction of the sodium salt of ethyl acetoacetate with benzenesulfonyl chloride.[5]

Utilization in Organic Synthesis.

The methylene group of ethyl (phenylsulfonyl)acetate (hereafter, abbreviated as EPSA) is more acidic than that of ethyl (phenylthio)acetate. Therefore EPSA generates a stable anion on its methylene carbon.[6] The Knoevenagel-type condensation with an aromatic aldehyde (eq 1),[7] the Michael-type addition to an α,β-unsaturated ester (eq 2),[8] the insertion reaction of a diazo compound,[9] and the condensation with DMF dimethyl acetal[10] can be applied to the chemistry of EPSA to give various phenylsulfonyl-containing compounds. The EPSA anion reacts with *N*-alkylisatoic anhydrides to yield phenylsulfonyl-substituted quinoline derivatives (eq 3).[11]

(1)

(2)

(3)

The anion of EPSA can react with an alkyl halide to give a mono- or dialkylated product (eq 4).[12,13] The most effficient method for alkylation of EPSA is the reaction of a π-allyl palladium complex with the EPSA anion (eq 5).[14] The introduced (ethoxycarbonyl)(phenylsulfonyl)methyl moiety is a synthetic precursor for many kinds of functionality

such as (ethoxycarbonyl)methyl, (phenylsulfonyl)methyl, hydroxymethyl, and formylmethyl.

Synthetic Utilization of Methyl (Phenylsulfonyl)acetate as a Methyl Analog of EPSA.

Methyl (phenylsulfonyl)acetate (hereafter, abbreviated as MPSA) is prepared by the reaction of sodium benzenesulfinate with methyl chloroacetate in DMF.[15] In an analogous manner to EPSA, MPSA undergoes Michael-type addition to α,β-unsaturated lactones (eq 6)[16] or sulfones.[17]

(6)

MPSA is also monoalkylated on the methylene carbon under a variety of conditions (NaOMe/MeOH,[18] NaH/THF,[19] NaH/DMF,[20-22] NaH/DMSO,[23] NaH/HMPA,[22] DBU/benzene[24]). The anion of MPSA reacts with a π-allyl palladium complex to provide a useful method for C-C bond formation between MPSA and allyl acetates (eq 7).[25] Other methods for generating π-allyl palladium complexes are also available (eqs 8 and 9).[26] The combination of these C-C bond formations serves as a synthetic method for constructing various cyclic compounds (eqs 6 and 10).[16,18,20-22,27]

(7)

(8)

Iodo-substituted MPSA is utilized in an atom-transfer radical addition to an alkene. Thus the iodo derivative of allylated MPSA undergoes the atom-transfer radical cyclization with allylamine to form a bicyclo[3.3.0]octane (eq 11).[28]

Ethyl β-Phenylsulfonylpropiolate

[80404-53-1] · $C_{11}H_{10}O_4S$ · Ethyl β-Phenylsulfonylpropiolate · (MW 238.28)

(dienophile[1,2] used in electrocyclic reactions, such as the Diels-Alder reaction; the adducts can be converted to substituted arenes)

Physical Data: lightly colored oil.

Solubility: sol most organic solvents.

Form Supplied in: prepared and used in situ.[1,3]

Analysis of Reagent Purity: based on spectral examination.[2]

Preparative Methods: Schultz and Shen[1] reported the first preparation of ethyl β-phenylsulfonylpropiolate (**1**) which involved ***m-Chloroperbenzoic Acid*** oxidation of methyl phenylthiopropiolate (**2**).[4] The latter is prepared from sequential treatment of ethyl propiolate with ***Lithium Diisopropylamide*** and phenyl phenylthiosulfonate (eq 1).[5] An alternate route to the synthesis of the corresponding methyl and *t*-butyl ester analogs of (**1**) has been recently reported.[3] Reaction of substituted alkynes with ***Mercury(II) Chloride*** and ***Sodium Benzenesulfinate*** produces a sulfonylmercury complex which under oxidative demercuriation conditions provides the desired β-phenylsulfonylpropiolate esters in modest yields.

Handling, Storage, and Precautions: undergoes polymerization to a viscous dark substance on standing at rt; refrigeration and short-path silica gel filtration chromatography prior to use is recommended.[1]

Diels-Alder Reaction.

The reagent is a reactive dienophile; it undergoes essentially quantitative Diels-Alder addition to a variety of dienes including furan, 1,3-cyclohexadiene, and pyrrole (eq 2). Extremely high regioselectivity is observed for the addition of (**1**) with 1-substituted butadienes.

(2)

The synthetic utility of (**1**) for the preparation of substituted arene systems is exemplified in eq 3. Thus adduct (**3**) under benzenesulfinic acid elimination conditions provides benzoate (**4**). On the other hand, simple dehydrogenation of (**3**) gives aryl sulfone (**5**) in modest yield.[1]

(3)

Methyl and ethyl β-phenylsulfonylpropiolates have been reported to participate in a [4 + 2] cycloaddition reaction with the vinyl and cross-conjugated porphyrin β,β´ double bonds of either ring A or B of protoporphyrin IX dimethyl ester in a regio- and stereospecific manner.[2] Corey et al., in their total synthesis of forskolin, utilized β-phenylsulfonylpropiolic acid as a dienophile for an intramolecular Diels-Alder reaction, wherein the alkyne unit is tethered to the required diene system through an ester moiety, to build the A/B ring system of the natural product.[6]

1-Ethylpiperidine

[766-09-6] · $C_7H_{15}N$ · 1-Ethylpiperidine · (MW 113.23)

(hindered nonnucleophilic amine used as base for the generation of tin enolates and aldol-like condensations;[1] aryl halide couplings; preparation of anhydrides)

Physical Data: bp 131 °C; fp 18 °C; *d* 0.824 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: liquid.

Handling, Storage, and Precautions: the liquid is corrosive and flammable. Bottles of 1-ethylpiperidine should be flushed with nitrogen or argon to prevent exposure to carbon dioxide. The vapors are harmful and care should be taken to avoid absorption through the skin. Use in a fume hood.

Aldol Condensations.

1-Ethylpiperidine is the base of choice for the in situ preparation of divalent tin enolates used in diastereoselective and enantioselective cross-aldol reactions (eq 1).[1] Preparation of the tin enolates involves treatment of a ketone with ***Tin(II) Trifluoromethanesulfonate*** in the presence of 1-ethylpiperidine. The aldol reaction is selective for the *erythro* diastereoisomer.[2]

base	isolated yield (1)	(2)
N-methylmorpholine	22	65
N-ethylpiperidine	80	trace

Enantioselective cross-aldol reactions between ketone-derived tin enolates and aldehydes result from the addition of a chiral nonracemic diamine (eq 2).[3] The methodology is useful for cross-aldol reactions between two ketones (eq 3),[4] and aldol-like reactions involving acyl-2-oxazolidones,[5] acylthiazolidine-2-thiones (eq 4),[6] and enantiomerically enriched 4-substituted acylthiazolidine-2-thiones (eq 5).[7]

75%; *erythro*:*threo* = 6:1
erythro isomer = 80% ee

Preparation of Anhydrides.

The base is used in preparing symmetrical (eq 6)[8] and mixed carboxylic acid anhydrides which are used in amide or peptide synthesis (eq 7).[9]

(7)

Aryl Halide Couplings.

Employment of ***Copper(I) Iodide*** and 1-ethylpiperidine as catalysts promotes coupling between aryl halides and alkynes (eq 8).[10]

(8)

Esterifications.

Treatment of crotonyl chloride with 1-ethylpiperidine in ethanol yields ethyl vinylacetate, while use of 2,4,6-trimethylpyridine as base produces ethyl *trans*-crotonate (eq 9).[11]

Ethyl β-(1-Pyrrolidinyl)acrylate

[53927-12-1] · $C_9H_{15}NO_2$ · Ethyl β-(1-Pyrrolidinyl)acrylate · (MW 169.25) (*E*)

[65651-80-1]

(precursor to β-vinyllithium derivative; reactions with electrophiles yield cyclopentenones, butenolides, maleic acid derivatives, and oxalacetic acid derivatives[1,2])

Physical Data: mp 41-43 °C; bp 80-105 °C/10^{-3} mmHg.[3]

Solubility: sol most organic solvents (ethanol, ethyl acetate, dichloromethane, chloroform, THF).

Form Supplied in: colorless solid.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 1.27 (t, *J* = 7 Hz, 3 H, CH_3), 1.95 (m, 4 H, CH_2CH_2N), 3.30 (m, 4H, CH_2N), 4.16 (q, *J* = 7 Hz, 2 H, CH_2O), 4.50 (d, *J* = 12.5 Hz, 1 H, 2-H), 7.72 (d, *J* = 12.5 Hz, 1 H, 3-H); ^{13}C NMR δ 14.7 (CH_3), 25.3 (CH_2CH_2N), 4.88 (CH_2N), 58.5 (CH_2O), 84.6 (2-C), 169.2 (1-C); IR ($CHCl_3$) 1600 (C=C), 1665 (C=O) cm^{-1}; UV (EtOH) 287 nm (ε = 2600).[4]

Preparative Method: reaction of ethyl propiolate with pyrrolidine in acetonitrile at rt yields ethyl β-(1-pyrrolidinyl)acrylate in 55% yield as a colorless solid.[3,4]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: store under nitrogen protected from moisture.

Acrylates with functional groups (for instance, amino, hydroxy, mercapto moieties) in the β-position exhibit: (i) nucleophilic character at the α-position, permitting reactions with various electrophiles; (ii) electrophilic character at the β-position, enabling nucleophilic exchange reactions which can be employed for ring closure reactions; and (iii) CH acidity at the β-position (and/or α-position) which, for instance with strong lithiating agents, leads to direct β-lithiation, thus generating highly versatile functionally substituted vinyllithium derivatives.[5,6] Typical examples for ethyl β-(1-pyrrolidinyl)acrylate are shown below.

Reaction with Diazonium Salts.

The reaction of ethyl β-(1-pyrrolidinyl)acrylate with diazonium salts as electrophiles leads to the formation of iminium hydrazone derivatives (**1**) which can be isolated in 65-90% yields (eq 1). These products can be converted into imidazole derivatives by action of base (eq 2) or into cinnoline derivatives (eq 3), depending on the substituents of the aromatic ring.[7,8]

(3)

Reaction with α-Amino Carbonyl Compounds.

The reaction of ethyl β-(1-pyrrolidinyl)acrylate with α-amino carbonyl compounds as nucleophiles in refluxing ethanol proceeds via 1,4-addition followed by elimination to give transamination intermediates which cyclize immediately to yield 3-substituted pyrroles (eq 4).[9]

(4)

Vinylcarbanion Generation.

Ethyl β-(1-pyrrolidinyl)acrylate can be converted by direct lithiation with ***t-Butyllithium*** below -100 °C into a β-vinyllithium derivative (**2**) (eq 5), which can be used as a C_3 synthon for cyclization reactions. Reaction with acrylates, aldehydes, or ketones as electrophilic-nucleophilic species leads to functionally substituted cyclopentenones (eq 6) and butenolides (eq 7).[1] Many examples involving reactions with heterocumulenes have been reported.[2] For instance, addition of ***Phenyl Isothiocyanate*** or ***Phenyl Isocyanate*** yields, after cyclization, the thiomaleic anhydride derivative (eq 8) or the *N*-phenylmaleimide derivative (eq 9), respectively. Addition of alkyl isocyanates does not lead to cyclization, and oxalacetic acid derivatives are obtained (eq 10). Similarly, addition of ***Carbon Dioxide*** yields, after

hydrolysis of the enamine, an oxalacetate derivative (eq 11).

Ethyl Pyruvate Diethyl Acetal

($R^1 = R^2 = Et$)

[7476-20-2] · $C_9H_{18}O_4$ · Ethyl Pyruvate Diethyl Acetal · (MW 190.27) ($R^1 = R^2 = Me$)

[10076-48-9] · $C_6H_{12}O_4$ · Methyl Pyruvate Dimethyl Acetal · (MW 148.18) ($R^1{}_2 = CH_2CH_2$, $R^2 = Et$)

[56624-93-2] · $C_7H_{12}O_4$ · Ethyl Pyruvate Ethylene Acetal · (MW 160.19)

(reactions with nucleophiles give various α-difunctional products;[1-8] useful reagents for synthesis of heterocyclic compounds;[8-10] several interesting results are obtained through transacetalizations[3,11-13])

Alternate Name: ethyl 2,2-diethoxypropanoate.

Physical Data: $R^1 = R^2 = Et$, bp 70-71 °C/10 mmHg; $R^1 = R^2 = Me$, bp 58-60 °C/13 mmHg; $R^1{}_2 = CH_2CH_2$, $R^2 = Et$, bp 70-76 °C/8 mmHg.

Preparative Methods: by acetalization of ethyl or methyl pyruvates (ROH, $HC(OR)_3$, HCl or TsOH or H_2SO_4; $HOCH_2CH_2OH$, TsOH, C_6H_6, Dean Stark).

Handling, Storage, and Precautions: should be stored at low temperature.

Reactions with Nucleophiles.

Reaction with organomagnesium compounds in HMPA leads to enolates of α-dicarbonyl compound monoacetals and then to α-keto acetals by hydrolysis. Therefore reactions require two molar equivalents of organomagnesium compounds (eq 1).[1] In several cases, an alcohol from ketone reduction is also formed; therefore the yield of the keto acetal is improved by oxidation of the crude product (eq 2).[1] Reduction of ethyl 2,2-diethoxypropanoate followed by oxidation of the resulting alcohol gives pyruvaldehyde diethyl acetal (eq 3).[1,2] Reactions with ketone,[3] ester,[4] and amide[5] enolates lead to Claisen condensation products (eq 4).[4] The nitromethane dianion (eq 5),[6] the lithium derivative of 1,3-dithiane,[7] and ammonia[8] also give substitution products.

(1)

(2)

52%; 61% if the crude product is oxidized before isolation

(3)

overall yield 43% or 87.4%

(4)

overall yield 80%

(5)

Synthesis of Heterocyclic Compounds.

Several syntheses of heterocyclic compounds using these reagents have been described.[8-10] For instance, 1-(3-methyl-1,2,4-oxadiazol-5-yl)ethanone has been prepared from 2,2-diethoxypropanamide (eq 6).[8]

(6)

Transacetalization.

Claisen rearrangement of the diallyl acetal obtained from methyl 2,2-dimethoxypropanoate gives the γ,δ-unsaturated-α-keto ester, methyl 2-oxo-5-hexenoate, in good yield (eq 7).[11] Its preparation is thus possible on a large scale. The corresponding dibenzyl acetal is prepared by a similar way and leads to the benzyl alcohol elimination product in the presence of P_2O_5/DMF.[12,13] Intramolecular acetalization occurs after reaction of methyl 2,2-dimethoxypropanoate with the 2-methyl-1,3-cyclohexanedione dianion (eq 8).[3]

(7)

overall yield 61%

(8)

Alcohol Elimination.

In many preparative experiments, elimination of alcohol in acidic medium has been encountered.[12-15] Such an elimination product led to 2-methoxyacrylic acid (eq 9),[15] an intermediate for synthesis of the ergot alkaloids and related structures.

(9)

Related Reagents.

Ethyl Diethoxyacetate; ***Glyoxal Diethyl Acetal***; ***Pyruvaldehyde Diethyl Acetal***.

Ethyl Trichloroacetate

CCl_3CO_2R

(R = Et)

[515-84-4] · $C_4H_5Cl_3O_2$ · Ethyl Trichloroacetate · (MW 191.44) (R = Me)

[598-99-2] · $C_3H_3Cl_3O_2$ · Methyl Trichloroacetate · (MW 177.41) (R = *i*-Pr)

[3974-99-0] · $C_5H_7Cl_3O_2$ · Isopropyl Trichloroacetate · (MW 205.47) (R = *t*-Bu)

[1860-21-5] · $C_6H_9Cl_3O_2$ · *t*-Butyl Trichloroacetate · (MW 219.50)

(convenient precursor of dichlorocarbene;[1a,2b] generates enolates that react with a number of electrophiles;[14b,19,22] effects addition reactions with alkenes[30,35-37])

Alternate Name: trichloroacetic acid ethyl ester.

Physical Data: R = Et, bp 168 °C, d^{20} 1.3836 g cm^{-3}; R = Me, bp 154 °C, d^{20} 1.4874 g cm^{-3}; R = *i*-Pr, bp 175 °C, d^{20} 1.3034 g cm^{-3}; R = *t*-Bu, bp 55 °C/7 mmHg, d^{20} 1.2363 g cm^{-3}.

Solubility: insol H_2O; miscible with alcohol, ether, benzene.

Form Supplied in: colorless liquid with odor resembling menthol; widely available. Purity 97-99%; typical impurity: CCl_3CO_2H <1%.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$) δ 1.4 (t, 3H, CH_3), 4.4 (q, 2H, CH_2). ^{13}C NMR ($CDCl_3$) δ 13.7 (q, CH_3), 65.5 (t, CH_2), 90.0 (s, CCl_3), 161.5 (s, CO). IR (CCl_4) 1769 cm^{-1} (C=O).

Handling, Storage, and Precautions: combustible liquid; harmful and irritant. Incompatible with strong oxidizing agents and strong bases. Avoid prolonged or repeated exposure and contact with eyes, skin, and clothing. Keep tightly closed and store in a cool dry place. Use in a fume hood.

Carbene Precursor.[1a,2b]

The reaction of trichloroacetic acid esters with alkali metal alkoxides (RONa or ROK) generates dichlorocarbene (eq 1), which affords *gem*-dichlorocyclopropane adducts by cycloaddition reaction with various kinds of double bonds.

$$Cl_3CCO_2R + R'OM \longrightarrow R'OCO_2R + MCl + Cl_2C: \quad (1)$$

The alkyl trichloroacetate can be methyl, ethyl, or *t*-butyl[1b] and the alkoxide can be MeONa, EtONa,[1a] *n*-BuONa,[5b] or *t*-BuOK;[1b] the most usual combination is CCl_3CO_2Et and MeONa.[2b,7b] The best results are obtained by the use of excess (1.1 to 5 equiv) of both CCl_3CO_2Et and MeONa components in a nonpolar solvent with cooling. Reaction with the double bonds[1] of alkenes leads to *gem*-dichlorocyclopropane adducts in good yield (eq 2).[1a]

(2)

Such cyclopropanation is also realized with enol ethers[2] (eq 3)[2b] and enol thioethers.[3] The yields of adducts obtained with this carbene procedure are generally higher than those obtained by other methods: ($CHCl_3$, *t*-BuOK),[4] (CCl_3CO_2Na, pyrolysis),[5] and (*n*-BuLi, $CBrCl_3$).[6]

(3)

This carbene procedure has also been applied to the preparation of cyclic allylic and vinylic dichloro derivatives by ring enlargement from polycyclic alkenic compounds (eq 4).[7] The initially formed dichloro adduct rearranges spontaneously[7b-d] or by solvolysis in the presence of silver salts[7a] to provide dichloro compounds by ring expansion. In the norbornene series, such one-carbon-atom expansion leads to derivatives (**1**)-(**5**)[7b-d] in better yields than other methods of generating dichlorocarbene: ($CHCl_3$, *t*-BuOK),[8] (CCl_3CO_2Na, pyrolysis),[5] (CCl_3HgPh, pyrolysis),[9] and ($CHCl_3$, NaOH).[10]

(4)

pet. ether **(1)** 74-88%,[7b] 4-45%[5,8,9]

exo pet. ether **(2)** 50%[7c]

hexane **(3)** 96%[7d]

endo hexane **(4)** 97%, [7e] 50%[10]

exo hexane **(5)** 91%, [7e] 65%[10]

The mild reaction conditions further allow access, albeit in moderate yields, to *gem*-dichloro adducts that are difficult to obtain by other routes. Reactive substrates such as allenes,[11] unstable divinyl ethers[12] that undergo polymerization with other methods, or highly strained polycyclic compounds such as bicyclo[3.2.0]hept-1(5)-ene[13] give dichloro adducts (16-40%) by treatment with this reagent system.

Enolate Precursor.

gem-Dichloroenolates are generated from CCl_3CO_2Et by C-Cl bond cleavage. The lithium enolate[14] prepared by reaction of Me_2NLi (generated from ***Lithium*** metal solution in HMPA/THF) with CCl_3CO_2Et at -78 °C, reacts with electrophiles (H_2O, allyl halides, α-chloroalkyl ethers, aldehydes) to give moderate yields of α,α-dichloroacetate derivatives (E-CCl_2CO_2Et, 35-50%) by two-carbon homologation. Reformatsky-type reactions[15] proceeding via magnesium *gem*-dichloroenolates lead to reduced β-hydroxy esters from aldehydes and ketones (eq 5), albeit with little preparative value.

(5)

Better yields (42-79%) of nonreduced compounds can be obtained[14b,16] by preparing Mg enolates by halogen-metal exchange from *i*-PrMgCl and CCl_3CO_2Et in THF, at low temperature. Subsequent reaction of these enolates with various electrophiles (H_2O, aldehydes, ketones, carboxylic anhydrides, alkyl halides, and α-halo ethers) affords nonreduced adducts (eq 6).

(6)

Reactions of D-glyceraldehyde[17a] and Boc-L-leucinal[17b] with the Mg enolates of methyl and isopropyl trichloroacetates (generated either by exchange with *i*-PrMgCl or by treatment of a phosphonium enolate (see below, eq 11) with $MgCl_2$) in THF at low temperature provide the corresponding α,α-dichloro-β-hydroxy alkyl esters (70% and 50%). The ratios of diastereoisomers are 70:30 for (3*R*,4*R*):(3*R*,4*S*) and (3*R*,4*S*):(3*S*,4*S*) respectively. By the same route, steroidal ketones lead to rearranged β-chloro-α-keto esters.[18]

The zinc dichloroacetate enolate (also called Reformatsky reagent) is prepared prior to use by reaction of CCl_3CO_2Et with ***Zinc*** metal in THF and it reacts with the same substrates as the Grignard reagent with comparable yields (22-81%) (eq 7).[19]

(7)

In the presence of a Lewis acid such as ***Diethylaluminum Chloride***,[20] the Zn enolate reacts with carbonyl compounds to give α-chloro-α,β-unsaturated esters by Knoevenagel-type reaction (51-91%, *Z* > *E*). A dimetalated species such as ClZnC(Cl)=C(OZnX)OEt is the assumed intermediate in this reaction, which constitutes an alternative to the Emmons-Wadsworth-Horner reaction.[21] This procedure has found use in the steroid field for the efficient preparation of α-chloro-α,β-unsaturated esters from ketones, with a two-carbon-chain extension (eq 8).[20b]

(8)

A phosphonium *gem*-dichloroenolate,[22,23] generated in situ by reaction of TDAP (trisdimethylaminophosphine) with CCl_3CO_2Et at low temperature, reacts with carbonyl compounds to give rise, depending on the stoichiometry and the nature of both solvent and substrate, either to α-chloroglycidic esters (eq 9)[22a,b] or to α-chloro-α,β-unsaturated esters (eq 10).[22c]

(9)

(10)

Depending upon both substrate reactivity and reaction conditions, mixtures[22b] of α-chloroglycidic and α-chloro-α,β-unsaturated esters could be formed, arising from path 1 or path 2 (eq 11). Glycidic esters derived from ketones very often undergo isomerization to β-chloro-α-ketoesters.[18,22a,b]

Methyl and isopropyl trichloroacetates have also been used[22b,c] for such transformations. Because of the different reactivity of the phosphine, the Ph_3P-CCl_3CO_2Me reagent system converts aromatic aldehydes into methyl α-chlorovinyl esters in good yields (60-74%, *E* > *Z*). Unlike $(Me_2N)_3P$ (path 2, eq 11), this reaction proceeds via the stabilized ylide, $Ph_3P{=}CClCO_2Me$.[24]

In a special case,[25] with $(Me_2N)_2P(OMe)$ as the P^{III} compound, the alkyl moiety of the phosphite part reacts with the initially formed enolate to provide a product with one-carbon extension instead of the expected phosphate from a Perkow reaction (eq 12).[26]

The ethyl dichloroacetate anion, cathodically generated[27] from CCl_3CO_2Et, adds to cyclic ketones.[27a] Rearrangement of the initially formed dichloro alkoxide affords α-chloro-β-keto esters with one-carbon ring expansion or the corresponding dehydrochlorinated ester (7-43%). Cycloaddition of such species with double bonds[27b] gives ethyl α-chlorocyclopropanecarboxylate (25-55%), expressing carbenoid properties.

Addition Reactions.

Double bonds undergo radical addition reactions with CCl_3CO_2Et (and other trichloroacetate esters) in the presence of various catalysts such as organic peroxides, UV irradiation, a redox system of copper salts, metal carbonyls, ruthenium salts-phosphine complexes, and palladium salts (eq 13).

(13)

On prolonged heating in the presence of $(PhCO)_2O$, CCl_3CO_2Et adds to 1-alkenes to give ethyl 2-alkyl-2,2,4-trichloroacetates with two-carbon chain elongation from the starting alkene. Thus ethyl 2,2,4-trichlorononanoate is obtained from 1-heptene after 20 h under reflux in ~50% yield (purified) as a mixture with the 2:1 adduct.[28] This method affords mainly telomers of high molecular weight with vinyl monomers and only a low yield of the 1:1 adduct with other reactive alkenes such as styrene.[36]

The parent ester CBr_3CO_2Et adds readily in a 1,4-manner to 1,3-butadiene. This reaction is induced by UV irradiation and provides the 1:1 adduct quantitatively[29] (compare with eq 15). The use of copper salts as catalysts directs the reaction mainly towards the formation of the 1:1 adduct, but the yields of products still remain moderate (30-65%) (eq 14).[30]

(14)

Telomerization, especially for 2:1 adduct formation from CCl_3CO_2Me and acrylic monomers with copper complex catalysis, has been studied.[31] The 1,4-addition reaction with 1,3-butadiene works well by redox catalysis with copper salts[32] (eq 15).[32b] The catalytic systems used make it possible to completely suppress polymer and telomer formation and to obtain the 1:1 adduct with good 1,4-selectivity, depending on the type of ligand on the copper complexes.

(15)

Microwave irradiation effects a 20-fold increase in rate in the reaction of CCl_3CO_2Et with styrene catalyzed by a CuCl/*i*-$PrNH_2$ complex (>90%, 15-40 min).[33] Under those conditions, but without microwave activation, the 1:1

adduct is formed exclusively with deactivated chloroethylenes (eq 16) and even with easily polymerizable alkenes such as styrenes.[34]

(16)

Reaction of CCl_3CO_2Me with 1-alkenes catalyzed by dinuclear metal carbonyls[35] ($Co_2(CO)_8$, $[CpMo(CO)_3]_2$, and $[CpFe(CO)_2]_2$) provides different results, depending on the catalyst nature. The Co catalyst gives methyl 4-alkyl-2,2,4-trichlorobutyrate (eq 17), while 4-alkyl-2,2-dichloro-γ-butyrolactone is the main product with the Mo (eq 18) and Fe catalysts. With benzene as the solvent the dichloro lactone (R = H, R´ = Me) is obtained almost exclusively.

(17)

(18)

In the presence of ***Dichlorotris(triphenylphosphine)ruthenium(II)*** the reaction of CCl_3CO_2Et (or CO_2Me) with 1-alkenes leads to the formation of ethyl 2,2,4-trichloroalkanoates (eq 19)[36] in good yields, even with easily polymerizable alkenes such as styrene, acrylonitrile, methyl vinyl ketone, and methyl methacrylate.

(19)

R = H, Me; R' = hexyl, phenyl, CN, Ac, CO_2Me

With CCl_3CO_2Me, 1-decene, and $Pd(OAc)_2$-Ph_3P as catalyst in the presence of base (AcONa or K_2CO_3) the addition reaction proceeds under milder conditions to afford the 1:1 adduct in good yield (eq 20). Unlike the reactions with previous catalysts, this reaction proceeds even at room temperature.[37]

Ethyl Trimethylsilylacetate[1]

[4071-88-9] · $C_7H_{16}O_2Si$ · Ethyl Trimethylsilylacetate · (MW 160.29)

(silylating agent;[2] source of an ethyl acetate anion equivalent[3])

Alternate Name: ETSA.

Physical Data: bp 157-158 °C; *d* 0.876 g cm^{-3}.

Solubility: sol ethereal and chlorinated solvents; reacts with protic solvents.

Form Supplied in: liquid (>98%); commercially available.

Preparative Methods: available by a Reformatsky reaction from ethyl bromoacetate,[4] and by reaction of ***Trimethylsilylmethylmagnesium Chloride*** with ***Ethyl Chloroformate***.[5] An alternative approach requires the treatment of ethyl acetate with triphenylmethylsodium followed by ***Chlorotrimethylsilane***.[6] The use of a nitrogen base with ethyl acetate in THF followed by reaction with chlorotrimethylsilane results in a mixture of *C*- and *O*-silylation. The use of HMPA as additive in the reaction medium increases the amount of *O*-silylation to 90%.[7] Similar methods can be used to prepare analogs.

Handling, Storage, and Precautions: reacts with protic solvents to give the desilylated product.

Ethyl trimethylsilylacetate (**1**) is reactive to nucleophiles and readily undergoes desilylation reactions with acid or alkali, ethanol, and bromine (eq 1).[5,8]

Br_2	= Br	= Br
EtOH	= H	= OEt

Silylation Reactions.

In the presence of a catalytic amount of ***Tetra-n-butylammonium Fluoride*** (TBAF), ester (**1**) is a very efficient silylating agent for a wide variety of substrates including carbonyl compounds, alcohols, phenols, carboxylic acids, and alkynes.[2,9] With unsymmetrical ketones the kinetic enol ether is the preferred product.[2,10] Indeed, the use of (**1**) can provide superior selectivity to the use of hindered bases for enolate formation.[11] This is illustrated with a β,γ-epoxy ester which provides an entry to γ-keto-α,β-unsaturated esters (eq 2).[12] These silylation reactions of (**1**) can also be catalyzed by TBAF supported on silica.[13]

Alkylation Reactions.

The use of fluoride ion or a base catalyst allows reaction of the silyl ester (**1**) with electrophilic substrates (eq 3). Some of these reactions are similar to those of the ester enolate derived from ethyl acetate.[3,14,15]

With conjugated enones a carbon-carbon bond is formed by a Michael addition with concomitant formation of the proximal silyl enol ether (eq 4).[16] In the presence of a Lewis acid, (**1**) undergoes conjugate additions with α,β-unsaturated carbonyl compounds (eq 5).[17]

(4)

(5)

Nitroaromatic compounds react with (**1**) in the presence of ***Potassium Fluoride*** to provide an anionic σ-complex.[18] Subsequent oxidation with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** then provides ethyl arylacetates.[19] With an areneiron(I) complex, the alkylcarbonyl substituent from (**1**) is introduced on to the ring.[20]

Electrophilic Reactions.

Silylacetate (**1**) reacts with 2 equiv of a Grignard reagent to provide 1,1-disubstituted alkenes in good to excellent yield (eq 6), but this synthesis is limited to Grignard reagents that are not sterically demanding.[21]

(6)

Analogs.

The methyl ester (**2**) undergoes similar reactions to the ethyl ester (**1**),[22] as do various silyl analogs.[23] These reactions

also include silylations with methyl trimethylsilylacetate in the presence of fluoride ion.[24,25]

Reaction of the lithium enolate of (**1**) followed by reaction with chlorotrimethylsilane provides ketene acetal (**3**). This enol reacts with aldehydes in the presence of a Lewis acid to provide (*Z*)-α,β-unsaturated esters (eq 7).[26] With conjugated enones, (**3**) undergoes conjugate addition when ***Titanium(IV) Chloride*** is used as catalyst (cf. eq 5).[27]

The use of ethyl diphenylmethylsilylacetate (**4**; R^1 = H) provides for some alternative methodology as the larger silyl group allows for the selective addition of only 1 equiv of Grignard reagent to afford the β-silyl ketone (eq 8).[28] The chemistry can also be extended to other carboxylic acid analogs. A number of approaches are then available for the preparation of ketones.[22,29,30]

In addition to these enolate reactions, β-silyl ketones can be thermally isomerized to silyl enol ethers by a regioselective rearrangement (eq 9),[22,31] or treated with another Grignard reagent to provide alkenes through Peterson

alkenation reactions.[32]

(9)

Many of the reactions of ethyl trimethylsilylacetate and its analogues involve the ester enolate; these are discussed in ***Ethyl Lithio(trimethylsilyl)acetate***.

Related Reagents.

Ethyl Trimethylsilyl Malonate[1-3]

(R = Et)

[18457-03-9] · $C_8H_{16}O_4Si$ · Ethyl Trimethylsilyl Malonate · (MW 204.30) (R = Me)

[51849-23-1] · $C_7H_{14}O_4Si$ · Methyl Trimethylsilyl Malonate · (MW 190.27)

(synthesis of β-keto esters[1-3])

Physical Data: R = Et, bp 75 °C/0.5 mmHg, *d* 1.000 g cm^{-3}; R = Me, bp 105-110 °C/19 mmHg.

Preparative Methods: ethyl trimethylsilyl malonate is commercially available, or it may be easily prepared from the potassium salt of ***Ethyl Malonate***.[1,2,6] Methyl trimethylsilyl malonate has been prepared from *t*-butyl methyl malonate by treatment with ***Trimethylsilyl Trifluoromethanesulfonate***,[4] or from Meldrum's acid (***2,2-Dimethyl-1,3-dioxane-4,6-dione***) and methyl trimethylsilyl ether.[5] The preparation and use of *t*-butyl trimethylsilyl malonate has been reported, although it has not been isolated and characterized.[7,8]

Handling, Storage, and Precautions: the ethyl derivative is reported to be moisture sensitive.

Ethyl trimethylsilyl malonate is a useful alternative to other malonates in the synthesis of β-keto esters. Trimethylsilyl 2-lithio-2-ethoxycarbonylacetate (**1**) adds smoothly to a variety of acid chlorides to provide intermediates which undergo spontaneous decarboxylation upon aqueous hydrolysis at room temperature. However, since the first report of its preparation and use,[1] it has seen only limited application in organic synthesis. The reagent has been utilized in the synthesis of γ,δ-unsaturated β-keto esters (Nazarov reagents), which are themselves useful annulating agents.[2a] Ethyl trimethylsilyl malonate undergoes deprotonation with ***n-Butyllithium*** at low temperature to provide the lithio derivative (**1**). Treatment with crotonyl chloride furnishes ethyl crotonylacetate (eq 1).

The scope of the reaction has been expanded to provide a general synthesis of β-keto esters. A variety of acid chlorides (alkyl, cycloalkyl, aromatic, and heteroaromatic) undergo the reaction (eq 2).[2b,9] The method is applicable to the preparation of bis-β-keto esters from diacid chlorides (eq 3).[2b]

More recently, the mixed anhydride (**2**) has been shown to undergo efficient homologation under these conditions to give keto ester (**3**), a highly functionalized intermediate in the synthesis of members of the acomonine family of diterpene alkaloids (eq 4).[8]

(4)

In the synthesis of corynomycolic acid derivatives,[10] a key β-keto ester intermediate has been prepared from a substituted malonate derivative (eq 5). In this case, higher yields are obtained when ***Lithium Diisopropylamide*** is employed in the deprotonation step instead of *n*-BuLi.

Ethyltriphenylphosphonium Bromide

$Ph_3{+}PEt\ X^-$

(X = Br)

[1530-32-1] · $C_{20}H_{20}BrP$ · Ethyltriphenylphosphonium Bromide · (MW 371.26) (X = Cl)

[896-33-3] · $C_{20}H_{20}ClP$ · Ethyltriphenylphosphonium Chloride · (MW 326.81) (X = I)

[4736-60-1] · $C_{20}H_{20}IP$ · Ethyltriphenylphosphonium Iodide · (MW 418.26)

(generation of the nonstabilized phosphorus ylide ethylidenetriphenylphosphorane for Wittig alkenation reactions[1])

Physical Data: Br, mp 209-210.5 °C;[2] Cl, mp ca. 235 °C (dec); I, mp 164-165 °C.

Form Supplied in: white to off-white solids; 98-99% (bromide; mp 206-208 °C), 98% (chloride), &egt;98% (iodide).

Preparative Methods: involves alkylation of triphenylphosphine with ethyl bromide, chloride, or iodide. The ethyl bromide reaction, performed in benzene at 135 °C in a pressure vessel for 20 h, gives an 89% yield of phosphonium salt (recrystallized from water and dried).[2]

Handling, Storage, and Precautions: may absorb moisture. Store in tightly sealed bottles in a dry place.

Ethylidene Transfer.

The most important synthetic reaction of the title phosphonium salts entails transfer of an ethylidene group, via ethylidenetriphenylphosphorane, to the carbonyl group of aldehydes and ketones in good yields.[1] This nonstabilized phosphorus ylide is prepared in situ by treatment of the phosphonium salt in a suitable dry solvent (e.g. THF, DMSO, toluene, *t*-butanol) with a reasonably strong base (e.g. sodium amide, potassium *t*-butoxide, sodium hydride, butyllithium, sodium hexamethyldisilazide, or dimsylsodium). The choice of base and solvent can significantly impact the yield and stereochemistry of the alkene products.[1,3] With standard aldehydes, the Wittig reaction affords (*Z*)-alkenes preferentially under most conditions. (*E*)-Alkenes are more likely to predominate in an alcohol solvent[3c,h] or by use of a lithium base;[3a,c-f] under lithium salt-free conditions in polar aprotic solvents, (*Z*) stereoselectivity is usually maximized (eqs 1-3).[3a-g]

Unsymmetrical ketones with similar substituents on the carbonyl do not furnish good alkene stereoselectivity.[1b,c] When one of the groups is bulkier, such as with *i*-PrCOMe, ethylidenetriphenylphosphorane furnishes a (*Z*)/(*E*) ratio of ca. 9:1 under lithium-salt conditions.[4] The stereochemistry of ketone alkenation with ethylidenetriphenylphosphorane can be strongly influenced by certain substituents in the carbonyl component, especially an α-alkoxy substituent, which enhances (*Z*) stereoselectivity (eqs 4 and 5).[5] An α-amido substituent can also direct (*Z*) stereoselectivity (eq 6).[5e]

Schlosser has developed a modification of the Wittig reaction in which the intermediate adducts from condensation of ethylidenetriphenylphosphorane and aldehydes (betaines or oxaphosphetanes) are equilibrated by the addition of excess alkyllithium or phenyllithium.[3c,6] This allows the preparation of alkenes highly enriched in the (*E*)-isomer (eq 7),[6] and forms the basis for alkenation reactions with elaborated ylides, sometimes referred to as the SCOOPY reaction.[7,8]

Elaboration of Ylides for Alkylidenation.

Ethylidenetriphenylphosphorane has been elaborated by electrophilic reagents into more complex phosphorus ylides, which can be effectively employed in subsequent alkenation chemistry. By using aldehydes as electrophiles, Schlosser and Corey independently developed useful stereocontrolled syntheses of various trisubstituted alkenes (eqs 8-10).[7,8] Intermediate β-oxido ylides were derivatized with electrophiles such as halogenating agents, reactive alkyl halides, aldehydes, and epoxides (SCOOPY reaction). Acylation of ethylidenetriphenylphosphorane can provide stabilized ylides for the synthesis of complex alkenes (eq 11).[9]

Ethyl 4-(Triphenylphosphoranylidene)acetoacetate

(**1**; R = Et)

[13148-05-5] · $C_{24}H_{23}O_3P$ · Ethyl 4-(Triphenylphosphoranylidene)acetoacetate · (MW 390.40) (**2**; R = Me)

[98815-59-9] · $C_{23}H_{21}O_3P$ · Methyl 4-(Triphenylphosphoranylidene)acetoacetate · (MW 376.37)

(Wittig reagent for the stereoselective synthesis of (*Z*)-enones;[1] annulation reagent for the synthesis of cyclohexenones[2])

Physical Data: R = Et, mp 105-106 °C; R = Me, mp 126 °C.

Solubility: insol cold ether and cold benzene; sol THF, CH_2Cl_2, and chloroform.

Preparative Methods: the title compound (**1**) and its methyl analog (**2**) are prepared in two steps from ethyl or methyl 4-chloroacetoacetates (see ***Ethyl 4-Chloroacetoacetate***), respectively, in 58-68% overall yield (eq 1).[3,4]

Wittig Reactions.

Under neutral conditions, reagent (**1**) exhibits only moderate reactivity in Wittig reactions with aldehydes and, like other stabilized Wittig reagents, generally produces (*E*)-enones (eq 2).[3,5] Although acid catalysis with ***p-Toluenesulfonic Acid*** or benzoic acid is known to effect rate acceleration, the reaction conditions are too destructive in the case of simple aliphatic aldehydes.[1,6] Wittig reaction of (**1**) with protected ribose derivatives provides *C*-glycosides (eq 3), which serve as precursors for the synthesis of *C*-nucleosides.[7,8]

(2)

(3)

The in situ transformation of the carbonyl group in (**1**) into its enolate counterpart using ***Sodium Hydride*** activated by the addition of a few drops of water results in dramatic enhancement of reactivity of the ylide and reversal of stereoselectivity in Wittig reactions.[1] Under these conditions, a high degree of (*Z*) selectivity can be achieved in reactions with aliphatic straight-chain aldehydes as well as with α-branched aldehydes (eq 4).[1,9]

Annulation Reactions.

In the presence of an added base, a variety of α,β-unsaturated aldehydes participate in a [3 + 3] annulation reaction with reagent (**1**) to give cyclohexenones in modest yield (eq 5).[2,10] An excess of sodium hydride activated by a few drops of water is the most effective base for promoting this reaction. Dienals produce a mixture of products resulting from initial 1,2- and 1,4-reactivity under these conditions. However, the use of a catalytic amount of ***Potassium Hydride*** instead of water for the activation of sodium hydride improves the selectivity of cyclohexenone formation (eq 6).[11] Annulation reaction of a highly reactive trifluoromethyl enone with reagent (**2**) proceeds efficiently without any added base (eq 7).[12] The [3 + 3] annulation reactions of (**1**) and (**2**) provide useful alternatives to the commonly used [4 + 2] counterpart, the Robinson annulation, for the synthesis of cyclohexenones.

Ethyl Vinyl Ether[1]

(R = Et)

[109-92-2] · C_4H_8O · Ethyl Vinyl Ether · (MW 72.12) (R = Me)

[107-25-5] · C_3H_6O · Methyl Vinyl Ether · (MW 58.09) (R = *n*-Bu)

[111-34-2] · $C_6H_{12}O$ · Butyl Vinyl Ether · (MW 100.18)

(protection of hydroxyl group; transvinylation, particularly to prepare allyl vinyl ethers for use in the Claisen rearrangement; condensation reactions; cycloaddition reactions)

Physical Data: R = Et, mp -115.8 °C, bp 35-36 °C, *d* 0.7589 g cm^{-3}; R = Me, mp -123 °C, bp 12 °C, *d* 0.7725 g cm^{-3} at 0 °C; R = *n*-Bu, mp -92 °C, bp 94 °C, *d* 0.7888 g cm^{-3}.[2]

Solubility: sol all common organic solvents; slightly sol water.

Form Supplied in: ethyl vinyl ether and *n*-butyl vinyl ether are colorless, extremely flammable liquids, while methyl vinyl ether is a colorless, extremely flammable gas. Ethyl vinyl ether is supplied stabilized with triethanolamine and methyl vinyl ether is supplied in stainless steel cylinders.

Purification: ethyl vinyl ether and *n*-butyl vinyl ether may be distilled from K_2CO_3 or Na if purification of the commercial materials is desirable.

Handling, Storage, and Precautions: all three compounds react *violently* with halogens and with strong oxidizing agents, and undergo rapid polymerization in the presence of acids. These vinyl ethers are lachrymatory and irritate the respiratory system; in particular, methyl vinyl ether can cause rapid suffocation if inhaled. Use in a fume hood.

Protection of the Hydroxyl Group.[3]

Acid-catalyzed reaction of primary and secondary alcohols with ethyl vinyl ether gives the α-ethoxyethyl (EE) group. Acids commonly used in the formation of the EE group include ***Trifluoroacetic Acid*** (eq 1),[4] anhyd ***Hydrogen Chloride*** (eq 2),[5] ***p-Toluenesulfonic Acid***,[6] and ***Pyridinium p-Toluenesulfonate*** (PPTS) (eq 3).[7] Whereas attempts to form the methyl or benzyl ether of the hemiacetal (eq 3), and reaction with DHP, result in decomposition, the

hemiacetal is successfully converted into the EE group with ethyl vinyl ether in the presence of PPTS (but not *p*-TsOH).[7] For extremely acid-sensitive substrates, ethyl vinyl ether generated in situ from 1-chloroethyl ethyl ether (MeCH(Cl)OEt) with $PhNMe_2$ in CH_2Cl_2 at 0 °C gives EE derivatives of primary, secondary, and some tertiary alcohols in excellent yields (eq 4).[8] Selective protection of a primary alcohol in the presence of a secondary alcohol with ethyl vinyl ether may be achieved at low temperatures (eq 5).[9] The EE group is more readily cleaved by acid hydrolysis than the THP ether, but is more stable than the 1-methyl-1-methoxyethyl ether.[3] In the case of the nucleoside (eq 2), which is subsequently converted into a nucleotide, the ethoxyethyl group is preferred to the THP group because of its ease of removal (5% HOAc, 2 h, 20 °C), with no detectable isomerization of the 3´-5´ nucleotide linkage.[5] Other methods of cleaving the EE group include 0.5N HCl in THF at 0 °C,[6] and PPTS in *n*-PrOH, where cleavage is possible in the presence of an acetonide group (eq 6).[10]

(1)

(2)

(3)

(4)

(5)

(6)

Augmenting its role as a protecting group, the EE group has been used to direct *ortho*-lithiation in suitably substituted aromatic ethers, yielding lithiated species that react rapidly with a variety of electrophiles, such as ***Carbon Dioxide***, to give the phthalide (eq 7).[11]

(7)

Transvinylation.

Acid-catalyzed transvinylation of allylic alcohols with ethyl vinyl ether gives allyl vinyl ethers, Claisen rearrangement[12] of which affords γ,δ-unsaturated aldehydes of varying complexity (eqs 8-12).[13,14,16-18] ***Mercury(II) Acetate*** (eq 8),[13] ***Phosphoric Acid*** (eq 9),[14] and *p*-TsOH[15] are frequently used to catalyze the transvinylation reaction, and the allyl vinyl ethers produced need not be isolated but may be subjected directly to the Claisen rearrangement, typically at 145-200 °C. $Hg(OAc)_2$, used in the transvinylation reaction, has been reported to effect the rearrangement at lower temperatures (eq 10).[16] Other examples illustrating the stereoselectivity of the reaction are given in eqs 11 and 12.[17,18]

(8)

(9)

(10)

(11)

(12)

Condensation Reactions.

Acetal Condensations.

The acid-catalyzed condensation of ethyl vinyl ether with acetals derived from α,β-unsaturated aldehydes and ketones is an excellent method to lengthen a carbon chain by two carbon atoms, particularly of polyenals. In an industrial process for the manufacture of the C_{16} aldehyde (eq 13), the C_{14} acetal is reacted with ethyl vinyl ether in the presence of ***Zinc Chloride*** to give an alkoxy acetal, which, without isolation, is then hydrolyzed with moist acetic acid.[19] Longer conjugated carotenals have been synthesized by this method,[20] and montmorillonite K-10 clay (see ***Montmorillonite K10***) has been reported to be an excellent replacement for the Lewis acids normally used in the condensation.[21]

(13)

Acyl Anion Equivalents.[22]

The α-H of simple vinyl ethers can be deprotonated with strong bases, such as ***t-Butyllithium***, to give highly reactive α-alkoxyvinyllithium reagents (see also ***1-Ethoxyvinyllithium*** and ***1-Methoxyvinyllithium***). These react rapidly with various electrophiles, including aldehydes and ketones (eq 14),[23] and can undergo conjugate addition to α,β-unsaturated carbonyl compounds via the corresponding cuprates (eq 15).[24]

(14)

(15)

Cycloaddition Reactions.

Diels-Alder and Related Reactions.

Owing to their electron-rich nature, vinyl ethers participate in a number of inverse electron demand Diels-Alder reactions.[25] α,β-Unsaturated aldehydes and ketones react rapidly with vinyl ethers to give dihydropyrans (eq 16),[26] with high *endo* selectivity (eq 17),[27] the proportion of *endo* adduct being increased by conducting the reaction at low temperatures under pressure (eq 18).[28] Lewis acids can also catalyze these reactions and control the stereochemistry of cycloaddition.[25b,29] *o*-Quinone methides yield chromans (eq 19),[30] and imines give tetrahydroquinolines (eq 20).[31] Vinyl ethers react regio- and stereoselectively with isoquinolinium salts giving cycloadducts, which on hydrolysis afford tetralins in excellent yields (eq 21).[32] The cycloaddition of vinyl ethers with nitrones proceeds smoothly, giving, where relevant, isoxazolines with extremely high diastereoselectivity (eq 22).[33] Vinyl ethers react with nitroalkenes to give nitronate esters in moderate yields (eq 23),[34] but excellent yields of cyclobutane derivatives are obtained with tetracyanoethylene (eq 24).[35]

Photochemical.

Vinyl ethers undergo the Paterno-Büchi reaction with simple aliphatic and aromatic carbonyl compounds to give regioisomeric mixtures of alkoxyoxetanes, with a preponderance of the 3-alkoxy regioisomer (eq 25).[36] Photoaddition of vinyl ethers to enones produces alkoxycyclobutanes in excellent yields, with the alkoxy group orientated predominantly away from the carbonyl group (eq 26).[36] Vinyl ethers also undergo photoaddition to arenes, giving, with benzene, a mixture of *ortho*- and *meta*-cycloadducts in low yields; only the *exo* isomer is produced in the *ortho*-cycloaddition, whereas the *meta*-cycloaddition gives a mixture of regio- and stereoisomers (eq 27).[37]

Ethylzinc Iodide[1]

EtZnI

[994-75-7] · C_2H_5IZn · Ethylzinc Iodide · (MW 221.36)

(used in combination with CH_2I_2 for the cyclopropanation of alkenes (Sawada reaction);[1] displays the typical reactions of an alkylzinc halide[2])

Physical Data: mp 98 °C dec; polymeric in the solid state, monomeric in ether, THF, and ethyl iodide.

Solubility: sol hexane, toluene, ether, THF, amines.

Form Supplied in: not commercially available.

Preparative Methods: by the reaction of commercially available ***Diethylzinc*** and ***Zinc Iodide*** in many solvents,[3] or directly from ***Ethyl Iodide*** and ***Zinc*** powder.[4]

Analysis of Reagent Purity: iodometric titration according to Job.[5]

Handling, Storage, and Precautions: ethereal solutions are stable for several months at 25 °C under an inert atmosphere, if contact with oxygen and moisture is avoided.

Cyclopropanation of Alkenes.

A wide range of alkenes and functionalized alkenes can be cyclopropanated by ***Diiodomethane*** and a ***Zinc/Copper Couple*** (Simmons-Smith reaction (see ***Diethylzinc*** and ***Iodomethylzinc Iodide***)).[1c] The easy insertion of zinc into diiodomethane leads to iodomethylzinc iodide[6] (ICH_2ZnI), which is the actual cyclopropanation reagent.[7] Diethylzinc[8] (Furukawa reaction) and ethylzinc iodide[9] (Sawada reaction) undergo a fast iodine-zinc exchange reaction with CH_2I_2, generating iodomethylzinc derivatives (eq 1). After the addition of an alkene, cyclopropanes are obtained in moderate to good yields (eq 2). A comparison between the three methods for generating iodomethylzinc-derived cyclopropanation reagents shows that the procedure using EtZnI often affords the best yields (Table 1).[9]

$$ICH_2ZnEt \xleftarrow[-\,EtI]{Et_2Zn} CH_2I_2 \xrightarrow[-EtI]{EtZnI} ICH_2ZnI \qquad (1)$$

(2)

Table 1 Comparison between the Simmons Smith,[10] Sawada,[9] and Furukawa[8] Cyclopropanation Procedures for Alkenes

Alkene	Yield (%) of the corresponding cyclopropane		
	Simmons Smith method[a]	Sawada method[b]	Furukawa method[c]
Cyclohexene	61	92	79
Styrene	32	78	76
1-Octene	70	77	60
Butyl vinyl ether		15	92
Methyl crotonate	9	24	

[a] Zn/Cu couple and CH_2I_2. [b] EtZnI and CH_2I_2. [c] Et_2Zn and CH_2I_2.

In some cases with the Sawada method the cyclopropanation succeeds, whereas the original Simmons-Smith procedure completely fails (eq 3).[10] The best experimental procedure consists of heating an excess of an ethereal solution of ethylzinc iodide (ca. 4 equiv) with diiodomethane (1.2 equiv) for an hour, adding the alkene (1.0 equiv) at 0 °C, and stirring the reaction mixture at 25 °C for several hours. Under these conditions, alkenylsilanes can be cyclopropanated in high yields (eq 4).[11]

Other Uses.

Like other alkylzinc halides,[11] ethylzinc iodide adds to aldehydes,[4a] although in moderate yields due to its low reactivity. Far better results are obtained when the reactions are performed in the presence of Cu^I salts.[12] For example, reaction with cinnamyl chloride in the presence of catalytic ***Copper(I) Cyanide*** produces the allylated product (preferential S_N2' substitution) in satisfactory yield (eq 5).[13] Ethylzinc iodide has also been used for performing metathesis[14] and aldol condensation[15] reactions (eq 6), and as a polymerization[16] catalyst.

Ethynyldimethylaluminum

[66530-06-1] · C_4H_7Al · Ethynyldimethylaluminum · (MW 82.08)

(conjugate addition of ethynyl groups to enones[1,2])

Alternate Name: dimethylaluminum acetylide.

Solubility: sol ether.

Preparative Method: from ***Lithium Acetylide*** and ***Dimethylaluminum Chloride***.[1]

Handling, Storage, and Precautions: generated in situ and used directly.

Conjugate Addition of Acetylides to α,β-Enones.

Ethynyldimethylaluminum and its derivatives are useful reagents for the 1,4-addition of alkynyl groups to α,β-unsaturated ketones (eq 1).[1,2] The complex formed by reaction of ***Nickel(II) Acetylacetonate*** and ***Diisobutylaluminum Hydride*** (1:1) catalyzes the conjugate addition of the alkynyl unit of dialkylaluminum acetylides to both *s-cis* and *s-trans* enones. A low yield is obtained for direct addition of dimethylaluminum acetylide (R = H) to α,β-enones. This conjugate adduct is destroyed over a relatively short period of time in the presence of the nickel species due to side reactions involving the product, a terminal alkyne.

Ethynylmagnesium Bromide

(X = Br)

[4301-14-8] · C_2HBrMg · Ethynylmagnesium Bromide · (MW 129.24) (X = Cl)

[65032-27-1] · C_2HClMg · Ethynylmagnesium Chloride · (MW 84.79)

(addition of acetylene to ketones;[1] preparation of TMSC&tbond;CH[2])

Preparative Methods: an *Organic Synthesis* preparation of ethynylmagnesium bromide[1] and chloride[2] from ***Acetylene*** and ***Ethylmagnesium Bromide*** or butylmagnesium chloride, respectively, is available. The use of butylmagnesium chloride instead of ethylmagnesium bromide is recommended[2] because of the greater solubility of the chloride.

Handling, Storage, and Precautions: ethynylmagnesium halides are air and moisture sensitive. They are usually used immediately after preparation.

Addition to Ketones and Aldehydes.[1]

Ethynylmagnesium bromide adds to ketones and aldehydes to give ethynyl carbinols (eq 1). The reagent is less prone to disproportionation to XMgC&tbond;CMgX than is monolithium acetylide. ***Lithium Acetylide*** provides the above product in 96% yield.[3] Ethynylmagnesium chloride also adds to aldehydes (eq 2).[4]

(1)

(2)

Preparation of TMS-acetylene.[2]

Treatment of ethynylmagnesium chloride with ***Chlorotrimethylsilane*** provides a good route to ***Trimethylsilylacetylene*** (eq 3).

(3)

Related Reagents.

Lithium Acetylide; ***Lithium Chloroacetylide***; ***Lithium (Trimethylsilyl)acetylide***.

β-Ethynyl-β-propiolactone[1]

(R = CH&tbond;C-)

[59092-51-2] · $C_5H_4O_2$ · β-Ethynyl-β-propiolactone · (MW 96.09) (R = CH_2=CH-)

[7379-79-0] · $C_5H_6O_2$ · β-Vinyl-β-propiolactone · (MW 98.11)

(five-carbon homologating reagents for synthesis of dienoic and enoic acid derivatives)

Physical Data: R = ethynyl, bp 34-36 °C/3 mmHg; R = vinyl, bp 44-48 °C/4 mmHg.

Solubility: miscible with alcohol, acetone, ether, chloroform.

Form Supplied in: colorless oil.

Preparative Methods: by [2 + 2] cycloaddition of ketene with propynal (for β-ethynyl-β-propiolactone)[2a] and with acrolein (for the β-vinyl analog).[2b,c]

Handling, Storage, and Precautions: can be stored in the refrigerator for several months without noticeable changes. Cancer suspect reagent; β-ethynyl- and β-vinyl-β-propiolactone should be handled with due care.

β-Ethynyl-β-propiolactone.

Studies on the ring opening of β-ethynyl-β-propiolactone indicate that, under the influence of a catalytic amount of ***Palladium(II) Chloride*** in methanol or ethanol at room temperature, the ring opening takes place smoothly to give 3-alkoxy-4-pentynoic acids (eq 1).[2a] When the crude mixture is refluxed for a few hours, a quantitative esterification takes place.

Regioselective attack at the terminal sp carbon is accomplished by the use of Grignard reagents in the presence of ***Copper(I) Iodide*** to give 3,4-alkadienoic acids (eq 2).[3] Results using a variety of Grignard reagents are summarized in Table 1. In the case of allylic metal reagents, diallylcuprate appears to be the reagent of choice.

Table 1 Reaction of (**1**) with Grignard Reagents in the Presence of Copper(I) Iodide (eq 2)

RMgX	Yield (%)	RMgX	Yield (%)
MeMgBr	97	PhMgBr	78
BuMgBr	97	VinylMgBr	72
s-BuMgCl	90	AllylMgBr	11
t-BuMgCl	85	$(Allyl)_2CuMgBr$[a]	54

[a] In the absence of copper(I) iodide.

The application of this procedure to the synthesis of pellitorine is accomplished by the use of this ring opening followed by isomerization of the allenic double bond and amide formation (eq 3).[4]

β-Vinyl-β-propiolactone.

The regioselectivity of the ring opening of the vinyl analog is dependent on the nucleophile used (eq 4). ***Sodium Methoxide***, a hard nucleophile, effects acyl-oxygen cleavage (path A), whereas methanol and benzylamine attack at the β-carbon to the carbonyl (path B), and a soft nucleophile such as ***Lithium Iodide*** or organocopper reagents favor path C.[5] In the case of organocopper reagents, the geometry of the resulting double bonds is (*E*) when the reaction is conducted at lower temperatures. Similar to the reaction with the β-ethynyl derivative, diallylcuprate seems to be a better reagent for allylation.[5,6] In addition to Grignard reagents, the regioselective ring opening proceeds with metalated *N*,*N*-dimethylhydrazone (**2**), an enolate equivalent, to give 7-oxo-3-alkenic acid,[7] whereas lithium dithioester enolate (**3**) effects the formation of 6-(methylthio)thiocarbonyl-(*E*)-3-alkenoic acid.[8]

(2) **(3)**

Under the influence of a catalytic amount of $PdCl_2$ in methanol or ethanol at room temperature, the β-vinyl derivative also undergoes ring opening smoothly to give 3-alkoxy-4-pentenoic acids (eq 5).[2a]

(5)

The reaction with ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) followed by sodium methoxide gives cyclopropylacetic acid (eq 6).[9]

(6)

β-Vinyl-β-propiolactone serves as a useful C_5 unit for the syntheses of royal jelly acid (**4**), queen substance (**5**),[10]

recifeiolide (**6**), and pyrenophorin (**7**).[11]

Ethynyl *p*-Tolyl Sulfone[1]

[13894-21-8] · $C_9H_8O_2S$ · Ethynyl *p*-Tolyl Sulfone · (MW 180.22)

(dienophile used in electrocyclic reactions such as dipolar cycloaddition,[2-4] Diels-Alder reaction,[5-7] and ene cyclization;[8] electron-poor Michael acceptor in conjugate additions;[9-17] undergoes direct displacement with organometallic complexes to give aryl- or alkylacetylenes[18])

Alternate Name: *p*-toluenesulfonylacetylene.

Physical Data: colorless crystals, mp 74-75 °C, mp 75 °C (hexane-ethyl acetate, 95:5).[19]

Solubility: sol most organic solvents.

Analysis of Reagent Purity: based on combustion and spectral examination.[19]

Preparative Methods: has been prepared by several groups over the years employing a variety of synthetic strategies including ethynyl Grignard addition to *p*-toluenesulfonyl fluoride,[20] dehydroiodination of (*E*)-2-iodo-1-tosyl-1-ethene,[21] oxidative elimination of β-[(4-methylphenyl)seleno]vinyl sulfone,[22] dehydrobromination of *cis*- and *trans*-2-bromovinyl 4-methylphenyl sulfone,[23] diazotization of 4-[(4-methylphenyl)sulfonyl]-5-aminoisoxazole,[24] and oxidation of ethynyl thioether.[25] The modified strategy commonly used today is an established Friedel-Crafts based procedure first performed by Bhattacharya et al.[26] but recently exploited by Waykole and Paquette (eq 1).[19] Its simplicity and mildness has shown it to be broadly useful since it bypasses the need for immoderate conditions encountered in the earlier strategies.[19]

Purification: recrystallization readily removes an impurity formed by flash chromatography.

Handling, Storage, and Precautions: decomposition of the intermediate complex *p*-toluenesulfonyl chloride-aluminum chloride-bis(trimethylsilyl)acetylene with hydrochloric acid and ice is exothermic and due caution is recommended. Also, a nitrogen atmosphere is suggested throughout its preparation due to the hygroscopic nature of the reagents and intermediate(s) involved.[19]

Dipolar Cycloadditions.

Padwa and Wannamaker[2] have shown recently that ethynyl *p*-tolyl sulfone (**1**) undergoes a thermal 1,3-dipolar cycloaddition reaction with diazomethane (eq 2). Surprisingly, regioisomer (**2**) is formed in preference to *N*-methyl-4-(*p*-tolylsulfonyl)pyrazole, the expected isomer. Substitution of the acetylenic proton in (**1**) with the bulky trimethylsilyl group, however, furnishes only the expected regioisomer in quantitative yield following desilylation with fluoride. Further studies with 2-diazopropane led Padwa and Wannamaker to conclude that the difference in regioselectivity was primarily due to steric hindrance and not to an electronic effect.[2]

Heteroaromatic *N*-oxides and ylides are also suitable dipoles in this reaction.[3,4] For example, 4-chloropyridine *N*-oxide undergoes a smooth and clean cyclization with (**1**) in boiling toluene to yield 3-tosylfuro[3,2-*c*]pyridine (**3**) in 65% yield (eq 3).

Diels-Alder Reactions.

The dienophilic properties of (**1**) in combination with the reductive elimination of the tosyl unit have made this compound a useful acetylene synthetic equivalent in various Diels-Alder reactions; it has a pivotal role in the synthesis of the elusive 7-azanorbornadiene (eq 4).[5] Cycloaddition is easily accomplished on a preparative scale in 60% yield by heating (**1**) with *N*-methoxycarbonylpyrrole. Desulfonation of (**4**) with 6% ***Sodium Amalgam*** in buffered medium affords a 42% yield of protected 7-azanorbornadiene (**5**), which is converted to the parent compound in two steps (72% yield). Notably, the first *C*-unsubstituted derivative, 7-tosyl-7-azanorbornadiene was synthesized by a laborious route by Prinzbach and Babsch;[27] however, cleavage of this protecting group was troublesome.[5]

(4)

Another use of (**1**) as an acetylene equivalent is in its central role in the construction of the polyhedron [4]peristylane, which can be prepared in only 11 steps (eq 5).[6] Examples of Diels-Alder reactions between ethynyl *p*-tolyl sulfone and other dienes also exist.[7]

Ene Cyclizations.

Ethynyl *p*-tolyl sulfone has been shown by Snider et al.[8] to undergo a ***Ethylaluminum Dichloride***-catalyzed ene cyclization with alkenes to furnish a functionalized two-carbon fragment, a vinyl sulfone, which is a versatile synthon.[28] For example, 2,3-dimethyl-2-butene reacts with (**1**) in the presence of catalytic ethylaluminum dichloride to give dienyl sulfone (**6**) in 89% yield (eq 6). In general, these reactions proceed at 25 °C in aromatic solvents and are best for highly substituted, i.e. electron-rich, alkenes. Good yields of ene adducts are obtained from all alkenes with at least one disubstituted carbon.[8] Monosubstituted alkenes give low yields of adducts while 1,2-disubstituted alkenes give low yields of a mixture of ene product and cyclobutene byproduct.[8] The choice of ethylaluminum dichloride as catalyst appears to be optimal.

(6)

(6)

Conjugate Additions.

As a class of compounds, arylsulfonylalkynes behave as good Michael acceptors toward nucleophiles such as amines,[9] alkoxides,[10] thiolates,[11] hydroxylamines,[12] cuprates,[13] malonate anions,[14] and other enolates[15] (eq 7). Some examples are provided in Table 1.

[a] 2 h reaction time. [b] 144 h reaction time. [c] Not given.

Oxygen- and sulfur-containing anionic nucleophiles such as alkoxides and thiolates add kinetically in a *cis* fashion to yield the (*Z*)-isomer; however, over extended periods of time, isomerization to the more stable (*E*)-isomer can be accomplished via an addition/elimination pathway.[11a,29] Nevertheless, several different mechanistic pathways have been postulated and may be operative, depending on the nature of the substrate.[11a,29] Cuprates, in general, react to give almost exclusively (100-95%) the (*E*)-isomer at 0 °C, but at lower temperatures, such as -78 °C, the (*Z*)-isomer begins to make a minor (5-20%) contribution, perhaps through reactive intermediate (*E*) to (*Z*) isomerization.[13] In contrast, soft enolates like malonate anions give predominately the (*Z*)-isomer.[14] Owing to transition-state stabilization of the *cis* configuration, neutral nucleophiles like amines add stereospecifically in a *trans* manner to give (*E*)-isomer unless the adducts are capable of immonium-type resonance, in which case the addition is followed by an extremely rapid isomerization to the (*Z*) configuration.[9] Moreover, hydroxylamines also undergo conjugate addition to (**1**), but ensuing tautomerization provides nitrones usually as the main product.[12]

Dialkylaminoalkynes have been shown by Himbert and Kosack[16] also to react with (**1**) through its extended conjugation at room temperature to give 2-amino-5-(*p*-tolylsulfinyl)furans, which, if desired, can be thermally isomerized to maleic acid derivatives. *N*-Methyl-*N*-ethynylamine (**8**), for example, was stirred at rt with ethynyl *p*-tolyl sulfone to give (**9**) in 64% yield.[17] Isomerization of (**9**) in refluxing acetonitrile for 3 h gave almost exclusively the (*Z*)-maleate (**10**) (eq 8). The (*E*)-isomer was barely detectable by NMR spectroscopy.

(8)

Direct Displacement.

Replacement of the arylsulfonyl group in substrates like (**1**) by various alkyl and aryl Grignard or lithium complexes has been reported.[17] The reaction is believed to involve initial attachment of the organometallic to the sulfonyl-bearing (α) carbon followed by expulsion of the arylsulfinate leaving group.[17] Such a transformation offers another synthetic route to aryl- or alkylacetylenes. As such, mesitylmagnesium bromide reacts with ethynyl *p*-tolyl sulfone to give mesitylacetylene (**11**) in 85% yield (eq 9).

Europium(III) Chloride[1]

$EuCl_3.6H_2O$

(anhydrous)

[10025-76-0] · Cl_3Eu · Europium(III) Chloride · (MW 258.32) (hexahydrate)

[13759-92-7] · $H_{12}Cl_3EuO_6$ · Europium(III) Chloride · (MW 366.41)

(member of a family of moderate Lewis acids capable of acting as catalysts in selected oxidative and reductive processes,[2-4] with particular utility in systems designed to exploit the chemistry of divalent and zerovalent reagents[2,4] and organometallic intermediates[5-7])

Alternate Name: europium trichloride.

Physical Data: mp 623 °C (dec); *d* 4.89 g cm^{-3}.

Solubility: anhydrous salt: sol dilute HCl; hydrolyzes in water to form oxychloride; sol alcohol and acetone; slightly sol in THF. Hydrate: sol water.

Form Supplied in: hydrated white crystalline solid which can be dehydrated to a yellow powder which intensifies in color upon heating; commercially available in both forms; readily recyclable; typically >99.9% pure with regard to total metallic impurities.

Preparative Methods: highest quality material is produced by reacting Eu_2O_3 at ca. 200 °C with the vapors of a suitable chlorinating agent (CCl_4 has been shown to work well).

Handling, Storage, and Precautions: hydrated salt is hygroscopic: keep tightly closed; hydration state may vary slightly; anhydrous salt should be handled and kept under nitrogen or argon; color modification to yellow-green may occur upon long-term storage under inert atmosphere.

Introduction.

The ability of selected lanthanide salts to promote an intriguing array of organic reaction mechanisms has led synthetic chemists to focus on key elements such as cerium,[8] lanthanum,[9] and samarium.[10] The relatively low cost of cerium and lanthanum reagents makes them particularly attractive for synthetic studies, whereas the use of samarium in organic synthesis features the unique chemistry of the Sm^{II} species, typically derived in situ or used in solution as the diiodide (see ***Samarium(II) Iodide***).[10,11] The other lanthanide species which form stable M^{II} oxidation states, ytterbium and

europium, have not been as extensively explored as synthetic organic reagents for a variety of reasons. In the case of europium, the primary factor has been material cost relative to the other lanthanides.

The accessibility of both Eu^{III} and Eu^{II} species has not been lost on researchers in various fields. Favorable thermodynamic parameters have been the basis for studies of new energy systems;[12] in the mid-1980s, investigation of solar energy conversion determined that both $SmCl_3$ and $EuCl_3$ (hydrated) catalyze the photogeneration of hydrogen in weakly acidic alcohol solutions, forming a variety of organic byproducts by a light-assisted solvent-to-ion single electron transfer.[13]

Hydroxymethylation.

Adapting hydrogen-generating Eu^{III}/Eu^{II} photoredox systems directly to organic photochemical reactions has shown limited synthetic promise. A radical mechanism governing the reaction of α-methylstyrene with a hydrogen atom and a hydroxymethyl radical was proposed for eq 1.[14] The formation of Eu^{II} ions as the key reactive intermediate for the reduction was confirmed by spectroscopic measurements.

(1)

When 1,3-dimethyluracil is used as substrate, efficient regioselective hydroxymethylation takes place via an electron transfer mechanism (eq 2).[15] The Eu^{II} resulting from the oxidation of the alcohol becomes the primary light-absorbing species, promoting hydrogen generation. This chemistry was deemed pertinent to the photoinduced cross-linking of uracil and amino acids.

(2)

Further insights into the scope of this redox system came from a study of the reaction of various alkenes with methanol solutions of europium trichloride. The process has been described as a useful, general hydroxymethylation method.[16] The potential of this technique in more elaborate organic synthesis was explored in a study involving hydroxyalkylation and lactone formation of dialkyl malonates, where the europium species serves as photocatalyst and also as a condensation catalyst (eq 3).[17] A similar reaction carried out in ethanol produced a more complex array of products at a significantly reduced rate of reaction. Diethyl maleate undergoes photoconversion according to eq 4.

Lewis Acid Catalyst.

More recent literature surveys of organic reactions involving europium trichloride offer little beyond comparative studies of lanthanide chlorides as Lewis acid catalysts in classical organic syntheses such as Friedel-Crafts reactions. The efficiency of a variety of anhydrous lanthanide chloride catalysts relative to ***Aluminum Chloride*** in the benzylation of benzene follows the order $AlCl_3$ > $DyCl_3$ > $SmCl_3$ > $YbCl_3$ > $EuCl_3$.[18]

Transesterification of phosphate diesters is an area in which the catalytic activity of trivalent lanthanide ions appears to exceed that of transition metal ions.[19] In the reaction shown in eq 5, the observed order of activity was Tb^{III} > Gd^{III} > Yb^{III} > Eu^{III} > Nd^{III} based on apparent-second-order rate constants. The catalytic activity of Eu^{III} in phosphorus(V) nucleophilic displacement reactions has also been demonstrated in the cleavage of transfer-RNA, where relative rates of cleavage follow the order Eu^{III} > Pb^{II} > Zn^{II} > Mg^{II}.[20] In this case, favorable Lewis acid character rather than redox potential seems to be the dominant factor in metal ion catalyst efficiency.

Overcoming the unfavorable economics of synthetic procedures involving europium species may depend upon the development of creative methods that combine europium's unique redox capabilities with the favorable Lewis acidity exhibited in selected bioinorganic processes. Otherwise, other lanthanide reagents will continue to dominate the attention of synthetic organic chemists.

---

1. To date, the chemistry of europium trichloride has been of insufficient scope to warrant review as a major contributor to organic synthesis. Inference of its potential in selected chemical transformations can be derived from reviews cited below.2-7

Ferrocene

[102-54-5] · $C_{10}H_{10}Fe$ · Ferrocene · (MW 186.05)

(source of most substituted ferrocenes and hence precursor of substituted cyclopentadienes and cyclopentanes; the derived ferrocenium salts find use as mild oxidants; replacement of one ring by arenes yields cationic complexes which undergo nucleophilic addition and substitution at the arene ring, leading to substituted arenes)

Alternate Name: bis(cyclopentadienyl)iron.

Physical Data: mp 173-174 °C; sublimes slowly at room temperature, rapidly at 100 °C; bp 249 °C; *d* 1.49 g cm^{-3}.

Solubility: sol all common organic solvents; insol water.

Form Supplied in: deep orange crystals; widely available.

Handling, Storage, and Precautions: stable up to 470 °C; stable to alkalis and, in the absence of air, to strong, non-oxidizing acids; oxidized by air in the presence of strong acids and by many oxidizing agents, including HNO_3 and the halogens, reversibly forming the cation $(C_5H_5)_2Fe^+$.

Introduction.

Ferrocene[1,2] is a typically aromatic system and as such has a wide-ranging chemistry based on its substitution reactions. As a synthetic reagent its primary use is as a source of useful ferrocene derivatives themselves. These include sensors, which make use of the readily reversible oxidation of ferrocene and its derivatives, monomers for the synthesis of redox active polymers, compounds with nonlinear optical properties, and antianaemic agents. Ferrocene also serves as the source of cationic complexes of benzene derivatives, which are thereby rendered reactive towards nucleophiles. Although ferrocene derivatives can be cleaved to yield cyclopentane or cyclopentadiene derivatives, it has only rarely found use for this purpose.

With only the limits imposed by their facile oxidation, ferrocene derivatives undergo all the common functional group transformations of arenes. It is appropriate here to review only the principal direct substitution processes with emphasis on differences from the chemistry of benzenoid aromatics. These arise chiefly from the impossibility of effecting direct halogenation or nitration since all potential reagents oxidize ferrocene to the unreactive ferrocenium cation $[Fe(C_5H_5)_2]^+$. This cation itself is a very mild one-electron oxidizing agent which has frequently been employed to oxidize other organometallic species.

The ferrocenyl group, $C_5H_5FeC_5H_4$, is commonly abbreviated as Fc.

Electrophilic Substitution Reactions.

Ferrocene shows very high reactivity towards electrophiles, making it more closely comparable to phenol than to benzene. Thus it undergoes facile Vilsmeier formylation to the aldehyde (eq 1)[3] and Mannich-type aminomethylation (eq 2).[4] The aminomethylated product is frequently utilized in the form of its quaternary ammonium salt, $FcCH_2NMe_3^+ I^-$, which is highly reactive towards nucleophiles, readily undergoing S_N1-type reactions due to the high stability of α-ferrocenyl carbocations.[5] This stability also accounts for the basicity of the aldehyde which keeps it in the protonated form during the reaction depicted in eq 1, thereby preventing further substitution. This and similar examples show that electronic effects are transmitted to a substantial degree from the substituted to the unsubstituted ring. In the case of eq 2, disubstitution to yield 1,1´-bis(dimethylaminomethyl)ferrocene can be achieved under forcing conditions.[6]

(1)

(2)

Friedel-Crafts acylation [with acid chlorides/$AlCl_3$ (eq 3) or acid anhydrides/BF_3] is readily regulated by the choice of reaction conditions to give mono- or disubstitution; the latter includes a very small amount of 1,2-disubstitution.[1] Column chromatography readily separates mixtures. Sulfonation, best done with ***Chlorosulfonic Acid***,[7] is more difficult to regulate (eq 4).

(3)

$$Cp_2Fe + ClSO_3H \xrightarrow{Ac_2O} FcSO_3H + Fe(C_5H_4SO_3H)_2 \qquad (4)$$

Arylation occurs when ferrocene is treated with arenediazonium salts and can likewise yield both mono- (eq 5) and 1,1´-disubstituted products; it has been shown to proceed via an initial electron-transfer step.[8]

$$Cp_2Fe + ArN_2^+ \longrightarrow FcAr + Fe(C_5H_4Ar)_2 + N_2 + H^+ \quad (5)$$

Most other simple ferrocene derivatives arise either by functional group transformations of the above products or via metallated compounds. Mercuration yields mixtures of mono- and bis(acetoxymercury) derivatives (eq 6), readily converted by ***Lithium Chloride*** or NaCl to the chloromercury derivatives and differing sufficiently in solubility to be fairly easily separated.[9] The chloromercury compounds in turn react with halogens, copper halides, or *N*-halosuccinimide to provide a good source of mono- and dihaloferrocenes.[10]

$$Cp_2Fe + Hg(OAc)_2 \longrightarrow FcHgOAc + Fe(C_5H_4HgOAc)_2 + HOAc \quad (6)$$

Lithiation is of wider use as well as more controllable. Whereas ***n-Butyllithium*** yields mixtures of mono- and 1,1´-dilithioferrocene (eq 7),[11] addition of ***N,N,N´,N´-Tetramethylethylenediamine*** leads almost exclusively to the dilithio derivative,[12] and replacement of *n*- by ***t-Butyllithium*** results in highly selective monolithiation.[13] Lithioferrocene in turn can then serve as the source of the haloferrocenes by reaction with polyhalocarbons or *p*-toluenesulfonyl halides, etc.,[10d,e] of nitroferrocene by reaction with, for example, alkyl nitrates (eq 8)[14a] or N_2O_4,[14b] of aminoferrocene by reaction with *O*-alkylhydroxylamines, e.g. eq 9,[15] and of ferroceneboronic acid by reaction with tributyl borate.[16]

$$Cp_2Fe + BuLi \longrightarrow FcLi + Fe(C_5H_4Li)_2 + C_4H_{10} \quad (7)$$

$$FcLi + RONO_2 \longrightarrow FcNO_2 + ROLi \quad (8)$$

$$FcLi + H_2NOCH_2Ph \longrightarrow FcNH_2 + PhCH_2OLi \quad (9)$$

The boronic acid is an alternative precursor of haloferrocenes and can similarly give acetoxyferrocene, both by reaction with copper salts (eq 10).[17] The acetate reacts with Grignard reagents to give hydroxyferrocene, but both this phenolic compound and aminoferrocene are very sensitive to oxidation and relatively little is known of their chemistry.

$$FcB(OH)_2 + CuX_2 \longrightarrow FcX \quad (10)$$

Lithiation also provides the principal route to 1,2-disubstituted ferrocenes since functionally substituted ferrocenes generally lithiate to yield 2-lithio derivatives at least as the kinetically favored products, as illustrated for (dimethylaminomethyl)ferrocene (eq 11).[11,18]

Formation and Uses of (Arene)cyclopentadienyliron Cations.

Replacement of one ring in ferrocene is the route chiefly used to obtain arenecyclopentadienyliron salts (eq 12);[19] they can also be obtained similarly from $CpFe(CO)_2Cl$. The reaction succeeds with a wide range of arene substituents and with polycyclic arenes. Electron-withdrawing substituents are preferentially retained,[19a,20] for example as in eq 13.[20]

The synthetic value of these complexes arises from their reactivity towards nucleophiles (significantly greater than that of $(arene)Cr(CO)_3$, but less than that of $[(arene)Mn(CO)_3]^+$).[21a] Hydride and carbon nucleophiles add to give cyclohexadienyl complexes (eq 14),[22] whereas fluoro and chloro or nitro substituents are substituted by softer

nucleophiles (eq 15).[23] Halogen substituents on the five-membered ring are much more difficult to replace.[22f]

(14)

(15)

Directive effects on the addition (eq 14) can be roughly summarized by stating that electron-withdrawing groups direct the incoming nucleophile to the 2-position while donating groups direct to the 3-position with some addition at the 4-position; these effects are weaker than in electrophilic aromatic substitution, so that a methyl substituent allows nearly random addition of hydride to carbons 2, 3, and 4.[21]

The cyclohexadienyl groups can generally be rearomatized by reaction with ***N-Bromosuccinimide*** (eq 16)[24] or in some cases trityl salts,[24b] thus opening the way to further additions, but cyano, benzyl, malonyl, and similarly reactive *exo* substituents are cleaved by these reagents.

The acidity of α-hydrogens in (alkylbenzene)cyclopentadienyliron salts allows alkylation,[25,26] as exemplified for the hexamethylbenzene complex (eq 17).[25a] The intermediate methylenecyclohexadienyl complexes in such reactions have sufficient carbanionic character to act as nucleophiles in Michael-type addition (eq 18).[26]

(17)

(18)

Side chains in these cations may also be oxidized, for example eq 19[27] and eq 20.[28]

(19)

Cleavage of the complexes to recover substituted arenes has been achieved by thermolysis,[23a,29] photolysis,[30] electrochemical reduction,[31] and rather inefficiently by oxidation (directly from cyclohexadienyl precursors).[22] It is also known to occur by reaction with a wide variety of donor ligands including phosphines or phosphites (preferably with electron transfer catalysis or with photolysis),[32] nitriles,[33] and thioethers;[34] these reactions are widely used to prepare the corresponding salts (eq 21), but yields of recovered arenes are rarely reported.[33b]

Heterocyclic syntheses employing this class of reaction are exemplified by eq 22[35] and eq 23.[29b]

(22)

Cleavage of Ferrocenes.

Ferrocene resists hydrogenation under conditions which readily convert benzene to cyclohexane and has only been reduced (to metal and cyclopentane) at ca. 350 °C using a ***Raney Nickel*** catalyst.[36a] It is cleaved by an excess of ***Bromine*** to give pentabromocyclopentane;[36] neither of these degradations has been applied to derivatives.

Cleavage to metal and cyclopentadienide anion is achieved smoothly with lithium and amines (ethylamine).[37] A few substituted ferrocenes have been degraded by this method and the resultant lithium cyclopentadienides used to prepare new complexes. Thus the product of eq 2 was shown to yield 1,1´-bis(dimethylaminomethyl)ferrocene by the sequence shown in eq 24,[38a] although a better route to this product was described at the same time.[38b] A low yield of 1,1´-dimethoxyferrocene was obtained in similar fashion from methoxyferrocene.[38c] Tris- and tetrakis(cyclopentadienyl)methane have been generated via the tri- and tetralithium salts $(LiC_5H_4)_3CH$ and $(LiC_5H_4)_4C$ by ***Lithium-Ethylamine*** reduction of Fc_3CH and $Fc_3C(C_5H_5)$, respectively.[38d,e]

Despite the considerable stabilization of α-ferrocenyl cations, allowing their facile formation and in suitable cases isolation as stable salts, they are relatively easily cleaved, particularly on irradiation. That a partial positive charge at the 2-position suffices is exemplified by (2-pyridyl)ferrocene. After quaternization with ***Iodomethane***, this amine, which is readily obtained from ferrocenyllithium and pyridine,[39] is photolyzed in good yield in aqueous alkaline solution (eq 25).[40]

This route has been applied to fused ferrocenodihydropyridines (generated in four steps from [$FcCH_2NMe_3$]I) (eq 26).[41]

(26)

In an attempt to extend the latter example to tricyclic systems, appropriately substituted (amidophenyl)ferrocenes were prepared as precursors via arylation (eq 5) of ferrocene with 2-nitro- and with 2-cyanobenzenediazonium salts. The final Bischler-Napieralski type cyclization step appeared to proceed smoothly, but instead of the expected fused ferrocenes (isolated in low yield when *n* = 1) the metal-free heterocycles were the main products (eq 27);[42] i.e. cleavage had occured without quaternization even in the dark.

9-Fluorenylmethyl Chloroformate[1]

[28920-43-6] · $C_{15}H_{11}ClO_2$ · 9-Fluorenylmethyl Chloroformate · (MW 258.71)

(base-labile protecting group for primary and secondary amines;[3] used in peptide synthesis;[5] used for derivatization of amines and amino acids prior to HPLC analysis and fluorescence detection[13])

Alternate Names: 9-fluorenylmethoxycarbonyl chloride; FMOC-Cl.

Physical Data: mp 62-64 °C.

Solubility: sol organics (CH_2Cl_2, THF, dioxane); reacts with alcohols, amines, and water.

Form Supplied in: white crystalline solid; widely available.

Handling, Storage, and Precautions: FMOC-Cl is an acid chloride, and should be protected from moisture and heat. The reagent can evolve CO_2 (pressure!) upon prolonged storage; therefore bottles should be opened carefully. FMOC-Cl is harmful if swallowed, inhaled, or absorbed through skin, is corrosive, and is a strong lachrymator. Inhalation may be fatal. Use in a fume hood.

N-Terminus Blocking in Peptide Synthesis.

Solid-phase peptide synthesis based on base-labile FMOC protection[1] is rapidly augmenting and/or replacing older methods based on Boc and Z (Cbz) protection. The major advantage offered by the use of FMOC protection is that repetitive treatment with HF or CF_3CO_2H is no longer required for the deprotection steps. Most FMOC-protected amino acids are commercially available, although the search for orthogonal side-chain functional group protection continues.[2] FMOC protection is currently the method of choice for the synthesis of glycopeptides which carry acid-labile *O*-glycosidic bonds (eq 1).[3,5b,7]

FMOC protection of amino acids is accomplished with Shotten-Bauman conditions (e.g. $NaHCO_3$/dioxane/H_2O or $NaHCO_3$/DMF), or with anhydrous conditions (e.g. pyridine/CH_2Cl_2) at room temperature or below (eq 1).[3a,4] A typical synthetic protocol for solid-phase peptide synthesis would involve coupling (eq 2), followed by deprotection with 20-30% ***Piperidine*** in DMF (eq 3), although other amines (e.g. 2% DBU, 10% Et_2NH, or 50% morpholine in DMF) have been used. Many workers no longer use the chloroformate ester FMOC-Cl (**1**), preferring the more shelf-stable carbonate FMOC-OSu (**2**) [*82911-69-1*],[5] or FMOC-pfp (**3**) [*88744-04-1*]. When used in the standard way,[4] FMOC-Cl (**1**) has been shown to promote the formation of FMOC-dipeptides in 3-7% yield, presumably via the mixed anhydride intermediate.[5a]

(2)

(3)

Use of FMOC-OSu (**2**) provides *N*-protected amino acids in comparable yields without the formation of the dipeptide impurities.[5] FMOC-pfp (**3**) has been used to prepare either FMOC-protected amino acids, or the corresponding pfp esters in one pot. Advantages of this reagent include supression of the dipeptide byproducts, as well as the production of the activated pfp esters using the same pentafluorophenol released during the *N*-protection step (eq 4).[6] This same *N*-protection/*C*-activation procedure has been used to produce serine glycosides (eq 5),[3b] and for the solid-phase synthesis of human intestinal mucin fragments (eq 6).[7] The use of FMOC-N_3 (**4**) is also claimed to reduce dipeptide formation during the protection step,[8] but the storage or use of potentially explosive oxycarbonyl azides cannot be recommended by this reviewer. Alternatively, the azide (**4**) may be generated in situ from (**1**).[4]

(4)

Fluorenylmethyl esters have been used for *C*-terminus protection in combination with FMOC *N*-terminus protection for solution-phase coupling of protected amino acids and peptide fragments. This permits simultaneous deprotection of both termini with Et_2NH/DMF (eq 7).[9]

(7)

Amine and Hydroxyl Protection for Nucleosides, Carbohydrates, and Natural Products.

FMOC has been used to protect the amino groups on various nucleoside bases (adenosine, cytosine, guanine, and their 2-deoxy derivatives) for solid-phase oligonucleotide synthesis in a one-pot procedure.[10] ***Chlorotrimethylsilane*** in dry pyridine was used for transient protection of the 2´,3´,5´- or 3´,5´-hydroxyls, followed by the addition of FMOC-Cl, and hydrolytic workup of the TMS ethers to produce crystalline FMOC-protected nucleosides and 2-deoxynucleosides in good yield (eq 8). The FMOC group was removed from the heterocyclic bases with excess ***Triethylamine*** in dry pyridine.

(8)

FMOC-Cl has been used for 3´,5´-hydroxyl protection of deoxyribose for the introduction of modified bases such as azacytidine using the classical Vorbrüggen reaction.[11] While the carbonate protecting groups do not alter the stereoselectivity of the *N*-glycoside formation, the FMOC groups can be removed under much milder conditions (Et_3N/pyridine) than the typical 4-methylbenzoyl group (eq 9).

Perhaps the most impressive use of the FMOC group in the synthesis of natural products is provided by the key tetrasaccharide intermediate to calicheamicin.[12] The robust nature of this particular FMOC group is amply demonstrated by the fact that it survives 15 discrete reaction steps, including exposure to cat. NaH/$HOCH_2CH_2OH$, Br_2, EtN_3, K-Selectride, i-Bu_2AlH, and NaSMe (eq 10). Clearly, the use of FMOC protection is not limited to peptide synthesis.

FMOC Derivatization for Fluorescence Detection and Analysis.

Derivatization of amino acids and other primary and secondary amines with (**1**) for HPLC analysis has been described. The chief advantage of this methodology is the high sensitivity due to the intense fluorescence of the fluorenyl moiety, but the FMOC also reduces polarity for faster elution from the column. Amino acids have been detected in concentrations as low as 26 femtomolar using a precolumn derivatization scheme.[13] FMOC derivatization of *lyso*-gangliosides in a two-phase Et_2O-H_2O system followed by chromatographic purification with fluoresence detection has also been reported.[14] Optically active 1-(9-fluorenyl)ethyl chloroformate (FLEC®) (**5**) is commercially available in both (+) [*107474-79-3*] and (-) forms for the analysis of racemates.

Fluorine[1]

[7782-41-4] · F_2 · Fluorine · (MW 38.00)

(strong fluorinating agent and oxidizer; substitutes F for H in either radical[2] or electrophilic[2b,3] reactions; electrophilic substitution of F for other halides;[1c] adds to multiple bonds;[2b,4] oxidatively adds to centers of coordinative unsaturation;[5] used in synthesis of other (mostly electrophilic) fluorinating agents;[6] with aq MeCN, oxidizes tertiary H to alcohols,[7] alcohols to ketones,[8] ketones to esters,[8] aromatics to phenols or quinones,[9] amines to nitro derivatives,[10] and alkenes to oxiranes;[7,11] cyclotron-produced $^{18}F_2$ provides ^{18}F-labeled compounds for positron emission tomography[12])

Physical Data: mp -219.6 °C; bp -188.2 °C; vapor pressure at 77 K = 280 Torr.

Solubility: slightly sol $CFCl_3$, $CF_2ClCFCl_2$, $CHCl_3$, CH_2Cl_2, MeCN, perfluoroethers, perfluorocarbons; dec H_2O giving HF, O_2 and trace O_3, OF_2.[13]

Form Supplied in: faintly yellow compressed gas in steel cylinders at pressures of 160-400 psi, purity 97-99%; impurities HF, N_2, O_2, CF_4, SF_6, SiF_4; also in cylinders prediluted with inert gases.

Analysis of Reagent Purity: titration of Cl_2 liberated from NaCl, followed by GC for inert components; IR for HF. Rarely performed by user.

Preparative Methods: electrolysis of KF-HF mixtures.[14]

Purification: HF removed by passage through column of NaF pellets; other impurities removed only by cryogenic distillation.[15]

Handling, Storage, and Precautions: toxic; strong oxidizer. Pure fluorine should only be used by trained personnel! Prediluted F_2 is handled much more easily. Compatible materials: copper, brass, steel, stainless steel, nickel alloys (Monel, Inconel, Hastelloy), fluoropolymers (PTFE, FEP, PFA, Kel-F), *dry* glass. Vendors and handbooks[4a,14a,16] *must* be consulted for more detailed recommendations! Proper equipment cleaning and passivation are imperative to avoid ignition. Use fume hood, barricade, faceshield, leather gloves. Odor threshold: 20 ppb. TLV: 1 ppm. PEL: 0.1 ppm. IDLH: 25 ppm. Leaks easily detected with paper moistened with aq KI; monitors/detectors available. Use only fluorinated greases and oils for joints, bubblers, valve lubricants. Lubricate pipe threads with PTFE tape; permanent installations should be welded. Scrub effluent with soda lime, activated alumina, or 5-15% aq KOH. (More dilute base gives toxic OF_2; KF produced is more soluble than is NaF.) Users of solid scrubbers with vacuum pumps should consider an O_2-compatible pump fluid. NaF, aq base, and $CaCl_2$ are useful for workup of reactions producing HF. *Caution:*

Many things will burn in pure fluorine given enough (sometimes insignificant) activation energy; even many materials (PTFE, metals, concrete) not usually considered to be fuels can ignite in F_2.

Introduction of Fluorine.

Substitution of Fluorine for Hydrogen.

Perfluorination.

The chief processes for perfluorination of organic compounds are the low-temperature gradient (LaMar) and aerosol fluorination methods. The goal of these is generally complete fluorination and saturation while minimizing fragmentation (eqs 1 and 2)[2a,17] although certain functional groups can be preserved (eq 3).[18] Perfluorination can also be achieved using inert solvents (eq 4).[19]

$$\xrightarrow[8\%]{F_2,\ NaF} \text{Perfluorodiamantane} \qquad (1)$$

$$\xrightarrow{F_2} \text{Perfluorodecalin} \qquad (2)$$

$$Me_2C{=}O \xrightarrow[\text{Cu, -100 to -40 °C}\ 38\%]{F_2/He,\ NaF} (CF_3)_2C{=}O \qquad (3)$$

$$MeOC(CF_3)_2OCH_2(CF_2)_4H \xrightarrow[\text{FC-72 (3M)}\ 71\%]{F_2,\ UV,\ -10\ °C} CF_3OC(CF_3)_2OCF_2(CF_2)_4F \qquad (4)$$

NaF is sometimes added to trap the HF produced as $NaHF_2$. The above reactions are generally radical in character; complete fluorination sometimes requires photochemical polishing to provide larger concentrations of F&bdot; since the organic material becomes increasingly unreactive as fluorine substitution proceeds (see ***Cobalt(III) Fluoride***).

Polymer Surface Modification.

Direct fluorination with F_2 is used to convert polymers (e.g. coal-tar pitch)[20] to highly fluorinated materials. Fluorination also increases the activity of sulfonic acid catalyst resins in alkylation reactions[21] and, when used sparingly, increases the surface energy of polymers, producing improved adhesion.[22]

Electrophilic Fluorinations.

Despite fluorine's extreme reactivity, its use in selective and electrophilic replacements is not only possible but synthetically useful when mild conditions and solvents such as $CFCl_3/CHCl_3$ mixtures are employed. Fluorine excels at replacement of unactivated tertiary hydrogens and complete retention of configuration is observed. High selectivity for tertiary H is due to the higher degree of p character in tertiary C-H bonds over that in primary and secondary bonds,[23] and this also influences the relative reactivity of competing tertiary positions (eq 5).[2b] Nearby electronegative centers, for example, deactivate tertiary H in this reaction. In contrast, LaMar fluorination of alkylcyclohexanes leaves some tertiary H as the only H remaining in the molecule,[24] perhaps for steric reasons. Direct electrophilic aromatic substitution is rare although recent improvements have involved the directing effects of Lewis acids.[25] Heteroaromatics can also be fluorinated (eq 6).[26] Both aliphatic and aromatic substitutions are often facilitated by the use of organometallic derivatives[27] in place of the parent molecules (eq 7), and 1,3-diketones can be fluorinated in the form of silyl enol ethers (eq 8).[28] Fluorination of fullerenes has been a topic of recent interest.[29]

(5)

(6)

(7)

23% radiochem. yield

(8)

74% from silyl enol ether

Electrophilic Substitution of F for Other Halogens.

While fluoride ion is useful for nucleophilic displacement of other halides, molecular fluorine uses an electrophilic mechanism to achieve this (eq 9).[30] Substitution proceeds most effectively when the intermediate carbocation is stabilized. The reactivity of the starting organic halide increases with the atomic weight of the departing species: Cl < Br < I.

(9)

Addition to Multiple Bonds.

Alkenes.

Fluorine often adds smoothly in an electrophilic manner to alkenic double bonds, predominantly in *syn* orientation.[2b] Fluorine addition has even been applied to conversion of alkene impurities in HFC-134a (CF_3CH_2F) to more easily removed saturated products.[31] Many reactions which are formally replacement of vinylic H by F are addition reactions followed by dehydrofluorination (eq 10).[32] Under radical conditions, coupling of intermediate fluorocarbon radicals is often observed. Alkynes react to give tetrafluoro or difluoro products, depending on the conditions.[1b]

(10)

Imines.

Carbon-nitrogen double bonds react to form *N*-fluoro derivatives; for already highly fluorinated compounds, this is most often done with the aid of a metal fluoride catalyst (eq 11).[33] Subsequent dehydrofluorination is often observed if the vicinal proton is relatively acidic.[1b]

$$CF_3(CF_2)_5N{=}CF(CF_2)_4CF_3 \xrightarrow[\substack{22\ ^\circ C \\ 95\%}]{F_2,\ CsF} [CF_3(CF_2)_5]_2NF \qquad (11)$$

Carbonyls.

Such catalytic pathways are also used to add fluorine across carbonyl groups, forming fluoroxy compounds (hypofluorites) (eq 12).[34] Some hypofluorites have found use as electrophilic fluorinating agents in their own right (see, for example, ***Trifluoromethyl Hypofluorite*** and ***Acetyl Hypofluorite***).

$$CF_3C(O)CF_2Cl \xrightarrow[\substack{-196\ \text{to}\ -10\ ^\circ C \\ 80\%}]{F_2,\ CsF} CF_3CF(CF_2Cl)OF \qquad (12)$$

Oxidative Addition.

Fluorine is capable of oxidizing most elements to their highest valence state. In organic compounds, centers of coordinative unsaturation undergo oxidative addition with little fragmentation if conditions are mild. The sulfur(II) in thiols[5a] and sulfides, for instance, is transformed to sulfur(VI) in the form of $-SF_5$ or $-SF_4-$ groups (eq 13).[5b]

(13)

Preparation of Other Fluorinating Agents.

Most alternative electrophilic fluorinating agents are themselves prepared from elemental fluorine using variations of the reactions above, with extensions to substitution of H on N or O producing N-F or O-F bonds[6] (see for example, ***N-Fluoro-N-t-butyl-p-toluenesulfonamide***). Some hypofluorites such as MeOF[35] and *t*-BuOF[36] can be formed in situ and used to add RO-F across alkenic double bonds. Fluorination of diselenides can be used similarly[37] when conditions are mild enough to avoid oxidation. Oxidative addition is represented by the synthesis of reagents such as ***Xenon(II) Fluoride***, ***N-Fluoropyridinium Triflate***, *N*-fluoroquinuclidinium salts, and *N*-fluoro-1,4-diazabicyclo[2.2.2]octane salts.

Oxidations.

Fluorine reacts with aq MeCN to form HOF stabilized by solvent complexation.[38] The complex can act as an efficient oxidizing agent and and can be used for ^{18}O labeling.

Tertiary Hydrogen to Hydroxyl.

Fluorine can be used selectively to hydroxylate tertiary hydrogens due to the interaction of the highly electrophilic oxygen atom in the HOF/MeCN complex with the relatively electron-rich tertiary H-C bond (eq 14).[7] Experiments with *cis*- and *trans*-decalin show that the hydroxylation occurs with full retention of configuration.

(14)

Alcohols to Ketones and Ketones to Esters.[8]

Oxidation of secondary alcohols with stabilized HOF yields ketones (eq 15); primary alcohols are less reactive. Ketones are converted to esters more slowly and with a larger excess of reagent (eq 16).

(15)

(16)

Aromatics to Phenols and Quinones.[9]

Aromatics and polynuclear aromatics are oxidized to the respective oxygenated derivatives. The reaction of mesitylene (eq 17) shows that phenols are likely intermediates to quinones. Quinones are quickly prepared in moderate yields (eq 18).

(17)

(18)

Amines to Nitro Compounds.

Primary aromatic[10a] and aliphatic[10b] amines are cleanly converted to nitro compounds without complications from other easily oxidized groups (eq 19).[10a] Amine salts are not reactive.[10b]

(19)

Alkenes to Oxiranes (Epoxides).[7,8,11]

Fluorine/aq MeCN readily epoxidizes electron-rich alkenes (eq 20).[7] More electron-deficient alkenes require a large excess of reagent and extended reaction time (eq 21).[7] Full retention of configuration is characteristic, since the oxides from *cis*- and *trans*-stilbene are exclusively *cis* and *trans*, respectively.[7] The epoxidation occurs preferentially over hydroxyl oxidation, as shown for dihydrocarveol (eq 22).[8] Dienes can form bis-epoxides (eq 23),[11b] or one double bond can react preferentially, given sufficient differences in electron density (eq 24).[11b] Other popular reagents such as ***m-Chloroperbenzoic Acid*** and ***Trifluoroperacetic Acid*** failed to react with *n*-$C_4F_9CH{=}CH_2$, which was epoxidized by the F_2/MeCN/H_2O system in 63% yield.[11b]

N-Fluoro-*N*-*t*-butyl-*p*-toluenesulfonamide[1]

(**1**; R = *t*-Bu)

[88303-13-3] · $C_{11}H_{16}FNO_2S$ · *N*-Fluoro-*N*-*t*-butyl-*p*-toluenesulfonamide · (MW 245.35) (**2**; R = *exo*-norbornyl)

[88303-14-4] · $C_{16}H_{22}FNO_2S$ · *N*-Fluoro-*N*-norbornyl-*p*-toluenesulfonamide · (MW 311.46) (**3**; R = *endo*-norbornyl)

[88303-15-5] · $C_{16}H_{22}FNO_2S$ · *N*-Fluoro-*N*-*t*-butyl-*p*-toluenesulfonamide · (MW 311.46) (**4**; R = neopentyl)

[88303-17-7] · $C_{12}H_{18}FNO_2S$ · *N*-Fluoro-*N*-neopentyl-*p*-toluenesulfonamide · (MW 259.38)

(reagent for the fluorination of carbanions)

Physical Data: (**1**) mp 59-62.5 °C; (**2**) mp 54-60 °C; (**3**) mp 78-81 °C; (**4**) mp 58-62.5 °C.

Solubility: sol hexane, ether, THF, toluene.

Form Supplied in: white to light yellow solid.

Analysis of Reagent Purity: TLC, ^{1}H NMR.

Preparative Methods: a solution of the *N*-alkyl-*p*-toluenesulfonamide in $CFCl_3/CHCl_3$ (1:1) at -78 °C is treated with fluorine (1-5%) in nitrogen[2] (description of apparatus[3]).

Purification: flash column chromatography on silica gel.

Handling, Storage, and Precautions: solid can be stored in glass containers and is stable to moisture but becomes yellow at ambient temperatures over time with no significant change in fluorinating ability observed after several weeks. No significant decomposition was observed after freezer storage for one year. Reagent (**4**) decomposed with abrupt changes in temperature and pressure when heated above 180 °C in a closed pressure vessel.[4] These reagents should be handled in a fume hood.

Fluorination of Carbanions.

Treatment of a broad variety of carbanions with an *N*-fluoro-*N*-alkyl-*p*-toluenesulfonamide results in the transfer of fluorine from nitrogen to carbon. The carbanions can be generated under standard conditions and fluorinated in typical ether or hydrocarbon solvents.

Selection of a particular reagent is dependent upon the basicity of the carbanion and polarity of the solvent. For strongly basic carbanions, β-elimination of HF from reagents (**2**), (**3**), and (**4**) can become a major competing side reaction. Use of a nonpolar solvent or mixed polar/nonpolar system, where possible, can suppress elimination. Alternatively, reagent (**1**) can be used, although it is more difficult to prepare. The selection of type of base or counterion is generally a matter of convenience. Examples of typical carbanion fluorination reactions are included in Table 1.[2,5]

Table 1 Carbanion Fluorinations

Substrate	Base	Product	Reagent	Yield (%)	Ref.
$PhCH(CO_2Et)_2$	NaH	$PhCF(CO_2Et)_2$	**(4)**	81	2a, b
PhMgBr	-	PhF	**(1)**	50	2a, b
1-Naphthol	KH	2-Fluoro-1-naphthol	**(1)**	60	2a, b
Veratrole	BuLi	3-Fluoroveratrole	**(2)**	24	2b
Isobutyrophenone	KH	2-Fluoroisobutyrophenone	**(2)**	81	2a
Indene	KH	1-Fluoroindene	**(2)**	31	2a
2-Nitropropane	Bu_4NOH	2-Fluoro-2-nitropropane	**(1)**	83	2a, b
p-$TolSO_2NH$-*t*-Bu	BuLi	2-Fluoro-*p*-$TolSO_2NH$-*t*-Bu	**(2)**	55	2a, b
	KH		**(2)**	52	2a, b
	-		**(3)**	76	5

In addition, *N*-[^{18}F]fluoro-*N*-alkyl-*p*-toluenesulfonamides have been utilized as radiolabeling agents.[6]

Related sulfonamide-based fluorinating agents include *N*-fluoro-*N*-*t*-butylbenzenesulfonamide[7] and camphor-[8] and saccharin-based *N*-fluorosultams.[9] *N*-Fluoro-*N*-*t*-butylbenzenesulfonamide was utilized in the preparation of fluoroalkenes[7] and difluoroanthracenes[10] and is reported to have solubility advantages over the corresponding tolylsulfonamide at very low temperatures.[7] Camphor-based *N*-fluorosultams were utilized to enantioselectively prepare α-fluoro ketones.[8] The *N*-fluoro saccharin-based sultam has been used in a one-pot procedure in the synthesis of α,α-difluoro ketones.[11]

While the mechanism of fluorination by *N*-fluoro-*N*-alkyl-*p*-toluenesulfonamides has not been examined directly, studies utilizing the closely related sulfonamide-based saccharin-derived sultam suggest that the pathway involves direct nucleophilic attack on fluorine versus a radical or electron transfer mechanism.[12]

Following the development of the *N*-fluoro-*N*-alkyl-*p*-toluenesulfonamide reagents, *N*-fluorosulfonimides were prepared and demonstrated to be stable and effective fluorinating agents themselves. Thus *N*-fluorotrifluoromethylsulfonimide,[13] *N*-fluorobenzenesulfonimide,[14] and *N*-fluoro-*o*-benzenedisulfonimide[15] have found a number of applications. In addition to carbanions, the sulfonimide-based reagents can also directly fluorinate aromatics. This difference with the sulfonamides has been correlated with the relative potentials of the first one-electron reductions of their N-F bonds.[16] Similar increased reactivity has been observed with perfluoro-[*N*-fluoro-N-(4-pyridyl)]methanesulfonamide.[17]

Fluorodimethoxyborane Diethyl Etherate

$(MeO)_2BF.OEt_2$

[367-46-4] · $C_6H_{16}BFO_3$ · Fluorodimethoxyborane Diethyl Etherate · (MW 166.03)

(electrophilic borylating agent, precursor of allylboronic esters)

Physical Data: bp 46-48 °C/760 mmHg.[1]

Solubility: sol common organic solvents (THF, Et_2O, toluene, CH_2Cl_2, etc.). The title compound is moisture sensitive and will hydrolyze when exposed to water.

Analysis of Reagent Purity: ^{1}H (δ 3.62 (br m, 4H), 3.51 (br s, 6H), 1.23 (6 H, t, *J* = 7.2 Hz)) or ^{11}B NMR.

Preparative Methods: by the disproportionation reaction of two moles ***Trimethyl Borate*** and one mole of ***Boron Trifluoride Etherate***. Distillation of the reaction mixture produces the title reagent as the diethyl etherate (76%).[1]

Purification: distillation.

Handling, Storage, and Precautions: reagent reacts with moisture and other protic solvents. It should be handled under an inert atmosphere in a well-ventilated hood. Contact with the eyes and skin should be avoided.

Fluorodimethoxyborane as an Electrophilic Borylating Agent.

The reagent has been used extensively as an electrophilic borylating agent in the synthesis of substituted allylboronic esters (eqs 1-5). Allyl anions used in these reactions include ***Allylmagnesium Bromide*** (eq 1),[2] crotylpotassium reagents (eqs 2-4),[1,3-5] and γ-alkoxyallyllithium reagents (eq 5).[6] The resulting allylboronate reagents undergo highly diastereoselective reactions with aldehydes (see ***Crotyldimethoxyborane***). The diastereoselectivity of these reactions depends on the isomeric purity of the reagent.[7]
