
(2)

(3)

This procedure was used initially for the synthesis of the tartrate ester modified crotylboronates (**7**) and (**8**) (eq 6).[5] On scales up to 100 mmol, it was found that crotylboronates (**7**) and (**8**) were obtained in 70-88% yield with excellent

isomeric purity. However, as the scale increased to 200 mmol the yields fell to 14-35% and (**7**) and (**8**) were obtained with much lower isomeric purity. These problems have been attributed to the competitive formation of tricrotylborane.[5] Much more consistent results, particularly for large scale reactions (up to 400 mmol), have been achieved by using ***Triisopropyl Borate*** as the borylating agent. A similar improvement in yield has been reported for the preparation of the tartrate ester modified allylboronate (**9**) (eq 7).[2]

A systematic study of the synthesis of alkyl boronic esters from the reaction of organometallic reagents and electrophilic borylating agents has been reported by Brown.[8] This study clearly identifies (i-PrO)$_3$B as the best reagent for these purposes. For example, the reaction of FB(OMe)$_2$ with ***Methyllithium*** gives only 10% yield of methylboronic ester and 28% of lithium tetramethylborate. However, treatment of triisopropyl borate with MeLi gives almost exclusively the methylboronic ester (&egt;98%) (eq 8).

Fluorodimethoxyborane as a Precursor for the Synthesis of (δ-Hydroxy)allylsilanes.

Metalation of homoallylsilane (**10**) with ***n-Butyllithium*** and ***Potassium t-Butoxide*** followed by treatment of the resulting allyl potassium derivative with FB(OMe)$_2$ gives the (Z)-δ-(trimethylsilylmethyl)allylboronate exclusively, which is further oxidized by using basic peroxide to give the (Z)-allylsilane (**11**) (61% yield) (eq 9).[9]

Related Reagents.

Triisopropyl Borate; ***Trimethyl Borate***.

2-Fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzisothiazole 1,1-Dioxide

[124170-23-6] · $C_9H_{10}FNO_2S$ · 2-Fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzisothiazole 1,1-Dioxide · (MW 215.24)

(electrophilic fluorinating agent)

Alternate Name: N-fluoro-2,α-cumenesultam.

Physical Data: mp 115-117 °C.

Solubility: sol various organic solvents including THF, diethyl ether, CH_2Cl_2, acetonitrile.

Form Supplied in: white or slightly yellow solid, &egt;98% purity; commercially available.

Analysis of Reagent Purity: ^1H and ^{19}F NMR.

Preparative Method: pressureless fluorination on a 100 g scale with F_2 in N_2 (F_2/N_2 10% v/v) in the presence of powdered NaF in $CHCl_3/CFCl_3$ (1/1 v/v) at -40 °C.[1,2]

Purification: flash chromatography (SiO_2, CH_2Cl_2) and/or crystallization from Et_2O/pentane.

Handling, Storage, and Precautions: handle and store at rt or below; protected from light, preferably under nitrogen or argon. Thermally stable up to 200 °C; decomposes exothermally above 200 °C. Reacts with easily oxidized compounds such as iodide or tetramethylphenylenediamine. This reagent should be handled in a fume hood.

Nitrogen-fluorine bond-containing compounds are among the most useful electrophilic fluorinating agents due to their easy access, their inherent stability, and the ease with which they can be handled. 2-Fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzisothiazole 1,1-dioxide (**1**) is one of the most thoroughly studied reagents, both from a preparative and a

mechanistic point of view.[1-8] There is evidence, both preparative and mechanistic, that direct nucleophilic attack at fluorine occurs. Electron transfer is a competing reaction, which leads to nonfluorinated products.[5,6,8]

Monofluorination of Enolates.

N-Fluorosultam (**1**) has been successfully used to prepare α-fluorocarbonyl compounds by electrophilic fluorination starting, for example, from disubstituted enolates derived from ketones, esters, and β-dicarbonyl compounds (eqs 1-3).[1] The related *N*-fluorosulfonamide reagents[9] give considerably lower yields due to the elimination of HF by proton abstraction from the carbon α to the nitrogen atom.[1]

(1)

(2)

(3)

Monosubstituted enolates can be selectively monofluorinated using slightly more than 1 equiv of base and *N*-fluorosultam. The influence of the counterion is crucial and the selectivity decreases in the order Li > Na > K, although ***Potassium Hexamethyldisilazide*** often gives higher yields, especially with esters (eqs 4-6).[4]

(4)

(5)

(6)

See also the related chiral *N*-fluorosultam reagents derived from camphor which allow for enantioselective fluorination with modest enantiomeric excesses (up to 75%).[10,11]

Double Fluorination of Enolates.

Double fluorination of monosubstituted enolates is achieved selectively in a one-pot procedure by adding the starting carbonyl compound to 2.4-3.6 equiv of base in THF at -78 °C followed by the addition of 2.6-3.6 equiv of the *N*-fluorosultam, and warming up to room temperatures. For this process, KHMDS and ***Potassium Diisopropylamide*** are the bases of choice (eqs 7-9).[4]

(7)

(8)

2-Fluoro-3,3-dimethyl-2,3-dihydro-1,2-benzisothiazole 1,1-Dioxide

Fluorination of Organometallic Reagents.

Aryl fluorides can be prepared by reacting the corresponding aryllithium compound with (**1**) (eq 10). Grignard reagents give significantly lower yields, probably due to competing electron transfer reactions since radical-derived side products have been isolated and characterized (eq 11).[6]

For a more reactive nitrogen-fluorine bond containing reagent, see ***N-Fluoro-N-(phenylsulfonyl)benzenesulfonamide***.[12]

1-Fluoro-2,4-dinitrobenzene

[70-34-8] · $C_6H_3FN_2O_4$ · 1-Fluoro-2,4-dinitrobenzene · (MW 186.10)

(identification of terminal amino acid residues in peptides;[1] amine protecting group;[4] deoxygenation of phenols;[11,12] thioamide protecting group[14])

Alternate Names: dinitrofluorobenzene; DNFB; Sanger's reagent.

Physical Data: mp 27.5-30 °C; bp 178 °C/25 mmHg; *d* 1.48 g cm^{-3}.

Solubility: sol benzene, Et_2O, EtOAc, acetone, DMF, propylene glycol.

Form Supplied in: 99% pale yellow crystals; widely available.

Purification: commercial sample can be recrystallized from diethyl ether.

Handling, Storage, and Precautions: stored at room temperature. Considered as highly toxic and cancer suspect agent. Use in a fume hood.

Peptide Analysis.

Sanger[1] developed an efficient method for the identification of the terminal amino acid residues in peptides and proteins using dinitrofluorobenzene. DNFB reacts at room temperature with the terminal amino functionality of the peptides in the presence of sodium bicarbonate and upon acid hydrolysis a dark yellow 2,4-DNP derivative of the terminal amino acid is liberated (eq 1). As the 2,4-DNP-amino acids produced are dark yellow in color, they may be estimated colorimetrically using the corresponding pure 2,4-DNP-amino acid as a standard. Partition chromatography or paper chromatography techniques can be used to separate the components; the DNP-amino acids provide visible yellow bands. DNFB is more widely used than dinitrochlorobenzene as the latter requires higher temperatures to react with amines especially in presence of sodium bicarbonate, which leads to hydrolysis of the protein. DNP derivatives of 4-

aminopentanoic acid[2] and 2,4-hexadiynylene esters of various amino acids[3] have been prepared for characterization purposes.

Amine Protection.

The use of DNFB for protection of amine functionalities in sugars during the synthesis of glycosides was first introduced by Lloyd;[4] the unprotected hexosamines gave poor yields in condensation reactions. Wolfrom[5] has used DNFB to install *N*-blocking groups in pyrimidine nucleoside synthesis from 2-amino sugars. DNP-D-glucosamine was prepared by treating 2-amino-2-deoxy-D-glucose hydrochloride with DNFB and sodium bicarbonate. After synthesis of the nucleoside the final deprotection was carried out by simply treating the DNP derivative with barium hydroxide to release the free amine (eq 2). Recently, Valli and co-workers[6] have shown that 2,4-DNP derivatives of some amines which are analogs of ranitidine, are good inhibitors of acetylcholinesterase.

Derivatization of Phenols and Alcohols.

DNFB reacts with phenols under mild conditions in the presence of catalytic ***Triethylamine*** in acetone to give the corresponding 2,4-dinitrophenyl ethers as solid derivatives in high yields.[7] 2,4-Dinitrophenyl ether derivatives of alditols and *myo*-inositol have been prepared at room temperature using DNFB in DMF and triethylamine; the products are usually crystalline with sharp melting points.[8] 2,4-Dinitrophenyl ethers from neryl and geranyl alcohol were prepared with 1,4-diazabicyclo[2.2.2]octane and DNFB.[9]

Allyl Alcohols to Allyl Chlorides.

Allyl alcohols are converted to the corresponding allyl chlorides via 2,4-dinitrophenyl ether derivatives.[10] The allyl alcohol is treated with DNFB in the presence of triethylamine to yield the corresponding 2,4-dinitrophenyl ether, which in turn is treated with ***Lithium Chloride*** in HMPA to give the allyl chloride (eq 3).

Deoxygenation of Phenols.

Pirkle[11] reported a method for the deoxygenation of phenols via the corresponding 2,4-dinitrophenyl ethers. The method was employed in their investigation of potential analgesic agents, morphinans and isomorphinans, derived from natural sources.[12] Treatment of the phenol derivative with DNFB in toluene-DMF using ***Sodium Hydride*** as catalyst gave the 2,4-dinitrophenyl ether in high yields. Catalytic hydrogenation to the 2,4-diaminophenyl ether followed by cleavage with ***Sodium-Ammonia*** gave the deoxygenation product in an overall yield of 93% (eq 4).

(4)

Degradation of Aldose Sugars.

2,4-DNP derivatives of aldose oximes are used in a Wohl degradation to obtain the next lower aldose sugars.[13] For example, D-glucose oxime when treated with DNFB in the presence of sodium bicarbonate provides the oxime aryl ether which decomposes to D-arabinose, 2,4-dinitrophenol, and hydrogen cyanide (eq 5).

Thioamide Protection.

6-Thiodeoxyguanosine upon treatment with DNFB in the presence of triethylamine in acetonitrile give the *S*-2,4-DNP derivative.[14] Deprotection to thiocarbonyl can be achieved simply by treating with ***2-Mercaptoethanol*** at room temperature (eq 6). Such *S*-2,4-DNP functionalities can also be transformed to free amino, methylamino, methoxy, and oxo groups.

Fluoromethylenetriphenylphosphorane

$Ph_3P{=}CHF$

[28096-33-5] · $C_{19}H_{16}FP$ · Fluoromethylenetriphenylphosphorane · (MW 294.32)

(can function for the introduction of =CFH into organic compounds)

Alternate Name: triphenylphosphonium fluoromethylide *[28096-34-6]*.

Preparative Methods: fluoromethylenetriphenylphosphorane is prepared in situ by the dehalogenation of fluoroiodomethyltriphenylphosphonium iodide with ***Zinc/Copper Couple*** in DMF,[1] or pregenerated by the dehydrohalogenation of fluoromethyltriphenylphosphonium iodide with ***n-Butyllithium***[1] or ***Phenyllithium***[2] at -78 °C. The precursor fluoromethyltriphenylphosphonium salt is prepared by the reaction of ***Triphenylphosphine*** with iodofluoromethane,[1] by the reaction of ***Methylenetriphenylphosphorane*** with $FClO_3$,[2] or by the reaction of hydroxymethyltriphenylphosphonium tetrafluoroborate with ***N,N-Diethylaminosulfur Trifluoride*** (DAST).[3]

Reaction with Carbonyl Compounds.

Reaction of the pregenerated ylide, fluoromethylenetriphenylphosphorane, with aldehydes and ketones at -78 °C gives the corresponding alkenes, RR´C=CHF, in 16-45% yields (eq 1). From aldehydes and asymmetrical ketones a mixture of *trans* and *cis* isomers was obtained in a 1:1 ratio.[2] A modification employs additional ***Potassium t-Butoxide*** in the above reaction sequence to achieve higher yields (28-69%) of RR´C=CHF.[1] Fluoromethylenetriphenylphosphorane could also be generated in situ. For example, treatment of fluoroiodomethyltriphenylphosphonium iodide with zinc-copper couple and aldehydes or fluorinated ketones in DMF gives the alkenes, RR´C=CHF, in 54-80% yields (eq 2).[1]

$$[Ph_3PCH_2F]^+\ I^- \xrightarrow[\text{-78 °C}]{\text{PhLi or BuLi}} [Ph_3P{=}CHF] \xrightarrow[\text{-78 °C}]{RC(O)R'} RR'C{=}CHF \qquad (1)$$

$$[Ph_3PCHFI]^+\ I^- + Zn(Cu) \xrightarrow[\text{DMF}]{RC(O)R'} RR'C{=}CHF \qquad (2)$$

Fluoromethyl Phenyl Sulfide[1]

[60839-94-3] · C_7H_7FS · Fluoromethyl Phenyl Sulfide · (MW 142.21)

(synthesis of α-fluoro substituted sulfoxides[1] and sulfones[1e,2])

Physical Data: bp 60 °C/0.3 mmHg; n_D^{22} 1.5415.

Solubility: sol CH_2Cl_2, $CHCl_3$, MeOH.

Preparative Methods: there are several methods of preparation. The reaction of ***Chloromethyl Phenyl Sulfide*** with ***Potassium Fluoride*** and ***18-Crown-6*** gives fluoromethyl phenyl sulfide in good yield (eq 1).[1c] Alternatively, the compound can be prepared by reaction of methyl phenyl sulfoxide with ***N,N-Diethylaminosulfur Trifluoride*** (F_3SNEt_2, DAST) (eq 2),[1d,2,3] or with DAST and ***Antimony(III) Chloride*** (eq 3).[1e,f,4]

Direct α-fluorination of methyl phenyl sulfides can be performed by using DAST, antimony(III) chloride (eq 4),[1f] *N*-fluoro-2,4,6-trimethylpyridinium triflate (eq 5),[5] and ***Xenon(II) Fluoride***.[6] α-Fluorination of sulfides by an electrolytic process is also known. However, it has not been used widely in organic synthesis.[7]

Of the methods reported, the routes shown in eqs 1-4 are more often used synthetically. α-Monosubstituted fluoromethyl phenyl sulfides are prepared from the reaction of the corresponding thioacetals with ***Mercury(II) Fluoride*** (eq 6).[8]

Handling, Storage, and Precautions: the compound should be used as soon as possible after

purification by distillation. Storing it at 5 °C overnight then warming it to room temperature causes polymerization. Handle in a fume hood.

Oxidation to Sulfoxides.

Fluoromethyl phenyl sulfide can be oxidized to ***Fluoromethyl Phenyl Sulfoxide*** by ***N-Bromosuccinimide***[1c] or one equivalent of ***m-Chloroperbenzoic Acid***[1d -f,3,4,8] (the latter method is the most convenient and most often employed) (eq 7).

(7)

Oxidation to Sulfones.

Oxidation to ***Fluoromethyl Phenyl Sulfone*** is conveniently carried out by using two equivalents of *m*-chloroperbenzoic acid (eq 8).[1d,e,f,2,4b,d]

Fluoromethyl Phenyl Sulfone[1]

[20808-12-2] · $C_7H_7FO_2S$ · Fluoromethyl Phenyl Sulfone · (MW 174.21)

(synthesis of α-fluoro-α,β-unsaturated sulfones,[1b,d,2] vinyl fluorides[1b,d,2])

Physical Data: mp 50-51 °C (from MeOH).

Solubility: sol THF, $CHCl_3$, CH_2Cl_2.

Preparative Method: by the oxidation of ***Fluoromethyl Phenyl Sulfide*** with two equivalents of ***m-Chloroperbenzoic Acid*** (eq 1).[1b,c]

α-Fluoro-α,β-Unsaturated Sulfones and Vinyl Fluorides.

The reaction of phenylsulfonylfluoromethyllithium, generated by the reaction of fluoromethyl phenyl sulfone with ***n-Butyllithium***, with carbonyl compounds gives the α-fluoro-β-hydroxyphenylsulfonyl derivatives in good yields; upon dehydration with ***Methanesulfonyl Chloride***, these give the corresponding vinyl sulfones. Reductive desulfonylation with ***Aluminum Amalgam*** yields vinyl fluorides (eq 2).[1b] The overall process represents the use of fluoromethyl phenyl sulfone as a fluoromethyl Wittig equivalent. This method of preparation of vinyl fluorides is complementary to the existing few methods, e.g. the use of ***Fluoromethylenetriphenylphosphorane***[3] and ***Fluoromethyl Phenyl Sulfoxide***.[4]

The Wittig-type reaction of the diethyl 1-fluoro-1-(phenylsulfonyl)methanephosphonate carbanion, generated in situ from fluoromethyl phenyl sulfone with diethyl chlorophosphate and two equivalents of either ***Lithium Diisopropylamide*** or ***Lithium Hexamethyldisilazide*** at -78 °C, with carbonyl compounds gives α-fluoro-α,β-unsaturated sulfones in good to excellent yields (eq 3).[1d]

A similar Wittig reaction of 1-fluoro-1-(phenylsulfonyl)methanephosphonate carbanion is used in the synthesis of 2´-deoxy-2´-fluoromethylene nucleosides (eq 4).[2]

Diethyl 1-fluoro-1-phenylsulfonylmethanephosphonate can also be prepared by the direct fluorination of diethyl (phenylsulfonyl)methanephosphonate with ***Perchloryl Fluoride*** ($FClO_3$) (eq 5).[5] The Wittig reagent derived from it is used in the preparation of a number of alkylated α-fluorophenylsulfonyl derivatives and α-fluoro-α,β-unsaturated sulfones (eqs 6 and 7).[5] 1-Fluoro-1-(phenylsulfonyl)ethylene can also be prepared by the elimination of 2-chloro-1-fluoroethyl phenyl sulfone (eq 8).[6] Diels-Alder cycloadditions, Michael reactions (eq 9),[5] 1,3-dipolar cycloaddition (eq 10),[7] and radical addition (eq 10)[6] reactions of 1-fluoro-1-(phenylsulfonyl)ethylene have been demonstrated.

Fluoromethyl Phenyl Sulfoxide[1]

[65325-68-0] · C_7H_7FOS · Fluoromethyl Phenyl Sulfoxide · (MW 158.21)

(synthesis of fluoro ketones,[1b,2] fluoroalkenes,[2,3] and aziridines[4])

Physical Data: bp 75 °C/0.3 mmHg; *n*22D 1.5375.

Solubility: sol THF, CH_2Cl_2, $CHCl_3$.

Preparative Methods: by the oxidation of ***Fluoromethyl Phenyl Sulfide*** with either ***N-Bromosuccinimide*** or ***m-Chloroperbenzoic Acid*** (eq 1).[1c-f] Studies of the structure of fluoro(phenylsulfinyl)methyllithium, investigated by NMR, suggest that lithium is bound to oxygen, rather than to the α-carbon atom.[5]

Purification: pure compound is obtained either by distillation or column chromatography on silica using hexane-ethyl acetate (1:4).

Handling, Storage, and Precautions: use in a fume hood.

Fluoro Ketones.

The reaction of fluoro(phenylsulfinyl)methyllithium, generated with ***Lithium Diisopropylamide***, with aldehydes gives the corresponding α-fluoro-β-hydroxy sulfoxides, which upon pyrolysis give fluoromethyl ketones (eq 2).[1b,2]

$PhCOCH_2F$ (2)

α-Fluoro-1,3-keto sulfoxides, prepared from the addition of alkylated α-fluoromethyl phenyl sulfoxide carbanion to aldehydes followed by Swern oxidation (***Dimethyl Sulfoxide-Oxalyl Chloride***), undergo desulfinylation with ***Ethylmagnesium Bromide*** to give α-fluoro ketones (eq 3).[6] Pyrolysis of the α-fluoro-1,3-keto sulfoxides gives α-fluoro-α,β-unsaturated ketones (eq 3).[6] Dienones can be prepared by this procedure and the product undergoes the Nazarov cyclization to give 2-fluoro-2-cyclopenten-1-one (eq 4).[6b]

(3)

(4)

Fluoroalkenes.

Fluoro(phenylsulfinyl)methyllithium can be alkylated with alkyl iodides or reactive alkyl bromides to give monoalkylated products which upon pyrolysis afford vinyl fluorides (eq 5).[2] The addition of the α-fluoromethyl-*N*-methyl(phenyl)sulfoximine carbanion, derived from α-fluoromethyl phenyl sulfoxide, to carbonyl compounds gives α-fluoro-β-hydroxy(phenyl)sulfoximine adducts, which upon reductive desulfinylation with ***Aluminum Amalgam*** yield fluoroalkenes (eqs 6 and 7).[3c]

(5)

(6)

(7)

α-Substituted α-fluoro phenyl sulfoxides, prepared from thioacetals (eq 8)[3b] or from the corresponding sulfoxides, are used in the synthesis of fluoroalkenes (eqs 9 and 10).[3d,7]

(8)

(9)

(10)

Fluoro(phenylsulfinyl)methyllithium adds to aryl imines to give phenylsulfinylaziridines as a mixture of isomers (eq 11). This method is complementary to the reaction employing chloro(phenylsulfinyl)methyllithium.[4]

N-Fluoro-*N*-(phenylsulfonyl)benzenesulfonamide

[133745-75-2] · $C_{12}H_{10}FNO_4S_2$ · *N*-Fluoro-*N*-(phenylsulfonyl)benzenesulfonamide · (MW 315.33)

(electrophilic fluorinating agent)

Alternate Names: *N*-fluorobenzenesulfonimide; *N*-fluorobis(phenylsulfonyl)amine; *N*-fluorodibenzenesulfonimide.

Physical Data: mp 114-116 °C.

Solubility: sol various organic solvents, including THF (0.24 g ml^{-1}), CH_2Cl_2 (0.40 g ml^{-1}), acetonitrile (0.25 g ml^{-1}), and toluene (0.09 g ml^{-1}).

Form Supplied in: white or slightly yellow solid, &egt;98% purity; commercially available.

Analysis of Reagent Purity: ^1H and ^{19}F NMR.

Preparative Method: pressureless fluorination on a 0.2 mol scale with F_2 in N_2 (F_2/N_2 10% v/v) in the presence of powdered NaF in acetonitrile at -40 °C.[1]

Purification: flash chromatography (SiO_2, CH_2Cl_2) and/or crystallization from Et_2O.

Handling, Storage, and Precautions: handle and store at rt or below; protected from light, preferably under nitrogen or argon. Thermally stable up to 180 °C; decomposes exothermally at higher temperatures. Reacts with easily oxidized compounds such as iodide. This reagent should be handled in a fume hood.

Fluorination of Enolates and Silyl Enol Ethers.

N-Fluoro-*N*-(phenylsulfonyl)benzenesulfonamide (**1**) can be used successfully to prepare α-fluorocarbonyl compounds starting from esters, ketones, or β-dicarbonyl precursors by electrophilic fluorination of the corresponding enolates (eqs 1-3) or silyl enol ethers (eq 4).[1] Diastereoselective fluorination of enolates with (**1**) has recently been reported.[7]

(1)

(2)

(3)

(4)

Fluorination of Organometallic Reagents.

Aryl and vinyl fluorides are conveniently prepared by reacting the corresponding lithium derivatives with (**1**).[1] For example, anthracenyllithium, generated from bromoanthracene with ***n-Butyllithium***, is fluorinated in THF at -78 °C (eq 5). 1-Phenyl-2-lithiopropene, obtained by reacting the corresponding iodoalkene with ***t-Butyllithium***, requires a lower reaction temperature (-105 °C, THF/Et_2O/pentane). This reaction affords the fluoroalkene with complete retention of configuration at the double bond (eq 6).

(5)

(6)

Fluorination of Alkyl Phosphonate Carbanions.

α-Fluoro- and α,α-difluoroalkyl phosphonates are prepared in good yields by electrophilic fluorination of phosphonate-derived carbanions (eqs 7 and 8).[2] The yields in the reaction strongly depend on the nature of the base, ***Potassium Diisopropylamide*** being the base of choice. α,α-Difluoroalkyl phosphonates are obtained in 54-70% yield from the corresponding monofluorinated precursors after deprotonation at low temperature (-90 °C). In situ double fluorination starting from alkyl phosphonates by using an excess of both base and (**1**) give only low yields (10-20%) of α,α-difluorinated products.

(7)

(8)

Electrophilic Addition to Aromatics.

Aromatic compounds are fluorinated with (**1**) by heating without a solvent to about 100-150 °C, or, for low-boiling compounds, up to reflux temperature.[1] Activated aromatics, such as anisole or *N*-acetylaniline, react smoothly, whereas toluene requires considerably longer reaction times and gives low yields (eqs 9-11). In all cases the regioselectivities are consistent with an electrophilic addition mechanism: *ortho* and *para* substituted products predominate over the *meta* isomers. (**1**) has recently been used in orthometalation-directed fluorination of aromatics.[8]

(9)

(10)

N-Fluoropyridinium Triflate[1]

[107263-95-6] · $C_6H_5F_4NO_3S$ · *N*-Fluoropyridinium Triflate · (MW 247.17)

(fluorinating agent for many nucleophilic substrates)

Physical Data: mp 185-187 °C.

Solubility: sol polar solvents such as MeCN; 0.6 mg mL^{-1} in CH_2Cl_2; 1.7 mg mL^{-1} in THF; insol Et_2O.

Form Supplied in: white crystals; widely available.

Analysis of Reagent Purity: ^1H and ^{19}F NMR, IR.[2]

Purification: recrystallization from MeCN-Et_2O at rt.[2]

Handling, Storage, and Precautions: nonhygroscopic and thermally stable. The reagent should be stored in a dry atmosphere protected from light. Handle in a fume hood.

Fluorination.[1]

N-Fluoropyridinium triflate (**1**) is an electrophilic fluorinating agent and is one of a series of *N*-fluoropyridinium triflates of differing strength. Typical related reagents include *N*-fluoro-2,4,6-trimethylpyridinium triflate (**2**), *N*-fluoro-3,5-dichloropyridinium triflate (**3**), *N*-fluoro-2,6-dichloropyridinium triflate (**4**), and *N*-fluoropentachloropyridinium triflate (**5**). The fluorinating power of these compounds varies in the order (**2**) < (**1**) < (**3**) < (**4**) < (**5**). The strongest reagent (**5**) smoothly fluorinates less reactive nucleophiles, while the mildest reagent (**2**) can be used satisfactorily for the more reactive nucleophiles. Reagents (**1**) and (**3**) fluorinate nucleophiles of intermediate reactivity. Because of this variation in strength, *N*-fluoropyridinium triflates fluorinate a wide range of nucleophiles including carbanions,[1] active methylene compounds,[1,3-6] sulfides,[7] enamines,[1] enol alkyl and silyl ethers,[1,8] vinyl acetates,[1] aromatics,[1,9-13] and alkenes.[1] In the following representative examples, *N*-fluoropyridinium triflate fluorinates enol silyl ethers (eq 1), alkyl enol ethers (eq 2), activated vinyl acetates (eq 3), and activated aromatics (eq 4).

(4)

In some cases, *N*-fluoropyridinium triflate exhibits selectivity in the fluorination of silyl enol ethers. As shown in eq 5, a trialkylated enol silyl ether moiety is thus fluorinated preferentially.[1]

N-Fluoropyridinium triflates (**1**), (**2**), (**3**) and (**4**) are commercially available. A series of *N*-fluoropyridinium tetrafluoroborates[1,2,7] are also available. The triflates often give better yields because of better solubility in organic solvents.[1] Since (**3**), (**4**), and (**5**) readily decompose in water, exposure of these reagents to moisture should be avoided.

Selective Hydrolysis.

Efficient and selective hydrolysis of dithioacetals by (**2**) was reported.[14]

Related Reagents.

Other useful electrophilic fluorinating agents which are commercially available include ***Xenon(II) Fluoride***,[15] F-+N(CH_2CH_2)$_3$+N-CH_2Cl.2BF_4^- (**6**),[16] C_5H_5+N-F(C_5H_5N)$B_2F_7^-$ (**7**),[17] and ($PhSO_2$)$_2$NF (**8**).[18] XeF_2 is not suitable for large scale reactions because of its high cost. The scope of fluorination by each of these reagents (**6**)-(**8**) is also covered by the *N*-fluoropyridinium salts (**1**)-(**5**). ***Acetyl Hypofluorite*** ($MeCO_2F$), a useful electrophilic fluorinating agent, must be prepared in situ because of instability.[19] ***Perchloryl Fluoride*** ($FClO_3$) is a potentially explosive material.[20]

Fluorosilicic Acid

H_2SiF_6

[16961-83-4] · F_6H_2Si · Fluorosilicic Acid · (MW 144.09)

(a fluoride source with both protic and Lewis acid properties providing efficient cleavage of silicon-oxygen bonds, e.g. silyl ether deprotection)

Physical Data: d 1.220 g cm^{-3} for a 25% aq solution.

Form Supplied in: 25% aq solution, clear and colorless. Upon dehydration, this reagent decomposes giving HF and SiF_4.

Handling, Storage, and Precautions: fluorosilicic acid is toxic and very corrosive. Like HF, this compound attacks glass and therefore must be stored in plastic containers. Use the same precautions as for aq HF solutions. Use in a fume hood.

Desilylation Reactions.

Fluorosilicic acid is a superior reagent for Si-O bond cleavage applications.[1] One of the common reagents used for desilylation is ***Hydrofluoric Acid***; however, significant problems can accompany its use. Standard protocols utilizing HF specify a large excess of the reagent, leading to low pH conditions which can decompose acid-sensitive substrates.[2] Hydrofluoric acid also lacks selectivity in removing silyl ethers. For example, a substrate which incorporates both a *t*-butyldimethysilyl (TBDMS) ether and a triisopropylsilyl (TIPS) ether will undergo cleavage of both protecting groups with little difference in cleavage rates. Of course, this is not problematic if the goal is to remove both groups; however, it is often desirable to remove one group selectively while retaining the other.

For the deprotection of silyl ethers, aq H_2SiF_6 is superior to aq HF. Fluorosilicic acid is a more potent cleaving agent than HF, allowing its use in stoichiometric or even catalytic quantities (eqs 1 and 2). The lower acid concentrations result in milder reaction conditions that are compatible with several acid labile moieties (see below).

(1)

(2)

Fluorosilicic acid also has the unique ability to differentiate effectively between TBDMS and TIPS ethers, as seen in the competitive deprotection experiment in eq 3. The presence of bulky cosolvents, such as *t*-butanol, which serve as ligands to silicon, further enhance selectivity at the expense of reaction rate. The reaction time can be reduced by increasing the amount of H_2SiF_6; however, the accompanying increase in acid concentration precludes the use of acid-labile substrates.

(3)

The optimal compromise between selectivity, reaction rate, and acid concentration is achieved by using a 90:10 acetonitrile-*t*-butanol solvent system. Under these conditions, selectivity is only slightly degraded and the reaction rate is relatively fast, so the amount of reagent can be reduced to 0.25 equiv (eq 4). Due to the lower acid concentration, certain acid labile groups are tolerated. In competitive deprotection experiments, Bn-O-TBDMS is deprotected in the presence of another acid labile protecting group (an example is shown in eq 5 for THP): MEM and MOM groups are 100% retained; THP (86%) and benzylidine derivatives (77%) are partially retained. An acetonide derivative is retained only to the extent of 16%.

Bn-OH + Bn-O-TBDMS + Bn-O-TIPS (4)

1% 91%

Bn-OH + Bn-O-TBDMS + Bn-O-THP (5)

1% 86%

The effects of increasing the steric bulk of the substrate at carbon were also probed. Compounds (**1**)-(**4**) (eq 6) were paired and used in competitive deprotection reactions, providing the results reported in Table 1. Excellent selectivity was observed in the deprotection of primary TBDMS vs. tertiary TBDMS, and secondary TBDMS vs. tertiary TBDMS derivatives. On the other hand, selectivity was only fair for primary TBDMS vs. secondary TBDMS, and secondary TBDMS vs. secondary TIPS ethers. As observed before, *t*-butanol provided greater selectivity than *t*-BuOH-MeCN solvent mixtures.

Fluorosulfuric Acid

HSO_3F

[7789-21-1] · FHO_3S · Fluorosulfuric Acid · (MW 100.08)

(strong Brønsted superacid[1] used as catalyst and reagent for alkylation, isomerization, rearrangement, cyclization, cycloaddition, ring-opening polymerization, and fluorosulfonation; also widely used in generation of stable carbocations)

Alternate Name: fluorosulfonic acid.

Physical Data: mp -89.0 °C; bp 162.7 °C; *d* 1.743 g cm^{-3}.

Solubility: sol nitrobenzene, diethyl ether, acetic acid, ethyl acetate; insol carbon disulfide, carbon tetrachloride, chloroform. It dissolves most organic compounds that are potential proton acceptors.

Form Supplied in: colorless liquid; commercially available.

Handling, Storage, and Precautions: fluorosulfuric acid is highly toxic and corrosive and should always be handled in a fume hood with proper protection. It can be purified by distillation under anhydrous conditions using common glassware. When water is excluded, it may be handled and stored in glass containers, but containers should always be cooled before opening because HF gas pressure may have developed due to hydrolysis. For long-term laboratory storage, however, Teflon bottles are recommended.

Isomerization and Rearrangement.

Many hydrocarbons, especially terpenes, rearrange readily in fluorosulfuric acid, usually at low temperatures, with the intermediacy of carbocations.[2-15] Compared to conventional acid systems, the use of HSO_3F often alters the normal course of acid-catalyzed isomerization and rearrangement, since the carbocation intermediates formed during the reactions are stabilized in the superacid system. For example, treatment of 1,8-*p*-menthadiene (limonene) with HSO_3F gave α- and β-phellandrenes (eq 1)[14] which were not obtained by other weaker acid systems.

Longifolene rearranges to isolongifolene and other tricyclic derivatives in the presence of 50% ***Sulfuric Acid/Acetic Acid*** in dioxane, but both longifolene and isolongifolene rearrange to a variety of bicyclic products under the catalysis of fluorosulfuric acid (eq 2).[15]

Temperature also plays an important role in determining the reaction pathway. Quenching of the reactions with bases or nucleophiles at specific temperatures can control the nature of the products.

Cyclization and Ring Opening.

Fluorosulfuric acid is a promising reagent in catalyzing intramolecular cyclizations at low temperature, giving better yields and higher degrees of structure selectivity compared to conventional acids. Monoterpenoids[16-21] and higher terpenoids[22-27] cyclize biomimetically by treatment with fluorosulfuric acid at low temperature (eq 3).[25]

Trienols and dienols cyclize in a similar way, in the presence of an excess of fluorosulfuric acid in 2-nitropropane at -90 °C, to afford 74-87% yields of diastereoisomeric mixtures of odoriferous norlabdane oxides (eq 4).[27]

(4)

Cyclic ethers can be obtained by reacting unsaturated alcohols in fluorosulfuric acid.[28-33] Treatment of geraniol or nerol with HSO_3F at low temperature gave good yields (78 and 57%) of an iridoid ether (eq 5).[21,29b]

(5)

Benzyl carbinols react with fluorosulfuric acid through various reaction pathways[34-36] (rearrangement, dehydration, cyclization, ring expansion), depending on the substrate (eq 6).[34]

(6)

As opposed to cyclization, ring opening of a number of substituted nopinones occurred under fluorosulfuric acid catalysis to give 4-(2-propyl)cyclohex-2-enones (eq 7).[37] In industry, fluorosulfuric acid is used as an efficient catalyst to initiate the ring-opening polymerization of tetrahydrofuran.[38]

(7)

Cycloaddition.[39-42]

Triphenylpropynol reacts in HSO_3F with alkenes or dienes to give [4 + 2] or [2 + 2] cycloaddition products (eq 8).[42]

(8)

Formation of Fluorosulfates.

Alkyl fluorosulfates can be prepared by addition of fluorosulfuric acid to alkenes, haloalkenes, and cyclopropanes at low temperatures with good to moderate yields (50-95%) (eq 9).[43]

(9)

Fluorosulfonation.[44]

Aromatics react with HSO_3F in the presence of variable amounts of ***Antimony(V) Fluoride*** to give aromatic sulfonyl fluorides and diaryl sulfones (see ***Fluorosulfuric Acid-Antimony(V) Fluoride***).

Generation of Stable Carbocations.

Fluorosulfuric acid is the strongest known simple Brønsted acid, with an H_0 value[45] of -15.1 (compared to -12 for 100% sulfuric acid, -14.1 for ***Trifluoromethanesulfonic Acid***, and -15 for absolutely anhydrous ***Hydrogen Fluoride***).[46] The acidity of HSO_3F can be increased by the addition of Lewis acid fluoride (see ***Fluorosulfuric Acid-Antimony(V) Fluoride***). HSO_3F has low viscosity, high thermal stability, and a wide liquid range (250 °C from mp to bp). These advantageous properties make HSO_3F one of the most frequently used superacids for generating stable carbocations from the corresponding alcohols at low temperature.[1,47-50] Generally, neat HSO_3F or acid diluted with solvents such as SO_2, SO_2ClF, freons, and dichloromethane is suitable for the preparation of carbocations stabilized by aryl, cyclopropyl, vinyl, or other π systems. Representative examples are dicyclopropyl carbonium ions (eq 10),[47] cyanodiarylmethyl cations (nitrenium ions) (eq 11),[48] and the pyramidal $(CMe)_6^{2+}$ dication (eq 12).[49]

(10)

(11)

(12)

An intriguing cyclopropyl cation with a ferrocene substituent has been generated from its trimethylsilyl ether by eliminating trimethylsilyl fluorosulfate (eq 13).[51] 1,6-Methano[10]annulene undergoes protonation by HSO_3F in SO_2ClF to form the corresponding arenium ion (eq 14),[52] while benzenium ion generation needs a combination of HSO_3F and SbF_5.[53]

(13)

Fluorosulfuric Acid-Antimony(V) Fluoride[1]

HSO_3F-SbF_5

[23854-38-8] · F_6HO_3SSb · Fluorosulfuric Acid-Antimony(V) Fluoride · (MW 316.83)

(a strong conjugate Brønsted-Lewis superacid system[1] widely used for the generation of stable carbocations and as catalyst and reagent for alkylation, isomerization, rearrangement, cyclization, oxyfunctionalization, formylation, sulfonation, and fluorosulfonation)

Alternate Name: Magic Acid®.

Physical Data: HSO_3F: mp -89.0 °C; bp 162.7 °C; *d* 1.743 g cm^{-3}. SbF_5: bp 149.5 °C; *d* 2.993 g cm^{-3}.

Solubility: sol SO_2ClF, liquid SO_2; solubilizes most organic compounds that are potential proton acceptors.

Form Supplied in: colorless liquid; commercially available.

Preparative Methods: HSO_3F-SbF_5 is prepared by mixing ***Fluorosulfuric Acid*** and ***Antimony(V) Fluoride*** at rt under dry nitrogen or argon atmosphere. The commercially available Magic Acid is a 50:50 mol % mixture of the two components. Magic Acid diluted in fluorosulfuric acid to various extents is also available. Commercial Magic Acid generally contains some HF in the form of conjugate acid.

Handling, Storage, and Precautions: Magic Acid is highly toxic, moisture sensitive, and corrosive, and should always be handled in a fume hood with proper protection. Glass is attacked by Magic Acid very slowly when moisture is excluded. Therefore, glassware may be used for handling and carrying out reactions involving Magic Acid. Teflon containers are recommended for long-term laboratory storage of Magic Acid.

Introduction.

Of all the superacids, Magic Acid is probably the most widely used medium for the study of stable long-lived carbocations and other reactive cations. The general rule is that the higher the acidity of the medium used, the more stable is the carbocation generated. The acidity of the fluorosulfuric acid-antimony pentafluoride system as a function of SbF_5 content has been studied.[2,3] The increase in acidity is very sharp at low SbF_5 concentration. The H_0 value changes from -15.1 for HSO_3F to -19.8 for a mixture containing 10% SbF_5.[2] The acidity continues up to the estimated value of H_0 = -26.5 for 90% SbF_5 content. The H_0 value for the 1:1 molar mixture of fluorosulfuric acid and antimony pentafluoride, known as Magic Acid®, is estimated to be about -23 by a dynamic NMR study.[3] The name Magic Acid originated in Olah's laboratory at Case Western Reserve University in the winter of 1966 when a piece of Christmas

candle was found to dissolve readily in this acid system, giving the sharp ^{1}H NMR spectrum of the *t*-butyl cation, a phenomenon considered by the research student involved to be magic.[1] A major reason for the wide application of Magic Acid compared with other superacid systems, besides its very high acidity, is probably the large temperature range in which it can be used. In the liquid state, it can be studied at temperatures as low as -160 °C (acid diluted with SO_2F_2 and SO_2ClF) and as high as 150 °C (neat acid).

Magic Acid has been employed as a high acidity medium for isomerization/rearrangement, alkylation, cyclization, carboxylation, formylation, oxyfunctionalization, and related reactions. It also serves as a fluorosulfonating/sulfonating agent for aromatics.

Generation of Stable Carbocations.

Thanks to its high acidity, Magic Acid can be used for the generation of such reactive carbocations as the *t*-butyl cation and other alkyl cations, while fluorosulfuric acid itself is suitable only for the generation of more stable cations such as aryl- or cyclopropyl-stabilized carbocations.

Carbocations and carbodications have been generated from a variety of precursors in Magic Acid systems.[4]

Carbocation Generation from Tertiary and Secondary Alcohols.[5-11]

A wide variety of aliphatic tertiary and secondary alcohols can be ionized to the corresponding alkyl cations by using Magic Acid. Formation of the *t*-butyl cation (eq 1)[5] and a cyclopropyl-stabilized dication (eq 2)[6] are representative examples. Primary (and some secondary) alcohols are protonated only at temperatures lower than -60 °C.[7] At more elevated temperatures they may cleave to give the corresponding carbocations, which, however, immediately rearrange to the more stable tertiary cations.[8,9]

(1)

(2)

Similar to alcohols, aliphatic ethers,[12] thiols,[13] and sulfides are also protonated on oxygen or sulfur, respectively, at -60 °C in Magic Acid; carbocations are subsequently formed upon raising the temperature. Protonated sulfides, excluding tertiary alkyl, are resistant to cleavage up to +70 °C.[13]

Carbocation Generation from Alkyl Halides.

Alkyl chlorides, fluorides, and bromides are convenient and frequently used precursors for generation of alkyl cations in HSO_3F-SbF_5 systems.[14] It should be noted, however, that the HSO_3F-SbF_5 system is less suitable than SbF_5 for the generation of alkyl, especially secondary alkyl, cations from the corresponding alkyl halides (see ***Antimony(V) Fluoride***). Ionization of cyclohexyl chloride in Magic Acid is accompanied by isomerization, yielding the 1-methyl-1-cyclopentyl cation (eq 3).[8]

(3)

Carbocation Generation from Unsaturated Hydrocarbons.

Carbocations can be generated by protonation of unsaturated hydrocarbons such as alkenes and cycloalkenes,[8,11] cyclopentadienes,[15] benzenes and naphthalenes (eq 4),[16] pyrenes and cyclophanes,[17] unsaturated heterocycles,[18] and their derivatives with carbon-heteroatom multiple bonds,[1] including carbonyl and nitrile compounds and diazoalkanes (eq 5).[19] Compounds with two sites for protonation may undergo diprotonation to give dications in Magic Acid (eq 6).[15a]

(4)

(5)

(6)

Carbocation Generation from Saturated Hydrocarbons.

Magic Acid, as a strong superacid, can abstract hydride from saturated alkanes, including straight-chain alkanes as well as branched and cyclic alkanes, at -125 to 25 °C to give alkyl cations.[6,20] For example, the 2-norbornyl cation is formed through protolytic ionization by dissolving norbornane in Magic Acid (eq 7).[20b]

(7)

Carbocation Generation by Oxidation.

Oxidation of polycyclic arenes such as naphthacene and 1,2-benzanthracene (eq 8)[21] gives arene dications (see also ***Antimony(V) Fluoride***).

(8)

Isomerization and Rearrangement.

HSO_3F-SbF_5 is frequently used as a catalyst for the isomerization and rearrangement of terpenoids. The extremely high acidity of HSO_3F-SbF_5 allows the reaction to be carried out at temperatures as low as -100 °C and with improved selectivity.

In superacid, i.e. HSO_3F-SbF_5 or HF-SbF_5 systems, bicyclic phenols are isomerized to dienones in good yields (eq 9).[22] This is an unconventional isomerization process, in which the phenols lose their aromaticity to form nonaromatic

dienones. Similar phenol-to-dienone isomerization of estrones occurs with HSO_3F-SbF_5 as catalyst, accompanied by major dehydrogenation products (eq 10).[23]

(9)

(10)

endo-Trimethylenenorbornane isomerizes to its *exo* isomer in quantitative yield at 0 °C under HSO_3F-SbF_5 catalysis (eq 11).[24] The isomerization will proceed further to adamantane when excess superacid is used (HSO_3F-SbF_5:substrate ratio = 1:3). For the rearrangement of trimethylenenorbornane to adamantane, HSO_3F-SbF_5 is, however, less efficient than CF_3SO_3H-SbF_5 or CF_3SO_3H-$B(OSO_2CF_3)_3$.[25]

(11)

Alkylation.

Benzene, alkylbenzenes, and halobenzenes undergo alkylation with 2,2,4-trimethylpentane in the presence of HSO_3F-SbF_5 at temperatures as low as -30 °C with good selectivity (eq 12).[26]

Cyclization.

HSO_3F-SbF_5 has been used as a high-acidity catalyst for the cyclization of acyclic isoprenoids at low temperatures. The reaction course and products of the cationic cyclization depend on the acidity of the catalyst and the structural differences in the substrates. Structural changes may also lead to dramatic changes in the reaction course and products. While geranate esters (eq 13)[27] and pseudoionones (eq 14)[28] are cyclized to monocyclic derivatives, geraniol or nerol (eq 15)[29] and geranylacetone (eq 16)[30] give bicyclic ethers.

(14)

(15)

(16)

Sulfonation and Fluorosulfonation.

Aromatic compounds react with HSO_3F to give arenesulfonyl fluorides.[31] When the reactions are carried out in the presence of variable amounts of SbF_5, significant amounts of diaryl sulfones are obtained (eq 17).[32] In this example, the yields of arenesulfonyl fluorides decreased with increasing amounts of SbF_5. In contrast, the yields of diaryl sulfones first increased and then decreased with increasing amounts of SbF_5. The highest yield of diphenyl sulfone was obtained when the molar ratio of SbF_5:benzene was 1:1.5. Diaryl sulfones were also obtained in high yield from toluene, xylenes, and 1,2,4-trimethylbenzene under similar conditions. Sulfonation of fluoro-, chloro-, and bromobenzenes required higher molar ratios of SbF_5:arene (1:3.5) to obtain good yields of the corresponding diaryl sulfones.

(17)

R = H	94%	4%
R = Me	95%	1%
R = F	83%	0%

Formation of Aromatic Sulfoxides.

By treatment with HSO_3F-SbF_5 (1:1) and ***Sulfur Dioxide***, alkylbenzenes, halobenzenes, and alkylhalobenzenes were converted to their corresponding diaryl sulfoxides along with small amounts of diaryl sulfides as minor products (eq 18).[33] In the absence of SO_2, aryl sulfone formation is the dominant process, although sulfoxide is also formed. Unsymmetrical (mixed) sulfoxides can be prepared by addition of one molar equivalent of an arene to the solution of the second arene and Magic Acid-SO_2 in Freon at low temperatures.

(18)

R = Me, 87%; F, 55%

Formylation and Carboxylation.

Formylation of aromatic compounds such as benzene, toluene, xylenes, mesitylene, indan, tetralin, and halobenzenes is achieved in HSO_3F-SbF_5 under atmospheric CO pressure at 0 °C (eq 19).[34] However, in the cases of alkylbenzenes, both formylation and sulfonation took place under these reaction conditions to give alkylbenzaldehydes and formylalkylbenzenesulfonyl fluorides, as well as small amounts of alkylbenzenesulfonyl fluorides and bis(alkylphenyl) sulfones. With benzene and halobenzenes, because of their lower reactivity only aldehydes were produced.

(19)

Saturated hydrocarbons, including branched and unbranched chain alkanes as well as cycloalkanes, react with carbon monoxide in the presence of ***Copper(I) Oxide*** in HSO_3F-SbF_5 to afford tertiary and secondary carboxylic acids in high yield (eq 20).[35] The reaction proceeds at 0 °C under 1 atm CO. In some cases the reaction involves cleavage of C-C bonds and isomerization of the intermediate carbocations.

(20)

Oxyfunctionalization of Hydrocarbons.

When treated with ***Ozone***[36] or ***Hydrogen Peroxide*** (98%)[37,38] under Magic Acid catalysis, alkanes, including methane, ethane, butanes, and higher alkanes as well as haloalkanes,[39] undergo electrophilic oxygenation followed by carbon-to-oxygen alkyl group migration giving, via alkoxycarbenium ions, ketones and alcohols (eq 21). Aliphatic alcohols, ketones, and aldehydes react with ozone in Magic Acid solution to give bifunctional oxygenated derivatives such as diketones, hydroxyl ketones, and glycols (eq 22).[40] The relative reactivity of σ-bonds in alkanes with protonated ozone was found to be R_3C-H > $R_2(H)C$-H > $R(H_2)C$-H > C-C.[36]

(21)

(22)

Aromatic compounds such as benzene, alkylbenzenes, and halobenzenes can be directly oxygenated with hydrogen peroxide in Magic Acid or other superacids, giving phenols (eq 23).[41] The phenols formed are protonated by the superacids and thus are deactivated against further electrophilic attack or oxidation. When naphthalene was treated with hydrogen peroxide in Magic Acid at -78 °C, 2-naphthol was obtained (92% regioselectivity) along with small amounts of dihydroxynaphthalenes (eq 24).[42] Unlike phenol derivatives, naphthols can be further hydroxylated with hydrogen peroxide in superacid systems to dihydroxynaphthalenes, since the unprotonated ring of the protonated naphthols can still be attacked by the electrophilic hydroxylating agent.

(23)

(24)

Miscellaneous Reactions.

In the presence of HSO_3F-SbF_5, ***Peroxydisulfuryl Difluoride*** ($S_2O_6F_2$) reacts smoothly with 1,1,2-trichlorotrifluoroethane at rt to give 1,2-dichlorotrifluoroethyl fluorosulfate (eq 25).[43] $S_2O_6F_2$ alone does not react with 1,1,2-trichlorotrifluoroethane even at 150 °C, while in the presence of HSO_3F the reaction occurs only at temperatures higher than 150 °C.

(25)

Polyfluoroarenes, such as *m*-$H_2C_6F_4$, *m*-$O_2NC_6F_4H$, *m*- and *p*-BrC_6F_4H, $(p\text{-}HC_6F_4)_2$, C_6F_5H, 1,3,5-$F_3C_6H_3$, and *m*-$FSO_2C_6F_4H$, have been thallated by ***Thallium(III) Trifluoroacetate*** in HSO_3F-SbF_5. The thallated products can be converted to polyfluoroiodoarenes by treatment with aqueous ***Sodium Iodide*** (eq 26).[44]

(26)

Although HSO_3F-SbF_5 is known to be a strong oxidizing system, it has been reported that octafluoroazoxybenzene was reduced by HSO_3F-SbF_5 at 20 °C to octafluoroazobenzene in quantitative yield (eq 27).[45] The mechanism of the process is still unclear.

(27)

Isoalkanes are brominated by Br_2 in HSO_3F-SbF_5 to yield mono-, di-, and tribromoalkanes (eq 28).[46] Cleavage of C-C bonds occurs when isooctane is reacted under similar conditions, leading to butyl bromides.

(28)

Fluorinative dediazoniation of an arenediazonium salt occurred at 0 °C in Magic Acid; (eq 29)[47] however, fluorosulfonation accompanied the dediazoniation.

(29)

Related Reagents.

Antimony(V) Fluoride; ***Fluorosulfuric Acid***; ***Hydrogen Fluoride***; ***Hydrogen Fluoride-Antimony(V) Fluoride***.

Fluorotributyl(methyl)phosphorane

[36121-19-4] · $C_{13}H_{30}FP$ · Fluorotributyl(methyl)phosphorane · (MW 236.40)

(fluorinating reagent[1-3] and fluoride source for silicon displacement[1])

Alternate Names: tributyl(methyl)phosphonium fluoride; tributylfluoro(methyl)phosphorane.

Physical Data: bp 74-76 °C/0.1 mmHg;[4,5] mp 11-13 °C.[5]

Solubility: sol THF, diethyl ether, petroleum ether, benzene, cyclohexane.

Form Supplied in: not commercially available.

Preparative Methods: can be prepared in three steps from commercially available starting materials. Alkylation of ***Tri-n-butylphosphine*** with ***Iodomethane*** or ***Bromomethane*** gives a phosphonium salt[6] which yields tributylmethylenephosphorane after deprotonation with ***n-Butyllithium*** in ether and subsequent product distillation.[7] The tributylmethylenephosphorane is then treated with ***Hydrogen Fluoride*** or KHF_2, and purified fluorotributyl(methyl)phosphorane is obtained by distillation.[4]

Handling, Storage, and Precautions: water sensitive; best kept at -10 °C.[4]

Fluoride Formation.

Fluorotributyl(methyl)phosphorane has been used as a fluorinating reagent in the displacement reactions of alkyl bromides, chlorides, and tosylates.[1-3] For the fluoride displacement of benzyl chloride, fluorotributyl(methyl)phosphorane at -78 °C gives an 80% yield, whereas fluorotriethyl(methyl)phosphorane and fluorotrimethyl(phenyl)phosphorane give only a 20% yield.[1]

Fluorotributyl(methyl)phosphorane is a milder fluorinating reagent for sensitive functionality than ***Potassium Fluoride*** with a crown ether.[8] A bromoepoxide will undergo fluoride displacement with fluorotributyl(methyl)phosphorane but will decompose under KF-crown ether conditions (eq 1).[2]

(1)

Secondary alkyl halides undergo elimination to afford alkenes; secondary alkyl tosylates give mixtures of alkyl fluorides and alkenes.[2,3] A comparison of fluorotributyl(methyl)phosphorane with other fluorinating reagents in the displacement of the secondary alcohol 2-hydroxyoctanol and derivatives thereof was made (eq 2).[3] The highest optical purity in the displacement reaction was obtained with fluorotributyl(methyl)phosphorane (X = OTs); however, this reagent also gave the most alkene (Table 1). ***(2-Chloro-1,1,2-trifluoroethyl)diethylamine*** (FAR) gave the best fluoride:alkene ratios. After publication of this comparison of fluorinating reagents, anhydrous ***Tetra-n-butylammonium Fluoride*** (TBAF) was shown to give a better fluorooctane yield (54%) and a higher optical purity than fluorotributyl(methyl)phosphorane (+14.2° vs. +13.6°).[9]

(2)

Table 1 Fluorinating Agents for S_N2 Displacement

Substrate	Reagent	Ratio (fluoro-octane: octenes)	Yield (%) (2-fluoro-octene)	Optical yield
(-)-$C_6H_{13}CH(OTs)Me$	Bu_3MePF	40:60	15	100
(+)-$C_6H_{13}CH(OTMS)Me$	$PhPF_4$	58:22	11	68
(+)-$C_6H_{13}CH(OH)Me$	FAR	78:22	40	88
(+)-$C_6H_{13}CH(OH)Me$	DAST[a]	48:52	23	98
(-)-$C_6H_{13}CH(OTs)Me$	KF	50:50	31	91

[a] DAST = *N,N*-diethylaminosulfur trifluoride

Aldol Condensation.

Fluorotributyl(methyl)phosphorane can act as a desilylating agent in the aldol condensation of the silyl enol ether of cyclohexanone with benzaldehyde (eq 3).[1] Similar yields are obtained with the more readily available TBAF.

Fluorotrimethylsilane

Me_3SiF

[420-56-4] · C_3H_9FSi · Fluorotrimethylsilane · (MW 92.21)

(capable of silylating ketones, alcohols, and terminal alkynes[3,4])

Alternate Name: TMSF.

Physical Data: bp 19 °C/730 mmHg.[1]

Solubility: sol most organic solvents.

Preparative Methods: from ***Chlorotrimethylsilane*** (TMSCl) by direct treatment with ***Hydrofluoric Acid***.[1,2] TMSF can also be generated in situ by reaction of ***Ethyl Trimethylsilylacetate*** (ETSA) and ***Tetra-n-butylammonium Fluoride*** (TBAF).[3]

Handling, Storage, and Precautions: typically generated in situ or used as prepared.

Ketones, alcohols, and terminal alkynes can be silylated in excellent yields using TMSF that has been generated in situ from ETSA and catalytic TBAF (eq 1).[3,4] Ketones silylated in this manner often show high regioselectivity as compared to those silylated with TMSCl.[3]

Addition of an aldehyde or ***N-Bromosuccinimide*** to the crude reaction mixture also afforded an aldol[3,4] or brominated product in good yield (eqs 2 and 3).[3]

(2)

(3)

Carbonyl compounds possessing no acidic α-protons undergo a Reformatsky-type reaction under ETSA-TBAF conditions to afford β-siloxy esters which can then be hydrolyzed to β-hydroxy esters (eq 4).[3]

(4)

Related Reagents.

Formaldehyde

[50-00-0] · CH_2O · Formaldehyde · (MW 30.03) ($(CH_2O)_n$)

[30525-89-4] ($3CH_2O$)

[110-88-3]

(ene reaction;[1,2] Prins reaction;[1,3] enolate trapping;[4] alkylation; Mannich reaction; acetalization; condensation; reduction)

Alternate Names: paraformaldehyde; *s*-trioxane.

Physical Data: monomeric formaldehyde: mp -92 °C; bp -19.5 °C; *d* 1.067 g cm^{-3}. Paraformaldehyde: mp 163-165 °C (dec). *s*-Trioxane: mp 64 °C, bp 114.5 °C, *d* 1.17 g cm^{-3} (65 °C); sublimes readily.

Solubility: formaldehyde gas: v sol water, up to 55%; sol alcohol, ether. Paraformaldehyde: slowly sol cold water; readily sol hot water with evolution of formaldehyde; insol alcohol, ether. *s*-Trioxane: readily sol water (21.1 g/100 mL at 25 °C), alcohols, ether, acetone, chlorocarbons, aromatics; sl sol pentane.

Form Supplied in: 37% aqueous solution (with 10 to 15% methanol to prevent polymerization) known as formalin; colorless and pungent liquid. Paraformaldehyde: polymer as a white crystalline powder. *s*-Trioxane: crystalline solid.

Preparative Methods: dry formaldehyde may be generated by heating solid paraformaldehyde or by decomposing with barium peroxide; ethereal solutions of monomeric formaldehyde can be obtained by pyrolysis of paraformaldehyde at 150 °C in a special apparatus; can be generated in situ from trioxane by ***Methylaluminum Bis(2,6-diphenylphenoxide)*** (MAPH).[15]

Handling, Storage, and Precautions: reported to be storable for an extended period at -78 °C under argon (unchecked *OS* procedure);[5] irritating to mucous membranes; carcinogen; should be used only in a well-ventilated fume hood.

Ene Reaction.

Thermal ene reactions of paraformaldehyde with reactive 1,1-di- and trisubstituted alkenes occur at 180-220 °C.[6,7] β-Pinene, for example, is transformed into nopol upon reaction with formaldehyde at 180 °C (eq 1).[6] Extension of this reaction has been reported using acetic acid-acetic anhydride as solvent.[8]

(1)

Lewis acids such as ***Tin(IV) Chloride***[9] and ***Boron Trifluoride Etherate***[10] can facilitate addition of formaldehyde to alkenes to afford ene adducts. Thus reaction with 2,6-dimethyl-2,5-heptadiene in the presence of $SnCl_4$ as catalyst provides lavanduol (eq 2).[11] The $BF_3.Et_2O$-promoted reaction with the ethylidene steroid shown in eq 3 takes place exclusively from the less hindered α-face to produce the ene adduct with the natural steroid configuration at C-20.[12]

(2)

(3)

Organoaluminum reagents can also be utilized as promoters for ene reactions to give homoallylic alcohol ene adducts in high yield and selectivity, although γ-chloro alcohols are formed in some cases as byproducts.[13] ***Diethylaluminum Chloride***-induced ene reactions of formaldehyde with 1,4-dienes occur selectivity at the less deactivated terminal bond,

and subsequent quasi-intramolecular Diels-Alder reaction with formaldehyde as dienophile leads to the formation of a dihydropyran (eq 4).[14] The formaldehyde-dimethylaluminum chloride complex acts on terminal alkynes to afford α-allenic alcohols and (*Z*)-3-chloroallylic alcohols as byproducts in a 2:3 ratio (eq 5).[13b] The aluminum reagent MAPH complexed with formaldehyde, generated from trioxane, also reacts with various alkenes to furnish ene adducts with excellent regioselectivities (see ***Methylaluminum Bis(2,6-diphenylphenoxide)***).[15]

(4)

(5)

Prins Reaction.

The condensation of aldehydes and ketones with alkenes in the presence of Brønsted acids is usually called the Prins reaction. The main products of this alkene-aldehyde condensation, depending on experimental conditions, may be a 1,3-dioxane, a 1,3-diol, a homoallylic alcohol, or an α-chloro ether (see ***Formaldehyde-Hydrogen Chloride***).[3]

Various catalysts have been used in the Prins reaction, although in the synthesis of 1,3-dioxane, sulfuric acid seems to be the most efficient. Thus stirring a mixture of formalin, sulfuric acid, and styrene under gentle reflux gives 4-phenyl-

m-dioxane (eq 6).[16]

(6)

Prins reactions involving formaldehyde have been used to prepare prostaglandin intermediates. An example is the acid-catalyzed addition of formaldehyde to the unsaturated lactone in acetic acid at 60-80 °C to give a prostaglandin intermediate (eq 7).[17]

(7)

Reaction of a 1,4-diaryl-1-butene with paraformaldehyde catalyzed by a 1:1 mixture of ***Methylaluminum Dichloride*** and ***Dimethylaluminum Chloride*** resulted in cylization to form a 1-aryltetralin (eq 8). The mixed catalyst was found to be more effective than Me_2AlCl alone.[18]

(8)

Enolate Trapping Reactions and Formation of α-Methylene Products.

Lactones when treated with ***Lithium Diisopropylamide*** in THF at -78 °C form enolate anions that react with gaseous formaldehyde to give the α-hydroxymethyl derivative. The product can be easily transformed to an α-methylene lactone by conversion to mesylate followed by treatment with refluxing pyridine (eq 9).[19] This method was used for bis-α-methylenation in the total synthesis of deoxyvernolepin, which contains a dilactone structure (eq 10).[20]

α-Thiobutyrolactones,[21] carboxylic acids,[22] sulfonyl-hydrazones,[23] enol phosphinites,[24] and α,β-enones[25] on treatment with lithium reagents and subsequent reaction with formaldehyde undergo the same reaction, providing aldol adducts.

α-Methylenation products can also result from reaction of the carbanion of α-alkyl β-keto esters or lactones with paraformaldehyde in THF, initially at -78 °C and followed by reflux (eq 11).[26]

Δ^1-5α-Androsten-3-one in DMSO containing paraformaldehyde and $BF_3.Et_2O$ when heated resulted in formation of the 4-methylene ketone (eq 12).[27]

(12)

Reductive Methylation.

The classical method of dimethylation of primary amines or monomethylation of primary and secondary amines involves reaction with formaldehyde and ***Formic Acid*** (eq 13).[28]

(13)

The use of either ***Sodium Borohydride***[29] or ***Sodium Cyanoborohydride***[30] in place of formic acid leads to the same reaction. However, $NaCNBH_3$ is usually the preferred reducing agent since the methylated amines can be formed without reduction of carbonyl compounds in the substrate.[31]

Potassium hydridotetracarbonylferrate prepared from ***Potassium Hydroxide*** and ***Pentacarbonyliron*** is likewise effective for the dimethylation of primary amines in ethanol under carbon monoxide at 20 °C (eq 14).[32] The use of a 1:1 molar ratio of amine and formaldehyde gives the monomethylated product.

$$PhNH_2 + 2\,CH_2O \xrightarrow[\text{CO, EtOH}]{KHFe(CO)_4} PhNMe_2 \qquad (14)$$

~100%

Carbonyl compounds having α-methyl or α-methylene groups also undergo methylation with formaldehyde in the presence of potassium or ***Sodium Tetracarbonylhydridoferrate*** (eqs 15 and 16).[33]

(15)

(16)

Ethyl *p*-nitrophenylacetate undergoes reductive methylation upon reaction with aqueous formaldehyde by catalytic hydrogenation with ***Palladium on Carbon*** (eq 17).[34]

(17)

Hydroxymethylation.

Reaction of carbonyl compounds with formaldehyde in the presence of base results in the formation of hydroxymethylated products. For example, allyl β-keto esters react with formaldehyde and ***Potassium Carbonate*** to give the α-hydroxymethyl ketone in quantitative yield (eq 18).[35] Sugar aldehydes undergo the same reaction with K_2CO_3.[36]

(18)

With a 2:1 ratio of formaldehyde and ***Diethyl Malonate*** and potassium bicarbonate as catalyst, the product is diethyl bis(hydroxymethyl)malonate (eq 19).[37]

(19)

Nitriles possessing at least one α-aryl group can be hydroxymethylated using paraformaldehyde and Triton B (***Benzyltrimethylammonium Hydroxide***) in pyridine (eq 20).[38]

(20)

Chromium tricarbonyl complexes of methoxyalkylbenzenes in the presence of ***Potassium t-Butoxide*** and formaldehyde undergo regiospecific alkylation only at the *meta*-position with respect to the methoxy group (eq 21).[39]

(21)

Reaction with Organometallic and Other Reagents.

Hydroxymethylation of Grignard reagents with formaldehyde can be represented by the synthesis of

cyclohexymethanol using cyclohexylmagnesium chloride.[40] ***Methylmagnesium Bromide***, in the presence of a nickel-aluminum catalyst, acts on 1-trimethylsilyl-1-octyne to provide a mixture of addition products which react with formaldehyde to give di- and trisubstituted vinylsilanes (eq 22).[41]

Boric Acid is a useful catalyst for the cyclocondensation of phenol with formaldehyde to give benzodioxaborin.[42] Phenylboronic acid, in combination with propionic acid, is found to be a more efficient catalyst.[43] Thus a high yield of dioxaborin is obtained in the reaction with a slight excess of phenylboronic acid, and the free hydroxymethylated phenol is liberated by an exchange reaction or by oxidation with ***Hydrogen Peroxide*** (eq 23).

Silyl enol ethers of aldehydes and ketones react with trioxane in the presence of ***Titanium(IV) Chloride*** to give cross-aldol adducts in good yield (eq 24).[44]

(24)

Ytterbium(III) Trifluoromethanesulfonate, a Lewis acid stable in aqueous media, is found to be effective in catalytic hydroxymethylation of silyl enol ethers with formalin (eq 25).[45]

(25)

Synthesis of Heterocyclic Compounds.

Condensation of ***Ethyl Acetoacetate***, formaldehyde, and ***Ammonia*** in 2:1:1 molar ratio furnishes a 1,4-dihydropyridine which is the first step in the synthesis of 2,6-lutidine (eq 26).[46]

(26)

Symmetric trimers such as *sym*-trithiane[47] and hexahydro-1,3,5-tripropionyl-*sym*-triazine[48] are obtained from formaldehyde reactions. The former is synthesized by passing ***Hydrogen Sulfide*** into a mixture of formalin and concentrated HCl, while the latter is prepared by addition of trioxane in propionitrile to a mixture of propionitrile and concentrated H_2SO_4 (eqs 27 and 28).

(27)

(28)

A general synthesis of piperidines involves the reaction of the acid salt of primary amines with allylsilanes and 2 equiv formaldehyde in H_2O. The iminium ion generated from the amine and formaldehyde reacts with the allylsilane to give a homoallyl amine, which then can form the second iminium ion and H_2O is captured to deliver the piperidinol (eq 29).[49]

(29)

Cyclization of the alkynylamine *N*-benzyl-4-hexyn-1-amine with formaldehyde, ***Sodium Iodide***, and ***10-Camphorsulfonic Acid*** gives the iodomethylenepiperidine (eq 30).[50] In the absence of the iodide nucleophile, no cyclization is observed.

(30)

Reactions of (*E*)- or (*Z*)-vinylsilanes with an excess of paraformaldehyde and camphorsulfonic acid give the cyclized product with >98% retention of the double bond configuration of the starting reactants (eq 31).[51]

(31)

A series of imine condensations and chain cleavage occur when D-fructose is heated with ammonium hydroxide, basic copper(II) carbonate, and formaldehyde, which ultimately gives 4-hydroxymethylimidazole (eq 32).[52]

(32)

Condensation.

For the preparation of aurin tricarboxylic acid, solid ***Sodium Nitrite*** was added to concentrated sulfuric acid to produce nitrogen oxides, then salicyclic acid and formalin were added dropwise with vigorous cooling (eq 33).[53]

(33)

3,4-Diethylpyrrole can be converted to octaethylporphyrin by condensation with aqueous formaldehyde in benzene in the presence of ***p-Toluenesulfonic Acid***; the water is removed and the methylenepyrrole tetramer is oxidized with oxygen (eq 34).[54]

The synthesis of *p*-*t*-butylcalix[4]arene is a three-step process which involves initial reactions of *p*-*t*-butylphenol, formalin, and a base, followed by pyrolysis at a later stage (eq 35).[55] The procedure is limited to *p*-alkylphenols in which the *p*-alkyl group is highly branched at the position adjacent to the phenyl ring. A single-step procedure is also described for *p*-*t*-butylcalix[6]arene[56] and *p*-*t*-butylcalix[8]arene,[57] which requires a larger amount of base for the preparation of the hexamer.

Acetalization.

1,3-Diols react with formaldehyde in an excess of alcohol under acid catalysis, such as *p*-TsOH or ion exchange resin,

to form cyclic acetals (eq 36).[58]

(36)

Cortisone, a steroid containing an α,α´-dihydroxyacetone side chain, is converted into the bismethylenedioxy derivative by stirring with chloroform, formalin, and concentrated HCl (eq 37).[59]

(37)

Cannizzaro and Related Reductions.

In the presence of calcium oxide and water, cyclohexanone reacts with 5 moles of paraformaldehyde to give the pentaol shown in eq 38.[60]

(38)

p-Tolylmethanol is formed in a Cannizzaro reaction involving *p*-tolualdehyde and formalin in aqueous KOH (eq 39).[61]

(39)

An interesting preparation of *p*-dimethylaminobenzaldehyde from *p*-nitrosodimethylaniline is accomplished by reaction

with dimethylaniline and 2 moles of formaldehyde in HCl solution. In the first step, one mole of formaldehyde is reduced and the other is oxidized to the formate level, furnishing the benzylidene derivative which is then hydrolyzed by exchange with formaldehyde (eq 40).[62]

Other Reactions with Nitrogen Compounds.

A reaction involving a mixture of formalin, ammonium chloride, and aqueous ***Sodium Cyanide*** provides *N*-(methylene)aminoacetonitrile (eq 41).[63]

Diethylaminoacetonitrile is prepared by adding formalin to a solution of sodium bisulfate, thereby forming the addition compound which is stirred in diethylamine after cooling, and the aqueous solution of sodium cyanide is added (eq 42).[64]

For the preparation of glycolonitrile, formalin is added to a stirred solution of ***Potassium Cyanide*** in water at 0-10 °C (eq 43).[65]

$$CH_2O \xrightarrow[0\text{-}10\ ^\circ C]{KCN,\ H_2O} \underset{76\text{-}80\%}{HOCH_2CN} + KOH \qquad (43)$$

For Mannich-type reactions involving formaldehyde, see ***Formaldehyde-Dimethylamine***.

Related Reagents.

Acetaldehyde; ***Formaldehyde-Dimethylamine***; ***Formaldehyde-Hydrogen Bromide***; ***Formaldehyde-Hydrogen Chloride***; ***Methylaluminum Bis(2,6-diphenylphenoxide)***; ***Sodium Cyanoborohydride***.

Formaldehyde-Dimethylamine[1]

HCHO-R^1R^2NH

(HCHO)

[50-00-0] · CH_2O · Formaldehyde-Dimethylamine · (MW 30.03) ($(CH_2O)_n$)

[30525-89-4] · $(CH_2O)_n$ · Formaldehyde-Dimethylamine (R^1 = Me, R^2 = Me)

[124-40-3] · C_2H_7N · Formaldehyde-Dimethylamine · (MW 45.10) (R^1 = Me, R^2 = Me; HCl salt)

[506-59-2] · C_2H_8ClN · Formaldehyde-Dimethylamine · (MW 81.56) (R^1 = Bn, R^2 = H)

[100-46-9] · C_7H_9N · Formaldehyde-Benzylamine · (MW 107.17) (R^1 = Bn, R^2 = H; HCl salt)

[3287-99-8] · $C_7H_{10}ClN$ · Formaldehyde-Dimethylamine · (MW 143.63)

(reagent for aminomethylation of active methylenes,[1a-c] aromatic compounds,[1d] and nucleophilic alkenes,[1e,f] reagent for generation of methyleneiminium species capable of participating in [4 + 2][2] and [3 + 2][3] cycloadditions)

Physical Data: Me_2NH, bp 7 °C (also supplied as a 40 wt % solution in water); $Me_2NH.HCl$, mp 170-173 °C; $BnNH_2$, bp 184-185 °C, *d* 0.981 g cm^{-3}; $BnNH_2.HCl$, mp 262 °C.

Form Supplied in: amine HCl salts are widely available as white solids; HCHO is available as 37 wt % soln in water; paraformaldehyde $(CH_2O)_n$ is available as a white solid

Handling, Storage, and Precautions: amines are irritants and corrosive; HCHO is highly toxic and a cancer suspect agent; paraformaldehyde is a moisture-sensitive irritant which can be expected to give off HCHO. Use in a fume hood.

Mannich Aminomethylation.

The generation of reactive methyleneiminium salts (eq 1) from formaldehyde and primary or secondary amines (usually as HCl salts) defines the classical Mannich conditions under which a wide variety of nucleophilic species can be aminomethylated. Historically, the most common nucleophiles have been active methylene compounds[1a-c] with a pK_a of 20 or less (e.g. ketones, aldehydes, and malonates) and nucleophilic aromatic compounds.[1d] Recent examples of each

include the aminomethylation of a ketone in the synthesis of the alkaloid (±)-glaucine (eq 2)[4] and the aminomethylation of a phenol, which occurs regioselectively *ortho* to the hydroxyl group (eq 3).[5]

(1)

(2)

(3)

Aminomethylation of active methylene compounds is often accompanied by elimination of the amine, comprising one of the most useful syntheses of α-methylene carbonyl compounds.[1a-c] This methylenation procedure was recently incorporated into a cephalosporin synthesis (eq 4).[6] Formation of the double bond is also often accomplished separately by quaternization and base-induced elimination.

(4)

Methyleneiminium species are sufficiently reactive to be attacked by moderately nucleophilic alkenes.[1f,7-10] In most cases, this reaction is terminated by addition of an external nucleophile, such as halide or water, to the opposite terminus of the alkene.[9,10] However, the addition of an alkene to the methyleneiminium ion can also occur in the context of a pericyclic reaction. The elegant stereoselective pyrrolidine synthesis reported by Overman proceeds via a tandem aza-Cope rearrangement/Mannich condensation and has been incorporated into a number of alkaloid total syntheses.[1f] The method is exemplified in eq 5.[11] An unprecedented aza-ene reaction was also recently observed during an intramolecular reaction of an alkene with a methyleneiminium ion (eq 6).[12]

(5)

(6)

Terminal alkynes will condense with secondary amines and HCHO in the presence of Cu^{+} or Zn^{2+} catalysts to afford aminomethylalkynes[13] or allenes.[14] Overman has exploited the intramolecular trapping of methyleneiminium ions with alkynes coupled with nucleophilic addition to the incipient vinyl cations to effect the syntheses of pyrrolidines and piperidines possessing exocyclic substituted methylenes of defined stereochemistry (eq 7).[15] Apparently the success of this cyclization depends on the presence of an external nucleophile.

(7)

The enhanced nucleophilicity of allyl and vinyl silanes relative to alkenes renders them particularly susceptible to reaction with methyleneiminium ions. Grieco has demonstrated that allylsilanes and -stannanes react readily, both inter- and intramolecularly.[16] The resulting homoallyl amines may react further with formaldehyde, affording 4-hydroxypiperidines via the subsequent intramolecular addition of the terminal alkene to the methyleneiminium ion (eq 8).[16a] Vinylsilanes are particularly valuable nucleophiles in that they add intramolecularly in a stereospecific fashion to methyleneiminium ions (eq 9).[1f,17]

(8)

(9)

Cycloadditions.

Böhme first demonstrated that dimethylmethyleneiminium ion is reactive enough to participate as a dienophile in Diels-Alder reactions with 1,3-dienes.[18] More recently it has been reported that methyleneiminium ions generated in situ from primary amines and HCHO undergo this reaction as well (eq 10).[2] Diastereoselectivity has been noted when amines bearing asymmetrical groups are employed (eq 11).[2a,19]

(10)

(11)

When HCHO is combined with a primary amine bearing an electron-withdrawing group (e.g. ester or nitrile) in the α-position, the resultant methyleneiminium ion can deprotonate at the α-carbon, generating an azomethine ylide capable of undergoing [3 + 2] cycloadditions with alkenic dipolarophiles.[3,20] A typical example is presented in eq 12.[20] This method suffers from a lack of regio- and stereoselectivity.

(12)

If the electron-withdrawing group is carboxyl, spontaneous decarboxylation occurs, comprising a remarkably mild and convenient generation of nonstabilized azomethine ylides.[21] Cycloaddition with various alkenes is stereospecific, providing 2,5-unsubstituted pyrrolidines (eq 13).[21b]

Formaldehyde Dimethyl Thioacetal Monoxide[1]

[33577-16-1] · $C_3H_8OS_2$ · Formaldehyde Dimethyl Thioacetal Monoxide · (MW 124.25)

(versatile synthetic reagent used for the production of aldehydes, ketones, α-keto carboxylates, α-amino acid derivatives, and arylacetic acid derivatives)

Alternate Names: methyl (methylthio)methyl sulfoxide (MMSO); formaldehyde dimethyl dithioacetal *S*-oxide; methyl methylsulfinylmethyl sulfide; (methylsulfinyl)methylthiomethane; bis(methylthio)methane *S*-oxide.

Physical Data: bp 222-226 °C; *d* 1.22 g cm^{-3} (20 °C); viscosity 11.78 cP (20 °C); refractive index (20 °C) 1.5524; specific heat (20 °C) 336 cal g^{-1} $°C^{-1}$; surface tension 37.04 dyn cm^{-1} (20 °C); dielectric constant (15 °C) 3.2; pK_a (DMSO) 29.0.[2]

Solubility: sol acetic acid, alcohol, THF, CS_2, CCl_4, $CHCl_3$, acetone, benzene, DMSO; slightly sol cyclohexane, hexane.

Form Supplied in: available as a colorless, clear liquid; commercially available.

Preparative Methods: substitution of chloromethyl methyl sulfoxide with sodium methanethiolate[3] or oxidation of formaldehyde dimethyl dithioacetal with hydrogen peroxide.[4]

Purification: distillation under a reduced pressure at a temperature below 100 °C.

Analysis of Reagent Purity: GC.

Handling, Storage, and Precautions: reagent decomposes slightly when heated under acidic conditions. It is stable in alkaline and neutral media. It is desirable to keep the reagent in a tightly sealed container over 4 Å molecular sieves.

Aldehyde and Ketone Synthesis.

The abstraction of a proton from MMSO with ***Sodium Hydride***, ***Lithium Diisopropylamide***, or ***Potassium Hydride*** affords a carbanion that readily reacts with a variety of electrophiles. Monoalkylation[5] employing alkyl halides or terminal epoxides,[6] followed by hydrolysis, yields the corresponding homologated aldehyde (eq 1). Dialkylation of this anion provides a pathway to symmetrical ketones.[7] The synthesis of cyclic ketones using this procedure has been effective in the production of both natural products (eq 2)[8] and theoretically interesting molecules.[9] It should be noted, however, that this method is not suitable for the synthesis of acyclic, unsymmetrical ketones as a protocol involving sequential alkylation with nonequivalent electrophiles failed.[10]

(1)

(2)

The addition of a Grignard reagent to MMSO, followed by hydrolysis of the intermediate dithioacetal, affords the corresponding aldehyde in moderate yield (eq 3).[11] This procedure is significant when compared to aldehyde formation through the use of ***1,3-Dithiane***. Since 1,3-dithiane requires an electrophilic coupling partner, the production of aromatic aldehydes is prohibited.

(3)

The anion of MMSO also reacts at activated sp^2 carbon centers. Michael addition proceeds efficiently when lithio MMSO is added to α,β-unsaturated carbonyl compounds.[12] The sodium anion of MMSO adds to 2-bromopyridine, displacing the bromide substituent (eq 4).[13] In both cases, hydrolysis of the coupled intermediate affords the corresponding aldehyde. Moreover, the lithium derivative of MMSO condenses efficiently with ketones to provide, after hydrolysis, the corresponding α-hydroxy aldehydes (eq 5).[14] The mild nature of the addition/hydrolysis sequence lends itself to the production of sensitive compounds. For instance, the aldehyde generated in eq 5 is difficult to prepare using certain other methods due to its lability toward both acid and heat.

(4)

(5)

Synthesis of α-Keto Acid and α-Amino Acid Derivatives.

Nitriles react with MMSO in the presence of NaH to give enamino sulfoxides. These versatile intermediates can serve as precursors for both α-keto acids (eq 6)[15,16] and α-amino acids (eq 7).[15,17] Treatment of the enamino sulfoxide with ***Copper(II) Chloride*** in ethanol provides an α-keto ethyl ester. Acetylation of the intermediate enamino sulfoxide, followed by methanolysis and reductive desulfurization, affords protected α-amino esters.

(6)

(7)

Synthesis of Arylacetic Acid Derivatives.

When a mixture of MMSO and an aromatic aldehyde is heated in the presence of a base, a Knoevenagel-type condensation results (eq 8). Reaction of the condensation products with HCl in an alcohol affords arylacetic esters.[18] In the case of electron-rich aromatic aldehydes, hydrolysis of the condensation product often generates the corresponding α-(methylthio)aryl acetate (eq 9). This undesired substrate can, however, be converted to the aryl acetate upon treatment with ***Raney Nickel***.[19] For acid-labile arylacetic acids, a two-step hydrolysis involving base can be employed.[20]

(8)

Friedel-Crafts Alkylation.

The α-thioalkylation of aromatic compounds can be carried out by subjecting the aromatic substrate to MMSO and a Lewis acid (eq 10).[21] Similar attempts employing chloromethyl methyl sulfide as the electrophile result in poor yields of the desired alkylated aromatics (35% as compared to the 90% in eq 10). ***Aluminum Chloride*** is the Lewis acid of choice, providing greater reproducibility than other catalysts that were examined. This method can be extended to heteroaromatic substrates. For example, thiophene and *N*-methylpyrrole are alkylated in 55% and 50%, respectively, when subjected to thioalkylation.

Heterocycle Addition.

The exposure of quinoxaline to the dianion of MMSO results in the production of an appended third ring (eq 11).[22] ***Dimethyl Sulfoxide***, participating in a similar process, affords annulated substrate in a slightly lower yield (51%). This reaction course is in contrast to the addition of a typical organometallic, such as a Grignard reagent, to quinoxaline. For this case, the 2-alkylquinoxaline is usually generated.

(11)

Ethyl Analog of MMSO.

Formaldehyde diethyl dithioacetal monoxide can be used in analogous synthetic applications,[10,23] although it is not commercially available.

Related Reagents.

N,N-Diethylaminoacetonitrile; ***N,N-Dimethyldithiocarbamoylacetonitrile***; ***(4aR)-(4aα,7α,8aβ)-Hexahydro-4,4,7-trimethyl-4H-1,3-benzoxathiin***; ***2-Lithio-1,3-dithiane***; ***Methylthiomethyl p-Tolyl Sulfone***; ***Nitromethane***; ***1,1,3,3-Tetramethylbutyl Isocyanide***; ***p-Tolylsulfonylmethyl Isocyanide***; ***2-(Trimethylsilyl)thiazole***.

Formaldehyde-Hydrogen Bromide[1]

(HBr)

[10035-10-6] · BrH · Formaldehyde-Hydrogen Bromide · (MW 80.92) (CH_2O)

[50-00-0] · CH_2O · Formaldehyde-Hydrogen Bromide · (MW 30.03) ($(CH_2O)_n$)

[30525-89-4] ($3CH_2O$)

[110-88-3]

(conversion of alcohols to bromomethyl ethers; bromomethylation agent for aromatic compounds)

Physical Data: HBr (gas): mp -89.6 °C; bp -66.8 °C; *d* rel. to air 2.71; HBr (48 wt % in water): bp 124.9 °C; *d* 1.490 g cm^{-3}; HBr (30 wt % in acetic acid): *d* 1.354 g cm^{-3}. H_2CO (37 wt % in water): *d* 1.081-1.085 g cm^{-3}; bp 96-99 °C; paraformaldehyde ($HO(CH_2O)_nH$ *n* = 8-100): mp 120-170 °C (depending on degree of polymerization); trioxane: mp 61-62.5 °C; bp 114.5-115.5 °C.

Solubility: HBr: sol water, alcohols, polar organic solvents, acetic acid, propionic acid; H_2CO (as a monomer/polymer equilibrium mixture): sol water, alcohols, acetone, acids; paraformaldehyde: sol (depolymerizes) water, alcohols; insol acetone, ether; trioxane: sol water, alcohols, ethers, ketones, aromatic and chlorinated hydrocarbons.

Form Supplied in: HBr gas: 48 wt % in water (colorless), 30 wt % in acetic acid (colorless); H_2CO: 37 wt % aqueous solution (formalin) (colorless to slightly turbid; generally contains 10-15 wt % methanol as stabilizer); paraformaldehyde (white solid; contains 1-10% water); 1,3,5-trioxane (white solid).

Handling, Storage, and Precautions: HBr solutions turn yellow on storage as the result of bromine formation caused by air oxidation and exposure to light. HBr is highly toxic and corrosive and causes severe burns to eyes, skin, and mucous membranes. H_2CO has a pungent suffocating odor, has an irritant action on eyes and skin, is highly toxic, and a cancer suspect reagent. Combination of HBr and H_2CO may yield highly toxic bis(bromomethyl) ether (see carcinogenic ***Bis(chloromethyl) Ether***). Handle in a fume hood.

Bromomethyl Ethers.

Bromomethyl alkyl ethers, which are useful for bromomethylation of aromatic compounds,[1-5] are prepared by the reaction of an alcohol with an equimolar amount of paraformaldehyde and hydrogen bromide (eq 1).[1,2,4,6] Use of metal chloride Lewis acid catalysts in the bromomethylation of aromatics with bromomethyl ethers[2,3] sometimes gives chloromethylated compounds as well. Bromomethyl methyl and bromomethyl octyl ethers are commercially available.

$$ROH + H_2CO + HBr \xrightarrow{0\text{-}5\ ^\circ C} ROCH_2Br + H_2O \qquad (1)$$

Higher alcohols are reported to react more smoothly than lower alcohols.[4] The reaction is best performed at low temperatures[2,9] to suppress formation of dialkoxymethanes (acetalization of formaldehyde). Bromomethyl alkyl ethers, in particular those of lower alcohols, are sensitive to hydrolysis and best yields are therefore obtained when the water formed is efficiently removed from the reaction medium by using water-immiscible solvents such as CH_2Cl_2 or $CHCl_3$ and/or by addition of desiccating agents like $CaCl_2$.[1,2,6] The reaction is quantitative in the case of primary alcohols. Secondary, tertiary, and benzylic alcohols form the corresponding bromides as side products.[1c,2] Formation of toxic bis(bromomethyl)ether (from formaldehyde and HBr) is noted when an excess of formaldehyde with respect to the alcohol is used and/or for secondary, tertiary, or benzylic alcohols.[2] No information is available on the toxicity of bromomethyl alkyl ethers, but it is likely that they are as toxic (carcinogenic) as the corresponding chloromethyl ethers (see ***Formaldehyde-Hydrogen Chloride*** and ***Bis(chloromethyl) Ether***).[7]

Bromomethylation of Aromatic Compounds.

The combination formaldehyde-HBr is, in many cases, a suitable replacement for the more reactive but highly toxic bis(bromomethyl) ether and bromomethyl alkyl ethers in the bromomethylation of aromatic compounds (eq 2).[1,8-10]

(2)

Bromomethylation is less well documented than chloromethylation (see ***Formaldehyde-Hydrogen Chloride***), but recipes for chloromethylation often can be adapted by substituting HBr for HCl.[1a,b,10,11] Among the catalysts employed are mild Lewis acids (***Zinc Chloride***, ***Tin(IV) Chloride***) and protic acids (***Sulfuric Acid***, ***Acetic Acid***), and often HBr by itself suffices.[1,3,6] Typical solvents are water, ether, chloroform, or (glacial) acetic acid. For aqueous systems, addition of a phase-transfer catalyst was found to improve rate and yield of the reaction.[9] Generally, product yields are high.

The source of formaldehyde in the reaction has been the aqueous solution,[1] paraformaldehyde,[1,8] or trioxane.[9] HBr can be introduced as a gas,[1,10] as an aqueous solution,[9] or in acetic acid solution.[8,12] It can also be generated in situ from sodium bromide and mineral acid.[1,13] The reactivity of the bromomethylating species is least in aqueous solvent systems and highest in anhydrous media containing $ZnCl_2$ or H_2SO_4. Benzene can only be bisbromomethylated by the anhydrous reagent.[13] The latter has a reactivity similar to bis(bromomethyl) ether, suggesting a common electrophile

(i.e. the bromomethyl carbenium ion, $^{+}CH_2Br$), whereas in water-containing media the less reactive hydroxymethyl cation ($^{+}CH_2OH$) is the electrophile.[3,4,11] Diarylmethane formation, i.e. condensation of the bromomethylated compound with the original aromatic compound, is the primary side reaction,[1] but this is less prevalent than in chloromethylation and is frequently absent.[8-10] Polycondensation with H_2CO may occur with phenols (Bakelite formation), but this side reaction is suppressed by the presence of electron-withdrawing groups or by esterification of the phenol group.[1a,c]

Bromomethylation is generally applicable to aromatic compounds such as benzene,[1,9] naphthalene (1-position),[10,13a] or anthracene (9,10-positions).[1] The reaction is faster with activated aromatics like alkylbenzenes (toluene,[9,13a] mesitylene,[8,9,12a] *t*-butylbenzene,[14] 1- or 2-methylnaphthalene[9a,10]), phenols (2- or 4-nitrophenol,[15a] 4-alkylphenol,[16b] 2-bromo-4-phenylphenol,[16b] 2-(3-bromo-5-phenylsalicyl)-4-*t*-butylphenol[16b]), alkoxy-[15b] or aryloxybenzenes[12c] (no ether cleavage observed). The reaction is retarded or even completely suppressed (in the case of aqueous media) by electron-withdrawing substituents like F,[14] Cl, Br,[13a] or CH_2Br.[8,9] In case of highly activated aromatics, the reaction is often difficult to stop after the introduction of one CH_2Br group and, for phenols in particular, bis-bromomethylation is observed.[16] For methylbenzenes the degree of bromomethylation can be controlled by adjusting the reaction temperature and/or the amount of reagent (e.g. selective mono-, bis-, or trisbromomethylation of mesitylene) (eq 3).[8,9]

Formaldehyde-Hydrogen Chloride[1]

(CH_2O)

[50-00-0] · CH_2O · Formaldehyde-Hydrogen Chloride · (MW 30.03) (HCl)

[7647-01-0] · ClH · Formaldehyde-Hydrogen Chloride · (MW 36.46)

(chloromethylation of activated aromatics[1] and heteroaromatics,[1b] cyclophanes,[2] aromatic polymers;[1b,3] synthesis of chloromethyl ethers;[4,1a] lactones from phenylacetic acid[5])

Preparative Methods: formaldehyde is usually in the form of formalin or paraformaldehyde. For aromatic chloromethylation, solvents such as glacial acetic acid, CS_2, CCl_4, or chloroform are often employed, although heterogeneous chloromethylations using excess aromatic as solvent are numerous.[1b] A Lewis acid catalyst (often ***Zinc Chloride*** but a range of other Friedel-Crafts type catalysts have been reported), or a protic acid catalyst (usually ***Sulfuric Acid***, conc ***Hydrochloric Acid***, syrupy ***Phosphoric Acid***) is often necessary, especially if electron-withdrawing groups are present on the arene. Typically, a rapid stream of HCl is passed through the formaldehyde-substrate mixture in a suitable medium until no more gas is absorbed.

Handling, Storage, and Precautions: many chloromethylated compounds are lachrymatory. Chloromethyl ethers are carcinogenic. The reagents should be handled in a well-ventilated fume hood.

Chloromethylation Reaction.

Chloromethylation of arenes is a typical electrophilic aromatic substitution (ρ = -5).[1a] Alkylbenzenes like toluene and anisole give mixtures of *ortho*/*para* chloromethylated isomers and the proportion of *meta* always remains low (eq 1).

The reaction is facilitated by alkyl and alkoxy substituents and hindered by electron-withdrawing groups (halo, especially nitro). Increasing steric crowding of the substituent increases the *para* isomer at the expense of the *ortho*.[1a,1b] On the other hand, the proportion of *ortho* increases on going from fluorobenzene to iodobenzene.[1a,1b] Although substrate selectivities (K_T/K_B) are variable, depending on reaction conditions, isomer distributions do not change much.[6]

Bischloromethylated arenes are often observed as byproducts. Diarylmethane formation is a known side reaction in chloromethylation with CH_2O/HCl, especially with reactive arenes.[1] Use of $AsCl_3$ or As_2O_3 as a chloromethylation catalyst apparently inhibits this side reaction.[1a]

Whereas there seems to be general agreement that CH_2O/HCl is a chloromethyl alcohol equivalent, there is difference of opinion as to the exact nature of the chloromethylation electrophile.[1a] Thus $HOCH_2^+$ and CH_2Cl^+ have both been invoked.[1a,6] *O*-Protonated chloromethanol (**1**), which is observable in solution under persistent ion conditions,[7] has been suggested as a possible electrophile. Protonated formaldehyde (**2**) and chloromethylcarbenium ion (**3**) have also been proposed.[1a,6] When acetic acid is used as solvent for chloromethylation, chloromethyl acetate or its protonated form may serve as the actual electrophile.

Bis(chloromethyl)ether (**4**) may be formed in situ in chloromethylation with CH_2O/HCl and it is likely that this could also act as the chloromethylating agent (eq 2). It is believed that (**4**) can become the chloromethylation reagent in reactions involving deactivated aromatics in the presence of protic acids, where its formation and further reaction effectively competes with direct chloromethylation via CH_2O/HCl.[1a] Environmental studies show that, under ambient conditions, (**4**) formation from CH_2O/HCl in moist air is insignificant.[8]

Scope and Limitations.

Alkylbenzenes such as toluene, xylene isomers, tri-, tetra-, and pentamethylbenzenes, ethyl-, isopropyl-, isomeric butyl-, and pentylbenzenes are all chloromethylated with CH_2O/HCl.[1b,1c] For example, mesitylene reacts with CH_2O/HCl (gas) in conc HCl solvent to give a 55-61% isolated yield of α^2-chlorodurene (eq 3).[9]

(3)

Biphenyl, diphenylmethane, indan, and tetralin also react.[1b] Whereas chloromethylations of halobenzenes are less efficient, haloalkylarenes are efficiently chloromethylated with CH_2O/HCl.[1b] The presence of nitro group(s) makes chloromethylation difficult unless activating substituents are present. With nitrobenzene and nitrotoluenes, the *meta* isomer is predominant.[1b] The higher reactivity of chloromethyl methyl ether makes it the reagent of choice for chloromethylation of nitroalkyl- and dihaloalkylbenzenes. In such instances, the reactions are often conducted in 60% H_2SO_4 (eq 4).[10]

(4)

The CH_2O/HCl reagent is suitable for chloromethylation of various polycyclic aromatic hydrocarbons,[1b] as well as heterocyclic aromatic compounds.[1a,1b] Thiophene gives 2-(chloromethyl)thiophene in 40-41% isolated yield,[11] and 4-methylimidazole gives the 5-chloromethyl derivative (51-68%) (eq 5).[12]

(5)

Phenols react readily with CH_2O/HCl but the initially formed product reacts further to give phenol-formaldehyde resin. Only if electron-withdrawing groups are present can the chloromethylation products be isolated.[1b]

Alkyl aryl ketones are chloromethylated at the side chain unless activating groups are present on the aromatic ring. It has been proposed that CH_2OH^+ attacks the enol tautomer.[1a] In the presence of activating groups, aromatic aldehydes and esters are chloromethylated. Otherwise, severe conditions are needed. *p*-Anisaldehyde chloromethylates in 90% yield with the CH_2Cl group entering *meta* to the formyl group (eq 6). Aryl alkyl sulfides and diaryl sulfides are usually ring chloromethylated in good yields.[1b]

(6)

[2.2]Paracyclophane is chloromethylated with the CH_2O/HCl reagent. The presence of an acyl group in one ring assures pseudogeminal substitution by the chloromethyl group (eq 7).[2] This is a useful reaction for the synthesis of superphanes.

(7)

Chloromethylated phenethyl bromide is produced in >70% yield by chloromethylation with $CH_2O/HCl/ZnCl_2$ (75% *para*) and subsequently polymerized to chloromethylated styrene.[13] The patent literature contains numerous examples of chloromethylation of polymers (for example polystyrene, divinylbenzene/styrene copolymer, and polyoxyphenylenes) using the CH_2O/HCl reagent, although there is a larger tendency to use chloromethyl alkyl ethers instead.[4c,14]

Comparison with Other Chloromethylating Agents.

Because of the limitations that exist in chloromethylation of deactivated arenes, the more reactive ***Chloromethyl Methyl Ether*** and ***Bis(chloromethyl) Ether*** appear more suitable. However, these are carcinogenic and alternative routes have been sought.

Methoxyacetyl Chloride/Aluminum Chloride is suitable for chloromethylation of certain aromatics.[15] The methoxymethyl cation has been suggested as the electrophile (eq 8).

The less volatile long-chain halomethyl alkyl ethers prepared from alkanols and CH_2O/HCl in chlorinated solvents have been used successfully for the chloromethylation of arenes and polystyrene.[4c] The amount of (**4**) produced is quite low and depends on the ROH:CH_2O ratio.

1-Chloro-4-(chloromethoxy)butane and 1,4-bis(chloromethoxy)butane in combination with ***Tin(IV) Chloride*** or ***Zinc Bromide*** can be used for arene chloromethylation. Literature examples are limited to alkylbenzenes.[6,15] Yields are 43-60%, depending on the arene (eq 9).

Synthesis of Chloromethyl Ethers.

Chloromethyl methyl ether can be prepared from MeOH/CH_2O/HCl in 86-89% isolated yield.[4a] The corresponding benzyl ether was obtained from $PhCH_2OH$ in 83% yield.[4b] Controlled addition of CH_2O to anhydrous MeOH or methylal saturated with HCl gas gives $ClCH_2OMe$ with little (**4**).[16]

Other Useful Reactions.

3,4-Dimethoxyphenylacetic acid reacts with CH_2O/HCl to give the corresponding lactone (eq 10).[5] Variations of this procedure are applicable to multi-ring compounds.[17] *sym*-Trithiane is formed by reaction of H_2S with CH_2O/conc HCl.[18] Long-chain thiols are chloromethylated with CH_2O/HCl to give $RSCH_2Cl$.[19]

Formaldoxime

[75-17-2] · CH_3NO · Formaldoxime · (MW 45.05)

(formylation of arenes via diazonium salts;[1,2] 1,3-dipolar cycloaddition with electron-deficient alkenes and alkynes to form isoxazolidines[3])

Alternate Name: formaldehyde oxime.

Physical Data: mp 2.5 °C; bp 84 °C.

Solubility: frequently used in aqueous solution or in admixture with aqueous methanolic solution.

Form Supplied in: commercially available as hydrochloride.

Preparative Methods: reaction of 37% aqueous formaldehyde with hydroxylamine hydrochloride to which sodium hydroxide in 30% aqueous methanol is added (eq 1).[3-5] This procedure affords useful solutions of formaldoxime in aqueous methanol.[3] Alternatively, paraformaldehyde with hydroxylamine hydrochloride in the presence of sodium acetate in aqueous medium produces a 10% solution of formaldoxime.[2]

Handling, Storage, and Precautions: stable as hydrochloride; the oxime readily polymerizes at room temperature and is more stable in aqueous solution. Handle in a fume hood.

In the older literature, the trimer of formaldoxime is often reported, although this form was an open-chain polymer.[6] In contrast, *O*-acetyl and *O*-benzoyl derivatives of formaldoxime are cyclic trimeric compounds, i.e. derivatives of 1,3,5-trihydroxyhexahydro-1,3,5-triazine.[6] The hydrochloride $(CH_2NOH)_3$.HCl and other salts also exist as the cyclic trimer. They depolymerize into monomeric formaldoxime by neutralization. The cyclic trimer, which can be isolated, is water soluble and rearranges fast into the water-insoluble polymer. ^{1}H NMR spectra (D_2O) demonstrate equilibration

between the monomer and the trimer. At high pH, this equilibrium is completely shifted to the monomeric form.[6] The ^{13}C NMR chemical shift and ^{13}C-^{15}N coupling constant have been reported.[7]

Formylation of Arenes via Diazonium Salts.

Formaldoxime reacts with aromatic diazonium salts to give the corresponding substituted benzaldehyde oxime derivative, which is hydrolyzed in acid medium to afford aromatic aldehydes (eqs 2 and 3).[1,2] The net reaction constitutes the conversion of anilines into aryl aldehydes (eq 4).[3,8-12]

(2)

(3)

(4)

1,3-Dipolar Cycloaddition with α,β-Unsaturated Nitriles and Acrylates.

Formaldoxime acts as a 1,3-dipole in cycloaddition reactions with acrylonitrile (eq 5) and methyl acrylate (eq 6), affording functionalized isoxazolidines.[3] In both cases, the 1,3-cycloadduct is partially converted into the Michael adduct of the isoxazolidine with the α,β-unsaturated nitrile or acrylate. In contrast, acetaldoxime reacts with the same electron-deficient alkenes to give mixtures of regioisomeric isoxazolidines.[13]

(5)

(6)

Cycloaddition with Propiolates.

The reaction of formaldoxime with ethyl propiolate (see ***Methyl Propiolate***) in 50% aqueous methanol leads to diethyl pyridine-3,5-dicarboxylate, during which a 1,4-dipolar cycloaddition mechanism is operative (eq 7).[3]

(7)

Additions of Carbanions Across the Carbon-Nitrogen Double Bond.

Formaldoxime undergoes addition of fluorodinitromethane in a biphase system of water-diethyl ether in the presence of sodium carbonate to afford 2-fluoro-2,2-dinitroethylhydroxylamine in moderate yield (eq 8).[14]

(8)

Related Reagents.

Acetaldoxime; ***Benzenediazonium Chloride***; ***Benzenediazonium Tetrafluoroborate***; ***Formaldehyde***; ***Hydroxylamine***; ***Methyl Propiolate***.

Formamidine Acetate

[40730-94-7] · $C_3H_8N_2O_2$ · Formamidine Acetate · (MW 104.13)

(condensing agent for the synthesis of pyrimidine[1] and imidazole[2] heterocycles)

Alternate Name: FA.

Physical Data: mp 162-164 °C.

Solubility: sol H_2O, hot alcohol.

Form Supplied in: white crystalline solid, widely available.

Handling, Storage, and Precautions: is nonhygroscopic and is stable on storage.

Synthesis of Pyrimidine Heterocycles.

The pyrimidine ring can be conveniently constructed by the reaction of unsaturated 2-aminonitriles (*o*-aminonitriles) with FA, as exemplified by the synthesis of 4-aminopyrimido[4,5-*d*]pyrimidine (eq 1)[2a] and 7-amino-2-(phenylamino)thiazolo[5,4-*d*]pyrimidine (eq 2).[3] 4-Amino-8-methyl-1,2,3-triazolo[1,5-*a*]-1,3,5-triazine is obtained from the reaction of 5-amino-4-cyano-4-methyl-4*H*-1,2,3-triazole with FA by translocative rearrangement (eq 3).[4] FA has also been widely used for the formation of fused pyrimidines in the synthesis of *C*-nucleosides (eqs 4 and 5).[5]

(5)

Pyrimidones are obtained by the reaction of FA with 5,8-dihydroisatoic anhydride (eq 6)[6] or with *o*-amino esters (eq 7).[7] No aromatization or conjugation of double bonds in the product is observed in the former case (eq 6).

(6)

(7)

A dihydropyrimidine is obtained by the reaction of FA with mesityl oxide (eq 8).[8]

(8)

Synthesis of Imidazole Heterocycles.

FA has been used as a reagent providing a one-carbon fragment in the synthesis of a wide variety of imidazole derivatives.[2] The reaction conditions are often mild, and therefore it is the reagent of choice in the Traube synthesis of 9-glycosylpurines (eq 9).[9] Imidazoles have also been synthesized by the reaction of FA with α-chloro ketones (eq 10)[2e] and α-hydroxy ketones (eq 11).[10]

(9)

(10)

(11)

The trifluoromethyl group, which is usually inert in most reactions, can change the outcome of the condensation of FA with α-halo ketones if it is located at an α-position to the ketone group. For example, the reaction of FA with α-chloro-β-trifluoromethyl ketones gives 4-substituted imidazoles (eq 12). However, α-chloro-α´-trifluoromethyl ketones afford 5´-substituted 4-fluoro-6-chloromethylpyrimidines (eq 13).[11]

(12)

(13)

Similarly, the structure of the product obtained from the reaction of FA with azirines is highly dependent upon the substitution of the azirine ring (eq 14).[12]

(14)

Advantages of Formamidine Acetate over Formamidine Hydrochloride.

It has been found that formamidine acetate could replace formamidine hydrochloride in syntheses previously reported using the latter. FA is nonhygroscopic and is stable on storage. FA, as the salt of a strong base and a weak acid, could often be used in most condensations without prior liberation of free formamidine. By contrast, formamidine hydrochloride is extremely deliquescent and cannot be used in most condensations but must be converted into the free base. The same restriction applies to the hydrogen methyl sulfate salt of formamidine; in addition, complications in synthesis may be anticipated from the fact that methyl hydrogen sulfate itself is an effective methylating agent.[2a]

Formic Acid[1]

HCO_2H

[64-18-6] · CH_2O_2 · Formic Acid · (MW 46.03)

(formation of formate esters,[3] amides;[7] reductions;[10] transfer hydrogenation;[12] rearrangements[22])

Alternate Name: methanoic acid.

Physical Data: strongest of the simple organic acids; pK_a 3.77 (4.77 for acetic acid). Pure acid, mp 8.4 °C; bp 100.7 °C, 50 °C/120 mmHg, 25 °C/40 mmHg. Formic acid and water form an uncommon maximum boiling azeotrope, bp 107.3 °C, containing 77.5% acid. The dielectric constant of formic acid is 10 times greater than acetic acid.

Solubility: misc water in all proportions; misc EtOH, ether; mod sol C_6H_6.

Form Supplied in: commercially available as 85-95% aqueous solutions and as glacial formic acid, containing 2% water.

Analysis of Reagent Purity: formic acid is determined by titration with base. If other acids are present, formic acid content can be determined by a redox titration based on oxidation with potassium permanganate. Methods for analysis of trace organic and inorganic materials are presented.[2,23]

Purification: fractional distillation in vacuo; dehydration over $CuSO_4$ or boric anhydride.[24]

Handling, Storage, and Precautions: the strongly acidic nature of formic acid is the primary safety concern. Contact with the skin will cause immediate blistering. Immediately treat affected areas with copious amounts of water. Do not use dilute base solutions as a first treatment. Formic acid has a large heat of solution; the combined heat of neutralization and dilution will lead to thermal burns. Eye protection, gloves, and a chemical apron should be worn during all operations with concentrated formic acid. Volatile; vapors will cause intense irritation to mouth, nose, eyes, skin, and upper respiratory tract. Use of an appropriate NIOSH/MSHA respirator is recommended. Use in a fume hood.

During storage, glacial formic acid decomposes to form water and carbon monoxide. Pressure can develop in sealed containers and may result in rupture of the vessel. Ventilation should be provided to prevent the buildup of carbon monoxide in storage areas. Storage temperatures above 30 °C should be avoided.

Formic acid is incompatible with strong oxidizing reagents, bases, and finely powdered metals, furfuryl alcohol, and thallium nitrate. Contact with conc sulfuric acid will produce carbon monoxide from decomposition.

Formation of Formate Esters.

Formic acid will esterify primary, secondary, and tertiary alcohols in high yield (eq 1).[3] The reaction is autocatalytic due to the high acidity of formic acid. The equilibrium position of this reaction is closer to completion than for other carboxylic acids.

(1)

Formate esters can also be produced during acid-catalyzed rearrangements (eq 2),[4] by addition to alkenes (eq 3),[5] or by ***1,3-Dicyclohexylcarbodiimide*** coupling (eq 4).[6]

(2)

(3)

(4)

Formation of Amides.

Most amines react with formic acid to produce the expected amide in high yield.[7] Reaction with diamines is an important reaction for the formation of heterocyclic compounds, including benzimidazoles (eq 5)[8] and triazoles (eq 6).[9]

(5)

(6)

Reductions with Formic Acid.

Formic acid is unique among the simple organic acids in its ability to react as a reducing agent. Ketones are reduced and converted to primary amines by reaction with ammonia and formic acid (see ***Ammonium Formate***) (eq 7).[10] Ketones or aldehydes will react with formic acid and primary or secondary amines to produce secondary or tertiary amines (eq 8).[10a,11]

Catalytic Transfer Hydrogenation.[12]

Catalytic transfer hydrogenation uses a metal catalyst and an organic hydrogen donor as a stoichiometric reducing agent. This is a useful laboratory alternative to normal catalytic reduction, as the use of flammable hydrogen gas is avoided. Formic acid and amine formates are common hydrogen donors. Formic acid has been used to reduce α,β-unsaturated aldehydes and acids[13] to the saturated compounds (eq 9). Benzyl ethers (eq 10)[14] and benzyl amines (eq 11)[15] are cleaved by transfer hydrogenation with formic acid. A variety of nitrogen functions are reduced including the nitro group,[16] azo group,[17] hydrazines,[18] and enamines.[19] The resulting amines will be formylated under the reaction conditions; use of water or alcohol as solvent will limit formylation. If the reduction results in a suitable diamine, formylation will lead to heterocycle formation (eq 12).[16a] Aromatic halides are reduced to the aromatic hydrocarbon.[20] See also ***Palladium-Triethylamine-Formic Acid***.

(10)

(11)

(12)

The Rupe Rearrangement.

Tertiary propargyl alcohols isomerize to α,β-unsaturated ketones in the Rupe rearrangement (eq 13).[21] The reaction has been reviewed.[22] Formic acid is the most common catalyst employed.

(13)

Formyl Chloride

[2565-30-2] · CHClO · Formyl Chloride · (MW 64.47)

(Gatterman-Koch aldehyde synthesis;[1] conversion of alcohols to formate esters[2])

Physical Data: unstable at room temperature.

Preparative Methods: prepared by chlorination of ***Formic Acid*** at -78 °C[3] and by introduction of dry ***Hydrogen Chloride*** at -60 °C to a solution of ***N-Formylimidazole*** in chloroform.[4]

The procedure described by Gatterman and Koch[1] for the preparation of *p*-tolualdehyde calls for stirring a suspension of ***Copper(I) Chloride*** and ***Aluminum Chloride*** in toluene and passing in ***Carbon Monoxide*** and ***Hydrochloric Acid*** and hydrolyzing the resulting complex with ice. Formyl chloride was regarded as the transient intermediate (eq 1).

(1)

Treatment of 4-(1-hydroxyethyl)-3,7,7-trimethylbicyclo[4.1.0]hept-3-ene and its position isomers with ***Formic Acid*** and ***Thionyl Chloride*** gave in 65% yield the three double bond isomers of 4-(1-formyloxyethyl)-3,7,7-trimethylbicyclo[4.1.0]hept-3-ene (eq 2).[2]

(2)

Related Reagents.

Formyl Fluoride.

Formyl Fluoride[1]

[1493-02-3] · CHFO · Formyl Fluoride · (MW 48.02)

(formylating agent for organic compounds[1])

Physical Data: bp -29 °C; mp -142 °C.

Preparative Methods: HCOF, one of the stable halides of formic acid, is generally prepared by combining ***Formic Acid*** with a fluorinating agent.[1] A variety of reagents such as ***Benzoyl Chloride***/***Potassium Fluoride***,[2] benzoyl fluoride,[3] benzoyl chloride/KHF_2,[4] cyanuric fluoride,[5] and tetramethyl-α-fluoroenamine[6] has been employed for this purpose. HCOF was also successfully prepared by reaction of ***Acetic Formic Anhydride*** with ***Hydrogen Fluoride*** at atmospheric pressure with continuous removal of formyl fluoride.[7] Combining benzoyl fluoride with sodium formate is another worthy procedure for its preparation.[5] Ozonolysis of 1,2-difluoroethylene and vinyl fluoride offers a potential new route to HCOF.[8] The best result among all the methods was achieved by fluorinating formic acid with tetramethyl-α-fluoroenamine.[6] A 100% yield was reported.

Handling, Storage, and Precautions: decomposes rapidly at room temperature into CO and HF.[1b] The reaction is autocatalytic since the HF formed initially catalyzes the decarbonylation. Therefore, acid-free HCOF should be stored at low temperature (of the order of -70 °C) under pressure over anhydrous sodium fluoride, which is able to absorb the hydrogen fluoride formed in decomposition. Use in a fume hood.

Formylation.

Formyl fluoride is used for Friedel-Crafts type formylation of arenes (eq 1). The best catalyst found for the reaction is ***Boron Trifluoride***.[3]

(1)

Formyl fluoride and BF_3 form a complex at low temperature, which has been isolated and characterized.[1b] ***Boron Trichloride*** and ***Boron Tribromide*** are also effective for the reaction; however, ***Aluminum Chloride*** and ***Aluminum Bromide*** were found to catalyze the decomposition of HCOF, giving lower yields of formylation products. If the aromatic substances are reactive and have a low freezing point, the reaction can be carried out by dissolving the HCOF neat in an excess of the cold arenes followed by saturation of the mixture with BF_3. When aromatic substrates are not sufficiently active to be formylated at low temperatures or have high freezing points, a solvent should be used. Solvents such as carbon disulfide or nitroalkanes are preferable for the reaction. The best results for such cases were obtained by passing HCOF and BF_3 gases simultaneously into the arenes at room temperature or higher. It is necessary to mention that HF and BF_3 should be removed from the reaction mixture as soon as the reaction is complete, since undesirable condensation reaction can occur with the aldehyde formed, which would decrease the yields.

Alkenes react in the presence of BF_3 with HCOF to give a β-fluoroaldehyde (eq 2).[1b] However, further reaction of the secondary C-F bond with BF_3 makes the isolation of pure products difficult.

(2)

Formyl fluoride is also found to react with alcohols and phenols in the presence of a base (such as ***Triethylamine***) to form the corresponding formates (eq 3).[4] Primary and secondary aliphatic alcohols are formylated in 73-92% yield, while benzyl alcohols and phenol give 69% and 75% yields, respectively. Formyl fluoride reacts with carboxylic acid salts to yield the corresponding mixed carboxylic formic anhydrides (eq 4). Even the elusive formic anhydride can be prepared by the reaction at -78 °C. Oximes have also been formylated by HCOF.[9] This reaction has been employed to prepare 3-phenylethynyl-1,2,4-oxadiazole (eq 5).

(3)

(4)

(5)

Reaction between HCOF and thiols yields thioformates in good yields (eq 6).[4]

(6)

Formylation of amines can also be achieved.[1a] A large variety of primary and secondary amines react with HCOF to give *N*-alkylformamides in good to excellent yields (eq 7). However, reaction between tertiary amines and HCOF leads to elimination of carbon monoxide and formation of the amine hydrofluorides.

(7)

Related Reagents.

Acetic Formic Anhydride; ***Methyl Formate***.

N-Formylimidazole

[3197-61-3] · $C_4H_4N_2O$ · *N*-Formylimidazole · (MW 96.10)

(active agent for formylation[1])

Alternate Name: 1*H*-imidazole-1-carbaldehyde.

Physical Data: mp 53-55 °C; dec 60 °C.[2]

Solubility: sol THF, acetone, chloroform; partially sol CCl_4, diethyl ether.

Preparative Method: a solution of 1.5 g (32 mmol) formic acid (98-100%) in 50 mL dry THF is added over a period of 15 min to a vigorously stirred suspension of 5.0 g (31 mmol) ***N,N´-Carbonyldiimidazole***[3] in 80 mL dry THF at rt. *N,N*-Carbonyldiimidazole dissolves rapidly and CO_2 is evolved. After 1 h the solvent is evaporated and the product is sublimed directly from the mixture, 35-40 °C/0.2 mmHg, to give 2.53 g (85%) of *N*-formylimidazole.[2]

Handling, Storage, and Precautions: like *N,N*-carbonyldiimidazole, *N*-formylimidazole is very sensitive to water. It should be kept sealed under an inert atmosphere.

Imidazole Reagents.

Like other derivatives of *N*-carbonyldiimidazole, *N*-formylimidazole is an activated form of formic acid, which can be used as a reactive intermediate in the synthesis of esters, amides, and isocyanides and for the formylation of Wittig reagents.[1] The high reactivity of carboxyimidazoles is due to the aromaticity of the imidazole ring. This exerts an electron-withdrawing effect on the exocyclic carbonyl bond, increasing the rate of nucleophilic attack at the carbonyl carbon. In most cases the freshly prepared reagent is used directly, without isolation. Good yields of products are usually obtained. *N,N*-Carbonyldiimidazole reacts with an equimolar amount of formic acid in THF or chloroform within a few minutes at rt to form *N*-formylimidazole (eq 1).

(1)

Reaction of this intermediate with a nucleophile leads directly to the desired product. One equivalent of alcohol in the presence of a catalytic amount of alcoholate (formed by addition of a base like ***Sodium Amide***[4] or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***[5]) yields the ester under mild conditions. Even sterically hindered alcohols like *t*-butanol react readily at rt (eq 1).[2] Under similar conditions, thioesters,[6] selenoesters,[6] and amides[2,7,8] can also be obtained. Triphenylphosphine-alkylidenes are readily *C*-acylated using 0.5 equiv of *N*-formylimidazole at rt in benzene or benzene/THF to give α-formyl derivatives.[9] Wittig reaction of these triphenylphosphine-α-formylalkylidenes leads to α,β-unsaturated aldehydes[10] (eq 2) or, after hydrolysis, to the aldehydes RCH_2CHO.

(2)

A simple synthesis of isoflavones with yields ranging from 60 to 76% was reported by Krishnamurty (eq 3). This involves the reaction between an *O*-hydroxydeoxybenzoin and *N*-formylimidazole whereby *C*-formylation at the benzylic position is followed by cyclization to the corresponding isoflavone.[11]

In the synthesis of substituted benz[*cd*]indoles (eq 4), *N*-formylimidazole was used to transform an amino group into an isocyanide group after dehydration of the resulting formamide with ***Phosgene***/***Triethylamine***.[12,13]

In organometallic chemistry, *N*-formylimidazole can act as a formylating reagent to produce formyl transition metal complexes. These can react with compounds of the type $Na_2M(CO)_4$ (M = Fe, Ru, Os) in THF or HMPA in the presence of a Lewis acid such as ***Trimethyl Borate*** to produce a mixture of $NaM(CO)_4CHO$ (e.g. sodium tetracarbonylformylferrate, sodium tetracarbonylformylruthenate, sodium tetracarbonylformylosmate) and $NaM(CO)_4H$. $NaM(CO)_4CRO$ is the product formed from the reaction with alkyl- and phenyl-*N*-acylimidazoles.[14]

Formylmethylenetriphenylphosphorane[1]

Ph_3P=CHCHO

[2136-75-6] · $C_{20}H_{17}OP$ · Formylmethylenetriphenylphosphorane · (MW 304.33)

(stabilized Wittig reagent used for the synthesis of α,β-unsaturated aldehydes from aldehydes; reagent for two-carbon chain homologation)

Alternate Name: (triphenylphosphoranylidene)acetaldehyde.

Physical Data: mp 187-188 °C (dec).

Form Supplied in: white solid, 97%; commercially available.

Preparative Methods: reaction of ***Chloroacetaldehyde*** and ***Triphenylphosphine*** affords formylmethyltriphenylphosphonium chloride, which furnishes the phosphorane reagent on treatment with ***Triethylamine*** in ethanol.[2]

Handling, Storage, and Precautions: unstable to moisture and acids. Keep dry.

(*E*)-α,β-Unsaturated Aldehydes.

This stabilized phosphonium ylide reacts with a wide variety of aliphatic and aromatic aldehydes to give α,β-unsaturated aldehydes, with a high predominance of the (*E*)-alkene.[2-5] This reagent has been applied in many areas of organic synthesis including natural products, carbohydrates, and heterocycles. Thus in the synthesis of swainsonine from D-mannose the chain-extended (*E*)-alkene (**2**) was prepared from the aldehyde (**1**) in good yield (eq 1).[6]

(1)

Tandem addition of the ylide has been successfully applied to the synthesis of (*E*,*E*)-dienyl aldehydes. For example, in the synthesis of natural leukotrienes, Rokach et al. converted epoxy aldehyde (**3**) to intermediate (**4**) en route to LTA_4 (eq 2).[7]

Reaction of the ylide with ketones is generally unsuccessful;[2] however, it has been reported to react with trifluoroacetone to give the expected trisubstituted alkene in low yield (eq 3).[8]

Alkenation with this ylide can be effected in good yield when a free hydroxyl group is present in the aldehyde substrate,[9,10] although a neighboring hydroxyl appears to detract from the normally high (*E*) stereoselectivity (eq 4).[10]

(*Z*)-α,β-Unsaturated Aldehydes.

In a complementary manner, Bestmann's group has shown that conversion of this ylide to a diethyl acetal in situ affords a new phosphorane that transforms aldehydes into α,β-unsaturated aldehydes with predominantly (*Z*) stereochemistry (86-97%).[11,12] The procedure involves treatment of the ylide with EtBr, followed by NaOEt, then addition of the aldehyde; the intermediate unsaturated diethyl acetals are hydrolyzed to obtain α,β-unsaturated aldehydes (eq 5). Higher yields of unsaturated diethyl acetals were usually realized by an alternative reaction sequence that employed a different base system: 1) EtBr; 2) sodium amide; and 3) ethanol.

N-Formylpiperidine

[2591-86-8] · $C_6H_{11}NO$ · *N*-Formylpiperidine · (MW 113.18)

(formylating agent for certain organometallics;[1] reacts with sulfur tetrafluoride/KF to give *N*-trifluoromethylpiperidine;[2] easily converted to reactive chloromethyleneiminium ions[3])

Physical Data: bp 222 °C; *d* 1.09 g cm^{-3}.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: IR, NMR.

Handling, Storage, and Precautions: toxic; irritant.

N-Formylpiperidine (**1**) is a good formylating agent for certain organometallics. Carbaldehydes can be obtained by reacting (**1**) with organolithium or Grignard reagents (eq 1).[1]

$$\mathrm{RM} \xrightarrow[72\text{-}96\%]{\textbf{(1)}} \mathrm{RCHO} \qquad (1)$$

$$\mathrm{M = MgX\ or\ Li;\ R = alkyl\ or\ aryl}$$

N-Trifluoromethylpiperidine will result on reaction of (**1**) with ***Sulfur Tetrafluoride*** and ***Potassium Fluoride*** (eq 2).[2]

(2)

Chloromethyleneiminium ions with different counterions can be easily prepared from (**1**).[3] The chloromethyleneiminium ion generated from (**1**) reacts with thioamides to give various products depending on the reaction conditions (eqs 3-5).[4,5] *N,N*-Disubstituted thioamides undergo condensation to give thioenamides (**2**) (eq 3).[4] Under similar reaction conditions, primary thioamides yield either the nitrile (**3**) (eq 4) or the salt (**4**) (eq 5).[5]

Furan[1]

[110-00-9] · C_4H_4O · Furan · (MW 68.08)

(versatile four-carbon synthon;[1] aromatic heterocycle which exhibits reactivity towards various electrophiles[2] and electrophilic carbon radicals;[3] 2-monolithio[4a] or 2,5-dimetalated furan derivatives can be readily generated and transmetalated;[4] ene employed for [2 + 2] photochemical[1d,5] and [2 + 3] dipolar cycloadditions;[6] diene widely used for [4 + 2] Diels-Alder[1e] and [4 + 3] dipolar cycloadditions;[7] can be oxidized by a number of reagents such as singlet oxygen[8])

Physical Data: mp -85.6 °C; bp 31.4 °C; fp -35 °C; *n*20D 1.421;[9c] *d*204 0.9514 g cm^{-3}.[9a,b]

Solubility: sol ethanol, ether, benzene, acetone; slightly sol chloroform; insol water.[9a]

Form Supplied in: commercially available as a water-white liquid in >99% purity (GC); usually a trace of 2,6-di-*t*-butyl-*p*-cresol (BHT) added as an inhibitor of oxidation.

Purification: shaken with aq 5% KOH, dried with $CaSO_4$ or Na_2SO_4, then distilled under nitrogen, from KOH or sodium, immediately before use.[10]

Analysis of Reagent Purity: GC; IR (neat) 1592, 1485, 1380, 1172, 1061, 869, 744, 601 cm^{-1};[11a] ^1H NMR ($CDCl_3$) δ 6.39 (2H), 7.44 (2H);[11b,c] ^{13}C NMR ($CDCl_3$) δ 109.7, 142.8.[11d]

Handling, Storage, and Precautions: on EPA Extremely Hazardous Substances List; reported in EPA TSCA Inventory.[12] The vapors are anesthetic; can be absorbed through skin.[12] Use in a fume hood.

Electrophilic Substitution Reactions.

Synthesis of 2-Halo-, Acyl-, Cyano-, Sulfonyl-, and Carbonyloxyfurans.

Furan is an electron-rich, aromatic heterocycle which readily undergoes electrophilic substitution reactions with a wide range of electrophiles. Therefore furan serves as a convenient starting material for the preparation of various

substituted furans, including halo, acyl/formyl, cyano, and other heteroatom substituted furans.[1] The C-2 position is generally more susceptible than C-3 towards electrophiles, presumably due to the extended conjugation of the intermediate cation generated by the addition of an electrophile at the former. However, the ratio of the C-2/C-3 products appears to be highly dependent upon the type of electrophile and the reaction conditions. For example, acylation of furan with ***Acetic Anhydride*** and ***Tin(IV) Chloride*** in dichloromethane gives C-2/C-3 products in ratios of 6800 and 800 at 25 and 75 °C, respectively. However, the reaction with acetyl trifluoroacetate at 75 °C results in a C-2/C-3 product ratio of 6000.[13] The acetylation can also be achieved cleanly at the C-2 position in excellent yield with ***Acetyl p-Toluenesulfonate***.[14] Other electrophilic substitution reactions of furan at the C-2 position include: bromination (Br_2, DMF) (eq 1),[15] cyanation ($OCNSO_2Cl$, DMF),[16] Vilsmeier formylation (Me_2NCHO, $POCl_3$),[17] sulfonation (SO_3.py),[18] and carbonylation ($PdCl_2$,Hg^{2+}, Cu^{2+}/CO/ROH).[19]

(1)

Synthesis of Alkylfurans.

Alkyl-substituted furans can be prepared by electrophilic substitution reactions of furan. For example, furan undergoes the Mannich reaction with aminals, α-amino ethers, and bis(alkoxymethyl)alkylamines under Lewis acid catalysis to give 2-(*N*,*N*-dialkylamino)methyl derivatives of furan (eq 2).[20] Furan can also add to the β-carbon of enones in the presence of ***Iodotrimethylsilane*** (eq 3).[21] In addition, Ag^+ has been reported to induce allylation of furan with 1,3-bis(phenylseleno)propene (eq 4)[22a] or cyclopropyl halides (eq 5).[22b] It should be noted that this Ag^+-catalyzed allylation of furan, illustrated in eq 4, has been shown to proceed with high stereoselectivity where the configuration of the stereochemically pure (*Z*)- or (*E*)-allylating agent is retained in the product.[22a] An arenecarbonylmolybdenum has been employed as a catalyst for the *t*-butylation of furan at C-2.[23]

(2)

(3)

(4)

(5)

Radical-Mediated Substitution Reactions.

Furan undergoes substitution reactions with electrophilic carbon radicals to provide 2-alkyl substituted furans (eq 6).[3] These radicals are generated from dialkyl malonates with Ce^{4+},[3] triethyl methanetricarboxylate with Mn^{3+},[24a] Fe^{2+}/H_2O_2 in DMSO,[24b] or ethyl iodoacetate with triethylborane.[24c]

(6)

Cross-Coupling Reactions.

Two major types of cross-coupling reactions have been reported in conjunction with the synthesis of arylated furans. Thus the photochemical coupling of furan with 2-bromo- or -iodo- (eq 7)[25a] or 4-iodopyridine[25b] produces the corresponding coupled products in moderate yield. Other five-membered heterocycles such as thiophenes and pyrroles also undergo similar reactions.[25] Interestingly, the direct aryl coupling reaction of furan can also be achieved in the presence of a Pd^0 catalyst with aryl bromides bearing an electron-withdrawing group (moderate yield) or 1-naphthyl

bromide (low yield) at elevated temperatures (eq 8).[26a] It is noteworthy that although similar Pd^0-catalyzed cross-coupling reactions with a wide variety of aromatic, benzyl, and cinnamyl bromides can be effected using 2-lithio- or 2-furylzinc chloride in generally higher yield,[26b] these require prior generation of the organometallic reagent. While the use of the ***Palladium(II) Acetate-Copper(II) Acetate*** catalyst system results in facile alkenylation reactions of furan at the α-position with methyl acrylate and acrylonitrile, the yields of the reactions are generally low with frequent complication due to the formation of the 2,5-dialkenylated products.[27] However, if the $Pd(OCOPh)_2$-catalyzed reaction of furan with ethyl acrylate is carried out in the presence of *t*-butyl perbenzoate (postulated to act as a hydrogen acceptor), ethyl 3-(2-furyl)acrylate is obtained in 53% yield with virtually no formation of the dialkenylated product.[28]

(8)

Organometallic Compounds.

Lithiated furans are presumably one of the most widely employed organometallic species in synthesis.[4a] Furan can be readily monolithiated at C-2 with ***n-Butyllithium*** and it can be dimetalated at C-2 and 5 either by careful control of reaction conditions using *n*-BuLi (to 2,5-dilithiofuran)[4b] or with the use of the Schlosser-Lochmann reagent (*n*-BuLi/BuOK)[29] (presumably to 2,5-dipotassiofuran) (eq 9).[4c] These metalated furans can react with a variety of electrophiles[4a] including TMSCl,[4a] CO_2,[4a] epoxides,[4a] ketones,[4a,30a] and aldehydes.[4a,30b] Additionally, 2-lithiofuran can also be readily transmetalated to the corresponding organometallic species such as organoboron ate complexes,[31a] lithium 2-furyltellurolate,[31b] and di(2-furyl)zinc (eq 10).[31c] Possibly the most useful of such C-2 organometallic furan species may be the higher-order cuprates, which can effectively undergo conjugate addition reactions at low temperatures onto enones (eq 11), as well as additions to epoxides and aldehydes, all under Lewis acid catalysis.[32]

Cycloaddition Reactions.

Furan is known to undergo various types of cycloaddition reactions. It functions as an ene and participates in [2 + 2] and [2 + 3] cycloadditions under photochemical and thermal conditions, respectively. With an embedded cyclic conjugated diene system in it, furan also functions as a diene that undergoes various [4 + 2] and [4 + 3] cycloaddition reactions.[1]

(10)

* (1*S*,2*R*)-(-)-*N*,*N*-dibutylnorephedrine

(11)

enone:cuprate equivalent:Lewis acid = 1:1.1:1.1

[2 + 2] Cycloaddition Reactions as an Ene.

It has been well established[5] that carbonyl compounds can be added to furan in a highly regioselective [2 + 2] fashion under photochemical conditions, providing relatively unstable 2,7-dioxabicyclo[3.2.0]hept-3-ene compounds (eq 12).[5c] These bicyclic oxetanes can be isomerized smoothly by acid treatment to 3-substituted furans (eq 12).[5c]

(12)

[2 + 3] Cycloaddition Reactions as an Ene.

Furan undergoes [2 + 3] cycloaddition reactions upon exposure to nitrile oxides generated in situ under high dilution conditions, giving rise to dipolar cycloaddition products in moderate yield (eq 13).[6] These regioselectively produced adducts have been employed in the synthesis of a number of amino-polyols including nojirimycin.[6a]

(13)

[4 + 2] Cycloaddition Reactions as a Diene.

The use of furan as a diene in intermolecular Diels-Alder reactions represents one of the most common applications of furan in synthesis, providing a highly versatile means for new C-C bond formation and for further synthetic manipulations.[1d,e] However, often these Diels-Alder reactions involving furan as a diene are sluggish, presumably due to its aromatic nature. Some otherwise difficult furan Diels-Alder reactions have been reported to be mediated by high pressure.[33] The initial report on the acceleration of furan Diels-Alder reactions with the use of catalytic quantities of the Lewis acid ***Zinc Iodide***[34] has been followed by similar observations of rate acceleration by a number of other

catalysts. These include $BF_3.OEt_2$,[35a] $Cu(MeCN)_4(BF_4)$,[35b] $Cy_3Sn(MeCN)_2SbF_6^-$,[35c] chromatography adsorbents,[35d] and K-10 bentonite clay doped with Fe^{3+} or $AlCl_3$.[35e] There is even a report describing observed acceleration of a Diels-Alder reaction between furan and maleic anhydride when the reaction is performed in an ultracentrifuge.[35f]

(14)

Furan has been shown to undergo Diels-Alder reactions with activated allenic compounds[36] with high regio- and stereoselectivity (eq 14).[36e] In addition, the Diels-Alder reactions with certain acetylenic compounds are also known.[37] Trapping of highly reactive arynes,[38] Dewar furans,[39] and strained bridgehead alkenes[40] with furan in a [4 + 2] Diels-Alder fashion is well documented. Particularly, reactions of furan with a variety of in situ-generated arynes followed by the aromatization of the 1,4-endoxide rings of the resulting cycloadducts constitute a well-established method for the synthesis of polyarenes (eqs 15 and 16).[38]

(15)

(16)

Asymmetric Diels-Alder reactions of furan with dienophiles have been developed for the synthesis of optically active 7-oxabicyclo[2.2.1]hept-5-ene derivatives, key intermediates for the synthesis of physiologically significant natural products. Diastereoselectivity is achieved with the use of a chiral oxazaborolidine as the catalyst (eq 17)[41a] or optically

active dienophiles[41b,c] (eq 18).[41b]

(17)

initial total yield = 58-60% with A/D:B/C = 65:35
D obtained in 29% yield in 98% purity after three recrystallizations

[4 + 3] Cycloaddition Reactions as a Diene.

Furan reacts with dipolar species generated from 2-oxyallyl cations generated from α,α´-polybromo ketones[7,42] or α,α-dialkoxy ketones (via their α´-enol TMS ethers)[43] to form 8-oxabicyclo[3.2.1]oct-6-en-3-ones (eq 19).[7,42] These [4 + 3] cycloadducts can be readily converted to cycloheptanones,[7] tropones,[7,43] highly substituted cycloheptane systems,[44] or even to substituted tetrahydrofuran compounds such as ribose.[7] Many of these have served as key synthetic precursors to a number of natural cyclic and acyclic compounds.[7,44]

(19)

Oxidation Reactions.

Electron rich furan is readily oxidized by a number of oxidizing agents.[1b] One of the most frequently employed reagents for the oxidation of furan is singlet ***Oxygen***,[8,45a] generating the six-membered endoperoxide by a [4 + 2] cycloaddition reaction followed by its rearrangement or solvolysis to give rise to a variety of products.[45a,b] Treatment of furan with ***Dimethyldioxirane*** results in the formation of the extremely unstable malealdehyde through oxidative ring opening (eq 20).[45c] Under anodic oxidation conditions, furan produces 2-acetoxyfuran, which can be trapped by several kinds of electrophiles to form 4-substituted butenolides (eq 21).[45d]

(20)

(21)

Carbenoid Reactions.

Other synthetically useful reactions include carbenoid addition to form 2-oxabicyclo[3.1.0]hex-3-ene systems.[46] The reaction of vinylcarbenoids with furan provides two products (eq 22).[47] These results may be rationalized invoking a nonsynchronous cyclopropanation mechanism that leads to two possible dipolar transition states.[47,48]

Galvinoxyl[1,2]

[2370-18-5] · $C_{29}H_{41}O_2$ · Galvinoxyl · (MW 421.70)

(stable radical and radical scavenger, extensively used as a mechanistic probe for radical chain processes;[2] used as an inhibitor to prevent undesired competitive radical paths in reactions[3,4])

Physical Data: mp 158-159 °C.

Solubility: sol organic solvents adequate for applications cited.

Form Supplied in: purple crystalline needles.

Handling, Storage, and Precautions: toxicological properties not investigated thoroughly. May be harmful by inhalation, ingestion, or skin absorption. Keep in tightly closed bottles away from oxygen in a refrigerator. Use in a fume hood.

Galvinoxyl is a stable phenoxy radical[5] which reacts with other radicals at a rate constant near the diffusion-controlled limit (eq 1). Scavenging of radicals leads to decolorization and colorimetric determination is a way of estimating the efficiency of radical formation. Galvinoxyl has been widely used as a probe in the study of organometallic[6] and radical[2] reaction mechanisms. A compilation of earlier work can be found in Kochi's monographs.[2,6]

In a classical example, the inhibition of the addition of alkyl boranes to α,β-unsaturated carbonyl compounds was interpreted to mean a radical pathway for this reaction.[7] Other reactions that have been investigated recently, include addition of trialkylaluminum to enones,[8] Ru^{II}-catalyzed Kharasch-type additions of carbon tetrachloride to alkenes,[9] 2,3-dichloropropene-mediated homocoupling of aryl Grignards,[10] $S_{RN}1$ reactions,[11] carbonyl additions of acyltin reagents, and radical polymerization of styrene.

A recent example of the use of galvinoxyl to affect the course of a reaction is in the chemoselective reduction of the carbonyl group of α-bromo ketones with dibutyltin dihydride.[3] Without the the radical inhibitor the reduction of the α-bromo group took place.

A more general use of free radical inhibitors in organic synthesis is illustrated by the use of galvinoxyl in the synthesis of (*R*)-(+)-cyclohex-3-enecarboxylic acid via a Diels-Alder reaction. The major complication arising from the ***Ethylaluminum Dichloride***-mediated polymerizations (presumably through a radical mechanism) is suppressed by galvinoxyl (eq 2).[4]

Germanium Dichloride-Dioxane Complex[1]

[28595-67-7] · $C_4H_8Cl_2GeO_2$ · Germanium Dichloride-Dioxane · (MW 231.60)

(germylene precursor; Lewis acid catalyst; insertion reactions; cycloadditions and polymerizations)

Physical Data: mp 176-178 °C.

Solubility: slightly sol Et_2O; sol THF.

Preparative Methods: a 100 mL flask equipped with a reflux condenser, nitrogen inlet, and gas outlet connected to a bubbling tower (for removing HCl) was charged with 21.8 g of germanium tetrachloride (0.102 mol), 18.7 mL of anhydrous 1,4-dioxane (0.220 mol), and 5 mL of hexane. To this solution at rt was slowly added 9.6 mL of 1,1,3,3-tetramethyldisiloxane (0.054 mol) through the condenser. The reaction mixture was heated at reflux for 8 h, cooled to rt, and filtered to remove a precipitated white solid via cannula. The solid was washed with three 20 mL portions of hexane, then dried in vacuo to give 14.5 g (63%) of the germanium dichloride-dioxane complex as a white solid.[2]

Handling, Storage, and Precautions: should be handled under nitrogen and stored in a refrigerator. Germanium is reputed to be of low toxicity. Use in a fume hood.

Germylene Precursor.

Germanium dichloride is a convenient starting material for the synthesis of germylenes with alkyl or heteroatom substituents, since the chloride ligands can be displaced by both lithium salts[3] and organolithium reagents.[4]

Lewis Acid Catalyst.

Germanium dichloride behaves as a Lewis acid toward aldehydes, and activates the carbonyl group to 1,2-addition by nucleophiles. For example, it catalyzes intramolecular ene reactions, as in the quantitative conversion of citronellal to isopulegol.[5] Germanium dichloride also catalyzes the conversion of aldehydes to β-keto esters with ***Ethyl Diazoacetate*** (see also ***Tin(II) Chloride***) (eq 1).[6] Finally, germanium dichloride has been used to promote self-condensation reactions with both carbonyl compounds and imines.[7]

(1)

Insertion Reactions.

Germanium dichloride can insert into hydrogen-halogen, carbon-halogen, metal-halogen, metal-hydride, and metal-metal bonds.[1] Recently, it has been shown that germanium dichloride-dioxane reacts with aldehydes in the presence of alcohols to give α-alkoxygermanes.[5] Similar products are obtained when $GeCl_2$.dioxane is added to an acetal of a saturated aldehyde (eq 2). In both cases, the products of these insertion reactions were converted to more stable derivatives using ***n-Butyllithium***, methyl Grignard, or ***Lithium Aluminum Hydride***. Interestingly, the reaction of $GeCl_2$.dioxane with α,β-unsaturated aldehydes and acetals leads to γ-germyl enol ethers instead of α-alkoxygermanes (eq 3).[8] These γ-germyl enol ethers can be stereoselectively converted to tetrasubstituted tetrahydrofurans via reaction with aldehydes in the presence of ***Boron Trifluoride*** (eq 4).[5]

(2)

(3)

(4)

Cycloadditions and Polymerizations.

Germanium dichloride reacts with alkenes, alkynes, and other unsaturated organic molecules to give organogermanium polymers.[9] In the case of dienes, 1,4-cycloaddition products are obtained (eq 5).[10]

(5)

Related Reagents.

Allyltrimethylgermane; ***Ethyl Diazoacetate***; ***Tin(II) Chloride***; ***Trifluoromethanesulfonic Anhydride***.

Glutaraldehyde

[111-30-8] · $C_5H_8O_2$ · Glutaraldehyde · (MW 100.13)

(useful annulating reagent for constructing heterocycles; most widely used in cross-coupling of proteins)

Alternate Name: pentanedial.

Physical Data: oil, bp 71 °C/10 mmHg; *n*25D 1.4338.

Solubility: very sol water, alcohol, ether.

Form Supplied in: 25 or 50% aqueous solution; commercially available.

Preparative Methods: in many cases, used as the commercial aqueous solution, but anhydrous glutaraldehyde can be obtained either by extraction of the aqueous solution by organic solvent followed by drying and distillation at reduced pressure,[1] or by preparation from 2-ethoxy-3,4-dihydro-2*H*-pyran.[2]

Handling, Storage, and Precautions: whereas aqueous glutaraldehyde solutions are stable, anhydrous glutaraldehyde has to be used immediately after distillation due to rapid polymerization. In ether solution, glutaraldehyde rapidly polymerizes even at low temperature.[3] Use in a fume hood.

2,6-Disubstituted Piperidines; Bicyclic Compounds.

The classical Robinson synthesis[2] of pseudopelletierine was the first example of a double Mannich reaction of glutaraldehyde (eq 1). It involved reaction of glutaraldehyde with methylamine and acetonedicarboxylic acid in a slightly acidic aqueous solution (for similar reactions, see also ***Succindialdehyde***).

Synthesis of *cis*-2,6-diacetonylpiperidine has been reported using this methodology (eq 2).[4]

In the absence of a nucleophile, 1,4-dihydropyridine is formed (eq 3).[3]

Stable equivalents of 1,4-dihydropyridine can also be obtained by the use of heteroatomic nucleophiles. The double condensation of glutaraldehyde with a chiral nonracemic amino alcohol in the presence of cyanide leads to the formation of a 2-cyano-6-oxazolopiperidine in an enantiomerically pure form and in 80% yield (eq 4).[5] This compound has proved to be a very useful tool for the asymmetric synthesis of piperidine derivatives and has been used largely in the asymmetric synthesis of alkaloids.[5b]

(4)

N-Substituted piperidines are obtained when glutaraldehyde reacts with primary amines in the presence of a reducing agent (reductive alkylation). The most popular reagent is ***Sodium Cyanoborohydride*** (eq 5),[6a] but other reagents are also efficient in this transformation.[6] This method is generally preferred to the condensation of a primary amine with 1,5-dihalogenopentane.

(5)

In the condensation of glutaraldehyde with tryptamine, one of the iminium salts can be trapped by the indole ring in a Pictet-Spengler reaction, and in the presence of ***Sodium Borohydride*** an indoloquinolizidine is obtained (eq 6).[7]

(6)

Other Uses.

Pyran derivatives can be prepared from glutaraldehyde, generally by monoalkylation with a carbon nucleophile,[1,8] as depicted in eq 7.

(7)

Active methylene compounds can add to glutaraldehyde to give cyclohexane derivatives (eq 8).[9]

(8)

Glutaraldehyde monoacetals have been reported. Their preparations include the partial acetalization of glutaraldehyde and the partial hydrolysis of 2-ethoxy-3,4-dihydro-2*H*-pyran. These monoacetals are widely used in many organic syntheses and have been reviewed.[10]

Glutarimide[1]

[1121-89-7] · $C_5H_7NO_2$ · Glutarimide · (MW 113.13)

(building block for synthesis of other heterocyclic compounds, especially via *N*-acyliminium cyclizations[2])

Alternate Name: 2,6-piperidinedione.

Physical Data: mp 163-165 °C; *d* 1.393 g cm^{-3}; dipole moment 2.58 D (dioxane, 30 °C); pK_a 11.43 (H_2O, 25 °C).

Solubility: sol H_2O, hot EtOH, boiling benzene; insol ether.

Form Supplied in: white solid.

Reactions at the Nitrogen Atom.

The direct reaction of glutarimide with a primary[3] or a secondary[4] alcohol, mediated by ***Triphenylphosphine*** and dialkyl azodicarboxylate (Mitsunobu reaction[5]) is the most widely used method for the *N*-alkylation (eq 1).[3] However, because of the tedious workup procedure (removal of Ph_3PO and $RO_2CNHNHCO_2R$), alkylation of alkali metal salts of glutarimide with primary halides or sulfonates is usually more convenient (eq 2).[6] The sodium salt is prepared by reaction with NaOMe in MeOH, followed by precipitation with ether. The alkali metal salts can also be generated from the metal hydride in DMF or HMPA, without isolation of the salt.

(1)

(2)

R = $CH_2C{\equiv}CCH_2TMS$, 84%; (*Z*)-$CH_2CH{=}CHCH_2TMS$, 83%

N-Alkylation of glutarimide in high yield is also possible by using primary chlorides, bromides, or tosylates under solid-liquid phase transfer conditions (***Potassium Carbonate***, 0.1 equiv ***18-Crown-6***, benzene or toluene, reflux).[7] Addition of 0.1 equiv ***Potassium Iodide*** increases the reaction rate for less reactive halides.

N-Alkenyl or *N*-alkynyl glutarimides are important intermediates for the synthesis of other heterocyclic systems; upon partial reduction to the hydroxylactam and treatment with acid, an *N*-acyliminium cyclization occurs.[2]

Reactions at the Carbonyl Group.

Addition of Grignard reagents (>2 equiv) to glutarimide gives rise to *t*-hydroxylactams (in equilibrium with the ring-opened keto-amide). In the case of alkenyl derivatives, *N*-acyliminium cyclizations to the 1-azaspiran derivatives are possible (eq 3).[8]

(3)

Reaction of sodium glutarimide with ***[1-(Ethoxycarbonyl)cyclopropyl]triphenylphosphonium Tetrafluoroborate*** leads to an indolizidine derivative via nucleophilic opening of the cyclopropyl ring and a subsequent intramolecular Wittig reaction (eq 4).[9]

Reactions at the Carbon Atom next to the Carbonyl Group.

Disodium glutarimide in liquid ammonia can be alkylated or acylated with ***Benzyl Chloride***, benzophenone, or methyl benzoate to give the 2-substituted glutarimides[10] (e.g. eq 5).[11]

Related Reagents.

Diethyl Azodicarboxylate; ***[1-(Ethoxycarbonyl)cyclopropyl]triphenylphosphonium Tetrafluoroborate***; ***4-Phenylsulfonyl-3-buten-2-one***; ***Phthalimide***; ***Succinimide***.

Glycidol[1]

[556-52-5] · $C_3H_6O_2$ · Glycidol · (MW 74.08) (*R*)

[57044-25-4] (*S*)

[60456-23-7] (±)

[61915-27-3]

(versatile bifunctional, three-carbon synthon)

Alternate Name: oxiranemethanol.

Physical Data: mp -53 °C; bp 161-163 °C (dec), 30 °C/1 mmHg, 54 °C/8 mmHg, 114 °C/114 mmHg; *d* 1.115 g cm^{-3}; $[\alpha]_D$ +15° (neat, L-(+)-glycidol).

Solubility: insol aliphatic hydrocarbons; sol H_2O, acetone, THF, toluene, most other organic solvents.

Form Supplied in: racemic, (*R*), and (*S*) forms; all as colorless, neat liquids. Solid derivatives: phenyl isocyanate, mp 60 °C; α-naphthyl isocyanate, mp 102 °C.

Analysis of Reagent Purity: ^1H NMR.

Handling, Storage, and Precautions: neat samples of glycidol should be stored in the freezer to slow the process of self-condensation; when stored neat, glycidol should be checked for purity before use and will usually require purification, which can be achieved by distillation under reduced pressure; self-condensation is greatly reduced by storage of glycidol in solutions, e.g. 50-70% in toluene or dichloromethane; distillation of glycidol should be done behind a safety shield; care should be taken when using glycidol under acidic conditions (e.g. acetic acid) since acid catalyzes self-condensation; use in a fume hood.

Glycidol and Glycidol Derivatives.

Two excellent reviews of glycidol and glycidol derivatives are available. The first is a very thorough review of the properties and reactions of glycidol written by Kleemann and Wagner.[1a] In the second, the use of glycidol and glycidol derivatives as synthons, with a strong emphasis on nonracemic glycidol, is the subject of a superb review by Hanson.[1b]

Glycidol is a versatile three-carbon synthetic building block and its value is greatly expanded through derivatization of the hydroxyl group. The use in synthesis of derivatives such as *O*-aryl and *O*-arylmethyl (e.g. *O*-benzyl) ethers, sulfonates, carboxylates, and silyl ethers is integrated with those of glycidol for this review. In the following discussion, glycidol and derivatives are occasionally referred to collectively as glycidols. Also note that reactions of nonracemic glycidol are illustrated only with one enantiomer, but apply equally to use of both.

Glycidol, like all 2,3-epoxy alcohols, is susceptible to the Payne rearrangement when exposed to base. Payne rearrangement of (*R*)- or (*S*)-glycidol is degenerate; consequently racemization does not occur.

(*R*) and (*S*) are empirical designations of absolute configurations and in comparing glycidol and an *O*-substituted glycidol derivative having the same absolute configuration, the designation changes (see eq 1). For further discussion of this point, see Hanson's review.[1b]

Preparations.

Racemic glycidol, (*R*) and (*S*)-glycidol, and a number of derivatives of each are commercially available. Preparations of these materials are described in the literature and a selected listing follows: (*S*)-glycidol via asymmetric epoxidation[2] and enzymatic kinetic resolution;[3] *O*-benzyl glycidol,[4] *O*-trityl glycidol;[5] (*R*)-(-)-***Glycidyl Tosylate***;[6] (*R*)-(-)-glycidyl 3-nitrobenzenesulfonate (a derivative whose optical purity is enhanced by recrystallization);[6] (*R*)-(-)-glycidyl *p*-nitrobenzoate (see eq 1).[2,7]

Reactions at C-1 of Glycidol.

A number of *O*-derivatives of glycidol are described in the preceding section and may be prepared directly from racemic or (*R*)- or (*S*)-glycidol. Alternatively, if carrying out the laboratory preparation of (*R*)- or (*S*)-glycidol, convenient in situ methods for derivatization have been developed.[2,7,8] Derivatization as *O*-sulfonate esters (e.g. tosylates) activates the C-1 position and permits displacement by nucleophiles. An example is displacement by phenolates to generate *O*-aryl glycidol ethers (see eq 2),[6] which find extensive use as intermediates in the synthesis of a variety of pharmacologically active agents (see additions of nitrogen at C-3, below).

(2)

O-Aryl glycidol ethers can be prepared from glycidol by the Mitsunobu reaction with phenols (see eq 3)[9a] and are also made from direct displacement by glycidol on activated haloaryls.[9b]

(3)

Addition of Hydrogen at C-3.

Both catalytic reduction of glycidol over Pd/C[10] and reaction with MeLi/CuBr$(PBu_3)_2$[11] give propane-1,2-diol as a consequence of addition of hydrogen at C-3. (*S*)-Glycidyl tosylate is reduced to (*S*)-propane-1,2-diol 1-monotosylate with ***Borane-Tetrahydrofuran*** and a catalytic amount of ***Sodium Borohydride***, as shown in eq 4.[6]

(4)

Nucleophilic Additions of Carbon at C-3.

One of the few reported additions of a carbon nucleophile to underivatized glycidol is that of diethyl sodiomalonate. The initial addition at C-3 is followed by lactonization between the C-2 hydroxyl group and one of the malonate carboxylic esters (eq 5).[12] Far more numerous are the additions of carbon nucleophiles to glycidol derivatives such as *O*-benzyl, *O*-phenyl, or *O*-tosyl glycidol. In addition to the examples included below, many others may be found in Hanson's review.[1b]

(5)

Single carbons can be added as cyanide using ***Acetone Cyanohydrin***,[6,7] diethylaluminum cyanide (eq 6),[6,7] or ***Lithium Cyanide***[13] or as methyl groups using an organocuprate (eq 7).[14] A single carbon may be added with dithiane salts and an example of addition of a substituted ***1,3-Dithiane*** to *O*-benzyl glycidol is shown in eq 8.[15]

(6)

(7)

(8)

Other alkyl groups, alkenyl groups (eq 9), and aryl groups have been added to glycidol via organometallic reagents. The reactions with organometallic reagents often are sensitive to conditions and frequently are improved by the addition of Cu^{I} or Cu^{II} to the medium.[16] Alkynic salts add to glycidols, giving 3-alkynyl derivatives in yields which are generally good but which may be enhanced in some cases by the addition of a Lewis acid such as ***Boron Trifluoride Etherate*** to the reaction (eq 10).[17]

(9)

Opening at C-3 of glycidol sulfonates generates a 1,2-diol monosulfonate array which is ideally situated for closure under mildly alkaline conditions to a new epoxide group, as shown in eq 10 and also, below, in eq 18. Either the intermediate monosulfonate or the new epoxide present an activated electrophilic site for further synthetic transformations.

Carbon nucleophiles such as ester enolates and α-carboxylic acid anions add to glycidols by opening the oxirane ring and forming an intermediate C-2 alcohol. As shown above in eq 5, the intermediate can cyclize to a five-membered lactone via further reaction with the newly introduced carboxylic acid or ester.[18] Variations on the theme of intramolecular transformations following the initial addition to glycidol have been described. These include seven-membered lactone formation following addition of a sulfone-stabilized anion to *O*-benzylglycidol (eq 11),[19] and oxetane formation following addition of ***Dimethylsulfoxonium Methylide*** to glycidol (eq 12).[20]

Other examples of carbon nucleophiles which have been added to a glycidol include the lithium salt of 1-trimethylsilyl-3-phenylthioprop-1-yne (eq 13),[21] the lithium salt of 1-phenylsulfonyl-2-trimethylsilylethane,[22] the lithium salt of pentacarbonyl(methoxymethylcarbene)chromium,[23] the dimsyl anion,[24] and the lithium salt of acetone dimethylhydrazone.[25]

(13)

Nucleophilic Addition of Oxygen at C-3.

Addition of water to glycidol or a glycidol derivative produces glycerol or a substituted glycerol, respectively. The oxygen nucleophiles used most frequently for addition to glycidols are alcohols, phenols, and carboxylic acids and their close relatives. For glycidol itself, Kleemann and Wagner summarize extensive studies of additions of these classes of compounds.[1a] Very good yields of products are achieved with all three classes when acid or, preferentially, basic catalysts are added to the reactions. Careful analyses of the reaction products reveal that in addition to the primary opening of the oxirane at C-3, most reactions include small (2-10%) amounts of product derived from opening at C-2. Other byproducts can result from self-reaction of glycidol with the reaction products. Opening of glycidol with primary alcohols with 0.5% NaOH as catalyst yields 70% of the 1-*O*-alkylglycerol together with 3% of the 2-*O*-alkylglycerol.[1a] Opening with phenols and 0.03% NaOH gives 70-80% yields of 1-*O*- and 2-*O*-arylglycerols in ratios of 90-95:5-10.[1a] Glycidol generated in situ from hydrolysis of the *p*-nitrobenzoate ester with MeOH/H_2SO_4 reacts further at C-3 with the MeOH to give 1-*O*-methoxyglycerol (eq 14).[7]

(14)

Lewis acid catalysis of additions to 2,3-epoxy alcohols often improves the regioselectivity of the ring-opening process.[26] $Ti(OR)_4$ catalyzed reaction of glycidol with primary alcohols gives 1-*O*-alkylglycerols in yields of 45-59%.[27] The addition of primary alcohols to (*R*)-glycidyl sulfonate esters give 1-*O*-alkylglycerol 3-sulfonates in yields of 73-89% when catalyzed with $BF_3.OEt_2$ (eq 15).[28] Non-racemic glycidol, generated by catalytic asymmetric epoxidation of allyl alcohol with $Ti(O\text{-}i\text{-}Pr)_4$ and a (+)- or (-)-dialkyl tartrate, undergoes ***Titanium Tetraisopropoxide*** assisted reaction in situ with sodium phenolates to generate 1-*O*-arylglycerols (eq 16).[8,29] The $BF_3.OEt_2$ addition of stearic anhydride to (*R*)-glycidyl tosylate gives (*R*)-1,2-distearoylglyceryl tosylate in 76% yield.[30]

(15)

(16)

Examples of other oxygen nucleophiles that have been added at C-3 include phosphorylcholine (eq 17)[31] and ethyl *N*-hydroxyacetimidate (eq 18).[32]

(17)

(18)

Nucleophilic Additions of Nitrogen at C-3.

Ammonia and amines add readily to glycidol and glycidol derivatives, giving the 1-aminopropane-2,3-diols (eq 19).[33] With ammonia and primary amines, an excess of the amine often is used to reduce the amount of addition by a second glycidol to the 1-aminopropane-2,3-diol. Secondary amines are used with glycidols in an equimolar ratio. Azide ion also opens glycidols at C-3. Ti(O-*i*-Pr)$_4$ or ***Aluminum Isopropoxide*** assisted openings with ***Azidotrimethylsilane*** have been examined with glycidol and a variety of derivatives[34] and give excellent yields of 3-azido-2-hydroxypropane 1-

O-derivatives (eq 20). ***Sodium Azide*** has also been used as a source of azide when combined with either ***Pyridinium p-Toluenesulfonate***,[7] NH_4Cl,[9,35] or ***Lithium Perchlorate***[36] to react with various glycidols.

(19)

(20)

The opening of glycidols, especially of *O*-aryl glycidol ethers, at C-3 with amines has found extensive application in pharmaceutical research.[1b] A typical example is in the opening of *O*-(1-naphthyl)glycidol at C-3 with isopropylamine to generate the β-adrenergic blocking agent propranolol (eq 21).[29] A similar application is the addition of the 4-substituted piperazine to glycidol shown in eq 22.[37] With (*R*)- and (*S*)-glycidol now readily available, the synthesis of individual enantiomers or diastereoisomers of a pharmacological agent by methods such as those shown in eqs 21 and 22 becomes an attractive goal.

(21)

60% from
(*S*)-glycidol tosylate

(22)

Other nitrogen nucleophiles added to glycidol include several heterocycles, an example of which is the addition of ***Imidazole***.[38] The iminodioxolane shown in eq 23 adds to glycidol and then undergoes further intramolecular cyclization to give a cyclic urethane.[39] ***Acetonitrile*** in a $BF_3.OEt_2$ catalyzed reaction adds to glycidyl tosylate to form

2-methyl-4-(tosyloxy)methyloxazoline (eq 24).[40] Dibenzylamine adds via an amidocuprate at C-3 of *O*-phenylglycidol to give 3-dibenzylaminopropane-1,2-diol 1-*O*-phenyl ether in 94% yield.[41]

(23)

(24)

Additions of Other Nucleophiles at C-3.

The halogens (F, Cl, Br, and I) and sulfur are the other elements most frequently found in C-3 additions to glycidols. Fluoride has been added to both glycidol and various glycidol (see eq 25) derivatives using tetrabutylammonium dihydrogentrifluoride.[42] Several methods have been used for the other three halogens, including reaction with the lithium salts in THF[43] or with the ammonium salts and $LiClO_4$ in AcCN.[44] Chlorine has also been added via HCl[45] or with ***Benzoyl Chloride*/*Cobalt(II) Chloride***;[46] the latter reaction also adds the benzoyl group to give the 2-*O*-benzoate derivative (eq 26). Bromine has been added with dimethylboron bromide[47] and iodine has been added with ***Sodium Iodide*** in a NaOAc/HOAc/$EtCO_2H$ system.[7]

(25)

(26)

Most additions of sulfur to glycidols have been of arylthiolates and are performed under either acidic [$Ti(O\text{-}i\text{-}Pr)_4$ (eq 27),[8] $BF_3.OEt_2$[48]] or alkaline conditions.[7,49] $LiClO_4$[50] or $CoCl_2$[51] have also been used as catalysts for addition of aryl thiols. The additions of lithium alkylthiolates and of thiobenzoic acid to *O*-trityl glycidol have been reported.[5a]

(27)

Oxidation of Glycidol.

Glycidol is oxidized to glycidic acid with ***Ruthenium(VIII) Oxide***.[52] Glycidaldehyde is a mutagenic compound that has been prepared in racemic form by epoxidation of ***Acrolein***[53] and in nonracemic forms by the degradation of mannitol.[54] Alternately, (*R*)- and (*S*)-glycidaldehyde may be prepared and handled more conveniently via asymmetric dihydroxylation of acrolein benzene-1,2-dimethanol acetal followed by conversion of the diol to an epoxide (see eq 28).[55]

(28)

Miscellaneous.

Glycidol reacts with dinitrogen pentoxide (N_2O_5) in CH_2Cl_2 in the presence of $AlCl_3$, giving trinitroglycerine (73%).[56] A useful review describing numerous synthetic transformations of 2,3-*O*-isopropylideneglyceraldehyde, a three-carbon synthon related to glycidol, has been published.[57]

Glycidyl Tosylate[1]

(*R*)-(-)

[113826-16-5] · $C_{10}H_{12}O_4S$ · Glycidyl Tosylate · (MW 228.29) (*S*)-(+)

[70987-78-9]

(chiral C_3 synthon;[2] undergoes regio- and stereoselective ring opening at C-3 with alcohols in the presence of $BF_3.OEt_2$,[3-8] Li_2CuCl_4-catalyzed Grignard reagents,[9,10] and carbanions (with[11] and without $BF_3.OEt_2$);[12-15] undergoes direct attack at the C-1 position by nucleophiles, including aryl oxides[9,16-26])

Physical Data: mp 47.5-48.5 °C; racemate mp 37.5-39 °C.[9] [α]25D (*S*) enantiomer (&egt;97% enantiomeric excess) +18.1° (*c* 2.1, $CHCl_3$),[9] (*R*) enantiomer (~94% enantiomeric excess) -17.0° (*c* 2.75, $CHCl_3$).[4]

Solubility: v sol chloroform, methylene chloride, and THF; insol hexane.

Form Supplied in: white solid; commercially available.

Analysis of Reagent Purity: enantiomeric purity can be assessed by the following procedures. *Procedure A* (no derivatization): Chiral HPLC on a Diacel OD column (10 µm, 0.46 × 25 cm); flow, 0.7 mL min^{-1}; 99:1 hexane-2-propanol; t_R: (*S*) enantiomer, 51.2 min; (*R*) enantiomer, 53.9 min.[27] *Procedure B*: the reagent is opened to the iodohydrin; the crude iodohydrin is esterified with (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl (MTPA) chloride; the resulting crude MTPA ester is analyzed by chiral HPLC and ^1H NMR.[28]

Preparative Methods: the title reagent (**1**) is obtained in 40% overall yield by the zeolite-modified Sharpless asymmetric epoxidation of allyl alcohol, using D-(-)-diisopropyl tartrate (DIPT) to obtain (*S*)-(**1**) and L-(+)-DIPT to obtain (*R*)-(**1**), followed by in situ low-temperature tosylation of glycidol.[28] Alternatively, (*R*)- and (*S*)-(**1**) can be prepared by direct sulfonylation of commercially available chiral ***Glycidol***. Note that the relative configuration of (*R*)-glycidyl tosylate is the same as that of (*S*)-glycidol.

Purification: multiple recrystallizations from 5:1 ether-petroleum ether, seeding (before refrigeration) each time with pure material.[28]

Handling, Storage, and Precautions: mutagenicity via reactions with biological nucleophiles has been assessed by using the Ames test in *Salmonella typhimurium* and by analysis of in vivo chromosomal aberrations.[29] (*S*)-(**1**) was more mutagenic than (*R*)-(**1**).[29] Use in a fume hood.

Displacement Reactions.

Aryl oxides attack (*R*)- or (*S*)-(**1**) at the C-1 position, displacing the tosylate group and affording aryloxymethyloxiranes (**2**) in good yield (see examples in Table 1). The latter react with amines in aqueous alcohol, yielding β-adrenergic blocking agents of high enantiomeric excess.[9] The regioselectivity for attack at the C-1 vs. C-3 position of (**1**) is very high, i.e. &egt;97:3 in DMF at rt[9] and 85:15 in refluxing acetone.[18] The ratio of C-1:C-3 attack on the related substrates, (*S*)-glycidyl 3- or 4-nitrobenzenesulfonate, by 1-naphthol in DMF at rt is >99.8:0.02.[9] A comparison of the C-1:C-3 product ratio obtained from several glycidyl arenesulfonates suggested that attack by aryl oxide nucleophiles at C-1 is enhanced when the electron deficiency of the leaving group is increased (see Table 1).[9]

Table 1 Alkylation of Phenolic Hydroxy Groups by **(1)**

Reactant	Reagent	Conditions	Yield of glycidyl **(2)**	Ref

1-Naphthol	(*R*)-**(1)** & (*S*)-**(1)**	NaH, DMF, rt	50-85	9, 19
8-Hydroxyisoquinoline	(*R*)-**(1)** & (*S*)-**(1)**	NaH, DMF, rt, 12 h	80	20
3-Acetyl-4-methoxy-1-naphthol	(*R*)-**(1)**	NaH, DMF, 50 °C, 4 h	75	21
4,8-Dibenzyloxy-6-methyl-1-naphthol	(*R*)-**(1)**	NaH, DMF, rt, 4 h	87	22
O^3-Benzyl-6β-naltrexol	(*R*)-**(1)**	KH, THF, 19 h	83	23
7-*O*-(3-*N*-Methyl-α-L-daunosaminyl)-β-rhodomycinone	(*R*)-**(1)**	heat	11	24

Reaction of ***Catechol*** with (*R*)- or (*S*)-(**1**) (***Potassium Carbonate***, DMF, 60 °C, 27 h;[25] or ***Sodium Hydride***, DMF, rt, 10 h[26]) affords (*S*)- or (*R*)-2-hydroxymethyl-1,4-benzodioxane in yields of 72%[25] and 18-21%[26] (eq 1).

(1)

Ring-Opening Reactions.

Epoxide opening takes place at the C-3 position of (**1**) with a wide variety of nucleophiles, as summarized below.

Alcohols and Benzenethiol.

These react with (**1**) in methylene chloride or chloroform, generally at rt, in the presence of catalytic ***Boron Trifluoride Etherate*** (eq 2). The following alcohols have been used (yields in parentheses): benzyl alcohol (81-84%);[3b,4,8] 1-hexadecanol (80%);[3] $Cl(CH_2)_6OH$ (80%);[5] $Cl(CH_2)_{16}OH$ (85%);[5] methanol (100%);[7] $MeO_2C(CH_2)_5OH$ (89%).[6] Benzenethiol gives 3-phenylthio-2-hydroxy-1-tosyloxypropane in 81-83% yield.[3b] The 4-methylbenzene- and 3- nitrobenzenesulfonate derivatives of glycidol give exclusive formation of the C-3-opened product in the BF_3-mediated reaction,[3,4] whereas the *t*-butyldiphenylsilyl ether derivative of glycidol gives a regioselectivity (C-3 vs. C-2 isomer ratio) of 89:11 with benzyl alcohol, 93:7 with benzenethiol, and 90:10 with long-chain alcohols.[3b]

(2)

Halide and Azide Anions.

These also open the epoxide regioselectively at the C-3 position. Addition of Li_2CuBr_4 results in bromide addition at the C-3 position of *rac*-(**1**), forming 3-bromo-1,2-propane 1-*O*-tosylate in 70-76% yield in THF or acetonitrile at rt, or 1,3-dibromo-2-propanol in 82% yield in refluxing acetonitrile.[30] Hydrofluorination takes place with KHF_2 under solid-liquid phase transfer conditions, but the yield of fluorohydrin is very low (eq 3).[31] ***Azidotrimethylsilane*** adds in the presence of a Lewis acid catalyst (eq 3).[32] Addition of cyanide ion is achieved by using ***Diethylaluminum Cyanide*** in toluene.[9]

(3)

Hydrofluorination: KHF_2 (2 equiv), $Bu_4N^+ H_2F_3^-$ (1 equiv), 120 °C;
X = F, Y = H, 6%
Azide opening: $TMSN_3$ (1.5 equiv), cat. $Al(O\text{-}i\text{-}Pr)_3$, CH_2Cl_2, 1 d, 93%
or cat. $Ti(O\text{-}i\text{-}Pr)_4$, THF, 6 d, 76%

Addition of concentrated HCl to solid (*S*)-(**1**) at rt, followed by treatment of the ring-opened intermediate with sodium ethyleneglycolate, forms (*R*)-epichlorohydrin in 54% yield.[33a] The analogous reaction was carried out using (*S*)-glycidyl mesylate in 85%[33b] and 68% yield,[33c] and with *rac*-(**1**).[33d]

Carbanions.

These add to the C-3 position of (*S*)-(**1**), affording epoxides (**3**) after intramolecular displacement of the tosylate group and in situ ring closure of the ring-opened intermediate (eq 4). Deprotonation of oxirane (**3**) leads to rearrangement to cyclopropane derivatives.[11a,12,13]

(4)

Lithium carbanion	Overall yield of **(3)** (%)
	81
	58
	59
	56
	38

There are many examples of $BF_3.OEt_2$ promoted openings of (**1**) by carbanions, including sulfone-stabilized anions,[11a] vinylic anions,[11b] allylic anions,[14] and phosphonate-stabilized anions.[15] For example, the lithium anion of ***trans-1,2-Bis(tributylstannyl)ethylene*** opens (*S*)-(**1**) in the presence of $BF_3.OEt_2$ in THF at -78 °C, affording *trans*-1-(tributylstannyl)-5-tosyl-4-hydroxypent-1-ene in 50% yield; the latter is converted into oxirane (**3**) in 76% yield on treatment with powdered ***Sodium***

Hydroxide in monoglyme.[11b]

The carbanion derived from pentacarbonyl(methoxymethylcarbene)chromium(0) reacts with (*R*)-(**1**) in the presence of $BF_3.OEt_2$ to give a lactone in low yield after oxidation of the ring-opened intermediate.[14]

Lithium diethylmethanephosphonate adds to *rac*-(**1**) in the presence of $BF_3.OEt_2$ at -78 °C to afford a phosphonate ester in good yield (eq 5).[15]

Organometallic Reagents.

The major product of the ***Dilithium Tetrachlorocuprate(II)***- or ***Copper(I) Iodide***-catalyzed Grignard reaction in THF or ether at low temperature arises from epoxide opening rather than from direct tosylate displacement (Table 2).[9,10]

Table 2 Copper-Catalyzed Grignard Reactions of **(1)**[9]

R	Conditions	Yields (%)		
		(4)	**(5)**	**(6)**
Ph	Li_2CuCl_4, -30 °C, THF	84	9	5
Vinyl	Li_2CuCl_4, -35 °C, THF	49	-	-
Bn	Li_2CuCl_4, -15 °C, THF	56	-	-
Hexyl	Li_2CuCl_4, -50 °C, THF	74	-	-
5-Hexenyl	Li_2CuCl_4, 20 °C, THF	44[b]	-	-
Mesityl	CuI, -25 °C, THF-Et_2O	90	-	-
Cy	CuI, -40 °C, Et_2O	69[a]	-	-

[a] *rac*-**(1)** was used. [b] Ref. 10.

Organolithium reagents add to (*R*)- and (*S*)-(**1**) as shown in eq 6.[9]

Hydride addition to (*S*)-(**1**) is achieved by use of BH_3 in THF with 0.05 equiv of ***Sodium Borohydride***, forming (*S*)-1-*O*-tosyloxy-2-hydroxypropane in 81% yield.[9]

Miscellaneous Addition Reactions.

Alkylation of MeC(OEt)=N-O$^-$ Na$^+$ with (*R*)-(**1**) gives (*S*)-*N*-(oxiranylmethoxy)ethanimidic acid ethyl ester in 34% yield.[34] Reaction of (*S*)-(**1**) with guanosine occurs at the N-7 position, giving (after deribosylation) (*S*)-7-(3-*O*-*p*-tolyl-2,3-dihydroxypropyl)guanosine in 56% yield.[35]

Fatty acid anhydrides react with (*R*)- and (*S*)-(**1**) in the presence of $BF_3.OEt_2$, giving a glyceryl tosylate with two identical fatty acid ester linkages in 76% yield.[36]

Reaction of (*S*)-(**1**) with acetonitrile at low temperature in the presence of $BF_3.OEt_2$ gives an oxazoline that is unstable at rt (eq 7).[9]

Glyoxal

[107-22-2] · $C_2H_2O_2$ · Glyoxal · (MW 58.04)

(undergoes condensations and Wittig reactions to form carbo- and heterocycles)

Alternate Name: ethanedial.

Physical Data: yellow prisms, mp 15 °C; bp 50.4 °C/760 mmHg; *d*204 1.29 g cm^{-3}.

Solubility: sol water, ether, ethanol.

Form Supplied in: crystalline trimeric dihydrate $(OHC\text{-}CHO)_3.2H_2O$ [*4405-13-4*], which is nonhygroscopic; also supplied as a 40% aqueous solution which may contain polymerization inhibitors. An addition compound with $NaHSO_3$ serves as a nonaqueous form of glyoxal (monohydrate; *[517-21-5]*).

Purification: for most reactions, can be used without further purification. Anhydrous form should be freshly prepared.[1]

Handling, Storage, and Precautions: should be handled carefully to avoid exposure. Use in a fume hood.

Condensations.

Glyoxal (**1**) undergoes the Weiss-Cook reaction with dimethyl 1,3-acetonedicarboxylate in aqueous buffer at pH 8.3 and affords tetramethyl *cis*-bicyclo[3.3.0]octane-3,7-dione-2,4,6,8-tetracarboxylate (eq 1).[2] It undergoes a condensation reaction in methanol in the presence of ***Formic Acid*** with ***Formaldehyde*** and benzylamine in a stoichiometric ratio 1:2:4 and provides 2,4,6,8-tetrabenzyl-2,4,6,8-tetraazabicyclo[3.3.0]octane (eq 2).[3] Condensation of (**1**) with *N*,*N*´-diisopropylurea in aqueous HCl at rt

affords 2,4,6,8-tetraisopropyl-2,4,6,8-tetraazabicyclo[3.3.0]octane-3,7-dione (eq 3).[4]

(1)

(2)

(3)

Glyoxal reacts with the (2,5)furano-4,4´-bis-(2-oxo-3-butyl) sulfide shown in eq 4 upon gradual addition of ***Sodium Methoxide*** in methanol to form 1,11-dioxo[3.3](2,5)furano(2,5)thiophenophane (eq 4).[5] Reaction of glyoxal with the nickel(II) complex of 1,5,8,12-tetraazadodecane followed by reduction with ***Sodium Borohydride*** and treatment with excess ***Sodium Cyanide*** affords 1,4,8,11-tetraazacyclotetradecane (cyclam) (eq 5),[6] a synthetically useful crown ether analog.

(4)

(5)

Condensation of glyoxal bisulfite with *o*-phenylenediamine in aqueous solution at 80 °C affords quinoxaline (eq 6).[7] Glyoxal also undergoes cyclocondensation upon heating with 3,4-diamino-1,2,5-thiadiazole and forms [1,2,5]thiadiazolo[3,4-*b*]pyrazine (eq 7).[8]

(6)

(7)

Wittig-Related Reactions.

Freshly prepared (dried) glyoxal,[1] when treated with phenacyltriphenylphosphorane, undergoes a Wittig condensation to form both the (*E*,*E*)- and (*E*,*Z*)-1,4-dibenzoyl-1,3-butadienes (eq 8).[9] A similar reaction of (**1**) with a bis-ylide [generated from 1,8-bis(bromomethyl)biphenylenetriphenylphosphonium salt and dimsylsodium] affords a complex mixture which contains 12% of the interesting cycloocta[*def*]biphenylene (eq 9).[10]

(8)

(9)

Aqueous glyoxal undergoes a Wittig-type condensation with the phosphorane generated from 1,3,4,6-tetrathiapentalene-2-(triphenylphosphonium) trifluoromethanesulfonate and triethylamine to form the mono-Wittig product 1,3,4,6-tetrathiapentalen-2-ylideneacetaldehyde (eq 10).[11] A similar reaction of (**1**)

with another phosphorane, derived by treating (4,5-dimethoxycarbonyl-1,3-diselenolyl)tributylphosphonium tetrafluoroborate with triethylamine in THF, affords 2-formylmethylene-4,5-dimethoxycarbonyl-1,3-diselenole (eq 11).[12]

(10)

(11)

Glyoxal undergoes formic acid-catalyzed condensations with (*R*)-PhCHMeNH$_2$ or with (1*S*,2*S*,3*S*,5*R*)-3-(aminomethyl)pinane, individually, to form the corresponding diazadienes represented by eq 12.[13] Reaction of glyoxal with a dicarboxamide (see eq 13) in the presence of the phase-transfer catalyst benzyltributylammonium hydroxide, in $H_2O/CHCl_3$ containing sodium hydroxide, affords the bicyclic compound shown.[14]

(12)

(13)

Powdered polymeric or monomeric glyoxal in dry benzene reacts with an ethereal solution of phenoxymagnesium bromide upon heating and directly produces the 2-hydroxyphenacyl alcohol (eq 14).[15] Reaction of glyoxal (obtained by concentration of 40% glyoxal) with gaseous HBr in methanol and dichloromethane at 0 °C affords 1,2-dimethoxy-1,2-dibromomethane which, upon treatment with sodium *t*-butoxide, undergoes dehydrobromination to yield 1,2-dimethoxyvinyl bromide (eq 15).[16]

(14)

(15)

Reaction of glyoxal with 2-*t*-butyl-4-methylphenol in refluxing acetic acid in the presence of ***Hydrogen Chloride*** or ***p-Toluenesulfonic Acid*** as a catalyst affords 5-methyl-7-*t*-butyl-2(3*H*)-benzofuranone (eq 16).[17] Condensation of (**1**) with *N*-aryl substituted ureas produces the corresponding 1-aryl substituted hydantoins (eq 17).[18]

(16)

(17)

Glyoxal reacts with chiral *N*-homoallyl-β-amino alcohols in water-THF solution to produce an iminium ion which undergoes cyclization with complete stereoselectivity and affords the bi- and tricyclic alcohols[19] represented in eqs 18 and 19, respectively.

(18)

(19)

Related Reagents.

Glyoxal Diethyl Acetal

(**1**; R = Et)

[5344-23-0] · $C_6H_{12}O_3$ · Glyoxal Diethyl Acetal · (MW 132.16) (**2**; R = Me)

[51673-84-8] · $C_4H_8O_3$ · Glyoxal Dimethyl Acetal · (MW 104.11)

(reagents for preparation of α,β-unsaturated aldehydes[1-8] and heterocyclic compounds[1,9-12])

Alternate Name: diethoxyacetaldehyde.

Physical Data: (**1**) bp 50-55 °C/10 mmHg; (**2**) bp 60-90 °C/150 mmHg.

Form Supplied in: liquids; commercially available.

Preparative Methods: preparations usually involve either oxidative cleavage of glyceraldehyde acetals,[12-15] or reductive ozonolysis of acrolein[5,16] or crotonaldehyde[1] dialkyl acetals. Three new preparative procedures were recently reported.[17-19]

Handling, Storage, and Precautions: these compounds are moisture sensitive. They should be stored under inert gas and at low temperature.

Wittig Reactions.

Wittig or Horner-Emmons reactions yield α,β-ethylenic acetals.[1-8,10,14] Subsequent deacetalization, usually by moist silica gel, gives α,β-ethylenic aldehydes.[1-8] This approach was used in the synthesis of ethyl (2*E*,4*Z*)-decadienoate, a natural product from *Pyrus communis*, in which two of the three steps are Horner-Emmons reactions with dimethoxy- or diethoxyacetaldehyde and then deacetalization[20] (eqs 1-4).[3-5,8]

Synthesis of Heterocyclic Compounds.

Synthesis of complex alkaloids[9] and 4-methoxycarbonyl-α-pyrone (eq 5)[1] are based on successive reactions towards both functions of diethoxy-[9] or dimethoxyacetaldehyde.[1] Another possibility is the formation of heterocyclic compounds bearing an acetal function.[10-12] For instance, the Pictet-Spengler reaction between tryptophan derivatives and diethoxyacetaldehyde gives substituted tetrahydro-β-carbolines (eq 6).[11]

Reactions with Nucleophiles.

Organomagnesium[18a,21] and organolithium[17,22] compounds as well as metal hydrides[18a] lead to the expected acyloin acetals. As mentioned above, reaction of nitrogen compounds often leads to heterocyclic compounds; however, there are various other interesting possibilities.[18a,23] For instance, a novel synthesis of α-aminoaldehydes involves a substitution reaction between organomagnesium compounds and products obtained from benzotriazole, diethoxyacetaldehyde, and primary or secondary amines (eq 7).[23d]

Other Reactions.

Dialkoxyacetaldehydes are also reagents for preparation of 1,4-dicarbonyl compounds[16] and of chiral α-hydrazono acetals.[24]

Related Reagents.

Pyruvaldehyde Diethyl Acetal; ***Ethyl Diethoxyacetate***; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl Lithioacetate***; ***Glyoxal***; ***Methyl Glyoxylate***.

Glyoxylic Acid

[298-12-4] · $C_2H_2O_3$ · Glyoxylic Acid · (MW 74.04)

(formaldehyde equivalent in Mannich reaction; reagent and its esters undergo a variety of additions, condensations, and Diels-Alder reactions)

Alternate Name: glyoxalic acid; oxoacetic acid.

Physical Data: deliquescent prisms; mp 98 °C (anhydrous), 50-52 °C (monohydrate); pK_a 2.32.

Solubility: sparingly sol ether, alcohol, benzene; v sol water.

Form Supplied in: crystalline solid as monohydrate [*563-96-2*] and in 50% aqueous solution.

Preparative Methods: glyoxylic acid is widely available, but the methyl, ethyl, and benzyl esters can be made easily from the ozonolysis of the corresponding maleate and fumarate esters.[1]

Purification: crystallized from water as the monohydrate.

Handling, Storage, and Precautions: corrosive and hygroscopic.

Mannich and Related Condensations.

Glyoxylic acid (**1**) has been extensively used in the Pictet-Spengler reaction to synthesize various β-carboline derivatives from the corresponding tryptamines (eq 1).[2] Reaction of glyoxylic acid and ***Hydroxylamine*** in water at pH 5 with excess $LiBH_3CN$ at rt affords α-hydroxyaminoacetic acid (eq 2).[3] The reagent reacts with an alkaline solution of *o*-methoxyphenol to form (*R*,*S*)-4-hydroxy-3-methoxymandelic acid (eq 3).[4] On the other hand, condensation of (**1**) with acetophenone gives 3-benzoylacrylic acid.[5]

Treatment of glyoxylic acid with ethyl aminoformate followed by benzothiophene gives *N*-ethoxycarbonylbenzothienylglycine (eq 4) via the Mannich reaction.[6] Reaction of (**1**) with an alkyl- or arylamine in the presence of ***Pentacarbonyliron*** in alcoholic 1N KOH, under an atmosphere of carbon monoxide followed by HCl acidification affords the corresponding *N*-alkyl- or arylglycines (eq 5).[7] Treatment of the thioacetals of various ketones and aldehydes with (**1**) in acetic acid and hydrochloric acid at rt results in transthioacetalization and liberates the carbonyl compounds (eq 6).[8]

(5)

(6)

Glyoxylic acid, in the presence of 2N NaOH in ethanol, adds to 3-nitropropanal ethylene acetal to give 2-hydroxy-3-nitro-5-ethylenedioxypentanoic acid in quantitative yield (eq 7).[9] Reaction of *n*-butyl glyoxylate (**2**) with 1-morpholinocyclopentene in refluxing cyclohexane (Dean-Stark trap), followed by cooling and hydrolysis affords butyl 2-oxocyclopentylideneacetate (eq 8).[10]

(7)

(8)

Treatment of methyl glyoxylate (**3**) with ***(S)-Proline*** in a 2:1 ratio in DMSO at 90 °C gives a diastereomeric mixture of oxapyrrolizidines (eq 9).[11]

(9)

Diels-Alder Reactions.

Methyl or ethyl glyoxylates react with acylaza-Wittig reagents in refluxing benzene to produce the diacylimines, as shown in eq 10.[12] These are moderately reactive dienophiles for Diels-Alder reactions with various dienes, such as the Danishefsky diene[13a] or Cohen diene,[13b] to furnish the corresponding tetrahydropyridines.[12]

(10)

Methyl glyoxylate (**3**) itself undergoes a hetero-Diels-Alder reaction with the Danishefsky diene in refluxing benzene. Hydrolysis of the resultant adduct furnishes a 1:1 mixture of stereoisomers of 2-methoxy-6-methoxycarbonyl-5,6-dihydro-γ-pyrone (eq 11).[12] Similarly, reaction of methyl glyoxylate with 1,1-dimethoxy-3-trimethylsiloxy-1,3-butadiene, catalyzed by $Eu(fod)_3$ in CH_2Cl_2 at rt, regioselectively produces 2-methoxy-6-methoxycarbonyl-5,6-dihydro-γ-pyrone which, on subsequent hydrolysis with dilute aq HCl in refluxing benzene, produces 6-methoxycarbonyl-3-oxo-δ-lactone (eq 12).[14] Hetero-Diels-Alder reaction of *n*-butyl glyoxylate with 2-ethoxy-1,3-butadiene at 60 °C affords 4-ethoxy-6-butoxycarbonyl-5,6-dihydro-2*H*-pyran as the main adduct (eq 13).[15]

(11)

(12)

(13)

Butyl glyoxylate (**2**) undergoes an addition reaction with cyclohexene in the presence of ***Tin(IV) Chloride*** at 40-45 °C to produce butyl 2-hydroxy-2-(2-cyclohexenyl)acetate (eq 14).[16] Methyl glyoxylate undergoes an asymmetric carbonyl-ene reaction with isobutene catalyzed by a chiral titanium complex (generated in situ from ***(R)-1,1´-Bi-2,2´-naphthol*** (BINOL) and ***Dichlorotitanium Diisopropoxide*** over molecular sieves in methylene chloride) to produce (*R*)-methyl α-hydroxy-γ-methyl-4-pentenoate in high optical purity (eq 15).[17] Under similar reaction conditions, methyl glyoxylate (**3**) reacts with the symmetrical bis-allyl silyl ether shown in eq 16 to produce the corresponding α-hydroxy ester (>99% ee) through an asymmetric catalytic desymmetrization (eq 16).[18]

(14)

(15)

(16)

Reaction of methyl or ethyl glyoxylate with (*S*)-4-benzyloxypent-(2*E*)-2-enyl(tributyl)stannane in the presence of $SnCl_4$ at -78 °C produces (1*R*,5*S*,3*Z*)-5-benzyloxy-1-methoxycarbonylhex-3-en-1-ol with excellent diastereoselectivity (eq 17).[19] Ethyl glyoxylate (**4**) undergoes a [3 + 2] cycloaddition with 5-ethoxy-2-phenyloxazole in the presence of a Lewis acid catalyst (a 1:1 mixture of ***Titanium(IV) Chloride*** and ***Titanium Tetraisopropoxide***) to produce a mixture of *cis*- and *trans*-4,5-bis(ethoxycarbonyl)-2-oxazolines in an 84:16 ratio, whereas use of $SnCl_4$ reverses the selectivity and yields the same mixture in a 15:85 ratio (eq 18).[20]

(17)

The imine derived from methyl glyoxylate and di-*p*-anisylmethylamine (DAM-NH_2)[21] reacts with ketene (generated in situ from the reaction of the corresponding alkanoyl chloride and triethylamine in refluxing hexane, benzene or methylene chloride) to afford the corresponding *cis*-4-methoxycarbonyl-β-lactams as single isomers (eq 19).[22]

(α-keto equivalent; alkylation of the anions, aldol condensations, and both 1,2- and 1,4-additions to α,β-unsaturated compounds; thioketene and α-oxo dithioester precursor)

Alternate Name: (**1**) bis(ethylthio)acetic acid; (**2**) 1,3-dithiolane-2-carboxylic acid; (**3**) 1,3-dithiane-2-carboxylic acid.

Physical Data: (**1**) bp 110 °C/0.2 mmHg. (**2**) mp 90-91 °C. (**3**) mp 114.5-116 °C. (**4**) bp 125-127 °C/5 mmHg. (**5**) bp 70 °C/0.1 mmHg. (**6**) bp 105 °C/0.6 mmHg. (**7**) bp 102 °C/2 mmHg. (**8**) bp 75-77 °C/0.2 mmHg.

Preparative Methods: esters (**5**), (**6**), and (**8**) are available from commercial sources. The thioacetal acids may be prepared by thioacetalization of glyoxylic acid monohydrate[3] or by reaction on the appropriate

thiol(ate) with 2,2-dichloroacetic acid (or the diethyl acetal) directly[4] or under phase transfer[5] conditions using Aliquat 336. The esters may be obtained via similar exchange processes or via acid-catalyzed esterification of the corresponding acids.

General.

The most common usage of the above compounds is as α-keto acid equivalents via their corresponding anions (or dianions). There are differences in the reactivity and selectivity of these systems which depend on the nature of the thioacetal as well as the gegenion present in the reaction. Hydrolysis under a variety of conditions to the corresponding ketone[1] or reductive desulfurization[2] generally proceeds in excellent yields.

Alkylation.

The esters may be deprotonated with ***Sodium Hydride*** or comparably strong bases and the resulting anions subsequently alkylated with alkyl halides in good to excellent yields (eq 1).[4,6a,b] The reaction may also be carried out using phase transfer catalysis.[5] Opening of epoxides,[6c] cyclic sulfonates,[6d] and displacement of triflates[6e] also proceeds in good yields. The thioacetal acids may be converted into the corresponding dianion with ***Potassium Hexamethyldisilazide***. The dianions are readily alkylated in high yield by a wide variety of electrophiles (alkyl halides, tosylates, epoxides, *N*-tosylaziridines).[3]

(1)

base: e.g. NaH, LDA, $KN(SiMe_3)_2$, K_2CO_3 (phase transfer)

1,4- and 1,2-Carbonyl Additions.

The anions of several of the esters undergo Michael addition with a wide variety of α,β-unsaturated compounds (aldehydes, ketones, esters, lactones, lactams, and nitroalkenes)[7] in high yields. The role of the gegenion is important in the regioselectivity of this addition (eq 2).[8] The reaction can also proceed under phase transfer[9a,b] (tetrabutylammonium hydrogensulfate) or crown ether (***18-Crown-6***) conditions.[9c] Trapping of the enolate resulting from conjugate addition to ketones with ***Formaldehyde*** provides a route to substituted lactones (eq 3).[10]

(2)

(3)

1,2,4-Benzenetriols may be prepared via a conjugate addition-cyclization-aromatization pathway (eq 4).[11]

(4)

Aldol Condensation.

Condensation of the anions of esters (**6**), (**7**), and (**8**) with aldehydes has been reported.[8,12] The reaction can proceed with excellent diastereofacial selectivity (eq 5).[12a]

Miscellaneous.

Reactive intermediate species have been derived from several of the thioacetals. Reaction of aldehydes with the lithium anion of (**7**) in the presence of ***Trimethylacetyl Chloride*** with subsequent dealkoxycarbonylation forms ketene thioacetals (eq 6).[12c] In addition, reactions of the acid chlorides derived from (**2**) or (**3**) in the presence of base yield products consistent with the formation of a ketene intermediate (eq 7).[13]

Retrocyclizations of *S*-alkylated derivatives of (**6**) yield α-oxo dithioester intermediates which react with alkenes in a Diels-Alder reaction (eq 8),[14] and cycloadditions with styrene derivatives and (**1**) yield 2-(ethylthio)butyrolactones.[15]

Ester (**6**) reacts with various dithiols in the presence of ***Trimethylaluminum*** to produce tetrathiafulvalenes in good yield (eq 9).[16]

(9)

A chiral variant of (**8**) (menthyl ester) has served as an auxiliary (eq 10) in the condensation of aryl alkyl ketones with ***n-Butyllithium*** to produce chiral tertiary alcohols (70%, 55% ee).[17]

(10)

Related Reagents.

1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene; ***1,3-Dithiane***; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl Diethoxyacetate***; ***2-Lithio-1,3-dithiane***; ***Methyl Glyoxylate***; ***8-Phenylmenthyl Glyoxylate***.

Glyoxylyl Chloride *p*-Toluenesulfonylhydrazone[1]

[14661-69-9] · $C_9H_{10}ClN_2O_3S$ · Glyoxylyl Chloride *p*-Toluenesulfonylhydrazone · (MW 261.73)

(synthesis of α-diazo esters and amides[2])

Physical Data: mp 103-110 °C (dec).

Solubility: sol methylene chloride, chloroform, THF, and warm benzene.

Preparative Methods: not commercially available; however, it can be prepared readily by the reaction of ***p-Toluenesulfonylhydrazide*** and ***Glyoxylic Acid***.[2]

Handling, Storage, and Precautions: anhydrous conditions are required; it is advisable to prepare the reagent freshly prior to use.

Introduction.

Glyoxylyl chloride *p*-toluenesulfonylhydrazone (**1**) is a versatile reagent for the synthesis of diazoacetyl esters and amides, which upon heating in the presence of a metal catalysts or irradiation generate reactive carbene intermediates.[1] Compound (**1**) undergoes reaction with alcohols to give the corresponding α-diazoacetyl esters under mild basic conditions. Typically, 2 equiv of ***Triethylamine*** are used in this reaction (eq 1). However, sulfinate species have been reported to contaminate the product.[1b] Corey and Meyers have shown that the formation of this undesired byproduct can be largely circumvented by the use of *N*,*N*-dimethylaniline instead of Et_3N (eq 2).[1b]

(1)

(2)

The existing alternative preparative methods for the α-diazo esters, such as diazotization of glycine esters,[3] pyrolysis of *N*-acyl-*N*-nitrosoglycine esters,[4] base-catalyzed cleavage of α-diazo-β-ketoacetates,[5] reactions of alkoxycarbonylmethylenephosphoranes with arenesulfonyl azides,[6] or acid-catalyzed decomposition of acetic esters with aryltriazene substituents,[7] all suffer from the disadvantage of being multistep synthetic procedures, and that at times harsh conditions (high temperature, strong acid or base) must be employed.

Intramolecular Cyclopropanation.

The resultant α-diazoacetyl ester from the reaction of (**1**) and an unsaturated alcohol undergoes cyclization in the presence of transition metals to give cyclopropyl derivatives (eqs 3, 4); the reaction proceeds via an intermediary carbene species.[1] Owing to the geometric constraints of the intramolecular cyclopropanation, the substituents and the product acquire all-*cis* configurations.[2] This is in contrast to the bimolecular cyclopropanation, which is unable to achieve sterochemical control, resulting in mixtures of products.

C-H and C-C Carbene Insertion Reactions.

Intramolecular carbene insertion at an unactivated bridgehead site is reported from an α-diazoacetyl ester precursor (eq 5).[8]

Decomposition of 6-(α-diazoacetamide)penicillanate in the presence of copper(II) or rhodium(II) in refluxing benzene resulted in the formation of a cycloheptatriene moiety (eq 6).[9]

Photoaffinity Labels.

As an application of the carbene insertion reaction in structural studies of macrobiomolecules, radioactively labeled α-diazo esters have been used as photoaffinity labels.[10] Such esters are designed to bind specific targetted biological receptors (e.g. enzymes, membrane receptor proteins, nucleic acids, etc.). Photolysis of the complex generates the high-energy carbene species that inserts into C-H or X-H (X = a hetero atom) bonds in the receptor molecule readily at ambient temperature. In the absence of a facile insertion reaction, the resultant unquenched carbene may undergo Wolff rearrangement, thereby wasting a percentage of the reactive species for photoaffinity labeling.[11] The structures of a number of such biologically active molecules are shown in (**2**)-(**9**); these molecules are prepared typically by the reaction of reagent (**1**) with the corresponding alcohols in moderate to good yields.[10]

(synthesis of heterocycles;[2] selective deacetylating agent;[3] synthesis of primary amines[4])

Physical Data: mp 48-49 °C; pK_a 13.6.

Solubility: free base readily sol alcohols, water; guanidinium salts of strong acids, e.g. HCl or HNO_3, sol water, DMF, alcohol; guanidinium carbonate water sol but virtually insol alcohol; guanidine acetate sl sol ether, while guanidine nitrate moderately sol acetone; guanidinium salts, in general, insol aliphatic or aromatic hydrocarbons.

Form Supplied in: commercially available salts include the acetate, carbonate, hydrochloride, nitrate, sulfate, and thiocyanate.

Preparative Methods: substituted guanidines can be prepared by several methods. The reaction of an *S*-alkylisothiourea with an amine is one of the oldest and most useful methods but it suffers from production of noxious side products, namely an alkanethiol.[7] An *O*-alkylisourea can also function in a similar manner,[8] although these reagents, generally, are not as reactive as the *S*-alkylisothioureas. Direct oxidation of ***Thiourea*** and substituted thioureas to sulfonic acids prior to reaction with amines avoids the problems of thiol production. The intermediate sulfonic acids are at least as reactive as the *S*-alkylisothioureas.[9] ***Cyanamide*** and substituted cyanamides react with amines or ammonium salts to produce guanidines.[10] This approach can be useful to prepare certain hindered guanidines, e.g. derivatives of ***t-Butylamine***.[11] Addition

of amines or ammonia to a disubstituted carbodiimide yields guanidines, but this method is limited by the availability of the carbodiimide.[11] Reaction of amines with either 1-guanyl-3,5-dimethylpyrazole nitrate[10] or 1-guanylpyrazole hydrochloride[12] affords good yields of substituted guanidines.

Handling, Storage, and Precautions: the free base is very hygroscopic and readily absorbs CO_2 from the air. It is liberated from a salt and used in situ. Hydrolysis occurs slowly at room temperature but more rapidly at elevated temperatures or in the presence of alkali to yield urea, then CO_2 and NH_3. Guanidinium salts of strong acids are stable to boiling water. Toxic fumes of NO_x are given off when guanidine is heated to decomposition. Use in a fume hood. Guanidine hydrochloride liberates toxic fumes of HCl and NO_x when heated to decomposition.[5] Guanidine nitrate is both a powerful oxidant and high explosive; *a warning cautioning against its preparation has been published.*[6]

Heterocycle Synthesis: Five-Membered Rings.

Synthesis of five-membered heterocycles proceeds well from guanidine and various bis-electrophiles. ***Glyoxal*** dihydrate condenses with monosubstituted guanidinium salts in aqueous solution to yield a mixture of *cis*/*trans* 1:1 adducts identified as 2-amino-4,5-dihydro-4,5-dihydroxy-1-substituted imidazolium salts.[13] Similarly, 1,1-disubstituted guanidinium salts react with 1-phenyl-1,2-propanedione in methanol to afford 2-(disubstituted amino)-4-hydroxy-4-methyl-4*H*-imidazoles, from which the corresponding imidazoles are available via catalytic hydrogenolysis.[14] A series of 2-amino-4-arylimidazoles has been prepared from cyclization of guanidine with an acetophenone using bromine as a condensing agent. Under these reaction conditions, the in situ generated phenacyl bromide reacts rapidly with guanidine to yield the product (eq 1).[15] When benzil is condensed with guanidine carbonate in ethanolic KOH, a good yield of 5,5-diphenyl-2-iminohydantoin is obtained. When 1-methylguanidine was used, this reaction afforded a 2.2:1 mixture of 5,5-diphenyl-2-methyliminohydantoin and 3-methyl-5,5-diphenyl-2-iminohydantoin (eq 2).[16]

(1)

Guanidine ring-opening of 1-methylcarbamoylisatin afforded an α-keto acylguanidine which cyclized under the reaction conditions to produce a 3:2 mixture of the disubstituted quinazolin-2-one and the spirohydantoin, respectively (eq 3).[17]

When 2,2-disubstituted propionitriles were cyclized with guanidine in DMF, a series of 5,5-disubstituted imidazolidine-2,4-diimines, including spiro analogs, were obtained.[18] ***Diethyl Oxomalonate*** and guanidine in ethanol give 2-amino-5-ethoxycarbonyl-5-hydroxy-4*H*-imidazolin-4-one in good yield (eq 4).[19] Use of isopropylguanidine affords the corresponding 2-isopropylamino derivative. L-Dehydroascorbic acid undergoes similar reactions. In this case the initially isolated products were refluxed in ethanol to effect dehydration as well.

(4)

Heterocycle Synthesis: Six-Membered Rings.

Cyclization of guanidine with 1,3-bis-electrophiles is one of the oldest and most common methods available for the preparation of 2-aminopyrimidines.[1,2] Isocytosine (**1**) is readily prepared from reaction of guanidine sulfate and formylacetic acid, generated from malic acid under the reaction conditions (eq 5).[20] It can also be prepared by nucleophilic addition of guanidine to C-6 of 1,3-dimethyluracil, with subsequent ring cleavage and cyclization with loss of 1,3-dimethylurea.[21] The cyclization of guanidine with 1,3-diketones, leading to 2-amino-4,6-dialkyl substituted pyrimidines, is pH dependent with optimum conditions found to be pH 9-10.[22] Conjugate addition of guanidine to 1,3-bis(heteroaryl)-2-propenones followed by cyclization affords 2-amino-4,6-bis(heteroaryl)pyrimidines in good yields.[23]

(1)

(5)

Condensation of cyanoacetic esters[24] or alkoxymethylene nitriles[25] with guanidine leads to 2,4-diaminopyrimidines in high yield. Cyclization of guanidine with ethyl acetamidocyanoacetate yields the expected 5-acetamidopyrimidine in high yield.[26] Extension of this methodology to reaction with diethyl ureidomalonate or 5-ethoxycarbonylhydantoin produced the 5-ureidopyrimidine analogs. The ureidomalonates did not react with ***O-Methylisourea*** or *S*-alkylisothioureas (see ***S-Methylisothiourea***).[27] The pyrimidines obtained from reaction of ***Ethyl Ethoxymethylenecyanoacetate*** with guanidine were greatly influenced by the stoichiometry of the reaction, with a fourfold excess of guanidine leading almost exclusively to (**2**) (eq 6).[28]

A simple, one-pot synthesis of 2-substituted 5-vinylpyrimidines involves cyclization of 1-vinylpiperidylacrolein (**4**) with amidines, including guanidine and 1,1-dimethylguanidine (eq 7).[29] Cyclization of acrylates and methacrylates with guanidine in *t*-butyl or isopropyl alcohol at room temperature provides a high-yield synthesis of the rather inaccessible dihydropyrimidines (eq 8).[30] With guanidine and methylguanidine the reaction proceeds in a few hours, whereas both 1,1- and 1,2-dimethylguanidine require 48 h and 1,2,3-trimethylguanidine is unreactive. No reaction was observed using methyl 3,3-dimethylacrylate. [$^{15}N_3$]Guanidine has been prepared and used to prove the mechanism for cyclization of heterocyclic *o*-aminonitriles to fused 2,4-diaminopyrimidines.[31]

(8)

R = H or Me; $R^1 = R^2 = H$; R^3 = H, Me or Et; R^4, R^5 = H or Me

A general synthesis of 2-amino- and 2-substituted amino-1,3,5-triazines involves cyclization of the appropriate guanidine sulfate with ***Tris(formylamino)methane***, a precursor to *N*-formylformamidine, the actual species involved in the reaction (eq 9).[32] Best results were obtained using a 1:2 ratio of guanidine to tris(formamido)methane. To prepare 2,4-diamino-1,3,5-triazine, guanidine has been treated with *N*,*N*-dimethylformamide dimethyl acetal (see ***N,N-Dimethylformamide Diethyl Acetal***).[33] This method could be used to prepare 2,4-bis(alkyl)- and -(aryl)amino-1,3,5-triazines from the corresponding monosubstituted guanidine, although mixtures of products and modest yields were reported in some cases. Guanidine reacts with an azirineacrylate in DMSO via addition to C-2 followed by C-C bond cleavage to yield, ultimately, a trisubstituted 1,3,5-triazine (for R = H) after air oxidation (eq 10).[34]

(9)

R = H, alkyl, aryl

For R = Me, with oxidation no longer possible a bicyclic lactam was isolated, although it was not possible to distinguish between the regioisomers. In the presence of excess NaOMe, guanidine reacts with some benzaldehydes to produce 2,4-diamino-6-aryl-1,3,5-triazines.[35] These have been postulated to arise via an intramolecular oxidation-reduction of the initially formed bis-aldimine. Deuterium labeling studies and isolation of Cannizzaro reaction products support this hypothesis. Reaction of guanidine carbonate with a pyridinesulfonyl chloride gave a sulfonylguanidine, which was cyclized to 3-amino-4*H*-pyrido[4,3-*e*]-1,2,4-thiadiazine 1,1-dioxide (**5**) (eq 11).[36] The 3-monoalkylamino analogs, evaluated as potassium channel openers, were prepared by amine displacement of the 3-methylmercapto derivative, presumably to avoid regioisomer formation expected using a monosubstituted guanidine.

A key step in the synthesis of ptilocaulin (**7**), an antitumor antibiotic isolated from a marine sponge, is conjugate addition of guanidine to enone (**6**) with subsequent cyclodehydration (eq 12).[37] In an alternative approach, the tricyclic guanidine was prepared by guanylation of an amino ketone and subsequent cyclization.[38]

(12)

Selective Deacetylating Agent.

Guanidine selectively deacetylates phenolic acetates in the presence of benzylic acetates.[3] Acetamides, methyl esters, benzoates, and pivalates are stable to the reaction conditions. Peracetylated carbohydrates can be instantaneously and quantitatively deacetylated using a 1:1 molar ratio of carbohydrate to guanidine. The stereochemical integrity of the products was not described.

Synthesis of Primary Amines.

Treatment of primary bromides, allylic and benzylic halides with guanidine followed by base affords the corresponding primary amine.[4]

Miscellaneous.

Acylation of guanidine by α-amino esters produces amino acid acylguanidines which were explored as intermediates in peptide bond formation.[39] Guanidine has been used to effect both ester hydrolysis and epoxide ring opening in a single step.[40] Direct phosphorylation of guanidine can be accomplished in good yield using diisopropyl phosphite in CCl_4 in the presence of NaOH.[41] The reaction also works well with *S*-alkylisothioureas.

Related Reagents.

Aminoiminomethanesulfonic Acid; ***Formamidine Acetate***; ***S-Methylisothiourea***; ***O-Methylisourea***; ***1H-Pyrazole-1-carboxamidine Hydrochloride***.

Hexabutyldistannane[1]

Bu_3Sn-$SnBu_3$

[813-19-4] · $C_{24}H_{54}Sn_2$ · Hexabutyldistannane · (MW 580.20)

(source of tributylstannyl radicals; used in palladium-catalyzed tin-carbon bond formation; used for deoxygenation and desulfurization reactions)

Alternate Name: hexabutylditin.

Physical Data: bp 147-150 °C/0.2 mmHg, 198 °C/10 mmHg; *d* 1.1520 g cm^{-3}; *n*20D = 1.5120.

Solubility: sol most organic solvents.

Form Supplied in: colorless oil; readily available and not expensive.

Analysis of Reagent Purity: ^{119}Sn NMR recommended (δ -83 ppm, $^1J(^{119}Sn\text{-}^{119}Sn)$ 2748 Hz).[9]

Preparative Methods: various methods are available. The classical method uses ***Tri-n-butylstannane*** and either ***Bis(tri-n-butyltin) Oxide*** (0.5 equiv), tributyldiethylaminotin, or ***Tri-n-butyl(methoxy)stannane*** in yields of 90-98%.[2] Since hexabutyldistannoxane is commercially available and not air-sensitive, its use is preferable. A second method involving the stannoxane involves its treatment with metals (Mg, Na, K, Ti/K); the yields lie between 70 and 80%.[3]

It can also be obtained from ***Tri-n-butylchlorostannane*** and either lithium, sodium,[4] or magnesium,[5] from tributyltin chloride and ***Tri-n-butylstannyllithium***[7] (the latter from tributyltin hydride and ***Lithium Diisopropylamide***[6]), or by catalytic elimination of hydrogen from tributyltin hydride. This can be effected either by various bases[8a] or by palladium catalysts such as ***Tetrakis(triphenylphosphine)palladium(0)***.[8b]

Purification: reversed-phase flash chromatography using C-18.[10]

Handling, Storage, and Precautions: must be stored in the absence of oxygen, moisture, and light (preferably under argon). Highly toxic. Use in a fume hood.

Introduction.

General aspects of the preparation and chemistry of hexaalkyldistannanes are reviewed in the Houben-Weyl volume on organotin compounds (literature coverage up to 1977).[1]

The chemistry of hexabutyldistannane is determined by the weakness of the tin-tin bond and dominated by three aspects:

- 1)it dissociates on heating to give tributylstannyl radicals, which are of considerable importance in organic synthetic transformations;
- 2)under the influence of palladium catalysts it can be used for tin-carbon bond formation in the sense of either substitution reactions or addition reactions to multiply bonded systems;
- 3)it can readily take up oxygen or sulfur and can thus be used for deoxygenation and desulfurization reactions.

It can also be used for the preparation of other organometallic reagents via transmetalation.

Use as a Source of Tributylstannyl Radicals.

Thermolysis or photolysis of hexabutyldistannane generates tributylstannyl radicals; these can in turn be used to generate other synthetically useful radicals, for example carbon radicals from reactions with organic halides or sulfides.[11] This reaction has the advantage over generation of stannyl radicals from triorganotin hydrides in that the latter can act as powerful hydrogen donors and thus strongly influence subsequent reactions.

The distannane can also be used in less than stoichiometric amounts, the reactants being irradiated in the presence of a small amount of the distannane (generally 0.1-0.3 equiv). This so-called atom transfer method has been developed by Curran and also applied by other authors. Examples include the radical cyclization of α-iodo ketones (or esters with a suitably placed double bond) (eq 1),[12] annulation reactions of iodomalonates (eq 2),[13] cyclizations of unsaturated α-iodocarbonyls,[14] and radical cyclization of α-fluoro-α-iodo and α-iodo esters and amides (eq 3).[15] A novel cyclization of an iodoepoxide to a cyclopentanol possessing the hydrindane skeleton has also been reported (eq 4).[16] This type of reaction may be subject to a temperature effect; thus the cyclization of allylic α-iodo esters and amines proceeds much more efficiently at 80 °C than at 25 °C.[17]

(1)

(2)

(3)

(4)

An in situ generation of nitrile oxides via photolysis of hexabutyldistannane has been reported (eq 5).[18]

(5)

Palladium-Catalyzed Reactions.

These can be of two types, either substitution of a (generally halide) ligand by a tributylstannyl group or addition to multiple bonds. These reactions have been reviewed by Stille[19] and Mitchell.[20]

The substitution reactions provide a useful alternative to the conventional use of ***Tri-n-butylstannyllithium***, which is a very strong base. The halides used have mainly been aryl or heteroaryl halides, while ***Tetrakis(triphenylphosphine)palladium(0)***, dichlorobis(triphenylphosphine)palladium(II), and ***Bis(allyl)di-μ-chlorodipalladium***/***Tetra-n-butylammonium Fluoride*** have been employed as catalysts.

The synthesis of symmetrical biaryls has been described.[21] This principle has recently been applied in an intramolecular manner and extended to include more complex cyclization reactions. Thus as well as two (symmetrical or mixed) aryl and benzyl halide moieties, a combination of two aryl iodide moieties with a carbon-carbon double or triple bond can be used (eq 6).[22]

(6)

Unfortunately the reaction of Bu_6Sn_2 with acyl halides is not suitable for the preparation of tributylacylstannanes, in contrast to the corresponding reaction of ***Hexamethyldistannane***.[23]

A further interesting development is the use of three-component systems: a mixture of hexabutyldistannane, an allyl halide or carbonate, and a heteroaryl bromide leads to allylation of the heteroaromatic moiety; the catalyst used was the somewhat exotic ***Dichloro[1,1´-bis(diphenylphosphino)ferrocene]palladium(II)***.[24] This method avoids the prior preparation of organotin reagents (eq 7).

(7)

In the case of the addition reactions, hexabutyldistannane adds readily to a variety of allenes; it is often possible to

distinguish a kinetic and a thermodynamic product (eq 8).[25]

On the other hand, the addition to alkynes does not proceed in a quantitative manner at atmospheric pressure (in contrast to the behavior of hexamethyldistannane), though it can be forced to do so by the application of high pressure.[26]

Deoxygenation and Desulfurization Reactions.

The deoxygenation of amine oxides has been described,[27] as has the photo-desulfurization of 1,3-dithiole-2-thiones to give tetrathiofulvalenes.[28]

Use as a Source of Other Tributylstannylmetal Compounds.

Hexabutyldistannane can be cleaved by lithium metal[29] or a lithium alkyl (e.g. MeLi)[30] to give tributylstannyllithium. These methods cannot be recommended: Bu_3SnLi can be better obtained either in a one-step process from Bu_3SnCl and Li (via Bu_6Sn_2 which is not isolated) or from the reaction between Bu_3SnH and LDA[6] (see ***Tri-n-butylstannyllithium*** for details). Hexabutyldistannane can also serve as a source of stannylcuprates ($Bu_3SnCu(CN)Li$, $(Bu_3Sn)_2Cu(CN)Li_2$, $Bu_3Sn(R)Cu(CN)Li_2$).[31]

Use in Electron-Transfer Reactions.

It has been shown in a very recent development that Bu_6Sn_2 (and in addition Bu_4Sn) can take part in novel substitution reactions when allowed to react with pyridine derivatives.[32] Thus treatment of 4-cyanopyridine with Bu_6Sn_2 leads to a new type of *ipso* substitution accompanied by a substitution of the type observed when lepidine reacts with Bu_6Sn_2 and *t*-butyl bromide (eqs 9 and 10)

Hexacarbonylchromium[1]

$Cr(CO)_6$

[13007-92-6] · C_6CrO_6 · Hexacarbonylchromium · (MW 220.06)

(catalyst for alkene isomerization, hydrogenation of 1,3-conjugated dienes, oxidation of allylic and benzylic positions; reagent for preparation of tricarbonyl(arene)chromium and Fischer carbene complexes)

Alternate Name: chromium hexacarbonyl.

Physical Data: sublimes at 50-80 °C; mp 154-155 °C (in sealed tube); *d* 1.77 g cm^{-3}.

Solubility: insol water, ethanol; slightly sol ether, $CHCl_3$.

Form Supplied in: white solid; widely commercially available.

Handling, Storage, and Precautions: highly volatile and must be stored and used in a well ventilated fume hood.

Oxidation.

Treatment of alkenes with ***t-Butyl Hydroperoxide*** in the presence of 0.5 equiv of $Cr(CO)_6$ or $Cr(CO)_x(MeCN)_y$ species in refluxing MeCN results in the oxidation of allylic methylene groups to give α,β-unsaturated ketones selectively in the presence of certain alcohols (eq 1).[2] Benzylic positions are also oxidized to phenyl ketone derivatives[3] under the same conditions (eq 2).

(1)

(2)

Hydrogenation and Isomerization of Dienes.

The catalytic behavior of (arene)$Cr(CO)_3$ complexes has been exploited in the homogeneous regioselective 1,4-hydrogenation of dienes to *cis*-alkenes.[4] Only 1,3-dienes that can easily achieve the less stable *s-cis* configuration to undergo this catalytic hydrogenation (eq 3). Similar catalytically active species $Cr(CO)_3H_2$(diene) (**1**) can be generated photochemically from $Cr(CO)_6$ or from kinetically thermally labile π-bonded ligated complexes (naphthalene, anthracene, MeCN) in coordinating solvents (THF, acetone, dioxane) under milder conditions (eq 4).[5] This regioselective hydrogenation of dienes can be applied to the total synthesis of complex natural products (eq 5) such as carbacyclin, cyanopcarbacyclin, and deplanchein.[6] 1,4-Hydrosilylation of dienes is also achieved to produce (*Z*)-allyltrimethylsilanes[7] under these conditions. The (arene)chromium complexes are superior catalysts for stereoselective hydrogenation of alkynes to (*Z*)-alkenes, and in addition, cisoid α,β-unsaturated enones and imines can be reduced.[8]

(3)

(4)

(1)

Chromium hexacarbonyl offers a highly regioselective method for the isomerization of cisoid 1,3-dienes to transoid dienes (eq 6).[9] (Naphthalene)chromium tricarbonyl catalyzes isomerization of silyloxymethylbutadiene derivatives to silyl dienol ethers in quantitative yields via a U-shaped pentadienyl intermediate (eq 7).[10]

(Arene)Cr(CO)$_3$ Complexes.

Complexation of an arene ring to the chromium tricarbonyl unit is easily accomplished by simple heating with $Cr(CO)_6$ or by ligand transfer with $Cr(CO)_3L_3$.[1,11] The significant properties of (arene)chromium complexes in organic synthesis are as follows: nucleophilic substitution to arene ring; enhancement of acidity of aromatic hydrogen; enhancement of acidity of benzylic hydrogen; enhancement of solvolysis at the benzylic position; and steric hindrance of the $Cr(CO)_3$ group.

Nucleophilic Substitution.[1]

Some carbon nucleophiles add to tricarbonyl(arene)chromium complexes to yield anionic η^5-cyclohexadienyl complexes (**2**) (eq 8), which give the substituted arenes via decomplexation by oxidation with iodine. Protolysis of the intermediate cyclohexadienylchromium complexes (**2**) generate cyclohexadienes, and reaction with electrophiles generates either the arene chromium complexes or produces the acylated species.

(8)

With substituted aromatics, the following regioselectivity for nucleophilic substitution is generally observed (eq 9); alkoxy substituents strongly direct to the *meta* position, and trimethylsilyl groups ensure *para* substitution.[12] Alkylation of the chromium complexes of indoles and benzofurans takes place at the C-4 or C-7 position, depending on the steric effect of the C-3 substituent.[13] Intramolecular nucleophilic alkylation can also be achieved; the products formed depend on chain length, reaction conditions, and other substituents on the aromatic ring (eq 10).[14] With an (anisole)chromium complex, 3-substituted cyclohexenone derivatives can be obtained by the protolytic cleavage of the intermediates (eq 11).[17] A combination of the intramolecular alkylation with protolysis gives an elegant synthesis of the spiro sesquiterpenoids acorenone and acorenone B (eq 12).[15,16]

Reaction with a range of electrophiles regenerates the (arene)chromium complexes under reversible conditions, but electrophilic attack upon the cyclohexadienyl complex formed under irreversible conditions from dithiane carbanions produces *trans* addition products (eq 13).[17]

Lithiation.

With anisole, fluorobenzene, and chlorobenzene chromium complexes, lithiation always occurs at an *ortho* position of the substituents under mild conditions (eqs 14 and 15).[18] Protected phenol or aniline chromium complexes with sterically bulky substituents produce *meta* lithiation exculsively.[19] The lithiated position of some (arene)chromium

complexes (**3**) differs from that of the corresponding chromium-free compounds (**4**).[20]

Y = H, OMe, F, Cl; $E^+ = CO_2$, MeX, TMSCl, aldehydes, ketones

(3) **(4)**

Activation of the Benzylic Position.

Both chromium complexed carbanions and carbocations are stabilized at the benzylic position.[21] Dialkylation of alkyl halides at the benzylic position occurs via stabilized carbanions under mild conditions (eq 16).[22] Regio- and stereoselective products are obtained via the benzylic carbanions, depending on the conformation of the tricarbonyl group to the arene (eq 17).[22] (Styrene)chromium complexes stabilize negative charges at the benzylic position by addition of nucleophiles to the β-position, giving bifunctionalization products by trapping with electrophiles (eq 18).[23]

(16)

(17)

(18)

Tricarbonylchromium stabilized benzylic carbocations can be captured by a large variety of nucleophiles,[24] such as alcohols, amines, thiols, nitriles, trimethylsilyl enol ethers, allylsilanes, electron-rich aromatics, dialkylzincs, and

trialkylaluminums (eq 19). The relative stereochemistry formed during these reactions via carbocations in acyclic systems proceeds with net retention.[21b,c,25] Friedel-Crafts acylation of (styrene)chromium complexes has been explored via the benzylic cations (eq 20).[26] Tricarbonylchromium-stabilized oxonium ions are also utilized for steroselective carbon-carbon bond forming reactions (eq 21).[27]

(19)

(20)

(21)

Steric Effect of the $Cr(CO)_3$ Group.[1]

A feature of (η^6-arene)chromium complexes is the steric interference offered to the approach of reagents, which occurs exclusively from the *exo*-face at the reactive center in cyclic chromium complexes (eq 22).[28] Even in the (acyclic arene)chromium complexes, such as *o*-substituted benzaldehyde and phenyl alkyl ketones with electron-donating *ortho* substituents (OMe, Me, F), addition of nucleophiles to the chromium complexed benzylic carbonyl group proceeds stereoselectively, giving one diastereomeric complex predominantly (eq 23).[29] A Friedel-Crafts reaction produces predominantly an *exo*-substituted complex (eq 24).[30]

(22)

(23)

(24)

A 1,2 or 1,3 unsymmetrically disubstituted arene is prochiral and therefore the corresponding chromium tricarbonyl compounds are chiral.[31] (Substituted arene) complexes with amine, carboxyl, and formyl groups at the *ortho* position are resolved into optically active chromium complexes through corresponding diastereomeric adducts (eq 25).[32] Biocatalysts also perform the kinetic resolution of racemic chromium complexes (eq 26).[33] The optically active

chromium complexes can be prepared by diastereoselective *ortho* lithiation[34] of the chiral benzaldehyde or acetophenone acetal complexes, and diastereoselective chromium complexation[35] of the chiral *ortho*-substituted benzaldehyde aminals (eq 27). Catalytic asymmetric cross-coupling of *meso* (1,2-haloarene)chromium complex produces chiral monosubstituted complexes.[36] The chiral (arene)chromium complexes can be used as ligands in asymmetric reactions.[37]

Hexacarbonylmolybdenum

$Mo(CO)_6$

[13939-06-5] · C_6MoO_6 · Hexacarbonylmolybdenum · (MW 264.00)

(starting material for many organomolybdenum compounds and reagents;[1] can be used as catalyst for catalytic allylations[2] and epoxidations)

Alternate Name: molybdenum hexacarbonyl.

Physical Data: mp 150 °C (dec); *d* 1.96 g cm^{-3}.[3]

Solubility: only very slightly sol most organic solvents; slightly sol THF, diglyme, MeCN.

Form Supplied in: white crystals; commercially available.

Handling, Storage, and Precautions: indefinitely stable at rt under nitrogen or argon. The crystals can be handled in air for short periods with no significant decomposition. Prolonged exposure to air produces some oxidation to a blue oxide. The compound readily sublimes and purification is effected conveniently by sublimation under static vacuum, which yields large crystals of pure material. In most cases, the material can be used as supplied. Owing to the high vapor pressure of the solid, caution should be taken to avoid accidental breathing of the vapor or ingestion of this potentially toxic material; however, $Mo(CO)_6$ is relatively innocuous compared to the high toxicity of liquid metal carbonyls. Many reactions involve displacement of carbon monoxide; hence they should be carried out in an efficient fume hood.

Organomolybdenum Complexes.

Hexacarbonylmolybdenum is the starting material for many organomolybdenum compounds and reagents. It is more readily available and less expensive than its other Group 6 counterparts. Although (arene)molybdenum carbonyl complexes are known, the chemistry of (arene)chromium carbonyl complexes has been better developed. The chemistry of importance to organic synthesis often involves molybdenum carbonyl complexes with cyclopentadienyl or other ligands and this chemistry has been more fully developed than that of chromium or tungsten. Although direct reactions of potential ligands occur with $Mo(CO)_6$, a typical organomolybdenum synthesis would begin by displacing three of the carbonyl ligands with a donor solvent while heating under vigorous reflux (eq 1) to yield a more reactive tricarbonyl intermediate. Displacement of carbonyl groups by other ligands occurs much more readily with $Mo(CO)_6$ than with ***Hexacarbonyltungsten***. For example, the reaction depicted in eq 1 is typically complete within 2 h, whereas the tungsten analog may still only be partially substituted after several days. UV irradiation or use of higher

boiling nitriles also increases the rate of displacement.

$$Mo(CO)_6 + \text{excess } MeCN \longrightarrow Mo(CO)_3(MeCN)_3 + 3\ CO \quad (1)$$

Oxidative additions of allylic halides occur to yield Mo^{II} species which usually contain η^3-allylic moieties.[3] Typical reagents and catalysts are then formed by the addition of lithium cyclopentadienide[3] or bisphosphines[4] (eqs 2-4).

Another convenient starting material is the dimer $[CpMo(CO)_3]_2$, which can be obtained by heating $Mo(CO)_6$ with high-quality cyclopentadiene dimer under reflux,[5] or the air oxidation of $CpMo(CO)_3H$ (not very reproducible),[6] or quite reliably by the oxidation of $CpMo(CO)_3^-$ with ***Iron(III) Sulfate*** (eqs 5 and 6).[7] Although the $CpMo(CO)_3^-$ anion, prepared as in eq 5, is often used directly in the preparation of $CpMo(CO)_3R$ by reaction with alkyl halides, it is more often prepared by reduction of dimer (**5**) with ***Sodium Amalgam*** in THF or by treatment with ***Lithium Triethylborohydride***.[8]

$$CpH + NaH \xrightarrow{THF} NaCp \longrightarrow Na[CpMo(CO)_3] \quad (5)$$

(4)

$$2\ Na[CpMo(CO)_3] + 2\ Fe^{3+} \longrightarrow [CpMo(CO)_3]_2 \quad (6)$$

(5)

Regiochemistry of Allylic Alkylations.

The reaction of the dimethyl malonate anion with an allylic acetate is catalyzed by $Mo(CO)_6$ and several complexes which are readily derived from it. Trost and Lautens[2] have carried out an extensive study of the regiochemistry of these catalytic reactions. A number of these reactions can be carried out stoichiometrically on isolated η^3-allylmolybdenum complexes.[2,4] The mechanism of the catalytic reaction is generally presumed to involve nucleophilic attack on an η^3-allyl intermediate formed via oxidative addition to a Mo^0 complex.[9] One of the classic examples is the reaction of crotyl acetate with an enolate (eq 7).[10]

The regiochemistry of the reaction can be drastically influenced by the ligands on molybdenum and this can provide useful syntheses for regioisomers that might not be available via the more commonly used palladium catalysts. For example, with some nucleophiles the preferred regioisomer for $Mo(CO)_6$ is the reverse of that obtained with a Pd^0 catalyst in eq 8.[2] The $Mo(CO)_6$ catalyst yields a ratio of (**6**):(**7**) of 15:85, whereas ***Tetrakis(triphenylphosphine)palladium(0)*** yields a ratio of 100:0. The $Mo(CO)_4$(2,2´-bipyridyl) catalyst shows better regioselectivity than $Mo(CO)_6$, however, and yields exclusively (**7**). Generally the palladium routes give additions at the least substituted terminus, whereas $Mo(CO)_6$ will often give a greater fraction of addition to the more substituted terminus. This generalization for molybdenum catalysis can vary substantially with nucleophiles, as seen in eq 7.

Another reaction which shows this reversal of regiochemistry between Mo and Pd reagents is the conversion of allylic acetates to allyltrimethylsilanes (eq 9).[11] The palladium-catalyzed reaction gives a ratio of (**8**):(**9**) of 61:39; whereas the $Mo(CO)_6$-catalyzed reaction gives a 0:100 ratio. The molybdenum-catalyzed reaction is also effective with carbonates and provides a route for α-allylation of ketones (eq 10).[12]

(9)

(10)

Although the reaction is stoichiometric, the Mo-catalyzed alkylation of an allyl sulfide results in desulfenylative allylation. The regiochemistry of the addition correlates with the original position of sulfur (eqs 11 and 12).[13]

(11)

Allylic alkylations catalyzed by Pd^0 complexes[14,15] and $Mo(CO)_6$[2,16] occur with net retention of configuration. This is consistent with double inversion, i.e. inversion in forming the η^3-allyl complex and nucleophilic attack *trans* to the metal. The use of chiral nonracemic allylic acetates in Pd-catalyzed reactions has shown that the first step involves inversion.[17] Thus the double inversion mechanism appears to be general for Pd^0. Net retention is also consistent with a double retention mechanism and this may occur in some molybdenum-catalyzed reactions, as suggested by the observation that addition of (*R*)-(*E*)-4-acetoxy-5-methyl-2-hexene to $Mo(CO)_3(MeCN)_3$ occurs with retention.[18] On the other hand, net inversion has been observed in a stoichiometric reaction.[18]

Hydrogenations and Reductions.

Although precious metal catalysts are more often used for hydrogenations, $Mo(CO)_6$ can function as a hydrogenation[19] or transfer hydrogenation catalyst.[20] However, some of the more synthetically useful reactions are those hydrogenations effected by hydrosilanes using catalytic amounts of $Mo(CO)_6$ that provide selective reductions of unsaturated ketones, esters, amides, and nitriles (eq 13).[21]

The low oxidation state of molybdenum in the hexacarbonyl complex gives it reductive capabilities which provide a route for dehydrosulfurization (eq 14).[22] The reaction of alkyl or aryl sulfonyl chlorides with excess (10-30%) $Mo(CO)_6$ in anhydrous tetramethylurea provides a route to disulfides (eq 15).[23]

The oxidative addition of halides to Mo^0 provides an alternate route for dehalogenation of α-halocarbonyl compounds.[24] For α-halo ketones, partitioning between the methyl ketone and the aldol product (eq 16) depends upon

the catalyst.[25] For $Mo(CO)_6$ in 1,2-dimethoxyethane the methyl ketone is formed as the major, if not the only, product. Use of $Mo(CO)_3(NCMe)_3$ with 2-chloroacetophenone allows stabilization and isolation of η^3-allylmolybdenum adducts of condensation of two and three acetophenone units (eq 17).[26]

Epoxidations and Oxidations.

Molybdenum carbonyl can be used as an alkene epoxidation catalyst in conjunction with ***t-Butyl Hydroperoxide***.[27,28] It provides a convenient route for monoepoxidation of 1,5-cyclooctadiene (eq 18).[27] This approach can be useful for epoxidation of enol ethers,[29] which complements approaches using peracids or ***Tetracarbonylnickel***, a far more toxic metal carbonyl.[30] This approach also provides a route to larger ring lactones, such as 6-ketononanolide (eq 19).[31] The molybdenum is oxidized to a peroxy species in these reactions. In the absence of *t*-BuOOH, however, epoxides can rearrange to aldehydes in the presence of catalytic amounts of $Mo(CO)_6$ (eq 20).[32] The $Mo(CO)_6$/*t*-BuOOH system also allows selective oxidation of a secondary alcohol to a ketone in the presence of a primary alcohol (eq 21).[33] The selectivity is improved upon addition of cetylpyridinium chloride.

(20)

(21)

Ring Formation and Opening.

Ring closures in (**10**) have been effected by $Mo(CO)_6$ (eq 22)[34] to form benzocyclobutenones in a stoichiometric reaction. Stabilization of a metallocyclobutene intermediate provides a route to α-naphthols from arylcyclopropenes (eq 23) in a catalytic reaction; however, nearly molar equivalents of $Mo(CO)_6$ increase the yield and the rate substantially.[35]

(22)

(10)

(23)

There are other examples of stabilization of carbene intermediates by molybdenum which are useful in heterocyclic synthesis. Pyrroles have been prepared from α-azidostyrene (eq 24)[36] and 2,5-pyrrolidones have been prepared from azirines and diethyl sodiomalonate (eq 25).[37] Although the reaction can be carried out with SbF_5, $Mo(CO)_6$ also

catalyzes cyclopropane formation for diazo additions to electron-deficient alkenes (eq 26).[38] The (*E*):(*Z*) ratio ranges from 0.7 to 2.2, depending on R^1 and R^2.

(24)

(25)

(26)

The N-O bond is easily cleaved by $Mo(CO)_6$ and this provides a route for conversion of oxime acetates to ketones (eq 27).[39] Ring openings of isoxazoles[40] and isoxazolines[41] provide routes to β-amino-α,β-unsaturated ketones (eq 28) and β-hydroxy ketones (eq 29). This is also a key step in an asymmetric synthesis of α-aminocarboxylic acids from 1-alkoxy-3-siloxy-2-aza-1,3-dienes which has been published recently (eq 30).[42] The acyl nitroso intermediate is generated in situ via oxidation of a hydroxylamine.

(27)

(28)

(29)

(30)

Other Organomolybdenum Reagents.

Recent reviews[43,44] have covered some of the extensive chemistry of organomolybdenum reagents derived from $Mo(CO)_6$, which allows stoichiometric regioselective and stereoselective C-C bond formation. Control of regiochemistry by differences in electronic character of the nitrosyl and carbonyl ligands can be observed in nucleophilic additions to $[CpMo(NO)(CO)(allyl)]^+$ complexes.[45] The stereogenic center at molybdenum has been resolved, which allows the preparation of chiral alkenes in high enantiomeric purity.[45] $[CpMo(CO)(dienyl)]^+$ systems, such as ***Dicarbonyl(cyclohexadiene)(cyclopentadienyl)molybdenum Tetrafluoroborate***, provide routes for stereocontrolled multiple functionalization of cyclohexene rings.[43,46] $CpMo(CO)_2$(2*H*-pyran) cations derived from the chiral pool have allowed enantioselective transformations for replacement of the pyran carbonyl group by two different substituents.[47] CpMo(NO)(halide)(crotyl) complexes, such as ***Bromo(crotyl)(cyclopentadienyl)(nitrosyl)molybdenum***, are useful reagents for stereocontrolled synthesis of β-methyl homoallyl alcohols via crotyl addition to aldehydes.[48] These reagents and their methallyl analogs have been

resolved and yield products of high enantiomeric purity, comparable to those obtained with crotyltitanium, crotylboron, and crotylboronate reagents. The molybdenum reagents have advantages in ease of separation of products and resistance to moisture.

Hexacarbonyltungsten

$W(CO)_6$

[14040-11-0] · C_6O_6W · Hexacarbonyltungsten · (MW 351.91)

(desulfurization[1] and dehalogenation[2] of organic compounds; alkene metathesis catalyst[3])

Alternate Name: tungsten hexacarbonyl.

Physical Data: dec. 150 °C; bp 175 °C.

Solubility: slightly sol alcohol, benzene, ether.

Form Supplied in: white crystals; commercially available.

Purification: recrystallized from diethyl ether or sublimed in vacuo at 65-70 °C. For most purposes, hexacarbonyltungsten is used without further purification.

Handling, Storage, and Precautions: highly toxic.

Desulfurization Reactions.

Treatment of sulfides or thiols with hexacarbonyltungsten leads to cleavage of the carbon-sulfur bond. Reactions proceed readily if the sulfur is in the benzylic position. For example, reaction of methyl 2-naphthylmethyl sulfide (**1**) with hexacarbonyltungsten in refluxing chlorobenzene provides dimeric compound (**2**) and the reduced compound 2-methylnaphthalene (**3**) (eq 1).[4] The reaction is thought to proceed via tungsten-induced homolytic cleavage of the carbon-sulfur bond. The resulting benzylic radical then either undergoes radical-radical coupling or hydrogen abstraction.

Desulfurization of dithioacetals by hexacarbonyltungsten results in dimerization and alkene formation (eq 2). Dithioacetals derived from ketones, aldehydes, and ketenes (eq 3) are all effective in this transformation. The reaction is believed to involve a carbene intermediate, which undergoes dimerization. In cases where the dimerization is inhibited by steric effects, a sizable amount of the thioketone (**7**) is observed (eq 4).[5] The mechanism for thioketone formation involves tungsten-induced homolysis of the carbon-sulfur bond, followed by elimination of ethylene. In addition, the alkene (**10**) was also observed and results from a C-C insertion of the carbene intermediate (**8**).

(4)

Dehalogenation-Dimerization of Geminal Dihalides.

Treatment of geminal benzylic dihalides with hexacarbonyltungsten leads to dehalogenation-dimerization (eq 5).[2] The reaction proceeds through a carbene or carbenoid intermediate, and leads to the more stable alkene stereoisomer. This transformation can also be effected using ***Tungsten(VI) Chloride*** and ***Lithium Aluminum Hydride***. Benzylic alcohols undergo deoxygenation-dimerization under similar conditions (eq 6).

(5)

(6)

Alkene Metathesis.

Irradiation of 2-pentene in the presence of hexacarbonyltungsten in carbon tetrachloride solution leads to a 2:1:1 mixture of 2-pentene, 3-hexene, and 2-butene (each compound is predominantly the *trans* isomer) (eq 7).[3] The true alkene metathesis catalyst is generated from irradiation of hexacarbonyltungsten in carbon tetrachloride, and has not been unequivocally determined.[6]

Hexachloroacetone

[116-16-5] · C_3Cl_6O · Hexachloroacetone · (MW 264.73)

(chlorination of enamines;[1] preparation of trichloroacetamides[2,3] and trichloroacetates[4,5] under neutral conditions; conversion of allyl[6] and cyclopropylcarbinyl[7] alcohols to the corresponding chlorides)

Alternate Name: hexachloro-2-propanone.

Physical Data: bp 66-70 °C/4 mmHg; mp -30 °C.

Solubility: sol CH_2Cl_2, $CHCl_3$, benzene.

Form Supplied in: commercially available as a liquid in 98-99% purity.

Analysis of Reagent Purity: GC, HPLC.

Purification: distillation.

Handling, Storage, and Precautions: is highly toxic and is suspected to be mutagenic. This reagent should be handled in a fume hood.

Chlorination of Enamines.

Hexachloroacetone rapidly reacts with enamines in THF at -78 to 0 °C to give, after acid hydrolysis, good yields of the corresponding α-chloroketones.[1] The reagent does not affect enol ethers, alkenes, or thioethers at rt.

This reagent is reported to provide cleaner products than Cl_2 or NCS in the chlorination of cyclohexanone enamines. For example, treatment of cyclohexanone enamines with hexachloroacetone followed by acid hydrolysis cleanly gives α-chlorocyclohexanone, whereas use of ***N-Chlorosuccinimide*** results in formation of substantial amounts of dichlorinated ketone byproduct. Direct chlorination of the ketone can also be problematic. Treatment of 2-methylcyclohexanone with ***Chlorine*** gives 2-chloro-2-methylcyclohexanone as the major product, plus *cis*- and *trans*-6-chloro-2-methylcyclohexanone along with 2,6-dichloro-2-methylcyclohexanone.

This reagent can exhibit different regioselectivity from other chlorinating agents. For example, the pyrrolidine enamine of 2-methylcyclohexanone reacts with hexachloroacetone to produce a 9:1 mixture of 6-chloro-2-methylcyclohexanone and 2-chloro-2-methylcyclohexanone (eq 1),[1] whereas ***Sulfuryl Chloride*** gives 2-chloro-2-methylcyclohexanone as the predominant product.

(1)

Trichloroacetylation of Alcohols and Amines.

Hexachloroacetone reacts under neutral conditions with dipeptides at rt in DMSO to produce the corresponding trichloroacetamides in high yield.[2] No reaction with the carboxylic acid functional group is observed (eq 2).

(2)

With modification of the reaction conditions, a number of alkyl, aryl, and heteroaryl amines can be efficiently trichoroacetylated using this reagent.[3]

Hexachloroacetone in the presence of a strong hydrogen bond acceptor such as DMF will convert alcohols into the corresponding trichloroacetates in high yield (eq 3).[4] This reaction is sterically sensitive, and thus can be used to selectively acylate less hindered hydroxy groups.[5]

(3)

Chlorination of Allyl and Cyclopropylcarbinyl Alcohols.

Hexachloroacetone reacts with allyl and cyclopropylcarbinyl alcohols in the presence of ***Triphenylphosphine*** to produce the corresponding chlorides. With primary and secondary allyl alcohols, the reaction proceeds to give mostly unrearranged allyl chloride with retention of double bond stereochemistry and inversion of configuration at the hydroxy-bearing carbon (eq 4).[6] Tertiary allylic alcohols predominantly give rearranged products. This reagent system is a useful substitute for ***Triphenylphosphine-Carbon Tetrachloride*** in preparing volatile allyl chlorides that are not easily separable from CCl_4.

(4)

Cyclopropylcarbinyl alcohols react with hexachloroacetone in the presence of triphenylphosphine to give high yields of cyclopropylcarbinyl chlorides that are free of homoallylic rearrangement products (eq 5).[7]

(5)

Related Reagents.

2,3,4,5,6,6-Hexachloro-2,4-cyclohexadien-1-one[1]

[21306-21-8] · C_6Cl_6O · 2,3,4,5,6,6-Hexachloro-2,4-cyclohexadien-1-one · (MW 300.76)

(regioselective chlorination of ketones[2] and phenols;[3] α´-chlorination of α,β-unsaturated ketones[3])

Physical Data: mp 50-51 °C.

Solubility: sol dichloromethane, methanol, ethanol, DMF.

Form Supplied in: crystalline material; commercially available.

Preparative Method: chlorination of the sodium salt of pentachlorophenol at 0 °C (eq 1).[2,4,5]

Analysis of Reagent Purity: mp, ^{13}C NMR.[6]

Handling, Storage, and Precautions: keep in a dark vessel, well protected from light to prevent isomerization (see below). The reagent should always be handled in a well-ventilated fume hood.

Regioselective *ortho*-Chlorination of Phenols and Naphthols.

The chlorination of phenol with 1 equiv of 2,3,4,5,6,6-hexachloro-2,4-cyclohexadien-1-one (**1**) in CCl_4 under irradiation of a 100 W mercury lamp gave rise to 2-chlorophenol and 4-chlorophenol in a 92:8 ratio (eq 2).[5] Similar selectivity was obtained for 4-methylphenol, which by direct chlorination with chlorine leads to mono-, di-, and trichloro derivatives, in addition to some oxidation products. Irradiation may not be necessary, as similar results are obtained on chlorination of phenols with this reagent in dichloromethane (sometimes in the presence of 25% DMF) at rt.[3,7]

The ability of this reagent to effect regioselective *ortho*-chlorination of phenols has been ascribed to charge transfer interactions and hydrogen bonding with the substrate (eq 3). The reagent can differentiate between phenols and phenolic ethers (eq 4).[7] It should be stressed that the isomeric reagent 2,3,4,4,5,6-hexachlorocyclohexa-2,5-dien-1-one gives *p*-chlorination of phenols by similar complexation.[3,7] Naphthols are chlorinated by 2,3,4,5,6,6-hexachloro-2,4-cyclohexadien-1-one to give *o*-chloronaphthols with even better selectivity than for phenols (eq 5).[8] Regioselective *ortho*-chlorination of naphthols substituted with alkoxy groups is cleanly achieved (eqs 6 and 7).[3,8] Again the isomeric 2,3,4,4,5,6-hexachloro derivative affords *p*-chlorinated naphthols preferentially.[8]

(7)

Selective α-Chlorination of Alkyl Aryl Ketones.

Enol derivatives of ketones can participate in donor-acceptor interactions with 2,3,4,5,6,6-hexachloro-2,4-cyclohexadien-1-one. The presence of an electron-rich aromatic ring is a necessary prerequisite for complex formation and the resulting α-chlorination. Aliphatic ketones do not form sufficiently stable complexes with the chlorinating reagent, and thus are not chlorinated.[2] However, alkyl aryl ketones react smoothly with the reagent in ethanol at reflux to give high yields of 1-chloroalkyl aryl ketones (eqs 8-11).[2,3] Chlorination of the aromatic nucleus is not observed in reactions of *p*-hydroxy aromatic ketones (eqs 9 and 10).

(8)

(9)

(10)

(11)

In DMF, however, selective chlorination of the aromatic system again takes precedence (eq 12).[9]

(12)

α,β-Unsaturated ketones are monochlorinated by this reagent at the α´-position (eq 13).[2,3]

(13)

Isomerization.

Care should be taken to avoid isomerization of 2,3,4,5,6,6-hexachloro-2,4-cyclohexadien-1-one to 2,3,4,4,5,6-hexachloro-2,5-cyclohexadien-1-one, because the regiochemical course of chlorinations with this reagent is different.[3,5,7] The former reagent rearranges to the latter by treatment with acid or ***Aluminum Chloride***, by heating, or upon irradiation.[5]

Hexachlorodisilane[1]

Cl_3Si-$SiCl_3$

[13465-77-5] · Cl_6Si_2 · Hexachlorodisilane · (MW 268.88)

(deoxygenation and desulfurization of phosphine oxides, phosphine sulfides, and amine oxides; reducing agent for nitro groups and sulfur diimides)

Physical Data: bp 144-145.5 °C; *d* 1.562 g cm^{-3}.

Solubility: sol $CHCl_3$, CH_2Cl_2, benzene, THF; reacts violently, producing toxic fumes, with H_2O, alcohols.

Form Supplied in: neat as clear colorless liquid.

Handling, Storage, and Precautions: neat liquid and solutions react violently with water and protic solvents to produce HCl gas. Avoid contact with strong bases. Hexachlorodisilane is corrosive and should be handled and stored in a tightly sealed vessel under N_2. Store cool. Vapor ignites in air when heated. Avoid prolonged and repeated exposure. Use in a fume hood.

Deoxygenation and Desulfurization.

Hexachlorodisilane has been shown to effect the stereospecific reduction of phosphine oxides to phosphines with inversion of configuration (eq 1),[2] although short reaction times are required to prevent chemical racemization of the phosphine products under the reaction conditions. This protocol complements ***Trichlorosilane*** which, under appropriate conditions, reduces phosphine oxides with retention of configuration.[2,3] Reductions of bridged bicyclic phosphine oxides[4] and cyclic halophospholene oxides[5] by hexachlorodisilane have also been reported.

(1)

In contrast to the deoxygenation of phosphine oxides by hexachlorodisilane, desulfurization of phosphine sulfides by this reagent occurs stereospecifically with *retention* of configuration (eq 2).[6]

(2)

Quinuclidine *N*-oxide was reduced by hexachlorodisilane (eq 3).[2] Likewise, azo oxide,[7] azo dioxide,[8,9] and sulfoxide deoxygenations[2] by the reagent were also reported. Treatment of aryl nitro compounds with hexachlorodisilane afforded products which suggested the possibility of a nitrene intermediate being involved (eq 4).[10] Other disilanes were evaluated in the study, including hexamethyl- and hexaphenyldisilane, pentamethylphenoxy- and pentamethylphenyldisilane, as well as novel benzodisilacyclopentane (**1**).

(3)

(4)

$SiCl_6$	47%	10%
(1)	1%	71%

(1)

Quinoxaline 1,4-dioxide derivatives were reduced by hexachlorodisilane to give the corresponding quinoxalines (eq 5).[11] Also evaluated in the study were the reducing agents ***Iodotrimethylsilane***, ***Trifluoroacetic Anhydride-Sodium Iodide***, and ***Titanium(IV) Chloride-Zinc*** dust. Hexachlorodisilane, for its convenience and efficiency, was recommended by the authors as the reagent of choice for this transformation.

(5)

Dehydroxylation occurred upon treatment of the alkoxide of a 1-hydroxyimidazole derivative with hexachlorodisilane (eq 6).[12] In the same report it was observed that nitrones are deoxygenated upon treatment with hexachlorodisilane, while C=N reduction occurs to yield hydroxylamines with ***Trichlorosilane*** (eq 7).

(6)

(7)

(Trichlorosilyl)phosphane Synthesis.

Chlorophosphanes or (trimethylsilyl)phosphanes are converted to trichlorosilylphosphanes upon treatment with hexachlorodisilane (eq 8).[14]

Sulfur Diimide Reduction.

N-Trichlorosilyldiaminosulfanes were prepared upon treatment of sulfur diimides with hexachlorodisilane (eq 9).[13] Likewise, the corresponding *N*-dichloromethylsilyldiaminosulfanes resulted by substituting 1,2-dimethyl-1,1,2,2-tetrachlorodisilane for hexachlorodisilane.

Related Reagents.

Trichlorosilane.

Hexachloroethane

Cl_3C-CCl_3

[67-72-1] · C_2Cl_6 · Hexachloroethane · (MW 236.72)

(mild chlorinating agent;[1,2] versatile reagent in organophosphorus chemistry[3-5])

Alternate Name: perchloroethane.

Physical Data: mp 190-195 °C (sublimes); *d* 2.091 g cm^{-3}; rhombohedric crystals from EtOH.

Solubility: insol H_2O; sol organic solvents.

Form Supplied in: white solid; widely available.

Purification: steam distillation, then recrystallization from 95% EtOH.[20]

Handling, Storage, and Precautions: cancer suspect agent; irritant. Use in a fume hood.

Chlorination of Carbon Compounds.

Hexachloroethane is a formal source of electrophilic chlorine in the chlorination of nucleophiles.[1,2] The reagent can conveniently be used in large-scale reactions.[6] THF[7-11] is the solvent of choice for chlorination of aryllithiums (eqs 1 and 2).

(2)

The reactions with Wittig reagents (eq 3) are usually conducted in ether,[12] and sulfoximine derivatives are chlorinated by Cl_3CCCl_3 in DMF.[13] Phase-transfer conditions are recommended for chlorination of allyl sulfones (eq 4)[14,15] and benzyl and benzal chlorides (eq 5).[6]

(3)

(4)

(5)

In a typical reaction, a mixture of equimolar amounts of the substrate and Cl_3CCCl_3, dichloromethane, 50% aq NaOH, and a catalytic amount of tetrabutylammonium bromide (TBAB) is stirred at rt.[15] The phase-transfer catalysis can be aided by sonication in the synthesis of *gem*-bromochlorocyclopropanes by the reaction of an alkene,

Bromoform, and Cl_3CCCl_3 in the presence of powdered ***Sodium Hydroxide***.[16]

Reactions with Organophosphorus Compounds.[3-5]

The important applications of Cl_3CCCl_3 in organophosphorus chemistry are the syntheses of 1-chloro-2-phenyl-2-(trimethylsilyl)-1-phosphaethylene (eq 6),[3,4] tetraphosphacubanes (eq 7),[17] and *trans*-1,2,4,5-tetraphosphatricyclo[3.1.0.0^{2,4}]hexane (eq 8).[18]

(6)

(7)

R = *t*-Bu, 70%;
CMe$_2$Et, 75%;
adamantyl, 30%

A combination reagent, ***Hexamethylphosphorous Triamide***-Cl_3CCCl_3-***1-Hydroxybenzotriazole***, has been used in the synthesis of oligopeptides containing arginine.[19]

Related Reagents.

t-Butyl Hypochlorite; ***Chlorine***; ***Chlorine-Chlorosulfuric Acid***; ***Dimethyl Sulfide-Chlorine***; ***Chlorine Fluoroxysulfate***; ***Chlorine-Pyridine***; ***N-Chlorosuccinimide***; ***Dichlorine Monoxide***; ***Phosphorus(III) Chloride***; ***Sulfuryl Chloride***.

Hexadecacarbonylhexarhodium[1]

$Rh_6(CO)_{16}$

[28407-51-4] · $C_{16}O_{16}Rh_6$ · Hexadecacarbonylhexarhodium · (MW 1065.62)

(catalyst for hydrogenation of alkenes, hydroformylations of alkenes; reducing agent for aldehydes, ketones, and nitro groups; catalyst for carbenoid reactions of diazo compounds)

Physical Data: mp 235 °C;[2] IR (KBr) CO 2073, 2026, 1800 cm^{-1}.[3]

Solubility: sol methanol, ethanol, acetone; slightly sol toluene, benzene, hexane.

Form Supplied in: black crystals.

Preparative Methods: from ***Rhodium(III) Chloride***[5] or from ***Pentacarbonyliron*** and $RhCl_3.3H_2O$.[4]

Catalytic Hydrogenation of Alkenes.

Alkenes are catalytically hydrogenated to alkanes in the presence of $Rh_6(CO)_{16}$,[5] although the reaction is slow in the absence of a ligand such as ***Triphenylphosphine***. Considerable improvement is seen by binding the catalyst to a phosphine-funtionalized polystyrene.[6] In the presence of phosphines, $Rh_6(CO)_{16}$ has been found to be a mild, effective catalyst for the hydrogenation of alkenes.[7] Cyclohexene, for example, can be quantitatively reduced to cyclohexane. Asymmetric hydrogenations have been performed in the presence of ***(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane*** [(+)-DIOP]. *N*-Acylenamine (**1**) was converted to (+)-*N*-acylphenylalanine (**2**) in 40% ee (eq 1) using $Rh_6(CO)_{16}$ and (+)-DIOP.[8] A wide variety of quinolines and isoquinolines have been reduced to 1,2,3,4-tetrahydroquinolines and *N*-formyl 1,2,3,4-tetrahydroisoquinolines in excellent yields under water-gas shift conditions.[9]

(1)

Hydroformylation.

Alkenes undergo hydroformylation to give aldehydes in good yields with $Rh_6(CO)_{16}$ when used as either a homogeneous catalyst or supported on zeolites,[10] to yield mixtures of normal and isoaldehydes.[11] Fluorinated alkenes, however, are hydroformylated with a high degree of selectivity (eq 2), with iso to normal aldehyde ratios of 97:3.[12] Hydroformylations also occur with $Rh_6(CO)_{16}$ under water-gas shift conditions to give mixtures of iso and normal aldehydes,[13] but these conditions have been reported to effect reduction of the resulting aldehydes to alcohols at extended reaction times.[14]

(2)

Reductions of Aldehydes, Ketones, and Aromatic Nitro groups.

Aldehydes and ketones are reduced under water-gas shift conditions to give alcohols in excellent yields.[15] Aromatic nitro compounds are reduced to anilines under similar conditions.[16] *o*-Nitrostyrenes have been converted to indoles (eq 3) in moderate (68%) yields.[17]

(3)

Reductive Amination.

Primary, secondary, and tertiary amines can be produced in good yield by the reaction of aldehydes and ketones with ammonia or amines in the presence of a catalytic amount of $Rh_6(CO)_{16}$ at 100-300 atm synthesis gas (CO/H_2 = 1:1).[18]

Metal Carbene Transformations.

$Rh_6(CO)_{16}$ has been found to be an efficient catalyst for dinitrogen extrusion from diazo carbonyl compounds to generate electrophilic metal carbenes that react with allyl sulfides, amines, or iodides to give ylides which undergo [2,3]-sigmatropic rearrangement to form homoallylic sulfides, amines, and iodides (eq 4) in good yield.[19] These carbenes can also react with alkenes to give cyclopropanes in good yields.[20]

(4)

Decarbonylation of Formate Esters.

Formate esters are decarbonylated at 200-220 °C in 2-methoxyethanol in the presence of 1 mol % $Rh_6(CO)_{16}$ to give alcohols in 69-94% yield.[21] The reaction is effective in decarbonylating secondary as well as primary formate esters, producing only small amounts of alkenes as byproducts.

Related Reagents.

Dirhodium(II) Tetraacetate; ***Dodecacarbonyltetrarhodium***; ***Tetracarbonyl(di-μ-chloro)dirhodium***.

N-[(Hexadecyloxy)sulfonylethyl]-*N,N,N*-trimethylammonium Fluorosulfate[1]

[66143-52-0] · $C_{21}H_{46}FNO_6S_2$ · *N*-[(Hexadecyloxy)sulfonylethyl]-*N,N,N*-trimethylammonium Fluorosulfate · (MW 491.81)

(alkyl transfer agent[1,2])

Alternate Names: 2-[(hexadecyloxy)sulfonyl]-*N,N,N*-trimethylethanaminium fluorosulfate; hexadecyl [2]betylate fluorosulfate.

Physical Data: white solid.[2]

Solubility: sol H_2O, MeOH, organic solvents (e.g. DME, toluene), two-phase H_2O-organic solvent mixtures.[2]

Analysis of Reagent Purity: [2]betylates show a characteristic signal (typically a broad singlet) at ~3.7 ppm in the ^1H NMR spectrum.[2]

Preparative Methods: [2]betylates (**3**) are prepared[2] from alcohols by the sequence ROH -> (**1**) -> (**2**) -> (**3**) (eq 1). Vinylsulfonyl chloride is easily made by the action of ***2,6-Lutidine*** or cold ***Triethylamine*** on 2-chloroethanesulfonyl chloride,[3,4] which is obtained commercially or made from sodium 2-hydroxyethanesulfonate (sodium isethionate) and ***Thionyl Chloride*** with a catalytic amount of DMF.[5]

(1)

Handling, Storage, and Precautions: [2]betylates (**3**) are usually prepared as needed, but may be stored under dry conditions for extended periods.

Alkyl Transfer Intermediates.

Betylates [$Me_3{+}N(CH_2)_nSO_2OR\ X^-$] are useful intermediates, enabling an alcohol to transfer its alkyl group to a variety of nucleophiles to form a wide array of products (eq 2). (The byproduct in these reactions is a betaine; hence the nickname betylate.)

(2)

Of the various betylates, those with n = 2 ([2]betylates) offer the most serviceable combination of ease of preparation and handling, and general reactivity under neutral or acidic conditions. [0]Betylates (n = 0) are extremely reactive and not usually isolated;[6] [3]- and [4]betylates (n = 3, 4) are less conveniently made than [2]betylates, but can be used in much more basic media.[2]

The title compound and related alkyl [2]betylates react readily (rt, 0.5-24 h) with a wide variety of water-soluble nucleophiles (***Sodium Azide***, ***Sodium Thiocyanate***, KBr, NaCl, KNO_3, ***Thiourea***, Na_2SO_3 and ***Sodium Thiosulfate***), either

in water or in such two-phase aqueous-organic mixtures as CH_2Cl_2-H_2O, to give the alkyl transfer products (azide, thiocyanate, bromide, etc.) in fair to excellent yields. Other tested alkyl groups include butyl, 1-methylheptyl, 3-phenylpropyl, and docosyl.[2]

The nucleophile may be made the counterion of the betylate cation (by ion extraction or with an ion-exchange resin); the salt so obtained may lead to a substrate-reagent ion-pair (SRIP) reaction,[2] as in eq 3. Nu^- in eq 3 may be not only I^-, SCN^-, picrate, and formate, but also ClO_4^-, FSO_3^-, $CF_3SO_3^-$, $CH_2{=}CHSO_3^-$, etc., yielding the alkyl perchlorate, fluorosulfate, triflate, or vinylsulfonate in fair to excellent yields.[2] SRIP reactions also take place with norbetylates (**4**), produced by addition of the conjugate acid of the nucleophile to the alkyl 2-(dimethylamino)ethanesulfonate (**2**).[2]

$$RO\overset{+}{S}O_2CH_2CH_2NMe_3\ Nu^- \xrightarrow{\Delta} RNu + Me_3\overset{+}{N}CH_2CH_2SO_3^- \qquad (3)$$

SRIP reactions at a chiral secondary center go with complete inversion of configuration. (*S*)-(+)-2-Iodooctane was obtained in high optical purity (i.e. without subsequent racemization by I^-) from (*R*)-1-methylheptyl [2]betylate iodide.[2] (*R*)-2-Octanol was converted into both (*S*)-2-bromooctane and (*R*)-2-bromooctane by the sequence shown in eq 4.[2]

(4)

The betylate procedure was found[7] to be valuable for introducing the isobutyl group to make (**5**) (eq 5).

2*H*-Hexafluoropropyl Azide

[2991-70-0] · $C_3HF_6N_3$ · 2*H*-Hexafluoropropyl Azide · (MW 193.07)

(mild fluorinating reagent for oxidative fluorination of P^{III} compounds[1-3])

Alternate Name: hexafluoroazidopropane.

Physical Data: bp 51-53 °C.

Solubility: insol water; sol most organic solvents.

Preparative Methods: readily prepared from hexafluoropropene (CF_2=$CFCF_3$) and ***Sodium Azide*** in alcohols.[1,4] Synthesis of up to 134 g has been described.[1]

Handling, Storage, and Precautions: easily handled and stored (several months in dark glass vessel at rt), provided due care is taken: avoid sharp strikes and heating. Explosions have not been reported, but a protective shield should always be used. Use in a fume hood.

Fluorination.

The reaction of $CF_3CHFCF_2N_3$ with various P^{III}-containing substrates results in oxidative fluorination (eq 1).[1-3] Usually the reactions are performed without solvent, the highly volatile CF_3CHFCN byproduct (bp 39-41 °C) being easily removed. The reaction has been applied to fluorophosphites, trialkyl phosphites, halophosphines, amidophosphites, and hydrophosphoryl compounds.

An unusual Arbuzov rearrangement was observed in the case of alkyl difluorophosphites, $ROPF_2$. If R = isobutyl or neopentyl, rearrangment to a corresponding tertiary group is observed (eq 2).[1]

(2)

Other Properties.

The azide decomposes slowly under heat or UV irradiation to give 3*H*-hexafluoro-2-aza-1-butene (eq 3).[5]

Hexa-μ-hydrohexakis(triphenylphosphine)hexacopper[1]

$[(Ph_3P)CuH]_6$

[33636-93-0] · $C_{108}H_{96}Cu_6P_6$ · Hexa-μ-hydrohexakis(triphenylphosphine)hexacopper · (MW 1961.16)

(chemo- and stereoselective conjugate reduction;[2,3] catalytic, hydride-mediated, reduction of enones and ketones;[4] reduction of alkynes and propargyl alcohols to *cis*-alkenes[5])

Alternate Name: triphenylphosphine copper hydride hexamer.

Physical Data: mp 111 °C (dec).[1b]

Solubility: sol benzene, toluene, THF (~1 g/10 mL); reacts with CH_2Cl_2 and $CHCl_3$.

Form Supplied in: bright red crystals to dark red powders; commercially available.

Analysis of Reagent Purity: assay by means of hydrogen evolution.[1b] ^1H NMR spectroscopy (deaerated benzene-d_6) shows ligated and, if present, free Ph_3P.

Preparative Method: prepared by hydrogenolysis of Ph_3P-stabilized ***Copper(I) t-Butoxide***,[1c,d] which can be generated in situ from *t*-BuONa and ***Copper(I) Chloride***.[1e]

Purification: Ph_3P is removed by recrystallization from benzene layered with hexanes or acetonitrile under anaerobic conditions, or by trituration with deaerated hexanes or acetonitrile.[1e]

Handling, Storage, and Precautions: has an indefinite shelf life if stored under an inert atmosphere; can be handled briefly in the air without harm and is stable toward water. The reagent is highly air sensitive in solution; thus only rigorously deoxygenated solvents should be used. For bench top manipulation, transfer of the bulk reagent to a Schlenk tube that can be easily opened under a purge of inert gas and evacuated and backfilled after each use is recommended.

Stoichiometric Reductions.

$[(Ph_3P)CuH]_6$ provides stoichiometric conjugate reduction of α,β-unsaturated ketones,[2,3] esters,[2a,3a] aldehydes,[2c] nitriles,[6a] sulfones, and sulfonates.[3b] The reagent is highly chemoselective. Isolated alkenes, carbonyl groups, halogens, and typical oxygenated functionality are not reduced under the reaction conditions (eq 1).[2,3]

When reducing substrates that are prone to aldol and Michael type reactions, it is advisable to include 5-20 equiv deaerated water in the reaction medium to hydrolyze the intermediate copper enolate. However, reductions run in wet solvents or in the presence of a chlorotrialkylsilane require a slight excess of the reagent to completely consume starting material (0.18-0.5 equiv $[(Ph_3P)CuH]_6$).[2,3]

Initial 1,2-reduction is not competitive and further reaction of the carbonyl product resulting from conjugate reduction is generally only observed with enals. Over-reduction is prevented by running the reactions in the presence of a chlorotrialkylsilane (eq 2).[2c] Both ketone and aldehyde enolates are thus trapped as their corresponding silyl enol ethers. Alternatively, in the presence of water and excess hydride, some enals can be completely reduced to the saturated alcohol.[2c]

Stoichiometric reductions are performed at rt in wet deaerated benzene or THF at or below the solubility limit of the reagent.

Starting material may remain during reduction of sterically demanding substrates, especially at higher dilution (eq 3).[6b] Performing such reductions as concentrated suspensions and/or by adding the reagent dropwise to a heated solution of the substrate can help alleviate this difficulty as well as shorten the reaction time.

Aside from offering broad chemoselectivity and complete regioselectivity, the reagent is highly stereoselective, delivering hydride to the less hindered face of the substrate (eqs 3 and 4).[2a,b,3] The selectivity exhibited towards 3,5-dimethylcyclohexanone (eq 4) is superior to that observed using either Boeckmans' hydridocuprate (9:1)[7a] or catalytic hydrogenation (15:1).[2a] The *cis* selectivity obtained when reducing tetra- and hexahydronaphthalen-6(7*H*)-ones (eq 3) parallels that observed with catalytic hydrogenation[8] and exceeds the selectivity observed when similar substrates are reduced with hydridocuprate reagents.[7] High selectivity for the *cis* A/B ring juncture is also observed when reducing 3-keto-$\Delta^{4,5}$ steroidal enones.[6b,9]

$[(Ph_3PCuH]_6$ is also compatible with γ-heteroatom-substituted enones (eqs 5 and 6).[2b] Conjugate reduction of such compounds without elimination of the γ-substituent is significant as they can suffer hydrogenolysis during catalytic hydrogenation[10] or elimination during reductions where electron transfer is mechanistically relevant.[11]

(6)

Conjugate reduction of β-heteroatom substituted enones is not straightforward.[12] However, endocyclic vinylogous esters[6b] and amides[3c] react under chlorotrialkylsilane-mediated conditions (eq 7) suggesting that they are reduced through the oxonium and iminium ion, respectively. All efforts to reduce exocyclic vinylogous esters and amides such as 3-substituted cyclohex-2-en-1-ones were unsuccessful.[6b]

(7)

The workup requires exposure of the reaction to air and dilution with ether and/or hexanes. Addition of a small amount of silica gel facilitates decomposition of the copper containing byproducts. After being stirred under air for at least 1 h, the mixture is filtered through silica gel and purified by column chromatography. Alternatively, free Ph_3P can be removed from products of similar polarity by oxidation with 5% NaOCl. The resulting phosphine oxide is then removed by simple silica gel filtration. Isolation of the silyl enol ethers requires exposure of the reaction to air and dilution as outlined above, with the usual precautions taken when chromatographing these compounds.

Hydrometalation of Alkynes.

$[(Ph_3P)CuH]_6$ reduces alkynes (eq 8) and propargyl alcohols (eq 9) to the *cis*-alkene.[5] Complications include overreduction (<=10%) with some substrates and partial fragmentation of unprotected secondary and tertiary propargyl alcohols. As with enone reductions mediated by $[(Ph_3P)CuH]_6$, alkyne reduction is concentration dependent, can be promoted by using higher temperatures, and benefits from the presence of water in the reaction medium.

(8)

(9)

Catalytic Reductions.

The presumed copper(I) enolate formed during conjugate reduction heterolytically activates H_2, allowing the reductions to proceed catalytically in copper.[4] In the presence of excess Ph_3P (4-6 equiv per Cu) and H_2 pressure (200-1000 psi) the catalytic enone reduction can be reasonably controlled, providing either conjugate reduction or complete reduction to saturated alcohol, depending on reaction conditions.[4] While work to provide a synthetically useful catalytic enone reduction continues, a practical catalytic reduction of ketones under one atmosphere of H_2 has been developed (eq 10).[6b] The catalytic reducing system is prepared simply by adding Me_2PPh (6-10 equiv per Cu) to $[(Ph_3P)CuH]_6$ followed by *t*-BuOH (10-20 equiv per Cu) and the reducible substrate (10-100 equiv per Cu) in dry, deaerated benzene (0.4-0.8 M in substrate) under an inert atmosphere. The solution is then subjected to one freeze-pump-thaw-degas cycle and an atmosphere of H_2 is admitted as the solution thaws. Alternatively, the catalyst can be prepared by substituting ***Copper(I) Chloride*** and NaO-*t*-Bu for $[(Ph_3P)CuH]_6$. Me_2PPh is superior to numerous other tertiary phosphines screened. This catalyst is quite robust, allowing the reactions to be monitored by TLC and displaying sustained turnover, as indicated by reduction of fresh substrate added to a completed reaction. The chemoselectivity is comparable to that of $[(Ph_3P)CuH]_6$ with the exception that this catalyst does reduce ketones effectively but reacts with enones to give mixtures of saturated and allylic alcohols. The reduction of cyclic ketones proceeds mainly by axial delivery of hydride, with stereoselectivity exceeding ***Sodium Borohydride*** and ***Lithium Aluminum Hydride*** in many cases (eq 11).[6b,13]

(chiral templates for the synthesis of enantiopure 4,4-dialkyl-2-cyclohexenones, 6,6-dialkyl-2-cyclohexenones, and 4,4-dialkyl-1(4*H*)-naphthalenones[1])

Physical Data: (**1**) mp 98-99 °C; [α_D] +13.5°. (**2**) mp 83-85 °C; [α_D] +12.6°. (**3**) mp 91 °C; [α_D] +166.7°.

Preparative Methods: the chiral bicyclic lactams are easily procured via condensation of commercially available (1*S*,2*S*)-(+)-2-amino-1-phenyl-1,3-propanediol and the appropriate δ-keto acid (eq 1).[1,2] Similar bicyclic lactams have been prepared from other amino alcohols and have been extensively utilized in the stereocontrolled formation of quaternary carbon-carbon bonds.[1,3]

Handling, Storage, and Precautions: no special precautions are warranted.

These compounds can be alkylated twice at the 6-position in a stereocontrolled fashion (eq 2).[4,5] Treatment of the unsubstituted bicyclic lactam with ***Lithium Diisopropylamide*** and reaction of the enolate anion with an alkyl halide affords the monosubstituted product. The epimeric mixture is treated again with LDA and a second alkyl halide to give the dialkylated bicyclic lactam. The initial epimeric mixture is used directly in the second alkylation since this subsequent step proceeds via a planar enolate. It is the second alkylation that dictates the final diasteromeric ratio. The order of addition also affects the final ratio.[4] Inverting the order of addition provides the antipode at position 6, although the highest diastereoselectivity is observed when the larger electrophile is added last.[6] The monoalkylated bicyclic lactam can also be prepared by condensation of the amino alcohol and the appropriately substituted keto acid.[1]

These compounds can be partially reduced to the carbinol amine, and then hydrolyzed and cyclized to afford the enantiomerically pure 4,4-dialkyl-2-cyclohexenones (eq 3).[4]

In addition, Grignard addition to the lactam followed by hydrolysis of the bicyclic lactam affords either 3,4,4- or 2,6,6-trisubstituted 2-cyclohexenones, depending upon the hydrolytic conditions employed (eq 4).[6]

(2S)-(2alpha,3beta,8abeta)-Hexahydro-3-(hydroxymethyl)-8a-methyl-2-phenyl-5H-oxazolo[3,2-a]pyridin-5-one

(4)

Similar manipulations with a dialkylated benzo tricyclic lactam lead to the corresponding 4,4-dialkylnaphthalenones (eq 5).[7]

[79618-03-4] · $C_{11}H_{20}OS$ · (4a*R*)-(4aα,7α,8aβ)-Hexahydro-4,4,7-trimethyl-4*H*-1,3-benzoxathiin · (MW 200.38)

[59324-06-0]

(useful chiral auxiliary for asymmetric synthesis of tertiary[1] and secondary[2] alcohols[3])

Physical Data: mp 37-38 °C; bp 70-94 °C/0.1 mmHg (for diastereomeric mixture).

Solubility: very sol most organic solvents at 20 °C; slightly sol pentane at 0 °C; insol H_2O.

Preparative Method: prepared in three steps from optically pure (+)-pulegone (eq 1).[4]

Handling, Storage, and Precautions: refrigerated storage is recommended. Use in a fume hood.

Asymmetric synthesis via the title reagent (**1**) is the result of two highly stereoselective reactions. The first involves the reaction of 2-lithio-1,3-oxathiane (**5**), with an aldehyde to give exclusively the equatorial addition product (**6**) (this reaction typically shows little aldehyde facial selectivity) (eq 2). The selectivity is due to the greatly enhanced stability of the equatorial lithium species (**5**) as compared to the axial isomer, a result of the stereoelectronics of the conformationally rigid oxathiane.[5] Swern oxidation of the resulting carbinols allows the preparation of 2-acyloxathianes as single stereoisomers in high yield.[6] Direct acylation of (**5**) has been achieved recently in selected cases by reaction with nitriles[7] or α-heteroatom-substituted esters.[8] Acyloxathianes (**7**) have also been prepared by acylation of the cuprate (**8**) (obtained from (**5**) and 0.5 equiv ***Copper(I) Iodide***) with acid chlorides (eq 3).[9]

The ketones (**7**) undergo highly stereoselective additions with Grignard reagents to give tertiary alcohols or can be reduced stereoselectively to secondary alcohols. In the case of Grignard reactions, the addition generally shows very high selectivity, typically >9:1, often >95:5 (**9**):(**10**) (eq 4).[10] The major isomer is that predicted to be formed by Cram's chelate rule.[11,12] The kinetics of Grignard reactions with α-alkoxy ketones have been measured by Eliel et al.[13] and these studies strongly support the intermediacy of a chelate structure.

When the R group of ketone (**7**) contains a heteroatom capable of competing with the oxathianyl oxygen for magnesium chelation, a sharp decrease or reversal in the selectivity has been observed (eq 5).[14] The selectivity was restored when the heteroatom (in this case oxygen) was rendered incapable of chelation by protection with a bulky silyl group.

(5)

n	R	(12) (%)
1	CH_2Ph	38
2	CH_2Ph	42
3	CH_2Ph	82
1, 2	$Si(i\text{-}Pr)_3$	98

Ketones having a heteroatom (O or S) at a second adjacent chiral center have also been studied.[15] High selectivity in the addition of a Grignard or lithium reagent was obtained in many cases, but the sterochemical outcome was found to depend on the configuration of the additional center, the organometallic reagent, and the heteroatom substituent (eq 6).[15]

Side chain configuration	M	(15):(16)
(*R*)	Li	53:47
(*R*)	Mg	100:0
(*S*)	Li	0:100
(*S*)	Mg	100:0

Ytterbium-mediated additions of alkynyllithium or -magnesium reagents to (**7**) have also been reported to show high selectivity, but for the opposite diastereomer (**10**) (eq 4) from that obtained in Grignard reactions.[16]

Hydride reductions of (**7**) can be controlled to give either the (*R*) or (*S*) secondary hydroxy compound with good selectivity by choice of the reducing agent. ***Lithium Tri-s-butylborohydride*** (L-Selectride®) provided the (*S*)-alcohol (according to Cram's chelate rule) and ***Diisobutylaluminum Hydride*** (DIBAL) gave the (*R*)-carbinol in excess (eq 7).[2] The DIBAL results were rationalized in terms of the open-chain Cornforth dipole model.[17]

R^1	Reducing agent	(17):(18)
Me	L-Selectride	21:79
Me	DIBAL	78:22
n-Hex	L-Selectride	11:89
n-Hex	DIBAL	87:13
i-Pr	L-Selectride	67:33
i-Pr	DIBAL	88:12
Cy	L-Selectride	52:48
Cy	DIBAL	89:11
t-Bu	L-Selectride	22:78
t-Bu	DIBAL	81:19

Hydrolysis of the 1,3-oxathiane moiety has been accomplished under mild conditions (0 °C, 5 min) by the use of ***N-Chlorosuccinimide-Silver(I) Nitrate***.[18] This oxidative hydrolysis produces α-hydroxy aldehydes in good yields and, in addition, two diastereomeric sultines (**19**) (eq 8).[1] The use of ***Iodine***-$AgNO_3$ for the oxidative hydrolysis of 1,3-oxathianes has also recently been reported.[19] The tertiary α-hydroxy aldehydes are easily oxidized directly to the acids (***Sodium Chlorite***)[20] or methyl esters (MeOH, I_2, KOH)[21] or are conveniently reduced to the diols by direct reduction of the hydrolysis mixture with ***Sodium Borohydride***. The secondary α-hydroxy aldehydes could likewise be reduced to the glycols without racemization; however, oxidation required protection as the benzyl ether prior to hydrolysis. The sultines (after chromatographic separation) are reduced to the hydroxy thiol (**4**) by ***Lithium Aluminum Hydride***.

Advantage has been taken of the fact that the diastereomers (**9**) and (**10**) are often easily separated by silica gel chromatography, particularly when both enantiomers of a compound are desired in pure form. Nonselective addition of (**5**) to 2-hexanone followed by chromatographic separation of the diastereomeric carbinols and hydrolysis of each gave both (+)- and (-)-2-hydroxy-2-methylhexanal in optically pure form.[22]

Hydroxy thiol (**4**) likewise has been used to resolve dimethyl 4-oxocyclopentane-1,2-dicarboxylate by crystallization of the mixture of the derived oxathianes. This provided the (*R*,*R*) enantiomer in >99% purity (eq 9).[23]

An interesting 1,4-addition to the vinyl sulfone derivative of a related 1,3-oxathiane[24] has also been reported (eq 10).[25]

(23) (24)

The use of stoichiometric, covalently bound chiral auxiliaries as a method of asymmetric synthesis is generally impractical and cannot compete with catalytic methods on a commercial scale. However, at the laboratory scale, the oxathiane method provides a predictable method to obtain a desired enantiomer with high selectivity. Since the intermediate compounds prior to hydrolysis are diastereomeric, they are easily separated (often by crystallization) and thus enantiomerically pure compounds are readily obtained.

1,1,1,3,3,3-Hexakis(dimethylamino)-1λ^5,3λ^5-diphosphazenium Fluoride

[137334-99-7] · $C_{12}H_{36}FN_7P_2$ · 1,1,1,3,3,3-Hexakis(dimethylamino)-1λ^5,3λ^5-diphosphazenium Fluoride · (MW 359.49)

(anhydrous stable organic fluoride salt; source of homogeneous, extremely basic solutions of naked fluoride ions of unprecedented reactivity and selectivity in E2 elimination reactions;[1] readily cleaves C-Si bonds, generating extremely reactive naked carbanions[1])

Alternate Name: P_2-F.

Physical Data: mp ca. 152 °C (dec); *d* 1.193 g cm^{-3}.

Solubility: very sol benzene, fluorobenzene (with partial deactivation); sol with deactivation in protic solvents, acetonitrile, DMSO; sparingly sol toluene, dioxane, HMPA, THF; reacts rapidly with partially halogenated alkanes and slowly with CCl_4.

Form Supplied in: commercially available as a 0.5 M solution in benzene.

Preparative Methods: a solution of 1,1,1,3,3,3-hexakis(dimethylamino)-1λ^5,3λ^5-diphosphazenium tetrafluoroborate[1] (12.8 g, 30.0 mmol) in anhydrous MeOH (20 mL) is treated with a solution of KF (1.83 g, 31.5 mmol, dried for 12 h at 240 °C in a high vacuum) in cold MeOH (25 mL) under N_2 and stirred vigorously for 10 min. The KBF_4 is removed by suction. The flask is then equipped with a glass-covered stirring bar, the solution concentrated in vacuo at 40-50 °C bath temperature, purged with N_2, and anhydrous *i*-PrOH (5 mL) is added. This sequence is repeated twice. The flask is then fitted to the cold trap of a (diffusion pump) vacuum apparatus, connected by a 10-mm flow cross-section stop-cock. The solution is concentrated in vacuo with stirring, the bath temperature being brought to 80 °C within 1 h and kept for 1 h at 80 °C and 1 h at 100 °C. For the following operations, rigorous exclusion of moisture (glove box) is essential. The completely solidified product is scratched from the surface of the flask and dried for 1 h at 120 °C. The product is slurried in absolute THF (20 mL), larger lumps are crushed with a pestle, the crystals filtered off with a D4 glass suction filter, washed with absolute THF (15 mL) and dried in a high vacuum, providing 9.7 g (90%) of colorless crystals, 98-99% in naked fluoride by titration; ca. 1% of

inorganic material can be removed by filtration of the benzene solution.

Analysis of Reagent Purity: ^{1}H NMR (benzene-d_6) δ 2.60; by titration in benzene with solid HPF_6 salt of 1,8-bis(dimethylamino)naphthalene, with triphenylmethane as indicator.

Handling, Storage, and Precautions: store and handle so as to rigorously exclude moisture. It is thermally stable up to ca. 100 °C and insensitive to dry oxygen.

E2 Eliminations.

P_2-F is the first reported, soluble source of naked fluoride.[1d] For substrates that tolerate its high basicity (P_2-F deprotonates DMSO in equilibrium), it is one of the most effective E2 elimination bases known. Due to formation of FHF^-, 2 mols are required for elimination of 1 mol of acid. Workup of reaction mixtures is achieved by precipitation of the salts formed with ether or benzene, by extracting the product from aqueous solution with diethyl ether or hydrocarbons, or by filtration over silica gel. All halides of the cation can be converted to tetrafluoroborates by precipitation from aqueous solution with $NaBF_4$.

Very high selectivity (low nucleophilicity) and very high reactivity are the main advantages of P_2-F over conventional bases. In general, reactivity is only slightly reduced when heterogeneous conditions are employed[1d,2] (e.g. THF, eq 1). These conditions have the advantage of slowing down double bond migration considerably. However, reaction of primary alkyl fluorides at rt is rapid only in a homogeneous benzene solution, affording a largely equilibrated mixture of alkenes.[2] Other primary alkyl halides react in THF at -78 °C, affording isomerically pure 1-alkenes[1d] (eq 2) (see also ***Potassium t-Butoxide***).

(1)

3 equiv P_2-F, THF, 25 °C, 30 min	99%
3 equiv P_2-F, benzene, 25 °C, 10 min	99%
3 equiv KO-*t*-Bu, THF, DMSO, 80 °C, 4 d	75%
10 equiv $Me_4N^+F^-$, THF, 65 °C, 4 d	< 5%

(2)

Strongly shielded protons are readily attacked,[3] even when other bases fail completely (eq 3).

(3)

P_2-F, benzene, 5 °C, 5 min	80%	12%
KO-*t*-Bu, THF	0%	<1%
LiCl, DMF	0%	12%

Highly strained alkenes like dodecahedrene[4] are formed with great ease (eq 4) in almost quantitative yield.

(4)

Epoxides are isomerized to allylic alcohols under relatively mild conditions (eq 5).[2] The stereochemistry differs considerably from that of the reaction with ***Lithium Diethylamide***, with *trans*-diaxial elimination predominating.

In benzene solution, unactivated aryl halides afford mixtures of regioisomeric aryl fluorides,[2] presumably via arynes, but only with higher phosphazenium fluorides[2] is partial reduction to the arene effectively suppressed.

Cleavage of Carbon-Silicon Bonds.

Allylsilanes are cleaved at -78 °C, forming naked allyl anions, which can be alkylated in situ (eq 6).[1d]

Hexamethyldisilane

Me_3Si-$SiMe_3$

[1450-14-2] · $C_6H_{18}Si_2$ · Hexamethyldisilane · (MW 146.42)

(silylating or reducing reagent in combination with a Pd catalyst or a nucleophile)

Physical Data: bp 112-114 °C; *d* 0.729 g cm^{-3}.

Solubility: sol common organic solvents; insol H_2O.

Form Supplied in: oil; commercially available.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$-Me_4Si) δ 0.045 (s).

Preparative Methods: by standard synthesis.[1]

Purification: grossly impure sample (25% impurities) is purified by repeated spinning band distillation. This lowered the impurity level to 500 ppm. The main impurity is identified as 1-hydroxypentamethyldisilane.

Handling, Storage, and Precautions: stable to H_2O and air; flammable liquid; irritant. Readily oxidized by oxidants such as halogen and peroxide. Use in a fume hood.

Trimethylsilyl Anion.

Treatment of hexamethyldisilane (**1**) with an alkyllithium, metal alcoholate, or fluoride ion generates the trimethylsilyl anion (**2**) (eq 1).[2] Reaction of (**2**) with aryl halides gives trimethylsilylarenes in 63-80% yields along with reduced products (ArH, 4-27%).[3] ***Tetra-n-butylammonium Fluoride*** (TBAF) catalyzed reaction of Me_6Si_2 with butadienes gives 1,4-disilyl-2-butenes (15-81% yield) with high (*E*) selectivity.[4]

$$\underset{\textbf{(1)}}{Me_3Si\text{-}SiMe_3} \xrightarrow[\text{or } F^-]{\text{RLi, ROM}} \underset{\textbf{(2)}\ M = Li, Na, K, Bu_4N}{Me_3Si^-\ M^+} \qquad (1)$$

Aliphatic aldehydes react with Me_6Si_2/TBAF in HMPA to afford 1-trimethylsilyl-1-alkanols (**3**), whereas aryl aldehydes give pinacols (**4**) under the same conditions (eq 2).[5]

(2)

The trimethylsilyl anion adds to α,β-unsaturated ketones in a 1,4-manner to give β-silyl ketones. This reaction has been applied to the synthesis of carbacyclin.[6]

α-Diketones (**5**) react with Me_6Si_2 in the presence of $PdCl_2(PMe_3)_2$ or $Pt_2(dba)_3$-$P(OCH_2)_3CEt$ to give the corresponding 1,2-bis(trimethylsilyloxy)ethylenes (**6**) (eq 3), while α-keto esters (**7**) provide pinacol 2,3-bis(trimethylsilyl) ethers (**8**) (eq 4).[7] The regio- and stereoselectivities are moderate (62:38-87:13).

(3)

(4)

Allyl alcohols are converted into allylsilanes (**11**) with ***n-Butyllithium*** and Me_6Si_2 (eq 5). Here, the in situ generated lithium allyl alcoholates (**9**) first react with Me_6Si_2 to produce trimethylsilyllithium and trimethylsilyl allyl ethers (**10**), which subsequently react in an S_N2' manner to give the products. Similarly, the lithium alcoholates generated from α,β-unsaturated aldehydes (or ketones) and an alkyllithium, or alternatively from ketones and vinyllithium, can be

converted into the corresponding allylsilanes.[8]

Palladium-Catalyzed Coupling Reaction with Organohalides.

In the presence of ***Tetrakis(triphenylphosphine)palladium(0)***, vinyl halides (**12**) are converted to the corresponding vinylsilanes (**13**) with the aid of Me_6Si_2 and ***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate*** (TASF) in 53-92% yields with high chemoselectivity and stereospecificity (eq 6).[9] Similarly, aryl-, benzyl-, and allylsilanes are obtained from the corresponding halides in 57-100, 8-48, and 52-93% yield, respectively.[10] Allyl esters also are transformed by Pd-catalyzed reaction of Me_6Si_2 into allylsilanes.[11]

Intermolecular Disilylation of Alkynes.

Intermolecular disilylation of 1-alkynes (**14**) are promoted using ***Palladium(II) Acetate-1,1,3,3-Tetramethylbutyl Isocyanide*** at reflux[12] or $Pd(dba)_2$-$P(OCH_2)_3CEt$ at 120 °C[13] to give (*Z*)-1,2-bis(trimethylsilyl)alkenes (**15**) in yields up to 91% (eq 7). Internal alkynes are unreactive. The latter catalyst system allows 1-alkynes to insert between the Si-Si bonds of poly[*p*-(disilanylene)phenylene] and poly(dimethylsilylene).

Silyl Vinyl Ethers.

Enolizable ketones (**16**) are readily transformed to silyl vinyl ethers (**17**) by the action of disilane and a catalytic amount of ***Sodium*** in HMPA (eq 8).[14] The regioselectivity of the silyl vinyl ether formation depends on the structure of the ketones.

Reductive Coupling of Acyl Halides.

Electron-deficient aromatic acid chlorides (Ar_W-COCl; **18**) are converted into biphenyls (**19**) by the dichlorobis(triphenylphosphine)palladium(II) catalyzed reaction of Me_6Si_2 in mesitylene at 165 °C (eq 9).[15] Arylsilanes are produced as byproducts, but these are switched to major products with $(ClMe_2Si)_2$.[16] In contrast, aromatic acid chlorides (Ar_D-COCl; **20**) bearing an electron-donating group give acylsilanes (**21**) upon catalysis with ***Bis(benzonitrile)dichloropalladium(II)-Triphenylphosphine*** (eq 10).[17]

(10)

Reduction of α-Halo Carbonyl Compounds and α-Halo Nitriles.

A halogen substituent on the carbon next to a carbonyl or cyano group is reduced with Me_6Si_2 in the presence of $Pd(PPh_3)_4$ catalyst (eq 11). In the case of α-halo ketones, oxy-π-allyl(trimethylsilyl)palladium intermediates are proposed.[18]

(11)

Palladium-Catalyzed Insertion of Isocyanides into Si-Si Linkage.[19]

A mixture of Me_6Si_2, aryl isocyanide (**24**), a catalytic amount of ***Palladium(II) Acetate*** and toluene is heated to reflux to give disilylformaldehyde imines (**25**) (eq 12). This reaction is applied to the insertion of the isocyanide unit into all the Si-Si linkages of (tetradecamethyl)hexasilane (**26**) to give oligomeric silylimines (**27**) (eq 13).

(12)

(13)

(27) Ar = 2,6-xylyl

Alkyl Bromides from Alcohols.

Alkyl bromides (**29**) are obtained in high yields by the reaction of the corresponding alcohols (**28**) with Me_6Si_2 and ***Pyridinium Hydrobromide Perbromide*** (eq 14).[20] The substitution reaction is very fast for tertiary, allylic, and benzylic alcohols, but very slow for primary and secondary alcohols. Inversion of configuration is observed with secondary alcohols.

(14)

Reductive Silylation of *p*-Quinones.

Me_6Si_2 in combination with a catalytic amount of ***Iodine*** converts *p*-quinones (**30**) into 1,4-bis(trimethylsiloxy)arenes (**31**) in almost quantitative yields (eq 15).[21] The products are a protected form of quinones, which are regenerated by oxidation with ***Pyridinium Chlorochromate*** (PCC).[22]

Reductive Coupling of *gem*-Dichloroalkanes.[23]

The reaction of *gem*-dichloroalkanes (**32**) with Me_6Si_2 proceeds smoothly in the presence of a catalytic amount of $Pd(PPh_3)_4$ to give dimerized alkenes (**33**) in fairly good yields (eq 16). The (*E/Z*) ratio of the products is moderate. R^1-CCl_2-$SiMe_3$ also reacts with Me_6Si_2 in the presence of Pd catalyst to yield (*E*)-$R^1(Me_3Si)C{=}CR^1(SiMe_3)$ quantitatively.

Hexamethyldisilazane

[999-97-3] · $C_6H_{19}NSi_2$ · Hexamethyldisilazane · (MW 161.44)

(selective silylating reagent;[1] aminating reagent; nonnucleophilic base[2])

Alternate Name: HMDS.

Physical Data: bp 125 °C; *d* 0.765 g cm^{-3}.

Solubility: sol acetone, benzene, ethyl ether, heptane, perchloroethylene.

Form Supplied in: clear colorless liquid; widely available.

Purification: may contain trimethylsilanol or hexamethyldisiloxane; purified by distillation at ambient pressures.

Handling, Storage, and Precautions: may decompose on exposure to moist air or water, otherwise stable under normal temperatures and pressures. Harmful if swallowed, inhaled, or absorbed through skin. Fire hazard when exposed to heat, flames, or oxidizers. Use in a fume hood.

Silylation.

Alcohols,[3] amines,[3] and thiols[4] can be trimethylsilylated by reaction with hexamethyldisilazane (HMDS). Ammonia is the only byproduct and is normally removed by distillation over the course of the reaction. Hydrochloride salts, which are typically encountered in silylation reactions employing chlorosilanes, are avoided, thereby obviating the need to handle large amounts of precipitates. Heating alcohols with hexamethyldisilazane to reflux is often sufficient to transfer the trimethylsilyl group (eq 1).[5] Completion of the reaction is indicated by either a change in the reflux temperature (generally a rise) or by the cessation of ammonia evolution.

$$HN(TMS)_2 + 2\,ROH \xrightarrow{\Delta} 2\,ROTMS + NH_3 \qquad (1)$$

Silylation with HMDS is most commonly carried out with acid catalysis.[5] The addition of substoichiometric amounts

of ***Chlorotrimethylsilane*** (TMSCl) to the reaction mixtures has been found to be a convenient method for catalysis of the silylation reaction.[5,6] The catalytically active species is presumed to be hydrogen chloride, which is liberated upon reaction of the chlorosilane with the substrate. Alternatively, protic salts such as ammonium sulfate can be employed as the catalyst.[7] Addition of catalytic ***Lithium Iodide*** in combination with TMSCl leads to even greater reaction rates.[8] Anilines can be monosilylated by heating with excess HMDS (3 equiv) and catalytic TMSCl and catalytic LiI (eq 2). Silylation occurs without added LiI; however, the reaction is much faster in the presence of iodide, presumably due to the in situ formation of a catalytic amount of the more reactive ***Iodotrimethylsilane***.

(2)

Hexamethyldisilazane is the reagent of choice for the direct trimethylsilylation of amino acids, for which TMSCl cannot be used due to the amphoteric nature of the substrate.[9] Silylation of glutamic acid with excess hexamethyldisilazane and catalytic TMSCl in either refluxing xylene or acetonitrile followed by dilution with alcohol (methanol or ethanol) yields the derived lactam in good yield (eq 3).[10]

(3)

The efficiency of HMDS-mediated silylations can be markedly improved by conducting reactions in polar aprotic solvents. For example, treatment of methylene chloride solutions of primary alcohols or carboxylic acids at ambient temperatures with HMDS (0.5-1 equiv) in the presence of catalytic amounts of TMSCl (0.1 equiv) gives the corresponding silyl ether and the trimethylsilyl ester, respectively (eq 4).[1] *N*-Silylation of secondary amines occurs in preference to primary alcohols when treated with 1 equiv of HMDS and 0.1 equiv TMSCl (eq 5). The silylation of secondary amines cannot be effected in the absence of solvent.[5] Secondary and tertiary alcohols can also be silylated at ambient temperatures in dichloromethane with HMDS and TMSCl mixtures; however, stoichiometric quantities of the silyl chloride are required. Catalysis by ***4-Dimethylaminopyridine*** (DMAP) is necessary for the preparation of tertiary silyl ethers.

(4)

(5)

DMF is a useful solvent for HMDS-induced silylation reactions, and reaction rates 10-20 times greater than those carried out in pyridine have been reported.[11] DMSO is also an excellent solvent; however, a cosolvent such as 1,4-dioxane is required to provide miscibility with HMDS.[12]

Imidazole (ImH) catalyzes the silylation reaction of primary, secondary, and tertiary alkanethiols with hexamethyldisilazane.[12] The mechanism is proposed to involve the intermediacy of ***N-(Trimethylsilyl)imidazole*** (ImTMS), since its preparation from hexamethyldisilazane and imidazole to yield 1-(trimethylsilyl)imidazole is rapid.[13] The imidazole-catalyzed reactions of hexamethyldisilazane, however, are more efficient than the silylation reactions effected by ImTMS (eq 6 vs. eq 7) due to reversibility of the latter. Imidazole also catalyzes the reaction of HMDS with ***Hydrogen Sulfide***, which provides a convenient preparation of hexamethyldisilathiane, a reagent which has found utility in sulfur transfer reactions.[14]

(6)

(7)

Silyl Enol Ethers.

Silylation of 1,3-dicarbonyl compounds can be accomplished in excellent yield by heating enolizable 1,3-dicarbonyl compounds with excess HMDS (3 equiv) and catalytic imidazole (eq 8).[15]

(8)

In combination with TMSI, hexamethyldisilazane is useful in the preparation of thermodynamically favored enol ethers (eq 9).[16] Reactions are carried out at rt or below and are complete within 3 h.

(9)

Related thermodynamic enolization control has been observed using metallated hexamethyldisilazide to give the more substituted bromomagnesium ketone enolates.[17] Metallation reactions of HMDS to yield Li, K, and Na derivatives are well known and the resulting nonnucleophilic bases have found extensive applications in organic synthesis (see ***Lithium Hexamethyldisilazide***, ***Potassium Hexamethyldisilazide***, ***Sodium Hexamethyldisilazide***).[2]

Amination Reactions.

Hexamethyldisilazane is a useful synthon for ammonia in amination reactions. Preparation of primary amides by the reaction of acyl chlorides and gaseous Ammonia, for example, is not an efficient process. Treatment of a variety of acyl halides with HMDS in dichloromethane gives, after hydrolysis, the corresponding primary amide (eq 10).[18] Omitting the hydrolysis step allows isolation of the corresponding monosilyl amide.[19]

(10)

Reductive aminations of ketones with HMDS to yield α-branched primary amines can be effected in the presence of ***Titanium(IV) Chloride*** (eq 11).[20] The reaction is successful for sterically hindered ketones even though HMDS is a bulky amine and a poor nucleophile. The use of ammonia is precluded in these reactions since it forms an insoluble complex with $TiCl_4$.

(11)

The reaction of phenols with diphenylseleninic anhydride and hexamethyldisilazane gives the corresponding phenylselenoimines (eq 12).[21] The products thus obtained can be converted to the aminophenol or reductively acetylated using ***Zinc*** and ***Acetic Anhydride***. The use of ammonia or tris(trimethylsilyl)amine in place of HMDS gives only trace amounts of the selenoimines.

Hexamethyldisiloxane

[107-46-0] · $C_6H_{18}OSi_2$ · Hexamethyldisiloxane · (MW 162.42)

(silylating agent for carboxylic acids[1,2] and alcohols;[3] used in preparation of aroyl chlorides;[4] precursor for a variety of trimethylsilyl derivatives[5])

Alternate Names: bis(trimethylsilyl) ether; bis(trimethylsilyl) oxide.

Physical Data: mp -59 °C; bp 101 °C/760 mmHg; *d* 0.764 g cm^{-3}.

Solubility: sol organic solvents such as toluene, chloroform.

Form Supplied in: colorless liquid; available in NMR (99.5%+) and technical (98 or 99%) grade; available in research and commercial quantities.

Analysis of Reagent Purity: ^1H NMR 0.49 ppm; ^{13}C NMR 1.94 ppm (in $CDCl_3$).

Handling, Storage, and Precautions: skin irritant. Incompatible with strong acids, strong bases, and oxidizing agents. Use in a fume hood.

Silylation of Carboxylic Acids.

Alkanoic and aromatic carboxylic acids can be readily silylated with hexamethyldisiloxane.[1] The reaction is carried out under acid catalysis (usually sulfuric acid) and azeotropic removal of water (eq 1). The rate of reaction is strongly influenced by the acidity of the carboxylic acid and increases with increased acidity. This method avoids the use of an amine and thus simplifies isolation of the product because it does not have to be separated from an amine hydrochloride. A limitation is the need for a solvent which allows for azeotropic removal of water.

(1)

An alternate silylation procedure employs ***Zinc Chloride*** as the catalyst and uses the carboxylic acid anhydride as starting material for the preparation of the silyl ester (eq 2).[2] A limited number of examples (benzoic and acetic anhydrides) of this reaction have been published. Distillation is the preferred method for isolation of the product.

(2)

Silylation of Alcohols.

Pyridinium p-Toluenesulfonate can be used as the catalyst in the silylation of primary and secondary alcohols and phenols (eq 3).[3] Even alcohols sensitive to acid-catalyzed rearrangements can be successfully silylated under these conditions. Continuous removal of the water generated during the reaction is necessary and is achieved via the use of a Soxhlet extractor filled with 4Å molecular sieves.

(3)

A special case for the preparation of a phenyl silyl ether involves ultrasound irradiation of benzenediazonium fluoroborate in the presence of hexamethyldisiloxane.[6]

Preparation of Aroyl Chlorides.

Substituted benzylidene chlorides (trichloromethylarenes) can be converted to the corresponding substituted benzoyl chlorides (aroyl chlorides) with hexamethyldisiloxane in the presence of a catalytic amount of ***Iron(III) Chloride*** (eq 4).[4] These mild reaction conditions offer a distinct advantage over procedures which employ inorganic oxides and high temperatures to achieve the transformation.[7]

(4)

Preparation of Other Trimethylsilyl Derivatives.

Hexamethyldisiloxane has been used as an inexpensive starting material for the preparation of numerous synthetically useful trimethylsilyl derivatives. Examples include ***Fluorotrimethylsilane***,[5a,b] ***Bromotrimethylsilane***,[5c] and ***Iodotrimethylsilane***,[5d,e] as well as polyphosphoric acid trimethylsilyl ester (PPSE).[5f]

Related Reagents.

N,O-Bis(trimethylsilyl)acetamide; ***N,N´-Bis(trimethylsilyl)urea***; ***Chlorotrimethylsilane***; ***Hexamethyldisilazane***; ***N-(Trimethylsilyl)imidazole***.

Hexamethyldistannane[1]

Me_3Sn-$SnMe_3$

[661-69-8] · $C_6H_{18}Sn_2$ · Hexamethyldistannane · (MW 327.66)

(palladium-catalyzed substitution and addition reactions)

Physical Data: colorless oil, bp 62-63 °C/12 mmHg, 182 °C/756 mmHg; mp 23 °C; *n*20D = 1.5321.

Solubility: sol most organic solvents.

Form Supplied in: colorless oil; readily available but highly expensive.

Analysis of Reagent Purity: ^{119}Sn NMR recommended (δ -109 ppm, $^1J(^{119}Sn\text{-}^{119}Sn)$ 4404 Hz).[8]

Preparative Methods: although the preparation from ***Trimethylstannane*** and trimethyl(diethylamino)stannane affords an excellent yield (95%), it has the disadvantage of requiring two extremely air-sensitive starting materials.[2] Better methods involve the use of ***Chlorotrimethylstannane*** with either ***Lithium*** or ***Sodium***,[3] or ***Trimethylstannyllithium*** (the latter from trimethylstannane and ***Lithium Diisopropylamide***[4]).[5] Catalytic elimination of hydrogen from trimethylstannane also affords hexamethyldistannane and can be effected either by various bases[6a] or by palladium catalysts such as ***Tetrakis(triphenylphosphine)palladium(0)***.[6b] This latter method can be recommended. The preparation of hexamethyldistannane starting from bis(trimethylstannyl) sulfide has also been described.[7]

Handling, Storage, and Precautions: the compound must be stored in the absence of oxygen, moisture, and light (preferably under argon). Very highly toxic. Use in a fume hood.

Introduction.

General aspects of the preparation and chemistry of hexaalkyldistannanes are reviewed in the Houben-Weyl volume on organotin compounds (literature coverage up to 1977).[1]

The chemistry of hexamethyldistannane is determined by the weakness of the tin-tin bond. The main reaction of synthetic importance is its use in palladium-catalyzed substitution reactions or addition reactions to multiply bonded systems.

While, in analogy to ***Hexabutyldistannane***, Me_6Sn_2 dissociates on heating to give trimethylstannyl radicals, these are generally no longer used in organic synthetic transformations because of the toxicity of methyltin compounds and their cost. Me_6Sn_2 can also be used in transmetalation reactions, leading to the formation of other trimethylstannylmetal reagents.

Palladium-Catalyzed Reactions.

These can be of two types, either substitution of a ligand (generally halide) by a trimethylstannyl group or addition to multiple bonds. These reactions have been reviewed by Stille[9] and Mitchell.[10]

The substitution reactions provide an extremely useful alternative to the conventional use of ***Trimethylstannyllithium***, which is a very strong base. The halides used have mainly been aryl or heteroaryl halides, while ***Tetrakis(triphenylphosphine)palladium(0)***, dichlorobis(triphenylphospine)palladium(II), and ***Bis(allyl)di-μ-chlorodipalladium-Tetra-n-butylammonium Fluoride*** have generally been employed as catalysts. In more recent developments, couplings involving enol triflates[11] and aryl triflates[12] have been described.

The first example of a *cine* substitution was observed when a vinylstannane derived from a camphor triflate and hexamethyldistannane was allowed to react with bromobenzene (eq 1).[13]

(1)

The synthesis of symmetrical biaryls (using Bu_6Sn_2) has been described.[14] This principle has recently been applied in an intramolecular manner and extended to include more complex cyclization reactions; hexamethyldistannane can be used as an alternative to hexabutyldistannane. Thus as well as two (symmetrical or mixed) aryl and benzyl halide moieties, a combination of two aryl iodide moieties with a carbon-carbon double or triple bond can be used (eq 2).[15]

(2)

The reaction of Me_6Sn_2 with acyl halides provides an excellent method for the preparation of trimethylacylstannanes (eq 3).[16]

$$Me_6Sn_2 + RCOCl \xrightarrow{[Pd]} Me_3SnCOR + Me_3SnCl \quad (3)$$

In the case of the addition reactions, hexamethyldistannane adds readily to a variety of allenes to give 2,3-distannyl-1-propenes; it is often possible to distinguish a kinetic and a thermodynamic product (eq 4).[17]

(4)

The addition to 1-alkynes proceeds in a quantitative manner at atmospheric pressure to give (*Z*)-1,2-distannylalkenes, which can in some cases undergo photochemical isomerization to afford the corresponding (*E*)-products in quantitative yields (eq 5).[18]

(5)

The presence of various functional groups is tolerated; thus the preparation of trimethylstannyl-substituted

allylglycine derivatives[19] and (*Z*)-4-trimethylstannyl-1,3-butadienes[20] (via the enones) have been described (eqs 6 and 7). The first tris(trimethylstannyl)ethylenes were obtained by using a more active precatalyst system.[21]

(6)

(7)

In spite of the development of new catalyst systems, additions to nonterminal alkynes remain a virtually unsolved problem. Two groups have described the addition of hexamethyldistannane to 1,3-dienes; depending on the reaction conditions, the products are either (*Z*)-1,4-bis(trimethylstannyl)-2-butenes[22] or the products of addition/dimerization (eqs 8 and 9).[23]

(8)

R = H, Me, Ph

Use as a Source of Trimethylstannyl Radicals.

Thermolysis or photolysis of hexamethyldistannane generates trimethylstannyl radicals, which can in turn be used to generate other synthetically useful radicals. On this basis, Curran has developed the so-called atom transfer method for radical cyclization, in which about 0.1 equiv. of the distannane is used. While in his original work[24] on the cyclization of α-iodo esters, ketones, and malonates Curran used both hexamethyl- and hexabutyldistannane, later papers by his and other groups have reported only the use of Bu_6Sn_2 (for reasons of cost and toxicity). Me_6Sn_2 has been used to effect a selective one-electron radical chain reduction of the 10-methylacridinium ion to 10,10´-dimethyl-9,9´-biacridine.[25] In combination with ***1,1-Di-t-butyl Peroxide*** (as the radical initiator) it can generate sulfonyl radicals from sulfonate esters.[26]

Use as a Source of Other Trimethylstannylmetal Reagents.

Hexamethyldistannane can be cleaved by lithium metal[27] or a lithium alkyl[28] (e.g. MeLi) to give trimethylstannyllithium. These methods cannot be recommended: Me_3SnLi can be better obtained either in a one-step process from Me_3SnCl and Li (via Me_6Sn_2 which is not isolated) or from the reaction between Me_3SnH and LDA (see ***Trimethylstannyllithium*** for details). Hexamethyldistannane can also serve as a source of stannylcuprates ($Me_3SnCu(CN)Li$, $(Me_3Sn)_2Cu(CN)Li_2$,[29] Me_3Sn(2-thienyl)$Cu(CN)Li_2$).[30]

Hexamethylenetetramine[1]

[100-97-0] · $C_6H_{12}N_4$ · Hexamethylenetetramine · (MW 140.22)

(oxidation of benzyl and alkyl halides and amines to aldehydes; ammonolysis of alkyl halides to primary amines; electrophilic formylation of aromatics; useful one-carbon unit in heterocyclic synthesis)

Alternate Name: HMTA.

Physical Data: mp 285-295 °C (subl.); *d* 1.331 g cm^{-3}.

Solubility: sol water, ethanol, ether, chloroform.

Form Supplied in: white solid.

Analysis of Reagent Purity: ^1H NMR ($CDCl_3$) sharp singlet at δ 4.70.

Purification: sublimation at aspirator pressure.

Handling, Storage, and Precautions: stable, low toxicity.

Oxidation of Benzylic Halides (Sommelet Reaction).[2]

Treatment of an activated (usually benzylic) halide with HMTA in a protic solvent such as aqueous acetic acid gives the aldehyde, via the Schiff base.[3] The reaction involves an intramolecular hydride transfer, as shown in eq 1. Hydrochloric acid is sometimes added at the end of the reaction to speed the hydrolysis of the Schiff base.

(1)

The method works well with phenolic (eq 2)[4] and heterocyclic (eq 3)[5] substrates, for which other methods would probably be unsuitable.

(2)

(3)

Secondary halides usually give poor yields, while highly hindered substrates such as 2,6-disubstituted benzyl bromides are unreactive, although mononitrobenzyl bromides are oxidized. With unreactive halides it is often better to form the quaternary salt in chloroform, and decompose it in a protic medium.

In a related reaction, HMTA transforms benzylamines into benzaldehydes (eq 4).[6]

(4)

Ammonolysis of Alkyl Halides (Delépine Reaction).[7,8]

The quaternary salt of HMTA and alkyl halides decomposes under strongly acidic conditions (usually EtOH, concentrated HCl) to give primary amines rather than aldehydes or ketones (eqs 5-7).[9-11]

(5)

(6)

(7)

As in the Sommelet reaction, the bromide or chloride must be activated in order to react with the HMTA. The Delépine reaction provides a ready synthesis of α-amino acids (eq 8). If the decomposition is performed with HCl gas in dry ethanol, the corresponding ethyl ester is obtained instead.[12]

(8)

The reaction may be combined with the Eschweiler-Clark methylation by heating the quaternary salt in formic acid, the formaldehyde deriving from the decomposition of the HMTA (eq 9).[13]

$PhCH_2NMe_2$ (9)

HMTA opens epoxides exclusively at the less substituted site. This is of importance because free amines react unselectively (eq 10).[14]

(10)

Overall, HMTA provides a cheap and nonhazardous alternative to ***Sodium Azide*** for the synthesis of certain primary amines from their halides.

Electrophilic Formylation of Aromatics (Duff Reaction).[15]

Electron-rich aromatics (phenols, indoles, etc.) are formylated by HMTA in glacial acetic acid (eqs 11 and 12) or glyceroboric acid (H_3BO_3 in dry glycerol) (eq 13). Yields are sometimes poor.[16-18]

(11)

(12)

(13)

With phenols there is a strong tendency to give the *ortho* product selectively (eq 13). Yields are higher, and *para* selectivity is observed, when the reaction is conducted in ***Trifluoroacetic Acid*** (eq 14).[19] Even unactivated aromatics react under these conditions.

(14)

Use in Heterocyclic Synthesis.

Treatment of phenanthroquinones with HMTA furnishes the fused imidazoles in good yield (eq 15).[20]

(15)

Benzodiazepines and quinazolines are accessible by treatment of the appropriate chloroacetamides and aminobenzophenones with HMTA (eqs 16 and 17).[21]

(16)

(17)

Isatins undergo ring expansion with HMTA in an alcoholic solvent (eq 18).[22]

Hexamethylphosphoric Triamide

[680-31-9] · $C_6H_{18}N_3OP$ · Hexamethylphosphoric Triamide · (MW 179.24)

(high Lewis acid basicity; dipolar aprotic solvent with superb ability to form cation-ligand complexes; can enhance the rates of a wide variety of main group organometallic reactions and influence regio- or stereochemistry; additive in transition metal chemistry; UV inhibitor in poly(vinyl chloride))

Alternate Names: HMPA; hexamethylphosphoramide; hexametapol; hempa; HMPT.

Physical Data: mp 7.2 °C; bp 230-232 °C/740 mmHg; *d* 1.025 g cm^{-3}; mild amine odor.

Solubility: sol water, polar and nonpolar solvents.

Form Supplied in: water-white liquid. *Drying:* distilled from CaH_2 or BaO[1] at reduced pressure and stored under N_2 over molecular sieves.

Handling, Storage, and Precautions: has low to moderate acute toxicity in mammals.[2a] Inhalation exposure to HMPA has been shown to induce nasal tumors in rats,[2b] and has been classified under Industrial Substances Suspect of Carcinogenic Potential for Man.[2c] Adequate precautions must be taken to avoid all forms of exposure to HMPA.

Introduction.

Hexamethylphosphoric triamide has been used extensively as an additive in organolithium chemistry.[3] It is among the strongest of electron pair donors and is superior to protic solvents in that it solvates the cation much better than the anion.[4] This coordinating ability gives HMPA its unusual chemical properties.[5,6] For instance, HMPA dramatically enhances the rates of a wide variety of organolithium reactions, as well as significantly influencing regio- or stereochemistry. The reactivity or selectivity effects of HMPA are usually rationalized in terms of changes in either aggregation state or ion pair structure.[7] The breaking up of aggregates to form reactive monomers or solvent-separated ion pairs is often invoked.

Organolithium Reagent Solution Structure.

The rate of metalation reactions with ***Lithium Diisopropylamide*** as base are significantly increased through the use of HMPA.[8] Treatment of LDA dimer with HMPA causes sequential solvation of the lithium cation, but no significant deaggregation;[8,9] nor does HMPA promote the break up of tetrameric unhindered phenoxides[10,11] or tetrameric MeLi.[12] A chiral bidentate lithium amide,[13] however, was converted from a dimer to a monomer by HMPA, with an increase in reactivity and enantioselectivity in deprotonation (eq 1). HMPA also converts ***Phenyllithium*** dimer into monomer.[12,14] Other aggregated lithium reagents[12] in THF (MeSLi, LiCl) or ether (Ph_2PLi, PhSeLi) are first deaggregated to monomers, and then solvent-separated ion pair species are formed.[12,15] HMPA may exert its reactivity effects by a combination of one or more of the following:

- 1)lowering the degree of aggregation[16,17] or forming separated ions,[18]
- 2)increasing reactivity through cation coordination,[17]
- 3)activating the aggregate through insertion into the aggregate site normally occupied by the anionic fragment,[5,19]
- 4)promoting triple ion (ate complex) formation.[16a,20]

(1)

HMPA can have large effects on equilibria. Phenyllithium reacts with ***Diphenylmercury***, ***Diphenyl Ditelluride***, and iodobenzene in THF to form ate complexes. In THF/HMPA the ate complex formation constants are dramatically higher than in THF.[14,21]

Enolate Formation.

The formation of lithium enolates is one instance where HMPA is sometimes needed.[22] The difficult generation of dimethyl tartrate acetonide enolate[23] and subsequent benzylation (eq 2), as well as the double deprotonation of methyl 3-nitropropanoate,[24] become possible (eq 3) with the addition of HMPA (or ***N,N´-Dimethylpropyleneurea***).[25]

Cosolvent (% vol)	Yield (%)
-	<5
HMPA (17)	54
DMPU (33)	52

(2)

Cosolvent (% vol)	Yield (%)
-	<5
HMPA (17)	50-85
DMPU (33)	50-85

(3)

Enolate Reactivity.

Not only is HMPA necessary to the generation of enolates, it is often needed in the electrophilic trapping of enolates (eqs 4-6).[26,31] Studies of the electrophilic trapping of enolates have demonstrated that substantial increases in reaction rates can be achieved through the use of a polar aprotic solvent like HMPA.[4]

(4)

(5)

(6)

Solvent	Yield
THF	43%
THF-HMPA	93%

The desired [2,3]-sigmatropic rearrangement of a bis-sulfur cyano-stabilized lithium salt did not proceed (eq 7) without the addition of 25% HMPA.[27] Sometimes higher *O*/*C*-alkylation ratios are obtained in THF-HMPA.[28]

(7)

Enolate Stereochemistry.

Stereochemical control of an ester enolate Claisen rearrangement was accomplished through stereoselective enolate formation.[29] The enolization of 3-pentanone with LDA afforded predominantly the (*E*)-enolate in THF and the (*Z*)-enolate in THF-HMPA, as shown by chlorotrialkylsilane trapping experiments (eq 8). Similar stereoselectivity (*Z*:*E* = 94:6) was obtained with the dipolar aprotic cosolvent DMPU.[30]

(8)

THF	77	:	23
THF-HMPA	5	:	95

In addition to altering the (*E*/*Z*) isomer ratio of enolates,[17,32] HMPA has a noticeable effect on the metalation of imines and their subsequent alkylation (eq 9).[33] When the metalation (by ***s-Butyllithium***) of an asymmetric imine is performed in THF, a subsequent alkylation gives about a 1:1 mixture of regioisomers. In the presence of HMPA, however, only the regioisomer due to alkylation at the less-substituted site was observed. A synthetically useful solvent effect for HMPA is also observed in the asymmetric synthesis of trimethylsilyl enol ethers by chiral lithium amide bases.[34] The asymmetric induction in THF can be greatly improved by simply adding HMPA as a cosolvent.

(9)

Carbanion Formation.

Often substrates that cannot be metalated by LDA or ***n-Butyllithium*** in THF can be successfully deprotonated by adding HMPA as a cosolvent. Many other weakly acidic C-H acids, e.g. (**1**)-(**6**), can be successfully metalated in the presence of HMPA.[35] HMPA also aids in the formation of dianions[36] and increases the proton abstraction efficiency of ***Sodium Hydride***.[37,38]

(1)

(2)

(3)

(4)

(5)

(6)

Carbanion Reactivity.

An increase in reaction rate is observed for the reaction of alkynyllithium reagents with alkyl halides[3] and oxiranes[39] (eq 10). The strongly coordinating HMPA probably complexes the lithium cation, thereby increasing the negative charge density on the carbon and creating a much more nucleophilic alkynyl anion. A similar effect is observed for ***(Trimethylstannylmethyl)lithium***, which does not react with oxiranes in THF but in THF-HMPA the reaction proceeds readily.[40]

(10)

Cosolvent (% vol)	Yield (%)
-	<5
HMPA (17)	70
DMPU (50)	59

The decarboxylation[41] of 4-*t*-butyl-1-phenyl-1-carboxycyclohexane with ***Methyllithium*** gave a mixture of axial and equatorial products (eq 11), which was highly dependent on the nature of the solvent at the time of aqueous workup. Axial protonation was favored in ether-HMPA.

(11)

HMPA is also the only dipolar aprotic solvent to be used extensively with organomagnesium compounds.[42] Large effects are observed when HMPA is used as either a solvent or a cosolvent. As examples, HMPA accelerates addition of an allylic organomagnesium compound to aryl-substituted alkenes,[43] addition of Grignard reagents to ***Carbon Monoxide***,[44] and addition of ***Propargylmagnesium Bromide*** to allylic halides to give allene products.[45]

Carbanion Regioselectivity (1,2- vs. 1,4-Addition).

The regioselectivity of addition of certain organolithium reagents to α,β-unsaturated carbonyl compounds is affected by the addition of HMPA. In the addition of 2-lithio-2-substituted-1,3-dithiane to cyclohexenone, there was a complete reversal of regioselectivity from 1,2-addition in THF to 1,4-addition with 2 equiv of HMPA present (eq 12).[46]

(12)

Additive	1,2-Addition	1,4-Addition
no HMPA	>99	<1
HMPA (2 equiv)	5	95

Lithium reagents that exhibit kinetic 1,4-addition in HMPA are shown as (**7**)-(**14**).[47] These include useful acyl anion equivalents[48] like phenylthio(trimethylsilyl)methyllithium (see ***(Phenylthiomethyl)trimethylsilane***).[49]

(7)

(8)

(9)

(10)

(11)

(12)

(13)

(14)

A carboxy anion equivalent was reported to undergo 1,2-addition in the absence of HMPA;[50] however, with 10 equiv of HMPA present only 1,4-addition was observed (eq 13). The addition of 1 equiv of HMPA promotes conjugate addition of alkyl and phenylthioallyl anions to cyclopentanones (eq 14) through the α-position, whereas in THF alone, irreversible 1,2-addition occurs with both α- and γ-attack.[51] The regioselectivities reported for the addition to cyclic enones of ketene dithioacetal anions[47a,52] or ***t-Butyllithium*** (eq 15)[53] are also influenced by HMPA (and counterion).

(13)

(14)

THF-5% HMPA	65	35
THF-20% HMPA	10	90

Ylide Reactivity.

HMPA is used as a cosolvent in the Wittig reaction to increase reaction rate, yield, and stereoselectivity. HMPA functions as a lithium cation-complexing agent and removes LiBr salt from ether solution (LiBr/HMPA complexes form precipitates in ether).[54] Such a salt-free Wittig reaction mixture[55] may be responsible for the high level of *cis*-alkene observed in reactions of nonstabilized ylides with aldehydes in THF or ether with added HMPA[25,56] (eq 16). Similarly, increased (*Z*) selectivity is observed in the Wittig alkenation of 2-oxygenated ketones (eq 17) to generate protected (*Z*)-trisubstituted allylic alcohols.[55,57]

(16)

Cosolvent (% vol)	Yield (%)	(*Z*)		(*E*)

TBS	7.6:1	61	26:1	90
Bz	1.1:1	55	36:1	86

With HMPA, Wittig reactions that give (*E*)-alkenes were also observed (eq 18),[58] as was the directed selectivity of a semistabilized arsonium ylide towards carbonyl compounds. The arsenic ylide was generated from LDA in THF or THF/HMPA solution to give exclusively epoxide (eq 19) or diene (eq 20), respectively.[59]

Nucleophilic Cleavage of Esters and Ethers.

The conversion of hindered methyl esters to carboxylic acids, and the demethylation of methyl aryl ethers, can be effectively performed by using HMPA to increase the nucleophilicity of lithium methanethiolate.[60] HMPA (or ***N,N-Dimethylformamide***) will also facilitate the cleavage of methyl aryl ethers and their methylthio analogs by sodium methaneselenolate (see ***Methaneselenol***) to give the phenol or thiophenol, respectively.[60,61] Sodium ethanethiolate (see ***Ethanethiol***) in refluxing DMF or HMPA attacks alkyl aryl selenides to give the corresponding diselenides. The most reactive combination of solvent and halide salt for the decarboxylation of β-keto esters was found to be ***Lithium Chloride***/HMPA, used as part of a stereoselective synthesis of 11-deoxyprostaglandin E_1.[62] In HMPA, the rate of ester cleavage of 2-benzyl-2-methoxycarbonyl-1-cyclopentanone with ***Sodium Cyanide*** is 30 times as fast as the more commonly used DMF.[62a]

Anion Reactivity.

HMPA is one of the most potent electron pair donor solvents available for accelerating S_N2 reactions.[3,43a] The formation, for example, of an α-silyl carbanion for use in a Peterson alkenation reaction[63] can be accomplished by the displacement of silicon using ***Sodium Methoxide***[64] or ***Potassium t-Butoxide***[65] in HMPA (eq 21). The increased nucleophilicity of halide ions in the presence of HMPA is seen by the increased rate of silyl-protecting group removal with fluoride ion (***Tetra-n-butylammonium Fluoride***).[66] The substitution of aryl chlorides can be performed using sodium methoxide in HMPA[67] to give anisole derivatives, or by using sodium methanethiolate (MeSNa) (see ***Methanethiol***) in HMPA[61b,68] to generate either aryl methyl sulfides or aryl thiols, depending on the reaction

conditions. The increased nucleophilicity of a magnesium alkoxide is demonstrated by the cyclization of a chloro alcohol to a 13-membered cyclic ether (eq 22) upon treatment of the compound with ***Ethylmagnesium Bromide*** in refluxing THF/HMPA.[69]

(21)

(22)

The conversion of cyclic alkenes to 1,3-cycloalkadienes can be performed through a bromination/dehydrobromination procedure using LiCl/***Lithium Carbonate***/HMPA (eq 23).[70] The dehydrobromination of 2,3-dibromo-3-methyl-1-butanol to generate a vinyl bromide has been accomplished through the use of 2.3 equiv of LDA and 0.5 equiv of HMPA in THF at -78 °C.[71]

(23)

Low-Valent Metal Coordination (Lanthanoids).

HMPA is used extensively as a solvent for dissolving-metal reductions.[72] Used as a cosolvent (5-10%), it remarkably accelerates the one-electron transfer reduction of organic halides by ***Samarium(II) Iodide***.[73] The reductions work on a variety of primary, secondary, or tertiary halides, including chlorides which could not be reduced in pure THF (eq 24). The samarium Barbier reaction, which requires hours in refluxing THF, can be performed as a titration in THF-HMPA at rt (eq 25).[74] The SmI_2/THF/HMPA system has recently been used in the deoxygenation of organoheteroatom oxides,[75] reductive dimerization of conjugated acid derivatives,[76] and selective reduction of α,β-unsaturated carbonyl compounds.[77] In addition, SmI_2 was used in a tandem radical cyclization,[78] and has been a useful reagent in Barbier-type reactions.[73b,79] The dramatic acceleration of electron transfer is also observed for ***Ytterbium(0)***.[80]

(24)

	THF		THF-HMPA	
	Time	Yield	Time	Yield
I	6 h	95%	5 min	>95%
Br	2 days	82%	10 min	>95%
Cl	no reaction		8 h	>95%

(25)

Additive	Time	Yield
none	4 h	82%
HMPA	1 min	95%

Transition Metal Coordination.

The ability of HMPA to complex to metals and alter reactivity is also expressed in palladium-catalyzed coupling reactions. For example, ethylbenzene can be formed from the Pd^0 catalyzed cross-coupling of ***Benzyl Bromide*** and ***Tetramethylstannane***, with the formation of almost no bibenzyl.[81] The reaction does not proceed in THF, but requires a highly polar solvent like HMPA or ***1-Methyl-2-pyrrolidinone***. Similarly, HMPA is necessary in the Pd^0-catalyzed coupling of acid chlorides with organotin reagents to give ketones. In highly polar solvents like HMPA the transfer of a chiral group from the tin occurs with preferential inversion of configuration (eq 26).[82] The relative rate of transfer of an alkynic or vinyl group to acid chlorides[82a] or aryl iodides[83] is also greatly accelerated by HMPA. It can increase the rate of alkylation of π-allylpalladium chloride by ester enolates,[84] and alter the chemoselectivity by leading to a cyclopropanation reaction instead of an allylic alkylation.[85]

(26)

Hydride Reductions.

The reduction of organic compounds by hydride can be influenced by the choice of cosolvent. Cyanoborohydrides (e.g. ***Sodium Cyanoborohydride***) in HMPA provide a mild, effective, and selective reagent system for the reductive displacement of primary and secondary alkyl halides and sulfonate esters in a wide variety of structural types.[86] A ***Sodium Borohydride***/HMPA reagent system was used in the reduction of *N*,*N*-disulfonamides[87] and in the reduction of dibromides to monobromides.[37a] Similarly, ***Tri-n-butylstannane***/HMPA[88] can be utilized to chemoselectively reduce aldehydes with additional alkene or halide functionality.[89] Finally, the reduction of aldehydes and ketones with hydrosilanes proceeds in the presence of a catalytic amount of Bu_4NF in HMPA.[90] The reaction rate was much lower in DMF than in HMPA, and the reaction yields decreased considerably if less polar solvents like THF or CH_2Cl_2 were used.

Oxidation.

The oxidation of acid sensitive alcohols with ***Chromium(VI) Oxide*** in HMPA is one example of the use of HMPA in oxidation reactions.[91] (CAUTION: Do not crush CrO_3 prior to reaction since violent decomposition can occur. The use of DMPU has been reported to have a similar hazardous effect). Recently, a ***Bromine***/$NaHCO_3$/HMPA system[92] was used for the oxidative esterification of alcohols with aldehydes, where the HMPA considerably accelerated the oxidation by bromine and lowered the rate of unwanted halogenation. Epoxidations of alkenes or allylic alcohols have been accomplished using MoO_5.HMPA.pyridine (***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)***; MoOPH).[93]

Effect of HMPA on Protonation.

The protonation of (9-anthryl)arylmethyllithium with various oxygen and carbon acids in THF or in THF-HMPA had a significant effect on the product ratio of C-α vs. C-10 protonation (eq 27).[94] Another study[95] found that a nitronate protonation led to mainly one diastereomeric product in a THF solution containing HMPA or DMPU (eq 28). Panek and Rodgers[96] observed stereospecific protonation of 10-*t*-butyl-9-methyl-9-lithio-9,10-dihydroanthracene: >99% *cis* protonation was observed in THF or ether with greater than >99% *trans* protonation observed in HMPA.

(27)

Additive	Proton. at C-α	Proton. at C-10
none	57	43
HMPA (12 equiv)	>95	<5

Inhibition by HMPA.

Finally, it should be added that there are a few cases where HMPA slows the rate of a reaction. Such examples typically involved the inhibition of lithium catalysis by strong coordination of HMPA to lithium.[97] For instance, two-bond ^{13}C-^{13}C NMR coupling in organocuprates is poorly observable in ether or THF at very low temperature.[98] Exchange, however, is slowed in THF/HMPA or THF/12-crown-4, so that coupling is easily observed. The effect of HMPA suggests that Li^+ is involved in the exchange process.

HMPA Substitutes and Analogs.

Researchers have searched for an alternative to HMPA. Such a solvent must be stable to polar organometallic compounds and be comparable to HMPA in its many functions. Replacement solvents typically are useful in some applications but have limited value in others. Examples of some useful alternatives are (**15**)-(**19**).[30,42,99]

Hexamethylphosphoric Triamide-Thionyl Chloride[1]

(HMPA)

[680-31-9] · $C_6H_{18}N_3OP$ · Hexamethylphosphoric Triamide-Thionyl Chloride · (MW 179.24) ($SOCl_2$)

[7719-09-7] · Cl_2OS · Hexamethylphosphoric Triamide-Thionyl Chloride · (MW 118.97)

(a chlorinating agent[2] for the preparation of alkyl chlorides, acid chlorides, esters, and amides)

Physical Data: see ***Hexamethylphosphoric Triamide*** and ***Thionyl Chloride***.

Chlorinating Agent.

The use of thionyl chloride with HMPA is a good procedure for the synthesis of alkyl chlorides from primary, secondary, and tertiary alcohols (eq 2).[3] The initial product of the reaction of an alcohol with $SOCl_2$ is thought to be a chlorosulfite (eq 1).[4] The further course of the reaction depends on both the structure of the chlorosulfite and the solvent. Highest yields are obtained with primary alcohols (eq 3).

$$ROH + SOCl_2 \longrightarrow ROSOCl + HCl \qquad (1)$$

$$ROH + SOCl_2 \xrightarrow{HMPA} RCl + SO_2 + HCl \qquad (2)$$

$$BuOH + SOCl_2 \xrightarrow[90\%]{HMPA} BuCl + SO_2 + HCl \qquad (3)$$

Decomposition of the secondary alkyl chlorosulfite is often greatly influenced by the solvent, forming alkenes and alkyl chlorides in dioxane with retention of configuration (S_N1), but forming an alkyl chloride in HMPA with inversion of configuration (S_N2). This method is also advantageous for making allylic chlorides and acid chlorides, in particular for α,β-unsaturated acid chlorides, since $SOCl_2$ does not add to the C=C bond (eq 4).[3] Esters and amides can be made by treating the carboxylic acid with $SOCl_2$-HMPA at -15 °C followed by addition of an alcohol or amine, respectively (eq 5).[2] Esters of tertiary alcohols can be formed in higher yield with HMPA than with pyridine or dimethylaniline.[3]

Hexamethylphosphorous Triamide[1]

$(Me_2N)_3P$

[1608-26-0] · $C_6H_{18}N_3P$ · Hexamethylphosphorous Triamide · (MW 163.24)

(strong nucleophile;[2] used to synthesize epoxides from aldehydes[2,3] and arene oxides from aryldialdehydes;[4-7] replaces Ph_3P in the Wittig reaction;[8] with CCl_4, converts alcohols to chlorides;[9] with I_2, converts disulfides to sulfides[10] and deoxygenates sulfoxides and azoxyarenes;[11] with dialkyl azodicarboxylate and alcohol, forms mixed carbonates;[12] reduces ozonides[13])

Alternate Name: tris(dimethylamino)phosphine.

Physical Data: mp 26 °C; bp 162-164 °C/760 mmHg, 50 °C/12 mmHg; *n*25D 1.4636; *d* 0.911 g cm^{-3}.

Form Supplied in: commercially available; liquid, pure grade >97% (GC).

Preparative Methods: reaction of ***Phosphorus(III) Chloride*** with anhydrous dimethylamine; the same procedure can be used to obtain higher alkyl homologs.[14]

Purification: distillation at reduced pressure; exposure of hot liquid to air should be avoided.

Handling, Storage, and Precautions: very sensitive to air; best stored in nitrogen atmosphere; reacts with carbon dioxide; inhalation should be avoided. Use in a fume hood.

Synthesis of Epoxides.

Reaction of $(Me_2N)_3P$ with aromatic aldehydes provides convenient direct synthetic access to symmetrical and unsymmetrical epoxides in generally high yields. A typical example is the reaction of *o*-chlorobenzaldehyde, which provides the corresponding stilbene oxide as a mixture of the *trans* and *cis* isomers (eq 1).[2,3]

The coproduct, ***Hexamethylphosphoric Triamide***, is readily separated by taking advantage of its water solubility. A competing reaction pathway leads to formation of variable amounts of a 1:1 adduct in addition to the epoxide product (eq 2). Originally the adduct was assigned the betaine structure (**1a**). On the basis of more detailed NMR analysis, this was subsequently revised to the phosphonic diamide structure (**1b**).[15]

The ratio of products depends upon the electronegativity of the aldehyde and the mode of carrying out the reaction. Aromatic aldehydes with electronegative substituents, especially in the *ortho* position, undergo rapid exothermic reaction to yield epoxides exclusively. Conversely, aldehydes bearing electron-releasing substituents react more slowly to afford mainly 1:1 adducts. Slow addition of $(Me_2N)_3P$ to the aldehyde tends to enhance the ratio of the epoxide product. These observations are compatible with a mechanism in which an initially formed 1:1 adduct reacts with a second aldehyde molecule to form a 2:1 adduct which collapses to yield the observed products (eq 3).

$(Me_2N)_3P$ reacts also with saturated and heterocyclic aldehydes, but 1:1 adducts rather than epoxides are the predominant products. The reaction with ***Chloral*** takes a different course[2] and yields the dichlorovinyloxyphosphonium compound $Cl_2C{=}CH{-}O{-}{+}P(NMe_2)_3\ Cl^-$.

The scope of the reaction is considerably extended by its applicability to the synthesis of mixed epoxides.[2] This is accomplished by addition of $(Me_2N)_3P$ to a mixture of aldehydes in which the less reactive aldehyde predominates. For example, addition of $(Me_2N)_3P$ to a mixture of *o*-chlorobenzaldehyde and 2-furaldehyde yields the corresponding mixed epoxide (eq 4).

An advantage of the method is that it allows the synthesis of epoxides unobtainable by the oxidation of alkene precursors with peroxides or peracids due to the incompatibility of functional groups with these reagents.

Synthesis of Arene Oxides.

Reaction of $(Me_2N)_3P$ with aromatic dialdehydes provides arene oxides such as benz[*a*]anthracene 5,6-oxide (**2a**) (eq 5).[4-7] These compounds, also known as oxiranes, are relatively reactive, undergoing thermal and acid-catalyzed rearrangement to phenols and facile hydrolysis to dihydrodiols. Consequently, their preparation and purification requires mild reagents and conditions. The importance of this is underlined by successful synthesis of the reactive arene oxide (**2b**) in 75% yield using appropriate care,[7] despite a previous report of failure of the method.[4] While compound (**2b**) is a relatively potent mutagen, it is rapidly detoxified by mammalian cells.[6] The principal limitation

of the method is the unavailability of the dialdehyde precursors, which are obtained through oxidation of the parent hydrocarbons, e.g. by ozonolysis.

Wittig and Horner-Wittig Reactions.

$(Me_2N)_3P$ may be used in place of ***Triphenylphosphine*** in Wittig reactions with aldehydes and ketones (eq 6).[8] It is advantageous because the water solubility of the byproduct, hexamethylphosphoric triamide, renders it readily removable. This method has been used for the preparation of unsaturated esters as well as alkenes (eq 7).

The phosphonic diamide products (**1b**) obtained from the reaction of arylaldehydes having electron-donating groups with $(Me_2N)_3P$ can be deprotonated by ***n-Butyllithium*** in DME at 0 °C.[15] These intermediates participate in Horner-Wittig-type reactions with aromatic aldehydes to give enamines in good yield (eq 8). In the examples studied the enamines have the (*E*) configuration. Mild acid hydrolysis of the reaction mixtures without isolating the intermediate enamines provides the corresponding deoxybenzoins.[15] The overall procedure represents an example of reductive nucleophilic acylation of carbonyl compounds.

Conversion of Alcohols to Alkyl Chlorides and Other Derivatives.

The reagent combination $(Me_2N)_3P$ and CCl_4 can be used in place of ***Triphenylphosphine-Carbon Tetrachloride*** for the conversion of alcohols to alkyl chlorides (eq 9).[9] An advantage is the ease of removal of the water-soluble coproduct $(Me_2N)_3P{=}O$. The mechanism entails initial rapid formation of a quasiphosphonium ion, followed by reaction with an alcohol with displacement of chloride, and nucleophilic attack by the chloride ion on the carbon atom of the alcohol in a final rate-determining step to yield an alkyl chloride.

This reagent reacts more rapidly with primary than with secondary alcohols. This property has been made use of to transform the primary hydroxy groups of sugars to salts, which then may be converted to halides (Cl, Br, I), azides, amines, thiols, thiocyanates, etc. by reaction with appropriate nucleophiles (eq 10).[16] Arylalkyl ethers and thioethers may also be prepared by appropriate modification of this method.[17] These reactions generally proceed with high stereoselectivity. Thus reaction of chiral 2-octanol with this reagent afforded 2-chlorooctane with complete inversion of configuration. Also, conversion of the salt prepared from reaction of (*R*)-(-)-2-octanol with $(Me_2N)_3P/CCl_4$ at low temperature to the corresponding hexafluorophosphate salt, followed by reaction of this with potassium phenolate in DMF, gave optically pure (*S*)-(+)-2-phenoxyoctane in 93% yield (eq 11).[17]

$(Me_2N)_3P/CCl_4$ may also be employed for the selective functionalization of primary long-chain diols.[17] Reactions of diols of this type with $(Me_2N)_3P$ and CCl_4 in THF followed by addition of KPF_5 gives mono salts in high yield (eq 12).[18] THF serves to precipitate the mono salts as they are formed, thereby blocking their conversion to bis salts. Reactions of the mono salts with various nucleophiles provides the corresponding monosubstituted primary alcohols.

Conversion of Disulfides to Sulfides.

Alkyl, aralkyl, and alicyclic disulfides undergo facile desulfurization to the corresponding sulfides on treatment with $(Me_2N)_3P$ or $(Et_2N)_3P$ (eq 13).[10] For example, reaction of methyl phenyl disulfide with $(Et_2N)_3P$ in benzene at rt for ~1 min furnishes methyl phenyl sulfide in 86% yield. The desulfurization process is stereospecific, in that inversion of configuration occurs at one of the carbon atoms α to the disulfide group. Thus desulfurization of *cis*-3,6-dimethoxycarbonyl-1,2-dithiane affords a quantitative yield of *trans*-2,5-dimethoxycarbonylthiolane (eq 14). It is worthy of note that the rates of these reactions are markedly enhanced by solvents of high polarity.

$$PhSSMe + (R_2N)_3P \longrightarrow PhSMe + (R_2N)_3P{=}S \qquad (13)$$

Deoxygenation of Sulfoxides and Azoxyarenes.

Sulfoxides are deoxygenated to sulfides under mild conditions with $(Me_2N)_3P$ activated with ***Iodine*** in acetonitrile (eq 15).[11] Equimolar ratios of the sulfoxide, $(Me_2N)_3P$, and I_2 are generally employed. Yields are superior to those obtained with either $(Me_2N)_3P/CCl_4$ or Ph_3P/I_2. Reaction time is reduced by addition of ***Sodium Iodide***. Azoxyarenes, such as azoxybenzene, are converted to azoarenes with this reagent combination under similar mild conditions (eq 16).[11]

$$Ph_2S{=}O + (Me_2N)_3P \xrightarrow{I_2} Ph_2S + (Me_2N)_3P{=}O \qquad (15)$$

Preparation of Mixed Carbonates.

The reaction of $(Me_2N)_3P$ with alcohols and dialkyl azodicarboxylates proceeds smoothly at rt to provide mixed dialkyl carbonate esters in moderate to good yields (eq 17).[12] An advantage of the method over the chloroformate

method is the neutrality of the conditions employed. It should be noted that the related system ***Triphenylphosphine-Diethyl Azodicarboxylate*** converts alcohols into amines.

$$R^1OH + R^2O_2C\text{-}N{=}N\text{-}CO_2R^2 \xrightarrow{(R^3{}_2N)_3P} R^1O\text{-}CO\text{-}OR^2 + HCO_2R^2 + N_2 \quad (17)$$

Reduction of Ozonides.

In the synthesis of ecdysone from ergosterol, the ozonide product produced from (**5**) was reduced with $(Me_2N)_3P$ under mild conditions to the aldehyde (**6**) without isomerization (eq 18).[13] The scope of this method has not been investigated.

n-Hexyllithium

[21369-64-2] · $C_6H_{13}Li$ · *n*-Hexyllithium · (MW 92.13)

(alkylating agent for various functional groups; metalating agent of aryl and heteroaryl ring systems; slightly less reactive than *n*-butyllithium)

Physical Data: viscous liquid in pure state; *d* (2.8 M hexane solution) 0.73 g cm^{-3} (20 °C).

Solubility: sol at all concentrations in aliphatic and aromatic hydrocarbons; reacts exothermically with water and protic solvents.

Form Supplied in: hexane or toluene solutions are available at concentrations from 2 to 3 M and are nonpyrophoric.

Analysis of Reagent Purity: titration of 0.5 N *s*-butanol in toluene (10 mL) with hexyllithium via tared syringe at 20 °C using 2,2´-biquinoline as an indicator.

Handling, Storage, and Precautions: should be handled as ***n-Butyllithium***; store in a cool, dry place in a tightly sealed container under an inert atmosphere.

Alkylation.

Hexyllithium adds to various carbonyl functionalities, which include both acyclic, i.e. acetophenone,[1] and cyclic ketones,[2] leading to dihydrojasmone[3] and steroid derivatives.[4] Carboxylic acid,[5,6] lactone,[7] bicyclic lactam,[8] and ester[9] substrates were also useful. Additions to ***Carbon Dioxide***[10] and ***Carbon Monoxide***[11] were reported. Other functionalities include activated epoxides[12] and alkenes.[13] Stereoselective addition to chiral *N*-metalloimines[14] and oxazolines[15] was achieved.

Unlike *n*-butyllithium, metalations with *n*-hexyllithium have not been cited in the literature, but will eventually appear because of its availability. It is already recognized as an alternative to *n*-butyllithium

which generates hexane instead of butane and thus reduces environmental problems when used on an industrial scale. Compared to *n*-butyllithium, *n*-hexyllithium, as well as *n*-octyllithium and 2-ethylhexyllithium, are less reactive.[16]

1-Hexynylcopper(I)[1]

[33589-44-5] · C_6H_9Cu · 1-Hexynylcopper(I) · (MW 144.70)

(coupling agent for the delivery of the 1-hexynyl group to electrophiles,[2] both as such and in the form of higher order lithioorganocuprates;[3] non-transferable dummy ligand used in mixed lithioorganocuprates;[4] dipolarophile used in cycloaddition with nitrile oxides[5])

Physical Data: yellow solid; mp 140-150 °C;[6] IR (KBr) 2962, 2937, 2895, 2870, 1930, 1471, 1455, 1430, 1376, 1357, 1316, 1240, 1210, 1107, 1006, 918, 894, 781, 720, 518 cm^{-1}.[7]

Solubility: sol pyridine, THF, ether; insol water. *Drying:* dried in vacuo at 50 °C.

Preparative Methods: addition of ***Copper(I) Chloride*** to an ammoniacal solution of 1-hexyne;[8] addition of 1-hexyne to a ***Copper(II) Sulfate-Hydroxylamine*** hydrochloride mixture;[2] addition of ***Copper(I) Iodide*** to 1-lithiohexyne.[4]

Handling, Storage, and Precautions: copper(I) salts are potentially explosive when dry; use in a fume hood.

Coupling Agent.

Hexynylcopper combines with acyl halides to yield alkynyl ketones in high yield,[9] the reagent being more efficient than the corresponding organolithium and -magnesium species[10] (see also ***Phenylethynylcopper(I)*** and ***1-Pentynylcopper(I)***). Coupling can also be achieved with aryl,[2,11-13] vinyl,[14] and alkyl halides,[8,15] and with activated amines.[16] The presence of competing functionality usually presents no problem due to the mildly nucleophilic nature of the reagent (eq 1).[13]

(1)

Lithioorganocuprates.

Hexynylcopper can serve as a nontransferable dummy ligand when incorporated into mixed lithioorganocuprates[4,17-19] (see also ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide*** and ***(3-Methoxy-3-methyl-1-butynyl)copper(I)***). Thus, generation of a mixed vinylic cuprate (eq 2) allows facile vinylation of allyl bromides to proceed.[4]

Chemoselectivity is often observed in the delivery of the transferable group.[17] Addition of a *s*-alkoxy transferable group to cinnamaldehyde is reported to proceed with exclusive 1,2-selectivity, and in good yield.[18] Lithium bis(hexynyl)copper effectively delivers one hexynyl group to suitable electrophiles.[20,21] Exclusive 1,2-addition to enals has been reported,[20] and in the addition to iodoalkoxyallenes (eq 3), a good yield of the corresponding S_N2' adduct is obtained.[21]

Higher Order Homocuprates.

Treatment of hexynyllithium with ***Copper(I) Iodide*** is reported to generate the higher order homocuprate indicated (eq 4).[3,22] Regardless of composition, this species selectively and efficiently directs 1,2-addition to cyclohexenones in yields ranging from 85 to 95%.[3]

(4)

Cycloaddition Reactions.

Hexynylcopper has also been used as a dipolarophile in the preparation of azetidin-2-ones (eq 5).[5] The cycloaddition is of note in that *cis:trans* adducts are formed in a 12:1 ratio (R = Ph), whereas using ***Phenylethynylcopper(I)*** as the dipolarophile the ratio is close to 1:1.

(5)

Related Reagents.

Lithium (1-Hexynyl)(2-tri-n-butylstannylvinyl)cuprate.

Hydrazine[1]

N_2H_4

(N_2H_4)

[302-01-2] · H_4N_2 · Hydrazine · (MW 32.06) (hydrate)

[10217-52-4] (monohydrate)

[7803-57-8] · H_5N_2O · Hydrazine Monohydrate · (MW 49.07) (monohydrochloride)

[2644-70-4] · ClH_5N_2 · Hydrazine Monohydrochloride · (MW 68.52) (dihydrochloride)

[5341-61-7] · $Cl_2H_6N_2$ · Hydrazine Dihydrochloride · (MW 104.98) (sulfate)

[10034-93-2] · $H_6N_2O_4S$ · Hydrazine Sulfate · (MW 130.15)

(reducing agent used in the conversion of carbonyls to methylene compounds;[1] reduces alkenes,[9] alkynes,[9] and nitro groups;[14] converts α,β-epoxy ketones to allylic alcohols;[32] synthesis of hydrazides;[35] synthesis of dinitrogen containing heterocycles[42-46])

Physical Data: mp 1.4 °C; bp 113.5 °C; *d* 1.021 g cm^{-3}.

Solubility: sol water, ethanol, methanol, propyl and isobutyl alcohols.

Form Supplied in: anhydrate, colorless oil that fumes in air; hydrate and monohydrate, colorless oils; monohydrochloride, dihydrochloride, sulfate, white solids; all widely available.

Analysis of Reagent Purity: titration.[1]

Purification: anhydrous hydrazine can be prepared by treating hydrazine hydrate with BaO, $Ba(OH)_2$, CaO, NaOH, or Na. Treatment with sodamide has been attempted but this yields diimide, NaOH, and ammonia. An excess of sodamide led to an explosion at 70 °C. The hydrate can be treated with boric acid to give the hydrazinium borate, which is dehydrated by heating. Further heating gives diimide.[1]

Handling, Storage, and Precautions: caution must be taken to avoid prolonged exposure to vapors as this can cause serious damage to the eyes and lungs. In cases of skin contact, wash the affected area immediately as burns similar to alkali contact can occur. Standard protective clothing including an ammonia gas mask are recommended. The vapors of hydrazine are flammable (ignition temperature 270 °C

in presence of air). There have been reports of hydrazine, in contact with organic material such as wool or rags, burning spontaneously. Metal oxides can also initiate combustion of hydrazine. Hydrazine and its solutions should be stored in glass containers under nitrogen for extended periods. There are no significant precautions for reaction vessel type with hydrazine; however, there have been reports that stainless steel vessels must be checked for significant oxide formation prior to use. Use in a fume hood.

Reductions.

The use of hydrazine in the reduction of carbonyl compounds to their corresponding methylene groups via the Wolff-Kishner reduction has been covered extensively in the literature.[1] The procedure involves the reaction of a carbonyl-containing compound with hydrazine at high temperatures in the presence of a base (usually ***Sodium Hydroxide*** or ***Potassium Hydroxide***). The intermediate hydrazone is converted directly to the fully reduced species. A modification of the original conditions was used by Paquette in the synthesis of (±)-isocomene (eq 1).[2]

(1)

Unfortunately, the original procedure suffers from the drawback of high temperatures, which makes large-scale runs impractical. The Huang-Minlon modification[3] of this procedure revolutionized the reaction, making it usable on large scales. This procedure involves direct reduction of the carbonyl compound with hydrazine hydrate in the presence of sodium or potassium hydroxide in diethylene glycol. The procedure is widely applicable to a variety of acid-labile substrates but caution must be taken where base-sensitive functionalities are present. This reaction has seen widespread use in the preparation of a variety of compounds. Other modifications[4] have allowed widespread application of this useful transformation. Barton and co-workers further elaborated the Huang-Minlon modifications by using anhydrous hydrazine and ***Sodium*** metal to ensure totally anhydrous conditions. This protocol allowed the reduction of sterically hindered ketones, such as in the deoxygenation of 11-keto steroids (eq 2).[4a] Cram utilized dry DMSO and ***Potassium t-Butoxide*** in the reduction of hydrazones. This procedure is limited in that the hydrazones must be prepared and isolated prior to reduction.[4b] The Henbest modification[4c] involves the utilization of dry toluene and potassium *t*-butoxide. The advantage of this procedure is the low temperatures needed (110 °C) but it suffers from the drawback that, again, preformed hydrazones must be used. Utilizing modified Wolff-Kishner conditions, 2,4-dehydroadamantanone is converted to 8,9-dehydroadamantane (eq 3).[5]

(2)

(3)

Hindered aldehydes have been reduced using this procedure.[6] This example is particularly noteworthy in that the aldehyde is sterically hindered and resistant to other methods for conversion to the methyl group.[6a] Note also that the acetal survives the manipulation (eq 4). The reaction is equally useful in the reduction of semicarbazones or azines.

(4)

In a similar reaction, hydrazine has been shown to desulfurize thioacetals, cyclic and acyclic, to methylene groups (eq 5). The reaction is run in diethylene glycol in the presence of potassium hydroxide, conditions similar to the Huang-Minlon protocol. Yields are generally good (60-95%). In situations where base sensitivity is a concern, the potassium hydroxide may be omitted. Higher temperatures are then required.[7]

(5)

Hydrazine, via in situ copper(II)-catalyzed conversion to ***Diimide***, is a useful reagent in the reduction of carbon and nitrogen multiple bonds. The reagent is more reactive to symmetrical rather than polar multiple bonds (C=N, C=O, N=O, S=O, etc.)[8] and reviews of diimide reductions are available.[9] The generation of diimide from hydrazine has been well documented and a wide variety of oxidizing agents can be employed: oxygen (air),[10] ***Hydrogen Peroxide***,[10] ***Potassium Ferricyanide***,[11] ***Mercury(II) Oxide***,[11] ***Sodium Periodate***,[12] and hypervalent ***Iodine***[13] have all been reported. The reductions are stereospecific, with addition occurring *cis* on the less sterically hindered face of the substrate.

Other functional groups have been reduced using hydrazine. Nitroarenes are converted to anilines[14] in the presence of a variety of catalysts such as ***Raney Nickel***,[14a,15] platinum,[14a] ruthenium,[14a] ***Palladium on Carbon***,[16] β-iron(III) oxide,[17] and iron(III) chloride with activated carbon.[18] Graphite/hydrazine reduces aliphatic and aromatic nitro compounds in excellent yields.[19] Halonitrobenzenes generally give excellent yields of haloanilines. In experiments where palladium catalysts are used, significant dehalogenation occurs to an extent that this can be considered a general dehalogenation method.[20] Oximes have also been reduced.[21]

Hydrazones.

Reaction of hydrazine with aldehydes and ketones is not generally useful due to competing azine formation or competing Wolff-Kishner reduction. Exceptions have been documented. Recommended conditions for hydrazone preparation are to reflux equimolar amounts of the carbonyl component and hydrazine in *n*-butanol.[22,23] A more useful method for simple hydrazone synthesis involves reaction of the carbonyl compound with dimethylhydrazine followed by an exchange reaction with hydrazine.[24] For substrates where an azine is formed, the hydrazone can be prepared by refluxing the azine with anhydrous hydrazine.[25] *gem*-Dibromo compounds have been converted to hydrazones by reaction with hydrazine (eq 6).[26]

(6)

Hydrazones are useful synthetic intermediates and have been converted to vinyl iodides[27] and vinyl selenides (eq 7) (see also ***p-Toluenesulfonylhydrazide***).[28]

(7)

R = I, PhSe; RX = I_2, PhSeBr
base = pentaalkylguanidine, triethylamine

Diazomalonates have been prepared from dialkyl mesoxylates via the ***Silver(I) Oxide***-catalyzed decomposition of the intermediate hydrazones.[29] Monohydrazones of 1,2-diketones yield ketenes after mercury(II) oxide oxidation followed by heating.[30] Dihydrazones of the same compounds give alkynes under similar conditions.[31]

Wharton Reaction.

α,β-Epoxy ketones and aldehydes rearrange in the presence of hydrazine, via the epoxy hydrazone, to give the corresponding allylic alcohols. This reaction has been successful in the steroid field but, due to low yields, has seen limited use as a general synthetic tool. Some general reaction conditions have been set. If the intermediate epoxy hydrazone is isolable, treatment with a strong base (potassium *t*-butoxide or ***Potassium Diisopropylamide***) gives good yields, whereas ***Triethylamine*** can be used with nonisolable epoxy hydrazones (eq 8).[32]

(8)

Some deviations from expected Wharton reaction products have been reported in the literature. Investigators found that in some specific cases, treatment of α,β-epoxy ketones under Wharton conditions gives cyclized allylic alcohols (eq 9). No mechanistic interpretation of these observations has been offered. Related compounds have given the expected products, and it therefore appears this phenomenon is case-specific.[33]

(9)

Cyclic α,β-epoxy ketones have been fragmented upon treatment with hydrazine to give alkynic aldehydes.[34]

Hydrazides.

Acyl halides,[35] esters, and amides react with hydrazine to form hydrazides which are themselves useful synthetic intermediates. Treatment of the hydrazide with nitrous acid yields the acyl azide which, upon heating, gives isocyanates (Curtius rearrangement).[36] Di- or trichlorides are obtained upon reaction with ***Phosphorus(V) Chloride***.[37] Crotonate and other esters have been cleaved with hydrazine to liberate the free alcohol (eq 10).[38]

(10)

Hydrazine deacylates amides (Gabriel amine synthesis) via the Ing-Manske protocol.[39] This procedure has its limitations, as shown in the synthesis of penicillins and cephalosporins where it was observed that hydrazine reacts with the azetidinone ring. In this case, ***Sodium Sulfide*** was used.[40]

Heterocycle Synthesis.

The reaction of hydrazine with α,β-unsaturated ketones yields pyrazoles.[41,42] Although the products can be isolated as such, they are useful intermediates in the synthesis of cyclopropanes upon pyrolysis of cyclopropyl acetates after treatment with ***Lead(IV) Acetate*** (eq 11).

(11)

3,5-Diaminopyrazoles were prepared by the addition of hydrazine (eq 12), in refluxing ethanol, to benzylmalononitriles (42-73%).[43] Likewise, hydrazine reacted with 1,1-diacetylcyclopropyl ketones to give β-ethyl-1,2-azole derivatives. The reaction mixture must have a nucleophilic component (usually the solvent, i.e. methanol) to facilitate the opening of the cyclopropane ring. Without this, no identifiable products are obtained (eq 13).[44]

(12)

Ar = Ph, 4-MeC6H4, 3-NO2C6H4

(13)

R1, R2 = Me, Ph
X = Cl, Br, OMe, OEt, OPh, OAc, CN, etc.

In an attempt to reduce the nitro group of nitroimidazoles, an unexpected triazole product was obtained in 66% yield. The suggested mechanism involves addition of the hydrazine to the ring, followed by fragmentation and recombination to give the observed product (eq 14).[45]

Finally, hydrazine dihydrochloride reacted with 2-alkoxynaphthaldehydes to give a product which resulted from an intramolecular [3+ + 2] criss-cross cycloaddition (42-87%) (eq 15).[46]

Peptide Synthesis.

Treatment of acyl hydrazides with nitrous acid leads to the formation of acid azides which react with amines to form amides in good yield. This procedure has been used in peptide synthesis, but is largely superseded by coupling reagents such as ***1,3-Dicyclohexylcarbodiimide***.[47]

8-Hydrazinoquinoline

[14148-42-6] · $C_9H_9N_3$ · 8-Hydrazinoquinoline · (MW 159.21)

(Fischer indole synthesis: pyrido[3,2-*g*]indoles)

Alternate Name: 8-HQ.

Physical Data: pale yellow solid; mp 63.5-64 °C.

Solubility: sol ether, dichloromethane, ethanol.

Preparative Methods: the original preparation of the reagent involved the diazotization of commercially available 8-aminoquinoline followed by reduction with tin(II) chloride.[1] An improved one-step method has been developed which starts with the less expensive 8-hydroxyquinoline.[2] Sulfur dioxide (10 g) is dissolved in hydrazine hydrate (80 mL), 8-hydroxyquinoline (10.16 g) is added and the mixture is refluxed for 7 d. Every 48 h, EtOH (10 mL) is added to dissolve any starting material which may have sublimed into the condenser. The mixture is cooled, 2 M NaOH (100 mL) is added, and the resulting emulsion is extracted with $CHCl_3$ (4 × 75 mL). The combined organic layers are washed with brine (20 mL), dried over $MgSO_4$, and concentrated. The residue crystallizes upon standing and may be recrystallized from CH_2Cl_2 and pentane to afford 8.7 g (78%) of 8-HQ as pale yellow needles (eq 1).

Handling, Storage, and Precautions: the reagent is sensitive to air and light and is best kept under an inert atmosphere at 0 °C in the dark. Slow decomposition occurs with time and the material turns brown. In the early stages it can be repurified by recrystallization. Use in a fume hood.

Pyrido[3,2-*g*]indole Synthesis.

8-Hydrazinoquinoline provides a very useful method for the direct introduction of the pyrido[3,2-*g*]indole subunit. Other isomers of 8-HQ behave in an analogous fashion.[3] Treatment of 5,6,7,8-tetrahydro-8-quinolone with 8-HQ in EtOH results in precipitation of the hydrazone in essentially pure from. This material may then be heated with ***Polyphosphoric Acid*** (PPA), basified, and extracted with CH_2Cl_2 to provide a dihydrodipyridocarbazole (eq 2).[2]

The reaction also works with appropriate diketones to introduce two pyridoindole subunits. If the reactants are only combined in equimolar amounts, an intermediate monoketone derivative may be obtained (eq 3).[2]

Related Reagents.

Acetone Hydrazone; ***Hydrazine***; ***Phenylhydrazine***; ***Polyphosphoric Acid***.

Hydrazoic Acid[1]

HN_3

[7782-79-8] · HN_3 · Hydrazoic Acid · (MW 43.04)

(adds electrophilically to alkenes, alkynes, and related conjugated systems;[1c] converts carboxylic acids to amines (Schmidt reaction)[1] and alcohols to azides;[11a] cleaves epoxides;[17] aminates arenes;[19] affords sulfoximines from sulfoxides;[21c] reacts with a variety of other functional groups[1a])

Solubility: sol halogenated hydrocarbons, Et_2O, C_6H_6.

Preparative Methods: treatment of ***Sodium Azide*** with ***Sulfuric Acid*** or ***Polyphosphoric Acid***;[1a,2,3] hydrolysis of ***Azidotrimethylsilane***.[4]

Handling, Storage, and Precautions: highly toxic; extremely explosive; use in a fume hood.

Addition to Unsaturated Systems.

Being a moderately weak acid (pK_a = 4.69 at 25 °C[5]), HN_3 has not been found to undergo electrophilic addition to alkenes except for phenyl-substituted cyclopropenes (eq 1)[6] and electron-rich alkenes, such as vinyl ethers (eqs 2 and 3).[3] With Lewis acid catalysis, it undergoes addition to styrenes and 1,1-dialkylalkenes (eq 4).[3,7]

(1)

(2)

(3)

(4)

R = Ph, 73%
R = Me, 39%

Protic acid catalyzed additions of HN_3 to alkenes have also been effected using ***Trifluoroacetic Acid***, ***Trichloroacetic Acid***, or ***Phosphoric Acid***.[8] However, azides readily undergo decomposition in the presence of Lewis acids and strong protic acids.[8b,9] Moreover, the necessity of generating and handling the highly toxic and explosive HN_3 limits the attractiveness of these methods. Recently it has been reported that silica gel and alumina mediate the addition of HN_3 to styrenes, 1,3-dienes (eq 5), and 1,1-dialkylalkenes (eq 6) in the presence of an acid catalyst to give good to excellent yields of alkyl azides.[4] Under these conditions, HN_3 can be conveniently prepared in situ by hydrolysis of ***Azidotrimethylsilane*** over silica gel or alumina.

(5)

(6)

HN_3 adds to enones and related conjugated systems (eq 7);[1c,10] however, addition does not occur to a number of enones having a phenyl substituent at the β-position.[10]

(7)

Alkynes commonly undergo 1,3-dipolar addition of HN_3 to afford triazoles; however, addition leads to azides in

exceptional cases.[1c]

Schmidt Reaction.

Acid-catalyzed reaction of HN_3 with carboxylic acids gives an amine with one less carbon atom.[1] Typically the procedure involves generating HN_3 in situ with NaN_3 and excess H_2SO_4 in the presence of the substrate. Although preformed HN_3 may be used, the presence of an acid catalyst is still required. The reaction is quite general, and the yields are often high for a variety of carboxylic acids, including aliphatic, aromatic, and sterically hindered systems (eq 8). Conditions can be controlled so that dicarboxylic acids yield either mono- or diamines as products.

(8)

Ketones and aldehydes similarly react with HN_3 in the presence of H_2SO_4. Whereas reaction with aldehydes typically gives nitriles, ketones afford amides (eq 9). With 2 or more equiv of HN_3, tetrazole products may be formed (eq 10), while imino esters are obtained in the presence of alcohols (eq 11). The different products arise through capture of a common intermediate.

(9)

(10)

(11)

Reaction with Alcohols.

Benzylic alcohols react with HN_3 in the presence of an acid catalyst to give the corresponding benzylic azides.[11] Typically HN_3 is generated in situ through treatment of NaN_3 with excess H_2SO_4, and the acid further catalyzes the substitution reaction. Moderate to good yields of triarylmethyl azides are formed from the corresponding triarylcarbinols, but diarylcarbinols such as 9-hydroxyfluorene give poorer yields due to further reaction of the azide with the acid catalyst. This problem can be circumvented by using the weaker acid ***Trichloroacetic Acid*** as catalyst (eq 12).[8b,12] Tertiary alcohols are converted to tertiary azides by HN_3 in the presence of H_2SO_4 as catalyst (eq 13).[13]

(12)

(13)

Acidic conditions in the substitution process can be avoided by subjecting primary and secondary alcohols to Mitsonobu conditions in the presence of HN_3.[14] Azides, with inverted stereochemistry at the carbon center, are formed in high yields (eq 14). A procedure has been developed in which alcohols are converted to azides via the Mitsonobu reaction and are then reduced to amines without prior isolation of the azide.[15] This process allows for a one-pot conversion of alcohols to amines.

(14)

In a related reaction, tertiary alkyl halides react with HN_3 in the presence of H_2SO_4 to give products derived from the corresponding tertiary azide.[1a]

Cleavage of Epoxides.

HN_3, generated in situ through reaction of Me_3SiN_3 with MeOH, cleaves epoxides in cases in which attempted nucleophilic ring opening with azide ion fails (eq 15).[16]

(15)

In the presence of the Lewis acid ***Triethylaluminum***, epoxides are efficiently cleaved under mild conditions in a regio- and stereospecific manner (eq 16).[17] This method is successful for cases in which nucleophilic methods fail or give mixtures of products.

(16)

Reaction with Arenes.

Photolysis of HN_3 in the presence of toluene results in formation of trace amounts of toluidine.[18] Higher yields (65%) of amination products are obtained through reaction of HN_3 with toluene in the presence of ***Aluminum Chloride***.[18,19] Reaction apparently occurs through a conventional electrophilic aromatic substitution mechanism, as revealed by the ratio of *o*-, *m*-, and *p*-substituted products formed. The use of H_2SO_4 as catalyst results in lower yields. Chlorobenzene can be similarly aminated in 19% yield.

Subjection of aryl-substituted alkanes to the oxidant ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** (DDQ) in the

presence of HN_3 results in regioselective oxidative nucleophilic substitution reactions to form benzylic azides (eq 17),[20] which can be readily reduced to benzylic amines.

(17)

Aryl nitroso compounds react with HN_3 under mild conditions to give aryl azides in high yields.[1c]

Formation of Sulfoximines.

The reaction of sulfoxides with HN_3 gives sulfoximines in good yields (eq 18).[21] Treatment of a series of appropriately substituted diaryl sulfoxides with HN_3 (generated in situ) gives 1,2,4-benzothiadiazine 1-oxides in moderate to high yields via cyclization of the initially formed sulfoximines (eq 19).[22] Interestingly, reaction of dialkyl sulfides with excess HN_3 in the presence of H_2SO_4 also gives sulfoximines.[21c,23]

(18)

(19)

Reaction with Other Functional Groups.

The reactions of HN_3 with various functional groups have been the subject of several reviews.[1a,24] Several examples are shown in eqs 20-23. The ready reaction of HN_3 with -C&tbond;N bonds affords convenient syntheses of a variety of substituted tetrazoles.

(20)

(21)

(22)

(23)

When subjected to HN_3 in the presence of pyridine, acid chlorides are converted to acyl azides, which can then be converted to isocyanates in good yield.[25]

Cyclic imidates are converted in high yields to azido-substituted amides via reaction with HN_3 generated in situ (eq 24).[26] The method is mild, requiring no acid catalyst, and tolerates the presence of other functional groups.

(24)

A method for the overall conversion of ketones to amines has been reported.[27] When the acetal or methyl ether derived from a ketone is subjected to HN_3 in the presence of catalytic amounts of ***Trifluoroacetic Acid***, α-alkoxy azides are formed, which are readily reduced to the amines with ***Lithium Aluminum Hydride*** in a one-pot procedure in good overall yields (eq 25).

Related Reagents.

Sodium Azide; ***Azidotrimethylsilane***.

Hydridotetrakis(triphenylphosphine)rhodium[1a,b]

$(PPh_3)_4RhH$

[1828-36-1] · $C_{72}H_{61}P_4Rh$ · Hydridotetrakis(triphenylphosphine)rhodium · (MW 1153.12)

(catalyst for hydrogenation of alkenes[2] and hydrosilylation of alkynes[3])

Physical Data: mp 162-163 °C.

Solubility: slightly sol benzene, toluene, THF, acetone.

Form Supplied in: yellow crystals.

Preparative Methods: from ***Rhodium(III) Chloride*** or rhodium(III) acetylacetonate by reduction with ***Triethylaluminum*** in the presence of ***Triphenylphosphine***.[1a,b]

Purification: by recrystallization from toluene or benzene.

Handling, Storage, and Precautions: solid material is moderately sensitive to oxygen, but in solution it is easily decomposed by air.

Hydrogenation of Activated Alkenes by using a Hydrogen Donor.[2]

A number of different substituted styryl ketones have been reduced by 1-phenylethanol at 50 °C in the presence of catalytic amounts of $(PPh_3)_4RhH$ (eq 1). The initial rate of reduction increases when the aromatic ring contains electron-withdrawing groups and decreases in the presence of electron-releasing substituents.

Hydrosilylation of Alkynes.[3]

Hydrosilylation of acetylene with trichlorosilane, triethoxysilane, methyldichlorosilane, methyldiethoxysilane, and *n*-hexyldichlorosilane takes place in either xylene or toluene in the presence of catalytic amounts of $(PPh_3)_4RhH$ (eq 2).

Synthesis of α-Trimethylsilyl Ketones.[4]

α-Trimethylsilyl ketones are useful compounds in the synthesis of di- and trisubstituted alkenes[5] and in aldol reactions.[6] The preparation of such ketones can be carried out by any of the following reactions catalyzed by $(PPh_3)_4RhH$: isomerization of β-trimethylsilyl allyl alcohols, isomerization of β´-trimethylsilyl allyl alcohols, or dehydrogenation of β-trimethylsilyl alcohols via hydrogen transfer to α,β-enones.

Isomerization of 1,3-Diene Monoepoxides to α,β-Unsaturated Carbonyl Compounds.[7]

(*E*)-α,β-Unsaturated carbonyl compounds can be selectively obtained from the Rh-catalyzed isomerization of vinyl epoxides (eq 3). The starting monoepoxides can be prepared according to eq 4.[7]

(3)

$R^1 = H, Et, C_5H_{11}, C_7H_{15}; R^2 = H, Et, Pr, i\text{-}Pr$

(4)

Other applications include removal of the allyl ether protecting group in the presence of trifluoroacetic acid,[8] and the synthesis of allylsilanes.[9]

Hydrobromic Acid[1]

BrH

[10035-10-6] · BrH · Hydrobromic Acid · (MW 80.91)

(preparation of alkyl and vinyl bromides; preparation of phenols from alkyl aryl ethers; in combination with hydrogen peroxide is an in situ source of bromine for the preparation of alkyl and aryl bromides)

Physical Data: aqueous solution forms a constant boiling azeotrope containing ca. 48% HBr at 760 mmHg; d = 1.49 g cm^{-3}. Anhydrous gas, d 2.71 g L^{-1}; mp -86.9 °C; bp -66.8 °C.

Solubility: very sol water and protic solvents.

Form Supplied in: as anhydrous gas in cylinders; as aqueous solutions of various concentrations; widely available in all forms.

Analysis of Reagent Purity: titration.

Handling, Storage, and Precautions: hydrogen bromide is a corrosive, colorless, nonflammable gas which forms a white cloud when exposed to air; as concentrated solutions, hydrobromic acid is a colorless to light yellow corrosive liquid which fumes when exposed to air; the acid can cause severe skin burns, damage to the respiratory and digestive tract, and/or visual damage; repeated exposure may cause dermatitis and photosensitization; the gas and solutions of hydrobromic acid should be handled with adequate ventilation and proper skin and eye protection. Use in a fume hood.

Acid Catalysis.

Hydrogen Bromide is completely ionized in all but the most concentrated aqueous solutions, making it a strong Lewis acid. However, the expense of hydrobromic acid relative to ***Hydrochloric Acid*** and other mineral acids, as well as the greater nucleophilicity of bromide, has limited its use as an acid catalyst.

Bromomethylation.

Concentrated hydrobromic acid or anhydrous hydrogen bromide have been used with ***Paraformaldehyde*** or 1,3,5-trioxane for the bromomethylation of aromatic compounds (eq 1). Formation of bis(bromomethyl) ether, a carcinogenic compound, under the reaction conditions is problematic. This side reaction has limited the use of the bromomethylation process. Phenols are so reactive under the reaction conditions that they are frequently deactivated

through preparation of their acyl derivatives prior to bromomethylation. The reaction may be run in the presence of Brønsted acid catalysts.[2] Treatment of dibenzyl diselenide with ***Zinc*** and hydrobromic acid followed by paraformaldehyde and hydrogen bromide produced high yields of bromomethyl benzyl selenide (eq 2).[3] Analogous chemistry is observed with benzyl sulfide (eq 3). Treatment of an aryl alkyl ketone with ***Bis(dimethylamino)methane*** and hydrogen bromide has produced moderate yields of the ketone, which was bromomethylated α to the carbonyl (eq 4).[4]

$$\mathrm{ArH} + \mathrm{CH_2O} + \mathrm{HBr} \longrightarrow \mathrm{ArCH_2Br} \qquad (1)$$

$$\mathrm{RSeSeR} + \mathrm{CH_2O} + \mathrm{HBr} \longrightarrow \mathrm{RSeCH_2Br} \qquad (2)$$

$$\mathrm{RSH} + \mathrm{CH_2O} + \mathrm{HBr} \longrightarrow \mathrm{RSCH_2Br} \qquad (3)$$

(4)

Addition to Single Bonds in Three-Membered Rings.

Hydrogen bromide is less commonly used for the preparation of derivatives of terpenes containing three-membered rings than hydrochloric acid. Cleavage of cyclopropanes produces addition products which are expected to arise from bromide addition to the most stable carbonium ion (analogous to Markovnikov addition), some rearrangements do occur, and steric factors do play a role in the reaction (eq 5). Simple alkyl derivatives of the parent cyclopropane can give polymeric materials as the main product. As an example, treatment of *cis*-carane with hydrogen bromide results in cleavage of the cyclopropane ring with isolation of the tertiary bromide.[5]

(5)

Cyclopropylcarbinols react with concentrated hydrobromic acid under mild conditions to yield 1-bromo-3-butenes (eq 6).[6] The reaction is regiospecific with secondary and some tertiary alcohols. With alkynic cyclopropylcarbinols, stereospecificity of the product double bond can be controlled through the use of ***Octacarbonyldicobalt***.[7]

(6)

In acetic acid, acyl cyclopropane derivatives add anhydrous hydrogen bromide to yield 4-bromobutanone derivatives (eq 7). This addition is stereo- as well as regioselective.[8]

(7)

Oxiranes react readily with hydrobromic acid to yield addition products (eq 8). The reaction proceeds with inversion at carbon. The expected product is that in which the bromide adds to the least-hindered carbon. Addition to epoxycyclohexanes gives products in which attack of bromide is axial.[9] Analogous chemistry is observed with aziridines (eq 9).[10]

(8)

(9)

Addition to Single Bonds in Four-, Five-, and Six-Membered Rings.

Although the parent acylcyclobutanes are stable to hydrogen bromide, [3.2.2]propellanes, [4.2.2]propellanes, and cubanes react to give addition products (eqs 10 and 11) or rearrangement products (eq 12), as shown.[11]

(10)

(11)

(12)

Oxetanes (eq 13) and tetrahydrofurans (eq 14) can be opened by anhydrous hydrogen bromide under a variety of conditions.[12]

(13)

(14)

Four-, five-, and six-membered lactones add anhydrous hydrogen bromide to yield the acyclic bromide (eq 15). When run in glacial acetic acid, the free carboxylic acid is isolated; in alcohols, the ester is produced.[13]

(15)

Reaction with Ethers.

Ethers react with hydrogen bromide under a variety of conditions to yield the corresponding bromide and alcohol (eq 16). Acetic acid is often used as solvent, but other carboxylic acids have also been used. Frequently, under the reaction conditions, the alcohol is also converted to its bromide.[14] Reports of explosive reactions of ethers and hydrogen bromide have been reviewed.[15]

$$R^2OR^1 + HBr \longrightarrow R^2OH + R^2Br + R^1OH + R^1Br \quad (16)$$

Aryl methyl ethers can be cleaved to phenols with hydrogen bromide in glacial acetic acid or by concentrated hydrobromic acid.[16] This transformation is commonly accomplished using boron trihalides, ***Pyridinium Chloride***, or ***Iodotrimethylsilane***.[17]

Addition to Carbon-Carbon Multiple Bonds.

Hydrogen bromide reacts with alkenes more rapidly than hydrogen chloride. When care is taken to avoid radical conditions, the products which are obtained are those expected from Markovnikov addition (eq 17). ***Iron(III) Chloride***, iron(III) bromide, or ***Aluminum Bromide*** are the most commonly used Lewis acids to activate unreactive double bonds. Hydrobromination of double bonds under radical conditions can lead to mixtures of products. When an electron-withdrawing group is attached directly to the double bond, the bromide typically adds β to that group.[18]

$$R^2HC{=}CHR^1 + HBr \longrightarrow R^2H_2C\text{-}CHBrR^1 \quad (17)$$

Treatment of allene with anhydrous hydrogen bromide results in formation of the expected Markovnikov addition product and 1,3-dimethyl-1,3-dibromocyclobutane (eq 18). 1,3-Disubstituted allenes, when treated with anhydrous hydrogen bromide, produce mixtures of HBr addition products resulting from addition of the proton to either the central ketene carbon or to a terminal ketene carbon (eq 19). 1,1-Disubstituted allenes add the proton to the central allene carbon and bromide to the terminal carbon to produce 1,1-dialkyl-3-bromo-1-propenes (eq 20).[19]

(18)

(19)

(20)

Addition of hydrogen bromide to alkynes is typically slow. Addition of ammonium bromide salts or ***Copper(I) Bromide*** produces a dramatic acceleration in the rate of the addition (eqs 21 and 22). In the absence of radicals, the isolated products are typically those expected from Markovnikov addition,[20] although mixtures of products have been reported when the carbon α to the triple bond bears an amine.[21] Under radical conditions, hydrogen bromide adds to alkynes to yield anti-Markovnikov products.[22] In the presence of ***Copper(II) Bromide*** and ammonium bromide, aqueous hydrobromic acid adds to vinylacetylene to yield 2-bromobutadiene (eq 23).[23]

$$R^2C{\equiv}CR^1 + HBr \longrightarrow R^2HC{=}CBrR^1 + R^2H_2C\text{-}CBr_2R^1 \quad (21)$$

(22)

(23)

Hydrobromic acid is superior to hydrochloric acid for the conversion of 3-acylprop-2-ynal diethyl acetals to 3-acylprop-2-enoic acids (eq 24).[24]

(24)

Reactions with Alcohols.

Hydrobromic acid reacts with primary, secondary, tertiary, allylic, benzylic, and propargylic alcohols to give the corresponding bromides (eq 25). As is the case with the conversion of alcohols to chlorides, a large number of alternative reagents are available. Although hydrobromic acid is readily available, greater selectivity is often achieved using reagents such as ***Zinc Bromide***/***Triphenylphosphine***/***Diethyl Azodicarboxylate***, ***Phosphorus(III) Bromide***, or PPh_3/***Carbon Tetrabromide***. Treatment of alkyl phosphites, phosphonates, and diphenyl phosphinites with hydrogen bromide produces the alkyl bromide in which inversion at carbon has occurred. Yields are higher and conditions milder than the corresponding reaction with hydrogen chloride.[25]

$$ROH \longrightarrow RBr \quad (25)$$

The reactions of carbohydrates and their derivatives with hydrogen bromide at the anomeric hydroxy are especially

facile examples of the conversion of alcohols to bromides.[26]

When treated with hydrogen bromide, cyclobutylcarbinol rearranges to cyclopentyl bromide (eq 26).[27] The analogous [2.1.1]bicyclocarbinol produces the primary bromide with hydrogen bromide (eq 27).[28]

(26)

(27)

Concentrated hydrobromic acid reacts with 1,1-dialkylpropargyl alcohols to give products which are dependent upon the reaction conditions. Products isolated when 3-methylbut-1-yn-3-ol was the starting alcohol include 1-bromo-3,3-dimethylallene, 3-bromo-3-methyl-1-butyne, 1-bromo-3-methyl-1,3-butadiene, 1,3-dibromo-3-methylbutene, and 1,2,3-tribromo-3-methylbutane (eq 28). Tertiary propargyl alcohols, in the presence of copper(I) bromide, ammonium bromide, and 45-48% hydrobromic acid, rapidly produce 1-bromoallenes. Secondary propargyl alcohols produce 1-bromoallenes using 60% hydrobromic acid, copper(I) bromide, and ammonium bromide.[29]

(28)

Reactions with Diazo Compounds.

Arylamines can be converted to aryl bromides by treatment with ***Sodium Nitrite***/hydrobromic acid/***Copper*** or copper(I) bromide (eq 29).[30] Hydrobromic acid converts α-diazo ketones to α-bromo ketones in good yield (eq 30).[31] Pure enantiomers of serine and threonine give good yields and high enantiomeric purity of α-bromo acids when treated with nitrite and hydrobromic acid.[32]

$$ArNH_2 \longrightarrow [ArN_3] \longrightarrow ArBr \qquad (29)$$

(30)

Reactions with Nitriles.

Addition of anhydrous hydrogen bromide to nitriles produces imidoyl bromides (eq 31).[33] Treatment of *N*-alkylimidoyl bromides with hydrogen bromide results in isolation of the corresponding iminium bromides (eq 32).[34] Methylene bis(thiocyanate) reacts with hydrogen bromide to produce the cyclic imidoyl bromide (eq 33).[35] Methyl and phenyl thiocyanate react with 2 equiv of hydrogen bromide to produce 1-bromothioformimidate salts (eq 34).[36] Cyanogen di-*N*-oxide reacts with hydrobromic acid to produce the hydroxamoyl bromide analog of oxalyl bromide (eq 35).[37]

(31)

(32)

(33)

(34)

(35)

Reactions with Sulfur Compounds.

Thiols react with paraformaldehyde and hydrobromic acid to yield bromomethyl thioethers (see bromomethylation above). Benzenesulfonamides, benzenesulfonohydrazides, and benzenesulfinic acids can all react with hydrobromic acid to yield disulfides or sulfenyl bromides, depending upon the reaction conditions (eqs 36-38). Hydrogen bromide appears to be better than hydrogen chloride for the preparation of disulfides from benzenesulfonamides, but less satisfactory than hydrogen chloride for the conversion of benzenesulfonohydrazides to disulfides.[38] Sulfoxides are converted into bromosulfonium bromides or sulfides (eq 39).[39] Chloro(trifluoromethyl)sulfine reacts with anhydrous hydrogen bromide to produce 1-bromo-1-chloro-2,2,2-trifluoroethylsulfenyl bromide in high yield (eq 40).[40] Additional information is included under the section on the in situ generation of ***Bromine*** (see below).

$$ArSO_2NR_2 \longrightarrow ArSBr + ArSSAr \qquad (36)$$

$$ArSO_2NHNR_2 \longrightarrow ArSBr + ArSSAr \qquad (37)$$

$$ArSO_2H \longrightarrow ArSBr + ArSSAr \qquad (38)$$

(39)

(40)

Reactions with Silicon Compounds.

Phenylsilanes react with hydrogen bromide to yield benzene and the bromosilane (eq 41). The reaction is more facile than the reaction with hydrogen chloride. Increasing the electronegativity of substituents on silicon decreases the ease with which the aryl-silicon bond is broken.[41] *t*-Butyldimethylsilyl ethers of phenols are cleaved to phenols at rt using a mixture of hydrobromic acid and ***Potassium Fluoride*** (eq 42).[42] Triethylaminosilanes are converted to the corresponding bromosilanes in the presence of hydrobromic acid/***Sulfuric Acid*** (eq 43).[43]

(41)

(42)

(43)

Transhalogenation Reactions.

Alkyl chlorides can be converted to alkyl bromides using hydrogen bromide in the presence of iron(III) bromide (eq 44).[44] This conversion can also be effected under neutral conditions by heating the chloride with a metal bromide in acetone, an alcohol, or ethyl bromide.[45]

(44)

Acid chlorides react with anhydrous hydrogen bromide to yield the corresponding acid bromides (eq 45).[46] This conversion may also be effected using ***Bromotrimethylsilane***.[47]

(45)

Trichloromethylsulfenyl chloride reacts with concentrated hydrobromic acid to yield trichloromethylsulfenyl bromide (eq 46).[48] Dichloromethyl methyl sulfide produces dibromomethyl methyl sulfide when treated with anhydrous hydrogen bromide (eq 47).[49]

(46)

(47)

Bromide Isomerization.

α,α-Dibromo ketones equilibrate to α,α´-dibromo ketones in the presence of dilute hydrobromic acid (eq 48).[50]

(48)

Organoselenium, Organogermanium, and Organorhenium Chemistry.

Selenols react with paraformaldehyde and hydrogen bromide to produce bromomethyl selenides (see bromomethylation above). Methyl phenyl selenides are cleaved by hydrogen bromide in acetic acid to yield phenyl selenols (eq 49).[51] Alkyl phenyl selenoxides react with hydrogen bromide to yield the alkyl bromides (eq 50).[52] Selenonium nitroylides give bromonitromethane derivatives when reacted with hydrogen bromide in ether (eq 51).[53]

(49)

(50)

(51)

1,1-Dihydroxy-2,3-diphenylgermirene is converted to the dibromide with anhydrous hydrogen bromide in benzene (eq 52).[54]

(52)

The pure enantiomer of the pseudotetrahedral rhenium alkyl complex in eq 53 reacts with concentrated hydrobromic acid to produce the pure reduced enantiomer. Cleavage of the rhenium-carbon bond occurs with retention at both carbon and rhenium.[55]

(53)

In Situ Generation of Bromine.

Dimethyl Sulfoxide reacts with hydrobromic acid at about 80 °C to produce dimethyl sulfide, water, and bromine (eq 54). The DMSO/HBr reagent has been used to oxidize 1,3-diketones to 1,2,3-triketones, acetophenones to phenylglyoxals, benzylamines to imines, and 4,5-dihydropyridazin-3(2*H*)-ones to pyridazin-3(2*H*)-ones.[56] The combination is also effective in converting stilbenes, 1,2-dibromo-1,2-diarylethanes, and 2-bromo-1,2-diarylethanols to benzils.[57] It is possible to use a catalytic amount of hydrogen bromide in some of these reactions.

(54)

Hydrobromic acid and ***Hydrogen Peroxide*** are an effective combination for the in situ generation of bromine (eq 55). This combination of reagents can be used for the bromination of alkenes and aromatics, for the preparation of bromohydrins from alkenes, and for the preparation of benzylic bromides.[58]

$$2\ HBr + H_2O_2 \longrightarrow 2\ H_2O + Br_2 \qquad (55)$$

Hydrobromic acid is a source of bromine when irradiated in the presence of air or oxygen (eq 56). Ethylbenzene, when photooxidized, yields a mixture of acetophenone, 1-phenylethanol, and 1-phenylbromoethane.[59]

$$4\ HBr + O_2 \xrightarrow{h\nu} 2\ Br_2 + 2\ H_2O \qquad (56)$$

Related Reagents.

Formaldehyde-Hydrogen Bromide; ***Hydrogen Bromide***.

Hydrochloric Acid[1]

ClH

[7647-01-0] · ClH · Hydrochloric Acid · (MW 36.46)

(strong Brønsted acid used for general acid catalysis; preparation of salts of amines; preparation of alkyl, allyl, aryl, benzyl, and vinyl chlorides; protodemetalation reagent; in combination with hydrogen peroxide is an in situ source of chlorine for the preparation of alkyl and aryl chlorides)

Physical Data: aqueous solution: freezing point of ca. 31% solution -46 °C; forms constant boiling azeotrope containing 20.22% HCl with water (bp 108.58 °C/760 mmHg; *d* 1.096 g cm^{-3}). Anhydrous gas: *d* 1.639 g L^{-1}; mp -114.22 °C; bp -85.05 °C/760 mmHg.

Solubility: very sol water, protic solvents, ethers.

Form Supplied in: as anhydrous gas in cylinders; as aqueous solutions of various concentrations; widely available in all forms.

Analysis of Reagent Purity: titration.

Handling, Storage, and Precautions: hydrogen chloride is a corrosive, colorless, nonflammable gas which forms a white cloud when exposed to air; as concentrated solutions, hydrochloric acid is a colorless to light-yellow corrosive liquid which fumes when exposed to air; the acid can cause severe skin burns, damage to the respiratory and digestive tract, and/or visual damage; repeated exposure may cause dermatitis and photosensitization; the gas and solutions of hydrochloric acid should be handled with adequate ventilation and proper skin and eye protection. Use in a fume hood.

Acid Catalysis.

Hydrogen Chloride is completely ionized in all but the most concentrated aqueous solutions. In addition, the nucleophilicity[2] of the halide ions follows the general order $I^- > Br^- > Cl^- > F^-$. Consequently, in many of the reactions in which it is employed, it is used as an acid catalyst. Reactions employing hydrochloric acid as a catalyst include the hydrolysis of esters to acids, the hydrolysis of nitriles and imides to amides, acids, and amines,[3] the hydrolysis of amides to acids and amines,[4] the hydrolysis of imines and enamines to ketones and amines, the hydrolysis of nitroso compounds to ketones, the hydrolysis of ketals, aminals, and enol ethers to ketones, the hydrolysis of acetals to aldehydes, and the hydrolysis of ethers to alcohols.[5] Anhydrous hydrogen chloride in an alcohol is frequently used in Fischer esterifications and in acetalization reactions. Hydrochloric acid has been used to effect numerous molecular

rearrangements. Carbon-carbon bond-forming reactions catalyzed by hydrochloric acid include the aldol condensation and the Mannich reaction.[6] The Bergius-Willstatter saccharification process utilizes hydrochloric acid to convert cellulose to fermentable sugar.

Amine Salt Formation.

Many amines form solid hydrochloride salts. The low toxicity of chloride ion and favorable physical properties of many of these salts has resulted in the use of such salts for a large number of pharmaceuticals.[7] Hydrochloride salts are also used for characterization of amines.

Chloroalkylation.

Concentrated hydrochloric acid and anhydrous hydrogen chloride have been used with ***Paraformaldehyde*** for the chloromethylation of aromatic compounds (eq 1). Formation of bis(chloromethyl) ether, a carcinogenic compound, under the reaction conditions is problematic. This side reaction has limited the use of the chloromethylation process.[8] In the presence of thiols, acetaldehyde will react with hydrogen chloride to yield alkyl chloroethyl thioethers (eq 2).[9]

$$\mathrm{ArH} + \mathrm{CH_2O} + \mathrm{HCl} \longrightarrow \mathrm{ArCH_2Cl} \qquad (1)$$

$$\mathrm{RSH} + \mathrm{RCHO} + \mathrm{HCl} \longrightarrow \mathrm{RSCHClR} \qquad (2)$$

Amidomethylation.

N-Acylhemiaminals can react with pyrroles in ethanol saturated with hydrogen chloride to produce the amidomethylated product (eq 3). Such amidomethylations are more commonly performed using ***Sulfuric Acid*** as catalyst.[10]

Addition to Single Bonds in Three-Membered Rings.

Hydrogen chloride will react with some cyclopropanes to yield ring-opened products (eq 4). These addition reactions typically yield products expected from Markovnikov addition. Δ^3-Carene (**1**) and Δ^4-carene (**2**) both produce a mixture of sylvestrene dihydrochloride (**3**) and dipentene dihydrochloride (**4**).[11]

Anhydrous hydrogen chloride can react with oxiranes and aziridines to yield addition products (eqs 5 and 6). Oxiranes and aziridines derived from cyclohexenes open preferentially through axial attack by chloride.[12] Other Lewis acids, including ***Aluminum Chloride***, ***Tin(IV) Chloride***, and ***Iron(III) Chloride***, also produce 2-chloroethanols when reacted with oxiranes. In the presence of sulfur nucleophiles, good yields of the sulfur addition product may be obtained.[13]

Addition to Single Bonds in Five-Membered Rings.

Treatment of γ-butyrolactone with hydrochloric acid produces 4-chlorobutyric acid in good yield (eq 7).[14] Ring opening of 1,4-dihydro-1,4-epoxybenzene derivatives with hydrochloric acid results in isolation of the corresponding phenols (eq 8). This aromatization may be very regiospecific.[15,5a]

Reaction with Ethers.

In addition to the reactions with cyclic ethers cited above, hydrogen chloride reacts with acyclic ethers to produce the corresponding alcohols and chlorides (eq 9). The rate of the reaction is dependent upon the structure of the ether.[16] In the presence of ***Zinc Chloride***, hydrogen chloride reacts with propargyl ethers to produce propargyl chlorides (eq 10).[17]

Addition to Carbon-Carbon Multiple Bonds.[1b]

Hydrochloric acid reacts with alkenes to produce either alcohols or alkyl chlorides. Anhydrous hydrogen chloride is typically the reagent used for the preparation of alkyl chlorides (eq 11). The product of the reaction is dependent upon the substrate and reaction conditions; Markovnikov addition is typically observed, but addition may be either *syn* or *anti*. The kinetic product formed from addition of HCl to alkenes may be unstable under the reaction conditions and may rearrange to yield thermodynamically more stable products. Addition of hydrogen chloride to α-pinene (**5**) leads initially to pinene hydrochloride (**6**), which isomerizes mainly to bornyl chloride (**7**) containing some fenchyl chloride (**8**).[18] Analogous rearrangements are observed with camphenes.[19] Addition to some alkenes and alkynes may require elevated temperatures, elevated pressures, or addition of a Lewis acid. The reaction with alkynes produces vinyl chlorides and dichloroalkanes (eq 12).[20] The addition to conjugated double bonds frequently leads to products which are a mixture of 1,2- and 1,4-addition products. When the diene is conjugated to an electron-withdrawing group, anti-Markovnikov addition is common.[21] Selectivity may be observed in the reaction of butadiene derivatives.[22] Allenes

frequently give mixtures of products due to acid-catalyzed migration of double bonds. The major product at low temperature is frequently the product formed from protonation at the central allene carbon.[23]

$$R^2HC{=}CHR^1 + HCl \longrightarrow R^2H_2C\text{-}CHClR^1 \qquad (11)$$

(5) **(6)** **(7)** **(8)**

$$R^2C{\equiv}CR^1 + HCl \longrightarrow R^2HC{=}CClR^1 + R^2H_2C\text{-}CCl_2R^1 \qquad (12)$$

Addition of anhydrous hydrogen chloride to 1-nitro-1-alkenes can produce 1,2-dichloroaldoximes (eq 13).[24]

(13)

Reactions with Alcohols.

Concentrated hydrochloric acid and anhydrous hydrogen chloride react with alcohols to produce alkyl chlorides (eq 14).[25] Allylic,[26] benzylic,[27] or tertiary alcohols[28] typically are most useful as substrates for conversion to chlorides. Rearrangement may occur. On a laboratory scale, hydrochloric acid has been largely replaced by the use of phosphorus reagents such as ***Triphenylphosphine***/CCl_4, ***Triphenylphosphine Dichloride***, or Ph_3P/***Diethyl Azodicarboxylate***/Cl^- to achieve the conversion of an alcohol to a chloride.[29] These reagents frequently give less rearrangement and more stereospecificity than hydrochloric acid, ***Phosphorus(V) Chloride***, ***Phosphorus Oxychloride***, ***Thionyl Chloride***, ***Phosphorus(III) Chloride***, or ***Dimethylchloromethyleneammonium Chloride***. Treatment of alkyl phosphites, phosphonates, and diphenyl phosphinites derived from alcohols with hydrogen chloride produces the alkyl chloride in which inversion at carbon has occurred. Yields are lower and conditions are more rigorous than the corresponding reaction with ***Hydrogen Bromide***.[30]

$$ROH \longrightarrow RCl \qquad (14)$$

The reactions of carbohydrates and their derivatives with hydrogen chloride at the anomeric hydroxyl are examples of the facile conversion of alcohols to chlorides.[31] Protected and unprotected sugars react with methanol in the presence of dilute hydrochloric acid to produce the methyl ether at the anomeric center.[32]

Reactions with Diazo Compounds.

The reaction of diazo compounds derived from α-amino acids or α-amino ketones with hydrochloric acid results in isolation of the corresponding racemic α-chloro carbonyl compound (eq 15).[33]

(15)

Reactions with Nitriles and Their Derivatives.

Addition of anhydrous hydrogen chloride to nitriles produces imidoyl chlorides (eq 16).[34] Treatment of *N*-alkylimidoyl chlorides with hydrogen chloride results in isolation of the corresponding iminium halides (eq 17).[35] Aryl cyanates react with hydrogen chloride to produce haloformimidinium halides (eq 18).[36] Molecules containing two nitrile groups frequently give cyclic amidinium products.[37] Hydrogen chloride reacts with nitrile oxides to yield hydroxamoyl chlorides (eq 19). Hydroxamoyl chlorides are also produced in the reaction of phenylnitromethane with hydrogen chloride and in the reaction of acetophenones with isopropyl nitrite and hydrogen chloride.[38]

(16)

(17)

(18)

(19)

Reaction with Nitrogen-Sulfur Bonds.

Hydrogen chloride has been used to cleave the nitrogen-sulfur bond of 2,2,2-trifluoro-1,1-diphenylethylsulfenyl-protected amines in high yield (eq 20).[39]

$$R^1NHSR^2 + HCl \longrightarrow R^1NH_2 + R^2SCl \qquad (20)$$

Hydrolysis of 1,1-Dichloroethylenes.

Hydrochloric acid in glacial acetic acid or alcohols has been used to convert 1,1-dichloroethylenes to carboxylic acids (eq 21).[40] This reaction appears to require additional conjugation or the presence of an allylic leaving group to proceed smoothly. The use of sulfuric acid appears to be more general since additional conjugation is not required.[41] ***Potassium Hydroxide*** has also been used to effect this hydrolysis.[42]

(21)

Silicon and Sulfur Chemistry.

Protodesilylation with hydrochloric acid is most useful for substrates in which the silicon-carbon bond to be cleaved is aryl (eq 22), vinylic (eq 23), benzylic, or allylic (eq 24).[43] Phenylsilanes react with hydrogen chloride to yield benzene and the chlorosilane. The reaction is less facile than the reaction with hydrogen bromide.[44] Increasing the electronegativity of substituents on silicon decreases the ease with which the aryl-silicon bond is broken. Hindered aryl silanes may require fluoride ion.[45] Allylic protodesilylation normally occurs with double bond migration (eq 24).[46] Protodesilylation of a silicon-carbon bond in which the carbon is sp hybridized may require the addition of a fluoride source (eq 25).[47]

$$ArSiR^1R^2R^3 + HCl \longrightarrow ArH \qquad (22)$$

(23)

(24)

(25)

Triethylaminosilanes are converted to the corresponding chlorosilanes in the presence of hydrochloric acid/sulfuric acid (eq 26).[48]

(26)

Silyl ethers may be cleaved using hydrochloric acid (eq 27).[49] Fluoride ion is an alternative which is frequently used when the substrate is acid sensitive.

(27)

Acylsilanes have been obtained from 1-silyl-1-enol ethers (eq 28), 1-silyl-1-aminoethylenes (eq 29), and mixed *O*-alkyl-*O*-silyl acetals of acylsilanes (eq 30) upon treatment with dilute hydrochloric acid.[50] Analogous chemistry has been observed with germanium and tin compounds.[51]

(28)

(29)

(30)

Phenylsilane reacts with anhydrous hydrogen chloride in ether in the presence of ***Aluminum Chloride*** to yield chlorophenylsilane (eq 31).[52]

$$PhSiH_3 \longrightarrow PhSiH_2Cl \qquad (31)$$

Diphenylsilanediol yields the cyclic siloxane in moderate yield when treated with concentrated hydrochloric acid in ether at reflux (eq 32).[53] This reaction is also effected using amines.

(32)

Thioacyl chlorides have been prepared from thioketenes and anhydrous hydrogen chloride at low temperatures (eq 33).[54]

(33)

Transhalogenation Reactions.

3-Bromo-4,5-dihydroisoxazole derivatives can be converted to the corresponding chlorides by treatment with hydrochloric acid and ***Lithium Chloride*** (eq 34).[55]

(34)

Organometallic Chemistry.

Carbon-metal bonds are typically cleaved by hydrochloric acid to yield the metal chloride and the hydrocarbon (eq 35).[56] Oxygen-tin bonds are also cleaved by treatment with hydrochloric acid.[57]

$$RM + HCl \longrightarrow RH \qquad (35)$$

Alkyl phenyl selenoxides react with hydrogen chloride to yield the alkyl chlorides (eq 36). Conversion to the bromide with hydrogen bromide proceeds faster and in higher yield.[58]

(36)

Treatment of the zirconium metallacycle shown with hydrochloric acid led to formation of the indole in high yield (eq 37).[59]

(37)

Treatment of a tungsten complex with 2 equiv of hydrochloric acid in ether led to formation of a new chlorotungsten compound (eq 38).[60]

(38)

1,1-Dihydroxy-2,3-diphenylgermirene is converted to the dichloride with anhydrous hydrogen chloride in benzene (eq 39).[61]

(39)

In Situ Generation of Chlorine and Hypochlorite.

Hydrochloric acid and ***Hydrogen Peroxide*** are an effective combination for the in situ generation of ***Chlorine*** (eq 40). This combination of reagents can be used for the halogenation of alkenes and aromatics.[62]

$$HCl + [O] \longrightarrow Cl_2 \qquad (40)$$

Treatment of 1,2-diphenylacetylene with HCl and ***Iodosylbenzene*** on silica gel appears to proceed through formation of chlorine to yield a mixture of (*E*)- and (*Z*)-1,2-diphenyl-1,2-dichloroethylene. However, under similar conditions, 1,1,2-triphenylethylene produces 2-chloro-1,1,2-triphenylethanol.[63] Chlorides are obtained in higher yields than bromides, which are obtained in higher yields than iodides when HBr or HI are substituted for HCl in the reaction. 1-Phenylpropyne reacts with oxone (***Potassium Monoperoxysulfate***) and hydrochloric acid in DMF to produce 2,2-dichloropropiophenone in high yield.[64] Replacement of oxone with ***m-Chloroperbenzoic Acid*** results in lower yields.

Related Reagents.

Formaldehyde-Hydrogen Chloride; ***Hydrogen Chloride***.

Hydrofluoric Acid[1]

FH

[7664-39-3] · FH · Hydrofluoric Acid · (MW 20.01)

(strong acid;[1b] fluorinating agent;[1b] forms complexes with organic bases as fluorination agents;[1a] deprotecting reagent[2])

Physical Data: mp -83.5 °C; bp 19.5 °C; *d* 3.0 (air = 1) at 25 °C.

Solubility: 100 wt % in water.

Form Supplied in: gas, colorless mobile liquid, or aq. solution; HF-pyridine, HF-triethylamine and HF-pyridine polymer bound are also available.

Handling, Storage, and Precautions: HF and its containing complexes are severely human tissue corrosive, causing extremely painful and slow-healing burns and ulcers. No glassware should be used for any reaction involving hydrofluoric acid. Wash thoroughly after handling. Since hydrogen fluoride burns may not be noticed for several hours, should you have any suspicion of skin contact, flush skin with water immediately for 5 min and apply calcium gluconate gel (2.5%) on the burned area. The container should be kept in a cool and dark place which should be well ventilated. Avoid storage in glass and some metals since it corrodes most substances except lead, wax polyethylene, and platinum. Use in a fume hood.

Hydrofluorination.

Anhydrous ***Hydrogen Fluoride*** and its base solutions are useful for the fluorination of various compounds and can add to alkenes, alkynes, and some other unsaturated systems (eq 1).[3] Due to the difficulties of handling anhydrous hydrogen fluoride, HF-organic base (amines,[1a] ketones,[4] or ethers[5]) solutions are often used. One of the important reagents is HF in pyridine solution, which contains 9 equiv of HF and 1 equiv of pyridine (Olah's reagent).[6,7] These HF-organic base solutions are very hygroscopic, and the absorption of water has a profound effect on the fluorination activity. HF-melamine (86/14, wt/wt %) complex has been reported to be superior to other HF-amine solutions (eq 2).[8] Aqueous HF solution has been rarely used for this addition because of the competitive incorporation of water.[9] Hydrogen fluoride adds to hydrocarbon alkenes to form the monofluoride, obeying Markovnikov's rule with the complicating effect of polymerization. By using excess HF, polymerization can be reduced. Activated charcoal[10] and ***Boron Trifluoride***[11,12] have been used for catalyzing this reaction. Addition of hydrogen fluoride to halogenated alkenes has less tendency for polymerization, but the ease of this reaction decreases with the increasing number of halogen atoms (eq 3).[12] Chlorine atoms can be exchanged by fluorine under some conditions (eq 4).[5] ***Lead(IV)***

Oxide[13] or ***Lead(IV) Acetate***[14] and anhydrous hydrogen fluoride can generate fluorine in situ to add across the double bond.

(1)

(2)

(3)

(4)

The addition of hydrogen fluoride across a triple bond can be effected by various reagents (eq 5).[4,9] It is difficult to stop the addition of HF at the intermediate fluoroalkene stage, indicating that the intermediate alkene is more reactive than the parent alkyne. Hydrofluorination of alkynes with solid poly(hydrogen fluoride) is found to be efficient and convenient.[9] HF is also a catalyst for addition of fluorine to alkynes by ***Xenon(II) Fluoride*** to form vicinal tetrafluorides (eq 6).[15] Anhydrous HF has been used in cyclization of 1-bromoalkynes with an *N*-acyliminium ion to form bromofluoro derivatives (eq 7).[16] The electrophilic *anti* addition of the elements of benzeneselenenyl fluoride to an alkyne has been achieved by using *N*-phenylselenophthalimide and Et_3N-3HF (eq 8).[17]

(5)

(6)

(7)

4:1 isom. mix.

(8)

Hydrogen fluoride can also add directly to other unsaturated compounds. Phenylcarbamoyl fluoride has been prepared by addition of HF to phenyl isocyanate in a quantitative yield (eq 9).[18,19] Hydrogen fluoride can also add across the C=N double bond in moderate to good yields (eq 10).[20]

(9)

(10)

Hydrogen fluoride and other fluoride sources in combination with electrophilic halogens (such as NCS, NBS, or NIS) can generate halofluorides (ClF, BrF, or IF) in situ, which then add across the alkene to give the halofluorination products.[21] ***N-Bromoacetamide*** or ***N-Bromosuccinimide*** with HF or its base solutions are convenient reagents for bromofluorination (eq 11).[22-25] The addition follows the Markovnikov-type regioselectivity. Bromofluorination of allylic alcohols gives the vicinal fluorobromohydrins, which can form α-fluoro epoxides and/or monofluoro oxetanes (eq 12).[26] Iodofluorinations are often very stereo- and regioselective (eq 13).[27-29] A carbonyl group has been transformed into a CF_2 moiety via its hydrazone by an in situ generated bromine monofluoride (BrF) method.[30]

(11)

(12)

(13)

Friedel-Crafts Reaction and Cyclodehydration.

Liquid anhydrous hydrogen fluoride is an effective dehydrating and condensing agent, comparable to strong acids such as conc. ***Sulfuric Acid***.[31] It catalyzes Friedel-Crafts acylation and alkylation to form a variety of products. Most of the reactions proceed at rt within a very short period of time. Methylcyclopropane reacts with benzene in the presence of HF to give *s*-butylbenzene as the only product (eq 14).[32] SbF_5 and BF_3 have been used as catalysts in some cases (eq 15).[33-35] HF has been used as a catalyst for intramolecular Friedel-Crafts acylation and is sometimes superior to ***Polyphosphoric Acid*** (eq 16).[36] Ring closure of tertiary alcohols and alkenes to an aromatic ring can be achieved by treating substrates with neat HF (eq 17).[37-39] Hydrogen fluoride can also effectively catalyze the Fries rearrangement.[40]

(14)

(15)

(16)

(17)

Hydrogen fluoride cyclodehydration provides a wide range of polycyclic aromatic compounds (eq 18).[41] This is also a very useful method to prepare some heterocyclic compounds (eq 19).[42,43] Trienes can undergo an intramolecular

Diels-Alder reaction with good stereoselectivity, when it is catalyzed by aqueous HF (eq 20).[44]

(18)

(19)

Fluorodehydroxylation and Fluorodeamination.

Secondary and tertiary alcohols and their derivatives, such as acetates and mesylates, are readily fluorinated by HF-amine solutions. Olah's reagent and HF-melamine convert free secondary and tertiary alcohols into the corresponding fluoride in moderate to good yield.[6,45] 1-Adamantanol has been converted to 1-fluoroadamantane by HF-pyridine at rt (eq 21).[46] The mesylates and tosylates of primary alcohols can be converted to the corresponding fluorinated compounds by tetrabutylammonium difluoride; however, secondary mesylates give lower yields due to the formation of alkenes as byproducts (eq 22).[47] Glycosyl fluorides can be made from protected sugars and β-isomers are the major product in most of the cases (eq 23).[48-50]

Aromatic amines can be transformed into their corresponding fluorinated compounds by a one-pot diazotization and fluorodediazonization in good yields (eq 24).[51-53] If sodium halide (chloride, bromide or iodide) is added, haloarene isomeric mixtures are formed in good yield with small amounts of fluoroarenes. α-Fluorocarboxylic acids and ketones have been prepared from amino compounds via diazotization in 70% poly(hydrogen fluoride)-pyridine, with some exceptions (eq 25).[54]

(24)

(25)

Halogen-Exchange Fluorination.

For most primary and secondary aliphatic halides, halogen-exchange fluorination can be carried out by using ***Potassium Fluoride*** or other inorganic fluorides. HF reagents are suitable for unreactive cyclic and tertiary alkyl halides where KF or ***Cesium Fluoride*** often fail to give good results. ***Copper(I) Oxide*** and ***Mercury(II) Oxide*** are effective catalysts for this halogen exchange reaction due to the formation of metal fluorides (eq 26).[55,56] The combination of ***Nitronium Tetrafluoroborate*** and HF-pyridine exchanges bridgehead adamantyl halides with fluoride in good yield.[57] Acyl fluorides can be readily made by treating acyl chlorides or anhydrides with hydrogen fluoride (eq 27).[57-59]

(26)

(27)

Trifluoromethylation of phenols can be achieved with carbon tetrachloride and hydrogen fluoride (eq 28).[60] Chlorines on other heteroatoms, such as boron,[61] silicon,[62] phosphorus,[63] and iodine, can be exchanged with fluoride by hydrogen fluoride.

(28)

Ring-Opening Fluorinating Reagent.

Three-membered rings, such as cyclopropanes, epoxides, aziridines, and azirines, can be opened upon treatment with HF reagents. Opening cyclopropanes with HF-pyridine gives fluoropropanes.[29] Treating substituted cyclopropylmethanols with HF-pyridine, in diisopropylamine and chlorobenzene in the presence of KHF_2, affords homoallylic fluorides in good yields (eq 29).[64] Epoxides are much more reactive than cyclopropanes and can be readily opened by a variety of HF reagents.[65-67] These reactions are often regioselective (eq 30).[68] Addition takes place to give the *trans* products when epoxyindane (eq 31), 1,2-epoxytetralin (eq 32), and 2,3-epoxytetralin (eq 33) are treated with HF-diisopropylamine.[69]

(29)

(30)

(31)

(32)

(33)

Addition of HF to aziridines gives β-fluoro amines (eq 34).[70] *N*-Alkylated aziridines are less reactive and often require higher reaction temperatures. On the other hand, *N*-activated aziridines give better regioselectivity but the reactions are often accompanied by the formation of oxazolines (eq 35).[71] Treatment of 1,2-epoxypyrrolidines with HF-pyridine can form different ring-opening products, depending on the stereochemistry of substrates (eqs 36 and 37).[72,73]

(34)

(35)

cis:*trans* = 41:38

(36)

90% 5%

(37)

0% 72%

In the addition of Olah's reagent to azirines, the products are very dependent on the substitution pattern of the azirines. Ethers and larger-ring heterocycles are usually stable to HF, with some exceptions.

Miscellaneous.

Deprotection of peptides with strong acid often causes serious side reactions. By using anhydrous HF in dimethyl

sulfide, most peptide-protecting groups and polymeric support can be cleanly removed.[2,74,75] Other silyl-protecting groups have been removed by aqueous hydrofluoric acid in excellent yields, although this reagent has not been widely used because there are better reagents available.[76] When HF is used with PbO_2, PbF_4, anodic oxidation,[77,78] or other oxidants, it can fluorinate a variety of compounds, and several perfluoroheterocyclic compounds have been made in good yields.[79-82]

Proton Sponge (***1,8-Bis(dimethylamino)naphthalene***)[83] hydrofluoride can be a useful fluoride donor. Adding an anhydrous HF ether solution to the base to form the hydrofluoride salt has been used for fluorination reactions (eq 38).[84]

(38)

Related Reagents.

N-Bromosuccinimide-Hydrogen Fluoride; ***Hydrogen Fluoride***; ***Hydrogen Fluoride-Antimony(V) Fluoride***; ***Pyridinium Poly(hydrogen fluoride)***.

Hydrogen Bromide[1]

HBr

[10035-10-6] · BrH · Hydrogen Bromide · (MW 80.91)

(reagent for electrophilic[5] and radical-mediated[1b] hydrobromination of alkenes and alkynes; cleaves epoxides[1c] and ethers;[20] converts alcohols[13] and chlorides[32] to bromides; converts α-diazo ketones to α-bromomethyl ketones,[28a] and 1,4-cyclohexanediones to phenols[29])

Alternate Name: ***Hydrobromic Acid***

Solubility: sol most organic solvents.[2]

Form Supplied in: widely available as compressed gas; 30% solution in AcOH or $EtCO_2H$; 48% aqueous solution.

Preparative Methods: can be generated in situ by treatment of refluxing tetrahydronaphthalene with Br_2;[3] treatment of Ph_3PHBr with refluxing xylene.[4]

Handling, Storage, and Precautions: highly toxic and corrosive. This reagent should be handled in a fume hood.

Hydrobromination of Alkenes and Alkynes.

HBr undergoes addition readily to most alkenes and alkynes.[1a] However, radical and ionic addition usually compete, affording a mixture of products unless the system is symmetrically substituted (eq 1).[5]

Radical addition can be facilitated by light, peroxides, and other radical-generating systems.[1b] Limiting reaction to ionic addition is more challenging, requiring the rigorous absence of light, oxygen, and peroxide impurities, along with the use of a radical inhibitor.[6] Ionic addition to alkenes without competing radical reaction can also be effected with aqueous HBr at 115 °C and a phase-transfer catalyst (eq 2).[7]

More conveniently, competing radical reaction can be avoided by conducting the addition in the presence of appropriately prepared silica gel or alumina, which also accelerates the rate of ionic addition.[5,8] Addition is rendered even more convenient by the use of various inorganic and organic acid bromides that undergo reaction with silica gel or alumina to afford HBr in situ (eq 3).[5]

Surface-mediated hydrobromination of phenylalkynes initially affords the *syn* adducts, which undergo subsequent equilibration with the thermodynamically more stable (*Z*) isomers (eq 4).[5] Thus either isomer can be obtained in high yield by the appropriate choice of reaction conditions. Surface-mediated hydrobromination of terminal alkylalkynes affords the corresponding 2-bromo-1-alkenes in good yield (eq 5).[5] Several other methods had previously been developed for this difficult transformation.[9]

R = Me, Ph or *t*-Bu

Cleavage of Epoxides to Bromohydrins.

The addition of HBr to epoxides to give bromohydrins proceeds readily with either 48% aqueous HBr or anhydrous HBr in a variety of organic solvents.[1c,10] The stereoselectivity generally parallels that of HCl additions (see ***Hydrogen Chloride***), and is similarly affected by changes in solvent and substitution. Typically, ring opening of unsymmetrical epoxides favors formation of the bromohydrin in which bromine is at the less highly substituted position. This preference is greater for HBr than HCl additions because of the greater size and nucleophilicity of the bromide ion.[1c,11]

Reaction with Alcohols.

The reaction of HBr with alcohols to form alkyl bromides is a general, high-yield reaction that can be effected under a variety of conditions. The conversion of primary and secondary alkyl alcohols to the corresponding bromides with anhydrous HBr requires elevated temperatures (100 °C),[12] but benzylic and allylic alcohols are reactive in $CHCl_3$ solution at 25 °C.[13] Alcohols are also converted to alkyl bromides at elevated temperatures with 48% aqueous HBr.[14] Alcohols resistant to substitution under these conditions are often reactive in the presence of H_2SO_4 as a catalyst.[12,15] The use of phase-transfer catalysts has little effect on the rate of the reaction, but has been found to reduce significantly the extent of skeletal rearrangement that often accompanies substitution (eq 6).[16] Tertiary bromides can be synthesized from the corresponding alcohols under especially mild conditions in the presence of ***Lithium Bromide***.[17]

Vicinal diols, when treated with 48% aqueous HBr in AcOH, give 2-bromo acetates with good regio- and stereoselectivity (eq 7).[18] In the absence of AcOH, some diols are dehydrated to give dienes.[19]

A series of bis(benzylic) diols has been converted to 2,3-disubstituted indenes with HBr in good yields (eq 8), whereas reactions with other hydrogen halides followed a different course.[20] This method failed for the synthesis of monoalkyl indenes but was satisfactory for the synthesis of monoaryl systems.

Cleavage Reactions.

The cleavage of ethers by HBr is a synthetically useful method for the synthesis of alkyl bromides and for the deprotection of phenols.[21] Dialkyl ethers are cleaved with 48% aqueous HBr at elevated temperatures in the presence

of H_2SO_4[22] or a phase-transfer catalyst.[23] Under these conditions, most dialkyl ethers give high yields (90-95%) of alkyl bromides, while alkyl aryl ethers give phenols (90%) and alkyl bromides (90%). Aryl methyl ethers are readily cleaved with the use of 48% aqueous HBr to give the phenol and MeBr.[24] The cleavage of cyclic lactones by HBr, in a manner analogous to the cleavage of ethers, has also been reported.[25] When triphenylphosphonium bromide is used as an in situ source of HBr, methyl, ethyl, and benzyl ethers are cleaved at elevated temperatures to give alkene products in good yield along with a tetrasubstituted phosphonium salt (eq 9).[26] Similarly, aryl alkyl ethers are converted to phenols, and benzyl and methyl esters to carboxylic acids.

AcOH and CF_3CO_2H solutions of HBr efficiently cleave benzyloxycarbonyl groups from protected peptides.[27] Anhydrous HBr selectively cleaves alkyl groups from aryl amines.[28] Thus dialkyl-substituted anilines were converted to monoalkyl-substituted anilines at 150 °C, and monoalkyl anilines converted to aniline at 195 °C. This method is not useful for cleavage of trialkyl amines.

Synthesis of α-Bromo Ketones.

α-Diazo ketones are converted to α-bromomethyl ketones by either anhydrous HBr in Et_2O or 48% aqueous HBr in various solvents (eq 10).[29] This is a useful, high-yield, method for the regiospecific conversion of a carboxylic acid to the corresponding bromomethyl ketone, since the required α-diazo ketone is readily synthesized from reaction of the corresponding acid chloride with ***Diazomethane***.

Reductions with HBr.

HBr has been used as a reagent for the reduction of 1,4-cyclohexanediones to phenols,[30] as well as for the cyclization and aromatization of a variety of carbonyl-substituted arenes (eq 11).[31]

(11)

Although HBr generally reduces aryl sulfoxides, its uses are limited due to ensuing bromination of the aryl ring.[32]

Miscellaneous Reactions.

Alkyl chlorides, which are generally more readily available than alkyl bromides, are converted into the corresponding bromides by anhydrous HBr in the presence of catalytic amounts of $FeBr_3$.[33] Secondary, tertiary, and allylic bromides are formed in high yields from the corresponding chlorides, while primary systems undergo extensive cationic rearrangement. Alkyl iodides have been converted into the corresponding bromides with 42% HBr in the presence of HNO_3.[34]

Several arylamines have been brominated at the *ortho* position by HBr in DMSO.[35] Since removal of the amine functionality is possible in good yield, this provides a regiospecific method of arene bromination.

HBr reacts with aldehydes in the presence of arenes to give bromoalkylated products[36] and in the presence of alcohols to give α-bromomethyl ethers in good yields (eq 12).[37]

(12)

Addition of anhydrous HBr to α,β-unsaturated aldehydes or ketones, followed by acetalization, readily affords β-bromoacetals (eq 13).[38]

(13)

Hydrogen Chloride[1]

ClH

[7647-01-0] · ClH · Hydrogen Chloride · (MW 36.46)

(reagent for hydrochlorination of alkenes and alkynes;[4] cleaves epoxides[1b] and ethers;[21a] converts alcohols to chlorides[12b] and diols to cyclic ethers;[17] chloroalkylates arenes;[22] converts aldehydes to α-chloro ethers[23b])

Alternate Name: ***Hydrochloric Acid***

Solubility: sol most organic solvents.[2]

Form Supplied in: widely available; compressed gas; 1 M solution in AcOH, Et_2O, or Me_2S; 4 M solution in dioxane; 37% aqueous solution.

Preparative Methods: addition of H_2SO_4 to NaCl or 37% aqueous HCl.[3]

Handling, Storage, and Precautions: highly toxic and corrosive; handle only in a fume hood.

Hydrochlorination of Alkenes and Alkynes.

HCl undergoes solution-phase addition readily to C=C double bonds that are strained or from which the resulting carbocation is benzylic or tertiary.[1a] However, other alkenes do not undergo addition at preparatively useful rates.[4] Although addition can be facilitated by Lewis acid catalysis,[5] mono- and 1,2-disubstituted alkenes undergo polymerization under these conditions.[5a] The rate of addition is inversely proportional to the electron donor strength of the solvent, following the order
heptane &AApprox; $CHCl_3$ > xylene > nitrobenzene >> MeOH > dioxane > Et_2O.[6,7] In the strongly donating solvent Et_2O, even highly reactive alkenes undergo slow addition unless one of the reactants is present in high concentration. Additions conducted in solutions saturated with HCl exhibit an inverse temperature coefficient because of the increased solubility of HCl at lower temperatures.[3b]

Alkynes undergo addition more slowly than alkenes, requiring extended reaction times, elevated temperatures, and, usually, Lewis acid catalysis.[1a] However, dialkylalkynes afford the (*Z*)-vinyl chloride on treatment with refluxing aqueous HCl (eq 1).[8]

(1)

Addition to alkenes and alkynes is greatly facilitated by the presence of appropriately prepared silica gel or alumina.[4] Alkenes and alkynes that exhibit little or no reaction with HCl in solution readily undergo addition under these conditions. The reaction is rendered even more convenient by the use of various inorganic and organic acid chlorides that afford HCl in situ in the presence of silica gel or alumina. Surface-mediated hydrochlorination of 1,2-dimethylcyclohexene in CH_2Cl_2 gives initially the *syn* adduct, which undergoes equilibration with the thermodynamically more stable *trans* isomer under the reaction conditions (eq 2).[4] Thus either isomer can be obtained in high yield through the proper choice of reaction conditions. Similarly, phenylalkynes initially afford *syn* adducts, which undergo subsequent equilibration with the thermodynamically more stable (*Z*) isomers (eq 3).[4] Again, either isomer can be obtained in high yield.

(2)

(3)

R = Me or Ph

Cleavage of Epoxides to Chlorohydrins.

The addition of HCl to epoxides to form chlorohydrins proceeds readily with either 37% aqueous HCl or solutions of

anhydrous HCl in a variety of organic solvents.[1b,9] For simple alkyl-substituted oxiranes, addition typically occurs through backside attack of chloride ion on the protonated epoxide, resulting in net inversion of the carbon center (eq 4).[1b,9] For aryl- or vinyl-substituted epoxides (in which more carbocationic character is involved in the transition state during ring opening), the stereochemical outcome may range from complete retention to predominant inversion and is highly solvent dependent.[10] Anhydrous conditions and solvents of low dielectric strength favor *syn* cleavage, while *anti* cleavage is favored in the presence of water or in hydroxylic solvents.[10]

(4)

Cleavage of simple alkyl-substituted epoxides under anhydrous conditions typically favors formation of the chlorohydrin in which chlorine is at the less highly substituted position (eqs 5 and 6).[11] More highly substituted epoxides, particularly aryl-substituted, give increasing amounts of the opposite regioisomer. Regioselectivity is also very sensitive to the solvent system employed for the reaction (eqs 5 and 6).

(5)

THF	84%	16%
THF/H_2O	40%	60%

(6)

THF	62%	38%
THF/H_2O	25%	75%

Reaction with Alcohols.

The reaction of HCl with alcohols to form alkyl chlorides is a general reaction, giving good to high yields of products. Primary and secondary aliphatic alcohols are most easily converted to the corresponding chlorides with either 37% aqueous HCl or anhydrous HCl at elevated temperatures in the presence of ***Zinc Chloride***.[12] Phase-

transfer catalysis has also been employed in the synthesis of primary chlorides from alcohols.[13] The need for a catalyst can be avoided by using the highly polar solvent HMPA.[14] Tertiary,[7,15a] benzylic,[15b] and allylic[15c] alcohols are readily converted to chlorides at 25 °C, or lower, without the need for catalysts. Glycerol can be selectively mono- or dichlorinated by controlled addition to HCl to AcOH solutions.[16] Bis(benzylic) diols have been converted in good yields to substituted cyclic ethers with HCl, whereas reaction with HBr or HI followed a completely different course (eq 7).[17]

(7)

Reductions with HCl.

HCl has been used to reduce a series of 1,4-cyclohexanediones to the corresponding phenols in good yield (eq 8).[18]

(8)

α-Diazo ketones are reduced to α-chloromethyl ketones by either anhydrous HCl in organic solvents or 37% aqueous HCl in Et_2O.[19] Generally, good to high yields are obtained. Chloroacetone was synthesized in this manner without the complicating formation of dichlorides (eq 9).[19c]

(9)

Although aryl sulfoxides are reduced to sulfides by HCl, accompanying ring chlorination limits the usefulness of the reaction.[20]

Cleavage of Ethers.

Allyl, *t*-butyl, trityl, benzhydryl, and benzyl ethers are cleaved by HCl in AcOH (eq 10).[21a] In some cases, aryl methyl ethers have been successfully cleaved (eq 11).[21b]

(10)

(11)

Reaction with Aldehydes.

Arenes react readily with mixtures of HCl and formaldehyde in the presence of a Lewis acid, usually $ZnCl_2$, to give the chloromethylated derivative.[22] Yields are good and the reaction conditions can be controlled to afford predominantly mono- or disubstituted products. Chloroalkylations can be effected with other aldehydes such as propanal and butanal. In the presence of alcohols, HCl and aldehydes give high conversions to α-chloro ethers (eq 12).[23]

Hydrogen Cyanide[1]

HCN

[74-90-8] · CHN · Hydrogen Cyanide · (MW 27.03)

(useful C_1 synthon)

Alternate Names: hydrocyanic acid; prussic acid.

Physical Data: mp -13.4 °C; bp 25.6 °C; *d* (gas) 0.941 g cm^{-3}; *d* (liquid) 0.687 g cm^{-3}.

Solubility: slightly sol ether; miscible with water and alcohol.

Form Supplied in: colorless gas at rt, or bluish-white when liquefied, with a characteristic odor resembling bitter almonds.

Preparative Methods: anhydrous HCN is prepared on a large scale by the catalytic oxidation of ammonia-methane mixtures (Andrussow process).[1c] In the laboratory it can conveniently be prepared by acidifying NaCN or potassium hexacyanoferrate, $K_4[Fe(CN)_6]$.[3]

HCN oligomers:[4] the HCN dimer (HN=CHCN) is too reactive to be isolated. Under acidic conditions the reaction proceeds to the trimer *s*-triazine[5] and under basic conditions to the tetramer ***Diaminomaleonitrile***[6] via the trimer intermediate 2-aminomalononitrile.

Handling, Storage, and Precautions: **Intensely poisonous. Avoid skin contact and inhalation. Must be handled by specially trained experts**. Use in a fume hood. Flash point -17.8 °C (closed cup); explosion limits: upper 40%, lower 5.6% by vol in air; when not pure or stabilized, can polymerize explosively. The principal routes of occupational HCN exposure are inhalation and absorption through the skin. *Inhalation of large amounts of cyanide causes immediate unconsciousness, convulsions, and death from respiratory arrest within 1-15 min*. TLV ceiling of 10 ppm has been recommended since 1980.[2]

Electrophilic Aromatic Substitution.

The preparation of aldehydes from phenols or phenol ethers by treatment of the aromatic substrate with HCN and ***Hydrogen Chloride*** in the presence of Lewis acid catalysts is known as the Gattermann aldehyde synthesis (eq 1).[7] The first stage consists of protonation of the nitrile to give a nitrilium ion or nitrile-Lewis acid complex, regarded as the electrophilic species attacking the substrates.[8]

Nucleophilic Substitution.

Chlorotrimethylsilane is converted into ***Cyanotrimethylsilane*** (eq 2),[9] which is also a versatile cyanidation agent,[10] whereas carbonocyanidic acid methyl ester *[17640-15-2]* and ethyl ester *[623-49-4]*, introduced by Mander as selective *C*-acylation agents,[11] are made from the corresponding chloroformates (eq 3).[12]

(2)

(3)

Epoxide Opening.

Addition of HCN to epichlorohydrin gives an intermediate, which on quaternization with ***Trimethylamine*** and subsequent hydrolysis of the nitrile gives carnitine (eq 4).[13]

Additions to Alkenes, Dienes, and Alkynes.

These occur in the presence of Ni^0, Pd^0, or cobalt carbonyl complexes.[14,15] The use of Lewis acids as cocatalysts generally improves the activity and lifetime of the catalyst.[16] Ethylene is hydrocyanated to propionitrile in the presence of ***Octacarbonyldicobalt*** or $[M(P(OR)_3)_4]$ (M = Ni, Pd; R = alkyl, aryl); with unsymmetrical higher alkenes, the cobalt catalyst gives exclusively the product from Markovnikov addition (e.g. propene gives 2-cyanopropane in 75% yield),[14] while the nickel and palladium phosphite systems give product mixtures.[17]

In the case of conjugated dienes, nickel catalysts are preferred; the mechanism involves a π-allyl intermediate. Both 1,4- and 1,2-addition occur, although the regiochemistry seems to be controlled by the thermodynamic stability of the intermediate allyl species, e.g. 1,3-pentadiene gives exclusively the branched nitrile (eqs 5 and 6).[18]

(6)

$L = (PhO)_3P$

In the presence of these catalysts, unconjugated dienes rearrange to conjugated dienes prior to the addition of HCN.

Addition to alkynes is best catalyzed by nickel complexes with *syn* stereochemistry. The regioselectivity is influenced by both steric and electronic effects.[19] The reactions with alkynols show evidence for some chelation between the oxygen and nickel in the transition state (eq 7).[20]

(7)

$L = (PhO)_3P$

$R^1 = Pr$, $R^2 = H$	60%	12:88
$R^1 = t\text{-}Bu$, $R^2 = Me$	78%	90:10
$R^1 = Me_2C(OH)$, $R^2 = H$	30%	20:80

Hydrolysis and cyclization of some cyanoalkenes containing methoxymethyl ethers gives α-alkylidene-γ-lactones (eq 8).[21]

(8)

The asymmetric Markovnikov addition of HCN to vinylarenes in the presence of Ni^0 complexes of 1,2-diolphosphinites derived from sugars gives 2-aryl-2-propionitriles in high yield and enantioselectivity (eq 9).[22]

(9)

Asymmetric Hydrocyanation.

Asymmetric hydrocyanation of aldehydes to chiral cyanohydrins is a convenient route to chiral α-hydroxy carboxylic acids and chiral 1-amino-2-alkanols; catalysts are often used, e.g. the cyclic dipeptide cyclo((*S*)-phenylalanyl-(*S*)-histidyl) (eq 10)[23] or the enzyme (*R*)-oxynitrilase (eq 11).[24] This reaction proceeds normally in aqueous solutions with NaCN; however, the noncatalyzed reaction leading to racemic product can be efficiently suppressed by the use of anhydrous HCN in organic solvents.

(10)

(11)

Enantioselective addition of HCN to ketones in organic solvents catalyzed by (*R*)-oxynitrilase proceeds similarly.[25]

Hydrogen Fluoride[1]

FH

[7664-39-3] · FH · Hydrogen Fluoride · (MW 20.01)

(strong Brønsted-Lowry acid[2] capable of fluorinating numerous organic substrates;[1] cleaves silyl[3] and peptide[4] protecting groups; effects lignocellulose solvolysis;[5] catalyzes a number of electrophilic aromatic substitution reactions[6])

Alternate Name: ***Hydrofluoric Acid***

Physical Data: mp -83.37 °C; bp 19.54 °C; *d* 1.015 g cm^{-3} (0 °C), 0.958 g cm^{-3} (25 °C).

Solubility: sol water (52.7 wt %, 6 theoretical plates); strong proton donor to alcohols, carboxylic acids, ethers, and ketones (unstable); insol aliphatic hydrocarbons; very slightly sol aromatic hydrocarbons.

Form Supplied in: anhydrous liquid; 48-50% aqueous solution; most common impurity is fluorosilicic acid (<100 ppm).

Purification: for virtually all synthetic purposes, anhydrous hydrogen fluoride (AHF) is supplied in sufficiently high purity from commercial sources. Ultrapure AHF can be obtained by either distillation[7] of commercially available AHF or thermal decomposition[8] of potassium acid fluoride.

Handling, Storage, and Precautions: HF is an extremely toxic material. HF can cause severe damage to the respiratory system and will cause severe burns to tissue, e.g. skin, fingernails, mouth, eyes, etc.; penetration through tissue into bone is possible. If contact with HF occurs, the affected area must be flushed immediately with copious amounts of water for at least 15 min. **Immediate medical attention must be sought**. Recommended personnel protective equipment includes the use of gloves (neoprene/nitrile/rubber composite), goggles, a face-shield, and an apron while working in a well-ventilated hood, preferably equipped with a HF monitor.

AHF is supplied either in lecture bottles or 3 lb metal cylinders; aq HF is supplied in polyethylene bottles. The use of glassware and stainless steel vessels should be avoided when handling either AHF or aq HF.[9] For reactions run at ambient temperature and pressure, polyethylene vessels can be employed; copper and iron vessels are also suitable. However, the use of an autoclave constructed of high metallurgy such as Monel or nickel, employing inert atmosphere techniques, is highly recommended.

Fluorinations.

AHF is an effective reagent for the fluorination of a wide variety of organic substrates.[1] However, AHF in combination with organic bases,[10] for example Olah's reagent (HF-pyridine),[11] and nucleophilic fluoride transfer agents[12] are more frequently employed than AHF, particularly when monofluorination of an organic substrate is desired.

Addition of AHF to unsaturated hydrocarbons occurs by an electrophilic mechanism and, for alkenes, in a Markovnikov fashion. Addition of AHF to alkynes[13] proceeds with poor stereochemical control to give mixtures of (*E*)- and (*Z*)-vinyl halides and is often accompanied by the formation of *gem*-difluoroalkanes and fluoropolymers.

AHF reacts with carboxylic acid halides,[14] esters,[15] and anhydrides[14] to give carboxylic acid fluorides. Acetoacetyl fluoride can be prepared in near quantitative yield by adding AHF to diketene.[16] At temperatures <=0 °C, AHF is known to add to isocyanates[17] to yield the corresponding carbamoyl fluorides.

Epoxides and aziridines undergo ring opening in the presence of AHF. For example, stereospecific ring opening of an epoxide[18] can be accomplished as a means of introducing fluorine into the B ring of a steroid (eq 1).

(1)

AHF addition to *trans*-2,3-diphenylaziridine[19] occurs stereospecifically to afford the *erythro* isomer exclusively, whereas the *threo* isomer predominates upon treatment with Olah's reagent (eq 2).

(2)

Halofluorination of alkenes with ***t-Butyl Hypochlorite***, ***N-Bromosuccinimide***, and ***N-Iodosuccinimide*** in the presence of AHF[20] proceeds in good yield, although superior yields again can be obtained with Olah's reagent.[21] In the presence of AHF, addition of ***N-Bromoacetamide*** and *N*-iodosuccinimide to cyclohexene occurs with a high degree of stereoselectivity to produce *trans* isomers in 43% and 72% yield, respectively.[22] Halofluorination occurs in a Markovnikov fashion.[23] Synthesis of *gem*-fluorohalides can be achieved by adding AHF to vinyl halides.[24]

Commercially,[25] the use of AHF for the synthesis of fluoroorganic compounds via either halogen exchange (HALEX) or decomposition of diazonium salts is carried out by this route for economic reasons. For synthetic purposes, inorganic fluorides,[1f] tetraalkylammonium fluorides,[12] and HF.base complexes[10] are preferred fluorinating agents. High yields of α,α,α-trifluoromethoxybenzene[26] via halogen exchange and fluoropyridines via decomposition of the corresponding diazonium salt[27] in the presence of AHF can be obtained.

Bond-Cleaving Reactions.

Desilylation of silyl ethers[28] and silyl enol ethers[29] is most frequently accomplished using HF/MeCN.[3] Compounds containing both alcoholic and phenolic *t*-butyldimethylsilyl ethers can be desilylated with HF/MeCN chemoselectively, leaving the silyl ether of the phenol unscathed (eq 3).[30]

(3)

Cleavage of silyl enol ethers result in the formation of α-alkylidene-β-lactams[31] and migration of C=C bonds, leading to γ-substituted cyclohexenals[32] and β-substituted cyclopentenones.[33]

Concomitant ring formation during desilylation of *t*-butyldimethylsilyl ethers occurs with a high degree of stereoselectivity to give lactones,[34] and is a facile route to butenolides,[35] β-methylene-γ-butyrolactones,[36] bis-β-ketomacrolides,[37] spiroacetals (eq 4),[38] and dispiroacetals.[39]

(4)

Similar treatment of *t*-butyldimethylsilyl enol ethers leads to the formation of cyclopentanecarboxylic acid[40] and *cis*/*trans* carbocycles.[41]

Desilylation of *erythro*-α-silyloxyalkylboranes with concomitant protiodeboronation gives alkenes (eq 5) with (*E*:*Z*) ratios as high as 95:5 in 73% isolated yield.[42]

Cleavage of Si-C bonds also is an entry into alkenes,[43] aldehydes,[44] and α,β-unsaturated aldehydes.[45] Cleavage of the Si-N bond gives amines.[46]

Hydrogen fluoride is a versatile reagent in peptide chemistry, cleaving *N*-benzyloxycarbonyl, *S*-benzyl, and *S*-*p*-methoxybenzyl protecting groups of peptides.[5] Removal of protecting groups of aspartine residues (eq 6),[47] *N*-nitroarginine residues,[48] *O*-dimethylphosphinyltyrosine,[49] and the *O*-phosphate ester of tyrosine[50] is accomplished in HF/anisole at 0 °C in <=1 h. However, under similar conditions, side reactions of glutamyl peptides[51] lead to Friedel-Crafts acylation of anisole.

Peptide protecting groups such as phosphonamides[52] and sulfonamides[53] are cleaved in the presence of HF/anisole. In the case of the tripeptide Gly-Lys-Gly, the sulfonyl protecting group of the Lys residue can be chemoselectively removed in the presence of a *t*-Boc protecting group.[54] Polysaccharide solvolysis and glycoprotein deglycosylation is efficiently performed with HF.[55]

Catalyst in Electrophilic Aromatic Substitutions.

In many instances, AHF offers distinct advantages over traditional Lewis acids for the catalysis of electrophilic aromatic substitution reactions. Unlike most Lewis acids, AHF acts as both catalyst and solvent,[56] and can be removed by distillation.[57]

Alkylation of arenes with alkenes,[6a,58] alkyl halides,[6b,59] and methylcyclopropane[60] proceeds in moderate to good yield. Alkylation of arenes with concomitant ring closure leads to cyclic[61] and heterocyclic compounds.[62] Alkylation of benzene with sodium nitronate in the presence of AHF gives benzaldehyde oxime in 78% yield.[63]

The distribution of *o*-, *m*-, and *p*-isomers is known to be a function of temperature. For example, alkylation of phenol

with ***Isobutene*** at -40 °C gives 2-*t*-butylphenol exclusively, while at 0 °C, 3-*t*-butylphenol is obtained in 88% yield; above 30 °C, 4-*t*-butylphenol begins to predominate.[64]

AHF is an excellent catalyst for Friedel-Crafts acylation of substrates as diverse as phenols,[65] thiophenes,[66] and ferrocene.[67] Acylation of phenols is known to proceed with a high degree of regioselectivity to yield *p*-isomers almost exclusively (eq 7).[68]

(7)

$R^1 = H, Me, Ph, OMe, SMe$
$R^2 = Me, Et, Ph, CH_2Cl$
$X = F, Cl, Br, OH, OAc$

Similarly, Fries rearrangement of phenyl esters leads to formation of the *p*-isomer[69] unless of course the *para* position is blocked; then *ortho* substitution occurs.[70] Although thiophenol does not undergo acylation in the presence of AHF, thioanisole does, giving the *p*-isomer.[71] As opposed to Lewis acids, AHF-catalyzed acylation of 2-methoxynaphthalene proceeds with high *para* regioselectivity to yield 6-methoxy-2-acetonaphthone.[72]

Intramolecular cyclizations of 3-phenylpropionic acid and 4-phenylbutanoic acid afford α-tetralone and α-hydrindone in 92% and 73% yield, respectively.[73] More sophisticated polycyclic compounds, such as anthracyclinones,[74] can be constructed, as can benzo[*a*]fluoranthene[75] via reductive cyclization.

Other electrophilic aromatic substitutions do not proceed generally as well in AHF, as is the case for the sulfonation of benzene[76] and rearrangement of *p*-cresyl benzenesulfonate[77] to 2-hydroxy-4-methyl diphenyl sulfone. However, nitration,[78] amidomethylation,[79] and thioamidation[80] of aromatic substrates can be achieved in good to excellent yield.

Related Reagents.

N-Bromosuccinimide-Hydrogen Fluoride; ***Hydrofluoric Acid***; ***Hydrogen Fluoride-Antimony(V) Fluoride***.

[16950-06-4] · F_6HSb · Hydrogen Fluoride-Antimony(V) Fluoride · (MW 236.76)

(strong liquid superacid system, used as a catalyst for Friedel-Crafts reactions, isomerization, polymerization, and other acid-related chemistry; efficient for preparation of carbocations and onium ions and their salts[1])

Alternate Name: fluoroantimonic acid; hexafluoroantimonic acid.

Physical Data: HF, bp -19.5 °C; SbF_5, bp 149.5 °C.

Form Supplied in: HF, gas; SbF_5, viscous liquid. Both are commercially available.

Preparative Methods: HF/SbF_5 is prepared by mixing required amounts of freshly distilled ***Hydrogen Fluoride*** and ***Antimony(V) Fluoride*** at low temperature.[2] The reaction is exothermic and must be carried out with careful temperature control. The reagent can also be prepared in situ in the reaction flask.

Handling, Storage, and Precautions: HF/SbF_5 is extremely corrosive, toxic, and moisture sensitive. It fumes when exposed to air; thus it should be stored under anhydrous conditions in a Teflon bottle and handled with gloves in a well-ventilated fume hood.

General Consideration.

Hydrogen fluoride-antimony pentafluoride (fluoroantimonic acid) is probably the strongest liquid superacid system, possessing the widest acidity range.[1] Compared to the widely used Magic Acid system (***Fluorosulfuric Acid-Antimony(V) Fluoride***), the acidity of fluoroantimonic acid is even higher with the same molar concentration of SbF_5. For example, fluoroantimonic acid with 0.5% SbF_5 has a H_0 of -21, while H_0 for HSO_3F/SbF_5 with the same amount of SbF_5 is only -17.[2] Hexafluoroantimonic acid ($HF:SbF_5$ = 1:1) has an estimated H_0 of -30.[1] The X-ray structure of the 1:1 $HF:SbF_5$ complex has recently been established.[3]

Very strong acidity (and low nucleophilicity of its conjugate anion) make fluoroantimonic acid an efficient medium for the preparation of carbocations and onium ions.[1] The same properties have also made the acid an effective catalyst for Friedel-Crafts type reactions, polymerization, isomerization, and other acid-related chemistry.[1]

Friedel-Crafts and Related Chemistry.

Alkylations of deactivated aromatic compounds such as acetophenone are generally difficult to achieve.[4] However, this problem can be overcome with the use of HF/SbF_5. It was demonstrated that acetophenone was readily ethylated with ethyl chloride in the presence of HF/SbF_5 (eq 1).[5] Other primary and secondary alkyl chlorides also react well with the substrate under similar conditions. However, poor results were obtained with tertiary chlorides.

In the presence of HF/SbF_5, even alkanes can alkylate aromatics.[6] This results from protolysis of alkanes to form carbocations and the subsequent trapping of these cations by arenes. The concept of alkane protolysis was also utilized for the preparation of 4,4´-dialkyl-1-tetralones from alkyl phenyl ketones via intramolecular cyclization by using a 5:1 ratio of $HF:SbF_5$ (eq 2).[7] The reaction yields are 68-95%.

Upon treatment with HF/SbF_5, *para*-substituted phenols (or their methyl ethers) can be diprotonated,[8] first on the oxygen atom and then on the *meta* carbon.[9] The resulting dipositively charged species are exceedingly reactive towards a variety of arenes.[9] 4-Arylcyclohexenones, the primary products of the reactions, can be further transformed to 3-arylcyclohexenones. The ratio between the two isomers depends on conditions such as reaction time, amount of acid, and the nature of substrates. For example, when *p*-cresol is reacted with benzene in the presence of HF/SbF_5, 4-methyl-4-phenylcyclohexenone and 3-phenyl-4-methylcyclohexenone are obtained in 29% and 33% yields,

respectively, after 90 s. With the reaction time increased to 15 min, the yield of 3-phenyl-4-methylcyclohexenone increased to 90% while that of 4-methyl-4-phenylcyclohexenone decreased to 2-3% (eq 3). With the substitution of *p*-cresol with 4-methylanisole, 6,7-benzo-5-methyltricyclo[3.2.1]octan-2-one is obtained as an additional minor product (eq 4).

(3)

(4)

Condensation of phenols with aromatic compounds has also been successfully applied to the preparation of spiroenones and/or their isomerized ketones via intramolecular cyclization of methoxydiarylethanes or -propanes (eq 5).[10] The starting materials are readily available by Friedel-Crafts acylation of phenols and subsequent reduction of the ketones. In the case of 2´-methoxy-5´-methyl-1,3-diphenylpropane, treatment of the substrate with HF/SbF_5 led to exclusive formation of a tetracyclic ketone (a derivative of benzobicyclo[3.2.1]octane) in 90% yield (eq 6).

(5)

(6)

Electrophilic formylation of arenes with CO in the presence of acids (Gatterman-Koch conditions) is an efficient method for the preparation of aromatic aldehydes. $HF/SbF_5/SO_2ClF$ is the most active system for this reaction.[11] When competitive formylation was performed on benzene and toluene in $HF/SbF_5/SO_2ClF$ at -95 °C, a k_T:k_B ratio of 1.6 was obtained. The observed k_T:k_B ratios for most typical acids range from 155 to 860.[11] It has been demonstrated that even diformylation can be achieved on polynuclear aromatics such as naphthalene and biphenyl with the use of fluoroantimonic acid (eqs 7 and 8).[12] In these cases, dialdehydes are generally formed only when the SbF_5:substrate ratios are larger than 1.

(7)

93:7

Hydroxylation of aromatics with peroxides and acids generally suffers from secondary oxidation, leading to low selectivity and low reaction yields. With superacids, these secondary reactions can generally be suppressed since *O*-protonation of the newly formed phenols prevents further reaction.[1] The strength of the acids used can play a significant role in the regioselectivity of the reaction. For example, hydroxylation of naphthalene in the weak acid 70% HF-30% pyridine yields 1- and 2-naphthols in a 98.4:1.6 ratio (eq 9); on the other hand, the ratio is changed to 1.8:98.2 when superacidic HF/SbF_5 is used (eq 10).[13] Benzaldehyde and aromatic ketones were reported to be hydroxylated in HF/SbF_5 without formation of products derived from Baeyer-Villiger oxidation.[14] When perfluoro-1-indanone was subjected to similar treatment with the $H_2O_2/HF/SbF_5$ system, 20% perfluorochroman was obtained along with 4% perfluoro-2-(2-carboxyethyl)phenol (eq 11).[15] By increasing the ratio of SbF_5:substrates, phenols can be further hydroxylated in HF/SbF_5. Resorcinols and some other dihydroxyarenes were prepared by this method (eq 12).[16,17] Hydroxylation of anilines by H_2O_2 in HF/SbF_5 yields all three possible isomers, with *meta* derivatives as major products.[18]

(10)

(11)

(12)

Bromination of *para*-alkylated or 2,6-dialkylated phenols and their ethers with Br_2 in HF/SbF_5 leads to formation of *meta*-brominated products (eq 13).[19] The results indicate that the bromination occurs on the *O*-protonated substrates, since halogenation of phenols under neutral conditions gives *ortho*- and *para*-substituted products. Sodium or potassium bromide can also be used in place of Br_2 in the reaction.[20]

(13)

Generally, nitration of aromatics is considered to be an irreversible reaction. However, the reversibility of the reaction has been demonstrated in some cases in the presence of HF/SbF_5 or superacidic ***Nafion-H***. 9-Nitroanthracene and pentamethylnitrobenzene will transnitrate benzene, toluene, and mesitylene in these acid media.[21]

HF/SbF_5 and other superacids, such as HF/TaF_5 and $HBr/AlBr_3$, are able to promote the hydrogenation of benzene and other aromatics to cyclohexanes and compounds derived from them in the presence of proper hydride donors.[22] The reaction proceeds through an ionic hydrogenation mechanism. The best hydride donors are isoalkanes (cycloalkanes) with tertiary C-H bonds. The use of molecular hydrogen in ionic hydrogenation reactions is also possible in the presence of tertiary C-H bond-containing hydrocarbons.[22a]

Upon treating deuteriated methane with HF/SbF_5, deuterium-protium exchange was observed.[23] Similar exchange was also observed with other alkanes. In the latter cases, protolysis of C-H and C-C bonds to form carbocations accompanies the exchange process.[24] It is interesting to compare the isotope exchange of isobutane using D_2SO_4 and DF/SbF_5.[25] When D_2SO_4 is used, all hydrogens on carbon atoms adjacent to the tertiary carbon atom exchange rapidly, whereas the hydrogen on the tertiary carbon is invariably recovered unexchanged (eq 14).[26] In contrast, with DF/SbF_5 at -78 °C, exchange on the methine proton was observed (eq 15).[25a,b] More recently, it was reported that deuterium-protium exchange occurs even on the *t*-butyl cation through the protio-*t*-butyl dication.[25c]

(14)

(15)

The carbenium ions formed in the protolysis of alkanes with HF/SbF_5 can be trapped in situ with CO.[27] Hydrolysis of the resulting acyl cations yields the corresponding carboxylic acids (eq 16) (Koch reaction).[28] With excess alkane present, ketones can be obtained (eq 17). It is noteworthy that in the carbonylation of propane, addition of catalytic amounts of bromides or halomethanes enhances the selectivity in favor of secondary C-H bond activation. Most (99%) of the products are derived from the isopropyl cation; only negligible amounts of methane and ethane are formed.[29]

(16)

(17)

Superacid-catalyzed oxygenation of alkanes has been well reviewed.[30] Both peroxy compounds and ozone can serve as oxidants. For example, in the oxygenation of neopentane with O_3 in $HF/SbF_5/SO_2ClF$, both methylated and ethylated acetones were obtained.[30]

1,2-Dichloroethane reacts with tetrafluoroethylene in HF/SbF_5 to form 1,1,1,2,2-pentafluoro-3-chlorobutane in 80% yield (eq 18).[31] The product is formed by addition of α-chloroethyl cation, rearranged from the initially formed β-chloroethyl cation, to tetrafluoroethylene and subsequent quenching with fluoride. Small amounts of 1,1,2,2-tetrafluoro-1,3-dichlorobutane and 1,1,2,2-tetrafluoro-1,4-dichlorobutane were also obtained. When 1,2-dibromoethane is used, 1,1,1,2,2-pentafluoro-4-bromobutane was obtained in 50% yield (eq 19).[31] No products arising from rearrangement were observed in this case.

(18)

(19)

An interesting synthetic method has been developed for carboxylation of bicyclic enones in HF/SbF_5.[32] It was demonstrated that the diprotonated α,β-unsaturated ketones react with CO to form acylium ions. Quenching of these acylium ions with methanol led to the corresponding carboxylic esters in good yields (eq 20).

(20)

Generally, alcohols with short carbon chains (C_1-C_4) are not carbonylated under the usual Koch conditions. However, it was found that these alcohols readily react with CO in fluoroantimonic acid to give the corresponding carboxylic acids in high yields.[33a] Even diols reacted under similar conditions to give dicarboxylic acids.[33b] Some cyclization products were also obtained. γ-Butyrolactones react with CO at atmospheric pressure in HF/SbF_5 containing an excess of SbF_5 to give dicarboxylic acids in good yields (eq 21).[33c] Methyl alkyl ketones with alkyl groups having five or more carbons can undergo Koch reaction to form the corresponding oxo carboxylic acids (eq 22).[34]

(21)

(22)

Oxidation of 3-keto steroids with O_3 has also been carried out in HF/SbF_5 (eq 23).[35] When oxygenations of ethers were performed under similar conditions, oxo alkyl ethers were obtained, with the oxo functionality generally three carbons away from the ether linkage (eq 24).[36]

(23)

(24)

Superacid-catalyzed ionic hydrogenation is not limited to aromatic compounds; it has been successfully applied in natural product chemistry (eq 25).[37-39] Protonated enones or dienones can be conveniently reduced in the presence of isoalkanes or with molecular hydrogen.

(25)

Isomerization and Rearrangements.

The high acidity of HF/SbF_5 makes fluoroantimonic acid an efficient isomerization catalyst for hydrocarbons. Isomerizations of fluorotoluenes, polyhalobenzenes, and aromatic sulfones have been carried out.[40,41] *Ortho*- or *para*-bromo phenols were reported to isomerize to *meta* isomers in HF/SbF_5 through intramolecular 1,2-Br shifts. In contrast, ***Trifluoromethanesulfonic Acid***-catalyzed isomerizations proceed through an intramolecular mechanism.[42] It was also reported that rearrangements of 4-alkylated and 2,6-dialkylated phenolic ethers can occur in HF/SbF_5. The alkyl groups originally attached to oxygen are rearranged to the *meta* positions of the compounds (eq 26).[43] This dealkylating ability of HF/SbF_5 has been successfully employed in the synthesis of 11-deoxyanthracyclines (eq 27).[44] Rearrangement of *s*-butylbenzene to isobutylbenzene under $AlCl_3$ catalysis necessitates higher temperatures; however, the isomerization proceeds under milder conditions when HF/SbF_5 is used.[45]

(26)

Rearrangement of phenols to dienones occurs readily in superacids. Some simple bicyclic phenols and their ethers were investigated as model compounds using HF/SbF_5.[46] The method is also applicable to natural products.[47] For example, treatment of estrone derivatives in HF/SbF_5 followed by aqueous bicarbonate workup led to estra-4,9-diene-3,17-dione (eq 28). The opposite rearrangement of phenols to dienones, i.e. dienones to phenols, can also be achieved in an HF/SbF_5 medium (eq 29).[48]

n-Alkanes can be readily isomerized to branched alkanes in superacidic media; HF/SbF_5 has been used for this process.[49] With a catalytic amount of HF/SbF_5, *endo*-trimethylenenorbornane was converted to *exo*-trimethylenenorbornane at rt in 98% yield.[50] With increasing amounts of acid, some adamantane was formed in the reaction mixture. Raising the reaction temperature to 100 °C increases the yield of adamantane to 47% (eq 30).[51]

(30)

HF/SbF_5 can induce isomerization of pregnane-3,20-diones to mixtures of isomers containing the 13α-isomer (eq 31).[52] The reaction is proposed to occur through the cleavage of the C(13)-C(17) bond. Many estrane derivatives can be prepared through HF/SbF_5-catalyzed isomerization.[53]

(31)

Isomerization or rearrangement catalyzed by superacids often differs from conventional acid catalysis; the high acidity leads to stabilized reaction intermediates. A pertinent example is the rearrangement of camphor. In concentrated H_2SO_4, it was mainly converted to 3,4-dimethylacetophenone (eq 32);[54] in HF/SbF_5, however, a mixture of three aliphatic ketones was obtained (eq 33).[55]

(32)

Carbocations and Onium Ions.

The corrosive and toxic nature of HF makes HF/SbF_5 a less frequently used acid system for the preparation of carbocations compared to HSO_3F/SbF_5. It is preferred, however, in the generation of arenium ions, since high acidity is required for their formation (eq 34).[56] Interestingly, upon treatment with HF/SbF_5, azoxybenzene is deoxygenated to form a dication believed to be responsible for the Wallach rearrangement product (eq 35).[57] HF/SbF_5 is able to dehydrate aliphatic ketones to form allyl cations (eq 36).[58] It was found that the rate of dehydration increases with the acidity of the medium.

HF/SbF_5 is frequently used for the preparation of onium ions. The early work has been reviewed.[1] More recently, HF/SbF_5 has been employed to protonate $(CN)_2$, XCN (X = halogen), CF_3CN, and $Me_nS(CN)_{2-n}$.[59]

Since SbF_6^- (and $Sb_2F_{11}^-$) is a stable anion, hexafluoroantimonic acid has been widely used in the preparation of carbocations and onium salts.[60] Representative examples include the *t*-butyl cation, and tricyclopropylcarbenium, 1-adamantyl, alkyloxocarbenium, haloacetylium, methoxycarbenium, dimethylbromonium, tetramethylenebromonium, nitronium, and nitrosonium salts (eqs 37 and 38). Many of these salts have found valuable applications in organic synthesis. The X-ray structure of the isolated *t*-butyl hexafluoroantimonate salt has recently been established.[61]

(37)

(38)

Polymerization.

HF/SbF_5 is also an efficient cationic polymerization catalyst.[1] Here, only its application in the preparation of macrocyclic ethers is included. The importance of these crown ethers has been well documented; however, their preparation is usually tedious and expensive. It was reported that HF/SbF_5 and other acids such as HF/BF_3 readily oligomerize ethylene oxide to mixtures of cyclic ethers[62] which can be subsequently separated (eq 39). The key to cyclic ether formation is the presence of anhydrous HF in the conjugate acid systems; chain polymers would otherwise be obtained.

Hydrogen Hexachloroplatinate(IV)[1]

$H_2PtCl_6.6H_2O$

[16941-12-1] · $Cl_6H_{14}O_6Pt$ · Hydrogen Hexachloroplatinate(IV) · (MW 517.92)

(catalyst for hydrosilylation, hydrogenation, carbonylation, coupling, and oxidation)

Alternate Names: CPA; chloroplatinic acid; hexachloroplatinic acid; Speier's catalyst.

Physical Data: mp 60 °C, *d* 2.431 g cm^{-3}.

Solubility: sol water, alcohol, ether.

Form Supplied in: brownish-yellow crystalline mass; very deliquescent; widely available.
Drying: compound decomposes on heating.

Handling, Storage, and Precautions: harmful if inhaled, swallowed, or absorbed through skin. The compound may be carcinogenic. Use in a fume hood.

Hydrosilylations.

Hydrosilylation is a process in which one or more silicon-hydrogen bonds add to a substrate.[1] The reaction typically involves the addition of silanes to alkenes, carbon-heteroatom double bonds, and alkynes (eq 1).

(1)

Y, Z = alkyl, aryl, heterocyclic, etc.
R = alkyl, aryl, Cl, OR, etc.
X = CR_2, O, NR, etc.

This reaction can be catalyzed by a variety of metals and metal complexes. One of the most useful catalysts for hydrosilylation is CPA. A dilute solution of CPA in isopropanol is typically used as the catalyst (Speier's catalyst).[2]

CPA also serves as the starting material for a very active form of homogeneous platinum(0) catalyst known as the Karstedt catalyst.[3] The major features of hydrosilylations are: an induction period; moderate to good yields; facility of the reaction on the nature of the silane, substrate, and the catalytic species; isomerization of the alkene substrate; and applications to a wide variety of substrates. A generally accepted mechanism for hydrosilylation has been proposed by Chalk and Harrod.[4] It involves the coordination of the metal to the alkene followed by oxidative addition of the silane to the metal to give a Pt^{IV} intermediate. Rearrangement gives σ-bonded Pt^{IV} and subsequent reductive elimination gives the hydrosilylated product and Pt^{II} species.

Hydrosilylation reactions of electron-rich alkenes with activated silanes such as halo- or alkoxysilanes are simple. Terminal alkenes react with ***Trichlorosilane*** under CPA catalysis to furnish high yields of the linear trihalosilane (eq 2).[5]

(2)

Hydrosilylations of internal alkenes with trichlorosilane and CPA as the catalyst proceed in a different manner. In these reactions, both bond migration and hydrosilylation occur. For example, reaction of 2-pentene with trichlorosilane for 30 min at 130 °C using CPA as the catalyst furnishes the terminal silane (eq 3).[5]

(3)

Styrene undergoes regioselective hydrosilylation with trichlorosilane in the presence of CPA and ***Triphenylphosphine***, providing the β-adduct selectively (eq 4).[6] The regioselectivity depends on the additive as well as the catalyst. For example, reaction of styrene with trichlorosilane and ***Tetracarbonylnickel*** as the catalyst furnished the α-adduct as the sole product. Rhodium catalysts have also been evaluated in hydrosilylations of styrene with various silanes.[7]

(4)

Additive	β-adduct:α-adduct (GC)
Triphenylphosphine	95:0
Benzyldimethylamine	85:0
Pyridine	92:0
Phenylacetonitrile	64:36

Reactions of terminal alkenes with dichlorosilane provides the monoalkyldichlorosilanes (eq 5).[8] In this reaction, the terminal double bond undergoes hydrosilylation preferentially. Hydrosilylation of terminal alkenes with dichlorosilane using triphenylphosphine complexes of Group 8-10 metals (Ni, Ru, Rh, Pd, Pt) gives the monoalkyldichlorosilanes in excellent yields.[9]

(5)

Internal alkenes produce a mixture of hydrosilylated products upon treatment with dichlorosilane and CPA (eq 6).[5] In this reaction, products from bond migration followed by hydrosilylation were not observed.

(6)

Hydrosilylation of alkenes with chiral silanes and CPA catalysis proceeds with retention of configuration at the silicon center (eq 7).[10] Similarly, Si-H to Si-D exchanges can also be carried out with retention of configuration using CPA catalysis.

1,1,3,3-Tetramethyldisiloxane, a compound with a preexisting Si-O-Si linkage, undergoes hydrosilylation with terminal alkenes and CPA catalysis to furnish silylated products in moderate yields (eq 8).[11]

Molecular oxygen and CPA can effectively catalyze the addition of unreactive monoalkyl silanes to terminal alkenes to furnish tetrasubstituted silicon compounds in high yields (eq 9).[12] In the absence of oxygen, these reactions do not go to completion since it is believed that the oxygen reactivates the CPA for hydrosilylation.

Intramolecular hydrosilylations of alkenylsilanes with CPA catalysis gives a mixture of regioisomeric cyclic silanes (eq 10).[13] The yields and ratio of products depends on the ring size, while the product distribution has been explained using the Chalk and Harrod mechanism for the hydrosilylation reaction. Vinylsilanes and allylsilanes gave no cyclized product.

(10)

n	(1):(2)	Yield (%)
0	100:0	46
1	10:90	58
2	1:1	70
3	1:1	16
4	0:100	2

Hydrosilylations using silane have not been extensively investigated. One example involves the hydrosilylation of 1,5-hexadiene with silane and CPA (pretreated with oxygen) catalysis and subsequent intramolecular hydrosilylation of the intermediate to provide a silaheptane as shown in eq 11.[14] $Pt(PPh_3)_4$ was a better catalyst than CPA for this reaction.

(11)

10:17

Hydrosilylations of alkenes containing a variety of functional groups have also been explored. The success of these reactions depends on the nature of the functional groups. A variety of functional groups survive the hydrosilylation conditions. These include epoxides, nitro groups, esters, carbamates, and acetals.[1d]

Epoxy organosilanes are very useful materials and are extensively used as silane-coupling agents. These compounds can be conveniently synthesized by the hydrosilylation of epoxyalkenes with a variety of alkoxysilanes in the presence of CPA (eq 12).[15]

(12)

Unsaturated sulfides undergo hydrosilylation with triethyl- and triethoxysilanes.[16] These reactions are generally nonselective and proceed in only moderate yields (eq 13). The selectivity and yields depend upon the nature of the substrate, hydrosilylating agent, and catalyst. In the case of diallyl sulfide, hydrosilylation using ***Triethylsilane*** and CPA produces the monosilylated product and a byproduct arising from cleavage of the sulfur-carbon bond (eq 14).

(13)

X = Et or OEt

(14)

Allylamine undergoes hydrosilylation with ***Triethoxysilane*** and CPA as the catalyst (eq 15).[17] The effect of additives such as triphenylphosphine and carboxylic acids have been evaluated with respect to regioselectivity. Hydrosilylation of secondary and tertiary allylamines have also been evaluated. With secondary allyl amines, the regioselectivity of the silane addition depends upon the size of the *N*-substituent, and the γ-isomer is formed predominantly. In the case of tertiary allyl amines, the γ-isomer is the sole adduct.[18]

(15)

Acetylene undergoes hydrosilylation with trialkylsilanes in the presence of CPA to provide a mixture of mono- and diadducts (eq 16).[19] A convenient laboratory method for hydrosilylation of acetylene with a variety of silanes to provide synthetically useful vinylsilanes has been reported by Watanabe.[20] Although CPA gives good selectivity and high yields with trichlorosilane, ruthenium, rhodium, and platinum triphenylphosphine complexes were found to be better suited for these reactions.

(16)

R	X	Solvent	T (°C)	**(3)** (%)	**(4)** (%)
Cl	Cl	xylene	60	90	0
OEt	OEt	benzene	40	42	37
Me	Cl	xylene	25	8	80
Cl	Cl	xylene	60	90	0

Hydrosilylation of monosubstituted alkynes may also be catalyzed with CPA. Generally the reaction proceeds through *cis* addition of the silane and gives a mixture of α- and *cis* and *trans* β-adducts, with the latter product predominating.[21] A comparison of CPA to Karstedt's catalyst in the hydrosilylation of monosubstituted alkynes has been reported.[22] Maricinec and co-workers have investigated the hydrosilylation of a variety of monosubstituted alkynes with (±)-α-naphthylphenylmethylsilane (eq 17).[23] Several other platinum catalysts were evaluated in this reaction with tetrakis(triphenylphosphine)platinum being as effective as CPA. In a similar fashion, hydrogermylation of monosubstituted alkynes with CPA catalysis gave the *trans*-germyl alkenes as the major product.[24]

Hydrogermylations with chiral germanes and CPA catalysis proceed with retention of configuration.[25]

R	Catalyst	Time (h)	T (°C)	Yield (%)	(6):(5)
H	H_2PtCl_6	6	60	99	100:0

TMS	H_2PtCl_6	85	25	99	89:11
t-Bu	H_2PtCl_6	85	25	98	100:0

Voronkov and Sushchinskaya[26] have shown that the hydrosilylation of phenylacetylene with triethylsilane and CPA catalysis can be markedly influenced by the addition of aluminum or germanium chlorides. For example, the reaction in the presence of ***Aluminum Chloride*** (CPA:$AlCl_3$ = 1:200) gave 93% of the hydrosilylated products, while in the absence of $AlCl_3$ the yield was only 24% (eq 18).

Doyle and co-workers have reported an alternate mode of selectivity of silane addition to monosubstituted alkynes, wherein allylsilanes are formed as the major products, along with minor amounts of the vinylsilanes (eq 19).[27] The reaction involves the slow addition of alkyne to a solution of silane and CPA catalyst. The allylsilanes are formed in good yields. Use of rhodium(II) perfluorobutyrate in place of CPA gave higher yields of the allylsilane. Addition of

silane to a solution of alkyne and CPA gave the normal vinylsilane product.

(19)

R	Yield (%)	(*E*)/(*Z*)
C_5H_{11}	60	11
Pr	73	15
MeO	49	2.8
BnO	57	3

Acetylene and monosubstituted alkynes undergo dehydrocondensative hydrosilylation in the presence of catalytic CPA and iodine (eq 20).[28] This method provides a convenient route to silylalkynes. The effect of various halide additives on the product distribution and yields has been examined. Elemental iodine gave good yields of the dehydrocondensation product and these reactions were found to be temperature dependent. Trimethylsilane can be used instead of triethylsilane with similar product distributions. However, the best yields of the dehydrocondensation product were obtained using trialkylsilyl iodides as the reactant. The role of solvents in these reactions has also been reported. Hydrosilylation of phenylacetylene with transition metal complexes containing a Si-H bond proceeds with CPA catalysis giving a *cis-trans* mixture of products in high yields.[29]

Hydrosilylation and hydrogermylation of disubstituted alkynes[30] using CPA as the catalyst have been explored en route to substituted furans (eq 21).[31] Similarly, alkynylsilanes can be hydrosilylated in a highly regioselective manner to give 1,2-disilaalkenes (eq 22).[32]

Intramolecular hydrosilylations of silicon-substituted silaalkynes have been achieved using CPA as the catalyst (eq 23).[33] Similar to the results obtained for intramolecular hydrosilylations of alkenes, the product distribution depends on the size of the ring formed.

R	n	(10)	(11)	Yield (%)
H	2	100	0	58
H	3	79	21	71
Ph	2	100	0	42

Hydrosilylations of dienes generally provide three 1:1 adducts arising from 1,2- and 1,4-addition. ***Isoprene***, a simple diene, reacts with a variety of silanes in the presence of catalytic CPA to furnish hydrosilylated products. For example, the reaction of isoprene with trichlorosilane and catalytic CPA gave the 1,4-adduct, with addition occurring across the least hindered double bond (eq 24).[34] However, trimethylsilane gave both 1,2- and 1,4-adducts with addition occurring at both ends of the diene.

1,4-Bis(trimethylsilyl)-1,3-butadiyne, a stable alternative to the highly reactive 1,3-butadiyne, undergoes hydrosilylation with CPA catalysis and a variety of silanes (eq 25).[35] The product distribution depends on the nature of the silane. The more reactive dimethylchlorosilane gave the 1:2 adduct (**12**) in moderate yields, while reactions with the less reactive and bulkier triisopropylsilane furnished the 1:1 adduct (**14**) in higher yields. Reaction with triethylsilane was unusual in that the product was an allene (**13**) arising from 1,4-addition of a second silane molecule to the intermediate 1:1 adduct (**14**).

R_3SiH	Conditions	Product (yield)
$HSiClMe_2$	80 °C, 2 h	**(12)** 54%
$HSiEt_3$	80 °C, 0.5 h	**(13)** 100%
$HSiMe_3$	100 °C, 2 h	**(13)** 46%, **(14)** 40%
$HSi(i\text{-}Pr)_3$	90 °C, 8 h	**(14)** 92%

Hydrosilylations of enynes occur at the more reactive alkyne end. An example of enyne hydrosilylation with methyldichlorosilane is shown in eq 26.[36] The reaction requires a small amount of either ***Dibenzoyl Peroxide*** or trichlorosilane as a cocatalyst and is believed to proceed by a radical pathway. An example of a highly chemoselective hydrosilylation has been reported by Voronkov (eq 27).[37] The reactions occur at the alkyne terminus in the presence of an alcohol and alkene.

(27)

Hydrosilylations of α,β-unsaturated esters, ketones, and nitriles with CPA catalysis have also been examined. The course of these reactions depends on the nature of the silane and the electron-withdrawing substituent. Hydrosilylation of a series of α,β-unsaturated esters using CPA catalysis was evaluated by Yoshii and co-workers (eq 28).[38] The reactions were generally nonselective and gave all three possible 1,2- and 1,4-addition products. When Wilkinson's catalyst (***Chlorotris(triphenylphosphine)rhodium(I)***) was used in place of CPA, the 1,4-addition products, silylketene acetals, were obtained as the major products.

(28)

Hydrosilylation of enones proceeds by a 1,4-addition of the silane to produce the enol silyl ethers, from which the reduced compounds are obtained through hydrolysis.[39] An application of this methodology is illustrated in the synthesis of a precursor to purpnigenin (eq 29).[40] Of the many silanes examined in this reaction, diethylethoxysilane gave the highest yields and least number of side reactions. Hydrosilylations of α,β-unsaturated carbonyl compounds proceeds well with a variety of silanes, generally with good regioselectivity when Wilkinson's catalyst is used.[41]

Hydrosilylation of acrylonitrile with trichlorosilane using CPA catalysis does not produce any hydrosilylated products.[42] However, hydrosilylation of α,β-unsaturated nitriles proceeds well when Wilkinson's catalyst is used.[43]

Hydrosilylation Followed by Oxidation.

Tamao and co-workers have developed elegant methodologies for the conversion of the silyl intermediates obtained in hydrosilylation of alkenes and alkynes to a variety of functional groups. The key transformations in these methodologies include the oxidation of a C-Si bond to a hydroxy group with retention of configuration,[44] the conversion of a C-Si bond to a C-Br bond,[45] and conversion of a C-Si bond to a C-C bond.[46]

The hydrosilylation-oxidation sequence can be effectively used for the transformations of terminal alkenes to the corresponding anti-Markovnikov alcohols (eq 30).[44] The silane used in these experiments, methyldiethoxysilane, is commercially available and air stable. Thus the hydrosilylations can be carried out without solvent under air using CPA catalysis. ***Hydrogen Peroxide*** oxidation proceeds smoothly only if there is at least one alkoxy group on the silicon. The reactivity of the carbon attached to silicon can be controlled by the nature of the alkoxy group.

(30)

The hydrosilylation-oxidation sequence can also be effectively used for the conversion of an alkyne to a ketone. An application of this methodology in the synthesis of 5-decanone is shown in eq 31.[44] The reaction involves the hydrosilylation of an alkyne to a vinylsilane using CPA catalysis followed by hydrogen peroxide oxidation to the decanone. The procedure can be carried out without isolating the intermediate vinylsilane.

(31)

The hydrosilylation-oxidation sequence is a convenient route for the preparation of α-hydroxy ketones from alkynes (eq 32).[47] The process involves hydrosilylation of an alkyne to a vinylsilane, epoxidation of the vinylsilane using ***m*-Chloroperbenzoic Acid**, and final oxidative cleavage using hydrogen peroxide.

(32)

Regioselective functionalization of unsymmetrical internal alkynes can be effected through the intramolecular hydrosilylation of homopropargyl alcohols (eq 33).[45] The hydrosilylation proceeds selectively through a 5-*exo*-dig ring closure to provide the vinylsilane (**15**). This intermediate can then be oxidized with hydrogen peroxide to give the β-hydroxy ketone in high yields. Alternatively, treatment of (**15**) with bromine provides the vinyl bromide in a highly selective manner. Vinylsilane (**15**) undergoes transition metal-catalyzed cross-coupling reactions with alkenyl and aryl halides to provide a convenient route to homoallyl alcohols (eq 34).[46]

(33)

(34)

The hydrosilylation-oxidation sequence is an attractive route to the regio- and stereoselective synthesis of the 1,3-diol skeleton. Intramolecular hydrosilylation of allyl and homoallyl alcohols containing di- or trisubstituted internal alkenes can be achieved through CPA catalysis. The reactions proceed with high regio- and stereoselectivity. The intermediate cyclosiloxane undergoes oxidative C-Si bond cleavage with retention of configuration to furnish the 1,3-diol product (eq 35).[48]

(35)

Hydrogenations and Carbonylations.

A complex prepared from CPA and ***Tin(II) Chloride*** dihydrate functions as a useful homogeneous hydrogenation catalyst. Ethylene can be quantitatively hydrogenated to ethane at 1 atm using this catalyst system (eq 36).[49] Similarly, a 1:1 mixture of acetylene and hydrogen gave ethane and ethylene in a 3:1 ratio. In these reactions, neither CPA nor tin dichloride catalyzed the hydrogenations individually. The homogeneous hydrogenation of polyalkenes using CPA/tin dichloride dihydrate catalyst has been evaluated. The hydrogenation of methyl linolenate using this catalytic system under 500 psi hydrogen gave diene products selectively.[50]

(36)

Terminal alkenes under relatively mild reaction conditions can be converted to a mixture of linear and branched esters by using CO and methanol with a CPA-$SnCl_2$ couple as the catalyst (eq 37).[51] Use of water in place of methanol produced the corresponding carboxylic acids in similar ratios. Internal alkenes gave a mixture of products in very low yields under these carbonylation conditions.

Methyl acetate can be hydrocarbonylated under a carbon monoxide-hydrogen atmosphere using a mixed ***Rhodium(III) Chloride***-CPA catalyst to furnish ethylidene diacetate (eq 38).[52] The reaction gave higher yields with rhodium trichloride-***Palladium(II) Acetate*** as the catalyst.

Miscellaneous.

Tetraalkylsilanes undergo redistributions selectively in the presence of trichlorosilane and CPA. Generally, the smallest alkyl group exchanges with the chloro group on the silane (eq 39).[53]

Allyl chloride and allyl bromide react with less hindered silanes under CPA catalysis to provide hydrosilylation products, along with minor amounts of silyl halides. Reactions of bulky silanes with excess allyl bromide in the presence of CPA furnishes the silyl bromide as the major or sole product (eq 40).[54]

Arenes react with CPA to give the σ-aryl complexes of Pt^{IV}.[55] Regioselectivity of the metallation with monosubstituted benzenes is quite poor, giving both *m*- and *p*-substituted complexes. These complexes then undergo further reaction to produce mixtures of chlorinated arenes and substituted biphenyls (eq 41).

Chlorination of alkanes and arenes in the presence of stoichiometric CPA in refluxing trifluoroacetic acid has been reported (eq 42).[56] These reactions furnish chlorinated arenes or *n*-chloroalkanes and require Pt^{II} as a cocatalyst.

Cyclopropanes react with CPA to form platinacyclobutanes (eq 43).[57] With substituted cyclopropanes, Ziese's dimer provides the best results. Alternatively, cyclopropanes form mixtures of pyrylium ions in very low yields upon treatment with acetic anhydride and catalytic CPA.[58]

2-Allyloxypyridines may be rearranged to *N*-allylpyridones when using CPA (eq 44).[59] The reaction is carried out by heating the pyridine at 125 °C for 36 h without solvent. The reaction can also be catalyzed by $Pt(PPh_3)_4$.

(44)

Alcohols can be converted to carbonyl compounds through a two-electron oxidation process using molecular oxygen, CPA, and visible light.[60] The reaction is catalytic in Pt^{IV} and requires Cu^{II} cocatalysis.

Hydrogen Iodide[1]

HI

[10034-85-2] · HI · Hydrogen Iodide · (MW 127.91)

(electrophilic hydriodination of alkenes and alkynes;[3-10] cleavage of epoxides,[1b,11,12] ethers, and acetals;[13] conversion of alcohols to iodides;[14-17] reducing agent for many groups including quinones,[24,25] α-diketones,[23] α-ketols,[23] α-halo ketones,[19] α-diazo ketones,[22] and sulfoxides;[30] reductive cyclization of keto acids[27,28])

Alternate Name: hydriodic acid.

Physical Data: 57% aqueous solution: bp 127 °C; *d* 1.70 g cm^{-3}.

Solubility: sol most common organic solvents.

Form Supplied in: compressed gas; colorless 57% aq solution; widely available.

Preparative Methods: from the reaction of tetrahydronaphthalene with I_2;[2] can be generated in situ (a) from Me_3SiCl and NaI in the presence of water,[3] (b) from I_2 and activated alumina,[4] (c) from KI and H_3PO_4,[5] and (d) from $Et_2PhN.BI_3$ and AcOH.[6]

Purification: distillation of the aqueous azeotrope; concentrated solutions can be regenerated after long storage by treatment with hypophosphorous acid.

Handling, Storage, and Precautions: store protected from air and light at or below rt. Highly corrosive and toxic. This reagent should be handled in a fume hood.

Hydriodination of Alkenes and Alkynes.

Being a stronger acid, HI undergoes addition more readily than ***Hydrogen Chloride*** or ***Hydrogen Bromide*** to most alkenes and alkynes.[1a] Moreover, there is no competing radical addition as with HBr. However, because of the difficulty in generating and transferring anhydrous HI, addition of HI has received less attention than addition of HCl and HBr. As mentioned above, several techniques have been developed for generating HI in situ. These include the use of KI and H_3PO_4 (eq 1);[5] Me_3SiCl and NaI in the presence of water (eq 2);[3] I_2 and activated Al_2O_3 (eq 2);[4] and the $Et_2PhN.BI_3$ complex and AcOH (eq 3).[6] Alternatively, $I(py)_2BF_4$ has been used with the hydride donor Et_3SiH (eq

1).[7]

(1)

KI, H_3PO_4, 80 °C, 3 h	88-90%
$I(py)_2BF_4$, HBF_4, Et_3SiH, 20 °C, 1 h	50%

(2)

TMSCl, NaI, H_2O, 25 °C, 1 h	98%
I_2, Al_2O_3, 36 °C, 2 h	83%
57% HI, $C_{16}H_{33}(Bu)_3PBr$, 115 °C, 0.25 h	97%
TMSI, SiO_2, 25 °C, 1 h	98%

(3)

Aqueous HI has been used with a phase-transfer catalyst to hydriodinate alkenes (eq 2).[8] Similarly, it has been used to convert dialkylalkynes to the corresponding (*Z*)-vinyl iodides (eq 4).[9]

(4)

A particularly convenient method for generating HI in situ involves the use of various inorganic and organic iodides in the presence of appropriately prepared silica gel or alumina (eq 2).[10] These adsorbents also facilitate the addition process. Surface-mediated hydriodination of phenylalkynes affords the (*E*) isomers, resulting from *syn* addition (eq 5).[10] The regiochemical course of these hydroiodinations follows Markovnikov's rule.

(5)

Cleavage of Epoxides to Iodohydrins.

The addition of HI to epoxides to give iodohydrins proceeds readily using either aqueous HI or anhydrous HI in organic solvents.[1b,11] Because of the difficulty of preparing anhydrous HI, aqueous solutions have most often been used for this transformation. The stereo- and regioselectivity of the addition process is similar to the general trends discussed for the corresponding additions with HCl (see ***Hydrogen Chloride***). Trimethylsilyl-substituted epoxides give the corresponding iodohydrins with particularly high stereo- and regiospecificity (eq 6).[12]

(6)

Cleavage of Ethers and Acetals.

HI readily cleaves ethers to alcohols and/or iodides[13] and is an attractive reagent for this transformation from the standpoint of economy and convenience. Primary and secondary alkyl methyl ethers are cleaved to afford alcohols (or derivatives), while benzyl and tertiary alkyl ethers often yield iodides. Acetals react in a similar fashion to produce ketones, although this deprotection method rarely offers advantages over more common procedures.

Conversion of Alcohols and Chlorides to Iodides.

The reaction of 57% aqueous HI with saturated primary and secondary alcohols at elevated temperatures leads in fair to high yield to the corresponding iodides.[14] Tertiary iodides have been synthesized in good to high yields from the corresponding alcohols under especially mild conditions by 55% aqueous HI in the presence of ***Lithium Iodide***.[15] Allylic alcohols are transformed to allylic iodides by HI generated in situ from Me_3SiCl/NaI.[16] Benzylic alcohols are subject to conversion to the saturated system, presumably via iodine substitution and ensuing reduction (eq 7).[17]

(7)

Alkyl iodides can also be synthesized via treatment of secondary and tertiary alkyl chlorides with anhydrous HI in the presence of catalytic amounts of FeI_3.[18]

Reduction of α-Substituted Ketones.

Treatment of various α-substituted ketones with HI leads to reductive scission of the α-substituent. Reductive dehalogenation of α-halo ketones can thus be accomplished with HI to furnish the corresponding ketones in high yield (eq 8).[19] Reaction occurs readily even with sterically hindered substrates. Related procedures employing cat. NaI or 57% aq HI and phosphorous acid in acetonitrile[20] or NaI in concd H_2SO_4[21] require long reaction times, high temperatures, and/or reactive substrates and are less satisfactory.

(8)

α-Diazo ketones are reduced to methyl ketones by 47% aqueous HI in $CHCl_3$ (eq 9).[22] The reaction with HI differs from that of HBr and HCl, which give halomethyl ketones as products. Presumably, the initially formed iodomethyl ketone is reduced to the saturated ketone under the reaction conditions.

(9)

α-Diketones and α-ketols are reduced to the corresponding saturated ketones in good yields by aqueous HI in acetic acid at reflux (eq 10).[23]

(10)

Reduction of Quinones and Phenols to Arenes.

Polycyclic quinones may be reduced to polyarenes by HI in HOAc at reflux (eq 11).[24,25] In resistant cases, concentrated aqueous HI may be employed; addition of phosphorus often results in cleaner reaction by removing the

I_2 formed. Large excess of HI or prolonged reaction time may lead to overreduction. Since hydroquinones and phenols are intermediates in these reactions, they are also readily reducible with this reagent. Reductive methylation of quinones can be accomplished in high yield by reaction of polycyclic quinones with excess ***Methyllithium*** followed by reduction with HI (eq 12).[26]

(11)

(12)

A method for the construction of fused polyarenes entails reaction of a smaller aromatic ring system with phthalic anhydride followed by reductive cyclization of the keto acid product with HI in acetic acid to form a polyarene with two additional rings (eq 13).[27,28] This method conveniently combines three steps (reduction of the carbonyl group, cyclodehydration, and reduction) into one step.

(13)

Reductive Deoxygenation of Aryl Ketones.

The combination HI/P/HOAc effectively deoxygenates aryl ketones (eq 14).[27-29] While this method is utilized infrequently, it represents a useful alternative to the better known Wolff-Kishner and Clemmensen reduction methods.

(14)

Reduction of Sulfoxides to Sulfides.

Sulfoxides are readily deoxygenated by HI without the complicating halogenation that often accompanies reduction using HBr or HCl.[30]

Reduction of Alkenylsilanes.

Hydriodic acid reacts with vinylsilanes with replacement of R_3Si by hydrogen (eq 15).[31] A small amount of I_2 and water (or D_2O) is also effective. These reactions usually occur with retention of configuration.

Hydrogen Peroxide[1]

HOOH

[7722-84-1] · H_2O_2 · Hydrogen Peroxide · (MW 34.02)

(nucleophilic reagent capable of effecting substitution reactions[2] and epoxidation of electron-deficient alkenes;[3] weak electrophile whose activity is enhanced in combination with transition metal oxides[4] and Lewis acids;[5] strong nonpolluting oxidant which can oxidize hydrogen halides[6])

Physical Data: 95% H_2O_2: mp -0.41 °C; bp 150.2 °C; *d* 1.4425 g cm^{-3} (at 25 °C). 90% H_2O_2: mp -11.5 °C; bp 141.3 °C; *d* 1.3867 g cm^{-3}. 30% H_2O_2: mp -25.7 °C; bp 106.2 °C; *d* 1.108 g cm^{-3}.

Solubility: sol ethanol, methanol, 1,4-dioxane, acetonitrile, THF, acetic acid.

Form Supplied in: clear colorless liquid widely available as a 30% aqueous solution and 50% aqueous solution; 70% and 90% H_2O_2 are not widely available.

Analysis of Reagent Purity: titration with $KMnO_4$ or cerium(IV) sulfate.[7]

Purification: 95% H_2O_2 (caution!) can be prepared from 50% solution by distilling off water in a vacuum at rt.[8]

Handling, Storage, and Precautions: H_2O_2 having a concentration of 50% or more is very hazardous and can explode violently, particularly in the presence of certain inorganic salts and easily oxidizable organic material. A safety shield should be used when handling this reagent.[9] After the reaction is complete, excess H_2O_2 should be destroyed by treatment with MnO_2 or Na_2SO_3 soln. Before solvent evaporation, ensure absence of peroxides. The use of acetone as solvent should be avoided.[10] The reagent should be stored in aluminum drums in a cool place away from oxidizable substances.

Synthesis of Peroxides via Perhydrolysis.

H_2O_2 and the hydroperoxy anion are excellent nucleophiles which react with alkyl halides and other substrates having good leaving groups to furnish hydroperoxides. The hydroperoxide (**2**) has been prepared employing 98% H_2O_2 (eq 1).[11] To a stirred mixture of THF (50 mL), ***Silver(I) Trifluoromethanesulfonate*** (0.04 mol), and pyridine (0.02 mol) kept at 6 °C under argon and protected from light is gradually added 98% H_2O_2 (0.32 mol). The chloride (**1**) (0.02 mol) dissolved in THF (10 mL) is next added dropwise with cooling (6 °C). The reaction mixture is kept at rt for 24

h; the organic layer is separated by gravity filtration, diluted with ether, and washed with saturated aq $NaHCO_3$ at 0 °C. The organic layer is dried. The solvent as well as traces of pyridine and starting material are distilled out at rt under vacuum. The residual material is the hydroperoxide (**2**) which has been distilled in high vacuum using a bath maintained at 40 °C. The hydroperoxide (**3**) has been prepared in a similar fashion employing 30% H_2O_2 (eq 2).[12]

(1)

(2)

Tertiary alcohols $R^1R^2R^3COH$ and other alcohols which can readily furnish carbenium ion intermediates are solvolyzed by 90% H_2O_2 in the presence of acid catalysts to yield hydroperoxides $R^1R^2R^3COOH$.[13] Trimeric hydroperoxides having a nine-membered oxa heterocyclic ring have been prepared from ketones and hydrogen peroxide in the presence of acid catalysts.[14]

N-Alkyl-*N*´-tosyl hydrazides are oxidized by H_2O_2 and Na_2O_2 in THF at rt to the corresponding hydroperoxides; by employing this procedure, cyclohexyl hydroperoxide has been obtained in 92% yield.[15]

Several *gem* hydroperoxides have been prepared from acetals (eq 3).[16]

(3)

The prostaglandin PGG_2 (**5**) has been synthesized from the dibromide (**4**) (eq 4).[17]

Perhydrolysis of acid anhydrides furnishes the corresponding peroxy acids (for an example, see ***Trifluoroperacetic Acid***). Perhydrolysis of acid chlorides also furnishes peroxy acids.[18] When an organic acid is mixed with H_2O_2 an equilibrium reaction is established, as shown in eq 5.[18] ***Methanesulfonic Acid*** has been used to accelerate the reaction and also to function as solvent (see preparation of ***Perbenzoic Acid***).

$$RCO_2H + H_2O_2 \underset{}{\overset{H^+}{\rightleftharpoons}} RCO_3H + H_2O \qquad (5)$$

A number of diacyl peroxides have been prepared in 90-95% yield by reacting the acid chloride (for example, phenylacetyl chloride) (1 equiv) with 30% H_2O_2 (0.55 equiv) in ether in the presence of pyridine (2 equiv) at 0 °C for 2 h.[19]

Reactions with Amides, Aldehydes, and Ketones.

The oxazolidinone (**6**) is deacylated regioselectively on treatment with ***Lithium Hydroperoxide*** (eq 6).[20] For another example, see Evans.[21]

Aromatic aldehydes can be transformed to phenols by oxidizing with H_2O_2 in acidic methanol (eq 7).[22] Dilute alkaline H_2O_2 can convert only aldehydes having an hydroxyl in the *ortho* or *para* position to the corresponding phenols (Dakin reaction).[1b] *m*-CPBA is not useful for the preparation of phenol (**8**) from (**7**).[22]

Alkyl and aryl aldehydes are oxidized to the corresponding carboxylic acids in high yields via oxidation with H_2O_2 in the presence of ***Benzeneseleninic Acid*** as catalyst.[23] Cyclobutanones and other strained ketones undergo Baeyer-Villiger oxidation with H_2O_2. The cyclobutanone (**9**) has thus been oxidized to the γ-lactone (**10**) (eq 8).[24] Baeyer-Villiger oxidation of some cyclobutanones proceeds under very mild conditions (-78 °C).[25] Baeyer-Villiger reaction of ketones having isolated double bonds can be carried out with H_2O_2 without reaction at the double bond; however, when organic peroxy acids are used, the alkene often is oxidized.[26]

(8)

Epoxidation of α,β-Unsaturated Ketones and Acids.

α,β-Unsaturated ketones furnish the corresponding α,β-epoxy ketones in high yields on treatment with H_2O_2 in the presence of a base.[3] In the cyclopentenone (**11**), approach to the β-face is sterically hindered. Epoxidation of (**11**) at -40 °C furnishes quantitatively a 94:6 mixture of α- and β-epoxides; the selectivity is less when the reaction is carried out at higher temperatures (eq 9).[27] Optically active epoxy ketones (about 99%) have been prepared with high ee by carrying out the epoxidation in the presence of a chiral catalyst such as polymer-supported poly(L-leucine).[28]

(9)

α,β-Unsaturated acids have been epoxidized with 35% H_2O_2 using a catalyst prepared from 12-tungstophosphoric acid (WPA) and cetylpyridinium chloride (CPC) (pH 6-7, 60-65 °C); by this method, crotonic acid furnishes the α,β-epoxy acid in 90% yield.[29]

Synthesis of Epoxides, Vicinal Diols, Dichlorides, and Ketones from Alkenes.

Terminal alkenes, as well as di- and trisubstituted alkenes, have been epoxidized at 25 °C using a molybdenum blue-***Bis(tri-n-butyltin) Oxide*** catalyst system (eq 10).[30] Epoxides have been prepared with 16% H_2O_2 using a (diperoxotungsto)phosphate catalyst (**12**) in a biphasic system.[31]

(10)

$$[(C_8H_{17})_3NMe]_3^+[PO_4\{W(O)(O_2)_2\}_4]^{3-}$$

(12)

Asymmetric epoxidation of 1,2-dihydronaphthalene has been achieved employing a chiral manganese(III) salen complex with an axial N-donor; even 1% H_2O_2 can be used as oxidant and the highest ee observed was 64%.[32]

Vicinal diols have been prepared from alkenes by oxidizing with H_2O_2 in the presence of Re_2O_7 catalyst, in dioxane at 90 °C for 16 h; the mole ratio of Re_2O_7:alkene:H_2O_2 is 1:100:120. The reaction proceeds via epoxidation followed by acid-catalyzed ring opening. Cyclohexene furnishes *trans*-cyclohexane-1,2-diol in 74% yield.[33]

Oxidative cleavage of ene-lactams takes place during oxidation with H_2O_2 in the presence of a selenium catalyst (eq 11).[34] The reaction proceeds under neutral and mild conditions. For the preparation of macrocyclic ketoimides, ***Palladium(II) Acetate*** is used as the catalyst.[34]

(11)

Alkenes have been chlorinated with concentrated HCl/30% H_2O_2/CCl_4 in the presence of the phase-transfer catalyst ***Benzyltriethylammonium Chloride***. Side reactions take place when gaseous chlorine and sulfuryl chloride react with alkenes; under ionic conditions these side reactions are not favored. The method has also been applied for the bromination of alkenes.[6] 1-Octene furnishes 1,2-dichlorooctane in 56% yield.

Oxidation of Alcohols and Phenols.

The system $H_2O_2/RuCl_3.3H_2O$/phase-transfer catalyst (didecyldimethylammonium bromide) oxidizes a variety of

alcohols selectively; the requirement of ruthenium is very low; ratio of substrate:$RuCl_3$ = 625:1.[35] By this method, *p*-methylbenzyl alcohol was oxidized to *p*-methylbenzaldehyde in 100% yield.

Vicinal diols are oxidized to α-hydroxy ketones by 35% H_2O_2 in the presence of peroxotungstophosphate (PCWP; 1.6 mol %) in a biphasic system using $CHCl_3$ as solvent. 1,2-Hexanediol has been oxidized in 93% yield to 1-hydroxy-2-hexanone.[36]

When 1,4-dihydroxybenzenes are reacted with stoichiometric quantities of iodine, the corresponding *p*-benzoquinones are formed in poor yields; however, they are oxidized in very good yields to *p*-quinones by reaction with 60% H_2O_2 in methanol or aq solution at rt in the presence of catalytic quantities of I_2 or HI. 2-Methyl-1,4-dihydroxynaphthalene has been oxidized to 2-methyl-1,4-naphthoquinone in 98% yield.[37]

Radical Reactions.

Homolytic substitutions of pyrrole, indole, and some pyrrole derivatives have been carried out using electrophilic carbon centered radicals generated in DMSO by Fe^{2+}/H_2O_2 and ethyl iodoacetate or related iodo compounds; the substrate is taken in large excess (eq 12).[38]

(12)

N-Acylpyrrolidines and -piperidines are oxidized by Fe^{II}/hydrogen peroxide in aqueous 95% acetonitrile to the corresponding pyrrolidin-2-ones and piperidin-2-ones;[39] *N*-phenylcarbamoyl-2-phenylpiperidine was oxidized to the corresponding lactam in 61% yield.

Oxidation of Organoboranes.

Oxidative cleavage of the C-B bond with alkaline H_2O_2 to convert organoboranes to alcohols is a standard step in hydroboration reactions. In some procedures, organoboranes are formed in the presence of 1,4-oxathiane. When a mixture of tri-*n*-octylborane and 1,4-oxathiane in THF was treated initially with NaOH and subsequently with 30% H_2O_2, the organoborane was selectively oxidized to furnish in 98% yield a mixture (93:7) of octan-1-ol and octan-2-ol.[40]

Oxidation of Organosilicon Compounds.

Organosilicon compounds having at least one heteroatom on silicon undergo oxidative cleavage of the Si-C bond when treated with H_2O_2 (eq 13).[41] For additional examples, see Roush[42a] and Andrey.[42b]

(13)

Oxidation of Amines.

H_2O_2 in the presence of Na_2WO_4 has been used to oxidize (a) 2,4,4-trimethyl-2-pentanamine to the corresponding nitroso compound in 52% yield,[43] and (b) a primary amine (containing β-lactam and phenolic OH) to the corresponding oxime in 72% yield.[44]

The secondary amine 2-methylpiperidine (**13**) has been oxidized to the nitrone (**14**) with H_2O_2/Na_2WO_4 (eq 14);[45] the oxidation product also contains about 6-15% of the isomeric 2-methyl-2,3,4,5-tetrahydropyridine *N*-oxide (***Selenium(IV) Oxide*** is also an effective catalyst for this oxidation).[46] 1,2,3,4-Tetrahydroquinoline is oxidized to the 1-hydroxy-3,4-dihydroquinolin-2(1*H*)-one in 84% yield by H_2O_2/Na_2WO_4.[47] The flavin, $FlEt^+ClO_4^-$ (**15**) is a good catalyst for the H_2O_2 oxidation of secondary amines to nitrones.[48]

(14)

(13) **(14)**

(15)

(16)
trans:*cis* = 95:5

The tertiary amine *N*-methylmorpholine has been oxidized to the *N*-oxide in 84-89% yield; the reaction is carried out at 75 °C with 30% H_2O_2 and the reaction time (0.3 mol scale) is about 24 h.[49] The *trans*-*N*-oxide (**16**) has been obtained stereoselectively (*trans*:*cis* = 95:5) by reacting the corresponding *N*-methylpiperidine with 30% H_2O_2 in acetone at 25 °C.[50]

Oxidation of Sulfur-Containing Compounds.

Oxidation of di-*n*-butyl sulfide with H_2O_2 in the presence of the catalyst $FlEt^+ClO_4^-$ (**15**) furnished the corresponding sulfoxide in 99% yield.[48] Sulfides have been oxidized to the corresponding sulfoxides with H_2O_2 in CH_2Cl_2 solution in the presence of the heterocycle (**17**); di-*n*-octyl sulfide yields *n*-octyl sulfoxide in 96% yield, and benzylpenicillin methyl ester is oxidized to the (*S*)-*S*-oxide in 90% yield.[51]

(17)

The oxidation of sulfides to sulfones proceeds in good yields when the reaction is catalyzed by tungstic acid; the cyclic sulfide thietane is oxidized to the sulfone (thietane 1,1-dioxide) in 89-94% yield.[52]

Oxidation of Selenium-Containing Compounds.

Oxidation of the phenyl selenide (**18**) with H_2O_2 in THF furnishes the alkene (**19**) (eq 15);[53] the selenoxide initially formed through oxidation of (**18**) undergoes facile *syn* elimination (see also Grieco[54]).

(18) (19) (15)

Hydrogen peroxide has a high (47%) active oxygen content and low molecular weight. It is cheap and is widely available. After delivering oxygen, the byproduct formed in H_2O_2 oxidations is the nonpolluting water. Hence the use of H_2O_2 in industry is highly favored. This reagent is able to oxidize SeO_2, WO_3, MoO_3, and several other inorganic oxides efficiently to the corresponding inorganic peroxy acids which are the actual oxidizing agents in many reactions described above.[4] Use of these oxides in catalytic amounts along with H_2O_2 as the primary oxidant reduces the cost of production, simplifies workup and minimizes the effluent disposal problem. Phase-transfer-catalyzed (PTC) reactions in a two-phase system are well suited for H_2O_2 oxidations and are widely used; epoxides are susceptible to ring opening by water and the PTC procedure allows the preparation of epoxides even with 16% aq H_2O_2 since the epoxide and water are in different phases.[31] Handling chlorine and bromine poses many problems, but HCl/H_2O_2 and HBr/H_2O_2 systems may be used as substitutes for chlorine and bromine, respectively.[6] The solids ***Sodium Perborate***, sodium percarbonate, and ***Hydrogen Peroxide-Urea***, which are prepared from H_2O_2, have wide applications since they release H_2O_2 readily.

Reactions with Nitriles.

Treatment of nitriles (**20**) with $NaOH/H_2O_2$ in aqueous ethanol is a standard synthetic procedure for the preparation of amides (**21**); aromatic nitriles furnish amides in high yields but aliphatic nitriles give amides in moderate yields (50-60%).[55] It has been suggested[56] that addition of the hydroperoxy anion to the nitrile (**20**) furnishes the peroxycarboximidic acid (**22**) which reacts with H_2O_2 to give the amide (**21**) and molecular oxygen.

(20) (21) (22)

It has been observed[57] that in the reaction of nitriles with 30% H_2O_2 in the presence of 20% NaOH there is a significant increase in the reaction rate when *n*-tetrabutylammonium hydrogen sulfate (20 mol %) is used as phase-transfer catalyst. The reaction is carried out at 25 °C for 1-2 h employing CH_2Cl_2; aromatic as well as aliphatic amides are obtained in high yields (e.g. eq 16). This method cannot be used if the nitrile has an electron-withdrawing substituent on the carbon atom α to the cyano group.[57]

(16)

Treating a DMSO solution of a nitrile with an excess of 30% H_2O_2 in the presence of a catalytic amount of K_2CO_3 for 1-30 min at 25 °C furnishes the corresponding amide in high yields[58] (e.g. eq 17). Under these conditions, esters, amides, and urethanes do not react. α,β-Unsaturated nitriles furnish α,β-epoxy amides.[58] For other routes for the synthesis of amides from nitriles, see Cacchi[57] and Katritzky.[58]

(17)

Related Reagents.

Hydrogen Peroxide-Ammonium Heptamolybdate; ***Hydrogen Peroxide-Boron Trifluoride***; ***Hydrogen Peroxide-Iron(II) Sulfate***; ***Hydrogen Peroxide-Tellurium Dioxide***; ***Hydrogen Peroxide-Tungstic Acid***; ***Hydrogen Peroxide-Urea***; ***Iron(III) Acetylacetonate-Hydrogen Peroxide***; ***Perbenzoic Acid***; ***Peroxyacetimidic Acid***; ***Trifluoroperacetic Acid***.

Hydrogen Peroxide-Ammonium Heptamolybdate[1]

H_2O_2-$(NH_4)_6Mo_7O_{24}.4H_2O$

(H_2O_2)

[7722-84-1] · H_2O_2 · Hydrogen Peroxide-Ammonium Heptamolybdate · (MW 34.02) ($(NH_4)_6Mo_7O_{24}$)

[12027-67-7] · $H_{24}Mo_7N_6O_{24}$ · Hydrogen Peroxide-Ammonium Heptamolybdate · (MW 1163.88) ($(NH_4)_6Mo_7O_{24}.4H_2O$)

[12054-85-2] · $H_{32}Mo_7N_6O_{28}$ · Hydrogen Peroxide-Ammonium Heptamolybdate · (MW 1235.96)

(epoxidation;[2] oxidation of secondary alcohols to ketones;[2,3] oxidation of aldehydes to acids;[2] chemoselection between epoxidation and alcohol oxidation[2,4])

Physical Data: $(NH_4)_6Mo_7O_{24}.4H_2O$: dec 190 °C; *d* 2.498 g cm^{-3}.

Solubility: $(NH_4)_6Mo_7O_{24}.4H_2O$: sol H_2O (43 g/100 mL); insol alcohol.

Form Supplied in: $(NH_4)_6Mo_7O_{24}.4H_2O$: colorless or slightly greenish or yellowish crystals; widely available.

Handling, Storage, and Precautions: $(NH_4)_6Mo_7O_{24}.4H_2O$: commercially available ammonium heptamolybdate tetrahydrate can be used and stored at rt under air. For H_2O_2, see ***Hydrogen Peroxide***.

Epoxidation.

Molybdenum complexes are among the best catalysts for epoxidations with peroxides.[1] The hydrogen peroxide-molybdate system is superior to others because of its accessibility, low cost, and easy handling. The epoxidation with hydrogen peroxide-molybdate requires tetraalkylammonium salts[2,5] or anion exchange polymers[6] for enhancement of the affinity between substrates and oxidizing agents (peroxomolybdates). Monosubstituted alkenes fail to react and disubstituted alkenes react very slowly. Competition experiments reveal high chemoselectivity for the reaction of tri- vs. disubstituted alkenes (eq 1).[2] Alkene geometry is retained in the product. A primary allylic alcohol activates and directs the epoxidation to the neighboring double bond (eqs 2 and 3).[2]

(1)

(2)

(3)

Oxidation of Alcohols.[7]

Oxidation of secondary alcohols to ketones with hydrogen peroxide-heptamolybdate is accelerated by the addition of ***Potassium Carbonate***.[2,3] The oxidation of a secondary alcohol chemoselectively occurs in the presence of a primary alcohol (eq 4).[2-5]

(4)

Steric factors play an important role in these oxidations: the more hindered alcohol is oxidized more rapidly.[2] This steric effect has been exploited for selective oxidations of steroids (eq 5).[2,3] Primary alcohols are oxidized to carboxylic acids at higher temperatures but the major products are the self-condensed esters. Aldehydes are oxidized to carboxylic acids by this reagent (eq 6).[2]

(5)

(6)

Chemoselection Between the Epoxidation and the Alcohol Oxidation.

By controlling pH, the chemoselectivity of the oxidation of unsaturated alcohols can be directed to produce either epoxides or ketones.[2] In the absence of potassium carbonate, epoxidation is observed, while in the presence of this base oxidation takes place preferentially (eq 7).[4]

Hydrogen Peroxide-Boron Trifluoride[1]

H_2O_2-BF_3.Et_2O

(H_2O_2)

[7722-84-1] · H_2O_2 · Hydrogen Peroxide-Boron Trifluoride · (MW 34.02) (BF_3)

[7637-07-2] · BF_3 · Hydrogen Peroxide-Boron Trifluoride · (MW 67.81) (BF_3.Et_2O)

[109-63-7] · $C_4H_{10}BF_3O$ · Hydrogen Peroxide-Boron Trifluoride · (MW 141.95)

(strong oxidant for the Baeyer-Villiger oxidation of ketones to esters;[2] promotes the benzylic hydroperoxide rearrangement of secondary and tertiary benzylic alcohols;[3] with hydrogen fluoride is a regioselective hydroxylating agent for aromatic rings[4])

Physical Data: BF_3: mp -127 °C; bp -100 °C; *d* 1.57 g cm^{-3}. BF_3.Et_2O: mp -58 °C; bp 126 °C; *d* 1.154 g cm^{-3}.

Form Supplied in: BF_3 is available as a gas packaged in lecture bottles; BF_3.Et_2O is available as a liquid.

Handling, Storage, and Precautions: in all peroxide oxidations of new compounds one must consider the possibility of explosive reactions. BF_3 and its etherate are highly toxic, corrosive to skin, and inhalation should be avoided. Use in a fume hood. See ***Boron Trifluoride Etherate***, ***Boron Trifluoride***, and ***Hydrogen Peroxide***.

Baeyer-Villiger Oxidations.

The difficult Baeyer-Villiger oxidation of straight-chain ketones,[5] which have only primary alkyl groups attached to carbonyl carbon, can be carried out rapidly at rt using a solution of 90% H_2O_2 in BF_3.Et_2O. Primary alkyl migrates in preference to methyl to form esters; some ester hydrolysis to form alcohol may occur.[2] The same oxidation is generally effected in better yield with ***Trifluoroperacetic Acid***, usually prepared using 90% H_2O_2,[5a,6] or with ***Bis(trimethylsilyl) Monoperoxysulfate***, a safer alternative prepared from 30% H_2O_2 (eq 1).[5a,7]

(1)

Benzylic Hydroperoxide Rearrangements.

Phenols can be prepared from benzylic secondary and tertiary alcohols by reaction with an aged preformed reagent from $BF_3.Et_2O$ and 90% H_2O_2. The reagent is especially suited for oxidation of substrates derived from hindered electron-rich acetophenones for which the Baeyer-Villiger oxidation is difficult. The reagent is especially useful for oxidation of molecules which have basic nitrogen in the benzylic alcohol substrate (eq 2).[3] Lewis acid coordination by BF_3 protects the amine function during the oxidation. The protic acid H_2SO_4 is less effective as a catalyst.

(2)

Selective Hydroxylations.

Regioselective hydroxylation of xylenes can be carried out directly in low yield with the $BF_3.Et_2O$-90% H_2O_2 reagent,[2] and in excellent yield with BF_3 and peroxytrifluoroacetic acid (the preparation of which requires 90% H_2O_2).[8] The safer reagent 30% H_2O_2 with superacidic HF/BF_3 cleanly converts benzene and alkylbenzenes into

monohydroxylated products.[4a] Oxidation of naphthalene with 90% H_2O_2 in HF/BF_3 superacid gives mainly 2-naphthol; in the absence of BF_3, 1-naphthol is formed (eq 3).[4b]

Hydrogen Peroxide-Iron(II) Sulfate[1]

H_2O_2-$FeSO_4.7H_2O$

(H_2O_2)

[7722-84-1] · H_2O_2 · Hydrogen Peroxide-Iron(II) Sulfate · (MW 34.02) ($FeSO_4.7H_2O$)

[7782-63-0] · FeO_4S · Hydrogen Peroxide-Iron(II) Sulfate · (MW 278.06)

(reagent for generation of organic radicals which undergo dimerization, oxidative insertion, dehydrogenation and hydroxylation; oxo-iron species formed in situ lead to oxo-transfer reactions)

Alternate Name: Fenton reagent.

Physical Data: $FeSO_4.7H_2O$; *d* 1.89 g cm^{-3}; forms tetrahydrate at 56.6 °C and monohydrate at 65.0 °C; loses the last H_2O at about 300 °C.

Solubility: $FeSO_4.7H_2O$: sol H_2O, practically insol in alcohols.

Form Supplied in: $FeSO_4.7H_2O$: blue-green, monoclinic, orderless crystals or granules.

Handling, Storage, and Precautions: $FeSO_4.7H_2O$: oxidizes in moist air to form a basic iron(III) sulfate. Store in closed container. Wear rubber gloves when handling. See ***Hydrogen Peroxide*** and ***Iron(II) Sulfate***.

General.[1,2]

The Fenton reagent, a combination of hydrogen peroxide and iron(II) sulfate, has been known since the 1890s.[2] The mild oxidizing ability of H_2O_2 is considerably enhanced by Fe^{II} ion. The hydroxyl radical generated by the decomposition of H_2O_2 in the presence of Fe^{II} can produce organic radicals (eq 1) which undergo a variety of organic transformations, such as dimerization,[3,4] oxidative insertion,[5] hydroxylation,[6] and dehydrogenation.[7] Since the attack of HO&bdot; on aliphatic compounds is not highly selective, isomeric products are obtained in these reactions except in cases where symmetric reactants containing only equivalent hydrogen atoms are used.

$$Fe^{II} + H_2O_2 \longrightarrow Fe^{III} + OH^- + HO\cdot \qquad (1)$$

Fe^{II} and Fe^{III} ions in solution can be further oxidized by HO&bdot; to form Fe^{IV}=O or Fe^{V}=O species (eq 2).[1c,8] The

high oxidation state of Fe^{IV}=O (or Fe^{V}=O) leads to some interesting oxo-transfer reactions.[9,10]

$$Fe^{III} + HO\cdot \longrightarrow Fe^{IV}{=}O + H^{+} \qquad (2)$$

Synthetic Applications.

2,5-Dimethyl-2,5-hexanediol is produced in 40-46% isolated yield by oxidative dimerization of *t*-butyl alcohol using Fenton reagent with 1 equiv of $FeSO_4.7H_2O$ (eq 3).[3] Analogous oxidative coupling has been accomplished with certain saturated lower, straight- and branched-chain aliphatic carboxylic acids, nitriles, amides, amines, alcohols, and ketones.[4]

Hydrocarbon derivatives can be converted to the corresponding carboxylic acids in low yields by Fenton reagents and carbon monoxide.[5]

Dehydrogenation of 2-amino-3,4-dihydroquinoxaline to 2-aminoquinoxaline is effected smoothly by H_2O_2 in the presence of trace amounts of Fe^{II} ions (eq 4).[6] The reaction does not proceed without using the iron(II) catalyst. The procedure appears to be general and has been successfully applied to the synthesis of a number of alkyl-, halo-, and hydroxy-substituted 2-aminoquinoxalines.[6]

The Fenton reagent has also been employed to hydroxylate aromatic rings (eq 5).[7] However, the yields are usually low, primarily due to the formation of biaryl products. The efficiency of this reaction is highly dependent on the concentrations of Fe^{II} and Fe^{III} ions[7] and can be improved by using phase-transfer catalysts.[11]

90% Stereoselectivity and 71% yield have been achieved in the synthesis of *cis*-1,3-cyclohexanediol by the reaction of cyclohexanol with Fenton reagent. A Fe^{IV}=O intermediate was proposed to account for the results.[9]

Oxidation of cholesterol with Fenton reagent in acetic acid gave dihydroxylation products as shown in eq 6.[10] Evidently 5α,6α-epoxycholestan-3β-ol was formed via an oxo-transfer process in the early stages, and the subsequent epoxide opening by solvents provided *trans*-diol derivatives.

Hydrogen Peroxide-Tellurium Dioxide[1]

H_2O_2-TeO_2

(H_2O_2)

[7722-84-1] · H_2O_2 · Hydrogen Peroxide-Tellurium Dioxide · (MW 34.02) (TeO_2)

[7446-07-3] · O_2Te · Hydrogen Peroxide-Tellurium Dioxide · (MW 159.60)

(selective oxidizing agent for conversion of sulfides to sulfoxides[1])

Handling, Storage, and Precautions: see ***Hydrogen Peroxide***. A mixture of 30% H_2O_2 (2.4 mL, 24 mmol) and TeO_2 (0.032 g, 2.0 mmol) or TeO_2 (0.32 g, 20 mmol) in methanol (10 mL) can be stored in a refrigerator for a prolonged time without loss of reactivity. For the oxidation of sulfides to sulfoxides, better results are obtained when hydrogen peroxide is added slowly to the mixture of the sulfide and tellurium dioxide in methanol. These operations should be conducted in an efficient fume hood.

Selective Oxidation of Sulfides.

The hydrogen peroxide-tellurium dioxide system is a remarkably selective agent for the oxidation of sulfides to sulfoxides. Sulfides are transformed into sulfoxides in high yields by treatment with hydrogen peroxide in the presence of a catalytic amount of tellurium dioxide at rt. Sometimes a small amount of over-oxidation product, the corresponding sulfone, is produced. This over-oxidation can be suppressed by slow addition of aqueous 30% hydrogen peroxide solution to a mixture of the sulfide substrate and tellurium dioxide in methanol. Even with 1 equiv of TeO_2, the resulting sulfoxide is not oxidized further to sulfone. Aromatic sulfides (eq 1) as well as aliphatic sulfides (eq 2) are transformed to sulfoxides in high yield.

(1)

(2)

Usually, the oxidation of aliphatic sulfides proceeds in better yield and requires shorter reaction times than that of aromatic derivatives. Chemoselective oxidation of a sulfide group by the H_2O_2-TeO_2 system in the presence of a double bond can be achieved (eq 3). Thus, to a mixture of crotyl phenyl sulfide (0.165 g, 1.00 mmol) and tellurium dioxide (0.016 g, 0.10 mmol) in methanol (2.0 mL), aqueous 30% hydrogen peroxide solution (0.136 g, 1.20 mmol) is added slowly at rt. After stirring at rt for 24 h, the reaction mixture is partitioned between methylene chloride and water. The product is purified by column chromatography.

(3)

One problem with the catalytic TeO_2-H_2O_2 system is that the reaction time is relatively long. While the use of a stoichiometric amount of tellurium dioxide considerably shortens the reaction time, the addition of a small amount of concentrated HCl (1/100 molar ratio of sulfide) drastically accelerates the oxidation of sulfide (eq 4).

(4)

TeO_2 (cat), H_2O_2, MeOH, 12 h	90%
TeO_2 (1 equiv), H_2O_2, MeOH, 8 h	90%
TeO_2 (cat), H_2O_2, conc HCl (trace), MeOH, 2 h	92%

The effect of concentrated HCl is especially pronounced in the oxidation of a carbohydrate sulfide; this substrate is not oxidized by 1 equiv of the TeO_2-H_2O_2 system after prolonged reaction time, but is oxidized to the sulfoxide in high yield in 2 h by using the catalytic TeO_2-H_2O_2-HCl system (eq 5). It is also noteworthy that the acid-labile isopropylidene group in the carbohydrate sulfide is not affected by the TeO_2-H_2O_2-HCl system. Also the carbonyl group in keto sulfides is not affected by the H_2O_2-TeO_2-HCl system (eqs 5 and 6).

(5)

TeO_2 (1 equiv), H_2O_2, MeOH, 3 days — No reaction

TeO_2 (cat), H_2O_2, conc HCl (trace), MeOH, 2 h — 83%

(6)

The reaction of benzaldehyde, geraniol, or ethylene glycol with H_2O_2-TeO_2 leads mainly to recovery of the starting material. In this regard, the TeO_2-H_2O_2 system appears to be superior to widely used reagents such as hydrogen peroxide, peroxy acids, and periodates, which sometimes cause over-oxidation or affect other functional groups.[2] Other recently reported oxidizing agents such as ruthenium porphyrin with heteroaromatic *N*-oxide,[3] $(Ph_4P)[RuO_2(OAc)Cl_2]$ with ***N-Methylmorpholine N-Oxide***,[4] sulfonimidoyl chloride with superoxide,[5] and ***Benzyltrimethylammonium Tribromide***[6] have similar drawbacks.

Oxidizing systems related to the H_2O_2-TeO_2 system include the H_2O_2-SeO_2 system and the H_2O_2-RSO_2H system. Sulfides are selectively oxidized to sulfoxides by treatment with H_2O_2 in methanol containing a catalytic amount of the sulfinic acid,[2a] and the H_2O_2-SeO_2 system is known to be an efficient and chemoselective agent for oxidation of sulfides to sulfones[7] and a selective oxidizing agent for sulfides to sulfoxides in certain cases.[8]

The true oxidizing species in the H_2O_2-TeO_2 system is likely to be peroxytellenious acid (H_2TeO_4), which will be reduced back to H_2TeO_3 and quickly regenerated by H_2O_2 during the reaction in the catalytic cycle shown in eqs 7-9.

Hydrogen Peroxide-Tungstic Acid

H_2O_2-H_2WO_4

(H_2O_2)

[7722-84-1] · H_2O_2 · Hydrogen Peroxide-Tungstic Acid · (MW 34.02) (H_2WO_4)

[7783-03-1] · H_2O_4W · Hydrogen Peroxide-Tungstic Acid · (MW 249.87)

(oxidation of alkenes,[1] alkynes,[15] and other organic substrates[18 -22])

Physical Data: H_2WO_4: *d* 5.500 g cm^{-3}.

Solubility: H_2WO_4: insol cold H_2O; slightly sol hot H_2O.

Form Supplied in: H_2WO_4: yellow powder; widely available.

Handling, Storage, and Precautions: see ***Hydrogen Peroxide***. All operations involving peroxides should be conducted behind a safety shield in a fume cupboard. It is also advisable, prior to work-up, to analyze the reaction mixture for peroxy compounds. These should be destroyed or removed before evaporation of the solvent.

Epoxidation of Alkenes.

Tungstic acid catalyzes the oxidation by hydrogen peroxide of alkenes to the corresponding epoxides.[1] As tungstic acid is a fairly strong acid, the reaction mixture requires buffering to prevent subsequent diol formation. Typical conditions are: tungstic acid 1 mol %, sodium acetate 2-3 mol % (pH 4.5), 35% hydrogen peroxide 1.5 mol % at rt.[2] Under these conditions the epoxidation occurs with complete retention of configuration for both *cis*- and *trans*-alkenes (eq 1). Reactivity increases with nucleophilicity of the double bond. Coordination to the catalyst by hydroxy groups in the substrate also enhances the rate of epoxidation, with allylic alcohols reacting faster than homoallylic alcohols,[3] and isolated alkenes being least reactive (eq 2). Dienols can be selectively epoxidized at the allylic position (eq 3).[4] Conjugated unsaturated acids and even diacids are epoxidized using sodium tungstate and hydrogen peroxide in water at 60-65 °C, with the pH controlled to within 5.8-6.8.[5] The use of pertungstate, $W_2O_{11}^{2-}$, generated from tungstic acid and benzyltriphenylphosphonium chloride, $Ph_3PCH_2Ph^+$ Cl^-, allows unbuffered conditions to be employed (eq 4).[6] The catalyst can be prepared in situ or preformed and stored for a long time. Other epoxidation methods include: sodium tungstate in a two-phase system of phosphate buffer/dichloromethane,[7] and a complex of tungstic acid and tributyltin chloride supported on charcoal.[8] See also ***m-Chloroperbenzoic Acid*** and ***Vanadyl Bis(acetylacetonate)***.

(1)

(2)

(3)

(4)

Diol Formation.

The oxidation of cyclooctadiene to the *trans*-diol has been effected using 30% hydrogen peroxide and a catalytic quantity of tungstic acid in *t*-butanol at 31 °C (eq 5);[9] however, similar conditions have also been used for the cleavage of cyclopentene to glutaraldehyde (eq 6).[10] More concentrated solutions of hydrogen peroxide have also been employed.[11] The use of 90% hydrogen peroxide in 2-propanol has been reported to yield cyclohexane-1,2-diol from cyclohexene. When methanol or ethanol are used as solvents the corresponding glycol monoethers are formed.[12] See also: ***Potassium Permanganate*** and ***Osmium Tetroxide***.

(5)

(6)

Carboxylic Acids.

Under the more forcing conditions of refluxing *t*-butanol, epoxidation followed by diol formation and oxidative alkene cleavage occurs. Using these conditions, cyclopentene gives glutaric acid (eq 7)[13] and 1-methyl-1-cyclohexene gives 2-oxoheptanoic acid (eq 8). Cyclohexanone has been oxidized to adipic acid in low yield.[14] See also: ***Sodium Periodate***.

(7)

(8)

α-Hydroxy Ketones.

Treatment of 12-tungstophospholic acid with hydrogen peroxide and cetylpyridinium chloride in water gives peroxotungstophosphate, an efficient catalyst for the oxidation of internal alkynes to the corresponding α,β-epoxy ketone (eq 9).[15] The same catalyst will also oxidize *vic*-diols into α-hydroxy ketones (eq 10).[16] See also: ***Iodosylbenzene***.

gem-Dihydroperoxides.

Reaction of acetals with hydrogen peroxide and tungstic acid in acetonitrile at low temperature gives the corresponding *gem*-dihydroperoxides (eq 11).[17]

Other Oxidations.

Tungstic acid has been used to catalyze the oxidation by hydrogen peroxide of sulfides to the corresponding sulfones.[18] Various amines have also been oxidized to the corresponding oximes,[19] nitrones,[20] hydroxamic acids,[21] and nitroso compounds.[22]

Hydrogen Peroxide-Urea[1]

[124-43-6] · $CH_6N_2O_3$ · Hydrogen Peroxide-Urea · (MW 94.09)

(alternative to 90% hydrogen peroxide as a source of anhydrous hydrogen peroxide for use in oxidation reactions)

Alternate Name: UHP.

Physical Data: mp 84-86 °C (dec).[2]

Solubility: sol water and alcohols; low solubility in organic solvents such as dichloromethane.

Form Supplied in: white crystalline powder with urea as impurity; commercially available. *Drying:* over calcium chloride in a desiccator.

Preparative Method: made by the recrystallization of ***Urea*** from aqueous ***Hydrogen Peroxide***

Handling, Storage, and Precautions: the pure material should be stored at low temperature but the commericial material, which has a purity of ca. 90%, may be stored at rt. In a sufficiently forcing test, it can be made to explode; its decomposition is acceleratory above 82 °C. Conduct work with this reagent in an efficient fume hood behind a polycarbonate safety screen.

Epoxidation Reactions.

The hydrogen peroxide-urea complex, which is normally known as urea-hydrogen peroxide (UHP), has been used in anhydrous organic solvents in combination with a number of carboxylic anhydrides together with disodium hydrogen phosphate for the epoxidation of a wide range of alkenes. The carboxylic anhydride of choice depends on the electron density in the double bond.[3] With electron-rich alkenes such as α-methylstyrene and α-pinene (eq 1), good yields of

the expected products can be obtained by using ***Acetic Anhydride***. Other anhydrides have also been used; for example, the epoxide from *trans*-stilbene is obtained in 80% yield using ***Maleic Anhydride***.[4] Monoperoxymaleic acid, prepared by the reaction of maleic anhydride with 90% aqueous hydrogen peroxide, is more reactive than other common peroxy acids with the exception of ***Trifluoroperacetic Acid***.[5] With relatively nonnucleophilic and nonvolatile terminal alkenes such as 1-octene, a good yield of the epoxide can be obtained by substituting ***Trifluoroacetic Anhydride*** for the acetic anhydride (eq 2). The addition of ***Imidazole*** increases the rate at which epoxidation reactions proceed when using UHP and acetic anhydride.[6] Presumably *N*-acetylimidazole is formed and rapidly perhydrolyzed. A comparison of the diastereoselective epoxidations of a steroidal allylic alcohol has been carried out using a range of peroxy acids, including peracetic acid generated by the interaction of acetic anhydride with UHP.[7]

(1)

(2)

The epoxidation of electron-deficient alkenes like methyl methacrylate can also be achieved using the trifluoroacetic anhydride method. In the case of α,β-unsaturated ketones such as isophorone (eq 3) and nitro alkenes such as β-methyl-β-nitrostyrene (eq 4), alkaline hydrogen peroxide has been generated from UHP.

(3)

(4)

The selective epoxidation of compounds such as α-ionone can also be achieved. The result of an epoxidation reaction frequently depends on the reagent and precise reaction conditions. This is exemplified in the reactions shown in eq 5. When using peroxytrifluoroacetic acid generated conventionally, water that is always present diverts the reaction exclusively to the hemiacetal (**1**). However, when using the UHP method, the spiroacetal (**2**) predominates over the other product.[8]

Baeyer-Villiger and Related Reactions.

The oxidation of aldehydes and ketones to afford esters and lactones can be achieved using a variety of peroxycarboxylic acids. The ease with which the reaction occurs is related to the strength of the conjugate acid of the leaving group and so the stronger the carboxylic acid the more powerful is the peroxy acid in its oxidation reactions. Reactions involving ketones are frequently slow when using weakly acidic peroxy acids and so the majority of the reactions using UHP have been carried out with trifluoroacetic anhydride as the coreactant (eqs 6-8).

(6)

(7)

(8)

Dakin reactions, where an aromatic aldehyde has an electron releasing substituent either *ortho* or *para* to the formyl group, can be carried out using UHP-acetic anhydride as shown in eq 9. In the absence of suitable activating substituents, hydrogen migration occurs in place of aryl migration and the product is then a carboxylic acid (eq 10). This is a potentially valuable way of converting a formyl group into a carboxyl group.

(9)

(10)

Heteroatom Oxidation.

The first example of the use of UHP in organic chemistry involved the formation of the *N*-oxide shown in eq 11,[9] and, in a modification of the UHP method, phthalic anhydride has been used to oxidize 4-*t*-butylpyridine to the *N*-oxide in 93% yield.[10] The oxidation of aliphatic aldoximes using UHP-trifluoroacetic anhydride has been achieved in good yields with retention of configuration at neighboring chiral centers (eq 12).[11]

Hydrogen Selenide[1]

H_2Se

[7783-07-5] · H_2Se · Hydrogen Selenide · (MW 80.98)

(reduction of carbonyl and nitro groups;[1] addition to activated double and triple bonds;[1] replacement of nitrogen, oxygen, or sulfur atoms by selenium[1,2])

Physical Data: mp -65.7 °C; bp -41.3 °C; *d* 3.66 g L^{-1}; pK_1 3.89; pK_2 11.0.

Solubility: fairly sol water (9.88 mg mL^{-1} at 22.5 °C/760 mmHg).

Form Supplied in: available commercially as gas in bottles or cylinders.

Preparative Methods: H_2Se is made by hydrolysis of Al_2Se_3, by the action of dilute mineral acids on FeSe, by the surface catalyzed reaction of gaseous ***Selenium*** and H_2 above 350 °C, or by heating Se with ***Lithium Hydroxide*** or $Mg(OH)_2$.[3] Se is readily reduced to H_2Se by ***Carbon Monoxide*** and H_2O (water gas) in the presence of ***Triethylamine***.[4]

Handling, Storage, and Precautions: colorless gas with a disagreeable odor; very toxic. It irritates the mucous membranes of the nose, eyes, and upper respiratory tract. It is easily oxidized by atmospheric oxygen and must be handled under inert gas. It burns in air and is decomposed by dust and rubber and in the presence of moisture with separation of Se. Aqueous solutions are oxidized in air with separation of red Se. Use in a fume hood.

Functional Group Reductions.

H_2Se reduces aldehydes and ketones (eq 1) under basic conditions to form diselenides.[5] With photochemical activation, primary and secondary alcohols are obtained[6] from aldehydes and ketones. Arylhydroxylamines, nitrosoarenes, and nitroarenes are reduced to primary aromatic amines with H_2Se formed in situ from Se and water gas.[7] In this reaction, only catalytic amounts of selenium need to be

used since the Se formed during the reaction is reduced by the excess of water gas (eq 2).[7b] ***Acetaldehyde*** treated with H_2Se and HCl gives intermediate bis(1-chloroethyl) selenide, which yields divinyl selenide on dehydrohalogenation (eq 3).[8]

$$\mathrm{PhCHO} \xrightarrow[76\%]{\mathrm{H_2Se.\ py,\ Et_3N}\ \mathrm{rt,\ 10\ d}} \mathrm{PhCH_2SeSeCH_2Ph} \qquad (1)$$

$$\mathrm{PhNO_2} \xrightarrow[86\%]{\mathrm{Se,\ CO,\ H_2O}\ \mathrm{Et_3N,\ THF,\ 80\ ^\circ C}} \mathrm{PhNH_2} \qquad (2)$$

$$\mathrm{MeCHO} \xrightarrow[15\%]{\mathrm{1.\ HCl,\ H_2Se,\ -10\ ^\circ C}\ \mathrm{2.\ PhNEt_2,\ 150\ ^\circ C}} \mathrm{(H_2C{=}CH)_2Se} \qquad (3)$$

Addition to Double and Triple Bonds.

Addition of H_2Se to ***Ethylene*** leads to diethyl selenide as a main product, but severe reaction conditions are required.[9] H_2Se adds to the cyano group in nitriles or to the azomethine group in imidoyl or iminium chlorides to produce selenoamides.[10] The action of H_2Se on formamidines gives *N*-alkylselenoformamidines, while the treatment of *N*-alkylcyanamides or carbodiimides yields *N*-substituted selenoureas (eq 4).[11]

Other Reactions.

Treatment of adenosine, its derivatives, and analogs with H_2Se in aqueous pyridine gives the

corresponding 6-seleno-substituted nucleosides and nucleotides.[12] The reaction of acid chlorides with H_2Se leads to diacyl selenides.[13] Ring opening of ***Ethylene Oxide*** with H_2Se affords a modest yield of a mixture of 2-hydroxyethylselenol and bis(2-hydroxyethyl) diselenide.[14]

Related Reagents.

Hydrogen Sulfide; ***Lithium Selenide***; ***Sodium Hydrogen Selenide***; ***Sodium Selenide***.

Hydrogen Sulfide[1]

H_2S

[7783-06-4] · H_2S · Hydrogen Sulfide · (MW 34.09)

(nucleophile and precursor of Na_2S, NaSH, K_2S, and KSH for the synthesis of thiols,[2] thioethers,[3] thiocarbonyl compounds,[4] and heterocyclic compounds; reducing agent, particularly for the conversion (via S^{2-}, HS^-, S_2^{2-}) of aromatic nitro compounds to amines[5])

Physical Data: colorless gas; bp -60.75 °C; mp -85.60 °C; *d* (0 °C) 1.539 g L^{-1} (more dense than air); dipole moment (C_6H_6) 0.85-0.97 D. pK_{a1} (aq) 6.88, pK_{a2} (aq) 14.15; E_0(H_2S -> S + $2H^+$ + $2e^-$) -0.14 V.

Solubility: sol H_2O (0.12 mol L^{-1} at 20.1 °C); sol polar and nonpolar organic solvents.

Form Supplied in: liquefied gas in steel cylinders.

Handling, Storage, and Precautions: extremely toxic, malodorous gas; use of a well-ventilated hood is a necessity; a scrubber flask containing 20% aqueous NaOH prevents loss of H_2S to the atmosphere. The sense of smell is paralyzed at concentrations of 150-250 ppm and death may ensue at concentrations above 300 ppm. An irritant to the eyes and mucous membranes; highly flammable; ignites spontaneously in air at around 250 °C; mixtures of H_2S (4.5-45%) and air are explosive; corrosive (especially in aqueous solutions) to many metals; anhydrous H_2S is unreactive to stainless steel at ambient temperatures.

Formation of Na_2S, NaSH, K_2S, and KSH.

Passage of H_2S into excess aq NaOH or KOH yields ***Sodium Sulfide***, and K_2S, which can be used in situ.[6] ***Sodium Hydrogen Sulfide*** and ***Potassium Hydrogen Sulfide*** are produced in ethanolic base saturated with H_2S;[7] addition of, for example, excess KOEt yields K_2S.[7a] In the formation of KSH, H_2S is passed into an ethanolic KOH solution until the mixture does not test alkaline with phenolphthalein.[7c] Solutions of hydrogen sulfide salts are in equilibrium with the sulfide and H_2S: 2NaSH &ibond; Na_2S + H_2S.

Thiols.

Thiols or their salts are obtained by displacement reactions[2] by SH^- or S^{2-} (derived from H_2S) on primary or secondary halides or sulfonate esters, on oxiranes and aziridines, on quaternary ammonium salts, and on activated aromatic

halides (eq 1).[8] The displacement of chloride ion shown in eq 1 takes precedence over the addition reaction of H_2S to the nitrile group (see below). Halonitrobenzenes may undergo both substitution of halogen and reduction of the nitro group.[2a,6,9] High temperatures are required for unactivated aryl halides (eq 2).[10] Elimination and thioether formation are side reactions with aliphatic substrates. To minimize thioether formation, an excess of H_2S is employed (see the above equilibrium).

(1)

(2)

Benzyl thiols can be obtained directly from the alcohol by the action of H_2S in the presence of ***Octacarbonyldicobalt*** (eq 3).[11a] Direct reaction between H_2S and alcohols normally requires high temperatures, high pressures, and special catalysts; this method is not generally suited for a laboratory preparation.[2b] The reaction of α-aryl-α-amino nitriles with H_2S under mild conditions gives high yields of thiols uncontaminated with α-amino thioamides (eq 4).[11b]

(3)

(4)

Thiolacids and their derivatives are obtained from the acid chloride or anhydride (eqs 5 and 6).[7c,12] Potassium thiotosylate, useful in the synthesis of thiotosylates, is obtained in a similar way from tosyl chloride (eq 7).[13] The solution must be saturated with H_2S. *gem*-Dithiols are obtained by treatment of ketones with H_2S and an organic base (or the preformed enamine may be used) (eq 8),[14] and best yields are obtained with cyclic ketones. Use of the ketimine or enamine gives satisfactory yields (53-83%) of *gem*-dithiols of acyclic ketones.[14b] Addition of H_2S to propionaldehyde in the presence of ***Chlorotrimethylsilane*** results in the silyloxythiol (eq 9).[15] A Michael-type of addition of H_2S to α,β-unsaturated systems provides β-mercapto derivatives that are readily desulfurized, thus providing a method for the selective reduction of the carbon-carbon double bond (eq 10).[16] Attempted reduction of this double bond (eq 10) by borohydride, hydride, and silane reagents was unsuccessful.

(5)

(6)

(7)

Thioethers and Disulfides.

Conversion of H_2S to sulfide ion, followed by treatment with a primary or secondary halide, sulfonate ester, quaternary ammonium salt, or an oxirane, aziridine, or activated aryl halide gives a good yield of symmetrical thioether via a thiolate intermediate.[3] Base-catalyzed addition of H_2S to electrophilic alkenes yields first the thiol which couples with excess alkene to give the thioether (eq 11).[17a] Disulfides are obtained via dithiol intermediates from addition of H_2S to aldehydes, ketones, and imines.[17b]

(11)

Thiocarbonyl Compounds.

Thioaldehydes, thioketones, thioesters, thioamides, and related compounds may be prepared by addition of H_2S (or SH^-, S^{2-}) to a C=X or a C=C-X bond where X is a group that is replaceable by sulfur.[4] In the total synthesis of chlorophyll, an important thioaldehyde intermediate was obtained by addition of H_2S to an imine salt (eq 12).[18] Related syntheses of thioaldehydes involve additions to Vilsmeier intermediates (iminium salts, etc).[19] The more common thioketones are prepared by addition of H_2S to ketones typically in the presence of HCl;[7b,14f,20] *gem*-dithiols[14] may be intermediates and they can be thermolyzed to thioketones. While aromatic thioketones are readily available (eq 13),[20a,b] their enethiolizable aliphatic analogs are often contaminated by the enethiol. Trimerization to 1,3,5-trithianes is a common side reaction. Methods for preparation of aliphatic thioketones (stable for 1 month at -15 °C) free from enethiols, and their conversion to pure enethiols free of the thioketone tautomer, have been reported (eq 14).[21] Aliphatic thioketones also are obtained in good yields (52-75%) by treatment of ketone anils with H_2S followed by removal of aniline from the initial adduct with ***Benzoic Anhydride***.[22] Thioketones are obtained by addition of H_2S to imines and iminium salts.[23]

(12)

(13)

Derivatives of thiocarboxylic acids[4c,24] are obtained from H_2S and orthoesters (eq 15),[25] carboxylic acid ester enolates (eq 16),[26] and imino esters.[27] A method for reduction of a tertiary alcohol to an alkane involves its conversion to a thioformate ester followed by treatment with ***Tri-n-butylstannane*** (eq 17).[27b] Addition of H_2S to thioimino esters provides derivatives of dithiocarboxylic acids (eq 18).[4d,28] The thioamide function[4e,29] is obtained by addition of gaseous or liquid H_2S to nitriles (eq 19),[17b,30] ynamines,[31] various imines (eq 20),[32] and to orthoesters or chloroform in the presence of an amine (eq 21).[32f,33] Thioureas, thiobiurets, and thio heterocycles,[32d,34] thioimides (eq 22),[32b,35] and thioacylhydrazines[36] are obtained by similar reactions.

Heterocyclic Compounds.

The following types of sulfur-containing heterocyclic compounds obtained from hydrogen sulfide are listed according to ring size and the number of sulfur and other heteroatoms: 3 (1 S),[37] 4 (1 S),[38a,b] 4 (2 S),[39] 5 (1 S),[40a-d] 5 (2 S),[41] 5 (1 S, 1 N),[42] 5 (1 S, 2 N),[43] 6 (1 S),[44] 6 (3 S),[45] 8 (2 S).[46] The first synthesis of a cyclopenta[*b*]thiophene by a keto alkyne cyclization is shown in eq 23.[40c] Hydrogen sulfide plays a key role (possibly by reducing elemental chlorine) in the suppression of chlorinated byproducts in the synthesis of α-methylthioindoles (eq 24).[47]

(23)

(24)

Reductions.

Hydrogen sulfide reduces nitro groups (eq 25),[5,9,48] nitroso groups,[49] azido groups,[50] the S=O group (eq 26),[51] the chlorosulfonyl group,[52] sulfur-sulfur,[53] sulfur-nitrogen,[54] nitrogen-nitrogen,[55] carbon-nitrogen,[11b,56] and carbon-mercury[57] bonds, the C-I and C-O bonds of some α-iodo and α-alkoxy ketones,[58] osmate esters,[59] and 1,2,3-tricarbonyl compounds[60a] and their hydrates[60b-d] (the 2-carbonyl functionality is reduced to the alcohol and dimers (eq 27)[60d] may be formed). Benzil is reduced quantitatively either to deoxybenzoin or benzoin, depending on conditions.[14c] The carbonyl group of aldehydes and ketones undergoes nucleophilic reduction with H_2S and a reducing thiol to give good yields of thiols via thiocarbonyl derivatives (eq 28).[61] The reduction of the azido group in 4-azidobutyryl derivatives of alcohols provides a mild method for deprotection of the hydroxy function (eq 29).[50a] Reduction of the azido group by elemental hydrogen instead of H_2S in the deprotection scheme may be accompanied by the reduction of other functional groups (eg alkene).

(25)

(26)

(27)

(28)

(29)

Miscellaneous.

Workup procedures of reactions that use salts of heavy metals (Hg, Pb, Ag, Cu) involve precipitation of the metal as its sulfide by H_2S.[62]

Hydrogen Telluride[1]

H_2Te

[7783-09-7] · H_2Te · Hydrogen Telluride · (MW 129.62)

(mild reducing agent for aromatic nitro, azoxy, azo, nitroso, hydroxylamino, imino, and aldehyde groups, and the carbon-carbon double bonds of enamines and electron-deficient alkenes; useful in reductive alkylation of amines with aldehydes and ketones)

Physical Data: bp -2.2 °C; mp -51.2 °C; *d* 5.81 g L^{-1}; pK_{a1} 2.64; pK_{a2} 10.8, 11.80; E_0(H_2Te -> $Te + 2H^+ + 2e^-$) +0.51 V.

Solubility: sol alkali, water (dec), ether, benzene.

Preparative Method: hydrolysis of Al_2Te_3 in an atmosphere of CO_2.[1] Can be generated in situ.

Handling, Storage, and Precautions: a malodorous, colorless gas. Use in a well-ventilated fume hood. Decomposes completely to elemental ***Tellurium*** and hydrogen above 0 °C. Unstable to heat and light. Oxidizes very rapidly in air to Te^0. Flammable. Corrosive (H_2Te is a stronger acid than HF). Irritant. Highly toxic, but the ready decomposition of H_2Te to relatively nontoxic elemental Te suggests it is unlikely to be a serious hazard if precautions are taken. (Ingestion or inhalation of small amounts of elemental tellurium produces transient, garlic-like breath that is said to be eliminated by oral dosage with vitamin C.) Hydrogen telluride is a strong reducing agent and may react explosively with strong oxidants. Forms insoluble heavy metal tellurides. Possible contaminants are H_2S, H_2Se, and HCl.

Reductions.

Aromatic nitro compounds are reduced to amines (47-94%) by addition of powdered Al_2Te_3 to a THF solution of the nitro derivative under N_2. Water is added gradually to the warmed solution to generate H_2Te in situ, and the mixture is refluxed (eq 1).[2] Likewise, phenylhydroxylamine gives aniline (98%); nitrosobenzene, azobenzene, and azoxybenzene give hydrazobenzene (63%, 96%, and 86%, respectively). Imines and enamines (eq 2) may be reduced at lower temperatures by the in situ procedure.[3] Addition of ***Triethylamine*** improves yields in reduction of imines. A convenient reductive alkylation of amines with carbonyl compounds involves in situ generation of both imine and H_2Te (eq 3).[3] Yields varied from a low of 12% for $PhNH_2$ and *n*-$C_7H_{15}CHO$ to a high of 96% for *n*-$BuNH_2$ and *n*-$C_7H_{15}CHO$. Hydrogen telluride cleaves bis(methylgermyl)carbodiimides to bis(methylgermyl) tellurides and dicyanodiamide.[4] The in situ reduction of aldehydes and ketones to alcohols proceeds in yields of 50-100%, and reduction of the carbon-carbon double bond occurs with several α,β-unsaturated carbonyl compounds (yields 54-

89%).[5] With the latter, reduction of the carbonyl group also may occur. Use of D_2O in the procedure for reduction to alcohols generates D_2Te, which introduces deuterium into the alcohol, thus avoiding the use of the more costly $NaBD_4$ (eq 4).[5] Hydrogen telluride reduces ***Tetracyanoethylene*** to tetracyanoethane (90%) but offers no advantage over ***Hydrogen Sulfide***.[6] Similar reductions of nitrogen-containing functional groups and aldehydes have been accomplished with benzenetellurol.[7] Treatment of aliphatic aldehydes with H_2Te generated in situ under acidic conditions affords moderate yields (34-56%) of dialkyl ditellurides (eq 5).[8] Under basic conditions (Et_3N), alcohols are produced.

2-Hydroperoxyhexafluoro-2-propanol[1]

[32751-01-2] · $C_3H_2F_6O_3$ · 2-Hydroperoxyhexafluoro-2-propanol · (MW 200.05)

(oxidizing agent capable of Baeyer-Villiger oxidation;[1] selective alkene epoxidation;[2] conversion of aldehydes to carboxylic acids;[3] *N*-, *S*-, *Se*-oxidation;[4] strong parallels in structure and function to biologically active flavin oxidants[5-7])

Alternate Name: HPHP.

Physical Data: liquid at rt.

Solubility: sol CH_2Cl_2.

Preparative Method: prepared by the reaction of hexafluoroacetone (HFA)[8] with either 30% or 90% ***Hydrogen Peroxide*** by the following representative procedure. A 250 mL roundbottomed flask is fitted with Claisen adapter, pressure-equalizing, graduated addition funnel, dry ice condenser, and $CaCl_2$ drying tube. Anhydrous HFA (14 mL, 0.12 mol) is collected in the addition funnel and the roundbottom is charged with CH_2Cl_2 (100 mL) and 90% H_2O_2 (3.0 mL, 0.11 mol), and then cooled to -60 °C. After dropwise addition of HFA, the mixture is allowed to warm to rt and a clear, homogeneous solution results which can be titrated (NaI, $Na_2S_2O_3$, ca. 0.7 M) and stored conveniently at -5 °C. Under these conditions, the reagent is stable for at least 2 months.

Handling, Storage, and Precautions: slowly decomposes at rt to form CO_2, O_2, CF_3OOH and other products. Hexafluoroacetone is a highly toxic, nonflammable gas and should only be handled in a fume hood. Concentrated solutions of hydrogen peroxide must be handled with care.

Baeyer-Villiger Oxidation.

The oxidation of ketones to esters or lactones, usually performed with peroxycarboxylic acids, can be readily accomplished using HPHP in CH_2Cl_2 at reflux (4-5 h).[1] Nonaromatic ketones are cleanly oxidized to the corresponding esters (Table 1) while the oxidation of aromatic ketones is accompanied by tar formation, probably due to electrophilic aromatic substitution. Notably, mesitylene affords mesitol. Aniline is converted to nitrobenzene, but pentafluoroaniline gives only decafluoroazobenzene in low yield.

Table 1 Baeyer Villiger Oxidations Using HPHP

Compound	Product	Yield (%)

Methyl *n*-pentyl ketone	*n*-Pentyl acetate	81
Cyclohexanone	Caprolactone	50
Acetophenone	Phenyl acetate	34
Aniline	Nitrobenzene	65
Pentafluoroaniline	Decafluoroazobenzene	10
Mesitylene	Mesitol	40

Selective Epoxidations.

With its close similarity to peroxyimidic, -carbamic, and -carboxylic acids, solutions of HPHP in methylene chloride or 1,2-dichloroethane transform unhindered alkenes to epoxides at rt or reflux.[2] Oxidations can be carried out either using stoichiometric quantities of oxidant, or in a two-phase mixture of substrate, solvent, catalytic hexafluoroacetone, and excess H_2O_2. Epoxidation of allylic alcohols or acetates occurs with high *syn* stereoselectivity. The alkenes shown in Table 2 gave the corresponding epoxides (yield and stereochemistry indicated parenthetically). A similar process was subsequently reported to occur with hexachloroacetone.[9]

Table 2 Epoxidation of Alkenes Using HPHP

Compound	Product	Yield (%)

Oxidation of Aldehydes to Carboxylic Acids.

HPHP is also synthetically useful as a nucleophilic reagent for the conversion of aldehydes to carboxylic acids in the

presence of other functional groups (Table 3).[3] Unlike most chromium and manganese reagents, HPHP does not oxidize alcohols, and it provides a useful, nonmetal-based alternative to ***Silver(II) Oxide***. Like epoxidations, aldehyde oxidations can be performed with H_2O_2 and a catalytic quantity of HPHP in a two-phase CH_2Cl_2-Na_2CO_3 system. The aldehydes shown in Table 3 can be converted to the corresponding carboxylic acids.

Table 3 Oxidation of Aldehydes to Carboxylic Acids Using HPHP

Compound	Product	Yield (%)
n-Heptanal	*n*-Heptanoic acid	92
n-Dodecanal	*n*-Dodecanoic acid	72
$CH_2{=}CH(CH_2)_8CHO$	$CH_2{=}CH(CH_2)_8CO_2H$	75
PhCH=CHCHO	$PhCH{=}CHCO_2H$	40

Oxidation of Amines to Amine Oxides and Sulfides to Sulfoxides and Sulfones.

As shown in Table 4, HPHP oxidizes tertiary amines to *N*-oxides in 60-95% yield, and can also transform sulfides to sulfoxides (1 equiv HPHP) or to sulfones (2 equiv).[4] Competitive amine-versus-sulfide experiments indicate that sulfur oxidation is faster. Conversion of diallyl sulfide to diallyl sulfoxide illustrates the additional selectivity which can be expected. Rates are fastest in CH_2Cl_2 and diminish considerably in hydrogen-bonding solvents.

Table 4 Heteroatom Oxidations Using HPHP

Compound	Product	Yield (%)

3-Hydroxy-1,2,3-benzotriazin-4(3*H*)-one

[28230-32-2] · $C_7H_5N_3O_2$ · 3-Hydroxy-1,2,3-benzotriazin-4(3*H*)-one · (MW 163.15)

(additive to improve yields and decrease racemization in DCC-promoted peptide synthesis[1])

Alternate Names: Dhbt-OH; 3-hydroxy-4-keto-3,4-dihydro-1,2,3-benzotriazine.

Physical Data: mp 180-181 °C (dec).

Preparative Method: reaction of ***Sodium Nitrite*** with *o*-aminobenzhydroxamic acid.[2]

Solubility: sol most organic solvents.

Handling, Storage, and Precautions: regarded as an irritant rather than toxic. Possible explosive hazard.

Peptide Synthesis.

An appreciable amount of racemization (up to 70%) is often found to accompany the DCC-promoted synthesis of peptides (see ***1,3-Dicyclohexylcarbodiimide***). The use of Dhbt-OH as an additive improves yields (by up to 15%) and decreases racemization to almost undetectable levels in all the solvents tried (DMF, THF, CH_2Cl_2, DMSO).[1] Undesirable side-products resulting from attack on the triazine-ring carbonyl have meant that this reagent has been little used, ***1-Hydroxybenzotriazole*** being preferred. Recently, Dhbt-amino esters have shown promise in solid-phase peptide synthesis.[3,4] By premixing the *N*-protected amino acid and DCC before addition of Dhdt-OH, side-reactions are eliminated. Dhbt-amino esters have a useful self indication property in peptide synthesis, the liberated Dhbt-O^- anion giving a transient yellow color to the reaction until all the reacting amino groups have been consumed.

Miscellaneous.

Oligodeoxynucleoside phosphorodithiolates have been been efficiently synthesized using a Dhbt-OH-based phosphorus reagent.[5] Reductive decarboxylation of cinnamic acid with ***Tri-n-butylstannane*** was accomplished in

excellent yield via the Dhbt-ester (eq 1).[6]

1-Hydroxybenzotriazole[1]

[2592-95-2] · $C_6H_5N_3O$ · 1-Hydroxybenzotriazole · (MW 135.14) (hydrate)

[123333-53-9]

(peptide synthesis; nucleotide synthesis)

Alternate Names: HOBT; HOBt.

Physical Data: mp 155-160 °C; exact melting point depends on the amount of water of hydration present.

Form Supplied in: white solid usually containing 12-17% water of hydration; widely available commercially.

Analysis of Reagent Purity: should be a white solid; if it becomes discolored, it is advisable to purify.

Purification: recrystallize from either water or aqueous ethanol.

Handling, Storage, and Precautions: should be stored in the dark; avoid contact with strong acids, oxidizing agents, and reducing agents; heating above 180 °C causes rapid exothermic decomposition; toxicity not fully investigated so should be treated with caution.

Peptide Coupling.

1-Hydroxybenzotriazole is most widely used in reactions involving the coupling of amino acid units to give peptides.[1] In this context it has been used mainly as an additive to a coupling reaction, although there are also examples of HOBT being incorporated into the coupling reagent itself. The most common use of 1-hydroxybenzotriazole in peptide synthesis is in conjunction with a carbodiimide such as ***1,3-Dicyclohexylcarbodiimide*** (DCC). Although it is quite possible to couple amino acids using DCC alone, it is found that the addition of 1-hydroxybenzotriazole to the reaction system results in improved reaction rates and suppressed epimerization of the chiral centres present in the peptide (eq 1).[2] This reaction appears to proceed via DCC-mediated formation of a hydroxybenzotriazole ester intermediate which then reacts with the amino function of a second amino acid to give the coupled product.

This coupling protocol is not limited to the synthesis of small peptides in solution, but can also be used in the solid-phase preparation of larger peptides, and for the coupling of larger peptide fragments. It should be noted, however, that there are some drawbacks to this method; most notably, it is sometimes difficult to purify the peptide due to contamination with dicyclohexylurea and the method is unsatisfactory for the coupling of *N*-methylated amino acids.[3] The problem of purification can often be overcome by using an alternative carbodiimide, e.g. ones that give water-soluble byproducts can be used, such as EDC.MeI (see ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride***).[4] Polymer-bound variants of HOBT have also been used to overcome purification problems,[5] since the urea byproduct can be removed from the polymer-bound active ester intermediate (**1**) by washing with chloroform-isopropyl alcohol mixtures. Once the urea has been removed, the active ester can be reacted with the second peptide fragment to give the product (eq 2), regenerating the polymer-bound HOBT. While this method appears quite successful for the preparation of small peptide fragments, it is clearly unsuitable for the preparation of larger peptides by solid-phase synthesis.

Although the addition of HOBT to the carbodiimide-mediated coupling of amino acids has been shown to suppress epimerization of the chiral centres present, there are still a number of cases where the level of epimerization is unsatisfactory. One method for further suppressing epimerization is to add ***Copper(II) Chloride*** to the reaction system.[6] In this case it is important that the correct stochiometry is determined, since the copper(II) chloride not only suppresses epimerization, but it also slows down the reaction rate and reduces the overall yield (eq 3).

(3)

HOBT	$CuCl_2$	% DL	% Yield
0 equiv	0 equiv	38	22
1 equiv	0 equiv	1.3	96
1 equiv	0.25 equiv	<0.1	79

The problem of epimerization during carbodiimide-mediated coupling of amino acids can also be overcome by the use of an alternative coupling agent. Once such system that still employs HOBT as an additive involves the use of bis(2-oxo-3-oxazolidinyl)phosphinic chloride (BOP-Cl) and *N*-methylmorpholine (NMM) (eq 4).[7] See also ***Bis(2-oxo-3-oxazolidinyl)phosphinic Chloride***.

(4)

HOBT has also been used as an additive in other reactions involving amino acid derivatives.[8] It would appear that most reaction systems that are capable of generating a hydroxybenzotriazole ester intermediate will give successful coupling. One such system involves the use of amino acid derived trichlorophenyl esters.[9] These can be readily reacted with a

second amino acid unit in the presence of HOBT to give the coupled product with little or no racemization (eq 5). *p*-Nitrophenyl and pentachlorophenyl esters can also be employed with similar success. This reaction again is thought to proceed via the hydroxybenzotriazole ester intermediate and it has been shown that use of the potassium salt of HOBT in conjunction with a crown ether can lead to substantial rate increase,[10] presumably by enhancing the rate of formation of the active ester intermediate.

(5)

HOBT has also been used in conjunction with amino acid chlorides to facilitate peptide bond formation. This has proved of particular use in the case of FMOC-protected amino acid chlorides in solid-phase peptide synthesis where direct coupling is rather slow and suffers from competing oxazolone formation.[11]

As mentioned earlier, HOBT has also been incorporated into the peptide coupling reagent itself and one example of such a reagent is benzotriazol-1-yloxytris(dimethylamino)phosphonium chloride (BOP).[12] BOP is prepared by the reaction of HOBT with ***Hexamethylphosphorous Triamide*** in the presence of carbon tetrachloride, and is very effective in the coupling of amino acids (eq 6). See also ***Benzotriazol-1-yloxytris(dimethylamino)phosphonium Hexafluorophosphate*** (also known as BOP).

(6)

A second peptide coupling reagent that incorporates the HOBT unit is ***O-Benzotriazol-1-yl-N,N,N´,N´-tetramethyluronium Hexafluorophosphate*** (HBTU),[13] which can be prepared by the reaction of tetramethylurea with oxalyl chloride followed by treatment with HOBT and ***Potassium Hexafluorophosphate***. HBTU can then be used as a direct coupling agent as outlined in eq 7.

(7)

Nucleotide Synthesis.

Phosphotriester derivatives of HOBT have been employed in the synthesis of nucleotides.[14] The phosphotriesters are readily formed by reaction of HOBT with the corresponding aryl phosphorodichloridates in the presence of pyridine

and can then be used to couple nucleosides as outlined in eq 8. This reaction takes advantage of the fact that a differentially protected nucleoside will react rapidly with the reagent, displacing one molecule of HOBT to form an intermediate phosphotriester (**2**), but at this stage reaction with a second nucleoside molecule is extremely slow due to steric hindrance. Consequently the intermediate can then be reacted with a second nucleoside, the more reactive primary hydroxy displacing the second molecule of HOBT and giving the coupled product. This method for coupling nucleosides has been applied to both solution and solid-phase synthesis of a variety of RNA fragments.

Ar = 2-chlorophenyl

(8)

Other Applications.

HOBT has also been employed as a catalyst for the conversion of isoamides into maleimides (eq 9).

(*S*)-(2-Hydroxy-*N,N*-dimethylpropanamide-*O,O´*)oxodiperoxymolybdenum(VI)

[70355-53-2] · $C_5H_{11}MoNO_7$ · (*S*)-(2-Hydroxy-*N,N*-dimethylpropanamide-*O,O´*)oxodiperoxymolybdenum(VI) · (MW 293.11)

(enantioselective epoxidation of unfunctionalized simple alkenes[1])

Physical Data: mp 149 °C (dec). According to X-ray structural analysis, the molecule has the pentagonal bipyramidal geometry with sevenfold coordinated molybdenum.

Solubility: sol ethanol; insol ether.

Form Supplied in: yellow microcrystalline powder. *Drying:* dried under vacuum.[1]

Preparative Method: to 5mL aqueous hydrogen peroxide solution (30%) is added, in portions, 1 g molybdenum(VI) oxide at 20 °C. The mixture is stirred at 20 °C for 20 min and at 40 °C for 4 h. After most of the molybdenum oxide has dissolved the mixture is filtered. The yellow solution is treated at 10 °C with 1 equiv of ligand dissolved in approx. 4 mL methanol. The mixture is stirred for 30 min at 20 °C, concentrated and kept 12 h at 0 °C. When the complex does not crystallize after addition of dichloromethane or benzene, the mixture is diluted with ethanol and carefully (shield protection) concentrated on a rotary evaporator. The procedure is repeated five times. The mixture is then further concentrated. The complex is usually obtained as a yellow microcrystalline powder, but if it is obtained as an oil the addition of diethyl ether with stirring at 5 °C yields a yellow powder.

Handling, Storage, and Precautions: necessary care should be taken when preparing and handling

peroxometal compounds. Fast and complete concentration of the mixture containing the compound may lead to deflagration of the complex. The complex decomposes at temperatures above 100 °C, changing color from yellow to blue and black. The complex is stored at 5 °C in <0.5 g portions.

Asymmetric Epoxidation.[2]

Methods[3] are known for asymmetric epoxidation of prochiral alkenes having activated C=C double bonds (styrene, allyl alcohol, conjugated ketones, quinone). The title optically active metal-peroxo complex (**1**) is capable of asymmetric epoxidation of simple unfunctionalized alkenes. Simple prochiral alkenes such as propene or *trans*-2-butene are epoxidized stoichiometrically to optically active oxiranes by (**1**) in nitrobenzene at 20 °C/1 bar. The chemical yield is about 70%. The enantiomeric excess is around 30% and the configuration of the dominant oxirane enantiomer is (*R*). A marked increase in enantiomeric yield for trimethyloxirane from 2-methyl-2-butene is observed on reducing the reaction rate by lowering the temperature. The increasing steric hindrance of the alkyl group in 3-methyl-1-butene surprisingly leads to a decrease in the asymmetric induction. The continuously monitored enantiomeric composition of the oxiranes during the reaction remained constant within experimental accuracy. This shows that the alkene epoxidation is asymmetrically induced and that no enrichment of the enantiomers of the epoxide that is formed takes place by kinetic resolution. The asymmetric induction decreases in the order of propene > 1-butene > 3-methyl-1-butene with the preferential formation of (*R*)-alkyloxiranes.[1] The ee increases with inversion of prochiral recognition for 3,3-dimethyl-1-butene, resulting in the preferential formation of (*S*)-*t*-butyloxirane. *trans*-2-Butene undergoes higher asymmetric induction than does *trans*-2-pentene, whereby (2*S*,3*S*)-*trans*-2-methyl/ethyl-3-methyloxiranes are preferentially formed. The asymmetric epoxidation of *cis*-2-pentene leads to the preferential formation of (2*S*,3*R*)-2-ethyl-3-methyloxirane. Geminal ethyl/methyl disubstitution at the double bond in 2-methyl-1-butene shows no enantiofacial discrimination and, consequently, only racemic 2-ethyl-2-methyloxirane is formed. In connection with the synthesis of aranciamycinone,[4] complex (**1**) has been used for the asymmetric epoxidation of the nonfunctionalized alkene (**2**).[5] The alkene (**2**) (eq 1) is treated with diluted solutions (1 mmol in 300 mL of dichloromethane) of the molybdenum(VI)-oxodiperoxo complex. Decreasing the temperature to 0 °C raises the enantiomeric yield to 53% ee. The absolute configuration of the predominantly formed enantiomer (**3**) was determined by an unequivocal sequence of reactions to a known glycoside.

β-Hydroxyethyltriphenylarsonium Bromide

[57813-28-2] · $C_{20}H_{20}AsBrO$ · β-Hydroxyethyltriphenylarsonium Bromide · (MW 431.22)

(epoxidation reagent for aromatic aldehydes with solid KOH under phase-transfer conditions)

Physical Data: mp 199 °C.

Preparative Methods: prepared from triphenylarsine and bromoethanol without solvent at 110 °C for 4 h in 69% yield;[1] mp and ^{1}H NMR spectrum coincide with those reported by another method[2] in which the reaction was carried out in an autoclave.

Handling, Storage, and Precautions: the toxicity of this reagent is unknown at present. Use in a fume hood.

2,3-Epoxy alcohols can be directly synthesized from aromatic aldehydes at ambient temperature in good yields by treatment with β-hydroxyethyltriphenylarsonium bromide using solid ***Potassium Hydroxide*** as a base (eq 1).

Weak bases such as triethylamine, piperidine, and K_2CO_3 do not promote this reaction; strong bases such as $KN(SiMe_3)_2$ and BuLi, usually employed to generate nonstabilized arsonium ylides,[3] are not suitable for this reaction. Using solid-liquid phase-transfer process (KOH (s)/THF (trace H_2O) system), the 2,3-epoxy alcohol products are obtained in good yields. The (*E*):(*Z*) ratio in each case is around 9:1 with the (*E*)-isomer predominating.

The general procedure is as follows. Arsonium salt (**1**) (1.2 mmol), aldehyde (1 mmol), and KOH (s) (1.2 mmol) are mixed in 4 mL of THF (trace H_2O) under N_2 and stirred at 25 °C. After the reaction is complete, the reaction mixture is

filtered. The products (**2**) (eq 1) are obtained after flash chromatography.

The related compound, (*E*)-4-hydroxy-2-butenyltriphenylarsonium halide (**3**), is a precursor of a good ylide epoxidation reagent for aromatic aldehydes. This reagent is prepared (75% yield) by treatment of Ph_3As with (*E*)-4-chloro-2-buten-1-ol and a catalytic amount of ***Potassium Iodide*** in MeCN. (*E*)-4-Chloro-2-buten-1-ol, in turn, is prepared via ***Lithium Aluminum Hydride*** reduction of butyne-1,4-diol with subsequent treatment with ***Thionyl Chloride*** (eq 2).[4]

Aromatic aldehydes react with arsonium salt (**3**) in MeCN (trace H_2O) at ambient temperature in the presence of $KF.Al_2O_3$[5] for 12-35 h to give exclusively (*E*)-5-aryl-4,5-*trans*-epoxy-2-penten-1-ols in moderate to good yields (53-78%) (eq 3). When cinnamaldehyde is used as substrate, (*E*)-5-(2-styrenyl)-4,5-*trans*-epoxy-2-penten-1-ol is obtained in 70% yield.[4] The formation of highly stereoselective *trans*-epoxide may be explained by the mechanism shown in eq 4.

The following is a typical procedure. A mixture of arsonium salt (**3**) (310mg), PhCHO (0.5 mmol), and $KF.Al_2O_3$ (120 mg) in MeCN (2 mL, trace H_2O) is stirred at ambient temperature under N_2 for 28 h (monitored by TLC). The reaction mixture is filtered and washed with acetone. The filtrate is evaporated under reduced pressure and the product is purified by flash chromatography.

(chiral auxiliary; acrylate[2] and acyl nitroso[3] derivatives undergo stereoselective [4 + 2] cycloadditions; enoate derivatives undergo stereoselective 1,4-conjugate additions of organocopper reagents;[4] enol ether derivatives undergo stereoselective Pauson-Khand cyclizations,[5] [4 + 2][6] and [2 + 2][7] cycloadditions; alkynyl ether derivatives undergo stereoselective Pauson-Khand cyclizations[5])

Alternate Name: 1,7,7-trimethylbicyclo[2.2.1]heptane-2,3-diol.

Physical Data: (**1**) mp 4-5 °C; [α]25D (EtOH) -42.4° (*c* = 1.40). (**2**) mp 4-5 °C; [α]25D (EtOH) +42.6° (*c* = 2.52). (**3**) oil; [α]25D (EtOH) -18.8° (*c* = 1.08). (**4**) oil; bp 130 °C/0.05 mmHg; [α]25D ($CHCl_3$) -36.1° (*c* = 1.44). (**5**) mp 43 °C; [α]25D (EtOH) +0.4° (*c* = 4.99). (**6**) mp 57 °C; [α]25D (EtOH) -107.6° (*c* = 1.70). (**7**) mp 69-70 °C; [α]25D (EtOH) -79.2° (*c* = 0.90). (**8**) mp 70-71 °C; [α]25D (EtOH) -61.5° (*c* = 0.57).

Preparative Methods: the 3-hydroxyisoborneol derivatives are readily prepared from (+)- or (-)-camphor. The preparation of the 2-neopentyl ether derivative (**1**) is representative (eq 1).[2b] Analogous alkylation with different electrophiles allows for easy variation of the shielding moiety.[2c,8] The corresponding 3-substituted derivatives have been prepared from either 3-hydroxyisoborneol after separation of the regioisomeric mixture or from 3-*exo*-hydroxycamphor regioselectively after reduction with ***Lithium Tri-s-butylborohydride*** (L-Selectride).[2c,9]

Handling, Storage, and Precautions: these auxiliaries vary from oils to white crystalline solids depending on the ether substituent and are stable indefinitely at ambient temperatures in sealed containers.

Introduction.

The abundance of (+)-camphor in the chiral pool provided Oppolzer with an excellent framework to develop a chiral auxiliary which provides high levels of stereoselectivity in a wide range of reaction classes. The 3-hydroxyisoborneol skeleton provides two derivatizable positions at C-2 and C-3 of the molecule which are in close proximity to each other. By appending a reactive functionality to one and a sterically shielding appendage to the other, high stereodirecting ability can be envisioned. Likewise by reversing the roles of C-2 and C-3 it is possible to tune the auxiliary to fit the reaction parameters and desired product configuration. These characteristics have provided a means for π-facial differentiation to acrylates, enol ethers, and alkynyl ethers.

Preparation of Derivatives.

Enoate derivatives are prepared from the corresponding chiral alcohol by treatment with acryloyl chloride in the presence of ***Triethylamine*** and catalytic ***4-Dimethylaminopyridine*** or the appropriate carboxylic acid chloride and ***Silver(I) Cyanide***.[2b] Alkynyl ethers are readily available from the potassium alkoxide by treating with ***Trichloroethylene***, in situ dechlorination with ***n-Butyllithium***, and electrophilic trapping.[10] Trapping the intermediate anion with a proton source or ***Iodomethane*** followed by Lindlar reduction of the alkynyl ether affords the corresponding vinyl and 1-(*Z*)-propenyl ether, respectively, while reduction of the alkynyl ether with ***Lithium Aluminum Hydride*** affords the 1-(*E*)-propenyl ether.

[4 + 2] Cycloadditions of Acrylate Derivatives.[2]

Acrylate derivatives undergo highly stereoselective Diels-Alder cycloadditions with 1,3-dienes when promoted by a Lewis acid, ***Dichlorotitanium Diisopropoxide*** or ***Titanium(IV) Chloride*** (eq 2). With the latter, care must be taken to avoid acid mediated cleavage of the auxiliary ether linkage. Generally, 2-substituted auxiliaries (**10**) show higher facial and *endo* selectivity than the corresponding 3-substituted analogs. This has been rationalized by a buttressing effect caused by the C-10 methyl forcing the ether side chain into close proximity to the acrylate. Of the range of shielding moieties examined, the neopentyl ether was shown to provide the highest selectivity. The stereochemical outcome can be explained by assuming that the acrylate adopts an *s-trans* conformation on coordination of the Lewis acid[11] and that the diene approaches from the face opposite the neopentyl ether. It should be noted that the analogous cycloadditions with crotonate derivatives give ve ry poor yields (<7%).[2b] Similar highly stereoselective Diels-Alder cycloadditions have also been reported for fumarate and allenic ester derivatives.[12]

[4 + 2] Cycloadditions of Enol Ether Derivatives.[6]

Asymmetric, inverse electron demand Diels-Alder reactions between nitroalkenes and alcohol (**1**)-derived vinyl and 1-(*E*)- and 1-(*Z*)-propenyl ethers have been reported to proceed with high stereoselectivity (eq 3). The resulting cycloadducts undergo an intramolecular [3 + 2] cycloaddition at rt to afford nitroso acetals which, after hydrogenolytic cleavage, provide tricyclic α-hydroxy lactams in high enantiomeric excess. The auxiliary alcohol can be recovered in 86-92% yield. The overall sense of asymmetric induction is dependent on the Lewis acid promoter employed, either Ti(O-*i*-Pr)$_2$Cl$_2$ or ***Methylaluminum Bis(2,6-diphenylphenoxide)*** (MAPh).[6b] This has been rationalized by a switch from a highly *endo* selective cycloaddition with Ti(O-*i*-Pr)$_2$Cl$_2$ to a highly *exo* selective cyclization with MAPh. When promoted by Ti(O-*i*-Pr)$_2$Cl$_2$ the corresponding 1-(*E*)-propenyl ether shows exclusive *endo* selectivity and 99% facial selectivity; however, facial

selectivity for the 1-(*Z*)-propenyl ether is only 50%.

(3)

98% ee (1*S*) $Ti(O\text{-}i\text{-}Pr)_2Cl_2$
99% ee (1*R*) MAPh

[4 + 2] Cycloadditions of Acyl Nitroso Derivatives.[3]

In situ formation of the acyl nitroso derivative by oxidation of the hydroxy carbamic acid under Swern-Moffat conditions in the presence of a functionalized diene affords the corresponding cycloadduct in 94% yield and 96% diastereomeric excess (eq 4). The resulting cycloadduct can be further elaborated to prepare optically active functionalized amino alcohols.

1,4-Conjugate Additions of Enoate Derivatives.[4]

Boron trifluoride-mediated conjugate additions of organocopper reagents to (*E*)-enoates derived from auxiliary (**1**) proceed with high stereoselectivity, affording optically active carboxylic acids after saponification (eq 5). The organocopper reagent is formed by addition of an alkyllithium reagent to ***Copper(I) Iodide***, ***Tri-n-butylphosphine***, and ***Boron Trifluoride Etherate*** in equimolar amounts, where Bu_3P is believed to stabilize the reagent. The overall sense of asymmetric induction can be controlled by changing either the order of substituent introduction (R^1 and R^2) or the configuration of the auxiliary. The stereochemical course of the reaction has been rationalized by assuming that the enoate exists in an *s-trans* conformation and the organocopper reagent approaches from the face opposite to the neopentyl ether. Conjugate additions of this type have been applied to the total synthesis of several natural products.

Pauson-Khand Bicyclization.[5]

Alkynyl and enol ether derivatives have been studied in the cobalt mediated intramolecular Pauson-Khand reaction and found to provide high diastereoselectivity, superior to previous work with the auxiliary 2-phenylcyclohexanol.[13] The 3-substituted auxiliary alcohol (**3**) provides higher selectivity than the 2-substituted analog. Also, the alkynyl ether derivatives exhibit higher reactivity and selectivity than the corresponding enol ether derivatives (eq 6).

Photochemical [2 + 2] Cycloadditions.[7]

Photochemical [2 + 2] cycloadditions between alkenes and chiral phenylglyoxylate derivatives of 3-hydroxyisoborneol show minimal diastereoselectivity (16% de).[14] Better results are obtained in [2 + 2] cycloadditions between chiral enol ethers and ***Dichloroketene*** (eq 7). After ring expansion and expulsion of the auxiliary (***Diazomethane***, ***Chromium(II) Perchlorate***), chiral α-chlorocyclopentenones are obtained in 60% yield. The observed diastereoselectivity is believed to arise from the enol ether *s-trans* conformation and approach of the ketene to the face opposite to the neopentyl ether.

Nondestructive Auxiliary Cleavage.

The high stability of the ether linkage to the shielding moiety generally allows for a very high recovery of the auxiliary alcohol. For acyl derivatives, primary alcohols can be obtained by $LiAlH_4$[2b] or AlH_3[15] reduction. Hydrolysis of the auxiliary under basic conditions providing the carboxylic acid has been accomplished with NaOH in aq. ethanol,[3] NaOH in methanol,[4b] or KOH in ethanol.[16] Intramolecular transesterification has been applied using KO-*t*-Bu in THF.[17] Enol ethers derived from Pauson-Khand cyclizations of alkynyl ether derivatives can be readily cleaved to the corresponding ketone and recovered auxiliary by catalytic HCl in methanol.[5]

(nucleophile in aromatic substitution,[63] oxime-,[36] hydroxamic acid-,[30] pyridine-[61] and isoxazole-forming[56] reactions; reducing agent;[66] in combination with dehydrating agents, used for the conversion of aldehydes to nitriles[43])

Physical Data: $HONH_2$: hydroscopic white needles or flakes; decomposes rapidly at rt; mp 32.05 °C; bp 56.5 °C/22 mmHg, 70 °C/60 mmHg, 110 °C/760 mmHg. $HONH_2.HCl$: white crystals; mp 151 °C; *d* 1.67 g cm^{-3}; pK_{a1} 5.97; pK_{a2} 13.7.[10] $(HONH_2)_3.H_3PO_4$: mp 169-171 °C. $(HONH_2)_2.H_2SO_4$: mp 170 °C (dec).

Solubility: $HONH_2$: decomposes in hot water; sol cold water, methanol; sparingly sol ether, benzene, chloroform, carbon disulfide.[2] $HONH_2.HCl$: 83 g/100 mL in cold water; very sol hot water; 4.43 g/100 mL in EtOH; 16.4 g/100 mL in MeOH; insol ether.

Form Supplied in: hydroxylamine hydrochloride is widely available and is the most commonly used hydroxylamine salt. Each of the other salts listed above is also commercially available, as are $HONH_2.HCl$-d_4 and $HONH_2.HCl$-^{15}N.[6]

Preparative Methods: hydroxylamine base has been prepared by the action of sodium butoxide on the hydrochloride in butanol.[3] The free base can be isolated as a white solid at -30 °C and is stable to storage for several days at -20 °C.[4] It can be prepared just prior to use or, more typically, in situ from one of the salts by treatment with hydroxide, alkoxide, carbonate, or amine base (see below). The preparation of hydroxylamine via the electrochemical reduction of nitric acid has been reported.[5]

Handling, Storage, and Precautions: all of the salts of hydroxylamine are corrosive and hygroscopic. Specific precautions in the literature indicate that the free base is a much more hazardous substance to work with than are the salts.[7] $HONH_2$: a moderately toxic, corrosive irritant to the eye, skin, and mucous membranes. *Explodes at 130 °C. Explodes in air when heated above 70 °C.* May ignite spontaneously in

air, or in contact with PCl_3 or PCl_5. Calcium reacts to give the heat-sensitive explosive bis(hydroxylamide). In the event of a spill, cover with sodium bisulfite and sprinkle with water. $HONH_2$.HCl: harmful if inhaled or swallowed (oral LD_{50} 400-420 mg kg^{-1}; mouse). Not compatible with oxidizing agents. May explode if heated above 115 °C; do not store above 65 °C. A comprehensive review of the biological activity of hydroxylamine and its salts has appeared.[2]

Introduction.

Hydroxylamine, usually as one of its more stable salts, has been used as a nucleophile in a wide variety of reactions and only the most common uses of this versatile reagent are described here. The name hydroxylamine is used throughout this review as a interchangable designator for either the free base or one of its salts. Where appropriate, the specific derivative will be named.

General Reactivity with Simple Electrophiles.

Hydroxylamine and its derivatives undergo reaction with many simple electrophiles such as alkylating, acylating, phosphinylating, and silylating agents, aldehydes and ketones, and Michael acceptors. The potent nucleophilic reactivity of hydroxylamine evident in these transformations is thought to arise as a consequence of what has been labeled the α-effect, an effect observed in a variety of nucleophiles which possess a heteroatom in the position α to the attacking nucleophilic atom.[8] Hydroxylamine reacts with simple electrophiles typically at both nitrogen and oxygen, with multiple reactions often giving rise to undesired side-products. Many derivatives of hydroxylamine have been prepared in an effort to circumvent this potential problem of ambident reactivity (see below).[9]

Reactions with Alkylating Agents: *N* vs. *O* Selectivity.

The products obtained in the reaction of simple alkylating agents with hydroxylamine are exemplary of the ambident reactivity discussed above. In a study directed toward the preparation of *O*-alkylated hydroxylamines, it was found that several benzylic and one alkyl halide react preferentially at oxygen in *t*-butoxide/*t*-butanol solution (eq 1).[10] Results similar to those obtained with benzyl bromide were found for five other benzylic halides.

$$\text{R-X} + \text{NH}_2\text{O}^- \longrightarrow \text{R-ONH}_2 + \text{R-NHOH} + \text{R}_2\text{NOH} \quad (1)$$

RX	Yield (%)	Product distribution
$PhCH_2Br$	52	66:22:12
1-Bromo-2-ethylhexane	30	79:21: -

Selective *N*-alkylation has been accomplished in a wide variety of cases using the hydroxylamine derivative *t*-butyl *N*-benzyloxycarbamate.[11] The preparation of *N*-octylhydroxylamine.HCl is illustrative of this process (eq 2). Ethyl 3-methylhydroxy-4-isoxazolecarboxylate[12] is another versatile reagent which has been developed for this purpose. *O*-

Trimethylsilyl- and *O*-(*t*-butyldiphenylsilyl)hydroxylamine[13] have also seen use in the preparation of *N*-alkylhydroxylamine derivatives, although these reagents have not been shown to be as generally useful in this regard as the previously mentioned two. *N*-Allylation has recently been accomplished via the Pd^0-mediated reaction of *N*,*O*-bis(Boc)hydroxylamine with allylic carbonates, chlorides, and acetates.[14] A similar study showed that the use of $HONH_2$.HCl in the same reaction leads to *N*,*N*-diallylated products.[15] ***N,O-Dimethylhydroxylamine***.HCl has been prepared on a large scale by dimethylation (***Dimethyl Sulfate***) of ethyl hydroxycarbamate at pH 11-12 followed by acidolysis.[16]

Reactions with Silylating Agents.

O-Mono-, *N*,*O*-bis-,[17] and *N*,*N*,*O*-tris(trimethylsilylated)[18] derivatives of hydroxylamine have been prepared. One distinct advantage of these silylated hydroxylamine reagents is their solubility in nonpolar solvents in which hydroxylamine and its salts show poor solubility. ***N,O-Bis(trimethylsilyl)hydroxylamine*** undergoes facile *O*,*N*-silyl transfer upon treatment with ***n-Butyllithium*** in ether, allowing the generation the lithium salt of *N*,*N*-bis(trimethylsilyl)hydroxylamine in situ.[19] This species plays an important role in the preparation of *O*-arenesulfonyl- and *O*-arenecarbonylhydroxylamines.[20]

Reactions with α-Halo or α-Hydroxy Esters: Preparation of *N*-Hydroxy-α-amino Acids.

Hydroxylamine and its derivatives have been reacted with both α-halo and α-hydroxy esters as a method to prepare *N*-hydroxy-α-amino acid derivatives.[21] While hydroxylamine has seen some utility along these lines with *t*-butyl esters (eqs 3 and 4),[22,23] the use of derivatives such as *N*-[(trichloroethoxy)carbonyl]-*O*-benzylhydroxylamine[24] and ***O-Benzylhydroxylamine Hydrochloride***[25] appear to offer some advantages. The latter reagent has been used in the displacement of the triflates of (*R*)- or (*S*)-α-hydroxy esters, leading to *N*-hydroxy-α-amino methyl esters with both excellent chemical yield and optical purity.[26]

(3)

R = H, 98%; Me, 97%; Et, 97%

(4)

Reactions with Michael Acceptors.

The reaction of hydroxylamine hydrochloride with Michael acceptors offers a convenient synthesis of β-amino acids and esters. The preparation of (±)-β-aminophenylpropionic acid has been reported wherein the reduction of the hydroxyamine is effected with a second equiv of $HONH_2$.HCl (eq 5).[27] In a more comprehensive investigation of this reaction, it was found that catalytic reduction of the intermediate hydroxylamine leads to better yields (70% in the case shown in eq 5) of the amino acid.[28]

(5)

Tandem Michael additions are also known, the reaction of phorone with hydroxylamine giving a highly congested, cyclic hydroxylamine derivative (eq 6).[29]

(6)

Reaction with Acid Derivatives: Preparation of Hydroxamic Acids.

Hydroxylamine and its derivatives have been reacted with esters and acid halides to prepare hydroxamic acids. The reaction of $HONH_2$.HCl with esters is particularly useful along these lines because overacylation is not a problem (eq 7).[30,31]

(7)

Reaction of hydroxylamine with acid halides can result in the formation of di- and triacylated products in addition to the desired hydroxamic acid. As is the case with alkylation, several hydroxylamine derivatives have been developed to address this problem. *O*-benzyl-,[32] *N*,*N*,*O*-tris(trimethylsilyl)- (eq 8),[33] *N*-Boc-*O*-TBDMS-, and *N*-Boc-*O*-THP-hydroxylamine (eq 9)[34] have all proven to be useful for the synthesis of protected hydroxamic acids.

(8)

R = Me, 85%; Et, 92%; Ph, 95%

(9)

The reaction of succinic anhydride with hydroxylamine (prepared from NaOMe and $H_2NOH.HCl$ in MeOH) leads to *N*-hydroxysuccinimide.[35]

Reaction with Aldehydes and Ketones: Oxime Formation.

Reaction of hydroxylamine with an aldehyde or ketone under basic or acidic conditions leads to the formation of the corresponding oxime. For example, the (*E*) and (*Z*) isomers of 4-acetylpyridine oxime have been prepared via the reaction of 4-acetylpyridine with $HONH_2.HCl$ (eq 10).[36]

(10)

Other examples of this reaction include the preparation of the oxime of methyl glyoxylate (eq 11)[23] and the oximes of some difluoromethylene-containing chiral aldehydes (eq 12).[37]

(11)

(12)

Both hydrazones (eq 13)[38] and enol esters (eq 14)[39] are efficient carbonyl surrogates in this transformation.

(13)

(14)

A solid-phase reagent which binds carbonyl compounds as their corresponding oximes has been developed and employed in the isolation of steroidal ketones.[40] α-Halo ketones produce α-hydroxylamino oximes on treatment with hydroxylamine.[41] The mechanism of this nucleophilic addition-dehydration process has been studied by a number of groups.[42]

Reaction with Aldehydes: Nitrile Formation.

Nitriles can be effectively prepared directly from aldehydes by a wide variety of methods involving hydroxylamine. Two convenient methods employ $HONH_2$.HCl and either refluxing formic acid[43] or pyridine with azeotropic removal of water with refluxing toluene (eq 15).[44] The former reaction has been used to convert a 4-formyl β-lactam into its corresponding nitrile derivative.[45]

(15)

Two hydroxylamine-derived reagents, *O*-(2-aminobenzoyl)hydroxylamine[46] and ***Hydroxylamine-O-sulfonic Acid***,[47] have also been used to effect this transformation, although in a more limited number of cases. Several methods exist which do not rely on hydroxylamine, including $NH_4Cl/Cu^0/py/O_2$,[48] $EtNO_2$/NaOAc/AcOH,[49] and *N*,*N*-dimethylhydrazine/MeOH/MMPP.$6H_2O$[50] (MMPP = magnesium monoperoxyphthalate).

Reaction with Phosphinylating Agents.

Both *N*- and *O*-phosphinylated hydroxylamine are available via reaction of the appropriate hydroxylamine derivative with diphenylphosphinyl chloride. Use of hydroxylamine base results in the formation of ***O-(Diphenylphosphinyl)hydroxylamine***,[4] while employment of $TMSONH_2$ followed by hydrolysis gives *N*-diphenylphosphinylhydroxylamine (eq 16).[51]

(16)

Reaction with Miscellaneous Electrophiles.

Hydroxylamine reacts with nitriles to yield amide oximes (eq 17).[52,53] The reaction of hydroxylamine with uracil and cytosine has been applied in the Chemical Cleavage of Mismatch (CCM) technique for identifying DNA mutants.[54]

(17)

Preparation of Isoxazoles and Isoxazolines.

Isoxazoles are conveniently prepared via the reaction of $HONH_2.HCl$ with 1,3-dicarbonyl compounds or their equivalents.[55] In some cases, the regiochemistry of the reaction can be controlled. For example, the regiochemistry of the reaction of hydroxylamine with acylketene dithioacetals depends on reaction conditions (eqs 18 and 19).[56]

(18)

(19)

In like fashion, reaction conditions are important in the preparation of 3-amino-5-*t*-butylisoxazole from 4,4-dimethyl-3-oxopentanenitrile (eqs 20 and 21).[57]

(20)

(21)

Functionalized 4,5-dihydroisoxazoles[58] have been prepared by the reaction of α,β-epoxy ketones with $HONH_2.HCl$ (eq 22)[59] and also by the cycloaddition reaction between styrene and aryl nitrile oxides prepared in situ from trichloromethylarenes and hydroxylamine.[60]

(22)

R^1 = Ph, cyclopropane derivs.; R^2 = Ph; 55-84%

Preparation of Substituted Pyridines.

Two novel approaches to the synthesis of substituted pyridines have appeared. Treatment of dihydropyran acetals[61] with $HONH_2$.HCl (eq 23) or bicyclic acetals[62] with $HONH_2$.HCl and ***Aluminum Chloride*** (eq 24) leads to good yields of pyridines. The first process appears to be the more general of the two, though it is limited somewhat by the availability of starting materials.

(23)

R^4 = Me, Et

R^1	R^2	R^3	Yield
Ph	Ph	H	81%
Ph	Cy	H	40%
2-furyl	Ph	H	95%

(24)

R =Me, 83%; Et, 99%; Pr, 84%

Aromatic Substitution Reactions.

In certain cases, hydroxylamine can act as a nucleophile in aromatic substitution reactions. This has shown to be the case in the reactions with 6-nitroquinoxalines (eq 25)[63] and *N*,*N*-dimethyl-2,4-bis(trifluoroacetyl)-1-naphthylamine (eq 26).[64] Other examples are known.[65]

(25)

(26)

Use as a Reducing Agent.

The combination of hydroxylamine and ethyl acetate in DMF represents a useful in situ preparation of ***Diimide*** and this procedure has been reported to reduce a variety of unsaturated compounds (eq 27).[66,67] Diimide formation from hydroxylamine has been used to explain the reductive cyclization of some *o*-nitroazobenzenes.[68]

(27)

Use in Peptide Chemistry.

Hydroxylamine has been used as a reagent to cleave the acetoacetyl amino acid protecting group[69] and has also been employed to cleave the asparaginyl-glycyl peptide bond.[70]

Hydroxylamine-*O*-sulfonic Acid

H_2NOSO_2OH

[2950-43-8] · H_3NO_4S · Hydroxylamine-*O*-sulfonic Acid · (MW 113.11)

(amination; hydroxymethylation; reduction; conversion of alkenes to primary amines[1-3])

Alternate Name: HOSA.

Physical Data: mp 210 °C (dec).

Solubility: sol cold water, methanol; slightly sol ethanol; insol ether, $CHCl_3$.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: quantitative analysis of HOSA can be made by iodometric titration.[4,5]

Preparative Methods: by reacting hydroxylamine sulfate with 30% fuming H_2SO_4[4] or 60% oleum[6] at rt, or by heating a mixture of hydroxylamine sulfate and chlorosulfonic acid at 100 °C for several hours.[5]

Handling, Storage, and Precautions: hygroscopic; should be stored in tightly sealed bottles in a refrigerator. Aqueous solutions are unstable, decomposing rapidly above 25 °C. It is thus important to use freshly prepared solutions in reactions. Use in a fume hood.

Introduction.

The use of HOSA in organic synthesis results from its ability to act both as a nucleophile and as an electrophile (eq 1), as well as being able to provide an in situ route to other chemical entities, such as diimide.

Amination at Nitrogen.

Monosubstituted and 1,1-disubstituted hydrazines can be prepared in fair to good yields by reacting HOSA with primary or secondary amines, respectively, in basic aqueous solution (eq 2).[7,8] Tertiary amines give 1,1,1-hydrazinium salts when they are treated with HOSA under basic conditions in aqueous or alcoholic solution (eq 3).[7-9]

(2)

(3)

Many nitrogen heterocycles, including pyridine,[7,8] quinoline,[7,8] pyrimidine,[9] azetidine,[10] pyridazine,[11] tetrazole,[12] indole (eq 4),[13,14] benzimidazole,[14,15] triazine,[16] benzoxazole,[17] and purine[14,18] ring systems, can also be aminated on nitrogen using HOSA.

(4)

Amination at Carbon.

One of the two published reports on carbanion aminations with HOSA[19] concerns its reaction with some β-diketo compounds to furnish symmetrically substituted pyrroles (eq 5).

The other attempted amination with HOSA[20] yielded a trace amount of an amino acid from an α-lithiated carboxylic acid. Triphenylborane, prepared from phenylmagnesium bromide and boron trifluoride, reacts with HOSA to give aniline in 35% yield.[21]

Two different methods have been reported for the direct amination of an aromatic ring in low yields using HOSA. The first employs ***Aluminum Chloride*** as a catalyst (eq 6);[22,23] the second is an homolytic amination procedure in which a protonated amino radical is generated using iron(II) ion together with HOSA (eq 7).[24]

Certain heterocycles react with HOSA to give *C*-substituted amino derivatives (eq 8).[25]

(8)

Amination at Sulfur.

Organosulfur compounds, including thiols,[26] thioacids (eq 9),[27] thioamides,[27,28] dithioacids,[27] and thioethers (eq 10),[29] undergo amination with HOSA in good yields.

(9)

(10)

Hydroxymethylation.

Quinolines can be hydroxymethylated in the 2-and/or 4-position using HOSA in methanol (eq 11).[30]

$R^1 = R^2 = H$	55%	25%
$R^1 = Me, R^2 = Cl$	-	95%

Reduction.

HOSA, alone[31] or together with hydroxylamine sulfate,[32] provides under basic conditions a source of ***Diimide***, HN=NH, which will reduce multiple bonds (eqs 12 and 13). Yields obtained by using HOSA alone seem to be lower compared with those obtained with HOSA-hydroxylamine sulfate.

Conversion of Alkenes into Primary Amines.

Methods for the conversion of alkenes into primary amines via the corresponding organoboranes using HOSA have been developed.[33 -36] Organoboranes are prepared in situ by the addition of ***Diborane*** to the alkene in THF (eq 14)[33] or by the addition of ***Boron Trifluoride Etherate*** to the alkene and ***Sodium Borohydride*** in diglyme, in which HOSA is soluble (eq 15).[35]

The limitation to quantitative utilization of the alkyl groups has been overcome by preparing a mixed organoborane, $R^1R^2{}_2B$, in which R^1 shows a significantly greater migratory aptitude than R^2. For this purpose, organodimethylboranes, prepared by hydroboration of alkenes with dimethylborane, were treated with HOSA to afford the corresponding primary amines stereospecifically in almost quantitative yields (eq 16).[37]

α-Chiral primary amines of high optical purity can be obtained from the chiral boronic esters through the intermediate formation of alkyl methyl borinic esters and their stereospecific reaction with HOSA in very good yields (eq 17).[38,39] Synthesis of chiral α-methylorganyl primary amines, which are difficult to prepare via direct asymmetric hydroboration, can be accomplished by treating borinate esters with HOSA (eq 18).[40]

Conversion of Carboxylic Acids to Primary Amines.

Heating a carboxylic acid or its anhydride with HOSA in mineral oil at 160-180 °C[41] or in polyphosphoric acid at 115-125 °C[42] gives a primary amine in a low yield (eq 19).

Conversion of Primary Amines to Hydrocarbons

(Reductive Deamination).

In an indirect route, a primary amine is converted into its sulfonamide which is isolated, dissolved in aqueous base, and then treated with HOSA to give the hydrocarbon in a high yield (eq 20).[43] In a direct route, a primary amine is allowed to react with 2-3 equiv of base to give the hydrocarbon in a moderate yield (eq 21).[44]

Conversion of Carbonyl Compounds to Oxime Sulfonates.

Aldehydes and ketones react with HOSA in aqueous solution to give oxime-*O*-sulfonic acids and salts in good yields (eq 22).[45,46]

Conversion of Aldehydes to Nitriles.

With aldehydes, prolonged treatment with HOSA, at rt or above, generates nitriles (eq 23).[46,47]

Conversion of Ketones to Oximes.

Reaction of aliphatic ketones with HOSA at 100 °C gives oximes in high yields (eq 24).[48] The method has the

advantage over the standard oxime preparation procedure employing hydroxylamine hydrochloride in that no adjustment in pH of the reaction medium is required to facilitate reaction and a solvent is not necessary, the ketone and HOSA simply being mixed together.

(24)

Conversion of Ketones to Amides.

Under the conditions described above, alkyl aryl ketones yield *N*-aryl aliphatic amides, again in high yields (eq 25).[48] Alicyclic ketones have been converted to lactams using HOSA (eq 26).[49]

(25)

(26)

Conversion of Oximes to Diazo Compounds.

Oximes react with HOSA in aqueous base to give diazo compounds (eq 27).[50]

(*S*)-3-Hydroxy-5-methyl-2,4-imidazolidinedione

[30293-99-3] · $C_4H_6N_2O_3$ · (*S*)-3-Hydroxy-5-methyl-2,4-imidazolidinedione · (MW 130.12)

(acyl activating agent for asymmetrically selective peptide synthesis[1])

Alternate Name: (-)-3-hydroxy-5-methylhydantoin.

Physical Data: mp 163-164 °C; $[\alpha]_D$ -36.0°.

Preparative Method: prepared from alanine (eq 1).[1]

Asymmetric Peptide Synthesis.[1]

The reagent activates amino acids through ***1,3-Dicyclohexylcarbodiimide*** (DCC) coupling to the *N*-hydroximide for subsequent coupling with chiral amino acids. The asymmetric center induces preferential reaction with L-amino acids and high optical purities of L-L-dipeptides can be achieved (eq 2). Enantioselectivity is improved if the 5-methyl group is replaced by isobutyl.[1]

(2*S*,2´*S*)-2-Hydroxymethyl-1-[(1-methylpyrrolidin-2-yl)methyl]pyrrolidine[1]

[66283-23-6] · $C_{11}H_{22}N_2O$ · (2*S*,2´*S*)-2-Hydroxymethyl-1-[(1-methylpyrrolidin-2-yl)methyl]pyrrolidine · (MW 198.35)

(chiral ligand for alkyllithium,[2] dialkylmagnesium,[3] alkynyllithium,[4] and functionalized organolithiums[5] in the enantioselective addition to aldehydes; accelerates the basicity of alkyllithiums;[5] catalyzes the addition of dialkylzinc to aldehyde[2])

Physical Data: bp 112 °C/4.5 mmHg; [α]28D -130° (*c* 0.36, EtOH).

Solubility: sol hexane, toluene, Me_2O, Et_2O, *n*-Pr_2O, THF, dimethoxymethane.

Preparative Method: reduction of *N*-[*N*(-benzyloxycarbonyl)prolyl]proline methyl ester with ***Lithium Aluminum Hydride*** affords the title reagent in 81% yield.

Enantioselective Addition of Alkyllithium Reagents to Aldehydes.

(2*S*,2´*S*)-2-Hydroxymethyl-1-[(1-methylpyrrolidin-2-yl)methyl]pyrrolidine (**1**) is a chiral amino alcohol which binds well to alkyllithium reagents.[2] Enantioselective addition of ***n-Butyllithium*** to benzaldehyde in the presence of (**1**) in a mixed solvent of Me_2O and dimethoxymethane (DMM) (1:1) at -123 °C affords (*S*)-1-phenylpentan-1-ol with 95% ee in 77% yield.[2] In the addition to 3-methylbutanal, the corresponding (*S*)-alcohol is obtained in 80% ee (eq 1).

(2S,2´S)-2-Hydroxymethyl-1-[(1-methylpyrrolidin-2-yl)methyl]pyrrolidine

(1)

$R^1 = Bu$, $R^2 = Ph$, 77%, 95% ee; $R^1 = Bu$, $R^2 = i\text{-}Bu$, 57%, 80% ee

These ee's are higher than those of the preceding reports[1a] and are comparable with those of the reports appearing afterwards.[1b,c] It should be noted that the absolute configuration of the alcohol obtained in the addition of EtLi to PhCHO depends on the solvent employed [(*R*): EtOH; (*S*): DMM]. The sense of the enantioselectivity of the addition of ***Methyllithium*** is opposite to that of BuLi. When the derivative of (**1**) possessing a neopentyl group (**2**) is used in the addition of MeLi to PhCHO, (*R*)-1-phenylethanol with 86% ee is obtained in 82% yield.[2b]

(2)

Enantioselective Addition of Dialkylmagnesium to Aldehydes.

Amino alcohol (**1**) is a chiral ligand for dialkylmagnesium reagents in the enantioselective addition to aldehydes.[3] Reaction of Et_2Mg with PhCHO in the presence of (**1**) in toluene at -110 °C affords (*R*)-1-phenylpropan-1-ol with 92% ee in 74% yield. When *n*-Bu_2Mg is employed, (*R*)-1-phenylpentan-1-ol with 88% ee is obtained in 94% yield. It should be noted that the sense of the enantioselectivity of *n*-Bu_2Mg-(**1**) is opposite to that of *n*-BuLi-(**1**) (eq 2).

(2)

$R^1 = Et$, $R^2 = Ph$, 74%, 92% ee; $R^1 = Bu$, $R^2 = Ph$, 94%, 88% ee

Enantioselective Addition of Alkynyllithium to Aldehydes.

The enantioselective addition of alkynyllithium to aldehydes in the presence of (**1**) provides optically active propargylic alcohols. (*S*)-1-Phenyl-2-propyn-1-ol with 92% ee is obtained in 87% yield from the enantioselective

addition of ***Lithium (Trimethylsilyl)acetylide*** to PhCHO in the presence of (**1**) and the subsequent removal of the Me_3Si group (eq 3).[4a]

Optically active aliphatic propargylic alcohols are converted to corticoids (90% ee) via biomimetic polyene cyclization,[4b] and to 5-octyl-2(5*H*)-furanone.[4c] The ee's of propargylic alcohols obtained by this method are comparable with those of the enantioselective reduction of alkynyl ketones with metal hydrides,[6] catalytic enantioselective alkylation of alkynyl aldehydes with dialkylzincs using a chiral catalyst (***(S)-Diphenyl(1-methylpyrrolidin-2-yl)methanol***) (DPMPM),[7a] and the enantioselective alkynylation of aldehydes with alkynylzinc reagents using *N*,*N*-dialkylnorephedrines.[7b,c]

Enantioselective Addition of Functionalized Organolithiums to Aldehydes.

Amino alcohol (**1**) is a chiral ligand for various functionalized organolithiums derived from acetonitrile and *N*-nitrosodimethylamine (eq 4).

An optically active β-hydroxy nitrile with 40% ee is obtained from the reaction of $LiCH_2CN$ with PhCHO in the presence of (**1**).[5] The same compound with higher ee (93% ee) is obtained using cyanomethylzinc bromide and the chiral ligand DPMPM.[8]

Amino alcohol (**1**) accelerates the basicity of BuLi. Thus methyl phenyl sulfide is deprotonated by BuLi in the presence

of (**1**) to afford $PhSCH_2Li$. Deprotonation does not occur without (**1**). Enantioselective addition of $PhSCH_2Li$ to PhCHO using (**1**) affords an optically active β-hydroxy sulfide, which is converted to (*R*)-2-phenyloxirane with 68% ee.[5]

Addition of Diethylzinc to Benzaldehyde.

The addition of ***Diethylzinc*** to PhCHO without added catalysts is very sluggish. Amino alcohol (**1**) acts as a catalyst precursor for the addition of Et_2Zn to PhCHO under mild conditions to afford 1-phenylpropan-1-ol in 76% yield (eq 5).[2b,3] Although the obtained alcohol is racemic, the result of the addition of Et_2Zn to PhCHO in the presence of amino alcohol (**1**) led to the recently developed highly enantioselective addition of Et_2Zn to PhCHO using chiral amino alcohols.[1b,c]

6-Hydroxynicotinic Acid

[5006-66-6] · $C_6H_5NO_3$ · 6-Hydroxynicotinic Acid · (MW 139.12)

(building block for the synthesis of pyridine derivatives useful as agrochemicals, pharmaceuticals, liquid crystals; metal complexing agent)

Physical Data: mp 314-316 °C (dec); pK_{a1} 3.8, pK_{a2} 10.8.

Solubility: sol DMSO, DMF, aq. NaOH; sol 0.6 g L^{-1} at 20 °C in water, 4 g L^{-1} in methanol; insol nonpolar organic solvents.

Form Supplied in: off-white solid, &egt;98% purity; impurities: max. 0.5% nicotinic acid, 0.3% water.

Analysis of Reagent Purity: HPLC, Karl Fischer (H_2O).

Preparative Methods: industrially, through bacterial oxidation of nicotinic acid[1] or 3-cyanopyridine;[2] from coumalic acid and NH_3.[3]

Handling, Storage, and Precautions: LD_{50} (oral, rat) >5000 mg kg^{-1}; no special precautions are necessary.

Reactivity.

6-Hydroxynicotinic acid displays reactivity patterns typical for both pyridones[4a] and pyridinecarboxylic acids.[4b] The carboxyl function can be transformed without affecting the pyridone moiety. Esters can be prepared either by the normal Fischer esterification procedure or through various known activation methods[5a] (e.g. ***N,N´-Carbonyldiimidazole***),[5b] including selective chlorination with ***Thionyl Chloride***.[5c] The same methods can be used to prepare amides or hydrazides of 6-hydroxynicotinic acid (eq 1).

(1)

nucleophile = alcohol, amine, thiol, etc.

6-Hydroxynicotinic acid chloride can also be hydrogenated to the corresponding aldehyde or alcohol under Rosenmund conditions.[6a,b] Moreover, the carboxyl group can be converted into a trifluoromethyl group using ***Sulfur Tetrafluoride***.[7]

As a pyridone, 6-hydroxynicotinic acid undergoes *N*-alkylation (eq 2) in good yields (typically, 70 and 84% for R^1 = Me and Bn, respectively)[8a,b] and *O*-acylation (eq 2), as well as substitution by strong electrophiles in the *ortho* position (eq 3) under mild conditions (0 °C). In this case, the carboxyl group can be easily substituted by a second electrophile, particularly under basic conditions.

(2)

(3)

E^1 = Cl, Br, I, NO_2 E^2 = Cl, Br, I, NO_2

Halogens (Cl_2, Br_2, I_2) or hypohalites, as well as nitric acid, have been used as electrophiles to produce a variety of disubstituted pyridones, e.g. E^1 = Cl,[9a] Br,[9b] NO_2,[9c] E^1 = E^2 = Cl,[9d] I,[9e] NO_2[9f] (eq 3). Such pyridones, like 6-hydroxynicotinic acid itself, can be converted into chloro-[10a,b,c] or bromopyridines[10d] through halodehydroxylation. Subsequently, the halopyridines can be engaged in nucleophilic substitutions with alcohols, amines, phenols, thiols, fluoride, and silicon[11] or carbon nucleophiles, to produce diversely substituted pyridines (eq 4). Finally, 6-

hydroxynicotinic acid can take part as the diene in Diels-Alder cycloadditions with electron-deficient dienophiles.[12]

Applications.

6-Hydroxynicotinic acid has been used as a complexing agent to elute metal-bound proteins in affinity chromatography of enzymes.[13] A few important synthetic derivatives of 6-hydroxynicotinic acid are illustrated below. Optically active esters of type (**1**) (eqs 1 and 2) (R^1 = aryl, R^2 = chiral alkyl) are used as components of liquid crystals and optical switching devices.[14] A large number of patents describe the preparation and use of chloropyridines of general structure (**2**) (X = primary or secondary amine) as insecticides.[15] Compounds (**2**) have been prepared on an industrial scale from the corresponding alcohol (**2**) (X = OH) derived from 6-chloronicotinic acid chloride[16] (eq 4). The compound (**3**), also derived from 6-chloronicotinic acid, represents a class of nicotinamide analogs useful for the treatment of psoriasis in humans.[17]

(1)

(2)

(3)

A great variety of 6-hydroxy- or 6-aminonicotinic amides have shown potentially useful biological activities.[18] 2,3,5-Trichloropyridine has been prepared on a large scale from 6-hydroxynicotinic acid (eqs 3 and 4) as an intermediate for the production of herbicides[19] of structure (**4**). A further application of the ring chlorination (eq 3) is illustrated by the synthesis of growth-stimulating agents (**5**) via 5,6-dichloronicotinic acid.[20a,b] The *N*-alkylation of 6-hydroxynicotinic acid or derivatives (eq 2) has served notably to prepare nucleoside analogs (e.g. **6**).[21]

(4)

(5)

(6)

Related Reagents.

2-Ethoxypyridine 1-Oxide; ***N-Hydroxypiperidine***; ***3-Hydroxypyridine***; ***2-Hydroxypyridine***; ***Pyridine***; ***Pyridine N-Oxide***; ***2-Pyridinethiol***.

(1*S*,2*S*,5*S*)-2-Hydroxypinan-3-one

(1*S*,2*S*,5*S*)

[1845-25-6] · $C_{10}H_{16}O_2$ · (1*S*,2*S*,5*S*)-2-Hydroxypinan-3-one · (MW 168.26) (1*R*,2*R*,5*R*)

[24047-72-1]

(chiral auxiliary for the asymmetric synthesis of α-substituted α-amino carboxylic acids,[1,2] phosphonic acids,[3] and phosphinic acids,[4] and of α-substituted benzylamines[5] and (2-pyridyl)methylamines;[6] resolution of racemic α-amino acids[7])

Alternate Name: (1*S*,2*S*,5*S*)-2-hydroxy-2,6,6-trimethylbicyclo[3.1.1]heptan-3-one.

Physical Data: mp 36-38 °C; bp 245 °C; *d* 1.059 g cm^{-3};[α]20D -37° (*c* = 0.5, $CHCl_3$).

Solubility: sol $CHCl_3$, CCl_4, ether, methanol, hot pentane.

Form Supplied in: available as the neat compound.

Analysis of Reagent Purity: NMR.

Preparative Method: prepared by oxidation of α-pinene.[8]

Purification: distillation, or recrystallization from pentane.

Handling, Storage, and Precautions: no reported instability or toxicity.

Asymmetric Synthesis of α-Amino Acids.

Chiral ketimines prepared from the title ketone and glycinates can be deprotonated and treated with electrophiles, such as alkyl halides (eq 1),[1] or Michael acceptors,[2] to give α-substituted α-amino acids with moderate to excellent levels of

diastereoselectivity.

(1)

The product imine diastereomers can usually be separated by chromatography, which enables synthesis of enantiomerically pure α-amino acids even if the reaction is not completely diastereoselective, and provides an alternative to the resolution of racemic α-amino acids.[7] The imine is cleaved by mild hydrolysis with aqueous citric acid or by reaction with hydroxylammonium acetate.

This method is of special value for the synthesis of α,α-disubstituted α-amino acids.[1b,d] Analogous chiral ketimine glycinates prepared from camphor[1e,9a] or a protected D-galactodialdehyde[9b] are also synthetically useful, and in some cases give higher diastereoselectivities; with these reagents, however, separation of the imine diastereomers by chromatography does not seem to be possible. Several other chiral glycinate enolate equivalents have been reported, many of which give excellent levels of selectivity.[10] If the synthetic objective is to prepare β-hydroxy-α-amino acids by reaction of a chiral glycinate with a carbonyl compound, one of these alternative reagents should be chosen.

Asymmetric Synthesis of α-Substituted α-Amino Phosphonic and Phosphinic Acids.

The title reagent can also be used to prepare chiral Schiff bases from α-amino phosphonic[3] and phosphinic[4] acid esters. Deprotonation and alkylation then gives α-substituted products with good to excellent diastereoselectivity (eq 2). Chromatographic separation of the imine diastereomers is often possible, giving access to enantiomerically pure products after hydrolysis. The corresponding Schiff bases prepared from camphor sometimes give higher diastereoselectivities in reactions with activated alkyl halides.[11] A useful alternative reagent based on a chiral phosphonamide has also been reported recently.[12]

(2)

Asymmetric Synthesis of α-Substituted Benzylamines and (2-Pyridyl)methylamines.

A strategy for the synthesis of chiral α-substituted benzylamines (eq 3)[5] and (2-pyridyl)methylamines[6] by alkylation of chiral ketimines has also been developed.

(3)

Ketimines derived from benzylamine and camphor can also be alkylated, but these reactions generally give lower diastereoselectivities.[13] Alternative approaches based on a chiral oxazoline or chiral oxazolidinones have been reported;[14] however, these reagents often give lower diastereoselectivities or problems with partial racemization during the reaction sequence required for cleaving off the chiral auxiliary.

N-Hydroxypiperidine[1]

[5801-58-5] · $C_5H_{11}NO$ · *N*-Hydroxypiperidine · (MW 101.17)

(acylation reactions; peptide synthesis)

Alternate Name: HOPip.

Physical Data: mp 39 °C; bp 110 °C/55 mmHg.

Form Supplied in: white solid; limited commercial availability.

Analysis of Reagent Purity: mp; should be a white solid; if it becomes discolored, it should be purified before use.

Preparative Method: prepared, in approximately 62% yield, by the oxidation of *N*-ethylpiperidine with ***Hydrogen Peroxide*** followed by Cope elimination in refluxing toluene.[2]

Purification: recrystallize from *n*-hexane or petroleum ether (40-60 °C fraction) at -60 °C.

Handling, Storage, and Precautions: best stored in a stoppered vessel at 0 °C or below; avoid contact with reducing agents; toxicity not fully investigated so should be treated with caution.

Acylation Reactions.

N-Hydroxypiperidine has been coupled with carboxylic acids using ***1,3-Dicyclohexylcarbodiimide*** (DCC) to give an activated ester which is capable of reacting directly with amines under acid catalysis (eqs 1-3).[3] This has proved of particular interest in the preparation of peptides because the activated ester intermediates are usually stable crystalline materials, and their coupling reactions have been demonstrated to proceed without racemization.[4] Unfortunately this procedure has not found widespread application because, as can be seen from eq 3, the reaction rate is rather sensitive to steric hindrance.[5]

The lack of reactivity of the activated ester systems towards sterically hindered amines can be useful if selective acylation of an amine is required.[3a] For example, the activated ester (**1**) will benzoylate primary amines such as *n*-butylamine at rt over 48 h, whereas more hindered amines such as *t*-butylamine are untouched (eq 4). There is also no reaction with less nucleophilic amines such as aniline or with hydroxy groups under these conditions.

Peptide Synthesis using the Kaiser Resin.

Perhaps the most common use of *N*-hydroxypiperidine today is in conjunction with solid-phase peptide synthesis using the Kaiser resin.[1,4,6] This involves the use of a polystyrene or polyamide (PA) based resin support on which peptides (up to about 40 residues) can be synthesized, the peptide being attached to the support by means of a hydroxylamine ester linkage. Once the desired peptide has been constructed on the support, it can be released under mild conditions by reaction with *N*-hydroxypiperidine (eq 5). The resulting *N*-hydroxypiperidine ester can then be cleaved by the action of ***Zinc-Acetic Acid***, to give the peptide free at the carboxyl terminus. This two-step operation proceeds in good overall yields and without racemization of the peptide unit. It is also compatible with a

wide range of common amino acid protecting groups,[6] making this a useful method for peptide synthesis.

3-Hydroxypyridine

[109-00-2] · C_5H_5NO · 3-Hydroxypyridine · (MW 95.11)

(acylation reactions; peptide synthesis)

Alternate Name: 3-pyridinol.

Physical Data: mp 126-129 °C; bp 151-153 °C/3 mmHg.

Form Supplied in: off-white solid; widely available commercially.

Analysis of Reagent Purity: mp; should be an off-white solid; if it becomes discolored it should be purified before use.

Purification: recrystallize from water or ethanol.

Handling, Storage, and Precautions: best stored in a stoppered vessel at 0 °C or below; avoid contact with strong acids and oxidizing agents; it is toxic and an irritant and so appropriate precautions should be taken.

Peptide Synthesis.

3-Hydroxypyridine has been coupled with amino acids using ***1,3-Dicyclohexylcarbodiimide*** (DCC) to give an activated ester (**1**) which can be used in the formation of peptides[1] as illustrated in eq 1. This can be useful if the purification of the peptide product proves to be a problem using other methods, since the intermediate (**1**) is soluble in dilute acid and hence easily removed from the reaction medium. In addition, the byproducts of the coupling reaction can easily be removed with aqueous acid.

Acylation Reactions.

3-Hydroxypyridine can be readily *O*-acylated using ***Acetyl Chloride*** and the product is of use as a selective acylating agent for alcohols and amines.[2] For example, it will react with primary amines at rt to give good yields of the corresponding amides, whereas secondary amines react more slowly and diarylamines do not react at all (eq 2).

It is possible to increase the reactivity of 3-acetoxypyridine towards amines by the addition of Lewis acids such as ***Boron Trifluoride*** (eq 3), and this does allow some fine-tuning of the reactivity.

2-Hydroxypyridine[1]

(-ol form)

[72762-00-6] · C_5H_5NO · 2-Hydroxypyridine · (MW 95.11) (-one form)

[142-08-5]

(acylating agent; nitrile formation; peptide coupling)

Alternate Names: 2-pyridinol; 2(1*H*)-pyridone.

Physical Data: mp 105-107 °C; bp 181-185 °C/24 mmHg.

Form Supplied in: off-white solid; widely available commercially.

Analysis of Reagent Purity: mp; should be an off-white solid; if it becomes discolored it should be purified before use.

Purification: distill under vacuum then recrystallize from ethanol.

Handling, Storage, and Precautions: best stored in a stoppered vessel at 0 °C or below; avoid contact with strong acids and oxidizing agents; it is toxic and an irritant and so appropriate precautions should be taken.

Introduction.

The pyridone tautomer is treated separately (see ***2-Pyridone***), where cycloaddition chemistry is discussed. This entry deals with uses of the reagent as an acylating and activating agent.

Bifunctional Catalysis.

2-Hydroxypyridine has been used as a bifunctional catalyst[2] in a number of reactions,[3] most notably in the formation of amides. In this context the addition of 2-hydroxypyridine to the reaction between methyl ester (**1**) and amine (**2**)

significantly enhances the yield of the amide product (eq 1).

Acyl Derivatives of 2-Hydroxypyridine.

The coupling of 2-hydroxypyridine with amino acids has been used as a means of activating the carboxyl function for peptide synthesis. The active esters can then be readily reacted with the amino function of another amino acid with minimal epimerization of any chiral centers (eq 2).[4]

The reaction rates for these coupling reactions decrease considerably in polar solvents such as DMF, which means that this method is only really useful for small peptide units which are soluble in less polar solvent systems such as dichloromethane. For larger peptides, it has been shown that good reaction rates can be achieved if this coupling reaction is used in conjunction with a Merrifield resin.

These active esters will also acylate a range of carbon nucleophiles including Grignard reagents,[5] organocopper reagents,[6] and ester enolates.[7] This chemistry has been used to prepare keto derivatives of amino acids as illustrated in eq 3.

O-Acyl derivatives of 2-hydroxypyridine have also been employed as general acylating agents;[3b,8] for example, the benzyloxycarbonate derivative will readily react with amino acids to give the corresponding benzyloxycarbamate. In the case of free amino acids such as serine, this reagent shows high chemoselectivity for the amino function (eq 4).

(4)

2-Trifluoroacetoxypyridine (TFAP), which is readily prepared from 2-hydroxypyridine, will trifluoroacetylate both amines and alcohols, as illustrated in eq 5.

(5)

As well as being a simple trifluoroacetylation agent, TFAP is also capable of effecting the dehydration of oximes and amides to give nitriles, as exemplified in eq 6.

N-Hydroxypyridine-2-thione

[1121-30-8] · C_5H_5NOS · *N*-Hydroxypyridine-2-thione · (MW 127.18)

(reaction with a carboxylic acid or acid chloride leads to the corresponding *O*-acyl thiohydroxamate; treatment of these intermediates with a radical source leads to alkyl or aryl radicals [R&bdot;], the fate of which depends on the precise reactions conditions[1])

Alternate Name: 1-hydroxy-2-(1*H*)-pyridinethione; the tautomeric *N*-oxide form *[1121-31-9]*, although the minor component, is often the source of alternate names for this compound, which include 2-pyridinethiol 1-oxide, 2-mercaptopyridine *N*-oxide, 2-mercaptopyridine 1-oxide, and the abbreviated form pyrithione.

Physical Data: mp 70-72 °C.

Form Supplied in: both the pyridinethione and the corresponding sodium salt (sometimes as the hydrate) are commercially available. A 40% aqueous solution of the sodium salt is also available and cheaper (also referred to as sodium omadine). The free thione can be obtained from this by acidification to neutrality using concentrated aq HCl, filtration of the crude product, and crystallization from EtOH. Alternatively, evaporation of the aqueous solution (<50 °C) and crystallization of the residue from ethanol provides the sodium salt, mp 285-290 °C, after slow crystallization from ethanol and drying at 50 °C under vacuum.[3]

Preparative Methods: prepared from 2-bromopyridine by oxidation to the *N*-oxide using either ***Perbenzoic Acid*** or ***Peracetic Acid***, followed by displacement of bromide using either ***Sodium Dithionite*** or ***Sodium Sulfide*** and ***Sodium Hydroxide***.[2] An alternative is to treat the *N*-oxide with ***Thiourea*** and then hydrolyze the resulting thiouronium salt.

Handling, Storage, and Precautions: all operations in this area should be carried out with due regard to both the thermal and photochemical sensitivity of the reagents and intermediate *O*-acyl thiohydroxamates.

Preparation of *O*-Acyl Thiohydroxamates.

There are three commonly used options available for the preparation of *O*-acyl thiohydroxamates, outlined in eqs 1-

3.[1,4] Firstly, the carboxylic acid can be activated by conversion into a mixed anhydride from ***Isobutyl Chloroformate*** and then coupled directly with the pyridinethione (**1**). Alternatively, *O*-acyl thiohydroxamates (**2**) can be obtained using the DCC (***1,3-Dicyclohexylcarbodiimide***) coupling method (eq 1). If acid chlorides are used, these are best converted into the hydroxamates (**2**) by reaction with the sodium salt (**3**) in the presence of ***4-Dimethylaminopyridine*** (eq 2). A further option is to activate the pyridinethione component by formation of the bicyclic system (**4**) from the parent and ***Phosgene*** and then react this with the triethylammonium salt of the carboxylic acid (eq 3). Compound (**4**) is commercially available as 1-oxa-2-oxo-3-thiaindolizinium chloride (2-oxo-[1.4.2]oxathiazolo[2,3-*a*]pyridinium chloride).[1,4b] The latter two methods appear to be the most favored; the sensitive esters are used promptly with little purification, often just filtration through a short silica column.[3]

(1) **(2)**

(3) **(2)**

(4) **(2)**

Decarboxylation.

Perhaps the best-known application of this type of pyridinethione derivative in synthesis is in the overall, radical-mediated decarboxylation of carboxylic acids, i.e. RCO_2H -> RH (eq 4).[1,4b] The transformation is of a wide generality and usually proceeds in good to excellent yields. The chain carrier and hydrogen radical source is either ***Tri-n-butylstannane*** or a tertiary thiol, most often *t*-butanethiol (but see Barton and Crich[6]), and the reactions are generally triggered thermally when tin hydride is employed, or photolytically (tungsten lamp suffices) when a thiol is used.[5] The latter method offers considerable advantages in terms of product purification; for details of this aspect as well as sound advice on how to conduct these and related radical reactions in general, consult Motherwell and Crich.[1]

(4)

$X = Bu_3Sn$, *t*-BuS, $C_{11}H_{23}Me_2CS$

A wide variety of functionality can be incorporated into the substrate acids, such as in the decarboxylation of α-amino acid derivatives which leads to amines (eq 5).[4d] Application of this methodology to the appropriate aspartate and glutamate derivatives provides access to the useful radicals (**5**) which can be trapped in many ways, such as by halides (overall, a Hunsdiecker reaction),[4d] as can many other radical species obtained using this chemistry (see below).

(5)

(5)

Alcohol Deoxygenation.

A limitation of the useful Barton-McCombie procedure for the deoxygenation of alcohols is its application to tertiary alcohols because of difficulties in preparing the required xanthate or other derivatives. A solution to this is to first form a monoester with ***Oxalyl Chloride*** and then react the remaining acyl chloride function with the sodium salt (**3**) (eq 6).[6] In these reactions, although *t*-butanethiol is suitable as the chain carrier, in some cases 3-ethyl-3-pentanethiol gives superior yields (50-90%). The intermediate tertiary radicals can be trapped by powerful Michael acceptors such as 1,2-dicyanoethylene.

(6)

Decarboxylative Rearrangement.

When *O*-acyl thiohydroxamates are simply heated or photolyzed alone, a decarboxylative rearrangement occurs to give 71-92% yields of 2-thiopyridines (eq 7).[4b,7] While the thermal process involves some contribution from a cage recombination mechanism, the photolytic reaction is a purely radical chain process.

(7)

Formation of Sulfides, Selenides, Tellurides, and Selenocyanates.

When *O*-acyl thiohydroxamates are decomposed in the presence of disulfides, diselenides, or ditellurides, mixed sulfides, selenides, or tellurides are formed, respectively (eq 8).[8] If the reactions are triggered thermally, a large excess of the disulfide etc. has to be used to avoid competition from decarboxylative rearrangement (see above); however, light-induced reactions proceed at lower temperatures and, in such cases, only a slight excess of the trap is required. When the trapping agent is dicyanogen triselenide then selenocyanates, RSeCN, are produced.

Decarboxylative Sulfonation.

When a solution of an *O*-acyl thiohydroxamate in CH_2Cl_2 containing excess SO_2 is photolyzed at -10 °C, the initially formed radicals are intercepted by the latter before decarboxylative rearrangement can take place. The resulting radicals (RSO_2&bdot;) then react with a second molecule of the *O*-acyl thiohydroxamate to give an *S*-pyridyl alkylthiosulfonate (38-91%) and the radical R&bdot; (eq 9).[9] The products are useful as precursors to unsymmetrical sulfones and sulfonamides, significantly by a nonoxidative procedure.

The Hunsdiecker Reaction.

The classical Hunsdiecker reaction is somewhat restricted due to the relatively harsh conditions required. In the Barton version, alkyl radicals generated from *O*-acyl thiohydroxamates, under either thermal or photolytic conditions, are efficiently trapped either by Cl_3C-X (X = Cl or Br; Cl_3C&bdot; is the chain carrier) or by ***Iodoform***.[1,4b,10] The method is applicable to sensitive substrates for which the classical methods are unsuitable,[4d,11] thus allowing the preparation of a wide range of alkyl chlorides, bromides, and iodides by the one-carbon degradation of a carboxylic acid. Similar reactions of aromatic acid derivatives tend to require an additional radical initiator (e.g. ***Azobisisobutyronitrile***), if high yields (55-85%) are to be obtained.[12]

Decarboxylative Hydroxylation.

A close relative of the foregoing degradation, the transformation RCO_2H -> ROH can be carried out in two ways. Perhaps the most practical version consists of thermolysis or photolysis of an *O*-acyl thiohydroxamate, typically in oxygen-saturated toluene, followed by reduction of the initial hydroperoxide (eq 10).[4b,13] In similar fashion to decarboxylative sulfonation (see above), the intermediate radicals are trapped much faster (~10^4) by oxygen than by H-abstraction from the thiol chain carrier. As an alternative, the initial hydroperoxides can be *O*-tosylated in pyridine to give the corresponding nor-aldehyde or ketone (53-62%). The alternative, mechanistically more convoluted but still efficient and simple procedure (82-93%), has tris(phenylthio)antimony, $(PhS)_3Sb$, as the radical trap in the presence of both oxygen and water (in practice, wet air).[14]

(10)

Decarboxylative Phosphorylation.

In similar fashion to the foregoing, radicals generated by decomposition of an *O*-acyl thiohydroxamate can be trapped by tris(phenylthio)phosphine (eq 11).[15] In some cases, the use of alternative thiohydroxamates may be advantageous.

(11)

Michael Additions and Other Radical Reactions.

As decomposition of *O*-acyl thiohydroxamates provides radicals, these can subsequently participate in a variety of other reactions, the most common of which are Michael additions to electron-deficient alkenes. The most commonly successful pathway (eq 12) involves reaction of the intermediate carbon-centered radical adjacent to the electron-withdrawing group with a second molecule of the thiohydroxamate, rather than hydrogen abstraction, to give an α-*S*-pyridyl derivative,[1,6,7b] which can subsequently be manipulated in a variety of ways.[16] Other thiohydroxamates can lead to higher yields; the mildness and potential of this methodology is illustrated in eq 13.[17]

(12)

(13)

Similar reactions, but using nitroalkenes as traps, lead to the corresponding α-pyridylthio nitroalkanes, which are useful as precursors to the one-carbon homologated carboxylic acids, aldehydes, or the related ketones, by starting

with an α-substituted nitroalkene (eq 14).[7b,18]

(14)

Radicals derived from decarboxylation of perfluorocarboxylic acids will undergo addition to ethyl vinyl ether to provide the expected homologs in ~60% yields (eq 15).[19]

(15)

Protonated pyridines can also be used as acceptors of carbon radicals generated from thiohydroxamates in general.[20] A useful extension of the Michael addition reactions is to incorporate an additional *t*-butylthio substituent into the acceptor component (eq 16).[18b,21] Tandem reactions are also possible, as exemplified by the conversion of a cyclopentenecarboxylic acid into a bicyclo[2.2.1]heptane (eq 17).[22]

(16)

Carbon radicals obtained from thiohydroxamates can also be trapped intramolecularly by unactivated alkene functions especially in the 5-*exo*-trig mode,[7b,23] as can aminyl radicals generated in the same way; better yields of cyclic products are obtained in the presence of a weak acid which presumably protonates the *N*-centered radical prior to cyclization (eq 18).[24]

3-Hydroxy-2-pyrone[1]

[496-64-0] · $C_5H_4O_3$ · 3-Hydroxy-2-pyrone · (MW 112.09)

([4 + 2] cycloaddition vinylketene diene equivalent[2,3])

Physical Data: white, crystalline solid; mp 92 °C; mp (dihydrate) 80-85 °C; bp 112 °C/20 mmHg; sublimes at 50 °C/4 mmHg; λ_{max} 294 nm (H_2O).

Solubility: 4-5 g/100 mL H_2O; sol EtOH, Et_2O, $CHCl_3$, hot C_6H_6; slightly sol CS_2, petroleum ether.

Preparative Methods: acid-catalyzed decarboxylation-dehydration of mucic acid provides 3-hydroxy-2-pyrone in 20-40% yield: a three-neck round-bottom flask equipped with an overhead stirrer, thermometer, and distillation head is charged with a 1:1 mixture of mucic acid and powdered $KHSO_4$. The mixture is heated at 160-165 °C while ca. 1 mL of a light brown distillate per 2 g of mucic acid used is collected. The distillate is filtered and the pH adjusted to 7 using 6 N HCl. Continuous extraction with ether for ca. 12 h is followed by drying of the ether extract; concentration by rotary evaporation provides the crude product as a yellow solid. Recrystallization from petroleum ether or sublimation provides pure white crystalline material.[3,4] 3-Hydroxy-2-pyrone also has been prepared by oxidation of ***2-Pyrone***.[5]

A degradation product commonly formed in nonenzymic browning of fruits, 3-hydroxy-2-pyrone and its analogs are useful synthetic reagents. When used in Diels-Alder reactions, bicyclic lactone adducts result and these can be elucidated into a variety of highly functionalized, stereochemically defined cyclohexenes, cyclohexadienes, and benzenes.

Although unreactive towards simple alkenes, 3-hydroxy-2-pyrone undergoes slow [4 + 2] cycloadditions with reactive dienophiles, including maleates, maleic anhydride, acrylates, acrylonitriles, methacrylates, crotonates, benzoquinone, and acetylenedicarboxylates.[3,6-8] Reaction temperatures and times required for cycloaddition are in the range 80-200 °C for 2-72 h, so that pyrolytic decarboxylation of the adduct is common. Typical is the regio- and stereospecific synthesis of tricyclic ketones using the hydroxypyrone and indene (eq 1);[9] isolated chemical yields usually are good. Similarly, chloronaphthazarin (**1**) (eq 2) undergoes cycloaddition with 3-hydroxy-2-pyrone with in situ extrusion of CO_2 and dehydrochlorination to provide digitopurpone diacetate (**3**), a model compound for anthracyclinone construction.[10]

Inhibition of adduct decarboxylation can be achieved using high-pressure cycloaddition conditions, which proceed at temperatures 50-180 °C lower than the corresponding thermal conditions.[11] Eq 3 compares the results of thermal[3] and high-pressure[11] addition of methyl crotonate to 3-hydroxy-2-pyrone. Esterification of the 3-hydroxy group allows for asymmetric inverse electron demand, high-pressure Diels-Alder reactions, providing a stereoselective route to highly oxygenated cyclohexanes when vinyl ethers are used as dienophiles (eq 4).[12]

(3)

(quant)
3:2 mixture of diastereomers

(4)

73:27 mixture of diasteromers

Both thermal and high-pressure Diels-Alder dimerizations of 3-acetoxy-2-pyrone lead to a normal *endo* dimer (**4a**), which reverts to the monomer upon heating at the melting point. Photodimerization, on the other hand, leads to regioisomeric *exo* dimers, (**5**) and (**6**). The parent hydroxypyrone appears to polymerize under thermal or high-pressure conditions, but does yield a single photodimer (**4b**).[13] At very high temperatures, substituted 2-pyrones are known to undergo rearrangements through reversible ring opening to vinylketene aldehydes, which undergo a [1,5]-sigmatropic hydrogen shift before reclosing to the isomeric pyrone form.[14] These rearrangements normally are observed at temperatures exceeding 350 °C, and so should not lead to rearrangement adducts under typical thermal Diels-Alder reaction conditions.

(4a) R = OAc
(4b) R = OH

(5)

(6)

A series of reagents based upon the sulfur analog 3-mercapto-2-pyrone have been introduced[2] and are excellent alternatives to 3-hydroxy-2-pyrone. 3-*p*-Tolylthio-2-pyrone acts as a classical Diels-Alder diene; lactone adducts from reaction with acrylates, acrylonitrile, and methacrylates form in 42-70% yields at temperatures <=90 °C.[2] Inverse electron demand thermal Diels-Alder reactions of 3-*p*-tolylsulfinyl-[15] and 3-*p*-tolylsulfonyl-2-pyrone[16] with vinyl ethers or vinyl thioethers are highly efficient; cycloaddition proceeds at sufficiently mild temperatures so that decarboxylation of the lactone does not compete. These pyrones have been used in formal total syntheses of chorismic acid,[15,16] vitamin D_3 analogs,[17] and shikimates.[18] For example, 3-*p*-tolylsulfonyl-2-pyrone[19] undergoes highly diastereoselective, Lewis acid promoted,[20,21] inverse electron demand [4 + 2] cycloaddition with (*S*)-2-methyl-1-phenylpropyl vinyl ether to provide a sulfonyl lactone (eq 5),[22] which can be used to prepare (-)-methyl triacetyl-4-epishikimate.[18] Diastereoselectivity is considerably enhanced compared to cycloadditions using 3-acetoxy-2-pyrone[12] (e.g. eq 4).

N-Hydroxysuccinimide

[6066-32-6] · $C_4H_5NO_3$ · *N*-Hydroxysuccinimide · (MW 115.10)

(activating agent for carboxylic acids in amide synthesis and related coupling reactions; acyl transfer reagent)

Alternate Name: HOSu.

Physical Data: mp 96-98 °C (99-100 °C).

Solubility: sol H_2O, DMF, alcohols, EtOAc; insol cold ether.

Form Supplied in: colorless crystalline solid, widely available.

Preparative Methods: by heating ***Succinic Anhydride*** with ***Hydroxylamine*** or, better, hydroxylamine hydrochloride followed by crystallizations from ether, 1-butanol, and finally EtOAc.[1]

Purification: can be crystallized from 1-butanol, EtOAc, or EtOH-EtOAc.

Peptide Bond Formation.

The most important use of *N*-hydroxysuccinimide is in the formation of (isolable) activated derivatives of N^{α}-protected α-amino acids, which subsequently undergo generally smooth coupling reactions with amino esters. Typically, ***1,3-Dicyclohexylcarbodiimide*** (DCC) is used as the initial coupling agent (the HOSu-DCC method) (eq 1).[1-3] *N*-Hydroxyphthalimide can be employed in much the same way, but a distinct advantage in the case of HOSu is its high water solubility, which facilitates product purification.

In some cases, up to 3% racemization has been observed when using the HOSu-DCC method, which renders it unsuitable for some types of peptide synthesis.[4,5] Esters derived from HOSu are relatively reactive, as shown by a kinetic study of their rates of hydrolysis in aqueous buffers[6] although, in some examples, *endo-N*-hydroxy-5-norbornene-2,3-dicarboximide has proven superior to HOSu in peptide bond formation.[7] Of course, the HOSu-DCC method is not limited to peptide synthesis and is well suited to the preparation of amides in general, both from ammonia and primary amines (e.g. eq 2).[8]

In order to avoid the need for DCC, a number of activated derivatives of *N*-hydroxysuccinimide itself have been developed which react directly with, for example, an α-amino acid to provide the required activated α-amino acid esters. These include the commercially available carbonate (**1**), a stable crystalline solid obtained from HOSu and ***Trichloromethyl Chloroformate*** or from *O*-trimethylsilyloxysuccinimide and ***Phosgene***,[9] and the related phosphate (**2**) derived from HOSu and ***Diphenyl Phosphorochloridate*** under Schotten-Baumann conditions.[10] Another alternative (also commercially available) is the oxalate (**3**), formed from HOSu and ***Oxalyl Chloride***.[11] In general, these intermediates react rapidly with an N^{α}-protected α-amino acid, usually in the presence of a mild base such as pyridine, to provide excellent yields of the required hydroxysuccinimide esters, generally with less racemization than is sometimes associated with the HOSu-DCC method. It is also possible to carry out the entire process of peptide synthesis in one pot using these reagents.

(1)

(2)

(3)

A rather different approach to peptide bond formation and amide synthesis in general is to treat a mixture of a carboxylic acid and an amine with an isocyanide (***2-Morpholinoethyl Isocyanide*** is especially suitable), which effectively acts as a dehydrating agent (eq 3). The procedure can result in extensive racemization of both reactants and products which may be supressed by the addition of HOSu; presumably an HOSu ester is the penultimate intermediate.[12] The addition of HOSu also decreases racemization in polypeptide synthesis when Bates reagent $\{[(Me_2N)_3P^+]_2O\ (BF_4^-)_2\}$ is used as the coupling agent.[13]

$$R^1CO_2H + H_2NR^2 + R^3NC \longrightarrow R^1CONHR^2 + R^3NHCHO \qquad (3)$$

A rather unusual coupling reaction between HOSu and glyoxylic acid tosylhydrazone leads to succinimidyl diazoacetate (eq 4); again, the leaving ability of the HOSu residue renders this a useful compound for effecting the direct transfer of a diazoacetyl function to amines, phenols, and peptides.[14]

(4)

Modified Barton-McCombie intermediates are best prepared from pentafluorophenyl chlorothionoformate and a catalytic quantity (15-20%) of HOSu in refluxing benzene rather than by using ***4-Dimethylaminopyridine***, the rather more conventional catalyst of acyl group transfer (eq 5).[15]

[Hydroxy(tosyloxy)iodo]benzene[1]

[27126-76-7] · $C_{13}H_{13}IO_4S$ · [Hydroxy(tosyloxy)iodo]benzene · (MW 392.22)

(reagent for the phenyliodination and oxytosylation of various functional groups;[4] excellent Hofmann reagent;[16] useful for bis-lactonizations,[7] oxidations and oxidative transformations[20])

Alternate Names: HTIB; Koser's reagent; phenyliodine(III) (hydroxyl)tosylate.

Physical Data: nearly colorless crystalline solid (pale `yellow' cast); mp 140-142 °C,[2] 136-138.5 °C.[3]

Solubility: insol Et_2O; largely insol CH_2Cl_2, $CHCl_3$, MeCN (rt); moderately sol H_2O; sol MeCN (reflux), MeOH, DMSO.

Form Supplied in: white solid; commercially available in 96% purity.

Preparative Methods: conveniently prepared by the treatment of ***(Diacetoxyiodo)benzene***/MeCN mixtures with warm solutions of ***p-Toluenesulfonic Acid*** in MeCN. When the acid is introduced, $PhI(OAc)_2$ dissolves to give deep yellow solutions from which HTIB readily separates. If the reaction mixtures are kept near the reflux temperature, the crystallization of HTIB from the solvent can be controlled. At lower temperatures, HTIB separates more rapidly but can, if necessary, be recrystallized by heating the final mixtures of dissolution or from fresh MeCN. Preparations of HTIB can be readily conducted on a 50-100 g scale.

Handling, Storage, and Precautions: a fairly stable compound which may be stored at rt; for extended storage, keep refrigerated in a dark bottle.

General Considerations.

Although hydroxy(tosyloxy)iodobenzene is largely insoluble in CH_2Cl_2, $CHCl_3$, and MeCN at rt, all are excellent solvents for the mediation of HTIB reactions. When HTIB is employed in CH_2Cl_2, the completion of a reaction is

signaled by the disappearance of the crystalline phase as the iodane is consumed. Since HTIB/MeCN mixtures afford deep yellow solutions at the reflux temperature, reactions conducted under these conditions can sometimes be followed by the fading of the color. HTIB is soluble in MeOH and in this solvent may lead to products containing one or more methoxy groups. DMSO should probably be avoided since HTIB may be reduced by this solvent under some conditions. Acetone reacts with HTIB.

HTIB is mildly electrophilic at iodine and may conveniently be regarded as the chemical equivalent of hydroxy(phenyl)iodonium tosylate[Ph+IOH $^-$OTs]. Thus HTIB reacts with a variety of organic substrates to give either phenyliodonium tosylates or tosylate esters. Phenyliodination occurs first and whether such reactions proceed to the oxytosylation stage depends on the stability of the iodonium compounds toward nucleophilic collapse. HTIB is also a mild oxidizing agent.

Selected Transformations of Organic Functional Groups.

Alkenes, Dienes.

The treatment of alkenes with HTIB (CH_2Cl_2) affords *vic*-ditosyloxyalkanes.[4] Dioxytosylation is thought to be initiated by the *trans* addition of HTIB to the carbon-carbon double bond, and, with alkyl-substituted alkenes, ultimately proceeds with *cis* stereospecificity (eq 1). In some cases (i.e. norbornene, neat styrene), dioxytosylation is accompanied by skeletal rearrangements. Several dienes have been observed to undergo conjugate dioxytosylation with HTIB but the 1,4-ditosyloxyalkenes are not very stable, and the yields are low.[4,5]

(1)

Alkenoic and Alkenedioic Acids.

Participation of the carboxyl group occurs when unconjugated alkenoic acids are mixed with HTIB.[6] Of seven alkenoic acids studied, five gave tosyloxylactones (eq 2). In two cases, TsOH was eliminated, and unsaturated lactones[6] were obtained, elimination apparently being favored by alkyl substitution at the carbon-carbon double bond. The oxytosyllactonization of 5-norbornene-*endo*-2-carboxylic acid proceeds with skeletal rearrangement. Alkenic dicarboxylic acids react with HTIB (CH_2Cl_2, rt) to give bis-lactones (eq 3).[7] More significantly, bis-lactonization proceeds with *cis* stereospecificity. The mildness and operational convenience of the HTIB procedure recommend this approach as an excellent alternative to methods requiring the treatment of alkenedioic acids or their tetrabutylammonium salts with an excess of ***Lead(IV) Acetate***[8] or the treatment of silver alkenedioates with ***Iodine/Silver(I) Acetate*** .[9]

(2)

Alkynes.

Terminal alkynes react with HTIB in $CHCl_3$ under reflux to give either alkynyl(phenyl)iodonium tosylates, β-tosyloxyvinyl(phenyl)iodonium tosylates, or mixtures of both.[10] The production of alkynyliodonium salts is favored by the presence of either aryl or bulky alkyl (e.g. *t*-Bu, *s*-Bu) groups in the alkyne (eq 4), while terminal alkynes with linear alkyl groups lead exclusively to the vinyliodonium compounds (eq 5). A desiccant (silica bead) has been employed with HTIB in CH_2Cl_2 (rt) to facilitate the alkynyliodonium pathway with propyne and 1-hexyne, but the product yields were low.[11] Internal alkynes afford β-tosyloxyvinyliodonium tosylates with HTIB.[10] When HTIB is employed in methanol, both terminal and internal alkynes undergo oxidative rearrangement to give carboxylate esters, $R^1R^2CHCO_2Me$.[12]

Ketones, β-Dicarbonyl Compounds, Silyl Enol Ethers, Silyl Ketene Acetals.

The treatment of ketones with HTIB (MeCN or CH_2Cl_2) affords α-toxyloxy ketones (eq 6),[13] presumably via α-phenyliodonio ketone tosylates [RCOC+IPh,$^-$OTs]. Silyl enol ethers (CH_2Cl_2, rt) also afford α-tosyloxy ketones with HTIB and can be employed to direct the regiochemistry of oxytosylation, while esters can be functionalized at α-carbon via their silyl ketene acetals (eq 7).[14] The conversion of β-dicarbonyl compounds to their α-toxyloxy derivatives with HTIB has also been demonstrated.[13] The reactions of 5-oxo- and 4,6-dioxocarboxylic acids with HTIB (CH_2Cl_2) eventuate in the production of keto and diketo lactones (eq 8).[15]

(6)

(7)

(8)

Carboxamides.

One of the most useful applications of HTIB is for the conversion of aliphatic primary carboxamides to amines (MeCN, reflux); the amines separate from the solvent (on cooling) as their hydrogen tosylate salts (eq 9).[16] This is a particularly advantageous method for the production of amines from long-chain amides,[17] which afford low yields (or none) of amines under the standard conditions (e.g. NaOH/Br_2, Δ) for the Hofmann reaction. The synthesis of bridgehead amines from carboxamides in the adamantane, cubane, and homocubane series of compounds has also been described.[18] Such reactions proceed via intermediate *N*-phenyliodoniocarboxamide tosylates [RCONH+IPh$^-$OTs] and their rearrangement with loss of TsOH and iodobenzene to alkyl isocyanates.[19] This is not a good method for the preparation of aromatic amines since they can be oxidized by HTIB as they are produced.

(9)

Further Applications of HTIB.

The synthetic utility of HTIB is further underlined by its use for the oxidation of allenes and allenyl ethers (CH_2Cl_2) to aldehydes or ketones,[20] the ligand-transfer oxidation of iodoarenes to give [hydroxy(tosyloxy)iodo]arenes (CH_2Cl_2),[21] the oxidative deiodination of alkyl iodides to alkyl tosylates ($CHCl_3$ or CH_2Cl_2),[22] including cubyl and homocubyl examples,[23] and as an iodination `catalyst' for the conversion of alkynols to α- and/or β-iodoenones.[24] Various [hydroxy(toxyloxy)iodo]arenes, ArI(OH)OTs, have been employed for the synthesis of diaryliodonium, aryl(2-furyl)iodonium, and aryl(2-thienyl)iodonium tosylates.[25] HTIB has also been used for the conversions of flavanones to flavones (MeOH)[26] and isoflavones (MeCN),[27] aromatic ketones to methyl arylalkanoates (MeOH or $(MeO)_3CH$),[28] chalcones to deoxybenzoins containing the $(MeO)_2CH$ group at the α-carbon (MeOH),[29] and flavonols to their *vic*-dimethoxy adducts (MeOH).[30]

Analogs of HTIB.

Various derivatives of HTIB with substituents in the iodoarene nucleus, ArI(OH)OTs,[21,25,31,32] and three arenesulfonyloxy analogs[33] have been reported. [Hydroxy(mesyloxy)iodo]benzene, $PhI(OH)O_3SMe$,[11,14,23,34,35] and [hydroxy((+)-10-camphorsulfonyloxy)iodo]benzene[36] are also known. [Hydroxy((bis(phenyloxy)phosphoryl)oxy)iodobenzene], $PhI(OH)OP(O)(OPh)_2$, shows considerable potential for phosphate ester synthesis. Thus far, the α-oxyphosphorylation of ketones and β-dicarbonyl compounds,[37] the oxyphosphoryllactonization of alkenoic acids,[37] and the conversion of terminal alkynes[38] to monoketol phosphates with HPIB have been reported.

3-Hydroxy-3*H*-1,2,3-triazolo[4,5-*b*]pyridine

[39968-33-7] · $C_5H_4N_4O$ · 3-Hydroxy-3*H*-1,2,3-triazolo[4,5-*b*]pyridine · (MW 136.13)

(coupling additive for peptide synthesis[1-4])

Alternate Names: HOAt; 7-aza-1-hydroxybenzotriazole.

Physical Data: mp: sample decomposes at temperatures above 205 °C.

Solubility: sol DMF.

Form Supplied in: white solid; commercially available.

Purification: by crystallization from ethanol or water.

Handling, Storage, and Precautions: is very stable, not hygroscopic, and can be stored indefinitely. HOAt solutions in DMF (0.3 M) can be stored in an inert atmosphere for weeks. Syntheses of peptides carried out with freshly prepared and 4-week old solutions show similar quality for the crude product.[5] Violent decomposition may occur when dried at elevated temperatures.

General Considerations.

HOAt is the 7-aza derivative of ***1-Hydroxybenzotriazole*** (HOBt), the most common peptide coupling additive.[6,7] These reagents are employed to decrease racemization, inhibit side reactions such as formation of *N*-acylurea, and increase yield and purity during peptide assembly. These compounds are used in conjunction with carbodiimides or active esters such as the pentafluorophenyl ester or built into stand-alone reagents such as ***N-[(Dimethylamino)-1H-1,2,3-triazolo[4,5-b]pyridin-1-ylmethylene]-N-methylmethanaminium Hexafluorophosphate N-Oxide*** (HATU) and 7-azabenzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate (PyAOP). Although known for many years, HOAt[8-12] has only recently been applied as an additive in peptide synthesis. The greater effectiveness of HOAt relative to HOBt is shown by its use in the coupling of 2-phenylpropionic acid with the highly hindered secondary amine (**1**) (eq 1), a reaction difficult to achieve in the presence of HOBt.[1]

(1)

The extent of racemization during stepwise and segment condensation methods for the assembly of peptides in solution via ***1,3-Dicyclohexylcarbodiimide*** (DCC) or ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride*** (EDC) in the presence of HOAt and HOBt has been examined. When the amino acid ester is used as a salt, various bases such as ***Diisopropylethylamine*** (DIPEA), *N*-methylmorpholine (NMM), and ***1,8-Bis(dimethylamino)naphthalene*** (Proton Sponge, PS) were also needed (eq 2) (Table 1). In all examples, racemization was lowered when HOBt was replaced with HOAt (run 1 vs. 2, 3 vs. 4, 5 vs. 6, 8 vs. 9). The level of epimerization was further lowered when methylene chloride (DCM) was substituted for DMF as the solvent (runs 8 vs. 10).[1]

(2)

Table 1 Racemization during HOAt/HOBt-Mediated Carbodiimide Couplings in DMF Solution

Entry	RCOOH	R¢NH$_2$ or R¢NH$_2$·HCl	Conditions	DL-isomer (%)
1	Z Phg OH	H Val OMe·HCl	HOAt, EDC, PS (1 equiv) 9 h	<1 2
2	Z Phg OH	H Val OMe·HCl	HOBt, EDC, PS (1 equiv) 9 h	3.7
3	Z Phe Val OH	H Ala OMe·HCl	HOAt, EDC, NMM (1 equiv) 1.25 h	<1 2
4	Z Phe Val OH	H Ala OMe·HCl	HOBt, EDC, NMM (1 equiv) 2.25 h	4.1
5	Bn Val OH	H Val OMe·HCl	HOAt, EDC, NMM (1 equiv) 20 h	28.1
6	Bn Val OH	H Val OMe·HCl	HOBt, EDC, NMM (1 equiv) 20 h	45.4
7	Bn Val OH	H Val OMe	DCC, 24 h	61.5
8	Bn Val OH	H Val OMe	HOAt, DCC, 24 h	14.4
9	Bn Val OH	H Val OMe	HOBt, DCC, 24 h	41.9
10	Bn Val OH	H Val OMe	HOAt, DCC, DCM, 24 h	<1 2

HOAt has also been applied to automated stepwise solid-phase synthesis via the Fmoc/*t*-Bu strategy.[2,3,5] The effectiveness of HOAt-based reagents was demonstrated in the assembly of the acyl carrier protein fragment 65-74 (H-Val-Gln-Ala-Ala-Ile-Asp-Tyr-Ile-Gln-Gly-NH$_2$). Coupling times and excesses of reagents (amino acid and activator) were reduced in order to exaggerate poor couplings. In *N*,*N*′-diisopropylcarbodiimide and pentafluorophenyl-mediated couplings, the superiority of HOAt over HOBt was clearly shown in terms of greatly enhanced purity. The extent of amino acid deletions depended on the exact conditions. Addition of HOXt in the case of guanidinium or phosphonium salt-based couplings did not significantly improve the coupling yield.

Solid-phase segment couplings were also aided by the use of HOAt. In a model study, Fmoc-Phe-Ser(*t*-Bu)-OH was coupled to H-Pro-PAL-PEG-PS-resin.[3,13] With HOAt in the presence of DCC, the extent of racemization was lowered

dramatically relative to HOBt. A more complex example involved synthesis of the *N*-terminal domain of γ-zein protein by eight repetitive couplings of the appropriate protected hexapeptide.[14]

N-Methyl amino acids are often very difficult to couple cleanly and in good yield, especially by solid-phase techniques. Excellent results were obtained for DIPCDI/HOAt-mediated couplings, leading to various cyclosporin (CsA) segments, including H-MeLeu-MeLeu-Ala-NH_2, H-Val-MeLeu-Ala-NH_2, and H-MeLeu-MeVal-Ala-NH_2, all of which were obtained in >99% yield.[15]

The HOAt-based uronium salt 1-(1-pyrrolidinyl-1*H*-1,2,3-triazolo[4,5-*b*]pyridin-1-ylmethylene)pyrrolidinium hexafluorophosphate *N*-oxide (HAPyU) was employed in solution for the efficient cyclization of a linear hexapeptide constructed exclusively from L-amino acids. Such systems are difficult to cyclize without *C*-terminal racemization.[16]

Significant improvements in the synthesis of phosphonamidate peptides were achieved via the HOAt esters of the phosphonochloridates (eq 3).[17]

2-Hydroxy-1,2,2-triphenylethyl Acetate[1]

(*R*)

[95061-47-5] · $C_{22}H_{20}O_3$ · 2-Hydroxy-1,2,2-triphenylethyl Acetate · (MW 332.42) (*S*)

[95061-51-1]

(enantiopure acetate for stereoselective aldol addition of the dilithioenolate to aldehydes to give chiral nonracemic β-hydroxy acids)

Alternate Name: HYTRA.

Physical Data: mp 239 °C (toluene); (*R*) [α]20D (*c* = 1, pyridine) +215° to +217°; (*S*) [α]20D (*c* = 1, pyridine) -214° to -216°.

Solubility: sol pyridine, boiling toluene; slightly sol THF, chloroform, cold toluene.

Form Supplied in: white solid; both isomers are commercially available.

Stereoselective Aldol Reactions.

The (*R*)- and (*S*)-2-hydroxy-1,2,2-triphenylethyl acetates (HYTRA) offer a simple solution for a stereoselective aldol addition of α-unsubstituted enolates. When a suspension of HYTRA is treated in THF with 2 equiv of ***Lithium Diisopropylamide***, a clear solution of the enolate forms (eq 1). Subsequent dilution with 2-methylbutane followed by the addition of 2-methylpropanal affords predominantly the (*R*,*R*)-diastereomeric adduct. Alkaline hydrolysis not only delivers (*R*)-3-hydroxy-4-methylpentanoic acid in 86-94% ee but also liberates the optically pure auxiliary reagent (*R*)-1,2,2-triphenylethane-1,2-diol, which can be removed and reused (eq 1).[2,3]

The diastereoselectivity has been enhanced by a transmetalation of the lithium enolate with ***Magnesium Bromide*** or ***Magnesium Iodide*** prior to the addition of benzaldehyde (eq 2).[3-5]

On the other hand, enantiomeric excesses up to 94% are reached even at -78 °C, provided that ***Lithium Hexamethyldisilazide*** (LHMDS) (3 equiv) is used for deprotonation instead of LDA (2 equiv) (eq 3).[6]

(3)

Predictable *lk*-topicity [i.e. (*R*)-enolate attacks predominantly the *re*-face of the carbonyl group whereas the (*S*)-reagent approaches predominantly from the *si*-face] has been observed in all additions of doubly deprotonated HYTRA to achiral as well as to enantiomerically pure aldehydes.[7,8] The aldol reaction of HYTRA has been used for the syntheses of natural products such as shikonin and alkannin,[9] D- and L-digitoxose (**1**),[10] FK506,[11] statin (**2**)[8] and analogs,[12] detoxinine (**3**)[13] and tetrahydrolipstatin (**4**).[14] Besides compactin and mevinolin (**5**),[15] a series of nonnatural HMG-CoA reductase inhibitors which serve as hypocholesterolemic agents have been synthesized by this method.[6,16] Peptide isosters,[17] deoxy- and aminodeoxyfuranosides,[18] 3-amino-2-hydroxybutanoic acid (GABOB) (**6**)[19] and intermediates for the preparation of antidepressants[20] are available as well.

(1) L-Digitoxose

(2) R = $CHMe_2$: Statin
R = Ph, cyclohexyl: Statin analogs

(3) Detoxinine

(4) Tetrahydrolipstatin

(5) R = H: Compactin
R = Me: Mevinolin

(6) *(R)*-GABOB

Related Reagents.

Boron Triiodide; ***(R)-2-t-Butyl-6-methyl-4H-1,3-dioxin-4-one***; ***(S)-4-Benzyl-2-oxazolidinone***; ***(R,R)-1,2-Diphenyl-1,2-diaminoethane N,N´-Bis[3,5-bis(trifluoromethyl)benzenesulfonamide]***; ***trans-2,5-Bis(methoxymethyl)pyrrolidine***; ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium***; ***10-Dicyclohexylsulfonamidoisoborneol***; ***Diisopinocampheylboron Trifluoromethanesulfonate***; ***α-Methyltoluene-2,α-sultam***; ***1,1,2-Triphenyl-1,2-ethanediol***.

Hypobromous Acid

HOBr

[13517-11-8] · BrHO · Hypobromous Acid · (MW 96.91)

(preparation of bromohydrins[5,8,12] by addition to alkenes; brominating reagent[3] and oxidant[4])

Solubility: sol H_2O, H_2O-DMSO, H_2O-acetone, H_2O-dioxane, H_2O-DME.

Form Supplied in: stable only in solution;[1,2] usually prepared in situ immediately before use.

Preparative Methods: traditional preparative methods[2-4] are the addition of ***Bromine*** to aqueous mixtures of mercury or silver salts to precipitate the bromide ion formed as a byproduct. Newer methods employ a source of positive bromine such as ***N-Bromosuccinimide***,[5-7] ***N-Bromoacetamide***,[8,9] or ***1,3-Dibromo-5,5-dimethylhydantoin*** (dibromantin)[10] to generate the equivalent to HOBr in aqueous solution.

Handling, Storage, and Precautions: strong oxidant; use in a fume hood.

Bromohydrin Synthesis.

The title reagent (**1**) usually adds to unhindered alkenes following Markovnikov's rule, in which the initial electrophilic adduct is a bromonium ion (eqs 1 and 2).[5,11] The resulting carbocation or bridged bromonium ion then reacts with hydroxide or water to yield the product bromohydrin.[8] Reactions are generally run in water or solutions of water and DMSO, acetone, or dioxane at 0-25 °C, although aqueous DME at -20 °C has also been employed (eqs 1 and 2).[7] Reactions run in moist DMSO generate bromohydrins in a regiospecific and stereospecific fashion with a minimum of rearrangement.[12] The role of the solvent in the reaction has been demonstrated by radiolabeling.[5]

(1)

(2)

Participation by a neighboring functional group may influence the regioselectivity of HOBr addition.[6,7,9] Oxime-assisted bromonium ion reaction has been invoked in the formation of a bromohydrin intermediate to the neurotoxin (±)-perhydrohistrionicotoxin (eq 3).[7] Similarly, participation by the 7-acetoxy group results in a single bromohydrin product in the addition of HOBr to a cholestane derivative (eq 4).[9]

(3)

(4)

Oxidation and Bromination.

The title reagent has been employed in the oxidation of a thiazole thiourea to a thiazolo[3,2-*b*]thiadiazoline (eq 5).[4] Reaction of HOBr with a variety of aryl methyl ketones yields ring-brominated products in a rapid reaction at rt.[3]

(5)

Related Reagents.

Hypochlorous Acid is utilized as an oxidant and for the preparation of chlorohydrins in a manner analogous to that of (**1**).

Hypochlorous Acid

HOCl

[7790-9-3] · ClHO · Hypochlorous Acid · (MW 52.46)

(preparation of chlorohydrins[6-9] and allylic chlorides[5,11] by addition to alkenes; chlorinating reagent[4] and oxidant[12])

Solubility: sol H_2O, Et_2O, CH_2Cl_2.

Form Supplied in: stable only in solution;[1,2] usually prepared in situ immediately before use. Most preparations are in water, water-acetone, or water-dioxane solutions under acidic conditions at 0-25 °C. The reagent can also be extracted into ether or other organic solvents for use under nonaqueous reaction conditions.

Analysis of Reagent Purity: standardized by iodometric titration.

Preparative Methods: traditionally prepared[3] by addition of ***Chlorine*** to a cold aqueous solution of ***Sodium Hydroxide*** and ***Mercury(II) Chloride*** to generate NaOCl. Careful acidification then liberates HOCl. A more convenient procedure is the use of commercial bleach (stabilized 5.25% ***Sodium Hypochlorite*** solution)[4] or 70% ***Calcium Hypochlorite***.[5] Reagents such as ***Chloramine-T***,[6] ***N-Chlorosuccinimide***,[7] and chlorourea[8] serve as equivalents to HOCl by the production of a positive Cl species in aqueous solution.

Handling, Storage, and Precautions: strong oxidizing agent; use in a fume hood.

Chlorohydrin Synthesis.

The title reagent (**1**) usually adds to unhindered alkenes following Markovnikov's rule, in which the initial electrophilic adduct is a chloronium ion (eqs 1 and 2).[7,8] The resulting carbocation or bridged chloronium ion then reacts with hydroxide or water to yield the product chlorohydrin. In some instances, anti-Markovnikov and dichloride side products are also observed.[9] α,β-Unsaturated acids, esters, nitriles, aldehydes, and ketones with an unsubstituted α-hydrogen predominantly add Cl to the α-position and OH to the β-position.

(1)

(2)

Allylic Chloride Synthesis.

Reaction of (**1**) with highly substituted alkenes[5] or conjugated ketones[10] in a two-phase reaction mixture yields allylic chlorides rather than chlorohydrins (eq 3). Other functional groups, such as alcohols, aldehydes, epoxides, ethers, esters, ketones, and nitriles, are generally unaffected. In some cases, a mixture of allylic chloride and vinyl chloride products is obtained. This reaction has been applied to (+)-carvone and (+)-limonene in a synthetic route to various monocyclic sesquiterpenes.[11]

(3)

Oxidation and Chlorination.

The title reagent has been used to oxidize a cyclic acetal in the preparation of optically active α-amino acids (eq 4).[12]

Oxidation by hypochlorite solutions is used industrially on a large scale for bleaching and sterilization applications.

Aqueous (**1**) at 25 °C rapidly transforms cyclic oximes into α-chloronitroso derivatives, which are intermediates in the preparation of secondary nitro compounds (eq 5).[4] Maintaining a pH of 5.5 in the chlorination medium was found to be critical in this reaction.

Related Reagents.

Hypobromous Acid is utilized as an oxidant for the preparation of bromohydrins in a manner analagous to that of (**1**). Direct chlorohydroxylation of alkenes can be achieved with ***t-Butyl Hydroperoxide*** or ***1,1-Di-t-butyl Peroxide*** and ***Titanium(IV) Chloride***,[13] as well as with ***Chlorotrimethylsilane*** and 30% ***Hydrogen Peroxide***.[14] Since these peroxide reactions probably proceed through an epoxide intermediate, the resulting chlorohydrin is the opposite regioisomer from that obtained by addition of (**1**).

Hypofluorous Acid[1]

HOF

(HOF)

[14034-79-8] · FHO · Hypofluorous Acid · (MW 36.01) (HOF.MeCN)

[147583-45-7] · C_2H_4FNO · Hypofluorous Acid-Acetonitrile · (MW 77.07)

(the HOF.MeCN complex is used for tertiary hydroxylations,[2] epoxidations,[3] and oxidation of amines,[4] alcohols and ketones,[5] aromatics,[6] and sulfides[7])

Physical Data: mp -117 °C; bp -79 °C/1 mmHg; ^{19}F NMR δ +27.5 ppm (of the MeCN complex, -8.5 ppm).

Handling, Storage, and Precautions: HOF is a very unstable substance and of little use in synthetic chemistry. Neat liquid HOF can be unpredictably explosive at temperatures above -40 °C. Its acetonitrile complex is much more stable but nevertheless has to be prepared in situ and, for all practical purposes, has to be reacted soon after its formation. The concentration of the reagent is determined iodometrically (HOF + 2KI -> I_2 + KF + KOH). Both forms of the hypofluorous acid may be toxic and should be treated accordingly. Use in a fume hood.

Epoxidation.

HOF was synthesized originally by Appelman,[8] but it was hardly a useful synthetic reagent since it was difficult to make and could be generated only in very minute amounts. Still, it was demonstrated that it can react with a few unsaturated compounds.[9] Recently, it was discovered that HOF can be prepared simply by passing ***Fluorine*** through aqueous ***Acetonitrile***, thus forming a stabilized complex HOF.MeCN.[3,10] Possessing a strong electrophilic oxygen, it is an excellent oxygen transfer agent which epoxidizes a wide variety of alkenes (eq 1),[3a,c] including very deactivated ones which cannot be directly epoxidized by any other method (eq 2).[3b]

Other Oxidations.

The electrophilic properties of the oxygen have been put to use for attacking the deactivated, relatively electron-rich, tertiary C-H bond, resulting in tertiary hydroxylation as demonstrated, for example, by 4-*t*-butylcyclohexanol acetate (eq 3).[2] Being a strong oxidizer, HOF.MeCN can oxidize amines to the corresponding nitro derivatives (eq 4),[4] alcohols to ketones (eq 5),[5] and sulfides to sulfones.[7] The reactions proceed at 0 °C, in a few minutes and usually in very good yields. On prolonging the reaction time and using an excess of reagent, ketones are also oxidized to the corresponding esters much faster than with the peroxy acids used in the conventional Baeyer-Villiger oxidation (eq 5).[5] The reagent can also hydroxylate and otherwise oxidize many aromatic compounds (eq 6), although yields are moderate.[6] It should be mentioned that ***Xenon(II) Fluoride***/H_2O form in situ HOXeF, which adds the elements of H and OF across some alkenes (eq 7).[11]

Hypophosphorous Acid[1]

H_3PO_2

[6303-21-5] · H_3O_2P · Hypophosphorous Acid · (MW 66.00) (tautomer)

[14332-09-3]

(reduction of aromatic diazonium salts,[1,2] nitro compounds,[3] and pyrrole derivatives;[4] synthesis of organic derivatives of hypophosphorous acid;[1,5,6] generation of selenols[7])

Alternate Name: HPA.

Physical Data: mp 26.5 °C; decomposes at 140 °C; *d* 1.493 g cm^{-3} (19 °C); pK_a 1.1.

Solubility: sol water, alcohol, ether, dioxane.

Form Supplied in: widely available as 50% aqueous solutions (*d* 1.274 g mL^{-1}).

Preparative Methods: the anhydrous acid is prepared from the commercial solution or from inorganic salts.[1,8]

Handling, Storage, and Precautions: decomposes upon heating above 140 °C into H_3PO_4 and poisonous, spontaneously flammable PH_3. Slowly decomposes at rt. Air sensitive. Use in a fume hood.

Reduction of Arenediazonium Compounds.

Hypophosphorous acid is widely accepted as the preferred reagent for the reduction of diazonium salts.[1,2,9] ***Copper(I) Oxide*** is a very effective catalyst of this reaction[9] (eq 1). Dediazonation with HPA can also be used in Pschorr-type cyclizations.[10]

(1)

Alkylphosphinic Acids.

Radical addition of HPA or its alkali salt to alkenes is initiated by organic peroxides and gives phosphinic acid derivatives in good yields (eq 2).[1,6,11,12] The alkene to HPA ratio controls the formation of alkyl- or dialkylphosphinic acid.[1,11] Alkyl phosphinates also add to alkenes in the presence of peroxides.[1] Alkylphosphinic acids can be prepared from HPA and alcohols,[13] and alkenylphosphinic acids have been obtained from enol esters.[14]

(2)

Hydroxyalkylphosphinic Acids.

HPA reacts with aldehydes, ketones, and 1,2-ketones to provide 1-hydroxyalkylphosphinic acids (eq 3).[1] When carbonyl compounds are used in excess, bis(1-hydroxyalkyl)phosphinic acids are formed.

(3)

1,2-Alkadienylphosphinic Acids.

Reactions of HPA with alkynic alcohols are accompanied by alkyne-allene rearrangement and lead to 1,2-alkadienylphosphinic acids (eq 4).[15]

Aminoalkylphosphinic Acids.

HPA reacts with azomethines under mild conditions, providing good yields of 1-(alkylamino)alkylphosphinic acids.[1] Synthetic possibilities of this reaction have been extended by replacing the azomethines with a mixture of aldehyde or ketone and amine or hydrazine.[6,16] Thus reaction of HPA with equimolar amounts of formaldehyde and secondary amines at rt in aqueous solution gives the corresponding dialkylaminophosphinic acids (eq 5). With an excess of amine and formaldehyde, bis(dialkylaminoalkyl)phosphinic acids are formed.[1,16]

Alkyl Hypophosphites.

A particularly easy preparation of alkyl hypophosphites involves the reaction of crystalline HPA with orthocarbonyl compounds (eq 6).[5] Treatment of HPA with diazoalkanes also gives good yields of the desired esters.[17] Reaction of HPA with orthoformates in the presence of ***p-Toluenesulfonic Acid*** leads to the formation of alkyl dialkoxymethylphosphinates.[18]

Reduction with Hypophosphorous Acid.

Palladium on Carbon catalyzed reduction with HPA converts the nitro group of arenes into an amino group,[3] and quinones into hydroquinones.[19] HPA in combination with ***Hydrogen Iodide*** is used for reduction and reductive alkylation of pyrrole derivatives.[4]

Selenols.

A commercial 50% solution of HPA is a convenient reagent for generation of selenols from diselenides or selenic acids.[7]

Imidazole

[288-32-4] · $C_3H_4N_2$ · Imidazole · (MW 68.09)

(nucleophilic catalyst for silylations and acylations; buffer; weak base; iodination methods)

Alternate Names: Im; iminazole; 1,3-diazole; glyoxaline.

Physical Data: mp 90-91 °C; bp 255 °C, 138 °C/12 mmHg.

Solubility: sol water, alcohols, ether, acetone, chloroform.

Form Supplied in: colorless crystalline solid; widely available. *Drying:* 40 °C in vacuo over P_2O_5.

Purification: can be crystallized from C_6H_6, CCl_4, CH_2Cl_2, EtOH, petroleum ether, acetone-petroleum ether, or water; can also be purified by vacuum distillation, sublimation, or by zone refining.

Introduction.

Imidazole has a pK_a of 7.1 and is thus a stronger base than thiazole (pK_a 2.5), oxazole (pK_a 0.8), and pyridine (pK_a 5.2). It is both a good acceptor and donor of hydrogen bonds. The pK_a for loss of the N-H is ~14.2, i.e. imidazole is a very weak acid.

Silylations.

Imidazole is a standard component in silylations of alcohols as well as carboxylic acids, amines, and a variety of other functions, typically in combination with a silyl chloride in DMF (eq 1).[1] A very widely used procedure for alcohol protection is by conversion into the corresponding *t*-butyldimethylsilyl (TBDMS or TBS) ether using the method;[2] in other solvents such as pyridine or THF the reactions are much slower, probably because the primary silylating reagent is *t*-$BuMe_2Si$-Im. In this and many other aspects, imidazole resembles another very useful transfer catalyst, ***4-Dimethylaminopyridine*** (DMAP). Similarly, bulkier and hence more stable silyl groups, such as *t*-butyldiphenylsilyl (TBDPS)[3] and triisopropylsilyl (TIPS),[4] can be introduced. Times for completion of reaction at 20 °C vary (0.5-20 h);

these silylating agents, originally developed for nucleoside protection,[5] usually react faster with primary alcohols and with certain secondary alcohols, thus allowing selective protection of polyols to be achieved efficiently. (A faster alternative involves the use of ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** (DBU) in place of imidazole, in a variety of solvents such as CH_2Cl_2, C_6H_6, or MeCN, in combination with R_3SiCl).[6] 1,3-Diones can be efficiently *O*-silylated using TBDMSCl-Im[7] or ***Hexamethyldisilazane*** (HMDS) and imidazole;[8] other reagents are not as suitable, even in cases where the enol content is high. The products are useful as *trans*-silylating agents.[7] The HMDS-Im combination is also useful for the silylation of thiols.[9]

(1)

Ester Hydrolysis.

Inspired by evidence that the imidazole ring of histidine residues present in various hydrolytic enzymes is responsible for their proteolytic activities, imidazole itself has been shown to be an excellent catalyst of ester hydrolysis (e.g. eq 2).[10] In intramolecular transesterifications and hydrolyses of 2-hydroxymethylbenzoic acid derivatives, the accelerating role of imidazole is due to its ability to act as a proton transfer catalyst rather than as a nucleophile.[11]

(2)

Peptide Coupling.

Peptide couplings involving *p*-nitrophenyl and related esters (see ***p-Nitrophenol***) are dramatically accelerated by the addition of imidazole.[12] However, such reactions, which probably proceed by way of an acylimidazole, can be prone to racemization, in which case ***1,2,4-Triazole*** can be a superior activator.[13] Imidazole also catalyzes peptide coupling using the ***Triphenyl Phosphite*** method, with negligible racemization when the reactions are carried out in dioxane or DMF,[14] and is useful for the activation of phosphomonoester groups in nucleotide coupling, in combination with an

arylsulfonyl chloride.[15]

Acylimidazoles and Nucleophiles.

Acylimidazoles are readily prepared from the parent carboxylic acids by reaction of the derived acid chloride with imidazole or directly using ***N,N´-Carbonyldiimidazole***. These intermediates react smoothly with a variety of nucleophiles including Grignard reagents (eq 3),[16] ***Lithium Aluminum Hydride*** (eq 4),[16] and nitronates (eq 5).[17] At -20 °C, aroylimidazoles can be reduced to the corresponding aldehydes in the presence of an ester function.[16]

(3)

(4)

(5)

The activation provided by an imidazole substituent is further illustrated in a route to 1,3-oxathiole-2-thiones from sodium 1-imidazolecarbodithioate, derived from the sodium salt of imidazole and CS_2 (eq 6).[18]

(6)

Other Uses.

Imidazole is one of the best catalysts for the preparation of acid chlorides from the corresponding carboxylic acids and phosgene.[19] Aryl triflates can be obtained from phenols, or better phenolates, using ***Trifluoromethanesulfonic Anhydride*** in combination with imidazole; *N*-triflylimidazole is the reactive species.[20] Photochemical deconjugations of enones can be erratic but are promoted by the presence of a weak base such as imidazole or pyridine in polar solvents.[21]

Iodination of Alcohols.

Imidazole, ***Triphenylphosphine***, and ***Iodine*** in hot toluene,[22] or preferably toluene-acetonitrile mixtures,[23] is an excellent combination for the conversion of alcohols into iodides, ROH -> RI. Secondary alcohols react with inversion (but see below), although the method can be used for the selective iodination of primary hydroxyls. Applications in the area of natural product synthesis[24] emphasize the mildness and generality of the method as well as providing alternative recipes; sometimes, 2,4,5-triiodoimidazole can be a superior reagent.[22] Similarly, Ph_3P-Cl_2-Im can be used for the preparation of alkyl chlorides, ROH -> RCl, and the addition of imidazole in the ***Triphenylphosphine-Carbon Tetrachloride*** method for alcohol chlorination has a beneficial effect.[25]

Diol Deoxygenation.

The Ph_3P-Im-I_2 combination can also be used to convert *vic*-diols into the corresponding alkenes, although 2,4,5-triiodoimidazole is more effective than imidazole itself.[26] Alternative combinations are ***Triphenylphosphine-Iodoform-Imidazole***, which can deoxygenate *cis*-diols but which is better suited to *trans*-isomers,[27] and ***Chlorodiphenylphosphine***-I_2-Im, which can be used to deoxygenate *vic*-diols when both are secondary or when one is secondary and one is primary.[28]

Epoxidation.

t-Butyl Hydroperoxide in combination with $MoO_2(acac)_2$ can be used to oxidatively cleave alkenes, but will epoxidize such functions in the presence of a metalloporphyrin or a simple amine, the choice of which depends upon the substrate structure. Imidazole is the most suitable for 1-phenylpropene, ***Pyridine*** for stilbene, and *N*,*N*-dimethylethylenediamine for 1-alkenes.[29]

Imidazolium Dichromate

[109201-26-5] · $C_6H_{10}Cr_2N_4O_7$ · Imidazolium Dichromate · (MW 354.20)

(mild selective reagent for the oxidation of allylic and benzylic alcohols to the corresponding carbonyl compounds)

Alternate Name: IDC.

Physical Data: mp 130-131 °C; nonhygroscopic; air stable yellow crystals.

Solubility: readily sol DMF, DMSO; very slightly sol acetone, dichloromethane, trichloromethane.

Preparative Method: easily prepared by the addition of ***Imidazole*** to a solution of an equimolar amount of ***Chromium(VI) Oxide*** in a minimum amount of water.[1] The yellow crystals are collected, washed with acetone, and dried in vacuo at rt.

Handling, Storage, and Precautions: all chromium(VI) reagents must be handled with care. The mutagenicity of chromium(VI) compounds is well documented.[2] This reagent should be handled in a fume hood.

Oxidation of Allylic and Benzylic Alcohols to Carbonyl Compounds.

Imidazolium dichromate oxidizes cinnamyl alcohol and benzhydrol to cinnamaldehyde (91%) and benzophenone (93%), respectively, at rt.[1] Allylic alcohols are oxidized faster than benzylic alcohols and saturated aliphatic alcohols react slowest. Geraniol is oxidized to geranial (82% yield) with 6% (*E*) to (*Z*) isomerization at the double bond. 4-(3-Hydroxypropyl)benzyl alcohol is selectively oxidized to 4-(3-hydroxypropyl)benzaldehyde (eq 1). The selectivity achieved with IDC is comparable to that of ***4-(Dimethylamino)pyridinium Chlorochromate*** (DMAP.$HCrO_3Cl$).[3,4]

Indium

In

[7440-74-6] · In · Indium · (MW 114.82)

(effective mediator for the allylation of carbonyl compounds)

Physical Data: mp 156 °C; *d* 7.300 g cm^{-3}.

Form Supplied in: available in the form of bars, foils, wire, granules, shot, and powders of various sizes. For synthetic purposes, indium powder of about 60 mesh is the most convenient form.

Handling, Storage, and Precautions: no special precautions are required.

Allylation of Carbonyl Compounds.[1]

Indium is a very effective mediator for the addition of allyl groups to carbonyl compounds under very mild reaction conditions. Typically, the organoindium reagent is prepared in situ by the addition of an allyl iodide to a suspension of indium powder in a suitable solvent. The preparation of highly activated indium powder (Rieke indium) via reduction of indium(III) chloride has been reported,[2] but in the vast majority of cases commercial indium powder is sufficient. Allyl bromides are equally well suited for this reaction, but allyl chlorides are not sufficiently reactive, resulting in diminished yields. Studies by Butsugan and co-workers[1] suggest that the active organoindium species is the allylic indium sesquihalide (eq 1), which is in accord with results of Gynane and Worrall.[3]

(1)

Studies of the variation of the yields of allylation as a function of the ratio of indium:allyl iodide:ketone have shown that two-thirds of the allyl groups are transferred to carbonyl compounds, and thus the stoichiometry of the reaction is 2:3:2 (indium:allyl halide:ketone).[1] In cases where quantitative utilization of the allyl halide is important, this can be achieved by substituting indium(I) iodide for metallic indium.[4]

Allylindium sesquihalides react readily with a variety of carbonyl compounds, including ketones (eqs 2 and 3),[1] aldehydes (eqs 4 and 5),[1] acid anhydrides,[5] quinones,[6] and aldimines.[7] In general, the stereoselectivity obtained in

these reactions is low to moderate. For example, indium-mediated allylation of 4-*t*-butylcyclohexanone (eq 3) gives an 83:17 mixture of axial:equatorial products. In the case of substituted allyl halides (eqs 4 and 5), regioselectivity is extremely high as only the products of γ-coupling are observed. α,β-Unsaturated carbonyl compounds give exclusively 1,2-addition products (eq 6).[1]

(2)

(3)

ax:eq = 83:17

(4)

erthyro:*threo* = 66:34

(5)

(6)

One significant advantage of allylindium sesquihalides over alternative organometallic allylating reagents (allylmagnesium halides, allyllithium compounds) is their low basicity. Yields remain high even in the presence of an active hydrogen, such as in the case of salicylaldehyde (eq 7).[1] This property has been exploited by Chan and Li, who have reported indium-mediated allylations of carbonyl compounds carried out in water.[8] These workers report that in contrast to similar reactions with zinc and tin, where acid catalysts, heat, or sonication are often required, the indium-mediated reaction proceeds readily without the need of a promoter.

(7)

The mildness of the reaction conditions employed for indium-mediated allylation can also be advantageous when allylating labile carbonyl compounds. For example, attempts to allylate the tricarbonyliron butadiene complex (**1**) with allylmagnesium bromide fail completely, yielding only unidentifiable decomposition products. In contrast, the indium-mediated allylation of (**1**) (eq 8) proceeds smoothly to give the corresponding homoallyl alcohols in 91% yield.[9]

Iodine

[7553-56-2] · I_2 · Iodine · (MW 253.80)

(electrophilic reagent that adds to alkenes[1] and alkynes[2] to give diiodides; alkenyl carboxylic acids react to give iodolactones[3] and alkenyl amides lead to iodolactams;[4] dehydrogenates amines[5] and reacts with ketones, in the presence of base, to give α-iodo ketones;[6] carboxylic acids are converted to α-iodo acid derivatives[7] and carbanions react to give the substituted iodides;[8] organoboranes can give alkyl iodides[9] and vinylboranes lead to substituted alkenes;[10] important spotting reagent for TLC analysis[11])

Physical Data: mp 113.6 °C; bp 185.24 °C; *d* 4.930 g cm^{-3}; vapor pressure 0.31 mmHg at 25 °C.

Solubility: the solubility of iodine, expressed in g/kg of solvent at 25 °C is: H_2O, 0.34; benzene, 164.0; CCl_4, 19.2; $CHCl_3$, 49.7; ethyl acetate, 157; ethanol, 271.7; diethyl ether, 337.3; *n*-hexane, 13.2; toluene, 1875.[12] Soluble glacial acetic acid; relatively insol dichloromethane.

Form Supplied in: the natural abundance isotope is ^{127}I. It is a massive bluish-black solid. When sublimed it forms near opaque, doubly refractory orthorhombic crystals that have a metallic luster. Heating iodine generates a violet-colored vapor. Commercially available in >99.5% purity, with bromine and chlorine the primary contaminants. Natural abundance iodine is diatomic, I-I.

Preparative Methods: commercially available but can be prepared by the reaction of potassium iodide and copper(II) sulfate.[13] It is also prepared by chlorination of natural brines or by treatment of brine with silver nitrate and then iron(II) iodide, followed by addition of chloride to liberate iodine.[14]

Purification: vacuum sublimation.

Handling, Storage, and Precautions: somewhat corrosive.[15] It is stored in a dark bottle or jar, at ambient temperatures. Iodine vapors have a sharp characteristic odor and they are irritating to eyes, skin, and mucous membranes (lachrymatory). Prolonged exposure should be avoided. Ingestion of large quantities can cause abdominal pain, nausea, vomiting, and diarrhea. If 2-3 g of iodine are ingested, death may occur.

Introduction.

Diatomic iodine (I_2) is a member of the halogen family that is widely used in organic chemistry. Iodine is less electronegative than the other halogens, and iodides are generally less stable than other halides.[16] Oxides of iodine and

compounds where iodine is in a positive valence state are much more stable than the other halogens. Iodine forms binary compounds with all elements except sulfur, selenium, and the noble gases, although it does not react directly with carbon, nitrogen, or oxygen.[15] Its applications in organic chemistry range from detection of organic molecules in TLC, to addition reactions with unsaturated molecules, to reactions as an electrophilic agent with nucleophilic species. Iodine is used not only as an agent for incorporating an iodine atom but also as an oxidizing agent, a dehydrogenation agent, and as a radiolabel in many biologically important systems.

One of the most common uses of iodine is as a spotting agent for the detection of organic molecules in TLC.[11] Many organic molecules either adsorb iodine vapors or react with iodine vapor to produce a visible spot on the TLC plate. In general, basic compounds and reducing compounds pick up iodine vapors very well, but acidic compounds and oxidizing compounds do not.[11] Many natural products can be detected via TLC, including steroids,[17] phenolic compounds,[18] and alkaloids.[19]

Addition to Alkenes.

Iodine is a highly polarizable molecule that behaves as electrophilic iodine (I^+) in the presence of a suitable Lewis base, such as an alkene or an alkyne. When an alkene reacts with molecular iodine, a characteristic iodonium ion is formed, and subsequent reaction with the nucleophilic gegenion (I^-) leads to the vicinal diiodide. There are many examples of this type of reaction. Addition of iodine to cyclohexene to give *trans*-1,2-diiodocyclohexane is a simple example (eq 1).[1] The reaction is believed to involve a radical intermediate, evidenced by formation of dimeric coupling products in many alkene iodination reactions. Reaction of styrene with iodine (neat), for example, gives not only 1,2-diiodo-2-phenylethane but also 1,4-diiodo-2,3-diphenylbutane as a minor product (eq 2).[20]

(1)

(2)

The iodine reaction can be modified by addition of other reagents, such as methanol, to produce iodo ethers. When iodine in methanol is reacted with cyclohexene, in the presence of ***Cerium(IV) Ammonium Nitrate*** (CAN), a 92% yield of 2-methoxy-1-iodocyclohexane is obtained (eq 3).[21a] Similar results are obtained when iodine and ***Copper(II) Acetate*** are used.[21b]

(3)

Iodine reacts with dienes to form a mixture of 1,2-diiodoalkenes and 1,4-diiodoalkenes. When done in the presence of ***Copper(I) Cyanide***, the 1,4-addition product predominates and 1,3-butadiene thus reacts to give an 84% yield of 1,4-dicyano-2-butene (eq 4).[22] Allenes react with iodine to give diiodides. When 2,3-pentadiene reacts with iodine in carbon tetrachloride, 2,3-diiodo-3-pentene is formed (eq 5).[23] When the reaction is done in methanol, however, 3-methoxy-2-iodo-3-pentene is the product.

(4)

(5)

There are two very interesting and useful variations of the fundamental addition reactions to alkenes: iodolactonization[3] (to form iodolactones) and iodolactamization (to produce iodolactams). When an alkenyl acid reacts with iodine in the presence of a base (such as sodium bicarbonate), the initially formed iodonium ion reacts with the carboxylate anion (generated in situ) to form the iodolactone (eq 6).

Lactones are also formed when iodine reacts with alkenyl amides or alkenyl carbamates. In initial studies, amides led to the formation of lactones whereas carbamates gave oxazolidinones. When *N*-(*S*)-phenethyl-2-allyl-4-pentenamide reacts with 3 equiv of iodine in aqueous THF, a 77% yield of 2-allyl-5-iodomethyl-δ-butyrolactone is obtained (16% optical purity) (eq 7).[24] Similarly, reaction of *N*-Cbz-*N*-methyl-2-propenamine with iodine in dichloromethane leads to a 95% yield of *N*-methyl-4-iodomethyl-2-oxazolidinone (eq 8).[25]

The more difficult lactam forming reaction (iodolactamization) can be accomplished by treatment of primary alkenyl amides with ***Trimethylsilyl Trifluoromethanesulfonate***, followed by iodination, as in the conversion of 4-pentenamide to 5-iodomethyl-2-pyrrolidinone in 68% yield (eq 9).[4] There are several other cyclization reactions that are initiated by the reaction of iodine with an alkene, in the presence of a nucleophilic atom elsewhere in the molecule.[26]

(9)

Addition to Alkynes.

Iodine undergoes addition reactions with alkynes as well as alkenes, although the reaction is generally more sluggish. Reaction of 1,4-dichloro-2-butyne with iodine, for example, requires 1,2-dichloroethane as a solvent and heating to 83 °C for 120 h to give (*E*)-1,4-dichloro-2,3-diiodo-2-butene (eq 10).[27] Treatment of this alkene with ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** leads to formation of iododienes. Another example is 1-hexyne, which reacts with iodine in methanol to produce (*E*)-1,2-diiodo-1-hexene (eq 11).[2] When ***Silver(I) Nitrate*** is added to this mixture, however, a mixture of 1,1-diiodo-2-hexanone, 1-iodo-1-hexyne, and (*E*)-1,2-diiodo-1-hexene is formed (31%, 46%, 23% yields).[15]

(10)

(11)

Cleavage of Cyclopropanes.

Iodine also reacts with cyclopropanes, leading to ring opening and formation of a diiodide.[28] The cyclopropane ring in benzocyclopropanes, for example, reacts with iodine to produce the diiodide (eq 12). Cyclopropylcarbinyl systems are opened by iodine, and when a leaving group is available, such as trimethyltin, an alkenyl iodide is formed (eq 13).

(12)

(13)

Conversion of Alcohols to Iodides.

Alcohols react with iodine and red phosphorus to produce a phosphorus iodide, in situ. Phosphorus iodides have poor shelf lives (they are unstable and decompose under mild conditions) and are prepared immediately prior to use. An

example is the conversion of cetyl alcohol to cetyl iodide in 85% yield (eq 14).[29] This is the most common method for the conversion of aliphatic alcohols to aliphatic iodides.

(14)

Reaction with Amines.

Dehydrogenation is another important reaction of iodine, and it is particularly useful for generation of enamines. Reaction of nuciferine with iodine, in dioxane containing sodium acetate, leads to an 87% yield of the enamine dehydronuciferine (eq 15).[30] Amines in general lead to enamines, as in the conversion of triethylamine to *N,N*-diethylvinylamine (eq 16).[5] This reaction can be applied to many systems.[31] For systems that do not contain an amino moiety, e.g. arenes such as ethylbenzene, a flow reactor and high temperatures (650 °C) are required for dehydrogenation. This particular example uses a molten ***Lithium Iodide*** reactor to convert ethylbenzene to the alkene product, styrene, in 96% yield (eq 17).[32]

(17)

Reactions with Ketones, Aldehydes, and Carboxylic Acid Derivatives.

Iodine reacts with ketones as well as with alkenes. The reaction is usually done in the presence of base and proceeds via the enolate anion. This is the fundamental process that occurs in the Lieben iodoform reaction,[33] in which a methyl ketone reacts with iodine and sodium hydroxide to give iodoform (CHI_3) with oxidative cleavage of the methyl group to produce a carboxylic acid. The H_3C-C bond of methyl carbinols [RCH(OH)Me] is also cleaved with this reagent to give the corresponding acid and iodoform. The iodoform reaction constitutes a classical test for the presence of a methyl ketone moiety or a methyl carbinol moiety in an unknown molecule.

Oxidative cleavage is not always the case in this reaction, especially when sodium methoxide is substituted for sodium hydroxide. Steroidal ketones react with iodine and sodium methoxide to give a 58% yield of the α-iodo ketone, when air is excluded from the reaction (eq 18).[6] When oxygen is introduced, an 85% yield of the α,α-diiodo ketone is produced.[6] Reaction of aryl ketones can lead to a different result. 1,2-Diphenyl-1-ethanone reacts with iodine and sodium methoxide at low concentrations to give a 99% yield of 1,2-diphenyl-2-hydroxy-2-ethanone (eq 19).[34] When the concentration of the ketone substrate is increased, the yield of the hydroxy ketone is diminished and a dimer is formed, 1,2,3,4-tetraphenyl-1,4-butanedione (47% yield at 0.2 M).[34]

(18)

0.0071 M	99%	trace	trace
0.2 M	46%	47%	3%

The iodoform reaction clearly shows that iodine behaves as an electrophile in the presence of enolate anions, particularly enolate anions of carboxylic acid derivatives. When 6-heptenoic acid is treated with 2 equiv of ***Lithium Diisopropylamide***, and then quenched with iodine, a 70% yield of 2-iodo-6-heptenoic acid is obtained (eq 20).[7] In this particular reaction, 12% of the dicarboxylic acid 2,3-di-4-pentenyl-1,4-butanedioic acid is also obtained, leading to the belief that radical anions are produced in this reaction.[7] Such coupling reactions are also observed with esters which form succinic acid ester derivatives, as in the reaction of ethyl 2-methylpropanoate with 2 equiv of LDA and subsequent reaction with iodine to give an 85% yield of diethyl 2,2,3,3-tetramethyl-1,4-butanedioate (eq 21).[35]

Carboxylic acid derivatives can react with iodine without an intermediary enolate anion to produce α-iodocarboxylic acids. α-Iodocarboxylic acid chlorides can also be produced, as when hexanoic acid reacts with iodine and ***Thionyl Chloride***, at 85 °C, to give an 80% yield of 2-iodohexanoyl chloride (eq 22).[36] Similarly, butanoic acid reacts with ***Chlorosulfonic Acid*** and iodine to give a 94% yield of 2-iodobutanoic acid (eq 23).[37] These examples are nothing more than the iodine analog of the Hell-Volhard-Zelinsky reaction.[38] The silver salt of pentanoic acid reacts with iodine to produce 1-iodobutane in 67% yield, where decarboxylation occurs under the reaction conditions (eq 24).[39] In general,

alkyl iodides are formed from silver carboxylates. This is the iodine version of the Hunsdiecker reaction.[40] Similar reaction occurs when mercury(II) oxide is added, although the yield is lower.

Iodination of Aromatic and Heteroaromatic Compounds.

Just as enolate anions react with the electrophilic iodine, so also other carbanions react. Iodoimidazoles can be formed, as when *N*-tritylimidazole reacts with ***n-Butyllithium*** and then with iodine, to give a 41% yield of 2-iodo-*N*-tritylimidazole (eq 25).[8]

Iodoindoles can also be produced by this approach. Reaction of indole with *n*-butyllithium and quenching with iodine first produces an *N*-iodoindole, but this is unstable and rearranges under the reaction conditions to 3-iodoindole, in near quantitative yield (eq 26).[41] When this iodo derivative is converted to the *N*-phenylsulfonyl derivative, reaction with LDA and then iodine gives a 98% yield of 2,3-diiodo-*N*-phenylsulfonylindole.[41]

Iodopyridine derivatives can also be generated with this technique. 3-Fluoropyridine reacts with LDA and iodine to give a 50% yield of 4-iodo-3-fluoropyridine (eq 27),[42] and 2-chloropyridine reacts with *n*-butyllithium and then iodine to give a 60% yield of 2-chloro-3-iodopyridine (eq 28).[43]

Iodofuran derivatives can be formed, as in the reaction of 2-(dimethyl-*t*-butylsilyl)furan-3-carboxylic acid with *n*-butyllithium and iodine, to give a 71% yield of the 4-iodofuran-3-carboxylic acid (eq 29).[44]

Simple aromatic derivatives can be iodinated to generate iodo-substituted aromatic compounds, if activating substituents are present on the aromatic ring. 1,3-Dicyanobenzene, for example, reacts with LDA and iodine to give a 79% yield of 2-iodo-1,3-dicyanobenzene (eq 30).[45] In general, unactivated aromatics are less useful since formation of the requisite carbanion is somewhat more difficult.

(30)

Conversion of Organoboranes to Iodides.

Another important area of chemistry where iodine reactions are important involves organoboranes. When an alkene is reacted with a borane to produce a trialkylborane, subsequent reaction with iodine and sodium hydroxide leads to an iodoalkane. 1-Decene reacts with tri-*n*-butylborane and then basic iodine to give a 65% yield of 1-iododecane (eq 31).[9]

(31)

Substituted alkenes can also be prepared from vinylboranes by reaction with iodine and sodium hydroxide. Reaction of dicyclohexylborane with 1-hexyne gives the vinylborane, and subsequent reaction with basic iodine, in THF, gives a 93:7 *cis*:*trans* mixture of 1-cyclohexyl-1-hexene in 85% yield (eq 32).[10] When the reaction is done in dichloromethane, a 77:23 *cis*:*trans* mixture is produced, but in only 13% yield.[10a] The poor yield is probably due to the poor solubility of iodine in dichloromethane.

(32)

Miscellaneous Reactions.

There are several specialized reactions of iodine that are useful in certain applications. Iodine induces coupling of sodium cyclopentadienide to form 9,10-dihydrofulvalene.[46] Iodine has also been used to cleave iron-carbon bonds in organoiron species.[47] Iodine reacts with hydrazone derivatives to give vinyl iodides.[48]

Reaction with Organic Halides.

An important reaction of iodine is exchange with an alkyl iodide. The most common method for exchanging an iodide is the Finkelstein reaction,[49] which involves treatment of alkyl halides with ***Sodium Iodide*** to produce alkyl iodides via an S_N2 reaction. Reaction of 1-bromobutane and sodium iodide in dry acetone, for example, gives 1-iodobutane. This exchange also occurs with alkyl iodides. The metal iodides used in this reaction are commercially available, but can be prepared from iodine.

Iodine itself is capable of exchanging the halide atom in alkyl halides, including alkyl iodides, to produce alkyl iodides. The reaction temperatures required are usually greater than 150 °C.[50] Aryl iodides undergo this exchange reaction at even higher temperatures (150-190 °C).[51] α-Iodo ketones also react with iodine, but this occurs at ambient temperatures.[52] The product of these reactions is, of course, another iodide but this is very important in radiolabeling using radioactive iodine isotopes. All of the reactions of iodine involve the use of the natural abundance stable isotope of iodine, ^{127}I. Radiolabeled molecules can be incorporated in a wide range of biological and mechanistic studies. There are at least 10 available isotopes of iodine, but only three are commonly used for labeling: ^{123}I, ^{125}I, and ^{131}I. If these isotopic iodines are used in the preceding reactions, radiolabeled iodides are produced. In the case of the Finkelstein reaction, sodium iodide or ***Potassium Iodide*** can be produced by synthesizing those salts with radiolabeled iodine. A variety of organic molecules have been radiolabeled for use in biological studies. These include fatty acids,[53] aniline derivatives,[54] quinolines,[55] nucleic acids,[56] steroids,[57] alkyl iodides,[58] aryl iodides,[59] carboxylic acids,[60] and carbohydrates.[61]

Related Reagents.

Dimethyl Sulfoxide-Iodine; ***Iodine-Aluminum(III) Chloride-Copper(II) Chloride***; ***Iodine-Cerium(IV) Ammonium Nitrate***; ***Iodine-Copper(II) Acetate***; ***Iodine-Copper(I) Chloride-Copper(II) Chloride***; ***Iodine-Copper(II) Chloride***; ***Iodine-Nitrogen Tetroxide***; ***Iodine-Potassium Iodate***; ***Iodine-Silver Acetate***; ***Iodine-Silver Benzoate***; ***Iodine-Silver(I) Fluoride***; ***Iodine-Silver Trifluoroacetate***; ***Lead(IV) Acetate-Iodine***; ***Mercury(II) Oxide-Iodine***; ***Thallium(I) Acetate-Iodine***; ***Triphenylphosphine-Iodine***.

Iodine-Aluminum(III) Chloride-Copper(II) Chloride

I_2-$AlCl_3$-$CuCl_2$

(I_2)

[7553-56-2] · I_2 · Iodine-Aluminum(III) Chloride-Copper(II) Chloride · (MW 253.80)
($AlCl_3$)

[7446-70-0] · $AlCl_3$ · Iodine-Aluminum(III) Chloride-Copper(II) Chloride · (MW 133.33)
($CuCl_2$)

[7447-39-4] · Cl_2Cu · Iodine-Aluminum(III) Chloride-Copper(II) Chloride · (MW 134.45)

(iodinating reagent for arenes)

Physical Data: $AlCl_3$: mp 192 °C (2.5 atm); subl. 180 °C. $CuCl_2$: mp 498 °C; *d* 3.054 g cm^{-3}.

Solubility: $AlCl_3$: sol benzene, CCl_4, chloroform; reacts violently with H_2O. $CuCl_2$: sol H_2O, ethanol, acetone.

Form Supplied in: $AlCl_3$: commercially available; colorless hexagonal plates. $CuCl_2$: yellow to brown, deliquescent microcrystalline powder.

Handling, Storage, and Precautions: $AlCl_3$: moisture sensitive. $CuCl_2$: irritating to skin, mucous membranes; forms dihydrate in moist air. Iodination reactions using this combination of reagents should be performed in a fume hood.

Iodinating Reagents.

Aryl iodides can be prepared by reaction of arene derivatives with ***Iodine*** and ***Antimony(V) Chloride***[1]

and copper salts.[2,3] These procedures can be applicable to more reactive substrates such as anisole and xylenes, but not to less reactive substrates such as benzene and halogenated benzene. The reaction of arenes containing halogen with I_2 and a mixture of ***Aluminum Chloride*** and ***Copper(II) Chloride*** gives the corresponding aryl iodides in good yield (eq 1).[4] The reaction fails with ethyl benzoate, acetophenone, and *o*-nitroanisole. The reagents are used in the ratio I_2:$AlCl_3$:$CuCl_2$ = 0.5:1:1.

Iodine Azide[1]

[14696-82-3] · IN_3 · Iodine Azide · (MW 168.93)

(additions to multiple bonds;[1-4] regioselective and stereoselective introduction of the azide function[1-3] and other nitrogen functions including amines; synthesis of aziridines[5] and azirines[6])

Physical Data: dark crystals;[7] explosive when neat.

Solubility: sol most organic solvents.

Form Supplied in: not available commercially; prepared in situ in solution.

Preparative Methods: the first reported preparation[7] from AgN_3 and I_2 is not recommended. IN_3 can be prepared in situ from ***Sodium Azide*** and ***Iodine Monochloride*** preferably in MeCN,[2] DMF, ether, or CH_2Cl_2.[2,3] It can also be prepared from TlN_3 and ICl[3c] in MeCN or CH_2Cl_2,[3] or from ***N-Iodosuccinimide*** and ***Hydrazoic Acid*** in CH_2Cl_2.[3] The following is a typical procedure for addition to alkenes:[2] to a slurry of 15.0 g (0.25 mol) of NaN_3 in 100 mL of MeCN at -10 to 0 °C is added, over 10-20 min, 18.3 g (0.113 mol) of ICl neat or in MeCN. After 10-20 min of further stirring, 0.1 mol of alkene is added neat or in MeCN and the mixture is warmed to 20 °C and stirred for 8-24 h. The red-brown slurry is poured into 250 mL of water and extracted three times with 85 mL portions of ether. The combined ether fractions are washed with 5% aq sodium thiosulfate until colorless (see precautions), then with water, and dried. Removal of the solvent in vacuo is followed by chromatography (neutral alumina) to afford the iodo azide adduct in 80-90% yield.

Handling, Storage, and Precautions: solutions of IN_3 in MeCN can be stored in the refrigerator for 1 d. Explosions have been reported on evaporation of solutions of IN_3 to dryness. Therefore, after reaction with multiple bonds, the mixture should be washed with sodium bisulfite until colorless to destroy excess IN_3 reagent. Violent reaction can also occur on addition of IN_3 to alkenes containing low-valent S-functions. An explosion shield should be used when handling this reagent. Operations should be conducted in a fume hood.

Additions to Alkenes.

Addition of IN_3 to alkenes (see also ***Bromine Azide***) usually proceeds via a three-membered ring iodonium species,

resulting from attack of I^+ on the double bond. The reaction is highly stereoselective (*anti*) and regioselective. Thus *cis*- and *trans*-2-butene give stereospecifically the *threo* and *erythro* adducts, respectively. The azide-carbon bond usually forms at the more substituted carbon or the one better able to support a positive charge in the transition state. *trans*-1-Phenylpropene gives, stereo- and regiospecifically, *erythro*-1-azido-2-iodo-1-phenylpropane (eq 1). *Anti* elimination of HI from the adduct leads to a vinyl azide.[4a] However, steric hindrance can influence the position of attack by azide ion. Thus *t*-butylethylene affords the terminal azide (eq 2).[2b]

(1)

(2)

The structure of the adduct with phenylcyclohexene has been questioned[8a] but it has been proven to be the one expected (eq 3).[8b,c] With 2-cholestene the *trans* diaxial adduct, 2β-azido-3α-iodocholestane, results from the α-iodonium species,[1,2] but products from β-attack on other steroid alkenes are also known.[9a] In rare cases, *syn* addition has been reported,[9] for instance to strained cyclobutenes.[9b,c]

(3)

Addition of IN_3 to conjugated ketones can lead to a mixture of regiosomers, sometimes depending on the presence of oxygen or on the method of generation of the reagent.[3,4] In such cases the addition can proceed via a radical mechanism,[3,11] in which the azide radical rather than I^+ is the attacking species and different regioisomers can result.[3] For instance, cyclopentenone affords 2-iodo-2-cyclopentenone, while cyclohexenone gives a mixture of products.[3e]

Enantioselective addition of IN_3 to conjugated amides derived from sultams or oxazolidones as chiral auxiliaries has been reported.[10] Although diastereoselection only averages 34% (eq 4), crystallization raises this to 94%.

Enol ethers, as expected, give α-azido-β-iodo ethers,[12a] but benzofuran and some indoles give a mixture of *cis*- and *trans*-2,3-diazido products.[12b] Allenes can give mono- or bis-adducts.[13] When the monoadduct is an allyl azide, then [3,3] rearrangements are observed (eq 5). When the monoadduct is a vinyl azide, addition of a second molecule of IN_3 is faster than the first addition and a bis-adduct results. The cyclopropane group in norcarane is opened by IN_3 to give a mixture of products.[14]

Synthesis of Aziridines.

IN_3 addition to alkenes followed by ***Lithium Aluminum Hydride*** (or ***Diborane***) reduction is a convenient method (Hassner aziridine synthesis) for the preparation of aziridines.[6] This method has been applied to the synthesis of monoaziridine derivatives of terpenes such as squalene, farnesol, and geraniol (eq 6).[15]

With *anti*-oriented iodo and azide functions, LAH leads to a large amount of IN_3 elimination.[6] Many other reagents can be used for the reduction of IN_3 adducts to aziridines,[6,16] including ***Hydrazine-Raney Nickel***, $Me_2NH.BH_3$, and phosphines or phosphites; the last reagents lead to *N*-phosphorylated aziridines.[16a] When alkyl- or aryldichloroborane is used, it provides stereospecific entry into *N*-substituted aziridines (eq 7).[16d]

(7)

Selective reduction of the adducts has also been achieved, as in the formation of β-amino acids from acrylic esters.[17] Rearrangements during IN_3 additions have been observed in rearrangement-prone systems such as methylenenorbornene, benzonorbornadiene, the pinenes, and tritylethylene.[18] In α- and β-pinene, rearrangement is accompanied by trapping with MeCN followed by N_3^- to afford tetrazoles.[19]

Synthesis of Vinyl Azides and Azirines.

Various bases, especially ***Potassium t-Butoxide***, cause stereospecific elimination of HI from the adducts and the resulting vinyl azides serve as useful intermediates for the synthesis of azirines (eq 8),[6,20] ketones,[21] and cyanoketenes,[22] and for the amination of aromatic compounds.[23]

(8)

Miscellaneous Reactions.

Addition of IN_3 to methylphenylacetylene leads to 2-azido-1-iodo-1-phenylpropene.[24] IN_3 also adds to isocyanides to produce iodotetrazoles.[2] Dimethyl thioacetals react with IN_3 to afford an α-azido thioether which can undergo Schmidt rearrangement in the presence of ***Trifluoroacetic Acid***.[25]

Iodine-Cerium(IV) Ammonium Nitrate

I_2-$(NH_4)_2Ce(NO_3)_6$

(I_2)

[7553-56-2] · I_2 · Iodine-Cerium(IV) Ammonium Nitrate · (MW 253.80) ($(NH_4)_2Ce(NO_3)_6$)

[15078-94-1] · $CeH_8N_8O_{18}$ · Iodine-Cerium(IV) Ammonium Nitrate · (MW 548.28)

(iodination of ketones, alkenes, and α,β-unsaturated ketones; oxidative aromatization of cyclohexenones; *cis*-hydroxylation of alkenes)

Physical Data: $(NH_4)_2Ce(NO_3)_6$: dec 225 °C.

Solubility: $(NH_4)_2Ce(NO_3)_6$: sol H_2O (136 g/100 mL at 12 °C), MeOH, EtOH, MeCN.

Form Supplied in: $(NH_4)_2Ce(NO_3)_6$: orange-red monoclinic crystals. *Drying:* $(NH_4)_2Ce(NO_3)_6$ can be dried by heating at 90 °C for 8 h.

Handling, Storage, and Precautions: bottles of $(NH_4)_2Ce(NO_3)_6$ should be kept tightly sealed to preclude contact with moisture and air. This reagent should be handled in a fume hood.

Iodination.

Oxidative iodination of ketones can be accomplished by utilizing ***Cerium(IV) Ammonium Nitrate*** (CAN) (0.5 molar equiv) and ***Iodine*** (0.5 molar equiv) at 25-50 °C in AcOH or MeOH (eq 1). The reaction is regioselective, providing the more highly substituted α-iodo ketones in very good yields (eq 2). This method is superior to an earlier alternative using I_2-$Cu(OAc)_2$ in AcOH.[1] Direct iodination of some ketones using I_2-CAN in MeCN or AcOH at 80 °C-reflux gives the corresponding α,α´-diiodo ketones in good yield (eq 3).[2] Asakura and Robins have reported a mild procedure for selective preparation of 5-iodouracil nucleosides with I_2-CAN (eq 4).[3] The method provides advantages over procedures reported heretofore. Cycloalkenes and steroidal alkenes react with I_2 in ROH (R = Me, Et, *n*-Pr, and *i*-Pr) in the presence of CAN to give the corresponding vicinal alkoxyiodocycloalkanes in good yield (eq 5). In the case of *t*-BuOH, *trans*-iodo nitrates are obtained (eq 6).[4] Moreover, it is interesting that cycloalka-1,3-dienes react with I_2 in the presence of CAN to give the *trans*-2-alkoxy-1-iodo compounds, not the 1,4-addition products (eq 7).[5] In the case of α,β-unsaturated ketones and

esters, *trans*-β-alkoxy-α-iodo derivatives are also obtained in 70-92% yield (eq 8).[6] Similar reagents have been used for the synthesis of aryl iodides (eq 9).[7]

Oxidations.

Much work has been reported on the *cis*-hydroxylation of alkenes using the Prévost reaction and Woodward

modification. The reaction of alkenes with I_2 and CAN in AcOH gives a mixture of products which can be hydrolyzed by KOH in MeOH-H_2O to *cis*-diols in high yields (eq 10).[8] The oxidative aromatization of α,β-unsaturated cyclohexenones to ethers has been investigated.[9-14] The reaction of cyclohexenone derivatives with I_2-CAN in ROH (R = Me, Et, *n*-Pr, *i*-Pr, Bu) under reflux gives the corresponding alkyl phenyl ethers in good yields (eq 11). This reaction is also applicable to diols (ethylene glycol, 1,3-propanediol, 1,4-butanediol).[15]

(iodination of ketones, alkenes, and aromatic compounds; oxidation of cycloalkenes and alkyl-substituted ketones)

Physical Data: $Cu(OAc)_2.H_2O$: mp 115 °C; *d* 1.882 g cm^{-3}.

Solubility: $Cu(OAc)_2.H_2O$: sol H_2O, ethanol; slightly sol ether, glycerol.

Form Supplied in: $Cu(OAc)_2.H_2O$: dark blue-green solid.

Handling, Storage, and Precautions: both reagents are toxic and should be handled in a fume hood.

Iodination.

The I_2-$Cu(OAc)_2$ reagent can be used for the directed iodination of ketones in acetic acid at 60 °C, leading to the corresponding α-iodo ketones (eqs 1 and 2).[1] Cyclohexene and steroidal alkenes react with ***Iodine*** in MeOH or AcOH in the presence of ***Copper(II) Acetate*** to give *trans*-1-iodo-2-methoxycyclohexane (eq 3)[2] and steroidal *trans*-iodo acetates (eq 4) in good yields.[2] Activated arenes such as mesitylene, aniline, and anisole can be iodinated in high yield by this reagent (eq 5).[3] Although phenol is iodinated mainly at the *ortho*-position, aniline and anisole are iodinated at the *para*-position. Iodination of estrogen derivatives having a hydroxy group at C-3 regioselectively affords 2-iodoestradiol derivatives (eq 6).[4]

Oxidation.

Much work has been reported on the *cis*-hydroxylation of alkenes using the Prévost reaction and its Woodward modification. The reaction of alkenes with I_2 and $Cu(OAc)_2$ in AcOH yields a mixture of products which is hydrolyzed by KOH in MeOH-H_2O to provide *cis*-diols. In the case of 5α-cholest-2-ene, the more hindered 2β,3β-diol is produced in high yield (eq 7). Cyclohexene and cycloheptene similarly give the *cis*-diol in good yield. This synthetic method affords several advantages over the Prévost reaction and other methods used heretofore.[5]

The reaction of diosphenol with I_2 and $Cu(OAc)_2$ in AcOH-H_2O (5:1) at 80 °C gives 3-hydroxythymo-1,4-quinone (79%).[6] Moreover, treatment of 3-iodo-3,6-dialkyl-1,2-cyclohexanediones with I_2-$Cu(OAc)_2$ gives 3-hydroxy-2,5-dialkyl-1,4-benzoquinones in 38-88% yield.[9] On the other hand, reaction with $Cu(OAc)_2$ under reflux affords 3,3´-dihydroxy-2,2´,5,5´-tetraalkyl-4,4´-diphenoquinones (eq 8).[7] A similar oxidation has been used for the synthesis of 3-alkyl-1,2-cyclohexanediones from 2-alkylcyclohexanones (40-70%) (eq 9).[8]

Aromatic Iodination.

Iodine-copper(II) chloride is a useful reagent combination for the preparation of aryl iodides from aromatic hydrocarbons.[1] Thus, heating mesitylene with I_2-$CuCl_2$ at 150 °C gives iodomesitylene in 86% yield (eq 1). The reaction proceeds in moderate to good yields with unsubstituted aromatics and compounds with alkyl, halogen, hydroxy, alkoxy, and dimethylamino substituents. Iodination fails, however, with strongly deactivated ring systems such as methyl benzoate, aniline, thiophene, and pyridine.[1] Because of the limitations of the simple I_2-$CuCl_2$ iodinating system, alternative procedures have been studied. For example, a mixture of I_2-$AlCl_3$-$CuCl_2$ is effective for the preparation of aryl iodides, one advantage being that lower reaction temperatures are required.[2] Recently, a very efficient iodinating system has been developed using alumina-supported iodine-copper(II) chloride;[3] in the absence of solvent at 40-120 °C, monoiodination of polymethylbenzenes, alkoxy aromatics, and polynuclear aromatic hydrocarbons occurs in high yield. The I_2-Al_2O_3-$CuCl_2$ system exhibits very good selectivity, i.e. alkoxy aromatic substrates are almost exclusively *para*-iodinated (eq 2).

(1)

(2)

Iodination of Alkynes.

The liquid-phase halogenation of alkenes with copper(II) chloride is well known and has been studied in some detail.[4] The halogenation of alkylphenylalkynes with $CuCl_2$-LiCl and $CuCl_2$-I_2 in acetonitrile has also been examined.[5] Chloroiodination with $CuCl_2$-I_2 proceeds more smoothly than chlorination and affords completely regiospecific and highly stereospecific (*E*)-chloroiodoalkenes in high yields (eq 3).

(3)

R = H, 93%, (*E*):(*Z*) = 100:0; R = Me, 93%, (*E*):(*Z*) = 100:0; R = *t*-Bu, 95%, (*E*):(*Z*) = 90:10

α-Iodination of Carboxylic Acids.

Combinations of iodine and copper(II) salts have been used for the introduction of iodine at the α-position of aliphatic straight-chain carboxylic acids.[6] While ***Iodine-Copper(II) Acetate*** gives a slightly higher yield of iodinated acid than $CuCl_2$-I_2, the reaction time with the latter reagent combination is considerably shorter. An ***Iodine-Copper(I) Chloride-Copper(II) Chloride*** mixture is also effective for this transformation.

Oxidant in Photochemical Reactions.

Photocyclization of 4,4´-dimethoxy-α,α´-dimethylstilbene in the presence of air with added $CuCl_2$-I_2 gives a significantly higher yield (54%) of the desired phenanthrene derivative than the same reaction performed with iodine alone (0.6%).[7]

Related Reagents.

Copper(II) Chloride; ***Iodine***; ***Iodine-Aluminum(III) Chloride-Copper(II) Chloride***; ***Iodine-Copper(II) Acetate***; ***Iodine-Copper(I) Chloride-Copper(II) Chloride***; ***Sodium Iodide-Copper***.

Iodine Isocyanate[1]

INCO

[3607-48-5] · CINO · Iodine Isocyanate · (MW 168.92)

(additions to multiple bonds;[1-11] regioselective and stereoselective introduction of the isocyanate, amine, or carbamate function;[1-8] formation of aziridines,[1-7] 2-oxazolidones,[1,2] 2-amino alcohols,[1,2] 1,2-diamines,[5] and azepines;[6] interconversion of alkene stereoisomers[9])

Physical Data: usually prepared in situ in solution.[1-4]

Solubility: sol most organic solvents.

Form Supplied in: not available commercially; prepared in solution.

Preparative Methods: INCO can be prepared in situ from silver cyanate and I_2 in anhydrous ether,[2,4] MeCN (faster),[2] THF,[2] or CH_2Cl_2 (faster).[4d] The preformed solution can be stored in the dark at -20 to -30 °C for 48 h,[2] and sometimes reacts faster with alkenes.[10] The purity of AgNCO is critical; it should be white or pale-gray, prepared fresh or kept in the dark in a desiccator.[2] A typical procedure for addition to alkenes is as follows:[2] to a stirred slurry of 20 g (0.13 mol) of fresh AgCNO in 200 mL anhydrous ether at 0 °C is added 0.1 mol of alkene followed by 25.4 g (0.1 mol) of I_2. The mixture is stirred at rt for 1-5 h (brown color lightens). Filtration of the salts through a filter aid (Celite) and washing with aqueous sodium bisulfite gives a solution of the iodo isocyanate which is converted to the methyl β-iodo carbamate by treatment with 100 mL of MeOH and 2-3 drops of dil LiOMe. Alternatively, the iodo isocyanate can be converted into a stable sodium bisulfite adduct, which can regenerate the isocyanate or lead to an aziridine.

Additions to Alkenes.

Addition of INCO to alkenes (see also ***Iodine Azide***) proceeds via a three-membered cyclic iodonium species resulting from attack of I^+ on the double bond. The reaction is highly stereoselective (*anti*) and regioselective. Thus *cis*- and *trans*-2-butene give, stereospecifically, the *threo*- and *erythro*-adducts, respectively.[8] The new N-C bond usually forms at the more substituted carbon or the one better able to support a positive charge in the transition state (eq 1),[1] although 1-hexene and methylenecyclohexene give a mixture of regioisomers.[8]

(1)

Steric effects play an important role in the attack by cyanate ion; thus *t*-butylethylene affords the terminal isocyanate. 2-Cholestene gives the diaxial adduct, 2β-isocyanato-3α-iodocholestane (eq 2),[2b] whereas 5-cholestene does not react.[1]

(2)

Mono addition of INCO to dienes or trienes can be achieved with the less-substituted double bond reacting first (eq 3).[8] Electron-poor double bonds, as in conjugated ketones or esters, do not react well with INCO.

(3)

Rearrangements have occasionally been observed, as in the case of 3,3-diphenylpropene which gives, in low yield, an iodo carbamate resulting from phenyl migration,[11] and also in the case of rearrangement-prone alkenes such as 5-methylene-2-norbornene (eq 4).[8] Enol acetates react fast but give an unstable adduct.[10]

(4)

Formation of Amines or Carbamates.

After the INCO adducts are converted with alcohol into the corresponding carbamates, the iodo function can be reduced by ***Zinc-Acetic Acid***-ether (eq 5), except in diaxial adducts which tend to undergo elimination.[8] Alternatively,

the carbamates can be hydrolyzed to amines and the iodo amine salt can be reduced by ***Lithium Aluminum Hydride*** to an amine.[4b]

(5)

Synthesis of Aziridines.

The iodo carbamates resulting from INCO addition to alkenes followed by reaction with alcohol are readily converted into aziridines with base (refluxing ***Potassium Hydroxide*** in MeOH) (eq 6).[1,2] Alternatively, the INCO adducts can be hydrolyzed by aq HI or HCl to *trans*-2-iodoalkylamines, which when heated with base afford aziridines.[2b,4b]

(6)

Aziridines can be converted into *trans*-2-amino alcohol derivatives (by heating with ***Acetic Acid***),[2b] or into *trans*-1,2-diamines (by treatment with ***Sodium Azide*** followed by hydrogenation).[5]

Synthesis of 2-Oxazolidones and *cis*-2-Amino Alcohols.

Pyrolysis of β-iodo carbamates neat at 140-190 °C or in solvents (*i*-PrOH, TCE, diglyme) leads to the formation of 2-oxazolidones (eq 7).[1]

Since addition of INCO to cycloalkenes affords *trans*-2-iodo carbamates and formation of 2-oxazolidones proceeds with inversion of configuration, hydrolysis (KOH in aq MeOH) of the oxazolidones provides a stereospecific entry to *cis*-2-amino alcohols (eq 7).[1]

Miscellaneous Reactions.

Addition of a preformed solution of INCO in THF to phenylacetylene yields a monoadduct which provides acetophenone on workup with dil HCl. A general route to 1*H*-azepines involves INCO addition to 1,4-dihydrobenzenes and conversion of the resulting fused aziridines into azanorcaradienes which rearrange to azepines (eq 8).[6]

Interconversion of *cis*- and *trans*-alkenes can be achieved using this reagent; for example, from a *cis*-alkene via the 2-oxazolidone and the derived (inverted) 2-amino alcohol. The latter is ring-closed with acid to a *trans*-aziridine, which on deamination with *n*-BuONO yields a *trans*-alkene (eq 9).[9]

Iodine Monobromide

IBr

[7789-33-5] · BrI · Iodine Monobromide · (MW 206.80)

(diastereoselective cyclizations of homoallylic carbonates;[1] electrophilic addition to alkenes;[2] α-bromination of steroidal aldehydes and ketones;[3,4] cleavage of carbon-metal bonds[5])

Physical Data: mp 40 °C; bp 116 °C (dec); *d* 4.416 g cm^{-3}.

Solubility: sol alcohol, ether, CS_2, acetic acid, acetone, CH_2Cl_2, MeCN, DME, toluene (but with limited solubility below -80 °C); sol H_2O, but hydrolyzes to HBr and IOH.

Form Supplied in: brownish-black crystals or very hard, black solid; widely available (usually 97-98% purity).

Handling, Storage, and Precautions: corrosive solid and vapor; readily absorbed through skin and mucous membranes; use in a fume hood and wear gloves and appropriate protective clothing; air-, moisture-, and light-sensitive; should be stored refrigerated (under N_2) in a tightly sealed amber bottle. Forms explosive mixtures with potassium and sodium, and reacts extremely exothermically with phosphorus and tin.

Electrophilic Cyclization of Homoallylic Carbonates.[1]

Iodine monobromide provides very good diastereoselectivity in electrophilic cyclizations of homoallylic carbonates (eq 1). Isolated yields of α-iodo cyclic carbonates are excellent, and these products can be easily and efficiently converted into the corresponding epoxides (eq 2). Optimal diastereoselectivity is obtained from reactions performed in toluene at -80 to -85 °C. Use of ***Iodine***/MeCN[6] or ***Iodine Monochloride***/CH_2Cl_2 yields much lower diastereoselectivity than iodine monobromide under similar conditions. Results of an equilibration experiment strongly indicate that the diastereoselectivity in iodine monobromide-induced cyclization stems from kinetic control.

Electrophilic Addition to Alkenes.[2]

Iodine monobromide addition across alkenes is very facile, yielding vicinal bromoiodoalkanes. In general, addition occurs with high *anti* stereospecificity, and mechanistic studies have implicated an iodonium ion intermediate in the overall reaction sequence. The regiochemistry of iodine monobromide addition is very sensitive to the initial alkene structure, such that anti-Markovnikov products are possible (Table 1).

Table 1 Regiochemistry of IBr Addition to Alkenes

Alkene	% Markovnikov	% anti-Markovnikov
$MeCH{=}CH_2$	65	35
$EtCH{=}CH_2$	45	55
i-$PrCH{=}CH_2$	15	85
t-$BuCH{=}CH_2$	0	100
$PhCH{=}CH_2$	100	0

α-Bromination of Steroidal Aldehydes and Ketones.

Iodine monobromide is an effective monobrominating reagent for steroidal aldehydes (eq 3).[3] The ratio of diastereomeric products is in part a function of the reaction site's proximity to an asymmetric center, with β-orientation favored for the entering bromine. In an analogous application, methyl 3-oxo-5β-cholanate has been monobrominated (IBr/$MeCO_2H$; 50% yield) to produce the 2β-bromo ketone.[4]

Bond Cleavage Reactions.[5]

Cleavage of carbon-metal bonds by iodine monobromide typically produces the organic iodide and the metal bromide. Cleavage of organotin,[5a-c] organoarsenic,[5d] organoantimony,[5d] organogermanium,[5e] and organolead[5e] bonds has been investigated (see also ***Iodine Monochloride*** for use in cleaving carbon-metal bonds).

Other Applications.

Iodine monobromide has been used for brominating phenol and aryl ether derivatives.[7] Ethers and esters have been cleaved by catalytic iodine monobromide in the presence of ***Bromotrimethylsilane***.[8] Aryl acetals can be directly oxidized to the corresponding esters in moderate yield.[9]

Iodine Monochloride[1]

ICl

[7790-99-0] · ClI · Iodine Monochloride · (MW 162.35)

(iodinating reagent for aromatic compounds;[2] chloroiodinating reagent for unsaturated compounds;[3] cleaves carbon-metal bonds[4])

Physical Data: mp 27.2 °C (α-form; black needles, ruby-red by transmitted light); mp 13.9 °C (β-form; black platelets, brownish-red by transmitted light); bp 97 °C (β-form, partial decomposition); *d* 3.10 g cm^{-3}.

Solubility: sol alcohol, ether, CS_2, acetic acid, acetone, pyridine; sol H_2O, but hydrolyzes to HCl and IOH.

Form Supplied in: low melting black or brownish-red solid; widely available (usually 97-98% purity).

Handling, Storage, and Precautions: corrosive solid and vapor; readily absorbed through skin and mucous membranes; use in a fume hood and wear gloves and appropriate protective clothing; air-, moisture-, and light-sensitive; should be stored refrigerated (under N_2) in a tightly sealed amber bottle. Explodes on contact with potassium metal; mixtures with sodium metal can explode if impacted. Reaction with PCl_3 is extremely exothermic.

Iodination of Aromatic Compounds.

As a source of electrophilic iodine, iodine monochloride is an effective reagent for iodination of a wide variety of aromatic compounds,[2] including heterocyclic aromatic compounds (eq 1).[5] In a related mode of reactivity, uracil bases and protected nucleosides can be iodinated in excellent yield (eq 2).[6] See also ***Iodine-Silver(I) Fluoride*** and ***Trifluoroacetyl Hypoiodite*** for iodination of aromatic compounds.

(1)

(2)

Chloroiodination of Unsaturated Compounds.[3]

Formation of vicinal chloroiodoalkanes via iodine monochloride addition to alkenes generally occurs with high *anti* stereospecificity, implicating the intermediacy of an iodonium ion in the reaction sequence. Unsymmetrical alkenes typically undergo predominantly Markovnikov addition (e.g. reaction of 1-hexene produces a 66:34 mixture of 2-chloro-1-iodohexane and 1-chloro-2-iodohexane in 75% overall yield[7]). Regioselectivity and stereoselectivity in additions to alkynes are very dependent on the alkyne structure.

Bond Cleavage Reactions.[4]

Except in the case of C-Fe and C-Co bonds, cleavage of carbon-metal bonds by iodine monochloride specifically produces the organic iodide and the metal chloride. Organosilicon[8] (eq 3), organoboron[9] (eq 4), and organoaluminum[10] (eq 5) bond cleavage reactions are probably of greatest utility to synthetic organic chemists.

(3)

(4)

(5)

Other Applications.

Iodine monochloride can function as a chlorinating agent because of its tendency to disproportionate to molecular iodine and molecular chlorine in nonpolar solvents.[11] Oxidation of dioxolanes to esters has been reported to proceed in good to excellent yield.[12] Also, a variety of conditions have been reported for the in situ generation of iodine monochloride, including ***t-Butyl Hypochlorite*/*Iodine***,[13] ***Antimony(V) Chloride***/I_2,[14] and ***Iodine-Copper(II) Chloride***.[15]

Iodine Monofluoride[1]

[13873-84-2] · FI · Iodine Monofluoride · (MW 145.90)

(adds iodine and fluorine atoms across double and triple bonds;[2] iodinates aromatic rings;[3] converts carbonyls, through their hydrazones, to the CF_2 group[4])

Physical Data: bp +1 °C (dec to I_2 and IF_3); has not been isolated in pure form; chocolate-colored polymeric solid at low temperatures;[8] relatively stable in the gas phase.[9]

Preparative Methods: unlike most organic reagents, the notation of [IF] has been used to designate a two-step reaction taking place when a mixture of two different agents, one a source of electrophilic iodine and the other of nucleophilic fluorine, is reacted with a substrate. The true molecule of IF can be prepared in situ by a reaction between the corresponding elements[5] or by reacting ***Iodine*** with IF_5[6] or iodine with ***Silver(I) Fluoride***.[7] Many reactions, but not all, of [IF] and IF are quite similar.

Handling, Storage, and Precautions: use in a fume hood.

Iodofluorination of Alkenes.

Adding the elements of iodine and fluorine across double bonds by using ***N-Iodosuccinimide*** (NIS) and anhydrous ***Hydrogen Fluoride*** is an old procedure employed extensively in steroid chemistry (eq 1).[10] The addition proceeds via a cyclic iodonium ion with good regio- and stereospecificity (*anti* addition). Since anhydrous HF is inconvenient for lab use, Olah suggested replacing it with the easier-to-handle HF.pyridine (eq 2).[2a] Many variations on this procedure have since appeared. These include the following combinations: NIS-Et_3N/3HF,[11] NIS-AgF/CaF_2,[12] NIS-Bu_4NHF_2,[13] NIS-NH_4HF_2/ultrasound,[14] and I(py) +2 or I(collidine) +2BF_4^-.[15]

Molecular IF, prepared in situ from the elements, adds across double bonds with similar results to [IF], but it also adds quite efficiently to much less reactive enones, usually with subsequent elimination of HF and resulting in the difficult-to-obtain α-iodo enones (eq 3).[2b] Various alkynes react as well to form α,α-difluoro-β,β-diiodo derivatives (eq 4).[2c]

(3)

(4)

The strong electrophilicity of the iodine in molecular IF is the driving force behind the successful iodination of various aromatic compounds. In the case of aromatic rings such as toluene, mono-, di-, or triiodo derivatives can be made at will by varying the temperature and amount of the reagent (eq 5), while with deactivated rings such as benzonitrile only the *meta* monoiodo derivative is obtained in high yields (eq 6).[3]

(5)

(6)

Iodine monofluoride has found yet another use in converting ketones, via their hydrazones, into the corresponding CF_2 derivatives (eq 7).[4] The reaction is general; aliphatic, alicyclic, benzylic, and steroidal carbonyls react successfully. Mono- and disubstituted hydrazones, semicarbazones, and DNPs can react as well. It should be noted that with [IF], this reaction does not give satisfactory results.[16]

INO_3

[14696-81-5] · INO_3 · Iodine Nitrate · (MW 188.91)

(additions to alkenes;[1-7] regioselective and stereoselective introduction of the iodine and oxygen (nitrate) function;[1-6,8] in the case of INO_2, introduction of iodine and nitro groups;[6c,7] iodination of alkylbenzenes[9])

Physical Data: prepared in situ in solution.[1,2]

Solubility: sol most organic solvents.

Form Supplied in: not available commercially; prepared in situ.

Preparative Methods: iodine nitrate (INO_3) and iodine nitrite (INO_2, more appropriately called nitryl iodide) often show similar chemical properties and can be prepared in situ from iodine and silver nitrate or silver nitrite, respectively. The first reported[4] preparation of INO_3 was from ***Mercury(II) Nitrate*** and ***Iodine*** in ether. ***Silver(I) Nitrate*** and I_2 in ether, acetonitrile, or MeOH, as well as $AgNO_3$ and ***Iodine Monochloride*** in $CHCl_3$-pyridine, have been used successfully for additions to alkenes,[1,4] although the latter reagent also leads to iodopyridinium adducts.[1] ***Nitrogen Dioxide*** and I_2 have also been used to generate INO_3.[2] The first reports[7] of INO_2 addition to alkenes employed ***Silver(I) Nitrite*** and I_2 in ether to produce iodo nitro adducts, but this reagent also can lead to INO_3 adducts.[6c,7]

A typical procedure for addition of INO_3 to alkenes is as follows:[1] to $AgNO_3$ (6.8 g, 0.04 mol) in 50 mL dry $CHCl_3$ and 15 mL anhyd. pyridine is added dropwise 6.5 g (0.04 mol) ICl in 20 mL $CHCl_3$. AgCl is filtered and washed with $CHCl_3$-pyridine and 0.04 mol of (*E*)-4,4-dimethyl-2-pentene is added. After 3 h of stirring, the mixture is poured into ether, filtered, and concentrated to yield 8.7 g (76%) of *erythro*-3-iodo-4,4-dimethyl-2-pentyl nitrate and 5% of an iodopyridinium salt.

A typical procedure for INO_2 addition is as follows:[7] $AgNO_2$ (7.55 mmol) and I_2 (15.1 mmol) in 75 mL ether is stirred for 30 min and 2-cholestene (7.55 mmol) is added under N_2. Workup after 4 h gives 2.033 g (51%) of 2β-iodo-3α-nitrocholestane and 5% (by IR) of 3α-iodo-2β-cholestanyl nitrate.

Handling, Storage, and Precautions: solutions of INO_3 or INO_2 are not stable on standing. These reagents should be handled in a fume hood.

Additions to Alkenes.

Addition of INO_3 to alkenes usually proceeds by ionic attack of I^+, leading to a three-membered ring iodonium species. The reaction is stereoselective (*anti*) and regioselective and steric hindrance plays a role[1,2] (see ***Iodine Azide***). With 2-cholestene, the *trans*-diaxial 3α-iodo-2β-nitrate adduct results either with $AgNO_3$-I_2 (79%) or with N_2O_4 and I_2 (60%) (eq 1).[2] In contrast, when N_2O_4 is added to 2-cholestene and I_2, the product is 2β-iodo-3α-nitrocholestane (60%) from radical attack by $.NO_2$ (eq 1).[7] The same product results from INO_2 addition to the alkene.[7]

(1)

In the presence of pyridine, some alkenes give large amounts of an iodopyridinium adduct, e.g. styrene gives 40% and dihydropyran gives 72% (*trans*) (eq 2).[1,5] The INO_3 adducts can be converted with Zn-Cu in HOAc into unstable iodohydrins which can be reduced to alcohols (eq 3).[1]

(2)

Addition of INO_3 to unsaturated fatty acids gives mixtures of INO_3 adducts and iodo ketones.[8] The reagent oxidizes secondary alcohols to ketones in fair yields.

Reaction of INO_2 with alkenes affords iodo nitro adducts which eliminate HI readily to give unsaturated nitro compounds (eq 4),[6a,7] but, in some sugar adducts, elimination of INO_2 has been reported.[6c] $AgNO_2$-I_2 has been used to iodinate alkylbenzenes at 20 °C, e.g. toluene gives a 5:2 mixture of *p*- and of *o*-iodotoluene.[9]

Iodine-Nitrogen Tetroxide

I_2-N_2O_4

(I_2)

[7553-56-2] · I_2 · Iodine-Nitrogen Tetroxide · (MW 253.80) (N_2O_4)

[10544-72-6] · N_2O_4 · Iodine-Nitrogen Tetroxide · (MW 92.02)

(adds to carbon-carbon multiple bonds to form the corresponding β-iodo-α-nitro compounds;[2] useful precursors for various nitro derivatives;[3,4] experimental variation with $I_2/AgNO_2$;[5,6] radical intermediates;[7] provides good chemo- and regioselectivity)

Alternate Names: iodine-nitrogen dioxide; iodine-dinitrogen tetroxide.

Physical Data: N_2O_4: mp -11.2 °C; bp 21.2 °C; *d* 1.449 g cm^{-3}; colorless substance; brown color due to NO_2 (nitrogen dioxide) in equilibrium: 0.1% (bp), 20% (27 °C), 40% (50 °C).[8] I_2: see ***Iodine***.

Solubility: N_2O_4: decomposes in H_2O; sol alcohol, chloroform, CS_2.

Form Supplied in: N_2O_4: brown liquid/gas supplied in pressure cylinders.

Purification: if necessary, N_2O_4 can be separated from lower nitrogen oxides and nitric acid by fractional distillation under dry oxygen. Gaseous N_2O_4 can be purified by passing through silica and P_4O_{10}; purified N_2O_4 can be resublimed at -70 °C and stored at rt in pressure vessels made of glass or V2A steel.[1,8]

Handling, Storage, and Precautions: N_2O_4 is highly corrosive and very toxic when inhaled;[8b] it is sensitive to moisture and decomposes with water or above 150 °C. This reagent must be handled in a well-ventilated fume hood.

General Discussion.

Nitrogen Dioxide derived from N_2O_4 adds to carbon-carbon multiple bonds to yield, in the presence of ***Iodine***, β-iodo-α-nitroalkanes and -alkenes, both versatile precursors of various nitrogen-containing products. The reaction of I_2/N_2O_4 with isolated double bonds gives the corresponding base-sensitive β-iodo-α-nitroalkanes, usually in good yield. The transformation is conveniently carried out at 0 °C or rt in an organic solvent like ether or

dichloromethane.[9] Reactions with unsymmetrically substituted alkenes lead to the iodonitroalkane with the nitro group at the less-substituted position (eq 1).[2] Both *trans*- and *cis*-stilbene are stated to furnish the same 1-iodo-2-nitro-1,2-diphenylethane (eq 2), proposedly of *erythro* configuration.[2]

(1)

(2)

Analogous results are obtained using $I_2/AgNO_2$[5,6,9] or $I_2/NaNO_2$;[10] these reagent combinations generate the same active species. Thermodynamic data on the equilibrium 2 O_2N&bdot; + Hal_2 &ibond; 2 O_2N-Hal confirm that nitryl halides NO_2X with X = F, Cl, Br do exist, with decreasing content in the equilibrium, but rule out the presence of detectable amounts of O_2N-I (nitryl iodide).[11,12]

In the addition of NO_2/I to C=C moieties, many other functional groups such as carboxy, acetal, ester (eq 3), or trialkylsilyl[13-15] are tolerated, as is some steric hindrance, cf. the cases of camphene[2] or 2-cholestene.[9] In general, best results are obtained with alkyl- or aryl-substituted alkenes, but carboxy- or halo-substituted[12] alkenes (including difluoroethylene[16]) also add I/NO_2 well.

(3)

Mechanistic considerations based on product analyses lead to the conclusion that the overall addition starts with the (probably reversible) attack of NO_2&bdot; on the double bond, forming the more stable radical intermediate.[2,9] In the presence of iodine (or bromine or chlorine, if these do not react faster alone),[12,17] the nitroalkyl radical is trapped to form the β-halo-α-nitroalkane. This mechanism accounts for both the reactivities and regioselectivities observed; in the case of electron-rich double bonds an ionic mechanism may compete, as shown by the formation of a some β-iodoalkyl nitrate.[9,17] Usually, however, side reactions like dihalogenation or formation of β-iodoalkyl nitrates are not important and become significant only if the reaction is carried out inversely or without solvent (eq 4).[1a,17,18]

(4)

Additions of NO_2/I to conjugated enynes and dienes have also been reported, but without experimental details.[19] While the reaction of 1,3-enynes with I_2/N_2O_4 proceeds selectively at the double bond (in a 3,4-mode), 1-iodo-4-nitro-2-alkenes are produced from 1,3-dienes.[19] With nonconjugated dienes, selective monoaddition has been observed.[4]

Further transformations of iodonitro addition products (often prone to decompose on standing) are sometimes effected without isolation, and include the elimination of HI to yield the respective nitroalkene[6] and reduction by ***Sodium Borohydride*** to give the corresponding nitroalkane.[4] While additions with nitryl chloride- or bromide-generating reagents give similar or sometimes even better yields of adducts,[1,12] the further elaboration of the adducts proceeds best with the iodo derivatives.

The reaction of I_2/N_2O_4 with alkynes similarly leads to monoadducts in high yield,[2,3] with analogous reactivity and regioselectivity. Due to steric requirements in the vinyl radical intermediates, iodonitroalkene products of varying (*E*/*Z*) ratios are obtained (eq 5).[1c,2,3,15,20] Subsequent base-induced HI elimination from these β-iodonitroalkenes provides a convenient way to obtain nitroalkynes.[3]

Iodine-Potassium Iodate

I_2-KIO_3

(I_2)

[7553-56-2] · I_2 · Iodine-Potassium Iodate · (MW 253.80) (KIO_3)

[7758-05-6] · IKO_3 · Iodine-Potassium Iodate · (MW 214.00)

(conversion of alkenes to iodohydrins;[1] iodination of some aromatic molecules;[2] the iodohydrins (or iodoacetates) formed are readily converted to *cis*-diols[3])

Physical Data: KIO_3: mp 560 °C; *d* 3.930 g cm^{-3}. I_2: see ***Iodine***.

Solubility: KIO_3: sol water: 9.16 g/100 g water at 25 °C and 32.2 g/100 g water at 100 °C.[4] In other work, the solubility in water was measured to be: 8.40 g KIO_3/100 g water at 25 °C; 13.7 g/100 g at 50 °C; and 24.4 g/100 g at 100 °C.[5] It shows some solubility in aqueous dioxane mixtures: 8.472 g/100 g (0% dioxane:100% water); 5.30 g/100 g (10% dioxane); 3.172 g/100 g (20% dioxane); 1.811 g/100 g (30% dioxane); 0.886 g/100 g (40% dioxane); and 0.471 g/100 g (50% dioxane). KIO_3 insol pure dioxane and most common organic solvents.

Form Supplied in: the active reagent is generated in situ, as needed. KIO_3: colorless monoclinic crystals; commercially available in at least 99.5% purity.

Preparative Method: in reactions with alkenes, the following ratio of reactants is typical: alkene:KIO_3:I_2, 4:1:2 in acetic acid.[3] The iodine and potassium iodate are premixed in acetic acid at ambient temperatures and then treated with the organic substrate and allowed to react at a suitable temperature.

Handling, Storage, and Precautions: the reagent should be prepared in solution, as needed, and used in situ. Potassium iodate is an irritant, particularly of the upper respiratory tract. Ingestion causes headache, nausea and vomiting, dizziness, and gastrointestinal irritation. Avoid ingestion, skin contact, and eye contact. Potassium iodate is a powerful oxidant and should not be stored near combustible materials, near flammable materials, or near powdered metals. Mixing with powdered metals can cause an explosion. It should be stored in a separate and tightly closed container. This combination reagent should be handled in a fume hood.

Addition to Alkenes.

Potassium iodate is a powerful oxidant and ***Iodine*** is an electrophilic reagent. When mixed together in acid media, the combined reagent converts alkenes to iodohydrins, which can be converted to *cis*-diols. Cornforth reacted propene with a mixture of iodine and potassium iodate, in aqueous sulfuric acid, and obtained a 92% yield of 1-iodo-2-propanol, along with 8% of 2-iodo-1-propanol (eq 1).[1] When the same reaction is done in acetic acid and aqueous dioxane, a 78% yield of the iodohydrin is obtained.

This fundamental iodohydrin procedure has been modified to produced *syn*-diols from alkenes. When cyclohexene is treated with I_2/KIO_3 in acetic acid, the *trans*-iodohydrin is formed. Subsequent reflux of this product with aqueous acetic acid or with aqueous DMSO produces *syn*-1,2-cyclohexanediol in 70% yield.[1] This same procedure has been applied to 5α-cholest-2-ene to give 2β-acetoxy-3α-iodo-5α-cholestene (eq 2). Refluxing in aqueous acetic acid leads to an 84% yield of 5α-cholestene-2β,3β-diol.[1,6] This two-step procedure is a useful alternative to the Woodward-Prévost reaction (see ***Iodine-Silver Acetate***) that produces *syn*-diols from alkenes. This I_2/KIO_3 procedure is attractive for this purpose since it does not rely on expensive silver reagents.

Quinones can be converted to iodoquinones with this mixed reagent. When 2-dimethylamino-1,4-benzoquinone is treated with iodine/potassium iodate in a solvent of ether and aqueous sulfuric acid, 2-dimethylamino-3-iodo-1,4-benzoquinone is formed, but in only 22% yield (eq 3).[3]

Iodine-Silver Acetate[1]

I_2-AgOAc

(I_2)

[7553-56-2] · I_2 · Iodine-Silver Acetate · (MW 253.80) (AgOAc)

[563-63-3] · $C_2H_3AgO_2$ · Iodine-Silver Acetate · (MW 166.92)

(source of positive iodine for stereoselective 1,2-functionalization of alkenes)

Physical Data: AgOAc: mp 210 °C (dec). I_2: see ***Iodine***.

Solubility: AgOAc: slightly sol acetic acid (0.54 g L^{-1}), methanol (0.17 g L^{-1}).

Form Supplied in: AgOAc: white solid; widely available.

Analysis of Reagent Purity: Ag can be assayed conveniently by volumetric titration of Ag^I.

Purification: usually used as supplied, but ***Silver(I) Acetate*** can be purified by treatment with acetic acid for a prolonged period, filtering, and drying of the solid in a vacuum oven at 40 °C for 48 h.

Handling, Storage, and Precautions: protect from light.

1,2-Dihydroxylation of Alkenes.

In acetic acid, which is the solvent of choice for these reactions, electron-rich alkenes can be converted into 1,2-dihydroxylated derivatives. The stereochemical outcome is dependent upon the conditions; if the reaction is performed in dry solvent, *trans*-1,2-diacetates are formed (the Prévost reaction) (eq 2).[2] On the other hand, if moist acetic acid is used as the solvent, monoacetylated *cis*-1,2-diols are formed (the Woodward-Prévost reaction) (eq 3).[3] A mechanism involving the intermediate formation of an acetoxonium ion has been suggested (eq 1).

One interesting aspect of the *cis*-hydroxylation method is that it is complementary to oxidation with ***Osmium Tetroxide***, which also gives *cis*-1,2-diols, but these are formed by attack on the least hindered face of the molecule (eq 4). Using the Woodward-Prévost conditions, the *cis*-1,2-diol resulting from attack on the most hindered face predominates (eq 5).

In the oxidation of 1-alkylindenes under both wet and dry conditions, identical facial selectivities were observed, supporting the proposed common acetoxonium ion intermediate (eqs 6 and 7). For example, the identical ratios (**1**)/(**2**) and (**3**)/(**4**), respectively, changed from 0.45 to >100 when going from R = Me to R = *t*-Bu, an effect of the increasing substituent size.[4]

Under certain conditions, 1,2-dihydroxylation does not occur; instead, intramolecular opening of the intermediate iodonium ion is observed, e.g. the lactam oxygen in (**5**) acts as a nucleophile to give (**6**) (eq 8).[5]

(8)

Oxidation of Enol Silyl Ethers.

Enol ethers, and in particular enol silyl ethers, can be transformed into the corresponding α-iodinated ketones by oxidation with I_2/AgOAc in CH_2Cl_2 followed by cleavage of the silyl ether (eq 9).[6]

Iodine-Silver Benzoate

I_2-$PhCO_2Ag$

(I_2)

[7553-56-2] · I_2 · Iodine-Silver Benzoate · (MW 253.80) ($PhCO_2Ag$)

[532-31-0] · $C_7H_5AgO_2$ · Iodine-Silver Benzoate · (MW 228.99)

(the mixture gives silver iododibenzoate as an active reagent which converts alkenes to *cis*-dibenzoates under mild conditions[1])

Alternate Names: Prévost's reagent; silver iododibenzoate.

Physical Data: cream-colored solid.

Solubility: the most common solvent for this reagent is benzene. No data are available for the solubility of the dibenzoate reagent. $PhCO_2Ag$: sol water to the extent of 2.66 g L^{-1} at 25 °C;[2] slightly sol ethanol, 0.169 g L^{-1} (cold) and 0.465 g L^{-1} (reflux).[2]

Form Supplied in: prepared as needed.

Preparative Method: prepared by reaction of ***Iodine*** with 2 equiv of ***Silver(I) Benzoate***.[1] In general, 2 equiv of silver benzoate are refluxed in benzene with 1 equiv of iodine per mole of alkene to be reacted.[3] If the reagent is to be isolated prior to reaction with the alkene, it is first washed with saturated aqueous ammonia to remove silver benzoate and then with saturated aqueous sodium bicarbonate to remove benzoic acid.

Purification: the crystalline complex can be purified by extraction with benzene in a Soxhlet apparatus.[3]

Handling, Storage, and Precautions: no special precautions have been reported for the dibenzoate.

Prévost Reaction.

The reaction of 2 equiv of silver benzoate and iodine initially forms $PhCO_2I$, but this reacts further to form silver iododibenzoate, $(PhCO_2)_2AgI$, containing two benzoate groups.[3] This intermediate can react further under the proper conditions to give the tribenzoate silver derivative, but the dibenzoate is taken to be the reactive species in reactions with alkenes, which is the most important reaction of this reagent. Prévost found that silver benzoate and iodine converts alkenes such as styrene to the 1,2-dibenzoate (eq 1), which can be saponified to the 1,2-diol.[4a] This

transformation (formally a hydroxylation) is now called the Prévost reaction.[4] Reaction with cyclic alkenes generates *trans*-diols, in contrast to permanganate and osmium hydroxylations which give *cis*-diols (see ***Potassium Permanganate*** and ***Osmium Tetroxide***). This reaction is generally related to the Hunsdiecker reaction (the coupling reaction of silver carboxylate; see ***Iodine***). When an alkene reacts with the silver iododibenzoate, an iodonium salt is generated and this is reacts with silver benzoate to form a cationic dioxolane species. Attack by a second molecule of benzoate gives the ester, a *trans*-dibenzoate. Saponification generates the *trans*-diol. A similar hydroxylation reaction, also called the Prévost reaction, uses silver acetate and iodine[5] (see ***Iodine-Silver Acetate***), although the acetate reaction (often called the Woodward-Prévost reaction) gives the *cis*-diol.

(1)

A synthetically useful example of the reaction with silver benzoate is the conversion of a dibenz[*a*,*j*]acridine derivative to the *trans*-dibenzoate in 35% yield (eq 2).[6] With relatively simple systems (such as styrene), the yields are usually quite good (80-90%).

(2)

There are interesting variations in the reaction when other functional groups are present. When 5-isopropyl-5-allylbarbituric acid is treated with silver benzoate and iodine, for example, a 28% yield of a furopyrimidine is obtained (eq 3).[7] The initially formed benzoate intermediate reacts with the proximate imide moiety to produce the final product.

(3)

In addition to quinone derivatives, silver iododibenzoate reacts with aromatic hydrocarbons to give different products.[8] Electron-deficient benzene derivatives such as nitrobenzene give biphenyl derivatives, electron-rich benzene derivatives such as anisole give iodoanisole derivatives, and alkylbenzenes give essentially no reaction.[8,9]

Oxidative Cleavage of 1,2-Diols.

Using an excess of this reagent, 1,2-diols can be cleaved oxidatively.[10] For example, the fatty chain diol in eq 4 is cleaved selectively using $I_2/PhCO_2Ag$.[11]

(4)

Allylic Oxidations.

In certain cases, oxidation of alkenes with $I_2/PhCO_2Ag$ in benzene causes allylic oxidation (eq 5).[12]

Iodine-Silver(I) Fluoride

I_2-AgF

(I_2)

[7553-56-2] · I_2 · Iodine-Silver(I) Fluoride · (MW 253.80) (AgF)

[7775-41-9] · AgF · Iodine-Silver(I) Fluoride · (MW 126.87)

(source of electrophilic iodine, I^+, in electrophilic aromatic substitution reactions;[1] IF addition reagent across double bonds;[2] mild oxidant which fluoridates selected polycyclic aromatic hydrocarbons via radical cationic intermediates[3])

Physical Data: AgF: mp 435 °C; bp 1150 °C; *d* 5.85 g cm^{-3}.

Solubility: AgF: sol acetonitrile; sparingly sol aromatic and halogenated solvents.

Form Supplied in: AgF: orange and brown chunks.

Handling, Storage, and Precautions: AgF: corrosive, harmful dust, hygroscopic, light sensitive. This reagent should be handled in a fume hood.

Electrophilic Reactions.

Up to 50% yield of an aryl iodide is obtained when ***Iodine*** and ***Silver(I) Fluoride*** are added to neat, activated aromatic compounds; much poorer yields result if the aromatic compound is weakly activated or deactivated toward electrophilic aromatic substitution (eq 1)[1] (see ***Trifluoroacetyl Hypoiodite*** for a superior iodinating reagent in electrophilic aromatic substitution reactions). Quantitative *trans* addition to double bonds is observed when a dilute solution of iodine (or bromine) in benzene is slowly added to a suspension of AgF in a solution of the target alkene in benzene (eq 2).[2]

(1)

(2)

Fluorination.

Polycyclic aromatic hydrocarbons with low oxidation potentials are oxidized by the Ag^+/Ag redox couple to radical cations which are attacked by a fluoride nucleophile to give low yields (10-50%) of fluorinated products.[3]

Iodine-Silver Trifluoroacetate

I_2-CF_3CO_2Ag

(I_2)

[7553-56-2] · I_2 · Iodine-Silver Trifluoroacetate · (MW 253.80) (CF_3CO_2Ag)

[2966-50-9] · $C_2AgF_3O_2$ · Iodine-Silver Trifluoroacetate · (MW 220.89)

(a source of positive iodine for iodination of aromatic compounds and for oxidation of alkenes)

Physical Data: CF_3CO_2Ag: mp 257-269 °C (dec).

Solubility: CF_3CO_2Ag: sol benzene, diethyl ether, water.

Form Supplied in: white solid; widely available.

Analysis of Reagent Purity: contents of Ag can be assayed conveniently by volumetric titration of Ag^I.

Preparative Method: extraction of an aqueous solution of $AgNO_3$ and CF_3CO_2Na with ether.[1]

Handling, Storage, and Precautions: should be protected from light.

Introduction.

The combination of ***Iodine*** and ***Silver(I) Trifluoroacetate***, usually in a chlorinated solvent, is believed to involve the formation of a complex between silver trifluoroacetate and electrophilic iodine trifluoroacetate.[1]

Aromatic Iodination.

The reagent can iodinate various aromatic compounds, the conditions being dependent upon the reactivity of the substrate. For example, benzoic acid was iodinated in nitrobenzene at 150 °C to give 3-iodobenzoic acid in 84% yield.[2] On the other hand, iodination of veratrole is performed in refluxing chloroform (eq 1).[3]

(1)

An elegant application of this mild aromatic iodination procedure was reported by Carruthers and co-workers (eq 2).[4]

(2)

Oxidation of Alcohols and Ketones.

Primary alcohols can be oxidized to the corresponding aldehydes in low yields. Secondary alcohols are oxidized to the corresponding ketones, but the reaction is complicated by further oxidation to the 1,2-dicarbonyl compounds. Ketones are transformed into the corresponding 1,2-dicarbonyl compounds, e.g. biacetyl can be isolated in 50% yield from 2-butanone. These reactions are usually not of synthetic value but, in cases where such functional groups are present, care should be taken to prevent their oxidation.[5]

Oxidation of Alkenes.

The positively charged iodine reacts with electron-rich alkenes by analogy with the combination ***Iodine-Silver Acetate***. Depending on the structure of the substrate, the intermediate iodonium ion can undergo intra- or intermolecular consecutive reactions. The simplest case is represented by the treatment of 5α-cholest-2-ene with I_2-CF_3CO_2Ag, where an intermolecular iodotrifluoracetoxylation was observed (eq 3).[6]

(3)

cis-Vinylsilanes behave similarly, i.e. on reaction with I_2-CF_3CO_2Ag, the corresponding 1,2-adduct can be isolated. On elimination with ***Potassium Fluoride***, *trans*-vinyl iodides are formed (eq 4). However, addition of only iodine to the same *cis*-vinylsilane gave the corresponding *cis*-vinyl iodide. Other halogens (Cl_2, Br_2) gave the 1,2-adduct, which can be converted into the corresponding *trans*-vinyl halide by treatment with ***Sodium Methoxide***.[7]

(4)

In a more elaborate approach, tetrahydrofurans were prepared in a stereoselective manner from the corresponding homoallylic alcohols by treatment with I_2-CF_3CO_2Ag (eqs 5-8).[8] From a stereochemical point of view it is interesting to note that the products observed are the results of *syn* addition across the double bond, which is contrary to the expected direction of addition. On the other hand, ***Benzeneselenenyl Chloride*** adds to form the corresponding 2,5-*trans*-tetrahydrofurans, i.e. the result of an *anti* addition. Both (*E*)- and (*Z*)-alkenes behave similarly, i.e. *syn* addition with I_2-CF_3CO_2Ag and *anti* addition with PhSeCl. Another unexplained observation is that the direction of the nucleophilic attack is dependent upon the stereochemistry of the alkene, i.e. (*E*)-alkenes are attacked by iodine on the most hindered side (eqs 5 and 7), whereas (*Z*)-alkenes are attacked on the least hindered side (eqs 6 and 8).

(5)

R = H, OBn, OTBDMS

(6)

(7)

(8)

The use of acetonitrile as the solvent is critical for the success of these reactions.

Iodine Tris(trifluoroacetate)[1]

$(CF_3CO_2)_3I$

[14353-86-7] · $C_6F_9IO_6$ · Iodine Tris(trifluoroacetate) · (MW 465.96)

(formation of trifluoroacetoxy-substituted alkanes,[5,6] reacts with alkenes to form bis(trifluoroacetates);[10] iodinates arenes;[7,8] preparation of iodonium salts via [bis(trifluoroacetoxy)iodo]arenes;[9] induces 1,2-migration in arylalkenes;[11] formation of α,β-trifluoroacetoxy diesters from cyclic ethers[5,12,13])

Alternate Names: ITT; tris(trifluoroacetoxy)iodane.

Physical Data: mp 120 °C (dec).

Solubility: sol CH_2Cl_2, $CHCl_3$.

Form Supplied in: yellow crystals; not commercially available.

Analysis of Reagent Purity: elemental analysis.[4]

Preparative Methods: ***Trifluoroacetic Acid*** oxidation of ***Iodine***;[2] reaction of ***Silver(I) Trifluoroacetate*** with ICl_3;[3] reduction of $IO_2(CO_2CF_3)$ with I_2;[2] or action of ***Nitric Acid/Trifluoroacetic Anhydride*** on I_2.[4]

Purification: sublimation (90 °C/10^{-3} mmHg).[4]

Handling, Storage, and Precautions: stable compound; store in the absence of moisture in a sealed container under nitrogen, protected from light. Handle in a fume hood.

Oxidation of Alkanes.

Alkanes react rapidly with iodine tris(trifluoroacetate). In the case of cyclohexane, $(AcO)_3I$ does not react at rt, but ITT reacts in 3 d (eq 1).[5]

(1)

16% 30%

cis:*trans* = 9:1

Alkanes possessing tertiary C-H groups are oxidized within minutes to form trifluoroacetate esters (eqs 2-4).[5]

(2)

(3)

(4)

99.9% *exo*

8α*H*-Cedrane reacts rapidly at rt to yield the ring contracted ketone (eq 5).[6]

(5)

Reaction with Arenes.

The reaction of arenes with ITT leads to introduction of the $(CF_3CO_2)_2I$ group onto the aromatic ring to yield the corresponding [bis(trifluoroacetoxy)iodo]arenes (eqs 6 and 7).[7] The reaction of ITT with a variety of aromatic compounds, including those substituted with electron-withdrawing groups, can be employed in a general method for the synthesis of iodoarenes.[8] For example, treatment of *p*-methoxyacetophenone with ITT at rt followed by reduction of the intermediate I^{III} species with aqueous ***Sodium Iodide*** provides the aryl iodide in excellent yield (eq 8).[8]

(6)

(7)

(8)

Similarly, toluene yields a 2:3 *o*:*p* ratio and chlorobenzene yields a 6:94 *o*:*p* ratio of products.

[Bis(trifluoroacetoxy)iodo]arenes can be used for the preparation of iodonium salts (eq 9).[9]

(9)

Miscellaneous Reactions.

Alkenes yield *vic*-*cis*-bis(trifluoroacetoxy) diesters upon addition of ITT (eq 10).[10]

(10)

1,2-Migration occurs in the reaction of $Ar_2C{=}CH_2$ with ITT following addition of water (eq 11).[11]

(11)

Ethers react with ITT to yield α,β-(trifluoroacetoxy) diesters (eqs 12 and 13).[5,12,13]

Iodoacetonitrile

ICH_2CN

[624-75-9] · C_2H_2IN · Iodoacetonitrile · (MW 166.95)

(used for alkylation of nucleophiles;[1-14] undergoes Reformatsky[15] and Wittig-type[16] reactions with aldehydes)

Alternate Name: iodomethyl cyanide.

Physical Data: bp 182-184 °C/720 mmHg, 75 °C/10 mmHg; *d* 2.307 g cm^{-3}.

Solubility: insol hexane; slightly sol H_2O; sol benzene, alcohol, acetone, ether, CH_2Cl_2.

Form Supplied in: yellow to amber liquid; commercially available.

Handling, Storage, and Precautions: lachrymator; avoid inhalation of vapors; flammable (toxic fumes); possible mutagen; refrigerate. Handle in a fume hood.

Iodoacetonitrile is commonly used for the alkylation (cyanomethylation) of a wide variety of nucleophiles (eq 1), including ketone enolates,[1] ester enolates,[2] amines,[3,4] thiols,[5] phosphines,[6] enolic hydroxyls,[7] enol-TMS intermediates,[8] borates,[9] thioamides,[10] arene π-complexes,[11] and miscellaneous nitrogen heterocycles.[12,13] The value of the resulting alkylation products often lies in their versatility with respect to further synthetic transformations, either straightforward reactions such as conversion to amides, amines, or acids, or more substrate-specific reactions including rearrangements,[14] ring expansion,[12] conversion to formaldehyde iminium intermediates,[3] or conversion to novel heterocycles.[13]

$$\text{Nu-H} \xrightarrow[\text{B}^-]{\text{ICH}_2\text{CN}} \text{Nu-CH}_2\text{CN} + \text{BH} + \text{I}^- \qquad (1)$$

In a Reformatsky-type reaction, aldehydes (not ketones) react with ICH_2CN in the presence of freshly prepared metallic ***Nickel*** (eq 2)[15] to give β-hydroxy nitriles. Yields are good due to the low basicity of the cyanomethylnickel halides, and the selectivity for aldehydes in the presence of ketones may prove useful in complex substrates.

(2)

α,β-Unsaturated nitriles are available in good yield by the reaction of ICH_2CN with carbonyl compounds mediated by tri-*n*-butylstibine, under mild and essentially neutral conditions (eq 3).[16]

(3)

The reaction of ICH_2CN with thioamides provides a racemization-free route to β-keto nitriles through the intermediacy of an α-cyanoenamine (eq 4).[17] When primary thioamides are alkylated with ICH_2CN, a substituted thiazole is the predominant product (eq 5).[18]

(4)

(5)

Radical addition of ICH_2CN to alkyl-substituted alkynes leads to γ-iodo-β,γ-unsaturated nitriles, which are good precursors for radical translocation reactions (eq 6).[19]

(6)

γ-Keto-nitriles (useful in the synthesis of heterocycles) and β,γ-unsaturated nitriles with controlled geometry and substitution pattern are synthesized by treating alkynyltrialkylborates with ICH_2CN followed by oxidation or protonolysis (eq 7).[20]

(7)

Gordon L. Bundy

(Iodoethynyl)trimethylsilane

[18163-47-8] · C_5H_9ISi · (Iodoethynyl)trimethylsilane · (MW 224.13)

(alkyne coupling reagent predominantly used in conjunction with organocopper species or palladium catalysis)

Physical Data: bp 96 °C, 55 °C/20 mmHg; *n*20D 1.5110.

Form Supplied in: not commercially available.

Preparative Methods: all involve iodination of trimethylsilylacetylenes. Direct iodination of metalated (lithium or magnesium) trimethylsilylacetylene has been largely supplanted due to the modest yields obtained.[1] Utilizing ***Trimethylsilylacetylene*** and ***Bis(trimethylsilyl) Peroxide*** in the presence of ***Copper(I) Iodide*** gives good yields.[2] Substituting ***Zinc Iodide*** requires using the lithium acetylide.[3] Copper(I) iodide (0.05 equiv.) in the presence of iodine, sodium carbonate, and a phase-transfer catalyst gives good yields without having to use *n*-butyllithium or a Grignard reagent to first deprotonate the trimethylsilylacetylene.[4] The most popular procedure uses ***Bis(trimethylsilyl)acetylene***, treating it with ***Iodine Monochloride*** in dichloromethane at 25 °C to obtain excellent yields of (iodoethynyl)trimethylsilane.[5,6]

Handling, Storage, and Precautions: use in a fume hood.

Introduction.

(Iodoethynyl)trimethylsilane has been largely confined to aryl- and vinylcopper coupling, where it serves well since the reverse procedure, i.e. coupling with alkynylcopper reagents, is not straightforward due to the lack of reactivity of alkynyl moieties bound to copper.

Cross Coupling with Organocopper Reagents.

Vinylcopper species, prepared by the copper-catalyzed addition of ***Ethylmagnesium Bromide*** to monosubstituted alkynes, react with (iodoethynyl)trimethylsilane (eq 1) in the presence of 1.2-2 equiv of

TMEDA to afford the enyne in good yield.[7] In the absence of TMEDA, iodine exchange to the vinyl group occurs instead of alkynyl-vinyl coupling. In a similar fashion,[8] addition of lithium tributylstannyl(cyano)cuprate across the alkyne gave a vinylcuprate which required the addition of ***Lead(IV) Acetate-Copper(II) Acetate*** to couple successfully with (iodoethynyl)trimethylsilane. In the absence of zinc(II) chloride, very low yields of the desired product are obtained.

(1)

Allenylcopper species, prepared by ***n-Butyllithium*** deprotonation of substituted allenes followed by addition to ***Copper(I) Bromide***, have been coupled with (iodoethynyl)trimethylsilane to give allenyne products (eq 2).[9]

(2)

$R^1 = t\text{-Bu}, R^2 = H; R^1 = R^2 = Me$

Arylcopper(I) adducts, prepared by adding an aryllithium or Grignard reagent to a slight excess of copper(I) bromide in ethereal solvent, give rise to arylalkynes when treated with (iodoethynyl)trimethylsilane (eq 3).[10] Yields are modest to good, with ***Phenylcopper*** giving 64%. It was noted that substitution of a catalytic amount of copper(I) bromide, with either ***Phenyllithium*** or ***Phenylmagnesium Bromide***, or using ***Lithium Diphenylcuprate***, gives iodine transfer to the phenyl group, resulting in the copper acetylide which undergoes coupling with the reactive (iodoethynyl)trimethylsilane to give bis(trimethylsilyl)butadiyne. Although yields are modest, the above sequence is complementary to the Stephens-Castro coupling where aryl iodides are heated in the presence of relatively unreactive copper acetylides to obtain arylalkynes.

(3)

Both (bromo- and (iodoethynyl)trimethylsilane undergo base-induced desilylation, followed by decomposition, when subjected to Cadiot-Chodkiewicz coupling conditions. Switching to the more stable (bromoethynyl)triethylsilane affords good yields of the terminal diynes after protodesilylation (eq 4).[11]

(4)

Palladium-Catalyzed Coupling.

Palladium catalysis (eq 5) has been successfully applied to the coupling of (iodoethynyl)trimethylsilane and acrylate esters. ***Palladium(II) Acetate*** (0.004 equiv.), reduced in situ to palladium(0), in the presence of the alkyne, methyl acrylate, carbonate base, and a phase-transfer salt at 25 °C, gave a 40% yield of the coupled product.[12]

(5)

At some point, cleavage of the alkynyl-silane bond is generally desired, which can be accomplished quickly and almost quantitatively by treatment with alkali in methanol at 25 °C.[13]

Iodoform

CHI_3

[75-47-8] · CHI_3 · Iodoform · (MW 393.72)

(precursor to both mono- and diiodocarbene for addition to alkenes and arenes; adds to alkenes by a radical chain mechanism when correctly initiated; iodine atom donor for quenching carbon radicals; used in conjunction with chromium(II) chloride for the homologation of aldehydes to (*E*)-iodoalkenes)

Alternate Name: triiodomethane.

Physical Data: mp 120-123 °C; *d* 4.008 g cm^{-3}.

Solubility: sol ethanol, acetone, ether, benzene, carbon disulfide, dichloromethane, THF; slightly sol petroleum ether.

Purification: crystallization from ethanol.

Handling, Storage, and Precautions: yellow crystalline solid with a disagreeable odor. Decomposes at high temp with evolution of iodine.

Diiodocarbenoid Precursor.

Diiodocarbene, formed by base-induced decomposition of iodoform, with or without phase-transfer catalysis, adds to alkenes giving diiodocyclopropanes which may be rearranged with Ag^I to iodoalkenes (eq 1).[1] Under phase-transfer conditions, reaction with adamantane gives 1-(diiodomethyl)adamantane.[2]

(1)

The triiodomethyl anion, formed from iodoform and 50% ***Potassium Hydroxide***, can be trapped by addition to pyridinium and isoquinolinium salts (eq 2).[3]

(2)

DCB = 2,6-dichlorobenzyl

Monoiodocyclopropanes may be prepared by reaction of alkenes with iodoform in the presence of copper, albeit in only low yield.[4] The iodocarbenoid formed from iodoform and ***Diethylzinc*** adds to alkenes in moderate yield with clean retention of configuration and with high preference for the *syn*-isomer (eq 3).[5]

(3)

syn only

Photolysis of iodoform in the presence of alkenes also leads to the formation of monoiodocyclopropanes, also with retention of configuration (eq 4). With *cis*-2-butene the *syn*:*anti* ratio was 1.6:1 (eq 5).[5c,6] Interestingly, with cyclic *cis*-alkenes such as cyclooctene only the *endo*-iodocyclopropane was formed both under photolytic conditions and with diethylzinc.[5c] Flash photolysis experiments indicated that the photochemical reaction proceeds via homolysis of iodoform to iodine atoms and diiodomethyl radicals.[7] Accordingly, photolysis in the presence of a more reactive alkene, norbornene, gave a mixture of radical and carbene addition products.[8]

(4)

(5)

Arenes also react with the diethylzinc/iodoform couple to give a cyclopropane adduct that suffers further reaction with diethylzinc and rearrangement to cycloheptatrienes (eq 6).[9]

(6)

Radical Reactions.

Triethylborane initiates the radical addition of iodoform to ketene silyl acetals, resulting in the isolation of β-iodo-α,β-unsaturated esters (eq 7).[10] With tetraiodomethane the corresponding β,β-diiodide was obtained. Radical addition of iodoform to methyl acrylate is also reported to be initiated with ***Pentacarbonyliron*** (eq 8).[11]

(7)

(8)

Addition to limonene (eq 9) serves to illustrate that terminal alkenes are more readily attacked than internal alkenes and that the reaction is not limited to electron-deficient substrates.[12]

(9)

Iodoform acts as an iodine atom donor in the Barton version of the Hunsdiecker reaction. Aliphatic, and to some extent aromatic, carboxylic acids undergo this oxidative decarboxylation and optimum yields were obtained when cyclohexene was used as solvent in place of benzene.[13] The reaction, which may be initiated thermally,[13,16] photolytically,[14] or with ultrasound,[15] tolerates many functional groups and has been applied to cyclopropanecarboxylic acids (eq 10)[16] and notably to electron-rich aromatic acids (eq 11).[13]

(10)

(11)

Alkenation Reactions.

Takai has described a very simple procedure for the homologation of aldehydes to iodoalkenes which involves treatment with iodoform and ***Chromium(II) Chloride*** and which proceeds with high selectivity for the (*E*)-product (eqs 12 and 13).[17]

(12)

(E):(Z) = 82:18

(13)

Although ketones are less reactive, as demonstrated by competition reactions, good yields of iodoalkenes are nonetheless obtained (eq 14).[17]

(14)

In the course of a synthesis of Macbecin I, Baker and Castro devised a synthesis of β-iodomethacrylic acid that involved alkylation of diethyl methylmalonate with iodoform followed by saponification and decarboxylation (eq 15).[18]

(15)

Other Applications.

Deuterated or tritiated methylene diiodide may be prepared from iodoform as reported by Saljoughian (eq 16), providing a convenient method for the incorporation of deuterium or tritium into cyclopropane rings via the Simmons-

Smith reaction.[19]

$$CHI_3 + Na_3AsO_3 + NaOT \xrightarrow[\text{HTO}]{60\ ^\circ C} TCHI_2 + NaI + Na_3AsSO_4 \quad (16)$$

74%

The Finkelstein reaction of iodoform with ***Silver(I) Fluoride*** or ***Mercury(II) Fluoride*** provides mixtures of diiodofluoromethane and difluoroiodomethane (eq 17).[20]

$$CHI_3 \xrightarrow[\text{or } HgF_2]{AgF} \underset{35\%}{CHFI_2} + \underset{15\%}{CHF_2I} \quad (17)$$

Related Reagents.

Bromoform; ***Diethylzinc-Iodoform***; ***Diiodomethane***; ***Triphenylphosphine-Iodoform-Imidazole***.

Iodo(iodomethyl)mercury

ICH_2HgI

[141-51-5] · CH_2HgI_2 · Iodo(iodomethyl)mercury · (MW 468.42)

(reagent for the methylenation of alkenes[1])

Physical Data: pale yellow crystals; mp 113-116 °C.

Solubility: sol THF, hot benzene.

Preparative Method: treatment of ***Mercury(0)*** with 5 equiv of ***Diiodomethane*** with mechanical stirring and irradiation with a sunlamp resulted in the disappearance of the liquid mercury. Upon cooling and addition of benzene, a precipitate was obtained, which after recrystallization from hot (93 °C) diiodomethane gave pale yellow crystals of product in 48% yield.[2]

Handling, Storage, and Precautions: little information is available about iodo(iodomethyl)mercury, but as with all mercury reagents, care should be taken when handling these toxic reagents. Use in a fume hood.

Iodo(iodomethyl)mercury was first prepared in 1880.[3] However, it was not until 1964 that its use as a methylene transfer reagent was reported.[1] The reaction of iodo(iodomethyl)mercury with cyclohexene affords the corresponding cyclopropane, norcarnene, in 24% yield after 8 d (eq 1). The reaction benefits from the addition of an equimolar quantity of ***Diphenylmercury*** (eq 2). The reaction is stereospecific, and the alkene geometry is retained during the cyclopropanation reaction (eqs 3 and 4). There is also sensitivity to the electronic nature of the alkene, since tetrachloroethylene was found to be inert to cyclopropanation (eq 5).

(1)

More recently, the use of iodo(iodomethyl)mercury for the methylenation of bis(trimethylsilyl)acetylene has been reported.[4] The unstable cyclopropene could be isolated in 10% yield, but by repeating the reaction in the presence of 1,3-diphenylisobenzofuran the Diels-Alder adduct could be isolated in 35% yield (eq 6).

It is believed that there is an exchange process between iodo(iodomethyl)mercury and diphenylmercury which affords the more reactive methylenating reagent bis(iodomethyl)mercury (eq 7).[5] Other mercury-containing reagents, including bis(bromomethyl)mercury and ***Phenyl(trichloromethyl)mercury***, have been reported to cyclopropanate alkenes.[6]

For many applications it would seem that the related Simmons-Smith cyclopropanation[7] using ***Diiodomethane*** and a ***Zinc/Copper Couple*** is more effective than the use of mercury-containing reagents. However, to date, stereoselective reactions have not been exploited with the mercury reagents.

Iodomethane

MeI

[74-88-4] · CH_3I · Iodomethane · (MW 141.94)

(methylating agent for carbon, oxygen, nitrogen, sulfur, and trivalent phosphorus)

Alternate Name: methyl iodide.

Physical Data: bp 41-43 °C; *d* 2.28 g cm^{-3}.

Solubility: sol ether, alcohol, benzene, acetone; moderately sol H_2O.

Form Supplied in: colorless liquid; stabilized by addition of silver wire or copper beads; widely available.

Purification: percolate through silica gel or activated alumina then distill; wash with dilute aqueous $Na_2S_2O_3$, then wash with water, dilute aqueous Na_2CO_3, and water, dry with $CaCl_2$ then distill.

Handling, Storage, and Precautions: toxic, corrosive and a possible carcinogen. Liquid should be stored in brown bottles to prevent liberation of I_2 upon exposure to light. Keep in a cool, dark place. Use only in well ventilated areas.

C-Methylation.

Methyl iodide is an active alkylating agent employed in the *C*-methylation of carbanions derived from ketones, esters, carboxylic acids, amides, nitriles, nitroalkanes, sulfones, sulfoxides, imines, and hydrazones.[1] The quantity of methyl iodide utilized in methylations varies from a slight (1.1 equiv) to a large excess (used as solvent).

The monomethylation of carbanions derived from 1,3-cyclohexanedione and acetylacetone has been described (eqs 1 and 2).[2] Selective monomethylation of β-diketones is dependent upon the base employed; variable amounts of *O*-methylation, dimethylation, and carbon-carbon bond cleavage may occur. The tetraethylammonium enolate of β-diketones reportedly provides higher yields of *C*-methylation without competing side reactions (eq 3).[3] Dimethylation is sometimes a desired reaction pathway. In this case, a large excess of both methyl iodide and base favors the dimethylated product (eq 4).[4] Recently, the combination of a potassium base and a catalytic amount of ***18-Crown-6*** (eq 5) has been described to provide a higher yield of dimethylation.[5,6]

(5)

Methylation of kinetically derived enolates is most readily accomplished via the corresponding silyl enol ether.[7] Lithium enolates, generated by treatment of the silyl enol ether with ***Methyllithium***, may then be alkylated with methyl iodide (eq 6).[8] Alternatively, quarternary ammonium enolates are produced by treatment of the silyl enol ether with the corresponding fluoride salt. For example, monomethylation of a ketone is cleanly effected by treatment of an anhydrous mixture of the trimethylsilyl enol ether of the ketone in methyl iodide with benzyltrimethylammonium fluoride (eq 7).[9] Kinetic enolates produced from the conjugate addition of an organocuprate to an unsaturated ketone or a dissolving metal reduction of an enone may be methylated directly.[7c] However, the choice of solvent is crucial for the success of these reactions. Ether, the solvent typically used in organocopper conjugate additions, is a poor solvent for alkylation reactions.[10] ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA), ***Hexamethylphosphoric Triamide*** (HMPA) and liquid ***Ammonia*** have been used as additives to increase the efficiency of alkylation. Alternatively, the solvent used in the conjugate addition can be removed in vacuo and replaced with a more effective medium for alkylation. For example the rate of methylation of the enolate produced in the conjugate addition of ***Lithium Dimethylcuprate*** to an enone is approximately 10^5 times faster in DME than in ether (eq 8).[11]

(6)

(7)

(8)

The stereoselectivity of the methylation of ketone enolates is determined by the structure of the substrate.[12] Stereoselective methylation of cyclic ketone enolates has been examined in detail and current models reliably predict the stereochemical outcome (eqs 9-11).[13-15] Diastereoselective methylation of acyclic ketone and ester enolates has been accomplished employing a variety of chiral auxiliaries (eq 12).[12,16] Efficient catalytic enantioselective methylation of 6,7-dichloro-5-methoxy-1-indanone has been accomplished via a chiral phase-transfer catalyst (eq 13).[17] An enantiomeric excess of 92% was observed when employing ***Chloromethane*** as the methylating agent, whereas methyl iodide provided a product of only 36% enantiomeric excess.

(9)

(10)

O-Methylation.

Carboxylic acids can be converted to the corresponding methyl ester by stirring a mixture of the carboxylic acid in methanol with an excess of methyl iodide and ***Potassium Carbonate***.[18] A recent report describes the esterification of carboxylic acids using ***Cesium Fluoride*** and methyl iodide in DMF (eq 14).[19] ***Dimethyl Sulfate*** has also been advantageously utilized to effect *O*-methylation of carboxylic acids as well as alcohols (eq 15).[18c,20] These methods

often serve as useful alternatives to ***Diazomethane*** for preparative scale esterification of carboxylic acids.

(14)

(15)

Phenolic hydroxyls are readily methylated by methyl iodide under basic conditions. The most common conditions are methyl iodide and potassium carbonate in acetone (eq 16).[18a,21] The use of ***Lithium Carbonate*** as the base allows for the selective protection of phenols with a pK_a < 8 (eq 17).[18c] The *peri*-hydroxy group of an anthraquinone is methylated using methyl iodide and ***Silver(I) Oxide*** in chloroform (eq 18).[18a,22]

(16)

(17)

(18)

Aliphatic alcohols are also methylated by methyl iodide under basic conditions in dipolar aprotic solvents (eqs 19 and 20).[23] Typical conditions employ ***Sodium Hydride*** as a base, DMF as the solvent and an excess of methyl iodide.[24] Alternatively, dimethyl sulfate or ***Methyl Trifluoromethanesulfonate*** may be used as the methylating agent. Under acidic conditions, diazomethane will also methylate aliphatic hydroxy groups. Finally, methylation of a hydroxy group may be achieved under essentially neutral conditions using silver(1) oxide (eq 21).[23,25]

(19)

(20)

(21)

S-Alkylation.

Methyl iodide alkylates thioalkoxides and sulfides to produce sulfides and sulfonium ions, respectively. For example, thioalkoxides produced from thiocarbonyl compounds are methylated with methyl iodide to generate the corresponding methyl thioether (eq 22).[26] Sulfonium halides, derived from the reaction of methyl iodide with an alkyl sulfide, are sometimes labile in solution and may undergo further reaction (eq 23).[27,28] ***Dimethyl Sulfoxide*** when refluxed with an excess of methyl iodide produces trimethyloxosulfonium iodide, which is collected as a white solid and recrystallized from water. Similarly, methylation of ***Dimethyl Sulfide*** produces trimethylsulfonium iodide.[29] Treatment of trimethyloxosulfonium and trimethylsulfonium salts with a base yields the corresponding ylides, which serve as useful methylene transfer reagents. ***Silver(I) Perchlorate*** promotes the methylation of less reactive sulfides (eq 24).[30]

(22)

(23)

(24)

Hydrolysis of sulfonium salts serves as a useful protocol for removal of a protecting group or hydrolysis of a carboxylic acid derivative. For example, thioamides are converted into the corresponding methyl esters by methylation with methanolic methyl iodide followed by treatment with aqueous potassium carbonate (eq 25).[31] Methyl thiomethyl ethers are readily hydrolyzed using an excess of methyl iodide in aqueous acetone (eq 26).[32] Under similar reaction conditions, thioacetals are hydrolyzed to the corresponding carbonyl compounds (eq 27).[33]

N-Methylation.

The direct monomethylation of ammonia or a primary amine with methyl iodide is usually not a feasible method for the preparation of primary or secondary amines since further methylation occurs. However, methylation of secondary and tertiary amines leading to the production of tertiary amines and quaternary ammonium salts, respectively, is a useful method. Secondary *N*-methylalkylamines can be prepared from primary amines by a multi-step sequence involving first methylation of the benzylidene of the primary amine followed by hydrolytic removal of the benzylidene group (eq 28).[34] An alternative to the methylation procedure using methyl iodide is the employment of Eschweiler-Clarke conditions.[35] Exhaustive *N*-methylation of amines results in the production of a quaternized amine. The use of ***2,6-Lutidine*** as base is beneficial to carry out quaternization of amines due to the slow rate of methylation of 2,6-lutidine (eq 29).[36] Quaternized ammonium salts are employed in the Hofmann elimination (eqs 30 and 31).[37,38] As in the case

of alcohol methylation, silver(I) salts may be used to facilitate the methylation process (eq 32).[39] Finally, conditions for the methylation of indole have been reported (eq 33).[40]

(28)

(29)

(30)

(31)

(32)

(33)

P-Methylation.

Phosphonium salts are prepared by the quaternization of phosphines with methyl iodide.[41] The displacement reaction is usually conducted in polar solvents such as acetonitrile or DMF. Dialkyl phosphonates are prepared from the reaction of trialkyl phosphites with alkyl halides, commonly known as the Arbuzov reaction.[42] For example, diisopropyl methylphosphonate is prepared by heating a mixture of methyl iodide and ***Triisopropyl Phosphite*** (eq 34).[43]

Iodomethyl Methyl Ether

ICH_2OMe

[13057-19-7] · C_2H_5IO · Iodomethyl Methyl Ether · (MW 171.97)

(reactive methoxymethylating agent for phosphorus,[1] carbon,[2] oxygen,[3] and nitrogen[4] nucleophiles; iodomethylating agent for aromatic systems[5])

Alternate Name: iodomethoxymethane.

Physical Data: bp 122 °C (dec), 39 °C/20 mmHg; *d* 2.030 g cm^{-3}.

Solubility: sol common organic solvents.

Form Supplied in: liquid, commercially available (stabilized with copper).

Preparative Methods: displacement of chloride from ***Chloromethyl Methyl Ether*** by iodide ion, followed by distillation of the product (eq 1);[2a,2b,5b] reaction of ***Formaldehyde*** or trioxane with methanol and ***Hydrogen Iodide*** (eq 2);[6] reaction of methylal (***Dimethoxymethane***) with ***Iodotrimethylsilane*** (eq 3).[1a] This last route has the advantage of not using or producing highly carcinogenic materials such as chloromethyl methyl ether or ***Bis(chloromethyl) Ether***.

$$ClCH_2OMe \xrightarrow{KI} \underset{\textbf{(1)}}{ICH_2OMe} \qquad (1)$$

$$CH_2O \xrightarrow[HI]{MeOH} \textbf{(1)} \qquad (2)$$

$$MeOCH_2OMe \xrightarrow{Me_3SiI} \textbf{(1)} \qquad (3)$$

Handling, Storage, and Precautions: corrosive and a lachrymator; a strong alkylating agent and as such is likely to be harmful if swallowed or absorbed through the skin. It should be handled accordingly. Use in a fume hood.

Methoxymethylations.

The addition of a methoxymethyl group to a reactive functionality is a useful process in organic chemistry. Quite often this can be carried out by using the reagents ***Chloromethyl Methyl Ether*** and ***Bromomethyl Methyl Ether***. However, occasionally the more reactive iodomethyl methyl ether (**1**) has been used instead.

Reaction of (**1**) with Grignard reagents produces methoxymethylated compounds, e.g. (**3**) from (**2**) (eq 4), in high yield.[2b]

(4)

The lithium salts of vinyl carbanions can also be methoxymethylated with (**1**).[2a] Reaction with alkoxides affords the methoxymethylated ethers (MOM ethers) in good yield, e.g. (**5**) from (**4**) (eq 5).[3a]

(5)

The commonly used methoxymethyltriphenylphosphonium halide (**6**) can also be easily prepared from (**1**) and ***Triphenylphosphine*** in good yield (eq 6) under milder conditions than with chloromethyl methyl ether.[1a]

(6)

Reaction with various amines, e.g. ***Triethylamine*** or ***Hexamethylenetetramine***, leads to the salts in good yield as expected.[4] A nice use of the reagent was in the trapping of the cyclopentanone enolate (**8**) generated by addition of the organolithium (**7**) to cyclopentenone to furnish the bis-alkylated cyclopentanone (**9**) in fine yield. This compound was then taken on to sarkomycin (**10**) (eq 7).[7]

Iodomethylations.

Treatment of various aromatic compounds such as styrene and their derived polymers, e.g. polystyrene, with iodomethyl methyl ether (**1**) in the presence of a Lewis acidic metal iodide, e.g. SnI_4 or ***Zinc Iodide***, affords the iodomethyl aromatic derivatives (eq 8).[5]

$$\mathrm{ArH} + \mathbf{(1)} \xrightarrow[\text{or } ZnI_2]{SnI_4} \mathrm{ArCH_2I} \qquad (8)$$

Related Reagents.

Bromomethyl Methyl Ether; ***Chloromethyl Methyl Ether***.

(Iodomethyl)trimethylsilane[1]

Me_3SiCH_2I

[4206-67-1] · $C_4H_{11}ISi$ · (Iodomethyl)trimethylsilane · (MW 214.14)

(electrophile for the preparation of allylsilanes[2] and propargylsilanes;[3] forms carbon alkylation adducts useful for alkene synthesis;[4] alkylation adducts are frequently a source of fluoride-induced reactive intermediates, forming nitrogen[5] and sulfur[6] alkylation adducts that function as ylide precursors; readily undergoes metal-halogen exchange to generate a reagent for Peterson methylenation[7])

Alternate Name: trimethylsilylmethyl iodide.

Physical Data: bp 140-142 °C; *d* 1.442 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: highly flammable liquid; corrosive; irritant; should be stored cold, protected from light, and stabilized with copper metal. Handle in a fume hood.

Allylsilane and Propargylsilane Synthesis.

(Iodomethyl)trimethylsilane has been used to prepare allylsilanes, which are typically utilized in Lewis acid or fluoride ion-promoted reactions with carbonyl compounds to provide homoallylic alcohols. Treatment of Me_3SiCH_2I with ***Methyltriphenylphosphonium Bromide*** and base produces an intermediate phosphonium salt which can be further utilized to prepare allylsilanes from carbonyl compounds.[2a,b] This procedure has been modified so that this series of transformations can be done as a one-pot procedure (eq 1).[2c]

(1)

More recently, it has been demonstrated that activated vinylcuprates can be directly added to Me_3SiCH_2I to give functionalized allylsilanes in moderate yields (eqs 2-4).[8]

(2)

(3)

(4)

The synthesis of propargylsilanes has also been thoroughly explored, and these useful reagents are readily prepared by the addition of substituted lithioacetylides to Me_3SiCH_2I.[3] Propargylsilanes have subsequently been used in ***Titanium(IV) Chloride***-promoted reactions with acetals to yield functionalized α-allenylsilanes or functionalized alkenes.

Alkene Synthesis.

α-Alkylation of ketones with Me_3SiCH_2I, followed by a bromination/elimination sequence, gives rise to α-methylene ketones (eq 5).[4a]

(5)

α-Alkylation of sulfones with Me_3SiCH_2I, followed by fluoride-induced elimination of the resultant β-silyl sulfones, cleanly produces alkenes, and this method has been applied to the synthesis of terminal alkenes, 1,4-dienes (by sequential dialkylation with ***Allyl Bromide*** and Me_3SiCH_2I), 1,3-dienes (eq 6), and *exo*-methylene compounds (eq 7).[4b] The intermediate β-silyl sulfones function as a synthon for $CH_2{=}CH^-$.

(Iodomethyl)trimethylsilane

(6)

(7)

Generation of Nitrogen and Sulfur Ylides.

N-Trimethylsilylmethyl amides, prepared by the alkylation of the deprotonated amide with Me_3SiCH_2I, provide convenient access to nonstabilized azomethine ylide precursors. This method involving fluoride-promoted generation of a nonstabilized imidate ylide for 1,3-dipolar cycloaddition has been applied to the efficient construction of a key intermediate for the synthesis of the pyrrolizidine alkaloids retronecine and indicine by in situ trapping of the ylide

intermediate with ***Methyl Acrylate*** (eq 8).[5] This more versatile desilylation method of ylide generation and trapping with dipolarophiles demonstrates applicability to a wider range of synthetic targets than those derived from α-deprotonation of iminium salts, where an often unwanted anion-stabilizing substituent is required.

Similarly, the ***Cesium Fluoride***-induced desilylation of α-trimethylsilylbenzylsulfonium alkyl triflate salts produces sulfur ylides, which rapidly equilibrate in DME solution to the thermodynamically more stable ylide prior to reaction with aromatic aldehydes to produce predominantly *trans*-diaryl epoxides in high yields.[6a] In the absence of an aldehyde trapping agent, Sommelet-Hauser rearrangements occur.

Related Reagents.

(methylene transfer reagent: cyclopropanates alkenes,[1] a^1/d^1 multicoupling reagent,[2] transmetalation with various metal halides affords other iodomethylmetal compounds[3])

Alternate Name: Simmons-Smith reagent.

Physical Data: an X-ray crystal structure of $(ICH_2)_2Zn$ complexed to a glycol bis-ether is known;[4] DME complexes of $(ICH_2)_2Zn$ and $(ClCH_2)_2Zn$ and an acetone complex of $(ICH_2)_2Zn/ZnI_2$ have been characterized by NMR spectroscopy;[4] ^1H NMR spectra attributed to THF complexes of $BrCH_2ZnBr$ and $(BrCH_2)_2Zn$ have been reported.[5]

Solubility: ICH_2ZnI generated from either CH_2I_2/Zn-Cu couple or $EtZnI/CH_2I_2$ is generally prepared in ethereal solvents (Et_2O, DME). The Et_2Zn/CH_2I_2 method of reagent generation can utilize noncoordinating solvents (CH_2Cl_2, $ClCH_2CH_2Cl$, toluene, etc.).

Preparative Methods: the two most widely used methods of preparing halomethylzinc reagents are the Simmons-Smith and Furukawa procedures, utilizing ***Diiodomethane/Zinc/Copper Couple*** and CH_2I_2/***Diethylzinc*** (or ***Chloroiodomethane***/Et_2Zn),[6] respectively. The reagent is often prepared in the presence of the substrate (usually an alkene). Various methods of reagent preparation are discussed below. The precursors are widely available.

Reagent Preparation.

There are a number of protocols for generating iodomethylzinc reagents, which can be categorized into three general classes: type 1, the oxidative addition of a dihalomethane to zinc metal, as typified by the original Simmons-Smith procedure;[7,8] type 2, the reaction of a zinc(II) salt with a diazoalkane, first reported by Wittig and co-workers;[9] and type 3, an alkyl exchange reaction between an alkyl zinc and a 1,1-dihaloalkane, often referred to as the Furukawa procedure.[10]

Type 1 reagent generation has been used most often in synthetic contexts due to the ease with which the reagent precursors can be handled. Although the initial method of preparation of the Zn-Cu couple was difficult and not easily reproducible,[7] several simpler and highly reproducible methods soon followed.[11] Treatment of the Zn-Cu couple with CH_2I_2 and a crystal of ***Iodine*** in Et_2O followed by heating to reflux generates the active reagent. Other modifications include the use of CH_2I_2/Zn/CuCl,[12a] CH_2I_2/Zn-Ag couple,[12b] CH_2Br_2/Zn/$TiCl_4$,[12c] and CH_2Br_2/Zn/AcCl/CuCl.[12d]

Type 2 reagent generation has been utilized much less frequently. The method consists of the treatment of an ethereal suspension of a zinc(II) salt ($ZnCl_2$, $ZnBr_2$, ZnI_2, or $Zn(OBz)_2$) with CH_2N_2 or an aryldiazomethane.[9a]

Type 3 halomethylzinc generation (originally reported in 1966)[10a] involves treatment of a solution (Et_2O, hexane, toluene, etc.) of Et_2Zn with CH_2I_2 to generate the reagent. The use of a 2:1 ratio of CH_2I_2 to Et_2Zn generates $(ICH_2)_2Zn$,[4] while a 1:1 ratio presumably generates $EtZnCH_2I$.[10] The reaction is accelerated by the presence of trace amounts of oxygen.[6b] Treatment of Et_2Zn with substituted diiodides, such as benzylidene and ethylidene iodide, also gives rise to active cyclopropanating reagents.[13] Recently, the substitution of $ClCH_2I$ for CH_2I_2 and the use of $ClCH_2CH_2Cl$ (DCE) as the reaction solvent has been demonstrated to provide a more reactive reagent for certain applications.[6a] In addition, the combination of EtZnI and CH_2I_2 has also been shown to provide ICH_2ZnI, thus avoiding the need for the highly pyrophoric Et_2Zn.[14]

Cyclopropanations.

The cyclopropanation of alkenes utilizing halomethylzinc reagents (ICH_2ZnI being the prototypical reagent), known as the Simmons-Smith reaction,[7] has proven to be an extremely versatile and general reaction. Typical examples of alkenes that have been successfully cyclopropanated are provided in eqs 1-5. A variety of isolated alkenes have been cyclopropanated with the Simmons-Smith reagent (e.g. eq 1),[1a,12b] and ICH_2ZnI provides for a unique preparation of numerous spiro derivatives (eq 2).[15] Electron-rich alkenes such as enol ethers (eq 3)[16a-c] and enamines (eq 4)[16d,e] also have been found to be good substrates under the proper conditions, as have certain steroidal enones (eq 5).[16f,g] Simmons-Smith reagents thus have been demonstrated to cyclopropanate alkenes ranging from electron rich to electron deficient. This contrasts with the analogous reagents generated from CH_2I_2/R_3Al[17] and $ClCH_2I$/Sm(Hg):[18] the former reacts preferentially with isolated alkenes, while the latter cyclopropanates allylic alcohols almost exclusively. Certain vinyl metal species (Al, Si, Ge, Sn, B) can also be cyclopropanated with some success with the Simmons-Smith reagent.[19] For example, vinylalanes produced in situ from alkynes and ***Diisobutylaluminum Hydride*** react readily with CH_2Br_2/Zn-Cu couple; the intermediate cyclopropylalanes react with bromine to produce cyclopropyl bromides (eq 6).[19b] Generally, the reaction is most successful with electron-rich alkenes, indicative of the electrophilic nature of halomethylzinc reagents.[1a]

(1)

(2)

(3)

(4)

(5)

(6)

The reaction is not limited to unsubstituted methylene transfers.[13] The combination of $MeCHI_2$[13a-c] or $PhCHI_2$[13a,d] with

Et_2Zn also provides active cyclopropanation reagents. The diastereoselectivity is highly substrate dependent, but good diastereoselectivity can be achieved in certain cases (eq 7), particularly with cyclic alkenes. The stereoselectivity is solvent dependent, with ethereal solvents affording the higher levels of selectivity.[13d] Halogen-substituted carbenoids can also be prepared from various $XCHI_2$ (X = I, Br, F) or X_2CHI (X = Br, Cl) and Et_2Zn (eq 8).[13e-g]

(7)

(8)

Perhaps the most intriguing aspect of the Simmons-Smith reaction is the strong accelerating and stereodirecting effect of oxygen functions proximal to the alkene. First discovered in 1959,[20] this reaction has been often utilized in synthetic efforts[21] and the reaction itself has been the subject of several investigations.[22] For example, cyclopropanation of 2-cyclohexen-1-ol provides the *syn*-cyclopropane almost exclusively.[22a] A study of various cyclic allylic alcohols demonstrates the generality of the effect (eq 9):[22c] the larger rings afford *trans* adducts due to conformational effects. The diastereoselectivity of the cyclopropanation of acyclic secondary allylic alcohols depends upon the configuration of the alkene. *cis*-Alkenes react with diastereoselectivities of >99:1 (eq 10), while *trans*-alkenes react with much less selectivity (<2:1).[22f] Homoallylic alcohols also show a similar directing effect in certain cases (eq 11).[20,21e]

Chiral auxiliary mediated cyclopropanations which exploit this oxygen-directing effect have recently been developed. The first Simmons-Smith reactions exhibiting effective diastereofacial control by chiral auxiliaries were reported simultaneously by two groups in 1985.[23,24] Chiral acetals derived from cyclic enones undergo highly diastereoselective cyclopropanations upon treatment with CH_2I_2/Zn-Cu couple (eq 12). Acyclic enones are cyclopropanated with greatly attenuated diastereoselectivity.

Similarly, chiral acetals[24] derived from α,β-unsaturated aldehydes and diisopropyl tartrate are cyclopropanated in a highly diastereoselective manner by CH_2I_2/Et_2Zn (eq 13). Diastereoselectivities are uniformly high for dioxolane acetals derived from *trans*-disubstituted α,β-unsaturated aldehydes, but acetals derived from α,β-unsaturated ketones react less selectively, as do 2-alkenyl-1,3-dioxane acetals.

A related oxygen-directed cyclopropanation has also been reported.[25] Vinyl boronates derived from tartaric esters or amides were shown to undergo highly diastereoselective cyclopropanations upon treatment with CH_2I_2/Zn-Cu couple. These adducts were conveniently converted to enantiomerically enriched cyclopropanols. The carbohydrate 2-hydroxy-3,4,6-tri-*O*-benzyl-β-D-glucopyranose appended to an allylic alcohol also functions as an effective chiral auxiliary, affording cyclopropanes with extremely high levels of diastereoselectivity (eq 14).[26] Other chiral auxiliaries have also been shown to direct halomethylzinc cyclopropanations with good to excellent stereocontrol.[13g,27]

Although the potential for preparing enantioselective halomethylzinc reagents was recognized early on,[28] only since 1992 have encouraging levels of enantioselectivity been observed.[29] The best results reported to date utilize chiral C_2-symmetric sulfonamides in substoichiometric amounts as the source of chirality (eq 15).[29a] A zinc complex of this ligand is proposed to act as a chiral Lewis acid catalyst in this reaction. All of the enantioselective halomethylzinc cyclopropanations reported to date utilize allylic alcohols as substrates, and the free hydroxy group appears to play an essential role.[29]

Methylene Homologation Reactions.

The carbon bound iodine atom of ICH_2ZnI can be easily displaced by nucleophiles to generate new organozinc reagents.[9b] For example, various copper nucleophiles displace the carbon bound iodine from ICH_2ZnI or $(ICH_2)_2Zn$, generating new organometallic reagents that react with allyl halides.[2,30] Copper nucleophiles such as CuCN/LiCl, $NCCH_2Cu$, copper amides, vinylcoppers, and heteroarylcopper compounds all participate in this reaction (eq 16). This reaction has proven to be especially useful for the conversion of alkenylcoppers into allylic copper-zinc reagents which react with aldehydes affording homoallylic alcohols (eq 17). An expedient route to α-methylene-γ-butyrolactones that

exploits this behavior has also been developed (eq 18).[30e]

Transmetalation Reactions.

Like other alkylzinc reagents,[31] halomethylzinc reagents have also been shown to participate in transmetalation reactions.[3,14a] This methodology provides an expedient route to iodomethylmercury and iodomethyltin compounds. For example, treatment of Me_3SnCl with ICH_2ZnI derived from EtZnI and CH_2I_2 provides Me_3SnCH_2I in 78% yield.[14a] Bu_3SnCH_2I may be prepared similarly in 96% yield.[32] Substituted diiodides also provide zinc reagents that participate well in this reaction.[14a]

[2,3]-Rearrangements.

A method for the generation of sulfur ylides from allylic phenyl sulfides and CH_2I_2/Et_2Zn has been described.[33] The intermediate sulfur ylides undergo a sigmatropic [2,3]-rearrangement affording homoallylic sulfides (eq 19). The reaction gives (*E*)-alkenes selectively.

Iodonium Di-*sym*-collidine Perchlorate

[69417-67-0] · $C_{16}H_{22}ClIN_2O_4$ · Iodonium Di-*sym*-collidine Perchlorate · (MW 468.75)

(very reactive electrophile, superior source of I^+,[1] useful in the synthesis of *cis*-β-hydroxy amines,[2] activates glycosides for glycosylation;[5,6] can be used for iodolactonization[12,13] and vicinal *cis*-diol[14] preparation)

Alternate Name: IDCP.

Solubility: sol chloroform; insol ether.

Form Supplied in: fine colorless crystalline powder. *Drying:* see ***Bromonium Di-sym-collidine Perchlorate***.

Handling, Storage, and Precautions: see ***Bromonium Di-sym-collidine Perchlorate***.

cis-Oxyamination.[2]

IDCP (**1**) is useful in the synthesis of *cis*-hydroxyamino sugars, e.g. methyl *N*-acetylristosaminide has been obtained from an oxazoline which can be made by the reaction of a trichloromethyl imidate with IDCP. The imidate can be prepared by reaction of the corresponding allylic alcohol with ***Trichloroacetonitrile*** in presence of ***Sodium Hydride*** (eq 1).

(1)

The synthesis of methyl α,L-garosaminide,[3] a key component of aminocyclitol antibiotics, is complicated by the presence of a *cis*-hydroxyamino group and by the tertiary character of the hydroxy group. The problems have been resolved by use of the allylic epoxide as starting material. This epoxide was converted in three steps into an allylic amine. Treatment of iodonium salt gave the iodooxazolidinone in 82% yield. The product was reduced and the ethoxy ethyl group was removed and finally converted to the desired product by hydrolysis (eq 2).

(2)

Similar methodology can convert an internal allylic amine into a *cis*-β-hydroxyamine, as illustrated in a synthesis of holacosamin, a component of some glycosteroids (eq 3).[4]

α-Linked Disaccharides.[5]

The reagent functions as a superior source of I^+, probably because of the nonnucleophilic counterion. Thus a pyranoid diene reacts with IDCP to give a planar ion to which an alcohol adds in a 1,4-sense to give an α-glycoside. Thus tetraacetylfructose reacts to give an α-disaccharide in 45% yield (eq 4). The β-isomer is not detected.

Examples are known where this reagent has activated pent-4-enyl glycosides for glycosylation,[6] but α- and β-glycosides were obtained in various proportions regardless of the nature of donors or acceptors (primary or secondary

hydroxyl groups). Glycosylations of 1,2:5,6-di-*O*-isopropylidene-α-D-galactopyranose and methyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside were investigated with pent-4-enyl-2,3,4-tri-*O*-benzyl-β-D-glucopyranoside derivatives in which 6-OH was protected by a benzyl, a trityl, or a TBDMS group in order to assess the effect of the bulk of the 6-substituents. The presence of a bulky 6-substituent (a) increases significantly the proportion of the α-product; (b) decreases the yield when a secondary hydroxy group is glycosylated, but the effect is less or opposite when a primary hydroxy group is involved; (c) lowers the increase in yield of the α-product when a primary hydroxy group is glycosylated; (d) gives a much better yield of the α-anomer when there is a higher proportion of ether in the solvent.

Chemospecific glycosidation of partially benzoylated thioglycosides (disarmed acceptors) with perbenzylated thioglycosides (armed donors) can be realized in the presence of the promotor IDCP (eq 5).[7]

(5)

Reaction of IDCP with unsaturated alcohols and carboxylic acids in dichloromethane at ambient temperature has afforded three- to seven-membered ring iodoethers and four- to seven-membered ring iodolactones, respectively, in moderate yields and generally with high regioselectivity. The reaction has particular utility for synthesis of 2-(1-iodoalkyl)oxiranes and -oxetanes.[11] Glycosylation has also been achieved by electrophile-induced activation of anomeric *O*-glycosyl *N*-allyl carbamates (eq 6).[8]

(6)

Treatment of fully benzylated 1-methylene-D-glucose with IDCP gives easy access to 1-iodoheptuloses or a 1-iodomethylene derivative.[9] The latter compound is, in turn, further amenable to similar IDCP-mediated addition reaction. In the synthesis of ciclamycin O the required trisaccharide glycol was assembled by substituent-directed iodinative coupling of glycals as shown in (eq 7).[10]

Iodolactonization of heptadienoic acid derivatives having oxazolidin-2-ones or a sultam[12] as chiral auxiliary gave the chiral iodolactone with moderate to excellent enantioselectivity.[13]

Vicinal *cis*-Diols.[14]

An allylic alcohol is converted into its primary urethane derivative, which is then subjected to iodonium ion induced cyclization to give a single iodocarbonate. The carbonate is then deiodinated reductively and hydrolyzed to afford the vicinal diol.

Iodo(phenyl)bis(triphenylphosphine)palladium(II)[1]

[55123-60-0] · $C_{42}H_{35}IP_2Pd$ · Iodo(phenyl)bis(triphenylphosphine)palladium(II) · (MW 835.03)

(used for the cross coupling of organic halides with other groups[3-9] and also the carbonylation of organic halides with subsequent coupling[10-13])

Form Supplied in: prepared and used in situ.

Preparative Methods: formed from $Pd(PPh_3)_n$ and PhI. The $Pd(PPh_3)_n$ can be generated from ***Palladium(II) Acetate*** and ***Triphenylphosphine***.[2]

Handling, Storage, and Precautions: very reactive and unstable, therefore formed in situ. Decomposition results in palladium metal, which should be retained for recycling.

Cross Coupling.

The title reagent is used to couple organic halides with carbanions stabilized by various metals. The organic halide initially oxidatively adds to the palladium catalyst, and so must be stable to β-elimination. This means that aryl and alkenyl halides are generally used. The general coupling reaction is shown in eq 1.

$$R^1M + R^2X \xrightarrow{(Ph_3P)_2PdPhI} R^1R^2 + MX \qquad (1)$$

Organomercury reagents have been used with various groups including R^1 = aryl, Me and R^2 = aryl, acyl.[3,4] The organometallic may also be a Reformatsky reagent[5] or a Grignard reagent.[6] Alkylstannanes[7] have also been used.

Terminal alkynes are so acidic that they may be used directly without the need to form an organometallic (eq 2).[8,9]

(2)

Other palladium reagents can be used to effect the aforementioned coupling reactions and the transformation may be either stoichiometric or catalytic in palladium. Generally, the choice of a particular palladium reagent is a matter of experimentation. This

Iodo(phenyl)bis(triphenylphosphine)palladium(II)

is also the case for the carbonylation reactions below.

Carbonylation.

$IPhPd(PPh_3)_2$ catalyzes carbonylation of organometallics with ***Carbon Monoxide***. This process is often accomplished in sequence with the aforementioned cross coupling. For example, ketones can be synthesized from organomercurials as shown in eq 3.[10]

$$R_2Hg \text{ or } RHgX \xrightarrow[\text{70-90\%}]{(Ph_3P)_2PdPhI,\ CO} R_2CO \qquad (3)$$

R = Ph, *p*-ClC_6H_4, *p*-$MeOC_6H_4$, *p*-$Me_2NC_6H_4$, *p*-$NH_2C_6H_4$, *o*-hydroxybiphenyl, 2-thienyl; X = Cl, Br, OAc

Aryl halides can be carbonylated and the intermediate acyl organometallics coupled with other groups. For example, treatment of active methylene compounds with aryl halides and CO.[11] When the reaction is carried out in the presence of alcohols or amines, esters or amides are formed.[12] Cyanocarbonylation has also been reported (eq 4).[13]

(4)

Other Reactions.

$IPhPd(PPh_3)_2$ has also been used for the reduction of iminoyl chlorides to the corresponding Schiff bases.[14] The germylation of organic halides has also been reported (eq 5).[15]

$$PhI \xrightarrow[(ClGeMe_2)_2,\ \text{92\%}]{(PPh_3P)_2PdPhI} PhGeMe_2Cl \qquad (5)$$

2-Iodopropane

[75-30-9] · C_3H_7I · 2-Iodopropane · (MW 170.00)

(heterolytic and homolytic alkylating agent; mediator of thiocarbonate conversion to alkenes; can add across carbon-carbon triple and double bonds; used in the preparation of the α-isopropoxymethylene blocking group)

Alternate Name: isopropyl iodide.

Physical Data: mp -90 °C; bp 88-90 °C; *d* 1.073 g cm^{-3}.

Form Supplied in: colorless liquid; stabilized with copper.

Purification: the reagent can be washed with aqueous $Na_2S_2O_3$ or $NaHSO_3$, then water, dried over magnesium sulfate and distilled at slightly reduced pressure. Alternately, the reagent can be simply filtered through a plug of activated alumina.[1]

Handling, Storage, and Precautions: the reagent is a cancer suspect agent and should be handled in a fume hood with protective gloves. Storage in the dark over a small quantity of mercury is recommended.

Alkylation.

2-Iodopropane is commonly employed as an alkylating agent toward, for example, the anions of esters,[2] nitriles,[3] sulfones,[4] phenols,[5] and pyrroles.[6] α,β-Unsaturated esters[7] and amides[8] undergo α-alkylation. Monoalkylation of the dianions of β-keto esters,[9] β-ketophosphonates,[10] and the trianion of Boc-protected glycine[11] has been achieved. The asymmetric alkylation of the sultam-derived glycinate equivalent (**1**) has been reported (eq 1).[12] An enantioselective synthesis of 3-substituted 2-keto esters has been achieved by the SAMP hydrazone method (eq 2).[13] A method for replacement of the *N*-methyl group of codeine (**2**) with an isopropyl group has been reported (eq 3).[14]

(1)

(2)

Homolytic Alkylation.

4-Methylpyridine (**3**) on protonation undergoes regioselective alkylation with 2-iodopropane in the presence of

Hydrogen Peroxide and an Fe^{2+} salt (eq 4).[15]

Alkene Synthesis.

Heating the thiocarbonate (**4**) in neat 2-iodopropane at reflux afforded the corresponding iodo thiocarbonate. Subsequent reduction with ***Zinc*** dust provided the alkene (**5**) in good overall yield (eq 5).[16]

Addition Across Carbon-Carbon Triple and Double Bonds.

Triethylborane induced addition of 2-iodopropane to alkynes[17] and vinylsilanes[18] has been reported (eqs 6 and 7). Similarly, the former process can also be induced with ***Triphenylstannane***.[19]

(7)

Isopropoxymethylene Blocking Group.

The ketone (**6**) has been methylated at the more sterically congested site by the use of the isopropoxymethylene blocking group (eq 8).[20]

(3-Iodopropyl)trimethylsilane

[18135-48-3] · $C_6H_{15}ISi$ · (3-Iodopropyl)trimethylsilane · (MW 242.20)

(reagent equivalent to $^{-}CH_2CH_2CH_2^{+}$[1])

Physical Data: clear liquid; bp 84-86 °C/25 mmHg.

Solubility: sol hexane, THF

Preparative Methods: from commerical (3-chloropropyl)trimethylsilane and NaI[2] or, alternatively, from the *p*-toluenesulfonate of commerically available 3-(trimethylsilyl)-1-propanol and NaI.[1]

Handling, Storage, and Precautions: no detail has been reported. However, the usual handling for common alkyl iodides (e.g. iodohexane) may be followed.

Introduction of 3-(Trimethylsilyl)propyl Group.

Phosphines and amines are alkylated by the title iodide (**1**) to give silylpropylated compounds (eq 1).[3,4]

(1)

Preparation of 2-Alkylcyclopentanones.

Reagent (**1**) serves as a $^{-}CH_2CH_2CH_2^{+}$ equivalent, which is illustrated in a preparation of cyclopentanones from carboxylic acids (eq 2).[1,2]

(3-Iodopropyl)trimethylsilane

(2)

Thus alkylation of carboxylic acid dianions with (**1**) affords the 2-[3-(trimethylsilyl)propyl]alkanoic acids in good yields. After the conversion of these acids to the corresponding acyl chlorides with ***Oxalyl Chloride***, intramolecular acylation of the alkylsilane with ***Aluminum Chloride*** affords cyclopentanones in good yields. Examples are shown in eqs 3 and 4.

(3)

(4)

A related bromide, $Me_3Si(CH_2)_3Br$, is also known and may be used in a similar way.[1]

Iodorhodium(III) Tetraphenylporphyrin

(R = Ph)

[69509-35-9] · $C_{44}H_{28}IN_4Rh$ · Iodorhodium(III) Tetraphenylporphyrin · (MW 842.57) (R = mesityl)

[85990-32-5] · $C_{56}H_{52}IN_4Rh$ · Iodorhodium(III) Tetramesitylporphyrin · (MW 1010.93)

(catalyst for cyclopropanation of alkenes by diazoesters[1])

Alternate Name: Rh(TPP)I.

Physical Data: NMR (δ in $CDCl_3$) 7.7 and 8.2 (multiplets, 20H, phenyl), 8.8 (singlet, 8H, pyrrole); visible (CH_2Cl_2) λ_{max} = 575 nm (ε = 4000), 535 nm (15 700), 422 nm (151 000).[2]

Solubility: sol dichloromethane, chloroform, acetone, ethyl acetate; insol pentane.

Preparative Method: readily prepared from the commerically available tetraphenylporphyrin and ***Tetracarbonyl(di-μ-chloro)dirhodium*** using a modification of Callot's method.[2] The initially formed Rh^{I} species is oxidized to Rh^{III} using ***Iodine*** or ***N-Iodosuccinimide***.

Handling, Storage, and Precautions: not air or moisture sensitive. For prolonged storage, the reagent should be protected from light. Toxicity has not been thoroughly investigated.

Numerous transition metal compounds are known to catalyze the cyclopropanation of alkenes by diazoesters.[3] Among these, compounds based on copper, palladium, and rhodium have been the leading choices for catalysts. Callot and co-workers reported that iodorhodium(III) tetraphenylporphyrin [Rh(TPP)I] (**1**) is also an efficient catalyst for this transformation.[1]

Porphyrin catalysts offer two distinct advantages over other transition metal species. The most important of these is their propensity to provide more of the *syn* cyclopropyl ester than most commonly used catalysts, which produce predominantly the *anti* diastereomer (eq 1).[1,4,5] The *syn* preference can be enhanced considerably by using bulkier macrocycles such as iodorhodium(III) tetramesitylporphyrin [Rh(TMP)I] (**2**) (eq 1).[5] *Syn*/*anti* ratios of up to 7.8:1 have been reported when *cis* disubstituted alkenes are used as substrates.[6]

(1)

M	*syn*:*anti*	Total yield (%)
Rh(TPP)I	88:12	71
Rh(TMP)I	98:2	78
$CuCl(OPh)_3$	40:60	84
$Rh_2(OAc)_4$	63:37	93

The second advantage is the higher number of turnovers porphyrin catalysts afford: several thousand compared to several hundred for other catalysts. Therefore, considerably less catalyst is needed to promote the reaction. In addition, the reactivity of the porphyrin catalysts approaches that of rhodium carboxylates, which have been reported to be the most efficient catalysts for this process.[7] Yields typically vary from 50-80% with (**1**) depending on the nature of the alkene substrate. Dimerization products (maleates and fumarates) resulting from diazoester attack on the putative metallocarbene intermediate are minimized by using large excesses of alkene or by slow addition of the diazoester.

Competitive cyclopropanation reactions have revealed steric interactions to be the dominant factor in determining relative reactivity for unfunctionalized alkenes.[6] In general, aromatic alkenes are slightly more reactive than aliphatic alkenes, and tetrasubstituted alkenes are poor substrates for the porphyrin catalysts. Differences between other substituted alkenes are modest but follow the trend reported by Doyle for rhodium acetate-catalyzed reactions.[8] The difference in reactivities can be enhanced by use of (**2**).

At present, rhodium porphyrins are the most useful catalysts for obtaining *syn* cyclopropyl esters from alkenes and diazoesters. Enantioselectivities reported using chiral porphyrin ligands are not synthetically useful.[6,9] When the chiral systems are fully developed, they should be particularly useful since optically pure *syn* cyclopropyl esters are not readily accessible with current methodology.[10]

N-Iodosuccinimide

[516-12-1] · $C_4H_4INO_2$ · *N*-Iodosuccinimide · (MW 224.99)

(electrophilic iodination of arenes, alkenes, and alkynes; activation of glycosyl donors)

Alternate Names: NIS; 1-iodo-2,5-pyrrolidinedione.

Physical Data: mp 193-199 °C (dec).

Solubility: sol dioxane, THF, MeCN; insol ether, CCl_4.

Form Supplied in: white powder; widely available, but quite expensive.

Preparative Method: reaction of *N*-silversuccinimide with I_2 in anhydrous dioxane, removal of AgI by fitration, and addition of CCl_4 to promote crystallization.[1]

Purification: recrystallization from dioxane-CCl_4 at -20 °C.

Handling, Storage, and Precautions: stored at 0 °C under nitrogen, and protected from light and moisture to avoid decomposition; an irritating solid and precautions should be taken to avoid inhalation of the powder.

Introduction.

N-Iodosuccinimide is an efficient reagent for the electrophilic iodination of organic compounds for which the reactivity of I_2 is often insufficient. A variety of functional groups are electrophilically iodinated using NIS with similar effectiveness to the corresponding brominations using ***N-Bromosuccinimide*** (NBS).[2] Electrophilic attack on soft nucleophiles (e.g. as in dithiane deprotection) is achieved in the presence of other sensitive groups with optimum selectivity by iodination using NIS under mild conditions (see also ***1,3-Diiodo-5,5-dimethylhydantoin***).[3] For other iodinations a more powerful source of iodonium ion can be generated by the combination of NIS with protic acids including AcOH, TsOH, and TfOH.[4]

Reaction with Organometallic Derivatives.

Similarly, the lesser reactivity of NIS compared with NBS allows it to be used for the synthesis of vinyl iodides by iodination of vinylaluminum intermediates in the presence of reactive alkenic groups.[5] NIS has also been found to be an excellent reagent for the oxidative cyclization of dipeptide dianions to β-lactams (eq 1).[6]

(1)

Iodination of Alkenic Compounds.

Iodolactonization and related reactions with alkenes can be achieved using NIS in aprotic solvents. In addition, iodoesters may also be prepared by the reaction of alkenes with NIS in the presence of carboxylic acids (eq 2),[7] and allylic trichloroacetimidates may be cyclized to 5-iododihydro-1,3-oxazines (eq 3).[8]

(2)

(3)

In combination with protic acid, NIS has been used for the preparation of α-iodo enones and β,β-dihalo enones (eqs 4 and 5; HTIB = ***[Hydroxy(tosyloxy)iodo]benzene***).[9] More reactive alkenes such as enol acetates react with NIS to afford α-iodo ketones.[10] The reaction of enol ethers with NIS in the presence of an alcohol, affording iodoacetals, allows the synthesis of acetals by dehalogenation or mixed ketene acetals by elimination.[11]

(4)

(5)

Activation of Glycosyl Donors.[12]

NIS is a useful reagent for the coupling of glycals to alcohols (eq 6)[13] or other carbohydrates,[14] affording 2-iodoglycosides which are readily dehalogenated to 2-deoxysugars, or can serve as precursors to 2-aminosugars via the epoxide intermediate.[15] Selective activation of glycosyl thioethers for coupling with carboxylic acids and heterocyclic compounds is achieved under mild conditions by reaction with NIS and ***Trifluoromethanesulfonic Acid*** (eq 7).[16] In addition, the combination of NIS and TfOH is also the reagent of choice for the activation of 4-pentenylglycosides.[17]

(6)

(7)

Oxidation Reactions.

Hypoiodite intermediates may be generated from the reaction of simple alcohols with NIS. When conducted under photochemical irradiation, the products of Barton-type or fragmentation reactions of alkoxyl radical intermediates may be obtained.[18] Aldehydes are oxidized to methyl esters via hemiacetal intermediates by reaction with NIS in methanol at rt.[19] However, such conditions are not effective for the oxidation of simple alcohols. The combination of NIS and ***Tetra-n-butylammonium Iodide*** in dichloromethane has been developed for the oxidation of a variety of alcohols to the corresponding carbonyl compounds (eq 8).[20] This reagent system is most widely used for the oxidation of lactols to lactones, in which near-quantitative yields are generally obtained under mild conditions (eq 9).[21]

(8)

Iodosylbenzene[1]

$(PhIO)_n$

[536-80-1] · C_6H_5IO · Iodosylbenzene · (MW 220.01)

(oxygen atom transfer to ketones,[4] metal-catalyzed oxygen atom transfer to alkenes,[7-13] formation of α-diketones,[14] bridgehead triflates,[16] α,β-unsaturated lactones and ketones,[19] α-hydroxymethyl acetals,[20] α-keto triflates,[17] α-hydroxy ketones,[18] C-C coupling,[22-24] oxidation of amines,[25,26] azidation[22-30])

Alternate Name: iodosobenzene.

Physical Data: mp 210 °C with decomposition (explodes); polymeric.

Solubility: slightly sol H_2O, MeOH. In MeOH the reagent is $PhI(OMe)_2$. Both solvents, as well as CH_2Cl_2 and MeCN, are used for reactions.

Form Supplied in: white to slightly yellow solid from synthesis.[2,3]

Preparative Method: prepared as a white solid by base hydrolysis of commercially available ***(Diacetoxyiodo)benzene*** in 75% yield.[2]

Purification: washing the solid with $CHCl_3$ to remove traces of PhI. The material is obtained in about 99% purity as determined iodometrically.[3]

Handling, Storage, and Precautions: indefinitely stable; refrigeration should be used for long-term storage.

Oxygen Atom Transfer from PhIO: α-Lactones from Ketenes (Uncatalyzed Epoxidation).

Ketenes react with PhIO to yield an intermediary α-lactone which undergoes polymerization to a polyester in yields ranging from 63 to 90% (eq 1).[4] Likewise, tetracyanoethylene forms tetracyanoethylene oxide in 74% yield upon reaction with PhIO.[4] α-Lactones have also been prepared by the ozonation of ketenes[5] and via the addition of triplet dioxygen to ketenes.[6]

Metal-Catalyzed Oxygen Transfer: Epoxide Formation.

Iron(III) and manganese(III) porphyrins catalyze oxygen transfer from PhIO to aromatic substrates to yield phenolic products, probably via arene oxides.[7] Alkene epoxidation can also be achieved using this system. Simpler ligands such as Schiff's bases,[8] amides,[9] phosphines,[10] and salts of heteropolyaromatics[11] have been used. Bleomycin complexes of iron, copper, and zinc also cause oxidation of alkenes.[12] Noteworthy is the epoxidation of cyclohexene (eq 2).[13] These systems are of theoretical interest as models for cytochrome P-450 and have not as yet achieved general preparative significance.

Oxidation of Alkynes to α-Diketones.

Ruthenium catalysis is effective in the oxidation of internal (eq 3) and terminal alkynes (eq 4).[14] Secondary alcohols are oxidized to ketones in good yield using *m*-iodosylbenzoic acid and the base-extractable *m*-iodobenzoic acid can be recycled.[15]

Activated PhIO using TMSOTf: Oxidative Displacement of Bridgehead Iodine to Yield Bridgehead Triflates.

A series of cubyl triflates was synthesized using PhIO and ***Trimethylsilyl Trifluoromethanesulfonate*** (forms the reactive intermediate $[PhIOTMS]^+$ TfO^-) (eq 5).[16] Cubyl alcohol is unstable and this direct functionalization was critically useful.

X = H, Me, CO_2Me, I, Br, Cl

Oxidation of Silyl Enol Ethers to α-Keto Triflates with PhIO-TMSOTf.

The oxidation of silyl enol ethers to α-keto triflates is a generally useful reaction (eqs 6 and 7).[17]

Ar = phenyl, furan, thiophene

(7)

Oxidation of Silyl Enol Ethers with PhIO in H_2O-$BF_3.Et_2O$ to α-Hydroxy Ketones.

A direct route to α-hydroxy ketones is achieved via oxidation of aromatic, heteroaromatic, and aliphatic silyl enol ethers with PhIO in ***Boron Trifluoride Etherate***-H_2O (eq 8).[18] This is a simple and broadly useful reaction for the α-hydroxylation of ketones.

(8)

X = H, 65%; Cl, 70%; NO_2, 78%; 2-pyridyl, 62%; 3-pyridyl, 64%; cyclohexyl, 80%; 2-benzofuran, 59%

Oxidation of Lactones to Higher Homologous α,β-Unsaturated Lactones.

Ring expansion of lactones occurs via oxidation of the derived trimethylsilyloxycyclopropanols to give the higher homologous α,β-unsaturated lactones (eq 9).[19] Silyl enol ethers behave analogously (eqs 10 and 11).[19]

(9)

n = 1, 72%; 2, 75%; 3, 62%; 9, 78%

Oxidation of Ketones to Form α-Hydroxydimethyl Acetals.

The reagent $PhI(OAc)_2$-KOH-MeOH is equivalent to PhIO-KOH-MeOH; however, $PhI(OAc)_2$ is commercially available whilst PhIO is not. Consequently, the reagent ***(Diacetoxyiodo)benzene***, [$PhI(OAc)_2$], is now used even though the original process was discovered using PhIO/MeOH.[20a] This reagent has been employed in the synthesis of the steroidal dihydroxyacetone side chain (eq 12).[20b]

Formation of Carbon-Carbon Bonds: 1,4-Diketones via Coupling Reaction with PhIO/BF_3.Et_2O.

The addition of BF_3.Et_2O to PhIO yields an intermediary reagent, [$PhI^+OBF_3^-$], which is reactive with silyl enol ethers derived from ketones. In the presence of water or an alcohol, α-hydroxylation or α-alkoxylation occurs (eq 13),[18] while in the absence of a protic nucleophile self-coupling occurs to yield a 1,4-diketone (eq 14).[21]

(13)

(14)

Unsymmetrical coupling occurs via in situ generation of a phenyliodonium intermediate at -78 °C and subsequent introduction of a silyl enol ether as a coupling partner (eq 15).[22]

(15)

Allylation of aromatic compounds takes place when allylmetal (Group 14) compounds react with aromatic compounds and iodosylbenzene in the presence of boron trifluoride etherate (eq 16).[23,24]

(16)

M = Si, Ge, Sn

Oxidation of Amines.

Primary amines yield nitriles (eq 17) or ketones (eq 18).[25]

(17)

R = Ph, 48%; C_5H_{11}, 56%

(18)

$n = 1, 2$

Cyclic secondary amines yield lactams (eq 19).[25] *N*-Methyl cyclic amines as well as nicotine behave analogously (eq 20).[25]

(19)

$n = 1$, 49%
$n = 2$, 58%

Cyclic amino acids such as L-proline, pipecolinic acid, and L-2-pyrrolidinone-5-carboxylic acid undergo oxidative decarboxylation with iodosobenzene in various solvents (including water) to yield the corresponding lactam (eq 21).[26]

Formation of Azides Using PhIO-NaN_3 or PhIO-$TMSN_3$.

Cholesterol is converted to the allylic azide with PhIO-NaN_3-$MeCO_2H$, namely 7α-azidocholest-5-en-3β-ol.[27] A similar reaction occurs with $Pb(OAc)_4$-TMSCl.[28]

Formation of β-Azido Ketones using PhIO-$TMSN_3$.

The reaction between ***Azidotrimethylsilane*** and PhIO must be carried out at low temperatures. At rt they react violently. Eq 22 shows the β-azido functionalization of triisopropylsilylenol ethers.[29]

N,*N*-Dimethylarylamines under these conditions yield *N*-methyl-*N*-azidomethyl arylamines (eq 23).[30]

(23)

$R^1 = Me$; $R^2 = Me, NMe_2$

The thiocarbonyl group of 2-thiouracil is converted to the carbonyl group with PhIO (eq 24).[31]

(24)

$R^1 = R^2 = H$; $R^1 = Me, R^2 = H$; $R^1 = H, R^2 = Me$

Related Reagents.

Iodosylbenzene-Boron Trifluoride; ***Iodosylbenzene-Dichlorotris(triphenylphosphine)ruthenium***.

Iodosylbenzene-Boron Trifluoride[1]

$PhIO.BF_3$

(PhIO)

[536-80-1] · C_6H_5IO · Iodosylbenzene-Boron Trifluoride · (MW 220.01) ($PhIO.BF_3$)

[108208-48-6] · $C_6H_5BF_3IO$ · Iodosylbenzene-Boron Trifluoride · (MW 287.82)

(iodonium-transfer reagent to alkenyl-[2a] and alkynylsilanes;[2b] oxidizing agent for silyl enol ethers[3])

Physical Data: PhIO: mp 210 °C (dec).

Solubility: PhIO is a polymer, linked by I-O-I bonds. Therefore it is insoluble in most organic solvents. Upon dissolution in acetic acid and methanol, it is known to react to form (diacetoxyiodo)benzene and (dimethoxyiodo)benzene, respectively.[10]

Form Supplied in: PhIO is a pale yellow solid. Some commercial compounds are contaminated with iodyl benzene ($PhIO_2$: colorless solid).

Analysis of Reagent Purity: iodometric titration.

Preparative Method: see Salzman and Sharefkin.[11]

Handling, Storage, and Precautions: PhIO decomposes explosively if heated to 210 °C. The solid gradually disproportionates to iodobenzene and iodyl benzene at rt and must be stored at -20 °C.

Iodosylbenzene is activated by coordination of ***Boron Trifluoride Etherate*** to the oxygen atom, presumably via the formation of the highly electrophilic species $C_6H_5I^{\delta+}$-$OBF_3^{\delta-}$.[2] This species undergoes an iodonium-transfer reaction, which makes possible the synthesis of alkenyl- and alkynyl(phenyl)iodonium salts. Because of the superleaving ability of the phenyliodonium group, alkenyliodonium salts serve as the progenitors for generating alkylidenecarbenes via base-induced α-elimination under mild conditions (eq 1)[4] and as the highly activated species of alkenyl halides in nucleophilic vinylic substitutions (eq 2).[2a] Nucleophilic vinyl substitutions of (*E*)-alkenyliodonium salts with *n*-Bu_4NX proceed with exclusive inversion of configuration.[5] Tandem Michael-carbene insertion reactions of alkynyl(phenyl)iodonium salts provide a useful tool for the synthesis of cyclopentenes (eq 3) and furans.[6]

(1)

(2)

(3)

Treatment of propargylsilanes, -germanes, and -stannanes with iodosylbenzene-BF_3 promotes a reductive iodonio-Claisen rearrangement under mild conditions, yielding *o*-propargyliodoarenes (eq 4).[7] Intermediate allenyl(phenyl)iodinanes are involved in this reaction.

Carbon-tin bond cleavage by iodosylbenzene-BF_3 makes possible the conversion of trimethylstannyl groups into hydroxy groups with retention of stereochemistry and the stereoselective osmylation of alkenes utilizing an intramolecular hypervalent tin-oxygen interaction.[8] Oxidative Grob fragmentation of γ-stannyl alcohols gives unsaturated carbonyl compounds and lactones (eq 5).[9]

Oxidation of silyl enol ethers gives α-hydroxy and α-methoxy ketones (eq 6).[3]

Iodosylbenzene-Dichlorotris(triphenylphosphine)ruthenium

$PhIO\text{-}RuCl_2(Ph_3P)_3$

(PhIO)

[536-80-1] · C_6H_5IO · Iodosylbenzene-Dichlorotris(triphenylphosphine)ruthenium · (MW 220.01) ($RuCl_2(Ph_3P)_3$

[15529-49-4] · $C_{54}H_{45}Cl_2P_3Ru$ · Iodosylbenzene-Dichlorotris(triphenylphosphine)ruthenium · (MW 958.87)

(mild oxidant for selective catalytic transformation of alkynes and several functional groups)

Physical Data: see ***Iodosylbenzene*** and ***Dichlorotris(triphenylphosphine)ruthenium(II)***.

Oxidation of Alkynes.

This reagent combination oxidizes disubstituted alkynes to α-diketones.[1] The reactions are carried out at rt by stirring the substrate in a CH_2Cl_2 suspension of PhIO (2-3 equiv) in the presence of the catalyst (1%) until the oxidant totally dissolves. The best results are obtained with aryl-substituted alkynes (eq 1), while alkynes with aliphatic substituents tend to undergo cleavage to carboxylic acids. Terminal alkynes react exclusively via cleavage (eq 2). Alkynyl ethers and amines afford α-keto esters and α-keto amides, respectively.[2]

(1)

R = Ph	86%
R = OEt	70%
R = NMe_2	84%

(2)

Oxidation of Alcohols and Phenols.

Primary alcohols are oxidized by PhIO-$RuCl_2(Ph_3P)_3$ to aldehydes which react further to form carboxylic acids (eq 3), while secondary alcohols afford ketones (eq 4).[3] The scope and limitations of this system in alcohol oxidations are similar to the combination of ***N-Methylmorpholine N-Oxide*** and ruthenium catalysts described by Sharpless.[4] The oxidation of primary alcohols may be stopped at the aldehyde stage when iodosyl diacetate[5] or *m*-iodosylbenzoic acid[6] is used instead of PhIO (eqs 5 and 6).

(3)

(4)

(5)

(6)

Hydroquinones are oxidized to quinones by PhIO (eq 7). In these transformations the reaction proceeds with similar yields in the presence or absence of catalyst. Catalysis, however, is required for oxidation of sterically

hindered phenols to quinones (eq 8). ***Boron Trifluoride Etherate*** as catalyst affords higher yields than $RuCl_2(Ph_3P)_3$,[7] and *m*-iodosylbenzoic acid-$RuCl_2(Ph_3P)_3$ or PhIO in AcOH lead to comparable results.

(7)

(8)

Oxidation of Sulfides and Selenides.

While the Ru-catalyzed oxidation of sulfides and selenides with PhIO proceeds to sulfones and selenones (eq 9), respectively, sulfoxides may be obtained selectively with *m*-iodosylbenzoic acid (eq 10).[6]

(9)

(10)

Oxidation of Amines.

Activated secondary amines are dehydrogenated to imines by PhIO alone or with Ru catalysis (eq 11).[8]

(11)

Other Variations of the System.

$RuCl_2(Ph_3P)_3$ may be replaced by other Rh salts, such as ***Ruthenium(III) Chloride*** with practically no effect on the results. Other oxidants which have been used in combination with rhodium salts include *N*-methylmorpholine *N*-oxide (oxidation of alcohols),[5] *N*-methylmorpholine/H_2O_2 (alcohols),[9] ***t-Butyl Hydroperoxide*** (amines,[10,11] hydroquinones,[12] nitriles[13]), ***Hydrogen Peroxide*** (hydroquinones and phenols),[14] ***Oxygen*** (alcohols,[15] catechols,[16] sulfides,[17]), ***Bis(trimethylsilyl) Peroxide*** (alcohols),[18] ***Acetone*** (alcohols),[19] and CCl_4 (alcohols).[20]

Paul Müller

University of Geneva, Switzerland

4-Iodo-2-trimethylgermyl-1-butene

[124897-71-8] · $C_7H_{15}GeI$ · 4-Iodo-2-trimethylgermyl-1-butene · (MW 298.71)

(precursor of lithium (3-trimethylgermyl-3-butenyl)cyanocuprate, a synthetically useful reagent for effecting annulation reactions[1-3])

Alternate Name: 3-iodo-1-methylenepropyltrimethylgermane.

Physical Data: colorless liquid; distillation temperature (bulb-to-bulb) 85-92 °C/15 mmHg.

Solubility: sol THF, $CHCl_3$.

Preparative Methods: from 4-chloro-2-lithio-1-butene (**1**) (see ***4-Chloro-2-trimethylstannyl-1-butene***) and from 1-trimethylsilyl-4-trimethylsilyloxy-1-butyne (**3**), as shown in eqs 1 and 2, respectively.[1,5] Of these two methods, the latter is experimentally more convenient and is also less expensive.

Handling, Storage, and Precautions: organogermanium compounds[4] and alkyl iodides are toxic and, therefore, the reagent should be prepared, distilled, and used in a fume hood. When stored in a freezer over copper wire under an inert atmosphere, the reagent is stable indefinitely. Should be distilled just prior to use; reactions should be carried out using dry THF and an inert atmosphere.

Annulation Methods.

The title reagent (**2**), upon sequential treatment with ***t-Butyllithium*** and ***Copper(I) Cyanide***, is readily converted into the structurally novel lower order heterocuprate (**4**) (eq 3).[1,2] The latter species has been employed in the development of the new, synthetically valuable annulation sequences outlined below.

(2) (4) (3)

Conjugate addition of (**4**) to the enone (**5**) affords the keto vinylgermane (**6**), which upon treatment with ***Iodine*** is transformed into the corresponding vinyl iodide (**7**) (eq 4).[1] Reaction of (**7**) with ***n-Butyllithium*** in THF provides, highly stereoselectively, the alkene alcohol (**8**), which serves as a suitable intermediate for the total synthesis of the isolabdane diterpenoid ambliol B (**9**).[1]

Reagent (**4**) has also found effective use in the development of a methylenecyclopentane annulation method shown in general terms by the conversion of (**10**) into (**11**).[2] This annulation process is regioisomeric with respect to the transformation of (**10**) into (**12**) (eq 5)[6] (see also ***4-Chloro-2-trimethylstannyl-1-butene***).

A specific example of the new method is shown in eq (6).[2] Conjugate addition of reagent (**4**) to (*R*)-(-)-carvone (**13**) provides (**14**), which is readily converted into (**15**). In the key step, the keto iodide (**15**) is treated with base in the presence of ***Tetrakis(triphenylphosphine)palladium(0)*** to afford the annulation product (**16**). Structures (**17**) and (**18**) represent likely intermediates in the reaction pathway of this novel cyclization process.[2]

(13)

(14) R = $GeMe_3$ (88%)
(15) R = I (94%)

(16)

(17) L = Ph_3P

(18) L = Ph_3P

When the α,β-unsaturated ketone substrate contains an α-proton in place of an α-alkyl group, the initially formed annulation product (β,γ-unsaturated ketone) isomerizes under the basic reaction conditions to the corresponding α,β-unsaturated ketone (eq 7).[2]

4-Iodo-2-trimethylgermyl-1-butene

(7)

This new annulation method played an important role in a total synthesis of the tetraquinane diterpenoid crinipellin B (**19**) (eq 8).[3]

Iodotrimethylsilane[1]

Me_3SiI

[16029-98-4] · C_3H_9ISi · Iodotrimethylsilane · (MW 200.11)

(a versatile reagent for the mild dealkylation of ethers, carboxylic esters, lactones, carbamates, acetals, phosphonate and phosphate esters; cleavage of epoxides, cyclopropyl ketones; conversion of vinyl phosphates to vinyl iodides; neutral nucleophilic reagent for halogen exchange reactions, carbonyl and conjugate addition reactions; use as a trimethylsilylating agent for formation of enol ethers, silyl imino esters, and *N*-silylenamines, alkyl, alkenyl and alkynyl silanes; Lewis acid catalyst for acetal formation, α-alkoxymethylation of ketones, for reactions of acetals with silyl enol ethers and allylsilanes; reducing agent for epoxides, enediones, α-ketols, sulfoxides, and sulfonyl halides; dehydrating agent for oximes)

Alternate Names: TMS-I; TMSI; trimethylsilyl iodide.

Physical Data: bp 106-109 °C; *d* 1.406 g cm^{-3}; *n*20D 1.4710; fp -31 °C.

Solubility: sol CCl_4, $CHCl_3$, CH_2Cl_2, $ClCH_2CH_2Cl$, MeCN, PhMe, hexanes; reactive with THF (ethers), alcohols, and EtOAc (esters).

Form Supplied in: clear colorless liquid, packaged in ampules, stabilized with copper; widely available.

Analysis of Reagent Purity: easily characterized by ^1H, ^{13}C, or ^{29}Si NMR spectroscopy.

Preparative Methods: although more than 20 methods have been reported[1] for the preparation of TMS-I, only a few are summarized here. ***Chlorotrimethylsilane*** undergoes halogen exchange with either ***Lithium Iodide***[2] in $CHCl_3$ or ***Sodium Iodide***[3] in MeCN, which allows in situ reagent formation (eq 1). Alternatively, ***Hexamethyldisilane*** reacts with ***Iodine*** at 25-61 °C to afford TMS-I with no byproducts (eq 2).[4]

$$\text{TMSCl} \xrightarrow[\text{or NaI, MeCN}]{\text{LiI, CHCl}_3} \text{TMSI} + \text{LiCl or NaCl} \qquad (1)$$

$$\text{TMS-TMS} + \text{I}_2 \xrightarrow{25\text{-}61\ ^\circ\text{C}} \text{TMSI} \qquad (2)$$

Several other methods for in situ generation of the reagent have been described.[5,6] It should be noted, however, that the reactivity of in situ generated reagent appears to depend upon the method of preparation.

Purification: by distillation from copper powder

Handling, Storage, and Precautions: extremely sensitive to light, air, and moisture, it fumes in air due to hydrolysis (HI), and becomes discolored upon prolonged storage due to generation of I_2. It is flammable and should be stored under N_2 with a small piece of copper wire. It should be handled in a well ventilated fume hood and contact with eyes and skin should be avoided.

Use as a Nucleophilic Reagent in Bond Cleavage Reactions.

Ether Cleavage.[5,7]

The first broad use of TMS-I was for dealkylation reactions of a wide variety of compounds containing oxygen-carbon bonds, as developed independently by the groups of Jung and Olah. Simple ethers initially afford the trimethylsilyl ether and the alkyl iodide, with further reaction giving the two iodides (eq 3).[7,8] This process occurs under neutral conditions, and is generally very efficient as long as precautions to avoid hydrolysis by adventitious water are taken. Since the silyl ether can be quantitatively hydrolyzed to the alcohol, this reagent permits the use of simple ethers, e.g. methyl ethers, as protective groups in synthesis. The rate of cleavage of alkyl groups is: tertiary &AApprox; benzylic &AApprox; allylic >> methyl > secondary > primary. Benzyl and *t*-butyl ethers are cleaved nearly instantaneously at low temperature with TMS-I. Cyclic ethers afford the iodo silyl ethers and then the diiodide, e.g. THF gives 4-iodobutyl silyl ether and then 1,4-diiodobutane in excellent yield.[7,8] Alcohols and silyl ethers are rapidly converted into the iodides as well.[8a,9] Alkynic ethers produce the trimethylsilylketene via dealkylative rearrangement.[4b] Phenolic ethers afford the phenols after workup.[5,7,10] In general, ethers are cleaved faster than esters. Selective cleavage of methyl aryl ethers in the presence of other oxygenated functionality has also been accomplished in quinoline.[11] γ-Alkoxyl enones undergo deoxygenation with excess TMS-I (2 equiv), with the first step being conjugate addition of TMS-I.[12]

Cleavage of Epoxides.

Reaction of epoxides with 1 equiv of TMS-I gives the vicinal silyloxy iodide.[8e] With 2 equiv of TMS-I, however, epoxides are deoxygenated to afford the corresponding alkene (eq 4).[13a,b] However, allylic alcohols are efficiently prepared by reaction of the intermediate iodosilane with base.[13c,d] Furthermore, acyclic 2-ene-1,4-diols react with TMS-I

to undergo dehydration, affording the corresponding diene.[13e]

Ester Dealkylation.[14]

Among the widest uses for TMS-I involves the mild cleavage of carboxylic esters under neutral conditions. The ester is treated with TMS-I to form an initial oxonium intermediate which suffers attack by iodide (eq 5). The trimethylsilyl ester is cleaved with H_2O during workup. Although the reaction is general and efficient, it is possible to accomplish selective cleavage according to the reactivity trend: benzyl, *t*-butyl > methyl, ethyl, *i*-propyl. Neutral transesterification is also possible via the silyl ester intermediate.[15] Aryl esters are not cleaved by TMS-I, however, since the mechanism involves displacement of R^2 by I^-. Upon prolonged exposure (75 °C, 3 d) of simple esters to excess TMS-I (2.5 equiv), the corresponding acid iodides are formed.[14b,16] β-Keto esters undergo decarboalkoxylation when treated with TMS-I.[17] An interesting rearrangement reaction provides α-methylene lactones from 1-(dimethylaminomethyl)cyclopropanecarboxylates (eq 6).[18]

Lactone Cleavage.[14,19]

Analogous to esters, lactones are also efficiently cleaved with TMS-I to provide o-iodocarboxylic acids, which may be

further functionalized to afford bifunctional building blocks for organic synthesis (eq 7). Diketene reacts with TMS-I to provide a new reagent for acetoacylation.[20]

(7)

Cleavage of Carbamates.[21]

Since strongly acidic conditions are typically required for the deprotection of carbamates, use of TMS-I provides a very mild alternative. Benzyl and *t*-butyl carbamates are readily cleaved at rt,[22] whereas complete cleavage of methyl or ethyl carbamates may require higher temperatures (reflux). The intermediate silyl carbamate is decomposed by the addition of methanol or water (eq 8). Since amides are stable to TMS-I-promoted hydrolysis,[7a] this procedure can be used to deprotect carbamates of amino acids and peptides.[21d]

(8)

A recent example used TMS-I to deprotect three different protecting groups (carbamate, ester, and orthoester) in the same molecule in excellent yield (eq 9).[23]

(9)

Cleavage of Acetals.[24]

Acetals can be cleaved in analogy to ethers, providing a newly functionalized product (eq 10), or simply the parent ketone (eq 11). Glycals have also been converted to the iodopyrans with TMS-I,[25] and glycosidation reactions have been conducted with this reagent.[26]

(10)

(11)

Orthoesters are converted into esters with TMS-I. The dimethyl acetal of formaldehyde, methylal, affords iodomethyl methyl ether in good yield (eq 12)[27a] (in the presence of alcohols, MOM ethers are formed).[27b] α-Acyloxy ethers also furnish the iodo ethers,[28] e.g. the protected β-acetyl ribofuranoside gave the α-iodide which was used in the synthesis of various nucleosides in good yield (eq 13).[28b] Aminals are similarly converted into immonium salts, e.g. Eschenmoser's reagent, ***Dimethyl(methylene)ammonium Iodide***, in good yield.[29]

(12)

(13)

Cleavage of Phosphonate and Phosphate Esters.[30]

Phosphonate and phosphate esters are cleaved even more readily with TMS-I than carboxylic esters. The reaction of phosphonate esters proceeds via the silyl ester, which is subsequently hydrolyzed with MeOH or H_2O (eq 14).

(14)

Conversion of Vinyl Phosphates to Vinyl Iodides.[31]

Ketones can be converted to the corresponding vinyl phosphates which react with TMS-I (3 equiv) at rt to afford vinyl iodides (eq 15).

(15)

Cleavage of Cyclopropyl Ketones.[32]

Cyclopropyl ketones undergo ring opening with TMS-I, via the silyl enol ether (eq 16). Cyclobutanones react analogously under these conditions.[33]

(16)

Halogen Exchange Reactions.[34]

Halogen exchange can be accomplished with reactive alkyl halides, such as ***Benzyl Chloride*** or ***Benzyl Bromide***, and even with certain alkyl fluorides, by using TMS-I in the presence of $(n\text{-Bu})_4NCl$ as catalyst (eq 17).

(17)

Use of TMS-I in Nucleophilic Addition Reactions.

Carbonyl Addition Reactions.[35]

α-Iodo trimethylsilyl ethers are produced in the reaction of aldehydes and TMS-I (eq 18). These compounds may react further to provide the diiodo derivative or may be used in subsequent synthesis.

(18)

An example of a reaction of an iodohydrin silyl ether with a cuprate reagent is summarized in eq 19.[36] An interesting reaction of TMS-I with phenylacetaldehydes gives a quantitative yield of the oxygen-bridged dibenzocyclooctadiene, which was then converted in a few steps to the natural product isopavine (eq 20).[35,37]

(19)

(20)

β-Iodo ketones have been produced from reactions of TMS-I and ketones with α-hydrogens.[38] This reaction presumably involves a TMS-I catalyzed aldol reaction followed by 1,4-addition of iodide.

Conjugate Addition Reactions.[39]

α,β-Unsaturated ketones undergo conjugate addition with TMS-I to afford the β-iodo adducts in high yield (eq 21). The reaction also works well with the corresponding alkynic substrate.[40]

(21)

TMS-I has also been extensively utilized in conjunction with organocopper reagents to effect highly stereoselective conjugate additions of alkyl nucleophiles.[41]

Use of TMS-I as a Silylating Agent.

Formation of Silyl Enol Ethers.[42]

TMS-I in combination with ***Triethylamine*** is a reactive silylating reagent for the formation of silyl enol ethers from ketones (eq 22). TMS-I with ***Hexamethyldisilazane*** has also been used as an effective silylation agent, affording the thermodynamic silyl enol ethers. For example, 2-methylcyclohexanone gives a 90:10 mixture in favor of the tetrasubstituted enol ether product.[42a] The reaction of TMS-I with 1,3-diketones is a convenient route to 1,3-bis(trimethylsiloxy)-1,3-dienes.[42c]

(22)

In an analogous process, TMS-I reacts with lactams in the presence of Et_3N to yield silyl imino ethers (eq 23).[43a]

(23)

Halogenation of Lactams.[43b]

Selective and high yielding iodination and bromination of lactams occurs with ***Iodine*** or ***Bromine***, respectively, in the presence of TMS-I and a tertiary amine base (eq 24). The proposed reaction mechanism involves intermediacy of the silyl imino ether.

(24)

Reaction with Carbanions.[44]

TMS-I has seen limited use in the silylation of carbanions, with different regioselectivity compared to other silylating reagents in the example provided in eq 25.

(25)

Silylation of Alkynes and Alkenes.[45]

A Heck-type reaction of TMS-I with alkenes in the presence of Pd^0 and Et_3N affords alkenyltrimethylsilanes (eq 26).

(26)

Oxidative addition of TMS-I to alkynes can also be accomplished with a three-component coupling reaction to provide the enyne product (eq 27).

(27)

Use of TMS-I as a Lewis Acid.

Acetalization Catalyst.[46]

TMS-I used in conjunction with $(MeO)_4Si$ is an effective catalyst for acetal formation (eq 28).

(28)

Catalyst for α-Alkoxymethylation of Ketones.

Silyl enol ethers react with α-chloro ethers in the presence of TMS-I to afford α-alkoxymethyl ketones (eq 29).[47]

(29)

Catalyst for Reactions of Acetals with Silyl Enol Ethers and Allylsilanes.

TMS-I catalyzes the condensation of silyl enol ethers with various acetals (eq 30)[48] and imines,[49] and of allylsilanes with acetals.[50]

Use of TMS-I as a Reducing Agent.

TMS-I reduces enediones to 1,4-diketones,[51] while both epoxides and 1,2-diols are reduced to the alkenes.[13a,b,52] The Diels-Alder products of benzynes and furans are converted in high yield to the corresponding naphthalene (or higher aromatic derivative) with TMS-I (eq 31).[53]

Styrenes and benzylic alcohols are reduced to the alkanes with TMS-I (presumably via formation of HI).[54] Ketones produce the symmetrical ethers when treated with trimethylsilane as a reducing agent in the presence of catalytic TMS-I.[55]

Reduction of α-Ketols.[56,57]

Carbonyl compounds containing α-hydroxy, α-acetoxy, or α-halo groups react with excess TMS-I to give the parent ketone. α-Hydroxy ketone reductions proceed via the iodide, which is then reduced with iodide ion to form the parent ketone (eq 32).

Sulfoxide Deoxygenation.[58]

The reduction of sulfoxides occurs under very mild conditions with TMS-I to afford the corresponding sulfide and iodine (eq 33). Addition of I_2 to the reaction mixture accelerates the second step. The deoxygenation occurs faster in pyridine solution than the reactions with a methyl ester or alcohol.[59]

(33)

Pummerer reactions of sulfoxides can be accomplished in the presence of TMS-I and an amine base, leading to vinyl sulfides.[60] An efficient synthesis of dithioles was accomplished with TMS-I and Hünig's base (***Diisopropylethylamine***) (eq 34).[61]

(34)

Reaction with Sulfonyl Halides.[62]

Arylsulfonyl halides undergo reductive dimerization to form the corresponding disulfides (eq 35). Alkylsulfonyl halides, however, undergo this process under somewhat more vigorous conditions. Although sulfones generally do not react with TMS-I, certain cyclic sulfones are cleaved in a manner analogous to lactones.[63]

(35)

Other Reactions of TMS-I.

Reaction with Phosphine Oxides.[64]

Phosphine oxides react with TMS-I to form stable adducts (eq 36). These *O*-silylated products can undergo further thermolytic reactions such as alkyl group cleavage.

(36)

Chlorophosphines undergo halogen exchange reactions with TMS-I.[65]

Reaction with Imines.

Imines react with TMS-I to form *N*-silylenamines, in a process analogous to the formation of silyl enol ethers from ketones.[66]

Reaction with Oximes.[67]

Oximes are activated for dehydration (aldoximes, with hexamethylsilazane) or Beckmann rearrangement (ketoximes) with TMS-I (eq 37).

Reactions with Nitro and Nitroso Compounds.[68]

Primary nitro derivatives react with TMS-I to form the oximino intermediate via deoxygenation, which then undergoes dehydration as discussed for the oximes (eq 38). Secondary nitro compounds afford the silyl oxime ethers, and tertiary nitro compounds afford the corresponding iodide. Nitroalkenes, however, react with TMS-I at 0 °C to afford the ketone as the major product (eq 39).[69]

An interesting analogy to this dehydration process is found in the reductive fragmentation of a bromoisoxazoline with

TMS-I, which yields the nitrile (eq 40).[70]

Rearrangement Reactions.

An interesting rearrangement occurs on treatment of a β-alkoxy ketone with TMS-I which effects dealkylation and retro-aldol reaction to give the eight-membered diketone after reductive dehalogenation (eq 41).[71] Tertiary allylic silyl ethers α to epoxides undergo a stereocontrolled rearrangement to give the β-hydroxy ketones on treatment with catalytic TMS-I (eq 42).[72]

Related Reagents.

Bromotrimethylsilane; ***Chlorotrimethylsilane***; ***Trimethylsilyl Trifluoromethanesulfonate***.

(*E*)-1-Iodo-3-trimethylsilyl-2-butene[1]

[52815-00-6] · $C_7H_{15}ISi$ · 1-Iodo-3-trimethylsilyl-2-butene · (MW 254.21) (*E*)

[52685-51-5]

(annulation reagent; alkylative equivalent of 3-buten-2-one; 3-ketobutyl synthon)

Alternate Name: (3-iodo-1-methyl-1-propenyl)trimethylsilane.

Physical Data: bp 60 °C/20 mmHg.

Solubility: freely sol organic solvents.

Form Supplied in: not commercially available.

Preparative Methods: the first reported preparation[2] of this reagent lacked full experimental details. The preparation given (eq 1) is a compilation of the work of several groups; the various steps have been selected to give optimum yields. 2-Propyn-1-ol is converted[3] into its 3-(trimethylsilyl) derivative (**1**), which is then reduced[4] using ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al). The intermediate vinylaluminum is reacted with ***Iodine*** to produce the (*Z*)-iodoalkene (**2**). Treatment of this with ***Lithium Dimethylcuprate*** gives the allylic alcohol (**3**);[5] transformation into ***(E)-(3-Chloro-1-methyl-1-propenyl)trimethylsilane*** (**4**) followed by halogen exchange[6] with ***Sodium Iodide*** then gives reagent (**5**).

An alternative, high-yielding synthesis of (**3**) (eq 2) involves the use of HMPA, but is otherwise straightforward.[7]

Enolate Alkylation.

One of the most useful applications of the Michael reaction[8] is Robinson annulation, using 3-buten-2-one as electrophilic acceptor. However, the Michael reaction, being reversible, is prone to side reactions, and Robinson annulation itself is of only significant utility in relatively simple cases. Hence there has been considerable effort[9] devoted to devising alkylative equivalents of 3-buten-2-one, with the goal of achieving regiospecific enolate alkylation under nonequilibrating conditions. Allylic halides possess sufficiently high reactivity for such alkylation. Useful reagents which have been devised include ***1,3-Dichloro-2-butene*** (Wichterle's reagent),[10] Stork's halomethylisoxazoles,[11] and Stotter's γ-iodotiglate.[12] However, these alternatives can all present problems either before or during further transformation to liberate the 3-ketoalkyl chain prior to

final cyclization. For example, the Wichterle sequence requires the use of concentrated sulfuric acid to hydrolyze the vinyl chloride moiety.

The use of halomethyl vinylsilanes would appear to offer significant promise. As allylic halides, they should be sufficiently reactive to permit regiospecific alkylation; as vinylsilanes, they can be converted, via α,β-epoxysilanes, into carbonyl compounds.[13] The conditions for this last transformation, with simple α,β-epoxysilanes, are rather vigorous, requiring hot methanol/sulfuric acid.

Examples of Use.

Iodide (**5**) reacts with lithium enolates,[9,14] generated in a variety of ways, including kinetic generation from enol acetates (eq 3), regiospecific production by lithium-ammonia reduction of enones, and similar regiospecific production by lithium dimethylcuprate addition to enones (eq 4). Enamines can also be used in a sequence which demonstrates the possibility of reducing enones without affecting the vinylsilane (eq 5); the reagent used in this case was chloride (**4**) in the presence of ***Potassium Iodide***, i.e. via the in situ generated iodide (**5**).

(3)

(4)

Release of the latent carbonyl function in these vinylsilanes can be achieved[9,14] under much milder conditions than for simple epoxysilanes, which require hot methanol/sulfuric acid. Here, treatment of the epoxide, formed using ***m-Chloroperbenzoic Acid***, with formic acid for 30 s led cleanly to the dione (eq 6); alternatively, use of a slight excess of *m*-CPBA and a reaction time of 4 h achieved the same conversion. The extreme and contrasting ease of this transformation has been ascribed to nucleophilic participation of the carbonyl group in epoxide opening (eq 7).

(6)

(7)

The diones so formed can be cyclized under basic conditions to the corresponding enones (eqs 8 and 9).

(8)

(9)

Iodide (**5**) has also been used[15] in a regiocontrolled route (eq 10) to 4,5-disubstituted 2-(and 3-)cyclohexenones. Alkylation of the anion of sulfone (**6**) with (**5**) gave (**7**), subsequent transformations leading sequentially to enones (**8**) and (**9**). No further manipulation of these enones has been reported.

A different application[16] of reagent (**5**) can be seen in the total synthesis of artemisinin (**10**). Alkylation of the kinetic enolate of (**11**), derived from (-)-isopulegol, with (**5**) gave an 6:1 mixture of epimeric products from which the major isomer (**12**) was isolated in 62% yield. Further transformations led to vinylsilane (**13**). Liberation of the latent carbonyl group to provide ketone (**14**) was again achieved under very mild conditions, although here the possibility of carbonyl participation would seem less likely. Further steps then led to artemisinin (**10**).

3-Iodo-2-trimethylsilylmethyl-1-propene

[80121-73-9] · $C_7H_{15}ISi$ · 3-Iodo-2-trimethylsilylmethyl-1-propene · (MW 254.21)

(a bifunctional conjunctive reagent that serves as a dipolar trimethylenemethane synthon;[1,6] treatment with SnF_2 affords a dianionic trimethylenemethane synthon[9])

Physical Data: bp 25 °C/0.5 mmHg.[2]

Solubility: wide range of organic solvents.

Preparative Method: from the corresponding mesylate upon treatment with ***Sodium Iodide*** in acetone.[2] The mesylate can be prepared from the commercially available alcohol.[3]

Purification: distillation in the dark (25 °C/0.5 mmHg, trap at -78 °C).[2]

Handling, Storage, and Precautions: can be stored in the dark at -20 °C for up to 3 months without significant deterioration.[2]

Dipolar Synthon for Trimethylenemethane.

The most common use of this reagent is as a 1,3-dipolar synthon for trimethylenemethane (TMM) (eq 1).[1]

(1)

The dipolar character is unmasked in two separate synthetic steps. In the first, the synthon reacts at the positive end upon treatment with a nucleophile such as an enolate or metalloenamine.[2] In the second step, the nucleophilic end is unveiled, usually by treatment with fluoride ion. This nucleophile attacks the carbonyl or imine, completing the sequence. A similar reagent to the iodide, also a 1,3-dipolar synthon for TMM, is derived by treatment of the corresponding acetate with Pd^0.[1] The resulting 1,3-dipolar synthon differs from the iodide in several ways:

- 1)one synthetic step is required to complete addition of the activated reagent;
- 2)the reaction simulates a cycloaddition, with an electron deficient alkene as a reaction partner, rather than a carbonyl or imine;
- 3)the nucleophilic end of the synthon reacts first, in contrast to the iodide.

Reagent (**1**) has been used successfully with several classes of substrates.[1,4,5] For example, ketone (**2**) was used in a synthesis employing the dipolar synthon as a means of annulating the third ring of the coriolin skeleton (eq 2).[4]

Enone alkylation using (**1**), followed by Michael addition of the activated silane constitutes a second class of reactions employing this synthon.[6] As shown in eq 3, the mode of addition in systems containing a second conjugated double bond can be controlled by changing the method used to activate the silane toward nucleophilic attack. Use of a Lewis acid favors 1,6-addition leading to seven-membered rings,[6b,7] while treatment with fluoride ion favors 1,4-addition and formation of five-membered rings.[6b]

Finally, imines can be used in the synthesis of nitrogen-containing heterocycles.[8] One particularly interesting method involves a sequential photoexcitation-electron-transfer desilylation method for generating a diradical species capable of forming a spirocyclic product (eq 4).[8c] Notably, the ionic cyclization method involving fluoride ion leads, in this case,

to mixtures of products including only small amounts (ca. 7%) of the desired spirocycle.[8c]

(4)

Dianionic Synthon for Trimethylenemethane.[9]

Reagent (**1**), upon metalation with ***Tin(II) Fluoride*** can be used as a dianionic synthon for trimethylenemethane (eq 5).[10] This versatile synthon, in conjunction with bis-electrophiles such as (**4**), has been used to synthesize rings that range in size from five to eight members. An intramolecular hemiacetalization reaction followed by cyclization of the allylsilane makes possible the formation of seven- and eight-membered rings (eq 6).[9b]

3-Iodo-1-trimethylsilylpropyne

[78199-88-9] · $C_6H_{11}ISi$ · 3-Iodo-1-trimethylsilylpropyne · (MW 238.16)

(addition to aldehydes in the presence of tin(II) chloride or metallic tin and aluminum to provide α-hydroxyallenes and β-alkynic alcohols; propargylic alkylating agent)

Alternate Name: (3-iodo-1-propynyl)trimethylsilane; trimethylsilylpropargyl iodide.

Physical Data: bp 42 °C/2 mmHg.

Solubility: typical reaction solvents are DMF, dichloromethane, THF.

Analysis of Reagent Purity: ^{1}H NMR.[1]

Preparative Methods: from ***Iodine*** and [3-(trimethylsilyl)-2-propynyl]-*o*-phenylene phosphite in dichloromethane (52%), or iodine and 3-(trimethylsilyl)-2-propyn-1-ol and ***Tri-n-butylphosphine*** (47%);[1] from trimethylsilylpropargyl bromide and ***Sodium Iodide***;[2] by treatment of trimethyl(2-propynyl)stannane with ***Ethylmagnesium Bromide***, ***Bromotrimethylsilane*** in THF followed by I_2 in CCl_4 (65-70%).[3]

Handling, Storage, and Precautions: the distilled trimethylsilylpropargyl iodide was found by ^{1}H NMR to have decomposed to the extent of 20% after 5 d at -10 °C in the dark.[1] Care should be taken when working with the tin derivative. Organostannane reagents are highly toxic and readily absorbed through the skin. Proper safety equipment (i.e. fume hood, gloves, protective eyewear) should be utilized when handling the organostannane derivative.[4]

Addition to Aldehydes.

Considerable attention has been focused on the control of regioselectivity in the addition of allenic and propargylic organometallic reagents to carbonyl compounds. Mukaiyama and Harada have found that the addition of trimethylsilylpropargyl iodide to aldehydes in a DMF/***1,3-Dimethyl-2-imidazolidinone*** (DMI) mixture in the presence of ***Tin(II) Chloride*** results in the formation predominantly of the α-hydroxy allenes (α-allenic alcohols) (eq 1).[2]

In a complimentary study, Nokami et al. found that trimethylsilylpropargyl iodide reacts with metallic ***Tin*** in the presence of metallic ***Aluminum*** to give bis(trimethylsilylpropargyl)tin diiodide. This then reacts with aldehydes to give either α-allenic or β-alkynic alcohols (homopropargyl alcohols) selectively, depending on the choice of solvent (eq 2).[5]

Analogous additions to aldehydes and ketones with metallated derivatives of 3-bromo-1-trimethylsilylpropyne (which is commercially available) are also known. Either α-allenic[6] or β-alkynic alcohols[7] may be obtained selectively by using the appropriate metal derivative. The organolithium species prepared from 1-trimethylsilylpropyne has also been utilized.[8]

Alkylation Reactions.

3-Iodo-1-trimethylsilylpropyne has been used in the trapping of enolates generated in 1,4-additions of organometallic

reagents to 2-cyclopentenone derivatives.[1] Noyori et al. used this reaction in the three-component coupling synthesis of prostaglandins (eq 3).[9] Reaction of trimethylsilylpropargyl iodide with an alkynic Grignard reagent in the presence of ***Copper(I) Cyanide*** has also been demonstrated in the synthesis of a preclavulone A model (eq 4).[10]

(3)

(4)

3-Bromo-1-trimethylsilylpropyne has also been used as an alkylating agent for trapping enolates and other carbanions.[11] It has also been used in the preparation of alkynic ylides.[12]

Related Reagents.

1,3-Bis(triisopropylsilyl)propyne; ***3-Triphenylstannyl-1-propyne***.

4-Iodo-2-trimethylstannyl-1-butene[1]

[99474-77-8] · $C_7H_{15}ISn$ · 4-Iodo-2-trimethylstannyl-1-butene · (MW 344.83)

(cyclopentane annulation;[2,3] intramolecular Stille coupling;[4] bifunctional reagent[5-7])

Alternate Name: (3-iodo-1-methylenepropyl)trimethylstannane.

Physical Data: bp 50-55 °C/0.1 mmHg.[8]

Analysis of Reagent Purity: ^{1}H NMR.[8]

Preparative Methods: by addition of trimethylstannylcuprate to 1-butyn-4-ol[9,10] followed by a Mitsunobu reaction,[11] or via the tosylate of 2-trimethylstannyl-1-buten-4-ol (NaI, DMF).[8]

Purification: by distillation.[8]

Handling, Storage, and Precautions: organostannanes should be considered as toxic compounds.[12] This reagent should be handled in a well ventilated fume hood and gloves should be worn.

Methylene Cyclopentane Annulations.

Alkylation-Intramolecular Stille Coupling.

Bicyclic dienes have been prepared by alkylation of the *N*,*N*-dimethylhydrazone of a cyclohexanone with 4-iodo-2-trimethylstannyl-1-butene, followed by the cleavage of the hydrazone, formation of the enol triflate and palladium-catalyzed Stille coupling (eq 1) (see also ***5-Chloro-2-trimethylstannyl-1-pentene***).[8,13]

Alkylation-Vinyllithium Addition.

Treatment of the stannane derived from the alkylation of cyclohexanone with 4-iodo-2-trimethylstannyl-1-butene (see above) with ***Iodine*** affords the vinyl iodide. Treatment of this intermediate with ***n-Butyllithium*** affords an allylic, angular hydroxy annulation product (eq 2).[14]

This annulation sequence provides the complimentary regioisomer to that obtained by a vinylcuprate-intramolecular

alkylation sequence.

Radical Annulation.

Addition of ***Tri-n-butylstannane*** to 4-iodo-2-trimethylstannyl-1-butene in the presence of ***N-Phenylmaleimide*** affords the bicyclic imide in 59% yield (eq 3). This reaction failed with methyl acrylate and phenyl vinyl sulfone.[12]

(3)

However, 1-*t*-butyldimethylsilyl-4-iodo-2-trimethylstannyl-1-butene undergoes an analogous reaction with acrylonitrile, methyl acrylate, and methyl vinyl ketone.[11]

Miscellaneous Related Reagents.

See also ***4-Chloro-2-trimethylstannyl-1-butene***, ***4-Iodo-2-trimethylgermyl-1-butene***, ***5-Chloro-2-trimethylstannyl-1-pentene***, and ***(Z)-5-Chloro-3-trimethylstannyl-2-pentene***.

A number of homologs of the title reagent have been prepared, differing in chain length and o-substitution (eq 4).[9] These have been used as methylenecyclopentane annulation reagents via the alkylation-intramolecular Stille coupling methodology (see above).[8]

(4)

A number of (*E*)- and (*Z*)-6-iodo-3-trimethylstannyl-2-hexenoates and related bifunctional reagents (**1,2**) have been prepared and used as cyclohexane annulation reagents through alkylation and intramolecular Stille coupling (eq 5).[15,16]

(1)

(2)

X = I, Cl; R = CO_2Me, CH_2OH, CH_2OMOM, $CH_2OTBDMS$

(5)

One of these reagents [(*E*)-1-(*t*-butyldimethylsiloxy)-6-iodo-3-trimethylstannyl-2-hexene] has been used in the synthesis of (±)-8,15-diisocyano-11(20)-amphilectene (eq 6).[17]

An annulation sequence using (*Z*)-1-bromo-4-methyl-3-trimethylstannyl-2-pentene has led to the synthesis of (±)-(14*S*)-dolasta-1(15),7,9-trien-14-ol and (±)-amijitrienol (eq 7).[18-20]

Another route to the synthesis of conjugated dienes has been accomplished using a ***Copper(I) Chloride***-mediated intramolecular coupling strategy.[21] This has been used to couple vinylstannanes and vinyl iodides in the absence of Pd^0 catalysts (eq 8 and Table 1). In only one case (entry 4), the reaction was not stereospecific. At 60 °C, a 13:1 mixture of (2*E*,3*E*) and (2*Z*,3*E*) isomers was obtained (See footnote to Table 1). Running the reaction at 25 °C afforded a 30:1 mixture of products. It was noted that the Pd^0 mediated coupling of this substrate was not stereospecific and in fact the copper-catalyzed reaction was superior.[21]

Table 1 Copper-Mediated Coupling Reactions

Entry	R^1	R^2	R^3	R^4	R^5	Yield (%)
1	CO_2Et	H	Me	H	Me	80

4	CO_2Et	Me	H	H	Me	94[a]
5	CO_2Et	Me	H	Me	H	89

[a] Obtained as a 30:1 mixture of (2*E*, 3*E*) and (2*Z*, 3*E*) isomers.

A general cyclopentane annulation sequence was developed using a vinylstannane that is embedded in a preexisting cycloalkene (eq 9). Initial attempts to extend this methodology to cyclohexane and cyclohexane annulations were accomplished only in low yield (12% and 35%, respectively).[22]

(9)

It was found subsequently that substitution of a pendent o-bromo functionality allows cyclization to both five- and seven-membered rings (eqs 10 and 11).[23]

This methodology was used in the synthesis of (±)-chiloscyphone and (±)-6-*epi*-chiloscyphone (eq 12).[23]

An entry into the preparation of [3.2.1]cycloheptenols utilizes vinylstannane-o-oxo compounds. Treatment of vinylstannanes (eq 13) with *n*-butyllithium affords the cyclopentenols in good yield.[24] The starting stannanes were

prepared by stannylcupration of ***Acetylene*** and cyclohexenone.[25]

(13)

Cyclobutenes can be synthesized using a variation of this methodology. Treatment of the o-*p*-toluenesulfonate-vinylstannanne with BuLi effects a tin-lithium exchange and ring closure (eqs 14 and 15).[24] Preparation of the substrate is accomplished by stannylcupration of ***Allene***,[26,27] acetylene, or phenylacetylene[25] followed by treatment with ***Ethylene Oxide***, and conversion to the tosylate.[24]

(14)

(15)

A disubstituted stannane, (*E*)-1,4-di(*t*-butyldimethylsiloxy)-2-trimethylstannyl-2-butene, has been used as an isocoumarin annulation reagent. This was accomplished by palladium-catalyzed coupling of this reagent with methyl 2-iodo-4-methylbenzoate followed by acid-catalyzed deprotection/cyclization (eq 16). This was a key sequence in the synthesis of lacramin A.[28]

Iodylbenzene[1]

$PhIO_2$

[696-33-3] · $C_6H_5IO_2$ · Iodylbenzene · (MW 236.01)

(ring cleavage of indole and imidazole derivatives;[2] quinone formation;[3] dehydrogenation of 3-keto steroids to dienones;[4] other enone dehydrogenations;[5] allylic oxidations;[6] the Nef reaction[7])

Alternate Name: iodoxybenzene.

Physical Data: mp 230 °C, *explosive decomposition* 250-253 °C.

Solubility: sol H_2O (2.8 g L^{-1} at 12 °C, 12 g L^{-1} at 100 °C). $PhIO_2$ is polymeric in the solid state and dissolution in solvent is due to a chemical reaction.

Analysis of Reagent Purity: by iodiometric titration.[12]

Preparative Methods: by disproportionation of ***Iodosylbenzene***,[8] by treatment of ***Phenyliodine(III) Dichloride*** with ***Sodium Hypochlorite***,[9] by ***Peracetic Acid*** (40%) oxidation of iodobenzene,[10] or oxidation with ***Potassium Bromate*** in ***Sulfuric Acid***[11] (which is the best method).

Purification: by crystallization from hot water[8] or by washing with chloroform followed by drying.[9,10]

Handling, Storage, and Precautions: should be freshly prepared and should not be heated in the absence of solvent because of the danger of explosion. This reagent should be handled in a fume hood.

Iodylbenzene is a weaker oxidant compared with iodosylbenzene. The systems $PhIO_2/(PhSeO)_2O$ and $PhIO_2/(PhSe)_2$ are synthetically useful and the oxidative capabilities of $PhIO_2$ are improved by Lewis acids or ***p-Toluenesulfonic Acid***.

Ring cleavage of amino acids using *p-t*-$BuC_6H_4IO_2$ in chlorobenzene is a useful reaction. For example, tryptophan *N*-benzoyl methyl ester gives the kynurenine derivative (eq 1),[2] and histidine-*N*-Cbz-methyl ester undergoes a similar process (eq 2).[2]

(1)

(2)

$PhIO_2$ itself or *m*-iodylbenzoic acid as the *N,N,N,´N´*-tetramethyl-*N´´*-*t*-butylguanidinium salts in CH_2Cl_2 are useful reagents for the oxidation of phenols to benzoquinones. β-Naphthol is oxidized to 1,2-naphthoquinone in 65% yield.[3] Use of *m*-iodylbenzoic acid has the advantage that it is recoverable as its reduction product, *m*-iodobenzoic acid. *m*-Iodylbenzoic acid is made by commercial hypochlorite solution oxidation of *m*-iodobenzoic acid.[4]

The dehydrogenation of steroidal 3-ketones either to the enone or dienone is an important process. The catalytic system of $PhIO_2$ and ***Diphenyl Diselenide*** offers an excellent method for this transformation (eq 3).[4]

(3)

$PhIO_2/(PhSeO)_2O$ was singularly useful in the synthesis of a 4a-methyl-4a*H*-fluorenone (eq 4).[5]

(4)

A valuable application of the $PhIO_2$/***2,2´-Dipyridyl Diselenide*** system is illustrated in the allylic oxidation of alkenes such as (1*S*)-(-)β-pinene to pinocarvone (eq 5),[6] cholesteryl benzoate to 4-ketocholesteryl benzoate (eq 6),[6] and α-terpineol to 6-keto-α-terpineol (eq 7).[6]

(5)

(6)

(7)

m-Iodylbenzoic acid in the presence of excess *N,N,N,´,N´*-tetramethyl-*N´´*-*t*-butylguanidine is a mild and efficient reagent for the Nef reaction for conversion of secondary nitro compounds to ketones, even in the presence of other oxidizable groups (eq 8).[7]

Iridium Catalysts[1]

Ir

[7439-88-5] · Ir · Iridium · (MW 192.22)

(moderately active hydrogenation catalysts useful for selective hydrogenation of α,β-unsaturated aldehydes to allylic alcohols;[2] for stereoselective hydrogenation of C-C double bonds;[3] for selective hydrogenation of aromatic nitro compounds[4,5] and quinolines[6])

Physical Data: mp 2454 °C; bp ca. 4800 °C; *d* (20 °C) 22.65 g cm^{-3}.

Solubility: sol aqua regia after fusion with Na_2O_2 or a mixture of KOH and KNO_3.

Form Supplied in: Ir/C (usually 5% Ir), Ir black, and IrO_2 (a precursor of Ir black) are commercially available.

Preparative Methods: $IrCl_3.3H_2O$, $IrCl_4.xH_2O$, Na_2IrCl_6, $(NH_4)_2IrCl_6$ are usual starting reagents for the preparation of supported and unsupported Ir catalysts. Unsupported Ir catalysts have been prepared by reducing IrO_2 (an Adams' type) at 165 °C under a stream of hydrogen[4] or by reducing $Ir(OH)_3$ or $Ir_2O_3.3H_2O$ (precipitated by adding aq NaOH or LiOH to an aq solution of $IrCl_3.3H_2O$) in H_2O at 80-90 °C under 8 MPa H_2.[7] Unsupported and supported Ir catalysts have also been prepared by the reaction of $IrCl_4.xH_2O$ with $NaBH_4$ in EtOH.[8]

Handling, Storage, and Precautions: Ir catalysts are rather stable and can be stored in the air without losing activity. Not attacked by any of the acids nor by aqua regia; only superficially oxidized on heating in air; oxidized at red heat to form IrO_2; direct contact with explosive gas mixtures containing H_2 or with alcoholic solvents, especially such as MeOH or EtOH, should be avoided.

Selective Hydrogenation of α,β-Unsaturated Aldehydes to Allylic Alcohols.

Allylic alcohols have been obtained in high yields from the hydrogenation of α,β-unsaturated aldehydes in EtOH with 5% Ir/C catalyst (eqs 1 and 2).[2] With 2-propenal (acrolein), however, the yield of allyl alcohol was lower (60%).

(1)

(2)

A number of alternative methods for the enal reductions using heterogeneous catalysts have also been reported.[9] Some of the effective catalyst systems are: Pt,[10] Pt/C or Pt/$CaCO_3$,[9] modified by $FeSO_4$-$Zn(OAc)_2$; Pt-Ge-Nylon (3% Ge);[11] prereduced Re_2O_7/pyridine;[12] and Raney type Ag-Zn.[13]

Stereoselective Hydrogenation of C-C Double Bonds.

Ir catalysts are highly stereoselective in the hydrogenation of alkenic and aromatic compounds. Thus hydrogenation of 1,2-dimethylcyclohexene and *o*-xylene with Ir black in *i*-PrOH at 25 °C and atmospheric pressure of H_2 gave *cis*-1,2-dimethylcyclohexane in 98.7 and 98.6% yields, respectively.[14] Eq 3 compares the stereoselectivity of the six platinum metals in the hydrogenation of 1,2-dimethylcyclohexene and *o*-xylene (data in parentheses) in *t*-BuOH.[3] Similarly, deuteration of $\Delta^{9,10}$-octalin with 5% Ir/C (25 °C, 2.5-2.7 MPa D_2) gave *cis*-decalin in 97.8% selectivity.[15] However, as has been observed with 1,2- and 1,6-dimethylcyclohexenes,[16] the deuteration products obtained with Ir catalyst are extensively exchanged in spite of high stereoselectivity in the formation of the *cis* isomer. The high stereoselectivity of Ir catalysts is associated with their low alkene isomerization activity during hydrogenation.[3] Excellent examples of stereoselective synthesis using Ir catalysts have been reported in the hydrogenation of the 16-methylene steroid (**1**) to the 16β-methyl derivative (**2**) (eq 4)[17] and in the hydrogenation of the unsaturated ketone (**3**) to the saturated ketone (**4**) (eq 5),[18] which was an important step in the total synthesis of (±)-9-isocyanopupukeanane. Both the hydrogenations gave mixtures of stereoisomers with other metal catalysts.

Pt	79.1 (89.6):20.9 (10.4)

* 50 °C

(1)

(4)

(2) <2%

(5)

Selective Hydrogenation of Aromatic Nitro Compounds.

Hydrogenation of aromatic nitro compounds with Ir catalysts often slows down after the uptake of 2 mol of H_2 and the corresponding hydroxylamines are obtained in good yields (eqs 6-8).[4,5] Usually higher yields are obtained at neutral pH, at low temperatures, and with substrates having electron-withdrawing substituents.[4,19]

(6)

(7)

(8)

Hydrogenation of halonitrobenzenes with Ir catalysts is accompanied by only slight dehalogenation. For example, hydrogenation of 3,4-dichloronitrobenzene with 5% Ir/C in *i*-PrOH gave the corresponding dichloroaniline almost quantitatively.[5] The rate of the dechlorination was only 1/250th of the rate of the hydrogenation. Other effective methods for suppressing dehalogenation have also been described using Pt/C and Ni catalysts in the presence of some inhibitors or a sulfided Pt/C catalyst.[20]

Selective Hydrogenation of Quinolines in the Heterocyclic Ring.

Both 2- and 4-methylquinolines are hydrogenated with iridium catalysts exclusively to the corresponding 1,2,3,4-tetrahydroquinolines without any additives (eqs 9 and 10).[6] With Pd, Pt, Ru, Rh, and Ni catalysts the same selective hydrogenation can be achieved only in the presence of sulfur compounds or carbon monoxide.

Iridium(IV) Chloride

$IrCl_4$

[10025-97-5] · Cl_4Ir · Iridium(IV) Chloride · (MW 334.02)

(catalyst precursor for the stereoselective reduction of cyclohexanones[1-3])

Physical Data: decomposes on heating.

Solubility: sol cold H_2O, alcohol.

Form Supplied in: dark brown, hygroscopic, amorphous mass. Pure iridium tetrachloride does not seem to have been made. Products sold as such contain water (about 10%) and may also contain some chloroiridic acid [H_2IrCl_6]. The manufacturer should state the iridium content. The ammonium salt [$(NH_4)_2IrCl_6$], which can be obtained in a pure state, can be used instead.

Stereoselective Reductions.

Iridium tetrachloride is a catalyst precursor for the reduction of unhindered (conformationally biased or rigid) cyclohexanones to cyclohexanols with the hydroxy group largely axial (often >95%). The reactions are carried out in 90% aqueous 2-propanol and require the presence of phosphorous acid, H_3PO_3, or its dimethyl or trimethyl ester. The phosphorus-containing compound acts as the main reducing agent in the system and 2-propanol as a very minor one. Dimethyl phosphite, $(MeO)_2P(O)H$, is the most convenient to use as phosphorous acid is hygroscopic and trimethyl phosphite is both very toxic and has an unpleasant odor.

Experimentally the reaction is very simple. There is no need to exclude atmospheric oxygen or moisture. The reactants are merely heated at reflux until reaction is complete. The phosphorus compound should be present in at least 100% excess with respect to the ketone. Some examples of the reduction of simple cyclohexanones are given in eqs 1-4.[2]

(1)

(2)

(3)

(4)

The Selectride reagents, developed by Brown,[4,5] give equal or even greater selectivity in the reduction of cyclohexanones to axial alcohols, but require anhydrous reaction conditions, an inert atmosphere, and often low temperatures.

Regioselective and Stereoselective Reductions.

Hindered ketones such as 2,2,6-trimethylcyclohexanone are not reduced. This property has been used for the regio- and stereoselective reduction of some steroidal di- and triketones in which the hindered carbonyl group(s) are not reduced (eqs 5 and 6).[6]

Similar transformations can be carried out with K-Selectride (***Potassium Tri-s-butylborohydride***), but seem difficult to take to completion.[7]

Catalyst.

The identity of the catalyst in these reductions is not known, but is presumably an iridium-phosphite complex. Some such complexes have been made in an attempt to shed light on the nature of the catalyst.[8,9]

Iron

Fe

[7439-89-6] · Fe · Iron · (MW 55.85)

(efficient catalyst for a wide variety of organic transformations)

Physical Data: mp 1535 °C; *d* 7.860 g cm^{-3}.

Solubility: insol water, alkalis, alcohols, ethers; sol acid (attacked or dissolved).

Form Supplied in: chip, foil, filings, powder, wire.

Analysis of Reagent Purity: atomic absorption methods can be used.

Handling, Storage, and Precautions: moisture sensitive.

General.

Iron is used to catalyze a wide variety of organic transformations. The nature of the iron catalyst depends on the reaction conditions (solvent, cocatalysts, etc.) employed for a specific transformation. The reaction descriptions included in this entry will be limited to those utilizing iron powder and to some reactions in which iron(0) is generated in situ, serving as the active catalyst during the reaction.

Iron Powder.

Formation of Lactones.

The lactonization of γ-bromo-α,β-unsaturated carboxylic methyl esters and acids is promoted by heating the substrate in the presence of iron powder (eq 1). Iron apparently facilitates the elimination of methyl bromide and rotation about the double bond.[1]

(1)

Preparation of Nonconjugated Dienes.

Nonconjugated dienes are conveniently prepared from allylic halides via an iron-promoted coupling reaction in DMF (Table 1).[2] Excellent yields are obtained in many cases and some catalytic effect of added halide salts is also observed. The iron salts in the DMF residue were analyzed as 70% Fe^{2+} and 30% Fe^{3+} (via oxidation of Fe^{2+}). Similar types of reaction are observed with a variety of transition metal catalysts, including Pd- and Ni-based catalysts.

Table 1 Coupling of Allyl Chlorides with Iron in DMF (150 °C, 1 h)

Allyl chloride	Conversion (%)	Product	Crude yield (%)
Allyl chloride	65	1,5-Hexadiene	61.5
b-Methallyl chloride	77	2,5-Dimethyl-1,5-hexadiene	60
Allyl chloride + b-methallyl chloride (1:1)	98	1,5-Hexadiene	21
		2-Methyl-1,5-hexadiene	44.8
		2,5-Dimethyl-1,5-hexadiene	24.1

Preparation of Ketones from Carboxylic Acids.

Carboxylic acids react with hydrogen-reduced iron powder to give an iron dicarboxylate intermediate which, upon thermolysis, decomposes to give the condensed ketone, CO_2, and FeO (eq 2).[3]

Reduction.

The reduction of nitroaromatics to anilines with iron powder is carried out in a mixture of methanol and concentrated ***Hydrochloric Acid*** (eq 3). In the absence of methanol, only partial reduction is observed.[4]

The reduction of optically active nitroalkanes to active amines is accomplished with iron in ***Acetic Acid***. The reaction proceeds with &egt;82% optical purity. Other reducing agents, such as ***Lithium Aluminum Hydride***, gave a completely racemic mixture of amines.[5]

Iron Cluster Compounds.

Gif Catalyst-Air Oxidation of Saturated Hydrocarbons.

The Gif catalyst, $Fe_2FeO(OAc)_6py_{3.5}$, is a triiron cluster compound that is generated from the reaction of iron dust, acetic acid, and pyridine. The use of this and a reducing agent in acetic acid and pyridine promotes the air oxidation of saturated hydrocarbons. It is a selective reagent in that least hindered, secondary positions are preferentially attacked, leading to the formation of ketones. It does not epoxidize simple alkenes.

The Gif catalyst is but one of a number of (μ_3-oxo) triiron complexes, some of which have been used as a catalyst for the epoxidation of alkenic alcohol acetates with molecular oxygen (see ***μ_3-Oxohexakis(μ-trimethylacetato)tris(methanol)triiron(III) Chloride***).[6]

Iron(0) Catalysts: Reduction of Fe^{III} Compounds.

Deprotonation of Aldehydes and Ketones: Preparation of Silyl Dienol Ethers.

Grignard reagents have been shown[7] to reduce Fe^{III} compounds to air sensitive Fe^0 and it is this reduced species that is responsible for catalyzing a number of useful organic reactions.[8] For example, aldehydes and ketones are smoothly converted to the corresponding, thermodynamically favored, trimethylsilyl enol ethers upon treatment with Fe^0, ***Chlorotrimethylsilane***, and ***Triethylamine*** (eq 4). When a stoichiometric amount of Fe^0 catalyst is reacted (no additional Grignard reagent) with cycloalkenones, the exocyclic through-conjugated dienol ether is predominantly formed.[9] When a stoichiometric amount of Grignard reagent is reacted with the cyclohexenone in the presence of a catalytic amount of ***Iron(III) Chloride*** (Kharasch reagent),[10] the endocyclic through-conjugated dienol ether is formed. Likewise, when 0.5-1 equiv of Fe^0 catalyst and 1 equiv of Grignard reagent is reacted with the same cyclohexenone (oxygen excluded), the endocyclic through-conjugated dienol ether is again the predominant dienol ether formed.

Iron(0) compounds have been proposed to be the active catalyst in a number of other organic reactions. For example, cross coupling reactions between Grignard reagents and alkyl, vinyl, allyl, and phenyl halides are catalyzed by various iron(III) complexes, such as ***Tris(dibenzoylmethide)iron(III)***.[11] It is proposed that the reaction between the Grignard reagent and the iron(III) compound produces the active iron(0) catalyst.

Iron(III) Acetylacetonate-Hydrogen Peroxide[1]

$Fe(MeCOCHCOMe)_3$-H_2O_2

($Fe(acac)_3$)

[14024-18-1] · $C_{15}H_{21}FeO_6$ · Iron(III) Acetylacetonate-Hydrogen Peroxide · (MW 353.21) (H_2O_2)

[7722-84-1] · H_2O_2 · Iron(III) Acetylacetonate-Hydrogen Peroxide · (MW 34.02)

(β-epoxidation of cholesterol derivatives;[2] *trans*-epoxidation of alkenes[3])

Alternate Name: tris(acetylacetonate)iron(III)-hydrogen peroxide.

Physical Data: $Fe(acac)_3$: mp 184 °C, *d* 1.33 g cm^{-3}.

Solubility: slightly sol cold and hot water; sol alcohol, acetone, benzene, chloroform.

Form Supplied in: dark red powder; widely available.

Preparative Method: reagent combination is generated in situ, via dropwise addition of 30% ***Hydrogen Peroxide*** (49 mmol) to a stirred solution of ***Tris(acetylacetonato)iron(III)*** (2.7 mmol), and substrate (0.26 mmol) in acetonitrile.[2,3]

Handling, Storage, and Precautions: use in a fume hood. $Fe(acac)_3$ causes severe eye irritation and may cause skin irritation. Toxic fumes of carbon monoxide and carbon dioxide are generated on decomposition. It is incompatible with strong oxidizing agents; thus the H_2O_2 has to be used in excess because it is decomposed by Fe^{III} ion.[4] Reactions should be worked up by decomposition of excess H_2O_2 with saturated aqueous sodium sulfite and then extraction of product with ether. See also ***Hydrogen Peroxide***.

β-Epoxidation of Cholesterol Derivatives.[2]

Steroidal alkenes are stereoselectively epoxidized from the β-face with $Fe(acac)_3$-H_2O_2 (eq 1), via a radical process.[5] In contrast, organic peracids (***m-Chloroperbenzoic Acid***) yield the α-epoxide via attack from the least hindered face.[6] Cholest-4-en-3β-ol yields β-epoxidation with $Fe(acac)_3$ and organic peracids, but this is due to hydroxyl coordination. Other cholest-4-ene derivatives yield β-epoxidation with $Fe(acac)_3$ and α-epoxidation with organic peracids (eq 2).[2]

Low yields of epoxide with some substrates are usually caused by formation of the allylic oxidation product, and indeed use of $Fe(acac)_3$-***t-Butyl Hydroperoxide*** or other transition metal acac salts yield predominantly allylic oxidation.[5a]

$R^1 = OH, R^2 = H$, 38%; $R^1 = H, R^2 = OH$, 46%; $R^1 = R^2 = H$, 74%

trans-Epoxidation of Alkenes.[3]

trans-Epoxide is obtained selectively in the $Fe(acac)_3.H_2O_2$ mediated oxidation of both *cis* and *trans* alkenes (eq 3).[3] This contrasts with *m*-CPBA oxidation in which alkene geometry is conserved.[7]

Iron(III) Azide[1]

$Fe(N_3)_3$

[14215-32-8] · FeN_9 · Iron(III) Azide · (MW 181.94)

(preparation of azidoalkanes[1])

Alternate Name: ferric azide.

Form Supplied in: made in situ.

Preparative Methods: the reagent is prepared and used in situ[1] by addition of ***Sodium Azide*** (15 mmol) and ***Iron(III) Sulfate*** (7.5 mmol) in methanol (20 mL) to the organoborane (5 mmol) stirred at rt for 30 min under nitrogen. The mixture is then cooled to 0 °C and 30% ***Hydrogen Peroxide*** added via a syringe pump (0.1 mL min^{-1}). Slow addition of hydrogen peroxide increases yields.

Handling, Storage, and Precautions: is poisonous by ingestion or skin contact. It is an unstable explosive, sensitive to impact. Decomposition yields toxic fumes of NO_x and Na_2O. Organic azides are sensitized by metal salts or traces of strong acid.[8] $Fe_2(SO_4)_3$ is harmful if swallowed or inhaled. It causes eye and skin irritation. Use in a fume hood.

Azidoalkanes.[1]

Azidoalkanes are useful intermediates in the synthesis of a variety of nitrogen derivatives, especially amines via reduction with ***Lithium Aluminum Hydride***. Trialkylboranes react with iron azide in the presence of hydrogen peroxide to generate alkyl azides (eq 1) at rt.[1] This procedure provides a good overall transformation of alkenes to azides in an anti-Markovnikov fashion, via conversion to the organoborane followed by the one-pot azidation with $Fe(N_3)_3$ (eqs 2-4). Secondary amines can be made stereospecifically via thermal conversion of an alkyl azide to a nitrene and reaction with an alkyl dichloroborane.[2]

$$BR_3 + Fe(N_3)_3 + H_2O_2 \longrightarrow RN_3 \qquad (1)$$

(2)

(3)

(4)

Reaction mixtures (5 mmol scale) are worked up with 3 N NaOH (20 mL) and 30% H_2O_2 to decompose residual organoborane. The products are extracted into ether.[1] Alternate procedures for generation of alkyl azides are available: nucleophilic displacement with azide ion[3] (high temperatures) and use of lead azide generated in situ from lead(IV) acetate azide[4] (toxicity and formation of regioisomers) offer no advantages over the iron azide method. The azidation reaction is related to the use of ***Iron(III) Chloride***, ***Iron(III) Thiocyanate***, and $Fe(SeCN)_3$ to generate alkyl halides,[5] thiocyanates,[5] and selenocyanates,[6] respectively. The $Fe(N_3)_3$ reaction mechanism is postulated to be different from the latter salts, being a radical process[1] thought to be initiated by H_2O_2 and trace Fe^{II} always present in $Fe_2(SO_4)_3$.[7]

Iron(III) Chloride[1]

$FeCl_3$

[7705-08-0] · Cl_3Fe · Iron(III) Chloride · (MW 162.20)

(mild oxidant capable of phenolic coupling,[1] dimerizing aryllithiums[6] and ketone enolates;[7,8] mild Lewis acid: catalyzes ene reactions,[21] Nazarov cyclizations,[18-20] Michael additions,[24] and acetonations[29])

Alternate Name: ferric chloride.

Physical Data: mp 306 °C; *d* 2.898 g cm^{-3}.[25]

Solubility: 74.4 g/100 mL cold water, 535.7 g mL^{-1} boiling water; v sol alcohol, MeOH, ether, 63 g mL^{-1} in acetone (18 °C).

Form Supplied in: black crystalline powder; widely available.

Preparative Methods: anhydrous $FeCl_3$ available commercially is adequate for most purposes. However, the anhydrous material can be obtained from the hydrate by drying with thionyl chloride[7] or azeotropic distillation with benzene.[12]

Handling, Storage, and Precautions: is hygroscopic and corrosive; inhalation or ingestion may be fatal. It causes eye and skin irritation. It should be stored and handled under an inert dry atmosphere.[36] Use in a fume hood.

Oxidative Properties.[1]

$FeCl_3$ oxidizes a wide array of functionalities, such as certain phenols to quinones (eq 1), dithiols to disulfides (eq 2), and 2-hydroxycyclohexanone to 1,2-cyclohexanedione.[1] Inter- and intramolecular oxidative dimerization of aromatics gives rise to such products as magnolol, metacyclophanes,[1] and crinine alkaloids (eq 3).[2] Phenolic ethylamines and *N*-acetyloxyamides can be cyclized to indoles (eq 4)[3] and oxindoles (eq 5),[4] respectively. Dimerization of aryllithium or Grignard reagents yields intermediates for cyclophane[5] and perylenequinone[6] synthesis (eq 6). Inter-[7] and intramolecular[8] ketone enolates can be converted to 1,4-diketones (eq 7), and lithium salts of allylic sulfones afford 1,6-disulfones.[9]

(5)

(6)

(7)

Stereoselective cross-coupling of alkenyl halides with Grignard reagents is catalyzed by $FeCl_3$ (45-83%) (eqs 8 and 9).[10] Propargyl halides also react to afford allenes.[11] A study of Fe^{III} catalysts revealed that

Tris(dibenzoylmethide)iron(III) was the most useful.[12]

(8)

(9)

Alkylcyclopentanones can be dehydrogenated to cyclopentenones, but ***Copper(I) Chloride*** is a better catalyst.[13] Trimethylsilyloxybicyclo[*n*.1.0]alkanes can be oxidatively cleaved, providing a three-step method of ring expansion (eq 10).[14] Cycloalkanones are cleaved with $FeCl_3$/MeOH under O_2 to o-oxo esters; this reaction works best with flanking methyl groups (eq 11).[15] Photooxidation of alkenes with $FeCl_3$ can yield a variety of useful chloroketones depending on the starting material,[16] and photoreaction of carbohydrates in pyridine induces a selective C(1)-C(2) bond cleavage, in contrast to ***Titanium(IV) Chloride*** (C(5)-C(6) cleavage) (eq 12).[17] $FeCl_3$/EtOH can also be used to disengage tricarbonyliron complex ligands.

(10)

(11)

(12)

Lewis Acid Mediated Reactions.

Silicon-directed Nazarov cyclizations occur readily in dichloromethane catalyzed by $FeCl_3$, utilizing the cation-stabilizing effect of silicon.[18] Cyclohexenyl systems afford only *cis*-fused ring products. The reaction has been elaborated to the preparation of linear tricycles with β-silyldivinyl ketones at low temperature (eq 13).[19] Optically active β´-silyl divinyl ketones have been used to demonstrate that cyclization occurs with essentially complete control by silicon in the *anti* S'_E sense.[20] $FeCl_3$ is the best Lewis acid catalyst for the intramolecular ene reaction of the Knoevenagel adduct from citronellal and dimethyl malonate at low temperature (eq 14).[21] However, the basic alumina supported catalyst can give more reliable results. The ene reaction of an unsaturated ester of an allylic alcohol yields a chlorolactone cleanly at 25 °C.[22] This reaction produces only one of four possible diastereomers, with clean *trans* addition to the double bond occurring (eq 15). 1-Silyloxycycloalkanecarbaldehydes undergo ring expansion to 2-silyloxycycloalkanones (82-89%) (eq 16). $FeCl_3$ catalysis provides the best selectivity derived from rearrangement of the more substituted α-carbon atom.[23] $FeCl_3$-catalyzed addition of primary and secondary amines to acrylates occurs exclusively 1,4 with no polymerization (79-97%) (eq 17).[24]

(13)

(14)

(15)

(16)

(17)

In the field of protecting group chemistry $FeCl_3$ will cleave benzyl[25] and silyl ethers,[26] convert MEM ethers to carboxylic esters,[27] and when dispersed on 3Å molecular sieves catalyzes the formation of MOM ethers.[28] In the area of carbohydrate chemistry, $FeCl_3$ is proving a versatile reagent for acetylation, acetonation, acetolysis, transesterification, *O*-glycosidation of β-per-*O*-acetates, formation of oxazolines, direct conversion of 1,3,4,6-tetra-*O*-acetyl-2-deoxy-2-acylamido-β-D-glucopyranoses into their *O*-glycosides, preparation of 1-thioalkyl(aryl)-β-D-hexopyranosides from the peracetylated hexopyranoses having a 1,2-*trans* configuration,[29] and as an anomerization catalyst for the preparation of alkyl-α-glycopyranosides (eq 18).[30]

(18)

Substituted amidines have been prepared from a nitrile compound, an alkyl halide, an amine, and $FeCl_3$ in a one-pot synthesis (40-80%) (eq 19).[31] $FeCl_3$ in ether converts epoxides into chlorohydrins. Fused bicyclic epoxides yield *trans*-chlorohydrins (eq 20).[32] Friedel-Crafts acylation of activated (Me, OMe substituents) aromatics occurs readily with optically active *N*-phthaloyl-α-amino acid chlorides catalyzed by $FeCl_3$ (1-5 mol%).[33] Trialkylboranes react with $FeCl_3$ in THF/H_2O to afford alkyl chlorides in excellent yield.[34] *t*-Alkyl and benzylic chlorides can be converted to the iodides on reaction with ***Sodium Iodide*** in benzene catalyzed by $FeCl_3$.[35]

(19)

Iron(II) Chloride[1]

$FeCl_2$

[7758-94-3] · Cl_2Fe · Iron(II) Chloride · (MW 126.75)

(synthesis of ferrocene[2] and derivatives;[3] Sandmeyer reaction;[4] alkane C-H functionalizations;[6,7] alkyne reductions;[5] catalytic additive[8])

Alternate Name: ferrous chloride.

Physical Data: mp 670-674 °C; sublimes; *d* 3.16 g cm^{-3}.

Solubility: 64.4 g/100 mL cold water (10 °C), 105.7 g/100 mL hot water (100 °C); 100 g/100 mL alcohol; sol acetone; insol ether.

Form Supplied in: green to yellow solid; widely available, can be obtained as 99.999% ultra dry material.

Preparative Methods: chlorobenzene (1 kg) and sublimed (anhydrous) ***Iron(III) Chloride*** is refluxed for 3.5 h. The iron(II) chloride is filtered and washed with anhydrous benzene (97% yield).[1]

Handling, Storage, and Precautions: incompatible with strong oxidizing agents; hygroscopic; may decompose on exposure to air, HCl being produced. It is an irritant. Use in a fume hood.

Ferrocene Synthesis.

Iron(II) chloride reacts with sodium cyclopentadienide in THF to give ferrocene (eq 1). This method has been described in detail[2] and is applicable to many ferrocene derivatives.[3]

(1)

Sandmeyer Reaction.

The Sandmeyer reaction has been performed with iron(II) chloride, in place of ***Copper(II) Chloride***. The reactions proceed in good yield, except with methyl substituents, where phenols are obtained (eq 2).[4]

(2)

$FeCl_2$-Lipoamide-NaH Reductions.

Iron(II) chloride in combination with simple dithiols are effective catalysts for the reduction of alkynes to alkenes with ***Sodium Borohydride*** (22-93% yields) (eq 3).[5] The best reaction conditions employ 5 equiv $NaBH_4$, 7.5 mol% lipoamide, and 10 mol% $FeCl_2$ stirred at rt for 8 h.

(3)

Amination of the C-H Bond.

Reaction of ***Chloramine-T*** with rigorously dry $FeCl_2$ and adamantane in dichloromethane under nitrogen, and column chromatography of the crude reaction mixture after 2 h, gives a 63% yield of the tertiary sulfonamide (eq 4).[6]

(4)

Gif^{IV} Oxidation Catalyst.

$FeCl_2.4H_2O$ is one of the catalysts used in the Gif^{IV} oxidation of saturated hydrocarbons using molecular oxygen. However, many iron catalysts have been used with varying results. $FeCl_2$ provides a good ratio of secondary to tertiary hydroxylation with a reasonable turnover (30). A combination of adamantane (2 mmol), ***Zinc*** (20 mmol), and $FeCl_2$ (7 μmol) in pyridine-acetic acid is stirred for 18 h, open to the atmosphere, to yield oxidation products (eq 5).[7]

Raney Cobalt Catalyst Additive.

Unsaturated alcohols can be obtained from α,β-unsaturated aldehydes via hydrogenation with Raney cobalt catalyst. $FeCl_2$ addition to the catalyst increases yields.[8]

Related Reagents.

Sodium Triethylborohydride-Iron(II) Chloride.

Iron(III) Chloride-Acetic Anhydride[1]

$FeCl_3$-Ac_2O

($FeCl_3$)

[7705-08-0] · Cl_3Fe · Iron(III) Chloride-Acetic Anhydride · (MW 162.20) (Ac_2O)

[108-27-7] · $C_4H_6O_3$ · Iron(III) Chloride-Acetic Anhydride · (MW 102.10)

(Lewis acid cleaving ethers,[2] *gem*-diacetates,[8] imides[11])

Alternate Name: ferric chloride-acetic anhydride.

Preparative Method: this reagent combination is used in situ via addition of anhydrous ***Iron(III) Chloride*** (6.2 mmol), to the substrate (35.5 mmol) and ***Acetic Anhydride*** (15 mL).[2]

Handling, Storage, and Precautions: reactions can be mildly exothermic. $FeCl_3$ is hygroscopic and corrosive, inhalation or ingestion may be fatal. Acetic anhydride is moderately toxic by inhalation, ingestion, and skin contact. It is a skin and severe eye irritant. It can react vigorously with oxidizing agents, and will react vigorously with water.[12] Use in a fume hood.

Cleavage of Ethers.[2]

Iron(III) chloride in acetic anhydride was first reported to cleave diethyl ether to ethyl acetate,[3] and has been developed into a very useful ether-cleavage reagent.[2a] Iron(III) chloride is added to the substrate and acetic anhydride. For simple substrates the reaction may be heated on a steam bath, while for sensitive functionality it is best conducted at 0 °C and monitored by TLC. The acetate ester is obtained as the product (44-92%). The reaction can be performed using ethyl acetate[2a] or ether[2b] as cosolvent and detailed procedures are available.[2] Reactions are usually worked up via extraction into hexane, and washing with water and sodium bicarbonate. Alternatively, saturated Na_2HPO_4 can be used to form $FePO_4$, which can be filtered off prior to extraction. This system will cleave a wide range of ethers: *n*-alkyl, isopropyl, *t*-butyl, benzyl, and TBDMS. The reaction conditions are compatible with easily isomerized alkenes (eq 1). Optically active ethers usually afford racemic acetates; however, the synthesis of (*R*)-(+)-4-acetoxycyclopent-2-enone[4] provides a notable exception (eq 2). The $FeCl_3$-Ac_2O procedure is the one of choice when an alcohol deprotection is to be

followed by acylation with a hindered acid chloride.[5] It also provides an excellent route to cyanohydrin esters from ketones (eq 3).[6] Deprotection of ethers is covered extensively in the literature.[1,7]

(1)

(2)

(3)

gem-Diacetates from Aldehydes.[8]

Aldehydes are converted to geminal diacetates (63-93%) via addition of iron(III) chloride to a solution of aldehyde in acetic anhydride (eq 4). A wide range aldehydes react: aliphatic, aromatic, heteroaryl, and α,β-unsaturated aldehydes. Alternative reaction conditions include acid catalysis[9] and ***Phosphorus(III) Chloride***.[10]

(4)

Imides.[11]

α-*t*-Butoxy- or α-acetoxyacrylonitriles can be converted into imides with $FeCl_3$-Ac_2O (eq 5) via cleavage of the *t*-butyl ether and addition to the nitrile. However this reaction is limited to *t*-butoxy- and acetoxyacrylonitriles.

Iron(III) Chloride-Alumina[1]

$FeCl_3$-Al_2O_3

($FeCl_3$)

[7705-08-0] · Cl_3Fe · Iron(III) Chloride-Alumina · (MW 162.20) (Al_2O_3)

[1344-28-1] · Al_2O_3 · Iron(III) Chloride-Alumina · (MW 101.96)

(proton scavenger; mild Lewis acid catalyst for ene reactions[1,2])

Alternate Name: ferric chloride-alumina.

Form Supplied in: the individual reagents are commercially available.

Preparative Method: anhydrous ***Iron(III) Chloride*** (62 mmol) is added to anhydrous CH_2Cl_2 (160 mL) under argon. The mixture is stirred vigorously while 50 g chromatography grade basic ***Alumina*** is added in small portions under argon. Stirring is continued for 1 h to obtain homogeneous adsorbtion and the solvent is then removed under reduced pressure. The basic alumina supported $FeCl_3$ obtained can be stored under argon for several months without loss of catalytic activity.

Handling, Storage, and Precautions: should be stored and manipulated in an inert, dry atmosphere; $FeCl_3$ is hygroscopic and corrosive, inhalation or ingestion may be fatal; basic alumina is an irritant. Use in a fume hood.

Lewis Acid Catalyzed Intramolecular Ene Reactions.[1]

Anhydrous iron(III) chloride on basic alumina proved to be the best Lewis acid catalyst for the intramolecular ene reaction of the Knoevenagel adduct from citronellal and dimethyl malonate. The *trans*-1,2-disubstituted cyclohexane was obtained as the major product in a 98.8:1.2 ratio in 92% yield in dichloromethane at -78 °C (eq 1).[1,2] The thermal ene reaction[3] yields a 9:1 ratio in 75% yield.[1]

(1)

Strong Lewis acid catalysts, (e.g. ***Aluminum Chloride*** and ***Titanium(IV) Chloride***) yield complex mixtures.[1] Anhydrous ***Zinc Chloride***[4] and alkyl aluminum halides[5] yield product but the overall yields and ratios are not quite as good.[1] $FeCl_3$ also works well; however, competing reactions attributable to traces of water were sometimes observed. The supported catalyst avoids this problem presumably because the catalyst acts as a proton scavenger similar to alkylaluminum halides.[2,6] The $FeCl_3$-Al_2O_3 mediated cyclization can be utilized for 1,6-dienes additionally to yield *trans*-1,2-substituted cyclopentanes. The allylsilane moiety on the ene component is necessary otherwise the reaction is limited to trisubstituted alkenes (eq 2).[7] Silica gel at high pressure (15 kbar) (see ***Iron(III) Chloride-Silica Gel***) may provide an alternative[8] as a mild acid catalyst for highly sensitive functionality, although the yield (73%) and selectivity (9.4:1) for eq 1 does not compare with $FeCl_3$-Al_2O_3 and is only equivalent to the best thermal ene reaction conditions.[1]

(2)

Electrophilic Cyclizations.

Intramolecular electrophilic cyclization of doubly activated imines using $FeCl_3$-Al_2O_3 yields an annulated piperidine lactone (eq 3). However, better chemoselectivities but lower yields are obtained with gallium trichloride or ***Trifluoroacetic Acid***.[9] Trialkylsilyl triflates yield the substituted piperidine predominantly. In the corresponding cyclizations to pyrrolidines, $FeCl_3$-Al_2O_3 was inferior to $GaCl_3$.[10]

Iron(III) Chloride-Dimethylformamide[1]

$[Fe(DMF)_3Cl_2][FeCl_4]$

[36654-49-6] · $C_9H_{21}Cl_6Fe_2N_3O_3$ · Iron(III) Chloride-Dimethylformamide · (MW 543.73)

(mild oxidant; oxidative coupling[2] of phenols, ketone enolates,[3] and allylic sulfones;[4] ring expansion of silyloxybicyclo[*n*.1.0]alkanes;[5] oxidative decomplexation of chromium carbonyl complexes[6])

Alternate Name: ferric chloride-DMF.

Physical Data: mp 220 °C.

Preparative Method: ***N,N-Dimethylformamide*** (1.5 mol) is added with stirring to a solution of ***Iron(III) Chloride*** (1 mol) in dry ether (1.6 L) to yield a precipitate which is filtered and dried in vacuo to yield a yellowish green powder (95%) which is sufficiently pure to use for oxidation reactions.[2]

Purification: recrystallize from dichloromethane and ethanol to give needles.

Handling, Storage, and Precautions: stable to air and moisture; $FeCl_3$ is hygroscopic and corrosive; inhalation or ingestion may be fatal; DMF is mildly toxic by skin contact and inhalation; it is a skin and eye irritant. Use in a fume hood.

Oxidative Coupling of Phenols.[2]

Oxidative aryl-aryl coupling represents a challenging synthetic transformation. Iron(III) chloride in DMF or $[Fe(DMF)_3Cl_2][FeCl_4]$ is a good reagent for intramolecular (eq 1) and intermolecular (eq 2) phenol coupling reactions.[1,2] As the redox potential of substrates differ, many alternate reagents exist for this transformation (intiated by one-electron abstraction from the substrate by the oxidant). Alternative reagents used are ***Vanadyl Trichloride***,[7] ***Thallium(III) Trifluoroacetate***,[8] manganese(II) acetylacetonate,[9] ***Potassium Ferricyanide***,[10] copper(II) amine complexes,[11] photolysis,[12] ***(Diacetoxyiodo)benzene***,[13] electrochemical anodic oxidation,[1a] and $FeCl_3$ in the solid state.[14]

Oxidative Coupling of Ketone Enolates.

Addition of anhydrous $FeCl_3$ in DMF to an enolate in THF yields the 1,4-ketone (eq 3).[3] This reaction has also been applied in an intramolecular fashion (eq 4).[15]

Oxidative Dimerization of Allylic Sulfones.

Lithium salts of allylic sulfones are oxidized by addition of $[Fe(DMF)_3Cl_2][FeCl_4]$ at 0 °C (eq 5) to give 1,6-disulfones by 3-3´ coupling.[4] These products can undergo Cope rearrangement to 1,2-disulfones.

(5)

Ring Expansion of Cyclic Ketones.

Trimethylsilyloxybicyclo[*n*.1.0]alkanes (available by Simmons-Smith reaction of enolates of cycloalkanones) can be oxidized by $FeCl_3$ in DMF at 0 °C to afford the one-carbon ring homologation product (eq 6).[5] This method has been utilized to synthesize 3-methoxycycloheptatrienones (eq 7).[16]

(6)

(7)

Oxidative Demetallation of Chromium Carbonyl Complexes.

$[Fe(DMF)_3Cl_2][FeCl_4]$ is an excellent reagent for oxidative workup of chromium tricarbonyl complexes to obtain the arene ligand or aryl product.[6] ***Cerium(IV) Ammonium Nitrate*** represents a viable alternative.[17]

Iron(III) Chloride-Silica Gel[1]

$FeCl_3$-SiO_2

($FeCl_3$)

[7705-08-0] · Cl_3Fe · Iron(III) Chloride-Silica Gel · (MW 162.20) (SiO_2)

[112926-00-8] · O_2Si · Iron(III) Chloride-Silica Gel · (MW 60.09)

(Lewis acid; dehydration;[2] acetal cleavage;[3,4] rearrangements;[2,6,7] thioacetalization;[9] mild oxidant; oxidative cyclizations[10-13])

Alternate Name: ferric chloride-silica gel.

Form Supplied in: pale yellow powder, 5% wt on silica gel; commercially available.

Preparative Methods: several procedures have been reported for preparation of this reagent depending on the synthetic transformation required. The two procedures described below have been used for cleavage of acetals.[1,2]

Silica gel (10 g, 70-230 mesh) is added to a solution of $FeCl_3.6H_2O$ (1.2 g) in acetone at rt. The solvent is removed on a rotary evaporator and the mixture then heated in vacuo at 60 °C for 30 min/0.1 mmHg to yield a yellow powder.[1]

Anhydrous $FeCl_3$ (4 g) and chromatography grade silica gel (50 g 70-230 mesh) are stirred together in the absence of solvent at rt for 24 h to achieve homogeneous adsorption. A pale yellowish green powder is obtained.[2]

Handling, Storage, and Precautions: the material obtained by procedure 1 is moisture- and light-sensitive, but can be stored for extended periods under dry nitrogen at rt in a brown bottle. The material obtained in procedure 2 is used immediately. $FeCl_3$ is hygroscopic and corrosive; inhalation or ingestion may be fatal. Silica gel is an irritant. Use in a fume hood.

Lewis Acid.

Iron(III) chloride-silica gel will dehydrate alcohols,[1] cleave acetals, open epoxides, rearrange carbonium or oxonium intermediates, catalyze ene reactions, and effect thioacetalization.

Alcohol Dehydration.

$FeCl_3$-SiO_2 is an effective reagent for the dehydration of allylic, tertiary, and sterically strained alcohols (eqs 1 and 2). The reaction is carried out by mixing the alcohol with 100× its weight of $FeCl_3$-SiO_2 in a volatile solvent, followed by evaporation under a high vacuum; this is usually sufficient to complete the reaction.[1] Dehydration of tertiary alcohols has been reported with the reagent prepared by procedure 2.[2]

(1)

(2)

Cleavage of Acetals.

The $FeCl_3$-SiO_2 reagent cleaves acetals in 2-8 h in chloroform at rt, and is now a well established procedure. Cleavage of TBDMS and trityl ethers is sluggish with typically 30% deprotection after 20 h, which provides for a very mild method for selective deprotections (eq 3). Interestingly, a TBDMS ether can be cleaved without affecting an isopropylidene group in acetone, as the solvent maintains the equilibrium in favor of the isopropylidene group (eq 4).[3,4] Benzyl ether cleavage was not observed in the presence of an acetal; chelation of iron to the latter ensures selectivity.[3] However, rapid benzyl ether deprotection has been reported in the absence of solvent, essentially using the same procedure as for dehydration.[5]

(3)

(4)

Rearrangements.

Tertiary cyclobutanols are converted to cyclopentene derivatives with $FeCl_3$-SiO_2 prepared by procedure 2 (eq 5).[2,6] Acyloin (eq 6) and pinacol rearrangements[1] (eq 7) are also observed with $FeCl_3$-SiO_2 from procedure 1. $FeCl_3$-SiO_2 has been reported to catalyze intramolecular ene reactions, although ***Iron(III) Chloride-Alumina*** is superior.[7]

(5)

(6)

(7)

Epoxides.

$FeCl_3$-SiO_2 containing 2% water facilitates the conversion of epoxides to diols in good yield (eq 8). Anhydrous $FeCl_3$-SiO_2 converts epoxides to mixtures of chlorohydrins.[1]

(8)

Thioacetalization.

Carbonyl compounds are thiacetalized with $FeCl_3$-SiO_2 (procedure 2) in excellent yields at rt.[8] Reaction occurs very rapidly in dichloromethane with 1,2-ethanedithiol, with the color turning from gray to pale yellow indicating completion of the reaction (eq 9); this method works well for hindered and aromatic ketones, unlike many of the alternate procedures.[9]

(9)

Oxidations with $FeCl_3$-SiO_2.[10]

Simple di- and trimethoxybenzenes can be coupled in good yield in dichloromethane with 1.1 equiv of $FeCl_3$-SiO_2. Solvent is removed on a rotary evaporator and the mixture is left spinning for 1 h at 30 °C (eq 10).[5,11] Precocene II has been dimerized in light petroleum with $FeCl_3$-SiO_2 to a mixture of two products (eq 11).[12] Intramolecular couplings are observed with appropriately substituted 1,2-diphenylethanes and [2.2]metacyclophanes.[5] Tricarbonylcyclohexadieneiron complexes are oxidatively cyclized with $FeCl_3$-SiO_2 (eq 12) via concentration from THF on a rotary evaporator (40 min).[13] This reaction highlights the moderation in reactivity of this supported reagent as ethanolic $FeCl_3$ can be used to oxidatively disengage an $Fe(CO)_3$-complex ligand.[14]

Iron(III) Chloride-Sodium Hydride[1]

$FeCl_3$-NaH

($FeCl_3$)

[7705-08-0] · Cl_3Fe · Iron(III) Chloride-Sodium Hydride · (MW 162.20) (NaH)

[7646-69-7] · HNa · Iron(III) Chloride-Sodium Hydride · (MW 24.00)

(mild reduction of aldehydes and ketones to alcohols;[2] reduction of alkenes and alkynes[3])

Alternate Name: ferric chloride-sodium hydride.

Preparative Method: generated in situ via addition of a solution of ***Iron(III) Chloride*** (14 mg equiv) in THF (20 mL) to a suspension of ***Sodium Hydride*** (42 mg equiv) in THF (5 mL). The yellow suspension is stirred at rt for 4 h under argon. A solution of the carbonyl compound (2 mmol) in THF (2 mL) is added and stirring continued at rt.

Handling, Storage, and Precautions: $FeCl_3$ is hygroscopic and corrosive; inhalation or ingestion may be fatal. NaH is a flammable solid which reacts violently with water. The powder ignites spontaneously in air. It should be handled in an inert dry atmosphere. Use in a fume hood.

Reduction of Carbonyl Compounds.[2]

$FeCl_3$-NaH is one of a class of reagents called complex reducing agents (CRA), which essentially lower the basicity of NaH. An iron hydride species is assumed to be the active component. A mixture of $FeCl_3$ and NaH in a 1:3 ratio produces the best results for reductions of aldehydes and ketones to alcohols in good yields (75-85%) (eqs 1 and 2). A related reagent, NaH-***Zinc Chloride-Chlorotrimethylsilane***, reduces a variety of aldehydes and ketones in good yield (81-100%).[4] $FeCl_2$-NaH also reduces carbonyl compounds to alcohols, but in lower yields.[2]

(1)

(2)

Reduction of Alkenes and Alkynes.[3]

Double and triple bonds of aliphatic and aromatic alkenes and alkynes, are reduced to alkanes with $FeCl_3$ or ***Iron(II) Chloride*** in THF (eq 3). Enones can be reduced to the corresponding saturated alcohol (eq 4). An alternate reagent NaH-*t*-BuONa-$FeCl_3$ represents a viable alternative for this reduction as it requires fewer equivalents of CRA and is selective. Also it does not reduce aldehydes or ketones.[5] Many combinations of these reagents containing different metal salts and sodium alkoxides have been developed for reduction of organohalides and alkenes/alkynes to alkanes.[1,5,6] The metal hydrides NaH, ***Potassium Hydride***, and LiH in combination with ***n-Butyllithium-N,N,N´,N´-Tetramethylethylenediamine*** or *t*-BuONa-TMEDA have been used as metallating and reducing agents.[7]

(3)

(4)

The combinations of $FeCl_3$-***Lithium Aluminum Hydride***[8] to reduce alkenes to alkanes and $FeCl_3$-BuLi to deoxygenate epoxides to alkenes[9] are of related interest.

Iron-Graphite

$C_{24}Fe$

[65522-66-9] · $C_{24}Fe$ · Iron-Graphite · (MW 344.09)

(reducing agent for organic bromides;[1] debrominates *vic* dihalides to alkenes;[1] debrominates α-bromo ketones[1])

Analysis of Reagent Purity: the determination of iron and potassium content by means of atomic absorption spectroscopy has been described.[1]

Preparative Method: ***Potassium-Graphite*** (C_8K), prepared from 1.17 g of potassium (30 mmol) and graphite (3 g), was covered with THF (15 mL) and a solution of ***Iron(III) Chloride*** (1.62 g, 10 mmol) in THF (20 mL) added dropwise with stirring. After 30 min, the solution was heated to 70 °C for 10 min.

Handling, Storage, and Precautions: freshly prepared $C_{24}Fe$ is used in situ under argon. Air exposure results in complete loss of reactivity. Potassium-graphite reacts violently with water, and care should be taken to avoid such exposure.

Debrominations.

Vicinal dibromides undergo highly stereospecific debromination to give alkenes when treated with a slurry of iron-graphite ($C_{24}Fe$) in wet THF at reflux (1 mmol in 10 mmol $C_{24}Fe$, THF 35 mL, H_2O 1 mL). Elimination is *anti*, such that *anti*-dibromides give (*E*)-alkenes and *syn*-dibromides give (*Z*)-alkenes (eq 1). Based on a limited number of examples, diastereomerically pure dibromides give product alkenes of &egt;97.5% geometric purity. 1,2-Dibromoalkanes give terminal alkenes without detectable amounts of 2-alkenes.

(1)

$C_{24}Fe$ debrominates α-bromo ketones to the parent ketones in high yields under conditions nearly identical to those for dibromoalkanes. Replacement of water by D_2O allows high levels of deuterium incorporation, while attempts to react other electrophiles with the presumed iron enolate intermediate gives only modest yields of condensation products (eq 2).

(2)

exo:*endo* = 85:15

Oxyallyl Cations.

α,α´-Dibromo ketones give oxyallyl cations under exposure to iron-graphite in benzene, which have been reacted with enamines or furan to give the products of [3 + 2] (eq 3) or [3 + 4] (eq 4) cycloaddition, respectively.

(3)

84%

Iron(III) Nitrate-K10 Montmorillonite Clay[1]

$Fe(NO_3)_3$-K10

· FeN_3O_9 · Iron(III) Nitrate-K10 Montmorillonite Clay

(mild, inexpensive NO^+ source;[2] oxidizes aromatic rings to radical cations[3])

Alternate Name: clayfen.

Solubility: clay support: insol water, organic solvents. $Fe(NO_3)_3$: sol water, acetone, ethanol.

Form Supplied in: rusty yellow, free-flowing floury powder.

Preparative Method: controlled solvent elimination from K10 clay (30 g) suspended in a solution of $Fe(NO_3)_3.9H_2O$ (22.5 g) in acetone (375 mL).[1]

Handling, Storage, and Precautions: most applications require freshly prepared (1-2 h) reagent. Clayfen is *unstable*, prone to vigorous or slow exothermic decomposition, together with evolution of NO_2 gas. Careful observance of the preparation procedure[1] is critical (in particular, T <50 °C and a crust on the glassware at the flaking-off stage). Never store in gas-tight containers, nor in contact with strongly reducing material such as aluminum. Nitrates are dangerous, and are to be used only with the appropriate precautions and protections. In particular, scaling-up should be attempted only after appropriate safety tests. This reagent should be handled in a fume hood.

Oxidation of Alcohols into Carbonyls.

Clayfen is an efficient and selective oxidation reagent[4,5] for the synthesis of ketones from secondary alcohols, aromatic aldehydes from benzylic alcohols (eq 1), and benzils from benzoins (eq 2). The reaction with primary aliphatic alcohols leads to complex product mixtures.

(1)

(2)

Nitrites formed with retention of configuration[2] are intermediates, indicating that in these reactions clayfen acts as an NO^+ source.

Oxidative Coupling of Thiols.

As a source of nitrosonium ions, clayfen couples thiols to disulfides[6] through transient thionitrites. In a manner similar to claycop (***Copper(II) Nitrate-K10 Bentonite Clay***), its reaction with ***Thiophenol*** (eq 3) is a good reactivity test.[1]

(3)

Carbonyl Group Deprotection.

Clayfen regenerates carbonyl groups from a variety of masking functionalities. For such applications, advantages of this reagent include its low cost, its efficiency under mild conditions, and the easy workup. The following are examples of this use of clayfen.

- 1)Generation of ketones and aldehydes from thioacetals[7] (*S*,*S*-diethyl acetals; 1,3-dithianes; 1,3-dithiolanes). This reaction (eq 4) does not require an additional source of water. Claycop is more suitable than clayfen for this particular purpose on account of its greater stability.

(4)

- 2)Generation of carbonyl groups from selenol acetals.[8] Clayfen complements and improves earlier procedures for the cleavage of bis(phenylseleno)acetals (eq 5), with better yields than with bis(methylseleno) derivatives.

(5)

- 3)Preparation of carbonyl compounds from imine derivatives (*N*,*N*-dimethylhydrazones;[9] tosylhydrazones;[10] phenylhydrazones;[10] 2,4-dinitrophenylhydrazones;[10] semicarbazones[10]). For the cleavage of $R^1R^2C{=}NR^3$ to $R^1R^2C{=}O$ (eq 6), clayfen offers an inexpensive alternative to previous methods, which sometimes require tedious and harsh conditions. However, the results of reactions involving imine derivatives of α,β-unsaturated carbonyl compounds are unsatisfactory, as is sometimes also the case with alternative methods[11,12]

(6)

Conversion of Hydrazines to Azides.

Treatment of various hydrazines with clayfen gives the corresponding azides in fair yield, by the nitrosation route (eq 7).[13] This provides a convenient access to intermediates essential for the preparation of iminophosphoranes.[14]

(7)

Aromatization of 1,4-Dihydropyridines.

1,4-Dihydropyridinedicarboxylates aromatize smoothly when treated by clayfen at rt (eq 8).[15] Use of claycop rather than clayfen leads to slightly higher yields and is devoid of the risks accruing from the instability of the latter.

Thiocarbonyl-to-Carbonyl Transformation.

In this transformation promoted by NO^+ ions, clayfen gives excellent results (77-100%) with aromatic substrates (eq 9)[16] and offers a cheap alternative to ***Nitrosonium Tetrafluoroborate***.[17] 1,2-Dioxa-4,5-dithiane six-membered rings are transient intermediates in these transformations.[18]

Regioselective Nitration of Phenols.

Clayfen nitrates phenols under extremely mild reaction conditions to produce exclusively *ortho* or *para* mononitration products (eq 10).[3,19]

(10)

The reaction is performed at rt in ether, in THF, or in toluene. The solvent is chosen so that it dissolves the nitro derivative formed. Aldehyde and nitrile groups are unaffected under these mild conditions. With *meta*-substituted phenols the reaction is nicely regioselective at the *ortho* position. For instance, the sole nitration product of estrone is 2-nitroestrone (eq 11).[19]

Iron(II) Perchlorate

$Fe(ClO_4)_2$

($Fe(ClO_4)_2.6H_2O$)

[13520-69-9] · Cl_2FeO_8 · Iron(II) Perchlorate · (MW 362.87)

(aromatic and aliphatic hydroxylation; reductive decarboxylation of peracids; dehydration and monooxygenation of organic compounds)

Alternate Name: ferrous perchlorate.

Physical Data: dec >100 °C.

Solubility: ~98 g/100 mL H_2O at 0 °C; sol alcohol, $HClO_4$.

Form Supplied in: light green crystalline powder.

Handling, Storage, and Precautions: eye irritant; hygroscopic; contact with combustible material may cause fire. **Warning**: conversion to lower hydrates by unintentional dehydration may cause explosion. Use due caution in handling, as for all perchlorates. Use in a fume hood.

Aromatic Hydroxylation (Fenton Oxidation).[1]

Aromatic substrates are hydroxylated under mild conditions when treated with iron(II) salts, such as iron(II) perchlorate or ***Iron(II) Sulfate***, ***Hydrogen Peroxide***, and an appropriate oxidant (eg Fe^{3+}, Cu^{2+}, O_2) in aqueous acetonitrile (eq 1). Yields are generally less than 50%. The rate-determining step in the reaction was shown to be the production of a hydroxyl radical which reacts directly with the aromatic substrate, generating a phenolic radical intermediate. This is ultimately converted to the corresponding phenol. An interesting rearrangement of a hydrogen atom during the oxidation (NIH shift),[2] as observed during enzymatic hydroxylation, also takes place during the reaction.

(1)

Aliphatic Hydroxylation.

C-H bond activation by metal complexes is of fundamental importance in hydrocarbon functionalization.[3] The regio- and stereospecific conversion of *O*-cholestan-3α-yl *S*-methyl dithiocarbonate to cholestane-1α,3α-diyl diacetate demonstrates the coordination of iron-dioxygen complexes, formed by the reaction of iron(II) perchlorate and oxygen, with electron-rich *S*-alkyl xanthates to lead to the oxidation of neighboring C-H bonds (eq 2).[4] In the absence of Fe^{II}, no reaction takes place.

Reductive Decarboxylation of Peracids.

Peroxycyclohexanecarboxylic acid is converted to cyclohexanol (25%) and cyclohexanecarboxylic acid (75%) when treated with iron(II) perchlorate at 0 °C in acetonitrile (eq 3).[5] Treating *cis*- or *trans*-3-hydroxyperoxycyclohexanecarboxylic acid in a similar manner leads to nearly pure *cis*-1,3-cyclohexanediol (85:15 *cis*:*trans*), indicating participation by hydroxy.

Dehydration and Monooxygenation of Organic Compounds.

Iron(II) perchlorate hexahydrate is used to prepare $Fe(MeCN)_4(ClO_4)_2$, a catalyst used in combination with H_2O_2 to dehydrogenate and monooxygenate organic substrates in dry acetonitrile.[6] No products resulting from &bdot;OH radical chemistry are observed, which suggests that classical Fenton-type chemistry[1,7] does not occur under these conditions. With alcohols, aldehydes, methylstyrene, thioethers, sulfoxides, and phosphines, the active catalyst, $Fe(H_2O_2)^{2+}$, promotes the monooxygenation to aldehydes, carboxylic acids, epoxide, sulfoxides, sulfones, and phosphine oxides, respectively.

Iron(II) Phthalocyanine

[132-16-1] · $C_{32}H_{16}FeN_8$ · Iron(II) Phthalocyanine · (MW 568.41)

(oxidation of terminal alkenes to methyl ketones; 1,4-oxidation of 1,3-dienes; allylic oxidation of cyclic alkenes; siloxane elimination from silylamides to form nitriles)

Physical Data: mp >300 °C.

Form Supplied in: black powder.

Handling, Storage, and Precautions: store tightly sealed in a cool, dry place.

Preparation of Methyl Ketones from Alkenes (Wacker Oxidation).

Methyl ketones are conveniently prepared from terminal alkenes by Wacker oxygenation using a catalytic amount of ***Palladium(II) Chloride*** and ***Copper(II) Chloride***.[1] The reaction can be slow and chlorinated byproducts are usually observed. Iron phthalocyanine (Fe(Pc)) serves as the oxygen-activating complex in a multicatalyst system used to perform Wacker-type[2] oxidation reactions (eq 1).[2b] This catalyst system offers a chloride-free environment in which alkenes are smoothly converted to methyl ketones with molecular oxygen, under mild conditions, in moderate to high yield. Unlike typical Wacker oxidations using $CuCl_2$, no chlorinated byproducts are formed.[1a,3] In addition, the removal of chloride from the system increases the rate of reaction.[4] In the catalyst system, Fe(Pc) reoxidizes hydroquinone to benzoquinone, which serves to reoxidize Pd^0 to Pd^{II} after Pd^{II} catalyzes the oxidation of the alkene to the ketone (eq 1). In the present catalyst system, acid ($HClO_4$) is added to prevent the rapid precipitation of Pd

from the aqueous DMF reaction mixture. The reoxidation of hydroquinone by other means,[5] including electrochemical reoxidation,[6] has been reported.

1,4-Oxidation of Conjugated Dienes.[7]

Conjugated dienes can be oxidized to *cis*-1,4-diols and 1,4-diacetates when treated with the above catalyst system in acetic acid or alcohol (eqs 2 and 3).

Aerobic Allylic Oxidation of Alkenes.[6c]

Exposure of cyclohexene to the above described catalyst system in acetic acid gives the desired allylic oxidation product (eq 4). Again, Fe(Pc) and molecular oxygen take the place of less convenient oxygen sources such as MnO_2.[8]

Epoxidation of Alkenes.

In a comparison of transition metal phthalocyanines, iron(II) phthalocyanine most effectively catalyzes the epoxidation of alkenes when ***Iodosylbenzene*** is the oxygen donor.[9] It is less effective than other metal-phthalocyanine catalysts when NaOCl is used as the oxygen donor. A mixture of *cis*- and *trans*-epoxides are produced from *cis*-alkenes. In the presence of 2,6-di-*t*-butyl-*p*-cresol, highly stereoselective epoxidation of the *cis*-alkene is observed.

Preparation of Nitriles from Amides.[10]

Iron phthalocyanine readily catalyzes the decomposition of bis(trimethylsilyl)amides to give nitriles under relatively mild conditions (75 °C, 6 h, 100%, eq 5). This serves as a useful alternative to the less general thermal decomposition of bis(silylamides)[11] or the thermal decomposition of monosilylamides in the presence of stoichiometric amounts of an acidic reagent.[12] Catalytic amounts of fluoride ion or simple Lewis acids such as $FeCl_3$, $ZnCl_2$, or $AlCl_3$, are also effective reagents for this transformation.

Iron(III) Sulfate

$\mathbf{Fe_2(SO_4)_3}$

($Fe_2(SO_4)_3$)

[10028-22-5] · $Fe_2O_{12}S_3$ · Iron(III) Sulfate · (MW 399.91) ($Fe_2(SO_4)_3.5H_2O$)

[-] · $Fe_2O_{12}S_3$ · Iron(III) Sulfate · (MW 490.01)

(catalyst for the dehydration of alcohols to give alkenes; serves as a useful oxidant during the alkoxylation of quinones; catalyzes the ring opening of 2-oxazolines with amines)

Alternate Names: ferric sulfate; ferric sesquisulfate; ferric tersulfate; diiron trisulfate.

Physical Data: hygroscopic.

Solubility: slowly sol H_2O; sparingly sol alcohol.

Form Supplied in: grayish white powder.

Handling, Storage, and Precautions: moisture sensitive; harmful dust; irritant.

Preparation of Alkenes: Dehydration of Alcohols.[1]

Silica gel supported iron(III) sulfate efficiently catalyzes the dehydration of secondary and tertiary alcohols under moderate conditions to give the corresponding alkenes. Iron(III) sulfate-SiO_2 was found to be more active than all other silica gel supported sulfates tested ($CuSO_4$, $NaHSO_4$, $Al_2(SO_4)_3$, $SnSO_4$, $ZnSO_4$, etc.), but promoted undesirable side reactions in some cases (Table 1).

Table 1 Dehydration Catalyzed by $Fe_2(SO_4)_3$ SiO_2

Substrate	Solvent	Time	Product	Yield (%)
Cyclododecanol	Hexane	60	Cyclo-dodecene	99
Cyclododecanol	CH_2Cl_2	60	Cyclo-dodecene	17
Cyclooctanol	CH_2Cl_2	30	Cyclo-octene	87
1-Phenylethanol	CH_2Cl_2	5	Styrene	0
Cholesterol	CH_2Cl_2	30	3,4-Didehydro-cholesterol	20

Primary alcohols generally give complex mixtures of products. The order of reactivity, tertiary > secondary > primary, implies that the generation of a cationic intermediate is a key step in the reaction. Conventional methods for dehydration utilize simple reagents such as HBr, H_2SO_4, and $NaHSO_4$, as well as non-silica gel complexed $NaHSO_4$ and $CuSO_4$.

Preparation of Alkoxyquinones: Addition of Alcohols to 1,4-Benzoquinones.[2]

Iron(III) sulfate oxidizes the initial adduct formed by the reaction of an alcohol with a dimethoxynaphthoquinone derivative under acidic conditions to give the desired alkoxyquinone in good to excellent yield (eq 1) (Table 2). In the absence of an added oxidant the starting material oxidizes the initial adduct, alkoxyhydroquinone, which greatly reduces the potential yield of the reaction. Other oxidants, such as DDQ and air/light, were found to be less effective than iron(III) sulfate.

$R^1 = H$, COMe; $R^2 = H$; $R^3 = H$, COMe; $R^4 = H$, Me, Et

Table 2 Alkoxylation of Quinones in the Presence of Iron(III) Sulfate

R^1	R^2	R^3	R^4	Yield (%)
H	H	H	H	95
COMe	H	H	H	35
H	COMe	H	H	45
H	H	COMe	H	95
H	H	H	Me	90
COMe	H	H	Me	36
H	COMe	H	Me	54
H	H	H	Et	80

Preparation of Substituted Ethylenediamines.

The catalyzed, nucleophilic ring opening of 2-oxazolines with amines provides a convenient method for preparing unsymmetrically substituted ethylenediamines (eq 2).[3] Coordination of the oxazoline with $Fe_2(SO_4)_3$ and other Lewis acids increases the electrophilic character of the oxazoline and increases its susceptibility for nucleophilic attack at the 2 (reversible) and 5 (irreversible) positions. Better yields were obtained with alternative catalysts, including $Zn(OAc)_2$, ***p-Toluenesulfonic Acid***, and ***Boron Trifluoride Etherate***. This method serves as an alternative to the reported synthesis of ethylenediamines from aziridines, phthalimides, nitriles, and 2-aminopropionamides.

Stereoselective 1,4-Addition of Alcohols to Phenylazostilbene to give Alkoxyphenylhydrazones.

The addition of alcohols to phenylazostilbenes in the presence of 2 equiv of iron(III) sulfate gives predominantly, or exclusively, the *anti* isomer of the resulting alkoxyphenylhydrazone.[4] No reaction took place in the absence of the iron ion (or copper ion) (eq 3).

R = Me, Et, Pr, *i*-Pr, Bu

Miscellaneous Reactions.

Alcohols react with 3-aroylpropionic acids in the presence of hydrated iron(III) sulfate to produce 3-aroylpropionic esters.[5] The condensation of cyclohexanone under the catalysis of hydrated iron(III) sulfate in the presence of cyclohexane, benzene, or toluene produces the desired aldol products in 49-52% yield.[6] The alkylation of *p*-cresol with mixed 2,3-dimethyl-1- and 2-butene in 1.5:1 cresol:alkene ratio in the presence of iron(III) sulfate gives 4,2-$Me(Me_2CHCMe_2)C_6H_3OH$ in ~75% yield.[7]

Iron(II) Sulfate[1]

$FeSO_4$

($FeSO_4.7H_2O$)

[7720-78-7] · FeO_4S · Iron(II) Sulfate · (MW 278.06)

(reductive cleavage of N-O bonds;[2-14] Skraup synthesis;[15] carboxylation of aromatic bases[17])

Alternate Name: ferrous sulfate.

Physical Data: mp 300 °C (-$7H_2O$); bp dec 671 °C; *d* 1.89 g cm^{-3}; refractive index 1.471.

Solubility: sol water (48 g/100 mL); slightly sol ethanol; sol methanol.

Form Supplied in: light blue or light green crystals; many commercial sources.

Handling, Storage, and Precautions: air and moisture sensitive; keep in a tightly closed container. Incompatible with strong oxidizing agents; irritant; ingestion may be lethal.[18]

Reductive Cleavage of N-O Bonds.[2-14]

Basic iron(II) sulfate is the reducing agent of choice for the conversion of *o*-nitrobenzaldehydes to *o*-aminobenzaldehydes.[2] $FeSO_4.7H_2O$ has been used in combination with ammonia;[3] however, ammonium hydroxide is the most synthetically useful base.[2] Detailed syntheses of *o*-aminobenzaldehyde have been reported using $FeSO_4/NH_4OH$ (eq 1).[2,4] The *o*-aminobenzaldehydes should be prepared immediately prior to use as they are prone to polymerize extensively on standing and when treated with acid. *o*-Aminobenzaldehyde is stable for up to 2 months at 5 °C.[5] Several alternate strategies are available for synthesis of *o*-amino aldehydes;[1] more recently, dihydrolipoamide-iron(II) under weakly alkaline conditions has been reported as a general nitrobenzene reducing agent.[6]

(1)

Reductive cyclization utilizing $FeSO_4.7H_2O$ has been used to synthesize thieno[*c*]-fused 1,5-naphthyridine 5-oxides (eq

2) (30-86%).[7] Reduction of the N-O bond in 1,2,4-oxadiazolines and amidoximes and hydrolysis of the intermediate iron complexes to amidines (eq 3)[8] provides an alternative to the reducing agents P/***Hydrogen Iodide***[9] or ***Pentacarbonyliron***.[10] Iron(II) sulfate has been used to cleave various *C*-substituted oxiridines.[11] Bicyclic oxaziridines have been cleaved to amides,[12] and tricyclic oxaziridines yield seven-,[13] eight- and nine-membered oxolactams (eqs 4 and 5).[14]

(2)

(3)

(4)

(5)

Skraup Synthesis.

The Skraup synthesis of quinolines from a nitrobenzene, glycerol, and H_2SO_4 proceeds with extreme violence unless $FeSO_4.7H_2O$ is included. A detailed synthetic procedure for quinoline has been reported,[15] which is amenable to synthesis of derivatives (eq 6).[16]

(6)

Carboxylation of Aromatic Bases.

Heteroaromatic bases can be carboxylated via reaction with the carboxyl radical generated with H_2O_2, keto ester, and $FeSO_4.7H_2O$ (eq 7).[17]

(7)

Related Reagents.

Iron(II) Sulfate-Oxygen[1]

$FeSO_4.7H_2O$-O_2

($FeSO_4.7H_2O$)

[7720-78-7] · FeO_4S · Iron(II) Sulfate-Oxygen · (MW 278.06) (O_2)

[7782-44-7] · O_2 · Iron(II) Sulfate-Oxygen · (MW 32.00)

(selective oxidant for 15-hydroxylation of steroids,[1] direct hydroxylation of aromatic and aliphatic substrates[7,8])

Alternate Name: ferrous sulfate-oxygen.

Preparative Methods: the reagent combination is generated in situ via dropwise addition of an aqueous solution (500 mL) of ***Iron(II) Sulfate*** (15 g, 54 mmol) to a stirred buffer (0.1 M Na_2HPO_4, pH 6.8, 2.5 L) solution of substrate (2.25 mmol) under bubbling oxygen at 70 °C. Room temperature may be adequate for some substrates.

Handling, Storage, and Precautions: is air and moisture sensitive; keep in a tightly closed container; incompatible with strong oxidizing agents; irritant; ingestion may be lethal.

Hydroxylation of Steroids.[1]

The bile acids deoxycholic (eq 1),[1] nordeoxycholic, and taurodeoxycholic acids[2] are 15-hydroxylated in aqueous buffer by dropwise addition of iron sulfate under a stream of oxygen at 70 °C. Acetone can be used as a cosolvent to improve solubility of some steroids.[3] It has been postulated that a positively charged species [Fe^{2+}-O_2] interacting with the carboxyl sidechain is responsible for the regiochemistry observed.[4] These transformations are in contrast to that observed with a hydroxylating system developed earlier by Udenfriend[5] which mimics the biological transformation of deoxycholic acid to cholic acid (eq 2)[6] via 7-hydroxylation with $FeSO_4$-O_2-ascorbic acid-EDTA.

(1)

(2)

Direct Hydroxylation of Aromatic and Aliphatic Substrates.

It should be pointed out that direct hydroxylation of organic substrates, so efficiently accomplished in nature (via

metalloenzymes), is very difficult to achieve synthetically. Adamantane carboxylic acids can be oxygenated with $FeSO_4$-O_2 in buffer solution at 40 °C (eq 3).[7] Aromatic compounds can also be hydroxylated: benzoic acid yields 41% of five products and phenol two products (eq 4).[8] Many alternate reagents have been reported for direct aryl hydroxylations, mostly as modifications of either Fenton's reagent ($FeSO_4$-H_2O_2) or Udenfriend's reagent ($FeSO_4$-O_2-ascorbic acid-EDTA).[9] Recently, attention has focused on alkane hydroxylations using metalloporphyrins,[10] cluster catalysts,[11] and the Gif oxidation.[12]

Iron(III) Thiocyanate[1]

$Fe(SCN)_3$

[4119-52-2] · $C_3FeN_3S_3$ · Iron(III) Thiocyanate · (MW 230.12)

(reacts with trialkylboranes to give alkyl thiocyanates;[2] thiocyanation of unsaturated acids and esters[7])

Alternate Name: ferric thiocyanate.

Solubility: very sol water; dec in hot water; sol alcohol, ether, acetone.

Preparative Method: the reagent is prepared and used in situ, via dropwise addition of a mixture of iron(III) ammonium sulfate (6 equiv) and potassium thiocyanate (18 equiv) in water to a solution of organoborane in THF. The mixture is refluxed for 24 h. The products are obtained via extraction with petroleum ether several times and distillation.[2]

Handling, Storage, and Precautions: metal thiocyanates on heating to decomposition, or on contact with acid or acid fumes, emit highly toxic fumes. Organic thiocyanates have low acute toxicity, but prolonged absorption may produce skin eruptions, running nose, nausea, and vomiting. Violent reactions have occurred with strong oxidizers.[8] Use in a fume hood.

Alkyl Thiocyanates.[2]

Trialkylboranes react with iron(III) thiocyanate to yield alkyl thiocyanates in good yield, with two alkyl groups per borane being utilized (eq 1). A small amount of the isothiocyanate is observed, easily separable on distillation of the alkyl thiocyanate. This reaction has been extended to mixed trialkylboranes which contain a useful secondary alkyl group, which is transferred preferentially to a primary alkyl group (eq 2).[3] This method presents a mild alternative to the usual displacement reaction between an alkyl halide and ***Sodium Thiocyanate***.[4]

(1)

(2)

Alkyl selenocyanates can be synthesized via reaction of iron(III) selenocyanate with an organoborane. Iron(III) selenocyanate is generated in situ via addition of a solution of iron(III) ammonium sulfate and potassium selenocyanate in water to the trialkylborane in THF. Alkyl selenocyanates are obtained in 40-47% yields.[5] Better yields are obtained for primary alkyl groups via reaction of an alkyl halide with potassium selenocyanate.[6] However, the $Fe(SeCN)_3$ method is applicable to secondary and tertiary alkyl selenocyanates (eq 3).[3]

(3)

Thiocyanation of Acids and Esters.

Ethylenic carboxylic acids react with $(SCN)_2$ to give mixtures of thiocyanate and isothiocyanates. Addition of $Fe(SCN)_3$ affords cleanly the vicinal dithiocyanate carboxylic acids in excellent yields (84-100%).[7]

Isatoic Anhydride[1]

[118-48-9] · $C_8H_5NO_3$ · Isatoic Anhydride · (MW 163.14)

(reacts with either electrophiles or nucleophiles; derivatives have been widely used in pesticides, dyes, pigments, flavors, fragrances, pharmaceuticals, and miscellaneous industrial chemicals)

Alternate Name: 2*H*-3,1-benzoxazine-2,4(1*H*)-dione.

Physical Data: mp 233 °C; bp 350 °C.

Solubility: sol most organic solvents.

Form Supplied in: gray-brown powder; commercially available.

Handling, Storage, and Precautions: store in a dry, cold area. Use in a fume hood; gradually decomposes at high temperature upon exposure to air and water, and generates toxic gases (CO, NO, CO_2).

Reactions with Electrophiles.

N-Substituted isatoic anhydrides can be obtained by reacting isatoic anhydride with various electrophiles (CH_2N_2, Me_2SO_4, MeI, RSCl) as shown in eq 1.[1-3] Aromatic substitution of isatoic anhydride usually occurs at the 6-position, as shown in eq 2.[4] However, the 8-substituted isatoic anhydride is obtained when the 6-position is already occupied (eq 3).[5]

(1)

(2)

(3)

Reactions with Nucleophiles.

Due to the different reactivity of the carbonyl groups, various nucleophiles react with isatoic anhydride at either the C-2 or C-4 position under controlled conditions.[1] In principle, C-4 acts like an anhydride and is more reactive than C-2, which is closer to a carbamate in reactivity. In contrast, ionization can transform isatoic anhydride into 2-carboxyphenyl isocyanate, which reacts with nucleophiles only at C-2.[1,6] Under the influence of acid or base catalysts, isatoic anhydride reacts with H_2O, ROH, and RSH at C-4 to give the corresponding anthranilic acid, anthranilate ester, and anthranilate thioester, respectively.[6,7] A less hindered primary amine (*n*-butylamine) also attacks C-4 to produce the corresponding anthranilamide (path a, eq 4). A bulky amine (*t*-butylamine) reacts through path b to give *o*-ureidobenzoic acid because C-2 is relatively unhindered relative to C-4.[8] However, *N*-substitution (*N*-methylisatoic anhydride) blocks C-2, and all nucleophiles attack at the 4-position.[9] In addition, highly nucleophilic species, such as carbanions, attack the C-4 carbonyl group and release a CO_2 molecule.[1]

(4)

Solvent effects are also important in reactions of isatoic anhydride with nucleophiles. In general, polar aprotic solvents increase the yield of anthranilamide significantly.[10] For example, the yield of the reaction of *t*-butylamine with isatoic anhydride is raised to 74% in DMF from 9% in water. In addition, the concentration as well as the ratio of the reactants is important.[11] For example, the highest yield of anthranilamide was obtained by reacting 5 equiv of ammonia with a 2 M solution of isatoic anhydride (eq 5). Increasing the concentration of the substrate or changing the ammonia:substrate ratio decreased the yield of anthranilamide. Polymeric side products were formed when only 0.5 equiv of ammonia were used.

(5)

Formation of Heterocycles.

The preparation of nitrogenous heterocycles from isatoic anhydride has been reported.[1] For example, the reaction of a derivative of isatoic anhydride with a lithium enolate gave a quinoline-type alkaloid (eq 6).[12] The reactions of isatoic anhydride with amides, ureas, thioureas, isocyanates, and thiocyanates produce quinazolinones in one step (eq 7).[1,13] The synthesis can also be carried out in a stepwise fashion. The displacement of the 3-oxygen of isatoic anhydride by an amine or hydrazine results in evolution of CO_2 gas. The reaction of the product *o*-aminobenzoylhydrazine with an orthoester, chloroformate, or phosgene also gives a quinazolinone (eq 8).[1,14] Treatment of the intermediate *N*-(2-aminobenzoyl)-α-amino ester with nitrous acid generates a benzotriazine (eq 9).[15] On the other hand, ethyl glycinate reacts with isatoic anhydride to give a moderate yield of benzodiazepinone in the presence of pyridine (eq 10).[16] A

benzotriazepinone was produced directly from the reaction of benzoylhydrazine with isatoic anhydride (eq 11).[17]

Isobutene

[115-11-7] · C_4H_8 · Isobutene · (MW 56.12)

(carboxy and hydroxy protection; photochemical cycloaddition with enones; ene reaction with enophiles; Friedel-Crafts and other alkylations; reacts with carbenes; acid-catalyzed cycloadditions)

Alternate Name: isobutylene.

Physical Data: mp -140.4 °C; bp -6.9 °C; vapor density 1.947.

Solubility: insol H_2O; sol THF, pet ether, benzene.

Form Supplied in: gas (lecture bottle); widely available.

Handling, Storage, and Precautions: flammable gas; store and use with adequate ventilation. Do not store with oxidizing materials and compounds that add across double bonds.

Protection for the Carboxy Group.

Isobutene has been widely used in synthesis to convert carboxylic acids into corresponding *t*-butyl esters.[1,2] *t*-Butyl esters of aliphatic acids (eq 1),[3] aromatic carboxylic acids (eq 2),[4] and *N*-protected amino acids (eq 3)[5] have been prepared. The hindered *t*-butyl esters are stable to saponification but can be cleaved by acid-catalyzed hydrolysis, with liberation of isobutene.

(1)

(2)

(3)

Protection for the Hydroxy Group.

In the presence of acid catalysts, isobutene reacts to convert a variety of alcohols and phenols to their corresponding *t*-butyl ethers. *t*-Butyl ethers are stable to most reagents but are readily cleaved by strong acids. Propargyl alcohols (eq 4),[6] steroidal alcohols (eq 5),[7] and phenols (eq 6)[8] have been protected. The *t*-butyl group has also been used to protect the hydroxy group of valinol (eq 7),[9] serine derivatives (eq 8),[10] and tyrosine.[11]

(8)

Photochemical Cycloadditions.

Isobutene has been widely used in intermolecular [2 + 2] photocycloaddition reactions with enones.[11] The weakly polarized isobutene is often used to study the regioselectivity of the photocycloaddition. Cyclohexenones (eq 9),[12] cyclopentenones (eq 10),[13] and functionalized enones (eq 11)[14] undergo cycloaddition with isobutene. Paterno-Büchi photoadditions with isobutene have produced various oxetanes (eq 12).[15]

(9)

(10)

(11)

(12)

Ene Reactions.

In the presence of Lewis acids, isobutene adds to various enophiles to yield ene adducts.[16] Enophiles such as alkoxyaldehyde (eq 13),[17] dialkyl aminoaldehyde (eq 14),[18] haloaldehyde (eq 15),[19] and vinyl sulfoxides (eq 16)[20] have been utilized. Chiral organoaluminum (eq 17)[21] and organotitanium reagents (eq 18)[22] have been reported to give high levels of asymmetric induction in the ene reaction of isobutene with activated aldehydes.

(13)

(14)

(15)

(16)

Friedel-Crafts and Other Alkylation Reactions.

A variety of *t*-butyl-substituted aromatics have been prepared with isobutene in the presence of acids (eqs 19-21).[23-25] Due to steric factors, the regiochemistry is enhanced. Isobutene can be alkylated by benzylic and allylic halides in the presence of ***Zinc Chloride*** (eqs 22-24).[26,27]

(22)

(23)

(24)

Carbene Chemistry.

Isobutene reacts readily with carbenes and metallocarbenes to form substituted cyclopropanes (eqs 25-27).[28] Reaction of ***Ethyl Diazoacetate*** with isobutene in the presence of a chiral copper catalyst affords the cyclopropane in high optical purity (eq 28).[29] Isobutene has also been used to form titanocyclobutanes that are more stable forms of the Tebbe reagent (see μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***) (eq 29).[30]

(25)

(26)

(27)

(28)

(29)

Other Acid-catalyzed Cycloadditions.

Isobutene has been used to form pyrylium salts (eqs 30 and 31),[31] oxetanes by ***Boron Trifluoride***-catalyzed [2 + 2] cycloaddition (eq 32),[32] and 3,4-dihydropyrans by Diels-Alder reactions (eq 33).[33]

(30)

(31)

(32)

(33)

Miscellaneous Reactions.

Isobutene, as the carbenium ion source for Ritter reactions, produces *N*-*t*-butyl amides (eq 34).[34] Isobutene undergoes highly regioselective cycloaddition with isocyanate to form azetidinones and with nitrones to yield isoxazolidines (eqs 35 and 36).[35,36] Allyl thioethers are formed by the electrophilic addition of ***Benzenesulfenyl Chloride*** to isobutene (eq 37).[37] Alkenylphosphonous dichlorides and alkenylthionophosphonic dichlorides are also formed by addition of PCl_5 and P_2S_5 (eqs 38 and 39).[38]

Isobutyl Chloroformate

[543-27-1] · $C_5H_9ClO_2$ · Isobutyl Chloroformate · (MW 136.59)

(used for making mixed anhydrides which serve as active intermediates for peptide synthesis;[1-3] used to block the 5´-hydroxy function of deoxyribosides in oligonucleotide synthesis;[4] condensing reagent[5])

Physical Data: bp 128.8 °C; *d* 1.04 g cm^{-3}.

Solubility: miscible with benzene, chloroform, ether.

Form Supplied in: clear colorless liquid.

Handling, Storage, and Precautions: gradually decomposed by water and alcohol; highly toxic; vapor irritates eyes and mucous membranes; stable on storage.[6,7] Use in a fume hood.

Peptide Reagent.[1,3]

Protected amino acids, such as the *N*-benzyloxycarbonyl (Cbz) derivatives, are brought into solution in toluene or THF by addition of enough ***Triethylamine*** to form the salt, and isobutyl chloroformate is added at 0 °C to produce the mixed anhydride. A solution of an amino acid ester (or peptide ester) to be *N*-acylated is added in an inert solvent and the mixture is allowed to come to rt. Evolution of carbon dioxide begins immediately (eq 1). The isobutyl chloroformate is preferred to lower esters for preparation of peptides of moderate or high molecular weight;[6,7] ethyl chloroformate is preferred for synthesis of dipeptides.

Boc-Gly-Gly-OEt and Boc-Gly-Gly-Gly-OEt have been successfully synthesized in reasonable yields (77% and 88%, respectively) via mixed anhydride derivatives from isobutyl chloroformate.[8] Previously it was reported[9] that considerable quantities of diacylated side products are formed in mixed anhydride syntheses with glycine when ethyl chloroformate is used.

5´-Hydroxy Function Blocking Agent for Deoxyribosides.

The reagent has been used to block the 5´-hydroxy function of deoxyribosides in oligonucleotide synthesis (eq 2).[4] The reagent shows good selectivity for the 5´-hydroxy group, as is evident in the high yield of (**2**). The blocking group is removed smoothly by alkaline hydrolysis to give (**4**).

N-Protection.[10]

In the synthesis of enantiomerically pure symmetric vicinal diamines involving chirality transfer from a single chiral source, 1,2-diphenylethane-1,2-diamine, hydrolysis of the bisacetamides to the corresponding vicinal diamines was attempted using a number of amide hydrolysis procedures. However, the various base- and acid-catalyzed procedures did not result in a clean hydrolysis of the acetamide groups. This was achieved by converting amines into biscarbamate derivatives, followed by treatment with 30% HBr in acetic acid (eq 3).

Cyclodehydration.[5]

In the synthesis of 1,4-dihydropyran[3,4-*b*]indolones, the reagent was used along with triethylamine for cyclodehydration of hydroxymethylindoleacetic acid to produce the lactone (eq 4).

Regioselective Arylation.[11]

Arylation in the 4-position in pyridines results from 1:1 adduct formation between an aryltriisopropoxytitanium reagent and an *N*-isobutyloxycarbonylpyridinium salt, and after successive ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** dehydrogenation and cleavage of the 1-substituent (eq 5).

Isobutyl Sulfonate.[12]

With ***Silver(I) p-Toluenesulfonate***, alkyl chloroformate forms sulfonic carbonic anhydride which when heated liberates carbon dioxide, producing alkyl sulfonate. In order to find out the mechanism of the decomposition of the mixed anhydride, reaction of isobutyl chloroformate and silver *p*-toluenesulfonate was investigated. If the free alkyl cation, i.e. isobutyl carbonium ion, is formed, the rearrangement to *s*-butyl and *t*-butyl carbonium ion would be expected, finally resulting in the formation of *s*-butyl *p*-toluenesulfonate. *t-B*utyl *p*-toluenesulfonate is unstable and is not expected to survive under the reaction conditions. In fact, decomposition gave a mixture of isobutyl *p*-toluenesulfonate and *s*-butyl *p*-toluenesulfonate in a 0.8:1 mol ratio, with a quantity of isobutene and free *p*-toluenesulfonic acid. Isobutene was considered to be derived from the *t*-butyl cation.

Isocyanic Acid[1]

(HNCO)

[75-13-8] · CHNO · Cyanic Acid · (MW 43.03) (HOCN)

[420-05-3] · CHNO · Isocyanic Acid · (MW 43.03) (KOCN)

[590-28-3] · CKNO · Potassium Cyanate · (MW 81.12) (NaOCN)

[917-61-3] · CNNaO · Sodium Cyanate · (MW 65.01) (AgOCN)

[3315-16-0] · CAgNO · Silver Cyanate · (MW 149.89)

(synthesis of isocyanates, allophanates, and some heterocyclic compounds)

Physical Data: mp -86 °C; bp 23.5 °C (by extrapolation); *d* 1.14 g cm^{-3}; pK_a 3.66.

Solubility: poorly sol aliphatic hydrocarbons; sol benzene, toluene, CCl_4, ether, THF, etc. *Drying:* over P_2O_5.

Analysis of Reagent Purity: see Belson and Strachan.[1c]

Preparative Methods: by the depolymerization of cyanuric acid,[1a,b] or by heating urea.[1c] The gas can be absorbed in ether, THF, $CHCl_3$, or CCl_4. Aqueous solutions of HNCO can be prepared in situ by reacting NaOCN or KOCN with 1 equiv of dil HCl or AcOH at temperatures of approx 0-15 °C.

Handling, Storage, and Precautions: isocyanic acid (gas, liquid, or as concentrated solution in anhyd organic solvents) readily polymerizes from -20 °C to rt to give an easily separable mixture of cyanuric acid and cyamelide (a polymer whose structure is as yet unknown), but dilute solutions in ether or CCl_4 can be kept at rt without serious decomposition.[1c] In contact with moisture, even at 0 °C, it hydrolyzes to NH_3 and CO_2.[1c] Stored at dry ice or liquid nitrogen temperature, it is quite stable.[1c] Besides being a strong acid, lacrymator, and vesicant, it possesses an acrid odor. The highly toxic character of isocyanic acid requires that it should be used only in a well-ventilated fume hood.

Introduction.

Of the two acids, cyanic acid (H-O-C&tbond;N) and isocyanic acid (H-N=C=O) (**1**), that arise from the ambident nucleophile cyanate, (**1**) is the more stable of the two. Since cyanic acid is kinetically unstable,[1a,b] it is vital to recognize at the outset that much of the preparative work mentioned in the scientific literature for cyanic acid has, in fact, utilized isocyanic acid. Isocyanic acid, for all practical purposes, whether in the gaseous, liquid, or solid state, has the carbimide structure H-N=C=O, and, although in principle it can tautomerize to give cyanic acid, the observed proportion of cyanic acid in organic solvents is essentially negligible.[1c] Even in aqueous media, it is the isocyanic acid tautomer that predominates.[1c]

Addition of Polar Compounds to Isocyanic Acid.

Because of the presence of electrophilic functionality (-N=C=O) in isocyanic acid (**1**), a wide range of polar reagents[2] adds across its HN=C bond, such that their nucleophilic end attacks at carbon, and the positive part at nitrogen. In this way, cyclohexylamine forms *N*-cyclohexylurea in 75% yield,[3a] alcohols (primary, secondary, and tertiary ROH) give moderate yields[3b-d] of crystalline allophanates (**2**), often contaminated with carbamates, and ***Diphenylphosphine*** reacts efficiently with (**1**) in degassed benzene at rt to form carbamoyldiphenylphosphine (**3**) in 75% yield.[4a] With an excess of ***Trifluoroacetic Anhydride*** at rt, (**1**) gives perfluorodiacetamide (**4**) in 90% yield.[4b]

(1)

(2)

(3)

(4)

Formation of Isocyanates.

Because of the ionizable H-N bond, isocyanic acid behaves like a pseudo hydrogen halide. In the presence of a suitable catalyst and appropriate conditions, it adds to reactive unsaturated compounds, and undergoes substitution reactions at Si, Sn, and P. Thus several novel isocyanates have been prepared,[5a] by reaction of (**1**) with electron-rich alkenes,[5b] vinyl ethers,[5c] reactive carbonyl compounds,[5d-g] chlorosilanes,[5f] phosphorus halides,[5f] organometal oxides,[5h] and pentafluoroguanidine,[5i] etc. Some selected examples of isocyanates thus obtained (including yields) are:

- 1)α,α-Dimethylbenzyl isocyanate ($PhCMe_2NCO$, 41%)[5b] from α-methylstyrene.
- 2)1-Butoxy-1-methylethyl isocyanate ($BuOCMe_2NCO$, 71%)[5c] from *n*-butyl isopropenyl ether.
- 3)1-(2-Methacryloyloxyethoxy)ethyl isocyanate (**5**) (83%)[5c] from vinyloxyethyl methacrylate.
- 4)Hydroxymethyl isocyanate ($HOCH_2NCO$, 90-95%)[5d] from formaldehyde at -78 °C. Most carbonyl compounds

capable of forming hydrates, e.g. chloral, trifluoroacetaldehyde, hexafluoroacetone, perfluorobutanone, *s*-dichlorotetrafluoroacetone, give α-hydroxy isocyanates which display their normal reactivity pattern. For example, $HOCH_2NCO$ polymerizes explosively above 0 °C, but it reacts with dihydropyran under catalysis with ***p-Toluenesulfonic Acid*** at -5 °C to give 2-tetrahydropyranyloxymethyl isocyanate ($THPOCH_2NCO$, 67%) and it has been converted into chloromethyl isocyanate ($ClCH_2NCO$) at -78 °C.[5e]

- 5)Acetyl isocyanate (AcNCO, 15%)[5f] from acetyl chloride.
- 6)Trimethylsilyl isocyanate (Me_3SiNCO, 57%)[5f] from Me_3SiCl.
- 7)Diphenyl phosphor(isocyanatidite) [$(PhO)_2PNCO$, 70%][5f] from diphenyl phosphorochloridite [$(PhO)_2PCl$], and [$PhOP(NCO)_2$, 61%][5f] from $PhOPCl_2$.
- 8)Trifluoroacetyl isocyanate (CF_3CONCO 37%)[5g] from trifluoroacetic anhydride.
- 9)Tri-*n*-butyltin isocyanate (Bu_3SnNCO, 90%)[5h] from dibutyltin oxide.
- 10)Bis(difluoramino)fluoraminomethyl isocyanate (**6**) (30-50%)[5i] from pentafluoroguanidine. Compound (**6**) on fluorination in the absence of NaF gives tris(difluoramino)methyl isocyanate [$(F_2N)_3CNCO$] in 80% yield.[5j]

(5)

(6)

Formation of Heterocycles.

Because of the ambident reactivity of isocyanic acid, when β-propiolactone and (**1**) are combined (1:1) with a catalytic amount of ***Boron Trifluoride Etherate*** at -22 to 0 °C, 3,4,5,6-tetrahydro-2*H*-1,3-oxazine-2,4-dione is obtained in 95% yield (eq 1).[6] Likewise, the vinylogous carbamate (**7**) upon condensation with (**1**) and acetaldehyde in ether at rt gives, in 72% yield, dihydropyrimidin-2-one (**8**) (eq 2), useful in the synthesis of the marine toxin saxitoxin.[7] Treatment of (**6**) with 1 equiv of (**1**) and 0.1 equiv of urea at -35 °C for 3 h gives the 5-fluorodihydro-*s*-triazine-2,4(1*H*,3*H*)-dione (**9**) in 90-100% yield (eq 3).[5i] Finally, the facile addition of the H-N bond of (**1**) across the HN=C bond of another molecule explains why (**1**) readily trimerizes to give cyanuric acid and the polymer cyamelide

(1)

Cyanic Acid Salts (Potassium, Sodium, and Silver).

In contrast to cyanic acid, its alkali metal salts (potassium cyanate, sodium cyanate, and silver cyanate) are stable,[1d] economical, and convenient starting materials for the synthesis of inorganic and organic isocyanates as well as for the in situ preparation of aqueous (**1**). In assessing their reactivity pattern, it is important to note that, whereas both Na^+ and K^+ are hard electrophiles, Ag^+ is a soft electrophile.

Inorganic Isocyanates.

Inorganic isocyanates are prepared by the displacement of halogen attached to the element of interest (B, Si, Ge, Sn, Pb, N, P, As, Sb, O, S, Cl, Br, and I) with a salt of cyanic acid. However, not all elements (N and O) give stable isocyanates, and some (e.g. I-NCO) can only be prepared in situ and utilized accordingly.[8] Thus reaction of AgOCN with ***Bromodimethylborane*** gives Me_2B-NCO in 90% yield.[9] Similarly, isocyanates have been prepared by the displacement of a halogen at Si, Ge, Sn, S, and P with AgOCN.[8] Isocyanates of Si (TMS-NCO), S (e.g. $PhSO_2$-NCO, *p*-$MeC_6H_4SO_2$-NCO, and $ClSO_2$-NCO), and I (I-NCO) are covered separately in this encyclopedia. More recently, methyl phenylsulfenylcarbamate (PhS-$NHCO_2Me$) and *N*-phenyl-*N*´-(phenylsulfenyl)urea (PhS-NH-CO-NHPh) have been obtained, in 47% and 36% yield, by trapping the in situ formed phenylsulfenyl isocyanate (PhSCl + AgOCN -> PhSNCO) in benzene, with MeOH or $PhNH_2$, respectively.[10] With NaOCN, displacement of a chloro group at P in MeP(O)ClF, MeP(O)ClN_3, and $PhPCl_2$, takes place to give the expected isocyanates.[8,11]

Organic Isocyanates.

Although conversion of a simple alkyl halide, sulfate, tosylate, or phosphate into its respective isocyanate using cyanic acid salts can be satisfactorily achieved in the laboratory, this topic is a subject of numerous patents. Thus while Et-NCO can be obtained in good yields by simply heating Et_2SO_4, ethyl *p*-toluenesulfonate, or triethyl phosphate[12] with KOCN, the reaction of EtBr with KOCN is best performed[8] in dimethyl sulfone as a solvent. In some cases, the choice of the solvent employed is very critical to the success of the reaction. Use of an aprotic solvent such as DMF alone should be avoided, since organic isocyanates readily trimerize in DMF to give isocyanurates.[13] Diluting DMF with xylene essentially overcomes this problem, and in this way $MeOCH_2$-NCO has been obtained from NaOCN and $MeOCH_2Cl$.[14] AgOCN in ether and 2,3-dichloro-1,4-dioxane (**10**) give the diisocyanate (**11**) in 40-50% yield (eq 4).[15]

(4)

(10) **(11)**

When crotyl bromide is treated with AgOCN in ether for 3 h at rt, 2-butenyl isocyanate (67%) and 1-methylallyl isocyanate (28%) are obtained in 84% yield.[16] The reaction of AgOCN with 3-bromopropanoyl bromide in benzene under sonication in an ice-water bath gives 3-bromopropanoyl isocyanate ($BrCH_2CH_2CO$-NCO) in 55% yield.[17] This procedure, when extended to 4-bromobutanoyl chloride, gives 4-bromobutanoyl isocyanate ($BrCH_2CH_2CH_2CO$-NCO) in only 10% yield.[17] The displacement of a halogen at carbon with metal cyanates has also been accomplished in the presence of a phase transfer catalyst.[18] Thus when bromoalkyl (meth)acrylate (**12**) (15 mmol) in 5 mL of anhyd MeCN is added to a slurry of NaOCN (22.5 mmol) and Bu_4NBr (3 mmol) in 15 mL of dry MeCN at rt and the mixture is heated at 55 °C for 21 h, the isocyanate (**13**) (59%) and the isocyanurate (**14**) (32%) are readily obtained. When the above mixture is heated at 65 °C for 62 h, the isocyanurate (**14**) is obtained in 75% yield. However, when the above reaction is performed in the presence of water (1.2 equiv), and the mixture is heated at 60 °C for 24 h, the symmetrical urea (**15**) is obtained in 81% yield. Substituting the water with 6 equiv of MeOH gives the carbamate (**16**) in 90% yield.[18] Finally, it should be noted that treatment of alkyl halides with alkali metal or silver cyanate is of no preparative value in the synthesis of cyanates.[19]

(12)

(13)

(14)

(15)

(16)

N-Carbamates and Polyurethanes.

The reaction of alkali metal cyanates with simple alkyl halides in DMF, in the presence of a suitable alcohol, provides a direct synthesis of *N*-substituted carbamates.[20] The initial reaction is an S_N2 process, which exhibits the expected reactivity, i.e. allylic, benzylic, and primary halides react faster than secondary halides, and the reaction fails with tertiary halides. In a typical experiment, an appropriate alkyl halide (50 mmol) in 5 mL of DMF is added to a well stirred slurry of KOCN (75 mmol) and EtOH (85 mmol) in DMF (40 mL) at 100-120 °C. After heating for an additional 4.5-45 h (depending upon the substrate), the *N*-carbamate can be isolated readily. In this way, 2-chlorobutane gives *s*-$BuNHCO_2Et$ (55%); the yields of *n*-$BuNHCO_2Et$ and $BnNHCO_2Et$) from *n*-BuCl and $PhCH_2Cl$ are 77% and 88%, respectively. By appropriately increasing the molar ratio of KOCN and EtOH, both the chlorine atoms in α,α´-dichloro-*p*-xylene or (*E*)-1,4-dichloro-2-butene can be displaced to obtain the expected *N*-biscarbamates in 70% and 77% yield.[20] Substituting EtOH with a diol $[HO(CH_2)_nOH]$ in the above reaction is the key to the synthesis of the poly(polymethylene tetramethylenedicarbamate) type of polyurethanes (eq 5).[21]

(5)

A simple synthesis of methyl *N*-(1-adamantyl)carbamate [1-(methoxycarbonylamino)adamantane] has been achieved in 54% yield by reaction of 1-adamantanol or its nitrate with KOCN, MeOH, and concd H_2SO_4 in $CHCl_3$.[22] The reaction probably proceeds by the alkylation of the 1-adamantyl cation with in situ formed carbamic acid (H_2NCO_2H) or methyl carbamate.

O-Carbamates.

Addition of alcohols to isocyanic acid in ether gives mixtures of *O*-alkyl carbamates and allophanates (**2**). However, when ***Trifluoroacetic Acid*** (2 equiv) is added to a suspension of 1 equiv of alcohol and 2 equiv of NaOCN (curiously enough, KOCN cannot be substituted for NaOCN) in benzene or methylene chloride and slowly stirred at rt, excellent yields of *O*-alkyl carbamates are obtained.[23] This method is applicable to the synthesis of carbamates from primary, secondary, or tertiary alcohols[24] (2 h reaction time affords 60-90% yield), including propargyl alcohol (eq 6), cyclic and acyclic 1,3-diols, phenols, aldoximes, ketoximes, *n*-BuSH, and *t*-BuSH.[23]

(6)

Reaction with Allenyl Cations.

Potassium cyanate in 70:30 acetone-water (v/v) reacts at rt, under solvolytic conditions,[25] with 1,3,3-triphenylchloroallene (**17**) to form an unstable propargylcarbamic acid which, upon treatment with base, gives the propargylamine (**18**) in 45% yield (eq 7).

(7)

(17) **(18)**

Reaction with Photogenerated Arylvinyl Cations.

When a two-phase mixture of 1-bromo-1,2,2-tris(*p*-methoxyphenyl)ethylene (**19**) (1 mmol), KOCN (10 mmol), and *n*-Bu_4NCl (2 mmol) in CH_2Cl_2 (90 mL) and H_2O (10 mL) is irradiated through a Pyrex filter under N_2 at 10-15 °C, the photogenerated arylvinyl cation (**20**) is captured by the cyanate ion via *N*-attack to form the β-aryl isocyanate (**21**) (eq 8). This readily cyclizes to give 7-methoxy-3,4-bis(*p*-methoxyphenyl)-1-isoquinolone (**22**) in 93% (at 70% conversion) yield.[26] The presence of the *p*-MeO group in the aromatic ring helps stabilize the vinyl cation and thus is responsible, in part, for the excellent yields obtained in this reaction.

Reaction with a α-Chlorocarbenium Ion.

Potassium cyanate in DMF reacts with the Vilsmeier-Arnold reagent (**23**) to form initially a highly reactive intermediate, 4-(dimethylamino)-1-oxa-3-azabutatrienium chloride (**24**), which reacts with DMF to give the Gold salt (**25**) in 86% yield (eq 9).[27] Similarly, when bis(4-chlorophenyl)chlorocarbenium hexachloroantimonate (**26**) is refluxed with KOCN in 1,2-dichloroethane, and the intermediate 1-oxa-3-azabutatrienium salt (**27**) is treated with 4,4´-dichlorobenzophenone, tetrakis(4-chlorophenyl)-2-azaallenium hexachloroantimonate (**28**) is obtained in 67% yield (eq 10).[28]

Reaction with Amines.

When 1 equiv of NaOCN or KOCN is added to an ice-cold solution of dilute HCl or AcOH, the in situ generated (**1**) reacts with aromatic and aliphatic amines to give ureas (RNH_2 -> $RHNCONH_2$ and R_2NH -> R_2NCONH_2). With excess isocyanic acid, biuret (R_2NCONH_2 -> $R_2NCONHCONH_2$) can also be formed.[1b] Hence, the temperature, pH, and the stoichiometry of the reagents employed should be carefully chosen.[29] More recently, 2-ureido-3,4,5-trimethoxybenzoic acid has been prepared from 2-amino-3,4,5-trimethoxybenzoic acid on >100 kg scale, with yields approaching nearly 100%.[30] Also, *N*-(2-sulfoethyl)urea ($H_2NCONHCH_2CH_2SO_3H$) has been obtained from taurine ($H_2NCH_2CH_2SO_3H$), KOCN, and HCl in 88% yield.[31a] Ureido derivatives of amines have been utilized in an efficient entry to the synthesis of cinodine antibiotics,[31b] and in a model study aimed at the synthesis of the marine hepatotoxin cylindrospermopsin.[31c]

Heterocyclic Synthesis.

The cyclization reactions of various bifunctional compounds with isocyanic acid or cyanate salts provide a general method for heterocyclic ring formation. Representative examples of these reactions are illustrated in eqs 11-18 by syntheses of 5,6-dimethoxy-4-methyl-2(1*H*)-quinazolinone from an *o*-aminoacetophenone (eq 11),[32] 4-methyl-5-pentyl-4-imidazolin-2-one from 3-bromo-2-octanone (eq 12);[33] N^3-substituted hydantoins (**30**) from chloroacetanilides (**29**) (eq 13);[34] 3-aryl-1,2,4-oxadiazol-5(4*H*)-ones (**33**) from aryl hydroxamoyl chlorides (**31**), presumably via the intermediate nitrile oxide (**32**) (eq 14);[35] 1-phenyl-3-trifluoromethyl-Δ^2-1,2,4-triazolin-5-one (**36**) from *N*-phenyltrifluorohydrazonoyl bromide (**34**), probably by [3 + 2] dipolar cycloaddition with the nitrilimine (**35**) (eq 15);[36] 7-methyl-2-phenyl-1,2,4,7-tetraazaspiro[4.5]decan-3-one (**38**) from the phenylhydrazone (**37**) (eq 16);[37] 2-morpholinothieno[2,3-*d*]pyrimidin-4(3*H*)-one (**40**) from the carboximidoyl chloride (**39**) (eq 17);[38] and 3,3´-bis(1,2,4-oxadiazol-5(4*H*)-one) potassium salt from dichloroglyoxime (eq 18).[39] Similar reactions of (**1**) occur with azines to form bitriazoles[40] and with Schiff bases to form four- or six-membered heterocyclic structures.[41]

Silver(I) Catalyzed Cyclization of *O*-Propargyl and *O*-(2,3-Butadienyl) Carbamates.

Silver cyanate, while serving as a source of Ag^+, can be efficiently utilized as a catalyst for the amino cyclization of *O*-propargyl[42] and *O*-(2,3-butadienyl)[43] carbamates according to eqs 19 and 20. Success of the cyclization according to eq 19 depends upon the presence of *t*-BuOK, while in eq 20, Et_3N is necessary. When R^1 = *t*-Bu (eq 20), the *trans* isomer is the predominant product, but with R^1 = Me or Et, mixtures of *trans* and *cis* isomers are produced. The reaction works best with R^2 = Ts, and poorly with R^2 = Ac.

R = PhCO, Ac, (*E*)-MeCH=CH-CO-

Isocyanomethyllithium[1]

[33742-77-7] · C_2H_2LiN · Isocyanomethyllithium · (MW 46.99)

(useful for the nucleophilic introduction of the α-aminomethyl group;[1] heterocyclic synthesis[1])

Alternate Name: lithiomethyl isocyanide.

Preparative Method: can be prepared by adding 25 mL of a solution of methyl isocyanide (0.1 mol, 4 M in anhyd THF) dropwise, to a stirred solution of *n*-BuLi (0.105 mol, i.e. 66 mL of a 1.6 M in hexane) in anhyd THF (100 mL) at -70 °C under nitrogen and stirring for additional 10 min.[2]

Handling, Storage, and Precautions: unstable above -60 °C, and is best utilized immediately after its preparation. Due to its extreme toxicity, all operations involving methyl isocyanide should to be performed in a well-ventilated hood. In order to eradicate its unpleasant odor, it is essential to clean glassware with acid.

Introduction.

Isocyanomethyllithium (**1**) is generated by lithiation of an α-C-H bond of ***Methyl Isocyanide*** with ***n-Butyllithium*** in THF at temperatures below -60 °C. In contrast to the cyano group (pK_a for MeCN = 25), which can help delocalize the adjacent negative charge through resonance, the isocyano moiety behaves as an electron-withdrawing group, and activates the α-C-H bond largely through an inductive effect. Like other isocyanides, the lithiated species is probably stabilized to some extent by resonance between the iminylidene contribution (**2a**) and the zwitterionic nitrilium form (**2b**). Perhaps isocyanomethyllithium (**1**) is best regarded as a dipole-stabilized carbanion which may be represented by either form (**2a**) or (**2b**).

(2a) **(2b)**

The synthetic utility of (**1**) arises from to its ambivalent reactivity. As an α-metalated isocyanide, its anionic carbon can act as a nucleophile, in both addition (e.g. carbonyl compounds) and displacement reactions (e.g. alkyl halides, tosylates, epoxides, etc.), and at the same time it can display the chemistry associated with the isocyanide moiety. An outcome of this reactivity combination is the use of (**1**) as a synthon for the nucleophilic introduction of the α-

aminomethyl group as well as for heterocyclic synthesis.

Reaction with Aldehydes and Ketones.

The reagent (**1**) reacts with aldehydes and ketones (e.g. **3**) in 1:1 ratio at -70 °C initially to give a tetrahedral intermediate, 2-isocyano lithioalkoxide (**4**), which owing to its reactive O-Li bond and the electron-deficient isocyanide carbon, attains an equilibrium with 2-lithiooxazoline (**5**) (eq 1). Some synthetically useful manipulations of intermediates (**4**) and (**5**) are given below.

At -70 °C the equilibrium lies entirely towards (**4**), since addition of AcOH immediately after the carbonyl compound (e.g. benzaldehyde and acetophenone) gave 2-isocyano alcohols (**6**) in 75% and 80% yield respectively.[2] In the case of benzaldehyde[2] the intermediate (**4**) can also be trapped with Ac_2O or PhCOCl to give the acetate or benzoate of (**4**). In the presence of proton donors such as water at rt or, better, methanol at -70 °C, 2-oxazolines (**7**) are obtained in 60-90% yield.[3] This novel synthesis of 2-oxazolines (**7**) has been applied to a variety of aldehydes (e.g. benzaldehyde, cinnamaldehyde, 2-furaldehyde) and ketones (e.g. acetone, acetophenone, benzophenone, and cyclohexanone, etc.).[3] In some instances, 2-(hydroxyalkyl)-2-oxazolines (**8**; $R^1 = R^2 = Ph$) have been observed as byproducts in this reaction. Indeed, such a reaction has been utilized preparatively in the synthesis of a benzylisoquinoline alkaloid precursor. Oxazoline (**10**) is obtained in 61% yield, by reaction of (**1**) with 2 equiv of piperonal (**9**), followed[4] by acetylation with ***Acetic Anhydride*** and ***Pyridine*** (eq 2).

When the addition product (i.e. **4**) derived from the reaction of (**1**) with aryl or vinyl carbonyl compounds, e.g. acetophenone, benzophenone or cinnamaldehyde, was refluxed for 40 h, α-methylstyrene (65%), 1,1-diphenylethylene (40%), and 1-phenyl-1,3-butadiene (28%), were formed by LiOCN elimination.[5] This outcome is presumably a case of a rarely observed 1,3-dipolar cycloreversion, initiated by the thermal fragmentation of the 2-lithiooxazoline (**5**).

2-Oxazoline (**7**; R^1 = Me, R^2 = Ph) was obtained in 87% yield[6] when 2-isocyano alcohol (**6**; R^1 = Me, R^2 = Ph) was treated with anhydrous acid or base, thus demonstrating the greater thermodynamic stability of the 2-oxazoline.

Treatment of 2-isocyano alcohol (**6**; R^1 = H, R^2 = Ph) with ***p-Toluenesulfonyl Chloride*** followed by KOH provides a useful synthesis of β-isocyanostyrene in 65% yield.[6]

2-Isocyano alcohol (**6**) or the 2-oxazoline (**7**) derived from cyclohexanone (eq 3) was converted with methanolic HCl to β-amino alcohol hydrochloride (**11**) in 63% yield; further treatment with aqueous ***Sodium Nitrite*** for 24 h at rt gave cycloheptanone in 71% yield (eq 3). This reaction sequence demonstrates the utility of (**1**) for the addition of an aminomethyl group to a carbonyl compound,[7] and as an application of the Tiffeneau-Demjanov ring expansion reaction. Likewise, bicyclo[3.3.3]undeca-2,6-dione (**14**), a precursor for the synthesis of the bridgehead alkene tricyclo[3.3.3.$0^{2,6}$]undec-2(6)-ene (**15**), was obtained[8] from bicyclo[3.2.2]nona-6,8-dione (**12**) via β-amino alcohol (**13**). For such β-amino alcohols which are sensitive to methanolic HCl, hydrolysis of (**6**) or (**7**) can be accomplished[9] under neutral (heating with aqueous MeOH) or mildly basic (MeOH in basic alumina) conditions, to give the *N*-(β-hydroxyalkyl)formamide, which is then deformylated with *p*-TsOH in dichloromethane or by warming with 2N NaOH.

(3)

(12)

(13)

(14)

(15)

Reaction with Acylating Agents.

Addition of (**1**) to acylating agents (RCOX; X = Cl, OMe, NMe_2, etc.) gives readily enolizable α-isocyano ketones which via lithium enolate (**16**) attain equilibrium with 2-lithiooxazole (**17**) (eq 4). Protonation of (**17**) or enolate (**16**)

(via enol **18**) with glacial acetic acid gives oxazole (**19**). In contrast to esters and *N*,*N*-dialkylamides (RCOX; X = OMe, NMe_2) where one mole of (**1**) is consumed, for acid chlorides (RCOX; X = Cl), two moles of (**1**) are required, since one mole is utilized in the conversion of initially formed α-isocyano ketone to its lithium enolate (**16**). In this way, *N*,*N*-dialkylamides ($RCONMe_2$; R = $PhCH_2$, *i*-Pr, Et, Ph, *p*-MeC_6H_4) were converted to 5-substituted oxazoles (**19**) (R = $PhCH_2$, *i*-Pr, Et, Ph, *p*-MeC_6H_4) in 41, 55, 48, 67, and 85% yields, respectively.[10] With ***Benzoyl Chloride*** or ethyl benzoate, 5-phenyloxazole (**19**) (R = Ph) was obtained in 72% yield. With ***Diethyl Carbonate*** and (**1**), $CNCH_2COOEt$ was obtained in 35% yield.[11]

This oxazole synthesis, when applied to a δ-lactone (eq 5), initially gave complex mixtures. However, when 1.1 equiv of (**1**) was allowed to react with 0.12 M solution of a lactone (**21**) in 33% DMF-THF, oxazole adduct (**22**) was produced in ~70% yield.

The solvent DMF seems to be critical for the successful outcome of this reaction. This strategy has been applied to the racemic synthesis of furanoterpene evodone (**23**)[12] and furanoeremophilane ligularone (**26**) (eq 6).[13] Reaction of diester (**27**) with 2 equiv of (**1**) at -78 °C gave, on protonation of intermediate (**28**), β-oxazolyl β-keto ester (**29**), an intermediate in the racemic synthesis of sesquiterpene gnididione and isognididione, in 75% yield (eq 7).[14] Likewise, oxazole (**31**), an intermediate in the synthesis of ellipticine, was obtained in 80% yield when the addition product of (**1**) and methyl 2-(3-indolyl)propionate (**30**) was quenched with glacial acetic acid (eq 8).[15]

(8)

When (**1**) reacts with benzonitrile, 5-phenylimidazole (**32**) is obtained in 40% yield.[16] Likewise, reaction of (**1**) with ***Phenyl Isocyanate***, ***Phenyl Isothiocyanate***, or ***Carbon Disulfide***/***Iodomethane*** gave heterocycles (**33**), (**34**), and (**35**), respectively, in moderate yields.[6,16,17] Also, addition of (**1**) to diethyl carbonate or ***Ethyl Chloroformate***, followed by mild hydrolysis, gives glycine ethyl ester.[11]

Alkylation with Alkyl Halides.

Substitution of alkyl bromides with (**1**) has been shown to proceed at -70 °C to give monoalkylated products. Thus, butyl isocyanide, 4-isocyano-1-butene, 1-isocyano-3-pentene, and 4-isocyano-1-phenyl-1-butene were obtained[18] from propyl bromide, ***Allyl Bromide***, 1-bromo-2-butene, and 3-bromo-1-phenyl-1-propene in 39, 27, 70, and 41% yields, respectively.

Alkylation of Epoxides.

Cleavage of epoxides (**36**) with (**1**) takes place from -70 to 0 °C at the less-substituted carbon atom in 42-85%

yields.[19] The intermediate 3-isocyano lithioalkoxide (**37**) on protonation gives γ-isocyano alcohols (**38**), which can be either hydrolyzed[9] to γ-amino alcohols (**39**) or cyclized by warming in MeOH or, better, with ***Copper(I) Oxide***, to 5,6-dihydro-4*H*-1,3-oxazine (**40**). In this way, a range of γ-isocyano alcohols (**38**) are readily obtained from epoxides (**36**) (yields in parenthesis) [i.e. ethylene oxide (42%), propylene oxide (78%), styrene oxide (74%), *cis*-2,3-epoxybutane (48%), 1-chloro-2,3-epoxypropane (48%), 1,1-diethoxy-2,3-epoxypropane (49%), and cyclohexene oxide (85%)].

Isocyanatotrimethylsilane

$Me_3SiN{=}C{=}O$

[1118-01-1] · C_4H_9NOSi · Isocyanatotrimethylsilane · (MW 115.23)

(preparation of primary amides from Grignard reagents;[1-3] synthesis of trifluoroacetyl isocyanate;[4] synthesis of cyclic imides[5])

Alternate Name: trimethylsilyl isocyanate.

Physical Data: colorless oil; bp 90-92 °C; fp -2 °C; *d* 0.851 g cm^{-3}.

Solubility: sol ethers, *o*-dichlorobenzene, etc.

Form Supplied in: commercially available.

Preparative Method: from ***Chlorotrimethylsilane*** and silver isocyanate.[6]

Handling, Storage, and Precautions: harmful vapor; irritant; flammable liquid; moisture sensitive; use in a fume hood.

Amidation.

Grignard reagents are carboxamidated by isocyanatotrimethylsilane to afford primary amides, presumably by way of the *N*-silyl amides (eqs 1 and 2).[1-3] The use of dioxane as an additive to the ether or THF solvent eliminates the formation of silylated Grignard products.[1] Isocyanatotriphenylsilane reacts similarly with phenyllithium and phenylmagnesium bromide to give benzamide (77-80%).[7] Reaction of heterocyclic benzyllithium reagents with isothiocyanatotrimethylsilane affords primary thioamides in moderate yield (eq 2).[2] *N*-Hydroxyurea has been prepared from *O*-silylhydroxylamine and isocyanatotrimethylsilane.[4]

(1)

(2)

Preparation of Acyl Isocyanates.

Isocyanatotrimethylsilane has been used to convert trifluoroacetyl chloride to trifluoroacetyl isocyanate.[5] In the reaction with 1-naphthalenecarbonyl chloride, cyclization of the intermediate acyl isocyanate provides the imide through an intramolecular Friedel-Crafts reaction (eq 3).[8]

(3)

Related Reagents.

Benzenesulfonyl Isocyanate; ***3-(2-Benzyloxyacetyl)thiazolidine-2-thione***; ***Chlorosulfonyl Isocyanate***; ***Isocyanic Acid***; ***p-Toluenesulfonyl Isocyanate***; ***Trichloroacetyl Isocyanate***.

Isopentyl Nitrite[1]

[110-46-3] · $C_5H_{11}NO_2$ · Isopentyl Nitrite · (MW 117.17)

(oxidant and nitrosating agent;[2] converts activated methylenes to oximes,[3] alkyl[4] and aryl[5] primary amines to diazo compounds and diazonium salts, hydrazines to azides,[6] 2,6-disubstituted phenols to diphenoquinones,[7] anthranilic acids to benzynes,[8] aminophenols to quinone diazides,[9] and phosphoramidates to phosphates[10])

Alternate Name: amyl nitrite.

Physical Data: bp 99 °C; *d* 0.872 g cm^{-3}.

Solubility: sol most nonhydrocarbon, organic solvents.

Form Supplied in: liquid; commercially available.

Handling, Storage, and Precautions: may be distilled prior to use. The material is a flammable, toxic liquid, which should be stored under nitrogen in a cool place. Use in a fume hood.

Nitrosation Reactions.

Isopentyl nitrite is a mild reagent for the introduction of the nitroso group. The nitrosations of aryl groups[11] and π-excessive heterocyclic systems (eq 1)[2,12] have been described. The nitrosation of alkenic carbons (eq 2)[13] is known, as is the conversion of silyl ketene acetals to α-nitroso esters (eq 3).[14] Isopentyl nitrite reacts with ureas, secondary amines, and amides to generate *N*-nitroso compounds.[15] Tertiary amines having an α-silyloxy substituent have been converted by isopentyl nitrite to *N*-nitroso compounds in which the silyloxy methyl group has been cleaved (eq 4).[16]

(1)

(2)

(3)

(4)

Oxime Formation.

Nitroso groups on carbons bearing α-hydrogens normally tautomerize to the oxime. The conversion of a methylene group adjacent to a carbonyl-containing functionality to an oxime group is a general reaction of isopentyl nitrite.[3,17-21] The reaction works well on acyclic[17] and cyclic systems, with ring sizes of four (eq 5),[18] five (eq 6),[19] six,[20] seven,[3] and eight atoms[21] having been described. As shown in eq 5, the *anti*-oxime is preferred to the *syn*-oxime in α-keto oximes of four-membered rings[18] and this preference has been assumed in other ring sizes.[19d,e] In situ hydrolysis of α-keto oxime compounds has given α-diketones.[20b,22] Other groups can also activate methylene and methyl groups toward oxidation with isopentyl nitrite. Methylene groups α to a nitrile functionality can form oximes with isopentyl nitrite (eq 7),[23] as can methylene or methyl groups adjacent to aromatic or heteroaromatic rings (eq 8).[24]

Diazo and Diazonium Compounds.

Isopentyl nitrite is a preferred reagent for the conversion of aromatic or heteroaromatic amines to diazonium salts in polar organic solvents such as ethanol,[25] isopropanol,[26] acetic acid,[27] acetonitrile,[28] DMF,[29] and acetone (eq 9).[5] In other organic solvents, isopentyl nitrite and solvent react with the aromatic or heteroaromatic amine to give substitution products. Isopentyl nitrite in THF[30] or dichloromethane[31] converts the amino group to a hydrogen while isopentyl nitrite in benzene (or other aromatic solvents) gives phenyl substitution for the amine.[32] Halogenated solvents such as diiodomethane[33] or carbon tetrachloride[34] react with isopentyl nitrite and the amine-containing substrate to give halogen substitution for the amine (eq 10). The use of dimethyl disulfide as a solvent with isopentyl nitrite gives methylthio substitution for the amine.[35]

Anthranilic acid[8,36] and derivatives[37] are converted to benzyne intermediates by isopentyl nitrite in organic solvents. Solvents such as glyme,[8] dimethoxyethane,[36a] THF,[36b,37a,b] acetone,[36c,37c] and dioxane[36d,e,37d] have been employed in these reactions with good yields of benzyne cycloadducts with both 2π- and 4π-electron partners.

Aliphatic amines are also converted to alkane diazonium compounds with isopentyl nitrite in organic solvents.[38] In THF,[38a] the overall reaction observed is substitution of hydrogen for the amine as was observed with aromatic and heteroaromatic amines. In acetic acid,[38b,c] acetate substitution for the amine is observed. In chloroform, intramolecular cyclization by attack of a secondary alcohol at the amine-bearing carbon has been observed.[38d] Isopentyl nitrite reacts with amines derived from acetylsilane *O*-silyl cyanohydrins to generate α-silyl ketones (eq 11).[39]

(11)

Diazo compounds are also generated from amines with isopentyl nitrite. α-Amino esters are converted to α-diazo esters with isopentyl nitrite and traces of an organic acid or water (eq 12).[4,40] Both 1,2- and 1,4-aminophenols are converted to quinone diazides with isopentyl nitrite in the presence of trace amounts of acid (eq 13).[9,41]

(12)

(13)

Azide Formation.

Acyl azides (eq 14),[6,42,43] which are important intermediates for the generation of peptide bonds and for the Curtius rearrangement,[6,42] are formed from acyl hydrazines with isopentyl nitrite. This transformation is rapid in the presence of a variety of different functional groups. The acetylhydrazine derived from D-glucosamine has been converted to the corresponding azido sugar with isopentyl nitrite in aqueous THF.[44]

(14)

Phosphoramidate Cleavage.

The phosphoramidate group has been utilized to protect phospho monoesters.[10,45] Part of the versatility of this particular protecting group is the facile cleavage of the P-N bond with isopentyl nitrite followed by treatment with pyridine to give an isolable monophosphate pyridinium salt.[4,45]

Other Reactions.

Isopentyl nitrite is one of several reagents that has been utilized for the coupling of 2,6-disubstituted phenols to give diphenoquinones (eq 15).[7] In this particular procedure the coupling may occur via the dimerization of radical intermediates. Isopentyl nitrite has also been utilized in the hydrolysis of primary amides to carboxylic acids[46] and in the hydrolysis to aldehydes and ketones of dithioacetals, which are resistant to both basic and acidic hydrolysis (eq 16).[47]

Isoprene

[78-79-5] · C_5H_8 · Isoprene · (MW 68.13)

(Diels-Alder diene and dienophile; natural product subunit)

Physical Data: mp -145.9 °C; bp 34.1 °C; *d* 0.6809 g cm^{-3} (20 °C).[1]

Solubility: sol most common hydrocarbons; practically insol water; forms binary and ternary azeotropes.[1]

Form Supplied in: liquid; widely available.

Preparative Methods: because of its industrial importance, many sequences have been developed suitable for the large scale synthesis of isoprene.[1] Eq 1 shows a typical example.[3]
