
Handling, Storage, and Precautions: highly flammable; forms explosive peroxides; forms dangerous ozonide; low narcotic effect but does cause bronchial irritation at high concentrations.[2]

Diels-Alder Chemistry.

Isoprene (**1**) has been employed as a substrate in numerous Diels-Alder reactions. Several publications have considered the equilibrium (eq 2) between the cisoid isomer (*s-cis*-**1**) and the transoid isomer (*s-trans*-**1**).[4] While the difference in energy between the two isomers is insufficient to affect the Diels-Alder reactions, this equilibrium may play a role in certain polymerizations.[5] The facile Diels-Alder reaction between ***Maleic Anhydride*** and isoprene has received considerable mechanistic scrutiny.[6] Similarly, combination of (**1**) and ***Cyclopentadiene*** yields the expected 2-isopropenylbicyclo[2.2.1]hept-5-ene.[7] Reaction of isoprene (**1**) and ***Acrylic Acid*** (**5**) affords the carboxylic acid (**6**) (eq 3), a useful synthetic intermediate as is shown by its conversion into terpinolene (**7**) (eq 4).[8] Reaction of isoprene and 2-

bromoacrylic acid gives a reasonable yield (eq 5) of the α-bromo acid (**8**).[9]

(5)

(8)

Lewis acid catalyzed reaction of (**1**) and ***Methyl Vinyl Ketone*** (**9**) exhibits a significant variation in isomer distribution of (**10**) and (**11**) (eq 6) versus the same reaction run without catalysis.[10] This effect also extends to the reaction of (**1**) and ***Acrolein***.[10] ***Tin(IV) Chloride*** mediated reaction of isoprene with isopropenyl methyl ketone (**12**) gives 1,4-dimethylcyclohex-3-enyl ketone (**13**) in good yield (eq 7).[11] This methodology can be extended to the synthesis of unusual spirocycles. Tin(IV) chloride mediated reaction of isoprene with 2-methylenecyclopentanone (eq 8) provides (**14**) and (**15**) in a ratio of 24:1. In the absence of the catalyst, the ratio of (**14**) to (**15**) fell to 2:1.[12] Applied to sesquiterpene synthesis, this approach has led to successful production of α-alaskene (**16**) and δ-acoradiene (**17**) using 3-methyl-2-methylenecyclopentanone as the common precursor.[13]

(17)

For Diels-Alder reactions that combine isoprene with a simple dienophile (**18**) in a reaction that is able to produce two regioisomers (**19**) and (**20**), the so-called 1,4-isomer (**19**) will generally predominate (eq 9).[14]

Like cyclopentadiene, isoprene may function as both a diene and a dienophile. With careful exclusion of peroxides and air, dimerization of isoprene affords four substituted cyclohexene Diels-Alder adducts (**21**), (**22**), (**23**), and (**24**) as well as two dimethylcyclooctadienes (**25**) and (**26**).[15]

An interesting Diels-Alder variant consists of the reaction of isoprene with the vinylchromium complex (**27**) to give (**28**) and (**29**) with 92:8 regioselectivity (eq 10). Adduct (**28**) is easily transformed into (**30**).[16]

Reaction of isoprene with 2-(morpholino)acrylonitrile (**31**) gives the adducts (**32**) and (**33**) (eq 11).[17] Each of these adducts can be hydrolyzed with water in ether/THF in the presence of ***Silver(I) Nitrate*** to yield the corresponding unconjugated cyclohexenone. Combination of isoprene, the anthracene analog (**34**) of juglone, and boron triacetate provides (**35**) (eq 12) exclusively in 60% yield.[18]

Dimerization, Oligomerization, and Polymerization.

Even in the typical Diels-Alder reaction, two byproduct cyclooctadienes, (**25**) and (**26**), are produced.[15] A variety of conditions and reagents (e.g. UV radiation,[19] sulfuric acid,[20] and Ziegler-Natta catalysts[21]) have been explored for dimerization of isoprene. The ratio of products, especially with regards to the presence of higher homologs, often varies greatly from one system to another. An efficient head-to-tail dimerization of isoprene can be achieved with certain organophosphine-ligated palladium catalysts.[22] One known reaction (eq 13) affords a reasonable yield of the *trans,trans,cis*-cyclododecatriene (**36**) as well as the linear dimer (**37**).[23] Numerous radical-mediated dimerizations of isoprene have been examined.[24] Polymerization of isoprene is also a vast topic, but the fundamental references have been reviewed.[1] Isoprene undergoes reaction with alkali metals, tritylsodium, and other organometallic reagents to produce a variety of products.[25] Thus reaction of isoprene, ***Sodium Naphthalenide***, and diethylamine gives (**38**) and (**39**) (eq 14).[26]

Building Block Chemistry.

Novel means exist whereby isoprene units (or their equivalents) can be attached to preexisting substrates in order to create the skeletal backbone of complex natural products. That these isoprenylation reactions[27] are often quite efficient is illustrated (eq 15) by the reaction of (**1**) with substituted phenols (**40**) to afford 2,2-dimethylchromans (**41**).[28] Epoxidation of isoprene produces a monoepoxide that has proven a useful synthetic intermediate.[29]

Miscellaneous Chemistry.

Isoprene reacts with dichlorophenylphosphine to afford, after hydrolysis, 3-methyl-1-phenyl-2-phospholene 1-oxide.[30] Isoprene undergoes an interesting cycloaddition with α,α´-dihalo ketones in the presence of ***Zinc/Copper Couple*** on alumina to yield cycloheptenones.[31] Halogenation of (**1**) and carbene addition to (**1**) have been reviewed.[1]

Isoprene Epoxide

[1838-94-4] · C_5H_8O · Isoprene Epoxide · (MW 84.13)

(ambident electrophile)

Alternate Names: 2-methyl-2-vinyloxirane; 3,4-epoxy-3-methyl-1-butene.

Physical Data: bp 80 °C; *d* 0.8563 g cm^{-3} (22 °C).

Solubility: sol most organic solvents.

Form Supplied in: clear liquid.

Preparative Methods: often made by reacting ***Isoprene*** with ***N-Bromosuccinimide*** and converting the bromohydrin to the epoxide under basic conditions.[1] Few attempts to epoxidize conjugated dienes have been reported. Recently, a manganese catalyst has been employed in a method developed to epoxidize isoprene selectively in one step (eq 1).[2]

Handling, Storage, and Precautions: flammable liquid, flash point -7 °C; irritant; use in a fume hood.

Nucleophilic Opening at C-4.

Isoprene epoxide is often used as a model substrate for S_N2' reactions.[3] Organocuprates deliver carbon nucleophiles to the vinyl terminus in this reaction.[4] One drawback to this method of introducing a five-carbon synthon is usually the lack of control over the geometry of the resulting trisubstituted alkene. However, in a synthesis of vitamin K_1, the Cu^I-catalyzed reaction of a Grignard reagent afforded the (*E*)-alkene with high selectivity; a &egt;99:1 (*E*):(*Z*) mixture could be isolated after recrystallization (eq 2).[5]

(2)

Palladium catalysts also have been used to facilitate the S_N2' addition of nucleophiles to isoprene epoxide.[6] The coupling reactions occur at mild temperatures in polar solvents. This method has been used for the large scale synthesis of an amino alcohol (eq 3).[7] While control of the geometry of the resulting alkene is problematic, distillation of the (*E*):(*Z*) mixture through a Vigreux column affords the higher boiling (*E*) isomer in 35-55% yield.

(3)

Carbonylation with carbon monoxide (30 atm) at the alkene terminus of isoprene epoxide has been accomplished with a palladium catalyst to yield the homologated ethyl ester (eq 4).[8] Other alkenyloxiranes afford β-lactones and dienes.

(4)

Nucleophilic Opening at C-1.

Cyanide has been used to open epoxides to provide β-hydroxy nitriles under phase-transfer conditions. These

conditions are not very successful for isoprene epoxide because the product is water soluble. This problem has been overcome by the use of ***Acetone Cyanohydrin*** to selectively open isoprene epoxide at the C-1 terminus. The product is isolated without an aqueous workup (eq 5).[9]

Functionalization at C-2.

In synthesis, one goal that remains elusive is the stereoselective construction of quaternary centers in acyclic systems. Employing ***Chromium(II) Chloride***, it is possible to functionalize the tertiary position of isoprene epoxide with reasonable diastereoselectivity (eq 6).[10] The reaction rate is slower and the yield is lower when the same reaction is run with butadiene monoxide.

Related Reagents.

1,3-Butadiene Monoxide; ***Ethylene Oxide***; ***Propylene Oxide***.

Isopropenyl Acetate[1]

[108-22-5] · $C_5H_8O_2$ · Isopropenyl Acetate · (MW 100.13)

(conversion of carbonyl compounds to their enol acetates;[5] acetylation of oxygen,[12] nitrogen,[14] and carbon;[12a] acetone equivalent in Lewis acid catalyzed aldol reactions;[15] conversion of malonic acids to their isopropylidene derivatives[17])

Physical Data: bp 97 °C;[2] *d* 0.909 g cm^{-3}; fp 18 °C.

Solubility: sol benzene, acetic acid.

Form Supplied in: 99 and 99+% pure liquid widely available.

Analysis of Reagent Purity: the acetone content may be determined by addition of an excess of ***Hydroxylamine*** hydrochloride to an ethanolic solution, followed by back titration against sodium hydroxide.[3]

Handling, Storage, and Precautions: flammable liquid; mild irritant; narcotic in high concentrations. LD_{50} orally in rats: 3.0 g kg^{-1}.[4]

Enol Acetylation.

In the presence of catalytic acid, isopropenyl acetate reacts with enolizable ketones to give the enol acetate plus acetone. This reactivity has been exploited to accomplish selective enolization of ketones, and to provide dienol acetates for Diels-Alder reactions. Each of these reactions is described in more detail in the following sections.

Selective Generation of Kinetic and Thermodynamic Enol Acetates.

While the use of isopropenyl acetate with catalytic acid is considered to provide conditions for the generation of kinetic enols, the ratio of kinetic to thermodynamic isomers obtained for a given enolizable ketone appears to be

highly dependent on the individual system being studied. For example, in steroid chemistry, isopropenyl acetate has been used to provide significant yields of the kinetic Δ^2-enol (**2**) over the thermodynamically favored Δ^3-enol (**3**) (eq 1).[5] For comparison, the results of the corresponding thermodynamically controlled enol acetylation reaction using perchloric acid catalyst and ***Acetic Anhydride*** are also given.

(1a) R = OH		**(2a)** R = OAc	**(3a)** R = OAc
	isopropenyl acetate, H_2SO_4, reflux 1 h	47%	53%
	acetic anhydride, $HClO_4$, PhH, CCl_4	25%	75%
(1b) R = H		**(2b)** R = H	**(3b)** R = H
	isopropenyl acetate, H_2SO_4, reflux 1 h	29%	71%
	acetic anhydride, $HClO_4$, PhH, CCl_4	6%	94%

As shown in eq 1, introduction of an 11β-hydroxy group causes a 16-18% increase in the amount of the kinetic Δ^2-enol acetate (**2**) regardless of the reaction conditions. Additionally, enol acetylation proceeds with concomitant acetylation of the 11β-hydroxy group under these same reaction conditions. While these conditions provide only a moderate predilection for formation of the kinetic enol acetate in the cases presented above, other related systems have shown excellent selectivity utilizing this method.[6,7]

Selective Generation of (*E*)- or (*Z*)-Enol Acetates.

The (*E*)- and (*Z*)-enol acetates of β-keto esters can be selectively generated by careful choice of acetylation conditions.[8] Under acidic conditions isopropenyl acetate gives, almost exclusively, the (*Z*) isomer (**6a**) (eq 2). This selectivity is believed to arise because the reactive form of methyl acetoacetate under acidic conditions is the internally hydrogen bound (*Z*)-enol (**5**) (eq 2). Alternatively, the corresponding (*E*)-enol acetate (**6b**) may be selectively generated under basic conditions utilizing ***Acetyl Chloride*** as the acetylating agent (eq 3). The selectivity in this reaction is believed to be due to the solvent-separated ion (**7**) generated in ***Hexamethylphosphoric Triamide*** and ***Triethylamine***. For the anion (**7**), the (*E*) conformation places the negatively charged oxygen atoms at a maximum separation.

(4) **(5)** (*Z*)-**(6a)** (2)

(*Z*):(*E*) = 18:1

(4) **(7)** (*E*)-**(6b)** (3)

(*Z*):(*E*) = 1:15

The use of isopropenyl acetate and catalytic acid for the formation of dienol acetates from α,β-unsaturated aldehydes and ketones is known to favor the formation of the (*E*) isomer (**10a**) (eq 4).[9] For the enolization of ***Crotonaldehyde*** (**8**) the reaction gives 1-acetoxy-1-propene (**10**) as an 83:17 (*E*:*Z*) mixture. This selectivity is credited to the intermediacy of cation (**9**) in this process. Cation (**9b**), which would lead to the (*Z*) isomer (**10b**), is disfavored due to an unfavorable steric interaction between the vinyl and acetoxy groups (eq 5).

Dienol Acetates for the Diels-Alder Reaction.

Wolinsky and Login[10] found that the methodology described above allows for the in situ generation of reactive dienes for use in Diels-Alder reactions (eqs 6 and 7). The enol acetate of 2-methyl-2-butenone (**11**) is generated by reaction with isopropenyl acetate and ***p-Toluenesulfonic Acid***. In the presence of ***Dimethyl Acetylenedicarboxylate*** (DMAD), the resulting diene undergoes a cycloaddition reaction, giving, after loss of acetic acid, the phthalic acid derivative (**12**) in 80% yield (eq 6). Similarly, crotonaldehyde (**8**) is converted to 1-acetoxy-1-propene (**10**), as shown in eq 4. Diene (**10**) is then trapped with chloromaleic anhydride (**13**). Loss of acetic acid and HCl gives phthalic anhydride (**14**) in 70% yield (eq 7).

(7)

Acetylation of Other O, N, and C Centers.

In addition to the preparation of enol acetates from ketones, isopropenyl acetate has also seen use in the acetylation of other O, N, and C centers. Hydroxy acetylation was first noted[11] as a simultaneous reaction occurring during the enol acetylation of steroids bearing unprotected hydroxy groups (eq 1). The reagent has since been used more deliberately for the protection of alcohols.[12] More recently the reagent has been used in conjunction with enzymes to afford chiral acylated material.[13] Kaupp and Matthies[14] were surprised to observe *N*-acetylation of the benzothiazepine derivative (**15**) with no formation of the isomer (**17**) (eq 8). Attempts by the authors to generate the expected isomer (**17**) were unsuccessful.

(8)

The 5-position of some *N*-methylpyrrole derivatives (**18**) were successfully acetylated using isopropenyl acetate in the presence of catalytic acid under refluxing conditions (eq 9).[12a]

(18a) R = CO_2Et
(18b) R = H

(19a) 81%
(19b) 55%

Aldol Reactions.

Isopropenyl acetate participates in some aldol-type reactions. This enol ester, like enol ethers, can react with various acetals (**20**) in the presence of a Lewis acid to afford the aldol-type addition products (**21** and **22**) (eq 10).[15] This same reactivity is observed in the condensation of ***Succinic Anhydride*** with isopropenyl acetate.[16]

(20a)	R = Ph	**(21a)**	81%	**(22a)**	5%
(20b)	R = *i*-Pr	**(21b)**	92%	**(22b)**	0%
(20c)	R = CH=CHPh	**(21c)**	0%	**(22c)**	65%

Isopropenyl Acetate as a Source of Acetone.

Under certain reaction conditions, isopropenyl acetate reacts to deliver an equivalent of acetone for acetonide formation or for oxidative addition to an enol. Under acidic conditions, isopropenyl acetate has been used to generate isopropylidene derivatives of malonic acids.[17] Isopropenyl acetate also undergoes an oxidative addition reaction with ketones in the presence of ***Manganese(III) Acetate***.[18] An acetone subunit is added to the α-position of a ketone to give a 1,4-diketone.

Related Reagents.

Acetic Anhydride.

Isopropenyllithium[1]

[3052-45-7] · C_3H_5Li · Isopropenyllithium · (MW 48.02)

(terpenoid synthesis; precursor of isopropenyl metals[2])

Alternate Name: 2-lithiopropene.

Physical Data: ^{1}H NMR data have been reported.[5a]

Preparative Methods: can be prepared in ethereal solution by reaction of ***Lithium*** powder (containing 2% of Na) with isopropenyl chloride or bromide (eq 1)[4] or by transmetalation between an organolithium and isopropenyltrialkyltin (eq 2).[5]

Related reagents can be prepared by reaction of ***n-Butyllithium*** with an arenesulfonyl hydrazone (eq 3)[6] and by the metal-halogen exchange reaction[7] between vinyl bromides or iodides and ***t-Butyllithium*** (eq 4).

Handling, Storage, and Precautions: the solution of isopropenyllithium in diethyl ether must be handled with care since it is flammable and may ignite on contact with moisture and air. It should be stored and handled in an inert atmosphere (argon) and measured or transferred by means of a hypodermic syringe or cannula. The solution may deteriorate with time and the concentration of the reagent should be measured by titration[3] before use.

Reactions.

Isopropenyllithium reacts with various electrophiles,[1-7] for example, aldehydes (eq 5),[7] ketones,[8] alkyl halides (eq 6),[4] amides (eq 7),[9] and epoxides (eq 8).[10]

(8)

The conjugate addition of isopropenyllithium to α,β-enones can be accomplished by using 2 equiv of MAD (***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)***) (eq 9).[11]

(9)

Isopropenyllithium reacts with trialkylboranes and tetraphenylphosphonium bromide (eqs 10 and 11).[12,13]

(10)

(11)

The corresponding cuprates,[2] obtained by transmetalation between copper salts and isopropenyllithium (see ***Lithium Diisopropenylcuprate***), react with alkyl halides (eq 12)[14] and α,β-enones in a 1,4-fashion (eq 13).[15]

(12)

(13)

The organocerium reagent, prepared from isopropenyllithium and anhydrous ***Cerium(III) Chloride***, reacts cleanly with easily enolizable ketones to afford the addition products in good yield (eq 14).[16]

(14)

Related Reactions.

α-Substituted vinyllithium reagents[7a,17] have been described. 4-Chloro-2-lithio-1-butene, readily prepared by transmetalation from the tin derivative, reacts smoothly with aldehydes or ketones (eq 15).[5b]

(15)

The reaction of an α-substituted vinyllithium with copper salts leads to an α-substituted vinylcuprate which reacts easily with an allyl bromide (eq 16).[18]

Related Reagents.

1,3-Butadienyl-1-lithium; ***1,3-Butadienyl-2-lithium***; ***Isopropenylmagnesium Bromide***; ***1-Propenyllithium***; ***Vinyllithium***.

Isopropenylmagnesium Bromide[1]

[1730-25-2] · C_3H_5BrMg · Isopropenylmagnesium Bromide · (MW 145.29)

(terpenoid synthesis; precursor of isopropenyl metals[2])

Alternate Name: 2-(bromomagnesio)propene.

Preparative Method: reaction of 2-bromopropene with magnesium in THF.[4]

Handling, Storage, and Precautions: the solution of isopropenylmagnesium bromide in THF must be handled with care since it is flammable and may ignite on contact with moisture and air. It should be stored and handled in an inert atmosphere (argon or nitrogen) and measured or transferred by means of a hypodermic syringe or cannula. The solution may deteriorate with time and the reagent should be titrated[3] before use.

Reactions.

Isopropenylmagnesium bromide reacts with various electrophiles, for example, aldehydes, ketones, esters, carboxylic acids, lactones, dialkyl oxalates, anhydrides, acid chlorides, nitriles, amides, and epoxides (eq 1).[1,4,5]

In the presence of copper(I) salts (1-5%) in THF, it undergoes a very efficient conjugate addition to α,β-unsaturated ketones (eq 2).[6] Under the same conditions, it reacts with alkyl halides (eq 3),[7] epoxides (eq 4),[8] and oxetane.[8]

(2)

(3)

X = I, OTs R = C_8H_{17}

(4)

Under palladium or nickel catalysis, isopropenylmagnesium bromide reacts with vinyl (eqs 5 and 6)[9,10] and aryl halides or sulfides (eqs 7 and 8)[10,11] to give dienes or aryl alkenes in good yields.

(5)

(6)

(7)

(8)

Related Reactions.

2-(3-Trimethylsilyl-1-propenyl)magnesium Bromide-Copper(I) Iodide reacts with epoxides and the allylsilanes obtained can be converted to α-methylene-γ-lactones (eq 9).[12]

(9)

In the presence of ***Copper(I) Iodide***, the same α-substituted vinylmagnesium bromide reacts with α,β-unsaturated ketones in an annulation sequence to give methylenecyclopentanes (eq 10).[13]

(10)

The nickel-catalyzed cross-coupling reaction of α-substituted vinylmagnesium bromides with vinyl bromides leads to terminal 1,3-dienes (eq 11).[14]

(11)

Related Reagents.

Isopropenyllithium; ***Vinylmagnesium Bromide***.

Isopropenyltriphenylphosphonium Bromide

[7301-95-3] · $C_{21}H_{20}BrP$ · Isopropenyltriphenylphosphonium Bromide · (MW 383.28)

(Michael-Wittig combinatorial reagent for preparation of 2-methyl allylic ethers,[1] 3-methyl-2*H*-1-benzopyrans,[1] 3-methyl-2-cyclopentenones,[2] 3-methyl-2,5-dihydrothiophenes,[3] and 1-methyltricyclo[3.2.1.$0^{2,7}$]octan-6-ones[4])

Alternate Name: ITB.

Physical Data: mp 195-197 °C.

Solubility: sol alcohol, CH_2Cl_2, DMF, DMSO.

Preparative Method: prepared by fusion of ***Triphenylphosphine*** with anhydrous ***Nickel(II) Bromide*** followed by addition of dry benzonitrile and azeotropic removal of the residual water, addition of 2-bromopropene, and heating of the resultant mixture from 50-80 °C to 200 °C over a period of 2 d.[1] Workup includes steam distillation to remove benzonitrile, filtration of a black insoluble material, and extraction of the filtrate with CH_2Cl_2. After drying and concentration at reduced pressure, the crude solid thus obtained is purified by recrystallization from CH_2Cl_2-EtOAc.

Michael-Wittig Chain Extension.

Although Michael addition of organolithiums to ITB had been known earlier,[5] the synthetic utility of ITB was only realized when Schweizer[1] reported his results on comparison studies of ITB with ***Vinyltriphenylphosphonium Bromide*** (VTB). As in the case of VTB, the treatment of ITB with sodium ethoxide and benzaldehyde in DMF gave the corresponding chain-extended product in 71% yield via the Michael-Wittig reaction sequence (eq 1).

Michael-Wittig Cyclization.

When the nucleophile used in the Michael-Wittig reaction sequence with ITB contains a carbonyl moiety, cyclization of the phosphorane intermediate occurs to give rise to a variety of methyl-substituted cyclic compounds. Thus 3-methyl-2*H*-1-benzopyran[1] (eq 2), 3-methyl-2,5-dihydrofuran[1] (eq 3), 2-methyl-3*H*-pyrrolizines[1] (eq 4), 3-methyl-2-cyclopentenones[2] (eq 5), and 3-methyl-2,5-dihydrothiophenes[3] (eq 6) can all be prepared.

R = Me, Et, C_5H_{11}

(6)

$R^1 = H$; $R^2, R^3 = -(CH_2)_5-$
$R^1, R^2 = -(CH_2)_4$; $R^3 = H$

Bicycloannulation of 2-cyclohexenones with ITB provides 1-methyltricyclo[3.2.1.0^{2,7}]octan-6-ones via Michael addition followed by intramolecular cyclopropanation (eq 7).[4] In addition, 3-methylpyrazole hydrobromide has been obtained via 1,3-dipolar cycloaddition of ITB with ***Diazomethane*** followed by thermal decomposition of the 1-pyrazoline cycloadduct (eq 8).[6]

Isopropyldiphenylsulfonium Tetrafluoroborate[1]

[1660-43-7] · $C_{15}H_{17}BF_4S$ · Isopropyldiphenylsulfonium Tetrafluoroborate · (MW 316.20)

(transformation of carbonyls to *gem*-dimethyloxiranes;[2] conversion of α,β-unsaturated systems[3] and diene esters[4] to geminal substituted cyclopropanes)

Preparative Methods: this reagent is not commercially available and must be made prior to use. The ylide isopropylidenediphenylsulfurane, obtained by deprotonation with an appropriate base, is usually formed in situ and used immediately because of its extremely low stability.[2] Two methods have been reported for the preparation of the sulfurane. Ethyldiphenylsulfonium tetrafluoroborate (formed by the reaction of diphenyl sulfide with triethyloxonium tetrafluoroborate, eq 1) is suspended in a solution of DME. The ylide is formed by addition of $LiCHCl_2$ at -70 °C and reacted with MeI (1.1 equiv). The desired sulfonium salt precipitates from solution. The isopropylidenediphenylsulfurane is formed by addition of LDA to this suspension at -78 °C (eq 2).[2]

A second, but less efficient, method of preparation involves the reaction of diphenyl sulfide, $AgBF_4$, and neat isopropyl iodide (eq 3).[2]

Three different base/solvent systems have been used to generate the isopropylidenediphenylsulfurane ylide: DME/$LiCHCl_2$, *t*-BuOK/THF,[5] and PhLi/THF.[6] All methods have proven equally efficient. Different diastereomer ratios have been obtained with the *t*-BuOK/THF method compared to the other systems.[7]

Reaction with Carbonyls to Form Oxiranes.

Addition of 1 equiv of benzaldehyde to a solution of the ylide, formed as described above, in DME at -60 °C results in the formation of the oxirane (eq 4) in 75-80% isolated yield.[2] Ketones may also react in good yields, but reaction times are somewhat longer.

(4)

Van Tamelen et al.[8] used isopropylidenediphenylsulfurane to synthesize radiolabeled 4-norsqualene 2,3-oxide (eq 5) and homosqualene oxide.

(5)

Reactions with α,β-Unsaturated Compounds.

If the carbonyl is α,β-unsaturated, reaction takes place at the alkene via addition/substitution to form *gem*-dimethyl-substituted cyclopropanes. For example, the *gem*-disubstituted cyclopropane was prepared from cyclohexenone in 74% yield (eq 6).[9]

(6)

Meyers et al. have reacted the ylide with a chiral bicyclic lactam to yield a tricyclic *gem*-disubstituted cyclopropane intermediate which, after four steps, gave deltamethric acid whose esters act as very potent insecticides (eq 7).[10]

(7)

In 1988, Krief et al. used isopropylidenediphenylsulfurane to synthesize (1*R*,3*S*),*cis*-hemicaronic aldehyde, a precursor to the (1*R*,3*S*),*cis*-dibromovinylchrysanthemic acid constituent of deltamethrin (eq 8).[6,11]

(8)

Wender et al. in 1989 used the ylide to synthesize an essential intermediate in the synthesis of phorbol (eq 9), a tumor promoter.[12]

(9)

Reaction with Diene Esters.

Rapoport et al. developed an elegant synthesis of the carene ring system via reaction of 1-ethoxycarbonyl-1,3-cyclohexadiene with isopropylidenediphenylsulfurane (eq 10).[4] The regiochemistry of the cyclopropane formation depends upon the solvent used in the reaction. This dependency of the regioisomer distribution provides a convenient route to either of the two carene ring systems.

(10)

Solvent	Ratio
DME	4:1
THF	1:2

(2,3-*O*-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane[1]

(*R*,*R*)

[32305-98-9] · $C_{31}H_{32}O_2P_2$ · (2,3-*O*-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane · (MW 498.57) (*S*,*S*)

[37002-48-5]

(chiral bidentate phosphine, useful in asymmetric catalysis[1])

Alternate Name: DIOP.

Physical Data: mp 88-89 °C; [α]20D -12.5° (*c* 4.6, C_6H_6).

Solubility: sol most usual organic solvents.

Form Supplied in: white solid; both enantiomers available.

Preparative Methods: can be prepared in four steps from diethyl tartrate.[2] The two phosphorus groups are introduced in the last step of the reaction sequence using $LiPPh_2$,[2] $KPPh_2$,[3] or $LiP(BH_3)PPh_2$.[4] DIOP has also been prepared from 1,2:3,4-diepoxybutane.[5]

Handling, Storage, and Precautions: air stable.

Introduction.

DIOP was the first example of a C_2 chelating diphosphine for transition metal complexes to be used in asymmetric catalysis. It was also one of the first examples of a useful C_2 chiral auxiliary.[6] DIOP can be considered as an example

of the first generation of chelating diphosphine ligands with a chiral carbon skeleton, which were followed over the next 20 years by many examples of chelating diphosphines, one of the most efficient of which is BINAP (***2,2´-Bis(diphenylphosphino)-1,1´-binaphthyl***).[1d] The ready availability of DIOP has stimulated research in asymmetric catalysis beyond the area of asymmetric hydrogenation.

Asymmetric Hydrogenation.

Conjugated acids (eq 1)[2,7] or various α-*N*-acyldehydroamino acids (eq 2)[2,8,9] are structural units which sometimes give quite high ee's in the presence of rhodium complexes formed in situ (such as Rh(Cl)(cod)(DIOP)) or isolated as cationic complexes, for example $[Rh(cod)(DIOP)]^+ PF_6^-$. Hydrogenation of *N*-acetamidocinnamic acid using $[Rh(DIOP)_2]^+ BF_4^-$ instead of $[Rh(cod)(DIOP)]^+ BF_4^-$ as catalyst (80 °C, 1 bar H_2) gives a slower reaction but with a significant increase in the ee (94% ee instead of 82% ee).[10]

(1)

R = Ph	benzene-EtOH	95%	63% ee
R = 	*i*-PrOH	97%	88% ee

(2)

R = H	95%	73% ee
R = Ph	90%	82% ee

Enamides lacking a carboxy group on the double bond also act as excellent substrates in asymmetric hydrogenations, as exemplified in eq 3.[11]

R = Et	90%	90% ee
R = Me	90%	92% ee

Ketones are known to be quite unreactive in homogeneous hydrogenations catalyzed by rhodium complexes. However, catalytic amounts of a base enhance the reactivity. In this way, acetophenone is hydrogenated to 2-phenylethanol in 80% ee in the presence of [Rh(Cl)(cod)(DIOP)]/NEt_3[12] or $N(CH_2OH)_3$.[13] Aromatic α-amino ketones are reduced to the alcohols with high ee's. For example, 2-naphthyl-*N*,*N*-diethylaminoethanol is produced in 95% ee by hydrogenation of the corresponding ketone.[13] Imines are very difficult to hydrogenate in the presence of rhodium catalysts, including [Rh(Cl)(cod)(DIOP)].[1] However, it was recently discovered that iridium complexes with a chiral chelating diphosphine are selective catalysts for the hydrogenation of imines. DIOP gives the best result (63% ee) for the reduction of $RN{=}C(Me)CH_2OMe$ (R = 2,5-$Me_2C_6H_3$).[14]

Asymmetric Hydrosilylation.

Hydrosilylation of ketones catalyzed by chiral metal complexes, followed by hydrolysis, produces enantiomerically enriched alcohols. Rhodium complexes with chiral chelating diphosphines have been used successfully. In this context, DIOP was one of the ligands investigated. Aryl alkyl ketones provide the corresponding alcohols in low ee with Ph_2SiH_2, but α-$NpPhSiH_2$ gives ee's in the range of 50-60%.[12] This silane is also excellent for hydrosilylation of *i*-butyl levulinate (84% ee) and *n*-propyl pyruvate (85% ee).[15] Imines are transformed into amines (ee <= 65%) by Ph_2SiH_2 with a rhodium-DIOP catalyst.[16]

Asymmetric Hydroformylation.

DIOP was very useful in the early stages of investigation of asymmetric hydroformylation of alkenes in the presence of rhodium or palladium catalysts. The combination of $PtCl_2$(diphosphine) and $SnCl_2$, where the diphosphine is a DIOP derivative (DIPHOL, eq 4), is an excellent system, although requiring high pressures.[17] In the case of the hydroformylation of styrene, the branched aldehyde is the major product. The various hydroformylations or hydroesterifications have been reviewed.[1e] Asymmetric hydroformylation of *N*-acylaminoacrylic acid esters is efficiently catalyzed by $[Rh(CO)(PPh_3)_3]$ + DIOP, giving the branched aldehyde in 60% ee.[18]

(2,3-O-Isopropylidene)-2,3-dihydroxy-1,4-bis(diphenylphosphino)butane

Asymmetric Hydroboration.

Hydroborations of alkenes by catecholborane have been catalyzed by [Rh(Cl)(cod)(diphosphine)].[19] For example, norbornene gives, after oxidation, *exo*-norborneol (82% ee) when a DIOP derivative (2-MeO-DIOP) was used (eq 5). Lower ee's were observed with DIOP, DIPAMP, and BINAP. The effectiveness of DIOP was also noticed in another report.[20]

Miscellaneous Reactions.

Hydrocyanation of norbornene is catalyzed by [Pd(DIOP)$_2$], leading to *exo*-2-cyanonorbornane (16% ee), while [Pd(BINAP)$_2$] gives 40% ee.[21] An asymmetric rearrangement was catalyzed by a nickel(0) complex bearing a diphosphine ligand (eq 6).[22] A DIOP derivative (MOD-DIOP) was more efficient than DIOP or BINAP. MOD-DIOP has previously been found to improve the enantioselectivity, with respect to DIOP, in rhodium-catalyzed

hydrogenation of conjugated acids (ee's 90-95%).[23] Structural modifications of DIOP are very easy to perform by changing the nature of the aromatic rings or the acetal group, allowing tuning of the enantioselectivity. Many publications describe modified DIOP derivatives. DIOP has been utilized in several stoichiometric reactions, for example in an intramolecular Wittig reaction for the synthesis of the bis-nor-Wieland-Miescher ketone (52% ee).[24]

Isopropylidenetriphenylphosphorane

[16666-80-1] · $C_{21}H_{21}P$ · Isopropylidenetriphenylphosphorane · (MW 304.39)

(highly reactive phosphorus ylide used in natural product alkene formation[1-3] and *gem*-dimethylcyclopropane formation[4])

Physical Data: red-colored ylide in solution.

Solubility: sol THF, DMSO, toluene, diethyl ether. *Drying:* the precursor phosphonium salt should be vacuum dried before use to drive off any residual water.

Preparative Methods: prepared in situ from commercially available isopropyltriphenylphosphonium iodide or bromide and an appropriate base. An isopropyltriphenylphosphonium bromide-sodium amide instant ylide[5] pre-mix is also available.

Handling, Storage, and Precautions: should be used immediately after formation. Most ylide solutions slowly decompose with time.

Wittig Reaction.

Many natural products have an alkene terminus substituted with two methyl groups, and isopropylidenetriphenylphosphorane (**1**) has proven ideal for its construction. Terpenoids,[1] pheromones,[2] and other natural products[3] with this substitution pattern have successfully been synthesized using this reagent (eq 1).

(1)

(±)-Oppositol

Tetrasubstituted alkene natural products have been obtained when isopropylidenetriphenylphosphorane reacts with cyclic ketones[6] (eq 2) and benzophenone.[7] Very few Wittig reagents are sufficiently reactive to allow formation of tetrasubstituted alkenes, and even the highly reactive (**1**) will fail to couple with hindered ketones.[8] Oxaphosphetanes are the only observable intermediates in the reactions of (**1**) with aldehydes[9] and ketones.[10] A single-electron transfer (SET) mechanism has been offered for oxaphosphetane formation in the reaction of both aldehydes[11] and ketones[7,8b] with (**1**).

(2)

α-Bulnesene

Wittig reaction with (**1**) also occurs with lactols[12] to give alkenes, with acyl chlorides to give allenes,[13] with isocyanates to give ketenimines,[14] and with imidates to give azadienes.[15] With this phosphorane, 1,2,3-tricarbonyl compounds give alkenes at the reactive central carbon,[16] and (cyclobutadienecarbaldehyde)irontricarbonyl gives a (vinylcyclobutadiene)iron tricarbonyl complex.[17] Isopropylidenetriphenylphosphorane reacts with ***Borane-Dimethyl Sulfide*** to give a triphenylphosphine-monoalkylborane adduct, which can undergo hydroboration reactions.[18] The reagent can react sequentially with an anhydride and an alkyllithium to generate alkenes (eq 3).[19]

Cyclopropane Formation.

Isopropylidenetriphenylphosphorane can add to activated double bonds, such as α,β-unsaturated esters, to give *gem*-dimethylcyclopropanes after elimination of triphenylphosphine.[20] If an aldehyde is also present in the conjugated π-system, the Wittig reaction can compete with the cyclopropanation reaction (eq 4).[4] The initial lithium halide-betaine complex can decompose directly to the dienoic ester, which undergoes no further reaction. Addition of a second equivalent of (**1**) to the lithium halide-betaine complex allows cyclopropane formation to occur. Ratios of the dienoic ester and the cyclopropane are solvent and base dependent.

Tandem cyclopropanations can occur with dienoic esters.[21] Racemic,[22] chiral,[23] and deuterated[24] chrysanthemic acid esters are readily prepared with isopropylidenetriphenylphosphorane. 2-Metallo-2-nitropropanes afford *gem*-dimethylcyclopropanes in comparable yields.[25] Other methods to introduce a *gem*-dimethylcyclopropane structure include replacement of bromine in *gem*-dibromocyclopropanes[26] and the reaction of chromium(II) salts and 2,2-dibromopropane with alkenes;[27] however, disposal of heavy metal salts is necessary with these alternative methods. The highly reactive isopropylidenetriphenylphosphorane has been shown to react with a triene to give a cyclopropane in 75% yield.[28]

Isopropylmagnesium Bromide[1]

***i*-PrMgX**

(X = Br)

[920-39-8] · C_3H_7BrMg · Isopropylmagnesium Bromide · (MW 147.31) (X = Cl)

[1068-55-9] · C_3H_7ClMg · Isopropylmagnesium Chloride · (MW 102.86)

(adds to many unsaturated functional groups; isopropyl can displace halide and like groups; functions as a strong base and a Lewis acid[1b-f])

Physical Data: *i*-PrMgCl is mainly dimeric in Et_2O.[2]

Solubility: *i*-PrMgBr and *i*-PrMgCl are sol Et_2O, THF; insol hydrocarbons.

Form Supplied in: solutions of *i*-PrMgCl in Et_2O and THF are commercially available.

Analysis of Reagent Purity: see ***Methylmagnesium Bromide***.

Preparative Methods: in spite of the commercial availability of *i*-PrMgCl solutions, *i*-PrMgBr[4] and *i*-PrMgCl are often prepared from reaction of an isopropyl halide and Mg, usually in Et_2O or THF.[1c,e,3]

Handling, Storage, and Precautions: see ***Methylmagnesium Bromide***. Isopropyl Grignard reagents do not significantly attack Et_2O or THF at normal reaction temperatures.

Representative Applications.[1b-f]

See also ***Methylmagnesium Bromide***. An isopropyl Grignard reagent is used most frequently in reactions that result in attachment of its organic group to an electrophilic carbon atom of the substrate, most often of a carbonyl group, nitrile, or other unsaturated function. The reaction with a chiral ketone (eq 1) serves as a reminder that, particularly with hindered substrates, isopropyl and other secondary Grignard reagents (see also ***t-Butylmagnesium Chloride***) can act significantly by transfer of an H atom rather than an alkyl group.[5]

i-PrMgBr, THF, -78 °C	29%	69:31	51%
MeMgBr, THF, -78 °C	99%	100:0	0%
MeLi, Et_2O, toluene, -83 °C	97%	57:43	0%

Related Reagents.

Isoselenocyanatotrimethylsilane[1]

$Me_3SiN{=}C{=}Se$

[16966-40-8] · C_4H_9NSeSi · Isoselenocyanatotrimethylsilane · (MW 178.19)

(chemoselective cyanosilylation of aldehydes;[2] selenocyanosilylation of oxiranes and oxetane[3])

Alternate Name: trimethylsilyl isoselenocyanate.

Physical Data: mp 5 °C; bp 175-177 °C, 65 °C/20 mmHg, 75-76 °C/30 mmHg; *n*20D 1.5153; *d*204 1.228 g cm^{-3}.

Solubility: sol most aprotic solvents: hexane, benzene, CH_2Cl_2, THF, MeCN, etc.

Preparative Methods: by reactions of Me_3SiCl or Me_3SiI with KSeCN or AgSeCN. The following simple method is recommended: a mixture of ***Chlorotrimethylsilane*** (10 mmol), ***Potassium Selenocyanate*** (18 mmol; dried at 90 °C under vacuum (0.05 mmHg) for 4 h), and hexane or CH_2Cl_2 (20 mL) is stirred for 5 h at rt. After filtration and removal of the solvent, the residue is distilled under vacuum.

Handling, Storage, and Precautions: strongly sensitive to moisture and air; its preparation should be carried out under a nitrogen atmosphere; a one-pot procedure is recommended in which $Me_3SiNCSe$ is not isolated and the substrate is added to the isoselenocyanate reaction mixture.

Chemoselective Cyanosilylation of Aldehydes.[2]

There is virtually no reaction between the title reagent and aldehydes in the absence of catalyst. ***Zinc Chloride*** and KSeCN increase the reaction rate, whereas KSeCN/18-crown-6 has a slight rate-diminishing effect. The reaction proceeds smoothly only in nonpolar solvents such as hexane and CH_2Cl_2, giving the corresponding *O*-silylated cyanohydrins (eq 1).

No reaction takes place with ketones and the reaction is very slow with aromatic aldehydes and α,β-unsaturated aldehydes. Consequently, highly chemoselective cyanosilylation of aldehydes is achieved: the results of competition experiments between hexanal and 2-heptanone (1:1 mixture, eq 2), between hexanal and benzaldehyde (1:1 mixture, eq 3), and between propionaldehyde and crotonaldehyde (1:1 mixture, eq 4) are summarized. The use of ***Cyanotrimethylsilane*** in place of the title reagent leads to lower chemoselectivities. Unfortunately, only slight chemoselectivity is achieved between hexanal and isobutyraldehyde (eq 5).

(3)

98:2

(4)

98:2

(5)

Ring Opening of Oxiranes and Oxetane.[3]

The reaction with oxiranes gives trimethylsiloxyalkyl selenocyanates (eq 6) in good to excellent yields. KSeCN, KSeCN/18-crown-6, KSeCN/XAD-4 (KSeCN impregnated on Amberlite XAD-4 resin), $ZnCl_2$, and Ti(O-*i*-Pr)$_4$ promote the reaction.

(6)

In general, the reaction proceeds smoothly in polar solvents such as MeCN. The reaction of 1,2-epoxyalkanes having a substituent at the C-3 position gives products in which the epoxide is opened selectively at the less-hindered carbon (product **1** in eq 6). On the other hand, the reaction of 2-phenyloxirane or 2,2-dimethyloxirane gives a mixture of regioisomers, the ratio of which depends on the catalyst and the solvent (eqs 7 and 8). The reaction of oxetane produces 3-trimethylsiloxypropyl selenocyanate in excellent yield.

(7)

KSeCN, hexane, 60 °C, 7 h	75:25	93%
Ti(O-*i*-Pr)$_4$, hexane, 40 °C, 0.5 h	3:97	72%

KSeCN/XAD-4, hexane, 60 °C, 7 h	82:18	84%
Ti(O-*i*-Pr)$_4$, hexane, 40 °C, 3 h	34:66	71%
KSeCN, MeCN, 60 °C, 2 h	37:63	66%

Itaconic Anhydride

[2170-03-8] · $C_5H_4O_3$ · Itaconic Anhydride · (MW 112.09)

(asymmetrical unsaturated anhydride; used as a dienophile[5] and in reactions with various nucleophiles[9,10])

Physical Data: mp 70-72 °C; bp 114-115 °C/12 mmHg.

Form Supplied in: white solid; widely available.

Preparative Methods: besides its synthesis from citric acid,[1] itaconic anhydride (**1**)[2] can also be prepared by chemical dehydration of itaconic acid.[3] The thermal isomerization of itaconic anhydride to citraconic anhydride (**2**) is facile.[4]

Handling, Storage, and Precautions: moisture sensitive; irritant.

Pericyclic Chemistry.

Diels-Alder chemistry employing (**1**) as a dienophile is well developed. ***Cyclopentadiene*** has been used to protect the exocyclic methylene of (**1**) with regeneration of the alkene moiety via a retro-Diels-Alder thermolysis.[5] By operating at 6.5 kbar for 8-10 d, excellent regioselectivity and face selectivity has been obtained in the reaction of (**1**) with the chiral diene (**3**).[6] Itaconic anhydride, with its conjugated carbonyl group participating in secondary orbital overlap, undergoes 1,3-dipolar cycloaddition (eq 1) with the nitrone (**4**) to afford (**5**).[7]

(3)

(1)

(4) (1) (5)

Reaction with Nucleophiles.

Because a variety of 2-methylenebutanedioic acids and acid derivatives display useful[8] pesticidal, herbicidal, and growth-regulatory activities, much effort has gone into exploring the reaction of the anhydride moiety with nucleophiles. Ring opening of (**1**) is highly regioselective. Thus (**1**) reacts with alcohols[9] to afford (**6a**) (with preferred addition at the unconjugated carbonyl). With amines,[10] similar regioselectivity affords the corresponding amides (**6b**). Reaction with hydroxylamine derivatives gives acids (**6c**), imides, or isoimides depending on conditions.[10b] Friedel-Crafts acylation of (**1**)[11] yields the ring-opened product (**7**) involving acylation at the less-substituted carbonyl.

(6a) X = OR
(6b) X = NH_2, NHR, NR_2
(6c) X = NHOR

(7)

Miscellaneous Chemistry.

Halogenation of (**1**) yields halomethylmaleic anhydrides (**8**).[12] Asymmetric hydrogenation of (**1**) has been explored.[13] Hydrocobaltation of (**1**) gives (**9**).[14] Reaction of (**1**) with thiourea in water or in acetic acid produces a variety of

heterocycle products,[15] as does the reaction of (**1**) with enamino esters.[16]

Ketene[1]

$H_2C=C=O$

[463-51-4] · C_2H_2O · Ketene · (MW 42.04)

(mild acetylating reagent;[1] performs [2 + 2] cycloadditions with alkenes and alkynes;[1c] performs nucleophilic addition to acetyl chlorides;[2] capable of certain organometallic transformations[3])

Physical Data: mp -150 °C; bp -56 °C.

Solubility: generally introduced as a gas but is soluble in a wide variety of solvents.

Preparative Methods: by the thermal decomposition of acetone,[4] diketene,[5] acetic anhydride,[6] alkoxy[7] or siloxy acetylenes,[8,9] and carboxylic acid over zeolites.[10] Acetic anhydride gives the purest stream of this gas. The use of acetone, diketene, or acetic acid may leave impurities such as acetone and carbon monoxide.

Handling, Storage, and Precautions: poisonous gas with a toxicity approximately eight times greater than phosgene.[11] All operations utilizing ketene should be carried out in an appropriate isolated apparatus in a well-ventilated fume hood.[5,11]

Acetylating Reagent.

The electrophilic nature of the sp carbon in ketene makes it a powerful yet mild acetylating reagent.[1,12,13] Unlike other reagents such as ***Acetic Anhydride***, ketene has no leaving group; the opening of the double bond being its equivalent.[14] This feature ensures fewer byproducts in the reaction mixture, allowing for easier purification of the product. Ketene will acetylate a wide variety of functional groups, including carboxylic acids, alcohols, amines, amides, thiols and 1,3-dione systems.[1a,14-16] One of the more recent uses of ketene in this area is the acetylation of β-diketone Cu^{II} intermediates (eq 1).[12] This reaction proceeds quickly at room temperature, without the need of a catalyst, the sole product being that arising from *C*-acetylation. Other attempts to introduce substitution into this system using alternative reagents not only required higher temperatures and the use of catalysts, but have resulted in the formation of both *C*- and *O*-acetylated products.[17,18] These reactions also resulted in the loss of the Cu-O bond, which the ketene reaction does not affect.

Ketene has also been used in acetylating cyclic diones to form the corresponding 1,3-cycloalkadienes (eq 2).[15,16] The formation of the 1,3-cycloalkadienes was previously accomplished by a Birch reduction of the corresponding aromatic derivatives.[15] For rings larger than six atoms in size, the use of ketene will result in *C*-acetylation as well as *O*-acetylation, and ***Isopropenyl Acetate*** has been shown to be more effective in this case.

Ketene is also a good acetylating reagent in reactions where the starting material has been absorbed onto a solid medium. The acetylation of phenol usually requires the use of high temperatures and a catalyst.[19] Even under these conditions, the reaction proves to be inconsistent. If phenol is first absorbed onto silica, however, acetylation may take place in good yield by passing a stream of ketene through the medium as a gas at room temperature. Phenol derivatives absorbed on alumina have also been shown to acetylate quantitatively at 0 °C when exposed to ketene gas.[19] This reaction has been shown to be quite versatile and may accommodate a wide variety of alcohols on many absorbants including celite, magnesium oxide, and zinc oxide.[20] The ease of acetylation using ketene may also be shown by the following example (eq 3). The thermal fragmentation of 1-alkoxyalkynes in chloroform allows for the easy formation of ketene in situ. When this process is carried out in the presence of an amine, the ketene is trapped upon formation, giving the resulting amide.[7] As shown in eq 3, this reaction offers a mild process for acetylation which should be suitable for a wide variety of nucleophiles.[7]

(3)

$R^1 = H, i\text{-Pr}$
$R^2 = C_6H_{13}, t\text{-Bu}, HOCH_2CH_2, Bn, Ph, i\text{-Pr}, Cy$

Cycloadditions.

Cycloaddition involving ketene and its derivatives is probably the most characteristic reaction involving this reagent. Examples of 1,2-cycloaddition to form four-membered rings are known to occur between ketene and C&tbond;C, C=C, C=O, C=N, C=S, N=N, N=O, N=S, and P=N groups.[1c,1a] These reactions are generally considered to proceed via a $_{\pi}2_s + {}_{\pi}2_a$ thermally allowed cycloaddition following the Woodward-Hoffmann rules.[1c] The cycloaddition proves to be highly selective,[13] the most nucleophilic alkenic carbon becoming bonded to the sp carbon of ketene in the product. Addition occurs with retention of configuration of the alkene.[1a] In many cases, ketene proves to be too unreactive for the task at hand and ***Dichloroketene*** has become the reagent of choice in recent years. The relative reactivities of some ketenes in reference to cycloadditions are shown in Scheme 1.[1a]

$$Cl_2C{=}{=}O \;>\; Ph_2C{=}{=}O \;>\; Me_2C{=}{=}O \;>\; H_2C{=}{=}O$$

Scheme 1

Alkene Addition.

There are few examples of alkene addition to ketene itself. The alkene generally has to be activated either through the use of an EDG or strain in the system, such as the case with cyclopentadiene (eq 4)[21,22] and 1,3-cyclohexadiene (eq 5).[22] Linear conjugated dienes will sometimes react with ketene but yields are generally quite low and the reaction is not synthetically useful. Again, dichloroketene is generally used in this case due to its greater reactivity (eq 6).[1c,23]

(4)

(5)

(6)

One example of the use of ketene with an activated alkene is in the case of vinyl ethers.[24,25] Staudinger had shown in 1920 that ***Diphenylketene*** would add to ethyl vinyl ether to form the 1,2-cycloaddition product.[1c] This reaction was repeated by others,[26,27] and in 1960 Hurd was able to show that ketene itself would also add to a vinyl ether.[24] Seija built upon this methodology later when he used a variety of vinyl ethers along with ketene to gain access to the synthetically interesting bicyclo[1.1.0]butane systems, as shown in eq 7.[25] The reaction is regiospecific in that the methylene group in the product is bonded to the carbon attached to the ether oxygen.[24,25]

(7)

Alkyne Addition.

The alkyne bond is sufficiently high in energy to perform 1,2-cycloadditions with ketene in the formation of cyclobutenones.[28] Wasserman[29] and Pericás[30] utilized this reaction in the formation of 1,3-cyclobutanedione. The latter synthesis used the alkyne as a source of ketene as well as the cycloaddition partner (eq 8). More recently, siloxyalkynes have been shown to undergo the same type of reaction utilizing a wide variety of R groups (eq 9); a multitude of cyclobutenone systems can thereby be constructed.[31]

(8)

(9)

C=X Cycloaddition.

The cycloaddition reaction of ketene to a C=O bond is a very synthetically useful reaction which allows formation of the 2-oxetanone system (β-lactone).[1] The rate of reaction is controlled somewhat by the polarization of the carbonyl bond. The greater the positive charge of the carbonyl carbon, the greater the rate of reaction.[32] The cycloaddition of ketene with the carbonyl bond requires a catalyst for reaction to occur.[1a] Ketene will readily couple with chloral in the presence of a catalyst to form β-(trichloromethyl)-β-propiolactone.[33] Using chiral cinchona alkaloid catalysts, it is possible to form the chiral 4-(trichloromethyl)-2-oxetanone beginning with ketene and chloral. Acid hydrolysis of the cyclic product allows the formation of optically pure (*S*)- or (*R*)-malic acid in 79% yield (eq 10).[32,34]

(10)

This compares quite well with more involved routes which begin with chiral tartaric acids[35] or the use of enzymatic catalysts, which allow for synthesis of the (*S*)-isomer but not the unnatural (*R*)-isomer.[36] Chiral polymeric cinchona alkaloids have also been employed in the reaction.[37] The use of polymeric catalysts allows greater ease of recycling and in some cases, such as poly(cinchona alkaloidacrylate), the enantioselectivity and yields were comparable to their monomeric counterparts.[37]

The cycloaddition of ketene to a C=N bond was first discovered by Staudinger in 1907 and is often referred to by that name.[38] The reaction proceeds regioselectively via a nonconcerted mechanism to give the β-lactam (eq 11).[39-41] Ketene itself is quite unreactive towards the imine group;[1c,42] however, reactions with the disubstituted ketenes proceed well.[42] Among the more popular ketenes utilized for this reaction are diphenyl-, chlorophenyl-, and dibromoketene.[42]

(11)

Diazomethane Cycloaddition.

The reaction of ketene with ***Diazomethane*** offers a simple, high yielding synthesis of cyclopropanone, a molecule of both theoretical and synthetic interest.[43] In the presence of methanol and excess ketene, cyclopropanone may be further acetylated, as shown in eq 12. Reaction with excess diazomethane results in the formation of cyclobutanone.[43,44] Earlier methods to prepare cyclopropanone from cyclobutanediones met with little success.[45]

(12)

1,3- and 1,4-Cycloaddition.

Cyclizations of this type are quite rare using ketene itself, although ketene derivatives have been known to undergo 1,3- and 1,4-cyclizations.[1]

Allene Formation.

The reaction of ketene with an ylide proves to be a convenient method for the formation of allenes. In the reaction with the ylide shown in eq 13, the α-vinylidene-γ-butyrolactone, which holds biological interest, may be formed in high yield.[46]

(13)

The same methodology has been employed in more complex systems, such as the formation of 4,5-dihydropyrazolo[1,5-*a*]pyridine beginning with azine phosphoranes (eq 14).[47]

(14)

If a ketene derivative is utilized (phenylacetoxyketene or monophenyoxyketene), the product will spontaneously eliminate acetic acid or phenol to aromatize, giving the pyridine ring.[47] The ability to use either ketene or its derivatives offers good flexibility in the synthesis of these molecules.

Organometallic Compounds.

Although not as well known as the organic chemistry of ketene, the organometallic chemistry of ketene does occur in a wide variety of systems.[3] An example is the insertion of ketene into metal hydrides, as shown in eq 15.[3,48]

(15)

Ketene will also insert into metal-alkyl bonds.[3] The mechanism of these reactions is unknown, but it should be noted that the products follow the same type of pattern as the acetylation reactions. Some more recent work in the organometallic area is the formation of disilver ketenide (eq 16).[49] This complex was formed via reaction of silver

acetate with ketene gas formed from pyrolysis of acetone or via in situ formation of ketene using acetic anhydride. The latter method could be run at temperatures as low as -28 °C in the presence of an amine base for a catalyst. The reaction was also run using enol acetates as the ketene source.[49] The formation of this complex shows the potential carbon acidity of the hydrogen atoms attached to ketene. The silver ketenide complex is quite stable but undergoes the transformations shown in eqs 17-19.

Although silver ketenide is more inert than expected, it has the potential of being a useful synthetic reagent for the introduction of disubstituted ketenes or regeneration of ketene itself.[49]

Ketene as a Nucleophile.

In acetylation reactions, ketene behaves as an electrophilic agent, but in the presence of hemiacetal chlorides,[2] acid chlorides, acetals,[2] etc., ketene behaves as a nucleophile. In a study by Hurd and Kimbrough, ketene was mixed with the hemiacetal chloride in the presence of ***Zinc Chloride*** to give, after workup, the corresponding acid.[50] Hurd went on to extend the study to acetals as well as the chloro derivatives.[2] More recently, Goure reacted ***Trifluoroacetyl Chloride*** with ketene followed by addition of ethyl 3-amino-4,4,4-trifluoro-2-butenoate. Subsequent rearrangement of this intermediate led to the pyridinecarboxylate in 86% yield.[51] The use of ketene in this reaction allows a two-step, one-pot synthesis of the previously unknown 2-hydroxy-4,6-bis(trifluoromethyl)pyridine-5-carboxylate (eq 20). Other methods utilized to form this compound lack the ability to incorporate a functional group in the 5 position of the pyridine ring.[51,52]

Miscellaneous.

Recently, ketene has become a tool for mechanistic probes and the formation of high energy molecules. It is known that the transformation of methanol to hydrocarbons goes through a ketene intermediate at some point. With this in mind, the thermal decomposition of ketene is being studied on metal surfaces in an effort to further elucidate this, as yet, unknown mechanism.[53,54]

Ketene is also used to form singlet methylene ($^1CH_2$) in an effort to study the insertion reactions of this short-lived intermediate.[55] Its use is also noted in the formation of distonic ions: ions that have a separated charge and radical site. The use of ketene in this instance offers an advantage over the known methods in that it allows greater ease of formation of the distonic ions and greater flexibility over the type of ion formed.[56]

Ketene Bis(trimethylsilyl) Acetal[1,2]

(R = Me)

[24697-35-6] · $C_8H_{20}O_2Si_2$ · Ketene Bis(trimethylsilyl) Acetal · (MW 204.46) (R = Et)

[24697-36-7] · $C_{14}H_{32}O_2Si_2$ · Ketene Bis(triethylsilyl) Acetal · (MW 288.64)

(stable equivalent of acetic acid dianion; enolate surrogate useful for aldol reactions[6] and similar Mukaiyama reactions; inverse-electron-demand dienophile for Diels-Alder reactions[8])

Alternate Name: 1,1-bis(trimethylsiloxy)ethylene.

Physical Data: R = Me, bp 50 °C/10 mmHg; R = Et, bp 77 °C/1 mmHg.

Solubility: freely sol organic solvents.

Form Supplied in: clear colorless liquid.

Analysis of Reagent Purity: NMR in dry (molecular sieves) solvent (data in Ainsworth and Kuo[3]). Likely impurities are trimethylsilyl (trimethylsilyl)acetate (bp 61 °C/10 mmHg) and α-trimethylsilylacetic acid.

Preparative Methods: disilylation of acetic acid dianion and silylation of the enolate of trimethylsilyl acetate are problematic because a mixture of *O*- and *C*-silyl compounds is generated in roughly equal proportions (eq 1)[3] and these isomers are nearly inseparable.

The reaction conditions can be modified to produce either of these compounds in good yields (eqs 2 and 3).[2] Rapid generation, and the subsequent quenching of the highly dissociated sodium enolate, at low temperature, is important for the preponderant formation of the *O*-silyl product.[4] In a related reaction, trimethylsilyl acetate upon reaction with excess of ***Triethylamine*** and ***Trimethylsilyl Trifluoromethanesulfonate*** gives a mixture of two bis-silylated isomers (eq 4).[5]

The first synthesis of the ketene bis(triethylsilyl) acetal involved the treatment of triethylsilyl α-(triethylstannyl)acetate (**3** in eq 6) with triethylsilyl iodide.[1] The intermediate (**3**) in turn was prepared from ketene and triethylsilyloxytriethylstannane (eq 5).

Handling, Storage, and Precautions: flammable; extremely moisture-sensitive. Use in a fume hood.

O to *C* Migration.

In contrast to the alkyl trialkylsilyl ketene acetals, the thermal *O* to *C* migration is sluggish in the case of ketene bis(trialkylsilyl) acetals. Yet the migration can be effected by heating the compound to temperatures above 170 °C. The reaction can be facilitated by addition of catalytic amounts of HgI_2, ***Chlorotrimethylsilane***, or ***Iodotrimethylsilane*** (eq 7).[1]

Electrophilic Reactions.

Bis(trimethylsilyl) acetal (**1**) adds to cinnamaldehyde to give exclusive 1,2-addition upon treatment with ***Titanium(IV) Chloride*** (eq 8). The same product can be prepared by reaction of the *C*-silyl compound (**2**) with the aldehyde in the presence of ***Tetra-n-butylammonium Fluoride*** (eq 8).[6]

Ketene acetal (**1**) reacts with dry ***Sulfur Dioxide*** to give trimethylsilyl [(trimethylsilyloxy)carbonyl]methanesulfinate (eq 9).[7] Reaction with $SiCl_4$ produces 1,1-bis(trimethylsilyloxy)-2-trichlorosilylethylene (eq 10).[1]

Cycloaddition Reaction.

Bis(trialkylsilyl) acetal (**1**) is an excellent inverse-electron-demand dienophile, as illustrated by the [4 + 2] cycloaddition reaction (eq 11).[8] Note that the initial adduct readily loses N_2 and subsequently, the elements of TMS-OH. With 3,6-bis(methoxycarbonyl)-1,2,4,5-tetrazine, compound (**1**) reacts 6 times faster than ethylene and about 30 times faster than styrene or 1-trimethylsilyloxyethylene at 20 °C in dioxane.

Ketene *t*-Butyldimethylsilyl Methyl Acetal[1]

[91390-62-4] · $C_9H_{20}O_2Si$ · Ketene *t*-Butyldimethylsilyl Methyl Acetal · (MW 188.34)

(silylation of a variety of substrates;[3] promotion of Pummerer reaction of sulfoxides;[4-8] Lewis acid mediated aldol-type[8-22] and Michael additions,[31-38] under either stoichiometric or catalytic conditions)

Physical Data: colorless liquid; bp 76-76.5 °C/24 mmHg.

Solubility: sol *n*-pentane, diethyl ether, dichloromethane, etc.

Analysis of Reagent Purity: (NMR) ^{1}H 0.14 (s, 6H), 0.93 (s, 9H), 2.95 (d, 1H, J = 3.0 Hz), 3.10 (d, 1H, J = 3.0 Hz), 3.49 (s, 3H) ppm.

Preparative Method: obtained by reaction of methyl acetate with ***Lithium Diisopropylamide*** in THF/HMPA and subsequent trapping with ***t-Butyldimethylchlorosilane*** (72% yield).[2]

Handling, Storage, and Precautions: should be stored in the absence of moisture at -15 °C.

Silylation.

The reagent silylates a variety of substrates (alcohols, acids, thiols, phenols, imides) under mild conditions (a catalytic amount of ***p-Toluenesulfonic Acid*** is occasionally added) with excellent yields (91-100%).[3]

Pummerer Reaction.

The reagent transforms sulfoxides in the presence of catalytic amounts of ***Zinc Iodide*** into the corresponding α-silyloxy sulfides (eq 1).[4] Vinyl sulfoxides undergo a Michael-Pummerer type reaction to give γ-silyloxy-γ-phenylthio esters (eq 2).[5]

(1)

(2)

As an extention of this reaction, the reagent promotes the intramolecular Pummerer-type rearrangement of o-carbamoyl sulfoxides to give α-thio lactams.[6] The reaction proves particularly useful in the field of β-lactam synthesis (eq 3).[7,8a]

(3)

Addition to C=X Double Bonds (X = N, O).[1b]

The reagent undergoes Lewis acid catalyzed Mukaiyama-type additions[1b] to azetinones, or their corresponding iminium ions, to give *trans*-azetidin-2-one esters with good yields and excellent stereoselectivity (eq 4).[7b,8,9]

In the presence of a diphosphonium salt (7 mol %),[10a] ***Trimethylsilyl Trifluoromethanesulfonate*** (10 mol %),[10b] or ***Iron(III) Nitrate-K10 Montmorillonite Clay***,[10c] the reagent adds to imines or *N*-tosyliminium ions to give the corresponding β-amino esters in good yield.

ZnI_2-catalyzed additions of the reagent to chiral α,β-dialkoxy nitrones (eq 5; R^1 = H) proceed with good yield (86-100%) and high diastereoselectivity (ca. 90:10) in favor of the *syn* isomer (R^1 = H, R^2 = CH_2Ph, R^3 = Me). The *anti* isomer is obtained (ca. 90:10) by increasing the steric hindrance of R^2 and R^3 (R^2 = $CHPh_2$, R^3 = *t*-Bu).[11a,b] Addition to a different nitrone (eq 5; R^1 = Me) gives the *anti* isomer (R^1 = Me, R^2 = CHMePh, R^3 = Me) in quantitative yield and 100% diastereofacial selectivity. This material has been further elaborated to *N*-benzoyl-L-daunosamine.[11c,d]

New catalysts have been recently developed for promoting the aldol-type addition of acetate-derived silyl ketene acetals with high efficiency: 10-methylacridinium perchlorate (5 mol %),[12a] cationic mono- and dinuclear iron complexes (5 mol %),[12b] *t*-butyldimethylsilyl chloride-indium(III) chloride (10 mol %),[12c] [1,2-benzenediolato(2-)-*O*,*O*´]oxotitanium (20 mol %),[12d] phosphonium salts (7 mol %),[12e] and trityl salts (5-20 mol %).[12f-i] The reagent undergoes Lewis acid promoted Mukaiyama-type additions[1b] to chiral aldehydes with moderate to good stereocontrol (eq 6).[13] It is remarkable that high chelation control can be obtained by using a catalytic amount (3 mol %) of ***Lithium Perchlorate***.[13e,f]

R	R^1	Promoter	R^2	Ratio	Yield (%)
Ph	Me	$BF_3 \cdot OEt_2$	*t*-Bu	97: 3	81[13a]
Ph	Me	10 kbar, 50 °C	Me	71:29	73[13b]
Me	OBn	$SnCl_4$	*t*-Bu	65:35	65[13c,d]
Me	OBn	cat. $LiClO_4$	Me	92: 8	84[13e,f]

$CyCH_2$	$NHCO_2$-*i*-Pr	$TiCl_4$	Me	96: 4	95[13k,l]

With other substrates and under different conditions (eqs 7 and 8), non-chelated products are obtained with excellent selectivity.[13f,14]

$R^1 = Me$, $R^2 = t$-Bu	cat. ZnI_2	96:4	67%[14a,b]
$R^1 = Et$, $R^2 = Me$	cat. $Eu(dppm)_3$	95:5	100%[14c]

$R^1 = Bn, R^2 = Me$	$EtAlCl_2$	>99:<1	94%[14d]
$R^1 = Me, R^2 = t\text{-}Bu$	cat. $LiClO_4$ in CH_2Cl_2	>98:<2	58%[13f]

In the field of *C*-glycoside synthesis, selective β-glycosylation is realized via neighboring group participation of a 2α-acyl group.[15a] In the case of 2-deoxy sugars the neighboring participation of a group at the 3α-position is exploited for selective formation of the β-anomer (β:α = 91:9) (eq 9).[15b]

Enantioselective Aldol-Type Additions.

Highly enantioselective aldol-type reactions are successfully carried out by the combined use of a chiral diamine-coordinated tin(II) triflate and tributyltin fluoride (eq 10).[16,17] A catalytic amount of chiral bis(sulfonamido)zinc(II), easily prepared from diethylzinc and chiral sulfonamides, promotes the aldol addition in high yield and good enantiomeric excess (72-93%) only with chloral and bromal (CX_3CHO).[18]

(10)

Chiral borane complexes (20 mol %) catalyze the aldol-type addition to achiral aldehydes in good to excellent yield and enantiomeric excess (eq 11).[19-21]

A chiral boron reagent, derived from equimolar amounts of (*R*)- or (*S*)-binaphthol and triphenyl borate, promotes the condensation of chiral imines with *t*-butyl acetate silyl ketene acetal in high diastereomeric excess (eq 12).[22]

Addition to Various Electrophiles.

Various Lewis acids promote the addition of the reagent to an allylic acetate, following a carbon-Ferrier rearrangement pathway.[23] ***Titanium(IV) Chloride*** promotes the addition of the reagent to 2,2-dialkoxycyclopropanecarboxylic esters to give 3-alkoxy-2-cyclopentenones (eq 13).[24]

1,3-Dioxolan-2-ylium cations, derived from aldehyde ethylene acetals and trityl cation, react with the reagent to give the corresponding β-keto esters.[25] ***Montmorillonite K10*** catalyzes the addition of the reagent to pyridine derivatives with electron withdrawing groups to give *N*-silyldihydropyridines.[26] The ketene silyl acetal of ethyl acetate reacts with a chiral bromide to give the corresponding *syn*-lactone in 64% yield via a direct S_N2-type displacement and inversion of stereochemistry (eq 14).[27]

Six-membered chiral acetals, derived from aliphatic aldehydes, undergo aldol-type coupling reactions with silyl ketene acetals in the presence of $TiCl_4$ with high diastereoselectivity (eq 15).[28] This procedure, in combination with oxidative destructive elimination of the chiral auxiliary, has been applied to the preparation of (*R*)-(+)-α-lipoic acid[28a] and mevinolin analogs.[28b]

Addition to chiral, bicyclic acetals has been exploited in an approach to the synthesis of the tetrahydropyran subunit of the polyether nigerin.[29] The particular acetal generated by the ***Diisobutylaluminum Hydride*** reduction of aliphatic esters undergoes aldol addition in good yields (eq 16).[30]

(16)

Michael Addition.

The reagent undergoes Michael addition to α,β-enones in acetonitrile in the absence of a Lewis acid to afford the corresponding *O*-silylated Michael adducts in high yield. These silyl enol ethers undergo site-specific reaction with a variety of electrophiles (eq 17).[31a,b] Inability to repeat this procedure led to the discovery that the `noncatalyzed' Michael reaction is due to traces of phosphorus compounds introduced by drying acetonitrile with P_4O_{10}. The new catalyst system, formed from P_4O_{10} in acetonitrile, was found to be highly effective with a variety of substrates.[31c]

(17)

In those instances where the thermal Michael reaction is sluggish due to sterically hindered substrates, the use of high pressure (15 kbar, 20 °C),[32a] or of $LiClO_4$ (3 mol % in CH_2Cl_2[13f] or 1.0-2.5 M in Et_2O[32b]) prove extremely advantageous (eq 18). The lithium perchlorate-catalyzed Michael reaction can be carried out on α,β-unsaturated δ-lactones and on sterically demanding β,β-disubstituted unsaturated carbonyl systems in high yield and under mild conditions.[32b]

Michael addition of the reagent to enoates and enones occurs at low temperature (-50 to -78 °C) in the presence of catalytic amounts of various Lewis acids.[33] A catalytic amount of ***Triphenylmethyl Perchlorate*** (5 mol %) effectively catalyzes the tandem Michael reaction of ethyl acetate-derived silyl ketene acetal to α,β-unsaturated ketones and the sequential aldol addition to aldehydes with high stereoselectivity.[34] HgI_2 mediates the Michael addition to chiral enones, followed by Lewis acid-mediated addition to aldehydes. The Michael-aldol protocol has been used for the stereoselective synthesis of key intermediates on the way to prostaglandins, compactin, and ML-236A (eq 19).[35]

The mechanism of the $TiCl_4$-mediated Michael addition of silyl ketene acetals has been investigated, and criteria for suppressing the electron transfer process have been devised.[36] Chiral enones show good to excellent diastereofacial preference in $TiCl_4$-mediated reactions with silyl ketene acetals (eq 20).[37]

ZnI_2-mediated multiple Michael additions to bis-enoates proceed in good yield and with modest stereocontrol (eq 21).[38]

Related Reagents.

1-t-Butylthio-1-t-butyldimethylsilyloxypropene; ***1-t-Butylthio-1-t-butyldimethylsilyloxyethylene***.

Ketene Diethyl Acetal

[2678-54-8] · $C_6H_{12}O_2$ · Ketene Diethyl Acetal · (MW 116.18)

(inverse electron demand Diels-Alder reactions; thermal and photochemical [2 + 2] cycloadditions; naphthoquinone and anthraquinone synthesis; Paterno-Büchi photocycloadditions)

Physical Data: bp 68 °C/100 mmHg, 84-86 °C/200 mmHg.

Solubility: sol THF, ether, benzene; decomposes in water, ethanol.

Form Supplied in: liquid, not commercially available.

Preparative Method: reaction of 2-bromo-1,1-diethoxyethane with potassium *t*-butoxide in *t*-butanol.[1]

Handling, Storage, and Precautions: storage in an alkaline glass bottle dusted with potassium *t*-butoxide is recommended.

Inverse Electron Demand Diels-Alder Reactions.

Ketene diethyl acetal undergoes Diels-Alder reactions with various electron deficient dienes especially heterodienes such as α,β-unsaturated aldehydes and ketones (eq 1),[2] acylketenes (eq 2),[3] triazines,[4] acyliminium ions (eq 3),[5] and azodicarboxylates.[6] The Diels-Alder adducts often undergo further reaction, as in the case of cycloaddition of ketene diethyl acetal to 2-pyrones which undergo Diels-Alder reaction followed by retro-Diels-Alder reaction and elimination to allow rearomatization to produce good yields of substituted aromatics (eq 4).[7]

(1)

Thermal [2 + 2] Cycloadditions.

Diethyl ketene acetal readily reacts with fumarate[8] and acrylate esters (eq 5)[9] in highly regioselective thermal [2 + 2] cycloadditions to give cyclobutanone acetals, and with propiolate esters[10] to provide cyclobutenone acetals (eq 6), in good yield. Reaction with aryl isocyanates can provide substituted β-lactams (eq 7),[11] but isocyanates with stabilizing groups on the nitrogen generally give ring opened products.[12] Dichloroketene undergoes thermal [2 + 2] cycloaddition with the ketene acetal followed by ring opening (eq 8).[13]

(5)

(6)

(7)

(8)

Photochemical [2 + 2] Cycloadditions with Enones.

One of the most common uses of ketene diethyl acetal has been in [2 + 2] photocycloadditions with enones.[14] This is a highly regioselective process which provides access to cyclobutanone acetals in high yields (eqs 9-11).[15-17] These intermediates can serve as important synthetic building blocks. One example which displays some asymmetric induction has been reported (eq 12).[18]

(11)

Naphthoquinone and Anthraquinone Synthesis.

The reaction of diethyl ketene acetal with benzo- and naphthoquinones to prepare naphtho- and anthraquinones respectively has been widely studied (eqs 13 and 14).[19-21] The yields vary depending on the substitution of the quinone, and benzofurans are sometimes byproducts.[22] A similar reaction has been carried out on pyridinium salts.[23]

(14)

Paterno-Büchi [2 + 2] Photocycloadditions.

Ketene diethyl acetal reacts with various ketones in the Paterno-Büchi reaction to produce substituted oxetanes in modest yields (eqs 15 and 16).[24-26] More electrophilic carbonyls tend to give higher yields.

(15)

(16)

Miscellaneous Reactions.

Ketene diethyl acetal has been used in the palladium-catalyzed orthoester Claisen rearrangement of allylic alcohols (eq 17)[27] and in reaction with phenyl selenocyanate (eq 18).[28]

Ketene Dimethyl Thioacetal Monoxide[1]

[111674-84-1] · $C_4H_8OS_2$ · Ketene Dimethyl Thioacetal Monoxide · (MW 136.26)

(formylmethyl synthon used as an acceptor in conjugate addition reactions[1])

Alternate Names: ketene bis(methylthio)acetal monoxide; 1-(methylsulfinyl)-1-methylthioethylene.

Physical Data: yellow liquid; bp 145-150 °C/27 mmHg; ^{1}H NMR ($CDCl_3$) δ 2.38 (3H, s), 2.64 (3H, s), 5.51 (1H, d, *J* = 2 Hz), 6.01 (1H, d, *J* = 2 Hz); IR (neat) 3490, 1593, 1429, 1330, 1070, 970, 893 cm^{-1}; MS (70 eV), *m*/*e* (rel. intensity) 136 (5.9, M^+), 126 (0.8), 120 (1.6), 108 (3.2), 90 (8.4), 73 (100.0), 58 (15.1).[2]

Solubility: sol most common organic solvents (i.e. THF, Et_2O, DME, CH_2Cl_2, MeCN, *t*-BuOH, CS_2, benzene).

Preparative Methods: prepared from glyoxylic acid in six steps.[1a] A shorter synthesis involving a two-pot reaction sequence has been developed.[2]

Conjugate Addition Reactions.

The reagent functions as a two-carbon acceptor in Michael reactions with a variety of sodium enolates of β-dicarbonyl compounds (i.e. β-keto esters (eq 1),[1] malonates,[1] and β-diketones[1]), and in conjugate addition reactions with lithium enolates of simple carbonyl compounds (i.e. ketones,[3a] esters (eq 2),[1] α,β-enoates (eq 3),[1] and α-methylthio esters[1]), and enamines.[1] The reagent provides for umpolung reactivity since hydrolysis of the dithioacetal monoxide affords a 1,4-disposition of carbonyl functionality rather than the 1,5-disposition obtained in the Michael reaction.

The synthesis of oxygenated Aspidosperma alkaloids involves addition of a tetracyclic nine-membered ring lactam enolate to CH_2=C(SOMe)SMe (eq 4).[3b] Conjugate additions of nitroalkanes proceed quantitatively when ***1,8-Diazabicyclo[5.4.0]undec-7-ene*** is used as the base.[4] Syntheses of the natural products (±)-prostaglandin $F_{2\alpha}$[5,6] and (±)-1-acetylaspidoalbidine[3a] employ this particular methodology as a key step.

Ketenylidenetriphenylphosphorane

$Ph_3P{=}C{=}C{=}O$

[15596-07-3] · $C_{20}H_{15}OP$ · Ketenylidenetriphenylphosphorane · (MW 302.3)

(cumulated phosphonium ylide)

Physical Data: mp 171-172 °C;[1] IR;[1] ^{31}P NMR;[1] crystal structure.[2]

Preparative Methods: prepared most conveniently by a β-elimination from ***(Methoxycarbonylmethylene)triphenylphosphorane*** using ***Sodium Hexamethyldisilazide*** or ***Sodium Amide*** as a base (eq 1).[1,3] Other preparations have been reported.[4,5]

Handling, Storage, and Precautions: absence of moisture and air is necessary.

Reactivity.

In spite of its structural similarity with ketenes, the cumulated ylide displays no tendency to dimerize.[6] However, addition of an electrophile X^+ from a compound X-Y affords a phosphonium salt which reacts in a manner that is typical for ketenes (eq 2).

Whenever the starting ylide is a stronger nucleophile than Y^-, the phosphonium salt undergoes [2 + 2] cycloaddition with a second molecule of unreacted ylide to give 1,3-cyclobutanedione derivatives. If the anion Y^- is a stronger nucleophile than the cumulated ylide, then a new carbonyl substituted ylide is formed in which the compound X-Y has been added to the C=C bond of the starting ylide. The cyclic ylide salts formed in the reactions with hydrochloride or halogeno compounds serve as substrates for a series of subsequent reactions (e.g. conversion to the corresponding bis-ylide, Wittig reaction, isomerization, ring opening).[4,7] The stabilized phosphoranes resulting from the cumulated ylide and alcohols, thiols, or acidic NH compounds are very useful for the synthesis of a great variety of α,β-unsaturated carboxylic acid derivatives via the Wittig reaction.[8] α,β-Unsaturated esters can be synthesized (*E*) stereoselectively in this way by means of a three-component synthesis, without isolating the intermediate phosphorane.[9] Synthesis of heterocycles is possible if the acidic compound contains an additional group capable of cyclization (e.g. in the Wittig reaction) with the initially formed ylide function (eq 3). This synthetic principle has proved to be most useful for the synthesis of five- and six-membered heterocycles,[10,11] as well as for the preparation of macrocyclic lactones.[12,13]

(3)

Grignard reagents react with ketenylidenetriphenylphosphorane to give addition compounds which are hydrolyzed to acyl ylides.[3] This chain-lengthening difunctionalization of a Grignard reagent together with subsequent carbonyl alkenation allows the synthesis of a wide range of (*E*)-α,β-unsaturated ketones (eq 4).

(4)

Reaction of ketenylidenetriphenylphosphorane with aldehydes and ketones yields 1,3-cyclobutanediones, presumably via [2 + 2] cycloaddition of a second molecule of cumulated ylide to the C=C bond of an intermediate Wittig product or its precursor (eq 5).[4]

(5)

Cycloaddition at the C=C bond of the cumulated ylide also occurs in the reaction with various other compounds. Thus acyl, thioacyl, and imidoyl heterocumulenes as well as α,β-unsaturated carbonyl compounds react to give six-membered heterocycles in formal [4 + 2] cycloadditions (eqs 6 and 7).[14,15] Heteroallenes yield four-membered rings

in a [2 + 2] cycloaddition or six-membered rings resulting via a [4 + 2] cycloaddition of a second molecule of heteroallene to a dipolar 1:1 intermediate (eq 8).[4] The phosphonium ylides which can be synthesized in this way can usually be converted to the parent phosphorus-free derivatives, thus providing a synthetic approach to a series of heterocyclic systems.

(6)

(7)

(8)

The cumulated ylide has also been used as a metal complex ligand.[16]

Lanthanide Shift Reagents

($Eu(fod)_3$)

[17631-68-4] · $C_{30}H_{30}EuF_{21}O_6$ · $Eu(fod)_3$ · (MW 1037.50) ($Yb(fod)_3$)

[18323-96-1] · $C_{30}H_{30}F_{21}O_6Yb$ · $Yb(fod)_3$ · (MW 1058.58) ($Eu(hfc)_3$)

[34788-82-4] · $C_{42}H_{42}EuF_{21}O_6$ · $Eu(hfc)_3$ · (MW 1193.73) ($Eu(tfc)_3$)

[34830-11-1] · $C_{36}H_{42}EuF_9O_6$ · $Eu(tfc)_3$ · (MW 893.72)

(mild Lewis acids capable of catalyzing a variety of synthetic transformations)

Alternate Names: $Eu(fod)_3$ = tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium; $Yb(fod)_3$ = tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)ytterbium; $Eu(hfc)_3$ = tris[3-(heptafluoropropylhydroxymethylene)-(+ or -)-camphorato]europium; $Eu(tfc)_3$ = tris[3-(trifluoromethylhydroxymethylene)-(+ or -)-camphorato]europium.

Physical Data: $Eu(fod)_3$: mp 203-207 °C; $Yb(fod)_3$: mp 108-111 °C; $Eu(hfc)_2$: mp 156-158 °C; $Eu(tfc)_3$: mp 195-198 °C.

Solubility: generally sol in a wide variety of organic solvents; commonly used in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$.

Form Supplied in: hygroscopic solids; commercially available. *Drying:* if necessary, they can be dried and stored over P_2O_5.

Purification: can generally be used directly without purification. Occasionally contain insoluble material which can be removed by filtration of a solution of the reagent through a millipore filter or a plug of cotton or glass wool. Insoluble material can also be separated and removed by centrifugation.

Handling, Storage, and Precautions: though hygroscopic, they can be handled for short periods of time in the presence of air without deleterious effect. In general, the use of glove bags or dry boxes is not required.

Fluorinated lanthanide dionato complexes are commonly employed as NMR shift reagents.[1] The Lewis acidity of these reagents has allowed them to be exploited as catalysts for a variety of synthetic transformations. In general, they are easy to use and handle and are mild enough to tolerate a variety of acid labile functionality. A wide array of these complexes is commercially available. They have an octahedral geometry with the general structure (**1**) but are capable of expanding their coordination environment in order to accommodate additional Lewis bases. Generally they are believed to function by coordination at a single site, though chelation to two sites has also been suggested to occur.[2-4] Achiral versions generally employ the heptafluorooctanedionato (fod) ligand while complexes of optically active camphor derived ligands, 3-(trifluoromethylhydroxymethylene)camphorato (tfc) or 3-(heptafluoropropylhydroxymethylene)camphorato (hfc), have been investigated in connection with enantioselective synthesis. Both the (+)- and (-)-isomers of $Eu(hfc)_3$ and $Eu(tfc)_3$ are commercially available. Most commonly employed is the europium derivative, $Eu(fod)_3$. In several cases, $Yb(fod)_3$ has been reported to be a stronger Lewis acid than $Eu(fod)_3$ and a more effective catalyst for certain transformations.

(1)

The first report of their use as catalysts involved the $Eu(fod)_3$ induced rearrangement of oxaspiropentanes to cyclobutanones (eq 1).[5] The lanthanide complex is more effective at catalyzing this reaction than other more conventional Lewis acid catalysts.

(1)

During a study of its shift reagent properties, $Eu(tfn)_3$ (tris(1,1,1,2,2,3,3,7,7,8,8,9,9,9-tetradecafluoro-4,6-nonanedionato)europium) was found to smoothly catalyze the Diels-Alder dimerization of (**2**) (eq 2).[6] More recently, it has been demonstrated that $Yb(fod)_3$ will catalyze the cycloaddition of a variety of dienes with acrolein (eqs 3-5).[7] Several of these reactions cannot be readily accomplished with other catalysts or reaction conditions because of problems associated with the polymerization of acrolein.

(2)

(3)

(4)

(5)

The lanthanide shift reagent catalyzed Diels-Alder cycloaddition reaction of oxygenated dienes with aldehydes has been extensively investigated. $Eu(fod)_3$ effectively catalyzes this reaction at room temperature and, in many cases, allows the relatively unstable silyl enol ether intermediates to be isolated (eqs 6-11).[3,8-10]

(6)

R = Ph, 82%

R = CH=CHPh, 94%

(7)

R = Ph, 66%
R = Me, 66%
R = C_6H_{13}, 49%

(8)

R = Ph, 85%
R = C_6H_{13}, 73%

Enol ethers undergo [4 + 2] cycloaddition with α,β-unsaturated aldehydes in the presence of catalytic amounts of lanthanide shift reagents to give dihydropyran derivatives (eqs 12 and 13).[11]

(12)

(13)

Lanthanide shift reagents catalyze the addition of silyl enol ethers to aldehydes.[4,12] The yield and diastereoselectivity obtained with lanthanide shift reagents are often better than those observed with more conventional catalysts (eq 14).

(14)

Shift reagents also catalyze the [2 + 2] cycloaddition of ketenimines with aldehydes to produce 2-iminooxetanes (eq 15).[13] Again, the acid labile product is not stable to other catalysts.

(15)

The ene reaction of aldehydes with alkyl enol ethers is effectively catalyzed by $Yb(fod)_3$ (eq 16).[14]

(16)

The optically active camphor derivative $Eu(hfc)_3$ has been used as an enantioselective catalyst. Though the enantioselectivity with this catalyst alone is often modest (eq 17),[8,15] when used in concert with additional chiral auxiliaries, high levels of enantioselectivity have been obtained in the hetero-Diels-Alder cycloaddition reaction (eq 18).[15] The reduction of methyl phenylglyoxylate by the NADH mimic *N*-benzyldihydronicotinamide is catalyzed by lanthanide shift reagents with a modest level of asymmetric induction (eq 19).[16]

Lanthanum(III) Chloride[1]

$LaCl_3.7H_2O$

(anhydrous)

[10099-58-8] · Cl_3La · Lanthanum(III) Chloride · (MW 245.26) (heptahydrate)

[17272-45-6] · $Cl_3H_{14}LaO_7$ · Lanthanum(III) Chloride · (MW 371.40)

(mild Lewis acid for acetalization;[2] selective reducing agent in association with $NaBH_4$[3] or $LiAlH_4$;[4] preparation of organolanthanum reagents;[5] catalyst for various acid mediated reactions[6-8])

Physical Data: triclinic crystals; mp (hydrate) 91 °C (dec); mp (anhyd) 852 °C; bp 1750 °C; density (anhyd) 3.8 g cm^{-3}.

Solubility: 3.89 g L^{-1} in H_2O; sol methanol, ethanol; anhydrous form sol pyridine.

Form Supplied in: white crystals, deliquescent.

Preparative Methods: anhydrous lanthanum chloride is obtained from the hydrate by refluxing in thionyl chloride, or by heating to 400 °C in a HCl stream (see also ***Cerium(III) Chloride***). The reagent can also be prepared by treatment of a lanthanum benzoate suspension with dry ethereal HCl solution.[9]

Handling, Storage, and Precautions: anhydrous $LaCl_3$ should be freshly prepared and used without delay. Oral toxicity: LD_{50} 4.2 g kg^{-1} in rats.

Acetalization and Thioacetalization.

$LaCl_3$ has been used in the preparation of acetals (eqs 1 and 2), though it is less efficient than ***Erbium(III) Chloride*** or ytterbium(III) chloride.[2,10]

$$C_5H_{11}CHO \xrightarrow[\text{90\%}]{\substack{LaCl_3 \cdot 7H_2O \\ HC(OMe)_3 \\ \text{rt, 10 min}}} C_5H_{11}CH(OMe)_2 \qquad (1)$$

(2)

The anhydrous form of $LaCl_3$ permits the convenient production of thioacetals (eqs 3 and 4).[11] Hindered (camphor) and aromatic (benzophenone) ketones react in low yield. Lanthanum trichloride is much less efficient than ***Samarium(III) Chloride*** for acetal cleavage.[12]

(3)

(4)

Regioselective Reduction of α,β-Unsaturated Carbonyl Compounds.

In the presence of ***Sodium Borohydride***, α,β-unsaturated ketones are reduced to allylic alcohols in high yield (eq 5).[3] In THF, ***Lithium Aluminum Hydride*** shows the same selectivity with both ketones and aldehydes (eq 6).[4]

(5)

(6)

Organolanthanum Reagents.

Upon treatment with 1 equiv of ***n-Butyllithium***, anhydrous $LaCl_3$ yields a reagent of reduced basicity and good nucleophilicity, similar to the analogous cerium reagent (eq 7).[5] With ***Methyllithium***, the reagent exhibits a good selectivity for additions to aldehydes in the presence of a ketone (eq 8). Lanthanum gives the highest selectivity of all the lanthanides tested.[13]

(7)

(8)

Catalytic Properties in Various Reactions.

The Diels-Alder cycloaddition of acrolein with *n*-butyl vinyl ether is catalyzed by lanthanum chloride.[6] Cross-aldol reactions can be effected with ketene trimethylsilyl acetals and aldehydes. For instance, the trimethylsilyl ether of methyl 2-methylpropionate couples with benzaldehyde in the presence of catalytic amounts of $LaCl_3$; a mixture of the protected and unprotected hydroxy esters is obtained (eq 9).[7]

(9)

A mixture of $LaCl_3$ and ***Tin(II) Chloride*** condenses α-bromo ketones with aldehydes to form aldol products (eq 10). Although cerium chloride is preferred for most cases, lanthanum chloride offers a combination of the highest yield and satisfactory selectivity.[8] With α,α´-dibromo ketones, the same reagent mixture leads to oxyallyl cations which add to furan under mild conditions (see ***Cerium(III) Chloride***).[14]

Lanthanum(III) Triflate[1]

$La(CF_3SO_3)_3$

[52093-26-2] · $C_3F_9LaO_9S_3$ · Lanthanum(III) Triflate · (MW 586.10)

(Lewis acid catalyst useful for aldol, Michael, Diels-Alder, and other C-C bond forming reactions; also useful for preparing organolanthanum reagents, which react with hindered tertiary amides to afford ketones)

Alternate Name: lanthanum trifluoromethanesulfonate.

Physical Data: mp >360 °C.

Solubility: sol H_2O; partially sol THF, CH_2Cl_2; sparingly sol Et_2O; insol hexane.

Preparative Methods: to an aqueous solution of triflic acid (50% v/v), a slight excess of lanthanum oxide (La_2O_3) is added; the resulting mixture is stirred for 15 min at rt and then filtered to remove the unreacted oxide; the filtrate is concentrated in vacuo at about 60 °C; residual water is removed by azeotropic distillation with toluene in vacuo to dryness; the resulting hydrate is placed in a flask equipped with a stirring bar, a stopcock filled with a glass wool plug, and a NaOH trap, and is then dehydrated by heating under vacuum (140 °C/0.1 mmHg or 180 °C/1.0 mmHg) for 16 h. The anhydrous $La(OTf)_3$ is a white to gray-white solid.[2-4]

Handling, Storage, and Precautions: anhydrous $La(OTf)_3$ is hygroscopic and should be stored and weighed in a glove-box. Use in a fume hood.

Preparation of Organolanthanum Reagents.[1,4]

Organolanthanum triflates $RLa(OTf)_2$ (R = alkyl, aryl), readily available by reaction of organolithium compounds with equimolar anhydrous $La(OTf)_3$ in ethereal solvents, are very effective nucleophiles in reactions with carbonyl derivatives but exhibit relatively low basicity. Generally these reagents behave in a parallel manner to their organocerium chloride counterparts,[5] but are soluble in ethereal solvents and thus are more reactive. In particular, the addition reaction of $RLa(OTf)_2$ to the highly enolizable compound 1,3-diphenylacetone is complete within a few minutes at -78 °C, affording the carbinol product in essentially quantitative yield (eq 1). The analogous reaction utilizing $RCeCl_2$ requires a higher reaction temperature (0 °C) and a longer reaction time (1.5 h).[5] One application of $MeLa(OTf)_2$ in organic synthesis is depicted in eq 2 in which efficient 1,2-addition is achieved.[6] In this case, the use

of MeLi or MeMgBr reagents gives a mixture of the starting material and mono- and di-1,2- and 1,4-addition products.

$$\mathrm{MeLi} + \mathrm{La(OTf)_3} \xrightarrow[\text{-78 to 0 °C}]{\text{THF}} \mathrm{MeLa(OTf)_2} \xrightarrow[\text{-78 °C, 30 min}]{(\mathrm{PhCH_2})_2\mathrm{CO}} (\mathrm{PhCH_2})_2\mathrm{C(OH)Me} \quad (1)$$

98%

A unique characteristic of organolanthanum triflate reagents is that they smoothly react with sterically hindered aliphatic, aromatic, and heterocyclic tertiary amides to provide the corresponding ketones in excellent yields (eq 3); unsatisfactory results are obtained when employing organocerium or conventional RLi or RMgX reagents.[4] If amides possess additional donor functionality (i.e. MeO), an excess of the $RLa(OTf)_2$ reagent is needed to ensure complete conversion. Even so, further addition to the ketone product is not usually observed due to the formation of stable tetrahedral adducts prior to aqueous workup.

$$\mathrm{MeLa(OTf)_2} + \mathrm{PhCONEt_2} \xrightarrow[\text{95\%}]{\text{THF, -78 °C, 30 min}} \mathrm{PhCOMe} \quad (3)$$

Lewis Acid Catalyst for Aldol, Michael, and Diels-Alder Reactions.

$La(OTf)_3$ has been used as a Lewis acid catalyst to promote aldol condensations between silyl enol ethers and formaldehyde under aqueous conditions (eq 4).[7] $La(OTf)_3$ can catalyze the Michael addition of silyl enol ethers to α,β-unsaturated ketones at rt in CH_2Cl_2 to afford the expected products in high yields (eq 5). In some of the cases studied, as little as 1 mol % of $La(OTf)_3$ is sufficient, and other lanthanide triflates are also effective. Enol silanes derived from ketones, thioesters, and esters are suitable, and no 1,2-addition products are obtained.[8] $La(OTf)_3$ is also an effective catalyst for the Diels-Alder cycloaddition of carbonyl-containing dienophiles with cyclopentadiene.[8] For all three catalytic processes mentioned here, $La(OTf)_3$ can be almost quantitatively recovered upon aqueous workup and can be reused.[7,8]

R^5 = OR, SR, R

(5)

Synthesis of Amidines.

In the presence of 1 mol % of $La(OTf)_3$, reaction of primary amines (2 equiv) with nitriles results in the formation of *N,N´*-disubstituted amidines in good yields (eq 6);[3] when primary diamines (1 equiv) are employed, cyclic amidines are obtained in good to excellent yields (eq 7).[3]

Lead(II) Acetate

$Pb(OAc)_2.3H_2O$

[301-04-2] · $C_4H_{12}O_7Pb$ · Lead(II) Acetate · (MW 379.33)

(desulfurization reagent[2,3])

Physical Data: mp 75 °C when rapidly heated; above 100 °C it begins to lose acetic acid and decomposes completely above 200 °C; *d* 2.55 g cm^{-3}.

Solubility: 0.456 g mL^{-1} in H_2O at 15 °C; 2.0 g mL^{-1} in H_2O at 100 °C; 0.033 g mL^{-1} in ethanol; slightly sol diethyl ether; freely sol glycerol.

Form Supplied in: colorless crystals or white granules or powder; slowly effloresces; widely available; may contain insoluble lead carbonate resulting from exposure to air. *Drying:* dry at rt because of facile dehydration. Drying over H_2SO_4 at rt leads to formation of the anhydride.

Purification: recrystallize from water containing 2-3% acetic acid.

Handling, Storage, and Precautions: poisonous; carcinogen; LD_{50} 200 mg kg^{-1} (intraperitoneal in rats); avoid breathing dust and handle only in a fume hood. Keep tightly closed for storage; readily converts to complex salts. Incompatible with acids, alkalies, sulfates, sulfites, citrates, tartrates, chlorides, carbonates, tannin, phosphates, resorcinol, salicylic acid, and phenol.

Neutralization of HCl.[1]

In the synthesis of α-aminodiethylacetic acid via acid hydrolysis of the cyanohydrin of diethyl ketone, the crude amino acid hydrochloride is neutralized by lead hydroxide (prepared by hydrolysis of this reagent with sodium hydroxide) to yield the amino acid in liberated form (eq 1). This procedure appears to be superior to that using ***Lead(IV) Oxide*** for this neutralization.

Removal of Selenium and Selenious Acid.[2]

Selenium(IV) Oxide and selenious acid are good reagents for the oxidation of the α-methylene carbon of carbonyl compounds to give 1,2-dicarbonyl compounds. However, it is difficult to remove the resulting colloidal selenium and excess of the oxidant from the desired product in this method. A procedure for the oxidation of paraldehyde to glyoxal and the isolation of the product as the bis-bisulfite addition compound specifies the use of lead(II) acetate. Thus the addition of aqueous solution of this reagent to the reaction mixture gives insoluble lead selenite as a precipitate which is removed readily by filtration.

Conversion of Isocyanides into Isothiocyanates.[3]

Reactions of isocyanides with dibenzoyl disulfide occur smoothly in the presence of this reagent to give isothiocyanates in high yield (eq 2). The activity of this reagent is almost identical with that of ***Thallium(I) Acetate***. In this reaction, a complex of the reagent with dibenzoyl disulfide is believed to be the key intermediate in the sulfurization of the isocyanide (eq 3).

Elimination of H_2S.[4]

This reagent is used for the conversion of thioureas to cyanamides by elimination of H_2S under mild conditions, as illustrated in eq 4.

Acetoxylation of Allylic Bromide.[5]

This reagent is used for the preferential replacement of a bromine atom by an acetoxy group in 1-chloro-3-bromocycloalkenes (eq 5). Lead(II) acetate is superior to ***Silver(I) Acetate*** for this transformation.

(5)

Preparation of Cyclic Disulfides.[6]

Reactions of dithiols with an aqueous solution of this reagent give lead dithiolates in nearly quantitative yield. The dithiolates react with sulfur in benzene at rt to give the cyclic disulfides in high yields without the formation of polymeric disulfides (eq 6).

Lead(IV) Oxide

PbO_2

[1309-60-0] · O_2Pb · Lead(IV) Oxide · (MW 239.19)

(oxidation of phenols[1] and hydroquinones[2] to quinones; oxidation of methyl groups in methylated phenols to carboxyl groups;[3] oxidative cyclization[4] and oxidative decarboxylation;[5] formation of hydrazyl radical[6])

Alternate Name: lead dioxide.

Physical Data: evolves oxygen when heated, first forming Pb_3O_4, and then PbO at high temperatures; *d* 9.38 g cm^{-3}.

Solubility: insol water; sol HCl with evolution of Cl_2; sol dil HNO_3 in the presence of H_2O_2; sol oxalic acid; sol alkaline iodide solutions with liberation of iodine; sol hot caustic alkaline solutions.

Form Supplied in: black powder; widely available.

Purification: commercial PbO_2 is not always satisfactory; it is necessary to prepare the fresh active reagent by one of the methods described by Kuhn[7] and Wilmarth.[8]

Handling, Storage, and Precautions: harmful by inhalation, in contact with skin, and if swallowed; irritating to eyes and respiratory system; danger of cumulative effects; reproductive hazard; contact with combustible material may cause fire; should be handled in a fume hood.

Historically, PbO_2 was used to effect a variety of oxidative transformations. However, because of its general toxicity and because of the inconvenience and expense of disposing of lead byproducts, PbO_2 has largely been replaced by other oxidizing agents, such as ***Cerium(IV) Ammonium Nitrate***, ***Silver(I) Oxide***, and ***Salcomine***.

Oxidation of Phenols.

This reagent oxidizes phenols to the corresponding *p*-benzoquinones and/or diphenoquinones in polar solvents, e.g. acetic acid or formic acid (eq 1).[1a] The product distribution depends on the mole ratio of phenol/PbO_2 and reaction conditions. A mechanism in which the initial step is the formation of the metal phenoxide has been proposed. In nonpolar solvents the oxidation yields mainly polymeric ethers.[1b]

Oxidation of Hydroquinones to Quinones.

PbO_2 can oxidize catechol and its derivatives to the corresponding quinones. In nucleophilic solvents, addition and a subsequent oxidation lead to substituted *o*-quinones. For example, when catechol is treated with PbO_2 in methanol which contains sodium methoxide, 4,5-dimethoxy-*o*-benzoquinone is obtained (eq 2).[3]

The intermediate *o*-quinone can also be trapped by annulation with *o*-phenylenediamine in acetic acid-benzene to form α-methoxyphenazine after a second oxidation.[9] PbO_2 also oxidizes 2,6-dihydroxynaphthalene to 2,6-naphthoquinone (eq 3),[10] and 2,6-naphthylenedibenzenesulfonamide to 2,6-naphthoquinone dibenzosulfonimide.[11]

Oxidative Cyclization.

Oxidation of a substituted *p*-hydroxybenzophenone with PbO_2 afforded dehydrogriseofulvin (eq 4), and oxidation of a related *o*-carboxydiphenyl ether gave a spiranic lactone.[4]

Oxidative Decarboxylation.

PbO_2 oxidizes 1,2-dicarboxylic acids and their anhydrides to the doubly decarboxylated alkenes (eq 5).[5]

In the presence of PbO_2, nepetonic acid (a β-carboxy ketone) is oxidized with decarboxylation to (-)-3-methylcyclopenten-1-yl methyl ketone (eq 6).[12] *Caution*: The reactants should be well mixed and air should be excluded from the hot residue of the decarboxylation reaction.

Other Oxidation Reactions.

The methyl groups of methylated phenols can be oxidized to carboxyl groups by PbO_2 (eq 7).[3] The oxidation of 1,1,4,4-tetraphenyl-2,3-dibenzoyltetrazane with PbO_2 affords the hydrazyl radical.[6]

Lead(IV) Acetate[1]

$Pb(OAc)_4$

[546-67-8] · $C_8H_{12}O_8Pb$ · Lead(IV) Acetate · (MW 443.37)

(oxidizing agent for different functional groups;[1] oxidation of unsaturated and aromatic hydrocarbons;[2] oxidation of monohydroxylic alcohols to cyclic ethers;[3] 1,2-glycol cleavage;[4] acetoxylation of ketones;[1] decarboxylation of acids;[5] oxidative transformations of nitrogen-containing compounds[6])

Alternate Name: lead tetraacetate; LTA.

Physical Data: mp 175-180 °C; *d* 2.228 g cm^{-3}.

Solubility: sol hot acetic acid, benzene, cyclohexane, chloroform, carbon tetrachloride, methylene chloride; reacts rapidly with water.

Form Supplied in: colorless crystals (moistened with acetic acid and acetic anhydride); widely available, 95-97%.

Analysis of Reagent Purity: iodometrical titration. *Drying:* in some cases, acetic acid must be completely removed by drying the reagent in a vacuum desiccator over potassium hydroxide and phosphorus pentoxide for several days.

Handling, Storage, and Precautions: the solid reagent is very hygroscopic and must be stored in the absence of moisture. Bottles of lead tetraacetate should be kept tightly sealed and stored under 10 °C in the dark and in the presence of about 5% of glacial acetic acid.

Oxidations of Alkenic and Aromatic Hydrocarbons.

Lead tetraacetate reacts with alkenes in two ways: addition of an oxygen functional group on the double bond and substitution for hydrogen at the allylic position.[2] In addition to these two general reactions, depending on the structure of the alkene, other reactions such as skeletal rearrangement, double bond migration, and C-C bond cleavage can occur, leading to complex mixtures of products, and these reactions therefore have little synthetic value (eq 1).[1a,b,2,7] Styrenes afford 1,1-diacetoxy derivatives when the LTA reaction is performed in acetic acid (eq 2), while in benzene solution products resulting from the addition of both the methyl and an acetoxy group to the alkenic double bond are formed.[7,8] Other nucleophiles, such as azide ion, carbanions, etc. can be introduced onto the alkenic bond in a similar fashion.[9] In the LTA oxidation of cyclic alkenes, depending on ring size, structure, solvent, and reaction conditions,

several types of products are formed. Thus 1,2-diacetates and 3-acetoxycycloalkenes are obtained from cyclohexene (cyclopentanecarbaldehyde is also formed),[10] cycloheptene, and cyclooctene.[11] Norbornene reacts with LTA to give rearrangement products in which 2,7-diacetoxynorbornane predominates (eq 3).[12] Conjugated dienes undergo 1,2- and 1,4-diacetoxylation,[13] while cyclopentadiene in wet acetic acid gives monoacetates of *cis*-cyclopentene-1,2-diol (eq 4).[14]

(1)

(2)

(3)

(4)

Aromatic hydrocarbons react with LTA in two ways: on the aromatic ring and at the benzylic position of the side chain. Oxidation of the aromatic ring results in substitution of aromatic hydrogens by acetoxy or methyl groups.[1c] Benzene itself is stable towards LTA at reflux and is frequently used as solvent in LTA reactions. However, mono- and polymethoxybenzene derivatives are oxidized by LTA in acetic acid to give acetoxylation products (eq 5).[15] Oxidation of anthracene in benzene gives 9,10-diacetoxy-9,10-dihydroanthracene, whereas in AcOH a mixture of 10-acetoxy-9-oxo-9,10-dihydroanthracene and anthraquinone is obtained.[16] The LTA oxidation of furan affords 2,5-diacetoxy-2,5-dihydrofuran (eq 6).[17]

(5)

(6)

Aromatic compounds possessing a C-H group at the benzylic position are readily oxidized by LTA to the corresponding benzyl acetates. Benzylic acetoxylation is preferably performed in refluxing acetic acid (eq 7).[18] Acetoxylation at the benzylic position can be accompanied by methylation of the aromatic ring, followed sometimes by acetoxylation of the newly introduced methyl group.[18]

(7)

Oxidative Cyclization of Alcohols to Cyclic Ethers.

The LTA oxidation of saturated alcohols, containing at least four carbon atoms in an alkyl chain or an appropriate carbon skeleton, to five-membered cyclic ethers represents a convenient synthetic method for intramolecular introduction of an ether oxygen function at the nonactivated δ-carbon atom of a methyl, methylene, or methine group (eq 8).[3,19,20] The reactions are carried out in nonpolar solvents, such as benzene, cyclohexane, heptane, and carbon tetrachloride, either at reflux temperature[1a,d,3,20,21] or by UV irradiation at rt.[22]

(8)

The conversion of alcohols to cyclic ethers is a complex reaction involving several steps: (i) reversible alkoxylation of LTA by the substrate; (ii) homolytic cleavage of the RO-Pb bond in the resulting alkoxy-lead(IV) acetate with formation of an alkoxy radical; (iii) intramolecular 1,5-hydrogen abstraction in this oxy radical whereby a δ-alkyl radical is generated; (iv) oxidative ring closure to a cyclic ether via the corresponding δ-alkyl cation (eq 9).[3,20] The crucial step is the formation of the δ-alkyl radical by way of 1,5-hydrogen migration. This type of rearrangement is a general reaction of alkoxy radicals, and, independently of the radical precursor, involves a transition state in which the δ-CH group must be conformationally suitably oriented with respect to the attacking oxygen radical.[1,3,23,24] Regioselective hydrogen abstraction proceeds preferentially from the δ-carbon atom, since in that case an energetically favorable quasi-six-membered transition state is involved.[3,23,24]

(9)

The LTA oxidation of primary aliphatic alcohols affords 2-alkyltetrahydrofurans in 45-75% yield. A small amount of tetrahydropyran-type ether is also formed (eq 10).[3a,20] The oxidation rate depends on the structural environment of the pro-activated carbon atom, with the rate decreasing in the order: methine > methylene > methyl δ-carbon atom.[3] When the δ-carbon atom is adjacent to an ether oxygen function, the reaction rate and the yield of cyclic ethers increases.[25] An ether oxygen attached to the δ-carbon atom increases considerably the yield of six-membered cyclic ethers (eq 11). An aromatic ring adjacent to a δ-methylene group does not noticeably affect the yield of tetrahydrofuran ethers, but when the phenyl group is attached to an ε-methylene group, the yield of six-membered cyclic ethers are enhanced.[26]

Secondary aliphatic alcohols containing a δ-methylene group afford a *cis*/*trans* mixture of 2,5-dialkyltetrahydrofurans in about 33-70% yield (eq 12).[20,22] The LTA oxidation of secondary alcohols is much slower than that of primary alcohols and isomeric six-membered cyclic ethers are not formed.[20,21] Tertiary aliphatic alcohols, because of unfavorable steric and electronic factors, are less suitable for the preparation of tetrahydrofurans by LTA oxidation.[22,27]

In the cycloalkanol series, the ease of intramolecular formation of cyclic ether products strongly depends on ring size. Cyclohexanol, upon treatment with LTA, affords only 1% of 1,4-cyclic ether, whereas cycloalkanols with a larger ring, such as cycloheptanol and cyclooctanol, can adopt appropriate conformations necessary for transannular reaction, affording bicyclic ethers in moderate yields (eq 13).[28] Large-ring cycloalkanols, such as cyclododecanol, cyclopentadecanol, and cyclohexadecanol, also give the corresponding 1,4-epoxy compounds as major cyclization products.[3a,28] However, the special geometry of cyclodecanol is not favorable for the normal reaction and the 1,4-cyclic ether is formed in only 2.5% yield, whereas 1,2-epoxycyclodecane (13%) and the rearranged 8-ethyl-7-oxabicyclo[4.3.0]nonane (13%) are the predominant cyclization products.[29]

(13)

The LTA oxidation of alcohols to cyclic ethers has been successfully applied as a synthetic method for activation of the angular 18- and 19-methyl groups in steroidal alcohols containing a β-oriented hydroxy group at C-2, C-4, C-6, and C-11 (eq 14).[3c,30,31] Hydroxy terpenoids with suitable stereochemistry can also undergo transannular cyclic ether formation (eq 15).[32]

X = H, Cl, Br, OH

(14)

(15)

Another possible reaction of alkoxy radical intermediates, formed in the LTA oxidation of alcohols in nonpolar solvents, is the β-fragmentation reaction.[3] This process, which competes with intramolecular 1,5-hydrogen abstraction, consists of cleavage of a bond between the carbinol (α) and β-carbon atoms, thus affording a carbonyl-containing fragment and products derived from an alkyl radical fragment (usually acetates and/or alkenes).[1a,3,22] Interesting synthetic applications of the LTA β-fragmentation reaction are the formation of 19-norsteroids from their 19-hydroxy precursors and the preparation of 5,10-secosteroids (containing a ten-membered ring) from 5-hydroxy steroids (eq 16).[32]

In the LTA oxidations of primary and secondary alcohols in nonpolar solvents, the corresponding aldehydes or ketones are usually obtained as minor byproducts (up to 10%).[3,20,21] However, in the presence of excess pyridine or in pyridine alone, either with heating or at rt, the cyclization and β-fragmentation processes are suppressed and good preparative yields of aldehydes or ketones are obtained (eq 17).[20,21,33] Carbonyl compounds are also obtained when the LTA oxidation of alcohols is carried out in benzene solution in the presence of manganese(II) acetate.[33]

In addition to cyclic ethers, β-fragmentation products, and carbonyl compounds, acetates of starting alcohols are also usually formed in the LTA oxidation, in yields up to 20%.[20]

Unsaturated alcohols, possessing an alkenic double bond at the δ or more remote positions, react with LTA in nonpolar solvents to give acetoxylated cyclic ethers in good yield (eq 18),[34,35] while 5-, 6- and 7-alkenols undergo in great predominance an *exo*-type cyclization, affording six-, seven- and eight-membered acetoxymethyl cyclic ethers, respectively.[35]

1,2-Glycol Cleavage.

LTA is one of the most frequently used reagents for the cleavage of 1,2-glycols and the preparation of the resulting carbonyl compounds (eq 19).[1,4] The reactions are performed either in aprotic solvents (benzene, nitrobenzene, 1,2-dichloroethane) or in protic solvents such as acetic acid.[36,37] The rate of LTA glycol cleavage is highly dependent on the structure and stereochemistry of the substrate. In general, there is correlation between the oxidation rate and the spatial proximity of the hydroxy groups.[36] 1,2-Diols having a geometry favoring the formation of cyclic intermediates are much more reactive than 1,2-diols whose structure does not permit such intermediates to be formed (eq 20).[38,39] The oxidation rates often provide a reliable means for the determination of the stereochemical relationship of the hydroxy groups.[39,40]

1,2-Glycol cleavage by LTA has been widely applied for the oxidation of carbohydrates and sugars (eq 21).[4,37] Because of structural and stereochemical differences, the reactivity of individual glycol units in sugar molecules is often different, thus rendering the LTA reaction a valuable tool for structural determination and for degradation studies in carbohydrate chemistry.[41]

α-Acetoxylation of Ketones.

The reaction of enolizable ketones with LTA is a standard method for α-acetoxylation (eq 22).[1,3,42] The reactions are usually carried out in hot acetic acid or in benzene solution at reflux. The reaction proceeds via an enol-lead(IV) acetate intermediate, which undergoes rearrangement to give the α-acetoxylated ketone. Acetoxylation of ketones is catalyzed by ***Boron Trifluoride***.[43] Enol ethers, enol esters, enamines,[1] β-dicarbonyl compounds, β-keto esters, and

malonic esters are also acetoxylated by LTA.[42]

Decarboxylation of Acids.

Oxidative decarboxylation of carboxylic acids by LTA depends on the reaction conditions, coreagents, and structure of acids, and hence a variety of products such as acetate esters, alkanes, alkenes, and alkyl halides can be obtained.[1,5] The reactions are performed in nonpolar solvents (benzene, carbon tetrachloride) or polar solvents (acetic acid, pyridine, HMPA).[5] Mixed lead(IV) carboxylates are involved as intermediates, and by their thermal or photolytic decomposition decarboxylation occurs and alkyl radicals are formed (eq 23).[5,44,45]

Oxidation of alkyl radicals by lead(IV) species give carbocations and, depending on the reaction conditions and structure of the substrate acids, various products derived from the intermediate alkyl radicals and corresponding carbocations (dimerization, hydrogen transfer, elimination, substitution, rearrangement, etc.) are obtained.[5] Decarboxylation of primary and secondary acids usually affords acetate esters as major products (eq 24).[44] When a mixture of acetates and alkenes is formed, it is recommended (in order to improve the yields of acetate esters) to run the reaction in the presence of potassium acetate (eq 25).[5] The LTA decarboxylation of tertiary carboxylic acids gives a mixture of alkenes and acetate esters.[46] For the preparative oxidative decarboxylation of acids to alkenes, see ***Lead(IV) Acetate-Copper(II) Acetate***.

(25)

A useful modification of the LTA reaction with carboxylic acids is the oxidation in the presence of halide ions, whereby the corresponding alkyl halides are obtained (eqs 26 and 27).[47] Halodecarboxylations of acids are performed by addition of a molar equivalent of the metal halide (lithium, sodium, potassium chloride) to a carboxylic acid and LTA, the reactions being performed in boiling benzene solution.[5,47] For the iododecarboxylation of acids, see ***Lead(IV) Acetate-Iodine***.

(26)

(27)

Bis-decarboxylation of 1,2-dicarboxylic acids by LTA is a useful method for the introduction of alkenic bonds (eq 28).[48] The reactions are performed in boiling benzene in the presence of pyridine or in DMSO. In some cases, LTA bis-decarboxylation can be effected by using acid anhydrides (eq 29).[49] Bis-decarboxylation of 1,1-dicarboxylic acids yields the corresponding ketones (eq 30).[50]

(28)

(29)

(30)

Oxidative Transformations of Nitrogen-Containing Compounds.

The LTA oxidation of aliphatic primary amines containing an α-methylene group results in dehydrogenation to alkyl cyanides (eq 31).[51] However, aromatic primary amines give symmetrical azo compounds in varying yield (eq 32).[52]

(31)

(32)

Primary amides react with LTA in the presence of alcohols to give the corresponding carbamates (eq 33), but in the absence of alcohol, isocyanates are formed.[53]

(33)

Aliphatic ketoximes, upon treatment with LTA in an inert solvent, undergo acetoxylation at the α-carbon producing 1-

nitroso-1-acetoxyalkanes (eq 34),[54] whereas hydrazones afford azoacetates (eq 35) or, when the reactions are performed in alcohol solvent, azo ethers.[55] Arylhydrazines, *N*,*N*´-disubstituted hydrazines,[56] and *N*-amino compounds[57] are oxidized by LTA to different products.

(34)

(35)

Other Applications.

By LTA oxidation of phenols, acetoxycyclohexadienones, quinones, and dimerization products can be formed.[58] Alkyl sulfides,[59] alkyl hydroperoxides,[60] and organometallic compounds[61] are also oxidized by LTA.

Lead(IV) Acetate-Copper(II) Acetate[1]

$Pb(OAc)_4$-$Cu(OAc)_2.H_2O$

($Pb(OAc)_4$)

[546-67-8] · $C_8H_{12}O_8Pb$ · Lead(IV) Acetate-Copper(II) Acetate · (MW 443.40) ($Cu(OAc)_2.H_2O$)

[142-71-2] · $C_4H_8CuO_5$ · Lead(IV) Acetate-Copper(II) Acetate · (MW 199.67)

(oxidative decarboxylation of acids to alkenes[1a])

Physical Data: see ***Lead(IV) Acetate*** and ***Copper(II) Acetate***.

Oxidative decarboxylation of aliphatic and alicyclic carboxylic acids by lead tetraacetate (LTA) usually affords a mixture of saturated hydrocarbons, alkenes, acetate esters, and other products, whose distribution depends upon the structure of the starting acid.[1a,b] However, when LTA is used in the presence of catalytic amounts of copper(II) acetate, the rates of decarboxylation are greatly enhanced and the yields of alkenes are increased so that the reactions become of synthetic value (eq 1).[2] This effect of copper(II) acetate is attributed to the rapid scavenging of the intermediately formed alkyl radicals by copper(II) ions (eq 2).[1a,3,5-7] A catalytic amount of $Cu(OAc)_2$ is sufficient, since it is regenerated in the course of the reaction (eq 3).[3,6] The reactions are usually carried out in an inert atmosphere in benzene solution, under thermal or photolytic conditions, using a minimal concentration of $Cu(OAc)_2$ (about 0.005 M).[1a,3]

(1)

+ CuOAc (2)

$$CuOAc + Pb^{IV} \longrightarrow Cu(OAc)_2 + Pb^{III}, \text{ etc.} \qquad (3)$$

The LTA-$Cu(OAc)_2$ reagent is particularly applicable for the oxidative decarboxylation of primary and secondary acids, whereby primary carboxylic acids afford terminal alkenes in high yields (eqs 4 and 5).[2-4,8-10] In the case of secondary acids, if unsymmetrical, oxidative elimination can take place in two directions, and frequently both possible alkenes are obtained (eqs 6 and 7).[2,11-14] Oxidative decarboxylation of secondary acids by the LTA-$Cu(OAc)_2$ reagent is approximately 20 times faster than that of primary acids.[1a,15]

$$Me(CH_2)_7CO_2H \xrightarrow[\text{87\%}]{\text{LTA, } Cu(OAc)_2,\ \text{PhCl, } h\nu\text{, 30 °C}} Me(CH_2)_5CH{=}CH \qquad (4)$$

Decarboxylation of tertiary carboxylic acids by LTA-$Cu(OAc)_2$ proceeds about 100 times faster than that of primary acids, and usually affords alkenes as main products (eqs 8 and 9).[6,16-19] However, with tertiary carboxylic acids, in

contrast to the behavior of primary and secondary acids, LTA alone reacts in the same way, so that addition of the Cu^{II} catalyst is not necessary.[1a]

(8)

(9)

In the oxidative decarboxylation of acids by LTA-$Cu(OAc)_2$ the solvent can play an important role, because the relative rates of oxidative elimination with alkene formation and competitive oxidative substitution leading to acetate ester formation may be considerably influenced by the solvent. Thus decarboxylation of cyclobutanecarboxylic acid by LTA-$Cu(OAc)_2$ in benzene affords cyclobutene as the main reaction product; in acetonitrile-acetic acid, cyclobutene is formed in low yield, the major products being a mixture of isomeric acetates (eq 10).[1a,2,7] A portionwise addition of LTA to a refluxing solution of carboxylic acid in benzene in the presence of pyridine and $Cu(OAc)_2$, in the absence of air, has been suggested as an improved procedure for oxidative decarboxylation to alkenes.[11]

Lead(IV) Acetate-Iodine[1]

$Pb(OAc)_4$-I_2

($Pb(OAc)_4$)

[546-67-8] · $C_8H_{12}O_8Pb$ · Lead(IV) Acetate-Iodine · (MW 443.37) (I_2)

[7553-56-2] · I_2 · Lead(IV) Acetate-Iodine · (MW 253.80)

(functionalization of nonactivated δ-carbon atoms;[2] mono- and disubstitution on methyl and methylene groups;[3,4] cyanohydrin-cyano ketone rearrangement;[5] β-fragmentation reactions;[6] iododecarboxylation[7])

Physical Data: see ***Lead(IV) Acetate*** and ***Iodine***.

Functionalization of Nonactivated δ-Carbon Atoms.

The original method for oxidative functionalization of δ-carbon atoms by lead tetraacetate (LTA), involving conversion of alcohols to cyclic ethers, is modified by using LTA-I_2 as reagent.[1] This modification is known as the LTA-hypoiodite reaction.[1] The reactions are performed under irradiation conditions (500 W lamp) in nonpolar solvents such as cyclohexane and CCl_4.[2] The selective introduction of a functional group on the δ-carbon atom by oxidative transformation of alcohols is based on the specific reactivity of LTA-I_2 for the conversion of alcohols to hypoiodites, and on the facile homopolar decomposition of alkyl hypoiodites, under irradiation, with formation of alkoxy radical intermediates (eq 1).[1,2]

Alkoxy radicals generated by this method from primary and secondary alcohols undergo intramolecular hydrogen transfer from the δ-carbon atom, thus forming intermediary δ-carbon radicals (eq 2), which under these experimental conditions are then intercepted by iodine with formation of 1,4-iodohydrins.[1,2] Depending on the conformational relationship of the hydroxy group, iodine, and δ-carbon atom in the iodohydrin, different products can be obtained (eq 2). In the case of a linear arrangement, the hydroxy group approaches the δ-carbon atom from the back side of iodine,

whereby oxidative monosubstitution takes place with elimination of HI, resulting in closure of a tetrahydrofuran ring (eq 2, path i).[1,8] This reaction has often been applied for the functionalization (with cyclic ether formation) of steroidal 18- and 19-methyl groups, and methyl groups in other rigid molecules (eqs 3 and 4).[3,9,10]

X = H, Cl, Br, OAc, OMe, OH

However, when a linear relationship of iodine, δ-carbon atom, and hydroxy group is not possible in the iodohydrin, a second oxidative sequence with double substitution on the δ-methyl group takes place (eq 2, path ii),[1,8] and acetoxy or iodo cyclic ethers are formed. Such a reaction at the angular 19-methyl group of 4β-hydroxy steroids affords 19-acetoxy- (or iodo-) 4β,19-cyclic ethers (eq 5).[8,11]

(5)

The LTA-I_2 oxidation of primary and secondary alcohols possessing a nonactivated δ-methylene group proceeds either with monosubstitution, i.e. cyclic ether formation, or double substitution to give unsaturated cyclic ethers (eq 6).[4,12]

(6)

By the LTA-I_2 oxidation of steroidal alcohols having a methine group at the δ-position, unsaturated cyclic ethers are obtained via alkenic alcohols as intermediates (eq 7).[4,13]

(7)

Cyanohydrin-Cyano Ketone Rearrangement.

A particularly interesting and specific reaction of the LTA-iodine reagent is the oxidative rearrangement of

cyanohydrins to δ-cyano ketones (eq 8).[1,5,14] Other hypoiodite forming reagents do not effect this rearrangement.

(8)

The cyanohydrin-cyano ketone rearrangement is successfully realized by the LTA-I_2 oxidation of 20-cyano-20-hydroxy steroids, and this reaction offers a good method for the introduction of a functional group, with C-C bond formation, at the nonactivated 18-methyl group in a one-pot reaction.[1,5] 1,4-Migration of the cyano group involves intramolecular addition of a δ-alkyl radical to the cyano group, followed by β-cleavage of the resulting imino radical, to give an α-hydroxy-δ-cyano radical and, as final product, the corresponding δ-cyano ketone (eq 9).[1]

(9)

It is important to note that all of the described reactions of hydroxy compounds with LTA-I_2 can take place only when at least one of the reactive centers, the hydroxy group or the δ-carbon atom, are part of a fixed system.[1]

β-Fragmentation Reaction.

In addition to cyclization, alkoxy radicals generated by means of LTA-I_2 can also undergo β-cleavage, this process being favored when stable alkyl radical and oxo-containing fragments are formed.[6] In this case, homolytic C_α-C_β bond breaking can be more important than functionalization at C_δ (eq 10).[6,15,16]

The relatively stable tertiary radicals generated by β-fragmentation in the LTA-I_2 reaction can be either quenched by iodine to give iodides or oxidized to the corresponding carbocations, which usually undergo proton elimination affording unsaturated products (eqs 10 and 11).[1] When cleavage of a bridged C_α-C_β bond is involved, the LTA-I_2 β-fragmentation can be usefully applied for the preparation of medium or large carbocyclic and heterocyclic rings (eqs 10 and 12).

Iododecarboxylation.

When treated with I_2 and LTA in refluxing CCl_4 under irradiation with a tungsten lamp, carboxylic acids undergo iododecarboxylation.[17] Good yields of alkyl iodides are obtained from primary and secondary acids (eqs 13 and 14).[17,18-20]

(14)

In the dark, the reaction proceeds more slowly and in lower yield. Decarboxylation of carboxylic acids by LTA-I_2 under thermal conditions, i.e. by heating at 150-180 °C in a suitable solvent, gives (particularly with primary acids) esters of these acids in fairly good yield (up to 54%) (eq 15).[21]

Lead(IV) Trifluoroacetate[1]

$Pb(OCOCF_3)_4$

[16656-82-9] · $C_8F_{12}O_8Pb$ · Lead(IV) Trifluoroacetate · (MW 659.13)

(functionalization of saturated hydrocarbons;[2] trifluoroacetoxylation, plumbation, and dimerization of substituted benzene derivatives;[3,4] oxidation of alkenic compounds[5])

Alternate Name: lead tetrakis(trifluoroacetate); LTTFA.

Physical Data: too hygroscopic for mp determination.

Solubility: reacts with aliphatic and aromatic hydrocarbons (such as heptane, benzene, toluene, etc.), but is stable and sol in trifluoroacetic acid (TFA), C_6F_6, CH_2Cl_2, and $MeNO_2$.

Form Supplied in: commercially available in the form of white crystals moistened with TFA. *Drying:* for some reactions, TFA must be completely removed; this is achieved by drying the reagent in vacuo (over KOH and P_2O_5) for several days.

Analysis of Reagent Purity: the oxidizing capability and purity of the reagent can be determined iodometrically.

Preparative Method: can be prepared in situ from ***Lead(IV) Acetate*** and ***Trifluoroacetic Acid***.

Handling, Storage, and Precautions: the solid reagent is very reactive and hygroscopic, and must be stored in the dark, in the absence of moisture, and below 10 °C.

Functionalization of Saturated Hydrocarbons.

The powerful oxidizing properties of lead tetrakis(trifluoroacetate) have been used for the introduction of functional groups on nonactivated carbon atoms,[1a] particularly of bridged hydrocarbons.[2,6] In these reactions, generally performed at rt, LTTFA is generated in situ from lead tetraacetate (LTA) and an excess of TFA in CH_2Cl_2 as solvent (eq 1).[2,6] The reactivity of the labile trifluoroacetoxy ester group permits alternative functionality to be introduced.[7] Thus by running the LTTFA oxidation of adamantane in the presence of acetonitrile, *N*-(1-adamantyl)acetamide is obtained in 85% yield.[6,7] Other nucleophiles such as CN^-, RS^-, Ar^-, and C^- can also be introduced on bridged carbon atoms in this way.[7] Only monosubstituted derivatives are obtained.[2]

(1)

Trifluoroacetoxylation of Benzenoid Compounds.

The synthesis of *p*-substituted aryl trifluoroacetates can be conveniently achieved in yields up to 76% by reaction of substituted benzenes with LTTFA in TFA (eq 2).[4,8] Nitrobenzene fails to react after two weeks at rt, while anisole reacts very violently.[8] Aryllead tris(trifluoroacetates) as intermediates are also formed from the corresponding arylmercury(II) or arylthallium(III) trifluoroacetates and from aryltrimethylsilanes, upon reaction with LTTFA.[4,9,10] The aryltrifluoroacetate esters are usually hydrolyzed and isolated as the corresponding phenols.[3,4]

(2)

X = H, Me, Et, *i*-Pr, *t*-Bu, F, Cl, Br

41-76%

By oxidation of methyl substituted benzenes with LTTFA (LTA + TFA) in TFA and CH_2Cl_2 at low temperature (0 °C or below), coupling occurs producing biaryl and diarylmethane compounds (7-65%) (eq 3).[11]

Oxidation of Alkenic Compounds.

LTTFA, as an electrophilic oxidizing agent, reacts readily with alkenic bonds. Thus styrene and substituted styrenes undergo oxidative rearrangement to give 1,1-bis(trifluoroacetoxy) derivatives, which are easily hydrolyzed to the corresponding carbonyl products (eq 4).[12,13]

Conjugated dienes also react with LTTFA and undergo 1,4-addition, affording 1,4-bis(trifluoroacetate) esters (eq 5).[12]

When treated with LTTFA, allylic hydroxy steroids are converted to epoxy trifluoroacetates (eq 6), whereas homoallylic steroid alcohols undergo C-C bond cleavage to give secosteroid compounds.[5]

(6)

Hydroxysulfenylation of alkenes to 1,2-hydroxythio ethers, via the corresponding trifluoroacetoxy addition intermediates, is readily achieved by means of LTTFA (LTA + TFA) and diaryl disulfides in TFA/CH_2Cl_2, at low temperature (from 0 °C to -40 °C) (eq 7).[14]

t-Leucine *t*-Butyl Ester[1]

(D)

[61169-85-5] · $C_{10}H_{21}NO_2$ · *t*-Leucine *t*-Butyl Ester · (MW 187.32) (L)

[31556-74-8] (DL)

[99285-38-8]

(chiral auxiliary used in asymmetric alkylations,[1] 1,2-additions,[2] and 1,4-additions[3] of aldehyde and ketone derived Schiff bases)

Physical Data: D,[4a] [α]20D -56°; bp 90-91 °C/21 mmHg. L,[4a] [α]20D +51.7° (92.3% ee); bp 87-89 °C/18 mmHg.

Solubility: sol hexanes, benzene.

Preparative Methods: prepared by esterification of *t*-leucine with ***Isobutene*** and conc ***Sulfuric Acid*** (under pressure).[4] Typical yields are 62-64% and 12-14% of recovered amino acid. *t*-Leucine itself is commercially available in racemic and optically pure forms. It can also be prepared by oxidation of pinacolone to trimethylpyruvic acid, followed by oxime formation and zinc reduction. Resolution of the *N*-formyl derivative of *t*-leucine has been carried out using brucine.[4a]

Handling, Storage, and Precautions: none.

Asymmetric Alkylations.

The use of nitrogen derivatives of carbonyl compounds (imines, imides, amides, sultams, oxazolines) is often the most efficient procedure for achieving α-alkylations.[1] Chiral auxiliaries bearing heteroatoms in a 1,2-relationship appear to work best, as they have chelation sites for the metal cation. High levels of asymmetric induction can thus be achieved due to the system rigidity. Cyclic ketones have been alkylated via the lithiated enamine formed from L-*t*-leucine *t*-butyl ester (eq 1).[5] High enantiomeric excesses and predictability of absolute configuration make this

method attractive.

1,2-Additions.

The imine prepared from L-*t*-leucine *t*-butyl ester and benzaldehyde has been used to prepare D-phenylglycine in 96.5% ee via a diastereoselective hydrocyanation.[2] A rigid five-membered ring transition state involving hydrogen bonding between nitrogen and carbonyl oxygen has been proposed. Attack of cyanide ion from the opposite side of the bulky *t*-butyl group accounts for the stereochemical outcome (eq 2).

1,4-Additions.

Asymmetric Michael additions[1] of Grignard reagents can be performed on α,β-unsaturated aldimines[3a] derived from either enantiomer of *t*-leucine *t*-butyl ester (eq 3).

Similarly, malonate anions[3b,c] add to aldimines with reasonably high enantioselectivity. The new asymmetric center, however, has the opposite absolute configuration to that shown in eq 3. A chelated aldimine of (*E*) geometry is the proposed intermediate for this reversal of stereoselection (eq 4).

Cyclic aldimines can also be used, and subsequent alkylation of the magnesioenamine intermediate achieved with good to excellent diastereoselectivity.[3d,e,f] *Cis* or *trans* products can be obtained, depending on the procedure chosen (eq 5).

A few natural product syntheses feature the use of both acyclic[6] and cyclic[7,8] aldimines of either enantiomer of *t*-leucine *t*-butyl ester. Kinetic resolution of racemic aldehydes has also been achieved using L-*t*-leucine *t*-butyl ester.[8]

For the three types of reactions presented above, *t*-leucine *t*-butyl ester has been shown to be the most efficient amino acid derivative. It is often mentioned that valine *t*-butyl ester affords lower enantioselectivities. Work-up procedures allow recovery of reusable optically pure auxiliary.

Lipases[1]

[9001-62-1] · (MW 30000-100000)

(catalyst for asymmetric transformations of chiral or prochiral alcohols or acids by hydrolysis or esterification reactions[1])

Solubility: powder sol aqueous solutions; suspension in organic media.

Form Supplied in: usually a white or brownish powder, but also immobilized on an appropriate support. Lipases from microbial sources are virtually homogeneous in terms of hydrolytic activity, while mammalian and plant lipase preparations contain several interfering enzymes including proteases and esterases.

Analysis of Reagent Purity: assay by titrimetry.[2]

Handling, Storage, and Precautions: must be stored in a refrigerator at 0-5 °C. Avoid breathing or inhaling dust. Avoid too vigorous stirring.

Lipase General Aspects.

Enzymes are now widely recognized as practical catalysts for asymmetric synthesis.[1b,c] Lipases are among the most widely applied and versatile biocatalysts in organic synthesis as can be witnessed by a number of recent reviews.[1] There are several reasons for this. They are readily available, do not require cofactors, are inexpensive and highly stable, exhibit broad substrate specificity, do not require water-soluble substrates, mechanistically are relatively well understood and, finally, are splendidly suited to retain a high degree of activity in organic media.

More than 20 lipases are now commercially available, either free or immobilized, from animal, plant, and microbial sources.[2] Amongst the lipases, the pig pancreatic lipase (PPL), the yeast lipase from *Candida cylindracea* (*rugosa*) (CCL), and the bacteria lipases from *Pseudomonas fluorescens* (*cepecia*) (PFL) and other unclassified *Pseudomonas* species (PSL) have been most widely used. The experimental methods are very straightforward and little different in their execution from conventional chemical reactions. Hydrolysis reactions are conducted on the soluble lipase in buffered aqueous solutions, commonly in the presence of an organic cosolvent. In organic media the enzyme is added as a powder or in an immobilized form and the resulting suspension stirred or (better) shaken at approximately 40 °C. The enzyme is removed by filtration.

Since their action toward substrates in terms of chemo-, regio-, and enantioselectivity varies considerably, it is important to have a large selection of lipases to find the right enzyme for a specific reaction by traditional biocatalyst screening. Alternative strategies for improving enantioselectivity of the already existing commercial lipases have been developed,[1a,3] including product recycling,[4] solvent screening,[5] water content control,[6] and immobilization. In addition to this, several active site models have been proposed to predict the enantiopreference of certain lipases.[1a,7]

Lipases have been used in three main types of asymmetric transformations: kinetic resolution of racemic carboxylic acids or alcohols, enantioselective group differentiations of *meso* dicarboxylic acids or diols, and enantiotopic group differentiation of prochiral dicarboxylic acid and diol derivatives. Hydrolysis has been the most widely used technique, but complementary esterification or transesterification procedures are increasingly coming into use. Lipases are used most frequently in transformations involving chiral alcohols rather than acids, unlike the pig liver esterase (PLE),[1a,b,c] which is most frequently employed on esters of chiral carboxylic acids. Lipases are also gaining increasing importance in solving problems of regioselectivity of various polyol and carbohydrate compounds.[1c,e,f,8] They have found application in stereoselective transformations involving lactonization and oligomerization of hydroxy acids and esters.[1e,f] Finally, a minor but useful advantage of the lipases is their mildness, which is particularly important in transformations involving labile compounds.[1a]

The range of nucleophiles that lipases accept is not confined to water or alcohols. There are numerous examples of amines,[9] hydrazine,[10] phenols,[11] and hydrogen peroxide.[12] Proteases have frequently been used in biocatalytic transformations involving ester hydrolysis and esterification reactions and their different stereoselection often provides a useful complement to the lipases.[1a,c,f]

Kinetic resolution of racemic compounds is by far the most common transformation catalyzed by lipases, in which the enzyme discriminates between the two enantiomeric constituents of a racemic mixture. It is important to note that the maximum yield of a kinetic resolution is restricted to 50% for each enantiomer based on the starting material. The prochiral route and transformations involving *meso* compounds, the *meso*-trick, have the advantage of potentially obtaining a 100% yield of pure enantiomer. A theoretical quantitative analysis of the kinetics involved in the biocatalytic processes described above has been developed.[1a,d,e] The enantiomeric ratio (E), an index of enantioselectivity, can be calculated from the extent of conversion and the corresponding enantiomeric excess (ee) values of either the product or the remaining substrate. The results reveal that for an irreversible process, such as hydrolysis, the optimum in both chemical and optical yield for the faster hydrolyzed enantiomer is to be expected near 40% conversion, and for the remaining slower hydrolyzed enantiomer around 60% conversion. For a high enantiomeric ratio (>100), high enantioselectivity is expected for both enantiomers at 50% conversion.

Under almost anhydrous conditions in organic medium,[1e,f] lipases can be used in the reverse mode for direct ester synthesis from carboxylic acids and alcohols, as well as transesterifications (acyl transfer reactions) which can be divided into alcoholysis (ester and alcohol), acidolysis (ester and acid), and interesterification (ester-ester interchange). The direct esterification and alcoholysis in particular have been most frequently used in asymmetric transformations involving lipases. The parameters that influence enzymatic catalysis in organic solvents have been intensively studied and discussed.[1a,e,f]

Besides ester synthesis being favored over hydrolysis, there are several major advantages of undertaking biocatalytic reactions in anhydrous media: increased solubility of nonpolar substrates, ease of product and enzyme recovery, enhanced thermal stability of enzymes and substrate specificity, and enantioselectivity regulation by the solvent. The main disadvantages include lower catalytic activity in organic media and reversibility, which limits the yield and works against the kinetic resolution, lowering the enantioselectivity of such processes. There are several strategies available to overcome these problems.[1a,e,f] Enol esters, such as vinyl or isopropenyl esters, are by far the most commonly used acyl transfer agents to ensure irreversibility by tautomerization of the enol leaving group.[13,14] Anhydrides,[15] *S*-phenyl thioacetate,[16] acyloxypyridines,[17] and oximes[18] have also been applied in a similar manner as acyl donors. Active trifluoro-[19] and trichloroethyl[20] esters have similarly been used to suppress the reversibility by speeding the acyl-enzyme formation and generating the weakly nucleophilic trifluoro- or trichloroethanol. Primary alcohols have also been used as acyl acceptors in transesterifications (deacylations) involving esters of more bulky and less nucleophilic secondary alcohols.[21]

Kinetic Resolution by Hydrolysis.

Until very recently, kinetic resolution of racemic alcohols as ester derivatives was by far the most common type of asymmetric transformations involving lipases.[1a] There are number of examples involving acyclic secondary alcohols, such as the glyceraldehyde derivative in eq 1[22] and various related alkyl- and aryloxy substituted chloride and tosylate glycerol derivatives.[22,23]

A wide variety of other alcohol substrates has been resolved,[1a] including aryl substituted secondary alcohols,[20,24] α-alkyl-β-hydroxy esters,[25] β-hydroxy nitriles,[26] and fluoroorganic compounds.[27] Active chloroacetate esters are commonly used to speed up the hydrolysis reactions, as exemplified in eq 2.[28] Primary acyclic alcohols possessing a stereogenic center that have been resolved include 2,3-epoxy alcohols,[29,30] 2-amino alcohols,[31] and crown ethers.[32]

Lipase-catalyzed asymmetric hydrolysis has also been conducted on numerous monocyclic, variously substituted five-, six-, and seven-membered cycloalkane and cycloalkene secondary alcohols and diols.[1a] More recent reports include *cis*-4-acetoxyflavan,[33] substituted cyclopentenones,[34] and the 1,2-bis(hydroxymethyl)cyclobutanol derivative exemplified in eq 3.[35]

(3)

Various bicyclic racemic alcohols have been resolved by asymmetric hydrolysis of their corresponding esters. Generally, the *exo* isomers appear to be far inferior substrates compared with the *endo* substrates.[1a] Eq 4 illustrates the resolution of a bicyclic derivative of the Corey lactone type.[36]

(4)

There are also several reports on the enantioselective hydrolysis of bicyclic secondary alcohols possessing the bicyclo[2.2.1]heptane and bicyclo[2.2.2]octane framework.[37] Again, with this type of substrate the lipases appear to exhibit strong preference for the *endo* isomers with the (*R*)-configured esters preferentially hydrolyzed.

Various chiral acids have also been resolved by lipase-catalyzed asymmetric hydrolysis.[1a] The reports include variously α-substituted acids[3,38] as well as the tertiary α-benzyloxy ester exemplified in eq 5.[39] Remethylation and repeated hydrolysis afforded the (*S*)-enantiomer in eq 5 optically pure. More recent examples include esters of glycidic acid,[40] β-aryl-β-hydroxy acid,[41] and sulfinyl alkanoates.[42]

Kinetic Resolution by Transesterification.

Asymmetric transformation involving acylation of chiral alcohols is by far the most common example of kinetic resolution by lipase-catalyzed transesterification, most commonly with irreversible vinyl esters.[1a,15] This field is now becoming the most widely applied technique involving lipases. Recent reports of the numerous secondary alcohol substrates include various monocyclic (eq 6)[43] and acyclic[44] compounds, cyanohydrins,[45] sulfones,[46] and glycals,[47] to name a few.

There are also several reports of enantioselective transesterification involving primary alcohols possessing stereogenic centers by similar acylation procedures, such as 2,3-epoxy alcohols (eq 7),[48] norbornene-derived iodolactones,[49] and 1,3-propanediols.[50]

Enantioselective lipase-catalyzed transesterification involving deacylation of esters of racemic primary or secondary alcohols with primary alcohols, most frequently *n*-butanol, serving as an acyl acceptor, is fairly common.[1a] Recent examples include esters of amino alcohols,[51] isoserine,[52] chlorohydrins,[53] and various tosyloxybutanoate esters (eq 8).[54]

Kinetic resolution involving acidolysis of esters of racemic secondary alcohols and acids or transesterification of chiral acids does not have many examples in the literature.[1a]

Kinetic Resolution by Direct Esterification.

This is the least common strategy for kinetic resolution and is most commonly executed on racemic alcohols with carboxylic acids in organic solvents.[1a] Reports include several alicyclic secondary alcohols such as menthol[55] and various aliphatic secondary alcohols.[56] Kinetic resolution of a variety of racemic saturated, unsaturated, and α-substituted carboxylic acids has also been effected by direct esterification with various alcohols.[20,57]

In addition to this, there are several reports of asymmetric esterification of racemic alcohols with anhydrides as acyl donors. Examples include various primary and secondary alcohols,[15] bicyclic secondary alcohols of the norbornane type,[58] amino alcohols,[59] and ferrocenes.[60] This is exemplified in eq 9 for 1-phenylethanol.[15]

Prochiral Compounds.

The enantiodifferentiation of prochiral compounds by lipase-catalyzed hydrolysis and transesterification reactions is fairly common, with prochiral 1,3-diols most frequently employed as substrates.[1a] Recent reports of asymmetric hydrolysis include diesters of 2-substituted 1,3-propanediols[61] and 2-*O*-protected glycerol derivatives.[8] The asymmetric transesterification of prochiral diols such as 2-*O*-benzylglycerol[8,13a] and various other 2-substituted 1,3-propanediol derivatives[13b,62] is also fairly common, most frequently with ***Vinyl Acetate*** as an irreversible acyl transfer agent.

There are also recent reports of the lipase-catalyzed enantioselective hydrolysis of prochiral diacid derivatives such as 2-substituted malonates,[63] barbiturates,[64] and highly substituted, sterically hindered 1,4-dihydropyridine derivatives using acyloxymethyl groups to enhance the reaction rate.[65] An example of a prochiral diester hydrolysis is illustrated in eq 10.[66]

(10)

Meso Compounds.

Although pig liver esterase is by far the most suitable enzyme for asymmetric transformations involving *meso* compounds, especially diacids, there are several reports on the lipase-catalyzed hydrolysis and transesterification reactions of cyclic diol derivatives.[1a] The former includes variously substituted cycloalkene diacetates, cyclohexylidene protected erythritol diacetate,[67] piperidine derivatives,[68] and the *exo*-acetonide in eq 11.[69] Complementary results are clearly demonstrated in eqs 11 and 12 for the hydrolysis and esterification processes.

(11)

(12)

The asymmetric transesterification of cyclic *meso*-diols, usually with vinyl acetate as an irreversible acyl transfer agent, includes monocyclic cycloalkene diol derivatives,[70] bicyclic diols,[71] such as the *exo*-acetonide in eq 12,[69] bicyclic diols of the norbornyl type,[72] and organometallic 1,2-bis(hydroxymethyl)ferrocene possessing planar chirality.[73]

Regioselective Biotransformations with Lipases.

Lipases are gaining increasing importance in solving problems of regioselectivity of various polyol and carbohydrate compounds.[1a,c,e,f,8] A variety of diols or the corresponding acetates as well as polyhydric phenol acetates[74] have been acylated or deacylated in a highly regioselective manner in high yields by lipase-catalyzed transesterification reactions. Regioselective direct esterification of aliphatic 1,2-diols[75] and inositol derivatives[76] using anhydrides as acylating agents has recently been reported. Primary hydroxyl groups are exclusively transformed, as would be anticipated on steric grounds. One example of a highly regioselective and at the same time highly enantioselective hydrolysis of a racemic diester is demonstrated in eq 13.[77]

(13)

There are also several reports on highly regioselective transesterification of various steroid derivatives, one example

being displayed in eq 14 in which butyration occurred exclusively at the 3β-hydroxyl group by *Chromobacterium viscosum* lipase (CVL).[78] Opposite regioselectivity toward the 17β-hydroxyl group was observed with subtilisin protease.[78]

(14)

There are numerous examples of highly regioselective lipase-catalyzed hydrolysis and acylation/deacylation processes involving monosaccharide and carbohydrate derivatives.[1a,f,8] Usually, the biotransformation processes occur preferentially and in many cases exclusively on the primary hydroxyl group (eq 15),[79] but highly regioselective transformations have also been described on secondary alcoholic groups for various carbohydrate derivatives possessing an acyl or alkyl protection on the primary hydroxyl moiety. Recent reports include highly regioselective acetylation of pyranosidic and furanosidic monosaccharide derivatives[80] and alkoxycarbonylation of nucleosides with oxime carbonates.[18]

(15)

Lactonization and Polycondensation.

The lipase-catalyzed intramolecular transesterification of a range of o-hydroxy esters has been investigated extensively[1a,e,f] and was observed to be very dependent on the chain length of the substrate (eq 16).

(16)

For longer-chain hydroxy esters (n = 13, 14) the corresponding macrolide was accomplished in high yield with very little diolide formed (diolide increased considerably with lower n). With medium-sized hydroxy esters the product profile became considerably more complex, consisting of a complex mixture of di-, tri-, tetra-, and pentalactones.[28,81] Shorter-chain unsubstituted β-, δ-, and ε-hydroxy esters almost exclusively underwent intermolecular transesterification to afford the corresponding oligomers. δ-Substituted δ-hydroxy esters[82] and γ-hydroxy esters[83] underwent lactonization with a high degree of enantioselectivity.

Prochiral γ-hydroxy diesters underwent enantioselective lactonization with PPL to afford the (S)-lactone in a highly enantioselective fashion (eq 17).[83a] Formation of macrocyclic lactones by the condensation of diacids or diesters with diols, leading to mono- and dilactones,[84] linear oligomeric esters, or high molecular weight optically active polymers,[85] depending upon type of substrates as well as reaction conditions, has also been described.

(17)

Mildness and Miscellaneous Reactions.

The mildness of the lipases has been particularly well suited in transformations involving labile compounds that are likely to undergo decomposition when conventional chemical methods are applied,[1a] such as the long-chain polyunsaturated o-3-type fatty acids[86] and highly labile prostaglandin precursor derivatives.[87] Under mild conditions, lipase was exploited to hydrolyze the peracetal protected hydroperoxy derivative in eq 18 to afford the corresponding acid without affecting the peracetal protection moiety.[88]

(18)

Various miscellaneous lipase-catalyzed reactions have been reported,[1a] including lipase-mediated epoxidation of alkenes,[12] transamidation,[89] thiotransesterification of thioesters for the preparation of optically active thiols,[90] regio- and chemoselective peptide acylation,[91] lactamization,[92] and highly enantioselective hydrolysis of racemic oxazolin-5-ones which undergo a rapid keto-enol tautomerism to afford optically pure amino acids, thus exceeding the 50% yield limit.[93]

Finally, lipases are able to differentiate enantiotopic faces of appropriately substituted enol esters to afford optically active ketones,[94] indicating that simultaneously upon hydrolysis of the acyl group, protonation occurs from one specified side of the double bond of the enol ester without formation of an enol intermediate (eq 19).[94a]

Lithioacetonitrile

($R^1 = R^2 = H$)

[20428-58-4, 55440-71-6] · C_2H_2LiN · Lithioacetonitrile · (MW 46.99) (R^1 = Me, R^2 = H)

[59263-57-9] · C_3H_4LiN · 2-Lithiopropionitrile · (MW 61.01) ($R^1 = R^2$ = Me)

[55440-70-5, 50654-53-0] · C_4H_6LiN · 2-Lithioisobutyronitrile · (MW 75.04)

(C_2 carbanion for nucleophilic cyanomethylation of alkyl halides, epoxides, carbonyl electrophiles, α,β-enals (1,2-addition), α,β-enones (1,2- or 1,4-addition), heteroelectrophiles, C=N double bonds, and diene and arene transition metal complexes; cyanomethylenation of aldehydes and ketones[1])

Preparative Methods: addition of ***Acetonitrile*** to ***n-Butyllithium*** in Et_2O and warming to 25 °C provides lithioacetonitrile as a white solid in 81% yield; this material is insol hexane, octane, Et_2O, THF, and DME but is sol DMSO.[2a] Lithioacetonitrile can also be prepared from lithium dialkylamides in THF; this material is sol THF even at low temperatures.

Handling, Storage, and Precautions: should be handled in a fume hood.

Alkylation.

The alkylation of lithioacetonitrile and related metalated derivatives with alkyl halides or sulfonates[2b-5] and with epoxides[6-8] proceeds in good yield (eq 1).[2b] An interesting example involves the alkylation with spiro[4.2]hepta-1,3-diene in which cyclopentadienyl anion functions as the leaving group.[9] The regioselective ring opening of epoxides with lithioacetonitrile finds application in the synthesis of γ-hydroxy nitriles.[6-8] The addition of ***Copper(I) Iodide*** to lithioacetonitrile gives a (cyanomethyl)cuprate that reacts efficiently with primary allylic bromides (eq 2).[10]

(1)

(2)

Addition to C=O Bonds.

The addition of lithioacetonitrile to diaryl, alkyl aryl, and alkyl ketones[11] as well as aryl[11-13] and aliphatic aldehydes[13b] provides the expected β-hydroxy nitriles (eq 3). The dehydration of these intermediates, typically using 85% ***Phosphoric Acid***,[11] provides substituted acrylonitriles. Bis(addition) products are observed under some conditions.[14] The addition of lithioacetonitrile[15a] or 2-lithiopropionitrile[15b] to cyclohexanones gives β-hydroxy nitriles principally with axial selectivity for the cyanomethyl or 1-cyanoethyl groups, respectively (eq 3). Organomanganese or organocerium reagents derived from lithioacetonitrile using $Mn(OCO\text{-}t\text{-}Bu)_2$ and ***Cerium(III) Chloride***, respectively, undergo selective carbonyl addition reactions.[16]

(3)

The addition of nitrile-stabilized anions to carbonyl electrophiles other than aldehydes and ketones affords several potentially useful products. The addition of 2-lithiopropionitrile to a trimethylsilyl ketone proceeds with migration of a silyl group from carbon to oxygen and cyanide elimination to give a trimethylsilyl enol ether (eq 4).[17] Lithioacetonitrile adds to *N*-methoxycarbonyl-protected succinimides to give γ-hydroxy lactams in modest yield.[18] The reaction of nitrile-stabilized anions with *N*,*N*′-di-*t*-butyldiaziridone leads to an acyclic hydrazide derivative with lithioacetonitrile and a pyrazolinone with 2-lithiopropionitrile.[19] The addition of 2-lithiopropionitrile to a γ-lactone gives an intermediate α-cyano ketone that cascades to a substituted tetrahydrofuran.[20]

(4)

Michael Addition.

The addition of nitrile-stabilized carbanions to α,β-unsaturated aldehydes favors 1,2-addition.[21,22] In an interesting variant of this process, the reaction of tricarbonyl(sorbaldehyde)iron with lithioacetonitrile initially gives a *cis*/*trans* mixture of acrylonitriles (eq 5). Migration of the $Fe(CO)_3$ group, reduction of the nitrile, and reiteration of the addition process furnishes the next higher homolog in the series (eq 5).[23]

(5)

Kinetically controlled 1,2-addition to α,β-unsaturated ketones occurs at -25 to -30 °C and dehydration leads to cyano-substituted dienes.[24] Higher temperatures lead to the thermodynamic 1,4-addition product. The axial selectivity noted in 1,2-additions to cyclohexanones[15a] increases for the addition of nitrile-stabilized carbanions to cyclohexenones[15b,c] and reaches very high levels (136:1) in the reaction of 2-lithiopropionitrile with pulegone.[15b] The 1,2-additions of lithioacetonitrile and 2-lithiopropionitrile to α-oxoketene dithioacetals and cycloaromatization of the intermediate β-hydroxy nitriles with phosphoric acid provides access to substituted pyridines.[25] The reaction of lithioacetonitrile with an α,β-unsaturated ester leads to both 1,2- and 1,4-addition products (for a solution to this problem, see ***Trimethylsilylacetonitrile***).[26] The 1,4-addition of lithioacetonitrile to other Michael acceptors, such as α,β-unsaturated sulfones[27,28] and vinyl sulfonium salts,[29] proceeds as expected.

Reactions with Heteroelectrophiles.

Trapping nitrile-stabilized carbanions with a variety of electrophiles provides access to sulfur-,[30] phosphorus-,[31] or silicon-substituted nitriles.[32]

Additions to C=N Double Bonds.

The addition of lithioacetonitrile to nitrones[33] and 2-aza-1,3-butadienes[34] furnishes hydroxylamines and, following hydrolysis in the latter case, β-amino nitriles (eq 6), respectively.

(6)

Addition to η^4-Diene, η^5-Dienyl, and η^6-Arene Metal Complexes.[35]

The addition of nitrile-stabilized anions to diene and dienyl transition metal complexes provides access to various cyano-substituted alkenes, ketones, or dienes. The addition of nitrile-stabilized anions to substituted (η^4-1,3-butadiene)tricarbonyliron complexes furnishes cyano-substituted alkenes[36] as, for example, in the synthesis of 2,2,3,4-tetramethyl-4-pentenenitrile (eq 7).[36b]

(7)

Trapping the intermediate iron complexes with carbon monoxide leads, in the case of most acylic 1,3-dienes, to cyclopentanones (eq 8),[37] or trapping with carbon monoxide followed by an alkylation gives γ,δ-unsaturated ketones.[38] The addition of 2-lithiobutyronitrile to tricarbonyl(η^5-dienyl)manganese complexes and a subsequent oxidation provides 1,3-dienes (eq 9).[39] The addition of nitrile-stabilized carbanions to various arene-transition metal complexes affords substituted arenes[35a,b] or 1,3-cyclohexadienes[35b,40] (see ***(η^6-Benzene)tricarbonylchromium***). In the case of a methoxy-substituted arene, the addition of 3-lithiobutyronitrile to (η^6-anisole)tricarbonylchromium(0) and the further acid-catalyzed hydrolysis of the intermediate 1-methoxy-1,3-cyclohexadiene provides a substituted cyclohexenone.[40e]

(8)

(9)

Related Reagents.

Acetonitrile; ***Cyanoacetic Acid***; ***Ethyl Cyanoacetate***; ***Ethyl Lithioacetate***; ***Pentacarbonyliron***; ***Tricarbonyl(cyclohexadienyl)iron Tetrafluoroborate***; ***Tricarbonyl(pentadienyl)iron Tetrafluoroborate***.

o-Lithioanisole

[31600-89-9] · C_7H_7LiO · *o*-Lithioanisole · (MW 114.08)

(strong base/strong nucleophile capable of both nucleophilic addition and nucleophilic substitution)

Physical Data: the pK_a for the *ortho* hydrogens in anisole has been estimated to be 39.0.[4]

Preparative Methods: by metalation of anisole in anhydrous ether with 2 equiv of ***n-Butyllithium*** and 2 equiv of ***N,N,N´,N´-Tetramethylethylenediamine*** at 25 °C for 1-2 h.[1a] Under these conditions a >95% conversion is obtained. If no excess of BuLi or other impurities can be tolerated, then the reagent can be prepared by metal halogen exchange of *o*-bromoanisole and purified by crystallization.[1b] Isolated *o*-lithioanisole is a pyrophoric white powder.

Form Supplied in: the reagent is prepared in situ as needed.

Handling, Storage, and Precautions: must be prepared and handled in an inert atmosphere, as for other organolithium reagents.

o-Lithioanisole as a Reagent.

Several factors influence the site and extent of metalation of an aromatic system containing a substituent group (DMG) that directs metalation.[2] The methoxy group of anisole was the earliest such group to be identified.[3] The important factors affecting the intrinsic (structural) effectiveness of such groups are: (1) the coordinating ability of the heteroatom in the DMG, (2) the electron-withdrawing (*o*-hydrogen-acidity enhancing) ability of the DMG,[4] and (3) the size of the ring structure resulting from the formation of the coordinated *o*-lithio intermediate.[5] The methoxy group occupies an intermediate position in the ranking of DMGs to direct metalation.

Early investigations of this reaction reported conversions of only 50-65% to the *o*-lithio intermediate.[6,7] Later work revealed that the reaction could be accelerated by sonication,[9] and by addition of a stoichiometric amount of ***N,N,N´,N´-Tetramethylethylenediamine*** (TMEDA),[8] with a yield of 73% of the *o*-trimethylsilyl derivative being reported. A better procedure, that affords 95% (GC yield) of the *o*-trimethylsilyl derivative,[1] involves use of 2 equiv

each of ***n-Butyllithium*** and TMEDA. Concentration also plays a role; solutions of anisole in the 1M range appear to be best. Significantly lower amounts of TMEDA are nearly as effective in promoting the metalation. For highest yields the reaction is run at 25 °C in ether solvent for about one hour.

o-Lithioanisole formally contains only a four-membered coordinated ring system, although more elaborated structures involving the organolithium oligomer allow a pseudo five-membered ring to be drawn.[5] Crystal structures of isolated complexes of *o*-lithioanisole[10,11] exhibit tetrameric unit cells supporting the idea of a pseudo five-membered coordinated ring structure.[12] For metalation solutions containing TMEDA, indirect NMR evidence and MNDO calculations favor an *n*-BuLi dimer-TMEDA-anisole interaction.[5b] Other efforts to understand the mechanism of the *o*-lithiation of anisole have been published.[13,14]

Two separate thermochemical studies have determined that *o*-lithioanisole is more stable than *p*-lithioanisole by either 15[15] or 35 kJ mol^{-1}.[16] That the stability of the coordinated intermediate is important, or that interference with the ability to form such an intermediate is important in the transition state, can be adduced from several studies involving steric effects.[6,17-19] The ability to generate the *o*-lithio intermediate for PhOR, where R is Me, Et, *i*-Pr, and *t*-Bu, falls off through the series.[6,17]

As stated earlier, the methoxy group is intermediate in its directing ability. A study of a series of *p*-substituted anisoles established the order CONHR, SO_2NHMe, SO_2NMe_2, CH_2NMe_2 > OMe > F, CF_3, $CH_2CH_2NMe_2$.[20] Subsequent reports added $CONEt_2$[21] and oxazoline[22] to the stronger- and SMe[23] to the weaker-than-methoxy directing categories. Some additional ordering within the categories has been established as well as certain other directing groups added to each of the categories.[1,2]

A number of other monosubstituted anisoles have been metalated. Varying yields of product derived from metalation *ortho* to the methoxy group have been obtained from *p*-F,[24-27] *p*-Cl,[24,28] *p*-Br,[24] and *p*-I[24] anisole. The best yields that can be obtained from these systems lie in the 50-60% range because of the opportunities for various side reactions involving the halogens. *p*-Methylanisole has been metalated in about 30% yield[29] and 1,4-dimethoxybenzene in about 75% yield.[8] The latter compound, by the addition of TMEDA to the metalation system, can be made to form a 2,5-dilithio intermediate.

Two interesting and potentially useful reversals of the site of metalation have been developed. For *p*-methoxydimethylbenzylamine the preferred site of metalation with *n*-BuLi is that *ortho* to the dimethylaminomethyl group. However, when TMEDA is added to the metalation system, the preferred site of metalation is *ortho* to the methoxy group.[30] Both *o*-and *p*-fluoroanisole can be made to exhibit the same phenomenon. With *n*-BuLi, metalation occurs exclusively *ortho* to the methoxy group,[26,27] while at -78 °C with *n*-BuLi/***N,N,N´,N´´,N´´-Pentamethyldiethylenetriamine***, metalation takes place *ortho* to the fluoro substituent.[26]

Disubstituted benzenes exhibiting an *ortho*- or *meta*-orientation of directing substituents can be successfully metalated. 1,2-Dimethoxybenzene easily affords the 3-substituted product of metalation while 1,3-dimethoxybenzene undergoes metalation specifically at the 2-position.[8] Similarly, 3-fluoroanisole, if metalated at -78 °C, provides derivatives at the 2-position.[31] For the hydroxyanisoles, mixtures were obtained for the metalation of the 1,2- and 1,3-isomers, but fairly regiospecific metalation *ortho* to the methoxy group was obtained for the 1,4-isomer.[32]

1-Methoxynaphthalene upon treatment with *n*-BuLi/TMEDA affords 2-metalation; with ***t-Butyllithium***/pentane, 8-metalation is achieved.[33] 2-Methoxynaphthalene undergoes metalation at the 3-position.[34] Certain methoxy heterocycles have also undergone successful directed metalation, although the yields are usually modest. 2-

Methoxypyridine has been derivatized in the 3-position using a novel metalating system: ***Methyllithium*** catalyzed by a small amount of ***Diisopropylamine***. This mixture of a kinetic and thermodynamic base avoids the competition of addition of RLi to the pyridine system.[35] 3-Methoxythiophene has been metalated in the 2-position[36] and 2,4-dimethoxypyrimidine in the 5-position using ***Lithium Diisopropylamide*** or ***Lithium 2,2,6,6-Tetramethylpiperidide***.[37] Methoxyferrocene is metalated with *n*-BuLi in the 2-position.[38]

A number of directing groups related to the methoxy group also provide good yields of the *o*-lithio intermediate. These include the methoxymethoxy group (OCH_2OMe),[39] the carbamate group ($OC(O)NEt_2$)[2,40] the methoxyethoxy group (OCH_2CH_2OMe),[41,44] the 2-(trimethylsilyl)ethoxymethoxy system ($OCH_2OCH_2CH_2SiMe_3$),[42] and the dimethylaminoethoxy group ($OCH_2CH_2NMe_2$).[43,44] Some of these derivatives can be transformed into the phenol upon hydrolysis or other suitable treatment. Lastly, phenol itself can undergo *o*-lithiation.[45] For the first three of the above-named directors the yields of *o*-lithiation are good.

More complex examples of the *o*-lithiation of substituted anisoles illustrate the utility of the reaction for synthesis. In the preparation of a series of phenethylamines the key precursor, 5-methoxybenzonorbornadiene, was generated from *m*-fluoroanisole (eq 1).[46] Using a one-pot lithiation/oxygenation procedure (***s-Butyllithium***, TMEDA; then ***Oxygen***) a series of methoxyphenols was prepared by direct hydroxylation in modest yields (eq 2).[47] Veratrole can be metalated and alkylated cleanly (eq 3).[48] Double metalation of anisole has led to a trisubstituted aryloxazoline (eq 4).[49] A centrally acting dopaminergic and serotoninergic agonist was synthesized by metalation/hydroxylation of a methoxytetralin (eq 5).[50] A total synthesis of the naturally occurring sesquiterpene, aplysin, in its racemic modification was accomplished by a surprisingly regiospecific metalation of a bromoanisole (eq 6). [51] Cram and co-workers have utilized the *o*-lithiation of a dimethoxybiphenyl in the synthesis of cavitands and caviplexes (eq 7).[52]

(6)

(7)

Examples of the utility of directing groups related to the methoxy group can also be found in the literature. A bipyridine derivative has been used to synthesize orelline, a toadstool metabolite. A test reaction established a fairly efficient bis-metalation of the bipyridine (eq 8).[53] In order to avoid lateral metalation of the methyl group, the methoxymethoxy group was utilized in the first step of a synthesis of anthramycin (eq 9).[54]

(8)

(9)

Regiospecific metalation of tamoxifen, an antiestrogenic agent currently employed in the treatment of breast cancer, has been utilized to synthesize an *o*-iodo derivative (derived from the *o*-Sn precursor); this technique has the potential of introducing a radioactive label (eq 10).[55] Utility of the carbamate group has recently been reviewed.[2b]

2-Lithio-3,3-diethoxy-1-propene[1]

[54780-30-2] · $C_7H_{13}LiO_2$ · 2-Lithio-3,3-diethoxy-1-propene · (MW 136.12)

(is able to transfer a masked acrolein unit to various electrophiles such as carbon dioxide,[1] aldehydes,[2] ketones,[2] and amides;[3] the corresponding cuprate also allows 1,4-addition to conjugated enones,[4] coupling with allylic halides,[4b] and 1,2-opening of 3,4-epoxycycloalkenes[5])

Alternate Names: 3,3-diethoxy-1-propen-2-yllithium; 3,3-diethoxy-2-lithio-1-propene.

Preparative Method: under nitrogen, ***n-Butyllithium*** (2 molar in hexane, 0.95 equiv) is slowly added at -70 °C to 2-bromo-3,3-diethoxy-1-propene in dry THF (1.6 mL $mmol^{-1}$ of bromoacrolein acetal).[2d]

Handling, Storage, and Precautions: this solution of a vinyllithium should be held under nitrogen at low temperature (the upper limit for the thermal stability has been estimated to be approx. -40 °C), kept out of oxygen and moisture, and used immediately for best results.

Organolithium Reagent.

Addition of ketones[2] or aldehydes[2,6] to the title organolithium (**1**) in THF at -70 °C leads to the corresponding β-hydroxy-α-methylene acetals in respectively 50 and 80% yields (eq 1). 1,2-Addition is also observed with conjugated enones[7] or enals. These secondary allylic alcohols can be stereoselectively transformed into trisubstituted functionalized alkenes.[2,8]

(1)

$$R, R^1 = H,\ R = H,\ R^1 \neq H \text{ or } R, R^1 \neq H$$

Reaction of (**1**) with enantiomerically pure 2,3-*O*-isopropylidene-D-glyceraldehyde gives the diastereoisomer adducts (*erythro*:*threo* = 2:1) in 70% yield (eq 2).[2c] These are precursors of C-2 branched chain pentoses, α-methylenelactones, or

2,4-disubstituted furans.[8b,9]

The reagent also reacts with other electrophiles such as ***Carbon Dioxide***,[1] ***Chlorotrimethylsilane***, and amides[3] (eq 3). In the latter case, α-methylene-β-oxoacetals are obtained in about 70% yield, except for R = H or Me (20-30% yield). These adducts lead to substituted β-keto enol ethers by addition of ***Lithium Dimethylcuprate***.[10]

Synthetic equivalents of 2-lithiopropenal[11] and of its diethyl acetal[12] (eqs 4 and 5) have also been reported.

Organocopper Reagents.

(**1**) can be transformed into other organometallic species such as vinylcopper (**2**),[4b] homogeneous diorganocuprates (**3**),[4a] and mixed diorganocuprates such as phenylthio-,[4b,c] alkynyl-,[4,5] or cyanocuprate (**4**)[5]

The (α-diethoxymethyl)vinylcopper reacts with allylic halides and gives only 1,2-addition reactions with conjugated enones.[4b] Homogeneous[4a,13] and mixed[4c] diorganocuprates react with a variety of α,β-unsaturated ketones to afford 1,4-adducts in moderate to excellent yields, depending upon steric hindrance in the enone (eq 6). These adducts have been shown to be suitable precursors to α-methylene-γ-lactones.[4c] Mixed diorganocuprates also allow coupling with allylic halides[4b] and allylic epoxides[5] (eqs 7 and 8), but not with vinyl or saturated halides.

(6)

(7)

(8)

Related Reagents.

Cyclic analogs (**5**)-(**7**) of the vinyllithium with a β-acetal function[14] have also proved useful in a variety of synthetic schemes.

(5)

(6) R = H, OMe

(7) $n = 1, 2$

Acrylate anion analogs such as orthoesters (**8**)[15] and (**9**)[16] and esters (**10**),[17] (**11**),[16] and (**12**)[18] have been described (Table 1). Cuprate (**10**) reacts with allylic and propargylic halides,[17,19] but in contrast to most organocuprate reagents, (**10**) reacts at low temperature with conjugated enones to yield predominately 1,2-addition products.[7,20]

2-Lithio-*N,N*-diethylbenzamide

[81380-82-7] · $C_{11}H_{14}LiNO$ · 2-Lithio-*N,N*-diethylbenzamide · (MW 183.179)

(reagent used for production of highly substituted benzene derivatives)

Preparative Method: solutions of the title compound can be obtained by deprotonation of *N,N*-diethylbenzamide using ***s-Butyllithium*** in THF/TMEDA at -78 °C.

General Considerations.

A variety of benzamides have been deprotonated at the *ortho* position to give the corresponding lithiated species which then undergo reaction with electrophiles (eq 1).

(1) **(2)** **(3)**

$E^+ = RX, RCHO, RCOR, R_3SiCl, HCONMe_2, CO_2, I_2$, epoxides

A large amount of data in this area has been compiled by Snieckus[1] and represents the state of the art in the use of (**2**) and related reagents. Two derivatives of (**1**) which undergo clean deprotonation and reaction with electrophiles are the *N,N*-diethyl and *N,N*-diisopropyl amides. Both can be converted near quantitatively to the corresponding *o*-lithio reagents with *s*-BuLi in THF/TMEDA at -78 °C. Both react with a variety of electrophiles in high yield.

Manipulation of Alkylated Products.

Although *N*,*N*-dialkylbenzamides are quite stable to acidic or basic hydrolysis, some adducts undergo replacement of the *N*,*N*-dialkyl group quite easily as a consequence of proximal functionality. Thus, adducts of the *o*-lithio species with aldehydes and ketones can be cyclized to phthalides (**6**) with acid (eq 2).[2] The phthalides in turn have been converted to anthraquinones (**7** -> **8**) (eq 3).[3] Anthraquinones may also be prepared without going through phthalide intermediates. After addition of the aryllithium to a benzaldehyde (**9**), the alkoxide (**10**) can be further metalated to (**11**), which closes to (**12**). Oxidation gives the anthraquinone (eq 4).[4]

(2)

(5) (6)

(3)

(7) (8)

Cross Coupling via Boronic Acids.

Ortho-lithiated benzamides can be converted to *o*-substituted boronic acids (**14**). These can be coupled with aryl halides in a palladium-catalyzed process leading to a general synthesis of biaryls.[5] This is only the beginning of a versatile synthetic method. The presence of the amide in (**15**) enables further metalation and elaboration to a diverse array of aromatic compounds.

Related Reagents.

o-Lithioanisole; ***3-Lithiofuran***; ***2-Lithiopyridine***; ***Phenyllithium***.

5-Lithio-2,3-dihydrofuran[1]

[75213-94-4] · C_4H_5LiO · 5-Lithio-2,3-dihydrofuran · (MW 76.02)

(nucleophilic nonbasic carbanion,[1] formally equivalent to a cyclic acyl anion,[2] which may be interacted readily with many electrophiles[3])

Physical Data: ^{13}C NMR chemical shifts[4] (22.6 MHz, 308 K, THF/hexane, TMS): δ (ppm) = 30.7 (C-3), 66.0 (C-2), 109.6 (C-4), 202.3 (C-5).

Solubility: sol ether, THF.

Form Supplied in: prepared in situ and used directly.

Preparative Methods: the easy deprotonation of 2,3-dihydrofuran (commercially available) at position 5 by strong bases has been known for some time[5] and extensively studied by several groups. While the original procedures described for the title reagent (**1**) employed a stoichiometric amount of ***t-Butyllithium*** in a minimum quantity of THF at low temperature,[1,2] it since has been reported that the deprotonation reaction takes place with mixtures of ***n-Butyllithium*** and ***N,N,N´,N´-Tetramethylethylenediamine*** in hexane at 0 °C[3] or *n*-BuLi in ether at 0 °C.[6,7] A representative procedure consists of the addition of 0.8 equivalent of *t*-BuLi (1.8 M in pentane) to a THF solution of freshly distilled 2,3-dihydrofuran at -40 °C for 0.5 to 1 h.[3] An alternative deprotonation method uses a 1:1:1 mixture of *n*-BuLi, ***Potassium t-Butoxide***, and TMEDA in hexane for 15 min at -30 °C.[8] (**1**) can be used in THF solution or in ether after evaporation of the original solvents.[3,9] The THF solution is stable for at least a few hours at room temperature.[1] However, lithiodihydrofuran in THF partly decomposes after 24 h at 25 °C into lithium alkynolate and ethylene.[10] This reaction in the presence of excess base and silylating reagent leads to bis(silyl)ketenes (eq 1).[10]

The deprotonation is regioselective, no allylic metalation having been observed to date, a result explained on the ground of orbital calculations as well as steric and electronic considerations.[11] The carbon-13 NMR spectrum of the lithiated compound exhibits a large downfield shift for the two carbon atoms of the double bond.[4]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture.

Reactivity.

(**1**) reacts readily with a variety of electrophiles, providing the expected substitution product in good to excellent yields. Some examples of its addition to ketones have been reported.[1,12] ***Acetone*** gives the expected carbinol in 78% yield.[1] ***Cyclobutanone*** yields a cyclobutanol derivative which rearranges quantitatively with ring expansion in the presence of Dowex-50X at room temperature (eq 2).[12b] Reiteration of this addition-ring expansion process gives access to belted spirocyclic tetrahydrofurans, which behave as potent ionophoric polyethers with extraction equilibrium constants close to those of ***12-Crown-4***.

(2)

Similarly, 1,2-addition of an unsaturated nitrile has been shown to yield an imine[13] and interaction with silyl (as well as germanyl and stannyl) chlorides afforded the expected 5-silylated[3,4,14] (germanylated[14b,c] and stannylated[3,15]) 2,3-dihydrofuryl derivatives. A related reaction with disulfides leads to cyclic ketene thioacetals.[8]

Alkylation Reactions: Stereoselective Synthesis of Homoallylic Alcohols.

Alkylations represent a major application of reagent (**1**). The early demonstration of the reactivity of (**1**) toward primary alkyl bromides or iodides[2] followed by the mild hydrolysis of the product illustrates the utility of 5-lithio-2,3-dihydrofuran as a protected substituted acyl anion (eq 3). While the first alkylation reactions have been conducted at moderate temperatures (-78 to 20 °C) in a THF/HMPA mixture,[1,2] later experiments have used THF only, sometimes at temperatures up to 50 °C (eq 3).[3,16]

(3)

The alkylation products easily rearrange, placing the double bond into the exocyclic position, as noticed at room temperature in deuteriochloroform (eq 4).[3,17]

(4)

This reaction has since been applied extensively to the preparation of 5-alkyldihydrofurans whose Ni^0-catalyzed coupling with Grignard reagents leads with high stereocontrol to homoallylic alcohols.[18a] Among the

numerous examples and applications to the stereoselective synthesis of trisubstituted alkenes,[3,9,16,19] an especially attractive example is the coupling with MeMgBr. This yields a useful isoprenoid structure well suited for the iterative approach to the terpene series adopted by Kocienski and colleagues.[19c] In this work, (**1**) is alkylated by 1-iodo-4-methylpent-3-ene in THF at -30 °C to provide the 5-substituted 2,3-dihydrofuran. The latter compound then is coupled with ***Methylmagnesium Bromide*** in benzene in the presence of a catalytic amount of a Ni^0 complex, providing efficient (89%) access to homogeraniol with almost total control (>97%) of the stereochemistry of the double bond. Conversion of this alcohol into the iodo compound provides the substrate for the next iteration, viz alkylation of (**1**), Ni^0-catalyzed coupling with MeMgBr, and iodination (see ***Iodine***). A third iteration is then applied, leading in excellent overall 46% yield (9 steps) to homogeranylgeraniol (eq 5).

The reaction, however, is restricted to Grignard reagents. On coupling of 5-(trimethylsilyl)- or 5-(trimethylstannyl)dihydrofuran with methylmagnesium bromide a versatile vinyl silane is obtained,[3] which, for instance, could be brominated with complete stereochemical inversion (eq 6).

The stereoselective access to (*E*)-disubstituted alkenes is within this methodology's reach.[3,18,20] The use of a Grignard reagent bearing β-hydrogen(s) involves a reduction reaction competing with the coupling

reaction,[18a] supposedly through a β-hydride elimination process and formation of nickel hydride complexes. The observed stereoselectivity depends strongly on the nature of the Ni ligands.[3,20] A recent application of this reduction process is the stereoselective synthesis of the macrolactonic fungal metabolite (±)-recifeiolide.[20]

The title compound can undergo double C-5 substitution. This reaction has been reported to proceed with copper catalysis,[15,19a,21] but has been observed also in the absence of any transition metal.[7] The dihydrofuran moiety is exposed to two successive reactions, first with a nucleophilic (Grignard or organolithium) reagent and then with an electrophilic partner, in a one-pot procedure.[7,15] The copper-catalyzed coupling reaction has been proposed to involve higher or lower order cuprate intermediates, followed by a 1,2-alkyl migration or a dyotropic rearrangement (eq 7).[15,19d]

(7)

Depending on the alkyllithium partner, this reaction may become catalytic in copper, a feature explained through a catalytic cycle involving ligand exchange at the metal.[19d]

Unlike the reaction of Grignard reagents with 2,3-dihydrofuran under Ni^0 catalysis[18,22] (coupling with retention of configuration), the corresponding Cu^I-catalyzed reaction appears to proceed with inversion of configuration, leading to di- or trisubstituted homoallylic alcohols (*E* &egt; 97% stereoselectivity). In the absence of any alkyl ligand on copper, this reaction leads to the self coupling of the enol ether, providing spiroacetals.[19d] The first application to natural product chemistry derived from this methodology is the synthesis of the antihypotensive agent lacrimin A.[23] In the case of the uncatalyzed reaction, an addition-elimination mechanism with a dilithiated intermediate has been proposed (eq 8).[7]

(8)

Other Transmetalation Reactions.

Only a few examples have been described. It has been shown that the low temperature addition of the THF solution of (**1**) to trialkylaluminum in hexane leads to the corresponding dihydrofuranyl triorganoaluminates.[24] These add to electrophiles such as cyclohexene oxide in the presence of a stoichiometric amount of ***Boron Trifluoride Etherate*** to yield the substituted cyclohexanols with a good diastereoselectivity. A 1,2-alkyl migration is proposed to explain this unexpected reactivity. On the other hand, the ring-opened product is obtained by treatment with the same Lewis acid in the absence of any

electrophile,[24] a reaction resembling the copper-catalyzed coupling described above (eq 9).[19d]

Dihydrofuranyl nickel(II) complexes have been prepared[6] starting from (**1**) and have been shown to yield Ni carbene complexes. Some of them could be crystallized.[6,25]

6-Lithio-2,3-dihydro-4*H*-pyran[1]

[72081-15-3] · C_5H_7LiO · 6-Lithio-2,3-dihydro-4*H*-pyran · (MW 90.05)

(acyl anion equivalent which reacts with a variety of carbon and other electrophiles via substitution and 1,2-addition;[2-6] after conversion to other organometallics via conjugate addition[7] and Pd^0-catalyzed coupling,[5] the resulting adducts are utilized for the preparation of substituted cyclopentenones and cyclohexenones and polycyclic spiro acetals[2,8,9])

Alternate Name: 6-lithio-3,4-dihydro-2*H*-pyran.

Physical Data: white to off-white, highly moisture and air sensitive solid which may be pyrophoric.[10] ^{13}C NMR (22.625 MHz in d_8 THF): δ 201.2, 111.1 ($^1J_{^{13}C-^1H}$ = 154.8 Hz), 62.8, 24.71, 20.99.[10]

Solubility: sol anhydrous THF, anhydrous ether, and mixtures of saturated hydrocarbons and THF; insol pure hydrocarbons. At high concentrations (> ca. 1M), the reagent will sometimes precipitate from THF-pentanes at -78 °C.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: the extent of metalation can be assessed by deuteration of an aliquot and ^1H NMR analysis of the recovered 2,3-dihydropyran,[10] or by direct observation using ^1H NMR.[2,11] The concentration of solutions of the reagent can be determined by titration.[12]

Preparative Methods: three basic preparative methods have been described: metalation with the *t*-BuLi-2THF complex (lemon yellow) in pentane at about -10 °C;[2] metalation with *n*-BuLi or *t*-BuLi in hexane or pentane containing a catalytic amount of TMEDA at 0 °C to room temperature or slightly above (the reagent precipitates from solution);[10,13] or metalation with *n*-BuLi in hexanes at 50-60 °C for several hours (also results in a precipate of the lithium reagent).[14] For difficult cases, the Schlosser base (*n*-BuLi/KO-*t*-Bu) has been used, usually followed by trapping with chlorotrialkylstannanes and transmetalation of 6-trialkylstannyl-2,3-dihydro-4*H*-pyran and substituted derivatives thereof with *n*-BuLi in THF at -78 °C,[8,15-21] or by palladium-catalyzed coupling of chlorotrialkylstannanes with enol triflates derived from δ-lactones.[22]

Purification: none is normally required; the reagent is used as prepared.

Handling, Storage, and Precautions: the reagent is customarily utilized shortly after preparation. Solvents and reagents should be anhydrous and free of oxygen. Commercial 2,3-dihydropyran is distilled before use. Solutions of the reagent must be protected from air and moisture utilizing standard inert atmosphere/syringe techniques.

Metalation of 2,3-Dihydro-4*H*-pyran (2) and Related Substituted 2,3-dihydro-4*H*-pyrans.

Recommended Procedure for (1).

Metalation of the parent 2,3-dihydro-4*H*-pyran (***3,4-Dihydro-2H-pyran***) (**2**) proceeds smoothly under a variety of reaction conditions to afford exclusively the 6-lithio derivative (**1**) (eq 1).[2] The preferred procedure employs the yellow 2*t*-BuLi-THF complex prepared by treatment of ***t-Butyllithium*** in pentane with a minimum amount (~2 equiv) of THF.[2,11] On a substantial scale, care must be taken to avoid localized heating owing to the heat of solvation which can cause loss of *t*-BuLi.[23] Thus it is advisable to provide efficient stirring and cooling, and to precool the THF to be added. Addition of dihydropyran at -78 °C and slow warming to ca. -10 to 0 °C results in decolorization of the yellow color and the formation of a colorless homogeneous solution of the metalated pyran (**1**). Since metalation is significantly exothermic and does not proceed rapidly at temperatures below -10 °C, when working at concentrations above ~0.25 M it is advisable to add a precooled solution of the dihydropyran to the solution of 2*t*-BuLi-THF complex dropwise at about -10 to 0 °C with efficient stirring.[2,11] Solutions of (**1**) are typically diluted with additional anhydrous THF and recooled to -78 °C prior to use (at higher concentrations, the reagent will sometimes precipitate from solution).

(1)

This procedure is suitable for use with many substituted dihydropyrans, and dihydrofurans, provided there are not additional remote coordinating heteroatoms present. In the absence of remote heteroatom substituents, the rates of metalation are related to the type of substitution at the β-position of the vinyl ether double bond.[2,11] Electron-deficient substituents and substituents containing heteroatoms suitably positioned to assist metalation by coordination of the metalating agent, and/or stabilize the metalated species by chelation, accelerate metalation (e.g. Cl, $(CH_2)_n$OR (n = 1,2)) and alkyl substituents retard it, although examples of successful metalation of a β-methyl substituted

system have been reported.[2,3,24]

Other Procedures.

Less reactive metalating agents such as ***n-Butyllithium*** can only be employed in saturated hydrocarbon solvents since complete metalation requires 1-2 h at 50-60 °C (incompatible with ethereal solvents), affording (**1**) as a precipitate.[14] Either *n*-BuLi at rt to ~30-40 °C or *t*-BuLi at 0 °C to rt can also be employed in the presence of a catalytic amount of ***N,N,N´,N´-Tetramethylethylenediamine*** to assist deaggregation of the alkyllithium metalation reagent, also affording (**1**) as a precipitate.[10,13]

In the cases where metalation fails with the usual procedures, successful metalation can often be achieved by use of the Schlosser base ***n-Butyllithium-Potassium t-Butoxide***.[25,26] Although the species formed can, in principle, be reacted directly with electrophiles, often the basicity of the species is such that clean reactions do not result. In these instances, trapping with chlorotrialkylstannanes cleanly affords the trialkylstannane from which the required lithiopyran can be regenerated by transmetalation with *n*-BuLi (eq 2).[8,15-21] In the presence of heteroatom substituents, use of excess *t*-BuLi with or without subsequent stannylation (eq 3)[2,20,27] or the Schlosser base/stannylation procedure is generally required.[2,8,15-21] The choice of protecting groups for oxygen and nitrogen is crucial to the success of the metalation. Generally, simple alkyl ether, MOM,[19] and TIPS[21] protecting groups are suitable, but benzyl ethers are not owing to competing metalation of the aromatic ring.[16] Oxygenated dihydropyrans bearing TBDMS protecting groups have been metalated,[27,28] but sometimes competing metalation of the methyl groups on the silicon occurs.[29-31] If the system undergoing metalation is exceedingly sterically congested, loss of regiospecificity during metalation has been observed.[32]

Addition of (1) and Related Systems to Carbonyl

Derivatives and Activated Alkenes.

Addition of lithiopyran (**1**) to all manner of carbonyl electrophiles generally occurs cleanly and in excellent yield (eqs 4-9),[2,6,36,37] although extensive purification of the resulting adducts is not advisable owing to their acid sensitivity.[2,3,13,33] Lithiopyran (**1**) behaves in all respects like a typical strongly nucleophilic and basic organolithium reagent in that multiple addition occurs to acid halides, esters, and related acylating agents, and 1,2-addition occurs exclusively in conjugated carbonyl compounds, including (*E*)-β-trimethylsilylacrolein which affords the corresponding ketone upon oxidation.[2,34] Successful addition of lithiopyran (**1**) exclusively 1,2 to a quinone monoacetal has also been reported.[35] Even complex aldehydes prone to epimerization and β-elimination undergo smooth addition.[36] Addition of lithiopyran (**1**) to acylsilanes followed by Brook rearrangement, ring opening, and silylation affords allenolsilanes very efficiently.[15] Amides, oxalic ester amides, nitriles, and γ-lactones can be employed to afford aldehydes, imines, ketones, and α-ketoamides.[2,3,37-39] Carboxylation affords the corresponding acid and the derived esters.[3,18] 1,4-Addition of (**1**) has been observed to an unsaturated sulfone.[6] Addition of (**1**) to fluoroacetylene (prepared in situ by metalation/elimination of 1,1-difluoroethylene at -110 °C) followed by elimination of fluoride also occurs.[6] These carbanions function as masked acyl anion equivalents and have been employed to prepare a variety of cyclopentenones, cyclohexenones, and 4- and 5-oxo esters.[2]

Alkylation and Related Substitution Reactions of (1) and Related Systems.

Lithiopyran (**1**) undergoes smooth alkylation by ***Iodomethane*** as well as a variety of primary saturated and homoallylic alkyl bromides and iodides, including examples containing protected oxygen functions and remote unsaturation (eqs 10-13).[2-4,8,14,19,40-48] Alkylation of (**1**) by primary and secondary allylic and benzylic bromides, as well as occasionally chlorides, has been reported to occur in good yield in many cases,[2,13,20] but sometimes α-metalation of the allylic halide competes.[2] To overcome this limitation, (**1**) has been converted to its less basic organocopper derivative for reaction with allyl iodide.[27] As is usual for hard organolithium reagents, (**1**) and its derivatives react poorly with epoxides,[2] and other organometallic derivatives are used (see below). Of course, (**1**) and related systems react readily with trialkylsilyl and trialkylstannyl halides, disulfides, and even sources of positive halogen such as NBS to afford the expected substitution products.[2,5,8,19-22,29,49-51] A conceptually related process involving alkylation-elimination of 2-phenylsulfonylpyrans has also been described.[52]

(10)

(11)

(12)

(13)

Conversion of (1) and Related Systems to Other Organometallic Derivatives and Subsequent Reactions.

In order to effect opening of epoxides in high yield, conversion of (**1**) and related systems to mixed diorganocuprate reagents is generally required (eq 14).[53-55] In highly functionalized systems, ***Boron Trifluoride Etherate*** has been employed as an additional Lewis acid to assist the opening.[56]

Lithiopyran (**1**) and related systems upon reaction with mixed cyanocuprate reagents at 0 °C and above afford stereoselectively (*E*) disubstituted and trisubstituted alkenic alcohols arising from ring cleavage by apparent substitution at the α-alkenic center by the alkyllithium reagent in an overall inversion at the α-alkenic carbon (eq 15).[53] This process may proceed by way of one of several mechanisms.[55] A conceptually similar reaction is observed between vinyl ethers and Grignard reagents catalyzed by nickel(II) complexes.[24] Lithiopyran (**1**) and related systems have also been found to react directly with simple alkyllithium derivatives to give the same spectrum of products with the same stereoselectivity upon quenching with protons, CO_2, and alkyl halides as occurs with the cyanocuprate derivatives of (**1**) and related systems.[57] The latter reaction does not occur with acyclic analogs of (**1**).

A derivative of (**1**) has been converted to a *C*-glycoside derivative by Pd^0-catalyzed coupling of the zinc derivative with an aryl iodide (eq 16).[28] Furthermore, aluminates formed from (**1**) undergo a novel 1,2-migration reaction upon treatment with benzaldehyde in the presence of $BF_3.Et_2O$, affording *trans*-2-methyl-3-(1-hydroxy-1-phenylmethyl)tetrahydropyrans and -furans (eq 17).[57]

(16)

(17)

Finally, in reaction with sterically hindered ketones, conversion to the dichlorocerium reagent by transmetalation of (**1**) and related derivatives with anhydrous ***Cerium(III) Chloride*** minimizes enolization of the substrate (eq 18).[58]

Conversion of (1) and Related Systems to Trialkylstananes and Regeneration of the Lithium Derivative or Direct Palladium-Catalyzed Crossed Coupling.

In addition to the aforementioned methods involving stannylation of lithiopyran (**1**) and related systems by reaction with chlorotrialkylstannanes (eqs 2 and 3),[5,8,16,18,20,21,51] a route from six- or seven-membered ring lactones is available (eq 19).[22] The method fails for five- and eight-membered rings owing to the inability to form the required enol triflates under the usual conditions.[22] These stannane derivatives are precursors for the lithium species by transmetalation (eq 2),[8,16,18,37,51] as well as undergoing direct Pd^0-catalyzed coupling with aryl, allyl, benzyl, and acyl halides (eqs 20 and 21).[5,20,21,50] The oxidative dimerization of the parent alkylstannane, derived from (**1**), catalyzed by $Cu(NO_3)_2$ has also been reported.[59]

Metalation and Reactions of Other Cyclic and Acyclic Vinyl Ethers.

Dihydrofurans[2,19,60,61] and the parent dihydrooxepin[10] afford the analogous α-lithio derivatives. Metalation of 1,4-dioxene derivatives has also been reported, although loss of metalation regiospecificity has been noted in hindered systems.[32,50] Metalation of acyclic vinyl and dienyl ethers has also been reported where metalation regiospecificity can be controlled by use of MOM ethers.[62-66] Selectivity for metalation of the α-vinyl H vs. allylic metalation is also observed and a theoretical model has been proposed.[67,68] Reactions of these lithiated ethers parallel those of lithiodihydropyran (**1**).[2,4,5,10,19,21,24,38,44,48,49,57,58,62,64,69-71]

Related Reagents.

(Z)-2-Ethoxyvinyllithium; ***1-Ethoxyvinyllithium***; ***5-Lithio-2,3-dihydrofuran***; ***1-Methoxyvinyllithium***.

Lithio-*N,N*-dimethylacetamide

[55259-70-6] · C_4H_8LiNO · Lithio-*N,N*-dimethylacetamide · (MW 93.05)

(relatively stable enolate;[1] used for aldol condensations[1,2] and conjugate addition;[3] reacts with epoxides;[1] can be alkylated[1,2] and silylated[4])

Physical Data: white solid; ^{1}H NMR (pyridine): 3.15 (d, 1H), 2.93 (d, 1H), 2.63 (s, 6H).

Preparative Methods: by deprotonation of *N,N*-dimethylacetamide with a variety of bases, most efficiently with ***Lithium Diisopropylamide*** in THF at -78 °C or at 0 °C.

Handling, Storage, and Precautions: air and moisture sensitive; solid can be stored for several weeks in sealed bottle; THF solutions are stable for at least several hours at 65 °C.

Aldol Condensations.

Lithio-*N,N*-dimethylacetamide reacts with a variety of aldehydes or ketones to give β-hydroxy amides in generally good yields,[2,5] especially at -78 °C.[1] Superior yields, compared to related ester enolates, were obtained with a hindered ketone (eq 1).[5b]

(1)

Asymmetric induction (up to 99% ee) has been reported for condensations with a chiral sulfoxide adjuvant.[5c] Condensation with an aldehyde imine has been described.[5d]

Conjugate Addition.

Conjugate addition of the reagent has been reported for nitrostyrenes,[3a] unsaturated thioamides,[3b,c] and a vinyl sulfone.[3d]

Reaction with Epoxides.

The reagent reacts with epoxides in refluxing THF to give γ-hydroxy amides.[1] Reaction of epoxides with related ester enolates gave lower yields, presumably because of the lesser stability of these enolates.

Alkylation and Silylation Reactions.

The reagent reacts with primary and secondary organic halides to give *C*-alkylated products without competing dialkylation.[1,2] The reagent gives primarily the *C*-silylated product with ***Chlorotrimethylsilane*** and a mixture of *O*- and *C*-silylated products with ***t-Butyldimethylchlorosilane***.[4]

Related Reagents.

t-Butyl α-Lithioisobutyrate; ***Dilithioacetate***; ***N,N-Dimethyl-2-(trimethylsilyl)acetamide***; ***Ethyl Bromozincacetate***; ***Ethyl Lithioacetate***.

2-Lithio-1,3-dithiane[1]

[36049-90-8] · $C_4H_7LiS_2$ · 2-Lithio-1,3-dithiane · (MW 126.19)

(umpolung; C-C bond formation)

Physical Data: pK_a values for several 1,3-dithianes;[1e,2] measurements/calculations on relative acidity of axial vs. equatorial C-2 hydrogens;[3] crystal structure for 2-methyl- and 2-phenyl-2-lithio-1,3-dithiane;[4] low-temperature ^{13}C NMR spectra of ^{6}Li- and ^{13}C-labeled reagent.[5]

Solubility: sol ether, THF; slightly sol pentane.

Analysis of Reagent Purity: solutions of the reagent are colorless, with the exception of solutions of the 2-vinyl- and 2-phenyl-substituted analogs, which are yellow; solutions of the reagent should be titrated before use by one of the standard methods, e.g. MeOD quenching studies (NMR).

Preparative Methods: the parent compound is most conveniently prepared from commercially available ***1,3-Dithiane*** by metalation with one equivalent of ***n-Butyllithium*** at -20 °C in THF.[6] 2-Lithio-1,3-dithianes with a substituent at C-2 can be prepared similarly; the reaction time for metalation varies.[6] Alternatively, Sn/Li transmetalation (LDA or MeLi) of 2-trimethylstannyl- or 2,2-bis(trimethylstannyl)-1,3-dithiane[7] is a much faster process than the direct metalation and occurs within a minute at -78 °C. This allows preparation of substituted 2-lithio-1,3-dithianes, in which the substituent has electrophilic sites, which otherwise would not survive the metalation process.[7] Some sodium[8] and potassium[9] analogs have been reported.[1e] A comprehensive review on the preparation of dithianes is covered under ***1,3-Dithiane***.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen or moisture; solutions in THF are stable for weeks at -20 °C; at room temperature, 2-lithio-1,3-dithiane does not decompose via a carbenoid pathway, but abstracts a proton from the solvent.[1f] Handle in a fume hood.

Alkylation.

On treatment with primary, secondary, or allylic alkyl halides, or primary sulfonates, the corresponding substituted dithianes are obtained, generally in good yield (eq 1).[1b -f,10,11]

Formally, these transformations give access to ketones from aldehydes (or aldehydes from ***Formaldehyde***, R = H),[12] i.e. the dithiane moiety here functions in a reactivity umpolung mode,[13] as acyl anion **A** or acyl dianion equivalent **B**.

Allylic alcohols, after appropriate in situ activation, can be used as alternatives to the alkyl halides (eq 2).[14]

Considerable chemoselectivity is observed in reactions with multifunctionalized electrophiles,[1b-f] e.g. epoxide vs. primary halide (eq 3),[15] or allylic vs. nonallylic halide,[16] or iodide vs. allylic mesylate (eq 6).[17]

Cycloalkylation products can be obtained from reactions with bifunctional electrophiles, an approach which has found use in the preparation of a variety of macrocycles (acyl dianion equivalent **B**, eq 4).[1b-f] Alternatively, dialkylation with the appropriate electrophiles can also be used for the straightforward preparation of large-ring compounds (eq 5)[1e,f,18] or to set the stage for the synthesis of polycyclic structures (eq 6).[17,19] More recent examples of alkylation of 2-lithio-1,3-dithianes include the preparation of backbone-rigid diamides,[20] the synthesis of (-)-ε-cadinene,[21] methyl ketones which undergo asymmetric reduction in the presence of the dithiane moiety,[22] aminoalkynyldithianes,[23] and dioxaspiro[5.5]undecane ring systems.[24]

2-Lithio-1,3-dithiane reacts with arene-metal complexes to give the corresponding arene substituted derivatives (eq 7).[25] Some regiochemical control can be achieved; side products often limit the utility of these reactions.[26]

Nitroalkenes (eq 8), as do nitroarenes, react with 2-lithio-1,3-dithianes by conjugate addition.[27] Vinyl sulfones, as described for an oxygenated cyclopentene (eq 9)[28] and an α,β-(phenylseleno)vinyl selenoxide[29] example, display a similar reactivity pattern.

(8)

(9)

Vinylphosphonium salts react with 2-lithio-1,3-dithiane to form the β-phosphonio substituted derivative. The inherent properties of the dithiane moiety then allow for the preparation of β-phosphinyl carboxylic acids (eq 10)[30] or other functionalized phosphorus compounds,[31] valuable building blocks in organic synthesis.

α/β-Aminoalkylation.

The reagent reacts with activated imines to afford the corresponding α-aminoalkylated derivatives (eq 11). Typical reaction partners are phenylazirines (eq 12)[32] or iminium salts.[33] In the case of the former, only the C-2 substituted reagent gives the α-aminoalkylated compound; the parent reagent will afford β-aminoketene dithioacetals instead (eq 13).[32a] Recently, the reaction with *N*-tosylated aziridines has been reported, which leads to the β-amino substituted ketone derivatives.[34] 1-Methyl-4-quinolone as reaction partner gives the α-aminoalkylated product, which in this case derives from a 1,4-addition reaction (see also α-Hydroxyalkylation/γ-Ketoalkylation below).[35]

(13)

β-Hydroxyalkylation.

Epoxide ring opening with 2-lithio-1,3-dithianes proceeds in general with good regio- and stereochemical control, following the rules for S_N2-type processes, and affording the β-hydroxyalkylated products in good to excellent yield, routinely exceeding 80% (eq 14).[1b-f]

(14)

More recent examples include stereoselective epoxide opening to access enantiomerically pure hydroxylated compounds,[36] e.g. propanal-type aldol products.[37] This reaction sequence also proved to be useful for the synthesis of C-3 formyl sugar derivatives,[38] chiral 4-hydroxycyclopentenones from glucose,[39] and was employed as a key feature in the construction of the Kishi intermediate[40] for aplysiatoxin (eq 15).[41] Noteworthy is the high chemoselectivity displayed by the reagent in these reactions.

2-Lithio-1,3-dithiane

(15)

An unusual example, in which the reagent reacts preferentially with a fulvene functionality over epoxide opening, has been reported (eq 16).[42]

α-Hydroxyalkylation/γ-Ketoalkylation.

Both types of product, obtained from the addition of 2-lithio-1,3-dithianes to aldehydes and ketones, or to the conjugate unsaturated analogs, represent one of the unique features available from the reactivity pattern of the reagent. By virtue of its role as acyl anion equivalent **A**, this reaction allows establishment of a 1,2-arrangement of oxygen functional groups, not so readily achieved by using classical reagents (eq 17). It is this feature of umpolung[1d] of the normal carbonyl reactivity pattern, which earned 2-lithio-1,3-dithianes so much attention in synthetic organic chemistry, and accounts for a significant proportion of all reactions involving the use of the reagent.[1b-f] The yields observed for these addition reactions are in general very good; product formation in the 70-90% range is not uncommon.

The scope of the reagent was broadened after a thorough investigation established the factors which influence the regioselectivity of the addition of the reagent to α,β-unsaturated aldehydes and ketones.[1d] As a complement to the standard 1,2-addition mode described above, 2-lithio-1,3-dithianes can also be used deliberately to establish a 1,4-arrangement of oxygen functional groups (eq 18), again by functioning as an acyl anion equivalent **A**.[1b-f,35,43] The outcome of the addition to enones can be influenced not only by the choice of solvent,[1d] but also with the help of alkene-complexing agents, as has been demonstrated for the tricarbonyl(tropone)iron complex.[44]

Recent literature reports the addition reaction of 2-lithio-1,3-dithiane to aldehydes for assembling the C(10)-C(19) moiety of FK506,[45] and the possibility of achieving asymmetric induction in this reaction sequence has been investigated (eq 19).[46]

(19)

Cyclic hemiacetals can be used in place of the free carbonyl compound with equal success.[47] The stereoselectivity of the reaction can be influenced by neighboring polar groups, as illustrated in the example with (*R*)-pantolactone (eq 20).[47]

(20)

Acylation.

The characteristic features of the reagent, as indicated in the foregoing section on addition reactions to carbonyl derivatives, also dominate the reactivity pattern observed for the reaction with carboxyl derivatives. The role of 2-lithio-1,3-dithianes as acyl anion equivalent **A**, establishing a 1,2-relationship between the functional groups, is the dominating feature (eq 21).

2-Lithio-1,3-dithiane reacts with acyl derivatives, such as esters or lactones, amides or aziridinones,[48] to afford the corresponding acyl dithiane in variable yield (eq 21).[1b-f] Little investigation has yet been carried out into the regioselectivity for the reaction with the corresponding α,β-unsaturated derivatives.[49,50] With an electron releasing substituent on C-2 the reagent reacts with butenolides in a 1,4-conjugated fashion (eq 22), a scheme specifically exploited in several syntheses of steganin lignans.[49] Also, unsaturated amides, thioamides, and nitriles are reported to react with the reagent in the 1,4-mode indicated in eq 22.[50c-f]

Acid chlorides will give the double addition carbinol product (eq 25),[51] nitriles afford either amino ketene dithioacetals (eq 24)[52,53] or ketones (eq 23),[54] nitrile oxides lead to oxime derivatives (eq 26), activated imides can be opened regioselectively (eq 29),[55] activated ketene acetals give the corresponding enol-type compound (eq 30),[56] and isocyanides afford the cyano substituted dithiane (eq 27).[57]

(25)

(26)

(27)

(28)

(29)

(30)

Carboxylation by reaction with ***Carbon Dioxide*** proceeds in excellent yield (eq 28).[1d,e,58] The reaction products find use as intermediates in a notable lactone synthesis.[59]

The reaction of 2-lithio-1,3-dithiane with carboxyl derivatives can be reversed. This result allows a synthetically useful C-C bond cleavage (eq 31).[1e]

2-P, Sn, Si, Ge, and Ti Derivatives.

The versatility of 2-lithio-1,3-dithiane as an acyl anion **A** or acyl dianion equivalent **B** is further amplified by the possibility of preparing the phosphorus,[60] tin,[1f,7] silicon,[60,61] germanium,[1f,62] or titanium[63] analogs, e.g. on simple treatment with the corresponding chlorides. The phosphorus and silicon analogs deserve special attention, as they allow a convenient entry to ketene dithioacetals (see below). Also, the silicon analog was used in the preparation of formyl-[61] and acylsilanes.[11] The tin and germanium, as well as silicon, derivatives react with acid chlorides to give 2-acyl-1,3-dithianes.[62] The special role of the tin derivative has been outlined already (see Preparation above);[7] the titanium analog was found to be more stable than the reagent, and as a consequence more selective.[63]

Ketene Dithioacetals.

The lithio derivative obtained from deprotonation of ***2-Trimethylsilyl-1,3-dithiane*** deserves special mention. On reaction with carbonyl compounds, ketene dithioacetals are obtained, compounds which are responsive to both electrophilic as well as nucleophilic attack. Other methods for the synthesis of ketene dithioacetals have been reviewed.[60] In addition to their normal reactivity pattern, these derivatives offer an exceptionally broad umpolung-type reactivity pattern, i.e. acyl anion **A**, enolate carbanion **C**, homoenolate anion **D**, and chemistry of the homolog **E** becomes available (eq 32). The

richness offered by this class of compounds in terms of their potential as strategical and useful intermediates in organic synthesis is documented amply, and reference to review articles have to suffice in this context.[1a,60]

Related Reagents.

Bis(methylthio)(trimethylsilyl)methane; ***Bis(phenylthio)methane***; ***N,N-Diethylaminoacetonitrile***; ***1-Ethoxyvinyllithium***; ***RL031-***; ***Methoxy(phenylthio)methane***; ***1-Methoxyvinyllithium***.

3-Lithiofuran

[53101-93-2] · C_4H_3LiO · 3-Lithiofuran · (MW 74.007)

(nucleophilic organolithium reagent useful for alkylation; addition to ketones, acid chlorides, aldehydes, amides, lactones, carbon dioxide, nitrones, epoxides, sulfinate esters, boronic esters, metal carbonyls, borates, metal halides; affords intermediates for organometallic coupling reactions)

Alternate Name: β-furyllithium.

Preparative Methods: metalation of ***Furan*** at the 3-position requires a metal-halogen[1-7] or metal-metal exchange[8] since deprotonation of furan occurs preferentially at the 2-position. 3-Lithiofuran (**1**) (eq 1)[1-3] is prepared by the treatment of 3-iodofuran (**2a**) with ***n-Butyllithium*** in ether or THF (-78 °C);[4,5] by the treatment of 3-bromofuran (**2b**) with *n*-butyllithium in THF (-78 °C);[6,7] or by the reaction of 3-tri-*n*-butylstannylfuran (**2c**) with *n*-butyllithium in THF (-78 °C).[8]

Handling, Storage, and Precautions: the reagent is generated in situ, under anhydrous conditions in an inert atmosphere at low temperatures (<=-40 °C), and used shortly after preparation. The ability to store the reagent is not clear. As *n*-BuLi is employed, the precautions for preparation and use would mirror those of *n*-BuLi and related organometallic reagents. It has been demonstrated that good temperature control is important to the regiochemical integrity of the reagent. Temperatures exceeding -40 °C during the course of reagent generation and use permit isomerization of 3-lithiofuran to the more thermodynamically stable 2-lithiofuran (eq 2).[7]

Alkylation.

3-Lithiofuran (**1**) reacts readily with allylic halides and primary alkyl halides, in the presence of ***Hexamethylphosphoric Triamide***, to give 3-substituted furans (eq 3).[7]

(3)

RX	R	Yield
		82%
$THPO(CH_2)_3I$	$THPO(CH_2)_3$	79%

Addition to Carbonyl Compounds.

3-Lithiofuran (**1**) adds to acid chlorides to give furyl ketones (eq 4),[5] to aldehydes (eq 5),[7,9,10] and to ketones (eq 6)[11] to give carbinols. The reaction of 3-lithiofuran (**1**) with lactones affords the related lactols (eq 7).[12] ***Carbon Dioxide*** reacts with 3-lithiofuran (**1**) to provide 3-furoic acid.[8,13] Although 3-lithiofuran is considered to be relatively unreactive, it will add to amides to give amines via the reduction of an intermediate enamine (eq 8).[14,15]

(8)

Reaction with Electrophiles.

Treatment of 3-lithiofuran (**1**) with $CuBr.SMe_2$ (see ***Copper(I) Bromide***) and 2-lithiofuran affords a higher order cuprate which adds to epoxides, giving carbinols (eq 9).[16] 3-Lithiofuran (**1**) affords branched hydroxylamines upon reaction with nitrones (eq 10).[17] (-)-(*S*)-Menthyl *p*-toluenesulfinate,[18] an optically pure boronic ester (see ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***),[19] and ***Hexacarbonylchromium***[20] also react with 3-lithiofuran (**1**) to provide an optically pure furyl sulfoxide (eq 11), an optically pure borinic ester (eq 12), and a furyl-substituted chromium carbene (eq 13), respectively.

(9)

(10)

(11)

(12)

(13)

Analogous Reagents.

A variety of substituted 3-lithiofurans has been prepared by metal halogen exchange [(**3**),[21] (**4**),[22] (**5**),[23] (**6**)[24]]. However, when blocking [(**7**),[25] (**8**)[26]] and/or coordinating groups at the 4-position (**9**)[27] are present, metalation reactions provide an effective path to 3-lithiofurans. 3-Lithiofurans (**8**) and (**9**) have undergone metal-metal exchange to afford the bromozinc[26] and tin reagents,[28] respectively. These reagents, as well as a boronic acid produced from (**9**),[27] have been employed in palladium-catalyzed carbon-carbon bond forming reactions.

1-Lithio-1-methoxycyclopropane[1]

[75697-62-0] · C_4H_7LiO · 1-Lithio-1-methoxycyclopropane · (MW 78.05)

(synthesis of 2-vinylcyclobutanones,[2] which are intermediates in the synthesis of higher-membered rings via ring expansion[3])

Solubility: sol THF, in which solvent it is prepared.

Preparative Methods: from 1-methoxy-1-phenylthiocyclopropane[4] via reductive lithiation with ***Lithium 4,4´-Di-t-butylbiphenylide*** (LDBB) or ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN) in THF at -78 °C.[5] Alternatively, a similar reagent, 1-ethoxy-1-lithiocyclopropane, is obtained by lithium-tin and lithium-bromine exchange reactions of 1-ethoxy-1-(tri-*n*-butylstannyl)cyclopropane and 1-bromo-1-ethoxycyclopropane, respectively.[6]

Handling, Storage, and Precautions: presumed to be unstable and is used immediately for further transformations. α-Metalated ethers undergo Wittig rearrangement[7] and/or carbenoid reactions.[8]

Reactions of 1-Lithio-1-methoxycyclopropane.

1-Lithio-1-methoxycyclopropane reacts at -78 °C with aldehydes to give the expected addition products in high yields (eq 1).[9]

(1-Methoxycyclopropyl)alkyl alcohols are usually not isolated and the crude reaction products are directly subjected to acid-catalyzed rearrangement to 2-substituted cyclobutanones (eq 2).

From a synthetic point of view, preparation of 2-vinylcyclobutanones is the most interesting application of the above procedure. Several different sets of conditions have been elaborated to accomplish the rearrangement of the intermediate secondary or tertiary cyclopropylalkyl alcohols. In most cases, a solution of 48% aqueous ***Tetrafluoroboric Acid*** in THF or ether was found to be most effective.[2] Vinylcyclobutanones are prepared from α,β-unsaturated aldehydes and ketones (eqs 3 and 4).[10]

In the case of acid sensitive molecules, the rearrangement can be conducted under neutral conditions by using ***Trifluoromethanesulfonic Anhydride*** in the presence of a hindered base, 2,6-di-*t*-butyl-4-methylpyridine (eq 5).[5]

Synthetic Utility of 2-Vinylcyclobutanones.

2-Vinylcyclobutanones are important synthetic intermediates since they undergo ring expansion reactions under a variety of conditions. Thermal,[5] acid catalyzed,[3] alkoxide accelerated,[11] or trimethylsilyl cyanide promoted[12] rearrangements lead to the formation of five-, six-, and eight-membered ring systems.

Synthesis of 2-vinylcyclobutanones from 1-lithio-1-methoxycyclopropane rivals the method of Trost,[13] which employs 1-lithio-1-phenylthiocyclopropane. In the latter method, substantial experimentation leading to different reaction conditions for each case is necessary to obtain good yields in the rearrangement step.[4b]

Related Reagents.

Cyclobutanones can also be prepared from 1-methylseleno-,[14] 1-phenylseleno-,[14] and 1-bromocyclopropyllithium reagents[15] (see ***1-Bromo-1-lithio-2-phenylcyclopropane***).

2-Lithio-*N*-phenylsulfonylindole

[40900-03-6] · $C_{14}H_{10}LiNO_2S$ · 2-Lithio-*N*-phenylsulfonylindole · (MW 263.26)

(nucleophilic organolithium reagent useful for addition to ketones, aldehydes, esters, lactones, acid chlorides, anhydrides, nitriles, methyl iodide, halogen sources, and sulfur dioxide; employed in the synthesis of 2-substituted indoles and alkaloids)

Preparative Methods: by deprotonation of *N*-phenylsulfonylindole[1] with ***t-Butyllithium*** in ether (-12 °C to room temperature),[1] by treatment of *N*-phenylsulfonylindole with ***n-Butyllithium*** in THF (-70 °C),[2] and by deprotonation of *N*-phenylsulfonylindole with ***Lithium Diisopropylamide*** in THF (-70 to 5 °C) (eq 1).[3]

Handling, Storage, and Precautions: the reagent is generated in situ, under anhydrous conditions, in an inert atmosphere, and used shortly after preparation. The stability in storage is unknown. Precautions for preparation and use are as for other reactive organolithium reagents.

Synthesis of 2-Substituted Indoles.

Heteroaromatic compounds such as ***Furan*** and thiophene are readily metalated at an α-position and the resulting organometallic reagents can be captured by a variety of electrophiles.[4a] *N*-Unsubstituted indoles and pyrroles suffer removal of the acidic N-H, affording ambident nucleophiles[4a] which give rise to mixtures of *C*- and *N*-substituted products upon reaction with electrophiles.[4b] 1-Methylindole can be lithiated at the 2-position to provide 1,2-disubstituted indoles after capture by an electrophile.[5] Difficulties associated with *N*-dealkylation restrict this method to the preparation of 1,2-disubstituted indoles.[1] Substitution at the 1-position of the indole moiety with a readily removable group provides access to 2-substituted indoles. *N*-Phenylsulfonylindole is readily deprotonated (eq 1) to give 2-lithio-*N*-phenylsulfonylindole (**1**)

which reacts with electrophiles (eq 2) such as aldehydes,[1] ketones,[1] acid chlorides,[1] ***Carbon Dioxide***,[1] anhydrides,[1,6] arylsulfonyl chloride,[7] ***Cyanogen Bromide***,[7] ***Iodine***,[7] and ***Sulfur Dioxide***[2] to give *N*-phenylsulfonyl substituted indolyl-2-carbinols (from aldehydes, ketones), 2-ketones (from acid chlorides, anhydrides), 2-carboxylic acid (from carbon dioxide), 2-sulfones (from arylsulfonyl chlorides), 2-bromide (from cyanogen bromide), 2-iodide (from iodine), and 2-sulfonic acid salt (from sulfur dioxide) in reasonable yields (25-85%). 2-Lithio-*N*-phenylsulfonylindole (**1**) appears to react poorly with alkyl halides. The reaction of (**1**) with ethyl benzoate gives 2-indolyl phenyl ketone (26%), a product of in situ phenylsulfonyl cleavage.[1] Similarly, the reaction of (**1**) with benzonitrile also yields 2-indolyl phenyl ketone (30%).[1] Cleavage of the *N*-phenylsulfonyl group to generate the target 2-substituted indole is readily accomplished with 2N ***Sodium Hydroxide*** in methanol (reflux, eq 3)[1] or ***Potassium Carbonate*** in methanol/water (3:1) at reflux (eq 4).[6]

(2)

(1)

(3)

(4)

Alkaloid Synthesis.

Indole alkaloids such as ellipticine (eq 5)[6] and the genotoxic amine TrpP-1 (eq 6)[8] have been prepared from 2-lithio-*N*-phenylsulfonylindole (**1**).

Related Reagents.

A number of indole *N*-protecting groups have been reported to afford variants of 2-lithio-*N*-phenylsulfonylindole which lead to the preparation of 2-substituted products amenable to further synthetic transformation. Table 1 shows a number of removable nitrogen blocking groups in the indole and pyrrole series. In the indole series, (**2a-g**)[1-3,9a-i] readily provide *N*-deprotected 2-substituted indoles. Indolyllithium reagents (**2g**)[1] and (**2h**)[1] are less well explored. In the pyrrole series, (**3a**)[9a] and (**3g**)[10g,h] are problematic due to competitive desulfonylation (**3a**) and silicon migration (**3g**). Pyrrolyllithiums (**3b**),[9a,10a] (**3c**),[9d,10b-d] (**3d**),[10e] and (**3e**)[9h] provide satisfactory yields of 2-substituted pyrroles, although (**3b**)[9a] has been reported to be thermally labile and (**3c**)[9d,10b-d] requires carefully controlled deprotection conditions. Pyrrolyllithium (**3f**) has not been widely examined.[10f]

2-Lithiopyridine[1]

[17624-36-1] · C_5H_4LiN · 2-Lithiopyridine · (MW 85.03)

(convenient 2-pyridinyl building block; can react with a variety of electrophiles[1])

Preparative Methods: lithiation of pyridine with simple lithio bases is difficult; addition across the C=N bond predominates with alkyllithiums,[2] whereas lithium amides give rise to bipyridyls.[3] However, pyridine can be regioselectively metalated by treatment with a complex of ***n-Butyllithium-Potassium t-Butoxide*** under carefully controlled conditions (eq 1).[4] Use of 2-3 equiv of the base is necessary and the excess has to be destroyed by reaction with the solvent (THF) at -25 °C prior to addition of the electrophile. *Ortho* deprotonation of pyridine can be facilitated by formation of a complex with hexafluoroacetone,[5] tricarbonylchromium(0),[6] or, more simply, with a Lewis acid like ***Boron Trifluoride*** (eq 2).[7] Another popular approach to 2-lithiopyridine utilizes an exchange reaction of 2-bromopyridine (eq 3).[8] The choice of method for the preparation of this reagent can depend upon the electrophile with which it is to be used. For instance, BF_3-complexed 2-lithiopyridine gives excellent yields with carbonyl compounds but reacts poorly with alkyl halides.[7]

(3)

Handling, Storage, and Precautions: should be prepared and handled in a moisture-free inert atmosphere and used immediately. Use in a fume hood.

Reaction with Electrophiles.

Reaction of 2-lithiopyridine with aldehydes and ketones gives α-pyridinyl alcohols cleanly (eq 4),[7] whereas use of carboxylic acid derivatives leads to the corresponding ketones (eq 5).[9] Treatment of the reagent with ***Copper(I) Iodide*** promotes 1,4-addition with α,β-unsaturated carbonyl compounds (eq 6).[8b]

(4)

(5)

(6)

Other electrophiles which react with 2-lithiopyridine include MeOD (eq 7),[4a] ***Chlorotrimethylsilane*** (eq 8),[4a] ***Iodine***,[4a] ***Dimethyl Disulfide***,[4a] 1,2-dibromo-1,1,2,2-tetrachloroethane (eq 10),[5] ***Iodomethane*** (eq 9),[6] and methyl benzoate.[8a]

(7)

(8)

(9)

(10)

Related Reagents.

Polar solvents favor 4-metalation of pyridine by the BuLi-*t*-BuOK mixed base.[4] Both 2- and 3-lithiopyridines can be obtained from the corresponding bromides through exchange reaction with BuLi.[8] Pyridines carrying *ortho* directing groups like alkoxy,[10] fluoro,[11b] chloro,[11] bromo,[11] carboxamido,[12] oxazoline,[13] pivaloylamino,[14] and diethylcarbamate[15] can be lithiated regioselectively.

Solubility: sol THF, DME, ether, ether/hexane.

Analysis of Reagent Purity: ^{1}H NMR (kinetics of transmetalation); GLC of a quenched aliquot from the transmetalation reaction

Handling, Storage, and Precautions: generated in situ; stable at low temperature and even for several hours in THF at rt; usual handling procedures for sensitive organometallics; no data available for toxicity (usual precautions for handling tin compounds). Use in a fume hood.

Preparation and Reactivity with Electrophiles.

Treatment of (*E*)-1,2-bis(tri-*n*-butylstannyl)ethylene with ***n-Butyllithium*** in THF at -78 °C generates cleanly the title lithium reagent (**1**).[1] Attempts to prepare *trans*-1,2-dilithioethylene were unsuccessful (eq 1).[2]

(1)

The transmetalation reaction is known to be an equilibrium process[3] and to occur with complete retention of configuration about the C=C bond.[4] Reaction of the monolithiated species with Me_3SiCl is competitive with transmetalation so that *trans*-1,2-bis(trimethylsilyl)ethylene is formed in variable amounts depending on reaction conditions. (*E*)-1-Lithio-2-tributylstannylethylene can also be generated at -78 °C in THF by using ***Methyllithium***,[5]

and conveniently at room temperature with *n*-BuLi in THF.[2] (*E*)-1-Tributylstannyl-2-trimethylsilylethylene is isolated in 58-63% yield, from which *trans*-1-lithio-2-trimethylsilylethylene is formed very cleanly by reaction with *n*-BuLi in THF (at -78 °C or rt) affording exclusively *trans* substituted products with different electrophiles. Efficient one-pot successive transmetalations and reactions with two different electrophiles have also been reported (eq 2).[2]

(2)

Ethyl (*E*)-3-(tributylstannyl)propenoate is prepared in 59% yield by reaction of (**1**) with ***Ethyl Chloroformate***. The product was used in a palladium-catalyzed coupling with an acid chloride.[5]

Reagent (**1**) reacts with aldehydes to yield stereospecifically *trans*-β-stannylated allylic alcohols. This route is preferred over the hydrostannylation of propargylic alcohols (protected or not), which under appropriate conditions (excess ***Tri-n-butylstannane*** radical initiator) yield mixtures of (*E*) and (*Z*) isomers (usually in a 5/1 to 10/1 ratio) and some nonterminal stannylated product (eq 3).[6,7a]

(3)

Such racemic *trans*-β-stannylated allylic alcohols undergo efficient kinetic resolution under Sharpless asymmetric epoxidation conditions and, after vinylic C-Sn bond cleavage with iodine, afford optically active vinyl iodides in high yield and enantiomeric excess.[7] Selective condensation of (**1**) with o-aldehyde esters gives the corresponding racemic β-stannylated allylic secondary alcohols,[7b,c] which were also resolved by the same methodology.[7b]

The lithio reagent (**1**) is not strongly basic, as shown by its reaction with a deconjugated aldehyde (eq 4),[8] or with an α-epoxy aldehyde (eq 5).[9] Thus the reaction of (**1**) with (3*Z*)-nonenal afforded the racemic alcohol in 70% yield, which also underwent an efficient Sharpless kinetic resolution and was further converted into the monochiral vinyl iodide.[8] Functionalized monochiral vinylstannanes were also prepared by reaction with the appropriate α-epoxy aldehyde. The products were coupled with halogenated isocoumarins with palladium catalysis, in a convergent stereospecific synthesis of monocillin I and monorden.[9]

(4)

(5)

The addition of (**1**) to several 17-keto steroids has also been reported.[10] The 17α-(*E*-tributylstannylvinyl) adducts can be destannylated in high yields with various electrophiles.[10a] Reaction with $Na^{125}I/AcONa\text{-}AcOH/H_2O_2$ produced ^{125}I-radiolabeled (*E*)-17α-iodovinylestradiol in high isolated radiochemical yield, with a radiochemical purity >98%, at the no-carrier-added level.[10b-e]

The addition of organolithium reagents to pyrylium salts gives (2*Z*,4*E*)-dienals with high stereoselectivity; the reaction with (**1**) is slow, however, and affords the desired trienal in moderate yield (eq 6).[11]

(6)

Derived Mixed Cuprate Reagents.

The mixed cuprate (**2**) is formed rapidly and cleanly when a solution of (**1**) in THF is treated with pentynylcopper in the presence of 2.7 equiv of HMPA. The reaction of the brown, soluble cuprate reagent with enones proceeds with excellent selectivity to afford the β-vinylstannyl ketones in good yields (85-93%). Treatment of these adducts with ***Lead(IV) Acetate*** in acetonitrile, at rt, affords the corresponding β-ethynyl ketones. This two-step procedure is therefore an alternative to the unreactivity of ethynyl Gilman reagents (eq 7).[1]

(2)

(E)-1-Lithio-2-tributylstannylethylene

(7)

An analogous mixed cuprate which was formed with *n*-hexynylcopper in THF (with no added HMPA) reacted with 3-furfuryl bromide to give (*E*)-1-(tributylstannyl)-2-(3-furfuryl)ethylene in 73% yield, which further underwent a palladium-catalyzed coupling with a vinyl triflate.[12]

Higher-Order Cyanocuprates.

Reaction of (*E*)-1,2-bis(tributylstannyl)ethylene with 1 equiv of $Me_2Cu(CN)Li_2$ in THF, at rt, leads to the quantitative formation of the mixed higher order cyanocuprate (**3**) (R = Me) and tri-*n*-butyl(methyl)tin. This mixed higher-order cuprate reagent adds by 1,4-addition to cyclohexenone in high yield (93%), with high selectivity for vinylstannyl over methyl transfer.[13a]

(3) R = Me, 2-thienyl

In situ cuprate formation from (*E*)-1,2-bis(tributylstannyl)ethylene and Me(2-thienyl)$Cu(CN)Li_2$ (1 equiv), from commercially available (2-thienyl)Cu(CN)Li and MeLi, generates (2-thienyl)($Bu_3SnCH{=}CH$)$Cu(CN)Li_2$. The in situ formation of the desired higher-order cuprate (dark red solution in THF-ether) and tributyl(methyl)tin can be monitored by gas chromatographic analysis of a quenched aliquot.[13b] Pure β-hydroxy-(*E*)-vinylstannanes are obtained in good yields (50-74%) by the reaction of this higher-order mixed reagent with mono- or disubstituted terminal epoxides, with excellent regiochemical control of the opening. This route has the advantage of yielding stereochemically pure (*E*)-vinylstannanes when compared to hydrostannylation of the corresponding alkynes, which is difficult and affords (*E*/*Z*) mixtures (eq 8).[6a,13b,14]

(8)

On the other hand, reactions of the higher-order cuprate (**3**) (R = 2-thienyl) with 1,2-disubstituted epoxides were not

useful, in the presence or absence of ***Boron Trifluoride Etherate***.[13b] The BF_3-catalyzed conjugate addition of $(Bu_3SnCH{=}CH)(2\text{-thienyl})Cu(CN)Li_2$ to an unsaturated lactone in excellent yield and high diastereoselection has been used in the synthesis of (+)-lepicidin A.[15]

Related Reagents.

The (*E*)- and (*Z*)-trimethylstannyl-2-alkenoates (**4**) can be prepared with a high stereoselectivity by the reaction of α,β-alkynic esters with a suitable (trimethylstannyl)copper(I) reagent. However, the intermediate vinylic organocopper adducts react only with proton donors, other electrophiles fail.[16] Hence, a two-step methodology has been developed for the stereospecific conversion of α,β-alkynic esters to stereochemically defined synthons of general interest. Reaction of (*E*)-2,3-bis(trimethylstannyl)-2-alkenoates with MeLi results in the selective transmetalation of the α-$SnMe_3$ group, to provide a vinylic lithio derivative nucleophilic enough to react with alkylating agents or carbonyl compounds to afford a pure geometric isomer in good yields (eq 9).[17] Such synthons should have a high potential for further elaboration.

(4)

(9)

The reaction of $Bu_3SnCu(Me)(CN)Li_2$ with some simple unactivated alkynes, affords stereochemically pure cuprates (**5**), which are nucleophilic enough to react with Me_3SiCl, Bu_3SnCl, Br_2, I_2, MeI, AcCl, or even ethylene oxide. Conjugate addition with cyclohexenone and methyl crotonate was also reported.[18]

(5) R = H, alkyl

(6)

Stannocupration of 3,3-diethoxypropyne by $Bu_3SnCu(Bu)(CN)Li_2$ affords a vinylic cuprate (**6**) which reacts with electrophiles such as MeOH, I_2, allyl bromide or methyl propynoate to yield isomerically pure products in good yields (70-95%).[19]

1,1-Bis(trimethylstannyl)-1-alkenes readily undergo transmetalation with MeLi to give strongly basic α-stannylvinyllithiums (**7**). These thermally labile lithio derivatives exist almost exclusively in the (*E*) form when R = *t*-Bu or Ph, but otherwise as an (*E*/*Z*) mixture (R = Me, *n*-Bu, Cy). For R = *t*-Bu or Ph, reactions with electrophiles (MeOD, MeI, Me_2SO_4, Me_3SiCl) were reported as highly stereoselective (more than 95/5). 1,2-Addition occurred with aldehydes or nonsterically hindered aromatic ketones, but enolizable ketones gave only the protonation product. With α,β-unsaturated ketones, conjugate addition was observed.[20] Formation of α-trimethylplumbylvinyllithiums has also been reported, these species being more stable and apparently less basic than the corresponding α-stannyl lithio derivatives.[21]

(7) R = *t*-Bu, Ph

3-Lithio-1-triisopropylsilyl-1-propyne

[82192-58-3] · $C_{12}H_{23}LiSi$ · 3-Lithio-1-triisopropylsilyl-1-propyne · (MW 202.38)

(functionalized nucleophilic C_3 building block; forms C-C bonds with many carbon electrophiles[1])

Alternate Name: 3-triisopropylsilyl-2-propynyllithium.

Physical Data: (precursor) bp 100-101 °C/5 mmHg; *d* 0.813 g cm^{-3}.

Solubility: good sol ether, THF.

Introduction.

The title reagent (**1**) was conceived as an improved version of TMS-C&tbond;C-CH_2Li.[2,3] The bulky triisopropylsilyl (TIPS) group provides efficient screening of the carbon atom to which it is attached, and (**1**) therefore usually forms propargylic rather than allenic products.[2,4] The TIPS group is much more inert in basic and nucleophilic reaction mixtures than the widely used TMS group. At the same time, TIPS (in contrast to tri-*t*-butylsilyl) is commercially available, easily introduced, and readily cleaved (F^-) from the product.

Reagent (**1**) is made by deprotonation of 1-TIPS-propyne[2] using ***n-Butyllithium*** in ether, better without than with TMEDA added,[5] or ***t-Butyllithium*** in ether/pentane, or preferably *n*-BuLi in THF (-20 °C, 15 min). 1-TIPS-propyne can be prepared from propyne by silylation of either its lithio derivative using TIPS triflate[2] or of the bromomagnesium derivative using TIPS chloride;[6] it is also commercially available.

Homopropargylic Alcohols.

Reagent (**1**) smoothly reacts with aldehydes and ketones (eqs 1-3).[2,7]

The reaction in eq 1, when performed in ether, gave rise to a 2:1 mixture of the same products. The TMS analog gave none of the corresponding adducts at all in ether/HMPA; in ether it produced both allenic and propargylic major products.

Conjugate Addition.

Reagent (**1**) in THF adds in 1,2-fashion to α,β-unsaturated ketones, whereas in THF/HMPA, 1,4-addition is observed as result of kinetic control (eq 4).[2] The hindered α,β-unsaturated ketone isophorone gave smooth 1,2-addition in THF (89%), while in THF/HMPA, 1,2- and 1,4-addition occurred (1:1) in low conversion. 1,2-Addition of (**1**) to ***Acrolein*** afforded a building block for bongkrekic acid.[8a] 1,4-Addition of (**1**) to η^4-(dienyl)$Fe(CO)_3$ substituted alkylidene malonates is highly stereoselective.[8b]

Reactions of similar organoalkynyl/allenyl silanes containing various metals with carbonyl compounds to give propargylic products have been reported.[9-11] Conjugate addition of allenyl stannanes to α,β-unsaturated carbonyl compounds to give propargylic products can be effected in the presence of ***Titanium(IV) Chloride***.[12]

Chain Elongation of Activated Halides or Phospates.

Reagent (**1**) displaces halide ion from benzyl and allyl halides (eqs 5 and 6).[2] The TMS analog reacted less selectively and gave lower yields.[13]

This type of coupling was routinely used by Marshall (allyl chlorides or phosphates) in the synthesis of cembranoids, employing a cuprate made from the bromomagnesium analog TIPS-C&tbond;C-CH_2MgBr (**2**), which is prepared from TIPS-C&tbond;C-CH_2Br.[14] As a rule, with these allylic electrophiles, S_N2' reaction is not observed. An OH function does not interfere if protected as its bromomagnesium salt,[14g] silyl ether,[14c,d] or even acetate.[14e,g]

Epoxide Opening and Cyclopropane Formation.

Reagent (**1**) cleanly opens epoxides (eq 7; S_N2).[2]

In vinyl epoxides, both exclusive S_N2 and exclusive S_N2' reactions were observed for similar reagents, depending on the substrate (eqs 8 and 9).[5,14a,b] In eq 9, the TMS analog gives a mixture of propargylic and allenic products.

The products of epoxide opening by (**1**) can be transformed into cyclopropanes (eq 10). The TMS analog gave 75% in the cyclization step.

3-Lithio-1-triisopropylsilyl-1-propyne

This method was triply used in the preparation of a carbocyclic *cis*-tris-σ-homobenzene (eq 11).[15]

The triple epoxide opening gave higher yields (up to 67%) when organocuprates were used.[16,17] The TMS analog of this tris adduct could not be obtained, due to uncontrolled desilylation reactions.

Transformations of the C&tbond;C-TIPS Group.

The C&tbond;C-TIPS group is cleaved by the action of various fluoride reagents, but not by the $AgNO_3$/KCN procedure employed for cleavage of C&tbond;C-TMS. Corey and Rücker describe other useful transformations.[2] The deprotected propargyl group may be further degraded to an acetic acid moiety by decarboxylative oxidation using RuO_2/$NaIO_4$ in CCl_4/MeCN/H_2O, as in the preparation of *cis*-tris-σ-homobenzenes (eq 12).[17]

Oxidation of the products by ***Ruthenium(VIII) Oxide*** with the TIPS group still in place gives a mixture of carboxylic acid and an α-keto acyl silane (silyl α-diketone; (eq 13),[7] an otherwise rare class of compounds;[18] compare the oxidation of disubstituted alkynes to 1,2-diketones by RuO_4[19] and the ***Osmium Tetroxide-t-Butyl Hydroperoxide*** oxidation of TMS-alkynes.[20]

TMS-alkynes are oxidized at the terminal carbon to carboxylic acids by hydroboration/oxidation (dicyclohexylborane/NaOH, H_2O_2). This does not work with TIPS-alkynes.[14b] Instead, TIPS-alkynes are cleanly monohydroborated at the internal carbon by ***9-Borabicyclo[3.3.1]nonane*** to give (*Z*)-β-borylvinylsilanes.[6] These can be oxidized in high yields to α-silyl ketones, or cross coupled with a bromide R^1Br (R^1 = aryl, benzyl, dimethylvinyl) in the presence of NaOH and ***Tetrakis(triphenylphosphine)palladium(0)*** to give β,β-disubstituted vinylsilanes (Suzuki reaction; eq 14).[21a] The same nucleophilic substituted vinylsilane can be added to an aromatic aldehyde to provide access to (*E*)-3-silyl allyl alcohols.[21b]

Propargyl Ketones.

The cyanocuprate derived from (**1**) reacts with esters to form propargyl ketones, even in the presence of epoxide functionality (eq 15).[16]

Bis(silyl)propynes.

Reaction of (**1**) with silylating agents affords 1,3-bis(silyl)propynes, valuable Peterson reagents (eq 16) (see ***1,3-Bis(triisopropylsilyl)propyne***).[2]

Isomeric Species.

The isomeric substituted lithium acetylide LiC&tbond;C-CH_2TIPS (**4**), from 3-TIPS-propyne,[22] was silylated to 1-TMS-3-TIPS-propyne.[23] Compound (**4**) isomerizes to (**1**) in THF/HMPA solution at rt, as shown by isolation of pure 1-TIPS-propyne after quenching a solution of (**4**) with H_2O.[7]

N-Lithio-*N,N´,N´*-trimethylethylenediamine

[-] · $C_5H_{13}LiN_2$ · *N*-Lithio-*N,N´,N´*-trimethylethylenediamine · (MW 108.14)

(reagent for the in situ formation of α-amino alkoxides, which are effective directing groups for *ortho* lithiation[1])

Alternate Name: LTMDA.

Preparative Methods: prepared in situ by adding *n*-BuLi to *N,N,N´*-trimethylethylenediamine in anhydrous solvents.

Handling, Storage, and Precautions: highly flammable; should be kept under a nitrogen or argon atmosphere. Handle in a fume hood.

The title reagent (**1**) is an excellent reagent for in situ protection of aldehydes.[1] Low temperature *ortho* lithiation/alkylation of aryl aldehydes can be achieved via an α-amino alkoxide intermediate generated by treating the aldehyde with LTMDA. The use of reagent (**1**) results in better yields of *ortho*-substituted products as compared to other reagents like ***Lithium N-Methylpiperazide*** and ***Lithium Morpholide***.[1] The *ortho*-lithiated intermediates can be trapped with various electrophiles (eq 1).[2]

(1)

The effectiveness of the *ortho* lithiations is attributed to an intramolecular TMEDA-like assisted metalation leading to a chelated intermediate such as (**2**) (eq 2).[2] A similar methodology has been used for metalating benzylic carbons (eq 3).[3]

(2)

(3)

The versatility of reagent (**1**) has been demonstrated in the regioselective lithiation of various heterocycles.[1] Thiophene-2-carbaldehyde and 2-furaldehydes undergo regioselective *ortho* substitution via *ortho*-lithiated LTMDA-derived α-amino alkoxides (eq 4).[4]

(4)

The scope of this reaction has been established by regioselectively metalating other regioisomers of the above mentioned aldehydes in excellent yields.[4] Indole-2-carbaldehyde behaved in a similar manner.[4] Interestingly, the *N*-methyl group of *N*-methylpyrrole-2-carbaldehyde underwent metalation with LTMDA/***n-Butyllithium*** (eq 5).[4]

(5)

Under similar reaction conditions, *N*-methylindole-2-carbaldehyde is known to give products resulting from ring-lithiated and *N*-methyl-lithiated intermediates.[5] This selectivity problem was solved by using 3-chloro-*N*-methylindole-2-carbaldehyde, which gave exclusive *N*-methyl lithiation.[5] Regioselective lithiation of α-amino alkoxides prepared from methoxypyridinecarbaldehydes can be achieved in good yield (Scheme 1).[6] Regioselective substitution of a 1-(Boc)-3-formyl-1,4-dihydropyridine has been carried out using (**1**) and ***Mesityllithium*** as the base.[7]

Scheme 1

LTMDA has been successfully utilized in the synthesis of schumanniophytine, isoschumanniophytine,[8a] and maxonine.[8b] A directed lithiation using an LTMDA-derived α-amino alkoxide was a key step in a short, asymmetric synthesis of (*S*)-camptothecin.[9] For another reagent similar to LTMDA, see ***Lithium N-Methylpiperazide***.[1]

1-Lithio-3-trimethylsilyl-1-propyne

[67965-43-9] · $C_6H_{11}LiSi$ · 1-Lithio-3-trimethylsilyl-1-propyne · (MW 118.20)

(powerful nucleophilic source of 3-trimethylsilylpropynyl unit for many electrophiles)

Solubility: sol THF, toluene.

Preparative Methods: prepared in situ under nitrogen by reaction of commercially available propargyltrimethylsilane[1] with ***n-Butyllithium*** in THF at -78 °C[2] or by reaction of 3,3-dichloroallyltrimethylsilane and *n*-BuLi in THF at -90 °C.[3]

Handling, Storage, and Precautions: must be prepared and transferred under inert gas (Ar or N_2) to exclude oxygen and moisture; stable at room temperature.

Additions to Carbonyl Compounds.

Paraformaldehyde reacts with 1-lithio-3-trimethylsilyl-1-propyne (**1**) at room temperature to give the hydroxymethylated product. Oxidation gave the alkynic aldehyde, which served as a synthetic equivalent for the butadienyl carbenium ion.[4] Reduction with ***Lithium Aluminum Hydride*** gave the allylic alcohol which was used to protect carboxylic acids as esters which could be deprotected under mild palladium-catalyzed conditions (eq 1).[5] Secondary and tertiary alcohols were prepared for hydrostannylation studies by addition of (**1**) to a range of aldehydes and ketones (eq 2).[2] 1,4-Benzoquinones were prepared by thermolysis in refluxing xylene of the adducts of cyclobutenediones and (**1**) (eq 3).[6] Addition to ethyl acetate, in the presence of ***Boron Trifluoride Etherate***, provided the alkynic ketone in superior yield to addition to acetaldehyde and oxidation, due to the low yield in the latter step (eq 4).[7]

(3)

(4)

Alkylations of Alkyl Halides.

Methylation of (**1**) with ***Iodomethane*** in THF/HMPA required extended time at reflux (eq 5).[2] Alkylation of THP-protected linear iodo alcohols was achieved in modest yield at rt in the same solvent system (eq 6).[8] ***(Iodomethyl)trimethylsilane*** reacted well in refluxing THF alone to give 1,4-bis(trimethylsilyl)-2-butyne.[9]

(5)

(6)

Additions to Epoxides.

1-Lithio-3-trimethylsilyl-1-propyne reacts well with epoxides only in the presence of Lewis acids. ***Diethylaluminum Chloride*** in toluene was used to promote addition to ***Ethylene Oxide***[10] (eq 7) while boron trifluoride etherate in THF at low temperature ensured high regioselectivity in additions to monosubstituted epoxides (eq 8).[11]

(7)

(8)

Reactions with Other Electrophiles.

n-Butyllithium deprotonates the vinyl proton of 3,3-dichloroallyltrimethylsilane in THF, which leads to elimination of lithium chloride, and subsequent metal-halogen exchange produces 1-lithio-3-trimethylsilyl-1-propyne in situ (eq 9). If excess *n*-butyllithium is present, further metalation occurs to give a dilithium species as confirmed by addition of ***Chlorotrimethylsilane*** (eq 10).[3] 1,3-Bis(trimethylsilyl)-1-propyne may be obtained by metalation of propargyltrimethylsilane with butyllithium and reaction with chlorotrimethylsilane (eq 11).[12] Lithium 3-trimethylsilyl-1-propynyltributylborate, formed by addition of 1-lithio-3-trimethylsilyl-1-propyne to ***Tri-n-butylborane***, reacted with ***Trimethylsilylmethyl Trifluoromethanesulfonate*** followed by protonolysis to give the bisallylsilane (eq 12).[13]

(9)

(10)

(11)

(12)

Related Reagents.

3-Chloro-1-propynyllithium; ***Lithium (Trimethylsilyl)acetylide***; ***Propynyllithium***.

Lithium[1]

Li

[7439-93-2] · Li · Lithium · (MW 6.94)

(powerful reducing agent;[1] used for partial reduction of aromatics and conjugated polyenes;[1e,m-o] conversion of alkynes to *trans*-alkenes;[1a,h] stereoselective reduction of hindered ketones;[1l] enone reduction and regioselective alkylation;[1f,j] reductive cleavage of polar single bonds[1a])

Physical Data: mp 180.5 °C; bp 1327 ± 10 °C; *d* 0.534 g cm^{-3}. Natural isotopic composition: ^{7}Li (92.6 %); ^{6}Li (7.4 %).

Solubility: 10.9 g/100 g NH_3 at -33 °C (= 74.1 g/L NH_3); 36.5 g/L $MeNH_2$ at -23 °C.

Form Supplied in: under Ar, as solid in the form of wire, ribbon, rod, foil, shot, ingot, or as a powder; in mineral oil, as wire, shot, or as 25-30 wt % dispersions.

Purification: commercially available in up to 99.97% purity. In general, lithium is not further purified except for cutting off the surface coating.

Handling, Storage, and Precautions: best stored under mineral oil in airtight steel drums and handled under Ar or He. Dispersions in mineral oil segregate on storage and uniformity is restored by stirring. The mineral oil is washed off under Ar with pentane or hexane, and the metal is either dried in an Ar stream or rinsed with the reaction solvent. Dry Li powder is extremely reactive towards air, H_2O vapor, and N_2. The metal reacts rapidly with moist air at 25 °C, but with dry air or dry O_2 only at higher temperatures (>100 °C). A slight blow can initiate violent burning. Reaction with N_2 already occurs at 25 °C, but is inhibited by traces of O_2. Li reacts readily with H_2O, but does not spontaneously ignite as the other alkali metals do. It reacts rapidly with dil HCl and H_2SO_4 and vigorously with HNO_3. Ready reaction occurs with halogens.

Reducing Systems.

For reductions with Li, liquid ***Ammonia*** or primary amines are most often the solvents of choice. Li dissociates in these solvents more or less completely into Li^+ and solvated electrons, producing deep-blue metastable solutions.[2] Ethereal solvents (peroxide-free!) such as THF or DME may be used alone, but are usually used as cosolvents with NH_3 or amines. Li solutions in HMPA are quite unstable in contrast to ***Sodium*** solutions, but are stabilized by THF.[3] Reduction occurs by a sequence of single electron and proton transfers to the organic substrate, leading to saturation of multiple bonds or fission of single bonds.[1a,i,4]

Li-NH_3.

Li has a higher normal reduction potential[5] and molar solubility[6] in liquid NH_3 than Na or ***Potassium*** (see Table 1). This permits the use of larger quantities of cosolvents for substrates that are less soluble in NH_3. The concentrations of Li in NH_3 used in reactions vary widely, from 0.1 to 3 g Li/100 mL NH_3. Concentrations near saturation form a second, less dense, bronze-colored phase which is normally avoided.[7]

Table 1 Solutions of Alkali Metals in Liquid Ammonia

Metal	Solubility[6] at - 33 °C (g metal/100 g NH_3) (g-atom M/mol NH_3)	Normal reduction potential[5] at - 50 °C (V)
Li	10.9 (0.26)	- 2.99
Na	24.5 (0.18)	- 2.59
K	47.8 (0.21)	- 2.73

Reductions are performed either in the absence or presence (Birch conditions[1h]) of a proton source, depending on the desired products.[1a,i,4b] An added proton source can effect reductions which do not occur in its absence (e.g. benzene reduction). It can lead to higher saturation (e.g. in enone reduction) or suppress dimerization and base-catalyzed transformations of primary products. EtOH and *t*-BuOH are the most common proton donors. Primary alcohols protonate the intermediate anions more rapidly, but tertiary alcohols react more slowly with the metal. Other proton donors are NH_4Cl, H_2O, and various amines.[1a,e,4b]

The order of adding the reagents can influence the product distribution.[1g] Most often, Li is added last, until the blue color of the solution persists. For less reactive substrates, alcohol addition is delayed (Wilds-Nelson modification).[5b] The reaction is concluded by quenching excess Li mildly and efficiently with sodium benzoate[8] or with excess EtOH and then NH_4Cl, and NH_3 is allowed to evaporate.

Distillation of NH_3 from Na or through a BaO column removes moisture and iron impurities. The latter catalyze the reaction of alkali metals with the added alcohol and NH_3.[2] The Li-NH_3-ROH system is less sensitive to traces of iron than Na-NH_3-ROH, which accounts in many instances for its superiority.[9] ***Lithium Amide*** is less soluble in NH_3 than ***Sodium Amide*** and ***Potassium Amide***, and base-catalyzed formation of side products is less frequent.[1g,i] Nevertheless, in many cases similar results are obtained with Li and Na in NH_3; Li is preferred for less reactive substrates and Na when overreduction is a problem.[1]

Lithium/Primary Amines.

Li forms stronger, but less selective, reducing agents with primary amines (Benkeser reduction).[1d,h,k] The higher reactivity is probably caused by higher reaction temperatures[1i,k] and possibly also by smaller electron solvation.[2] The reactivity can be modified by addition of alcohols.[1h] The Li-amine solutions seem more sensitive to catalytic decomposition than Li in NH_3.[10] The choice of the amine is limited by the solubility of Li; ethylamine and ethylenediamine are most common. Na is hardly soluble in amines (e.g. more than 100 times less soluble in ethylenediamine at room temperature than Li).[11] Reactions of calcium in amines have been described.[12]

Reduction of Aromatic Compounds.[1,13]

Benzene and its derivatives are reduced to 1,4-cyclohexadienes with Li-NH_3 in the presence of a proton source (see also ***Sodium-Ammonia***). Derivatives with electron-donating substituents lead to 1-substituted cyclohexadienes. Thus reduction of anisole derivatives furnishes 1-methoxycyclohexa-1,4-dienes (eq 1).[9]

Hydrolysis of such dienol ethers to cyclohex-3-enones or with isomerization to cyclohex-2-enones has found wide application in syntheses of steroids, terpenoids, and alkaloids.[1f,m] Li is superior to Na for the more difficult reductions of 1,2,3-substituted anisole derivatives,[5b] though sometimes even excess Li gives poor results.[14] Anisoles are more readily reduced than phenols (eq 2),[15] but higher concentration of Li in NH_3 may effect phenol reduction to cyclohexenols (eq 3).[16]

Electron-acceptor substituents enhance reduction rates and promote 1,4-reduction at the substituted carbon atoms, irrespective of alkoxy, amino, or alkyl substituents. Benzoic acid derivatives are readily reduced to the 1,4-dihydro derivatives. The presence of an alcohol is not necessary, in contrast to the derivatives with electron-releasing substituents. It can even result in overreduction, as the lithium alcoholate facilitates isomerization of the 1,4-dihydro product to the 3,4-dihydro isomer (eq 4).[17]

(4)

The dienolate formed during the reduction can be alkylated in situ with alkyl halides,[18,19] epoxides,[19] or α,β-unsaturated esters (eq 5)[20] to give 1-substituted dihydrobenzoic acids. Rearomatization provides alkyl-substituted aromatic compounds.

(5)

Benzamides and alkyl benzoates can be reduced to the 1,4-dihydro amides and esters, respectively, with Li-NH_3-*t*-butanol, but K-NH_3-*t*-butanol appears superior.[13] However, Li may be better for in situ reductive alkylations, or K^+ may be exchanged with Li^+ before the alkylation step.[21] Reductive methylation of *N*-benzoyl-L-prolinol derivatives afforded excellent diastereoselectivities, irrespective of the use of Li, Na, or K (eq 6).[22]

(6)

The strongly activating and easily removable trimethylsilyl group has been used to direct the regioselectivity of reduction (eq 7).[23]

(7)

The Li-amine-alcohol reagents also reduce benzene derivatives to cyclohexadienes, and are usually applied when reduction in NH_3 fails.[1h,k] Thus reduction of dehydroabietic acid with Li-NH_3-*t*-BuOH afforded 35% of diene while Li-EtNH_2-*t*-$C_5H_{11}OH$ gave 81% (eq 8).[24] The importance of the nature of the proton source is demonstrated by the fact that neither Li-NH_3-EtOH nor Li-EtNH_2-EtOH gave any appreciable amount of reduction product.

(8)

Reduction with Li-amine gives mainly cyclohexenes due to isomerization of the initially formed 1,4-diene by the strong alkylamide base.[1h,i] Mixtures of regioisomers are formed, and best results favoring the most stable isomer are obtained with mixtures[1h] of primary and secondary amines (eq 9).[25]

(9)

Li-EtNH$_2$	79%, 87:13
Li-EtNH$_2$-Me$_2$NH (1:1)	88%, 96:4

Condensed aromatic hydrocarbons are reduced more easily than those in the benzene series. Carefully chosen reaction conditions lead to the selective formation of different products.[1b] Most extensive reductions are achieved with Li-ethylenediamine,[26] while Na-NH$_3$ is one of the mildest reagents.[27] Birch and Slobbe discuss the reduction of heterocyclic aromatics.[4b]

Lithium-induced cyclization of 1,1´-binaphthalenes followed by oxidation of the dianion affords perylenes.[28] 3,10-Dimethylperylene was obtained in 95% (eq 10a).[28a] Cyclizations to tetrasubstituted perylenes proceeded in 36-40%,[28b] while similar reactions with K seem somewhat higher yielding.[29a] However, the synthesis of an 1-alkylated perylene was only successful with Li (eq 10b).[29b]

(10)

(a) $R^1 = Me$, $R^2 = H$	1. Li, THF, Δ; 2. O_2; 95%
(b) $R^1 = H$, $R^2 = (CH_2)_5Me$	1. Li, DME, Δ; 2. $CdCl_2$; 30%
	1. K, DME, 25 °C; 2. $CdCl_2$; <5%

Reduction of Alkynes.[1b,h]

Internal alkynes are reduced to *trans*-alkenes with Li-NH$_3$ or stoichiometric amounts of Li in amines. Excess Li in amines leads to alkanes. Li-EtNH$_2$-*t*-BuOH efficiently reduced an alkyne precursor of sphingosine to the *trans*-alkene with simultaneous *N*-debenzylation, while triple bond reduction was incomplete with Na-NH$_3$ and Li-NH$_3$ (eq 11).[30]

(11)

Dissolving metal reduction is the method of choice for the reduction of triple bonds in the presence of nonconjugated carboxyl groups,[31] where ***Lithium Aluminum Hydride***$_4$ in THF fails. Li-NH_3 afforded higher amounts of *trans*-alkenes in the reduction of some cyclic alkynes compared with Na-NH_3.[32] Terminal triple bonds are protected against reduction with Li-NH_3 by deprotonation with alkali amide, but are completely reduced to double bonds by Li (or Na)-NH_3-$(NH_4)_2SO_4$ or by Li in amines.[1c] Suitably located carbonyl groups give rise to cyclization, yielding vinylidenecycloalkanols,[33] e.g. eq 12.[33a] However, the use of K[33a,34a] or electrochemical reduction[34b] may give better results.

(12)

Reduction of Ketones.[1a,b,l,35]

Li-NH_3-EtOH reduces sterically hindered cyclic ketones to equatorial alcohols (eq 13)[36] and has been widely applied in the syntheses of 11α-hydroxy steroids.[37] This method is complementary to complex hydride reductions, which mainly afford the axial alcohols. Bicyclo[2.2.1]heptanones are reduced predominantly to the *endo*-alcohols. Similar results have been found with Na, K, and Ca.[35]

(13)

α,β-Unsaturated ketones are reduced to the ketone by Li-NH_3.[1j] In fused ring enones the relative configuration at the ring

junction is determined by protonation at the β-carbon.[38] Regioselective alkylation is achieved by trapping the intermediate enolate with an alkyl halide,[39a] a strategy also applied to enediones (eq 14).[39b] In the presence of a proton source, reduction to the saturated alcohols occurs.[40] Li-$EtND_2$-*t*-BuOD reduction gives high yields of saturated ketones and has been used for the stereoselective deuteriation at the β-carbon.[41] Conversion to alkenes is accomplished by phosphorylation of an enolate formed by Li-NH_3 reduction and subsequent hydrogenolysis with Li-$EtNH_2$-*t*-BuOH (eq 15).[42]

(14)

(15)

Reductions of aromatic ketones are complicated by possible pinacol formation, reduction of the aromatic ring, and hydrogenolysis of the C-O bond. Depending on the reaction conditions, 1-tetralone is reduced to tetralin or 1-tetralol (eq 16);[43a] in fact, seven different products can be produced.[43b]

(16)

Aromatic aldehydes and ketones are alkylated and deoxygenated in a one-pot procedure using alkyl- or aryllithium, followed by Li-NH_3 (eq 17).[44]

(17)

Aliphatic Carboxylic Acids.

Simple straight chain carboxylic acids are reduced by Li-$MeNH_2$ or Li-NH_3 to an intermediate imine which can either be hydrolyzed to the aldehyde or catalytically reduced to the amine.[45]

Reductive Cleavage of Polar Single Bonds.[1a]

Li in various solvents provides effective reagents for the cleavage of polar single bonds. The cleavage tendency decreases in the order C-I > C-Br > C-Cl > C-S > C-O > C-N > C-C. Polyhalo compounds are completely reduced with Li and *t*-BuOH in THF (Winstein procedure).[46] Allylic, geminal, bridgehead, and vinylic halogen atoms are removed, the latter stereospecifically. NH_3 and amines have been avoided as solvents due to potential reaction with the alkyl halides by elimination or substitution.[1a,47a] However, Li-NH_3 systems successfully reduce vinylic, bridgehead, and cyclopropyl halides[47b,c] and sometimes give better results than the Winstein-Gassman procedures (eq 18).[47c]

(18)

Alkyllithium reagents nowadays often replace Li for the preparation of organolithium compounds from alkyl or aryl bromides.[48] Li has been used to couple alkyl and aryl halides in Wurtz or Wurtz-Fittig-type reactions,[49] though the use of Na is much more important. Reduction of monosubstituted alkyl halides or selective reduction of geminal dihalides are best carried out with metal or complex hydrides or by catalytic hydrogenation.[1b]

Sulfides, sulfoxides, and sulfones are reductively cleaved with lithium.[50] Reduction of sulfides in THF is improved with catalytic naphthalene. Li-$EtNH_2$ gave better results than ***Sodium Amalgam*** for the cleavage of the C-S bond in sulfones (eq 19),[51a,b] and than ***Raney Nickel*** for some sulfide cleavage.[51c] Selenides are cleaved similarly.[52] Thio- and selenoacetals are reduced to alkanes.

(19)

Allyl, benzyl, and aryl ethers are cleaved by Li in NH_3 or amines.[1a,b] Sterically hindered steroid epoxides, which are not cleaved with $LiAlH_4$, are converted into axial alcohols by Li-$EtNH_2$.[1b] Li-ethylenediamine efficiently cleaves sterically hindered epoxides to tertiary alcohols (eq 20).[53]

(20)

Li promoted reductions of allyloxy and benzyloxy esters[54a] and esters of sterically hindered secondary and tertiary alcohols[54b] give rise to carboxylate cleavage, thus presenting a means of indirect deoxygenation of alcohols. Further reductive cleavages have been found with activated cyclopropanes,[55] *N*-oxides,[56] and sulfonamides.[57]

Li (and K) promoted reduction of $TiCl_3$ in the McMurry reaction has been reported to be more reliable than the $TiCl_3/LiAlH_4$ reagent.[58]

Related Reagents.

Lithium Acetylide

HC&tbond;CLi

[1111-64-4] · C_2HLi · Lithium Acetylide · (MW 31.97) (ethylenediamine complex)

[6867-30-7] · $C_4H_9LiN_2$ · Lithium Acetylide-Ethylenediamine · (MW 92.09)

(reagent for addition of acetylene to ketones,[1] opening of epoxides,[2] and ethynylation of alkyl halides[3])

Solubility: sol THF; LiC&tbond;CH.EDA sol alkyl amines, slightly sol THF.

Form Supplied in: lithium acetylide.EDA is supplied as a powder.

Preparative Method: monolithium lithium acetylide is prepared by treating a THF solution of ***Acetylene*** with ***n-Butyllithium*** at 78 °C (eq 1).[1]

It is critical to keep the temperature at -78 °C. The concentration should be 0.5 M or less. At higher concentrations and temperatures, a white precipitate forms (presumably ***Dilithium Acetylide***) and yields of addition product fall appreciably. Properly formed, lithium acetylide in THF should be a clear, colorless solution.

Handling, Storage, and Precautions: lithium acetylide/THF solution must be used immediately after preparation. It decomposes above -78 °C. A saturated solution of THF/acetylene should not be used during the preparation of lithium acetylide since this may lead to an acetylene atmosphere above the THF. *n*-Butyllithium dropping through the acetylene atmosphere may react violently. Lithium acetylide is air and moisture sensitive.

Addition to Ketones.

Lithium acetylide rapidly adds to a variety of aldehydes and ketones (eq 2).[1]

(2)

Hindered ketones such as di-*t*-butyl ketone give best results if an excess of reagent is used. The reagent freshly prepared in THF generally gives better results than lithium acetylide.EDA[4] or lithium acetylide in ammonia.[5] In the case of easily enolizable ketones, the cerium reagent works well (eq 3).[6]

(3)

The TMS cerium acetylide reportedly gives better results than the unsubstituted cerium regent (eq 4).[7]

(4)

Reaction with Epoxides.

Lithium acetylide in THF decomposes before it can react with epoxides. However, in the presence of ***Boron Trifluoride Etherate*** epoxides are readily opened (eq 5).[2]

(5)

Lithium acetylide.EDA in THF/HMPA[8] or DMSO[9] may also be used to open epoxides (eq 6).

(6)

Ethynylation of Alkyl Halides.

Lithium acetylide.EDA in DMSO can be used to convert alkyl halides and sulfates into terminal alkynes (eq 7).[3]

(7)

Monolithium acetylide in THF in the presence of HMPA is stable at 0 °C. This reagent may also be used to ethynylate alkyl halides (eq 8).[10]

(8)

An alternative route to terminal alkynes involves iodination of lithium ethynyl trialkylborates (eq 9).[11] These are prepared by treating a trialkylborane with lithium acetylide.EDA. This method retains the stereochemistry of the boron-carbon bond.

(9)

Related Reagents.

Dilithium Acetylide; ***Ethynylmagnesium Bromide***; ***Lithium Chloroacetylide***; ***Lithium (Trimethylsilyl)acetylide***; ***Propynyllithium***.

Lithium Aluminum Hydride[1]

$LiAlH_4$

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride · (MW 37.96)

(reducing agent for many functional groups;[1] can hydroaluminate double and triple bonds;[2] can function as a base[3])

Alternate Name: LAH.

Physical Data: mp 125 °C; *d* 0.917 g cm^{-3}.

Solubility: sol ether (35 g/100 mL; conc of more dil soln necessary); sol THF (13 g/100 mL); modestly sol other ethers; reacts violently with H_2O and protic solvents.

Form Supplied in: colorless or gray solid; 0.5-1 M solution in diglyme, 1,2-dimethoxyethane, ether, or tetrahydrofuran; the $LiAlH_4$.2THF complex is available as a 1 M solution in toluene.

Analysis of Reagent Purity: Metal Hydrides Technical Bulletin No. 401 describes an apparatus and methodology for assay by means of hydrogen evolution. See also Rickborn and Quartucci.[39a]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be stored in the absence of moisture. Cans or bottles of $LiAlH_4$ should be flushed with N_2 and kept tightly sealed to preclude contact with oxygen and moisture. Lumps should be crushed only in a glove bag or dry box.

Functional Group Reductions.

The powerful hydride transfer properties of this reagent cause ready reaction to occur with aldehydes, ketones, esters, lactones, carboxylic acids, anhydrides, and epoxides to give alcohols, and with amides, iminium ions, nitriles, and aliphatic nitro compounds to give amines. Several methods of workup for these reductions are available. A strongly recommended option[4] involves careful successive dropwise addition to the mixture containing *n* grams of $LiAlH_4$ of *n* mL of H_2O, *n* mL of 15% NaOH solution, and 3*n* mL of H_2O. These conditions provide a dry granular inorganic precipitate that is easy to rinse and filter. More simply, solid Glauber's salt ($Na_2SO_4.10H_2O$) can be added portionwise until the salts become white.[5] In certain instances, an acidic workup (10% H_2SO_4) may prove advantageous because the inorganic salts become solubilized in the aqueous phase.[6] Should water not be compatible with the product, the use of ethyl acetate is warranted since the ethanol that is liberated usually does not interfere with the isolation.[4] Although the stoichiometry of $LiAlH_4$ reactions is well established,[1] excess amounts of the reagent are often employed (perhaps to make accommodation for the perceived presence of adventitious moisture). This practice is wasteful of reagent, complicates workup, and generally should be avoided.

The reduction of amides can be adjusted in order to deliver aldehydes. Acylpiperidides,[7] *N*-methylanilides,[8] aziridides,[9] imidazolides,[10] and *N,O*-dimethylhydroxylamides[11] have proven especially serviceable. All of these processes generate products that liberate the aldehyde upon hydrolytic workup. The powerful reducing ability of $LiAlH_4$ allows for its application in the context of other functional groups. Alkanes are often formed in good yield upon exposure of alkyl halides (I > Br > Cl; primary > secondary > tertiary)[12] and tosylates[13] to $LiAlH_4$ in ethereal solvents. Chloride reduction is an S_N2 process, while iodides enter principally into single electron transfer chemistry.[14] Benzylic[15] and allylic halides[16] behave comparably, although the latter can react in an S_N2' fashion as well (eq 1).[17] Select aromatic halides can be reduced under forcing conditions (e.g. diglyme, 100 °C),[18] but chemoselectivity as in eq 2 can often be achieved.[19] Vinyl,[20] bridgehead,[20] and cyclopropyl halides (eqs 3 and 4)[20,21] have all been reported to undergo reduction. The SET mechanism is also believed to operate in the latter context.[22]

(1)

(2)

(3)

(4)

$LiAlH_4$ is normally unreactive toward ethers.[1] Unsaturated acetals undergo reduction with double bond migration (S_N2'); in cyclic systems, the usual stereoelectronic factors often apply (eq 5).[23] Orthoesters are amenable to attack, giving acetals in good yield (eq 6).[24] The susceptibility of benzylic acetals to reduction can be enhanced by the co-addition of a Lewis acid (eq 7).[25]

(5)

(6)

(7)

When comparison is made between $LiAlH_4$ and related reducing agents containing active Al-H and B-H bonds, $LiAlH_4$ is seen to be the most broadly effective (Table 1).[1h] Its superior reducing power is also reflected in its speed of hydride transfer.

Table 1 Comparison of the Reactivities of Hydride Reducing Agents toward the More Common Functional Groups

	Reduction products[a]						
Reagent/functional group	Aldehyde	Ketone	Acyl halide	Ester	Amide	Carboxylate salt	Iminium ion
$LiAlH_4$	Alcohol	Alcohol	Alcohol	Alcohol	Amine	Alcohol	Amine
$LiAlH_2(OCH_2CH_2OMe)_2$	Alcohol	Alcohol	Alcohol	Alcohol	Amine	Alcohol	
$LiAlH(O\text{-}t\text{-}Bu)_3$	Alcohol	Alcohol	Aldehyde	Alcohol	Aldehyde	NR	
$NaBH_4$	Alcohol	Alcohol		Alcohol	NR	NR	Amine
$NaBH_3CN$	Alcohol	NR		NR	NR	NR	Amine
B_2H_6	Alcohol	Alcohol		NR	Amine	Alcohol	
AlH_3	Alcohol	Alcohol	Alcohol	Alcohol	Amine	Alcohol	
$[i\text{-}PrCH(Me)]_2BH$	Alcohol	Alcohol		NR	Aldehyde	NR	
$(i\text{-}Bu)_2AlH$	Alcohol	Alcohol		Aldehyde	Aldehyde	Alcohol	

[a] NR indicates that no reduction is observed.

Hydroalumination Agent.

Ethylene has long been known to enter into addition with $LiAlH_4$ when the two reagents are heated under pressure at 120-140 °C; lithium tetraethylaluminate results.[2] Homogeneous hydrogenations of alkenes and alkynes to alkanes and alkenes, respectively, performed in THF or diglyme solutions under autoclave pressure, are well documented.[26] Such reductions are greatly facilitated by the presence of a transition metal halide ranging from Ti to Ni.[27] Replacement of the hydrolytic workup by the addition of appropriate halides constitutes a useful means for chain extension (eq 8).[28] 1-Chloro-1-alkynes are notably reactive toward $LiAlH_4$, addition occurring regio- and stereoselectively to give alanates that can be quenched directly (MeOH) or converted into mixed 1,1-dihaloalkenes (eq 9).[29]

(8)

(9)

A pronounced positive effect on the ease of reduction of C=C and C&tbond;C bonds manifests itself when a neighboring hydroxyl group is present. In such cases, $LiAlH_4$ is used alone because reduction is preceded by formation of an alkoxyhydridoaluminate capable of facilitating hydride delivery (eqs 10-12).[30-32] The regio- and stereoselectivities of these reactions, where applicable, appear to be quite sensitive to the substrate structure and solvent.[33] Generally, the use of THF or dioxane results in exclusive *anti* addition. When ether is used, almost equivalent amounts of *syn* and *anti* products can result. Considerable attention has been accorded to synthetic applications of the alanate intermediates produced upon reduction of propargyl alcohols in this way. Simple heating occasions elimination of a δ-leaving group to generate homoallylic[34] and α-allenic alcohols (eqs 13 and 14).[35] Other variants of this chemistry have been reported.[36] The addition at -78 °C of solid iodine to alanates formed in this way greatly accelerates the elimination (eq 15).[37] Solutions of iodine in THF give rise instead to vinyl iodides.[38]

(10)

(11)

(12)

(13)

(14)

(15)

Epoxide Cleavage and Aziridine Ring Formation.

Epoxides are reductively cleaved in the presence of $LiAlH_4$ with attack generally occurring at the less substituted carbon.[1g] 1,2-Epoxycyclohexanes exhibit a strong preference for axial attack (eqs 16 and 17).[39] In general, *cis* isomers are more reactive than

their *trans* counterparts; ring size effects are also seen and these conform to the degree of steric inhibition to backside attack of the C-O bond.[40] Vinyl epoxides often suffer ring opening by means of the S_N' mechanism (eq 18).[41]

(16)

(17)

(18)

Two types of oximes undergo hydride reduction with ring closure to give aziridines. These are ketoximes that carry an α- or β-aryl ring and aldoximes substituted with an aromatic group at the β-carbon (eqs 19 and 20).[42]

(19)

(20)

Use as a Base.

Both 1,2- and 1,3-diol monosulfonate esters react with $LiAlH_4$ functioning initially as a base and subsequently in a reducing capacity (eqs 21 and 22).[3,43]

(21)

(22)

Reduction of Sulfur Compounds.

Sulfur compounds react differently with $LiAlH_4$ depending on the mode of covalent attachment of the hetero atom and its oxidation state. Reductive desulfurization is not often encountered.[44] Arylthioalkynes undergo stereoselective *trans* reduction (eq 23)[45] and α-oxoketene dithioacetals are transformed into fully saturated *anti* alcohols under reflux conditions (eq 24).[46] While $LiAlH_4$ catalyzes the fragmentation of sulfolenes to 1,3-dienes,[47] the lithium salts of sulfolanes are smoothly ring contracted when heated with the hydride in dioxane (eq 25).[48]

(23)

(24)

(25)

Stereoselective Reductions.

The reduction of 4-*t*-butylcyclohexanone and (**1**) by $LiAlH_4$ occurs from the axial direction to the extent of 92%[49] and 85%,[50] respectively. When a polymethylene chain is affixed diaxially as in (**2**), the equatorial trajectory becomes kinetically dominant (93%).[50] Thus, although electronic factors may be an important determinant of π-facial selectivity,[51] steric demands within the ketone cannot be ignored. The stereochemical characteristics of many ketone reductions have been examined. For acyclic systems, the Felkin-Ahn model[52] has been widely touted as an important predictive tool.[53] Cram's chelation transition state proposal[54] is a useful interpretative guide for ketones substituted at C_α with a polar group. Cieplak's explanation[55] for the stereochemical course of nucleophilic additions to cyclic ketones has received considerable scrutiny.[56]

(1)

(2)

Useful levels of diastereoselectivity can be realized upon reduction of selected acyclic ketones having a proximate chiral center.[57] The contrasting results in eq 26 stem from the existence of a chelated intermediate when the benzyloxy group is present and its deterrence when a large silyl protecting group is present. In the latter situation, an open transition state is involved.[58,59] In eq 27, $LiAlH_4$ alone shows no stereoselectivity, but the co-addition of ***Lithium Iodide*** gives rise to a *syn*-selective reducing agent as a consequence of the intervention of a Li^+-containing six-membered chelate.[60]

R = Bn, ether, -10 °C 98:2
R = TBDMS, THF, -20 °C 5:95

syn:*anti* = 95:5

The reduction of amino acids to 1,2-amino alcohols can be conveniently effected with $LiAlH_4$ in refluxing THF.[61] The higher homologous 1,3-amino alcohols have been made available starting with isoxazolines, the process being *syn* selective (eq 28).[62,63] The *syn* and *anti* *O*-benzyloximes of β-hydroxy ketones are reduced with good *syn* and *anti* stereoselectivity, respectively.[64] However, when NaOMe or KOMe is also added, high *syn* stereoselectivity is observed with both isomers (eq 29).[65]

88:12

syn:*anti* = 96:4

Addition of Chiral Ligands.

If a chiral adjuvant is used to achieve asymmetric induction, it should preferentially be inexpensive, easily removed, efficiently recovered, and capable of inducing high stereoselectivity.[53] Of these, 1,3-oxathianes based on (+)-camphor[66] or (+)-pulegone,[67] and proline-derived 1,3-diamines,[68] have been accorded the greatest attention.

Extensive attempts to modify $LiAlH_4$ with chiral ligands in order to achieve the consistent and efficient asymmetric reduction of prochiral ketones has provided very few all-purpose reagents.[1f,69] Many optically active alcohols, amines, and amino alcohols have been evaluated. One of the more venerable of these reagents is that derived from DARVON alcohol.[70] The use of freshly prepared solutions normally accomplishes reasonably enantioselective conversion to alcohols.[71] As the reagent ages, its reduction stereoselectivity reverses.[70] This phenomenon is neither understood nor entirely reliable, and therefore recourse to the enantiomeric reagent[72] (from NOVRAD alcohol) is recommended.[73] The highest level of enantiofacial discrimination is usually realized with $LiAlH_4$ complexes prepared from equimolar amounts of (*S*)-(-)- or (*R*)-(+)-2,2´-dihydroxy-1,1´-binaphthyl and ethanol.[74] Often, optically pure alcohols result, irrespective of whether the ketones are aromatic,[74] alkenic,[75] or alkynic in type.[76] A useful rule of thumb is that (*S*)-BINAL-H generally provides (*S*)-carbinols and (*R*)-BINAL-H the (*R*)-antipodes when ketones of the type R_{unsat}-C(O)-R_{sat} are involved (eq 30).[74]

(30)

For a more detailed discussion of asymmetric induction by this means, see also the following entries that deal specifically with $LiAlH_4$/additive combinations.

Related Reagents.

Lithium Aluminum Hydride-(2,2´-Bipyridyl)(1,5-cyclooctadiene)nickel[1]

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-(2,2´-Bipyridyl)(1,5-cyclooctadiene)nickel · (MW 37.96) ((bipy)(cod)Ni)

[55425-72-4] · $C_{18}H_{20}N_2Ni$ · Lithium Aluminum Hydride-(2,2´-Bipyridyl)(1,5-cyclooctadiene)nickel · (MW 323.09)

(reagent for desulfurization)[1]

Physical Data: see entry for ***Lithium Aluminum Hydride***. A crystal structure of (2,2´-bipyridyl)(cod)Ni has been reported.[3d]

Solubility: sol THF.

Preparative Methods: as a red-violet solution[1a] by addition of an equimolar quantity of $LiAlH_4$ to a solution of the nickel complex in THF at rt with production of a mole of hydrogen. The nickel complex can be prepared according to literature procedures.[2]

Handling, Storage, and Precautions: highly flammable hydrogen is liberated during the formation of the complex. Solutions should be protected from open flames, moisture, and oxygen under an atmosphere of argon. Nickel and nickel salts are reputed to be carcinogenic and should be handled with due precautions. $LiAlH_4$ is highly flammable as the solid or in solution.

Homogeneous Desulfurizing Agent.

$LiAlH_2$-$(THF)_n$-$C_{10}H_8N_2$-Ni (**1**), resulting from addition of $LiAlH_4$ to (2,2´-bipyridyl)(1,5-cyclooctadiene)Ni, is a powerful desulfurizing agent for some aromatic sulfur heterocycles. For example, desulfurization[3] of dibenzothiophene was achieved with two molar equivalents of the reagent (**1**) (eq 1).[1a]

(1)

Phenothiazine (X = NH), phenoxathiine (X = O), and thianthrene (X = S) can be desulfurized under the same conditions (eq 2).[1a] Note that for thianthrene, good chemoselectivity is obtained as only one sulfur atom is removed.

(2)

The use of $LiAlD_4$ resulted in only minor incorporation of deuterium, while quenching with DOAc provided almost no incorporation of the label. Other amine ligands such as ethylenediamine, HMPA, TMEDA, or pyridine (2 equiv), instead of 2,2´-bipyridyl, proved equally effective. Only the limited number of systems described above[1a] have been studied and the generality of this reagent has not been demonstrated. Other reports of homogeneous desulfurizing agents related to (**1**) have appeared in the literature and show broader applicability.[3]

Lithium Aluminum Hydride-Bis(cyclopentadienyl)nickel

$LiAlH_4$-$NiCp_2$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Bis(cyclopentadienyl)nickel · (MW 37.96)
($NiCp_2$)

[1271-28-9] · $C_{10}H_{10}Ni$ · Lithium Aluminum Hydride-Bis(cyclopentadienyl)nickel · (MW 188.90)

(desulfurization reagent for thiols, thioethers,[1,2] thioacetals,[1] sulfoxides, and sulfones;[2] used as a homogenous catalyst for catalytic hydrogenation[3])

Physical Data: see ***Lithium Aluminum Hydride***.

Solubility: see ***Lithium Aluminum Hydride***. Reactions using the mixture are run in THF.

Form Supplied in: prepared in situ from commercially available components.

Preparative Methods: bis(cyclopentadienyl)nickel is added as a THF solution to an equimolar amount of $LiAlH_4$ at rt under nitrogen, resulting in the formation of a dark brown solution after 15 min. A THF solution of the organic substrate is then added to the mixture dropwise. Each carbon-sulfur bond requires at least 1 equiv of the reagent. Catalytic hydrogenation is performed in the presence of 1-5 mol % of the reagent.

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride***.

Desulfurization.

The mixture of lithium aluminum hydride-bis(cyclopentadienyl)nickel has been used for reductive carbon-sulfur bond cleavage as a homogeneous alternative to the more common reagent, ***Raney Nickel***.[4] It has been found to desulfurize thiols, thioethers, and thioacetals effectively (eqs 1-3).[1,2]

(1)

(2)

(3)

Benzylic, α-acyl substituted, and aryl carbon-sulfur bonds were found to be easily reduced with this reagent, whereas alkyl carbon-sulfur bonds required more vigorous conditions, resulting in lower yields. Carbonyl groups, esters, and alkenes are stable to the reaction conditions, however, similar to Raney nickel,[4] and nitro groups are reduced to the corresponding primary amines. In addition, sulfoxides and sulfones can also be desulfurized with this reagent. Longer reaction times and an excess of the reagent are required in order to prevent simple deoxygenation of the sulfoxide or sulfone and achieve complete reduction.[2]

Catalytic Hydrogenation.

Alkenes and alkynes can also be hydrogenated in the presence of a catalytic amount of $LiAlH_4$-$NiCp_2$.[3] This reagent shows selectivity for disubstituted alkenes and conjugated polyenes (eq 4), whereas trisubstituted and sterically hindered alkenes (eq 5) are inert to the reaction conditions. Alkynes may be fully or partially reduced to the corresponding alkanes or alkenes, respectively, giving rise to products derived from *cis* and *trans* addition in the latter case.

Lithium Aluminum Hydride-Boron Trifluoride Etherate[1]

$LiAlH_4$-BF_3.Et_2O

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Boron Trifluoride Etherate · (MW 37.96)
(BF_3.Et_2O)

[109-63-7] · $C_4H_{10}BF_3O$ · Lithium Aluminum Hydride-Boron Trifluoride Etherate · (MW 141.95)

(reducing agent for esters,[2] thiol esters,[3] acetals, and ketals;[4] also a reagent for hydroboration of alkenes[5])

Physical Data: see ***Lithium Aluminum Hydride*** and ***Boron Trifluoride Etherate***

Solubility: most reactions are performed in ether or THF.

Preparative Methods: for reductions, a solution of the carbonyl compound and BF_3.Et_2O in ether is added to a cooled suspension of $LiAlH_4$ in ether.[2] For hydroborations, BF_3.Et_2O is added to a solution of the alkene in ether or THF followed by the addition of $LiAlH_4$ in ether at 0 °C.[5]

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride*** and ***Boron Trifluoride Etherate***.

Reduction of Esters.

The direct reduction of esters and lactones to ethers can be accomplished by employing a reagent prepared from lithium aluminum hydride and boron trifluoride etherate. When 30 mol of BF_3.Et_2O and 2 mol of $LiAlH_4$ per mol of ester is used, a γ-lactone is converted to the tetrahydrofuran in good yield (eq 1).[6]

(1)

Also, the yield of ether appears to increase as the alcohol portion of the ester goes from primary to tertiary, as seen in the three isomeric butyl esters (**1a**), (**1b**), and (**1c**) (eq 2).[7] This reagent has also been used to generate crown ethers from crown lactones (eq 3).[8]

(1a) R = Bu
(1b) R = *s*-Bu
(1c) R = *t*-Bu

(2)

(2a) R = Bu, 7%
(2b) R = *s*-Bu, 41%
(2c) R = *t*-Bu, 71%

(3)

Reduction of Thiol Esters.

The combination of $LiAlH_4$ and a large excess of $BF_3.Et_2O$ will reduce thiol esters to sulfides. This reaction is similar to the reduction of esters to ethers. Thus cyclohexyl thiolacetate, when treated with $LiAlH_4$-$BF_3.Et_2O$, gives the corresponding sulfide (eq 4).[3]

(4)

Reduction of Acetals.

Acetals are inert to $LiAlH_4$, and are normally used as protecting groups for ketones and aldehydes. However, when the reagent prepared from $LiAlH_4$-$BF_3.Et_2O$ is employed, they are reduced to ethers. Lithium aluminum hydride and ***Aluminum Chloride*** also reduces acetals, but $LiAlH_4$-$BF_3.Et_2O$ is preferred because the yields are slightly better and $BF_3.Et_2O$ is less troublesome during the workup. When treated with this reagent, acetal (**3**) gives the corresponding diether (eq 5).[4]

(3)

(5)

Hydroboration of Alkenes.

Diborane can be generated in situ by adding $LiAlH_4$ to $BF_3.Et_2O$, which upon oxidative workup hydrates alkenes to alcohols. For example, when alkene (**4**) reacts with this reagent, it gives the corresponding alcohol (eq 6).[9] Yet, when treated with diborane generated from ***Sodium Borohydride***-$BF_3.Et_2O$, the alcohol is formed in a 55% yield and 40% of starting alkene is recovered. This method cannot be used in the presence of acetals and esters.

Lithium Aluminum Hydride-Cerium(III) Chloride

$LiAlH_4$-$CeCl_3$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Cerium(III) Chloride · (MW 37.96) ($CeCl_3$)

[7790-86-5] · $CeCl_3$ · Lithium Aluminum Hydride-Cerium(III) Chloride · (MW 246.47) ($CeCl_3.7H_2O$)

[18618-55-8] · $CeCl_3H_{14}O_7$ · Lithium Aluminum Hydride-Cerium(III) Chloride · (MW 372.61)

(reducing agent for alkyl halides and phosphine oxides;[1] in combination with $NaBH_4$ is a system used to prepare phosphine boranes;[2] catalyst for the isomerization and dimerization of alkenes[3,4])

Physical Data: see ***Lithium Aluminum Hydride*** and ***Cerium(III) Chloride***.

Solubility: see ***Lithium Aluminum Hydride*** and ***Cerium(III) Chloride***; reactions using this reagent system typically use THF or DME as solvent.

Form Supplied in: formed in situ from widely available reagents.

Preparative Method: the organic substrate (1 equiv) and lithium aluminum hydride (4.5 equiv) are added to a suspension of dried cerium(III) chloride (1.5 equiv) in THF.[1]

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride*** and ***Cerium(III) Chloride***.

Reduction of Fluorides and Chlorides.

Alkyl fluorides and chlorides are reduced to their alkane counterparts upon treatment with lithium aluminum hydride-cerium(III) chloride. Despite the relatively inert nature of alkyl (eq 1) and aryl fluorides, they are reduced as readily as chlorides (eqs 2 and 3).[1] The hard Lewis acid character of the cerium cation is believed

to perturb the halogen to an extent such that reduction is easily effected by lithium aluminum hydride. Furthermore, a radical mediated process has been postulated in which hydrogen abstraction from the solvent (THF or DME) is operational.[1]

$$Me(CH_2)_{10}CH_2F \xrightarrow[\text{90\%}]{LiAlH_4,\ CeCl_3,\ THF,\ reflux} Me(CH_2)_{10}Me \qquad (1)$$

(2)

R = F, 94%
R = Cl, 95%

(3)

Reduction of Phosphine Oxides.

Worthy of increased attention is the use of this reagent system in the reduction of phosphine oxides (eq 4).[1] The results from these reductions are general, and sterically hindered phosphine oxides are no exception (eq 5).[1] Unfortunately, racemization is observed in cases where the phosphine oxide is optically active.

$$Ph_3P{=}O \xrightarrow[\text{95\%}]{LiAlH_4,\ CeCl_3\ (2{:}1.5),\ THF,\ 40\ ^\circ C} PPh_3 \qquad (4)$$

(5)

Formation of Phosphine Boranes.

The scope of the lithium aluminum hydride-cerium(III) chloride reduction of phosphine oxides is broadened when the reagents are used in conjunction with ***Sodium Borohydride***. Tertiary and secondary phosphine oxides are transformed into their respective phosphine boranes with great facility (eqs 6 and 7).[2] Further manipulations of these phosphine boranes provide access to a variety of useful phosphine and tethered phosphine derivatives. The borane protecting/activating group is easily removed with retention of configuration when assisted by ***Triethylamine***. The utility of this reagent has been demonstrated through the synthesis of optically pure ligands for use in catalytic asymmetric hydrogenation such as (*S*,*S*)-1,2-ethanediylbis[(*o*-methoxyphenyl)phenylphosphine].[2]

(6)

(7)

Isomerization and Dimerization of Alkenes.

The title reagent system is also known to promote the isomerization of alkenes. Bicyclo[3.2.1]oct-2-ene was synthesized in a single maneuver from 4-vinylcyclohexene in 48% yield.[3] Similar activity of the reagent system was realized in the dimerization of 2-alkenes.[4] It should be noted, however, that the use of the reagent in this manner is of limited synthetic value due to the harsh conditions necessary to effect the transformations.

(used for enantioselective reduction of prochiral ketones to alcohols[1])

Alternate Name: BINAL-H.

Physical Data: BINAL: white solid, mp 208-210 °C. Also see ***Lithium Aluminum Hydride***.

Solubility: sol THF.

Preparative Methods: prepared in situ from commercially available lithium aluminum hydride and BINAL.

Handling, Storage, and Precautions: sensitive to moisture (see ***Lithium Aluminum Hydride***).

Overview and General Considerations.

This article will cover the title reagent and other chiral reducing agents derived from lithium aluminum hydride and chiral additives, with initial emphasis on the title reagent. The enantioselective reduction of prochiral ketones is a reaction of

considerable importance to the synthetic organic chemist and can now be accomplished by a variety of methods and reagents.[1,2] Particularly the use of chiral oxazaborolidines for the catalytic asymmetric reduction of ketones has received much recent interest. This method has been shown to be useful for the preparation of a variety of chiral alcohols with high optical purities. This transformation can also be realized using catalytic hydrogenation with a chiral catalyst or by use of chiral borane reducing agents such as ***(R,R)-2,5-Dimethylborolane*** and ***B-3-Pinanyl-9-borabicyclo[3.3.1]nonane***. Enzyme-catalyzed transformations, for example ***Baker's Yeast*** reductions of carbonyl compounds, can also provide access to a range of chiral alcohols with high optical purities.

The use of complexes of lithium aluminum hydride (LAH) with various chiral ligands to achieve the enantioselective reduction of prochiral ketones has been extensively studied for over 40 years.[1] However, this method, with some exceptions, has not found widespread use due to a number of limiting factors. These factors vary from moderate to poor enantioselectivities, often observed in these reductions, to ready availability of only one antipode of a desired chiral ligand. The recovery of the often expensive chiral ligand that is used in stoichiometric quantities to form the LAH complex is obviously an important experimental concern. Also, in some cases the LAH complex with the chiral ligand may disproportionate to achiral reducing species under the reaction conditions, resulting in poor optical purities of the desired products. Further, no single complex appears to have a sufficiently broad substrate specificity. Aromatic and unsaturated ketones are in general the better substrates and they can be reduced with good enantioselectivities using this method. A useful article comparing the merits of some of the more promising asymmetric reducing agents known for ketones has been published.[3]

Chiral Alcohol Modifying Agents.

Complexes of a variety of chiral alcohols (see Figure 1) with LAH have been prepared in situ and examined for their ability to effect enantioselective reduction of prochiral carbonyl compounds. However in most cases, the optical purities of the products obtained have not been satisfactory. This is in part due to the tendency of these chiral ligand-hydride complexes to disproportionate under reaction conditions yielding achiral reducing agents. An exception is the complex of LAH and (-)-menthol (**1**) which has been used to reduce α and β-aminoketones with good enantioselectivities.

The reduction of carbonyl compounds with LAH complexes of a number of chiral diols derived from carbohydrates and terpenes has been studied. In general, the enantioselectivities observed with such reagents have been low to moderate. Acetophenone, which is the model substrate in many of these reduction studies, is reduced by a complex of LAH and the glucose-derived diol (**2**) in about 71% ee under optimized conditions.

The reagent (*R*)- or (*S*)-BINAL-H, (**7**) developed by Noyori, is undoubtedly the most useful LAH complex reported so far for the asymmetric reduction of a variety of carbonyl compounds.[4] The reagent is prepared from (*R*)- or (*S*)-2,2´-dihydroxy-1,1´-binaphthyl (**3**) (BINAL). Both enantiomers of BINAL are commercially available, although they are somewhat expensive. The chiral ligand, however, can be recovered after the reduction and reused. Equimolar quantities of BINAL and LAH are initially mixed together to form a LAH complex that has a C_2 axis of symmetry, which makes the two hydrogens on the aluminum homotopic. It is interesting to note that the 1:1 complex of BINAL and LAH is a reducing agent that exhibits extremely low enantioselectivity as seen in the case of acetophenone (2% ee). Replacement of one of the hydrogens with an alcohol, like methanol or ethanol, gives a single reducing agent (**7**), which exhibits much higher specificity in the reduction of prochiral ketones. Another useful observation is that reduction of carbonyls with the (*R*)-BINAL-H reagent tends to give the (*R*)-alcohol while the (*S*)-reagent gives the (*S*)-alcohol. The use of lower reduction temperatures enhances optical purities of the product alcohols, but lowers the yields. Optimized conditions for reductions involve reaction of a ketone with 3 equiv of the reagent formed from LAH, BINAL, and ethanol (1:1:1) in THF for 1 h at -100 °C and then at -78 °C for 2 h.

(*R*)-(7)

(*S*)-(7)

A number of structurally diverse ketones have been reduced using BINAL-H. Some of the results are summarized in Table 1.[5] Aryl alkyl ketones, alkynic ketones, and α,β-unsaturated ketones are reduced to alcohols with good to excellent % ee, while aliphatic ketones give products with lower optical purities. The asymmetric reduction of a number of acylstannanes with (**7**) gives synthetically valuable α-alkoxystannanes with high optical purities after protection of the initially formed unstable alcohols as their MOM or BOM ethers.[6]

Table 1 Reduction of Ketones with (**7**)

Ketone	(7)	Yield (%)	ee (%)	Product
	(*R*)	61	95	(*R*)
	(*S*)	74	90	(*S*)
	(*R*)	91	91	(*R*)
	(*S*)	69	96	(*R*)
	(*S*)	67	24	(*R*)

BINAL-H has been used to prepare deuterated primary alcohols with high optical purities. For example, benzaldehyde-*1-d* is reduced in 59% yield and 87% optical purity. β-Ionone is reduced with this reagent to the corresponding alcohol in 100% ee and 87% yield. Simple cyclic enones like 2-cyclohexenone are not reduced by the BINAL-H reagent under standard reduction conditions.[5]

The chiral nonracemic enone (**8**) is reduced with (*S*)-(**7**) to give the (15*S*)-alcohol in 100% de and 88% yield. The product is a valuable intermediate in the synthesis of prostaglandins.[5]

(8)

The asymmetric reduction of lactone (**9**) to give predominantly one atropoisomer can be achieved using 10 equiv of a complex prepared from LAH and BINAL (1:1) at -40 °C.[7] This reduction gives an 88:12 ratio of (**10a**):(**10b**) in good yield (80%). Reduction of the same substrate with 8 equiv of a complex of LAH with (*S*)-(+)-2-(anilinomethyl)pyrrolidine in ether at -40 °C leads to opposite stereochemical results (38:62 ratio of **10a**:**10b**).

(9)

(10a)

(10b)

BINAL-H has also been used for the asymmetric reduction of methylaryl- and methylalkylphosphinylimines to the corresponding phosphinylamines in high % ee (Table 2).[8] Similar to the reduction of ketones, reduction of the imines with (*S*)-(**7**) produces the (*S*)-amine and reduction with (*R*)-(**7**) gives the (*R*)-amine.

Table 2 Reduction of Imines with (7)

R^1	R^2	(7)	Yield (%)	ee (%)	Product
Me	Ph	(*R*)	20	100	(*R*)
Me	Et	(*S*)	38	93	(*S*)
Me	C_5H_{11}	(*S*)	83	64	(*S*)

The complex of the biphenanthryl diol (**4**) with LAH has been prepared and its reduction properties have been examined.[9] This reagent gives excellent enantioselectivity in the reduction of aromatic ketones. For example, acetophenone is reduced in 75% yield with 97% ee. As with Noyori's reagent, reductions with the (*S*)-reagent give (*S*)-alcohols and aliphatic ketones are reduced with low enantioselectivity. Both enantiomers of this auxiliary can be readily prepared and can also be recovered for reuse at the end of the reduction.

The LAH complex of the chiral spirodiol (**5**) has recently been prepared. This complex exhibits excellent enantioselectivity in the reduction of some aromatic ketones.[10] Acetophenone is reduced at -80 °C in 98% ee and 80% yield. Reduction of other aryl alkyl ketones also gives excellent stereoselectivity, but the use of this reagent with a variety of ketones has not been studied. The chiral auxiliary can be recovered and reused.

Recently, the preparation of the chiral biphenyl (**6**) and its use as a modifying agent with LAH has been reported.[11] A complex of LAH-(**6**)-EtOH (1:1:1) at -78 °C gives the best enantioselectivities in the reduction of prochiral ketones. Similar to Noyori's reagent, use of the LAH complex with (*S*)-(**6**) leads to the (*S*)-alcohol. Enantioselectivity is usually high for aromatic ketones (acetophenone 97% ee, 93% yield). This reagent reduces 2-octanone in higher enantioselectivity (76% ee) than 3-heptanone (36% ee).

Chiral Amino Alcohol Modifying Agents.

A number of chiral amino alcohols have been examined as ligands for the preparation of chiral LAH reducing agents (Figure 2). The complex of (-)-*N*-methylephedrine (**11**) with LAH has been widely studied and has shown promise for the asymmetric reduction of prochiral ketones. It has been found that addition of an achiral component such as 3,5-dimethylphenol (DMP), *N*-ethylaniline (NEA), or 2-ethylaminopyridine (EAP) to the complex of LAH with (**11**) can enhance the enantioselectivity observed in these reductions. Both enantiomers of (**11**) are commercially available and the ligand can be recovered subsequent to the reaction and reused.

Vigneron and co-workers have observed that a complex of LAH, (-)-(**11**), and DMP (1:1:2), in ether at -15 °C, appears to show the highest enantioselectivity in the reduction of a series of aromatic and alkynyl ketones to the corresponding (*R*)-alcohols (Figure 3).[12] Interestingly, the optical purities of the products obtained were lower both at higher and lower reaction temperatures.

The complex of LAH, (-)-(**11**), and DMP has also been used to reduce stereoselectively a steroidal alkynic ketone. Reduction of the alkynic ketone (**16**) with 3 equiv of the complex at -15 °C gave a 17:1 ratio of the two diastereomers (22*R*/22*S*) in 94% yield, to provide a key intermediate for the synthesis of a vitamin D_2 metabolite.[13]

(16)

The enantioselective reduction of cyclic conjugated enones may be best accomplished using a complex of LAH with (**11**) to which EAP has been added.[14,15] Optimum conditions for these reductions involve treatment of the ketone with 3 equiv of a 1:1:2 complex of LAH-(-)-(**11**)-EAP in ether at -78 °C for 3 h (Table 3). However, under these conditions, acetophenone is reduced to the (*R*)-alcohol in only 54% ee.

Table 3 Reduction of Ketones with LAH/(-)- **(11)**/EAP to give (*R*)-Alcohols

Ketone	Yield (%)	ee (%)
	82	96
	93	96
	91	96

It has been found that the addition of 2 equiv of NEA to a 1:1 complex of LAH and (-)-(**11**) in ether produces a reagent capable of reducing some α,β-unsaturated ketones to the (*S*)-alcohols in good optical purities at -78 °C (Table 4).[16] It is interesting to note that, with this reagent, the (*S*)-alcohol is the product that is formed preferentially.

Table 4 Reduction of Ketones with LAH/(-)- **(11)**/NEA to give (*S*)-Alcohols

Ketone	Yield (%)	ee (%)
	87	86
	100	>90
	92	88
	88	76
	90	41

The preparation and use of a polymer supported LAH-ephedrine-DMP reducing reagent has been reported.[17] In preparing this reagent, ephedrine is attached to a 1% crosslinked polystyrene backbone prior to mixing with LAH and DMP. Careful control of the degree of functionalization of the polymer gives a reducing reagent comparable in efficacy to the analogous nonpolymeric complex.

The use of the complex formed between LAH and Chirald (often called Darvon alcohol in the literature) (**12**) for the reduction of conjugated enones and ynones was first reported by Yamaguchi and Mosher.[18] The mode of preparation of the complex, its age, and the precise experimental conditions of the reduction all appear to have significant impact on the enantioselectivities obtained using this reagent. Thus when 1.5 equiv of a freshly prepared complex of LAH and Chirald (1:2.3) is used to reduce acetophenone at 0 °C, the (*R*)-alcohol is obtained in 68% ee and nearly quantitative yield. If however, the reagent is allowed to stir overnight, or is refluxed in ether prior to the addition of the ketone, the (*S*)-

enantiomer is obtained in 66% ee and 43% yield. Unfortunately, this observed reversal in stereochemical outcome is not predictable. Hence, it may be preferable to use the complex of LAH with the enantiomer of Chirald to reverse the stereoselectivity of the reduction.[19]

A number of alkynic ketones have been reduced with the complex of LAH and (**12**) (1.1:2.5 equiv, ether, -78 °C, 30-60 min) to give the corresponding (*R*)-alcohols (Table 5).[20,21] Johnson and co-workers have reported[22] the reduction of ynone (**17**) to the (*R*)-alcohol in 84% ee and 95% yield with the LAH-Chirald complex. The resulting alcohol was an intermediate in an enantioselective synthesis of 11α-hydroxyprogesterone.[22] The thiophene ketone (**18**) is reduced by the same reagent in ether at -70 °C for 16 h to give the (*R*)-alcohol in 85-88% ee and 80-90% yield.[23] The resulting alcohol has been used in the synthesis of LY248686, an inhibitor of serotonin and norepinephrine uptake carriers.

Table 5 Reduction of Alkynic Ketones with LAH/(-)-**(12)** to give (*R*)-Alcohols

R^1	R^2	Yield (%)	ee (%)
H	C_5H_{11}	96	72
TMS	C_5H_{11}	96	66
C_5H_{11}	C_5H_{11}	97	62

(17)

(18)

A macrocyclic alkynic ketone has been protected as the Co derivative and then reduced with the complex of LAH with (**12**)

(eq 1). Deprotection gave the (*R*)-alcohol (71% ee) which was an important intermediate in a synthesis of (+)-α-2,7,11-cembratriene-4,6-diol.[24]

(1)

In general, structural variations to the backbone of the Chirald ligand have not led to the development of more selective or reliable LAH complexes for use in asymmetric reductions.[25] Other complexes of amino alcohols with LAH have been studied for their ability to achieve enantioselective reduction of prochiral ketones. However, in most cases the selectivities observed have been moderate.[26] The complex of LAH with the amino alcohol (**15**) reduces some enones, such as cyclohexenone and cyclopentenone, to the corresponding (*S*)-alcohols in high optical purities (100% and 82% ee, respectively).[27]

Chiral Amine Modifying Agents.

Some chiral amine additives (Figure 4) have also been studied for their potential to give useful chiral LAH reagents, but the results so far have not been very promising. An exception to this is the complex of LAH with the chiral aminopyrrolidine (**19**) (R = Me), which reduces aromatic ketones in good ee.[28] This reagent reduces acetophenone in 95% ee and 87% chemical yield. LAH complexes of diamine ligands (**20**), analogs of BINAL-H, have also been prepared and examined.[29] In general, the optical purities obtained with this reagent are significantly lower than those observed for BINAL-H in the reduction of aryl ketones.

Lithium Aluminum Hydride-Chromium(III) Chloride[1]

$LiAlH_4$-$CrCl_3$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Chromium(III) Chloride · (MW 37.96) ($CrCl_3$)

[10025-73-7] · Cl_3Cr · Lithium Aluminum Hydride-Chromium(III) Chloride · (MW 158.35)

(reducing agent for reductive dimerization of allylic halides,[2] halide reduction,[2,3] and reductive alkylation of carbonyls[2,4,5])

Physical Data: see ***Lithium Aluminum Hydride***.

Solubility: sol THF, DMF, HMPA.

Form Supplied in: prepared in situ from commercially available compounds.

Preparative Method: by adding lithium aluminum hydride to anhydrous chromium(III) chloride suspended in THF at 0 °C under an argon atmosphere. A small amount of zinc metal helps solubilize the chromium(III) chloride. A 2:1 molar ratio of chromium(III) chloride to lithium aluminum hydride yields the most effective reagent.[2]

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride***. Bottles of the lithium aluminum hydride-chromium(III) chloride reagent should be refrigerated and stored under argon.

Reductive Dimerization of Allylic Halides.

Chromium(II) Chloride is commercially available but expensive and susceptible to oxidation.[6] One method of generating Cr^{II} ions in situ is through reduction of chromium(III) chloride with lithium aluminum hydride. Allylic and benzylic halides are reduced by this reagent to give mainly head-to-head coupling products (eq 1).[2]

Halide Reduction.

gem-Dibromocyclopropanes are reduced by the title reagent to give allenes (eq 2).[2] Propargylic alkynes are also reduced to form allenes. Addition of HMPA favors allene formation over alkyne formation (eq 3).[3] α-Bromo ketones are reduced to ketones (eq 4).[2]

Reductive Alkylation of Carbonyls.

Treatment of aldehydes and ketones with allylic halides in the presence of $LiAlH_4$-$CrCl_3$ gives carbonyl addition products (eq 5). Generally, the more substituted carbon of the allylic halide adds to the carbonyl carbon, affording

homoallylic alcohols.[7] Acetals, esters, and nitriles are not affected by the reagent and aryl, vinyl, and alkyl halides are not reduced. Aldehydes are more reactive than ketones, and 1,2-addition occurs with α,β-unsaturated carbonyls.[2]

Chiral α-substituted aldehydes frequently give low asymmetric induction, but in some cases, chiral allylic halides (eq 6)[8] and chiral aldehydes (eq 7)[9] have given excellent diastereoselectivity.[10]

Intramolecular addition of allylic halides to aldehydes is useful for large ring formation (eq 8).[11]

Treatment of aldehydes and ketones with propargyl bromide and $LiAlH_4$-$CrCl_3$ gives allenic alcohols (eq 9).[5]

(9)

Alkynyl halides have been coupled with aldehydes using $LiAlH_4$-$CrCl_3$. 1,2-Addition predominates with α,β-unsaturated aldehydes but ketones are unaffected (eq 10).[4]

(10)

Aldehydes have been coupled with 2-phenylsulfonyl allylic bromides to give mainly *syn*-homoallylic alcohols (eq 11).[12]

Lithium Aluminum Hydride-Cobalt(II) Chloride

$LiAlH_4$-$CoCl_2$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Cobalt(II) Chloride · (MW 37.96) ($CoCl_2$)

[7646-79-9] · Cl_2Co · Lithium Aluminum Hydride-Cobalt(II) Chloride · (MW 129.83)

(reducing agent for alkenes,[1,2] alkynes,[1,2] halides,[1,3,4] and tosylates;[3] catalyst for the reduction of arenes[5])

Physical Data: see ***Lithium Aluminum Hydride*** and ***Cobalt(II) Chloride***

Solubility: see ***Lithium Aluminum Hydride*** and ***Cobalt(II) Chloride***; reactions using this reagent system typically utilize THF as solvent.

Form Supplied in: formed in situ from widely available reagents.

Preparative Method: the organic substrate (1 equiv) in THF is transferred via syringe into a cold (-40 °C) flask containing dry cobalt(II) chloride (1 equiv for stoichiometric use, 0.1 equiv for catalytic use). To this mixture is slowly added the calculated amount of lithium aluminum hydride (1 equiv) in THF solution, which is accompanied by a color change to black, concomitant with the evolution of gas.[1]

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride*** and ***Cobalt(II) Chloride***.

Reduction of Alkenes and Alkynes.

Reduction of alkenes by lithium aluminum hydride alone has historically proven to be an inefficient manipulation. Addition of $CoCl_2$ to the system dramatically overcomes most obstacles to this process. 1-Octene is reduced by $LiAlH_4$-$CoCl_2$ when using the transition metal chloride in either stoichiometric or catalytic amounts (eq 1).[1] Yields in excess of 90% are not atypical for the reduction of mono-, di-, and trisubstituted carbon-carbon double bonds. Eq 2 is illustrative of the efficiency of this reagent.[2] Benzene is reported to have been fully reduced in 76% yield in the presence of hydrogen.[5]

$$Me(CH_2)_5CH{=}CH_2 \xrightarrow{LiAlH_4,\ CoCl_2} Me(CH_2)_6Me \qquad (1)$$

stoichiometric $CoCl_2$, 100%;
catalytic $CoCl_2$, 98%

(2)

Alkynes may be reduced to alkenes in similar fashion. Terminal alkynes are reduced to the alkene oxidation state without event (eq 3).[1] However, reduction of aryl-substituted or internal alkynes is typically a low yield process.[1,2] Reduction of these π-systems is postulated to proceed through a metal-hydride reducing agent.[2]

(3)

Reduction of Halides and Tosylates.

The title reagent system is perhaps of most use in the reduction of halides and tosylates. Alkyl halides are reduced in high yield irrespective of the halogen (eq 4).[1,3] Furthermore, *n*-octyl tosylate was reduced in quantitative yield using the catalytic variation of this system. Secondary and tertiary bromides are reduced easily when stoichiometric quantities of the transition metal chloride are used (eq 5).[1,3]

(4)

X = I, 100%; Br, 98%; Cl, 98%; F, 100%

(5)

Replacement of bromine by hydrogen in triarylvinyl bromides, with concomitant loss of stereochemical integrity where applicable, has been achieved in high yield.[4] Similarly, phenyl bromide and iodide are reduced to benzene in 74% and 98% yield, respectively, when stoichiometric amounts of $CoCl_2$ are utilized.[3]

The use of ***Nickel(II) Chloride*** as the transition metal chloride provides a reagent that behaves similarly to the cobalt(II) chloride system, often giving higher yields.[3]

Lithium Aluminum Hydride-Copper(I) Iodide

AlH_2I

[58602-50-9] · AlH_2I · Lithium Aluminum Hydride-Copper(I) Iodide · (MW 155.90)

(in situ prepared hydridoaluminum reagent; 1,4-reduction of enones[1,2])

Alternate Name: aluminum hydride iodide.

Physical Data: (.2THF): mp 165-166 °C.[3]

Preparative Methods: an anhydrous THF solution of ***Lithium Aluminum Hydride*** (1 mmol) is added dropwise to a suspension of dry ***Copper(I) Iodide*** (4 or 2 mmol)[1] in THF maintained at 0 °C under an inert atmosphere. A deep black color is immediately produced with hydrogen gas evolution. After stirring for 3-20 min at 0 °C, the substrate (1 mmol) is added and stirring is continued for 15-60 min. The reaction is quenched with water and treated with a saturated aqueous ammonium chloride solution. Ether is added and the organic layer is dried.[4]

Modifications.

An important modification of the method utilizes HMPA as the co-solvent and a reaction temperature of -78 °C. In this case, the reactive agent is thought to be LiHCuI.[2] Copper(I) iodide can be replaced with ***Copper(I) Bromide***,[5-7] ***Copper(I) t-Butoxide***, or ***Mesitylcopper(I)***.[8]

The alane $HAl[N(i\text{-}Pr)_2]_2$ as well as the boron derivative HBI_2 are effective at conjugate reduction of α,β-unsaturated ketones.[9]

Enones.

The reagent prepared in THF at 0 °C is AlH_2I and not CuH or $CuAlH_4$.[1] This reagent reduces α- and β-substituted ketones in high yield (eqs 1-4). The *cis* analog of (**1**) is reduced to (**2**), albeit at a much slower rate. Cyclohexen-2-one is not reduced to cyclohexanone in THF at 0 °C;[4] however, the enone is readily reduced at -78 °C when HMPA is added.[2] This method is used to reduce *trans*-hex-2-enal to hexanal in 63% yield, along with 12% of the 1,2-reduced product.

(1)

(2)

(3)

(4)

The HMPA-THF method was used to reduce α,β-unsaturated ester (**3**),[10] the unsaturated ketone (**4**),[11] and the bicyclic enone (**5**) (eq 5).[12] This method was used for other 1,4-reductions of enones.[13-16] Interestingly, the cyclohexenone (**6**) was reduced by the $LiAlH_4$-CuI-THF method. This reduction required 6 equiv of $LiAlH_4$ and 24 equiv of CuI to produce ketone (**7**) in 40% yield (eq 6). The corresponding triene diols were also isolated.[17]

(3)

(4)

(5)

(5)

60%
plus *cis*-1,2 isomer
10%

(6)

(6)

(7)

Limitation.

Treatment of enone (**8**) with $LiAlH_4$-CuI-THF produced only the alcohol (**9**), whereas the ***Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride*** method produced the desired ketone (**10**) (eq 7).[18]

Alternative Methods.

For a discussion on alternative methods of 1,4-reduction of enones, see ***Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride***.

Lithium Aluminum Hydride-Nickel(II) Chloride[1]

$LiAlH_4$-$NiCl_2$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Nickel(II) Chloride · (MW 37.96) ($NiCl_2$)

[7718-54-9] · Cl_2Ni · Lithium Aluminum Hydride-Nickel(II) Chloride · (MW 129.59)

(reducing agent for alkenes, alkynes,[2,3] and organic halides;[2,4] can effect N-O bond cleavage and open epoxides.[5])

Physical Data: see ***Lithium Aluminum Hydride*** and ***Nickel(II) Chloride***.

Solubility: see ***Lithium Aluminum Hydride*** and ***Nickel(II) Chloride***; reactions using the mixture are run in THF.

Form Supplied in: prepared in situ from commercially available components.

Preparative Method: nickel(II) chloride (1 equiv for stoichiometric reactions and 0.1 equiv for catalytic reactions) is placed in the reaction vessel at -40 °C and the organic substrate (1 equiv) in THF is added using a syringe. Lithium aluminum hydride (1 equiv) in THF is added slowly, resulting in a black color and gas evolution.

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride*** and ***Nickel(II) Chloride***.

Halide Reductions.

Reductions of organic halides using lithium aluminum hydride and nickel(II) chloride are more efficient than reductions using lithium aluminum hydride alone.[2,4] This mixed reagent converts primary chlorides, bromides, iodides, and tosylates into the corresponding alkanes in near quantitative yields using only a catalytic amount of the nickel species (eq 1). High yields are also realized using stoichiometric amounts of metal halide in the reduction of secondary, tertiary, and aryl chlorides, bromides, and iodides (eqs 2 and 3). These reductions may also be carried out with similar results using ***Iron(II) Chloride***, ***Cobalt(II) Chloride***, or ***Titanium(III) Chloride*** as the metal halide.

$$Me(CH_2)_7I \xrightarrow[NiCl_2]{LiAlH_4} Me(CH_2)_6Me \qquad (1)$$

98%, cat $NiCl_2$

(2)

100%, stoich. $NiCl_2$

(3)

87%, cat. $NiCl_2$
100%, stoich. $NiCl_2$

Furthermore, triarylvinyl halides can be reduced to the corresponding hydrocarbons using $LiAlH_4$-$NiCl_2$ at temperatures below 0 °C (eq 4).[6]

$$Ph_2C{=}C(Br)Ph \xrightarrow[95\%]{} Ph_2C{=}C(H)Ph \qquad (4)$$

The strong reducing nature of this reagent has limited its use in synthesis, as many other functional groups do not survive the conditions. For example, esters are reduced faster than tertiary halides (eq 7).[7]

(5)

Reduction of Carbon-Carbon Double and Triple Bonds.

The admixture of lithium aluminum hydride-nickel(II) chloride has been used to efficiently reduce alkenes to the corresponding alkanes and to effect the partial reduction of an alkyne to an alkene.[2,3] Such transformations require only catalytic amounts of the nickel species for monosubstituted alkenes or alkynes, but higher orders of substitution require stoichiometric amounts of nickel(II) chloride (eqs 6-8). Cobalt(II) chloride works equally well when used as the metal halide species for these reductions.

(6)

(7)

(8)

This mixed reagent has been used to reduce alkenes in the presence of ethers and acetals (eq 9),[8] but fails to selectively reduce triple bonds in the presence of esters.[9]

(9)

Cleavage of N-O Bonds and Epoxide Opening.

Amino alcohols have been prepared in high yield from isoxazolidines with $LiAlH_4$-$NiCl_2$ (eq 10). This mixed reagent

has also been used to open epoxides to alcohols.[5] This admixture reacts with styrene oxide to yield β-phenylethanol (eq 11). In contrast, use of lithium aluminum hydride alone gives α-phenylethanol.

(10)

(11)

Reduction of an N-O bond with lithium aluminum hydride-nickel(II) chloride has been used in an approach to anatoxin *a* (eq 12).[5] Initial N-O bond cleavage gives an epoxide which is opened by the reducing agent to give an alcohol.

Lithium Aluminum Hydride-Titanium(IV) Chloride[1]

$LiAlH_4$-$TiCl_4$

($LiAlH_4$)

[16853-85-3] · AlH_4Li · Lithium Aluminum Hydride-Titanium(IV) Chloride · (MW 37.96) ($TiCl_4$)

[7550-45-0] · Cl_4Ti · Lithium Aluminum Hydride-Titanium(IV) Chloride · (MW 189.68)

(generation of dihalocarbenes;[2,3] hydrogenolysis of allylic alcohols;[4] deoxygenation of oxygen-bridged compounds[9,10] and *N*-oxides;[12] preparation of alkenes;[15] reducing agent for sulfoxides,[17] alkenes, alkynes,[18] and 3-amido ketones;[20] catalyst for hydroaluminations of alkenes and alkynes[22])

Physical Data: see ***Lithium Aluminum Hydride*** and ***Titanium(IV) Chloride***.

Solubility: see ***Lithium Aluminum Hydride*** and ***Titanium(IV) Chloride***; reactions using the mixture are run in anhydrous THF or diethyl ether.

Form Supplied in: for most applications, the reagent is prepared in situ from commercially available components.

Preparative Method: for applications involving the initial formation of low-valent titanium, lithium aluminum hydride (1 equiv) is added under nitrogen to a cooled (0 °C) solution of titanium(IV) chloride (1 equiv) in anhydrous THF, resulting in a black suspension with gas evolution.[13] The molar ratio of $LiAlH_4$ and $TiCl_4$ can vary and the addition of various organic tertiary amine bases following the addition of $LiAlH_4$ is also common.

Handling, Storage, and Precautions: see ***Lithium Aluminum Hydride*** and ***Titanium(IV) Chloride***. Use in a fume hood.

Generation of Dihalocarbenes.

Carbon tetrachloride reacts with $LiAlH_4$-$TiCl_4$ in the presence of alkenes to provide *gem*-dichlorocyclopropanes (eq 1).[2] The reaction conditions are slightly acidic, in contrast to other methods that require strongly basic conditions. 1-Chloro-1-fluorocyclopropanes can be prepared in good yields using $CFCl_3$ and low-valent titanium (eq 2).[3] Other methods of generating chlorofluorocarbene in the presences of alkenes give lower yields.

(1)

(2)

Deoxygenations.

Secondary allylic alcohols react with $LiAlH_4$-***Aluminum Chloride*** and $LiAlH_4$-$TiCl_4$ in a similar fashion to provide hydrogenolysis products in fair yields.[4] However, upon reaction with $LiAlH_4$-$AlCl_3$, tertiary allylic alcohols undergo dehydration whereas $LiAlH_4$-$TiCl_4$ gives the expected hydrogenolysis product (eq 3). In some cases, double bond migration occurs via a reductive S_N2' reaction. In a related reaction, reductive demethoxylation of allyl methyl ethers using low-valent titanium is accompanied by double bond migration, providing predominantly the (*Z*)-alkene from either the (*E*)- or (*Z*)-allyl ethers (eq 4).[5]

(3)

(4)

Photooxygenation of (-)-β-pinene followed by reduction of the resulting peroxide to the corresponding alcohol and then treatment with low-valent titanium provides a simple route to (-)-α-pinene via hydrogenolysis of the allylic alcohol (eq 5).[6] The peroxide also provides (-)-α-pinene upon treatment with low-valent titanium.

(5)

Alkenes can be prepared from epoxides with low-valent titanium generated from ***Titanium(III) Chloride*** and $LiAlH_4$.[7] The same reduction with $TiCl_4$ in the presence of ***Triethylamine*** has been used to prepare a key intermediate in the synthesis of *trans*-γ-irone (eq 6).[8]

(6)

Low-valent titanium has been used to deoxygenate furan cycloadducts in the preparation of arenes (eq 7).[9] Substituted furan adducts provide substituted benzenes with $LiAlH_4$-$TiCl_4$ in the presence of triethylamine, while in the absence of triethylamine, 1,3-cyclohexadienes are obtained (eq 8).[10]

A third pathway involves the presence of small amounts of triethylamine and results in reduction of the enedicarboxylate portion of the molecule without deoxygenation (eq 9).[11] Isolated double bonds are not reduced using low-valent titanium, but $LiAlH_4$-$TiCl_4$ does reduce diethyl maleate to diethyl succinate in 59% yield.

Aromatic *N*-oxides, typically resistant to deoxygenation, can be reduced under mild conditions using low-valent titanium.[12] These conditions have been used to reduce heteroaromatic *N*-oxides with labile halogen atoms *ortho* and *para* to the ring nitrogen (eq 10).[13] These compounds do not undergo dehalogenation, but it has been reported that 1-chloronaphthalene is reduced to naphthalene in 83% yield under similar conditions.[14]

(10)

Reductive Couplings.

Upon treatment with low-valent titanium in the presence of tertiary amines, carbonyl compounds undergo reductive dimerization in high yields to produce symmetrical alkenes (eq 11).[15] Acetals of aromatic aldehydes and ketones couple to provide pinacol ethers or alkenes in high yields (eq 12), while dialkyl acetals derived from aliphatic aldehydes and ketones provide ethers as a result of reductive dealkoxylation (eq 13).[16]

(11)

(12)

(13)

Miscellaneous Reductions.

Lithium aluminum hydride/titanium(IV) chloride provides a mild method for the reduction of sulfoxides to the corresponding sulfides (eq 14).[17] Yields are generally higher than when $LiAlH_4$ is used alone and reductions are complete within 2 h at or below room temperature. Complex formation between the metal ion and the sulfinyl oxygen has been invoked to explain the effect that $TiCl_4$ has in facilitating this reduction.

(14)

Sulfides are reduced to the corresponding hydrocarbons in good yield with $TiCl_4$-$LiAlH_4$ in THF at reflux.[14] Terminal alkenes and alkynes are reduced to the corresponding alkanes in good yields using equamolar quantities of $LiAlH_4$ and $TiCl_4$.[18] Disubstituted double bonds are only partially reduced, while internal alkynes give predominately the *cis*-alkene in good yield.

Stereoselective Reductions.

Reduction of 1,3-dicarbonyl compounds with lithium aluminum hydride in the presence of chelating agents such as $TiCl_4$ provides 1,3-diols with good diastereoselectivity (eq 15).[19] Cyclic models have been used to explain the course of reductions (eq 16). It has been suggested that the major isomer is formed via addition of hydride to both carbonyls from the least hindered side.

(15)

Chelation control with $TiCl_4$ has been applied to the stereoselective synthesis of 1,3-amino alcohols from *anti*-3-amido ketones (eq 17).[20,21] Again the stereochemical results are explained by a rigid cyclic transition state.

Hydroaluminations.

Titanium(IV) chloride catalyzes the addition of lithium aluminum hydride to alkenes to provide the corresponding organoaluminates in high yields under mild conditions.[22] The relative rates of reaction decrease with increased substitution on the alkene, and with nonconjugated alkenes, $LiAlH_4$ selectively adds to the least hindered double bond. Organoaluminates provide a convenient route to primary acetates,[23] alkyl halides (eq 18),[22,24] and alcohols,[22] terminal allenes[25] and alkynes,[26] alkanes,[22] and trialkenylboranes.[27] Coupling reactions between organoaluminates and allylic halides can be accomplished in the presence of copper(I) salts.[28]

(18)

Methylenation of Carbonyl Compounds.

β-Elimination of 2-(phenylthio)ethanols, prepared via reaction of ketones with phenylthiomethyllithium, occurs with $TiCl_4/LiAlH_4$ in the presence of a tertiary amine to provide the terminal alkene in high yield.[29]

Related Reagents.

Titanium(III) Chloride-Lithium Aluminum Hydride.

Lithium Amide[1]

$LiNH_2$

[7782-89-0] · H_2LiN · Lithium Amide · (MW 22.97)

(strong base; used in *N*-alkylation of aromatic amines,[5,6] Claisen condensations,[7] α-alkylations of carbonyl compounds,[13] eliminations[21] and isomerizations,[26] synthesis of ethynyl compounds[16] and alkynyl carbinols[30])

Physical Data: mp 380-400 °C; *d* 1.178 g cm^{-3}.

Solubility: sl sol liq NH_3, ethanol; insol ether, benzene, toluene.

Form Supplied in: gray-white powder; widely available.

Analysis of Reagent Purity: several titration procedures are available.[2]

Preparative Method: in a typical procedure[3] for the preparation of lithium amide in ammonia, a small piece of ***Lithium*** metal is added to commercial anhyd liquid NH_3 with stirring; after the almost immediate appearance of a blue color, a few crystals of iron(III) nitrate are added, followed by small portions of lithium metal; after about 20 min the blue color disappears and a gray suspension of lithium amide is formed.

Handling, Storage, and Precautions: the dry solid is flammable, air- and moisture-sensitive, and must be stored in tightly stoppered bottles; in water, it decomposes slowly when in lumps, faster in smaller particle sizes; like other alkali metal amides, the reagent must be guarded against air oxidation to prevent the formation of potentially explosive substances;[4] samples which develop a yellow or green or darker color should be properly disposed of; if left open for minimal periods during weighing, the titer remains fairly constant; contact with skin causes burns; use in a fume hood.

N-Alkylation of Amines.

Lithium amide has been employed as a powerful base in the *N*-alkylation of heterocyclic aromatic amines.[5] A variety of *N*-substituted 2-aminopyridines, 2-aminopyrimidines, and 2-aminolepidines have been prepared by treating the respective amine with 2 equiv $LiNH_2$ and the alkyl halide (eq 1).[6] Lithium amide is more easily handled than ***Sodium Amide*** and is therefore the reagent of choice in these reactions.

(1)

Condensations of Esters with Carbonyl Compounds.

Hauser and Puterbaugh found $LiNH_2$ superior to sodium amide in condensations of *t*-butyl acetate with ketones (eq 2).[7] Condensations with acetophenone, *p*-nitrocaprophenone, benzaldehyde, acetone, and cyclohexanone proceeded in good yields (53-76%).

(2)

This condensation method is a useful alternative to the Reformatsky reaction, and in certain cases compares favorably in terms of yields and practicality. Later studies simulated a Reformatsky-type reaction employing *t*-butyl acetate instead of an α-halo ester.[8] It was found that this type of aldol condensation may be effected more conveniently and in higher yields by means of $LiNH_2$, and that the use of ***Zinc Chloride*** was unnecessary in this case. Use of $NaNH_2$ under similar conditions failed to give β-hydroxy esters. Hauser and Lindsay further reported[9] that when ethyl acetate was employed instead of *t*-butyl acetate, self-condensation of the ester could be circumvented by using 2 equiv $LiNH_2$. Under these conditions, even benzophenone could be condensed with ethyl acetate. It is suggested that the extra equivalent of $LiNH_2$ coordinates with the monolithio salt of ethyl acetate, as in (**1**), or in a dimer or trimer. Some sort of coordination is indicated, since an extra equivalent of $LiNH_2$ retards the self-condensation of EtOAc; $NaNH_2$, which should coordinate to a smaller degree, fails to exhibit such a retarding effect under similar conditions.[3,10]

(1)

Ethyl 3-alkoxy-2-butenoates have been condensed with aldehydes in the presence of $LiNH_2$ at the γ-position to give dihydropyrones which, under the basic conditions employed, give rise to 3-alkoxy-*cis*-2-*trans*-4-unsaturated acids (eq 3).[11]

(3)

Along similar lines, enol silyl ethers are alkylated in high yields with lithium amide and alkyl halides.[12] When alkylation of (**2**) is attempted with ***Methyllithium*** and 3-bromopropionitrile, E2 elimination predominates, yielding polyacrylonitrile and cyclohexanone; the same reaction using $LiNH_2$ instead results in a 48% yield of the alkylated product (eq 4).

(4)

Alkylation of *t*-Butyl Esters with Organic Halides.

The direct alkylation of *t*-butyl acetate is a valuable alternative to the malonic ester method for preparing mono- and dibasic carboxylic acids. Monoalkylation is observed with various alkyl or alkenyl halides in very good yields using $LiNH_2$ (eqs 5 and 6);[13] in contrast, $NaNH_2$ gives rise to dialkylated products under the same conditions. *t*-Butyl propionate and *n*-butyrate have also been alkylated in excellent yields using $LiNH_2$. With 1,4-dibromobutane, suberic acid was obtained in quantitative yield after saponification. 1,2-Dibromoethane gave succinic acid in moderate yield,

whereas use of $NaNH_2$ in the latter case did not provide any product.

(5)

(6)

Treatment of *t*-butyl acetate with $LiNH_2$ and 1,4-dibromo-2-butene gave the diester of 4-octenedioic acid (eq 7). α,β-Unsaturated esters furnished α-mono- and α,α-dialkylation products with $LiNH_2$ (eq 8); no γ-alkylated products were formed in these reactions.[14]

(7)

(8)

Alkylation and Condensation of Substituted Succinic Acid Derivatives.

Both monoester isomers of 2-alkyl- or arylsuccinic acids were alkylated exclusively on the carbon adjacent to the ester function (see **3**) using 2 equiv $LiNH_2$.[15] In contrast, the anion obtained from diethyl 2-methylsuccinate gave on methylation a mixture of alkylated esters, including the diesters of 2,2-dimethylsuccinic and 2,3-dimethylsuccinic acids.

(3) (4) (5)

Condensation of monoester dianions with ketones or benzaldehyde similarly took place at the carbon α to the ester group, but only when the methylene group was not substituted (i.e. **4**). Condensation products were not obtained from the isomer (**3**).

Reactions with Alkyne Derivatives.

Alkynes carrying functional groups such as NHR or OH can be alkylated in high yields in the presence of lithium amide (eqs 9 and 10).[16-20] 1-Alkyn-o-ols are alkylated by primary or secondary alkyl halides in 50-80% yields, and it is not necessary to protect the alcohols.

(9)

(10)

Eliminations and Isomerizations.

$LiNH_2$ has been found superior to sodium amide in dehydrohalogenations of γ-methallyl chloride and α-methallyl chloride to give 3-methylcyclopropene and 1-methylcyclopropene, respectively (eqs 11 and 12).[21-23] ***Potassium Amide***, on the other hand, isomerizes the α-isomer to methylenecyclopropane.[24]

(11)

(12)

In the dimerization of cyclopropene in the presence of alkali amides (eq 13), two opposing factors influence the course of the reaction.[25] On the one hand, the rate of cyclopropenylcyclopropane formation is retarded in the presence of stronger base (KNH_2) due to lower concentrations of unmetalated cyclopropene. On the other hand, increasing base strength favors the equilibrium between (**6**) and (**7**) in favor of (**7**), thus securing a greater yield of bicyclopropylidene (**8**). The best yields of (**8**) were obtained using $LiNH_2$ in liquid NH_3, albeit with much longer reaction times (4 weeks at -50 °C) than with $NaNH_2$.

(13)

The propargyl sulfides (**9**) and (**10**) have been isomerized in good yields to the corresponding allenes with $LiNH_2$ in liquid NH_3 (eqs 14 and 15).[26-28]

(14)

(15)

Chiral propargyl alcohols can be prepared[29] from allylic alcohols by Sharpless asymmetric epoxidation,[30] conversion of the alcohol product into the corresponding chloride, and treatment with $LiNH_2$ in liquid NH_3 (eq 16). Use of ***Lithium Diisopropylamide*** (LDA) gives comparable yields. The same reaction with ***n-Butyllithium*** in THF at -33 °C

results in mixtures of the chlorovinyl alcohol, propargyl alcohol, and starting material. It appears that *n*-BuLi reacts indiscriminately with both the epoxy chloride and the chlorovinyl alcohol formed during the reaction.

(16)

2-Chloromethyltetrahydrofuran undergoes ring opening followed by dehydrochlorination with 3 equiv of $LiNH_2$.[31] The lithio acetylide (**11**) formed in situ can be alkylated to give 4-alkynyl alcohols (eq 17).

(17)

This reaction has been employed in the synthesis of chiral alkynyl compounds from simple carbohydrate precursors (eq 18).[32] The elimination reaction here is chemoselective, since the other isopropylidene group in the substrate remains unaffected.

(18)

Related Reagents.

Lithium *N*-Benzyltrimethylsilylamide

$LiN(SiMe_3)CH_2Ph$

[113709-50-5] · $C_{10}H_{16}LiNSi$ · Lithium *N*-Benzyltrimethylsilylamide · (MW 185.31)

(less-basic lithium amide capable of regioselective conjugate addition to α,β-unsaturated esters;[1] amide cuprates have increased selectivity and reactivity toward enoates[2])

Alternate Name: LSA.

Solubility: sol THF.

Preparative Method: to a solution of freshly distilled *N*-benzyltrimethylsilylamine (0.2 mL, 1.0 mmol)[3] in THF at -78 °C is slowly added a solution of ***n-Butyllithium*** (0.61 mL, 1.64 M in hexane, 1.0 mmol) under Ar; a pale yellow solution of lithium *N*-benzyltrimethylsilylamide in THF is obtained after stirring for several min at -78 °C.[1]

Handling, Storage, and Precautions: is moisture- and air-sensitive, and should thus be handled under inert atmosphere; prepare just prior to use; use in a fume hood.

Conjugate Additions.

Lithium dialkylamides (e.g. ***Lithium Diisopropylamide***, LDA) with weak nucleophilicity are commonly used as strong bases for deprotonation. However, lithium *N*-benzyltrimethylsilylamide acts as a nucleophile with a basicity weaker than LDA. For example, the reaction of LSA with (*E*)-crotonates affords the conjugate adducts, β-amino esters, in high yields without formation of 1,2-adducts (amides) or products arising from deprotonation at the γ-position of the enoates (eq 1).[1] On the other hand, the reaction of LDA with (*E*)-methyl crotonate gives a mixture of the conjugate adduct and deprotonation product (eq 2).[1,4] The reaction of lithium benzylamide gives the 1,2-adduct as a major product. The (*E*) geometry of α,β-unsaturated esters is essential for conjugate addition, since the treatment of (*Z*)-methyl 2-decenoate with LSA gives the deconjugated ester, methyl 3-decenoate, in high yield.[5] Since the N-Si bond is cleaved easily under weak acidic conditions, purification of the conjugate adduct (see eq 1) by silica gel column chromatography provides desilylated benzylamino esters.

(1)

(2)

The conjugate addition of LSA to methyl crotonate followed by trapping of the resulting enolate with ***Chlorotrimethylsilane*** affords the (*Z*)-ketene silyl acetal nearly exclusively (*Z*:*E* = 99:1) (eq 3). On the other hand, if the conjugate addition reaction is quenched with methanol, deprotonation of the resulting β-amino ester with LDA followed by treatment with Me_3SiCl gives the (*E*)-ketene silyl acetal with very high stereoselectivity (*Z*:*E* = 2:98) (eq 4). Accordingly, the stereodivergent synthesis of (*Z*)- or (*E*)-enolates of β-amino esters is achieved via the direct conjugate addition of LSA or the two-step procedure, respectively.[6]

(3)

(4)

The conjugate addition of LSA to enoates followed by trapping with alkyl halides gives α-alkyl-β-amino esters, which are converted to α-alkylated α,β-unsaturated esters upon deamination with silica gel.[1] The reaction of the

enolates with aldehydes produces β-amino-β´-hydroxy esters, which are converted to β-lactams having a 1-hydroxyalkyl group at the C-3 position (eq 5). Thus the β-lactam skeleton is prepared stereoselectively and expeditiously via a three-component coupling reaction.[6] The amide cuprate reagents, prepared from 2 equiv LSA and ***Copper(I) Cyanide***, react effectively with α,β,γ,δ-unsaturated esters to give the corresponding β-amino esters. Based upon this procedure, asymmetric syntheses of β-lactams have been accomplished (eq 6).[2]

The reaction of LSA with o-halo-α,β-unsaturated esters produces cyclization products.[5] In the case of α,β,χ,ψ-unsaturated dioic acid esters, tandem conjugate additions occur stereoselectively; this cyclization strategy has been applied to the synthesis of racemic cyclopentane monoterpenes.[5]

Lithium Bis(3,3-diethoxy-1-propen-2-yl)cuprate

[58384-87-5] · $C_{14}H_{26}CuLiO_4$ · Lithium Bis(3,3-diethoxy-1-propen-2-yl)cuprate · (MW 328.85)

(organocopper reagent for the transfer of a protected acrolein group to allyl halides, vinyl epoxides, and carbonyl compounds; reagent for the construction of α-methylene-γ-butyrolactones)

Physical Data: thermally unstable organocuprate generated between -60 and -70 °C; stable and reactive at temperatures below -40 °C.

Solubility: sol THF at -40 °C or below.

Preparative Method: from the reaction of ***2-Lithio-3,3-diethoxy-1-propene***[2] with Me_2S complex of ***Copper(I) Bromide*** at -60 to -70 °C in THF.

Handling, Storage, and Precautions: should be generated in the absence of O_2 and moisture at low temperatures under an N_2 or Ar atmosphere.

Conjugate Additions to Enones.

The generation of the title reagent (**1**)[1] is straightforward at -70 °C (eq 1). In addition to the homocuprate (**1**) a mixed cuprate containing a *t*-butyl-alkynyl ligand may also be prepared at -40 °C.[1]

This cuprate (**1**) is the one organometallic reagent in the highest oxidation state capable of adding an acrolein and hence

an acrylate unit in a conjugate addition to enones. In a typical example, (**1**) adds 1,4 to carvone at -70 °C to produce the adduct (**2**) (eq 2). Hydrolysis of (**2**) and mild oxidation with ***Silver(I) Oxide*** produces the acrylic acid (**3**) (eq 3).[1]

In a total synthesis of (+)-hanegokedial, a modified version of reagent (**1**) was added in a 1,4-manner to the cycloheptenone (**4**) to prepare a 2:1 mixture of stereoisomers of adduct (**5**) in 84% yield. In this example the copper enolate intermediate was trapped with gaseous ***Formaldehyde*** (eq 4).[3]

Additions to Cyclic Allylic Halides.

The direct alkylation of 3-bromocycloheptene with (**1**) produces the adduct (**6**) in 60% yield at -40 °C. The adduct (**6**) was a convenient precursor to an acrylic acid (**7**) and iodolactone (**8**) (eq 5).[4]

While the title reagent reacted well with allylic halides, it did not react with allylic acetates. All attempts to open simple epoxides with (**1**) also failed at various temperatures below 0 °C.[4]

Additions to Cyclic Vinyl Epoxides.

Reactions of the cuprate (**1**) with monoepoxides of cyclic 1,3-dienes yielded mixtures of 1,2 and 1,4 ring-opened products, with the former as the major products.[5] The ratio of 1,2 to 1,4 products varied slightly depending on whether THF or ether was used as a reaction solvent. In the case of cyclopentadiene monoepoxide in THF, the yield of adducts was 87% with a 1,2:1,4 ratio of 7:3 (eq 6).

(6)

The best regioselectivity found for an epoxide opening was for the cycloheptadiene monoepoxide system which produced a 1,2:1,4 ratio of 3:1 in THF and 6:1 in diethyl ether (eq 7).

(7)

The 1,2-adduct (**9**) could be transformed into a *trans*-α-methylenebutyrolactone (**11**) or a *cis*-α-methylenebutyrolactone (**12**) (eq 8).[5]

Related Reagents.

3,3-Diethoxy-1-propen-2-ylcopper; ***Lithium (3,3-Diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate***.

Lithium Bis(*N,N*-diethylcarbamoyl)cuprate

$(Et_2NCO)_2CuLi$

[71435-48-8] · $C_{10}H_{20}CuLiN_2O_2$ · Lithium Bis(*N,N*-diethylcarbamoyl)cuprate · (MW 270.76)

(carbamoylation of organic halides[1,2])

Alternate Name: lithium bis[(diethylamino)carbonyl]cuprate.

Solubility: sol THF, HMPA.

Preparative Method: prepared in situ under N_2; an equimolar reaction of ***Copper(I) Chloride*** and ***Lithium Diethylamide*** in a mixed solvent of THF and HMPA (4:1) at -20 °C produced a precipitate of $CuNEt_2$, which was dissolved by an additional 1 equiv of $LiNEt_2$; 2 equiv ***Carbon Monoxide*** were absorbed by this homogeneous solution under ambient conditions; the resulting solution was used in the carbamoylation directly.[1]

Handling, Storage, and Precautions: stable below 80 °C, decomposes partly at 100 °C; air- and moisture-sensitive; handle in a fume hood under inert gas (Ar or N_2);[1] the hazards of HMPA and CO are well-documented.[3]

Carbamoylation.

Various organic halides can be carbamoylated by this reagent. The active allyl halide gave a 45% yield of *N,N*-diethyl-3-butenamide (based on $LiNEt_2$), with concomitant evolution of CO nearly equivalent to copper; the yield was 76% under a CO pressure of 50 kg cm^{-2}. Reaction with acid bromides took place smoothly under mild conditions to produce α-keto amides, but for some less reactive chlorides a higher reaction temperature was required.[1] This reaction with acid halides provides an effective method of preparing α-ketoamides (eq 1); several other reagents utilized for direct carbamoylation did not give this functionality.[4,5] Lithium *N,N*-dimethylcarbamoylnickel carbonylate,[5f] which is effective for the carbamoylation of vinylic and aromatic halides, reacted with acid halides to produce the corresponding amides instead of α-ketoamides. *N,N*-Diisopropylcarbamoyllithium[5c,5e] and *N,N*-dimethylcarbamoyllithium react with aldehydes and ketones readily, but their reaction with acid halides has not been reported.

(1)

R = Me, $H_2C{=}CHCH_2$, MeCO
X = Br, Cl

Under palladium catalysis, the carbamoylation of iodobenzene was optimized.[2] A related reagent, ***Lithium Bis(N-methyl-N-phenylcarbamoyl)cuprate***, reacts with iodobenzene with relatively higher yield under the same catalysis conditions (eq 2).

(2)

The title reagent undergoes conjugate addition with methyl vinyl ketone to give *N*,*N*-diethyllevulinamide in 78% isolated yield, but reaction with cyclohexenone was not successful (eq 3).[1]

(3)

Conversion to Oxamide and Carbamate Derivatives.

Under suitable conditions, lithium bis(*N*,*N*-diethylcarbamoyl)cuprate can be converted to the corresponding oxamide, oxamic acid, and carbamate (eqs 4-6).[2]

Lithium Bis[dimethyl(phenyl)silyl]cuprate[1]

$(PhMe_2Si)_2CuLi$

[75583-57-2] · $C_{16}H_{22}CuLiSi_2$ · Lithium Bis[dimethyl(phenyl)silyl]cuprate · (MW 341.01)

(dimethyl(phenyl)silyl nucleophile for making Si-C bonds by reaction with α,β-unsaturated carbonyl compounds, alkynes, allenes, and allylic acetates)

Physical Data: typically a 0.6M, dark, reddish-brown solution in THF.

Analysis of Reagent Purity: the silyllithium solution can be double-titrated for active reagent using ***Allyl Bromide***, but the cuprate is usually used without further checks; NMR (of the cuprate made with CuCN in THF-d_8): ^{1}H δ 0.09; ^{13}C δ 5.1; ^{29}Si δ -24.4; ^{7}Li δ -3.33.[2]

Preparative Methods: the silyl cuprate is prepared[1] from the corresponding silyllithium reagent (***Dimethylphenylsilyllithium***); commercially available ***Chlorodimethylphenylsilane*** is stirred with ***Lithium*** shot, wire, or powder under Ar or N_2 in THF at 0 °C for 4-12 h; the silyllithium solution may also be prepared, free of halide ion, by cleaving tetramethyldiphenyldisilane with lithium and ultrasound irradiation;[2] the silyllithium solution (2 equiv), after assay, is transferred by syringe on to anhyd ***Copper(I) Iodide***, ***Copper(I) Bromide***, or ***Copper(I) Cyanide*** (1 equiv), kept under argon or nitrogen at 0 °C, stirred at this temperature for 20 min, and then used immediately.

Handling, Storage, and Precautions: must be kept free of O_2 and H_2O; while somewhat more stable thermally than alkyl cuprates, surviving for a few hours at 0 °C, it is best used immediately after its preparation; the copper salts, and especially copper(I) cyanide, are toxic; the solutions should therefore be handled in a fume hood wearing impermeable gloves, and the aqueous washings disposed of appropriately, immediately after use.

Introduction.

Because dimethyl(phenyl)silyllithium is much easier to prepare than ***Trimethylsilyllithium***, the most commonly used silyl cuprate reagent is derived from this silyl group. The reagent can be prepared using CuI, $CuBr.SMe_2$, or CuCN. The three reagents appear to be very similar in their reactivity, except for the higher regioselectivity of the cyanide-derived reagent with terminal alkynes. The dimethyl(phenyl)silyl group in products like allyl- and vinylsilanes appears to impart very similar reactivity to that imparted by the trimethylsilyl group, and it has an advantage over the trimethylsilyl group in that the presence of the phenyl group allows the dimethyl(phenyl)silyl group to be converted into a hydroxyl group with retention of configuration at carbon (eq 1). This transformation requires first a reaction with an electrophile, such as a proton,[3] bromine, or the mercury(II) cation,[4] to remove the phenyl ring and place a

nucleofugal group X on the silicon atom. This step is followed by treatment either with peracid or with ***Hydrogen Peroxide*** and a base. The two steps may be combined in one pot;[4] bromine itself does not have to be used, since the ***Peracetic Acid*** oxidizes bromide ion to bromine in situ.

(1)

This capacity of the dimethyl(phenyl)silyl group cannot be drawn upon, however, when there is a C=C double bond in the molecule; no matter which electrophile is used, it attacks the double bond more rapidly than it removes the phenyl ring from the silyl group. This limitation has been overcome using the corresponding diethylamino(diphenyl)silyl-[5] and 2-methylbut-2-enyl(diphenyl)silylcuprate[6] reagents.

A mixed cuprate, [dimethyl(phenyl)silyl]methyl(or-butyl)cuprate,[7] containing one silyl and one alkyl group, has some advantages. Only the silyl group is transferred to the substrate, and hence only one silyl group is needed, and the byproduct of the silyl-cupration step, methane or butane, is volatile. Yields in silyl-cupration reactions carried out with only 1:1 stoichiometry are apt not to be quite so good, however. Other silyl copper reagents and cuprates with more specific or limited applications are (*t*-butyldimethylsilyl)butylcuprate,[8] triphenylsilylcopper,[9] the bis(*t*-butyldiphenylsilyl)cuprate,[10] and the bis[tris(trimethylsilyl)silyl]cuprate.[11]

Reaction with α,β-Unsaturated Carbonyl Compounds.

Although silyllithium reagents add kinetically at the β-position of α,β-unsaturated ketones,[12] the reactions are better with the cuprate when the enone is hindered.[13] The cuprate, unlike the lithium reagent, also reacts with α,β-unsaturated aldehydes, esters (eq 2), amides, and nitriles[13] and with vinyl sulfoxides.[14] With esters, the intermediate enolates, which have the (*E*) geometry (**1**), may be used directly in highly stereoselective reactions with alkyl halides and aldehydes.[15,16] The β-hydroxy esters, such as (**2**), can be used in the synthesis of allylsilanes.[17]

(2)

α,β-Unsaturated carbonyl compounds attached to a homochiral auxiliary, such as Koga's lactam or Oppolzer's sultam, give products with a stereogenic center carrying a silyl group having high levels of enantiomeric purity.[18,19]

Reaction with Alkynes.

The silyl cuprate reacts with alkynes by *syn* stereospecific metallo-metallation (eq 3). Provided that the cuprate is derived from copper cyanide, the regioselectivity with terminal alkynes is highly in favor of the isomer with the silyl group on the terminus. The intermediate vinyl cuprate (**3**) reacts with many substrates, familiar in carbon-based cuprate chemistry, to give overall *syn* addition of a silyl group and an electrophile to the alkyne.[20] A curious feature of this reaction is that the intermediate (**3**), although uncharacterized, has the stoichiometry of a mixed silicon-carbon cuprate, and yet it transfers the carbon-based group to most substrates, in contrast to the behavior of mixed silyl alkyl cuprates.

Disubstituted alkynes also react, and, if the two substituents are well differentiated sterically, as with a methyl group on one side and a branched chain on the other, the regioselectivity is highly in favor of the silyl group appearing at the less hindered end.

Reaction with Allenes.

Allenes react with the silyl cuprate at low temperature. The regiochemistry with allene itself places the silyl group on the central carbon atom and the added electrophile at the terminus (eq 4).[21] One surprising exception to this rule is with iodine as the electrophile, when the product (**5**) has the opposite regiochemistry even from that of the reaction with chlorine. Since the iodide (**5**) can be converted into a lithium reagent [and a cuprate that is not identical with (**4**)], it is possible to achieve overall either regiochemistry in additions to allene. Monosubstituted allenes give mixtures of regioisomers,[21,22] and disubstituted and trisubstituted allenes give largely allylsilanes whatever electrophile is used. The metallo-metallation step is stereospecifically *syn*.[23]

Reaction with Allylic Acetates.

Silyl cuprates react with allylic acetates to give allylsilanes directly (eqs 5-7). Allylic acetates that are secondary at both ends are apt to give both regioisomers. Some control of the regiochemistry is possible, however, by using a *cis* double bond; this encourages reaction with allylic shift, especially when the silyl group is delivered to the less-hindered end of the allylic system (eq 5).[24] An alternative protocol, assembling a mixed silyl cuprate on a carbamate group, is even better in controlling the regioselectivity, usually giving complete allylic shift (eq 6).[24,25] Tertiary acetates, on the other hand, are very well behaved regiochemically, giving only the product with the silyl group at the less-substituted end of the allylic system (eq 7).[25,26] Allylsilanes have many uses as carbon nucleophiles in organic synthesis.[27]

The acetate reaction (eq 5) and the carbamate alternative (eq 6) are complementary in their stereochemistry, the former taking place stereospecifically *anti* and the latter stereospecifically *syn*.[24,25]

Other Reactions.

Other substrates that have been found to react with silyl-copper reagents and with silyl cuprates are allyl chlorides,[28] an alkyl bromide,[29] epoxides,[8,22] acid chlorides,[9,30] propargyl acetates[31] and sulfides,[32] a vinyl iodide,[9] an aminomethyl acetate,[33] ethyl tetrolate,[34] and some strained allylic ethers.[35]

Lithium Bis(*N*-methyl-*N*-phenylcarbamoyl)cuprate

[85138-79-0] · $C_{16}H_{16}CuLiN_2O_2$ · Lithium Bis(*N*-methyl-*N*-phenylcarbamoyl)cuprate · (MW 338.80)

(carbamoylation of organic halides[1])

Alternate Name: lithium bis[(methylphenylamino)carbonyl]cuprate.

Preparative Method: prepared in situ: a solution of 18.7 mmol of *N*-methylaniline in 45 mL of anhyd ether was placed in a reaction flask equipped with a balloon; ***n-Butyllithium*** in hexane (12 mL of a 15% solution) was added with stirring at 0 °C; the resulting pale yellow solution was stirred for 1 h and exposed to ***Carbon Monoxide*** for 0.5 h at 0 °C to inactivate excess *n*-BuLi; a homogeneous solution was formed after adding 9.35 mmol of purified ***Copper(I) Iodide*** at 0 °C; after reaction with CO at 0 °C for 3.5 h, the reagent formed as a white precipitate.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive; handle under dry N_2; irritant; the hazards of CO are well-documented.[2]

Carbamoylation.

This reagent behaves very similarly to ***Lithium Bis(N,N-diethylcarbamoyl)cuprate***, a carbamoylation reagent reactive towards organic halides.[1,3,4] The reaction with ***Benzyl Bromide*** and iodobenzene gave carbamoylation products (**5**) and (**6**) in low yield (eq 1). *N,N´*-Dimethyl-*N,N´*-diphenylethanediamide (**7**), formed as a byproduct, proved to be an oxidative dimerization product arising from the organic group in the CO-containing copper complex. Reaction with ***N-Bromosuccinimide*** gave *N,N´*-dimethylcarbanilide in 46% yield. The similar reaction with 1,2-epoxyethylbenzene gave the expected 3-hydroxy-*N*-methyl-*N*-phenyl-3-

phenylpropanamide (**10**) in 52% yield.[1]

R	Yield (%)	
Me	71	**(2)**
$CH_2{=}CHCH_2$	88	**(3)**
MeCO	72	**(4)**
CH_2Ph		**(5)**
Ph		**(6)**
CON(Me)Ph		**(7)**
NHPh		**(8)**
N(Me)Ph		**(9)**
$CH_2CH(OH)Ph$		**(10)**

The reaction with iodobenzene could be optimized under the catalysis of palladium; otherwise, the yield was less than 5% (eq 2).[1,3]

Conversion to Oxamide and Carbamate Derivatives.

Like lithium bis(*N*,*N*-diethylcarbamoyl)cuprate, lithium bis(*N*-methyl-*N*-phenylcarbamoyl)cuprate can also be converted to the corresponding oxamide by treatment with ***Bromine*** or ***Titanium(IV) Chloride*** (eq 3).[3] Formation of the corresponding oxamic acid was accomplished by reaction with ***Carbon Dioxide*** and warming with dilute acid (eq 4). Its carbamate was produced on treatment with bromine and then with

Sodium Methoxide in methanol (eq 5).[3]

Lithium Bis(3-trimethylsilyl-1-propen-2-yl)cuprate

[-] · $C_{12}H_{26}CuLiSi_2$ · Lithium Bis(3-trimethylsilyl-1-propen-2-yl)cuprate · (MW 297.05)

(precursor to diene used in tandem Diels-Alder reactions)

Preparative Method: ***2-Bromo-3-trimethylsilyl-1-propene*** is lithiated with ***n-Butyllithium*** in ether at -78 °C, followed by addition of 0.5 equiv ***Copper(I) Iodide***[1].

Handling, Storage, and Precautions: air- and moisture-sensitive; use in a fume hood.

Lithium bis(3-trimethylsilyl-1-propen-2-yl)cuprate (**1**) has been used to prepare 2,3-[bis(trimethylsilyl)methyl]-1,3-butadiene (**2**) via an oxidative dimerization reaction promoted by ***Copper(II) Chloride*** (eq 1). Reaction of (**2**) with ***Dimethyl Acetylenedicarboxylate*** afforded the cyclohexadiene (**3**) in 82% yield. Oxidative bis-desilylation of (**3**) and reaction with ***N-Phenylmaleimide*** provided the linear tricycle (**4**) in moderate yield (eq 2). Additional examples of the tandem Diels-Alder sequence with a variety of dienophiles are also given.[1]

Lithium Bis(2-vinylcyclopropyl)cuprate

[61863-88-5] · $C_{10}H_{14}CuLi$ · Lithium Bis(2-vinylcyclopropyl)cuprate · (MW 204.73)

(organometallic reagent for the introduction of a vinylcyclopropyl unit via conjugate additions to enones and ynones; useful for the construction of divinylcyclopropane and vinylcyclopropane systems as precursors to 1,3-cycloheptadiene and cyclopentenes, respectively)

Solubility: sol THF-ether (2:1) at -78 °C.

Preparative Method: prepared at -78 °C by adding a solution (THF-ether; 2:1) of 2-vinylcyclopropyllithium to 0.5 equiv of $CuBr.SMe_2$ (see ***Copper(I) Bromide***); the cyclopropyllithium intermediate can be generated by the metal-halogen exchange of 2-vinylcyclopropyl bromide with ***t-Butyllithium*** at -95 °C (eq 1).[1]

Handling, Storage, and Precautions: thermally unstable; must be generated in the absence of H_2O and O_2 at -78 °C; reactions with (**1**) and unsaturated carbonyl compounds should be carried out at -78 °C.

Conjugate Additions to Unsaturated Carbonyl Compounds.

The major utility of lithium bis(2-vinylcyclopropyl)cuprate (**1**) is its reaction with α,β-alkynic esters and ketones in order to construct the divinylcyclopropane system. The 1,4-addition of (**1**) to the alkynic ketone (**2**) to produce an 8:1 mixture of the divinylcyclopropane (**3**) and the rearranged product (**4**) in 90% yield is illustrated in eq 2.[2]

The 1,3-cycloheptadiene product (**4**) is the result of the facile 3,3-sigmatropic rearrangement of the *cis*-(2-vinylcyclopropyl)enone isomer. In fact, the *trans* isomer also rearranges at higher temperatures (140-150 °C) to the same cycloheptadiene (**4**).

In studies directed towards the synthesis of ring-fused cycloheptadienes,[2,3] an analogous cuprate containing a phenylthio ligand (see ***Lithium Phenylthio(2-vinylcyclopropyl)cuprate***) has been added 1,4 in an addition/β-elimination process to a β-iodocyclohexenone (**5**) (eq 3). Subsequent rearrangement of adduct (**6**) leads to a ring-fused 1,3-cycloheptadiene (**7**).

Other variants[4] of eq 3 have led to the synthesis of spirocycloheptadienes (**8**) (eq 4) after thermal rearrangement of the divinylcyclopropane.

2-Vinylcyclopropylcuprates also undergo rapid acylations with acid chlorides to produce 2-vinylcyclopropyl ketones such as (**9**) (eq 5). Ketone (**9**) may also be converted to a divinylcyclopropane system via its enol ether (**10**), and then to a spirocycloheptadiene (**11**) (eq 6).[5]

Lithium 9-boratabicyclo[3.3.1]nonane[1]

[76448-08-3] · $C_8H_{16}BLi$ · Lithium 9-boratabicyclo[3.3.1]nonane · (MW 129.99)

(selective reducing agent for esters, aldehydes, ketones, primary halides and tosylates, epoxides, aromatic nitriles, and tertiary amides; catalyst for $LiBH_4$ reduction of esters; with 9-BBN-H, reduces carboxylic acids to aldehydes)

Alternate Name: Li(H_2-9-BBN).

Physical Data: colorless in THF solution.

Solubility: sol THF; evolves H_2 in protic solvents.[2]

Form Supplied in: 1.0 M solution in THF.

Analysis of Reagent Purity: ^{11}B NMR resonance in THF at δ -17.4 (t, *J* = 72.1 Hz) ppm.[2a]

Handling, Storage, and Precautions: THF solutions of the reagent are stable indefinitely at 25 °C when stored under N_2; exposure to O_2, H_2O, or protic solvents results in its potentially dangerous rapid oxidation and/or the exothermic generation of H_2; its generation and use involves handling air-sensitive reagents (i.e. LiH, ***9-Borabicyclo[3.3.1]nonane***); use in a fume hood.[1]

Selective Reductions.

The reagent is conveniently prepared from an excess of LiH and 9-BBN in THF (48 h, 65 °C)[2] and is omnipresent as a byproduct from the reaction of alkyllithium reagents with 9-BBN.[3] Its reactivity with representative compounds containing different functional groups has been surveyed.[2b] Primary alcohols, phenols, and aliphatic and aromatic thiols react with excess reagent in THF at 25 °C with rapid and quantitative H_2 evolution. However, *n*-hexylamine is unreactive, and secondary and tertiary alcohols react very slowly under these conditions. The reagent reduces acid chlorides, esters, lactones, aldehydes, and even highly substituted ketones to the corresponding alcohols (eq 1), but

anhydrides are only reduced to an equimolar mixture of alcohol and carboxylate. Cinnamaldehyde undergoes clean 1,2-reduction to produce cinnamyl alcohol. Epoxides are reductively opened from the least substituted side while acetals and orthoesters are inert to the reagent. Treatment of primary amides with Li(H_2-9-BBN) leads only to slow H_2 evolution, whereas caprolactam is reduced slowly and tertiary amides are reduced to the corresponding amines (24 h, 25 °C). Aromatic nitriles are also reduced to the amine under these conditions, but aliphatic nitriles react sluggishly. Isocyanates are reduced to formamides while treatment of oximes results only in H_2 evolution. Azobenzene is essentially inert to the reagent, while pyridine, azoxybenzene, and nitropropane are partially reduced. Nitrobenzene and pyridine *N*-oxide are reduced, but the actual products have not been determined. Disulfides are reduced to thiolates, while sulfoxides, sulfones, sulfonic acids, and sulfides are inert. The reduction of *n*-alkyl derivatives follows the order: I > OTs > Br >> Cl, whereas secondary bromides and tosylates are not effectively reduced at 25 °C. *B*-Halo-9-BBN derivatives are also conveniently reduced to 9-BBN by the reagent.[4]

(1)

Catalyst for the $LiBH_4$ Reduction of Esters.

The reduction of ethyl caproate by Li(H_2-9-BBN) is rapid in THF (1 h, 25 °C), while its reduction by ***Lithium Borohydride*** is significant slower (ca. 50% in 8 h, 25 °C). With 10 mol % of Li(H_2-9-BBN) or *B*-MeO-9-BBN as well as other organoboranes as catalysts, a markedly enhanced rate of reduction of esters by $LiBH_4$ in THF (8 h, 25 °C) or ether (eq 2) is observed.[5] A modest catalytic effect is observed for epoxides and primary tosylates, and the reduction of benzonitrile by $LiBH_4$ is observed only with added catalyst. *n*-Octyl bromide is not reduced under catalytic conditions, but is reduced slowly by using stoichiometric amounts of Li(H_2-9-BBN) (6 h, 25 °C). This reagent may be the active species in these catalytic reductions.

(2)

Aldehydes from Carboxylic Acids.[6]

The reaction of 9-BBN with carboxylic acids evolves H_2, producing the corresponding acyloxy-9-BBN derivative which, upon treatment with Li(H_2-9-BBN) at room temperature, gives high yields of the corresponding aldehydes (76-99%). The procedure is widely applicable, being effective for both aromatic and aliphatic substrates (eq 3). Dicarboxylic acids are also reduced to dialdehydes efficiently (eq 4), and the process tolerates aromatic functionality

(e.g. Cl, NO_2, OMe).

(3)

(4)

Related Reagents.

Lithium Borohydride; ***Lithium 9,9-Dibutyl-9-borabicyclo[3.3.1]nonanate***; ***Potassium 9-Siamyl-9-boratabicyclo[3.3.1]nonane***.

Lithium Borohydride[1]

$LiBH_4$

[16949-15-8] · BH_4Li · Lithium Borohydride · (MW 21.78)

(reducing agent for esters and lactones,[1,2a,b] acyl chlorides,[2c] epoxides,[1] aldehydes and ketones;[1,2a,b,d] precursor of other borohydrides;[1] catalyst for hydroborations[3])

Physical Data: mp 284 °C (dec); *d* 0.666 g cm^{-3}.

Solubility: sol ethers (3 g/100 mL Et_2O, 25 g/100 mL THF),[4] lower primary amines ($MeNH_2$, $EtNH_2$, *i*-$PrNH_2$),[5] diglyme[6] (9 g/100 mL);[4] sol (with reaction) alcohols[7] (1.6 g/100 mL MeOH, 3 g/100 mL *i*-PrOH);[4] solution in absolute EtOH shows no appreciable decomposition after 2-4 h at about 0 °C;[7] solution in *i*-PrOH shows no decomposition after 24 h;[4] sol (with slow decomposition) water.

Form Supplied in: off-white solid; 2.0 M solution in THF.

Analysis of Reagent Purity: hydrolysis with dilute acid and titration for boron;[8] ethereal or THF solutions can be titrated with 2 N HCl-THF (1:1).[4]

Purification: recrystallization from Et_2O; the purified material is pumped free of ether at 90-100 °C for 2 h.[8]

Handling, Storage, and Precautions: both solutions and (especially) the solid[9] are flammable and must be stored under N_2 in the absence of moisture; the solid is capable of creating a dust explosion; $LiBH_4$ reacts with water and acids, generating flammable and/or explosive gas (H_2 and borane), and is incompatible with strong oxidizing agents.

Reduction of Functional Groups.

Lithium borohydride is more reactive as a reducing agent than ***Sodium Borohydride*** and less reactive than ***Lithium Aluminum Hydride***.[1] In THF, $LiBH_4$ readily reduces aldehydes and ketones to alcohols at room or even ice-bath temperature,[9] whereas esters and lactones require higher temperatures and prolonged reaction times to give the corresponding alcohols and diols. Thus selective reductions are possible. Epoxides are reduced by $LiBH_4$, while carboxylic acids, carboxylic acid salts, tertiary amides, nitriles, nitro compounds, alkenes, and halogeno derivatives do not usually react.[1]

The chief advantage of $LiBH_4$ over $LiAlH_4$ is its much greater chemoselectivity, while the chief advantage over $NaBH_4$ is its higher solubility in ethereal solvents. The different reactivity of the two lithium hydrides ($LiBH_4$ and $LiAlH_4$) is essentially due to the different hardness of the two hydride-delivering anions, while the different reactivity of the two borohydrides ($LiBH_4$ and $NaBH_4$) is essentially due to the different Lewis acidity of the associated cation, rather than to differences in solubility.[6,10]

Lithium borohydride reactivity is greatest in media of low dielectric constant: increasing the polarity decreases reactivity.[4] The order of reactivity is $LiBH_4$ in Et_2O > THF &AApprox; diglyme > 2-propanol; this trend is exactly reversed for $Ca(BH_4)_2$.

Several papers have dealt with the effects of solvent,[4,6,11] concentration,[10a] added salt,[6] and added cation complexing agents[10] both on the reaction rate and the regiochemistry of $LiBH_4$ reductions, regarding essentially ester reduction.

Since carbonyl compounds are rapidly reduced by $LiBH_4$ alone, less attention has been devoted to this reaction. Nevertheless, it has been shown that the rate of the reduction of acetone in *i*-PrOH[11] ($k = 50.3 \times 10^{-4}$ L mol^{-1} s^{-1}) is not appreciably affected by the addition of ***Triethylamine***, while addition of ***Lithium Chloride*** accelerated the reduction. The added lithium salt probably has a double effect: on one hand, it can modify the nature of the ionic cluster; on the other, it can activate the carbonyl group. In contrast, $NaBH_4$ reductions are almost unaffected by added ***Sodium Iodide*** and accelerated by Et_3N. Reaction rates for reduction of some aliphatic and aromatic ketones with borohydrides in various solvents have been reported.[12]

In the reduction of cyclic ketones, $LiBH_4$ generally attacks more from the more hindered side than $LiAlH_4$;[13] stereochemical aspects of cyclic ketone reduction by complex borohydrides have been widely discussed in some reviews.[14] In the reduction of conjugated cyclic enones[1,10,13] $LiBH_4$ usually gives more 1,4-attack than does $LiAlH_4$. This tendency is enforced by the presence of a lithium-complexing agent, such as [2.1.1]cryptand: when lithium cation is removed from the reaction medium, the reaction rate of 1,2-attack is decreased more than that of 1,4-attack, probably because of different influence of Li^+ on the carbonyl LUMO and on reducing agent HOMO levels, so that 1,4-attack becomes predominant.[10b] For example, cyclohexen-3-one is reduced to give predominantly the corresponding allylic alcohol by $LiBH_4$ alone, while in the presence of [2.1.1]cryptand the saturated ketone and alcohol are largely predominant (eq 1). Results comparable to that reported in eq 1 have also been obtained using ***Tetra-n-butylammonium Borohydride*** in several aprotic solvents.[15]

(1)

Regio- and diastereoselective reductions of steroidal ketones have been achieved by using $LiBH_4$.[7,16a] Stereoselective reduction of a polyfunctionalized ketone, intermediate in the synthesis of oleandomycin, was realised via $LiBH_4$ reduction (THF-MeOH, -78 °C) of the dibutylboron aldolate derived from reaction of the ketone itself with dibutylmethoxyborane.[16b]

More studies have been devoted to the reduction of esters, regarding the solvent and possible additives. Different solvents can be used: Et_2O, THF, diglyme, or *i*-PrOH, although in the latter case a large excess of $LiBH_4$ is required to compensate the loss due to the side reaction with the solvent.[5] A clean procedure to reduce esters in high yield using an essentially stoichiometric amount of $LiBH_4$ in Et_2O or THF has been reported.[4] Under these reaction conditions, hindered esters, such as ethyl adamantanecarboxylate, and lactones are also readily reduced, while other functional groups, such as alkyl and aryl halides, nitro groups, ethers, and nitriles remain unaffected. Diesters have been reduced to the corresponding diols using $LiBH_4$,[4,17] while reduction of ***Ethyl Acetoacetate*** has been reported to give rise to some problems, due to the formation of a borate complex, from which the reduction product cannot be isolated.[9]

The reducing ability of $LiBH_4$ has been found to be greatly enhanced in mixed solvents containing methanol, and to be dependent on the amount of added alcohol.[18] Using the $LiBH_4$-Et_2O-MeOH (1 equiv with respect to $LiBH_4$) reducing system, esters, lactones, and epoxides are selectively reduced, even at room temperature, with respect to nitro groups, aryl halides, primary amides, and carboxylic acids. By employing the $LiBH_4$-diglyme (or THF)-MeOH (4 equiv with respect to $LiBH_4$) systems, a further enhancement of reducing capabilities is observed: nitro compounds and nitriles are reduced to amines, and carboxylic acids are reduced to alcohols, while amides show different behaviors depending on substitution. Tertiary amides are reduced essentially to alcohols, through C-N bond fission, while primary amides are cleanly reduced to amines, via C-O bond fission. Secondary amides show different behavior depending on nitrogen substituent.

The chemoselective reduction of an ester moiety in the presence of a carboxylic acid, using $LiBH_4$, or vice versa, using diborane, has been applied in the stereoselective synthesis of both (*R*)- and (*S*)-mevalonolactone.[19a] The chemoselective reduction of an ester with respect to an amide using $LiBH_4$ in THF has been reported in carbohydrate chemistry.[19b] Sterically hindered acyloxazolidinones have been reduced to the corresponding primary alcohols using $LiBH_4$ in Et_2O containing water (1 equiv) in better yields than using $LiBH_4$ or $LiAlH_4$ alone.[19c]

An interesting stereoselective 1,4 reduction of an acetoxy unsaturated nitrile has been realized by using $LiBH_4$ in THF, probably through the intermediate formation of an alkoxyhydride; the same reaction has been realized on a preparative scale using $LiAlH_4$ in THF.[20a] Sparse reports on the reduction of other functional groups (carbazole derivatives of carboxylic acids to aldehydes,[20b] hydrazides to hydrazines,[20c] cyclic anhydrides to lactones,[20d] acyl chlorides to alcohols[2b]) using $LiBH_4$ in various nonhydroxylic solvents have appeared.

Reactivity of $LiBH_4$ towards *n*-octyl chloride has been found to be extremely low; ***Lithium Triethylborohydride*** is 10^4 times more efficient in carrying out the reduction to *n*-octane.[21a] Alkyl tosylates are almost inert towards $LiBH_4$, while they are readily reduced by $LiEt_3BH$.[21b]

Epoxides are smoothly reduced by $LiBH_4$,[18,22] with attack occurring mainly at the less hindered site and *cis* epoxides being reduced more rapidly than *trans* ones. 2,3-Epoxy alcohols and their derivatives can be regioselectively reduced to 1,2-diols by using a suspension of $LiBH_4$ in hexane at ambient temperature;[23] results are superior to that obtained using completely dissolved $LiBH_4$ in THF or a ***Titanium Tetraisopropoxide***-$LiBH_4$ system (see below).

Addition of Lewis Acids.

In the effort to tune up the selectivity of lithium borohydride, several combinations of the reducing agent with a variety

of Lewis acids have been assayed.

Addition of boranes or alkoxyboranes greatly enhances the reactivity of $LiBH_4$ towards esters in Et_2O or THF;[24] a particularly high catalytic effect is shown by *B*-MeO-9-BBN and ***Trimethyl Borate***. Many other additives that generate a borane species under the reaction conditions (e.g. $LiEt_3BH$, $LiEt_3BOMe$, ***Tri-n-butylborane***) show a catalytic effect. These additives also exert a catalytic effect on epoxide reductions, but have little if any influence on the reduction of carboxylic acids, tertiary amides [which can be reduced by *n*-Bu_4NBH_4 or by $NaBH_4$-***Titanium(IV) Chloride*** (see under ***Sodium Borohydride***)], nitriles, sulfur compounds, and pyridine. ***Borane-Tetrahydrofuran*** and ***Boron Trifluoride Etherate*** are ineffective as catalysts. Alkenes, although normally inert to the action of $LiBH_4$, are hydroborated (see below) by this reagent in the presence of esters, with concomitant enhancement of the ester reduction rate: as a consequence, unsaturated esters are transformed into a mixture of regioisomeric diols.

Lithium borohydride combined with ***Chlorotrimethylsilane*** generates a more powerful reducing system.[25] Amino acids can be reduced to amino alcohols, with retention of optical purity; primary, secondary, and tertiary amides, as well as nitriles, are reduced to amines, and sulfoxides to sulfides; a nitrostyrene derivative is reduced to the corresponding saturated amine, in better yield than with alternative reducing systems ($LiAlH_4$ or catalytic hydrogenation). These reactions are believed to proceed through the formation of a borane-THF complex.

Lithium borohydride combined with ***Europium(III) Chloride*** in MeOH-Et_2O has given the best result in regio- and diastereoselective reduction of a polyfunctionalized conjugated enone intermediate in the synthesis of palytoxin.[26] Inferior results were obtained with other reducing systems.

Lithium borohydride combined with titanium tetraisopropoxide in THF, benzene, or CH_2Cl_2 reduces 2,3-epoxy alcohols regioselectively to 1,2-diols in high yield.[27a,b] Good 1,2 regioselectivity is shown also by ***Diisobutylaluminum Hydride*** (DIBAL) in benzene, while 1,3-diols can be regioselectively obtained by using Red-Al (***Sodium Bis(2-methoxyethoxy)aluminum Hydride***) in THF.[27c,d] The $LiBH_4$-Ti(*i*-PrO)$_4$ system is effective in *syn* diastereoselective reduction of β-hydroxy ketones to 1,3-diols,[27e] although other hydrides ($LiAlH_4$, $NaBH_4$) combined with different additives [Ti(*i*-PrO)$_4$, Ti(OEt)$_4$, $TiCl_4$, LiI] show the same trend and often give better results.

The addition of titanium tetrachloride reverses the diastereoselectivity of the $LiBH_4$ reduction of 3,3-dimethyl-2,4-pentanedione,[28] so that *meso*-2,4-pentanediol is obtained as the main product.

Lithium borohydride (but also $LiAlH_4$ and $NaBH_4$) combined with boron trifluoride etherate in Et_2O, THF, or THF-diglyme reduces cyclic lactones to cyclic ethers.[29]

Addition of Grignard Reagents.

Synthesis of secondary alcohols from esters can be realised by combining $LiBH_4$ with Grignard reagents via formation of an intermediate ketone, which is reduced by $LiBH_4$ much more rapidly than the ester.[30a] When 2-alkoxy esters are used, stereoselective formation of *anti* 1,2-diols is observed, especially when THF is used as solvent.[30b] The reversed diastereoselectivity is observed when DIBAL is added to the ester, with formation of an intermediate aldehyde, before adding the Grignard reagent.

Addition of Chiral Ligands.

N-Benzoylcysteine, a chiral ligand available in both enantiomeric forms, is highly effective in enantioselective $LiBH_4$ reductions of alkyl aryl ketones in THF-*t*-BuOH (ee up to 92%).[31a] Analogous results are obtained using the dimer *N*,*N*-dibenzoylcystine,[31b] which also reduces a conjugated enone to the corresponding chiral allyl alcohol.[31b] The $LiBH_4$-*N*,*N*-dibenzoylcystine system has also been used to enantioselectively reduce β-keto esters,[31c] β-chloro ketones[31d] (which are precursors of optically active oxetanes), acetylpyridines, and α- and β-amino ketones.[31e]

Other Reductions.

In an attempt to reduce the ester moiety of some functionalized 2-methylthiopyrimidines, it has been found that $LiBH_4$ (and also $LiAlH_4$) in THF reduces the heteroaromatic ring, leaving almost unaffected the ester and other functional groups, so that differently substituted 1,6-dihydroxypyrimidines can be obtained in good yields (eq 2).[32] Differently functionalized pyrimidines are similarly reduced by $LiBH_4$ in DMF. It should be emphasized that a tertiary amide like DMF can be a suitable solvent for $LiBH_4$ (see above for discussion of amide reductions).

(2)

R = Me, CN, Cl, CH=NOH

Alkyl- and arylhalostibines can be reduced to hydrides, having general formula R_nSbH_{3-n}, both by $LiBH_4$ and other complex hydrides ($LiAlH_4$, $NaBH_4$).[2e]

Hydroboration.

Lithium borohydride is an effective catalyst for the hydroboration of alkenes with ***Catecholborane*** at rt in THF.[3] This method is superior to that employing ***Chlorotris(triphenylphosphine)rhodium(I)*** as catalyst, since trisubstituted and even tetrasubstituted ethylenes can also be almost quantitatively hydroborated. Other borohydrides ($LiBEt_3H$ in THF, $NaBH_4$ in diglyme) were tested and found to be less effective as catalysts.

Preparation of Other Borohydrides.

Lithium borohydride has been used to synthesize other borohydrides,[5] particularly aluminum borohydride (a volatile, liquid source of borohydride groups) through the metathesis between ***Aluminum Chloride*** and $LiBH_4$ (eq 3). For this process, $LiBH_4$ is superior to $NaBH_4$, both for a more pronounced reactivity and for a more favorable equilibrium position, so that lower temperatures and a much smaller excess of $AlCl_3$ are required.

$$AlCl_3 + 3\,LiBH_4 \rightleftharpoons Al(BH_4)_3 + 3\,LiCl \qquad (3)$$

Miscellaneous.

The addition of $LiBH_4$ in the carbonylation of trialkylboranes not only has the effect of stopping the reaction after the transfer of only one alkyl group, but also enhances the rate of the uptake of ***Carbon Monoxide***[2f,33] (see also ***Potassium Triisopropoxyborohydride***). Aldehydes or alcohols are obtained, depending on workup conditions (eq 4).

(4)

Lithium borohydride has been used in the degradation of peptides, in order to determine the terminal carboxylic groups.[1f]

Isotopically labelled lithium borohydrides, $LiBD_4$ and $LiBT_4$, have been used in reaction mechanism studies.[2g,20a]

Lithium Bromide[1]

LiBr

[7550-35-8] · BrLi · Lithium Bromide · (MW 86.85)

(source of nucleophilic bromide;[2] mild Lewis acid;[1] salt effects in organometallic reactions;[1] epoxide opening[1])

Physical Data: mp 550 °C; bp 1265 °C; *d* 3.464 g cm^{-3}.

Solubility: 145 g/100 mL H_2O (4 °C); 254 g/100 mL H_2O (90 °C); 73 g/100 mL EtOH (40 °C); 8 g/100 mL MeOH; sol ether, glycol, pentanol, acetone; slightly sol pyridine.

Form Supplied in: anhyd white solid, or as hydrate.

Purification: dry for 1 h at 120 °C/0.1 mmHg before use; or dry by heating in vacuo at 70 °C (oil bath) for 24 h, then store at 110 °C until use.

Handling, Storage, and Precautions: for best results, dry before use in anhyd reactions.

Alkyl and Alkenyl Bromides.

LiBr has been extensively used as a source of bromide in nucleophilic substitution and addition reactions. Interconversion of halides[2] and transformation of alcohols to alkyl bromides via the corresponding sulfonate[3] or trifluoroacetate[4] have been widely used in organic synthesis. Primary and secondary alcohols have been directly converted to alkyl bromides upon treatment with a mixture of ***Triphenylphosphine***, ***Diethyl Azodicarboxylate***, and LiBr.[5]

(*Z*)-3-Bromopropenoates and -propenoic acids have been synthesized stereoselectively by the reaction of LiBr and propiolates or propiolic acid (eq 1).[6]

(1)

Heterolytic Cleavage of C-X Bonds.

In the presence of a Lewis acid, LiBr acts as a nucleophile in the opening of 1,2-oxiranes to produce bromohydrins (eq 2).[7] In the absence of an external Lewis acid or nucleophile, epoxides generally give rise to products resulting from ring-contraction reactions (eq 3).

(2)

(3)

LiBr-mediated decomposition of dioxaphospholanes results in the exclusive formation of the epoxide, whereas the thermal decomposition produces a mixture of products (eq 4).[8]

(4)

Protection of alcohols as their MOM ethers can be achieved using a mixture of ***Dimethoxymethane***, LiBr, and ***p-Toluenesulfonic Acid***.[9]

Bifunctional Reagents.

Activated α-bromo ketones are smoothly converted into the corresponding silyl enol ethers when treated with a mixture of LiBr/R_3N/***Chlorotrimethylsilane***.[10] Aldehydes are converted into the corresponding α,β-unsaturated esters using ***Triethyl Phosphonoacetate*** and ***Triethylamine*** in the presence of LiBr (eq 5).[11,12] Similar conditions were extensively used in the asymmetric cycloaddition and Michael addition reactions of *N*-lithiated azomethine ylides (eq 6).[13]

(5)

MX = LiCl, 77%; LiBr, 93%; $MgCl_2$, 15%; $MgBr_2$, 71%

(6)

Additive for Organometallic Transformations.

The addition of LiBr and ***Lithium Iodide*** was shown to enhance the rate of organozinc formation from primary alkyl chlorides, sulfonates, and phosphonates, and ***Zinc*** dust.[14] Beneficent effects of LiBr addition have also been reported for the Heck-type coupling reactions[15] and for the nickel-catalyzed cross-couplings of alkenyl and α-metalated alkenyl sulfoximines with organozinc reagents.[16] The addition of 2 equiv of LiBr significantly enhances the yield of the conjugate addition products in reactions of certain organocopper reagents (eq 7).[17]

(7)

LiBr (0 equiv), 61%
LiBr (2 equiv), 96%

Finally, concentrated solutions of LiBr are also known to alter significantly the solubility and the reactivity of amino acids and peptides in organic solvents.[18]

Lithium *t*-Butoxide

***t*-BuOLi**

[1907-33-1] · C_4H_9LiO · Lithium *t*-Butoxide · (MW 80.07)

(weakly basic and nucleophilic metal alkoxide)[1]

Physical Data: crystalline solid, subl over 170-205 °C/760 mmHg; dec above 250 °C.[2]

Form Supplied in: commercially available as a white powder.

Preparative Methods: the crystalline material is prepared using a Schlenk apparatus by reaction of *t*-BuOH with a small excess of ***Lithium*** sand in PhMe at rt for 24 h;[2] the excess metal is removed by filtration and the solvent is removed in vacuo; the remaining solid is sublimed at 110-120 °C/0.01 mmHg. In situ preparation is accomplished by adding a solution of anhyd *t*-BuOH in THF to 1.6 M ***n-Butyllithium*** in hexane,[1a] or by slowly adding a 1.55 M solution of *n*-BuLi in hexane to an excess of the anhyd alcohol under N_2;[1b] the reaction is exothermic, and a water bath should be used to keep the temperature of the mixture near rt.

Handling, Storage, and Precautions: use same procedure as for ***Potassium t-Butoxide***, i.e. handle and conduct reactions in a fume hood under an inert atmosphere; for critical experiments, it is recommended that the reagent be freshly prepared.

Preparation of *t*-Butyl Esters.

t-BuOLi reacts with acid chlorides of hindered carboxylic acids to give the corresponding *t*-butyl esters in high yields (eq 1).[1] The ester product shown in eq 1 is not obtained by the more conventional method of reacting the acid chloride with *t*-BuOH in the presence of $PhNMe_2$.[3]

Oxidation of Alcohols.

Alkoxymagnesium bromides of secondary alcohols and allylic and benzylic alcohols are oxidized to the corresponding ketones or aldehydes with ***N-Chlorosuccinimide*** in the presence of *t*-BuOLi.[4] The method is ineffective for primary saturated and some unsaturated alcohols, but oxidations of the former substrates to aldehydes occur readily if ***t-Butoxymagnesium Bromide*** is substituted for *t*-BuOLi.[5] Secondary alcohols (eq 2) and primary benzylic (eq 3) and allylic alcohols are oxidized to the corresponding carbonyl compounds in good yields using 2-3 equiv of a 1:1 mixture of ***Copper(II) Bromide***-*t*-BuOLi in THF at rt.[6] However, the reagent is not effective for the conversion of primary aliphatic alcohols to aldehydes.

(2)

(3)

Condensation Reactions.

In the presence of dipolar aprotic additives, e.g. ***Hexamethylphosphoric Triamide*** (eq 4) or ***12-Crown-4***, which reduce the degree of aggregation, *t*-BuOLi catalyzes the Michael addition of methyl cyanoacetate to benzylideneacetophenone.[7] A similar yield of the Michael adduct is obtained if *t*-BuOK is used as the base, and no additive is required.

(4)

Additions to Hindered Ketones.

In the absence of various additive salts, the reaction of *i*-Pr_2Mg with *t*-Bu_2CO leads mainly to simple reduction of the carbonyl group.[8] In the presence of *t*-BuOLi, addition to the carbonyl group occurs in good yield (eq 5).[8] *t*-BuOLi, MeOK, and $(Me_2CH)_2CHOK$ are more effective than MeONa or quaternary ammonium salts in preventing the reduction process. The exact role of the additive in favoring addition to the hindered ketone over reduction is unknown.

t-BuOLi (1.0-2.0 equiv)	81-84%	0%
no additive	1.3%	88%

β-Elimination Reactions.

1-Methoxyacenaphthene undergoes loss of MeOH via an E1cB mechanism.[9] *t*-BuOLi/*t*-BuOH favors exchange and elimination of the proton *syn* to the methoxy group much more than do other alkali metal alkoxides. It has been suggested that the strong tendency of the lithium cation of the base ion pair (or an aggregate) to coordinate with the ether oxygen of the substrate accounts for this.[9]

Drury Caine

University of Alabama, Tuscaloosa, AL, USA

Lithium *t*-Butoxy(*t*-butyl)cuprate[1]

***t*-BuCu(O-*t*-Bu)Li**

[41655-91-8] · $C_8H_{18}CuLiO$ · Lithium *t*-Butoxy(*t*-butyl)cuprate · (MW 200.71)

(heterocuprate of greater thermal stability than analogous homocuprate;[2] capable of nucleophilic additions[2] and substitutions[3])

Solubility: sol THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl; the yield of PhCO(*t*-Bu) is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: ***Lithium t-Butoxide*** is prepared[2] under N_2 by dropwise addition of 1.00 equiv of ***n-Butyllithium*** in hexanes to a solution of dry *t*-BuOH in dry THF[3b] (***Potassium t-Butoxide*** should not be substituted for the lithium salt); a stirred suspension of 1.00 equiv of ***Copper(I) Iodide***[5] in dry THF at rt under N_2 is treated with the *t*-BuOLi solution dropwise; after 15 min, the resulting cloudy, green-brown suspension is cooled to -78 °C and then treated with 1.00 equiv ***t-Butyllithium*** in pentane; the product, a cloudy, brown mixture, is ready for use after stirring for 5 min at -78 °C (alternative methods also may be acceptable; high-purity *t*-BuOLi is commercially available).[6,7]

Handling, Storage, and Precautions: best results are obtained with high-purity copper(I) salts,[5,8] dry, oxygen-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides;[9] the *t*-BuLi used to prepare the reagent is pyrophoric[10] and due care must be exercised in its handling; use in a fume hood; thermal decomposition occurs at &egt;-30 °C, but the reagent is stable for one or more h at <=-50 °C.

Introduction.

The title reagent is representative of the heterocuprate class of organocopper reagents. The *t*-Bu group is reactive as a nucleophile, whereas the *t*-BuO group is not; such nontransferable groups are called dummy ligands.[11] For *t*-Bu heterocuprates, *t*-BuO, PhO, and especially PhS dummy ligands are found to provide thermal stability compared to the parent homocuprate, $(t\text{-Bu})_2CuLi$.[12] Heterocuprates generally exhibit less nucleophilic reactivity than corresponding homocuprates;[13] however, increased thermal stabilities coupled with greater efficiency in use of the

transferable ligand[12] make them reasonable alternative reagents. This is particularly true when relatively high reaction temperatures are required, or when the organolithium used to form the cuprate is difficult or expensive to prepare.

Nucleophilic Substitutions of Halides.

The thermal stability of the cuprate typically results in higher chemical yields using highly reactive substrates such as ***Benzoyl Chloride*** (eq 1);[12] in contrast, copper(I)-catalyzed reactions with *t*-BuLi or *t*-BuMgX are unsatisfactory. The low temperatures at which the reactions proceed allow for other, less reactive, functional groups to be present (eq 2).[12]

(1)

R = *t*-BuO 98%
R = *t*-Bu 76%

(2)

Reaction with α,α´-dibromo ketones provides a regioselective, efficient route to α-tertiary and α-secondary alkylations of ketones (eq 3);[5a,12,14] α-*t*-Bu alkylations using enolates or enolate equivalents generally are difficult and yields may be unsatisfactory. A related report indicates that the reagent is not effective when α-chlorophosphonates are used as substrates.[15]

(3)

56% 10%

The reagent has been used to effect simple S_N2 reactions of iodoalkanes;[12] it follows normal trends, providing good chemical yields for primary substrates only. Secondary *exo*-norbornenyl tosylates react to provide 2-*t*-butylnortricyclanes in good yield.[16]

1,4-Additions to 2-Alkenones.

While apparently not as effective as mixed homocuprates of general formula RC&tbond;CCu(*t*-Bu)Li, the reagent does act as a conjugate donor, undergoing slow 1,4-addition to 2-cyclohexenone (eq 4).[11]

Related Reagents.

Lithium Butyl(cyano)cuprate

***n*-BuCuCNLi**

[41742-63-6] · C_5H_9CuLiN · Lithium Butyl(cyano)cuprate · (MW 153.62)

(organometallic reagent for the addition of an *n*-butyl group to enones, vinyl epoxides, simple epoxides, vinyl sulfones, and allylic halides)

Solubility: sol diethyl ether, THF at -78 °C.

Preparative Method: the title reagent, like other alkyl or arylcyanocuprates, is prepared at -78 °C from the addition of the alkyl- or aryllithium precursor to 1 equiv anhyd ***Copper(I) Cyanide***.[1]

Handling, Storage, and Precautions: thermally unstable organocuprate; generated at -78 °C in the absence of moisture and oxygen.

Additions to Epoxides.

The ring-opening reactions of the title reagent (**1**) with epoxides are typical of most organocuprates in that the less hindered carbon of an epoxide is attacked selectively. The cyclohexene epoxide of eq 1 illustrates this reactivity.[2]

(1)

In the case of the more activated epoxy ester (**2**), the reagent delivers an *n*-butyl group α to the ester (eq 2).[2]

(2)

The real uniqueness of the cyano reagent (**1**) is evidenced by its reactions with vinyl epoxides. In reactions with cyclic

vinyl epoxides[1] such as 1,3-cyclohexadiene monoepoxide and 1,3-cycloheptadiene monoepoxide, 1,4-addition predominates in ether at -78 °C (eq 3).[1,3] These selectivities are possible only in the less polar ether solvent, as illustrated for the latter epoxide.

(3)

In a similar fashion, exocyclic vinyl epoxides such as the cyclohexenyl epoxide (**3**) react regiospecifically with (**1**) to produce the tertiary alcohol (**4**) (eq 4).[4,5]

(4)

(3) (4)

When enol ethers of keto epoxides are employed as the vinyl epoxide system, the higher alkyl- and arylcyanocuprates, such as (**1**), add in a *trans*-1,4-manner for cyclohexyl and cyclopentyl systems. In eq 5 a silyl enol ether of the cyclohexenone epoxide (**5**) reacts with (**1**) to produce the adduct (**6**).[6]

(5)

(5) (6)

In the cyclopentenone epoxide system, both the silyl enol ether (**7**) and the enol phosphate epoxide (**8**) yield the 1,4-*trans*-adduct (**9**) with (**1**) (eqs 6 and 7).[7]

Vinyl epoxides which are disubstituted at the terminus of the alkene often react selectively in a 1,2-ring opening, as is the case for the epoxyvinyl sulfone (**10**) (eq 8).[8]

Lithium Cyano(isohexyl)cuprate.

By analogy with the *n*-butylcyanocuprate reagent (**1**), the isohexyl reagent (**11**) is easily prepared from the isohexyllithium precursor and 1 equiv of anhyd copper(I) cyanide at -78 °C in ether. A direct application of (**11**) to the synthesis of the side chain of cholesterol involves the 1,4-addition of (**11**) to the *exo*-vinyl epoxide (**12**) (eq 9).[9]

In a synthetic application for the preparation of the side chain of α-tocopherol, the isohexylcyanocuprate (**11**) was added in a 1,4-manner to a (*Z*)-alkenyl butyrolactone (**13**) in high yield (eq 10).[10]

Lithium Cyanophenylcuprate.

As a further extension of the cyanocuprate reagents, the lithium cyanophenylcuprate reagent (**14**) was easily prepared by adding commercially available ***Phenyllithium*** to anhyd copper(I) cyanide at -78 °C in ether. This reagent is usually more thermally stable than the higher alkylcyanocuprates and, therefore, reactions can be performed at temperatures as high as 0-25 °C. The regioselectivity of cyanocuprates towards vinyl epoxides is, by and large, maintained for the cyanophenylcuprate (**14**). In the case of the *exo*-vinyl epoxide (**15**), the 1,4-addition occurs selectively to give (**16**) in 75% yield (eq 11).[4]

(11)

(15) (14) (16)

Other examples involving enol ether epoxides are shown in eqs 12 and 13.[6,7] In the case of the enol phosphate of the cyclopentenone epoxide, the regioselectivity is skewed towards the 1,2-product to the extent of 2:1.[7]

(12)

(13)

In summary, both the *n*-butylcyanocuprate reagent (**1**) and the isohexylcyanocuprate (**11**) behave consistently in their 1,4-regioselectivity towards cyclic vinyl epoxides. Only the phenylcyanocuprate (**14**) exhibits mixed selectivity with the enol ethers of cyclopentenone epoxides.

Related Reagents.

Lithium *t*-Butyl(diisobutyl)aluminum Hydride

$LiAlH(i\text{-}Bu)_2(t\text{-}Bu)$

[62779-60-6] · $C_{12}H_{28}AlLi$ · Lithium *t*-Butyl(diisobutyl)aluminum Hydride · (MW 206.28)

(sterically hindered and mild reducing agent for aldehydes, ketones, α,β-unsaturated ketones, esters, and lactones[1-5])

Physical Data: see ***Diisobutylaluminum Hydride*** and ***t-Butyllithium***.

Solubility: see ***Diisobutylaluminum Hydride*** and ***t-Butyllithium***; reactions using the title reagent sol THF, toluene, hexane.

Preparative Method: prepared in situ by dropwise addition of equimolar amounts of *t*-butyllithium in hexane to a solution of diisobutylaluminum hydride in hexane at -78 °C followed by dilution with THF at 0 °C; a suspension is formed when toluene is used in place of THF.[4]

Handling, Storage, and Precautions: see ***Diisobutylaluminum Hydride*** and ***t-Butyllithium***.

Stereoselective Reductions.

This mixed reducing reagent provides a convenient method for converting sterically hindered ketones into alcohols (eq 1).[1] Exceptionally high stereoselectivity is reported, even with an unhindered bicyclic ketone such as norcamphor (eq 2).[1b] Reduction of conformationally rigid and hindered bicyclic ketones such as decalin derivatives has been reported to give a single stereoisomer in quantitative yield (eq 3).[2]

Regioselective Reductions.

This mixed reagent has been used effectively to reduce a lactone in the presence of an ester in good yield (eq 4).[3] The absence of overreduction under the reaction conditions is notable.

Lithium n-Butyl(diisobutyl)aluminum Hydride, which is similar to the title reagent, reduces α,β-unsaturated ketones to allyl alcohols.[4] The reduction of enones by the title reagent in the presence of ***Methylaluminum Bis(2,6-di-t-butyl-4-***

methylphenoxide) (MAD) results in reversal of the selectivity (eq 5).[5]

Lithium *n*-Butyl(diisobutyl)aluminum Hydride[1]

Li(*n*-Bu)(*i*-Bu)$_2$AlH

[62779-58-2] · $C_{12}H_{28}AlLi$ · Lithium *n*-Butyl(diisobutyl)aluminum Hydride · (MW 206.28)

(reducing system for selectively converting conjugated enones and esters to allylic alcohols, esters, lactones, and acid chlorides to alcohols, acid anhydrides to alcohols and carboxylic acids, tertiary amides to aldehydes, primary, benzylic, and allylic halides to hydrocarbons, epoxides to alcohols, and disulfides to thiols)

Preparative Method: the reagent system (ate complex) is prepared and utilized in either hexane/THF or hexane/toluene solutions from equal molar quantities of ***Diisobutylaluminum Hydride*** (DIBAL) in hexane and ***n-Butyllithium*** in hexane and diluted with either THF or toluene;[2a] such combinations have been described as lithium trialkylaluminum hydrides, although the exact structures are unknown.[2b-e]

Analysis of Reagent Purity: by analysis of the reduction product of 4-*t*-butylcyclohexanone.[2a]

Handling, Storage, and Precautions: use in a fume hood; see also ***n-Butyllithium*** and ***Diisobutylaluminum Hydride***.

Reduction of Enones to Allylic Alcohols.

This reagent system is effective for the selective 1,2-reduction of acyclic and cyclic α,β-unsaturated enones to allylic alcohols (eqs 1 and 2[2a and 3]), particularly in hexane/toluene media.[2a] Small amounts (1-10%) of saturated ketones and/or saturated alcohols are observed with cyclic enones and β-phenyl enones.[2a] On the other hand, prior complexation of enones with ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD) and subsequent reduction with Li(*n*-Bu)(*i*-Bu)$_2$AlH affords high yields of the corresponding saturated ketones resulting from 1,4-reduction (eq 3),[4] except when the enone is substituted at the β position; in this case, 1,2- or a mixture of 1,2- and 1,4-reduction is obtained.[4]

(1)

(2)

(3)

Reduction of Esters to Aldehydes and Alcohols.

At low temperatures (-78 °C), Li(*n*-Bu)(*i*-Bu)$_2$AlH reduces esters, including lactones and conjugated examples, to the corresponding aldehydes and/or alcohols as mixtures (eqs 4 and 5[6 and 7a]).[2a,5-7] Often, the mixtures are further reduced with borohydride[7c,d] to give alcohols or oxidized to the aldehydes.[5,7a,b] The process appears selective for the reduction of methyl esters in the presence of *t*-butyl derivatives (eq 5).

(4)

Reduction of *t*-Amides to Aldehydes and Alcohols.

Although primary and secondary amides are inert to Li(*n*-Bu)(*i*-Bu)$_2$AlH, tertiary derivatives are reduced to mixtures of aldehydes and alcohols (eq 6[8a]).[2a,8]

Reduction of Other Functional Groups.

This reagent system reduces acid chlorides to alcohols (eq 7), anhydrides to alcohols and acids (eq 8), primary alkyl iodides to hydrocarbons (eq 9), epoxides to alcohols (eq 10) and disulfides to thiols (eq 11).[2a] Chemoselectivity is possible, as illustrated in eq 12.[2a]

Lithium *n*-Butyl(hydrido)cuprate[1]

LiCuH(*n*-Bu)

[53093-27-9] · $C_4H_{10}CuLi$ · Lithium *n*-Butyl(hydrido)cuprate · (MW 128.63)

(in situ hydrido copper reagent; reductive removal of halogen, mesyloxy, or tosyloxy groups; reduction of aldehydes or ketones to alcohols; 1,4-reduction of enones[2])

Preparative Method: copper(I) hydride (4 mmol, prepared by the method of Whitesides[3]) is placed in a round-bottom flask at -50 °C under an inert atmosphere, washed with -50 °C ether (4 times), and then treated with -40 °C ether before the addition of cold ***n-Butyllithium*** in hexane (4 mmol); the resulting dark brown solution (reagent partially insoluble) is stirred for 10 min, an ethereal solution of the substrate (1 mmol) is added, and the reaction mixture is allowed to warm to rt; after 2 h stirring time, the mixture is poured into saturated aqueous ammonium chloride solution, the aqueous phase is extracted with ether, and the combined organic phase is dried.[2]

Primary, secondary, and tertiary halides as well as mesylates and tosylates are reduced by lithium butyl(hydrido)cuprate in 70-100% yield (Table 1). Although aldehydes and ketones are reduced to their corresponding alcohols, α,β-unsaturated ketones are only reduced to their ketones (eqs 1-3). The *n*-butyl group is not incorporated into the product.

Table 1 Reductions with Lithium Butyl(hydrido)cuprate

Substrate	Product	Yield (%)
1-Bromoadamantane	Adamantane	70
2-Bromononane	*n*-Nonane	95
1-Bromonaphthalene	Naphthalene	95
n-Octanyl tosylate	*n*-Octane	80
Cyclohex-3-enyl tosylate	Cyclohexene	75
Ethyl 12-bromostearate	Ethyl 12-stearate	85
Heptanal	Heptan-1-ol	100
Cyclohexanone	Cyclohexanol	100

(1)

(2)

cis:*trans* = 7:3

(3)

Modifications.

Other ate complexes of the general formula LiCuHR (where R = *t*-Bu,[2] *i*-Pr,[2] 1-pentynyl,[2,4] *O*-*t*-butyl,[4] or PhS[4]) were prepared. The *n*-butyl ate complex is the most reactive hydride reducing agent. The use of THF as solvent provides no advantage,[2] whereas THF/HMPA is an effective solvent.[4]

Alternative Methods.

For a discussion of alternative methods for reductive removal of halogen, hydroxy, mesyloxy, or tosyloxy groups, see ***Copper(I) Iodide-Lithium Trimethoxyaluminum Hydride***.

For a discussion of alternative methods for reduction of aldehydes or ketones to alcohols, see ***Lithium Aluminum Hydride*** and related reagents, or ***Sodium Borohydride*** and related reagents.

For a discussion of alternative methods for 1,4-reduction of enones, see ***Copper(I) Bromide-Sodium Bis(2-methoxyethoxy)aluminum Hydride***.

Lithium *n*-Butyl(3-methoxy-3-methyl-1-butynyl)cuprate

(**1**; R = *n*-Bu)

[66777-74-0] · $C_{10}H_{18}CuLiO$ · Lithium *n*-Butyl(3-methoxy-3-methyl-1-butynyl)cuprate · (MW 224.77) (**2**; R = *t*-Bu)

[66777-76-2]

(mixed cuprate butyl transfer agents)

Preparative Methods: these reagents are prepared in situ by deprotonation of 3-methoxy-3-methyl-1-butyne with ***n-Butyllithium***, followed by addition of ***Copper(I) Iodide*** and then either ***t-Butyllithium*** or *n*-butyllithium.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive; use in a fume hood.

Butyl Transfer Agents.

The less expensive 3-methoxy-3-methyl-1-butyne was introduced as an alternative to *t*-butylacetylene for mixed cuprate reactions. Cuprates synthesized using this reagent maintain the same solubility profile, thermal stability, and ligand transfer preferences as obtained using *t*-butylacetylene. Lithium *n*-butyl(3-methoxy-3-methyl-1-butynyl)cuprate (**1**) underwent displacement reactions with cyclohexyl iodide and cinnamyl bromide in moderate yield, but produced a quantitative yield upon 1,4-addition to 2-cyclohexen-1-one. The much more sterically hindered lithium *t*-butyl(3-methoxy-3-methyl-1-butynyl)cuprate (**2**) also underwent 1,4-addition to 2-cyclohexen-1-one in excellent yield (eqs 1-4).[1]

(1)

(2)

(3)

(4)

Reagent (**1**) was used to study the reaction of cuprates with α-oxoketene dithioacetals.[2] Reaction of (**1**) with (**3**) gave a 92:8 (*E*)/(*Z*) ratio of addition products (**4**) in 55% yield, along with a 12% yield of reduction product (**5**) and 38% recovered (**3**) (eq 5). When (**1**) was reacted with the α-oxoketene dithioacetal (**6**) only the addition product (**7**) (89:11 *E*/*Z*) was obtained in 93% yield (eq 6).

(5)

(3) **(4)** **(5)** 12%

(E):*(Z)* = 92:8

(6)

(6) **(7)**

(E):*(Z)* = 89:11

During a study of the effects of trimethylsilyl halides on the structure and reactivity of higher order (HO) cuprates, it was discovered that addition of 2 equiv ***Chlorotrimethylsilane*** irreversibly transformed the HO cuprate (**8**) (R = Me) into the lower order (LO) cuprate (**9**) and 1 equiv ***Cyanotrimethylsilane*** and LiCl (eq 7).[3] To determine if (**9**) was the

reactive intermediate, TMSCl, TMSCN, and LiI were added to a solution of (**1**). 1,2-Addition to aldehyde (**10**) produced alcohols (**11**) and (**12**) in a 10-12:1 (*syn*:*anti*) ratio in high chemical yield (eq 8). This is analogous with the results obtained from reaction of (**10**) with HO cuprates using TMSX (X = Cl, Br, I, OTf) as an additive. No reaction between (**1**) and TMSCl could be detected by ^{1}H, ^{7}Li, or ^{29}Si NMR, leaving the role of TMSX in these reactions somewhat elusive.

Lithium *t*-Butyl-*t*-octylamide

[90702-60-6] · $C_{12}H_{26}LiN$ · Lithium *t*-Butyl-*t*-octylamide · (MW 191.33)

(relatively accessible hindered amide base)

Alternate Name: LOBA.

Preparative Methods: a variety of di-*t*-alkylamines which are more hindered than the commercially available ***2,2,6,6-Tetramethylpiperidine*** can be prepared by multistep routes;[1-4] the precursor to LOBA, 1,1,3,3-tetramethylbutyl-*t*-butylamine, is obtained in three steps from commercially available materials in an overall yield of 73%;[4] LOBA is prepared by metalation of this amine with ***Methyllithium***; metalation with BuLi occurs sluggishly, if at all.

Handling, Storage, and Precautions: lithium amide bases are reactive to air and water; use in a fume hood.

Selective Enolate Formation.

In a comparison with ***Lithium Diisopropylamide***, LOBA exhibits greater regioselectivity (eq 1) and greater stereoselectivity (eq 2) in the formation of ketone and ester enolates, as judged by an in situ quenching procedure using ***Chlorotrimethylsilane*** (TMSCl).[5,6]

Ester (**1**), an intermediate in a synthesis of pseudomonic acid C,[7] is converted by the Ireland-Claisen rearrangement,[8] using LDA, into a 4:1 mixture of epimers (**2**) and (**3**) (eq 3). ***Lithium 2,2,6,6-Tetramethylpiperidide*** and LOBA give higher selectivities (6:1 and 7:1, respectively) but the yield is much lower (<30%).

Related Reagents.

See entries for similar amide bases, e.g. ***Lithium Amide***, ***Lithium Diethylamide***, ***Lithium Diisopropylamide***, ***Lithium 2,2,6,6-Tetramethylpiperidide***, ***Potassium Diisopropylamide***.

Lithium *n*-Butyl(phenylthio)cuprate[1]

***n*-BuCu(SPh)Li**

[53128-68-0] · $C_{10}H_{14}CuLiS$ · Lithium *n*-Butyl(phenylthio)cuprate · (MW 236.80)

(primary heterocuprate capable of nucleophilic additions and substitutions[2])

Solubility: sol THF, ether.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[3] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl, and the yield of PhCO(*n*-Bu) is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: 1.0 equiv of ***n-Butyllithium*** is added dropwise to a 0.2 M, 0 °C THF solution of ***Thiophenol*** in a three-neck flask equipped with N_2 inlet, solid addition funnel, and rubber septum; after stirring for 10 min, 1.0 equiv of ***Copper(I) Iodide*** is added via the addition funnel; stirring for an additional 15 min provides a clear, yellow solution which is cooled to -78 °C; 1.0 equiv of *n*-BuLi is then added dropwise via syringe;[4,5] after 1 h, the light brown, opaque solution is ready for use. Alternate sources of PhSCu may be acceptable; PhSCu in purities of 95->98% is commercially available.[6]

Handling, Storage, and Precautions: use in a fume hood; best results are obtained with high-purity copper(I) salts,[7] dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides;[8] *n*-BuLi is pyrophoric,[9] and due care must be exercised in its handling; the reagent has greater stability in THF than in ether; thermal decomposition is minimal at or below -25 °C but is substantial at 0 °C.[3b]

This primary alkyl organometal reagent is representative of the heterocuprate class of organocopper reagents.[10] The *n*-Bu group is nucleophilically reactive, whereas the SPh group is not. Such nontransferable groups are called dummy ligands;[11] the SPh dummy ligand in particular provides enhanced thermal stability and solubility compared with the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than the corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when relatively high reaction temperatures are required, or when the organolithium used to form the cuprate is difficult or expensive to prepare.

Lithium *n*-butyl(phenylthio)cuprate has been used in nucleophilic substitution reactions of arenesulfonyl fluorides,[12] allylic acetates,[13] 9-BBN,[14] propargylic carbamates,[15] and bromoalkenes,[16] as well as in nucleophilic additions to

acetoxyepoxides.[17] It is a good choice for 1,4-addition of an *n*-Bu group, having been used in 1,4-addition-elimination reactions of α-oxoketene dithioacetals[4] and 3-halo-2-cycloalkenones,[18] and in tandem vicinal dialkylation reactions of 5-methyleneoxazolones[19] and alkynes.[20] A typical example is the use of the reagent in the stereospecific synthesis of (*Z*)-2-heptenoic acid from acetylene (eq 1).[20a]

Lithium Carbonate

Li_2CO_3

[554-13-2] · CLi_2O_3 · Lithium Carbonate · (MW 73.89)

(base for dehydrohalogenation reactions and halide displacements; reagent for regioselective alkylations)

Physical Data: mp 723 °C; bp 1310 °C; *d* 2.11 g cm^{-3}.

Solubility: sol cold (1 g/78 mL), hot H_2O (1 g/140 mL); insol alcohol, acetone.

Form Supplied in: white powder; widely available. *Drying:* details are available.[1]

Dehydrohalogenation.

Lithium carbonate in refluxing DMF is an excellent base for dehydrohalogenation reactions. LiCl in DMF caused rearrangement of the alkene to the more substituted α,β-position.[2] Treatment with a stronger base, lithium carbonate, led to good yields of the less substituted enone (eq 1). Substituted tropones have been prepared in a similar manner from alkyl-substituted tribrominated cycloheptanones (eq 2).[3]

(1)

(2)

Halide Displacement.

A preparation of steroidal oxetanones has been reported using Li_2CO_3 in refluxing DMF. It was found that either the *cis* or the *trans* bromides can give the α-oxetanone in good yield (eq 3).[4]

Alkylations.

Lithium carbonate used in conjunction with DMF and various alkylating agents has been found to regioselectively alkylate bisphenolic, 1,3-dicarbonyl, and thiol substrates that contain hydrogens that are more acidic than phenol (pK_a &AApprox; 8).[5] It has been determined that phenolic compounds containing electron-withdrawing groups alkylate at either the *ortho* or *para* positions exclusively (eq 4). Attempts to use other bases such as ***Potassium Carbonate*** or ***Sodium Carbonate*** showed a loss of selectivity. Using more reactive alkylating agents such as propargyl bromide (see under ***Propargyl Chloride***) or ***Benzyl Bromide*** also reduces the selectivity of alkylation. This sequence has been used to differentiate between the two hydroxyl groups present in alizarin (eq 5).[5]

1,3-Dicarbonyl compounds such as β-keto esters or β-diketones are sufficiently acidic to alkylate as well (eq 6).[5]

(6)

Thiophenoxyphenols have shown selectivity of alkylation with lithium carbonate. The more acidic S-H can be preferentially alkylated in deference to a phenolic O-H bond.[5] Using potassium carbonate in the same alkylation scheme gives only 4% of the desired product.

Base Assistance.

Spirocyclic ethers can be generated via intramolecular nucleophilic attack of hydroxide upon π-(allyl)palladium complexes (eq 7). The attack of an external nucleophile can then be directed for either *cis* or *trans* addition, depending on the concentration of nucleophile present.[6] In the presence of 3 equiv of Li_2CO_3, *cis* migration of acetate was the only reaction observed. Conversely, the addition of 1.8 equiv of chloride ion causes chloride to be added from the face opposite the metal.

Lithium Carbonate-Lithium Bromide

Li_2CO_3-LiBr

(Li_2CO_3)

[554-13-2] · CLi_2O_3 · Lithium Carbonate-Lithium Bromide · (MW 73.89) (LiBr)

[7550-38-8] · BrLi · Lithium Carbonate-Lithium Bromide · (MW 86.85)

(reagent for dehydrohalogenation of α-halo ketones)

Physical Data: see ***Lithium Carbonate*** and ***Lithium Bromide***.

Dehydrohalogenations.

The combination of lithium carbonate and lithium bromide has been found to be a powerful reagent for effecting the dehydrohalogenations of α-halo ketones.[1] A typical procedure involves heating of the halo ketone with a 1:1 mixture of lithium carbonate-lithium bromide in refluxing DMF. Frequently this procedure is used for the introduction of a conjugated alkene. This method has been shown in certain cases to be superior to other dehydrohalogenation methods. An interesting example is given by the dehydrobromination of dibromoacetoxyetiocholane (eq 1).[1]

(1)

Excellent yields (96%) of the 1,4-dienone were obtained using the carbonate-bromide pair. However, when ***Lithium Chloride*** in DMF was used as the base, a mixture of the 1,4- and 1,6-dienones was obtained. The same investigators have also observed that the use of shorter reaction times allows for the isolation of the monodebrominated compound

in lower yield without contamination from the didebrominated product (eq 2).[2]

This procedure was utilized by Grieco to prepare a key dienophile for a synthesis of quassin (eq 3).[3] The octalone is selectively brominated at the more substituted position and then dehydrobrominated to furnish the enone in excellent overall yield. A similar dehalogenation procedure was also attempted using collidine as the base, producing the enone in 40% yield.

This reaction has been employed in the synthesis of tuberiferin.[4] Selective bromination of the less substituted α-position, followed by treatment of the crude bromide with lithium carbonate-lithium bromide, produced the enone in good overall yield (eq 4).

This combination of reagents also proved to be valuable for the synthesis of dienones from enone precursors. A two-step sequence of halogenation-dehydrohalogenation was engaged to produce substituted cyclohexadienones (eq 5).[5] Bromination of the enone through its enol acetate, followed by base-induced bromide elimination, yields the dienone in 85% isolated yield. When the dehydrobromination was attempted using collidine, the dienone was produced in an attenuated 40% yield.

(5)

Paquette has recently applied this methodology towards an intermediate found useful for the synthesis of 18-oxo-3-virgenene (eq 6).[6] The overall yield for the sequential bromination-dehydrobromination was 71%.

(6)

Certain dienones can be prepared directly from ketones: dibromination of the ketone followed by bis-dehydrohalogenation yields the dienone. This methodology proved valuable in a synthesis of substituted homotropones (eq 7).[7]

(7)

A key dienone for the construction of linear tetraquinane intermediates used in the synthesis of fusiccosin and ophiobolin natural products was prepared by a similar protocol. Bromination of the enone with elemental bromide followed by exposure to the carbonate-bromide combination produced the dienone in acceptable yield (eq 8).[8]

(8)

This dehalogenation procedure has been documented to work effectively on α-chloro ketones as well. The protocol was employed in a synthesis of dihydrojasmone (eq 9).[9]

Lithium Chloride

LiCl

[7447-41-8] · ClLi · Lithium Chloride · (MW 42.39)

(source of Cl^- as nucleophile and ligand; weak Lewis acid that modifies the reactivity of enolates, lithium dialkylamides, and other Lewis bases)

Physical Data: mp 605 °C; bp 1325-1360 °C; *d* 2.068 g cm^{-3}.

Solubility: very sol H_2O; sol methanol, ethanol, acetone, acetonitrile, THF, DMF, DMSO, HMPA.

Form Supplied in: white solid, widely available. *Drying:* deliquescent; for most applications, drying at 150 °C for 3 h is sufficient; for higher purity, recrystallization from methanol, followed by drying at 140 °C/0.5 mmHg overnight, is recommended.

Handling, Storage, and Precautions: of low toxicity; take directly from the oven when dryness is required.

Source of Chloride Nucleophile.

The solubility of LiCl in many organic dipolar solvents renders it an effective source of nucleophilic chloride anion. Lithium chloride converts alcohols to alkyl chlorides[1] under Mitsunobu conditions,[2] or by way of the corresponding sulfonates[3] or other leaving groups.[4] This salt cleanly and regioselectively opens epoxides to chlorohydrins in the presence of acids and Lewis acids such as ***Acetic Acid***,[5] Amberlyst 15 resin,[6] and ***Titanium(IV) Chloride***.[7] In the presence of acetic acid, LiCl regio- and stereoselectively hydrochlorinates 2-propynoic acid and its derivatives to form the corresponding derivatives of (*Z*)-3-chloropropenoic acid.[8] Oxidative decarboxylation of carboxylic acids by ***Lead(IV) Acetate*** in the presence of 1 equiv of LiCl generates the corresponding chlorides.[9]

In wet DMSO, LiCl dealkoxycarbonylates various activated esters (eq 1).[10,11] If the reaction is performed in anhyd solvent the reaction generates a carbanion intermediate, which can undergo inter- or intramolecular alkylation or elimination. Other inorganic salts (NaCN, NaCl, ***Lithium Iodide***) and other dipolar aprotic solvents (HMPA, DMF) can also be employed. Under similar conditions, lithium chloride cleaves alkyl aryl ethers having electron-withdrawing substituents at the *ortho* or *para* positions.[12]

(1)

$X = CO_2R$, COR, CN, SO_2R; $R^3 = Me$, Et

Source of Chloride Ligand.

In palladium-catalyzed reactions, LiCl is often the reagent of choice as a source of chloride ligand. Lithium chloride is a necessary component in palladium-catalyzed coupling and carbonylative coupling reactions of organostannanes and vinyl triflates.[13,14] Lithium chloride has a dramatic effect on the stereochemical course of palladium-catalyzed 1,4-additions to 1,3-dienes.[15] Treatment of 1,3-cyclohexadiene with ***Palladium(II) Acetate*** and LiOAc and the oxidizing agents ***1,4-Benzoquinone*** and ***Manganese Dioxide*** affords 1,4-*trans*-diacetoxy-2-cyclohexene (eq 2). In the presence of a catalytic quantity of LiCl, the *cis* isomer is formed (eq 3). If 2 equiv LiCl are added, the *cis*-acetoxychloro compound forms (eq 4). These methods are general for both cyclic and acyclic dienes, and have recently been extended to the stereospecific formation of fused heterocycles.[16] Lithium chloride is also used in the preparation of ***Dilithium Tetrachloropalladate(II)***[17] and zinc organocuprate reagents.[18]

(2)

(3)

(4)

Weak Lewis Acid.

Lithium chloride is a weak Lewis acid that forms mixed aggregates with lithium dialkylamides, enolates, alkoxides, peptides, and related hard Lewis bases.[19] Thus LiCl often has a dramatic effect on reactions involving these species. In the deprotonation of 3-pentanone by ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LTMP), addition of 0.3 equiv LiCl increases the (*E*)/(*Z*) selectivity from 9:1 to 52:1 (eq 5).[20] Enhancement in the enantioselectivity of deprotonation of prochiral ketones by a chiral lithium amide has also been reported.[21] Lithium chloride stabilizes anions derived from α-phosphonoacetates, permitting amine and amidine bases to be used to perform Horner-Wadsworth-Emmons reactions on base-sensitive aldehydes under exceptionally mild conditions.[22] Lithium chloride and other lithium salts disrupt peptide aggregation and increase the solubilities of peptides in THF and other ethereal solvents, often by 100-fold or greater.[23] These effects render LiCl a useful additive in the chemical modification of peptides (e.g. by the formation and alkylation of peptide enolates).[19,24] Lithium chloride has also shown promise as an additive in solid-phase peptide synthesis, increasing resin swelling and improving the efficiencies of difficult coupling steps.[25]

Lithium Chloride-Diisopropylethylamine

LiCl-*i*-Pr_2NEt

(LiCl)

[7447-41-8] · ClLi · Lithium Chloride-Diisopropylethylamine · (MW 42.39) (*i*-Pr_2NEt)

[7087-68-5] · $C_8H_{19}N$ · Lithium Chloride-Diisopropylethylamine · (MW 129.28)

(lithium salt-amine base combination for Horner-Wadsworth-Emmons alkenation; alkylation of β-keto esters; palladium-catalyzed cross-couplings)

Physical Data: see ***Lithium Chloride*** and ***Diisopropylethylamine***.

Handling, Storage, and Precautions: the combination reagent is prepared in situ; use in a fume hood; see ***Lithium Chloride*** and ***Diisopropylethylamine*** for handling of each reagent.

Horner-Wadsworth-Emmons Alkenation.

The combination of LiCl and DIPEA (1:1 molar ratio) finds utility in the Horner-Wadsworth-Emmons alkenation involving base-sensitive compounds.[1] Treatment of aliphatic, α,β-unsaturated, and aromatic aldehydes with ***Triethyl Phosphonoacetate*** and LiCl-DIPEA (or ***1,8-Diazabicyclo[5.4.0]undec-7-ene***) in acetonitrile leads to high yields of (*E*) isomeric unsaturated esters (eq 1).

(1)

R	yield (%)	(*E*):(*Z*)
i-Pr	97	50:1
MeCH=CH	85	20:1
Ph	87	100:1

Treatment of the base-sensitive phosphonate (**1**) and aldehyde (**2**) with LiCl-DIPEA in acetonitrile at rt for 24 h affords the ketone (**3**) in high yields, with no evidence of epimerization at the α-position or self-condensation of the aldehyde (eq 2). Use of ***Sodium Hydride*** or ***Potassium t-Butoxide*** leads to much lower yields (0-34%).

(2)

(3)

β-Keto Ester Alkylations.

Ethyl Acetoacetate and ***Diethyl Malonate*** are monoalkylated in high yields using a 1:2 mixture of LiCl-DIPEA with ***Benzyl Bromide*** (1 equiv) in refluxing THF (eq 3).[2] The presence of the lithium cation is critical for a successful alkylation. Replacement of the lithium salt by NaCl or KCl leads to no alkylation products.[3] *O*-Alkylation does not take place under these reaction conditions; however, dialkylation occurs using acetonitrile as solvent. Acetylacetone does not alkylate under these reaction conditions.

(3)

Cross-Couplings.

The optimal conditions for a successful palladium-catalyzed cross-coupling between aryl halides and unsaturated epoxides involve 10% ***Palladium(II) Acetate***, *n*-Bu_4NCl (1 equiv), lithium formate (3 equiv), and the combination of LiCl (1 equiv) and DIPEA (3 equiv) at 50 °C in DMF. Following these optimized reaction conditions, the cross-coupling of iodobenzene and 4,5-epoxy-1-hexene (**4**) leads to a 79:21 mixture of (*E*):(*Z*) allylic alcohols (**5**) in 78% yield (eq 4).[4] The mechanism involves a palladium migration process.

Lithium Chloride-Hexamethylphosphoric Triamide[1]

$LiCl\text{-}(Me_2N)_3PO$

(LiCl)

[7447-41-8] · ClLi · Lithium Chloride-Hexamethylphosphoric Triamide · (MW 42.39) (HMPA)

[680-31-9] · $C_6H_{18}N_3OP$ · Lithium Chloride-Hexamethylphosphoric Triamide · (MW 170.24)

(chloride displacement reactions, dehydrohalogenation reactions, and decarboxylative alkylations)

Physical Data: see ***Lithium Chloride*** and ***Hexamethylphosphoric Triamide***.

Chloride Displacement.

In an early example, S_N2 attack of chloride ion on an (*S*)-tosylate produced the (*R*)-alkyl chloride in 62% yield with nearly complete inversion of stereochemistry (98% ee) without rearrangement of the neopentyl group (eq 1).[2] Allylic chlorides can be easily prepared from the corresponding allylic alcohols (eq 2).[3] Attempts to use a mesitoate nucleophile failed under these conditions.[4] In situ generation of the allylic tosylate and subsequent displacement by chloride led to good yields of allylic chlorides that were further used for Grignard coupling reactions. Utilization of these conditions precluded any formation of the tertiary halide via S_N2'-like reactions.

(1)

(2)

$R = CH_2CH_2CH(OMe)_2$

Dehydrohalogenation.

Lithium chloride, with HMPA as solvent and ***Lithium Carbonate*** as a buffer, has been used for large-scale dehydrobromination reactions to prepare 1,3-cyclohexadiene (eq 3).[5] The same reaction sequence has been used to prepare a mixture of two deuterium-labeled cyclohexadienes that have been further reacted with ***Maleic Anhydride*** to prepare labeled Diels-Alder adducts (eq 4).[5]

(3)

(4)

A similar protocol has been used in more substituted examples to provide substrates that can be utilized for bis-epoxidation (eq 5).[6] Diepoxide compounds of this type are novel antitumor agents.

(5)

Decarboxylative Alkylation.

It has been reported that the decarboxylation of β-diesters with LiCl and HMPA provided evidence that it was possible to alkylate the putative anion with various electrophiles such as ***Benzyl Bromide***.[7] Further, it was shown that replacement of HMPA with ***Dimethyl Sulfoxide*** as the solvent retarded the rate of the reaction. The use of any base other than LiCl gave poorer yields.[8] β-Vetivone has been prepared utilizing an intramolecular alkylation via an anion derived from the induced decarboxylation of a β-keto ester (eq 6).[9] Similar results can be achieved using ***1-Methyl-2-pyrrolidinone***, but replacement of this solvent with ***N,N-Dimethylformamide*** resulted in a substantial reduction in yield.

Lithium Chloroacetylide[1]

Cl-C&tbond;C-Li

[6180-21-8] · C_2ClLi · Lithium Chloroacetylide · (MW 66.41)

(nucleophilic organolithium reagent capable of reacting with a variety of electrophiles[2,3])

Alternate Name: chloroethynyllithium.

Solubility: sol ether.

Preparative Method: prepared in ether solution under anhyd conditions by treatment of *cis*- or *trans*-1,2-dichloroethylene with 2 equiv ***Methyllithium*** at 0 °C under N_2.[2]

Handling, Storage, and Precautions: dry lithium chloroacetylide is explosive (as are the other metal haloacetylides), but may be safely handled and kept in the solution in which it is prepared under N_2.

Lithium chloroacetylide reacts with aldehydes and ketones in good yield to form chloroethynyl substituted carbinols (eq 1).[1-3] Alkylations, silylations, and stannylations all proceed well.[1] Other electrophiles such as ***Carbon Dioxide*** and α-naphthyl isocyanate also produce the expected addition products.[2]

(1)

A protected tetrahydroxylactone is reported to give the monoaddition product (eq 2).[4] Reaction with ***Methyl Chloroformate*** at -78 °C can be used to prepare methyl chloropropiolate (eq 3).[2,5] In this reaction, explosions have occurred in more than one instance, possibly due to the formation of tris(chloroethynyl)carbinol.[5,6]

(2)

(3)

Lithium chloroacetylide has been used in coupling reactions. In the presence of ***Copper(I) Iodide***, coupling to ***Allyl Bromide*** was observed (eq 4).[7] When treated with cyclohexenylzinc bromide, lithium chloroacetylide gives 2-cyclohexenylacetylene (43%) and 1,1-bis(2-cyclohexenyl)ethylene (16%), in analogy to its reactions with other allylic organozinc compounds (eq 5).[8]

(4)

(5)

The chloroacetylides of Na, K, and Ca have also been prepared, as well as some bromo and fluoro analogs.[9] All these chloroacetylides react with the organohalides of Al, Sn, Pb, As, Sb, or Bi to exchange the metal (e.g. eq 6)[3,10]

(6)

Suzuki et al.[11] have used lithium chloroacetylide to prepare lithium 2-chloroethynyltrialkylborates, which react with ***Iodine*** to give the corresponding symmetric alkynes (eq 7).

Related Reagents.

Dilithium Acetylide; ***Dipotassium Acetylide***; ***Ethynylmagnesium Bromide***; ***Lithium Acetylide***; ***Lithium (Trimethylsilyl)acetylide***.

Lithium Cyanide

LiCN

[2408-36-8] · CLiN · Lithium Cyanide · (MW 32.96)

(synthesis of nitriles from halides, alcohols, aldehydes, ketones; synthesis of cyanohydrins; deoxygenation of ketones)

Physical Data: mp 160 °C, *d* 1.025 g cm^{-3};[1] hygroscopic solid.

Solubility: sol H_2O, DMF, THF.

Form Supplied in: solid or 0.5 M solution in DMF.

Preparative Methods: from ***Lithium*** metal and ***Silver(I) Cyanide***,[2] from lithium hydride and ***Hydrogen Cyanide***,[3] or, more conveniently, from ***Acetone Cyanohydrin*** and lithium hydride.[4]

Handling, Storage, and Precautions: moisture-sensitive; like ***Sodium Cyanide*** and ***Potassium Cyanide***, LiCN is highly toxic; use in a fume hood.

Nitriles (from Halides).

Nitriles can be prepared from halides (Br or I) under nonaqueous conditions using LiCN in refluxing THF for 1 h (seven examples; >90% yields).[5] A simple alkyl chloride gave only a 50% yield after 18 h (one example).

Nitriles (from Alcohols).

The quantitative conversion of a tosylate to a nitrile (one example) in refluxing THF has been reported.[5]

Manna et al. have reported the conversion of alcohols to nitriles using LiCN under Mitsunobu conditions (***Diethyl Azodicarboxylate*** and ***Triphenylphosphine***; two examples, 50% yields).[6]

β-Hydroxynitriles (from Epoxides).

Ciaccio et al. have reported the preparation of β-hydroxynitriles from epoxides using LiCN in 60-88% yield (10 examples; eq 1).[7] Cycloalkene oxides gave exclusively the *trans*-hydroxynitriles. Monosubstituted epoxides were

reported to give exclusive attack at the less substituted carbon. Acetals, alkenes, and *t*-butyldimethylsilyloxy groups were shown to be stable to the reaction conditions. After an aqueous extractive workup or passage through a plug of Florisil, the crude compounds are reported to be pure by TLC, IR, and ^{1}H and ^{13}C NMR analysis.

(1)

Previously, in a synthesis of a dideoxynucleoside, Matsuda et al. reported the opening of an epoxide with LiCN in refluxing THF; however, LiCN in DMF gave intractable mixtures.[8]

Alkylsilyl Cyanides.

LiCN is reported to be the method of choice for the preparation of alkylsilyl cyanides from the corresponding chlorides.[4,9] Both dialkylsilyl[9] and trialkylsilyl[4,9] cyanides have been reported.

Cyanohydrins.

Yoneda et al. have reported the preparation of trialkylsilyl cyanohydrins and acyl cyanohydrins from aldehydes and ketones.[10,11] Addition of LiCN to a THF solution of the carbonyl compound and ***Benzoyl Chloride*** (nine examples),[10] ***Acetyl Chloride*** (five examples),[10] ***Chlorotrimethylsilane*** (six examples),[10] or ***t-Butyldimethylchlorosilane*** (eight examples),[11] followed by stirring at rt, results in the appropriate cyanohydrin (eq 2). Yields ranged from 47 to 100% (generally >80%; distillation or column chromatography).

(2)

Conjugate Additions.

Treatment of 4-cholesten-3-one with lithium cyanide (THF, 16 h, reflux) gives 5-cyanocholestan-3-one (80%, 5α:5β-cyano = 3:1).[5]

Cyanophosphates.

Aldehydes and ketones react rapidly with LiCN and ***Diethyl Phosphorocyanidate*** (DEPC) in THF to form

cyanophosphates (eq 3).[12] These cyanophosphates can serve as intermediates in the synthesis of structurally diverse nitriles. These syntheses are discussed in the appropriate sections below.

(3)

α,β-Unsaturated Nitriles.

Several procedures have appeared for the preparation of α,β-unsaturated nitriles using LiCN as a reagent (e.g. eq 4; six examples; 61-94%; column chromatography).[12] A cyanophosphate when treated with ***Boron Trifluoride Etherate*** will undergo elimination to form the α,β-unsaturated nitrile. However, in the compounds examined, this elimination only occurs if R^1 is an aromatic group. If R^1 is an alkyl group, the cyanophosphate does not eliminate. This reaction has been used in the synthesis of lysergic acid and related compounds.[13,14]

(4)

A second synthesis of α,β-unsaturated nitriles, also from ketones, has been reported (eq 5).[15] Reaction of a ketone to form the vinyl trifluoromethanesulfonate is followed by treatment of the triflate with LiCN, ***Tetrakis(triphenylphosphine)palladium(0)***, and ***12-Crown-4*** to give the α,β-unsaturated nitrile. This procedure may provide an alternative to the procedure of Harusawa, since an aromatic ketone is not required. Eight examples (all cycloalkyl ketones) were given, including one β-keto ester and two α,β-unsaturated ketones. Isolated yields (chromatography or distillation) were 59-87%.

(5)

A similar transformation on an *O*-triflyl imidate has been reported to occur without the need for transition metal catalysis (eq 6).[16]

A synthesis of α-methylenenitriles has been reported (eq 7).[17] Treatment of an *N*-(*p*-tolylsulfonyl)vinylsulfoximine with LiCN in DMF for 1 h at rt gave 63-81% yields of the α-methylenenitriles (three examples).

β,γ-Unsaturated Nitriles.

Aldehydes and ketones can be transformed into β,γ-unsaturated nitriles.[18] Treatment of the cyanophosphate derived from the carbonyl compound with ***Samarium(II) Iodide*** in THF gives the β,γ-unsaturated nitrile in 60-94% yield (eq 8; column chromatography; 14 examples).

Nitriles (from Carbonyl Compounds).

Cyanophosphates can be used to prepare nitriles by treating them with either lithium in liquid ammonia (seven examples; 72-91% yields; column chromatography)[19] or samarium iodide (12 examples; 61-95%; column chromatography) (eq 9).[18] The Li/NH_3 reduction should be carried out at -78 °C; when the reaction is done in refluxing NH_3, reduction of the cyanophosphate to a methylene group can be the major product (see below).[20]

(9)

If one of the R groups is aromatic, then hydrogenation with a Pd catalyst will also give nitriles (two examples; 75, 81%).[21]

Deoxygenation of Ketones.

Cyanophosphates have also been used for the deoxygenation of α,β-unsaturated ketones and aromatic ketones (eq 10; five examples; 80-99%; no chromatography) by treatment with lithium in liquid ammonia.[20] As noted above, this reaction should be carried out in refluxing NH_3; at lower temperatures, reduction to the nitrile predominates. The reduction to the alkene is reported to be free of double bond isomerization or migration.

(10)

Allenic Nitriles.

Treatment of a cyanophosphate (derived from an α,β-alkynyl ketone) with a higher-order cuprate gives trisubstituted allenes (eq 11; three ketone and one aldehyde examples; five cuprate examples; 32-87%; column chromatography).[22]

Lithium Cyano(dimethylphenylsilyl)cuprate

$Me_2PhSiCuCNLi$

[75583-56-1] · $C_9H_{11}CuLiNSi$ · Lithium Cyano(dimethylphenylsilyl)cuprate · (MW 231.79)

(organometallic reagent for the silylcupration of enones, alkynes, and strained alkenes)

Solubility: sol ether, THF from -78 to 25 °C.

Preparative Method: the title reagent (**1**), as well as lithium cyano(trimethylsilyl)cuprate *[81802-36-0]*, can be prepared from the corresponding silyllithium species and 1 equiv ***Copper(I) Cyanide*** in ether or THF at -78 to -5 °C;[1,2] the precursor silyllithium (**2**) is generated by the reaction of ***Chlorodimethylphenylsilane*** with ***Lithium*** metal in THF or ether (eq 1).

Handling, Storage, and Precautions: thermally stable up to ambient temperatures; oxygen- and moisture-sensitive; use in a fume hood.

Structure and Properties.

Low-temperature ^{29}Si, ^{13}C, and ^{1}H NMR spectroscopic techniques have been used to probe the structure of (**1**),[2] which is referred to as a lower-order cuprate. When 2 equiv of the silyllithium (**2**) are combined with 1 equiv copper(I) cyanide, a new reagent, referred to as a higher-order cuprate, is generated (see ***Dilithium Cyanobis(dimethylphenylsilyl)cuprate***).[3] Evidence for the different cuprate structures comes from separate signals in the ^{29}Si and ^{13}C spectra.[2]

Conjugate Additions to Enones.

Reagent (**1**) effectively adds the dimethylphenylsilyl group to α,β-unsaturated ketones, esters, and alkynic analogs. In a typical case, (**1**) adds to cyclohexenone in ether at -78 °C in 58% yield (eq 2).[2]

(2)

The analogous trimethylsilylcuprate (**3**) adds to ethyl-2-butynoate at 0 °C to give a mixture of stereoisomers, while the higher-order species reacts at -78 °C to yield a single geometrical isomer (eq 3).[4]

(3)

The lower-order silyl cuprates are apparently less reactive than the higher-order cuprates in conjugate addition reactions. Reagent (**1**) has been added in an addition-elimination sequence to an alkylidenemalonate system as a route to vinylsilanes (eq 4).[5]

(4)

This reaction was a prelude to a more elaborate scheme for producing more substituted vinylsilanes. The product of eq 4 further reacted with a geminal diorganometallic species to yield an (*E*)/(*Z*) (86:14) mixture of a vinylsilane (eq 5).

Alkylations with Allyl Halides.

The enhanced reactivity of allyl halides is reflected in the reactions of both (**1**) and (**3**). Thus (**1**) reacts with 2-*t*-butylsulfonylallyl bromide at low temperatures (eq 6).[6]

Reagent (**3**) can be employed in the preparation of the 2-bromoallylsilane (eq 7).[7]

Silylcuprations of Unsaturated Systems.

Carbocupration of alkynes is a major synthetic route to substituted alkenes. With (**1**), additions to terminal alkynes usually lead to regioisomeric vinylsilanes (eq 8).[2,8] In contrast to the lower-order cuprates, the corresponding higher-order cuprates generally are regioselective for the generation of the 1-silyl-substituted vinylsilanes (98:2 ratio).

(8)

The regioselectivity of the addition of the title reagent (**1**) to 1,2-allenes, such as 1,2-undecadiene, is much more favorable for silylation at the 1-carbon atom. In fact, the major regio- and stereoisomer produced is the (*Z*)-1-dimethylphenylsilyl-2-undecene (eq 9).[9]

(9)

In general, (**1**) does not add to unactivated alkenes. However, strained bicyclic alkenes do undergo silylcupration with the reagent. The [2.2.1] bicyclic ethers (**4**) react with (**1**) at 0 °C, ultimately giving substituted 1,3-cyclohexadienes (**7**) via intermediates (**5**) and (**6**). The latter intermediate undergoes a Peterson alkenation to give (**7**) (eq 10).[10]

(10)

$R^1 = Me$, $R^2 = H$ (81%)
$R^1 = Me$, $R^2 = Me$ (83%)

Silylcupration of the oxabicyclic ketone (**8**) takes a different course, in that the bridged oxygen system is not cleaved.

Instead, the initial *exo* adduct (**9**) produces a cyclobutanol product (**10**) exclusively (eq 11).[11]

In the same [3.2.1] bicyclic ether system with methyl substitution α to the carbonyl, (**1**) adds to the double bond without cyclobutanol formation (eq 12). With the monomethylated ketone (**11**) an 8:1 mixture of regioisomers is produced, with (**12**) predominating.

(11) $R^1 = Me$, $R^2 = H$ **(12)** $R^1 = Me$, $R^2 = H$

By allowing the above reaction to proceed for extended periods of time, the corresponding cyclobutanol product derived from (**11**) is favored, while with the dimethyl ketone (**13**) ($R^1 = R^2 = Me$), no cyclobutanols are formed. Intermediate cuprates (**9**) derived from higher-order cuprate additions may be trapped with ***Iodomethane***, acid, or hydroxyl groups (eq 13).

In summary, the lower-order cyanotrialkylsilylcuprates (**1**) and (**3**) react as do most carbon-based cuprates in conjugate additions and carbocupration processes. These reagents are less basic than higher-order cyanocuprates, and less reactive with some less electrophilic partners.

Related Reagents.

Lithium Cyano(methyl)cuprate

MeCuCNLi

[41753-78-0] · C_2H_3CuLiN · Lithium Cyano(methyl)cuprate · (MW 111.55)

(regioselective organocuprate reagent for the 1,4-addition of a methyl group to vinyl epoxides and enones)

Solubility: sol ether at -20 °C; precipitates from solution at -78 °C.

Preparative Method: an ether solution of low-halide ***Methyllithium*** is added to 1 equiv of anhyd ***Copper(I) Cyanide*** at -78 °C;[1] in order to maximize the 1,4-addition mode of lithium cyano(methyl)cuprate to vinyl epoxides, commercial methyl lithium with no halide present should be used.

Handling, Storage, and Precautions: thermally stable up to a temperature of about 0 °C; more stable than most organocuprates at rt or 0 °C; oxygen- and moisture-sensitive.

Ring Opening Reactions of Epoxides.

One of the first reports of the use of the cyano ligand in cuprates came from the work of Acker[2] in the ring opening of simple epoxides (eq 1). As predicted, the cuprates added regiospecifically to the less-substituted carbon atom of the epoxide.

(1)

The regioselectivity of cyanocuprates can be further demonstrated with the reaction of the reagent (**1**) with the bis-epoxide (**2**).[3] With 1 equiv of reagent at -78 °C, the less-hindered pendent epoxide is opened selectively to form (**3**), which can then undergo intramolecular ring openings of the cyclic oxirane to produce the bicyclic ether (eq 2).

(2)

(2) (3) 58% 38%

In an interesting ring opening of an epoxide derived from an allylic alcohol, 3 equiv of (**1**) reacted with the epoxy alcohol (**4**) to produce the diol (**5**), which was an intermediate in the synthesis of (+)-*exo*-brevicomin (eq 3).[4]

(3)

(4) (5)

While it had been well known that homoorganocuprates add in a 1,4-manner to acyclic vinyl epoxides,[5] reactions of ***Lithium Dimethylcuprate*** with cyclic vinyl epoxides gave mixtures of 1,2 and 1,4 ring-opened products.[6] The greater reactivity of cyclic vinyl epoxides usually resulted in the competitive 1,2 ring opening. In 1979 it was recognized that the cyanoalkylcuprates in ether regioselectively added 1,4 to cyclic vinyl epoxides.[1] A typical example of this selectivity is shown for the reaction of (**1**) with 1,3-cycloheptadiene monoepoxide (eq 4). These reactions must be done in ether and not THF in order to observe the selective 1,4-addition.

(4)

In the case of the 1,3-cyclohexene monoepoxide, only the 1,4-adduct is observed with *trans* stereochemistry. Lithium methyl acrylate cuprates transfer a methyl group to these epoxides with even greater regioselectivity (97:3). The conclusion reached is that the strongly electron-withdrawing cyano and acrylate ligands are responsible for this enhanced regioselectivity.[1] This ligand effect exhibited by the cyano group is general for all cyanoalkylcuprates.

Other examples of the 1,4-addition of (**1**) include the *exo*-methylene epoxide (**6**) (eq 5).[7] The product of this reaction (**7**) was used as an intermediate in the synthesis of the pheromone α-multistriatin.[8]

(5)

The unique ability of the cyano group to direct the ring openings of cyclic vinyl epoxides in a *trans*-1,4 manner provided new methodology for the synthesis of chiral molecules. The reiterative sequence of cyclohexadiene monoepoxides reacting with cyanocuprates allowed for the introduction of three stereocenters within the cyclohexene ring, as outlined in eq 6.[9]

(6)

A further variation in the 1,4-additions of cyanocuprates to vinyl epoxides comes from the use of enol ethers derived from α,β-epoxy ketones as the vinyl component of the vinyl epoxide system.[9] This strategy places an alkyl group α to a ketone in an umpolung manner, as illustrated for α,β-epoxycyclohexanones in eq 7.[10]

The use of a silyl enol ether in a cyclopentanone epoxide system was the basis for a synthesis of prostaglandins.[11] A simple version of this ring opening is shown in eq 8 for (**1**) and enol ether epoxide (**8**) to give the hydroxycyclopentanone (**9**).

In addition to the silyl enol ethers of ketones, enol phosphates of epoxy ketones undergo the regioselective 1,4 ring openings with (**1**).[11] In the epoxycyclopentanone system, the enol phosphate (**10**) is prepared from the ketone with ***Lithium Diisopropylamide*** and ***Diethyl Phosphorochloridate*** at -78 °C. Reaction of (**10**) with (**1**) gives exclusively the 1,4-product (**11**) in 94% yield (eq 9).

(9)

An additional advantage of the enol phosphates is that the phosphate unit may be reductively removed to produce an alkene.[8] This last process was used in the synthesis of α-multistriatin via intermediate (**12**) (eq 10).

(10)

Reactions with Allylic Acetates.

The reagent (**1**) is also very effective in the allylations of allylic acetates and benzoates in an S_N2' sense. The reaction of (**1**) with the allyl acetate (**13**) proceeds in high yield to produce a mixture of the substituted enyne (**14**) and the allene (**15**) (eq 11).[12] The latter product results from addition of the cyanocuprate to the propargyl acetate system.

In another example, (**1**) added cleanly to the bis-allyl benzoate (**16**) to give the diene (**17**) (eq 12).[13]

An example of the cyanocuprate (**1**) undergoing a conjugate addition to an allenyl sulfone is shown in eq 13. The allenyl *p*-tolyl sulfone is converted to the allyl sulfone (**18**) in good yield.[14]

Lithium Cyclopropyl(phenylthio)cuprate[1]

[84180-46-1] · $C_9H_{10}CuLiS$ · Lithium Cyclopropyl(phenylthio)cuprate · (MW 220.72)

(heterocuprate useful in 1,4-addition-elimination reactions[2] and annulations[3])

Solubility: sol THF; less sol ether.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl, and the yield of cyclopropyl phenyl ketone is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Method: cyclopropyllithium[5,6] is prepared by cooling a 0.25 M THF solution of bromocyclopropane under Ar to -78 °C; dropwise addition of 1.0 equiv of a solution of ***s-Butyllithium*** is followed by stirring for 2 h; this cyclopropyllithium solution is transferred by cannula to a stirred, -78 °C THF slurry of ***Phenylthiocopper(I)***[7] under Ar; the resultant mixture is warmed to -20 °C; a clear, light brown solution of cuprate forms after stirring for 20 min; it is cooled to -78 °C and is used directly.[8]

Handling, Storage, and Precautions: best results are obtained with PhSCu prepared from high purity Cu^I salts,[9] dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides;[10] *s*-BuLi is pyrophoric;[11] care must be exercised in its handling, and a fume hood should be used; the reagent is more stable than lithium dicyclopropylcuprate, which decomposes upon prolonged standing at -78 °C.[5]

This cyclopropyl organometal reagent is representative of the heterocuprate class of organocopper reagents.[12] The cyclopropyl group is nucleophilically reactive, whereas the SPh group is not. The nontransferable SPh group, or dummy ligand,[13] provides enhanced thermal stability and solubility compared with the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than the corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when higher reaction temperatures are required, or when the organolithium used to form the cuprate is difficult or expensive to prepare.

Lithium cyclopropyl(phenylthio)cuprate has been used in 1,4-addition-elimination reactions with α-oxoketene dithioacetals[14] and 3-halo-2-alkenones.[8,15] The latter substrates yield 3-cyclopropyl-2-alkenones which undergo high-yield thermal ring expansions, providing a two-step, five-membered ring annulation method.[8] Bicyclo[4.3.0]-1-nonen-2-ones (eq 1) and bicyclo[3.3.0]-1-octen-2-ones of use in the synthesis of zizaene-type sesquiterpenoids can be

prepared.[8] Spiro[4.5]-1-decen-6-ones and spiro[4.4]-1-nonen-6-ones, which provide access to vetivane-type sesquiterpenoids, also can be prepared.[15]

Lithium Diallylcuprate[1]

$(CH_2{=}CHCH_2)_2CuLi$

[21500-57-2] · $C_6H_{10}CuLi$ · Lithium Diallylcuprate · (MW 152.63)

(allylating reagent; undergoes conjugate addition reactions[1a,b,d] and substitution reactions[1a,c,d])

Alternate Name: lithium di(2-propenyl)cuprate.

Physical Data: ^{13}C NMR δ 150, 91, 24.[2b]

Solubility: sol THF, Et_2O.

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***[2a,3a] or $CuI.SBu_2$[3b]) under N_2 or argon atmosphere (see ***Lithium Dimethylcuprate***) and ***Allyllithium***[3a,3c] which is prepared from ***Allyltributylstannane*** or ***Tetraallylstannane*** and ***Phenyllithium*** or ***n-Butyllithium***.

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Introduction.

Lithium diallylcuprate displays the characteristic reactivity patterns of lithium diorganocuprates (see e.g. ***Lithium Di-n-butylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***). The very high reactivity of $(CH_2{=}CHCH_2)_2CuLi$ is sometimes problematic, and allylcopper reagents can be more effective (see ***Allylcopper***).[3a]

Addition Reactions.

Lithium diallylcuprate reacts with α,β-alkenyl ketones (eq 1),[1,9] lactones,[4] esters,[5] nitriles,[6] lactams (eq 2),[7] and phosphonates[8] with conjugate transfer of the allyl ligand. Addition of ***Chlorotrimethylsilane*** can accelerate the conjugate addition reaction and results in improved yields.[9]

(1)

(2)

The reagent adds stereoselectively (*cis* addition) to α,β-alkynoates, affording 2,5-dienoates (eq 3).[10] Dienyl esters and dienyl nitriles exclusively afford 1,6-addition products in good yields.[6] Diethyl 2-vinyl-1,1-cyclopropanedicarboxylate gives mixtures of 1,5- and 1,7-addition products.[11] Tandem conjugate addition-enolate trapping is a powerful synthetic method, although additives[12] and solvent changes are sometimes required. Conjugate addition of the reagent to ketoketenimines affords β-enamino ketones under mild reaction conditions.[13] 1-Alkoxycarbonylpyridinium halides undergo both 1,2- and 1,4-addition reactions, leading to regioisomeric dihydropyridines (eq 4).[14] Lithium diallylcuprate reacts with α,β-enals in the presence[15] of TMSCl to give the 1,2-addition products regioselectively.

(3)

Substitution Reactions.

Lithium diallylcuprate participates in substitution reactions with alkyl halides,[2a] carboxylates,[16] and sulfonate esters.[17] Secondary tosylates undergo the substitution reaction with clean inversion of configuration; the reaction is greatly facilitated when a heteroatom (e.g. O, S) is proximate to the nucleofugal substituent and elimination pathways are minimized (eq 5).[18] 4-Bromo-2-butenyltributylphosphonium salts undergo substitution reactions with the reagent, with formation of an ylide which can react with aldehydes to afford dienes.[19] Allylic ammonium salts participate in *syn*-S_N2' pathways with good stereo- and regioselectivity (eq 6).[20]

Miscellaneous Reactions.

1-Cyclooctenyl phenyl sulfones fail to undergo conjugate addition with lithium diallylcuprate, instead affording reduction products.[21]

Related Reagents.

Lithium Bis(1-ethoxyvinyl)cuprate; ***Lithium Diisopropenylcuprate***; ***Lithium Bis(1-methoxyvinyl)cuprate***; ***Lithium Di-(E)-1-propenylcuprate***; ***Lithium Divinylcuprate***; ***Lithium Divinylcuprate-Tributylphosphine***.

Lithium 4,4´-Di-*t*-butylbiphenylide[1]

[61217-61-6] · $C_{20}H_{26}Li$ · Lithium 4,4´-Di-*t*-butylbiphenylide · (MW 273.40)

(reductive lithiations of thiophenyl ethers,[11] carbonyl groups,[23] phosphinates;[25] generation of alkyllithiums,[2] α-lithio ethers,[3] allyllithiums,[17,18] β-,γ-,δ-lithio alkoxides;[19] propellane bond cleavage[22])

Alternate Name: LDBB.

Solubility: sol THF

Preparative Methods: anhydrous THF and 4,4´-di-*t*-butylbiphenyl (DBB) are cooled to 0 °C under a blanket of argon and stirred with a glass-coated stirring bar; ***Lithium*** foil (or ribbon) is added in portions and the mixture is stirred for 5 h at 0 °C; the appearance of the deep blue-green radical anion appears within 5 min.

Handling, Storage, and Precautions: LDBB will slowly decompose at room temperature.

Reductive Lithiation.

There are several advantages for using LDBB over the traditional ***Lithium Naphthalenide*** or ***Sodium Naphthalenide*** (LN, NaN). LDBB is a more powerful reducing agent than the alkali naphthalenides and the resulting carbanion will be trapped as an organolithium. The high steric environment of the *t*-butyl groups lead preferentially to electron transfer and to little or no radical combination. This is in contrast to LN, where alkylation of naphthalene is frequently observed. Another advantage is the ease in separation of nonvolatile DBB from the reaction mixture.[2]

LDBB has been used in place of ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN), leading to slightly higher yields of the desired products or when reaction conditions dictate.[3]

Alkyllithiums.

The conversion of alkyl halides to alkyllithiums is highly effective with LDBB. The corresponding hydrocarbons can be formed in high yields upon the addition of H_2O (eq 1).[2]

(1)

The alkyllithiums can be trapped by a variety of electrophiles including aldehydes (eq 2),[4] carbon dioxide (eq 3)[5] and aryl groups (eq 4).[6] The use of LDBB to generate the organolithium in the latter example proved critical since other methods (***n-Butyllithium***, ***t-Butyllithium***, ***s-Butyllithium***, and ***Methyllithium***) led to lower yields and longer reaction times. One possible reason for the enhancement in organolithium activity may be a result of lowered aggregation.[6]

(2)

(3)

(4)

The geminal dilithio species can also be generated and trapped with electrophiles in good yields (eqs 5 and 6).[7]

(5)

(6)

The generation of alkyllithium (**1**) proved pivotal in the enantioselective synthesis of spiculisporic acid.[8] Derived from the corresponding alkyl bromide, this homoenolate equivalent could not be made from lithium metal and the corresponding Grignard reagent led to the wrong isomer.

(1)

Reductive Lithiation of Thiophenyl Ethers.

A variety of thiophenyl ethers are reduced with LDBB and can be trapped with electrophiles, leading to 1-substituted bicyclo[1.1.1]pentanes[9] and vinyl substituted compounds (eqs 7 and 8).[10] The latter procedure to generate the alkenyllithium is a better and more cost efficient route than the Bond modification of the Shapiro reaction. The cuprate reagent from both the bicyclo[1.1.1]pentane and alkenyl compounds can be generated and reacted with electrophiles.

(7)

(8)

Homoenolate (**2**) is produced from the reductive lithiation of the corresponding phenylthio derivative and can be reacted with many electrophiles in high yields (72-83%).[11]

(2)

(3)

The use of LDBB was advantageous in the total synthesis of (+)-(9*S*)-dihydroerythronolide A, converting the thiophenyl group in (**3**) to an alkyllithium and then to a Grignard reagent.[12]

An unusual 1,4 O -> C silicon shift was observed when a tris(trimethylsilyl) ether was treated with LDBB to yield the *scyllo*-tris(trimethylsilylmethyl)cyclohexanetriol.[13]

α-Lithio Ethers.

The generation of α-lithio ethers can be performed using LDBB followed by trapping with electrophiles. The α-lithio ethers of 1-methoxy-1-phenylthiocyclopropanes are reacted with conjugated aldehydes or ketones to yield 1-cyclopropylallyl alcohols. The addition of ***Trifluoromethanesulfonic Anhydride*** led, after rearrangement, to 2-vinylcyclobutanones (eq 9).[3a] Previous investigations of these cyclopropanes used LDMAN for reductive lithiation, which led to lower yields of the alcohol and, for acid sensitive compounds, significant drops in yield.

The reductive lithiation of 2-(phenylthio)tetrahydropyrans led selectively to the axial 2-lithio species which, upon equilibration, could be converted to the more thermodynamic equatorial α-lithio ether. Treatment with electrophiles such as acetone led to good yields of products (eq 10).[3b] The use of LDBB led to higher yields and cleaner reductions compared with LDMAN or LN.

The placement of a vinyl group at the 6-position on the tetrahydropyran moiety and addition of LDBB leads to competing [1,2] and [2,3] Wittig rearrangements, with inversion of configuration at the lithium bearing carbon (eq 11).[14] A *t*-butyl group at position 4 significantly changes the reaction course, leading to a small amount of [2,3] Wittig rearranged product. The major product is derived from a 1,4-transannular H-transfer to the lithium-bearing carbon, with inversion of configuration.[15]

(Dialkoxymethyl)lithium compounds can be generated from the corresponding phenylthio derivative and reacted with aldehydes and ketones (eq 12).[16] The cyclic lithium reagent could be generated from LN, while the acyclic required LDBB.

Allyllithiums.

The treatment of allyl phenylthio ethers with ***Lithium 1-(Dimethylamino)naphthalenide*** leading to allyllithiums has been performed. Allyllithiums derived from treatment with LDBB can be converted to the allylcerium reagent and trapped with unsaturated aldehydes. Homoallylic alcohols were obtained by 1,2-addition with attack by the least substituted terminus of the allyl anion (eq 13).[17] Regiocontrol of the double bond is attained by a slight temperature modification.

(13)

The ability to control the regiochemistry of allyllithium terminus and double bond geometry led to a one-pot synthesis of the Comstock mealy bug sex pheromone in a 45% yield, and a four-step synthesis of the California red scale pheromone in 23% yield.[18]

β-,γ-,δ-Lithio Alkoxides.

The treatment of epoxides with LDBB leads to β-lithio alkoxides which can be reacted with an aldehyde or ketone to yield varying amounts of a diol and an alcohol.[19] The diol is obtained from cleavage of the least substituted carbon oxygen bond, while the other alcohol arrives via a hydride transfer (eq 14). Reductive lithiation of vinyloxiranes led to ring opening in the opposite direction. The allylic anions could be treated with Ti^{IV} or Ce^{III} and added to aldehydes at the most or least substituted terminus, respectively.

(14)

The generation of γ-lithio alkoxides from the corresponding oxetanes require higher temperatures (0 °C) than epoxide ring opening with LDBB.[20] γ-Lithio alkoxides can be trapped by electrophiles in modest yields. The addition of trialkylaluminums yields the lithium trialkylaluminates, which react with electrophiles in modest yields (eq 15).

(15)

68%

The next higher analog, δ-lithio alkoxides, can be obtained by LDBB reductive lithiation in the presence of ***Boron Trifluoride Etherate***.[21] The Lewis acid helps stabilize the resulting open-chain oxyanion. Treatment with various electrophiles led to products in high yields and is a good protocol for the preparation of the synthetically useful [5.*n*] spiroacetal units (eq 16). The most branched alcohol is obtained upon cleavage of substituted epoxides and oxetanes, while the opposite regioselectivity is observed for THF.

(16)

Propellanes.

The central bond in [1.1.1]propellanes can be reductively cleaved to the corresponding dilithio species, which can be trapped by electrophiles to make bicyclo[1.1.1]pentane derivatives (eq 17).[22]

(17)

Carbonyl groups.

Aromatic ketones, benzylic alcohols, and ethers can be converted to the dilithio species with lithium and a catalytic

amount of DBB followed by trapping with electrophiles (eq 18).[23] The generation of aliphatic ketones in good yield from the corresponding esters proceeds with LDBB (eq 19), whereas sodium leads to high yields of the acyloin product.[24]

(18)

(19)

Phosphinates.

Reduction of diastereomerically pure menthyl phosphinate with LDBB followed by treatment with alkyl halides yields the phosphine oxides in good yield with high optical purity (eq 20).[25]

[56050-29-4] · $C_{16}H_{32}BLi$ · Lithium 9,9-Dibutyl-9-borabicyclo[3.3.1]nonanate · (MW 242.23)

(mild, selective reagent for the reduction of tertiary, allyl, and benzyl chlorides and bromides,[2] aldehydes and ketones,[3] and epoxides[4])

Physical Data: white gelatinous solid in hexane (reagent generated in situ).

Solubility: insol to sparingly sol hexane; sol MeOH, THF, benzene.[2-5]

Preparative Methods: a slurry of the reagent (**1**) is prepared by the dropwise addition of ***n-Butyllithium*** (14.4 mL of 1.39 M, 20.0 mmol) in hexane to *B*-Bu-9-BBN (3.76 g, 20.0 mmol) in hexane (25 mL) at 0 °C under a nitrogen atmosphere.[2]

Analysis of Reagent Purity: exhibits a single resonance in its ^{11}B NMR (THF) spectrum at δ -18.5 (s) ppm.[5]

Handling, Storage, and Precautions: the generation of (**1**) involves handling air-sensitive reagents which can be pyrophoric (i.e. BuLi, *B*-Bu-9-BBN) and consequently should be performed in a well ventilated hood. Individuals should thoroughly familiarize themselves with the special handling techniques required for such reagents prior to using (**1**).[1]

Selective Reduction of Halides.

Exhibiting unique behavior among organoborane-based reducing agents, (**1**) serves as an α-hydride source reducing allylic, benzylic, and tertiary halides to hydrocarbons with the accompanying rearrangement of the bicyclo[3.3.1]nonanate skeleton to *cis*-bicyclo[3.3.0]oct-1-yl(dibutyl)borane (**2**) (eqs 1, 2).[2-5] Although significantly more reactive than other common tetraalkylborates, the reagent fails to reduce primary, secondary, or aryl halides, a feature which can be utilized in selective reductions. These reductions, which are thought to involve carbocationic

rather than radical intermediates,[2b] are carried out in hexane, a medium in which (**1**) is only sparingly soluble.

(1)

(2)

Selective Reduction of Carbonyl Compounds.[3]

In THF solution, the reduction of acetyl chloride occurs at low temperature to produce ethyl acetate and (**2**).[5a] The reagent reduces neither esters nor nitriles. While useful for the reduction of both aldehydes and ketones, the former are reduced selectively in admixtures. Moreover, methyl ketones are reduced faster than their straight or branched chain isomers, and also faster than aryl ketones (eqs 3-5).

(3)

(4)

(5)

Cycloalkanones are reduced from their least hindered face to give *cis*-cyclohexanols, a process enhanced with added MeOH to suppress equilibration. However, with added lithium salts (i.e. LiOMe, LiBr) or excess ketone in the absence of MeOH, a Meerwein-Ponndorf-Verley type equilibration occurs to give the more thermodynamically favored isomer (eq 6). Methanol is thought to inhibit the formation of alkoxyborate complexes while lithium ions are believed to function as Lewis acids, making the carbonyl a better hydride acceptor.

(6)

Additive		
none	47	53
MeOH	84	16
LiOMe	10	90

Selective Reduction of Epoxides.[4]

Unsymmetrical epoxides are reduced by (**1**) in a regioselective manner, the course of which is determined by the nature of the substituents. Aromatic derivatives give primary alcohols whereas aliphatic derivatives exhibit the opposite selectivity, suggesting that a steric basis for the regiochemistry is more important in these substrates (eq 7).

Lithium Di-*n*-butylcuprate[1]

***n*-Bu_2CuLi**

[24406-16-4] · $C_8H_{18}CuLi$ · Lithium Di-*n*-butylcuprate · (MW 184.75)

(butylating reagent; undergoes conjugate addition reactions,[1a,b,e,f] 1,2-addition reactions,[1e,2] substitution reactions with alkyl, vinyl, aryl, and allylic substrates,[1a,c,e] reduction of carbon-heteroatom bonds,[3] oxidative dimerization,[4a] and oxidative coupling with amines[4b])

Physical Data: ^1H NMR (Et_2O) δ -6.99 to -7.14 ppm (t, *J* = 7.0 Hz, 2 H, -60 to +20 °C); (C_5H_{12}) δ -7.29 to -7.32 ppm (-50 to +35 °C).[5]

Solubility: sol THF, Et_2O.

Preparative Methods: prepared in situ from Cu^I salts under N_2 or argon atmosphere.[1a] Rate of cuprate formation is temperature- and Cu^I salt-dependent; reagent prepared from Cu^I halides may contain free BuLi.[6a] Dark-colored solutions are indicative of decomposition (see ***Lithium Dimethylcuprate*** for purification of CuI and CuBr). Colorless solutions of Bu_2CuLi can be prepared from BuCu obtained by low-temperature centrifugation.[1b] Polymer-bound *n*-Bu_2CuLi can be prepared.[7]

Handling, Storage, and Precautions: stable in solution for several hours below 0 °C (10% decomposition at 0 °C for 30 min)[6b] and is very sensitive to O_2. Use in a fume hood.

Addition Reactions.

Reaction of Bu_2CuLi with α,β-alkenyl ketones (eq 1),[1,8] aldehydes,[9] esters,[1] lactones,[1] sulfoxides,[10a] sulfones,[10b] sulfoximines,[10c] *N*-tosylamides,[11a] nitriles,[11b] *N*-nitroso[11c] and nitro[11d] compounds, phosphonates,[12a] phosphine oxides,[12b] phosphinates,[1a] and phosphonium salts (eq 2)[12c] results in conjugate addition of the butyl ligand; ligand transfer can be facilitated by bis-activation[1,13] of the alkene (e.g. alkylidene malonates). Bis-activated cyclopropanes[1d] afford products of homoconjugate addition, and dienyl systems[14,15] generally yield 1,6-addition products. Byproducts consistent with an equilibrium presence of *n*-BuLi[6a] are sometimes observed.[15] The reagent is compatible with transition metal carbonyls (eq 1)[8] and nitroalkanes[16] under appropriate conditions.

Bu_2CuLi	98%	76:24
$Bu_2CuCNLi_2$	98%	80:20
$BuCu \cdot BF_3$	96%	8:92

80%
$(E):(Z) = 3:97$

Exploitation of the anion resulting from conjugate addition[17] provides for powerful synthetic opportunities (eq 2).[12c] β-Nucleofuge-substituted α,β-unsaturated systems undergo substitution with varying degrees of stereoselectivity (eq 3).[18] Procedures for achieving absolute asymmetric conjugate addition of Bu_2CuLi are available.[19]

THF, DMS	93%	97:3
Et_2O	97%	5:95

Although Bu_2CuLi effects carbocupration of alkynes more readily than Me_2CuLi, copper-catalyzed Grignard additions are more efficient and widely employed.[1a]

Addition of ***Chlorotrimethylsilane*** facilitates 1,2-addition of Bu_2CuLi to ketones[2] and to aldehydes with increased Cram selectivity,[2,20a] while addition of crown ethers favors formation of anti-Cram[20b] products. 1,2-Addition of Bu_2CuLi to *N*-silylformamides affords imines.[20c]

Substitution Reactions.

Bu_2CuLi participates in substitution reactions with alkyl (e.g. halides (eq 4),[21] carboxylates, sulfonate esters) and alkenyl substrates (e.g. enol triflates and phosphates); the reaction is very general.[1a,c] Substitution reactions occur with β-lactones[22] and often proceed with good regio- and stereocontrol with oxiranes[1] (eq 5)[23] and tosylated aziridines.[24] Acylation of Bu_2CuLi with thiol esters provides a good route to ketones.[25]

Although the preference of allylic substrates (e.g. halides, sulfonimides, carboxylates, oxiranes, sulfones, carbamates, and nitro compounds[26]) for *anti*-S_N2' pathways is synthetically useful, steric effects, leaving groups, and substrate structure can alter regiochemistry and stereochemical integrity can be lost by isomerization pathways.[27] Propargyl substrates generally give substitution with rearrangement (eq 6).[28]

(6)

Miscellaneous Reactions.

Bu_2CuLi will reduce a variety of carbon-heteroatom bonds, and the reaction can be exploited synthetically.[1a,d] Reduction of cyclopropyl halides gives an intermediate copper species that can be alkylated or acylated (eq 7)[3] with some stereocontrol. Oxidative dimerization[4a] of Bu_2CuLi affords octane; an oxidative coupling reaction can be used to prepare butylated amines (eq 8).[4b]

Lithium Di-*t*-butylcuprate[1]

***t*-Bu_2CuLi**

[23402-75-7] · $C_8H_{18}CuLi$ · Lithium Di-*t*-butylcuprate · (MW 184.75)

(*t*-butylating reagent which undergoes conjugate addition reactions,[1,2] 1,2-addition reactions,[3] substitution reactions,[2b,4,5] carbocupration of alkynes,[6] and oxidation reactions[7])

Physical Data: dark red-brown to black solution; decomposes at 25 °C.[1b]

Solubility: sol Et_2O, THF, pentane-Et_2O-Me_2S (1:1:1).

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***,[1b,5] ***Copper(I) Bromide***[1b]) and complexes ($CuBr.SMe_2$[8a] and ***Copper(I) Iodide-Tributylphosphine***[7a]) under an inert atmosphere of N_2 or argon in Et_2O or THF. Polymer-supported *t*-Bu_2CuLi can be prepared.[9] Preparation, stability and reactivity of organolithium- and organomagnesium-derived cuprate reagents and mixed hetero-*t*-butylcuprate reagents have been noted.[1,4c,10,11] See ***Lithium Dimethylcuprate*** for purification of Cu^I salts.

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Introduction.

Lithium di-*t*-butylcuprate displays the typical reactivity patterns of lithium diorganocuprates (see, e.g. ***Lithium Di-n-butylcuprate***, ***Lithium Diethylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***, ***Lithium Di-n-propylcuprate***).

Addition Reactions.

t-Bu_2CuLi reacts with α,β-alkenyl ketones[1,2,9] (mechanistic studies[8]), chiral esters[12] (in the presence of ***Chlorotrimethylsilane***) (eq 1), sulfoxides,[13] *N*-tosyl-1-azoalkenes,[14] ketoketenimines,[15] and vinylphosphonium salts[16] with conjugate transfer of the *t*-butyl ligand. Stereoselective *cis* addition can be achieved in the reaction of *t*-Bu_2CuLi with α,β-alkynyl sulfones.[17] Reaction of α,β-alkynyl trifluoromethyl ketones[18] with *t*-Bu_2CuLi affords mixtures of 1,2- and 1,4-addition products with modest regiocontrol; regioselective control can be obtained with the cyanocuprate reagent. Systems with extended conjugation, such as 3-alkynyl-2-cycloalkenones, undergo 1,6-addition.[19]

(1)

1,2-Addition of *t*-Bu_2CuLi to a chiral γ-alkoxy-α,β-enal[3] occurs with vinylogous Cram stereoselectivity in the presence of ***t-Butyldimethylchlorosilane***. Alkylated 3,4-dihydro-β-carbolines[20] can be synthesized by 1,2-addition of *t*-Bu_2CuLi to BF_3 iminium salts.

Substitution Reactions.

t-Bu_2CuLi effects substitution reactions with alkyl halides,[2b,4,9] α-halo ketones,[4b,21] alkyl tosylates,[2b,4c,5,9] acetates,[22] arene sulfonyl fluorides,[23] and alkenyl substrates (e.g. vinyl triflates[24] in the presence of ***Boron Trifluoride Etherate*** and enol phosphates[25]). Simple[26a] and alkenyl oxiranes[11,26b-d] undergo substitution reactions (eq 2); however, reactions of oxiranes with *t*-Bu_2CuLi can be complicated by the formation of reduction products[11] and mixtures of S_N2- and S_N2'-type products.[26c,d]

(2)

Chiral α,β-alkenyl oxazolidines[27] undergo allylic substitution reactions with *t*-Bu_2CuLi. β´-Aminocyclopentenyl sulfones[28] participate in stereoselective *syn*-S_N2' substitution with *t*-Bu_2CuLi in modest yield (eq 3). Acyl halides[4b] and *S*-2-pyridyl thioates[7c] participate in nucleophilic acyl substitution reactions with *t*-Bu_2CuLi to give ketones.

Carbocupration.

Acetylene undergoes a stereoselective *syn* carbocupration[6] with *t*-Bu_2CuLi and can be manipulated further in subsequent additions to α,β-alkenyl sulfones[29] with retention of double bond configuration.

Oxidation Reactions.

Oxidative dimerization of *t*-Bu_2CuLi proceeds poorly.[7a] Oxidative coupling of amines[7b] with *t*-Bu_2CuLi affords *t*-butylated amines. Reaction of *t*-Bu_2CuLi with *S*-2-pyridyl thioates[7c] in the presence of O_2 gives esters.

Miscellaneous Reactions.

Reduction of 1,3-thiazole-5(4*H*)-thiones by electron transfer pathways can occur with *t*-Bu_2CuLi.[30] A vinylic bromide[31] undergoes reduction-elimination reactions with *t*-Bu_2CuLi. *t*-Bu_2CuLi reduces *gem*-dihalocyclopropyl[32] derivatives to give an intermediate copper species that can be alkylated. o-Halo-1-phenylalkynes[33] are reduced by *t*-Bu_2CuLi, affording an organocopper intermediate that can undergo intramolecular carbocupration (eq 4).

Related Reagents.

Copper(I) Iodide-Tributylphosphine; ***Lithium t-Butoxy(t-butyl)cuprate***.

Lithium Dicyclohexylamide

[4111-55-1] · $C_{12}H_{22}LiN$ · Lithium Dicyclohexylamide · (MW 187.29)

(performs as a strong base, allowing deprotonation of ketones,[1] esters,[2] aryl[3] and allyl[4,5] halides, alkyl dihalides,[6] allenes,[7] alkylboron reagents,[8] azulene and methylazulenes;[9] used for the formation of formamides, glyoxylamides, oxomalonamides, and tartronamides[10])

Physical Data: IR (solution/suspension in benzene, 3000-2400 cm^{-1}): 2916s, 2880s, 2850s, 2831s, 2757m, 2620w, 2572w; 635s and 270s also reported.[11]

Solubility: partially sol benzene, hexanes; sol THF.

Preparative Methods: from the reaction of dicyclohexylamine with ***n-Butyllithium*** in hexanes and benzene at 0 °C; solvent can then be removed under reduced pressure and the resulting free flowing solid dissolved in THF.[12]

Handling, Storage, and Precautions: both solution and solid are pyrophoric and air- and moisture-sensitive; also the solid is spontaneously flammable in air. The reagent is corrosive and extremely destructive to tissues of the mucous membranes and the upper respiratory tract, eyes, and skin. Note that dicyclohexylamine is a suspected carcinogen and may cause chemical pneumonitis and pulmonary edema.[13] Use in a fume hood.

Introduction.

The title reagent (Cy_2NLi) has generally been used as a base in the formation of organolithium substrates in a similar way to ***Lithium Diisopropylamide*** and related lithium amides. It is reported, however, to be a stronger base than LDA, ***Lithium Diethylamide***, and lithium isopropylcyclohexylamide (LiN(*i*-Pr)Cy).[14] Also the conjugate acid (Cy_2NH) has been shown to be a weaker acid than diisopropylamine, isopropylcyclohexylamine, and diethylamine.[14]

As a general note, a number of different methods for the removal of the dicyclohexylamine byproduct have been developed because of the formation of a precipitate with HCl workups. Use of HCl will cause the formation of a precipitate, which has been removed by filtration and the filtrate then subjected to standard workup.[9] Citric acid[1,3] and ammonium chloride[4] have been used without any problems of precipitation (the former used specifically to prevent this problem). In one case, the amine has been removed by distillation. Both MeI and $BF_3.Et_2O$ have been used to precipitate the amine followed by

filtration and subsequent standard workup of the filtrate.[5]

Deprotonation of Carbonyl Compounds.

In the formation of β-keto esters from unsaturated ketones, Cy_2NLi was found to give better results than the other bases examined (LDA, ***Sodium Hydride***, ***Potassium t-Butoxide***) (eqs 1 and 2).[1] It was reported that Cy_2NLi overcomes the problems of substrate self-condensation side-products and nucleophilic attack of base on diethyl carbonate. It has also been used in condensation reactions between ethyl 2-(trimethylsilyl)acetate and a number of ketones (eq 3).[2]

(1)

(2)

(3)

Deprotonation of Allenes.

Normally the deprotonation of alkoxyallenes leads to α-lithiation;[15] however, in conjunction with bulky alkoxy groups on alkoxyallenes, the steric size of Cy_2NLi has been used to give selective γ-deprotonation of alkoxyallenes (eq 4).[7]

Deprotonation of Alkyl Halides.

In studies of the deprotonation of mono- and dihaloalkyl and -aryl compounds, the choice of base has been found to be crucial for the deprotonation of substrates that contain sites more reactive towards nucleophilic attack (eq 5).[6] In one example, the dihalomethylhydroxy product of the condensation of dihalolithiomethane with a carbonyl has been used to obtain the ring expanded ketone (eq 6).[16]

For the formation of carbenes via deprotonation of aryl halides (eq 7), a number of bases have been investigated including Cy_2NLi.[3] These studies also looked at the formation of benzyne intermediates from *o*-chloroanisole (eq 8).

(8)

While Cy_2NLi was found to give consistently better results than LDA, LiN(*i*-Pr)Cy, and $LiNEt_2$, ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LiTMP) was reported to be the best reagent for these processes.

Deprotonation of allyl chlorides with Cy_2NLi gives a lithiated carbenoid intermediate which has been silylated to give an allyl halosilane, which can subsequently be used in reactions with carbonyl and acetal substrates (eq 9).[4] Allylsilanes can be used in a number of synthetically useful transformations.[17]

(9)

$(Z):(E) = 10:1$

More recently the carbenoid intermediate, prepared from allyl chloride and Cy_2NLi, has been reacted with 9-methoxy-9BBN to give the homologous boron product (**1**) (eq 10). This can in turn undergo a number of transformations to give cyclooctane derivatives (eqs 11-13).[5]

(10)

(1)

(11)

(12)

(13)

In these transformations, Cy_2NLi was the reagent of choice as other bases ($LiNEt_2$, ***Lithium Pyrrolidide***, $LiN(t\text{-}Bu)SiMe_3$) gave reduced yields due to the problems of nucleophilic displacement of the methoxy group from the boron atom.

Deprotonation of Alkyl Boron Compounds.

Lithium dicyclohexylamide has been used in the formation of α-boron anion intermediates, the reactions of which have been extensively studied (eqs 14-17).[8,12] In the coupling of the α-boron anion with metal compounds, a number of reagents and metals have been used, with $HgCl_2$ giving the lowest yields.

(14)

(15)

(16)

(17)

In these studies, good yields were obtained with Cy_2NLi, although ***Mesityllithium*** gave more consistent results. LiTMP has

also been used in studies in this area.[18]

Miscellaneous.

Extensive studies of the reaction of lithium amides with carbon monoxide at atmospheric pressure have led to the formation of formamides (**2**), glyoxylamides (**3**), tetraalkylureas (**4**), tartronamides (**5**) and oxomalonamides (**6**) with good selectivity depending on the conditions of the reaction and workup (eq 18) (Table 1).[10,14]

Table 1 Conditions and Yields for Reaction with CO

Ratio NLi:NH	Product (2)	(3)	(4)	(5)	(6)
5:4[a]	91	8		1	
5:1[a]		10		90	
5:4[b]		3	66		31
5:1[b]		4			96

[a] LiBr cat.; H_2O workup. [b] LiBr cat.; O_2, $NaHCO_3$, H_2O workup.

One example of the use of Cy_2NLi in studies with nonbenzenoid aromatic compounds has been reported. These results examined the deprotonation and carbonylation of a variety of azulenes (eqs 19 and 20). Good yields of the monocarboxy

products were obtained, although the di- and triesters were also formed with azulene.[9]

(19)

(20)

One example of the use of Cy_2NLi for dehydrochlorination has also been reported, giving the selective formation of *trans*-cyclodecene (eq 21) (cf. *t*-BuOK, eq 22).[19]

Lithium (3,3-Diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate

[58419-23-1] · $C_{13}H_{22}CuLiO_2$ · Lithium (3,3-Diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate · (MW 280.84)

(mixed organocuprate; acrolein and acrylate equivalent)

Preparative Methods: prepared in situ from ***3,3-Dimethyl-1-butynylcopper(I)*** and ***2-Lithio-3,3-diethoxy-1-propene*** at -78 °C; ether or a mixture of ether/THF can be used as solvent.

Handling, Storage, and Precautions: air- and moisture-sensitive; use in a fume hood.

Mixed Cuprate Acrolein Equivalent.

Lithium (3,3-diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate (**1**) has been used primarily as an α-acrolein and α-acrylate anion equivalent (eq 1). The *t*-butyl acetylide ligand has proven to be superior over other typical mixed cuprate ligands due to improved solubility, increased thermal stability, and higher yields. The 3,3-diethoxypropenyl unit is cleanly transferred in 1,4-additions to enones (eq 2), though the reaction was reported to be slower and the yields moderate when β-substituents of increasing bulk were introduced.[1,2] The addition of (**1**) to cyclic γ-hydroxy enones provides useful intermediates for the synthesis of α-methylene-γ-lactones (eq 3).[2] The reagent will not react with primary or vinyl halides but will add to allylic halides in excellent yield (eq 4).[2]

(1)

(2)

(2)

(3) (4)

(5) (6)

(3)

(7)

(4)

The addition of (**1**) to cyclic allylic epoxides was shown to give predominantly 1,2-addition vs. 1,4-addition.[3] Maximum yields were obtained at -40 °C, giving exclusively *trans* addition products (eq 5). Hydrolysis of acetals (**8**) and (**9**) was followed by oxidation to give the mixture of acids (**10**) and (**11**). If this mixture was treated with ***1,3-Dicyclohexylcarbodiimide*** (conditions a), only the acid with the proximal hydroxy group

(5)

cyclized to give *trans*-α-methylenelactone (**12**). When the mixture of (**10**) and (**11**) was refluxed in benzene in the presence of ***p-Toluenesulfonic Acid*** (conditions b), (**12**) was isolated along with the *cis*-α-methylenelactone (**13**).

Related Reagents.

3,3-Dimethyl-1-butynylcopper(I); ***3,3-Diethoxy-1-propen-2-ylcopper***; ***Lithium Bis(3,3-diethoxy-1-propen-2-yl)cuprate***; ***Lithium (3,3-Diethoxy-1-propen-2-yl)(phenylthio)cuprate***.

Lithium (3,3-Diethoxy-1-propen-2-yl)(phenylthio)cuprate[1]

[57428-24-7] · $C_{13}H_{18}CuLiO_2S$ · Lithium (3,3-Diethoxy-1-propen-2-yl)(phenylthio)cuprate · (MW 308.87)

(α-bromoacrolein-derived heterocuprate capable of nucleophilic additions and substitutions;[2] useful in the preparation of α-methylene-γ-butyrolactones[3])

Alternate Name: lithium [(α-diethoxymethyl)vinyl](phenylthio)cuprate.

Solubility: prepared as a solution in ether; presumably can also be prepared in THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl. The yield of phenyl ketone is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: preparation of the heterocuprate[5] requires synthesis of 2-bromo-3,3-diethoxypropene,[6] which can be obtained from the widely available diethyl acetal of acrolein via bromination-dehydrobromination. Under an inert atmosphere of nitrogen or argon, a 0 °C solution of distilled ***Thiophenol*** in anhydrous ether is treated with 1 equiv of ***n-Butyllithium***. The resultant solution is transferred to a room-temperature suspension of 1 equiv of ***Copper(I) Iodide*** in anhydrous ether under nitrogen or argon, to provide a yellow suspension of ***Phenylthiocopper(I)***; this suspension is cooled to -78 °C. In a separate flask under nitrogen or argon at -78 °C, 1 equiv of 2-bromo-3,3-diethoxypropene in anhydrous ether is treated dropwise with 1 equiv of *n*-BuLi; the 3,3-diethoxy-2-lithiopropene[7] that results is added dropwise to the -78 °C solution of PhSCu. The heterocuprate that forms is typically reacted with electrophiles at -78 °C with subsequent warming to -40 °C. Modifications using other sources of PhSCu may be acceptable.[8]

Handling, Storage, and Precautions: best results are obtained with high purity copper(I) salts,[9] dry, oxygen-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides.[10] *n*-BuLi is used to prepare the intermediate reagents lithium thiophenoxide and 3,3-diethoxy-2-lithiopropene, and is pyrophoric;[11] due care must be exercised in its handling. Thermal decomposition occurs at &egt;-40 °C. Use in a fume hood.

Introduction.

This vinylic organometallic reagent is representative of the heterocuprate class of organocopper reagents. The vinylic group is reactive as a nucleophile, whereas the SPh group is not. Such nontransferable groups are called dummy ligands;[12] the SPh dummy ligand in particular is typically found to provide enhanced thermal stability and solubility compared to the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than the corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when relatively high reaction temperatures are required, or when the organolithium used to form the cuprate is difficult or expensive to prepare.

Lithium (3,3-diethoxy-1-propen-2-yl)(phenylthio)cuprate can be used to prepare a variety of 2-substituted propenoic acid derivatives, especially α-methylenelactones. The reagent, along with cognate mixed homocuprate reagents, is generally considered to be superior to analogous (ethoxycarbonyl)vinylcuprate reagents. These latter reagents usually undergo 1,2- as opposed to expected 1,4-additions to α,β-unsaturated carbonyl compounds.[13]

Nucleophilic Substitutions of Halides.

Although unreactive with benzyl bromide and vinyl iodides, lithium (3,3-diethoxy-1-propen-2-yl)(phenylthio)cuprate undergoes clean substitutions with allylic bromides[5] to afford 1,4-dienes (eq 1). The mixed homocuprate ***Lithium (3,3-Diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate*** provides similar results.[14]

(1)

1,4-Additions to 2-Alkenones.

The reagent undergoes 1,4-addition to cyclohexenone, cyclopentenone, and 3-penten-2-one in 50-80% chemical yields in diethyl ether; the use of THF greatly diminishes formation of 1,4-adducts.[5] A comparative study indicates that mixed homocuprates, especially lithium (3,3-diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate, are the reagents of choice in 1,4-additions (eq 2).[14]

R = SPh	50%
R = Pr—≡	65%
R = *t*-Bu—≡	92%

1,4-Adduct (**1**) has been used to prepare α-methylene-δ-valerolactones (eq 3),[5] common structural motifs in marine cembranolides.[3a] If a 4-trimethylsilyloxy- or 4-*t*-butyldimethylsilyloxy-2-cycloalkenone is used as substrate for the 1,4-addition, *trans*-α-methylene-γ-butyrolactones can be prepared;[14] this strategy utilizes the steric control effect of the 4-silyloxy substituent, which causes the nucleophile to attack at the opposing face of the double bond.

Additions to Epoxides.

Although the phenylthiocuprate is reported to be unreactive with cyclohexene epoxide, the homocuprate ***Lithium Bis(3,3-diethoxy-1-propen-2-yl)cuprate*** and mixed homocuprate lithium (3,3-diethoxy-1-propen-2-yl)(3,3-dimethyl-1-butynyl)cuprate undergo both 1,2- and 1,4-additions to cycloalkadiene monoepoxides (eq 4).[15] 1,4-Addition is distinctly favored when diethyl ether is used as solvent. The hydroxyacetal adducts can be used in the stereospecific construction of α-methylene-γ-butyrolactones of 1,3-diols. For example, when (**2**) is isolated from (**3**) by vacuum

distillation, transacetalization affords a cyclic mixed acetal. Upon oxidation with Jones reagent, the corresponding *trans*-α-methylene-γ-butyrolactone is isolated (eq 5). If 1,4-adduct (**3**) is hydrolyzed, the resultant aldehyde can be oxidized to its corresponding acid; iodolactonization provides a *cis*-α-methylene-γ-butyrolactone (eq 6).

(4)

(5)

Other potential methods to prepare 2-substituted propenoic acid derivatives include Pd-catalyzed formylation of vinyl iodides and vinyl triflates[16] and hydrocupration of alkyl propiolates using ***Hexa*-μ-*hydrohexakis(triphenylphosphine)hexacopper***.[17]

Lithium Bis(1-ethoxyvinyl)cuprate[1,2]

[123206-02-0] · $C_8H_{14}CuLiO_2$ · Lithium Bis(1-ethoxyvinyl)cuprate · (MW 212.71)

(vinylcuprate reagent and acyl anion equivalent which undergoes 1,4-addition reactions,[3] 1,2-addition reactions,[4] and substitution reactions[3])

Physical Data: homogenous, red solution displaying some temperature sensitivity; dec. estimated between -35 and -25 °C.[3]

Solubility: sol THF.

Preparative Methods: prepared under an inert atmosphere of argon by the rapid addition of 2 equiv of ***1-Ethoxyvinyllithium***[5] in THF at -78 °C to a suspension of purified ***Copper(I) Iodide*** at -78 °C, which is stirred at -30 °C for 1 h to afford a deep red solution.[3]

Handling, Storage, and Precautions: air- and moisture-sensitive reagent prepared in situ. Use in a fume hood.

Addition Reactions.

Lithium bis(1-ethoxyvinyl)cuprate affords transfer of the 1-ethoxyvinyl ligand, an acyl anion equivalent,[6] via conjugate addition to α,β-alkenyl ketones[7] (25-91% yield)[3] (eqs 1 and 2). This reaction is sensitive to steric hindrance resulting from substitution in the α,β-enone, especially at the β-position, resulting in slow 1,4-addition. Use of excess reagent can sometimes overcome this limitation. The *n*-propynyl mixed cuprate reagent can be used effectively to give conjugate transfer of the 1-ethoxyvinyl ligand to 2-cyclohexen-1-one (83% yield).[3]

(1)

(2)

Employment of ***Boron Trifluoride Etherate*** in conjunction with lithium bis(1-ethoxyvinyl)cuprate gives an enhancement of reagent efficiency as well as improved control over the regioselectivity in the reaction, preventing 1,2-addition (eq 3).[8]

(3)

A lithium bis(1-ethoxyvinyl)cyanocuprate reagent can be prepared by the transmetalation of the vinylstannane with lithium dimethylcyanocuprate to give effective conjugate addition of the 1-ethoxyvinyl ligand to an α,β-enone.[9] The resulting vinyl ether 1,4-adducts can be readily hydrolyzed under mildly acidic conditions (0.1 N HCl/ether, 0.1 N oxalic acid/MeOH, or SiO_2 in wet benzene) to afford 1,4-diketones in 57-95% yield.[3]

Chemoselective 1,2-addition of lithium bis(1-ethoxyvinyl)cuprate to an aldehyde can be achieved in moderate yield (eq 4).[4]

(4)

Substitution Reactions.

Coupling of lithium bis(1-ethoxyvinyl)cuprate with allylic bromides occurs in good yield (eq 5).[3,10] However, this reagent fails to give desired coupling products with saturated primary and secondary alkyl bromides, affording cuprate reagent self-coupling products; attempted opening of oxiranes was also unsuccessful.[3]

(5)

Related Reagents.

1-Ethoxyvinyllithium; ***Lithium (Z)-Bis(2-ethoxyvinyl)cuprate***; ***Lithium Bis(1-methoxyvinyl)cuprate***; ***Lithium Divinylcuprate***.

Lithium (*Z*)-Bis(2-ethoxyvinyl)cuprate[1]

[64823-09-2] · $C_8H_{14}CuLiO_2$ · Lithium (*Z*)-Bis(2-ethoxyvinyl)cuprate · (MW 212.71)

(a lower order cuprate reagent, prepared in situ, which undergoes conjugate addition reactions and substitution reactions[2])

Solubility: sol THF.

Preparative Methods: ***1-Ethoxy-2-tributylstannylethylene*** is prepared by the hydrostannation of ***Ethoxyacetylene***, which is then reacted with 1.1 equiv of ***n-Butyllithium*** in THF at -78 °C for 1 h to afford ***(Z)-2-Ethoxyvinyllithium***. To this solution is added 0.5 equiv purified ***Copper(I) Iodide*** and 2.0 equiv ***Dimethyl Sulfide*** in THF. The mixture is stirred for 1 h, affording lithium bis(2-ethoxyvinyl)cuprate, a red-brown solution.[2]

Handling, Storage, and Precautions: air- and moisture-sensitive reagent prepared and used in situ. Use in a fume hood.

1,4-Addition Reactions with α,β-Unsaturated Carbonyl Compounds.

Lithium bis(2-ethoxyvinyl)cuprate undergoes 1,4-addition to α,β-alkenyl and α,β-alkynyl ketones by conjugate transfer of the 2-ethoxyvinyl ligand (eqs 1 and 2).[2]

Substitution Reactions.

Lithium bis(2-ethoxyvinyl)cuprate reacts with alkyl halides in substitution reactions (eq 3).[2]

In reactions of enantiomerically pure alkyl bromide, substitution occurs with inversion of configuration at carbon. If the halogen is iodine, the reaction affords racemic product.[3]

Related Reagents.

1-Ethoxyvinyllithium; ***Lithium Bis(1-ethoxyvinyl)cuprate***; ***Lithium Bis(1-methoxyvinyl)cuprate***; ***Lithium Divinylcuprate***.

Lithium Diethylamide

$LiNEt_2$

[816-43-3] · $C_4H_{10}LiN$ · Lithium Diethylamide · (MW 79.09)

(strong base; nitrogen nucleophile)

Physical Data: pK_a = 31.7.[1]

Solubility: sol THF, Et_2O, Et_2O-hexane mixtures, Et_2O-benzene mixtures; insol hydrocarbon solvents.

Form Supplied in: white solid.

Preparative Methods: by treating diethylamine with ***Phenyllithium*** or ***n-Butyllithium*** or, alternatively, by treating diethylamine with ***Lithium*** metal in the presence of ***Hexamethylphosphoric Triamide***[2] or an electron acceptor.[3]

Handling, Storage, and Precautions: reacts with water vigorously and ignites spontaneously in air. When heated to decomposition, it emits toxic fumes of NO_x. Should be kept and handled under argon. Use in a fume hood.

Lithium Diethylamide as Base.

Lithium diethylamide is a strong base whose use may be complementary to ***Lithium Diisopropylamide***. For example, $LiNEt_2$ serves to abstract the o-proton of sorbic acid to generate a lithium trienolate which undergoes regioselective condensation with aldehydes and ketones (eq 1),[4] and to prepare carbocyclic nitriles by a sequential inter- and intramolecular alkylation route (eq 2).[5] $LiNEt_2$ has been employed with a sterically hindered lactam for an α-deprotonation-cyclization reaction as part of the synthesis of (-)-δ-*N*-normethylskytanthine, an alkaloid from *Tecoma arequipensis* (eq 3).[6] $LiNEt_2$ may be a superior base to LDA for enolate formation.[7]

(2)

(3)

(-)-δ-*N*-Normethylskytanthine

Lithium diethylamide is widely used for base-induced epoxide opening to allylic alcohols and rearrangement via carbenoids.[8] Two reaction pathways are observed: β-*syn*-elimination[8c] to afford an allylic alcohol (eq 4) and α-elimination to generate a carbenoid followed by C-H insertion (eqs 5 and 6). Allylic deprotonation followed by intramolecular epoxide ring opening has been observed (eq 6). The β-elimination process is often highly stereoselective and therefore has synthetic value.[8h]

(4)

(5)

$LiNEt_2$ is sufficiently basic to effect α-deprotonation of allenic ethers. Subsequent reaction with ketones followed by acid treatment affords 3-furanones (eq 7).[9]

Treatment of tetraphenylphosphonium bromide with $LiNEt_2$ leads to 9-phenyldibenzophosphole[10] which may be further transformed into Wittig-Horner reagents (eq 8), useful for highly stereoselective synthesis of alkenes.

Lithium Diethylamide as Nucleophile.

Treatment of aldehydes with a $LiNEt_2$-***Titanium Tetraisopropoxide*** complex generates α-amino alkoxides which undergo reaction with Grignard reagents to afford tertiary amines (eq 9).[11] $LiNEt_2$ attacks THP ethers of 2,4-alkadien-1-ols regioselectively at C-5 to furnish amino dienes with predominately (*E*,*E*) stereochemistry (eq 10).[12] Treatment of perfluorinated alkanes with $LiNEt_2$ results in β-elimination to provide terminal alkenes (eq 11).[13] Further treatment with $LiNEt_2$ leads to addition and fluoride elimination to give enamines which, after hydrolysis, produce perfluorinated amides. Similarly, chloroalkynes lead to ynamines (eq 12).[14]

Lithium Diethylcuprate[1]

Et_2CuLi

[38297-20-0] · $C_4H_{10}CuLi$ · Lithium Diethylcuprate · (MW 128.63)

(ethylating reagent; undergoes conjugate addition reactions,[1a,b,d] substitution reactions,[1a,c,d] and carbocupration[1])

Physical Data: black solution (prep. from CuI).[2]

Solubility: sol THF, Et_2O

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***,[2,3a] ***Copper(I) Iodide-Tributylphosphine***[3b]) under N_2 or argon atmosphere (see ***Lithium Dimethylcuprate***).

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Introduction.

Lithium diethylcuprate displays the characteristic reactivity patterns of lithium diorganocuprates (see ***Lithium Di-n-butylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***).

Addition Reactions.

Lithium diethylcuprate reacts with α,β-alkenyl ketones (eq 1),[1,4] esters,[5] and amides[6] with conjugate transfer of the ethyl ligand. Conjugate addition of Et_2CuLi to the enol tosylate of an α-dione followed by elimination of the tosylate group affords the substituted α-dione (eq 2).[7] The reagent adds stereoselectively (*cis* addition) to α,β-alkynoates[8a] and alkynamides (eq 3),[8b] affording alkenyl esters and amides.

Dienones undergo a 1,6-addition reaction.[9] Reaction of Et_2CuLi with thiones[10] and aldehydes[11] affords 1,2-addition products.

Substitution Reactions.

Lithium diethylcuprate participates in substitution reactions with alkyl halides,[12] carboxylates,[13] tosylate esters,[2b,12a,14] sulfinate esters,[15] and thioesters.[9] Reaction of Et_2CuLi with acyl halides[16] results in nucleophilic acyl substitution, providing a useful route to ketones. Vinyl bromides[17] couple with Et_2CuLi to afford substitution products; the reaction proceeds with retention of configuration. Vinyl triflates[18] derived from β-dicarbonyl compounds afford substitution products that may result from addition-elimination reaction pathways.

Carbocupration.

Carbocupration of alkynes with Et_2CuLi affords alkenylcopper compounds which can react with alkyl halides,[19] enones,[20] and oxiranes[21] to give substitution, 1,4-addition, and ring-opened products, respectively. Carbocupration of acetylene with Et_2CuLi followed by addition of a 1-alkyne affords a dienylcuprate that can undergo reactions with various electrophiles (eq 4).[22] Carbocupration of methoxyallenes has been reported.[23]

(4)

Miscellaneous Reactions.

Reaction of this reagent with aziridines affords ring-opened products.[24] Propargylic halides (eq 5),[3a] α,β-alkenyl acetals,[25] and vinyl lactones (eq 6)[26] undergo S_N2' reactions. Vinyl oxiranes[27] participate in *anti*-stereoselective S_N2' pathways. Propargylic oxiranes[28] give α-allenic alcohols upon reaction with Et_2CuLi.

Lithium Diethylcuprate-Tributylphosphine[1]

$Et_2CuLi.(n\text{-}Bu)_3P$

(Et_2CuLi)

[38297-20-0] · $C_4H_{10}CuLi$ · Lithium Diethylcuprate-Tributylphosphine · (MW 128.63)
(Bu_3P)

[998-40-3] · $C_{12}H_{27}P$ · Lithium Diethylcuprate-Tributylphosphine · (MW 202.36)

(representative phosphine-ligated homocuprate for 1,4-addition,[2] nucleophilic substitution,[3] and reductive metalation[4])

Solubility: sol ether, THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[5] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl. The yield of propiophenone is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: the following general procedure has been used to prepare a variety of $R_2CuLi.P(n\text{-}Bu)_3$ reagents:[6] a round-bottom flask equipped with magnetic stirring bar and rubber septum is charged with ***Copper(I) Iodide-Tributylphosphine***.[7] Under a nitrogen atmosphere, ether or THF is added. After cooling the resultant solution to -78 °C, 2.0 equiv of the appropriate RLi reagent is added dropwise. Formation of a colorless, pale pink, or yellow cuprate is immediate. Alternate preparations by addition of 1.0 equiv of ***Tri-n-butylphosphine*** to an ether or THF slurry of ***Copper(I) Iodide*** before addition of two equiv of RLi or by use of $CuBr[(n\text{-}Bu)_3P]_2$[8] may be possible.

Handling, Storage, and Precautions: best results are obtained with high purity Cu^I salts,[9] dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides.[10] Like most alkyllithium reagents, ***Ethyllithium***[11] is pyrophoric;[12] care must be exercised in its

handling. Homocuprates are stabilized in the presence of stoichiometric quantities of $(n\text{-Bu})_3P$; there is no noticeable decomposition at -78 °C.[6] Use in a fume hood.

General Discussion.

Phosphine-ligated homocuprates were introduced early in the development of organocopper chemistry.[6,13] The $(n\text{-Bu})_3P$ ligand solubilizes the homocuprate in ether solvents, increasing its reactivity, and also retards thermal decomposition. Generally, the presence of stoichiometric quantities of the ligand makes reaction workup unsatisfactory;[6,13a,14] for this reason, various heterocuprates[15] have found wider application in organic chemistry. Eq 1 provides a typical comparison.[15]

$$x\,(t\text{-Bu})\text{CuRLi}\cdot\text{L} + \text{C}_5\text{H}_{11}\text{Br} \xrightarrow{\text{THF}} t\text{-Bu}\text{C}_5\text{H}_{11} \qquad (1)$$

x	R	L	
5	*t*-Bu	Bu_3P	92%
2	SPh	-	98%

Lithium diethylcuprate-tributylphosphine has been essentially unused in organic synthesis. Phosphine-ligated organocopper reagents, however, have found recent applications in tandem vicinal dialkylation reactions leading to prostaglandins.[16] Other reports suggest that the presence of a phosphine ligand during organocopper-mediated epoxide openings is important in promoting reductive metalation of substrate.[4,8]

Lithium Diisobutyl(methyl)aluminum Hydride[1]

Li[(*i*-Bu)$_2$(Me)AlH]

[17034-29-6] · $C_9H_{22}AlLi$ · Lithium Diisobutyl(methyl)aluminum Hydride · (MW 164.23)

(used to hydroaluminate triple bonds[2,3] and to reduce α,β-unsaturated carbonyl compounds regioselectively in conjuction with MAD[4])

Physical Data: see ***Diisobutylaluminum Hydride*** and ***Methyllithium***.

Solubility: reactions using the title reagent are conducted in ether or glyme.

Preparative Methods: prepared in situ by adding methyllithium in ether to diisobutylaluminum hydride in ether or glyme while maintaining the temperature below 25 °C or at 0 °C.[2]

Form Supplied in: prepared in situ from commercially available reagents.

Handling, Storage, and Precautions: see ***Diisobutylaluminum Hydride*** and ***Methyllithium***.

Hydroalumination of Alkynes.

Lithium diisobutyl(methyl)aluminum hydride hydroaluminates symmetrical disubstituted alkynes in a *trans* fashion.[2] On the other hand, *cis* hydroalumination takes place if diisobutylaluminum hydride (DIBAL) and methyllithium are introduced sequentially.[5] The later sequence also hydroaluminates monosubstituted triple bonds to generate vinylalanate complexes with the aluminum adding exclusively to the alkyne terminus (eq 1).[5]

(1)

Studies on the hydroalumination of conjugated diyne systems revealed that the addition occurs in a *trans* fashion, with the aluminum attacking exclusively the less hindered side. The reaction stops at the enyne stage even when an excess of the hydride complex is used (eq 2).[3]

(2)

R	Yield (%)	Geometrical purity (%)
n-Bu	92	99
i-Bu	89	98
i-C_6H_{11}	91	98
t-Bu	80	96

The hydroalumination products have been captured by various electrophiles including carbon dioxide,[2] halogens,[6] and cyanogen,[8] with retention of double bond geometry (eq 3). This provides a method to prepare isomerically pure α,β-unsaturated acids, nitriles, and vinyl halides.

(3)

Condensation of vinylalanates with aldehydes affords an efficient route to allylic alcohols (eq 4).[7,8]

(4)

The reaction of the aluminum ate complex with an allylthiosulfonate provides a strategy for preparing a thioether of (*Z*) stereochemistry about the vinyl moiety. The method serves as a general route to stereodefined thioethers as precursors for thio-Claisen rearrangements (eq 5).[9]

(5)

The vinyl ligand of the ate complex has also been added in a 1,4-manner to α,β-unsaturated ketones. No 1,2-addition

was observed, and no reaction occurred at the ester group (eq 6).[10]

Selective Reduction.

It was reported that Li(R)(i-Bu)$_2$AlH (R = n-Bu, t-Bu, Me) can accomplish 1,4-reduction of α,β-unsaturated ketones in combination with ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD) (eq 7).[4]

Lithium Diisopropenylcuprate[1,2]

[21329-14-6] · $C_6H_{10}CuLi$ · Lithium Diisopropenylcuprate · (MW 152.65)

(isopropenylating reagent; undergoes conjugate addition reactions,[1a] 1,2-addition reactions,[3] substitution reactions with oxiranes[4] and alkyl, vinyl, and aryl substrates,[1e] carbocupration of alkynes,[5] and acylation reactions[1e])

Physical Data: chocolate-brown slurry in Et_2O at -78 °C.[2]

Solubility: sol THF, Et_2O.

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide*** or $CuBr.SMe_2$ (see ***Copper(I) Bromide***)) under N_2 or argon atmosphere.[2] Rate of cuprate formation is temperature- and Cu^I salt-dependent, and reagent prepared from Cu^I halides is critically dependent on the purity of the salt used (see ***Lithium Dimethylcuprate*** for purification of CuI and CuBr). Dark-colored solutions are indicative of decomposition.

Handling, Storage, and Precautions: stable in solution for several h below -60 °C; however, at elevated temperatures of 0 °C to -15 °C, thermal dimerization occurs and only 2,3-dimethyl-1,3-butadiene can be detected.[2] Air and moisture sensitive.

Introduction.

Lithium diisopropenylcuprate (**1**) displays the characteristic reactivity patterns of lithium diorganocuprates (see ***Lithium Di-n-butylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***).

Addition Reactions.

Reaction of (**1**) with α,β-alkenyl ketones (eq 1),[1,6] esters,[1e] and lactones[7,8] results in 1,4-transfer of the isopropenyl ligand. Several natural product syntheses employ this particular methodology as a key step.[6,7,9] A homoconjugate addition reaction of (**1**) with 1-(arylsulfonyl)bicyclobutanes (eq 2) has been observed.[10] The resultant substituted

cyclobutane derivative arises from addition across the central bond of the bicyclobutane from the *endo* side. Acylvinylcyclopropanes also afford homoconjugate addition products, and dienyl systems generally yield 1,6-addition products (eq 3).[11] 2-Pyrones can be converted to 2-siloxypyrylium salts,[12] which undergo regioselective addition at the 4-position (eq 4).

(4)

The key step in the synthesis of the C(7)-C(13) subunit of erythronolide B involved the reaction of (**1**) with (*R*)-3-benzyloxy-2-methylpropionaldehyde to afford the 1,2-addition product.[3] The stereochemistry of addition was controlled by chelation effects.

$[CH_2{=}C(Me)]_2CuLi$ effects carbocupration of acetylene in good yield. Generally, only those vinylic cuprates having a substituent geminal to copper afford satisfactory yields.[5]

Substitution Reactions.

Although isopropenyl transfers in epoxide substitutions are rare, (**1**) reacts with β,γ-epoxy alcohols[4] and epoxy esters (eq 5).[13] Reaction regioselectivity and yields are temperature dependent, and Cu^I-catalyzed Grignard additions are preferred. Cyanocuprates [e.g. $(CH_2{=}C(Me))CuCNLi$ and 2 $(CH_2{=}C(Me))Li$ + CuCN] afford better results in oxirane cleavage reactions.

(5)

The title reagent participates in general substitution reactions with alkyl (e.g. halides[14,15] and tosylates[15]), vinyl (eq 6),[16] and aryl (eq 7)[14] substrates.[1a,e] Acylation of (**1**) with acid chlorides is a poor synthetic route to 1-methylvinyl ketones.[2] Mixtures result from conjugate addition of the organocopper reagent to the product α,β-enone.

Lithium Diisopropylamide[1,2]

***i*-Pr$_2$NLi**

[4111-54-0] · $C_6H_{14}LiN$ · Lithium Diisopropylamide · (MW 107.15)

(hindered nonnucleophilic strong base used for carbanion generation, especially kinetic enolates,[4] α-heteroatom, allylic,[5,6] and aromatic and heteroaromatic carbanions;[7-9] unavoidable in organic synthesis)

Alternate Name: LDA.

Physical Data: powder, melts with decomposition; pK_a = 35.7 in THF.[3]

Solubility: sol Et_2O, THF, DME, HMPA; unstable above 0 °C in these solvents; stable in hexane or pentane (0.5-0.6 M) at rt for weeks, when not cooled or concentrated;[10] the complex with one molecule of THF is soluble in alkanes like cyclohexane and heptane.

Form Supplied in: solid; 2.0 M solution in heptane/THF/ethylbenzene stabilized with Mg(*i*-Pr$_2$N)$_2$; 10 wt % suspension in hexanes; LDA.THF complex, 1.5 M solution in cyclohexane and 2.0 M in heptane.

Analysis of Reagent Purity: several titration methods have been described.[120]

Preparative Methods: generally prepared directly before use from anhydrous ***Diisopropylamine*** and commercially available solutions of ***n-Butyllithium***. Another process, especially useful for the preparation of large quantities, is the reaction of styrene with 2 equiv of ***Lithium*** and 2 equiv of *i*-Pr$_2$NH in Et_2O.[11]

Handling, Storage, and Precautions: very moisture- and air-sensitive, and should always be kept in an inert atmosphere; irritating to the skin and mucous membranes; therefore contact with skin, eyes, and other tissues and organs should be avoided; proper protection is necessary. Use in a fume hood.

Enolates.

LDA is undeniably the first-choice base for the quantitative formation of enolates in general and kinetic (usually less substituted) enolates in particular. It was first used for this purpose by Hamell and Levine;[12] now it is a rare day (or night) that a chemist does not use or a graduate student does not propose LDA for a carbanionic transformation. Its advantages (fast, complete, and regiospecific enolate generation, unreactivity to alkyl halides, lack of interfering products) over earlier developed bases (e.g. ***Sodium Hydride***, ***Triphenylmethyllithium***)[13] are no longer noted. Except for enolates of aldehydes, which are very reactive and undergo self-aldol condensation reactions,[14] the derived lithio

enolates can be used for a broad spectrum of reactions including *O*- and *C*-alkylations and acylations, transmetalation to other synthetically useful metallo enolates,[15] and a multitude of carbanion-based condensations and rearrangements. The trapping of kinetically derived lithio enolates with ***Chlorotrimethylsilane*** as silyl enol ethers[16] (e.g. eqs 1 and 2),[17] originally used for separation from minor regioisomers and regeneration (with ***Methyllithium*** or ***Lithium Amide***) for the purpose of regiospecific alkylation, has been superseded in general by methods of their direct alkylation under Lewis acid catalysis.[18]

(1)

(2)

Consonant with its pK_a, LDA is used to derive a variety of α-stabilized carbanions, e.g. ketones (eqs 1 and 3),[19,20] α-amino ketones,[21] o-bromo ketones (eq 4),[10] imines (eqs 6 and 7),[22-24] imino ethers (eq 8),[25] carboxylic acids (eq 9),[26] carboxylic esters,[27] lactones,[28] amides,[29] lactams,[30] imides,[31] and nitriles[32] which may be alkylated or used in aldol condensations. Enolates of methyl ketones may be *O*-alkylated with ***Diethyl Phosphorochloridate*** to give enol phosphates which, upon β-elimination, afford terminal alkynes in high yields (eq 5).[33]

The (*Z*)/(*E*) stereoselectivity of enolate formation is dictated by the structure of the starting carbonyl compound and the base used for deprotonation. Compared to LDA, ***Lithium 2,2,6,6-Tetramethylpiperidide*** usually favors (*E*)-enolates whereas ***Lithium Hexamethyldisilazide*** preferentially leads to (*Z*)-enolates (eq 10).[34] With a *caveat* for any generalization, enolate configuration usually determines the stereochemical result in the product; for example, using a hindered ester and a bulky aldehyde combination, excellent stereoselectivities in aldol reactions are observed (eq 11).[27]

A useful reaction of ketone enolates is their oxidative coupling,[35] e.g. in the formation of a tricyclic intermediate towards the synthesis of the diterpene cerorubenic acid-III (eq 12).[36]

(12)

Alkylation of β-lactone enolates proceeds with high stereoselectivity dictated by strong stereocontrol from the C-4 R substituent (eq 13).[28] A similar result is obtained with the lithium enolates of diarylazetidinones which, on reaction with aldehydes, alkylate with high *cis* diastereoselectivity (eq 14).[30]

(13)

$R^1 = t\text{-Bu}$, $R^2 = \text{Me, Et, CH}_2\text{Ph, CH}_2\text{CO}_2\text{Me}$
$R^1 = i\text{-Pr}$, $R^2 = \text{Me, CH}_2\text{CH=CH}_2\text{, CO}_2\text{Me, CH}_2\text{C}\equiv\text{CH, COPh}$

(14)

Sarcosine (*N*-methylglycine)-containing tripeptides and hexapeptides are poly-deprotonated in the presence of excess ***Lithium Chloride*** to give amide enolates which give *C*-alkylated sarcosine products with ***Iodomethane***, ***Allyl Bromide***, and ***Benzyl Bromide*** (eq 15).[29] With (*S*) configuration amino acids, the newly formed stereogenic center tends to have

the (*R*) configuration. α-Nitrile carbanions are generally useful in alkylation and other reactions with electrophiles, e.g. eq 16.[32]

(15)

(16)

α,β-Unsaturated Carbonyl Compounds.

Of particular synthetic value is the generation of kinetic enolates of cyclic enones which may be alkylated (e.g. eq 17)[37] or undergo more demanding processes, e.g. double Michael addition (eq 18).[38] Imines of α,β-unsaturated aldehydes and ketones with δ-acidic hydrogens undergo clean deconjugative α-alkylation (eq 19).[23,39]

(17)

(18)

(19)

R = Me, $H_2C{=}CHCH_2$, $HC{\equiv}CCH_2$, $PhCH_2$, *i*-Pr, Bu
X = I, Br

Copper dienolates of α,β-unsaturated acids, prepared by ***Copper(I) Iodide*** transmetalation, can be selectively γ-alkylated with allylic halides; the use of nonallylic electrophiles leads mainly to α-alkylation (eq 20).[40] Copper enolates of α,β-unsaturated esters[41] and amides[42] show similar behavior.

(20)

Enolates with Chiral Auxiliaries.

Enantioselective alkylation of carbonyl derivatives encompassing chiral auxiliaries constitutes an important synthetic process. The anions derived from aldehydes,[43] acyclic ketones,[44,45] and cyclic ketones with ***(S)-1-Amino-2-methoxymethylpyrrolidine*** (SAMP)[46] are used to obtain alkylated products in good to excellent yields and high enantioselectivity (e.g. eq 21).[46]

(21)

Metalation[47,48] of chiral oxazolines, derived from (1*S*,2*S*)-1-phenyl-2-amino-1,3-propanediol, followed by alkylation and hydrolysis, leads to optically active dialkylacetic acids, e.g. eq 22,[49] 2-substituted butyrolactones and valerolactones,[50] β-hydroxy and β-methoxy acids,[51] 2-hydroxy carboxylic acids,[52] and 3-substituted alkanoic acids (eq 23).[53]

(22)

(23)

Imide enolates derived from (*S*)-valinol and (1*S*,2*R*)-norephedrine and obtained by either LDA or ***Sodium Hexamethyldisilazide*** deprotonation (eq 24)[54] exhibit complementary and highly diastereoselective alkylation properties. Mild and nondestructive removal of the chiral auxiliary to yield carboxylic acids, esters, or alcohols contributes to the significance of this protocol in small- and large-scale synthesis.[55,56]

(24)

Metalated *t*-butyl 2-*t*-butyl-2,5-dihydro-4-methoxyimidazole-1-carboxylate is alkylated in good yields and with high *trans* diastereoselectivity (>99:1); hydrolysis of the resulting adducts liberates the α-amino acid methyl esters in high yields (eq 25).[57] Using this method, the (*S*)-*t*-butyl 2-*t*-butylimidazole derivative gave, upon isopropylation and hydrolysis, the L-valine methyl ester with 81% ee.

(25)

RX = MeI, EtI, $H_2C{=}CHCH_2Br$, *i*-PrI, $PhCH_2Br$

Alkylations and aldol condensations of aldehydes and ketones with enolates of chiral dioxolanes proceed generally with high diastereoselection, e.g. eq 26[58,59] and eq 27.[60] The magnesium enolate of *S*-(+)-2-acetoxy-1,1,2-triphenylethanol generated by transmetalation with ***Magnesium Bromide*** has enjoyed considerable success in aldol condensations, e.g. eq 28.[61]

(26)

RX = EtI, PrI, BuI, $C_7H_{15}I$, $H_2C{=}CHCH_2Br$, $PhCH_2Br$

R = Ph, Pr, *i*-Pr

$M^+ = Li^+$	68:32-96:4
$M^+ = Mg^{2+}$	73:27-90:10
$M^+ = Zr^{4+}$	45:55-19:81

(28)

β-Lactams with high ee values[62] result from the condensation of lithium enolates of 10-diisopropylsulfonamide isobornyl esters with azadienes (eq 29).[63,64]

(29)

Enolate Rearrangements.

Ireland-Claisen Rearrangement.[65,66]

Silyl enol ethers of allyl esters undergo highly stereoselective Ireland-Claisen rearrangement to afford 4-pentenoic acids.[67] The structure of the ester and the reaction conditions dictate the stereoselectivity. It has seen wide synthetic application, e.g. the construction of unnatural (-)-trichodiene (eq 30).[68]

(30)

Wittig Rearrangements.[69]

Enolates derived from chiral propargyloxyacetic acids lead to chiral allenic esters, via a rapid diastereoselective [2,3]-Wittig rearrangement followed by esterification (eq 31).[70] Analogous rearrangements are feasible with carbohydrate derivatives[71] and steroids (eq 32).[72] In some cases, improved enantioselectivities resulted when the lithium enolate was transmetalated with ***Dichlorobis(cyclopentadienyl)zirconium***.[73] Benzylic, allylic, propargylic, and related lithio derivatives of cyanohydrin ethers undergo the [2,3]-Wittig rearrangement to afford ketones, e.g. eq 33.[74,75] Lithiated *N*-benzyl- and *N*-allylazetidinones lead, via [1,2]-Wittig rearrangement exhibiting radical character, to pyrrolidones (eq 34).[76]

(31)

(32)

(33)

(34)

Stevens Rearrangement.

Ammonium ylides undergo a stereoselective Stevens [2,3]-rearrangement when treated with LDA to afford *N*-methyl-

2,3-disubstituted piperidines (eq 35).[77]

(35)

Heteroatom-Stabilized Carbanions.

Heteroatom-stabilized and allylic carbanions serve as homoenolate anions and acyl anion equivalents,[5,78] e.g. α-anions of protected cyanohydrins of aldehydes and α,β-unsaturated aldehydes are intermediates in general syntheses of ketones and α,β-unsaturated ketones (eq 36).[79] Allylic anions of cyanohydrin ethers may be α-alkylated (eq 37)[80,81] or, if warmed to -25 °C, may undergo 1,3-silyl migration to cyanoenolates which may be trapped with TMSCl.[82] Metalated α-aminonitriles of aldehydes are used for the synthesis of ketones and enamines (eq 38).[83] Similarly, allylic anions from 2-morpholino-3-alkenenitriles undergo predominantly α-*C*-alkylation to give, after hydrolysis, α,β-unsaturated ketones (eq 39).[84]

(36)

R = Bu, Hex, Dec	80-85%

(38)

$R^1 = H, Me, CH_2CH_2Br$
$R^2 = H, Me$

R^1 = Me, Ph; R^2 = Me, Et, hexyl

(39)

α-Sulfoxide- and sulfone-stabilized carbanions are highly useful synthetic intermediates, e.g. α-lithiated (+)-methyl *p*-tolyl (*R*)-sulfoxide reacts with α,β-unsaturated aldehydes to give, after dehydration, enantiomerically pure 1-[*p*-tolylsulfinyl]-1,3-butadienes (eq 40),[85] metalation of phenyl 3-tosyloxybutyl sulfone leads to efficient cyclopropane ring formation (eq 41),[86] and precursors for the Ramberg-Bäcklund rearrangement are prepared via α-lithiated cyclic sulfones (eq 42).[87]

R^1 = Me, Et, Ph, 2-$MeOC_6H_4$
R^2 = H, Me

(40)

(41)

$R^1 = Ph, Hex; R^2 = H$
$R^1 = H; R^2 = H, Me$

(42)

Lithiated allylic sulfoxides may be α-alkylated and the resulting products subjected to [2,3]-sigmatropic rearrangement induced by a thiophile to give allylic alcohols (eq 43).[6,88] In contrast, alkenyl aryl sulfoxides produce α-lithiated species which are alkylated with MeI or PhCHO in good yields (eq 44).[89,90] LDA has also been used to metalate allylic[91] and propargylic selenides[92,93] as well as aryl vinyl selenides.[94]

$R^1 = H, Me; R^2 = H, Me$ $R^3 = Me, Et, H_2C{=}CHCH_2$

(43)

50-85% overall

Aromatic and Heteroaromatic Metalations.

Aromatics.

The utility of LDA for kinetic deprotonation of aromatic substrates is compromised by its insufficient basicity compared to the alkyllithiums.[8] Selective lateral deprotonation may be achieved which complements the *ortho*-metalation process (eq 45).[95]

Of considerable synthetic utility is the LDA-induced conversion of bromobenzenes into benzynes. Thus low-temperature deprotonation of *m*-alkoxyaryl bromides followed by warming to rt in the presence of furan gives cycloadducts (eq 46);[96] the lithio species may also be trapped with CO_2 at -78 °C to give unusual aromatic substitution patterns. Treatment of aryl triflates with LDA leads to *N*,*N*-isopropylanilines in good yield (67-98%).[97]

Remote metalation of biaryls and *m*-teraryls provides a general synthesis of substituted and condensed fluorenones (eq 47).[98] Similarly, biaryl *O*-carbamates undergo remote metalation and anionic Fries rearrangement to 2-hydroxy-2´-carboxamidobiaryls, which are efficiently transformed into dibenzo[*b*,*d*]pyranones.[99]

Lateral Lithiation.[7]

Laterally metalated *o*-toluic acids (eq 48),[100] esters (eq 49),[101] and amides (eq 50)[102] are important intermediates for chain extension and carbo- and hetero-ring annulation. Remote lateral lithiation of 2-methyl-2´-carboxaminobiaryls constitutes a general regiospecific synthesis of 9-phenanthrols (eq 51).[103-105]

(48)

(49)

(50)

(51)

α-Lithiated *o*-tolyl isocyanides may be alkylated and, following a second metalation with LiTMP, converted into 3-substituted indoles, e.g. eq 52.[106] Michael addition of α-lithiated 3-sulfonyl- and 3-cyanophthalides to α,β-unsaturated ketones and esters initiates a regioselective aromatic ring annulation process to give naphthalenes, e.g. eq 53.[107] Lithiated 3-cyanophthalides also undergo reaction with in situ-generated arynes to give anthraquinones (eq 54).[108] Similarly, aza-anthraquinones are obtained using 3-bromopyridine as the 3,4-pyridyne precursor.[109]

(52)

(53)

Heteroaromatics.[9]

LDA (and LiTMP) are advantageous bases for the directed *ortho*-metalation chemistry of pyridines[110,111] and, to a much lesser extent, pyrimidines.[112] Several halopyridines can be lithiated *ortho* to the halo substituent and trapped with various electrophiles (eq 55).[113]

Lithiated furan- and thiophenecarboxylic acids (eq 56),[114,115] indoles (eq 57),[116] indole-3-carboxylic acids (eq 58),[117] benzofurancarboxylic acids,[118] and thiazole- and oxazolecarboxylic acids[119] serve well in heteroaromatic synthesis.

Lithium Bis(1-methoxyvinyl)cuprate[1,2]

[56646-93-6] · $C_6H_{10}CuLiO_2$ · Lithium Bis(1-methoxyvinyl)cuprate · (MW 184.65)

(vinylcuprate reagent and acyl anion equivalent which undergoes 1,4-addition reactions,[3] substitution reactions,[3] and reductive elimination reactions[4])

Physical Data: yellow mixture, prepared in situ.

Solubility: sol THF.

Preparative Methods: by the slow addition of a -40 °C solution of ***1-Methoxyvinyllithium***[5,6] to a solution of purified ***Copper(I) Iodide*** in a ***Dimethyl Sulfide***-THF mixture (1:4 mole ratio of CuI:Me_2S) at -40 °C; stirring for 30 min gives a yellow mixture.[3]

Handling, Storage, and Precautions: air- and moisture-sensitive reagent prepared in situ. Use in a fume hood.

Addition Reactions.

Lithium bis(1-methoxyvinyl)cuprate affords transfer of the 1-methoxyvinyl ligand, an acyl anion equivalent,[7] via conjugate addition to α,β-alkenyl ketones (eq 1).[3] This cuprate reaction is sensitive to the substitution patterns of the α,β-enone, especially at the C-3 and C-5 positions of cyclohexenone derivatives. The vinyl ether 1,4-adducts can be efficiently converted to either 1,4-diketones under dilute acidic conditions [0.025 N HCl/MeOH-H_2O (4:1)] or 1,4-keto esters by ozonolysis in CH_2Cl_2-MeOH (9:1) at -60 °C.[3]

(1)

Substitution Reactions.

Lithium bis(1-methoxyvinyl)cuprate couples with ***Benzyl Bromide*** to afford a substitution product that, upon hydrolysis, yields 1-phenyl-2-propanone (eq 2). This reaction failed with 2-bromooctane.[3]

(2)

A lithium bis(1-methoxyvinyl)cyanocuprate reagent prepared from tetrakis(α-methoxyvinyl)tin reacts with ***Allyl Bromide*** to afford the coupling product in 60% yield.[8]

An allylic epoxide undergoes reaction with lithium bis(1-methoxyvinyl)cuprate to yield a substituted allylic alcohol (eq 3).[9]

(3)

Miscellaneous.

γ-Mesyl-α,β-enoates undergo reductive elimination with either lithium bis(1-methoxyvinyl)cuprate.BF_3 or lithium bis(1-methoxyvinyl)cyanocuprate.BF_3.2LiCl to afford β,γ-enoates (eq 4) in excellent yield.[4]

(4)

Related Reagents.

1-Ethoxyvinyllithium; ***Lithium Bis(1-ethoxyvinyl)cuprate***; ***Lithium (Z)-Bis(2-ethoxyvinyl)cuprate***; ***Lithium Divinylcuprate***.

Lithium 1-(Dimethylamino)naphthalenide[1]

[74379-76-3] · $C_{12}H_{13}LiN$ · Lithium 1-(Dimethylamino)naphthalenide · (MW 178.20)

(reductive lithiations of thioacetals;[2] generation of α-lithio ethers,[3] α-lithio silanes;[6] synthesis of α-trialkylsilyl ketones;[7] generation of allyllithiums;[1b] desulfurization[10])

Alternate Name: LDMAN.

Solubility: generated in THF

Preparative Methods: anhydrous THF and lithium metal ribbon are cooled to between -40 and -55 °C by use of a 1-hexanol/dry ice bath; 1-(dimethylamino)naphthalene is added slowly; the appearance of the dark green radical anion is evident within 10 min but complete conversion to LDMAN takes 3.5-4 h at -45 °C.

Handling, Storage, and Precautions: LDMAN must be prepared and stored below -45 °C. No method of titration has been developed.

Reductive Lithiation.

The major advantage of LDMAN for reductive lithiation over ***Lithium Naphthalenide*** is the ease in removal of the byproduct dimethylaminonaphthalene (DMAN) from the reaction mixture by extraction with dilute acid.[2]

Thioacetals.

Cyclopropane dithioacetals undergo reductive lithiation leading to cyclopropyllithium species which can be trapped by various electrophiles in high yields (eq 1).[2] Ketene phenyl thioacetals can also be used under these conditions to yield vinyl substituted thioethers (eq 2).[2]

R = H (90%), TMS (81%), Me (88%)

α-Lithio Ethers.

The generation of stabilized and unstabilized α-lithio ethers can be prepared and subsequently reacted with a variety of electrophiles (eq 3).[3] Treatment of 1-methoxy-1-phenylthiocyclopropanes with LDMAN followed by 1,2-trapping with conjugated aldehydes or ketones yields 1-cyclopropylallyl alcohols. These alcohols rearrange to the corresponding 2-vinylcyclobutanones upon the addition of acid (eq 4).[4] It was observed that ***Lithium 4,4´-Di-t-butylbiphenylide*** (LDBB) was a better reagent for this transformation when the alkoxy cyclopropyl vinyl carbinols are acid sensitive.[4b]

The α-lithio derivatives of substituted tetrahydrofurans and tetrahydropyrans can be generated and reacted with aldehydes (eq 5).[5] This approach led to the first stereoselective synthesis of (±)-*trans*-rosoxide. The organolithium derived for the tetrahydropyran was axial and could be equilibrated to the more stable equatorial species. A two-flask synthesis of brevicomin was performed with the α-lithio ether of a dihydropyran (eq 6).[3]

α-Lithio Silanes.

The use of α-lithio silanes is an excellent protocol for the Peterson alkenation.[6] Diphenyl thioacetals are treated with LDMAN, ***Chlorotrimethylsilane***, and LDMAN again, followed by trapping with an aldehyde or ketone leading to high yields of the β-silyl carbinol (eq 7). Elimination to the alkene can be accomplished with ***Potassium Hydride*** on the carbinol.[6a] An improved one-pot synthesis involves treatment of the lithium alkoxide with ***Potassium t-Butoxide***.[6b] This route has led to the synthesis of a variety of synthetically versatile alkylidene- and allylidenecyclopropanes.[6]

(7)

α-Trialkylsilyl Ketones.

LDMAN cleaves selectively the weak C-Se bond of silyl enol ethers of α-phenylseleno ketones.[7] The corresponding α-trialkylsilyl ketones were obtained in good yields after rearrangement of the trialkylsiloxyvinyllithium (eq 8). Modest yields were obtained for the acyclic analogs accompanied by the formation of alkynic compounds, which presumably arise via β-elimination of the siloxyvinyllithium species.

(8)

Allyllithiums.

The use of LDMAN provides a general route to the preparation of hydrocarbon allyl anions.[1b] The treatment of allylphenylthio ethers with LDMAN followed by reacting with ***Crotonaldehyde*** leads to a mixture of regioisomers (eq 9). A slight preference for attack at the more substituted allyl terminus was observed. Transmetalation of the allyllithium with Ti^{IV} leads selectively to the 1,2-addition product (derived from the more substituted terminus) as a 9:1 mix of diastereomers in high yield.

(9)

The regioselectivity of the allyl system can be reversed to favor the least substituted position by transmetalation with Ce^{III} leading to *cis*- or *trans*-homoallylic alcohols (eq 10).[8]

(10)

Synthesis of the elusive (1,1,3,3-tetramethylallyl)lithium was accomplished via LDMAN reductive lithiation.[9]

Desulfurization.

LDMAN has been used to remove the phenylthio group of substituted cyclobutanones (eq 11).[10] This method proved

superior to ***Raney Nickel***, which led to desulfurization and ketone reduction; lithium in ammonia led to an amide via ring cleavage.

(11)

Removal of the phenylthio group in 2-substituted 2-(phenylthio)cyclopropanecarboxamides led to high yields of the *trans*-substituted products (eq 12).[11]

Lithium (3,3-Dimethyl-1-butynyl)methylcuprate

[41602-02-2] · $C_7H_{12}CuLi$ · Lithium (3,3-Dimethyl-1-butynyl)methylcuprate · (MW 166.68)

(mixed cuprate methyl transfer agent)

Alternate Name: lithium (*t*-butylethynyl)methylcuprate

Preparative Methods: by the addition of ***Methyllithium*** to ***3,3-Dimethyl-1-butynylcopper(I)*** at -40 °C in ether or THF.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Methylating Agent.

House and Umen demonstrated that lithium (3,3-dimethyl-1-butynyl)methylcuprate (**1**) would transfer a methyl group to the relatively unreactive isophorone (**2**) in 76% yield with a 12% recovery of starting material.[1] The reaction rate was significantly slower than the rate of methyl transfer from the homocuprate ***Lithium Dimethylcuprate*** to (**2**). While Me_2CuLi reacted slowly with enone (**4**), there was no reaction with mixed cuprate (**1**) (eqs 1 and 2).

(1)

(2)

A study designed to evaluate the electron transfer abilities of several organocuprates showed that mixed cuprate (**1**) effectively converts keto-mesylate (**5**) into cyclopropyl ketone (**6**). Reaction of (**1**) with (**5**) at -78 °C in THF produced a 50% yield of (**6**), and at 0 °C the yield of (**6**) improved to 95% (eq 3).[2]

(3)

Related Reagents.

3,3-Dimethyl-1-butynylcopper(I); ***Lithium (3,3-Dimethyl-1-butynyl)vinylcuprate***; ***Lithium Dimethylcuprate***.

Lithium (3,3-Dimethyl-1-butynyl)vinylcuprate

[41602-03-3] · $C_8H_{12}CuLi$ · Lithium (3,3-Dimethyl-1-butynyl)vinylcuprate · (MW 178.69)

(mixed cuprate vinyl transfer agent)

Alternate Name: lithium (*t*-butylethynyl)vinylcuprate.

Preparative Methods: prepared in situ by addition of ***Vinyllithium*** to ***3,3-Dimethyl-1-butynylcopper(I)*** in ether at -40 °C.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Vinyl Transfer Agent.

Lithium (3,3-dimethyl-1-butynyl)vinylcuprate (**1**) is thermally more stable than ***Lithium Divinylcuprate*** and has been shown to transfer the vinyl group preferentially in 1,4-addition to enones (eq 1). Reaction of (**1**) with isophorone (**2**) is sluggish but will proceed, even though partial decomposition of the cuprate was reported.[1]

Related Reagents.

3,3-Dimethyl-1-butynylcopper(I); ***Lithium (3,3-Dimethyl-1-butynyl)methylcuprate***; ***Lithium Dimethylcuprate***; ***Lithium Divinylcuprate***.

Lithium Dimethylcuprate[1]

Me_2CuLi

[15681-48-8] · C_2H_6CuLi · Lithium Dimethylcuprate · (MW 100.57)

(methylating reagent; undergoes conjugate addition reactions,[1a,b,e,f] 1,2-addition reactions,[2] substitution reactions with alkyl, vinyl, and allyl substrates,[1a,c,e,f] carbocupration of alkynes,[1a] and reduction of carbon-heteroatom bonds[3])

Physical Data: colorless solution in THF or Et_2O; ^1H NMR (Et_2O) δ -1.46 to -1.55 ppm (at 25 to -70 °C);[4,5] ^7Li NMR δ 0.75 to -0.38 ppm (at 25 to -70 °C for Me_2CuLi) and δ 0.495 to -0.38 ppm (at 25 to -70 °C for Me_2CuLi + LiI);[5] X-ray scattering measurements;[4] molecular association data.[4,6]

Solubility: sol THF, Et_2O

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***, ***Copper(I) Bromide***, ***Copper(I) Trifluoromethanesulfonate***, ***Copper(I) Chloride***) and ***Methyllithium*** under N_2 or argon.[1a] Impurities present in CuI or CuBr can promote decomposition of the reagent. Pure, light tan CuI is obtained by dissolving crude CuI in boiling NaI(aq) followed by cooling, precipitation of CuI by addition of H_2O, filtration, sequentially washing the solid with H_2O, EtOH, EtOAc, Et_2O, and pentane, and then drying in vacuo for 24 h.[7] CuBr can be purified in a similar manner[8] with NaBr (aq) or by dissolving in 48% HBr, precipitating with H_2O, sequentially washing the solid with H_2O, EtOH, and Et_2O, and drying in vacuo.[9] CuI has also been purified by continuous extraction with THF in a Soxhlet extractor (12 h) followed by drying in vacuo.[10] Me_2CuLi free of LiI can be prepared from isolated ***Methylcopper***,[8] and the reagent can also be prepared in the presence of complexing agents from $CuI.SBu_2$,[8] ***Copper(I) Iodide-Tributylphosphine***,[8] or $CuBr.SMe_2$.[11] Polymer-supported Me_2CuLi is also available.[12]

Handling, Storage, and Precautions: air- and moisture-sensitive; handle under inert atmosphere in a fume hood.

Organocuprate Reagents.

Organocuprate reactivity and thermal stability are functions of Cu^I precursor,[1a,11b,13] solvent,[1,14] temperature,[1b] cuprate composition,[5,11b] cation (e.g. Li,[1a] Mg,[1a] Zn,[15a] Mn[15b]), and alkyl[1b] ligand. Experimental evidence for ligand and metal lability has been interpreted in terms of a dynamic equilibrium between Me_2CuLi, MeLi, and Me_3Cu_2Li.[5]

Me_2CuLi is formulated as a dimer, and since cuprate reactivity is a function of composition (e.g. Me_3Cu_2Li, $Me_5Cu_3Li_2$[16]), stoichiometric considerations are important in preparing the reagent. For any given application the reactivity profile of Me_2CuLi should be compared with a range of mixed homocuprates (e.g. MeCuC&tbond;CRLi, ***Lithium Cyano(methyl)cuprate***, and $Me_2CuCNLi_2$ or $Me_2CuCN.LiCN$),[17] mixed heteroatom alkylcuprates (i.e. amido,[10,18] phosphido ,[18] thioxy,[10] and alkoxy[10]), and methylcopper in the presence of additives (e.g. TMEDA/TMSCl,[19] TMSI,[20] and TMSCl + LiI[20]).

Conjugate Addition Reactions.

Me_2CuLi transfers the methyl ligand in a 1,4-fashion to a wide range of α,β-unsaturated substrates which include enones,[1,21,22b] enals,[22] enoates,[1,14d,23] ynones,[24a] ynoates,[24b] and α,β-unsaturated lactones,[25] imides,[26] and phosphonates.[27] α,β-Alkenyl sulfoxides,[28] sulfones,[29] and phosphine oxides,[30] α,β-allenyl phosphine oxides,[31a] sulfoxides, sulfones,[31b] and ketones,[31c,d] ketoketenimines,[31e] and α,β-alkynyl sulfones[32] also undergo 1,4-addition of methyl upon reaction with Me_2CuLi. These reactions proceed most readily in nonpolar solvents (Et_2O, PhMe, CH_2Cl_2, pentane), since good donor solvents (e.g. THF, DME, HMPA) diminish cuprate reactivity toward conjugate addition.[1,14] Less reactive substrates can often be activated toward conjugate addition by use of Lewis acid additives[1] and by solvent modifications (eq 1[14d]).[14] Utilization of low temperatures and nonpolar solvents[22] gives, with the more reactive enals,[22] better ratios of 1,4-/1,2-addition products, and $Me_5Cu_3Li_2$[16] is generally more effective than Me_2CuLi (see ***Dilithium Pentamethyltricuprate***).

(1)

Solvent	% Yield	% de
THF	<1	-
Diethyl ether	18	68
Diethyl ether, TMSI	83	0
Toluene	91	82
Dichloromethane	94	69-79

Conformational (eq 2)[33] and steric factors often control diastereoselectivity, although electronic[34] effects have been observed and stereodivergent pathways (eq 3)[35a] can sometimes be achieved by use of Lewis acid additives. Stereocontrol in conjugate addition to γ-heteroatom substituted α,β-unsaturated substrates is a function of heteroatom identity and substitution patterns (eq 4).[35b]

(2)

cis:*trans* = 80:20

(3)

-78 to 0 °C	61%	8:92
TMSCl, -78 °C	70%	99:1

(4)

R = H	TMSCl	80%	94:6
R = CO_2Et	-	68%	21:79

The conjugate addition reaction is compatible with alkyl bromide[36] and nitroalkane (eq 5)[37] functionality, although substitution of mesylates is competitive[36] with conjugate addition. Substrates with extended conjugation generally afford products of 1,6- or 1,8-addition.[38] Reaction of Me_2CuLi with ynenoates gives nonconjugated allenyl esters upon careful protonation of the enolate (eq 6).[38c] Bis-activation (e.g. alkylidenemalonates (eq 4), perhydro-1,4-oxazepine-5,7-diones,[39a] malononitriles,[39b] α-keto sulfoxides,[39c] and 2-acyl- or 2-alkoxycarbonyl-4-chromones[39d]) of the alkene facilitates conjugate addition, allowing participation of normally unreactive functionality (e.g. α,β-unsaturated nitriles

and 4-chromones).

(5)

(6)

Transition metal-alkene complexes undergo conjugate addition (eq 7),[40a] and Me_2CuLi and MeLi can effect different[40b] regioselectivities. Reaction at metal carbonyls can be a side reaction, and the efficiency of cuprate conjugate addition is dependent upon the ligands attached to the metal.[40b]

(7)

The enolate resulting from conjugate addition can be trapped with a variety of electrophiles (e.g. alkyl halides, halosilanes (eq 5), acid chlorides, formaldehyde, sulfenyl halides, selenenyl halides, aldehydes, Mannich salts,

triflating agents, CO_2, and chlorophosphates), although solvent modifications and use of additives (e.g. HMPA, ***Zinc Chloride***) are sometimes required.[41] The wide range and variability of reaction conditions required for successful tandem conjugate addition-enolate trapping reflect the complexity of these reaction mixtures and the generally diminished reactivity of the enolate, although enolates generated by conjugate addition of Me_2CuLi to γ-methylenebutenolides[42a] and simple butenolides[42b] participate in conjugate addition reactions with the starting lactone. Although acylation of these enolates is often problematic,[43a] *O*- vs. *C*-acylation can be controlled by use of ***Methyl Cyanoformate***[43b] in either Et_2O or THF (eq 8). A powerful application of cuprate 1,4-addition lies in the generation of regiospecific enolates which can undergo subsequent chemistry such as Dieckmann cyclization (eq 9)[23a] or Claisen rearrangement (eq 10).[44]

(8)

THF	89%	95:5
Et_2O	84%	7:93

(9)

(10)

α,β-Unsaturated substrates containing a good leaving group (e.g. halide, alkoxycarbonyl, sulfonate esters, phosphonate esters, alkyl- or arylthioxy, alkoxy) on the β-carbon atom undergo substitution reactions,[45] and tandem addition-elimination-addition pathways[46] can be designed (eq 11)[46b] for substrates with an α-CH_2L substituent; ***Chlorotrimethylsilane*** is necessary to prevent elimination of the nitro group in the reaction of Me_2CuLi with an α-nitromethylenone[37] (eq 5).

(11)

Several scalemic substrates[26,37,39a,47] (eqs 11 and 12[46b and 47c]) afford good to excellent asymmetric induction in the conjugate addition reaction, while more modest ee's have been achieved with chiral coordinating[47a] ligands.

(12)

Although simple cyclopropyl ketones do not react with Me_2CuLi, 1,1-bis-activated cyclopropanes (e.g. cyclopropylmalonates,[48a] β-keto esters,[48a] β-keto phosphonates[48b]) undergo a homoconjugate addition reaction (eq 13),[48a] and methylenecyclopropyl ketones[48c] participate in 1,5-additions.

(13)

Carbonyl Additions.

1,2-Addition of Me_2CuLi to ketones is generally limited to alkyl aryl[49a] and diaryl[49b] ketones, although an α,α´-

dialkoxy ketone (eq 14)[49c] gave good yields of the 1,2-addition product. Although enals preferentially react in a 1,4-fashion, 1,2-addition is often a serious side reaction and is favored by addition of TMSCl (which also facilitates 1,2-addition to ketones[2]); this additive also increases Cram stereoselectivity.[2,50]

(14)

Carbocupration.

Carbocupration of alkynes with Me_2CuLi appears limited to propynal diethyl acetal;[51a] the reaction fails with a higher homolog. Carbocuprations of 1-methoxyallene[51a] and of cyclopropene derivatives (eq 15)[51b] have been reported.

(15)

Substitution Reactions.

Me_2CuLi participates in S_N2-type substitution reactions[1a,c,e] with alkyl halides[8,52] (e.g. α-halo ketones[52a] and β-alkoxy-β-OLi intermediates[52b]), sulfonate esters,[53] oxiranes (epoxides),[54] tosylated aziridines,[55a] oxetanes,[55b] cyclic sulfinates,[56a] trifluoromethyl sulfonimides,[56b] β-lactones,[57] and with vinyl halides,[58a] triflates,[58b,c] and selenones.[58d] 1,1-Dibromocyclopropanes[59] can undergo a double substitution reaction with Me_2CuLi. Proximate heteroatoms facilitate the reaction of secondary tosylates.[53b] Alkyl substrates generally react with inversion of configuration, while

substitution on alkenyl substrates (eq 16)[58a] proceeds with retention of configuration. Although Me_2CuLi reacts with iodobenzene, it is unreactive towards aryl triflates and bromides and thus the reaction[8] is unsatisfactory for effecting aryl substitution.

(16)

Regioselective cleavage of oxiranes is a powerful synthetic method.[1a,c,e] Me_2CuLi cleaves epoxides at the least substituted center; 1,2-disubstituted epoxides afford mixtures of regioisomers. Regiocontrol is possible in 2,3-epoxy acids,[54a] esters,[54b,c] and 4-alkyl-substituted 2,3-epoxy alcohols,[54d] and regiocontrol is enhanced by solvent effects with 2,3-epoxy alcohols[54e] lacking a C-4 substituent.

Allylic substrates react with (S_N2') or without (S_N2) rearrangement via a π-allyl copper complex, with the *anti* S_N2' pathway predominating. Regio- and stereochemistry is generally governed by steric factors, although stereoelectronic effects may also operate.[1a] Allylic carbamates display high *syn* S_N2' stereo- and regioselectivity (eq 17[60a]).[60] Propargyl substrates uniformly give S_N2' substitution.[1a] Vinyloxetanes,[61] vinyloxiranes (eq 18),[62a] and allylic sulfoxides and sulfones[62b] undergo S_N2' substitutions, and the vinyloxiranes react with good diastereoselectivity.

(17)

Reaction of Me_2CuLi with acyl halides[1c] or thiol esters[63] results in nucleophilic acyl substitution, providing a useful route to ketones. Substitution reactions also occur between Me_2CuLi and sulfonium salts,[64] and via benzyne[65] intermediates.

Miscellaneous Reactions.

The reagent adds to 1-acylpyridinium salts[66] and to transition metal carbene complexes.[67] Me_2CuLi can reduce α-halo[3a] and α-acetoxy ketones[3a] and α,β-epoxy[3b] ketones. Reduction of α,β-epoxy sulfoxides affords enolates.[68] Me_2CuLi reacts with α,α´-dibromo ketones to afford α-methyl ketones via a cyclopropanone intermediate (eq 19).[36a,68] Reaction of Me_2CuLi with α´-nucleofuge α,β-enones leads to mixtures of reduction and substitution products.[70] Chiral allenes have been prepared by reaction of Me_2CuLi with allylic sulfinyl mesylates.[71]

Lithium Dimethylcuprate-Boron Trifluoride[1]

Me_2CuLi-BF_3

(Me_2CuLi)

[15681-48-8] · C_2H_6CuLi · Lithium Dimethylcuprate-Boron Trifluoride · (MW 100.57) (BF_3)

[7637-07-2] · BF_3 · Lithium Dimethylcuprate-Boron Trifluoride · (MW 67.81) ($BF_3.Et_2O$)

[109-63-7] · $C_4H_{10}BF_3O$ · Lithium Dimethylcuprate-Boron Trifluoride · (MW 141.95)

(methylating reagent that undergoes accelerated conjugate addition reactions,[1] 1,2-addition reactions,[2] substitution reactions with alkyl[1,3] and allylic substrates,[1,4] and reduction reactions[4])

Physical Data: clear solution in THF; ^1H NMR data for Me_2CuLi + 2 $BF_3.Et_2O$ at -80 °C is suggestive of a four-component system: Me_2CuLi (δ -1.57 ppm) + Me_3Cu_2Li (δ -1.31 and -0.35 ppm) + $MeLi.BF_3$ (δ 0.16 ppm) + BF_3.[1b]

Solubility: sol THF, Et_2O

Preparative Methods: addition of 2 equiv of ***Boron Trifluoride Etherate*** to ***Lithium Dimethylcuprate*** prepared from Cu^I salts and ***Methyllithium*** at -78 °C gives a clear solution in THF; warming the solution from -78 to -60 °C over 10 min generates a solution of Me_3Cu_2Li + BF_3 + $MeLi.BF_3$.[1b] The reagent can also be prepared by addition of ***Boron Trifluoride*** to Me_2CuLi, although use of $BF_3.Et_2O$ is more convenient and affords identical results.[3b]

Handling, Storage, and Precautions: air- and moisture-sensitive; handle under inert atmosphere in a fume hood.

Addition Reactions.

Addition of $BF_3.Et_2O$ to solutions of Me_2CuLi affords a reagent and reaction conditions in which conjugate transfer of the methyl ligand to α,β-alkenyl ketones (eq 1[5b]),[5] enoates,[6] lactones[5b,7] and alkylidenemalonates[6a,8] is accelerated relative to Me_2CuLi. The reagents $MeCu.BF_3$ and $Me_2Cu(CN)Li_2/BF_3$ can also be used, and the relative effectiveness of each reagent is generally substrate dependent. γ-Silyloxy- (eq 2)[6a] and γ-amino-α,β-enoates[6b] as well as γ-

alkoxyalkylidenemalonates[6a] undergo conjugate addition reactions with these reagents with varying degrees of stereoselectivity and yield. The reagent has often been used on substrates with reduced reactivity resulting from substitution and steric factors. This reagent combination has been effectively used in a homoconjugate addition reaction with a cyclopropyl ketone (eq 3).[9]

(1)

(2)

MeCu	68:32	6%
Me_2CuLi	73:27	26%
$Me_2Cu(CN)Li_2$	92:8	92%

(3)

1,2-Addition of $Me_2CuLi/BF_3.Et_2O$ to chiral imines provides a synthetic route to chiral amines that is stereodivergent relative to the 1,2-addition reactions of organolithium and organocerium reagents (eq 4).[2]

(4)

Me_2CuLi, BF_3 (from CuI)	14:86	52%
Me_2CuLi, BF_3 (from $CuBr \cdot SMe_2$)	10:90	56%
MeLi	95:5	66%
$MeCeCl_2$	97:3	65%

Substitution Reactions.

Addition of $BF_3.Et_2O$ to solutions of Me_2CuLi provides a reagent and reaction conditions that can effect substitution reactions on substrates, such as aziridines (eq 5)[10] and acetals,[3] that are normally unreactive toward Me_2CuLi alone. Although ***Titanium(IV) Chloride*** can also be employed, superior yields are generally obtained with $BF_3.Et_2O$ (eq 6).[3b] A β-bromobutenolide undergoes a substitution reaction with varying combinations of Me_2CuLi, MeLi, and $BF_3.Et_2O$ (eq 7).[11]

(5)

$R = PhCH_2$	80%
$R = (4\text{-}MeOC_6H_4)_2CH$	97%

(6)

Me_2CuLi, BF_3	95%	67% de
Me_2CuLi, $TiCl_4$	48%	88% de
MeCu, BF_3	50%	72% de

(7)

Me_2CuLi (1.5 equiv), 0 °C, 2 h	26-29%
Me_2CuLi, $MeBF_3Li$ (1.5 equiv), 0 °C, 2 h	57%
$MeBF_3Li$ (2 equiv), then Me_2CuLi (2 equiv) 0 °C, 30 min	78%

Allylic acetals[12] and oxazolidines[13] undergo reaction with Me_2CuLi/BF_3 to afford mixtures of rearranged (S_N2') and unrearranged (S_N2) substitution products, while allylic acetals[12] afford, exclusively, substitution products via S_N2' pathways. Chiral allylic oxazolidines give substitution products with very modest asymmetric induction.[13] Good asymmetric induction has been achieved with chiral γ-sulfonyloxy-α,β-enoates, which undergo preferential allylic substitution (eq 8).[4]

(8)

Me_2CuLi, BF_3	61%	>99% de	25%
$Me_2Cu(CN)Li_2$	78%	>99% de	11%
$Me_2Cu(CN)Li_2$, BF_3	96%	>99% de	-

Reduction Reactions.

γ-Acyloxy-α,β-enoates[4] undergo reduction upon treatment with Me_2CuLi/BF_3, in contrast to the γ-alkoxy derivatives,[6a] which undergo conjugate addition, and the γ-mesyloxy derivatives,[4] which undergo allylic substitution. $BF_3.Et_2O$ as an additive attenuates the electron transfer properties of Me_2CuLi.[14]

Related Reagents.

Lithium Cyano(methyl)cuprate; ***Lithium Dimethylcuprate***; ***Methylcopper***; ***Methylcopper-Boron Trifluoride Etherate***.

Lithium Diphenylcuprate[1]

Ph_2CuLi

[23402-69-9] · $C_{12}H_{10}CuLi$ · Lithium Diphenylcuprate · (MW 224.71)

(phenylating reagent; undergoes conjugate addition reactions,[1a,b,d] substitution reactions with alkyl, vinyl, and allylic substrates,[1a,c,d] oxidative coupling,[2] and addition to benzynes[3])

Physical Data: $Ph_2CuLi.0.4Et_2O$ isolated as white crystals or yellow powder when dry; [$Ph_2CuLi.3.25LiBr.4.2C_4H_8O_2$] precipitated from dioxane;[4a] X-ray structure of [$Ph_2CuLi.Et_2O$] prepared from $CuI.PBu_3$;[4b] ^{13}C NMR (DMS) of Ph_2CuLi prepared from CuBr: δ 163.1, 143.6, 128.1, 127.0 ppm; ^6Li NMR δ -0.57 ppm.[4c]

Solubility: sol THF, Et_2O, benzene, hexane.

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***, ***Copper(I) Bromide***, $CuBr.SMe_2$ or ***Copper(I) Iodide-Tributylphosphine***) under N_2 or argon atmosphere (see ***Lithium Dimethylcuprate***).[1a] Polymer-supported Ph_2CuLi can be prepared.[5]

Handling, Storage, and Precautions: dry crystals are stable at 25 °C, but the reagent decomposes in solution. Air and moisture sensitive. Use in a fume hood.

Addition Reactions.

Ph_2CuLi reacts with α,β-alkenyl ketones, aldehydes,[6] esters,[7] lactones,[8] malonates,[9] sulfones, and *N*-tosyl-1-azoalkenes[10] with conjugate transfer of the phenyl ligand.[1] α,β-Ynones,[11a] ynoates,[11b] and ynoic acids[11b] also participate in 1,4-additions with Ph_2CuLi, while yields vary widely[1d] with nitroalkenes. Appropriate location of nucleofuge substituents, including σ-complexed transition metals,[12a] can result in addition-elimination[12b,c] or addition-elimination-addition (eq 1)[12d] reactions. Subsequent exploitation of chemo- (eq 2)[7b] or regioselectively generated enolate anions represents a powerful dimension of cuprate conjugate addition reactions (eq 3[7c]).[13] Acylvinylcyclopropanes undergo 1,6-addition[14a] and 1,1-diactivated cyclopropanes undergo homoconjugate addition.[14b]

(1)

trans:*cis* = 95:5

(2)

α-H:β-H = 7:1

(3)

n = 1, X = Cl, 50%, 76% de
n = 2, X = I, 61%, 78% de

1,2-Addition of Ph_2CuLi to a chiral γ-alkoxy-α,β-enal occurs with vinylogous Cram selectivity in the presence of ***Chlorotrimethylsilane*** despite the general preference of this reagent to add 1,4 to enals.[15] Although carbocupration of acetylene has been achieved with Ph_2CuLi, the generality of the reaction has not been established.[1d]

Substitution Reactions.

Ph_2CuLi participates in substitution reactions with alkyl halides,[1] sulfinates,[16] and sulfonate esters (eq 4).[17] Vinyl halides,[18] triflates,[19a,b] and phenyl(vinyl)iodonium salts (eq 5)[19c] afford good yields of substitution products with retention of configuration, which is in marked contrast to the poor participation of aryl halides.[1] Anhydrides,[20a] thiol esters,[20b] and acyl halides[1d] react with Ph_2CuLi to afford aryl ketones.

(4)

(5)

Allylic halides (eq 6),[21] oxiranes (eq 7),[22] carboxylates, oxazolidines,[23] sulfonimides,[24] and ammonium salts[25] participate in *anti*-S_N2' pathways, although regio- and stereochemistry can vary.[1]

(6)

(*E*):(*Z*) = 92:8

(7)

X = TMS, 95%
X = Li, 72%

Miscellaneous Reactions.

Ph_2CuLi undergoes oxidative dimerization[2a] and oxidative coupling[2b] with amines. Reaction of Ph_2CuLi with α,α´-dibromo ketones[26] leads to α-phenyl ketones via cyclopropanone intermediates; the reagent also adds to benzynes.[3]

Related Reagents.

Lithium Dimethylcuprate; ***Lithium Di-p-tolylcuprate***.

Lithium Di-(*E*)-1-propenylcuprate[1]

[33462-38-3] · $C_6H_{10}CuLi$ · Lithium Di-(*E*)-1-propenylcuprate · (MW 152.65)

(propenylating reagent; undergoes conjugate addition reactions,[2-4] 1,2-addition reactions to aldehydes,[5,6] substitution reactions with alkyl[7] and vinyl substrates,[8] and oxidative dimerization[9])

Physical Data: colorless solution in Et_2O with CuI;[7] ink-blue color with CuI.P(OMe)$_3$.[4]

Solubility: sol Et_2O, THF.

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***)[7] or complexes (***Copper(I) Iodide-Tributylphosphine***[5,9] and ***Copper(I) Iodide-Trimethyl Phosphite***[4]) in Et_2O or THF at -78 °C under argon[1c] by the addition of *trans*-1-propenyllithium.[7] See ***Lithium Dimethylcuprate*** for purification of Cu^I salts.

Handling, Storage, and Precautions: air- and moisture-sensitive; use in a fume hood.

Introduction.

Lithium di-(*E*)-1-propenylcuprate displays the typical reactivity patterns of lithium diorganocuprates (see ***Lithium Dimethylcuprate***).

Addition Reactions.

Lithium di-(*E*)-1-propenylcuprate undergoes 1,4-addition to simple α,β-alkenyl ketones[2] with retention of alkene configuration by conjugate transfer of the (*E*)-1- propenyl ligand. This reaction has been applied to the synthesis of (±)-dechloromycorrhizin A (eq 1).[10] 1,4-Additions have been achieved with ethyl acrylate and ethyl propiolate in limited yields.[4] In the synthesis of aucantene, 1,4-addition to an α,β-alkenyl aldehyde[3] was achieved (eq 2). Diastereoselective 1,2-additions of lithium di-(*E*)-1-propenylcuprate to aldehydes can be performed in good yields[5] and in the presence of ***Magnesium Bromide*** etherate, which facilitates chelation control (eq 3).[6]

Substitution Reactions.

Lithium di-(*E*)-1-propenylcuprate reacts with alkyl halides and tosylates in high-yield substitution reactions, with and without HMPA additive, in Et_2O or THF.[7] Coupling of lithium di-(*E*)-1-propenylcuprate with a vinyl chloride was used in the synthesis of fulvoplumieren (eq 4).[8]

Oxidation Reactions.

Oxidative dimerization of a copper(I) ate complex prepared from *trans*-1-propenyllithium affords a good yield of the dimer *trans*,*trans*-2,4-hexadiene, without loss of stereochemical integrity (eq 5).[9]

Related Reagents.

Lithium Diallylcuprate; ***Lithium Bis(1-ethoxyvinyl)cuprate***; ***Lithium Diisopropenylcuprate***; ***Lithium Bis(1-methoxyvinyl)cuprate***; ***Lithium Divinylcuprate***; ***Lithium Divinylcuprate-Tributylphosphine***.

Lithium Di-*n*-propylcuprate[1]

***n*-Pr_2CuLi**

[43093-17-0] · $C_6H_{14}CuLi$ · Lithium Di-*n*-propylcuprate · (MW 156.69)

(propylating reagent; undergoes conjugate addition reactions,[1a,b,e] epoxide addition reactions,[1a,e] substitution reactions with alkyl and vinyl substrates,[1a,c,e] carbocupration with alkynes,[1e] and acylation reactions[1e])

Physical Data: dark suspension in Et_2O at 0 °C;[2] brown-black solution in THF between -20 and -10 °C.[3]

Solubility: sol THF, Et_2O.

Preparative Methods: prepared in situ from Cu^I salts (CuI or CuBr.SMe_2) under N_2 or argon atmosphere.[4] Rate of cuprate formation is temperature- and Cu^I salt-dependent, and reagent prepared from Cu^I halides is critically dependent on the purity of the Cu^I salts used (see ***Lithium Dimethylcuprate*** for purification of CuI and CuBr).

Handling, Storage, and Precautions: stable in solution for several hours below -60 °C; cuprate reactions are generally carried out at -78 °C. Air- and moisture-sensitive; use in a fume hood.

Introduction.

Lithium di-*n*-propylcuprate displays the characteristic reactivity patterns of lithium diorganocuprates (see ***Lithium Di-n-butylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***).

Addition Reactions.

n-Pr_2CuLi reacts with α,β-alkenyl ketones,[1e,4,5] esters,[1e,6,7,8] lactones,[8] and 1,3-dioxin-4-ones (eq 1)[2] with 1,4-transfer of the propyl ligand. *n*-Pr_2CuLi undergoes 1,6-addition to dienyl amides[9] and 1,8-addition to trienyl ketones and esters (eq 2).[10] Conjugate addition to 2-alkynoic esters proceeds in an exclusively *cis* manner (eq 3).[11]

(1)

(2)

R = Me, 52%
R = OEt, 61%

(3)

(*E*):(*Z*) = 93:7

Substitution Reactions.

n-Pr_2CuLi participates in substitution reactions with alkyl halides[1a,e,12-14] and sulfonate esters.[1a,e,12a,c,d,13,15-17] Several natural product syntheses employ this coupling methodology as the key step.[12,13,15-17] Vinyl iodides (eq 4)[11b] afford good yields of substitution products with retention of configuration. 2-Trimethylsilylpentanoyl chloride[1e] and γ-bromobutanoyl chloride react with *n*-Pr_2CuLi to afford the corresponding propyl ketones.

α,β-Epoxysilanes (eq 5),[18] alkenyl lactones,[3] and alkynyl carboxylates[1e] participate in *anti*-S_N2' pathways, although regio- and stereochemistry can vary.[1] Reaction of α,β-unsaturated oxazolidines with *n*-Pr_2CuLi (eq 6)[19] also proceeds in an S_N2' manner. The steric course can be reversed and the diastereoselectivity enhanced by salt and/or solvent effects.

Miscellaneous Reactions.

n-Pr_2CuLi reacts with ***9-Borabicyclo[3.3.1]nonane*** (9-BBN) to afford *B*-alkyl-9-BBN.[20] This procedure can be extended to prepare mixed organoboranes.

Lithium Diselenide

Li_2Se_2

[65027-50-1] · Li_2Se_2 · Lithium Diselenide · (MW 171.80)

(an excellent nucleophilic agent for synthesis of organic diselenides; can be used for synthesis of bis(trimethylsilyl) selenide[1])

Alternate Name: dilithium diselenide.

Solubility: sol H_2O; mod sol THF, HMPA, DMF, ethanol.

Form Supplied in: brownish-red solid, or suspension in THF.

Preparative Methods: reduction of ***Selenium*** with 1 equiv ***Lithium Triethylborohydride***[2] or with ***Lithium*** in THF in the presence of diphenylacetylene or naphthalene as catalyst.[1,3]

Handling, Storage, and Precautions: Li_2Se_2 is unstable in air and decomposes with separation of Se. It can be stored for a limited period of time under an inert gas atmosphere in a refrigerator. It should be used directly as prepared, without isolation. Use in a fume hood.

Lithium diselenide reacts with many carbon electrophiles. It is a more reactive nucleophile than K_2Se_2 and ***Sodium Diselenide***.[1] Substitution of halogens, mesyl, tosyl, or diazonium groups takes place to form bisaryl or bisalkyl diselenides in fair yields (eq 1).[1,4] In some cases, aromatic and heteroaromatic diselenides are accompanied by minor amounts of selenides as byproducts.[1]

(1)

The electrophilic carbon atoms of the oxirane or the lactone ring are attacked by the diselenide anion formed from Li_2Se_2 and ring opening leads to bis(β-hydroxyalkyl) diselenides (eq 2) or bis(carboxyalkyl) diselenides (eq 3).[1]

(2)

(3)

Bis(trimethylsilyl) Selenide is obtained when ***Chlorotrimethylsilane*** is treated with Li_2Se_2 (eq 4).[1]

Lithium Di-*p*-tolylcuprate[1]

(p-$MeC_6H_4)_2CuLi$

[54747-02-3] · $C_{14}H_{14}CuLi$ · Lithium Di-*p*-tolylcuprate · (MW 252.77)

(tolylating reagent which undergoes conjugate addition reactions,[2] addition reactions to pyrylium[3,4] and pyridinium salts,[5] and substitution reactions[6,7])

Physical Data: a clear yellow solution results from the reaction of a 1:1 mixture of $(p\text{-}MeC_6H_4)_4Cu_4$ and $p\text{-}MeC_6H_4Li$ in Et_2O, from which dimeric and tetrameric species have been isolated. Cryoscopic molecular weight determinations in C_6H_6 support a $(p\text{-}MeC_6H_4)_4Cu_2Li_2.2OEt_2$ composition. This complex is stable up to 135 °C. ^1H NMR (C_6D_6) δ = 0.64 (t, OCMe), 2.08 (s, *p*-Me), 2.72 (q, OCH_2), 7.0 (d, H-3), 8.20 (d, H-2, $J_{2,3}$ = 7.5 Hz). If prepared in C_6H_6, an unsolvated complex is formed which decomposes at ~110 °C.[1c,8]

Solubility: sol Et_2O, THF.

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***,[5,6] ***Copper(I) Bromide***[9]) under an inert atmosphere of N_2 or argon in Et_2O, THF, or C_6H_6.[1c,8] See ***Lithium Dimethylcuprate*** for purification of Cu^I salts.

Handling, Storage, and Precautions: extremely sensitive to moisture and oxygen; ignites spontaneously in air. Use in a fume hood.

Lithium di-*p*-tolylcuprate displays the typical reactivity patterns of lithium diorganocuprates (See ***Lithium Dimethylcuprate***).

Addition Reactions.

Lithium di-*p*-tolylcuprate transfers the *p*-tolyl ligand in a 1,4-addition to enantiomerically pure 3-methyl-2-(*p*-tolylsulfinyl)cyclopentenones to give 3,3-disubstituted cyclopentanones (eq 1) with a high degree of enantioselectivity.[2] 2,4,6-Trimethyl-[3] and 2-siloxypyrylium salts (eq 2)[4] also undergo 1,4-addition to give 4*H*-pyrans with good to high regioselectivity. There are some differences in yield and reactivity between organolithium and Grignard-derived cuprate reagents. 1-Acylpyridinium salts, prepared in situ from ***Pyridine*** and ***Methyl Chloroformate***, react with lithium di-*p*-tolylcuprate to afford 4-substituted 1,4-dihydropyridine

derivatives[5] with high regioselectivity (eq 3).

(1)

(2)

p-Tol_2CuLi, 65%; *p*-$Tol_2CuMgBr$, 28%

(3)

92:8

Substitution Reactions.

Lithium di-*p*-tolylcuprate participates in substitution reactions with alkyl (eq 4)[6] and aryl halides.[7] Aryl coupling with 1,8-diiodonaphthalene occurs to give 1,8-di-*p*-tolylnaphthalene.[7]

(4)

Miscellaneous Reactions.

A transmetalation reaction with diborane[9] can be effected to give aryl boron compounds which can be manipulated to give phenols, aryl amines, and triaryl boron complexes in limited yields. The reagent (p-$MeC_6H_4)_4Cu_2Li_2$ reacts with rhodium(I) complexes[10] under a carbon monoxide, nitrogen, or ethylene atmosphere to give 4,4´-bitolyl and 4,4´-ditolyl ketone. The product ratios and yields vary with reactant stoichiometry, and minor byproducts are formed.

Related Reagents.

Lithium Dimethylcuprate; ***Lithium Diphenylcuprate***.

Lithium Divinylcuprate[1]

$(CH_2{=}CH)_2CuLi$

[22903-99-7] · C_4H_6CuLi · Lithium Divinylcuprate · (MW 124.59)

(vinylating reagent; undergoes conjugate addition reactions[1a,b,d] and substitution reactions[1a,c,d])

Physical Data: clear yellow (prep. from $CuI.PBu_3$[2a]) or light gray solution (prep. from $CuBr.SMe_2$)[2b]

Solubility: sol THF, Et_2O

Preparative Methods: prepared in situ from Cu^I salts (***Copper(I) Iodide***,[2b] ***Copper(I) Bromide***.SMe_2,[3,2b] ***Copper(I) Iodide-Tributylphosphine***[2a]) and ***Vinyllithium*** under N_2 or argon atmosphere (see ***Lithium Dimethylcuprate***).

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Introduction.

Lithium divinylcuprate displays the characteristic reactivity patterns of lithium diorganocuprates (see ***Lithium Di-n-butylcuprate***, ***Lithium Dimethylcuprate***, ***Lithium Diphenylcuprate***).

Addition Reactions.

Lithium divinylcuprate reacts with α,β-alkenyl ketones,[1] esters (eq 1),[4] lactones,[5] nitro compounds,[6] and aldehydes[7] with conjugate transfer of the vinyl ligand (see ***Vinylcopper***). Addition of ***Chlorotrimethylsilane*** can accelerate the conjugate addition reaction and promote increased stereoselectivity (eq 2).[8]

The reagent adds stereoselectively (*cis* addition) to α,β-alkynoates, affording 2,4-dienoates.[9] Dienyl esters exclusively afford 1,6-addition products.[10] Tandem conjugate addition-enolate trapping is a powerful synthetic method (eq 3).[11] The reagent adds to vinyltriphenylphosphonium bromides to provide phosphoranes which can generally be exploited in subsequent chemistry.[12] 2-Siloxypyrylium salts undergo 1,4-addition, leading to 4-substituted 4*H*-pyrans.[13] 1,1-Diactivated cyclopropanes undergo a homoconjugate addition reaction with $(CH_2{=}CH)_2CuLi$.[14]

Substitution Reactions.

Lithium divinylcuprate participates in substitution reactions with alkyl halides[3c,15] and carboxylates.[3b,16] Vinyl triflates derived from β-dicarbonyl compounds afford substitution products that may result from addition-elimination reaction pathways (eq 4).[17] *gem*-Dibromocyclopropanes give mono- and disubstituted products, depending upon the reaction temperature.[18] Allylic ammonium salts participate in *syn*-S_N2' pathways with good stereo- and regioselectivity.[19]

Miscellaneous Reactions.

Alkylation of a tricarbonylcyclohexadienyliron salt with lithium divinylcuprate gives moderate yields.[20] Reaction of this reagent with oxiranes (eq 5; iodide from CuI),[21] 2-alkenyl oxetanes (eq 6),[22] activated cyclopropanes,[23] and aziridines[24] affords ring-opened products. Carbocuprations of cyclopropene derivatives have been reported.[25] Arylmercurials couple with this reagent, giving fair to good yields of cross-coupled products.[26]

Lithium Divinylcuprate-Tributylphosphine[1]

$(CH_2{=}CH)_2CuLi.n\text{-}Bu_3P$

[24743-97-3] · $C_{16}H_{33}CuLiP$ · Lithium Divinylcuprate-Tributylphosphine · (MW 326.95)

(phosphine-ligated divinylcuprate for 1,4-addition[2] and nucleophilic substitution[3])

Physical Data: see entries for ***Lithium Divinylcuprate***, ***Tri-n-butylphosphine***.

Solubility: sol ether, THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl. The yield of phenyl vinyl ketone is measured by GC, the response of which is calibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: a round-bottom flask equipped with magnetic stirring bar and rubber septum is charged with ***Copper(I) Iodide-Tributylphosphine***.[5-7] Under a nitrogen atmosphere, THF is added and the flask cooled to -78 °C; to the resultant cold solution is slowly added 2.0 equiv of ***Vinyllithium***[8] in THF. A blue-black mixture forms, which can be used immediately. Alternate preparations, by addition of 1.0 equiv of $n\text{-}Bu_3P$ to a THF slurry of CuI before addition of 2 equiv of vinyllithium, or by use of $CuBr(n\text{-}Bu_3P)_2$,[9] may be possible.

Handling, Storage, and Precautions: best results are obtained with high purity Cu^I salts,[10] dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides.[11] Like most alkyllithium reagents, vinyllithium is pyrophoric;[12] care must be exercised in its handling. Homocuprates are stabilized in the presence of stoichiometric quantities of $n\text{-}Bu_3P$; there is no noticeable decomposition at -78 °C.[6] Use in a fume hood.

Phosphine-ligated homocuprates were introduced early in the development of organocopper chemistry.[6,13] The $n\text{-}Bu_3P$ ligand solubilizes the homocuprate in ether solvents, increasing its reactivity, and also retards thermal decomposition. Generally, the presence of stoichiometric quantities of the ligand make reaction workup unsatisfactory;[6,13a,14] for this reason, various heterocuprates[15] have found wider application in organic chemistry.

Lithium divinylcuprate-tributylphosphine undergoes efficient substitution reactions with primary iodoalkanes when

used in excess.[6] It is more commonly found as a reagent in 1,4-additions to 2-alkenones, and has found application in the stereocontrolled synthesis of 1,3,5-triols[16] and 11-substituted 11-deoxyprostaglandins.[17] A typical example is the 1,4-addition to isophorone (eq 1);[5] the thermal stability of the reagent allows normally sluggish 3,3-disubstituted 2-alkenones to be used as substrates. The isolated chemical yield (60%), when compared to GC analysis of the crude product (85%), is indicative of the difficulty that can be encountered in efficiently separating the phosphine from the product.

Lithium α-Ethoxycarbonylvinyl(1-hexynyl)cuprate

[54111-85-2] · $C_{11}H_{16}CuLiO_2$ · Lithium α-Ethoxycarbonylvinyl(1-hexynyl)cuprate · (MW 250.76)

(organometallic reagent for the introduction of an acrylate unit onto allylic halides, vinyl epoxides, and carbonyl compounds; also effective for the synthesis of α-methylene-γ-butyrolactones from allylic halides)

Physical Data: thermally unstable organocuprate generated at -78 °C in the absence of moisture and oxygen.

Solubility: sol diethyl ether and THF at temperatures approaching -78 °C.

Preparative Methods: generated at -78 °C in ether by the metal-halogen exchange reaction of ethyl α-bromoacrylate and lithium 1-hexynyl(methyl)cuprate.[1]

Handling, Storage, and Precautions: must be prepared in the absence of moisture and oxygen at -78 °C. Diethyl ether should be freshly distilled from lithium aluminum hydride. Reaction temperatures should be maintained below -60 °C.

Generation and Reactivity of α-Alkoxycarbonylvinylcuprates.

In general, α-alkoxycarbonylvinylic cuprates have been generated in situ from the conjugate additions of organocopper reagents to alkynic esters and acids.[2-4] The unsubstituted title reagent can best be prepared by the reaction of methylcuprates with ethyl α-bromoacrylate (eq 1).[1] This metal-halogen exchange was first observed by Klein and Levene for substituted α-alkoxycarbonylvinylcuprates.[5] While oxidation, protonation, and iodination of the vinylcuprates have met with success, alkylations with simple alkyl halides other than methyl iodide have not been reported.[4]

The parent α-ethoxycarbonylvinylcuprate selectively reacts with allyl halides and propargyl halides to produce 1,3-dienes (**2**) and 1,3-enynes (eq 2).[1] The adduct (**3**) of the title reagent with 3-bromocyclohexene produces the acrylic acid

(**4**) after basic hydrolysis (eq 3). Iodolactonization of acid (**4**) and subsequent deiodination with ***Tri-n-butylstannane*** yields the α-methylene-γ-butyrolactone (**6**) (eq 4).[1]

An application of cuprate (**1**) in the synthesis of swazinecic acid dilactone[6] is provided in eq 5 for the allylation of halide (**7**).

Reactions with Carbonyl Compounds.

By analogy to reagent (**1**), α-methoxycarbonylvinylcuprate (**8**) was prepared from methyl α-bromoacrylate according to the aforementioned procedure.[1] A study of the reactivity of reagent (**8**) with ketones and α,β-unsaturated ketones was carried out. Unlike most organocuprates, reagent (**8**) added in a 1,2-manner to the carbonyl group of a series of cyclic ketones at -78 °C in high yield (eq 6).[7]

$n = 1$, R = Me	100%
$n = 2$, R = H	100%
$n = 1$, R = OAc	80%

More unusual is the fact that cuprate (**8**) preferentially adds 1,2 and not 1,4 to a variety of enones.[7] Cyclohexenone, cyclohexenecarbaldehyde, and acylcyclohexenes all gave 1,2-adducts exclusively with cuprate (**8**) (eqs 7 and 8). Only the reaction of (**8**) with methyl vinyl ketone resulted in the 1,4-adduct being the major product (eq 9).

(7)

(8)

R = H 80%
R = Me 92%
R = *i*-Pr 90%

(9)

This reactivity profile suggested that the α-alkoxycarbonylvinylcuprates are structurally indicative of an allenoate species. Evidence for the allenoate-type structure (**9**) comes from IR data[5] and trapping of substituted α-alkoxycarbonylvinylcuprates generated in the conjugate addition of alkylcuprates to ethyl propiolate (eq 10).[8] After the addition of ***Lithium Dimethylcuprate*** to ethyl propiolate at -78 °C, the reaction mixture was quenched with ***Chlorotrimethylsilane*** in triethylamine. The *O*-silylated allene (**10**) was isolated and characterized by IR and NMR.

Lithium-Ethylamine[1]

Li-EtNH$_2$

(Li)

[7439-93-2] · Li · Lithium-Ethylamine · (MW 6.94) (EtNH$_2$)

[75-04-7] · C_2H_7N · Lithium-Ethylamine · (MW 45.10)

(powerful reducing agent;[1] used for (partial) reduction of aromatics;[1a-d,f] conversion of alkynes to *trans*-alkenes and alkanes;[1a,f] stereoselective reduction of hindered ketones[1a,e,13b] and oximes;[16] reductive cleavage of polar single bonds[1a,b,d,f,19,27a])

Physical Data: Li: mp 180.5 °C; bp 1327 ± 10 °C; *d* 0.534 g cm^{-3}. EtNH$_2$: mp -81 °C; bp 16.6 °C; *d* 0.689 g cm^{-3}.

Form Supplied in: see ***Lithium***; ethylamine, 99% anhydrous, packaged in steel cylinders fitted with stainless steel valves.

Purification: see ***Lithium***; ethylamine can be purified by distillation from sodium under exclusion of H_2O and CO_2.

Handling, Storage, and Precautions: see ***Lithium***. Ethylamine is a toxic, colorless, and highly flammable gas with a low flash point (-16 °C). It should be handled in a well-ventilated hood, only after having eliminated all potential sources of ignition. It is corrosive to Cu, Al, Sn, Zn, and their alloys, but is stored satisfactorily in stainless steel.

Lithium-Ethylamine Solutions.

Lithium dissolves in EtNH$_2$ to give deep-blue solutions due to solvated electrons.[2a-d] Similar solutions are obtained with Li in other primary amines.[2a,b] EtNH$_2$ and ethylenediamine (EDA) are the most common solvents, but methylamine, propylamine, isopropylamine, and butylamine have also been used for reductions. The other alkali metals are less soluble in these amines and rarely used for reductions in amines. For instance, the solubilities in EDA at room temperature are 2.9×10^{-1} mol L^{-1} (Li), 2.4×10^{-3} (Na), 1.0×10^{-2} (K), 1.3×10^{-2} (Rb), and 5.4×10^{-2} (Cs).[2e] However, the solubilities can dramatically be increased by using crown ether and cryptand complexants.[2a,b] In contrast to the Li-amine solutions, the amine solutions of K, Rb, and Cs contain, besides solvated electrons, the metal anion as major species, while Na-amine solutions contain only the metal anion and are in general not blue at all.[2a,b] More recently, methylamine-assisted solubilization of Li and Li-Na mixtures (up to 1:1) in several amine and ether solvents,

in which the metals alone are not or only slightly soluble, has been reported.[3]

The reducing agents formed by Li in amines (Benkeser reduction) are more powerful but less selective than Li in NH_3.[1a,4] The higher reactivity is caused by higher reaction temperatures and possibly also by a smaller degree of electron solvation; the better solubility of many organic compounds in amines is also advantageous. The reactivity can be modified by using lower reaction temperatures and by addition of alcohols and secondary amines. Li-amine solutions are more sensitive to catalytic decomposition than Li in NH_3,[5] and clean solvents are mandatory.

Experimental.

Detailed procedures are available,[1b,c] as are details for reaction assemblies.[6] Reduction occurs by a sequence of single electron and proton transfers to the substrate, resulting in saturation of multiple bonds or fission of single bonds (see also ***Lithium***).

Reduction of Aromatic Compounds.

Li-$EtNH_2$ reduces benzene and its derivatives to cyclohexenes.[1a-d] Monoalkylbenzenes give mixtures of regioisomers. More selective formation of the Δ^1-ene is achieved when the reaction is performed in a mixture of primary and secondary amines.[1a] With excess Li and at higher temperatures, further reduction to cyclohexanes can occur (eq 1).[4]

Li-$EtNH_2$ affords, in the presence of alcohols (alcohol:-Li > 1:1), Birch reduction products, i.e. 1,4-cyclohexadienes.[1a,d] This procedure is more powerful than the Birch method (eq 2) and useful for the reduction of highly substituted benzene rings.[7] Li-EDA reductions of benzene derivatives have been performed (eq 2),[7b,8a,b] but Li-$EtNH_2$ appears to be superior for cyclohexene formation, probably due to the presence of *N*-lithioethylenediamine in refluxing EDA.[7b] Cyclohexenes and cyclohexa-1,4-dienes are formed in high yields by electrolysis of benzene derivatives with LiCl in $MeNH_2$ in a divided or undivided cell, respectively.[1a]

Reduction of polycyclic aromatic compounds is complex, and the products delicately depend on the exact reaction conditions. Most extensive reductions have been achieved with Li-EDA.[1f] Ferrocenes have been reductively cleaved with Li-propylamine in 35-77% yield.[9]

Alkenes.

Terminal[10a-c] and internal double bonds may be reduced by Li-amine; however, the latter react more slowly.[1a,b,d] Strained cyclic alkenes are more easily reduced, and ring size effects are observed. Na-*t*-BuOH-HMPA is more powerful and reduces even nonterminal alkenes in nearly quantitative yields.[10d]

Alkynes.

Internal alkynes are rapidly reduced to *trans*-alkenes by stoichiometric amounts of Li in amines.[1a] Excess Li leads to alkanes.[11] Ca in $MeNH_2$/EDA (1:1) has been used for similar reductions.[12] Li-$EtNH_2$-*t*-BuOH efficiently reduced an alkyne precursor of sphingosin, while triple bond reduction was incomplete with Na- and Li-NH_3.[6b] For the conversion of 1-alkynes to 1-alkenes, Na-NH_3-$(NH_4)_2SO_4$ is the system of choice.[1a] Li-EDA reduction of 1-alkynes usually gives alkanes.

Ketones.

Steroidal and triterpenoid ketones have been selectively reduced to the equatorial alcohols by Li-EDA in high yields.[10b,13] Stereoselective reduction of an α,β-unsaturated ketone to the (20*R*)(β)-alcohol was achieved with Li-EDA, while ***Sodium Borohydride*** led to a mixture of the (20*R*)(β)-alcohol and the Δ^{16}-(20*S*)-alcohol (eq 3).[14] Li-$EtND_2$-*t*-BuOD reduces α,β-unsaturated ketones to the saturated ketones in high yields and deuteriates the β-C-atom stereoselectively.[15] Li-$EtNH_2$ reduction of 3-oximino steroids is apparently the best procedure to prepare 3β-amino steroids.[16]

Li-EDA, reflux, 2 h	95%	-
$NaBH_4$, MeOH, py, rt, 100 h	45%	47%

Carboxylic Acids and Derivatives.

Li-$MeNH_2$ or -$EtNH_2$ reduce aliphatic saturated acids to aldehydes or imines in 53-84% yield, depending on the workup procedure.[17] Tertiary carboxamides are cleaved to aldehydes.[18] A major limitation is the substantial formation of transamidation byproducts. *N*-Proline peptide bonds have been cleaved to an extent of 50-70 %.[18a]

Reductive Cleavage of C-S and C-Se Bonds.[19]

Mainly sulfones,[20] but also sulfoxides,[21] sulfides,[22] and dithioacetals[23] have been desulfurized by Li in amines, most often in $EtNH_2$, but also in EDA[20g,h] and $MeNH_2$.[20f] As an excess of reducing agent is normally used, functional groups sensitive to SET may be reduced. Li-$EtNH_2$ cleaves allylic C-S bonds generally without side-reactions and has

thus proven to be especially useful in terpene synthesis for the reductive removal of sulfur-containing functional groups.[20a-c,22a,b]

Allylic aryl sulfones were converted to the alkenes by Li-$EtNH_2$ in 77-98 % yield,[20a-c] while ***Sodium Amalgam*** caused double bond migration (eq 4)[20a] or (*E*)/(*Z*) isomerization.[20b] However, in some cases, extensive double bond migration using Li-$EtNH_2$ or Li-EDA has been observed.[20d]

Li-$EtNH_2$, 0 °C, 30 min	77%		-
$Na(Hg)_x$, EtOH, 1.5 h	9	:	4 (90%)

Vinyl sulfones have been hydrogenolyzed to 2-alkenes by Li-$EtNH_2$ or C_8K in Et_2O with extensive isomerization of the *cis* double bond, forming *cis*/*trans* mixtures, while ***Aluminum Amalgam*** gave no reduction at all.[20e] Besides arylsulfonyl groups, some alkylsulfonyl groups have also been reductively removed by Li-$EtNH_2$ or -$MeNH_2$.[20c,f] Allylic alcohols survived the reductive cleavage of a sulfoxyl group by Li-$EtNH_2$ at -78 °C, whereas the double bond was simultaneously reduced when ***Raney Nickel*** was used.[21] While unsatisfactory results were obtained from attempts to desulfurize a 4-thiacyclohexene with Raney Ni, stepwise reduction using Li-$EtNH_2$, followed by Raney Ni to reduce the intermediate Li thiolate, yielded the alkene in 55-70%.[22c] Li-$EtNH_2$ reductively cleaves allylic *N*,*N*-dimethyldithiocarbamates that have been employed in the synthesis of disubstituted alkenes, in 90-95% yield.[24] Selenides and diselenoacetals are reduced to the corresponding alkanes by Li-$EtNH_2$ or Raney Ni in good yields.[25]

Epoxides.

Sterically hindered steroid and triterpenoid epoxides are reductively opened to the axial alcohols by Li-$EtNH_2$[26a] and Li-EDA.[26b] Thus Li-EDA reduced 3α,4α-epoxyfriedelan to the 4α-alcohol (eq 5), while ***Lithium Aluminum Hydride*** did not give any reduction at all, and the 3β,4β-isomer to the 3β-alcohol (eq 6).[26b] Reductive opening of other tri- and tetrasubstituted epoxides with Li-$EtNH_2$[26c-e] and Li-EDA[26f] are high yielding, but depending on the substrate, mixtures of alcohols are encountered.[26d-g] Reductions with Li in propylamine and butylamine seem to give more side-products.[26e]

(5)

(6)

Li-EDA[27a,b] and Ca-EDA[27a] are excellent reductants for epoxides of bicyclic compounds which react sluggishly and often undergo rearrangements with $LiAlH_4$ (eq 7)[27b] ***Lithium Triethylborohydride*** has proven to be a powerful reductant for bicyclic and tri- and tetrasubstituted oxiranes and is in some instances superior to Li-EDA.[27c]

		+ starting material	+ rearranged alcohols	(7)
Li-EDA, 50 °C, 1 h	87%			
$LiAlH_4$, diglyme 100 °C, 24 h	47%	19%	(44%)	

Reductive Cleavage of Miscellaneous Single Bonds.

Allyl and benzyl ethers are cleaved by Li-$MeNH_2$ or -$EtNH_2$ in fair to good yields[28] (eqs 8 and 9[28d,e]).

(8)

Similarly, the reductive cleavage of the *O*-alkyl bonds of esters of allylic alcohols is effected by Li-$EtNH_2$;[28e] allylic alcohols are normally not efficiently cleaved unless they are sterically hindered (eq 9).[28e]

(9)

R = Ac, 15 equiv Li	94%
R = Me, 30 equiv Li	84%
R = H, 22 equiv Li	15% + 61% S.M.

Esters of tertiary and sterically hindered secondary alcohols are cleaved to the corresponding alkanes and carboxylates by Li-$EtNH_2$[29a] and Li-EDA,[29b], whereas the parent alcohol is regenerated from nonhindered esters. This allows the selective deoxygenation of suitable diesters (eq 10).[29a]

Esters of moderately hindered secondary alcohols often give mixtures of alkane and alcohol. Using ***Potassium 18-Crown-6*** in ***t-Butylamine***, the alkane:alcohol ratio seems to be somewhat higher.[29a] ***Sodium-Hexamethylphosphoric Triamide***-*t*-butanol is another efficient system for the transformation of hindered esters to alkanes.[29c] K-Na eutectic solubilized with 18-crown-6 in *t*-butylamine and THF deoxygenates hindered and nonhindered esters.[29a] Alcohol regeneration by Li in refluxing $EtNH_2$ seems to be essentially due to transacylation, leading to *N*-ethylamides, while at low temperature the Bouveault-Blanc reaction predominates.[29a] Methyl esters of bulky carboxylic acids have been converted to the acids by Li in refluxing EDA.[29d]

Phosphorodiamidates are cleaved to alkanes by Li-$EtNH_2$, providing another indirect method for the deoxygenation of alcohols (eq 11).[30]

Li-amine reagents have been used for the cleavage of vinyl phosphates to alkenes,[31] of oxetanes,[32] of bicyclobutanes,[33] and of allylic *N*,*N*′-diacylhydrazines.[34] Li-EDA cleaves glycosyluronic acid-containing oligosaccharides specifically at the site of the acid residue.[35]

Lithium Fluoride[1]

LiF

[7789-24-4] · (MW 25.94)

(mild base;[2] can replace other halogens with fluorine;[3] desilylation reagent for forming reactive azomethine ylides;[4] stereoselective oxidative desulfurization when used with MeI and Li_2CO_3[5])

Physical Data: mp 848 °C; bp 1681 °C; *d* 2.639 g cm^{-3}.

Solubility: sol 0.27 g per 100 g water at 18 °C.

Form Supplied in: white solid; fused pieces and random crystals; widely available.

Handling, Storage, and Precautions: avoid breathing dust and contact with eyes, skin, or clothing.

Fluorination Agent.

Lithium fluoride can be used to exchange other halogens with fluorine. The reactivity of lithium fluoride is weaker than ***Potassium Fluoride*** and it cannot displace less reactive halogens, such as aryl chlorides or bromides. Glycerol chlorohydrin can be converted to the corresponding fluorohydrin in moderate yield (eq 1).[3] Treatment of dichloroboranes with lithium fluoride in ether gives the corresponding difluoroboranes in good yield (eq 2).[6] Lithium fluoride can also exchange with chlorine atoms[7] and trifluoromethanesulfonyloxy groups[8] on silicones to give the corresponding fluorinated silane derivatives (eqs 3 and 4).

(4)

Desilylation Agent.

Lithium fluoride has been found to be the most effective desilylating reagent for *N*-[(trimethylsilyl)methyl]amino ethers in the formation of azomethine ylides which can undergo 1,3-dipolar cycloaddition reactions with reactive dipolarophiles in high yield.[4] This is a very useful method for the preparation of pyrrolidines. A mixture of *N*-benzyl-*N*-methoxymethyl-*N*-(trimethylsilyl)methylamine and *N*-phenylmaleimide with LiF in anhydrous acetonitrile was sonicated for 3 h to give the cycloadduct in 72-75% yield (eq 5).[9] The cycloaddition proceeded with complete stereospecificity with dimethyl maleate and fumarate, giving rise to *cis* (eq 6) and *trans* (eq 7) cycloadducts, respectively. This cycloaddition did not take place with methyl propiolate; instead, the reaction gave the conjugate addition product (eq 8).

Desulfurization.

A mixture of lithium fluoride, ***Iodomethane*** and ***Lithium Carbonate*** is an effective reagent for the desulfurization of allylic dithiocarbamates.[5] All-*trans*-2,4,6,8-decatetraene was prepared in 75-80% yield (eq 9).[10] Terminal silyl derivatives can undergo this oxidative desulfurization regioselectively to form the terminal double bond, leaving the existing double bonds intact (eq 10).[11]

Lithium Hexamethyldisilazide

$(Me_3Si)_2NLi$

[4039-32-1] · $C_6H_{18}LiNSi_2$ · Lithium Hexamethyldisilazide · (MW 167.37)

(strong nonnucleophilic base)

Alternate Names: LHMDS; lithium bis(trimethylsilyl)amide.

Physical Data: distillable low-melting solid; mp 70-72 °C, bp 115 °C/1 mmHg.[2] LHMDS is a cyclic trimer in the solid state,[3] whereas in benzene solution it exists in a monomer-dimer equilibrium.[4] LHMDS is less soluble, less basic, more stable, and much less sensitive to air compared to ***Lithium Diisopropylamide***. pK_a 29.5 (THF, 27 °C).[1]

Solubility: sol most nonpolar solvents, e.g. aromatic hydrocarbons, hexanes, THF.

Form Supplied in: colorless crystalline solid, 1 M solution in THF or hexanes, 1.3 M solution in THF, 1 M solution in THF/cyclohexane.

Preparative Methods: conveniently prepared by the reaction of ***Hexamethyldisilazane*** with ***n-Butyllithium*** in hexane. For most uses the hexane is then evaporated and replaced with THF.[5]

Handling, Storage, and Precautions: a flammable, moisture sensitive solid; stable in a nitrogen atmosphere. Use in a fume hood.

Ketone Enolates.

A high yielding synthesis of 6-aryl-4,6-dioxohexanoic acids, precursors to antiinflammatory agents, is achieved using LHMDS (eq 1).[6] This process is applicable to large scale and involves relatively high reaction temperatures. The use of LDA gives reduced yields and small amounts of a diisopropylamide byproduct.

(1)

Ar = 4-ClC_6H_4, 2-thienyl, 3-pyridyl, 4-MeC_6H_4

Ester Enolates.

Enantiomerically pure amino acids may ultimately be prepared via stereospecific ester enolate generation using an oxazolidine chiral auxiliary (eq 2).[7] Moderate diastereoselectivity is observed using ***Potassium Hexamethyldisilazide***.

(2)

trisyl = 2,4,6-triisopropylbenzenesulfonyl

Lithio ethyl acetate is prepared in quantitative yield by reaction of LHMDS with ethyl acetate in THF at -78 °C.[8a] Reaction with carbonyl compounds leads to condensation products in high yield (eqs 3 and 4).[8] No racemization of the α-silyloxy esters occurs (eq 4).

(3)

(4)

Kinetic Enolates.

LHMDS is the recommended base for the generation of kinetic enolates. The resulting enolates are more regiostable than those generated with the corresponding sodium base, ***Sodium Hexamethyldisilazide***. Thus reaction of Δ^4-3-keto steroids with LHMDS yields 2,4-dienolate ions which can be methylated at C-2 or trapped as 2,4-dienolsilyl ethers (eq 5).[9] Use of ***Potassium t-Butoxide***/*t*-BuOH produces the thermodynamically more stable 3,5-dienolate. Acid-catalyzed conditions yields the 3,5-enol ether. Enolates generated with LHMDS may serve as ketone protecting groups during metal hydride reductions (eq 6).[10]

(5)

(6)

LHMDS has also been used in directed aldol condensations. The compatibility of the base with a silyl ether moiety is of note in the synthesis of (±)-[6]-gingerol (eq 7).[11]

Darzens Condensation.

The Darzens reaction invariably fails with aldehydes due to competing base-catalyzed self-condensation reactions.[12] With LHMDS as base, even acetaldehyde provides the desired glycidic ester products in high yield (eq 8).[13]

Intramolecular Cyclizations.

LHMDS-mediated intramolecular cyclizations have been demonstrated (eq 9).[14] The choice of counter cation has a dramatic effect on the stereochemistry of the cyclization.

Ester Enolate Claisen Rearrangement.

LHMDS is comparable to LDA for the stereoselective Ireland-Claisen rearrangement of ester enolates (eq 10).[15]

Intramolecular Double Michael Addition.

LHMDS-mediated sequential Michael reactions constitute the key component of a total synthesis of the diterpene alkaloid atisine (eq 11).[16]

(11)

Synthesis of Primary Amines.

N,*N*-Bis(trimethylsilyl)methoxymethylamine, formally a $^{+}CH_2NH_2$ equivalent, is obtained in high yield by treating chloromethyl methyl ether with LHMDS. Treatment of the bis-silylamine with organometallic reagents followed by mild solvolysis gives primary amines in good to excellent yield (eq 12).[17]

(12)

N-Trimethylsilylaldimines.

Aldehydes, even enolizable ones, undergo Peterson reactions with LHDMS to give *N*-trimethylsilylaldimines (eq 13),[18] which are valuable intermediates for a variety of systems, including primary amines,[18a,19] β-lactams,[18] and α-methylene-γ-lactams (eq 14).[20] Extension of this chemistry to include α-keto ester substrates allows for the preparation of α-amino esters.[21]

N,N-Bis(trimethylsilyl)aminomethyl Acetylide.

The reaction of LHMDS with propargyl bromide constitutes a straightforward route to a γ-amino lithium acetylide, a useful precursor to a wide variety of unsaturated protected primary amines (eq 15).[22]

For example, reaction with aromatic aldehydes gives α-alkynyl amino alcohols, which can be trapped as their silyl ethers. Base-catalyzed isomerization to an allenic isomer followed by hydrolysis and concomitant cyclization affords 2-substituted pyrroles (eq 16).[22]

β-Ketosilanes.

β-Ketosilanes may be prepared from α-bromo ketones using LHMDS to generate intermediate silyl enol ethers followed by metal-halogen exchange (eq 17).[23] They undergo facile rearrangement to silyl enol ethers and are also substrates, after carbonyl reduction, for overall Peterson alkenation.

Related Reagents.

Lithium Diethylamide; ***Lithium Diisopropylamide***; ***Lithium Piperidide***; ***Lithium Pyrrolidide***; ***Lithium 2,2,6,6-Tetramethylpiperidide***.

Lithium (1-Hexynyl)(2-tri-*n*-butylstannylvinyl)cuprate

[91158-78-0] · $C_{20}H_{38}CuLiSn$ · Lithium (1-Hexynyl)(2-tri-*n*-butylstannylvinyl)cuprate · (MW 467.78)

(mixed organocuprate; introduces vinylstannane group)

Preparative Methods: prepared in situ from ***1-Hexynylcopper(I)*** and ***(E)-1-Lithio-2-tributylstannylethylene***.[1]

Handling, Storage, and Precautions: air and moisture sensitive; use in a fume hood.

Lithium (1-hexynyl)(2-tri-*n*-butylstannylvinyl)cuprate (**1**) provided a *trans* ethylene dianion equivalent in the total synthesis of pleraplysillin-I. Addition of (**1**) to 3-furfuryl bromide (**2**) gave the furanylstannane (**3**). Palladium-catalyzed coupling of (**3**) with triflate (**4**) in the presence of ***Lithium Chloride*** provided pleraplysillin-I in two steps with complete retention of the *trans* alkene stereochemistry (eq 1).

Related Reagents.

1-Hexynylcopper(I); ***Lithium (1-Pentynyl)(2-tri-n-butylstannylvinyl)cuprate***; ***1-Pentynylcopper(I)***; ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide***.

Lithium Hydroperoxide

LiOOH

[23594-83-4] (.H_2O)

[54637-08-0] · $HLiO_2$ · Lithium Hydroperoxide · (MW 39.95)

(nonbasic hydrolysis of imides, amides, and esters; nondestructive recovery of chiral auxiliaries[3])

Physical Data: hydrate: white crystalline solid; *d* 1.69 g cm^{-3}.

Solubility: sol THF/H_2O (3:1), dioxane.

Preparative Methods: prepared in situ from ***Lithium Hydroxide*** and aq. ***Hydrogen Peroxide***.

Handling, Storage, and Precautions: reagent is typically generated in situ immediately prior to use. The hydrate can be prepared in an inert atmosphere from ethanolic LiOEt and 30% H_2O_2.[1] Extended storage over desiccants such as P_2O_5 leads to the formation of Li_2O_2. LiOOH.H_2O reacts spontaneously with atmospheric CO_2 to form Li_2CO_3 and O_2, and gradually decomposes on standing at room temperature to LiOH.H_2O.

Cleavage of *N*-Acyloxazolidones and Related Imides.

Effective use of the high diastereoselectivity realized from enolate chemistry of optically active *N*-acyloxazolidones,[2a-d] or Diels-Alder cycloaddition[2e] reactions of their α,β-unsaturated derivatives, depends upon clean removal of the chiral auxiliary in a regioselective fashion and without racemization at any acidic chiral centers. Lithium hydroperoxide was originally introduced as an alternative to reductive cleavage of sensitive β,γ-unsaturated *N*-acyloxazolidones with ***Lithium Borohydride***, and showed exceptional regioselectivity for attack at the exocyclic carbonyl with no epimerization or double bond conjugation (eq 1).[3]

In a subsequent, more complete study, lithium hydroperoxide was demonstrated to be the reagent of choice for regioselective cleavage of a variety of sterically hindered *N*-acyloxazolidones which underwent competing oxazolidone ring opening with LiOH or $LiOCH_2Ph$ (eq 2).[4] Similarly high selectivity for attack at the more hindered carbonyl group was also seen with an acyclic imide (eq 3). The reaction is usually carried out in aqueous THF and is typically quenched with aqueous Na_2SO_3 to reduce the peracid intermediate and consume unreacted LiOOH. Recent examples include the use of this cleavage step in the synthesis of amino acid derivatives,[5a] the calyculins,[5b-c] macbecin,[5d] baclofen,[5e] and polyketide intermediates in the biosynthesis of nargenicin.[5f]

1. LiOOH, aq THF, 0 °C 2. Na_2SO_3	76%	16%
LiOH, aq THF, 0 °C	0%	100%

(3)

In a route to optically active α-alkylsuccinates, LiOOH proved to be highly chemoselective for imide cleavage, with no competing cleavage of a methyl ester also present.[6] In a recent approach to β-amino acids, regioselective cleavage of an intermediate in the synthesis of thienomycin was found to require the addition of DMF (3:3:1 DMF/THF/H_2O) as a cosolvent (eq 4).[7] Importantly, this reagent can be used in the presence of α-phenylselenyl groups with no competing oxidation of the selenide.[8]

(4)

Other examples (shown in **1**-**6**) include the cleavage of *N*-acylbenzoxazolinones,[9] carbohydrate-derived *N*-acyloxazolidones,[10] camphor-derived *N*-acyloxazolidonethiones,[11] camphor-derived imides,[12] *N*-acylpiperidone derivatives of Kemp's triacid,[13] and chiral *N*-acylpyrimidones.[14] Also, cleavage of *N*-acyl and *N*-carbamoyl derivatives of an oxazolidone obtained from *endo*-borneol has been described as a method for resolving racemic carboxylic acids or alcohols.[15]

(1)

(2)

(3)

(4)

(5)

(6)

Cleavage of *N*-Acylsultams.

In addition to imide carbonyls, optically active *N*-acylsultams can be cleaved using LiOOH. Following either asymmetric alkylation[16a] or conjugate addition,[16b] bornanesultam chiral auxiliaries can be removed with good recovery and without racemization of the resulting carboxylic acids (eq 5). This cleavage method was also used in the preparation of a toluenesultam chiral auxiliary.[16c]

(5)

Cleavage of Esters and Amides.

Notwithstanding the previously noted chemoselectivity for imides,[6] LiOOH has been used to saponify esters under mild conditions. For example, in a synthesis of a bifunctional chelate molecule, an ethyl ester was cleaved in high yield using LiOOH.[17] Also, in the synthesis of a heparin analog, simultaneous deprotection of a series of primary and secondary acetates and two methyl esters was effected via LiOOH without the intervention of undesired β-elimination.[18] LiOOH was also used to cleave a methyl ester in a recent total synthesis of the leukotriene precursor (15*S*)-HPETE (eq 6).[19] Interestingly, cycloheptene was used to reduce the resulting peroxy acid selectively in the presence of an allylic hydroperoxide. Finally, deprotection of an *N*-formylamino polyol was carried out using LiOOH/THF.[20] The authors noted that stabilization of the THF with BHT was desirable to suppress side reactions involving radicals.

Lithium Hydroxide

LiOH

[1310-65-2] · HLiO · Lithium Hydroxide · (MW 23.95) (.H_2O)

[1310-66-3] · H_3LiO_2 · Lithium Hydroxide · (MW 41.97)

(very strong alkali; reacts readily with acids and is used as a base as well as a nucleophile in organic reactions, particularly in the hydrolysis of esters and amides)

Physical Data: d (anhyd.) 2.54 g cm^{-3}; (monohyd.) 1.51 g cm^{-3}; mp (anhyd.) 471 °C.

Solubility: sol water: (w/w) 10.7% at 0 °C, 10.9% at 20 °C, 14.8% at 100 °C; pH of 1.0 N soln. about 14; slightly sol ethanol.

Form Supplied in: the commercially available material is the monohydrate: small, white monoclinic crystals.

Handling, Storage, and Precautions: corrosive. Harmful if swallowed, inhaled, or absorbed through skin. Toxicity in rat: LD_{50} 365 mg kg^{-1} (oral dose). Material is extremely destructive to tissue of the mucous membranes and upper respiratory tract, eyes, and skin. Inhalation may be fatal; do not breathe dust. Avoid contact with eyes, skin, and clothing. Incompatible with strong oxidizing agents and strong acids. Absorbs moisture and CO_2 from air. Hygroscopic; store in a cool dry place. Wash thoroughly after handling.

Hydrolysis of Esters.

The methyl ester of the 9,11-azo analog of prostaglandin endoperoxide PGH_2 (**1**) was hydrolyzed under mild conditions using 0.15 N LiOH in 2.5:1 THF-H_2O at 0 °C for 2.5 h to give the 9,11-azo analog of PGH_2 (**2**) in 99% isolated yield (eq 1).[1]

Hydrolysis of Urethanes to Alcohols.

The *p*-phenylphenylcarbamoyl group served as a protecting group for the C-11 alcohol and also as a directing group to control the stereochemistry of the carbonyl reduction at C-15 in the synthesis of the prostaglandin synthon (**3**). This protecting group was removed following the ketone reduction by treating (**3**) with 1 M aq LiOH at 120 °C for 72 h to afford (**4**) in >90% yield.[2]

(3) R = *p*-PhC$_6$H$_4$NHCO-
(4) R = H

Hydrolysis of Bile Acid Methyl Esters.

Bile acid methyl esters were hydrolyzed under mild conditions with LiOH in aq. methanol at 25 °C to the bile acids. This procedure gave higher yields (80-98%) compared to conventional ***Sodium Hydroxide*** or ***Potassium Hydroxide*** hydrolysis reactions (48-55%). The procedure caused no racemization or elimination side reactions, e.g. (23*R*)-methyl 3α,7α,23α-trihydroxy-5β-cholan-24-oate (**5**) gave the corresponding acid (**6**) in 96% isolated yield (eq 2).[3]

Hydrolysis of *N*-Boc Lactams and *N*-Boc Secondary Amides.

N-Boc derivatives of lactams were regioselectively hydrolyzed with LiOH in aq. THF to the corresponding o-amino acids. For example, *N*-Boc valerolactam was hydrolyzed with 3.0 equiv of LiOH in aq. THF at rt to give the *N*-Boc-δ-aminovaleric acid in 90% yield (eq 3). The reaction conditions are very mild and provide the o-amino group in a protected form, thus permitting further elaboration of the carboxylic acid residue. The procedure was applied successfully to the hydrolysis of *N*-Boc secondary amides to the corresponding acids.[4]

Cleavage of 2-Oxazolidinone Chiral Auxiliaries.

The hydrolysis of the *N*-(α-azidoacyl)- and *N*-[α-((+)-MTPA-amino)acyl]-2-oxazolidinone derivatives (**7**) with LiOH (2 equiv) in THF-H_2O (3:1) for 30 min at 0 °C afforded the corresponding α-amino acid synthons (**8**) in 95-100% yields (eq 4). No detectable racemization was observed when R = Bn and about 1% racemization occurred with the phenylglycine synthons (R = Ph).[5]

(4)

Regioselective Hydrolysis of Carboximide Derivatives.

The regioselective hydrolysis of the carboximide derivative (**9**) was achieved with excess 2 N aq LiOH in dioxane at rt overnight to give the desired β-hydroxy-α-amino acid (**10**) and a byproduct (**11**) (eq 5) in isolated yields of 83% and 17% respectively (a 5:1 ratio). The products (**10**) and (**11**) are the result of endocyclic and exocyclic carbonyl attack by the hydroxide ion, respectively. The success of this procedure was based on the selection of the sterically demanding *N*-protecting Boc group, which largely directed the regioselectivity of the attack by the hydroxide ion to the less hindered oxazolidinone carbonyl.[6]

If, on the other hand, the hydrolysis was to be directed towards the exocyclic carbonyl of a highly branched *N*-acyl oxazolidinone derivative, a complementary procedure was developed employing lithium hydroperoxide to achieve that regioselectivity.[7]

Hydrolysis of *N*-Monosubstituted Amides via Acetoxypivalimides.

Hydrolysis of *N*-monosubstituted amides under mild conditions without epimerization at the α-position was accomplished in two steps. The amides (**12**) were first converted into the *N*-acetoxypivaloyl derivatives (**13**) (eq 6). These derivatives were then treated with LiOH in THF to give the carboxylic acids (**15**) in good yields. The procedure takes advantage of the easier hydrolysis of imides than amides and the intramolecular nucleophilic attack by the acetoxy oxygen on the imide carbonyl (eq 7) causing an *N*-*O* acyl migration to form the intermediate acyloxypivalamide (**14**). Further hydrolysis of (**14**) gave the desired carboxylic acids (**15**) and *N*-alkylhydroxypivalamides (**16**).[8]

The method is mild enough to use with *N*-butyl-(2*S*,3*S*)-dimethyl-4-pentenamide to give (2*S*,3*S*)-dimethyl-4-pentenoic acid in 76% yield with practically no epimerization (eq 8).[8]

Selective *O*-Acetyl Hydrolysis of *N,O*-Diacetylhydroxamates.

Treatment of *N*-acetoxy-*N*-{1-[4-(phenylmethoxy)phenyl]ethyl}acetamide (**17**) with LiOH in 2:1 *i*-PrOH-H_2O selectively hydrolyzed the *O*-acetyl to give the hydroxamic acid (**18**) (eq 9). The procedure was described as part of a two-step conversion of hydroxylamines into hydroxamic acids.[9]

(9)

Selective *O*-Deacetylation in Carbohydrates.

The *O*-acetyl groups in the penta-*O*-acetyl tri-*N*-acyl disaccharide (**19**) (eq 10) were selectively hydrolyzed with 0.6 M LiOH for 1 h at rt to give, after purification and recrystallization, the pentahydroxy tri-*N*-acyl disaccharide (**20**) in 92% yield.[10]

(10)

Dihydroquinoxalones from Ethyl Alkylglycidates.

The reactions of *o*-phenylenediamine with ethyl 2,3-epoxycrotonate (**21a**), ethyl 2,3-epoxypentenoate (**21b**), or ethyl 2,3-epoxy-3,3-dimethylacrylate (**21c**) were catalyzed by LiOH and gave the dihydroquinoxalones (**22a-c**) (eq 11). The initial nucleophilic attack occurred on the α-carbon of (**21**) followed by intramolecular aminolysis to give the cyclized product. When unsubstituted epoxyacrylates and cinnamates were used, the initial attack occurred on the β-carbon and gave the uncyclized hydroxyamino esters.[11]

Synthesis of 3-Hydroxybenzo[*b*]thiophene-2-carboxylates.

Substituted methyl 3-hydroxybenzo[*b*]thiophene-2-carboxylates (**24**) were prepared in yields ranging from 50 to 85% by the LiOH-catalyzed reaction of substituted methyl *o*-nitrobenzoates (**23**) and methyl thioglycolate in dry DMF (eq 12). Under the reaction conditions the activated nitro group was displaced by the thiolate anion, followed by cyclization.[12]

(12)

Stereochemical Control in Conversion of Diols to Epoxides.

The intermediate 22-tosyloxy-23-pivaloxy steroid (**25**) was prepared from the corresponding diol and then treated with LiOH in dioxane-H_2O at rt for 8 h to give the 22,23-epoxy steroid (**26**) in 92% yield (eq 13).[13]

(13)

Oxetane Formation from 3,4-Epoxy Alcohols.

Treatment of the 3,4-epoxy alcohol (**27**) with LiOH, NaOH, or KOH in aq DMSO at 140-150 °C gave a mixture of the oxetane (**28**) in 49% yield and the 1,2,4-triol (**29**) in 32% yield (eq 14). Reaction times were 15, 45, and 90 min for LiOH, NaOH, and KOH, respectively. The procedure was presented as a nonphotochemical synthesis of oxetanes.[14]

(14)

(27) **(28)** **(29)**

M = Li, Na or K

Formation of *trans*-Hydrindanones.

Treatment of 8-oxo-2-methyl-6-nonenal (**30**) with LiOH in MeOH gave a 4:1 mixture of *trans*- and *cis*-hydroxyhydrindanones (**32**). The reaction proceeded via consecutive intramolecular Michael and aldol addition reactions. The stereochemical control was greatly improved by using the better chelating Zr^{IV} *n*-propoxide in benzene to effect the initial Michael addition, yielding the monocyclic ketoaldehyde (**31**), and then adding LiOH/MeOH to effect the aldol addition step (eq 15). This modification gave the desired hydroxyhydrindanone (**32**) in 90% yield as a 40:1 mixture of the *trans* and *cis* isomers.[15]

(15)

(30) **(31)** **(32)**

trans:*cis* = 40:1

Synthesis of 1-Deoxy-D-*erythro*-2-pentulose.

Treatment of a solution of methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**33**) in ether with an aq. soln. of LiOH and vigorously stirring the two-phase system at 20 °C for 16 h gave 3,5-*O*-benzylidene-1-deoxyketo-D-*erythro*-2-pentulose (**34**) in 55% isolated yield (eq 16).[16]

(16)

Conversion of Mixed Phosphoric Acid Triesters to Mixed Phosphoric Acid Diesters.

In a three-step sequence for the conversion of bis(*p*-nitrophenyl) hydrogen phosphate to dialkyl phosphates (**36**), the intermediate dialkyl *p*-nitrophenyl phosphates (**35**) were selectively hydrolyzed with 1N LiOH in acetonitrile at rt to give the desired dialkyl phosphates under mild conditions (eq 17). Various mixed dialkyl phosphates were prepared in good overall yields without isolation of any synthetic intermediate.[17]

(17)

R^1	R^2	overall yield
$Ph(CH_2)_2$	$MeO(CH_2)_2$	80%
$Ph(CH_2)_2$	≡—CH_2	76%
$MeO(CH_2)_2$	≡—CH_2	75%

Lithium Iodide[1]

LiI

[10377-51-2] · ILi · Lithium Iodide · (MW 133.84)

(ester cleavage and decarboxylation;[2] source of nucleophilic iodide;[3] mild Lewis acid;[1] salt effects in organometallic reactions;[1] epoxide opening[4])

Physical Data: mp 449 °C; bp 1180 °C; *d* 4.076 g cm^{-3}.

Solubility: 165 g/100 mL H_2O (20 °C); 433 g/100 mL H_2O (80 °C); 251 g/100 mL EtOH (20 °C); 343 g/100 mL MeOH (20 °C); 43 g/100 mL acetone (18 °C); very sol NH_4OH.

Form Supplied in: anhydrous white solid or as the hydrate.

Preparative Methods: the anhydrous salt of high purity can be prepared from lithium hydride and iodine in ether.[5]

Purification: crystallized from hot H_2O (0.5 mL g^{-1}) by cooling in $CaCl_2$-ice or from acetone. LiI is dried for 2 h at 120 °C (0.1 mmHg, P_2O_5) before use.

Handling, Storage, and Precautions: for best results, LiI should be dried prior to use in anhydrous reactions.

Heterolytic C-X Bond Cleaving Reactions.

In the presence of amine bases, LiI has been extensively used as a mild reagent for the chemoselective cleavage of methyl esters (eq 1).[6] Decarboxylation of methyl esters usually occurs when an electron-withdrawing group is present at the α-position of the ester (eq 2).[7] Ester-type glycosyl linkages of acidic tri- and diterpenes can also be selectively cleaved under these conditions.[8] Aryl methyl ethers can be demethylated to afford the corresponding phenols upon heating with LiI and *s*-collidine.[9]

(1)

(2)

1,2-Oxiranes are readily opened by LiI and a Lewis acid to produce iodohydrins (eq 3).[4] Conversely, 1-oxaspiro[2.2]pentanes and 1-oxaspiro[3.2]hexanes give rise to bond migration products.[10] β-Vinyl-β-propiolactone is efficiently opened by LiI to produce the corresponding substituted allyl iodide (eq 4).[11]

(3)

(4)

Alkyl and Alkenyl Iodides.

LiI has been used as a source of iodide in nucleophilic substitution and addition reactions. Primary alcohols have been directly converted to alkyl iodides upon treatment with a mixture of ***Triphenylphosphine***, ***Diethyl Azodicarboxylate***, and LiI.[3] Tertiary alcohols can be converted into tertiary alkyl iodides upon treatment with ***Hydrogen Iodide*** in the presence of LiI.[12]

(*Z*)-3-Iodopropenoates and -propenoic acids have been synthesized stereoselectively by the reaction of LiI and

propiolates or propiolic acid.[13]

C-C Bond Forming Reactions.

LiI was shown to efficiently catalyze the Michael addition of β-dicarbonyl compounds,[14] and the intramolecular allylsilane addition to imines to produce 4-methylenepiperidine derivatives (eq 5).[15]

(5)

LiI as an Additive for Organometallic-Mediated Transformations.[16]

The *syn*/*anti* selectivity in the reduction of β-alkoxy ketones is drastically increased by the addition of LiI (eq 6).[17]

(6)

The addition of ***Lithium Bromide*** and LiI was shown to enhance the rate of organozinc formation from primary alkyl chlorides, sulfonates, and phosphonates, and zinc dust.[18] Beneficial effects of LiI addition have also been reported for Heck-type coupling reactions[19] and in conjugate addition to chiral vinyl sulfoximines.[20]

The (*E*)/(*Z*) alkenic ratio in Wittig-type alkenations was shown to be dependent on the amount of Li salt present.[21]

Reduction of α-Alkoxycarbonyl Derivatives.

α-Halo ketones are reduced to the corresponding ketones upon treatment with a mixture of LiI and ***Boron Trifluoride Etherate***.[22]

Lithium 2-Lithiobenzenethiolate

[117526-82-6] · $C_6H_4Li_2S$ · Lithium 2-Lithiobenzenethiolate · (MW 122.05)

(reagent for preparation of *ortho*-substituted thiophenols[1])

Preparative Methods: easily prepared in the form of a white viscous slurry by stirring ***Thiophenol*** with 2 equiv ***n-Butyllithium*** and 2 equiv ***N,N,N´,N´-Tetramethylethylenediamine*** in dry cyclohexane in a nitrogen atmosphere for 20 h.[1] No purification of the crude product is generally required. It is stable in the absence of air and moisture.

Handling, Storage, and Precautions: the title reagent (**1**) is best made as needed and should be handled and stored under nitrogen in a fume hood. Both preparation and decomposition of (**1**) on exposure to moisture release the foul smelling, toxic thiophenol. Great care should be taken in disposing of (**1**) and cleaning apparatus exposed to (**1**). Excess thiophenol or reagent (**1**) should be destroyed in a good fume hood using an oxidizing agent such as sodium hypochlorite solution (see ***Thiophenol***).

Reaction with Electrophiles.

Diverse thiophenols can be prepared by trapping 2-LiC_6H_4SLi (**1**) with various electrophiles, as illustrated in eq 1 and Table 1.

Table 1 Thiophenols formed by Reaction of Lithium 2-Lithiobenzenethiolate with Electrophiles

Electrophile	Product	Yield (%)	Ref.
D_2O		97	1a

DMF, $MeCOCH_2Cl$  75 9

If 2-LiC_6H_4SLi is treated with elemental sulfur[1b] followed by acid,[5] 1,2-benzenedithiol is formed in 96% yield. 1,2,3-Benzenetrithiol can be prepared in 35% yield by extension of this procedure.[1b] This reaction represents the method of choice to prepare 1,2-benzenedithiol. If 2-LiC_6H_4SLi is coupled with chlorophosphines or phosphonic chlorides, a variety of 2-phosphino- or 2-phosphinylbenzenethiols results.[6] These two classes of compounds have utility as multidentate ligands for metals such as Ni,[7a] Os,[7b] and Tc[7c] and have been used in the synthesis of a cyclophane phosphine.[7] With ***Chlorotrimethylsilane***, chlorotriethylsilane, chlorotriphenylsilane, and chloro(*t*-butyl)dimethylsilane, the products were the corresponding 2-[tris(organosilyl)]benzenethiols in 92, 79, 43, and 28% yields, respectively.[1b] Multiple silylation could be used to prepare 2,6-bis(trimethylsilyl)benzenethiol in 55% overall yield from 2-LiC_6H_4SLi. With dichlorosilanes or dichlorodisilanes, various bis(thiophenols) could be prepared.[1b] These thiophenols are useful as hindered ligands.[2,3] Through reaction of 2-LiC_6H_4SLi with ***Trichlorosilane***, a novel cyclophane silane was prepared.[4]

This procedure can be used with substituted thiophenols,[1b] with 2-naphthalenethiol,[1b] and with 2-mercaptopyridine.[8] 2-Acetylbenzo[*b*]thiophene, a key intermediate in the synthesis of the 5-lipoxygenase inhibitor zileuton, has been prepared in 75% overall yield from thiophenol via condensation of lithium 2-lithiobenzenethiolate with DMF followed by chloroacetone (eq 2).[9] If 0.5 equiv of iodine is used instead of chloroacetone, the product is 2,2´-dithiobisbenzaldehyde, a stable precursor to 2-mercaptobenzaldehyde.[9]

Lithium 2-Lithiomethyl-2-propenolate[1]

[-] · $C_4H_6Li_2O$ · Lithium 2-Lithiomethyl-2-propenolate · (MW 83.98)

(nucleophilic reagent for the generation of functionalized isoprenoid compounds through alkylation or addition reactions)

Physical Data: gold colored solid.

Solubility: insol hexane.

Preparative Methods: metalation of methallyl alcohol with ***n-Butyllithium-Potassium t-Butoxide***.

Handling, Storage, and Precautions: air, water, and temperature (greater than 0 °C) sensitive.

The allylic dianion is prepared by the action of *t*-BuOK/*n*-BuLi (i.e. Schlosser's base) in hexane on methallyl alcohol.[1] The active reagent is formed immediately upon the completion of the alcohol addition (0 °C). The yield of allylic anion formed appears to be extremely sensitive to reaction conditions (e.g. fresh *n*-BuLi,[1] solvent[2]).

The methallyl alcohol dianion can be alkylated with alkyl halides (eq 1)[3] or epoxides (eq 2),[4] silylated (eq 3),[2,5] or undergo addition reactions with aldehydes or ketones (eq 4).[1] This carbon-carbon bond-forming process introduces a functionalized isoprenoid unit.

(1)

Malynolide

(2)

(3)

Related Reagents.

A similar transformation is observed with 2-ethylallyl alcohol derived from commercially available 2-ethylacrolein (eq 5). The observed addition products are mixtures of 1,4-diols derived from attack on both the primary and secondary carbons. Oxidation with activated ***Manganese Dioxide*** gives the α-methylene- and (*Z*)-α-ethylidenebutyrolactones (eq 5).[6] See also ***Methallyllithium***.

Lithium 2-Lithiophenoxide

[55274-02-7] · $C_6H_4Li_2O$ · Lithium 2-Lithiophenoxide · (MW 105.98)

reacts with electrophiles to give substituted phenols

Solubility: sol ethereal solvents.

Preparative Methods: conveniently prepared and used in situ by one of two methods. The first reported preparation[1] involves the treatment of *o*-bromophenol with ***n-Butyllithium*** at 25 °C to generate the dilithio species (eq 1). A subsequent report[2] described an alternative preparation by directed *ortho* deprotonation of phenol with ***t-Butyllithium*** (eq 2).

Handling, Storage, and Precautions: moisture sensitive; freshly prepare before use. Long term stability has not been determined. Reactions should be run under an inert atmosphere.

Reactions.

The reagent prepared by either route has been shown to react with electrophiles at the *ortho* carbon (eqs 3 and 4).[3] The electrophiles studied included hindered ketones and enolizable aldehydes and ketones.

(3)

Method	R	R'	Yield
A	Ph	Ph	75%
"	Ph	H	88%
"	Me	Me	80%
"	CH_2=CH	Me	80%
"	CH_2=CH	H	88%

(4)

Method	E-X	E	Yield
B	MeI	Me	44%
"	CO_2	CO_2H	42%
"	$PhCO_2H$	PhCO	48%
"	CBr_4	Br	46%
"	TMSCl	TMS	67%

The corresponding *meta*[4] and *para* isomers are prepared by the halogen-metal exchange route with *t*-BuLi. The dilithio species (both *meta* and *para* isomers) react with a variety of electrophiles including aldehydes, ketones (eq

5), and amides.

Related Reagents.

The corresponding sulfur analogs are prepared similarly to the phenolic examples.[5] Treatment of thiophenol with *n*-BuLi at room temperature in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** gives rise to the lithium 2-lithiothiophenoxide in solution which can be trapped with electrophiles (eq 6).

The *meta* and *para* isomers are prepared by the halogen-metal exchange route and have been shown to react with acylating reagents (eq 7).[4]

Similar reagents in which the phenolic oxygen is protected (methyl or silyl ether) prior to lithiation have been reported.[6] An example in the synthesis of thromboxane A2 antagonists is shown (eq 8). See also ***o-Lithioanisole***.

It is also possible to generate related *C,O,O*-trilithiated species by the halogen-metal exchange strategy (eq 9).[7] Higher temperatures and sonication appear to be necessary for trianion formation.

Lithium 3-Lithiopropionate

[117951-86-7] · $C_3H_4Li_2O_2$ · Lithium 3-Lithiopropionate · (MW 85.95)

(useful for the synthesis of γ-lactones from aldehydes and ketones[1])

Form Supplied in: 3-bromopropionic acid, mp 61-63 °C, is commercially available; hexane solutions of *n*-butyllithium are commercially available in several concentrations; naphthalene, mp 80-82 °C, is commercially available.

Preparative Method: for the in situ preparation of the reagent, ***n-Butyllithium*** (10.40 mL of a 1.73 M solution in hexane) is added dropwise with stirring under nitrogen over ca. 30 min to a solution of 2.75 g (18 mmol) of 3-bromopropionic acid in 75.0 mL anhydrous THF at -70 °C. The resulting solution of lithium 3-bromopropionate is held at -70 °C and added dropwise with rapid stirring to a solution containing 30 mmol of ***Lithium Naphthalenide*** in 100 mL of anhydrous THF at -70 °C until the dark green color of the solution changed to dark brown.

Handling, Storage, and Precautions: n-butyllithium is pyrophoric and moisture sensitive; 3-bromopropionic acid is corrosive; lithium naphthalenide is air and moisture sensitive. Avoid contact of all ingredients and the reagent itself with the eyes, skin, and clothing. Prepare and handle the reagent under an inert nitrogen or argon atmosphere. It is recommended that the reagent be prepared immediately prior to use.

In recent years there has been a great deal of interest in the preparation and reactions of metal homoenolates and homoenolate equivalents.[2,3] The conversion of 3-bromopropionic acid into its lithium salt provides protection of the carboxyl group so that bromine-lithium exchange can occur with lithium naphthalenide to give the parent lithium homoenolate system. Under the reaction conditions the homoenolate system does not rearrange into the more thermodynamically stable lithium enolate of the carboxylate. Treatment of 3-bromopropionic acid with 2.2 equiv of *n*-butyllithium at -70 to -100 °C provides a very low yield of the reagent.[1] Instead, heptanoic acid, which results from an unusually facile Wurtz coupling of the lithium 3-bromocarboxylate and *n*-butyllithium, is obtained.

The addition of carbonyl compounds to solutions of the reagent at -70 °C followed by warming to rt and neutralization of the reaction mixture produces γ-hydroxy acids, which produce γ-lactones in moderate yields upon mild acid treatment. Saturated aliphatic and aromatic aldehydes (eq 1) yield the corresponding γ-monosubstituted γ-lactones.[1] Unconjugated unsaturated aldehydes also react similarly (eq 2).[4]

(1)

(2)

Acyclic and cyclic saturated ketones yield γ,γ-disubstituted or spirocyclic γ-lactones upon treatment with the reagent. The reagent adds to 4-*t*-butylcyclohexanone from the equatorial direction with low stereoselectivity to produce the *syn* spirolactone as the major product (eq 3).[1] Interestingly, the *anti* spirolactone is produced with high stereoselectivity in the SmI_2-induced coupling of 4-*t*-butylcyclohexanone with ethyl acrylate.[5]

(3)

The reagent also reacts with α,β-unsaturated ketones, e.g. isophorone, to provide a direct route to allylic spirolactones (eq 4).[6] A more lengthy synthesis of the allylic spirolactone shown in eq 4 was reported recently.[7]

(4)

A variety of other metal homoenolate reagents are capable of converting carbonyl compounds into γ-lactones in a straightforward manner. Some of these include the dilithium dianion prepared from treating 3-tri-*n*-butylstannylpropionamide with 2.0 equiv *n*-BuLi at low temperature,[8a,b] trichlorotitanium homoenolates of propionate esters prepared from treatment of 1-alkoxy-1-trimethylsilylcyclopropanes with ***Titanium(IV) Chloride***,[8c,d] esters of zinc homoenolates mediated by titanium(IV) reagents,[8e] and esters of lanthanoid homoenolates.[8f] ***Samarium(II) Iodide***-promoted couplings of carbonyl compounds with α,β-unsaturated[5] and 3-halopropionate esters[9] also provide useful direct routes to γ-lactones.

See also ***1-Ethoxy-1-(trimethylsilyloxy)cyclopropane***.

Lithium 1-Methyl-2-(2-methyl-1-(*E*)-propenyl)cyclopropyl(phenylthio)cuprate

(*E*)

[87084-08-0] · $C_{14}H_{18}CuLiS$ · Lithium 1-Methyl-2-(2-methyl-1-(*E*)-propenyl)cyclopropyl(phenylthio)cuprate · (MW 288.88)

(intermediate for the synthesis of natural products, terpenes, and substrates for Cope rearrangement, divinylcyclopropane and [3,3]-sigmatropic shift studies)

Preparative Methods: to a stirred solution of 1.03 g (5.4 mmol) of 1-bromo-1-methyl-2-(2-methyl-1-propenyl)cyclopropane in 50 mL of dry THF-ether (1:1) at -78 °C under nitrogen was added dropwise a solution of ***t-Butyllithium*** (10.8 mmol) in pentane. After the pale yellow solution had been stirred at -78 °C for 30 min, 0.93 g (5.4 mmol) of ***Phenylthiocopper(I)*** was added from a bent tube attached to the reaction flask. The suspension was warmed to -20 °C and stirred for 30 min, which gave a red brown solution of the cuprate. The solution was cooled to -78 °C for addition to the iodo enone.[2]

Handling, Storage, and Precautions: best used immediately following its preparation. THF and ether need to be anhydrous (distill from sodium benzophenone). Air and moisture should be excluded.

The title reagent (**4m**) and the related reagents (**1-5**) shown in Table 1[2-12] are generally used to prepare divinylcyclopropanes that undergo Cope rearrangements to form seven-membered rings (eq 1). Formation and rearrangement of (**7**) is nearly quantitative, yielding a single product (**8**), which was converted to (±)-β-himachalene. In this case, the *trans* cuprate gave excellent results, but in certain other cases a *cis* cuprate is desirable[1,7] (see below).

[a] Stereochemistry of cyclopropyl ring (*Z*:*E* refers to **3**, **4m**, and **5**). [b] 73 from reduction with *n*-Bu_3SnH, 5:1 from reduction with Zn/ether HOAc.[6] [c] Double bond stereochemistry 4:1 *cis*/*trans*. [d] Double bond stereochemistry 3:5 *cis*/*trans*.

Preparation of Vinylcyclopropyl Bromides and their Organolithium Derivatives.

The bromides corresponding to reagents (**1h**) and (**4h**) were prepared by adding the dibromocarbene to butadiene and then replacing one bromide (eq 2). Treatment of (**9**) with *t*-butyllithium and then either ***Hydrogen Bromide*** or ***Iodomethane*** gives mixtures of products with the *trans* isomer predominating[4,5] (see Table 1 for ratios). The *cis* and *trans* bromides are separable by spinning band distillation. Dibromide reduction with ***Tri-n-butylstannane*** or ***Zinc-Acetic Acid*** gives mixtures with the *cis* isomer predominating.[6-9] The reaction of (**10**) with *t*-butyllithium produces (**1h**) and (**4h**) (M = Li) which can then be converted to the cuprate using $CuBr_2.SMe_2$ or PhSCu. Starting with 2-methylbutadiene leads to (**3**) in the same

way.[11] The lithium reagent (**3**) (M = Li) was converted to the more selective MgBr variant by treatment with ***Magnesium Bromide***.

(2)

To obtain a substituted vinyl group,[4,5] acrolein acetal (**11**) was converted to the dibromide (**12**), which reacts with ethylidenetriphenylphosphorane or ***Diethyl Phenylthiomethylphosphonate*** to form (**13**) (eq 3). Treatment with *t*-butyllithium followed by HBr formed the monobromide and then reaction with *t*-butyllithium produced (**1m**) or (**1s**).

(3)

A highly stereoselective synthesis[7] of (**2c**) and (**2t**) starts with dibromocarbene addition to the THP derivative of 3-methyl-2-buten-1-ol to produce (**14**) (eq 4). Hydrolysis of the THP ether, ***Pyridinium Chlorochromate*** oxidation, and Wittig alkenation results in (**15b**), which undergoes Zn/acetic acid reduction to selectively form *cis*-bromide (**16**). Treatment of (**14**) with *n*-BuLi gives only *trans*-bromide (**17**), which was converted to *trans*-bromide (**19**) by hydrolysis, PCC oxidation, and Wittig reaction. Both (**16**) and (**19**) were converted to thiophenylcuprates in the same way as the title compound.

(4)

In a similar way (eq 5),[2] acetal (**20**) was transformed into (**21**) which was treated with *n*-BuLi/MeI in HMPA-THF to selectively make (**22**). The mixture (ca. 90% *trans*) could be separated by chromatography and crystallization. Hydrolysis of the acetal in formic acid followed by Wittig reaction with ***Isopropylidenetriphenylphosphorane*** generated the bromide needed to produce the *trans* cuprate (**4m**) (M = PhSCuLi).

(5)

Bromoenone (**23**) and $Me_2SCH_2CO_2Et$ have been combined[12] to form (**24**) (eq 6), which was elaborated to (**25**) by a five-step sequence. Bromide (**25**) was converted to (**5**) (M = Li) using *t*-butyllithium.

(6)

Stereochemistry of Divinylcyclopropane Rearrangements.

For reagents (**1**)-(**5**), the *cis* isomers lead to the *cis*-divinylcyclopropanes that are excellent substrates for the Cope rearrangement. However, in many cases the *trans*-divinylcyclopropane works sufficiently well that separating *cis* and *trans* isomers is not necessary.[1] In certain compounds where the Cope rearrangement is disfavored by steric factors, *cis* to *trans* isomerization and 1,5-shifts compete with the Cope rearrangement.[7] In one such case (eq 7), an ingenious simultaneous photolysis/thermolysis overcame these side reactions and gave a high yield of Cope product from a *cis*/*trans* mixture.[13]

(7)

Choice of Organometallic Reagent.

The cuprate reagents (**1**), (**2**), and (**4**) have been used effectively for coupling reactions with β-iodoenones,[2,7,9,10] e.g. (**6**) or 2-iodomethylenecyclohexanone, acyl chlorides[6,8] (followed by conversion to the silyl enol ether), propargyl ketones,[5] and propargyl esters.[5] The phenylthiocuprates are efficient for transfer of secondary and tertiary cyclopropyl compounds and are readily made from ***Phenylthiocopper(I)***.[14] The lithium reagents add in 1,2-fashion to β-alkoxy enolates[3,5,15] to form some of the same compounds available from the cuprate route exemplified in eq 1. For example (eq 8), 3-methoxy-2-methylcyclopentanone gives products similar to (**7**).

(8)

They can also be used to add to aldehydes or ketones (eq 9); the resultant alcohol group can then be used to form the second vinyl group. Scopadulcic acid-B has been prepared[11] using this approach with (**3**) (M = MgBr). The lithium reagent (**3**) (M = Li) was found to attack the aryl iodide of the starting aldehyde. Some of the lithium reagents have also been used to prepare chromium carbene complexes.[16]

Lithium Methyl(phenylseleno)cuprate[1]

MeCu(SePh)Li

[91365-06-9] · $C_7H_8CuLiSe$ · Lithium Methyl(phenylseleno)cuprate · (MW 241.60)

(heterocuprate designed for 1,4-addition-elimination reactions[2] with aryl β-(phenylseleno)vinyl sulfones[3])

Solubility: sol ether, THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl; the yield of acetophenone is measured by GC, precalibrated using authentic product and *n*-dodecane as internal standard.

Preparative Methods: ***Phenylselenocopper(I)*** is prepared by portionwise addition of 1.0 equiv ***Diphenyl Diselenide*** to a mechanically stirred, rt solution of 2.0 equiv ***Sodium Borohydride*** in 1:1 2 M aqueous NaOH:EtOH. The resultant yellow suspension is heated at reflux under N_2 for 30 min; a clear solution results. Cooling to 0 °C and acidification to pH 5-6 using conc HCl is followed by addition of 1.0 equiv Cu_2O in one portion. The mixture is heated at reflux under N_2 for 18 h. Cooling is followed by filtration and washing of the brownish-yellow precipitate with ethanol and water; drying overnight in vacuo provides the selenide.[3]

MeCu(PhSe)Li is prepared by stirring a 0 °C suspension of 1.0 equiv PhSeCu in THF under N_2 and adding 1.0 equiv of an ether solution of ***Methyllithium*** dropwise. After 15 min the resultant clear green-brown solution is cooled to -78 °C and is ready for use.

Handling, Storage, and Precautions: best results will be obtained with PhSeCu prepared from high purity Cu_2O, dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides.[5] MeLi is pyrophoric;[6] care must be exercised in its handling. The reagent appears to have thermal stability equal to that of ***Lithium Methyl(phenylthio)cuprate***. Use in a fume hood.

Lithium methyl(phenylseleno)cuprate is a novel representative of the heterocuprate class of organocopper reagents.[7] The methyl group acts as a nucleophile, while the SePh group does not. This latter nontransferable or dummy ligand[8] provides enhanced thermal stability and solubility compared to the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than the corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when higher reaction temperatures are required, or when the organolithium used to form the cuprate is difficult or expensive to prepare.

Designed for 1,4-addition-elimination reactions with aryl β-(phenylseleno)vinyl sulfones, these cuprates offer specific advantages over the corresponding homocuprates and alkyl(phenylthio)cuprates (eq 1).[3] Applications include stereospecific net *anti* addition of R-H to alkynes via a selenosulfonation/1,4-addition-elimination/reductive sulfurization[9] sequence complementary to traditional *syn* carbocupration,[10] and the synthesis of marine sterols.[11]

Lithium Methyl(phenylthio)cuprate[1]

MeCu(SPh)Li

[56831-21-1] · C_7H_8CuLiS · Lithium Methyl(phenylthio)cuprate · (MW 194.71)

(heterocuprate, useful in 1,4-additions,[2] carbocuprations,[3] and substitutions[4])

Solubility: sol ether, THF.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[5] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl; the yield of acetophenone is measured by GC, after calibration using authentic product and *n*-dodecane as internal standard.

Preparative Method: from ***Phenylthiocopper(I)*** prepared in situ: 1.0 equiv of ***n-Butyllithium*** is added dropwise to a 0.2 M, 0 °C THF solution of ***Thiophenol*** in a three-neck flask equipped with N_2 inlet, solid addition funnel, and rubber septum. After stirring for 10 min, 1.0 equiv of ***Copper(I) Iodide*** is added via the addition funnel. Stirring for an additional 15 min provides a clear, yellow solution, to which 1.0 equiv of a solution of ***Methyllithium*** is added dropwise via syringe. After 15 min, the brown solution is ready for use.[6] Alternate sources of PhSCu may be acceptable.[7]

Handling, Storage, and Precautions: best results are obtained with high purity Cu^I salts,[8] dry, O_2-free solvents, and methyllithium solutions free of contaminating alkoxides or hydroxides.[9] MeLi is pyrophoric;[10] due care must be exercised in its handling. Thermal decomposition of the reagent is minimal at or below room temperature.[11] Use in a fume hood.

Lithium methyl(phenylthio)cuprate is representative of the heterocuprate class of organocopper reagents.[6] The Me group is nucleophilically reactive, whereas the SPh group is not. These nontransferable groups are called dummy ligands;[12] the SPh group in particular provides enhanced thermal stability and solubility compared to the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when relatively high reaction temperatures are required, when the organolithium used to form the cuprate is difficult or expensive to prepare, or when overalkylation using the homocuprate is observed.

The reagent has been used in nucleophilic substitution reactions of allylic acetates[13] and 9-BBN,[14] as well as in conjugate additions to α-oxoketene dithioacetals[15] and α,β-unsaturated oxazolidines[16] and ketones.[17] Good results

have been reported in carbocupration reactions using alkynes (eq 1)[18] and cyclopropenes;[19] the analogous lithium methyl(methylthio)cuprate is used to synthesize tertiary thiols from dithio esters.[20] On the other hand, cross coupling with organomercury reagents is unsatisfactory.[11] Preferential transfer of the phenylthio group[21] has been observed; this behavior is substrate dependent and should not normally be anticipated.

Related Reagents.

Lithium *N*-Methylpiperazide

[105563-31-3] · $C_5H_{11}LiN_2$ · Lithium *N*-Methylpiperazide · (MW 106.12)

(in situ protection of aryl aldehydes via α-amino alkoxide formation; α-amino alkoxides can direct or block *ortho*-lithiation[1])

Alternate Name: LNMP.

Preparative Method: prepared in situ by adding ***n-Butyllithium*** to *N*-methylpiperazine in anhydrous solvents.

Handling, Storage, and Precautions: highly flammable; should be kept under a nitrogen or argon atmosphere.

Lithium *N*-methylpiperazide is conveniently used as a reagent for in situ protection of aryl aldehydes through α-amino alkoxide formation.[1] Stability of LNMP-derived α-amino alkoxides to alkyllithium reagents and their solubility in organic solvents are reasons why LNMP is preferred over similar reagents.[1] The α-amino alkoxides obtained in situ from substituted benzaldehydes are not easily *ortho*-lithiated; however, refluxing a benzene solution of the α-amino alkoxide and excess ***n-Butyllithium*** for 3-12 h effects *ortho*-metalation. Addition of excess electrophile followed by aqueous workup gives moderate to good yields of the desired *ortho*-substituted aryl aldehydes (eq 1).[2]

(1)

Regioselective substitution of bis-activated benzaldehydes can be achieved by lithiation/alkylation of an α-amino alkoxide obtained from LNMP. *p*-Anisaldehyde, on treatment with LNMP and ***s-Butyllithium*** in the presence of ***N,N,N´,N´-Tetramethylethylenediamine*** and subsequent quenching with ***Iodomethane***, gives 4-methoxy-3-methylbenzaldehyde (eq 2).[3] This is in sharp contrast to the analogous reaction using ***N-Lithio-N,N´,N´-trimethylethylenediamine*** (LTMDA) in place of LNMP, where 4-methoxy-2-methylbenzaldehyde is produced in good yield.[1] Under the same reaction conditions, *o*- and *m*-anisaldehydes give C-3 and C-4 lithiated products, respectively. Both 3,5- and 2,4-dimethoxybenzaldehydes can be metalated between the methoxy substituents in excellent yield using LNMP, *s*-BuLi, and TMEDA.

(2)

Heterocyclic aldehydes can be metalated regioselectively using similar methodology to that described above.[4] For example, 2-thiophenecarbaldehyde on reaction with LNMP, *n*-BuLi, and TMEDA and subsequent quenching with iodomethane, gives 5-methyl-2-thiophenecarbaldehyde in 77% yield (eq 3).

(3)

When LTMDA is used instead of LNMP, a mixture of 3- and 5-methyl-2-thiophenecarbaldehydes is obtained. However, 3-thiophenecarbaldehyde and LNMP under similar reaction conditions give a mixture of C-5 and C-2 substituted products in a ratio of 83:17. Alkylation of 2-furaldehyde occurs exclusively at the 5-position when treated with LNMP, *n*-butyllithium, and iodomethane.[4] In a similar manner, 3-furaldehyde gives mainly C-2 alkylation, but 2-methyl-3-furaldehyde, on treatment with LNMP, *n*-BuLi, and iodomethane, gives 2,5-dimethyl-3-furaldehyde in 50% yield. Using similar reaction conditions, *N*-methylpyrrole-2-carbaldehyde and *N*-methylindole-2-carbaldehyde give the corresponding C-5 and C-3 substituted products on reaction with LNMP, *n*-BuLi, TMEDA, and iodomethane.[4] Interestingly, methoxypyridinecarbaldehydes, on treatment with LNMP, alkyllithium, and TMEDA, give metalation *ortho* to the methoxy group (Scheme 1).[5] This is in sharp contrast to LTMDA-assisted metalations, where substitution occurs *ortho* to the aldehyde group.

Scheme 1

A regioselective lithiation/alkylation of a 1-Boc-3-formyl-1,4-dihydropyridine has been effected using LNMP and ***Mesityllithium*** as the base.[6] Dealkylation of several *o*-alkoxyaryl aldehydes can be achieved via the corresponding α-amino alkoxides prepared with LNMP.[7]

Related Reagents.

N-Lithio-N,N´,N´-trimethylethylenediamine; ***Lithium Morpholide***.

Lithium Methylsulfinylmethylide[1]

$LiCH_2SOMe$

[57741-62-5] · C_2H_5LiOS · Lithium Methylsulfinylmethylide · (MW 84.08)

(a strong base and nucleophile, very useful for the introduction of the methylsulfinylmethyl group[1])

Alternate Names: lithium dimsylate; dimsyllithium; LiDMSO.

Solubility: sol DMSO; sparingly sol THF.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: titration with formanilide using triphenylmethane as indicator.[2]

Preparative Methods: by the reaction of alkyllithiums or ***Lithium Amide*** with ***Dimethyl Sulfoxide*** in DMSO or ethereal solvents.[2,3] May also be prepared by the reaction of freshly prepared (but not commercial) LiH.[4]

Handling, Storage, and Precautions: best prepared as needed, although synthesis and storage procedures similar to those used in some preparations of ***Sodium Methylsulfinylmethylide*** (NaDMSO) would probably result in long shelf life.[5] Complexes of LiDMSO with ethereal solvents have been isolated and characterized. Solvent-free LiDMSO is shock sensitive.[6] Hydrogen gas or hydrocarbon may be emitted during the preparation of this reagent and due caution should be exercised in its preparation, particularly on a large scale. Problems encountered in the preparation of NaDMSO may be relevant to LiDMSO.[7]

Dimethyl sulfoxide is a weakly acidic compound (pK_a = 35) whose conjugate base is both a strong nucleophile and base. The sodium and potassium salts of DMSO have found considerable use in synthesis (see ***Potassium Methylsulfinylmethylide*** and ***Sodium Methylsulfinylmethylide***) and much of the chemistry of those reagents is shared with lithium methylsulfinylmethylide. This reagent was introduced nearly contemporaneously with NaDMSO, though the latter has seen more application.[2]

Lithium Methylsulfinylmethylide as Base.

Carbanion Accelerated Claisen Rearrangement.

LiDMSO, particularly in the presence of excess ***Lithium Chloride***, serves as the best base for inducing the anionic Claisen rearrangement of (**1**) (eq 1).[8] With NaDMSO and KDMSO, 1-(*p*-tolylsulfonyl)-2-butanone is formed as a side product in 24% and 65% yield, respectively. The side reaction leading to this elimination product is completely suppressed with LiDMSO in the presence of LiCl and leads to the conclusion that undesired reactions mediated by powerfully basic reagents might be minimized through the use of added lithium and other metal salts (see, for example, ***Cerium(III) Chloride***).

Ether Synthesis.

The modification of polysaccharides via alkylation of free hydroxy groups (Hokomori reaction) has been performed using LiDMSO as base.[9] Glycoprotein glycans have been similarly modified to facilitate their handling and analysis.[10] The superiority of LiDMSO as a reagent for this reaction vis-à-vis NaDMSO has been reported.

Lithium Methylsulfinylmethylide as Nucleophile.

Reactions with Acid Derivatives.

The condensation of dimsyl anions with acid derivatives, almost exclusively esters, leads to the formation of β-keto sulfoxides, whose rich chemistry makes them versatile and useful intermediates (eqs 2 and 3).[11,12] For example, the conversion of (**4**) to (**5**), an intermediate in a synthesis of vindoline, occurs via a Pummerer reaction followed by cyclization and carbocation rearrangement. Many other transformations of β-keto sulfoxides are known.[13] A one-pot conversion of carboxylic acids to β-keto sulfoxides has been developed.[13]

Reaction of a carboxylic acid with ***N,N´-Carbonyldiimidazole*** leads to acyl imidazolides which give β-keto sulfoxides upon reaction with LiDMSO (eq 4). β-Enamino sulfoxides can be prepared by condensation of amines with the adduct from the reaction of LiDMSO and DMF (eq 5).[14] Finally, methylsulfinylketene dithioacetals are formed stereoselectively when LiDMSO is reacted with dialkyl thiocarbonates and the resulting lithium salts are quenched with alkyl halides (eq 6).[15] With NaDMSO, mixtures of (*E*) and (*Z*) isomers are produced.

Reactions with Aldehydes and Ketones.

Non-enolizable ketones and aldehydes react successfully with dimsyl anions.[1] An interesting route to naphthols was reported involving the nucleophilic addition of LiDMSO to an indenone followed by a ring expansion (eq 7).[16] Reaction with a cyclohexadienone has also been reported (eq 8).[17]

(7)

(8)

A one-pot synthesis of alkenes from non-enolizable ketones begins with a carbonyl addition reaction, the product of which is treated with a chlorophosphite. Decomposition of the adduct gives the alkene in high yield (eq 9).[18]

(9)

The reaction of LiDMSO with cyclohexanone is reported to give a 45% yield of the addition product along with 51% of recovered starting material, arising from competitive enolization of the ketone. This compares favorably with NaDMSO, with which the same products are formed in 17 and 80% yields, respectively. This is another example of the potential of LiDMSO in circumventing untoward reactions precipitated by the potent basicity of dimsyl anions.

Reaction with Imines and Related Compounds.

As with NaDMSO, the addition of LiDMSO to aromatic nitrogenous heterocycles has been examined. A recent report describes a tandem addition to quinoxaline to give an annulated product in fair yield (eq 10).[19]

(10)

Reaction with Halides.

LiDMSO reacts with chloromethyl alkyl ethers to give substitution products in poor to fair yields.[20]

Reaction with Michael Acceptors.

α,β-Unsaturated thioamides react in a 1,4-fashion with LiDMSO (eq 11).[21] No information on the diastereoselectivity of this reaction was reported.

(11)

Reaction with Sulfur Electrophiles.

Optically active β-disulfoxides are available from the reaction of optically pure menthyl sulfoxides and LiDMSO.[22]

Other Applications.

The use of DMSO as a dummy ligand in cuprate chemistry has been reported.[23] The reaction of LiDMSO with

Copper(I) Iodide followed by reaction with an alkyllithium (RLi) gives a cuprate ($MeSOCH_2$)RCuLi. Subsequent reactions including conjugate additions, ketone formation from acid chlorides, S_N2' reactions, and coupling with primary iodides and tosylates result in selective transfer of the alkyl group. This inexpensive and readily available dummy ligand should find considerable application in cuprate chemistry.

Lithium Morpholide

[37828-58-3] · C_4H_8LiNO · Lithium Morpholide · (MW 93.07)

(in situ protection of aromatic aldehydes via α-amino alkoxides;[1] nucleophile capable of adding to activated triple bonds[6-8])

Preparative Methods: prepared in situ by adding ***n-Butyllithium*** to ***Morpholine*** in anhydrous organic solvents at -40 °C.

Handling, Storage, and Precautions: highly flammable; should be kept under a nitrogen or argon atmosphere. Use in a fume hood.

Lithium morpholide (**1**) is conveniently used for in situ protection of aldehydes as α-amino alkoxides.[1a] This method has been used to regioselectively alkylate substituted benzaldehydes (eq 1)[2] and furaldehydes. Better solubility of (**1**) and the corresponding α-amino alkoxide in THF at low temperature makes (**1**) more convenient to use than other reagents such as lithium *N*-methylanilide and ***Lithium Piperidide***.[2]

(1)

N-Formylmorpholine can be prepared by reacting (**1**) with ***Carbon Monoxide*** in THF.[3,4] Electrochemically, (**1**) can react with THF to give the aminotetrahydrofuran (**2**) (eq 2).[5]

(2)

Like other lithium amides, lithium morpholide adds to various activated triple bonds to give vinyllithiums (**3**) (eq 3)[6] or allenes (**4**) (eq 4).[7]

(3)

(3)

$R^1 = H, CO_2R; R^2 = Me, Et$

(4)

(4)

The morpholyl imine (**5**) is the product from the reaction of triethoxyacetonitrile with lithium morpholide (**1**) (eq 5).[8]

(5)

(5)

N-(α-Cyanoacetyl)morpholine is prepared by the nucleophilic substitution of ethyl cyanoacetate with lithium morpholide.[9] Dimerization resulting in bimorpholine has been observed when (**1**) is treated with ***Copper(I) Chloride***.[10]

Related Reagents.

N-Lithio-N,N´,N´-trimethylethylenediamine; ***Lithium N-Methylpiperazide***; ***Lithium Piperidide***.

Lithium Naphthalenide[1]

[7308-67-0] · $C_{10}H_8Li$ · Lithium Naphthalenide · (MW 134.12)

(reductive metalation reactions;[1c] reduction of metal salts;[27] initiation of polymerization reactions[28])

Alternate Name: LN.

Physical Data: no data on the isolated material; only available in solution.

Solubility: sol ether, benzene, THF; reacts with protic solvents and THF at elevated temperatures.[2]

Preparative Methods: made by addition of freshly cut ***Lithium*** metal to a solution of naphthalene in THF. Preparation can be accelerated by ultrasonication.[3]

Analysis of Reagent Purity: two titration methods have been described;[4] the more convenient[4b] involves conversion of 1,1-diphenylethylene by lithium naphthalenide to an intensely red-colored dianion, which is then titrated against *s*-butanol.

Handling, Storage, and Precautions: can be stored in solution up to several days; must be protected from air and moisture; can be used to ambient temperature.

Reductive Metalation.

The powerful reductive nature of this reagent makes it an important tool for lithium-heteroatom exchange reactions. Thus, it was established early on that (phenylthio)alkanes can be converted into their requisite alkyllithium species.[5] This has become the method of choice over generation by lithium metal alone. The resultant alkyllithium species can either be quenched with a proton source (eq 1),[6] or intercepted with an electrophile. This has subsequently evolved into a powerful technique, since the reaction is general for all chalcogens (eq 2)[7] and halides (eq 3).[8]

Metal-heteroatom exchange can also be persuaded to occur with a variety of other systems, resulting in allyl-[9] and vinyllithium[10] species, as well as α-lithio ethers (eq 3),[1c,8,11] α-lithio thioethers,[1c,12] α-lithio amines,[11b] and α-lithio silanes.[1c,12b,13] The latter class provides useful intermediates for the Peterson alkenation reaction (eq 4).[13a]

In some cases, however, it may be advantageous to proceed via either ***Lithium 1-(Dimethylamino)naphthalenide*** (LDMAN), or ***Lithium 4,4´-Di-t-butylbiphenylide*** (LDBB).[1c] With the former reagent, the byproduct formed, (dimethylamino)naphthalene, is more easily removed than is naphthalene from product mixtures. In the latter case, the greater reduction potential of di-*t*-butylbiphenyl appears to lead to more efficient halogen-lithium exchange.[8b]

Dianion Generation.

Lithium naphthalenide efficiently deprotonates β-alkynyloxy[14] and carboxylate anions (eq 5).[15] In addition, the previously mentioned phenomenon of reductive metalation has been exploited to access dianions from halohydrins,[16] β-halo carboxylic acids,[17] and β-halo carboxamides,[18] and even trianions from β,o´-dihalo alcohols.[19] A major pathway for the polyanionic species is β-elimination (eq 6);[16a,19] when such processes can be avoided, the polyanions react according to Hauser's rule (eq 7).[16a,20]

(5)

(6)

(7)

Dehalogenation Reactions.

Since lithium naphthalenide is a particularly effective initiator for halogen-metal exchange, it has found widespread use for the conversion of dihalides to unsaturated species. Thus, 1,2-dichlorodisilanes have been converted to silenes (eq 8)[21] and diphosphiranes to phosphacumulenes.[22] In a related field, silicon cages[23] have been constructed from trichlorodisilanes.

(8)

Metal Redox Reactions.

Lithium naphthalenide is a convenient reducing agent for a variety of metals, and shows great promise in the synthetic area. Thus, Cu^{I} complexes have been reduced to Cu^{0}; the resultant highly reactive species adds in an oxidative fashion across the carbon-halogen bond.[24] As a consequence, the well known organocuprate addition chemistry can be carried out in one step from halocarbons, without having to initially prepare the organolithium species (eq 9). In addition to the reduction of Cu^{I}, lithium naphthalenide reduces Si^{IV} to Si^{II},[25] Sn^{IV} to Sn^{II} (eq 10),[26] and various lanthanide compounds.[27]

(9)

(10)

Oligomerization Reactions.

Lithium naphthalenide has long been a convenient initiator for anionic living polymerization reactions.[28] Thus, styrenes, acrylates, dienes, and other monomers have been polymerized using lithium naphthalenide as an anionic initiator. In some circumstances, however, oligomerization can be controlled to furnish only dimers (eq 11).[29] Also, in the presence of a secondary amine, 1,3-dienes can be persuaded to react in a formal 1,4-fashion to produce allyl amines (eq 12).[30]

(11)

(12)

Interesting approaches toward functional polymers have recently been detailed,[31] wherein previously described chemistry involving lithium naphthalenide is conducted on suitably substituted polystyrene derivatives (eq 13).

(13)

Lithium (1-Pentynyl)(3-tetrahydropyran-2´-yloxy-1-propenyl)cuprate

[66915-91-1] · $C_{13}H_{20}CuLiO_2$ · Lithium (1-Pentynyl)(3-tetrahydropyran-2´-yloxy-1-propenyl)cuprate · (MW 278.82)

(mixed organocuprate useful in the synthesis of *trans*-allylic alcohols)

Preparative Methods: prepared in situ by lithiation of *trans*-3-tetrahydropyran-2´-yloxy-1-(tri-*n*-butylstannyl)-1-propene with ***n-Butyllithium*** in THF. The resulting lithium reagent is then added to ***1-Pentynylcopper(I)*** in the presence of ***Hexamethylphosphorous Triamide*** at -40 °C.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Lithium (1-pentynyl)(3-tetrahydropyran-2´-yloxy-1-propenyl)cuprate (**1**) allows the synthesis of *trans*-allylic alcohols from α,β-enones. For example, reaction of (**1**) with 2-cyclohexen-1-one affords the conjugate addition adduct (**2a**) in 85% yield (eq 1).[1] The utility of the intermediates generated by reaction of (**1**) with enones has been demonstrated (eq 2). Reaction with 2-cyclopenten-1-one followed by deprotection, mesylation, and base treatment provides vinylcyclopropane (**4**), which is thermolyzed at 600 °C to provide bicyclic ketone (**5**). Compound (**5**) is reduced with ***Sodium Borohydride*** and the alkene is oxidatively cleaved with ***Sodium Periodate-Osmium Tetroxide***; methanolysis in the presence of a catalytic amount of ***Boron Trifluoride Etherate*** is followed by epimerization with base to afford aldehyde (**6**). The transformation of (**6**) to 11-deoxyprostaglandin E_2 (**7**) had been previously reported.[2]

(1)

(2a) R = H, 85%
(2b) R = Me, 84%

(2)

(7)

A report in the patent literature (eq 3) utilizes (**1**) to prepare the prostaglandin analog (**9**).[3] Starting with 2-cyclopenten-1-one, the intermediate anion is trapped with $MeO_2C(CH_2)_5COCl$ to provide cyclopentanone (**8**) in 49% yield. Hydrolysis of the THP group and saponification gives the desired analog (**9**) in ~30% overall yield.

(3)

Related Reagents.

1-Hexynylcopper(I); ***Lithium (1-Hexynyl)(2-tri-n-butylstannylvinyl)cuprate***; ***Lithium (1-Pentynyl)(2-tri-n-butylstannylvinyl)cuprate***; ***1-Pentynylcopper(I)***; ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide***.

Lithium (1-Pentynyl)(2-tri-*n*-butylstannylvinyl)cuprate

[-] · $C_{19}H_{36}CuLiSn$ · Lithium (1-Pentynyl)(2-tri-*n*-butylstannylvinyl)cuprate · (MW 453.75)

(mixed organocuprate; introduces angular acetylene equivalent to enones via vinylstannanes)

Preparative Method: prepared in situ by first monolithiating ***trans-1,2-Bis(tributylstannyl)ethylene*** with ***n-Butyllithium*** in THF at -78 °C, then transferring the anionic solution via cannula to a mixture of ***1-Pentynylcopper(I)*** and ***Hexamethylphosphorous Triamide*** at -40 °C.[1]

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Lithium (1-pentynyl)(2-tri-*n*-butylstannylvinyl)cuprate (**1**) undergoes 1,4-addition to α,β-enones in high yields.[1] The resulting addition products can then be readily transformed into terminal alkynes with ***Lead(IV) Acetate*** in acetonitrile. This sequence provides a two-step method for the introduction of angular acetylenes (eqs 1 and 2).

(2)

Related Reagents.

Lithium Perchlorate[1]

$LiClO_4$

[7791-03-9] · $ClLiO_4$ · Lithium Perchlorate · (MW 106.39)

(mild Lewis acid[1] for cycloaddition reactions,[2] conjugate additions,[3] ring opening of epoxides,[4] and ring expansion of cyclopropanes[5])

Physical Data: mp 236 °C; bp 430 °C (dec); *d* 2.428 g cm^{-3}.

Solubility: 60 g/100 mL H_2O (25 °C); 150 g/100 mL H_2O (89 °C); 152 g/100 mL EtOH (25 °C); 137 g/100 mL acetone (25 °C); 182 g/100 mL MeOH (25 °C); 114 g/100 mL ether.

Form Supplied in: white solid; widely available in anhydrous form or as the trihydrate; it is usually used in solution in ether or MeOH.

Purification: anhydrous lithium perchlorate is prepared by heating the commercially available anhydrous material or its trihydrate at 160 °C for 48 h under high vacuum (P_2O_5 trap).

Handling, Storage, and Precautions: the anhydrous material should be used as prepared for best results. The decomposition of lithium perchlorate starts at about 400 °C and becomes rapid at 430 °C, yielding lithium chloride and oxygen. Perchlorates are potentially explosive and should be handled with caution.

Lewis Acid Catalyst for Cycloaddition Reactions and Carbonyl Addition Reactions.

This reagent, usually prepared as a 5.0 M solution in diethyl ether, produces a dramatic rate acceleration of Diels-Alder reactions (eq 1). Evidence shows that this rate acceleration, which was initially thought to be a result of high internal solvent pressure, is due to the Lewis acid character of the lithium ion.[6]

Under these conditions, reasonable levels of diastereoselectivity have been observed in the reaction between a chiral diene and ***N-Phenylmaleimide*** (eq 2).[7] An interesting protecting group dependence of diastereoselectivities has also been observed in the hetero-Diels-Alder reaction of *N*-protected α-amino aldehydes with 1-methoxy-3-*t*-butyldimethylsilyloxybutadiene to produce dihydropyrones (eqs 3 and 4).[8]

(3)

(4)

O-Silylated ketene acetals undergo 1,4-conjugate addition to hindered α,β-unsaturated carbonyl systems[3] and quinones[9] in the presence of $LiClO_4$.

[1,3]-Sigmatropic Rearrangements.

In contrast to the [3,3]-sigmatropic rearrangement observed under thermal conditions, allyl vinyl ethers undergo [1,3]-sigmatropic rearrangements at rt when submitted to 1.5-3.0 M $LiClO_4$ in Et_2O (eq 5).[10]

(5)

Epoxide Opening.

$LiClO_4$ is an efficient promotor for the regioselective nucleophilic opening of oxiranes with amines,[11] cyanide,[12] azide,[13] thiols,[14] halides,[15] and lithium acetylides.[16] The regioselective opening of oxiranes with lithium enolates derived from ketones has also been observed in the presence of $LiClO_4$ (eq 6).[17]

(6)

Ring Expansion.

The condensation of aldehydes and ketones with diphenylsulfonium cyclopropylide produces oxaspiropentanes which undergo ring expansion to produce cyclobutanones upon treatment with lithium perchlorate.[18]

Lithium Phenylethynolate

[57015-19-7] · C_8H_5LiO · Lithium Phenylethynolate · (MW 124.07)

(ambident nucleophile producing ketenes or alkynol esters in reactions with acid chlorides;[1] intermediate reagent in carboxylic acid homologation;[2] starting reagent in the synthesis of silyl ynol ethers[3])

Physical Data: the pK_a of phenylethynol is estimated to be less than 2.8.[4]

Solubility: THF; reacts with water and protic solvents.

Form Supplied in: prepared in situ and used directly.

Preparative Methods: four methods can be used for the preparation of lithium phenylethynolate and other lithium alkynolates: reaction of α,α-dibromo ketones with alkyllithium reagents (eq 1);[1,2] a multistep, one-pot synthesis from ethyl esters (eq 2);[2] reaction of isoxazole with ***n-Butyllithium*** (eq 3);[5] and oxidation of lithium phenylacetylide by lithium *t*-butyl peroxide (eq 4).[6] The first two reactions (eqs 1 and 2) are the most general and usually give the best results in the preparation of a variety of lithium alkynolates.[2,3] The other two methods (eqs 3 and 4) lack generality and have only limited application. All these methods are used for the preparation of lithium alkynolates in situ; no attempts to isolate pure compounds have been reported.

Handling, Storage, and Precautions: must be prepared and handled under inert gas (Ar or N_2) to exclude moisture. Solutions in THF are stable for several hours at room temperature.

Reactions with Acid Chlorides.

Lithium alkynolates are ambiphilic nucleophiles and can form products of both *O*- and *C*-attack in reactions with electrophilic reagents. Reaction of lithium alkynolates with dialkyl chlorophosphates affords alkynyl phosphate esters as the major products (eq 5). However, reactions with acyl chlorides under similar conditions results in both the alkynyl benzoate *O*-acylation product and the corresponding ketene due to *C*-acylation (eq 6).[1]

Reactions with Ketones and Aldehydes.

Carbon electrophiles such as ketones and aldehydes react with alkynolates, forming exclusively products of *C*-attack. Addition of phenylethynolate to cyclohexanone affords a spirolactone resulting from the cyclization of the originally formed ketene (eq 7). Similarly, the reaction of lithium alkynolates with benzaldehyde can be rationalized by the intermediate formation of ketene (eq 8); however, the final product in this case is the unsaturated acid, not a lactone.[2a]

(7)

(8)

R = Ph, *t*-Bu

Reactions with Alcohols.

Alcoholysis of lithium alkynolates yields esters (eq 9).[2] This reaction is especially useful in organic synthesis as a method of ester homologation. In this case, ethyl esters of carboxylic acids are used for the generation of lithium alkynolates in situ (eq 2). Subsequent ethanolysis of lithium alkynolates in the presence of HCl gives homologated esters in good yield.[2]

(9)

R = Ph, Cy, BuC≡C, PhCH=CH, $PhCH_2CH_2$, etc.

Preparation of Silyl Ynol Ethers.

Silylation of lithium alkynolates with trialkylchlorosilanes can be used for the preparation of silyl ynol ethers.[3] However, this method gives good yields only in reactions of sterically hindered alkynolates (eq 10).[3c] The analogous reaction of lithium alkynolates with trialkylgermanium and trialkyltin chlorides results in the exclusive formation of the corresponding ketenes.[3a]

$$RC{\equiv}COLi + R'_3SiCl \xrightarrow[50\text{-}93\%]{THF,\ -78\ ^\circ C\ to\ rt} RC{\equiv}COSiR'_3 \quad (10)$$

Lithium Phenylthio(trimethylstannyl)cuprate

$Me_3SnCu(SPh)Li$

[69608-62-4] · $C_9H_{14}CuLiSSn$ · Lithium Phenylthio(trimethylstannyl)cuprate · (MW 343.50)

(trimethyltin transfer to the β-carbon of α,β-unsaturated carbonyl compounds[1-5] and α,β-alkynic carboxylic acid derivatives[6-12])

Physical Data: prepared in situ; the THF solution is dark red.

Solubility: sol THF.

Preparative Methods: lithium (phenylthio)(trimethylstannyl)cuprate (**2**) is prepared by the addition of solid ***Phenylthiocopper(I)***[14] to a THF solution of ***Trimethylstannyllithium*** (**1**)[15] (eq 1).

Handling, Storage, and Precautions: should be prepared in dry solvent and used under an inert atmosphere. Since organotin compounds are toxic,[13] reaction workup should be carried out in a fume hood.

Reaction With α,β-Unsaturated Carbonyl Systems.

Reagent (**2**) readily effects conjugate addition of the Me_3Sn moiety to a variety of α,β-unsaturated carbonyl compounds, including enones,[1,2] β-iodo enones,[1,2] and β-trifluoromethanesulfonyl enoates[3] (eqs 2-4). Notably, the intermediate enolate anion derived from the reaction of (**2**) with (*R*)-(-)-5-methyl-2-cyclohexen-1-one can be trapped with ***Iodomethane*** to give, stereoselectively, the ketone (**3**) (eq 5).[4,16] It is pertinent to mention that the conjugate additions of reagents (**1**) and (**2**) to bicyclic enones are stereochemically complementary. For example, reaction of (**4**) with (**1**) affords the *trans*-fused substance (**5**), while reagent (**2**) converts (**4**) into the *cis*-isomer

Reaction With α,β-Alkynic Carboxylic Acid Derivatives.

The stereochemical outcome of the regioselective addition of the elements of Me_3Sn-H across the triple bond of α,β-alkynic esters by reagent (**2**) can be controlled simply by varying the reaction conditions. Thus, reaction at -78 °C in the presence of a proton source provides alkyl (*E*)-3-trimethylstannyl-2-alkenoates (eq 6),[6-8] while use of the reaction conditions outlined in eq 7 produces the corresponding (*Z*)-isomers.[6-8,10-12,18] Similar stereochemical control can be accomplished with α,β-alkynic *N*,*N*-dimethylamides as substrates.[9] Alkyl (*E*)- and (*Z*)-3-trimethylstannyl-2-alkenoates have been shown to be useful synthetic intermediates in a range of contexts, including natural product syntheses.[6,8,10,12,16b,19]

(6)

(7)

Related Reagents.

A number of lower order heterocuprates related in composition to (**2**) have been reported. These include $Me_3SnCu(Y)Li$ (Y = C&tbond;$CCMe_2OMe$[2,7,20] and CN[2,18]) and $Bu_3SnCu(Y)Li$ (Y = SPh[2,21] and CN[22-24]). To date, these reagents have been employed primarily in reactions similar to some of those described above for (**2**).

A recent report describing the use of $Bu_3SnCu(CN)Li$ for the preparation of (*Z*)-1-tributylstannyl-1-alken-3-ynes (eq 8)[24] is noteworthy.

Lithium Phenylthio(2-vinylcyclopropyl)cuprate[1]

[61754-34-5] · $C_{11}H_{12}CuLiS$ · Lithium Phenylthio(2-vinylcyclopropyl)cuprate · (MW 246.79) (*cis*)

[71647-04-6] (*trans*)

[102511-64-8]

(heterocuprate useful in 1,4-addition-elimination reactions[2] and annulations[3])

Solubility: sol THF; less sol ether.

Analysis of Reagent Purity: an assay to determine relative thermal stabilities[4] can be used to estimate reagent quality and concentration: a sample of known volume and temperature is quenched with excess PhCOCl; the yield of 2-vinylcyclopropyl phenyl ketone is measured by GC or HPLC, the response of which is calibrated using authentic product and an appropriate internal standard.

Preparative Method: 2-vinylcyclopropyllithium[5] is prepared by cooling a 0.25 M ether or THF solution of 1-bromo-2-vinylcyclopropane[6] under Ar to -78 °C. Dropwise addition of 1.1-1.4 equiv of a solution of ***t-Butyllithium*** is followed by stirring for 2 h. One equiv of ***Phenylthiocopper(I)***[7] is added, and the resultant slurry is diluted with 5 mL THF per mmol of cyclopropane. The reaction is warmed to -20 °C; a clear, light brown solution of cuprate forms after stirring for 20 min. It is cooled to -78 °C and is used directly.

Handling, Storage, and Precautions: best results are obtained with PhSCu prepared from high purity Cu^{I} salts,[8] dry, O_2-free solvents, and alkyllithium solutions free of contaminating alkoxides or hydroxides.[9] *t*-BuLi is pyrophoric;[10] care must be exercised in its handling. Use in a fume hood.

This cyclopropyl organometallic reagent is representative of the heterocuprate class of organocopper reagents.[11] Only the cyclopropyl group, and not the SPh group, is nucleophilically reactive. The nontransferable SPh group, or dummy ligand,[12] provides enhanced thermal stability and solubility compared to the analogous homocuprate. Heterocuprates generally exhibit less nucleophilic reactivity than the corresponding homocuprates; however, increased thermal stabilities coupled with greater efficiency in use of the transferable ligand make them reasonable alternative reagents. This is particularly true when higher reaction temperatures are required, or when the organolithium used to form the

cuprate is difficult or expensive to prepare.

Lithium phenylthio(2-vinylcyclopropyl)cuprate has been used in acylations[3] and 1,4-addition-elimination reactions with 3-halo-2-alkenones.[13] The products of these reactions undergo high-yield thermal ring expansions (see ***Lithium Cyclopropyl(phenylthio)cuprate***), providing a two-step, seven-membered ring annulation method. 4-Cycloheptenones and various seven-membered ring bicycloalkadienones and spiroalkadienones (eq 1)[13] can be prepared.

Either the *cis*- or *trans*-isomer or a mixture of isomeric 1-bromo-2-vinylcyclopropanes can be used in the reaction, although rearrangement is more facile with the *cis*-isomer. The method has been used in a convergent total synthesis of the sesquiterpene β-himachalene to assemble the 7,6-fused ring core of the natural product.[14]

Related Reagents.

Lithium Piperidide

[4442-11-9] · $C_5H_{10}LiN$ · Lithium Piperidide · (MW 91.10)

(nucleophilic base used to probe aromatic substitution and benzyne-type reactions;[1-7] useful base to effect elimination of dihalocarbenoids to prepare α-halo ketones,[8] dichloro alkenes,[9] and chloro alkynes[9])

Physical Data: white solid,[10] unstable in air, pK_a 30.7 (THF at 30 °C).[11]

Solubility: sol THF,[10] DME,[1] Et_2O;[1] insol hexane[10] (at 0 °C).

Preparative Method: lithium piperidide in piperidine is prepared by adding a calculated amount of standardized ***Phenyllithium*** or ***n-Butyllithium*** in hexane to a solution of ***Piperidine*** (dried over KOH or activated alumina and distilled from KOH or sodium) in DME or Et_2O at 0 °C under an inert atmosphere.[1]

Handling, Storage, and Precautions: best prepared in situ prior to use. Use in a fume hood.

Nucleophilic Aromatic Substitution.

In 1956, Wittig[2] used lithium piperidide to explore benzyne formation. Its dual properties of strong basicity and nucleophilicity have led to the use of lithium piperidide as a probe for exploring nucleophilic aromatic substitution via the addition-elimination and benzyne pathways on a range of systems (haloimidazoles,[3] -pyridines,[4] -quinazolines,[5] -benzenes[6]); for example, substitution of 1- and 3-bromo-10-methylacridones[1] (eq 1) is not accompanied by rearrangement and presumably proceeds entirely by the addition-elimination mechanism (Table 1).

Table 1 Products from Reaction of Bromo-10-methylacridones with Lithium Piperidide in Piperidine at 27 °C[a]

Starting material	Reaction after 10 min (%)	1-Pip	2-Pip	3-Pip	4-Pip
1-Bromo	65	74	0	0	0
2-Bromo	9	1	72	10	0
3-Bromo	39	0	0	73	0
4-Bromo	46	0	0	31	0

[a] Yields based on unrecovered starting material.[1]

2-Bromo-10-methylacridone reacts with lithium piperidide in piperidine at 27 °C much more slowly than the 1- and 3-isomers to give rearrangement products, indicating the intermediacy of arynes (**1**) and (**2**); the direction of addition is controlled by the inductive effect of the heterocyclic nitrogen atom and the carbonyl group.

(1)

(2)

Reaction of lithium piperidide with methoxy aromatics in refluxing THF leads to products resulting from direct *ipso* substitution (eq 2).[7]

(2)

Preparation of α-Halo Ketones,[8] Dichloro Alkenes,[9] and Chloro Alkynes[9] via Elimination of Dichloro Carbenoids.

Lithium β-alkoxy carbenoids are quite unstable even at -120 °C and undergo α-elimination.[8] A subsequent migration of a group from the neighboring alkoxy carbon to the carbenoid center leads to the formation of an α-bromo enolate and constitutes a facile one-step preparation of α-halo ketones (eq 3). It is particularly suitable for the synthesis of C_{n+1} chlorocyclanones from C_n cyclanones (eq 4) (superior yields compared with *n*-BuLi).

$RCOCH_2Br + RCHBrCHO$ (3)

(4)

β-Silyloxy carbenoids,[9] however, generally undergo β-elimination, leading to the formation of dihalo alkenes which, with excess base, undergo elimination to halo alkynes in good yields (eq 5).

(5)

Carbonylation.

Carbamoyl- and acyllithium species are potentially useful intermediates, but their instability has prompted an extensive search for their synthetic equivalents. Widdowson[12] has shown that the carbamoyl anions, produced by bubbling carbon monoxide into a solution of lithium piperidide in THF (-78 °C), can be bottled as the corresponding carbamoyltin reagents (eq 6). These are useful in Stille[13] cross-coupling reactions, yielding a variety of aroyl, alkenoyl, and hetaroyl amides in good yields (eq 7). This may be useful for the synthesis of ^{11}C-labeled compounds for biological and clinical studies, such as positron emission tomography.[14]

(6)

Lithium 1-Propanethiolate

[16203-40-0] · C_3H_7LiS · Lithium 1-Propanethiolate · (MW 82.11)

(cleavage of the alkyl-oxygen bond of methyl esters under mild conditions;[1] lithium thiolates have also been used for selective demethylation of aryl methyl ethers[2] and quaternary ammonium salts[3])

Preparative Methods: a 5.0 M stock solution in HMPA is typically used. Addition of ***n-Butyllithium*** to a stirred solution of freshly distilled 1-propanethiol in dry hexane at 0 °C is followed by stirring for 10 min. The resulting suspension is then concentrated in vacuo to dryness at 0 °C and dissolved in the appropriate amount of HMPA.[4]

Handling, Storage, and Precautions: the reagent is stored under argon at 0 °C. Contact with oxygen results in rapid oxidation of the thiolate. Propanethiol must be handled with care and used in a hood due to its strong odor. For most applications the reagent is prepared and stored in HMPA, a potent carcinogen; therefore due caution should be exercised when handling this reagent. Note that 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (***N,N´-Dimethylpropyleneurea***; DMPU) has been used as a substitute for the more hazardous HMPA in applications of this reagent.[5]

Demethylation of Methyl Esters.

Lithium propanethiolate was introduced as a reagent for the mild deprotection of methyl esters in 1970.[1] The reagent readily cleaves the alkyl-oxygen bond by an S_N2 process.[6] Due to this mechanism, the reagent offers advantages over conventional hydrolytic processes, particularly when the substrate carboxylate is sterically hindered or has additional functionality which is sensitive toward acid or base. For example, the sterically hindered ester methyl *O*-methylpodocarpate is readily cleaved to *O*-methylpodocarpic acid in quantitative yield at 25 °C in 1.5 h (eq 1). Additionally, methyl 3β-acetoxy-Δ^5-etienate which contains both a hindered ester and a hydrolytically sensitive acetate functionality, is readily cleaved to the etianic acid in high yield without concomitant acetate cleavage (eq 2).[1] It should be noted that the lithium thiolate in HMPA is superior to the sodium thiolate in DMF for methyl ester cleavage. Bartlett and Johnson report a rate enhancement for the cleavage of methyl mesitoate by a factor of 57.[1]

(1)

(2)

Additional examples include the cleavage of an acid-sensitive methyl gibberellate to afford gibberellic acid in high yield (eq 3),[7] and the selective cleavage of a sterically hindered bridgehead ester in the presence of a pyridyl methyl ether to afford a late intermediate in the synthesis of (*Z*)-huperzine A (eq 4).[8] Lithium propanethiolate will also selectively cleave vinylogous methyl esters in the presence of alkyl methyl esters. For example, in work related to the synthesis of chlorothricolide, the selective cleavage of a butenolide ester gave the corresponding ester acid in 79% yield (eq 5).[4] This methodology has also been used to prepare tetronic acid analogs of thiolactomycin, and it is reported to be superior to other demethylating agents such as ***Iodotrimethylsilane***[9] and dilute acid hydrolysis.[10]

(3)

Demethylation of Aryl Methyl Ethers.

The demethylation of aryl methyl ethers using thiolate ion was also reported in 1970; a variety of anisoles were demethylated using sodium ethanethiolate in hot DMF to afford high yields of the corresponding phenols.[2] Lithium propanethiolate has been used for this purpose; however, there appears to be no advantage over the sodium thiolate reagents as is seen with the cleavage of methyl esters. For example, the aryl methyl ether of *O*-methylpodocarpic acid (see eq 1) can be removed with lithium propanethiolate, but only at elevated temperatures.[1] Another example for this class of reagents is the cleavage of a 7-methoxyindole using lithium butanethiolate in HMPA at 110 °C to afford the corresponding phenol in 88% yield (eq 6).[11]

Demethylation of Quaternary Ammonium Salts.

The selective demethylation of quaternary ammonium salts has also been accomplished using lithium propanethiolate.[3] The method has been used to prepare a variety of unsymmetrical tertiary amines and is reported to give superior yields and selectivity over other reagents used for this purpose such as ***Lithium Aluminum Hydride***, ***Sodium-Ammonia***, thiophenoxide anion, or ***Lithium Iodide***. For example, *n*-dodecyldimethylpropylammonium iodide is readily demethylated using lithium propanethiolate in HMPA at 50 °C after 3 h to afford *n*-dodecylmethylpropylamine in 99% yield (eq 7).

Lithium Pyrrolidide

[4439-90-1] · C_4H_8LiN · Lithium Pyrrolidide · (MW 77.07)

(reduction of nonenolizable ketones;[3] carbonylation;[5] nucleophilic additions[6,8] and substitutions[4,9])

Physical Data: white, amorphous solid, $[(CH_2)_4NLi]_n$; mp 150 °C (dec); X-ray structures of $[((CH_2)_4NLi)_3.PMDETA]_2$ and $[((CH_2)_4NLi)_2.TMEDA]_2$ have been reported.[1]

Solubility: sol THF, Et_2O; insol pentane, hexane (at rt).

Preparative Method: prepared from ***Pyrrolidine*** (dried over and distilled from CaH_2) and ***Methyllithium*** or ***n-Butyllithium*** in Et_2O or THF usually at 0 °C for 30 min.[3,4]

Handling, Storage, and Precautions: unstable in THF solution at rt, forming LiH after a short period of time.[2] Best prepared in situ immediately prior to use. Use in a fume hood.

Reduction.

In 1971, Wittig[3] reported that treatment of nonenolizable ketones with lithium pyrrolidide (2 equiv) leads to alcohols in good yields (eq 1).

R	R'	Temp. (°C)	Time (min)	Yield (%)
Ph	1-Naphthyl	0	10	95
Ph	CPh_3	0	10	95
Ph	Ph	20	180	74
t-Bu	*t*-Bu	0	10	77

Carbonylation.

Treatment of lithium pyrrolidide with CO at atmospheric pressure leads to a carbamoyllithium species which, when quenched with R_3SnCl, affords amidostannanes (eq 2).[5] These may be cross-coupled with alkenyl, aryl, and heteroaryl halides under Pd^0 catalysis to give acylpyrrolidines. Trimethyltin derivatives are the most effective cross-coupling partners. This procedure was developed for the introduction of ^{11}C (from ^{11}CO) into molecules for biological and clinical studies.

Nucleophilic Addition.

Treatment of 1-chloro-2-phenylacetylene with lithium pyrrolidide yields 1-(1-pyrrolidinyl)-2-phenylacetylene (eq 3), which may be used as an electron-rich partner in [2 + 2] cycloaddition reactions with heterocyclic compounds.[6] In general, ynamines are versatile reagents.[7]

(3)

Addition of lithium pyrrolidide to activated alkynes leads to (*Z*)/(*E*) mixtures of synthetically useful vinyllithium species (eq 4).[8] Yields given correspond to the protonated products obtained by quenching with MeOH.

(4)

2 equiv	12%	69%
0.75 equiv	0%	100%

Nucleophilic Substitution.

The reaction of lithium pyrrolidide with ***Dimethyl Disulfide*** in pentane gives the corresponding sulfenamide (eq 5).[9] This reaction fails in THF. Sulfenamides have been used as sulfenyl-group transfer reagents.[10]

(5)

Treatment of 1,2-dimethoxybenzene with lithium pyrrolidide leads to displacement of only one methoxy group (eq 6)[4] in a reaction which appears not to proceed via a benzyne intermediate.

(6)

Related Reagents.

Lithium Diethylamide; ***Lithium Diisopropylamide***; ***Lithium Hexamethyldisilazide***; ***Lithium Piperidide***; ***Lithium 2,2,6,6-Tetramethylpiperidide***.

Lithium Selenide

Li_2Se

[12136-60-6] · Li_2Se · Lithium Selenide · (MW 92.84)

(nucleophilic agent for synthesis of organic selenides[1,2])

Physical Data: d 2.91 g cm^{-3}; red-brown solid or milky white crystalline suspension in THF.

Solubility: sol water; sparingly sol THF.

Preparative Methods: reduction of ***Selenium*** with ***Lithium*** in liquid ammonia produces red-brown Li_2Se after NH_3 evaporation.[3] Reaction of Se with 2 equiv ***Lithium Triethylborohydride*** in THF gives a suspension of Li_2Se. The method is somewhat limited by scale and produces flammable byproducts.[1] For large-scale preparations, reduction of Se with Li in THF in the presence of naphthalene as a catalyst is safe and more economical.[2]

Handling, Storage, and Precautions: should be used directly as prepared. Use in a fume hood.

The reaction of Li_2Se with alkyl halides gives dialkyl selenides in high yields. It is less reactive than K_2Se or ***Sodium Selenide***.[1,2] Benzyl, 4-chlorobenzyl, 2-phenylethyl, and pentyl bromides give selenides in yields of above 54% (eq 1), but no selenide is obtained when 2-octyl bromide is used as a substrate.[1,2] Bis(trialkylsilyl) selenides are obtained when trialkylchlorosilanes are treated with Li_2Se (eq 2).[4,5]

$$2\ PhCH_2Br \xrightarrow[80\%]{Li_2Se,\ THF\ 0\text{-}5\ ^\circ C,\ 1.5\ h} (PhCH_2)_2Se \qquad (1)$$

Related Reagents.

Hydrogen Selenide; ***Sodium Hydrogen Selenide***; ***Sodium Selenide***.

Lithium Tetrafluoroborate[1]

$LiBF_4$

[14283-07-9] · BF_4Li · Lithium Tetrafluoroborate · (MW 93.75)

(fluoride source for cleavage of silyl ethers;[2] mild Lewis acid capable of promoting acetal hydrolysis,[3] rearrangement of oxaspiropentanes,[4] facilitating the addition of arenesulfenyl chlorides to alkenes;[5] catalysis of Diels-Alder cycloadditions;[6] used as an electrolyte in oxidative cleavage of 2-oxo-1-cyclohexanones[7])

Physical Data: mp 5 °C.

Solubility: sol methanol, acetonitrile.

Form Supplied in: anhydrous white solid; also available as a 1 M solution in acetonitrile. *Drying:* anhydrous material is obtained by overnight drying in an oven at 80-90 °C.[1]

Handling, Storage, and Precautions: extremely hygroscopic; should be handled and stored under an inert atmosphere; contact irritant.

Cleavage of Ethers.

$LiBF_4$ is an effective reagent for the removal of silyl ethers.[2,8,9] An excess of the salt in acetonitrile at ambient temperature effects cleavage of *t*-butyldimethylsilyl ethers (eqs 1-3).

82%
HO
O

(2)

Use of this reagent under more vigorous conditions results in removal of (trimethylsilyl)ethoxymethyl (SEM) ethers and methoxymethyl (MOM) ethers (eqs 4, 5).[11]

$LiBF_4$ is particularly effective in the deprotection of β-trimethylsilylethyl protected glycosides (eq 6).[12] Notably, the β-anomers undergo hydrolysis more rapidly than the corresponding α-anomers. Benzylidene acetals are cleaved under these conditions (eq 7).

Hydrolysis of Acetals.

Treatment of acetals with $LiBF_4$ in wet acetonitrile provides carbonyl compounds in moderate yield.[3] Aliphatic acetals (eq 8) give the corresponding carbonyl products in near quantitative yield. Cyclic dioxolane derivatives are hydrolyzed at a slower rate (eq 9). Substitution of the dioxolane further hinders the reaction (eq 10). Aliphatic aldehydes protected as 1,3-dioxanes are inert to these hydrolysis conditions.

(9)

(10)

Lewis Acid Promoted Reactions.

$LiBF_4$ promotes a high yielding rearrangement of oxaspiropentanes to cyclobutanones (eq 11).[4] In this regard, $LiBF_4$ is reported to be superior to ***Lithium Perchlorate***.

(11)

$LiBF_4$ is an effective catalyst for the intramolecular Diels-Alder reaction. A single *cis*-fused cycloadduct was obtained in quantitative yield from the triene (eq 12).[6] The use of other Lewis acids gives poor selectivity and lower yields of the bicyclic product.

(12)

$LiBF_4$ has been employed as an electrolyte in the oxidative cleavage of 2-oxy-1-cyclohexanones, which gives good

yields of the ring-opened dicarbonyl compound (eq 13).[7]

(13)

The Lewis acid character of $LiBF_4$ enhances the electrophilicity of arenesulfenyl chlorides in their additions to carbon-carbon double bonds.[5] In appropriately disposed bicyclic systems (eq 14), transannular bond formation is observed.

Lithium 2,2,6,6-Tetramethylpiperidide

[38227-87-1] · $C_9H_{18}LiN$ · Lithium 2,2,6,6-Tetramethylpiperidide · (MW 147.22)

(strong, highly hindered, nonnucleophilic base (pK_a = 37.3)[1] capable of selective deprotonation of aromatics, heteroaromatics, and aliphatic C-H acidic sites in the presence of a variety of functional groups; also compatible with several electrophiles for in situ quenching of kinetically derived lithiated species[2-5])

Alternate Names: LiTMP; LTMP.

Physical Data: exists in THF solution as a dimer-monomer equilibrium mixture; additives such as HMPA increase monomer concentration.[6,7] X-ray structure determination shows that LiTMP crystallizes as a tetramer from hexane/pentane mixtures.[8]

Solubility: sol most organic solvents including THF, Et_2O, hexane.

Preparative Method: prepared in Et_2O or THF solutions immediately before use by treatment of commercially available dry ***2,2,6,6-Tetramethylpiperidine*** with ***n-Butyllithium*** (1:1). Tetramethylpiperidine is dried by heating a mixture of the base with CaH_2 at reflux for 4 h in a preflamed flask, followed by distillation at atmospheric pressure (bp 152 °C). It should be stored in a septum sealed bottle.

Handling, Storage, and Precautions: LiTMP solutions are pyrophoric, can cause severe burns, and should always be handled and transferred under an inert atmosphere. Solutions of LiTMP show a loss of activity (50% in THF; 60% in Et_2O) after 12 h at 24 °C.[9] Use in a fume hood.

Benzyne Formation.

The earliest uses of LiTMP as a base involved the deprotonation of benzyl chloride to give phenylcarbene and of 2-chloroanisole to give 3-methoxybenzyne.[10] LiTMP may also be used for heteroaryne generation; for example, treatment of 1,3-bis(TMS)isobenzofuran with 3-bromopyridine in the presence of LiTMP gives the corresponding cycloaddition product (eq 1).[11]

In situ Compatibility with Electrophiles.

Martin first demonstrated that the low nucleophilicity of LiTMP makes it compatible, at low temperatures, with certain electrophiles, e.g. ***Chlorotrimethylsilane***, ***Trimethyl Borate***.[2a] This allows the preparation of 2- and 2,6-silylated benzoates and benzonitriles by equilibrium controlled *ortho*-lithiation processes (eq 2). The distribution of mono- and disilylated products may be controlled by the number of equivalents of LiTMP; these products may be converted into corresponding bromo and iodo derivatives by *ipso*-halodesilylation.[2a,12] Similar ***Lithium Diisopropylamide***-TMSCl compatibility has been demonstrated.[5,13]

Analogous use of the LiTMP-***Mercury(II) Chloride*** combination allows selective functionalization of cubanecarboxamides (eq 3) and cyclopropanecarboxamides (eq 4),[14,15] presumably as a consequence of the high s character of the C-H bonds in these systems.

(4)

Am = CON(*i*-Pr)$_2$

Application of Martin's conditions to *N*,*N*-dimethylbenzamide leads, surprisingly, to α,α´-disilylation in good yield (eq 5).[16] Further treatment with LiTMP/TMSCl gives the *ortho*-silylated product. The bis-TMS derivative serves as a useful directed metalation group and may be readily converted to benzoic acid, benzaldehyde, and benzyl alcohol derivatives.

(5)

Remote Metalation.

LiTMP may be used interchangeably with LDA to effect conversion of diaryl amides into fluorenones by virtue of a complex induced proximity effect (eq 6).[17] This general route complements Friedel-Crafts chemistry for the preparation of fluorenones.

(6)

Directed *ortho* Metalation.

N-*t*-Boc-pyrrole undergoes clean deprotonation with LiTMP.[18] Low-temperature LiTMP lithiation of pyrazinecarboxamide followed by deuteration leads to isomeric products reflecting the temperature at which the reaction is quenched (eq 7).[3] This is rationalized by the thermodynamic stability of the *ortho*-amido lithiated species at the higher temperature.

(7)

Am = CONH-*t*-Bu	0 °C	0%	75%
	-70 °C	40%	25%

The use of LiTMP in heterocyclic directed *ortho*-metalation chemistry is advantageous. For example, pyridine amide and oxazoline derivatives are smoothly deprotonated and lead, after electrophile quench, to 4-substituted products (e.g. eq 8),[19] which may be used for the synthesis of natural products (e.g. eq 9) and pharmaceuticals.[20-22] In contrast to LDA and, of course, alkyllithiums, no nucleophilic attack of the pyridine ring is observed.[19] The considerable C-H acidity of methylpyridines allows deprotonation-condensation reactions which are of general synthetic value (eq 9).[20]

(8)

$E^+ = D_2O$, 70%; PhCHO, 50%; Et_2CO, 52%; MeI, 80%; BuI, 9%

(9)

In some cases, LiTMP complements the metalation regioselectivity of LDA. For example, LDA metalation of 2,4-dichloropyrimidine gives the 5-substituted product whereas LiTMP affords mainly the product of 6-substitution (eq 10).[23]

(10)

base =		
LDA	100	0
TMP	35	65

Enolate Formation.

LiTMP is widely used to generate α-stabilized carbanions. For example, in the synthesis of paniculide A, the use of LiTMP is critical; LDA fails to give the required product (eq 11).[24]

(11)

LiTMP is especially useful in cases where the reactants are sensitive to nucleophilic attack (e.g. eq 12) (cf. 66% yield with LDA).[10]

(12)

LiTMP is also used to deprotonate nonenolizable sites. For example, bridgehead deprotonation of (-)-camphenilone is followed by self-condensation to give a high yield of dimeric product (eq 13).[25]

(13)

Under similar conditions, LiTMP generates the acyllithium of a nonenolizable aldehyde which undergoes self-condensation to give an acyloin (eq 14).[25]

(14)

The primary reservation concerning the use of LiTMP in synthesis, particularly on a large scale, is the cost of tetramethylpiperidine relative to other amine bases. However, an aqueous acid extraction of the reaction mixture allows the recovery of tetramethylpiperidinium salt from which the free base can be obtained by neutralization and distillation. This recovery method is dependent on the acid stability of the reaction products.

Related Reagents.

Lithium Diethylamide; ***Lithium Diisopropylamide***; ***Lithium Hexamethyldisilazide***; ***Lithium Piperidide***; ***Lithium Pyrrolidide***.

Lithium Tri-*t*-butoxyaluminum Hydride[1]

$LiAlH(OR)_3$

(R = *t*-Bu)

[17476-04-9] · $C_{12}H_{28}AlLiO_3$ · Lithium Tri-*t*-butoxyaluminum Hydride · (MW 254.32) (R = Et_3C)

[79172-99-9] · $C_{21}H_{46}AlLiO_3$ · Lithium Tris(3-ethyl-3-pentoxy)aluminum Hydride · (MW 380.59) (R = Et)

[17250-30-5] · $C_6H_{16}AlLiO_3$ · Lithium Triethoxyaluminum Hydride · (MW 170.14) (R = Me)

[12076-93-6] · $C_3H_{10}AlLiO_3$ · Lithium Trimethoxyaluminum Hydride · (MW 128.05)

(reducing agent for many functional groups; cleaves cyclic ethers)

Physical Data: R = *t*-Bu: mp 300-319 °C (dec); sublimes at 280 °C/2 mmHg. All the other reagents are unstable and are prepared in situ.

Solubility: R = *t*-Bu: (at 25 °C) diglyme (41 g/100 mL), THF (36 g/100 mL), DME (4 g/100 mL), ether (2 g/100 mL).

Form Supplied in: R = *t*-Bu: solid; 0.5 M or 1.0 M solutions in diglyme or THF. The other reagents are prepared in situ just prior to use.

Preparative Methods: for R = Me,[2] Et,[3] or 3-ethyl-3-pentyl,[4] in situ preparation can be carried out as follows: addition of 3 mol of the desired alcohol to 1 mol of standardized ***Lithium Aluminum Hydride*** solution in ether, THF, or diglyme results in the formation of the corresponding trialkoxyaluminohydride reagent. The *t*-Bu[5] derivative can also be prepared in situ by this method.

Analysis of Reagent Purity: standardization of $LiAlH(O\text{-}t\text{-}Bu)_3$ solutions is best carried out by reduction of cyclohexanone and with GC and/or spectroscopic analysis to measure the extent of reaction. Iodometric titrations are not suitable in this case.[6]

Handling, Storage, and Precautions: the dry solid and solutions are corrosive and/or highly flammable and must be stored in the absence of moisture. While the *t*-BuO compound appears to have long term stability in terms of storage, the MeO compound degrades in its reactivity within one week. Therefore it is advised to use freshly prepared reagent solutions.[2a]

Functional Group Reductions.

The high reactivity for reduction exhibited by $LiAlH_4$ can be attenuated by modifying this reagent. Altered reagents can be prepared by the addition of an alcohol such that a 3:1 complex of alcohol:$LiAlH_4$ is formed. The reactivity of these new trialkoxyaluminohydride reagents can be modulated by the selection of the appropriate alcohol. In terms of relative reactivity one can rank[7] hydride reagents as follows: $LiAlH_4$ > $LiAlH(OMe)_3$ > $LiAlH(O\text{-}t\text{-}Bu)_3$ > $NaBH_4$. Table 1 provides a comparison of the aluminum based reagents with various functional groups. For a detailed discussion of the reduction properties of $LiAlH_4$, see ***Lithium Aluminum Hydride***.

Table 1 Comparison of the Reactivities of Aluminohydride Reducing Agents

Reaction	$LiAlH_4$	$LiAlH(OMe)_3$	$LiAlH(O\text{-}t\text{-}Bu)_3$
Aldehyde to alcohol	+	+	+
Ketone to alcohol	+	+	+
Acid chloride to alcohol	+	+	+
Lactone to lactol	+	+	slow
Epoxide to alcohol	+	slow	slow
Ester to alcohol	+	+	slow
Carboxylic acid to alcohol	+	+	-
Carboxylic acid salt to alcohol	+	+	-
t-Amide to amine	+	+	-
Nitrile to amine	+	+	-
Nitro to amine	+	-	-
Alkene	-	-	-

This observation of diminished reactivity of the trialkoxyaluminohydrides is opposite to that observed with $NaBH_4$ and its alkoxy analogs (see ***Sodium Borohydride*** and ***Sodium Trimethoxyborohydride***). The stoichiometry for the reaction can be determined from the theoretical number of hydrides required for the reduction based on the observation that the trialkoxyaluminohydrides can be considered to be the source of one hydride. For example, the reduction of an aldehyde or ketone theoretically requires one hydride and so one equivalent of the reagent is needed for this reduction.

The differential reducing abilities of these reagents allows selective reduction of one functional group in the presence of another. While simple saturated aldehydes can be reduced by both $LiAlH(OMe)_3$ and $LiAlH(O\text{-}t\text{-}Bu)_3$ as rapidly as by $LiAlH_4$ at 0 °C, cyano aldehydes can be reduced at low temperature to the corresponding alcohol derivatives (eq 1).[8]

Aldehyde lactones can also be reduced chemoselectively (eq 2).[9]

The reduction of aldehyde esters can lead to the formation of lactones with or without subsequent acidic workup (eqs 3 and 4).[10,11] Aldehydes can also be reduced preferentially in the presence of ketones (eq 5).[4]

With unsaturated aldehydes such as cinnamaldehyde, LiAlH(O-*t*-Bu)$_3$ gives the corresponding allylic alcohol, whereas LiAlH(OMe)$_3$ affords the saturated alcohol. This difference in reactivity can be exploited (eq 6).[12] The course of the reduction can be changed if a copper species is also used (eq 7).[13]

Similarly, ketones can be reduced with LiAlH(O-*t*-Bu)$_3$ in the presence of esters,[14a] lactones,[14b] amides,[5] halogens,[15] epoxides,[5] *O*-alkyl oximes,[5] azides,[16] and cyano groups.[5] A ketone can be reduced in the presence of an aldehyde, provided the aldehyde is first masked as an aldimine, for example. The reduction of an acid halide to the corresponding alcohol can be carried out with LiAlH(O-*t*-Bu)$_3$ at 0 °C, while the corresponding aldehyde can be obtained if the reduction is performed at -80 °C in diglyme.[17] Aldehydes can also be obtained by the reduction of nitriles[3a] or tertiary amides[3b] if LiAlH(OEt)$_3$ is used as the reductant.

In addition to the differences in relative functional group reactivities that LiAlH(OR)$_3$ has over LiAlH$_4$, these reagents also exhibit improved stereoselectivities in these reductions.[18] For example, the reduction of norbornanone to give the *endo*-alcohol proceeds with greater control (eq 8).[2b] Further examples of this stereoselectivity are illustrated in eqs 9-11.[19-21] The use of LiAlH$_4$-***Lithium Iodide*** in the reaction depicted in eq 11 results in complete inversion of stereochemistry (*syn*:*anti* = 5:95). Therefore the choice of reagents allows preparation of either diastereomer.

(8)

$LiAlH_4$	89:11
$LiAlH(OMe)_3$	98:2

(9)

$LiAlH_4$	*trans*:*cis* = 32:68
$LiAlH(O\text{-}t\text{-}Bu)_3$	*trans*:*cis* = 90:10

(10)

$LiAlH_4$	60:40
$LiAlH(OCMe_2Et)_3$	100:0

(11)

anti:*syn* = 95:5

Enantioselective reductions are also possible if the alcohol used to form the trialkoxyaluminohydride is optically active. For example, treating $LiAlH_4$ with MeOH and BINAL-H[22] in a mole ratio of 1:1:1 in dry THF generates an optically active hydride[23] reagent which can reduce ynones with good enantioselectivity, as shown in eq 12. The (*R*)-antipode of BINAL-H results in the isolation of the (*R*)-propargylic alcohol. See ***Lithium Aluminum Hydride-2,2´-Dihydroxy-1,1´-binaphthyl*** for additional examples of this type.

(*S*)-BINAL-H

(12)

84% ee

While unsubstituted lactams are reduced to the corresponding amines, the intermediates in these reductions can be diverted into other reactions when the substrate is suitably functionalized. One example is shown in eq 13.[24] The trialkoxyaluminohydrides are capable of reducing most nitrogen based functional groups; however, imides do not react. This attribute has been used in a diastereoselective synthesis of D-*threo*-sphingamine (eq 14).[25] Oximes react with these

reagents only to generate hydrogen. No reduction is observed. *N*-Methylamines are formed by the reduction of isocyanates with $LiAlH(OMe)_3$,[2a,26] while $LiAlH(O\text{-}t\text{-}Bu)_3$ gives formamides (eq 15).[5b,27] Unsaturated isocyanates are also reduced to the corresponding vinylic formamide (eq 16).[28] Thiocyanates are inert to $LiAlH(O\text{-}t\text{-}Bu)_3$.[29]

(13)

(14)

(15)

(16)

The trialkoxyaluminohydrides generate 1 equiv of hydrogen upon exposure to thiols and are inert to dialkyl and/or aryl sulfides, while disulfides are reduced to thiols (eq 17).[30] Alkyl 1-alkynyl sulfides are reduced to the corresponding alkyl *cis*-1-alkenyl sulfides when the reaction is carried out in the presence of ***Copper(I) Bromide*** (eq 18).[31] The *trans*-isomer is obtained with $LiAlH_4$. Two equivalents of hydride are required to reduce sulfoxides by $LiAlH(OMe)_3$,[2a,26] while $LiAlH(O\text{-}t\text{-}Bu)_3$[32] is unreactive to sulfoxides. Sulfones do not react with these reagents.[2a,5b,26] While alkyl mesylates and tosylates are inert to the trialkoxyaluminohydrides, $LiAlH(OMe)_3$ can reduce acetylenic mesylates to the corresponding allene in an *anti* fashion to maintain chirality (eq 19).[33]

(17)

(18)

(19)

A related reagent is $NaAlH_2(OCH_2CH_2OMe)_2$, which is abbreviated to SMEAH or Red-Al, and has in some cases comparable reactivity and chemistry and in other cases complementary activity (see ***Sodium Bis(2-methoxyethoxy)aluminum Hydride***).

Reductive Cleavage of Ethers.

Dialkyl ethers, alkyl aryl ethers, diaryl ethers, and cyclic ethers react very slowly with these reductants, if at all. However, the addition of ***Triethylborane***, in varying amounts, produces a complex which is capable of ring opening some cyclic ethers (eqs 20 and 21).[34] Epoxides also react very slowly with $LiAlH(O\text{-}t\text{-}Bu)_3$,[26] which allows for differentiating functional groups during their reduction. Formation of a complex with BEt_3 now can be used to open the epoxide (eq 22).[29,35] A mixture of $LiAlH(OMe)_3$ and ***Copper(I) Iodide*** can also be used to open epoxides (eq 23).[36]

(20)

(21)

(22)

(23)

Reduction of Halogenated Compounds.

The reduction of 1-iodoalkanes with $LiAlH(OMe)_3$ is comparable to reduction by $LiAlH_4$, while the reactivity with bromo and chloro compounds is very low. There is no reaction of $LiAlH(O\text{-}t\text{-}Bu)_3$ with chloro compounds. As a result, one can reduce aldehydes in the presence of chloro groups. The mixture of CuI and $LiAlH(OMe)_3$ provides a species which is capable of reducing primary chlorides, and primary and secondary bromides.[5b,37]

Lithium Tri-*s*-butylborohydride[1]

$LiBH(s\text{-}Bu)_3$

[38721-52-7] · $C_{12}H_{28}BLi$ · Lithium Tri-*s*-butylborohydride · (MW 190.15)

(reducing agent for various functional groups;[2] selective reducing agent;[3-6] stereoselective reducing agent for ketones[7,8] and other functional groups;[5,9,10] regioselective reducing agent for cyclic anhydrides;[11] used for conjugate addition and alkylation of α,β-unsaturated esters or ketones[12] and for Michael-initiated ring closure reactions;[13] reduces (2-arylprop-1-en-3-yl)trimethylammonium iodides to 2-arylpropenes;[14] hydroborates substituted styrenes;[15] reacts with carbon monoxide in the presence of free trialkylborane[16])

Alternate Name: L-Selectride®.

Physical Data: not isolated; prepared and used in solution.

Solubility: solubility limits have not been established. The reagent is normally used as a 1.0 M solution in THF or Et_2O. Use of a solution in toluene is reported and one method of preparation results in a THF-pentane solvent mixture.

Form Supplied in: 1.0 M solution in THF (L-Selectride®).

Analysis of Reagent Purity: solutions of pure reagent exhibit doublets (*J* &AApprox; 70 Hz) centered in the range δ -6.3 to δ -6.7 in the ^{11}B NMR spectrum.[17-20] Concentration of hydride is determined by hydrolysis of aliquots and measurement of the hydrogen evolved or by quenching aliquots in excess 1-iodooctane and analysis of the octane formed by GLC.[17] Concentration of boron is verified by oxidizing aliquots using alkaline hydrogen peroxide and analyzing the 2-butanol formed by GLC.[21]

Preparative Methods: direct reaction of tri-*s*-butylborane with LiH is not suitable, proceeding only to about 10% completion after 24 h in refluxing THF.[17] The preferred methods are reaction of the organoborane with ***Lithium Aluminum Hydride*** in the presence of ***1,4-Diazabicyclo[2.2.2]octane***[18] or with ***t-Butyllithium***.[19] Reaction with lithium trimethoxyaluminum hydride is effective but leads to byproducts not easily separated from the reagent.[20]

Handling, Storage, and Precautions: solutions are air- and water-sensitive and should be handled in a well-ventilated hood under an inert atmosphere using appropriate techniques.[22] Potentially pyrophoric *s*-Bu_3B is a byproduct of reductions; thus standard organoborane oxidation[21] is recommended as part of the workup.

Functional Group Reductions.

Alkanes are formed from primary and some secondary alkyl halides via S_N2 processes with potential chemoselectivity based on relative ease of displacement (I > Br > Cl).[2a] The corresponding reaction for tosylates has not been investigated thoroughly.[2b] Dealkylation of quaternary ammonium halides yields the corresponding amines, demethylation being strongly favored.[2c] Rates and regioselectivities for reduction of various epoxides have been determined.[2d] Reduction of conjugated nitroalkenes gives nitroalkanes[2e] or ketones,[2f] depending on the workup used (eq 1).

(1)

Certain γ-keto esters undergo reduction-lactonization[2g] which, in some cases, is followed by reduction of the γ-lactones to the γ-lactols (eq 2).[2h] Some esters of Δ^2-isoxazolinylcarboxylates are reduced to the corresponding primary alcohols (no yields given).[2i]

(2)

The reagent is ineffective compared to *t*-butylmagnesium chloride as a hydride source for a hydrozirconation procedure.[2j]

Selective Reductions.

Ketones are reduced selectively in the presence of other functional groups: carboxylic acids;[3a] esters,[3b -n] including γ-lactones[3j,k] and 1,3-dioxolan-4-ones;[3e] amides,[4] including benzenesulfonamides[4a,b] and 2-acetyl β-lactams;[4f,g] and internal epoxides.[31] An enamine is reduced selectively in the presence of a sulfoxide.[5]

Diastereospecific 1,2-reduction of a conjugated enone occurs in the case of 2β-*t*-butyldimethylsilyloxycyperone (eq 3).[6a] The corresponding 2α-silyloxy diastereomer requires $LiAlH_4$ for reduction, also yielding the 3β-ol. A conjugated enone undergoes 1,2-reduction while a lactone (both functions in the same 14-membered ring) remains untouched (see below).[12o]

(3)

Amides are reduced to aldehydes in the presence of other readily reducible functional groups by first treating with ethyl trifluoromethanesulfonate (EtOTf) or MeOTf in CH_2Cl_2, removing the solvent, dissolving the residue in THF, and treating with L-Selectride (eq 4).[6b] In all cases, some unreacted starting material is recovered. K-Selectride® (***Potassium Tri-s-butylborohydride***) gives a lower yield; other hydrides give byproducts.

(4)

A keto aldehyde is reduced selectively (eq 5).[6c] The resulting hydroxy ketone is in equilibrium with its cyclic hemiacetal.

Stereoselective Reductions.

The synthetic use that first brought attention to L-Selectride was the diastereoselective reduction of alkyl-substituted cyclic ketones to alcohols.[20] Numerous applications for cyclic[7,11m] and acyclic[8,23c] ketones have now been reported, including various ketocarboxylate[3] and ketonamide[4] systems.

Various theoretical models are used to rationalize observed diastereoselectivity.[23] In simple cases, the bulk of the reagent appears to dictate that hydride approach from the less sterically hindered face of the carbonyl (eq 6).[20] However, complexation effects, including those of heteroatoms,[7b] crown ethers,[3i,8u] and cryptands,[8u] may reverse the direction of approach. It is also observed that varying the coordinating ability of the solvent influences the ratio of diastereomers.[3e]

In most cases, imines can be reduced stereoselectively to amines (eq 7).[9a-e] However, some 2-substituted imines resist reduction and require using the more reactive ***Lithium Triethylborohydride***. Enamino sulfoxides are also

stereoselectively reduced to amines.[5] Chiral β-imino sulfoxides are reduced stereoselectively but in poor yield.[9f] Reduction of a tartarimide gives >99% stereoselection in the formation of the corresponding hydroxylactam (eq 8).[10]

Regioselective Reduction of Cyclic Anhydrides.

Various succinic and phthalic anhydrides are reduced to lactones.[11] With certain exceptions (eq 9),[11d] reduction occurs preferentially at the less hindered carbonyl function. A mechanistic interpretation of the results has been proposed.[11d,e]

(9)

Reduction of Enones and Enoates.

Following the first reported stereoselective reduction of an acyclic enone to an allylic alcohol,[12a] a reasonably systematic study using K- and L-Selectride was conducted.[12b] With certain exceptions, results for the latter are comparable to those for the former:

- 1)whereas one equivalent of K-Selectride gives exclusively 1,2-addition with 3,5-dimethyl-2-cyclohexenone, L-Selectride gives a 1:1 mixture of 1,2- and 1,4-addition products;
- 2)in reductive alkylation of enones use of L- rather than K-Selectride leads to higher yields of monoalkylated products;
- 3)while attempted reduction of α,β-unsaturated esters with K-Selectride leads to Claisen condensation products, slowly adding a mixture of ester and *t*-butyl alcohol to a THF solution of L-Selectride at -70 °C gives the saturated ester cleanly.

Replacing *t*-butyl alcohol with various electrophiles in the procedure of (3) allows reductive alkylation, although Claisen condensation product also forms if the enoate lacks α- or β-substitution.

Other reports confirm that stereoselective 1,2-reduction is likely with both acyclic enones[12c,d] and β-substituted cyclic enones.[12e-g] However, in one case, treating the latter first with ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** followed by L-Selectride (2 equiv, -78 °C, 30 min) gives the 1,4-reduction product in quantitative yield.[12g] Terminal acyclic enones undergo 1,4-reduction with predominant formation of the *s-trans* enolate, the exact ratio *s-trans*:*s-cis* depending on the relative bulk of *R* and *R´* (eq 10).[12h] Systems with extended conjugation, such as a phenyldienone, resist conjugate addition and undergo stereoselective 1,2-reduction.[12i] Unlike simpler substrates, a complex methyl enoate is reduced to the corresponding allylic alcohol.[12j]

(10)

Cyclic enones without β-substituents often undergo 1,4-reduction,[12k-m] which may be followed by alkylation;[12k,m,n]

the alkylation may be stereoselective.[12k,m] In some cases, mixtures of 1,2- and 1,4-reduction products are obtained,[12o,p] in contrast to 1,2-reduction only for K-Selectride.[12o] Vinyl triflates may be produced from enones if 1,4-reduction is facile.[12q] In the presence of 1,3-dimethyl-3,4,5,6-tetrahydro-2 (1*H*)-pyrimidinone, a conjugated cyclic dienone is reduced to the conjugated enone.[12r]

α,β-Alkynic esters tend toward nearly exclusive 1,2-reduction with formation of propargylic alcohols.[12b] Likewise, α,β-alkynic ketones yield only propargylic alcohols.[8e,f]

Michael Initiated Ring Closure (MIRC) Reactions.

Formation of five- and six-membered rings results from treatment of o-alkylidenemalonates with L-Selectride, but better yields are realized with nucleophiles other than hydride.[13a] A MIMIRC procedure using 2-cyclohexenone and ***Vinyltriphenylphosphonium Bromide*** (VTB) is highly successful (eq 11).[13b] The 1-*t*-butyl 9-methyl diester of (*E*,*E*)-(*S*)-2,4-dimethyl-2,7-nonadienedioic acid is converted to a cyclohexane diester as a single stereoisomer (eq 12).[13c]

(11)

(12)

Reduction of (2-Arylprop-1-en-3-yl)trimethylammonium Iodides.

Treatment of [2-(4-methoxyphenyl)prop-1-en-3-yl]trimethylammonium iodide with L-Selectride results in addition of hydride with displacement of Me_3N, giving 2-(4-methoxyphenyl)propene in virtually quantitative yield (eq 13).[14] This reaction may be applicable for derivatives containing a wide variety of aryl groups.

(13)

Hydroboration of Styrenes.

This reaction is quantitative with ***Lithium Triethylborohydride*** but proceeds to the extent of less than 40% with L-Selectride, polymerization of styrene being the predominant result.[15]

Reaction with Carbon Monoxide.

Carbonylation of LiBH-(*s*-Bu)$_3$ followed by treatment with refluxing aqueous NaOH gives 2-methyl-1-butanol.[16a] Since LiBH(*s*-Bu)$_3$ is an intermediate in hydride-induced carbonylation of *s*-Bu$_3$B using LiAlH(OMe)$_3$,[16b,20] different workup procedures yield 2-methylbutanal[16c] or 3,5-dimethyl-4-heptanol.[16d]

Related Reagents.

Lithium Aluminum Hydride; ***Lithium Triethylborohydride***; ***Lithium Trisiamylborohydride***; ***Potassium Tri-s-butylborohydride***.

Lithium Tri-*t*-butylzincate

t-Bu_3ZnLi

[63676-98-2] · $C_{12}H_{27}LiZn$ · Lithium Tri-*t*-butylzincate · (MW 243.72)

(1,4-addition to enones;[1] halogen-zinc exchange reactions)

Alternate Name: tri-*t*-butylzinclithium.

Solubility: sol ether, THF.

Preparative Methods: lithium triorganozincates (R_3ZnLi) such as lithium tri-*t*-butylzincate are prepared by the reaction of RLi (3 equiv) with ***Zinc Chloride*** or by the treatment of R_2Zn with RLi in ether or THF.[1-4]

Handling, Storage, and Precautions: like other polar organometallics, lithium tri-*t*-butylzincate is very sensitive to oxygen and moisture. It is best generated in situ and should be stored at low temperature.

Halogen-Zinc Exchange Reactions.

Lithium tri-*t*-butylzincate is a highly efficient reagent for performing bromine-zinc exchange reactions with various types of 1,1-dibromoalkanes,[5] 1,1-dibromoalkenes,[6,7] and 1,1-dibromocyclopropanes.[8,9] The initial halogen-zinc exchange reaction is followed by a 1,2-migration of the *t*-butyl group, leading to a zinc reagent which can be trapped with various electrophiles (eqs 1-3).[5,6,9] Other primary and secondary lithium triorganozincates behave in a similar way.[5-9] Interestingly, the halogen-zinc exchange proceeds with a high stereoselectivity and, in the case of β-disubstituted 1,1-dibromoalkenes, the Br/Zn exchange takes place preferentially at the sterically more hindered bromine atom (eq 4).[7] This constitutes an excellent method for the stereospecific preparation of alkenyl halides (eq 5).[7]

Michael Addition Reactions.

Lithium tri-*t*-butylzincate undergoes a Michael addition to enones (eq 6).[1] A similar reaction is observed with magnesium tri-*t*-butylzincate (eq 7).[4] If mixed trizincates are used, the *t*-butyl group is transferred with moderate selectivity (eq 8).[4] In strong contrast, an *n*-butyl group is transferred with a high chemoselectivity (eq 9).[4,10-12] Related mixed heterozincates, R_2(O-*t*-Bu)ZnMgBr.TMEDA, prepared by the reaction of $ZnCl_2$.TMEDA, *t*-BuOK, and RMgX (2 equiv), add readily to enones to provide the 1,4-adducts in satisfactory yields. By using chiral TMEDA analog ligands, moderate optical yields (5-14% ee) are obtained.[13-15] The addition of Bu_3ZnLi to nitrostyrene in the solvent mixture pentane-(*S*,*S*)-1,4-dimethylamino-2,3-dimethoxybutane (DDB) affords the Michael adduct in optically active form (eq 10).[3]

Lithium Tricarbonyl(*n*-pentanoyl)nickelate

[26402-51-7] · $C_8H_9LiNiO_4$ · Lithium Tricarbonyl(*n*-pentanoyl)nickelate · (MW 234.80)

(acyl anion equivalent in alkylations;[1] acylation of vinyl halides,[3] conjugate additions[3,5])

Physical Data: the pure reagent has not been isolated, but solutions have been characterized by ^{1}H NMR, ^{13}C NMR, and IR.[1a]

Solubility: the reagent has been used in diethyl ether and THF.

Preparative Methods: solutions of the title reagent can be prepared by adding *n*-BuLi to $Ni(CO)_4$ in THF at -78 °C.[1b]

Handling, Storage, and Precautions: the reagent is oxygen sensitive and is best used directly after preparation. NMR studies, however, indicate stability from +20 °C to -78 °C over a period of 8 h.[1a] See ***n-Butyllithium*** and ***Tetracarbonylnickel*** for handling of these reagents.

General Considerations.

The title reagent is the most studied of a family of reagents prepared by addition of nucleophiles to tetracarbonylnickel. Other members of this family include lithium tricarbonyl(dimethylcarbamoyl)nickelate,[2d] lithium *t*-butoxycarbonyl(tricarbonyl)nickelate,[3a] lithium tricarbonyl(methoxycarbonyl)nickelate,[3a] and selected lithium aroyl(tricarbonyl)nickelates.[2c] This article will focus on reactions of the title reagent, but will discuss the behavior of this family of reagents in general terms. For additional information on these reagents, see ***Tetracarbonylnickel***.

Nickel acylate complexes are synthesized from the reaction of an anionic compound, such as an alkyl- or aryllithium, an amide, or an alkoxide, with tetracarbonylnickel in an ether solvent.[1-3] The alkoxide reactions are often performed with the corresponding alcohol as the solvent. The complexes are usually formed as the lithium salt, but some sodium salts, especially for the alkoxides, are also known.

The structure of the alkyl nickel acylate complex generated in THF is monomeric; however, there is some controversy about the structure of the alkyl acylate complex when it is generated in Et_2O.[1] Both the monomeric structure[3] and a

dimeric structure[2] have been proposed for this complex. In contrast, the structures of the amido and alkoxy acylate complex are monomeric regardless of the solvent used.[2]

Oxidation, Hydrolysis, and Thermolysis of the Alkyl or Aryl Nickel Acylate Complex.

The oxidation of the acylate complex is easily accomplished by the addition of an oxidant, such as oxygen, iodine, or ferrocenium ion, to give a variety of diketones and keto esters. It has been shown with an alkyl acylate complex that a 17-electron intermediate is formed initially and that this then decomposes to give the observed organic products (eq 1).[1] Similar types of products are obtained upon thermolysis of an acylate complex, but the mechanism of this reaction is not known.[2]

When the alkyl acylate complex is treated with water or a mineral acid, an acyloin derivative is generated (eq 2).[1,2] The formation of an acyloin is in contrast to the results obtained from the reaction of an acid with an iron, chromium, molybdenum, or tungsten acylate complex, which gives an aldehyde upon hydrolysis.[4] The nickel acylate complex will not add to the carbonyl of a simple ketone; however, it will deprotonate a ketone which has a pK_a of 16 or less.

Alkyl and aryl acylate complexes react with alkyl halides. One of the cleanest and fastest reactions is with ***Allyl Bromide***. This is a very efficient synthesis of β,γ-unsaturated ketones (eq 3).[3] Using Et_2O as the solvent, the highest yields are obtained when the solution is kept below -30 °C;[3] however, in THF the reaction can be done either cold or at

room temperature in about an hour.[1]

(3)

In contrast, ***Iodomethane*** reacts with a nickel acylate complex rather slowly. The reaction, which may be done using either Et_2O or THF as the solvent, requires overnight at rt. Another major difference in the reaction with iodomethane, in comparison to the reaction with allyl bromide, is that here, after protonation, an acyloin derivative is generated and not the simple ketone (eq 4). It is believed that this product results from attack of the acylate complex on a first-formed nickel complex. This attack is possible when using iodomethane, but not with allyl bromide, due to the much slower rate of the former compared to the latter reaction.[1,3]

(4)

The rate of the reaction of an alkyl or aryl nickel acylate complex with ***Benzyl Bromide***, qualitatively, is between that found for the reaction with allyl bromide and that for the reaction with iodomethane. Consistent with this observation is the formation of a mixture of the ketone and the acyloin derivatives.[1,2]

An alkyl and aryl acylate complex also will react with a terminal alkyne to generate a 1,4-diketone (eq 5).[2]

(5)

Also, in contrast to the acylate complexes of iron, chromium, molybdenum, and tungsten, a nickel acylate complex reacts readily with a vinyl halide, such as bromostyrene. The major product is a 1,4-diketone. In addition, smaller amounts of an α,β-unsaturated ketone, the proposed first formed intermediate, are generated (eq 6).[3] This discovery led to the development of the use of nickel acylate complexes for Michael additions to α,β-unsaturated ketones and esters.

Michael Additions of Alkyl and Aryl Nickel Acylate Complexes.

As just mentioned, a nickel acylate complex will undergo a Michael addition to an α,β-unsaturated ketone. This reaction also works very well with an α,β-unsaturated ester. In fact, the cleanest reactions of the alkyl and aryl nickel acylate complexes are these Michael additions (eq 7).[3]

Michael additions of acylate complexes have been used for the synthesis of natural products such as naphthoquinone antibiotics (eq 8).[5]

Heteroatom Nickel Acylate Complexes.

The synthesis of nickel acylate complexes is not restricted to the attack of an alkyl- or aryllithium reagent on tetracarbonylnickel. As mentioned in the introduction, a dialkyl amide also reacts with tetracarbonylnickel to form an

amido nickel acylate complex, using either Et_2O or THF as the solvent. This acylate complex reacts readily with allyl bromide, a vinyl halide, an aryl halide, or with a terminal alkyne to generate a large variety of organic compounds (eq 9).[2,3]

Lithium Trichloropalladate

$LiPdCl_3$

[22587-92-4] · Cl_3LiPd · Lithium Trichloropalladate · (MW 219.71)

(catalyst for alkylation and arylation of alkenes by organomercurials;[1-12] catalyst for heteroannulation reactions;[13-16] catalyst for coupling of organometallics with aryl and alkyl halides[17-20])

Solubility: prepared and used in acetonitrile; THF, DMSO, HMPA, H_2O have been used as solvent additives in reactions.

Preparative Methods: usually prepared as a solution in acetonitrile by stirring anhydrous ***Palladium(II) Chloride*** with a small excess of anhydrous ***Lithium Chloride*** overnight at rt,[1] or by refluxing for 30-60 min.[5-8] Obviously, this reagent exists as a complex with the solvent.

Handling, Storage, and Precautions: the solution of $LiPdCl_3$ in acetonitrile is usually used immediately after preparation. No data are available for the toxicity of this compound.

Arylation and Alkylation of Alkenes with Organomercurials.

Organomercury compounds react with $LiPdCl_3$ (see also ***Dilithium Tetrachloropalladate(II)***) to give organopalladium compounds that undergo the alkene insertion-elimination process to give aryl(alkenyl)-substituted alkenes (eq 1).[1] This reaction is sometimes called the Heck reaction.

(1)

Palladium is readily reoxidized under the reaction conditions by mercury(II) salts (or ***Copper(II) Chloride***) and thus only catalytic amounts are required.[1,3,4,9] Practically any arylmercury(II) salt will function as an arylating agent in this reaction. In general, strong electron-donating groups (*p*-methoxy, *o*-hydroxy, *p*-diethylamino) decrease the yields, while good coordinating groups, for example amino groups, retard or even completely stop the reaction because they form stable, unreactive complexes with palladium.[1] The rates of reaction and the regioselectivity depend on both steric

and electronic factors.[1,2] The less sterically hindered the alkene, the greater the rate, and the new C-C bond is formed at the least sterically hindered or at the most electron-deficient carbon atom. The regioselectivity is highest when a strong electron-withdrawing group such as CN, CO_2Me, or Ph is attached to the double bond and therefore styrene, acrylonitrile, acrolein, and methyl acrylate are the most useful alkenes in the Heck reaction.[1-9] Quinones can be also used as substrates for arylation.[11] Several interesting examples of heterocyclic mercury salts have been used as arylation agents, including porphyrins,[5,12] substituted pyrroles,[8] and sydnones.[7] Utilization of vinyl mercurials gives conjugated dienes.[3,4]

Heteroannulation.

A variety of oxygen- and nitrogen-containing heterocycles can be prepared from π-allylpalladium compounds bearing carboxylic acid,[14,15] phenol,[14,16] alcohol,[14] amide,[14] and amino[13] functionality. Addition of base liberates an oxygen or nitrogen nucleophile that displaces the palladium with the formation of the carbon-heteroatom bond. Usually these π-allylpalladium compounds are prepared in situ by reaction of alkenes or dienes, as well as vinylcyclopropanes, with organomercurials and $LiPdCl_3$. Functional groups necessary for further cyclization can be attached either to the organomercurial (eq 2)[14,16] or the alkene (eq 3).[15] The shortcoming of this procedure is the need to use equal amounts of the palladium salt and organomercurial.

(2)

(3)

Arylation of Unsaturated Compounds.

Arylmercurials react with allylic halides in the presence of $LiPdCl_3$ and $CuCl_2$ (as reoxidant) at room temperature in acetonitrile to produce allyl aromatic derivatives (eq 4). A wide variety of allyl aromatic compounds can be obtained by this procedure, even ones containing nitro, ester, and aldehyde groups.[17] Catalytic amounts of $LiPdCl_3$ and 10-30 mol% of $CuCl_2$ generally must be used to obtain optimum yields.

(4)

$LiPdCl_3$ has also been used, among other palladium catalysts, for cross-coupling reactions of organometallic compounds with aryl halides.[18-20]

Lithium Triethylborohydride[1]

$LiBHEt_3$

[22560-16-3] · $C_6H_{16}BLi$ · Lithium Triethylborohydride · (MW 105.97)

(exceptionally powerful nucleophile in S_N2 displacement reactions with super hydride activity; powerful and selective reducing agent)

Alternate Name: Super Hydride®.

Physical Data: mp 66-67 °C;[2] *d*420 0.920 g cm^{-3} for 1 M solution in THF.

Solubility: sol THF, benzene; reacts violently with water.

Form Supplied in: 1 M solution in THF.

Preparative Methods: prepared by the reaction of ***Triethylborane*** with ***t-Butyllithium***,[3a] lithium hydride,[2,3b] or ***Lithium Aluminum Hydride*** in the presence of triethylenediamine.[3c]

Analysis of Reagent Purity: IR: 2060 cm^{-1} (BH). ^{11}B NMR (THF) δ, ppm, -12.2 (d, J_{B-H} = 61 Hz).[3a] Active hydride is determined by hydrolysis of an aliquot and measuring the hydrogen evolved according to the standard procedure.[4] Low concentrations may be determined by iodometric titration.[5]

Handling, Storage, and Precautions: corrosive flammable liquid. Handle and store under nitrogen or argon in a cool dry place. Avoid contact with skin and clothing. Use in a fume hood.

Reduction of Functional Groups.

Lithium triethylborohydride shows super hydride activity. Its reactivity in comparison to other nucleophiles is given in Table 1.[6] The reduction of representative functionalities by the reagent under standard conditions has been described.[7]

Table 1 Reactivity of Et_3BH^- in Comparison to Other Nucleophiles

Reagent	Relative Nucleophilicity
Et_3BH^-	9 400 000
n-BuS^-	680 000
PhS^-	470 000
AlH_4^-	230 000
I^-	3 700
EtO^-	1 000
BH_4^-	940
Br^-	500
PhO^-	400
NO_3^-	1

Alkyl Halides.

Lithium triethylborohydride is the reagent of choice for dehalogenation of alkyl halides (eq 1).[6,8] Primary iodides are the most reactive. Fluorides are reduced at slower rates (eq 2).[9] Secondary halides may give elimination products in some cases. Mechanistic aspects of the reaction have been studied.[10]

(1)

(2)

Deoxygenation of Alcohols.

Tosylates,[11] mesylates,[12] and alkoxytris(dimethylamino)phosphonium salts[13] of primary alcohols are cleanly reduced to hydrocarbons. Tosylates of secondary alcohols may undergo elimination reactions. Even in such cases the reduction may be synthetically useful (eq 3).[11f] Differences in the reactivity of tosylates and alkylsulfonates have been observed.[11e]

(3)

Allylic Derivatives.

Allylic groups such as -OR, -SR, -SO_2R, -SeR, and -OTBDMS undergo reductive cleavage by lithium triethylborohydride catalyzed by palladium compounds (eq 4).[14a] Squalene (*E*/*Z* = 97:3) has been prepared using this reaction as a key step.[14b]

(4)

(*E*):(*Z*):terminal = 94:3:3

Epoxides and Oxetanes.

The reduction of epoxides by the reagent is quite facile, yielding exclusively the Markovnikov product.[5,7,15] Its advantage is evident in the reduction of labile epoxides prone to electrophilic rearrangements (eq 5).[16] Oxetanes are opened in a similar fashion.[17] Conjugated epoxides may undergo 1,4-reduction.[18]

Ketones and Derivatives.

Aldehydes and ketones are reduced by lithium triethylborohydride rapidly and quantitatively to the corresponding alcohols, even at -78 °C.[7] Enthalpies of these reactions have been estimated.[19] Selective reduction of a keto group in the presence of an electron-rich aldehyde group has been achieved.[20a] Although the stereoselectivity of the reagent is lower as compared to other trialkylborohydrides containing bulky sterically demanding groups, several α-, β-, or γ-substituted ketones undergo reduction with high selectivity.[20b-j] α,β-Unsaturated ketones and esters undergo 1,4-additions.[21] *N*-Alkylimines derived from cyclic ketones are reduced to the corresponding secondary amines which can be transformed into primary amines.[22]

The reduction of α-trityl ketones with lithium triethylborohydride proceeds with cleavage of the trityl group. Stereoselective aldol reaction, combined with the reduction, provides access to stereodefined acyclic 1,3-diols[23] (eq 6).[23b] Trityl alkynic ketones are cleaved without affecting the triple bond.[24] Acetals are stable to the reagent and can be used as protective groups (eq 2).[7,9,11c,d] However, acetals are cleaved in the presence of ***Titanium(IV) Chloride***.[25]

Carboxylic Acid Derivatives.[7]

The inertness of carboxylic acids to the reagent is noteworthy. Anhydrides are reduced to alcohols and acids. Cyclic

anhydrides can be transformed into the corresponding lactones via intermediate hydroxy acids. The reactivity of lithium triethylborohydride toward ester groups is exceptionally high. Even esters of aromatic carboxylic acids are selectively reduced to alcohols in the presence of other functional groups (eq 7).[26] Selective reduction of the less hindered MEM ester groups of a diester has been achieved.[27a] The reduction of esters with ***Lithium Borohydride*** is catalyzed by lithium triethylborohydride.[27b]

(7)

X = H, Y = NH_2, 82.5%
X = H, Y = NO_2, 99.7%
X = Cl, Y = OMe, 94.4%

Unlike most other hydride reducing agents, lithium triethylborohydride reduces tertiary amides to the corresponding alcohols.[7,28] Benzonitrile cleanly gives benzylamine with an excess of the reagent. With an equimolar ratio of the reactants, an 85-97% yield of benzaldehyde is obtained.[7] Aliphatic nitriles give lower yields of the corresponding amines.

Other Functionalities.

The formation of ethylbenzene in the reaction of lithium triethylborohydride with diphenyl sulfone illustrates a general reactivity pattern of trialkylborohydrides with aromatic sulfones (eq 8).[29]

(8)

α,β-Unsaturated nitro compounds are transformed into lithium nitroalkanes.[30a] In the presence of borane, *N*-ethylamine derivatives are formed (eq 9).[30b] 1,2-Iodo thiocyanates[31a] and vinylthiophthalimides[31b] yield thiiranes (eq 10). The reagent is useful for selective demethylation of quaternary ammonium salts containing at least two methyl groups.[32] It also finds application in the synthesis of di- and trialkyldihydronaphthalenenes.[33a] Pyridine is reduced to tetrahydropyridine.[7,33b]

(9)

R	R^1	R^2
H	H	H
Me	H	H
H	Br	H
Me	EtO	EtO

(10)

Hydroboration.

The reagent hydroborates aromatically conjugated alkenes in a Markovnikov fashion (eq 11).[34] Substituents that decrease the electron density of the double bond increase the rate of reaction. Lithium triethylborohydride promotes hydroboration of alkenes by dialkoxyboranes; the addition is anti-Markovnikov.[35]

(11)

Synthesis of Borates and Boronates.

The reagent promotes the reaction of alcohol with borane to give borates in high yields[36] (see also ***Borane-Dimethyl Sulfide***). Ethyl boronates can be conveniently prepared by the reaction with 1,2-diols.[37]

Organometallic Synthesis.[38]

Lithium triethylborohydride is recommended for the generation of chloro(cyclopentadienyl)hydrozirconium (Schwartz hydrozirconation reagent).[39] The reagent is used for the reduction of other transition metal halide complexes.[40] The major area of its application in transition metal chemistry involves metal-metal and metal-metalloid bond cleavage[38,41] and formation of anionic and neutral formyl complexes.[38,42] It finds various other applications.[43-45]

Related Reagents.

Potassium Triethylborohydride.

Lithium Trimethylmanganate[1]

Me_3MnLi

[105870-26-6] · C_3H_9LiMn · Lithium Trimethylmanganate · (MW 107.00)

(less expensive, more stable[2] cuprate[3] analog that undergoes nucleophilic additions,[4] conjugate additions,[5] and substitutions[6])

Solubility: sol THF; sol ether if prepared from MnI_2.

Preparative Methods: can be prepared as an ether solution from MnI_2 and ***Methyllithium***, or as a THF solution from ***Manganese(II) Chloride*** or Li_2MnCl_4 and MeLi. For instance, to prepare Me_3MnLi in THF from MeLi, charge a dry, N_2-purged round-bottom flask equipped with magnetic stirring bar, N_2 inlet, and septum stopper with 1.0 equiv of high purity, (>99%) dried (2 h at 180 °C) $MnCl_2$ and add sufficient dry, O_2-free THF to form a ca. 0.2 M slurry. Cool the slurry to -10 to 0 °C and add 3.0 equiv of a solution of MeLi dropwise. After the addition is complete, stir the reaction at room temperature for 30 min. A brownish-red to clear yellow solution results and can be used directly.[7]

Handling, Storage, and Precautions: best results are obtained with high purity, dry, O_2-free solvents and manganese salts. MeLi is pyrophoric;[8] due care must be exercised in its handling. The reagent has greater thermodynamic stability when prepared in THF than in ether.

Originally prepared from MnI_2 and MeLi in ether,[9] the formulation of the reagent as Me_3MnLi is a convenience only and this may not be the reactive species in solution. There is considerable evidence that, over a wide range of reagent ratios, the reaction equilibrium favors formation of $Li_2[MnMe_3]_4$; $[MnMe_3]^-$ species form only as intermediates.[10]

Trialkylmanganates are sufficiently nucleophilic to react with good electrophiles, such as phenyl isocyanate, in good yield (eq 1).[3] Conjugate additions to 2-alkenones are more problematic: relatively rare β-reductive dimerization[5] (eq 2) is sometimes observed in addition to β-alkylation[11] (eq 2). Dimerization is, however, substrate specific;[7] it may be possible to improve yields using catalytic or stoichiometric amounts of Cu^I salts.[12]

(1)

Although cuprate reagents generally are found to be superior in nucleophilic substitution reactions with haloalkanes, trialkylmanganates provide the same products, usually in good yields.[6] Primary iodoalkanes, allylic halides (eq 3), and vinylic halides are satisfactory substrates; secondary and tertiary haloalkanes are not. Cross-coupling reactions between trialkylmanganates and enol phosphates are catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)***; Li_2MnCl_4 catalyzes similar coupling between Grignard reagents and enol triflates, presumably via formation of an R_3MnLi species.[13]

Lithium (Trimethylsilyl)acetylide

Me_3SiC&tbond;CLi

[54655-07-1] · C_5H_9LiSi · Lithium (Trimethylsilyl)acetylide · (MW 104.17)

(synthesis of unsymmetrically disubstituted alkynes, where use of the silyl protecting group ensures selective monofunctionalization of the acetylide anion; the reaction products can be deprotected by cleavage of the Si-C bond, or the silicon group can be displaced with other electrophiles)

Form Supplied in: solution in THF (0.5 M).

Preparative Methods: most often prepared in situ by treatment of ***Trimethylsilylacetylene***[1] with ***n-Butyllithium***,[2] ***Lithium Diisopropylamide***,[3] or ***Ethyllithium-Lithium Bromide***.[4] It can also be prepared by monodesilylation of ***Bis(trimethylsilyl)acetylene*** with MeLi-LiBr complex (see ***Methyllithium***).[5]

Transmetalation.

Lithium (trimethylsilyl)acetylide can be transmetalated to enhance reactivity. Reaction with $CuBr.SMe_2$ (see ***Copper(I) Bromide***) provides the lithium (trialkynyl)cuprate, which can undergo electrophilic amination to provide 1-alkynylamines.[6] Transmetalation to cerium using ***Cerium(III) Chloride*** allows superior yields of addition products with cyclic ketones (eq 1).[7,8]

Addition to Carbonyl Compounds.

The title compound reacts with a variety of aldehydes[5,9-12] and ketones[13,14] to provide propargylic alcohol derivatives. Other carbonyl compounds used as substrates include quinones[2a] and quinone monoacetals,[15] alkynyl aldehydes[16] and ketones,[17] and dialkyl squarates (eq 2).[18] The propargylic alcohol products can be stereospecifically reduced to (*E*)-vinylsilanes, with ***Sodium Bis(2-methoxyethoxy)aluminum Hydride*** (Red-Al®).[19]

The reagent has been added to α-chiral aldehydes[20,21] and ketones,[22-25] with moderate to good stereoselectivity, although in one case the Grignard reagent proved superior to the lithium acetylide.[23a] Alternatively, optical activity can be introduced by employing a chiral ligand.[26]

(2)

Addition to Epoxides.

Lithium (trimethylsilyl)acetylide has been used to open terminal epoxides in the presence of Lewis acids such as $GaMe_3$[27] or ***Boron Trifluoride Etherate*** (eq 3).[28]

(3)

Alkynyl Ketones.

Treatment of a Weinreb amide[29] (see ***N,O-Dimethylhydroxylamine***) or an isoxazolidide[30] with the title compound provides good to excellent yields of α,β-ynones (eq 4).

(4)

Miscellaneous.

Lithium (trimethylsilyl)acetylide has been employed in the nucleophilic displacement of bromides[10] and iodides[31] and the Grignard analog in aryl chloride substitution.[32] The reaction of lithium (trimethylsilyl)acetylide with 2-chloroethyl thiocyanate is an efficient route to 1-vinylthioacetylene.[33] Trisubstituted vinylsilanes can be prepared from the reaction of lithium (trimethylsilyl)acetylide with trialkylboranes and electrophiles.[34] The title reagent has been added to *N*-acyl imines to form α,α´-disubstituted amino acid bis-amides.[35] Excellent stereocontrol has been observed in addition reactions of lithium (trimethylsilyl)acetylide to 3-thiazolines (eq 5)[3] and β´-aminocyclopentenyl sulfones (eq 6).[36]

(5)

Related Reagents.

Dilithium Acetylide; ***Ethynylmagnesium Bromide***; ***Lithium Acetylide***; ***Lithium Chloroacetylide***; ***Propynyllithium***.

Lithium Trimethylzincate

Me_3ZnLi

[52196-05-1] · C_3H_9LiZn · Lithium Trimethylzincate · (MW 117.45)

(strong nucleophile; undergoes 1,4-additions to enones;[1-6] can be used for performing halogen-zinc exchange reactions[8,9])

Solubility: sol ether, THF; reacts with H_2O, protic solvents, and oxygen.

Preparative Methods: THF or ether solutions can be prepared by the reaction of ***Methyllithium*** (3 equiv) with ***Zinc Chloride*** or by the treatment of Me_2Zn with MeLi.[1-4]

Handling, Storage, and Precautions: should be handled under an inert atmosphere; like organolithiums, it may react with THF; best generated in situ and used rapidly.

Michael Additions.

Lithium trimethylzincate, like most lithium or magnesium triorganozincates, undergoes 1,4-additions to enones with high chemoselectivity (see ***Lithium Tri-t-butylzincate***). The nature of the lithium salts present in the reaction mixture strongly influences the yield obtained (eq 1).[1] It must also be noted that lithium trimethylzincate is one of the least reactive triorganozincates and that the transfer of a methyl group proceeds generally with moderate yield (eq 2).[4] This has been exploited synthetically by preparing mixed alkyldimethylzincates which were shown to transfer selectively the alkyl group in the Michael addition (alkyl = *n*-Bu, *i*-Pr, *t*-Bu, *i*-Bu, Ph, vinyl, Me_2PhSi; eqs 3 and 4).[4,5] If the addition of lithium trimethylzincate to cyclohexenone is performed in a chiral solvent like (+)-1,4-dimethylamino-2,3-dimethoxybutane (DDB), the resulting 3-methylcyclohexane is obtained in low enantioselectivity.[3] α,β-Unsaturated epoxides react rapidly affording a mixture of S_N2 and S_N2' substitution products (eq 5).[6] Lithium trimethylzincate adds with moderate stereoselectivity to 4-*t*-butylcyclohexanone, producing a mixture of axial and equatorial alcohols (70:30).[7]

Halogen-Zinc Exchange Reactions.

Interestingly, lithium triorganozincates can be used for performing halogen-zinc exchange reactions.[8,9] 1,1-Dibromoalkanes such as (**1**) react readily with Me_3ZnLi at -85 °C, providing the corresponding zinc carbenoid (**2**) which undergoes 1,2-migration[10,11] upon warming to 0 °C to afford the organozinc reagent (**3**); after protonolysis, this gives the cyclopropane derivative (**4**) (eq 6).[8] The reaction can be extended to acyclic 1,1-dibromoalkanes, thus offering unique homologation possibilities (eq 7).[9]

Lithium Trisiamylborohydride

[60217-34-7] · $C_{15}H_{31}BLi$ · Lithium Trisiamylborohydride · (MW 232.19)

(highly chemo- and stereoselective reducing agent)

Alternate Name: LS-Selectride®.

*Physical Data: d*420 = 0.903 for 1 M solution in THF.

Solubility: sol THF, diethyl ether.

Form Supplied in: 1 M solution in THF.

Preparative Methods: by the reaction of ***t-Butyllithium*** with trisiamylborane,[1] of ***Lithium Aluminum Hydride*** with trisiamylborane in the presence of triethylenediamine,[2] or of lithium trimethoxyaluminohydride with trisiamylborane.[3]

Analysis of Reagent Purity: ^{11}B NMR (THF), δ, ppm, two pairs of doublets, -12.5 (d, *J* = 78 Hz), -13.9 (d, *J* = 79 Hz) area 3:1;[1] IR: 2150 cm^{-1}. Active hydride is determined by hydrolysis and measuring the hydrogen evolved according to the standard procedure.[4]

Handling, Storage, and Precautions: air- and moisture-sensitive, flammable liquid. Reacts violently with water. Handle and store under nitrogen or argon. Use in a fume hood.

Lithium trisiamylborohydride ($LiBSia_3H$) is a highly hindered trialkylborohydride containing three bulky β-methyl-substituted secondary alkyl groups. The reagent reduces, rapidly and quantitatively, unhindered cyclic and bicyclic ketones with exceptional steric control. Thus, 2-, 3-, and 4-methylcyclohexanones are all reduced at -78 °C in >99% stereoselectivity to give the less stable isomer of the corresponding methylcyclohexanol (Table 1). Attack from the less hindered side is also favored for the alkaloid and steroidal ketones.[6-8]

Table 1 Reduction of Representative Cyclic Ketones with Lithium Trisiamylborohydride and Other Trialkylborohydrides[1]

Ketone	Product alcohol (%)			
	Less stable isomer	LiB-Sia_3H	LiB-$(s\text{-Bu})_3H$	Other hydrides
2-Methylcyclopentanone	*cis*	98.5	98.5	75[a], 79.2[b]
2-Methylcyclohexanone	*cis*	99.7	99.3	
3-Methylcyclohexanone	*trans*	99.6	95.0	
4-Methylcyclohexanone	*cis*	99.0	90.0	
4-*t*-Butylcyclohexanone	*cis*	99.4	96.5	99.2[c], 20[b]
Norcamphor	*endo*	>99.5	99.6	
Camphor	*exo*	99.3	99.0	

[a]$LiBEt_3H$.[5a] [b]$KBEt_3H$.[5b] [c]$KBSia_3H$.[5c]

Conjugate reduction of the macrocyclic keto lactone occurs only as a minor side-reaction, accounting for 10% of the reaction product, whereas with L-Selectride (***Lithium Tri-s-butylborohydride***) (but not with K-Selectride (***Potassium Tri-s-butylborohydride***)), 53% of the product is the saturated ketone (eq 1).[9] Both L- and K-Selectrides reduce α,β-enones and α,β-enoates in a conjugate fashion.[10]

High stereoselectivity is also observed in the reduction of acyclic ketones with LS-Selectride. Thus, the α,β-dialkoxy ketone is reduced with 97% *syn* diastereoselectivity (eq 2).[11] The reagent is the most stereoselective among the borohydrides used for the reduction of (-)-menthyl phenylglyoxalate and (-)-menthyl pyruvate (eq 3).[12] Only lithium trialkoxyaluminohydrides derived from very hindered tertiary alcohols show higher stereoselectivity in this reaction (86-90% de).[12]

(2)

67%, 97% *syn*
83%, 98% *syn* (L-Selectride)

(3)

74% de

Chemoselective reduction of a tertiary amide to an aldehyde in the presence of an ester group is possible with LS-Selectride, but L-Selectride gives better results.[13] Unsymmetrical cyclic anhydrides are reduced to lactones at the less hindered carbonyl group. In contrast, other less bulky hydrides attack the anhydride preferentially at the more hindered carbonyl group (eq 4).[14-16]

(4)

	92%	8%
$LiAlH_4$[15]	5%	95%
$NaBH_4$[16]	0%	100%

2,6-Lutidine

[108-48-5] · C_7H_9N · 2,6-Lutidine · (MW 107.17)

(basic reagent/catalyst for silylation of alcohols,[2-10] for Rosenmund reduction,[14] and for preparation of boron enolates[15])

Physical Data: colorless oily liquid with an odor of pyridine and peppermint; bp 144.0 °C/760 mmHg, 79 °C/87 mmHg; mp -5.9 °C; *d* (20 °C) 0.9252 g cm^{-3}; *n*20D 1.49797. The major synthetic applications reported for 2,6-lutidine exploit its weakly nucleophilic nature (a result of steric crowding at the ring nitrogen) but moderately basic character (pK_a of its conjugate acid is 6.7).

Solubility: sol common organic solvents (e.g. ether, THF, DMF, alcohol); shows considerable water solubility (ca. 27% (w/w) at 45 °C).

Form Supplied in: a widely available article of commerce. Redistilled (99+ % purity) is available commercially. *Drying:* commonly dried by treatment with KOH or sodium followed by distillation, or by refluxing with, followed by distillation from, BaO[1] or CaH_2.[2]

Purification: both 3- and 4-picolines are common contaminants which can be removed by distillation from $AlCl_3$ (14 g/100 mL 2,6-lutidine, which also removes traces of water), or by addition of BF_3 (4 mL/100 mL of 2,6-lutidine) to anhydrous, fractionally distilled 2,6-lutidine, followed by redistillation.[1]

Handling, Storage, and Precautions: toxic flammable liquid; should be handled with caution in a fume hood.

Alcohol Protection Reactions.

The protection of alcohols as hindered silyl ethers proceeds in >90% yield using the appropriate trialkylsilyl triflate in the presence of anhydrous 2,6-lutidine as an acid scavenger. ***Triisopropylsilyl Trifluoromethanesulfonate***/2,6-lutidine in CH_2Cl_2 (-78 °C to 0 °C) allows for the protection of primary and secondary (but not tertiary) alcohols (eq 1).[2,3] Tertiary alcohols can be protected as the somewhat less crowded *i*-$PrEt_2Si$ ether (*i*-$PrEt_2SiOTf$/2,6-lutidine, CH_2Cl_2, rt).[4] The silylation of tertiary and unreactive secondary alcohols can also be achieved using ***t-Butyldimethylsilyl Trifluoromethanesulfonate***/2,6-lutidine in CH_2Cl_2 (0-25 °C);[2,5] silylation at -78 °C allows for the selective protection

of a secondary alcohol in the presence of a secondary allylic alcohol (eq 2).[6] The silylation of secondary allylic alcohols as the bulky tribenzylsilyl ether or tri-*p*-xylylsilyl ether can be accomplished using the appropriate tris(arylmethyl)chlorosilane/2,6-lutidine in DMF at -20 °C.[7] The bis-protection of 1,2-, 1,3-, and 1,4-diols as the corresponding dialkylsilylene derivatives can be achieved in high yield using ***Diisopropylsilyl Bis(trifluoromethanesulfonate)*** or ***Di-t-butylsilyl Bis(trifluoromethanesulfonate)*** at rt in $CDCl_3$ in the presence of 2,6-lutidine (eq 3);[8] interestingly, 2,6-lutidine was found to retard the 3´,5´-protection of nucleosides in DMF solution.[9] Protection of a 1,3-diol as its methylene acetal can be achieved using ***Trimethylsilyl Trifluoromethanesulfonate***/2,6-lutidine in $MeOCH_2OMe$ (0 °C, 15 min, 79%).[10]

(1)

(2)

(3)

Other Protection/Deprotection Reactions.

2,6-Lutidine is more effective than ***Silver(I) Carbonate*** or other amine bases at mediating the conversion of a 2-acetylpyranosyl bromide to an orthoester (eq 4).[11] Side reactions are minimized due to the lower acidity of the conjugate acid of 2,6-lutidine (pK_a 6.7) when compared to the other substituted pyridines examined. *Exo* stereoselectivity is maximized when using 2,6-lutidine rather than silver carbonate. 2,6-Lutidine considerably accelerates bond cleavage during the triarylamine radical cation-mediated oxidative cleavage of primary and secondary benzyl[12] and *p*-methoxybenzyl[13] ethers to the corresponding alcohols.

Rosenmund Reduction.

2,6-Lutidine is usefully employed as an HCl scavenger in the catalytic hydrogenation of aliphatic acyl chlorides to aldehydes (Rosenmund reduction) (eq 5).[14] These reactions are run in THF at <0.25 M in substrate to prevent poisoning of the Pd catalyst. 2,6-Lutidine is far superior to other basic additives (e.g. ***Diisopropylethylamine***, *N*,*N*-dimethylaniline, NaOAc). This method can tolerate ketone and ester functionality, proceeds on both unhindered and crowded acyl chlorides, and is especially suitable for the preparation of sensitive aldehydes. These reactions are faster and superior to those performed under classical Rosenmund reduction conditions (no added base), where high reaction temperatures are required and where the HCl byproduct can mediate side reactions.

Preparation of Boron Enolates.

Dialkylboryl triflates react with ketones in the presence of a hindered tertiary amine base (typically 2,6-lutidine or ***Diisopropylethylamine***) to afford boron enolates that are useful in stereoselective directed aldol condensation reactions.[15] 2,6-Lutidine is superior to other tertiary amines for the regioselective formation of the more stable 9-BBN boron enolate from alkyl methyl ketones using ***9-Borabicyclononyl Trifluoromethanesulfonate*** (eq 6).[15b,16,17] The 2,6-lutidinium triflate byproduct is presumably sufficiently acidic to facilitate enolate equilibration, resulting in thermodynamically controlled enolate formation.[15b,17] Interestingly, alkyl ethyl ketones are converted under apparently identical conditions to the less substituted boron enolate[18] with relatively high (>10:1) (*Z*) stereoselectivity (eq 7);[17,18] these reactions presumably proceed under kinetic control.[17] An opposite sense of regiocontrol has been observed when preparing dibutylboron enolates rather than 9-BBN enolates from alkyl methyl ketones using ***Di-n-butylboryl Trifluoromethanesulfonate***/2,6-lutidine,[17] although use of the more hindered and basic diisopropylethylamine in place of 2,6-lutidine affords much higher levels of regiocontrol.[17] Poor (*Z*)-dibutylboron enolate stereoselectivity is observed with alkyl ethyl ketones using 2,6-lutidine under kinetic control;[19,20] somewhat improved (>3:1) (*Z*) selectivity is

achieved under thermodynamic control.[20] Much higher (*Z*) stereoselectivity is achieved under strictly kinetic control using diisopropylethylamine as base.[17,19,20]

(6)

(7)

Radical Cyclopentannulation Reactions.

Zinc*/*Chlorotrimethylsilane-mediated cyclopentannulation reactions, involving the addition of an α-siloxy radical to an alkene or alkyne, are best performed in the presence of 2,6-lutidine, which prevents proton and $ZnCl_2$-catalyzed elimination of the tertiary siloxy group in the immediate product (eq 8).[21]

(8)

Oxidation of Allylic Alcohols.

2,6-Lutidine is added to prevent HCl-mediated side reactions during the ruthenium(II)-catalyzed oxidation of allylic alcohols (including labile allylic alcohols such as retinol) to α,β-unsaturated aldehydes using molecular oxygen (eq

9).[22] Other less hindered pyridine derivatives poison the catalyst and are ineffective.

(9)

Bromination of Sensitive Allylic Alcohols.

Preparation of highly labile allyl bromides can be achieved using ***Thionyl Bromide***/2,6-lutidine (eq 10).[23] Virtually no bromide is formed in the absence of 2,6-lutidine.

(10)

Related Reagents.

2,4,6-Collidine; ***1,5-Diazabicyclo[4.3.0]non-5-ene***; ***1,8-Diazabicyclo[5.4.0]undec-7-ene***; ***Diisopropylethylamine***; ***Pyridine***; ***Quinoline***; ***Triethylamine***.

Magnesium[1]

Mg

[7439-95-4] · Mg · Magnesium · (MW 24.31)

(formation of organomagnesium compounds; reduction of metal halides; reduction of organic functional groups)

Physical Data: mp 651 °C; bp 1107 °C; *d* 1.74 g cm^{-3}.

Preparative Methods: widely commercially available in forms (most commonly turnings and powders) and in purity (98-99.95%) suitable for many applications in organic synthesis. For some applications magnesium powder or activated magnesium is freshly prepared via the reduction of a magnesium(II) salt or the evaporative deposition of magnesium metal. The commercially available magnesium-anthracene adduct *[86901-19-1]* also provides a highly reactive form of magnesium metal.

Handling, Storage, and Precautions: most freshly prepared magnesium powders and organomagnesium compounds are pyrophoric.

Formation and Reactions of Organomagnesium Compounds.

The carbon-carbon bond forming reactions of organomagnesium (Grignard) reagents via their reaction with carbon electrophiles constitute one of the cornerstones of organic synthesis (eq 1). Much is known about this most famous of organometallic reactions. The mechanisms of Grignard formation[2-13] and reaction[14,15] have been studied extensively. Structural[16,17] and thermochemical[18] data of the organomagnesium compounds have been reported.

$$RX + Mg \longrightarrow [RMgX] \xrightarrow{E^+} RE \qquad (1)$$

Many novel organomagnesium compounds have been prepared. These include dimetallic species[19,20] such as methylenedimagnesium dibromide (see also ***Magnesium Amalgam***)[21] and 1,*n*-(dimagnesio)alkanes such as 1,4-bis(bromomagnesio)pentane, an intermediate which has been used for the stereoselective conversion of esters to *trans*-1,2-disubstituted cyclopentanols (eq 2).[22] Remarkably, even a soluble trimagnesium compound was recently prepared under relatively routine reaction conditions (eq 3).[23]

(2)

(3)

The form of the magnesium metal employed is often critical to the successful formation of the organomagnesium reagent. For simple primary or secondary alkyl bromides or iodides, and simple aryl or vinyl bromides or iodides, commercially available magnesium turnings or powders of modest purity (>98%) are often suitable. If necessary, activating the surface of the magnesium with iodine,[1,24] dibromoethane,[1,25] or ultrasound[26] treatment, or employing ultrapure magnesium metal,[27] is usually sufficient to facilitate Grignard reagent formation with such substrates. In the case of many organochlorine or organofluorine compounds, as well as unreactive bromides and iodides, a more reactive form of magnesium must be employed. Three practical methods have been developed for the preparation of highly reactive magnesium (active magnesium) for use in organic synthesis. A highly reactive magnesium slurry is prepared via the evaporative deposition of magnesium in THF using a relatively simple preparative apparatus.[28-30] Magnesium halides are reduced by ***Potassium*** metal,[31,32] or better ***Lithium Naphthalenide***,[33,34] to afford an active magnesium powder often referred to as Rieke magnesium. Magnesium metal can be activated by treatment with anthracene,[35] or the magnesium-anthracene adduct,[36] which is in equilibrium with the finely divided metal powder, can be used directly.

The formation of allyl or benzylic Grignard species is often accompanied by dimerization of the allylic or benzylic halide. Indeed, this reductive dimerization can be preparatively useful using the classical Grignard-forming reaction conditions,[37] but to avoid it, an active magnesium is typically employed.[38,39] Oppolzer[40] reported a comparison of the three methods discussed above in a 1984 study of the metallo-ene reaction. The magnesium variant of the metallo-ene reaction[41] features the formation and subsequent cycloisomerization of an allylmagnesium chloride from an allylic chloride. As shown in eq 4, magnesium-mediated cyclization and trapping with the electrophilic oxygen source ***Oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric triamide)*** (i.e. MoOPH) proceeds in 55% yield with magnesium slurry prepared by evaporative deposition, in 55% yield with Rieke magnesium, and in 56% yield with magnesium-anthracene.

(4)

The extent to which these activated forms of magnesium have expanded the range of substrates suitable for formation of organomagnesium species cannot be overemphasized. For example, alkyl fluorides are very poor substrates for the classical Grignard conditions. In contrast, treatment of octyl fluoride with Rieke magnesium[32,34] affords the corresponding organomagnesium reagent which reacts with ***Carbon Dioxide*** in 89% yield (eq 5). The chloride shown in eq 6 is benzylic, thus prone to dimerization with classical magnesium sources, and requires formation of a dianionic intermediate. Magnesium powder is reported to afford the diorganomagnesium species in only 43% yield. In contrast, the dichloride reacts with magnesium-anthracene in 92% yield.[36,42] Cyclopropylmethyl compounds are prone to rearrange via ring opening to the *n*-butenyl isomers. Formation of the Grignard reagent from cyclopropylmethyl bromide under classical conditions followed by trapping with carbon dioxide affords 4-pentenoic acid (eq 7). In contrast, treatment of cyclopropylmethyl bromide at -78 °C with the magnesium slurry prepared via evaporative deposition affords mostly cyclopropylacetic acid (92% of the product mixture, 78% yield) after trapping with carbon dioxide.[28]

(5)

(6)

(7)

The chemistry of organomagnesium compounds is extraordinarily rich and diverse. It is impossible to detail comprehensively their many reactions with classical organic electrophiles (e.g. aldehydes, ketones, carboxylic acid derivatives, carbon dioxide, C-N multiple bonds, epoxides, alkyl halides, etc.) within the space limitations here. Fortunately, several standard texts give a good account of these procedures.[43,44] The following paragraphs highlight several of the many less routine uses of these reagents. For example, in addition to the reaction with traditional carbonyl electrophiles, organomagnesium reagents add efficiently to certain mixed orthoformates to afford acetals. For example (eq 8), *n*-butylmagnesium bromide adds to phenyl diethyl orthoformate in 90% yield.[45]

(8)

The one-pot combination of alkyl halide, magnesium metal, and carbon electrophile is often referred to as the Barbier reaction.[46] This strategy is particularly appropriate for the cyclization of substrates containing both reacting partners within their structure. The intramolecular reaction of halo ketones can afford cyclized products, but often in only modest-to-good yield with magnesium.[47] For example (eq 9), the cycloheptanone derivative cyclizes to the hydroazulene ring skeleton in 54% yield. Lithium/ultrasound,[48,49] ***Lithium***, ***Tin(II) Chloride***,[50] and ***Samarium(II) Iodide***[51] may offer suitable alternative reagents for such cyclizations.

(9)

The complementary magnesium-mediated cyclizations of cyanoiodoalkanes can be an efficient reaction. For example, the iodonitrile shown (eq 10) undergoes magnesium-mediated cyclization to form the relatively sterically congested 2,2-

disubstituted cyclohexanone in 71% yield.[52]

(10)

Magnesium is an alternative to zinc metal for effecting the Reformatsky reaction and has been used in the synthesis of β-keto esters.[53] For example (eq 11), *t*-butyl bromoacetate is condensed with cyclohexanone in 80% yield.[54]

(11)

Organomagnesium species can effect the carbometalation of alkenes and alkynes.[55,56] The more common variants, however, are the copper-catalyzed reactions, a subject which has been comprehensively reviewed by Lipshutz and Sengupta.[57] For example (eq 12), the ***Ethylmagnesium Bromide*/*Copper(I) Bromide*** combination effects net *syn* addition across 1-octyne. The resulting alkenyl metal species can be stereospecifically trapped by a variety of electrophiles, including ***Allyl Bromide*** (85%) and 1-heptene oxide (94%).[58] This reaction constitutes a useful stereoselective alkene synthesis. ***Dichlorobis(cyclopentadienyl)titanium*** also catalyzes the net *syn* addition of organomagnesium reagent across alkynes.[59] (See also the corresponding organolithium and organocopper compounds for alternative reagents.[57])

(12)

$E = CH_2CH{=}CH_2$ (85%)
$CH_2CH(OH)C_5H_{11}$ (94%)

Organomagnesium reagents undergo efficient copper-catalyzed conjugate addition reactions.[57] For example (eq 13), *n*-butylmagnesium bromide undergoes CuBr-Me_2S-catalyzed addition to acrolein in the presence of ***Chlorotrimethylsilane*** and ***Hexamethylphosphoric Triamide*** (HMPA) to afford the (*E*)-silyl enol ether in 89% yield (96% *E*).[60]

(13)

Organomagnesium reagents undergo copper-catalyzed reaction with alkyl, allyl, vinyl, and aryl halides or sulfonates, and with epoxides.[57] For example (eq 14), *n*-butylmagnesium bromide undergoes copper-catalyzed substitution of the propargyl methyl ether to afford an allene.[61] The substitution proceeds in high chemical yield and with good stereochemical control.

(14)

A number of other transition metals catalyze interesting reactions of organomagnesium reagents.[59,62] Of particular novelty is the titanium-catalyzed hydromagnesiation of alkenes. For example (eq 15), vinylcyclohexanol transmetalates with ethylmagnesium bromide in the presence of catalytic Cp_2TiCl_2 to afford, after capture by carbon dioxide, the γ-lactone shown in 58% yield.[63-65]

(15)

Reductions with Magnesium.

Magnesium is a common agent for reducing a variety of transition metal salts,[66-68] for example the reduced titanium reagent (***Titanium(IV) Chloride***-Mg) used widely in carbonyl coupling reactions.[69] Magnesium itself effects the reductive dimerization (pinacol coupling) of ketones[70] and enones[71] (see also ***Magnesium Amalgam*** and $TiCl_4$-Mg). Magnesium effects the reductive dimerization of organotin oxides[72] (eq 16) and dialkylantimony bromides (eq 17).[73]

$$(i\text{-Bu})_3\text{SnOSn}(i\text{-Bu})_3 \xrightarrow[82\%]{\text{Mg, THF}} (i\text{-Bu})_3\text{SnSn}(i\text{-Bu})_3 \qquad (16)$$

$$2\ \text{Bu}_2\text{SbBr} \xrightarrow{\text{Mg, THF}} \text{Bu}_2\text{SbSbBu}_2 \qquad (17)$$

Magnesium has been used for the reduction of 1,1-dibromoalkanes,[74] although reductive dimerization has been found to compete in some cases,[75,76] and in the formation of $Ph_3P{=}CCl_2$ from triphenylphosphine and carbon tetrachloride.[77] Magnesium has been used as an alternative to ***n-Butyllithium*** or lithium amalgam for the conversion of 1,1-dibromoalkenes to alkynes (eq 18).[78]

$$\text{RCHO} \xrightarrow[\text{CBr}_4]{\text{Ph}_3\text{P}} \text{RCH}{=}\text{CBr}_2 \xrightarrow[\substack{65\ ^\circ\text{C}\\ 75\text{-}95\%}]{\text{Mg, THF}} \text{RC}{\equiv}\text{CH} \qquad (18)$$

Magnesium reacts with amines to form magnesium amides,[79] and with alcohols to form magnesium alkoxides. In the latter context, magnesium has been used as a drying agent for alcohols,[80] but the combination of magnesium-methanol has also found significant utility as a selective reducing agent for certain organic functional groups (e.g. conjugated ketones, esters, nitriles, amides).[81] The combination of ***Cadmium Chloride***-magnesium in aqueous THF also shows interesting selective functional group reductions, e.g. the selective 1,2-reduction of enones (eq 19) and the selective reduction of an epoxide in the presence of an allylic acetate (eq 20).[82,83]

(19)

(20)

The combination of magnesium-***Chlorotrimethylsilane*** has been used for the reductive silylation of 1,1-dibromides,[84]

conjugated trienes,[85] heterocycles,[86] and, as shown in eq 21, certain chloro-substituted enynes.[87] Magnesium has been also used as a reactive metal electrode in an electroreductive silylation of alkenes.[88]

(21)

1,3-Dienes form reactive complexes with magnesium.[89] In this capacity, active magnesium has been used for the reductive silylation and dialkylation of certain conjugated 1,3-dienes. For example (eq 22), treatment of 1,4-diphenyl-1,3-butadiene with Rieke magnesium affords the magnesium-diene complex. Addition of ***Dichlorodimethylsilane*** affords the *cis*-diphenylsilacyclopentene in 66% yield.[90]

Magnesium Amalgam

Mg(Hg)

[37237-15-3] · Mg · Magnesium Amalgam

(reduction of metal halides, particularly for the synthesis of organometallic compounds; preparation of a reduced titanium species from $TiCl_4$ that is useful for the reductive dimerization of ketones, aldehydes, their derived imines, and the chemoselective reduction of nitro groups; preparation of bis(bromomagnesio)methanes; reductive dimerization of germane derivatives; deoxygenation of epoxides)

Preparative Methods: prepared fresh, or generated in situ, from ***Magnesium*** metal and typically 1-3 mol % of a mercury(II) salt such as ***Mercury(II) Chloride*** in THF or aromatic hydrocarbon solvent.

Handling, Storage, and Precautions: mercury salts are toxic. Proper disposal is required.

Reductions and Reductive Dimerizations.

Mg(Hg) is the classical reagent for the reductive dimerization of acetone to form pinacol,[1] and still finds occasional use in that regard.[2,3] More recently, the pinacol coupling has been effected by the combination of ***Titanium(IV) Chloride*** and 2 equiv of Mg(Hg).[4] For example, using the latter mixture, cyclohexanone is dimerized in 93% yield (eq 1). The intramolecular dimerization can be facile, as illustrated by the reductive cyclization of 2,5-hexanedione to the *cis*-cyclobutanediol (eq 2), and the intramolecular ketoaldehyde cross coupling illustrated in eq 3. Other reagents for pinacol-type coupling of carbonyl derivatives include a variety of reduced titanium reagents,[5-7] ***Samarium(II) Iodide***,[8] Niobium Trichloride,[9] and ***Aluminum Chloride-Zinc-Acetic Acid***.[10]

(1)

(2)

(3)

The Mg(Hg)-$TiCl_4$ mixture is also an effective reagent for the stereoselective reductive dimerization of aldimines to 1,2-diamines.[11,12] For example (eq 4), treatment of the aldimine derived from benzaldehyde leads to a 80:20 mixture of *syn* (±) and *anti* (*meso*) isomers in 63% yield. Simple reduction of the aldimine competes with the dimerization. Similarly, the *N*-benzylimine derived from acetaldehyde affords a 90:10 *syn*:*anti* mixture in 67% yield. Other reagents for the reductive dimerization of imines include $TiCl_4$-Mg,[13] SmI_2,[14,15] ***Niobium(IV) Chloride***,[16] ***Indium***,[17] ***Ytterbium(0)***,[18] and ***Zinc***.[19]

(4)

(a) R = Ph, R^2 = Me (63%)
(b) R^1 = Me, R^2 = CH_2Ph (67%)

syn (±) *anti (meso)*

Rivière and Satge[20] reported the Mg(Hg)-mediated reductive dimerizations of organogermanes. For example (eq 5), treatment of phenylchlorogermane with Mg(Hg) (THF, 20 °C) affords the diphenyl-1,2-digermane in 75% yield. Similarly, diphenylchlorogermane affords tetraphenyl-1,1,2,2-digermane in 73% yield.

The Mg(Hg)-$TiCl_4$ mixture is an effective reagent for the chemoselective reduction of the nitro group.[21] For example (eq 6), chloro-, cyano-, and carboxy-substituted nitro aromatics are each reduced in high yield by the Mg(Hg)-$TiCl_4$ mixture (THF-*t*-butanol, 0 °C, 1 h). Aliphatic nitro compounds are also efficiently reduced. Others have used this procedure successfully.[22 -24] Other reagents for this transformation include ***Titanium(III) Chloride***,[25] $TiCl_4$-Te(*i*-Bu)$_2$,[26] $TiCl_4$-***Sodium Borohydride***,[27] ***Palladium on Carbon-Ammonium Formate***,[28] ***Raney Nickel-Hydrazine***,[29] ***Chromium(II) Chloride***,[30] ***Tin(II) Chloride***,[31] and ***Nickel Boride*** (Ni_2B).[32]

Mg(Hg) has been used occasionally for the reduction of 1,2-dihalides[33] and enones,[34] and has been extensively used for the preparation of reduced organometallic complexes.[35-40]

Preparation of 1,1-Diorganometallic Reagents.

Mg(Hg) has been widely used for the preparation of 1,1-dimagnesium reagents[41] by reaction with methylene dibromides and diiodides. For example (eq 7), Cainelli and co-workers[42] found that treatment of ***Dibromomethane*** or ***Diiodomethane*** with Mg(Hg) affords a solution of organomagnesium reagent. Bis(bromomagnesio)methane reacts with CO_2 to afford the malonic acid and with aldehydes and ketones to give alkenes. This reagent has found use in organic synthesis[43-47] and offers an alternative to ***Methylenetriphenylphosphorane***, ***Trimethylsilylmethyllithium***, ***Trimethylsilylmethylmagnesium Chloride***, the Tebbe reagent (μ-***Chlorobis(cyclopentadienyl)(dimethylaluminum)***-μ-***methylenetitanium***), dimethyltitanocene (***Bis(cyclopentadienyl)dimethyltitanium***),[48] CH_2I_2-$CrCl_2$,[49] CH_2I_2-Zn-Me_3Al,[50] CH_2I_2-Zn-$TiCl_4$,[51,52] and $CH_2(AlR_2)_2$,[53] reagents. Similarly, Mg(Hg) has been used for the preparation of the 1,1-dimagnesium species bis(bromomagnesio)trimethylsilylmethane[54] and bis(bromomagnesio)bis(trimethylsilyl)methane.[55]

(7)

$R^1 = C_{11}H_{23}$, $R^2 = H$ (65%)
$R^1 = Ph$, $R^2 = H$ (70%)
$R^1, R^2 = -(CH_2)_5-$ (68%)

Bickelhaupt and co-workers[56] reported the use of bis(bromomagnesio)methane as a reagent for the preparation of 1,3-dimetallacyclobutanes. For example (eq 8), treatment of bis(bromomagnesio)methane (prepared using Mg(Hg) as described above) with Cp_2TiCl_2 and ***Dichlorodimethylsilane*** affords the novel mixed 1,3-dimetallacyclobutane in quantitative yield.

(8)

Miscellaneous.

Mg(Hg) has been used in combination with ***Magnesium Bromide*** as a reagent for the deoxygenation of epoxides.[57] Yields are typically modest, for example 50% for the formation of cyclohexene from cyclohexene oxide, and several good alternative reagents are available for this transformation.[58]

Magnesium Bromide

$MgBr_2$

($MgBr_2$)

[2923-28-6] · Br_2Mg · Magnesium Bromide · (MW 184.11) ($MgBr_2.6H_2O$)

[13446-53-2] · $H_{12}Br_2MgO_6$ · Magnesium Bromide · (MW 292.23) ($MgBr_2.OEt_2$)

[29858-07-9] · $C_4H_{10}Br_2MgO$ · Magnesium Bromide Diethyl Etherate · (MW 258.25)

(Lewis acid capable of catalyzing selective nucleophilic additions,[1] cycloadditions,[2] rearrangements,[3] coupling reactions;[4] effective brominating agent[5])

Physical Data: mp 165 °C (dec) (etherate >300 °C; fp 35 °C).

Solubility: sol alcohol, H_2O; etherate sol common organic solvents.

Form Supplied in: white solid, widely available; etherate gray solid.

Preparative Method: the etherate is easily prepared from reacting a slight excess of ***Magnesium*** turnings with ***1,2-Dibromoethane*** in anhydrous diethyl ether.[13]

Handling, Storage, and Precautions: etherate is flammable and moisture sensitive; freshly prepared material is most reactive and anhydrous. Irritant.

Nucleophilic Additions.

$MgBr_2$ has been shown to form discrete bidentate chelates with various species,[6] particularly α- and/or α,β-alkoxy carbonyl compounds,[7] and thus functions as a diastereofacial control element in many nucleophilic addition reactions. In many cases, its inclusion completely reverses the nonchelation-controlled stereochemistry observed with nonchelating Lewis acids such as ***Boron Trifluoride Etherate***. Highest diastereoselectivity is observed with α-substituted aldehydes (eq 1).[8] High selectivities are observed for β-alkoxy aldehydes as well, including cases where three contiguous chiral centers are defined during the reaction (eq 2).[9]

(1)

(2)

Nucleophilic additions to α,β-dialkoxy aldehydes via allyl silanes (eq 3)[10] or silyl ketene acetals (Mukaiyama reaction) (eq 4)[11] exhibit similarly high selectivities. α-Thio aldehydes also react under $MgBr_2$-catalyzed Mukaiyama conditions with efficient stereocontrol (eq 5).[1]

(3)

(4)

(5)

Rearrangements.

The oxophilic nature of $MgBr_2$ renders it effective in mediating many rearrangements wherein polarization of a C-O bond initiates the process. A classic application involves the conversion of an epoxide to an aldehyde (eq 6).[12]

(6)

β-Lactones, when treated with $MgBr_2$, undergo ionization with further rearrangement to afford either butyrolactones or β,γ-unsaturated carboxylic acids (eq 7).[3] The reaction course is dependent upon whether the cation resulting from lactone ionization can rearrange to a more or equivalently stable cation, in which case ring expansion is observed. If the β-lactone bears an α-chloro substituent, ring expansion is accompanied by elimination of HCl to afford butenolides (eq 8).[13]

(7)

(8)

Cycloadditions.

The $MgBr_2$-mediated cyclocondensation of a Danishefsky-type diene with chiral α-alkoxy aldehydes affords a single diastereomer, which reflects a reacting conformer in which the alkoxy group is *syn* to the carbonyl, which is then attacked from its less-hindered face (eq 9).[2] The cycloaddition of ynamines with cycloalkenones occurred selectively at the carbonyl, while in the absence of $MgBr_2$ reaction at the alkene C=C bonds was observed (eq 10).[14]

(9)

(10)

Organometallic Reactions.

$MgBr_2$ often increases the yields of Grignard reactions, as in the synthesis of cyclopropanols from 1,3-dichloroacetone (eq 11).[15] It also serves to form Grignard reagents in situ via first lithiation followed by transmetalation with $MgBr_2$. This technique enables the formation of vinyl Grignards from vinyl sulfones (eq 12),[16] and of α-silyl Grignard reagents from allyl silanes (eq 13).[17] In the latter case, the presence of $MgBr_2$ provided regioselectivity at the α-position; without it, substitution at the γ-position was predominant.

(11)

(12)

(13)

Bromination.

Magnesium bromide serves as a source of bromide ion, for displacement of sulfonate esters under mild

conditions and in high yield. The reaction is known to proceed with complete inversion at the reacting carbon center when backside attack is possible (eq 14).[5] Even bromination of highly congested bridgehead positions is possible via triflate displacement, although the reaction requires high temperatures, long reaction times, and activation via ultrasound (eq 15).[18]

(14)

(15)

Epoxides are also converted regiospecifically to bromohydrins by $MgBr_2$.[19]

Carbonyl Condensations.

Bis- or tris-TMS ketenimines condense with ketones, mediated by $MgBr_2$, to produce an intermediate that loses hexamethylsiloxane, affording 2-alkenenitriles in high yield with high (*E*) selectivity (eq 16).[20] $MgBr_2$ also enables the use of very mild bases like ***Triethylamine*** in Horner-Wadsworth-Emmons reactions, enabling the synthesis of unsaturated esters from aldehydes or ketones without the need for strongly basic conditions (eq 17).[21]

Magnesium Ethyl Malonate[1]

[64679-38-5] · $C_5H_6MgO_4$ · Magnesium Ethyl Malonate · (MW 154.42)

(reagent for conjugate addition to α,β-unsaturated carbonyl compounds followed by in situ decarboxylation to give 1,5 keto-esters;[2] conjugate addition to other functionality;[2] acylation of active esters[1,3])

Alternate Name: MEM.

Physical Data: high melting solid salt; ethanol complex.

Solubility: sol DMF; slightly sol THF.

Form Supplied in: off-white solid or slurry in THF.

Analysis of Reagent Purity: ^{1}H NMR. *Drying:* azeotrope with benzene or toluene; high vacuum.

Handling, Storage, and Precautions: hygroscopic solid; stable for at least several weeks as a solid or slurry in dry THF.

Introduction.

Magnesium ethyl malonate (**1**) undergoes conjugate addition reactions with α,β-enones and other activated alkenes,[2] as well as acylation of active esters.[1,3] Decarboxylation occurs upon neutralization with acetic acid or during workup, affording a single-step addition of an acetic ester residue. ***Ethyl Malonate*** reacts with magnesium metal turnings in ethanol to give (**1**), a basic salt, complexed with 1 equiv of ethanol (eq 1) or with isopropylmagnesium bromide to form a bromide complex.[1]

(1)

(1)

Dilithio ethyl malonate undergoes alkylation with alkyl halides and subsequent decarboxylation (eq 2).[4] Little or no reaction occurs with ketones or enones.

(2)

Conjugate Additions.

As the magnesium salt, (**1**) gives exclusive conjugate, 1,4 addition to α,β-enones, probably due to the reversibility of 1,2-addition (eq 3).[2] Steric hindrance at either the α- or β-position can inhibit addition of (**1**) and starting material is then recovered.[2] Conjugate addition of (**1**) to 6-methyl-2-cyclohexenone occurs with stereoselection (axial attack) (eq 4).[5] Other α,β-unsaturated electron-withdrawing groups give conjugate addition with (**1**) (eqs 5-7).[2,6]

(3)

(4)

(5)

(6)

(7)

Acylations.

Magnesium ethyl malonate adds the acetic ester residue to activated carboxylic acid derivatives, acid chlorides (eq 8),[1,3a] acyl imidazolides (eqs 9-12),[1,3b-f] and mixed anhydrides (eq 11).[3b] Decarboxylation is more facile after acylation with (**1**) than after conjugate addition and does not require prolonged treatment after neutralization with acetic acid.

(8)

(9)

(10)

R = H (91%), Ph (78%)

(11)

R = OCO_2Et (50%), (73%)

(12)

Electrophiles such as (methylthio)alkylideniminium salts react with (**1**) to give the expected addition products (eq 13).[7]

(13)

Analogous Magnesium Malonates.

The neutral magnesium carboxylate salt of *S*-thioethyl methylthiomalonate has been prepared and added to acyl imidazolides (eq 14).[8] The methyl ester analog of (**1**) is also reactive (eq 15).[8]

(15)

Related Reagents.

Bis(trimethylsilyl) Malonate; ***Diethyl Ethoxymagnesiomalonate***; ***Diethyl Malonate***; ***2,2-Dimethyl-1,3-dioxane-4,6-dione***; ***Ethyl Bromozincacetate***; ***Ethyl Lithioacetate***; ***Ethyl Lithio(trimethylsilyl)acetate***; ***Ethyl Malonate***; ***Ethyl Trimethylsilylacetate***; ***Ethyl Trimethylsilyl Malonate***.

Magnesium Hydride-Copper(I) Iodide

CuH.HMgI

(MgH_2)

[7693-27-8] · H_2Mg · Magnesium Hydride-Copper(I) Iodide · (MW 26.33) (CuI)

[7681-65-4] · CuI · Magnesium Hydride-Copper(I) Iodide · (MW 190.45)

(in situ prepared hydridocopper reagent; reduces alkynes stereoselectively to *cis*-alkenes[1])

Physical Data: prepared in situ.

Preparative Method: a slurry of MgH_2 (4 mmol)[1,2] in THF is added via syringe into a mixture of alkyne (1 mmol) and ***Copper(I) Iodide*** (4 mmol) at -78 °C under an inert atmosphere. The cooling bath is removed and the reaction temperature is allowed to warm slowly to rt. The mixture becomes a deep black color with slight effervescence. After stirring for 24-48 h the reaction is quenched with water and the aqueous layer is extracted with THF. The combined organic extract is dried over $MgSO_4$.

Reactions.

The reagent reduces terminal alkynes to the corresponding alkenes (alkanes were not detected) with 100% selectivity in 80-98% yield. Internal alkynes are reduced only to the *cis*-alkene (no *trans*-alkene or alkane detected) in 80-95% yield (Table 1).

Table 1 Reduction of Alkynes by Magnesium Hydride Copper(I) Iodide

Alkyne	Product	Yield (%)
1-Hexyne	1-Hexene	80
1-Octyne	1-Octene	84
Phenylacetylene	Styrene	98
2-Hexyne	*cis*-2-Hexene	80
Diphenylacetylene	*cis*-Stilbene	95

Modifications.

Copper(I) t-Butoxide can be substituted for copper(I) iodide.[1]

Alternative Methods.

The reduction of alkynes to *cis*-alkenes can be accomplished by many other methods, such as catalytic hydrogenation,[3,4] dialkylaluminum hydride,[5,6] or ***Hexa-μ-hydrohexakis(triphenylphosphine)hexacopper***.[7] See also ***Copper(I) Bromide-Lithium Trimethoxyaluminum Hydride***.

Magnesium Iodide

MgI_2

[10377-58-9] · I_2Mg · Magnesium Iodide · (MW 278.11)

(mild Lewis acid for Diels-Alder reaction;[12] enol acetylation of ketones;[14] deoxygenation of oxiranes;[1] iodination and opening of epoxides and cyclopropylmethanols[8,9])

Physical Data: mp (dec) <637 °C; *d* 4.43 g cm^{-3}.

Solubility: sol water (1.48 g mL^{-1} of H_2O at 18 °C); slightly sol alcohols, ethers, ammonia.

Preparative Method: mostly prepared in situ from ***Magnesium*** turnings and ***Iodine*** in refluxing ether.

Handling, Storage, and Precautions: toxicity data not available. May be harmful by inhalation, ingestion, or skin contact.

MgI_2 is used in the deoxygenation of oxiranes to the corresponding alkenes via iodohydrins with retention of configuration in high yields.[1]

Vinyl[2] and bridgehead triflates[3] are converted into the corresponding iodides by reaction with MgI_2, generally in nonpolar solvents such as CS_2 (eq 1).

(1)

MgI_2 can effect the transformation of cyclopropylcarbinols into homoallylic iodides in refluxing Et_2O (eq 2).[4,5] Tertiary and benzylic alcohols are more reactive than secondary. MgI_2 can also be used in the regioselective opening of 2,3-epoxy alcohols and β,γ-epoxy sulfones, leading to the corresponding 3-iodo-1,2-diols (eq 3) and β-hydroxy sulfones (eq 4), respectively.[6,7]

(2)

(3)

(4)

Treatment of silyloxiranes[8] and glycidic esters[9] with MgI_2 results in their rearrangement to the corresponding silyl ketone (eq 5) and α-keto esters.

(5)

Carboxylic esters can be hydrolyzed with MgI_2 in aprotic solvents like CS_2 and toluene.[10] It can also be used to demethylate a methoxy group *ortho* to an acyl group under mild conditions without isomerization of an isopropenyl group (eq 6).[11]

(6)

As a Lewis acid, MgI_2 has been shown to increase the regioselectivity, having equal but opposite effect to that of ***Boron Trifluoride Etherate*** in Diels-Alder reactions of perihydroxylated naphthoquinones with 1-methoxy-3-methyl-1,3-butadiene (eq 7).[12]

25 °C	45%	55%
MgI_2	[2]25%	[3]95%
$BF_3 \cdot Et_2O$	[3]95%	[2]25%

(7)

Radical-mediated reduction of α-iodo-β-alkoxy esters with ***Tri-n-butylstannane*** in the presence of catalytic MgI_2 results in excellent *erythro* selectivity. *Threo* selectivity is seen in the absence of a Lewis acid.[13]

$MgI_2.Et_2O$ can be used as a mild Lewis acid catalyst for the enol acetylation of ketones.[14]

Magnesium-Methanol

Mg-MeOH

(Mg)

[7439-95-4] · Mg · Magnesium-Methanol · (MW 24.31) (MeOH)

[67-56-1] · CH_4O · Magnesium-Methanol · (MW 32.05)

(reducing system for α,β-unsaturated nitriles, amides, esters, ketones, imines, halides, sulfones, and azides)

Physical Data: Mg: mp 651 °C; bp 1107 °C; *d* 1.74 g cm^{-3}. MeOH: bp 64.65 °C; *d* 0.796 g cm^{-3}.

Form Supplied in: Mg: powder, ribbon, chips, shavings; widely available. MeOH: anhydrous and reagent grade widely available.

General Reductions.

Reductions with ***Magnesium*** in methanol are usually accomplished simply by stirring the reactants at ambient temperature using an excess (5-40-fold) of magnesium. There is often an induction period, probably needed to cleanse the surface of the magnesium for efficient reaction. The ensuing reaction with methanol is exothermic, and may or may not require cooling in an ice bath.[1-8]

Carbon-Carbon π-Bond Reductions.

The dissolving metal reducing system generated by this reagent combination provides convenient electron transfer/protic source reductions of α,β-unsaturated nitriles[1] (eq 1),[1d] amides[2] (eq 2),[2c] and esters[3] (eq 3)[3b] to the saturated derivatives. Conjugated alkynic esters (but not acids) also afford saturated products (eq 4),[4] while α,β-unsaturated ketones and imines give the corresponding saturated alcohols or amines, respectively, resulting from concomitant reduction of the carbonyl or imine group.[5] However, α,β-unsaturated ketones further conjugated to furan rings are selectively converted to the saturated ketones (eq 5)[6] without affecting the carbonyl.[6] Deuterium may be introduced by using MeOD as the solvent (eq 4).[3b,4] Isolated double and triple bonds are not affected[4,1d,2,3c] unless conjugated to two (but not one) phenyl groups (eq 6).[4,7]

(6)

Functional Group Reductions.

The reagent system effectively and selectively reduces alkyl and aryl iodides and bromides to hydrocarbons.[5a,8a] Vinyl bromides are reduced if conjugated to an aromatic ring, while only benzylic and allylic chlorides are reduced (eq 7).[8a] Deuterium may be incorporated using MeOD as the solvent (eq 8).[8a] Aryl chlorides convert to hydrocarbons using a similar system involving magnesium powder and isopropanol in refluxing decahydronaphthalene.[8b]

(7)

(8)

Mono- and bisulfones are effectively desulfonated with magnesium-methanol to afford mostly alkenes (with 1,2-disulfones, eq 9)[9] or hydrocarbons (with 1,1-disulfones or monosulfones, eq 10).[9] In these cases, the magnesium was preactivated by treatment with dilute HCl.

Alicyclic, benzylic, and allylic azides are efficiently reduced to the corresponding amines with magnesium powder in methanol (eq 11).[10] Aromatic nitro compounds are reduced to mixtures of azo and azoxy derivatives.[5a] Reduction of an *N*-magnesium imine to the amine has been reported.[11]

This reagent combination provides a convenient, mild, chemoselective, and inexpensive dissolving metal process for reduction of double bonds in conjugated esters, nitriles, and amides and for selective reductions of alkyl and aryl iodides and bromides.

Magnesium Methoxide

$(MeO)_2Mg$

[109-88-6] · $C_2H_6MgO_2$ · Magnesium Methoxide · (MW 86.39)

(weakly basic metal alkoxide; forms stable chelates with enolizable carbonyl compounds[1])

Solubility: slightly sol MeOH, EtOH, DMF.

Form Supplied in: commercially available as neat white powder or as 8 wt % solution in MeOH.

Preparative Method: by addition of small batches of ***Magnesium*** metal to anhydrous MeOH.[1]

Handling, Storage, and Precautions: use same precautions as for other metal alkoxides (see ***Potassium t-Butoxide***); avoid contact with eyes and clothing; handle and conduct reactions under an inert atmosphere. For critical experiments, it is recommended that the reagent be freshly prepared. Use in a fume hood.

Preparation of Magnesium Methyl Carbonate.

The reaction of $(MeO)_2Mg$ with CO_2 in DMF solution leads to the formation of $MeOMgOCO_2Me$ (eq 1).[2] This reagent is very useful for the carboxylation of α-methylene ketones, lactones, nitro compounds, etc. (see ***Methyl Magnesium Carbonate*** (MMC)).[2]

$$(MeO)_2Mg + CO_2 \xrightleftharpoons[\text{DMF}]{} MeOMgOCO_2Me \qquad (1)$$

Carbonyl Condensation Reactions.

Because of the ability of the magnesium cation to form stable chelates with carbonyl compounds, $(MeO)_2Mg$ is a useful base for the promotion of a variety of carbonyl condensation reactions. The reagent catalyzes the condensation of triacetic acid lactone methyl ether with aromatic aldehydes to yield styryl monopyrone methyl ethers (eq 2).[3] The condensation of 2,2-dimethoxy-3-butanone with benzaldehyde in the presence of $(MeO)_2Mg$ leads to a magnesium chelate of the initially formed α-diketone condensation product, which undergoes intramolecular Michael addition to form 4-phenylcyclopentane-1,2-dione (eq 3).[4] Dimethyl oxalate reacts with 2,2-dimethoxy-3-butanone under similar conditions to give 2,5-dimethoxy-*p*-benzoquinone.[4] The use of other bases such as sodium alkoxides, tertiary amines,

or quaternary ammonium salts in these reactions leads to unidentified products. Treatment of cyclohexenone with dimethyl 2-methoxycarbonylglutarate in the presence of $(MeO)_2Mg$ in MeOH results in a Michael addition followed by an aldol condensation to yield a decalin-1,8-dione derivative which exists primarily in its tautomeric enol forms (eq 4).[5]

(2)

(3)

(4)

A mixture of diastereomers of 6-isopropyl-9-methylbicyclo[4.3.0]nonen-3-one is obtained by a tandem Michael-aldol reaction of an appropriate acyclic unsaturated keto aldehyde using $(MeO)_2Mg$ as the base (eq 5).[6] The reaction is reasonably stereoselective for the *trans*-fused ring system, but it is somewhat more stereoselective and the overall yield is considerably higher when ***Zirconium Tetraisopropoxide*** is used as the base. The ability of the zirconium cation to form even stronger chelates than the magnesium cation presumably accounts for this.[6b] A good yield of the cyclization products is also obtained with ***Sodium Methoxide***, but the stereoselectivity is low.

(5)

$(MeO)_2Mg$	10:1.5:1	51%
$(i\text{-}PrO)_4Zr$	10:1:1	80%
MeONa	3.4:1.2:1	80%

The methyl ester of phenylsulfinylacetic acid condenses with aliphatic aldehydes to give γ-hydroxy-α,β-unsaturated esters directly (eq 6).[7] The α-phenylsulfinyl-α,β-unsaturated ester, which is obtained by dehydration of the aldol product, undergoes deconjugation of the double bond to the β,γ-position. Then, a [2,3]-sigmatropic rearrangement of the sulfoxide group occurs, followed by cleavage of the sulfenate. A two-step process which involves the use of ***Sodium Hydride/Zinc Chloride*** catalyst to effect the aldol condensation and dehydration followed by treatment with an amine base yields the same types of products.

(6)

The Darzens condensation of methyl chloroacetate with benzaldehyde occurs relatively slowly in the presence of $(MeO)_2Mg$ in MeOH.[8] These conditions allow the isolation of methyl 2-chloro-3-hydroxy-3-phenylpropanoate and methyl 2-hydroxy-3-methoxy-3-phenylpropanoate, as well as the products of the Cannizzaro reaction of benzaldehyde, in addition to the expected methyl 2,3-epoxy-3-phenylpropanoate (glycidic ester).

Since the magnesium cation has a high affinity to form stable chelates with β-dicarbonyl compounds, the course of cyclizations of polyketonic-polyenolic systems may change significantly in going from alkali metal alkoxide bases to $(MeO)_2Mg$.[3b,9,10] For example, dimethyl 2,4-diacetylglutaconate cyclizes to an acyl pyrone in relatively high yield upon treatment with &egt;2.0 equiv of MeONa in MeOH/PhH (eq 7).[9a] The same pyrone is formed if the diester is

treated with 1.0 equiv of $(MeO)_2Mg$, but when &egt;2.0 equiv of this reagent is used, a phenol derivative and a resorcinol derivative are also formed. Apparently, the chelate of the initially formed acyl pyrone undergoes ring opening with the excess base to form the chelate of a glutaconic ester dianion, which undergoes an intramolecular Michael or aldol reaction to form a phenol derivative or an intramolecular Claisen condensation to form a resorcinol derivative.[9a] Also, bispyrones undergo ring openings to triketo esters followed by aldol cyclizations, sometimes accompanied by decarboxylations to mixtures of resorcinol derivatives upon treatment with KOH in MeOH (eq 8),[10] but phloroglucinol derivatives, which apparently arise via Claisen condensation of open chain magnesium bischelates, are obtained in low yields with excess $(MeO)_2Mg$ (eq 9).[3b,9a]

2.0 equiv $(MeO)_2Mg$	-	55%	26%
2.0 equiv MeONa	81%	-	-

(8)

(9)

Triacetic acid methyl ester is conveniently prepared by treating dehydroacetic acid with $(MeO)_2Mg$ in MeOH (eq 10).[11] The ring opening reaction occurs more slowly when MeOLi or MeONa are employed as the bases.

Magnesium Oxide

MgO

[1309-48-4] · MgO · Magnesium Oxide · (MW 40.31)

(dehydrohalogenation;[1] reductions;[2,6-8] alkene synthesis;[3] oxidations;[9] epoxide opening;[10] acylations[12,13])

Physical Data: mp 2852 °C; bp 3600 °C; *d* 3.58 g cm^{-3}.

Solubility: sol water (0.0086 g/100 mL at 30 °C).

Form Supplied in: white powder.

Preparative Method: dehydration of $Mg(OH)_2$ at 1100 °C for 2 h.

Handling, Storage, and Precautions: tumorigenic (olfactory and respiratory system); avoid breathing dust; incompatible with strong oxidizing agents; air and moisture sensitive. May react violently on mixing with phosphorus pentachloride, chlorine trifluoride, or bromine pentafluoride.

Reactions with Aldehydes and Ketones.

α,β-Unsaturated ketones can be prepared from α-bromo ketones when treated with magnesium oxide in DMF (eq 1).[1]

(1)

In the presence of a hydrosilane, magnesium oxide catalyzes the conversion of carbonyl compounds to silyl alcohols (eq 2).[2]

$$R_2CO + (EtO)_3SiH \longrightarrow R_2CH\text{-}OSi(OEt)_3 \qquad (2)$$

Aldehydes are converted to alkenes in a biphasic solid-liquid system with magnesium oxide via Wittig-Knoevenagel or Wittig-Horner reactions (eq 3).[3]

$$PhCHO + NC\text{-}CH_2PPh_3Cl \xrightarrow[87\%]{MgO} PhCH{=}CHCN \qquad (3)$$

$$PhCHO \xrightarrow[\substack{MgO \\ 94\%}]{NCCH_2CN} PhCH{=}C(CN)_2$$

Allylic silylcyanohydrins can be prepared in excellent yields upon treatment of an α,β-unsaturated ketone with ***Cyanotrimethylsilane*** and magnesium oxide. In most cases, less than 1% of the 1,4-adduct was detected (eq 4).[4]

(4)

Reaction with Alkynes.

Both 1 and 2-butyne can be isomerized at low temperature (<100 °C) to yield 1,3-butadiene.[5]

Reductions, Hydrogenolyses, and Dehydrogenation.

As a reduction catalyst, magnesium oxide aids in the dechlorination of dichloropyrimidines to yield pyrimidines.[6] 1,3-Butadiene is converted to *cis*-2-butene under similar conditions.[7] In a unique modification of the Meerwein-Pondorf-Verley reduction, α,β-unsaturated ketones are converted to allylic alcohols in moderate yield (eq 5).[8]

(5)

Conversely, magnesium oxide serves as a dehydrogenation catalyst. Primary amines are converted to nitriles in good yield (eq 6).[9]

(6)

Miscellaneous.

Epoxides are opened regioselectively by cyanotrimethylsilane in the presence of magnesium oxide (eq 7).[10]

(7)

This reagent also serves as an efficient acid scavenger during the *N*-protection of α-amino acids with benzyloxycarbonyl chloride (***Benzyl Chloroformate***).[11] In acylation reactions, magnesium oxide can be used to *C*-acylate malonates[12] and *N*-acylate anilines.[13]

Maleic Anhydride[1]

[108-31-6] · $C_4H_2O_3$ · Maleic Anhydride · (MW 98.06)

(reactive dienophile and dipolarophile; undergoes thermal and photochemical [2 + 2] cycloadditions; alkylating and acylating agent)

Alternate Name: MA.

Physical Data: mp 54-56 °C; bp 200 °C; *d* 1.314 g cm^{-3}.

Solubility: sol ether, acetone, chloroform, ethyl acetate, benzene, toluene, carbon tetrachloride, petroleum ether, dioxane.

Form Supplied in: white solid; widely available. *Drying:* at 100 °C.

Purification: recrystallization from acetone/petroleum ether or from hot water. Alternatively sublimed.

Handling, Storage, and Precautions: toxic, an irritant, and corrosive. Avoid inhalation. Store in a tightly sealed brown bottle; avoid exposure to moisture.

Cycloadditions.

Maleic anhydride has served as an excellent dienophile in a variety of Diels-Alder cycloadditions.[2] The use of purified maleic anhydride in the Diels-Alder reaction is recommended in order to remove trace amounts of maleic acid, which may lead to polymerization or diene isomerization. Of historical significance, the first [4 + 2] cycloaddition reported by Otto Diels and Kurt Alder employed maleic anhydride as a dienophile and butadiene as the diene component. Since the initial report, many variations on the cycloaddition process have been published. Reaction conditions vary from below rt to greater than 250 °C. As a representative example, the Diels-Alder reaction of ***Cyclopentadiene*** and MA proceeds at rt to provide the *endo* product in quantitative yield (eq 1).[3] Heterosubstituted dienes typically undergo *endo* selective cycloaddition reactions with maleic anhydride (eqs 2-4).[4] Maleic anhydride also reacts stereoselectively with *ortho*-

quinodimethanes. For example, photoenolization of *o*-tolualdehyde stereoselectively generates an (*E*)-dienol, which is trapped by MA (eq 5).[5]

(1)

(2)

(3)

(4)

(5)

A number of maleic anhydride derivatives have been examined in the Diels-Alder reaction. For example, the conjugate addition of thiophenol to maleic anhydride followed by chlorination and finally dehydrochlorination affords 2-(phenylthio)maleic anhydride in good overall yield (eq 6). 2-(Phenylthio)maleic anhydride reacts with cyclopentadiene at rt to provide the corresponding Diels-Alder adduct in 83% yield.[6] Maleic anhydride readily undergoes Diels-Alder reactions with furan. However, the Diels-Alder reaction of furan with dimethylmaleic anhydride fails due to the rapid reversion of the Diels-Alder adduct to starting material. On the other hand, the dihydrothiophene derivative of maleic anhydride reacts with furan at high pressure to produce a 20:80 mixture of *endo* and *exo* Diels-Alder adducts in good yield (eq 7).[7] Subsequent ***Raney Nickel*** desulfurization produces the dihydro version of the Diels-Alder adduct corresponding to the dimethylmaleic anhydride product.

(6)

Maleic anhydride undergoes [2 + 2] photocycloadditions with a variety of substrates. Aromatic species (eq 8),[8] isolated alkenes (eq 9),[9] and alkynes (eq 10)[10] readily undergo sensitized photochemical cycloadditions with maleic anhydride. Photochemical [2 + 2] cycloadditions usually employ benzophenone as a sensitizer; however, other sensitizers such as acetophenone, propiophenone, benzaldehyde, and diacetylbenzene have also been utilized. For example, irradiation of a solution of benzene and maleic anhydride in the presence of benzophenone produces a 2:1 maleic anhydride/benzene adduct, which presumably arises from a photochemical [2 + 2] photocycloaddition followed by a Diels-Alder reaction of the resulting diene with a second equivalent of maleic anhydride (eq 8). Irradiation of a solution of maleic anhydride in acetone produces the Paterno-Büchi product in good yield (eq 11).[11] Maleic anhydride can also undergo thermal [2 + 2] cycloadditions. For example, thermolysis of a mixture of allene and maleic anhydride produces the corresponding cyclobutane in 22-26% yield (eq 12) (also see ***Dimethyl Maleate***).[12]

(10)

(11)

(12)

Maleic anhydride reacts with a variety of dipoles to produce the corresponding cycloadducts in good to excellent chemical yield. For example, cycloadditions with nitrones,[13] diazo compounds,[14] nitrile oxide,[15] and azomethine ylides[16] have been reported (eqs 13-16).

(13)

(14)

(15)

(16)

Acylations and Alkylations.

Maleic anhydride acylates aromatic ring systems under Friedel-Crafts acylation conditions.[17] A typical example is the acylation of benzene (eq 17) to provide β-benzoylacrylic acid in 80-85% yield.[18] The useful quinone naphthazarin can be prepared from dihydroxybenzene and MA under rigorous reaction conditions (eq 18).[19] Substituted aryl-1,3-dioxocarboxylic acids have been prepared by the generation of enolates from aryl ketones followed by acylation with MA (eq 19).[20]

(17)

(18)

(19)

Maleic anhydride can also partake in Michael-type reactions. As previously described, thiophenol adds in a conjugate fashion to maleic anhydride (eq 6).[6] On the other hand, amines undergo acylation with maleic anhydride to afford the corresponding amides (eqs 20 and 21).[21] It should be mentioned that maleic anhydride is a poor radical acceptor relative to other commonly used radical traps (see ***Dimethyl Fumarate*** and ***Dimethyl Maleate***) due to competing polymerization. For example, benzyl radicals generated by heating a mixture of dibenzylmercury and MA at 100 °C produce only 22% of benzylsuccinic anhydride (eq 22).[22]

(20)

(21)

(22)

Miscellaneous.

Under thermal conditions, alkenes bearing an allylic hydrogen will undergo an ene reaction with maleic anhydride. Historically, the first reported ene reaction employed maleic anhydride as the enophile component. This reaction has proven to be quite general and typically requires elevated temperatures to occur (eqs 23 and 24). As an alternative to harsh thermal conditions, high pressure has been reported to induce the ene reaction. For example, maleic anhydride reacts with β-pinene at elevated temperatures to afford the corresponding ene adduct (eq 23), while the same reaction occurs at ambient temperature utilizing 4000 MPa pressure to afford the same adduct in 74% yield.[23]

(23)

(24)

Maleic anhydride has been utilized as a ligand in a coupling reaction between an alkenylzirconium(IV) complex and a (η^3-allylic)palladium chloride dimer to produce a 1,4-diene (eq 25).[24] In contrast, the overall rate of the coupling reaction was retarded by the addition of a phosphine ligand.

(25)

Related Reagents.

(Maleic anhydride)bis(triphenylphosphine)palladium

[17830-50-1] · $C_{40}H_{32}O_3P_2Pd$ · (Maleic anhydride)bis(triphenylphosphine)palladium · (MW 729.08)

(zerovalent palladium complex which catalyzes the dimerization of 1,3-dienes and 1,2-dienes[5-9])

Alternate Name: bis(triphenylphosphine)(maleic anhydride)palladium.

Physical Data: mp 147-151 °C (dec).[1]

Solubility: sol THF, acetone, chloroform; low sol benzene.

Form Supplied in: not widely available.

Analysis of Reagent Purity: ^{1}H NMR in $CDCl_3$,[1] benzene-d_6;[2] IR.[2]

Preparative Methods: reaction of ***Tetrakis(triphenylphosphine)palladium(0)*** with ***Maleic Anhydride*** at rt in benzene,[1] benzene/THF,[2,3] or THF[3] yields the title complex as a stable monomeric species, which is purified by crystallization from methanol/hexane.[2] The title reagent has also been synthesized from the putative bis(triphenylphosphine)palladium.[4]

Handling, Storage, and Precautions: stable in air for many hours in the solid state.[2]

Dimerization of Conjugated Dienes.

(Maleic anhydride)bis(triphenylphosphine)palladium (**1**) is a zerovalent palladium complex that has been used extensively as a catalyst for the dimerization of conjugated dienes.[5-7] For example, complex (**1**) efficiently promotes the coupling of ***1,3-Butadiene*** to form linear dimers (eq 1).[5] These reactions are most commonly carried out in

benzene, THF, and acetone. In the presence of protic nucleophiles such as MeOH or ***Morpholine***, the dimerizations take place with addition of the protic component (eq 2). Further studies have demonstrated that (**1**) catalyzes the reaction of 1,3-dienes with acyloin derivatives to yield mainly the product of *O*-alkylation (eq 3).[6]

(1)

(2)

(3)

The title reagent promotes the co-cyclization of conjugated dienes with isocyanates (eq 4).[7]

Reaction of Allenes.

Allenes can be condensed with dienes,[8] amines, enamines, and activated methylenes,[9] using reagent (**1**). Secondary amines react efficiently with allenes in the presence of 0.2 mol % of (**1**) to provide substituted 1,3-dienes (eq 5). Primary amines give the corresponding bis(dienyl)amines, albeit in lower yields. Carbon acids also react with allenes in the same way to yield substituted dienes (eq 6). In all these reactions, complex (**1**) was the palladium reagent of choice due of its ease of preparation, good stability, and high reactivity.[9]

Miscellaneous.

In the presence of an acid catalyst, reagent (**1**) promotes the addition of cyclic amines to homoconjugated dienes such as norbornadiene (eq 7).[10]

(7)

Reagent (**1**) catalyzes the hydrosilation of allenes and dienes. The reaction between allene and triethylsilane gives the 1:1 addition product, allyltriethylsilane, in 48% yield.[9] The analogous reaction with 1,3-dienes yields the linear dimer of the diene (eq 8).[11] Catalysis of a Si-Si/Si-Si metathesis reaction, which proceeds very slowly at 200 °C, can be catalyzed by reagent (**1**) (eq 9).[12]

Malondialdehyde[1]

[542-78-9] · $C_3H_4O_2$ · Malondialdehyde · (MW 72.07)

(behaves as multifunctional compound;[1] aldehyde reactions;[2-4] forms both cyclic and acyclic acetals;[5] may react as vinylog of formic acid;[6-8] chelates with metal ions as β-dialdehyde;[8] behaves as push-pull alkene[9])

Alternate Names: MDA; malonaldehyde; 1,3-propanedial.

Physical Data: free aldehyde: hygroscopic needles; mp 72-74 °C; sodium salt: mp 245 °C (dec); UV λ_{max} (0.1 N HCl) 245 nm (ε 12 800), (0.1 N NaOH) 267 nm (ε 29 400); ^{1}H NMR (D_2O) δ 5.73 (t, 1H, J = 10.1 Hz), 9.08 (d, 2H, J = 10.1 Hz); ^{13}C NMR (D_2O) δ 110.3, 193.6; pK_a (H_2O) = 4.5.[1]

Solubility: sodium salt: sol EtOH, MeOH, H_2O; moderately sol CH_2Cl_2; insol ether.

Form Supplied in: can be generated in situ from commercially available malondialdehyde bis(dimethyl acetal) *[102-52-3]* or bis(diethyl acetal) *[122-31-6]*. However, it is unstable and is best handled as its sodium salt.

Handling, Storage, and Precautions: unstable and easily polymerizes. The generation of MDA in situ from the hydrolysis of its bis-acetals results in the formation of a number of side products, including β-alkoxyacrolein, 3,3-dialkoxypropionaldehyde, and fluorescent condensation polymers of MDA. Crystalline sodium MDA, which is much more stable than MDA, is the recommended synthetic reagent. Sodium MDA, if stored under nitrogen in a refrigerator, is stable for months.

Preparation of Sodium Malondialdehyde.

This reagent is most conveniently prepared by the acid hydrolysis of malondialdehyde bis(dimethyl acetal) with 1 N HCl and then conversion of the released MDA to its sodium salt by treatment with 5 N NaOH (pH 10).[1] Sodium MDA crystallizes from ethanol-ether as white needles.

Derivatives of Malondialdehyde.

A number of 2-substituted derivatives of MDA are known, including alkyl, aryl, halo, nitro, amino, cyano, diazo, formyl, and methylene compounds.[10-15]

Structure of Malondialdehyde.

MDA exists almost entirely in its enolic form. There are three possible tautomeric forms of enolic MDA, all of which are interconvertible by the processes of tautomerization and carbon-carbon single bond rotation.[3,16-18] In organic solvents such as CCl_4 and $CHCl_3$, the major form is the intramolecularly hydrogen-bonded *cis* form. In polar hydroxylic solvents such as water, MDA exists largely as the *trans* form (eq 1).[3]

(1)

Reactions of Malondialdehyde.

MDA behaves in some respects as a typical aldehyde. Thus it forms dianils[3] and cyclic and acyclic acetals,[5] and forms chelates with metal ions.[8] MDA may also be looked upon as a vinylog of formic acid in that it undergoes reactions that are typical of carboxylic acids, such as salt formation and conversion to vinylogous esters with diazomethane.[6-8] In some of its reactions, MDA behaves as a push-pull alkene and participates in both nucleophilic and electrophilic substitution reactions.[9] For example, MDA undergoes nucleophilic attack at the terminal positions in its reaction with amines and electrophilic substitution at C-2 in its reaction with bromine (eqs 2 and 3).[3,9,19,20]

(2)

(3)

MDA reacts with dimethyl 3-oxoglutarate to form phenolic or bicyclic adducts, depending on the pH of the reaction.[20] The synthesis of secologanin, a biosynthetic precursor of secoiridoid glycosides, was achieved using sodium MDA in a key step of the synthesis (eq 4).[21]

(4)

The thiobarbituric acid (TBA) test is used extensively as a spectrophotometric method for the detection of peroxidation of unsaturated fatty acids.[22] The assay apparently is for the detection of MDA, and the red pigment (TBA-MDA adduct) formed is a mixture of equilibrating structures of the type (**1**).[23]

(1)

Nucleic acid bases are modified by MDA. For example, treatment of guanosine or deoxyguanosine with MDA results in the formation of a nucleoside with a tricyclic base as the primary product. Further reaction of this adduct with MDA produces a compound bearing a tetracyclic base moiety (eq 5).[24-27] The modification of other nucleic acid bases has also been studied.[28,29]

R = ribosyl or deoxyribosyl

Interestingly, MDA reacts with amines and amino acids in the presence of a monoaldehyde to produce highly fluorescent and stable dihydropyridines.[1,30,31] A plausible mechanistic explanation of this transformation involves the condensation of MDA with the amine to form an enaminal (eq 6), and with the additional aldehyde to produce an alkylidene MDA derivative. Subsequent Michael reaction between these two species, followed by cyclization and elimination of water, results in the formation of the dihydropyridine (eq 7).

R^1, R^2 = alkyl, aryl

Methylenemalondialdehydes (alkylidenemalondialdehydes), intermediates in the synthesis of the aforementioned dihydropyridines, were first utilized under conditions of in situ generation by Woodward and co-workers in the synthesis of cephalosporin C.[32] Various masked forms of MDA have also been used in synthesis (see, for example, Cho et al.[33]).

Related Reagents.

Formic Acid; ***Glyoxal***; ***Succindialdehyde***.

Malonic Acid[1]

[141-82-2] · $C_3H_4O_4$ · Malonic Acid · (MW 104.07)

(useful reagent for synthesis of cinnamic and acrylic acid derivatives via the Doebner modification[2] of the Knoevenagel condensation[3])

Alternate Name: 1,3-propanedioic acid.

Physical Data: mp 135-137 °C; *d* 1.619 g cm^{-3}; pK_a (H_2O) 2.38 and 5.69.[1a]

Solubility: very sol H_2O; sol Et_2O, EtOH; insol benzene; moderately sol pyridine.

Form Supplied in: white powder; widely available.

Preparative Method: can be prepared from chloroacetic acid;[1c] a number of monosubstituted derivatives are also commercially available.

Handling, Storage, and Precautions: strong irritant; LD_{50} 1310 mg/kg (rat).[1a]

Synthetic Applications.

Malonic acid has been widely used in the Knoevenagel condensation with aldehydes and some ketones.[3] The alkylidene or arylidene malonic acid derivatives can be obtained when ethanolic ammonia or acetic acid is the reaction solvent (eq 1).[4] The Doebner modification, in which pyridine is used as the solvent, generally results in condensation with decarboxylation to provide cinnamic or acrylic acid derivatives.[2,5] Other amines, such as piperidine, or amine salts, such as piperidinium acetate, have also been used to catalyze the reaction. 2,3-Dimethoxycinnamic acid has been prepared in good yield under these conditions (eq 2).[5c] The *trans*-α,β-unsaturated acids are generally obtained. The Doebner conditions are usually the method of choice for the preparation of cinnamic acid derivatives, in comparison with other classical synthetic procedures.[2]

Yields are generally high, and the reaction is usually not complicated by side reactions, such as the Michael addition of a second malonic acid molecule to the product.[3] Monosubstituted malonic acid derivatives also undergo condensation with aldehydes to provide α-alkylcinnamic acids, but the synthetic utility is limited due to steric problems.[3]

The condensation sometimes proceeds inefficiently with aliphatic aldehydes, resulting in low yields or mixtures of the α,β- and β,γ-unsaturated acids. For these reasons, a number of modified or improved Knoevenagel/Doebner procedures for the synthesis of acrylic acid derivatives have been reported.[6] One such modification, in which acrolein is added dropwise to malonic acid in pyridine at 60 °C, provides *trans*-2,4-pentadienoic acid in a higher and more reproducible yield than earlier procedures (eq 3).[5a] The conditions can also be modified to provide *trans*-β,γ-unsaturated acids exclusively in moderate yield.[6a]

The final step in the synthesis of strychnine (**2**) has been accomplished by treatment of the aldehyde (**1**) with malonic acid.[7] Knoevenagel condensation under these conditions is accompanied by decarboxylation and cyclization to form the final two rings (eq 4).[7]

Efforts to effect asymmetric decarboxylation of disubstituted malonic acids have met with some success. Thus enzyme-mediated decarboxylation of prochiral α-methyl-α-phenylmalonic acid led to (*R*)-α-methylphenylacetic acid methyl ester in high yield with 98% ee after esterification (eq 5).[8]

Malononitrile[1]

[109-77-3] · $C_3H_2N_2$ · Malononitrile · (MW 66.07)

(active methylene reagent useful for condensation reactions, for preparing synthetic intermediates, and for the synthesis of heterocycles)

Alternate Names: propanedinitrile; dicyanomethane; malonic (acid) dinitrile; propiodinitrile; methylene cyanide; cyanoacetic acid nitrile; malonitrile; malodinitrile; malonodinitrile.

Physical Data: mp 32-34 °C; bp 218-219 °C; *d* 1.191 g cm^{-3}; pK_a 11.

Solubility: sol acetone, benzene, ethanol, ether, water.

Form Supplied in: white crystals; available commercially.

Preparative Methods: prepared from cyanoacetamide.[2,3] The high temperature, continuous, one-step process for the synthesis of malononitrile by Lonza Inc. permits commercial-scale production of high purity reagent.

Purification: crystallization.[4]

Handling, Storage, and Precautions: **caution**: highly toxic irritant and should be stored in a well-ventilated fume hood. Over time, colorless malononitrile becomes dark and eliminates hydrogen cyanide. Inhalation should be avoided. Persons who suffer from a poor sense of smell, heart condition, or blood circulation problems should not be exposed to malononitrile. Above 100 °C, malononitrile may decompose spontaneously.

Introduction.

Fatiadi[1b] in his comprehensive review stated that malononitrile has become the keystone for synthesis of unique heterocyclic systems, fungicides, pharmaceuticals, pesticides, charge-transfer salts that conduct electricity, and solvatochromic dyes. Malononitrile is easily converted to derivatives, including dimers and trimers, which are also valuable in synthesis.[1]

Condensation Reactions with Aldehydes and Ketones.

Malononitrile undergoes the Knoevenagel condensation with aldehydes and ketones. Effective catalysts for the condensation include glycine[5] and β-alanine.[5,6] Benzaldehyde condenses with malononitrile in the presence of a catalytic amount of glycine to give benzalmalononitrile, which is valuable in heterocyclic synthesis, in quantitative yield (eq 1).[5] The condensation of 1,4-cyclohexanedione with malononitrile proceeds almost quantitatively to 1,4-bis(dicyanomethylene)cyclohexane under catalysis by β-alanine (eq 2).[7] 1,4-Bis(dicyanomethylene)cyclohexane is used to prepare the quinomethane electron acceptor 7,7,8,8-tetracyanoquinonedimethane (TCNQ).[7] In general, the Knoevenagel condensation of malononitrile with ketones[8] or esters[9] is efficiently catalyzed by weak bases (β-alanine, ammonium acetate) while stronger bases (KF, KOAc, NaOAc) promote telomerization of malononitrile.[8] Dimethylformamide (DMF) is a useful solvent for a wide variety of Knoevenagel reactions.[10] Dialkylidenemalononitriles having cyclic and terpenoid groups are potential cytostatic and pesticidal agents that may be useful in regulating insect juvenile hormone activity.[11,12]

(1)

(2)

2,3-Butanedione reacts with malononitrile to produce 4,5-dimethyl-5-hydroxy-2-oxo-3-pyrroline-3-carbonitrile (**1**), 1,5-dimethyl-3,7-dioxo-2,6-diaza-*cis*-bicyclo[3.3.0]octane-4,8-dicarbonitrile (**2**), 3-imino-1,5,9,11-tetramethyl-7-oxo-2,10-dioxa-6-azatetracyclo[6.3.0.0^{4,11}.0^{5,9}]undecane-4,8-dicarbonitrile (**3**) (eq 3), and the isomeric bislactam 1,5-dimethyl-3,7-dioxo-2,8-diaza-*cis*-bicyclo[3.3.0]octane-4,6-dicarbonitrile (**4**) (eq 4).[13,14] Benzil reacts with malononitrile to give the Knoevenagel product (**5**) or the γ-lactam (**6**) (4-cyano-2,3-diphenyl-5-oxo-3-pyrrolin-2-ylmalononitrile) (eq 5).[15-17]

(3)

(4)

(5)

2-Acetylcyclohexanones react with malononitrile to give a mixture of products including polyhydrobenzo[*c*]pyridines (isoquinolines) and tetrahydronaphthalenes (eq 6).[18-20] The reaction with 2-acetylcyclopentanone proceeds similarly. Enolizable aliphatic and aromatic 1,4-diketones (e.g. 2,5-hexanedione) react with malononitrile in benzene in the presence of ammonium acetate or piperidinium acetate to give an array of products including double Knoevenagel adducts, cyclopentadiene derivatives, and 1-pyrindine derivatives (eq 7).[21-23]

(6)

(7)

Condensation Reactions with Esters.

Ethyl pyruvate condenses with malononitrile to yield ethyl 2-dicyanomethylenepropanoate (eq 8), a useful dienophile in the Diels-Alder reaction and in natural products synthesis.[9,24] Ethoxycarbonyl-1-cyclohexanone reacts with malononitrile to give the Knoevenagel condensation product, which rearranges to the tetrahydroisoquinoline (eq 9).[18-20,25,26]

(8)

(9)

Reactions with α,β-Unsaturated Carbonyl Compounds.

The Knoevenagel reaction of aliphatic methyl ketones with malononitrile produces 6-alkyl-2,4-diamino-3,5-dicyanopyridines in moderate yield.[27] The Michael reaction between aliphatic α,β-unsaturated ketones and

malononitrile gives 2-amino-3-cyano-4,6-dialkylpyridines.[27] Conjugated aromatic ketones react with malononitrile in the presence of ammonium acetate to give 2-amino-4,6-diarylnicotinonitriles.[28] The Michael addition of malononitrile to α-acetylcinnamamides and chiral α-acylacrylates to form 2-amino-4*H*-pyrans and polyfunctionalized carbocycles,[29,30] and the first asymmetric synthesis of polyfunctionalized 4*H*-pyrans via Michael addition of malononitrile to 2-acyl acrylates, have been reported.[31] Polyfunctionalized 4*H*-pyrans are a common structural unit in a number of natural products.

Reaction with Allene.

Malononitrile reacts with allene in the presence of catalytic Pd^0 complexes, such as ***(Maleic anhydride)bis(triphenylphosphine)palladium***, to afford a 2-(1,1-dicyanoethyl)-3-methyl-1,3-butadiene (eq 10).[32]

(10)

Reaction with Tetracyanoethylene.

Tetramethylammonium 1,1,2,3,3-pentacyanopropenide, which is useful for preparation of pentacyanopropenide salts of other metals and quaternary ammonium cations by metathesis, is prepared from malononitrile and tetracyanoethylene (eq 11).[33]

(11)

Reactions with Alkyl- and Cycloalkylureas.

Malononitrile condenses with heptylurea and ethyl triorthoformate to form the 3-heptylureidomethylenemalononitrile, which is a precursor to 3-heptyl-5-cyanocytosine (eq 12).[34] The reaction is effective for preparing 3-alkyl- and 3-cycloalkyl-5-cyanocytosines, but not for 3- and 5-cyanocytosines from arylureas.

(12)

Reactions with Carbon Disulfide and/or Sulfur.

Malononitrile reacts with carbon disulfide in aqueous ammonia to yield 4,6-diamino-3,5-dicyano-2*H*-1-thiapyran-2-thione (eq 13).[35] Malononitrile reacts with carbon disulfide and sulfur in the presence of secondary or tertiary amines to give 4-cyano-5-amino-1,2-dithiole-3-thione.[36] 2-Amino-3-cyano-4,5-dialkylthiophenes are obtained from malononitrile, ketones, and sulfur.[37] Cholestan-3-one reacts with malononitrile and sulfur in ethanol containing morpholine to produce cholestanothiophene (2´-aminocholest-2-eno[3,2-*b*]thiophene-4´-carbonitrile) (eq 14).[38]

(13)

(14)

Other Applications.

Malononitrile forms synthetically useful dimers and trimers[1] and can be alkylated under a variety of experimental conditions.[39,40] Ethyl orthoformate reacts with malononitrile to form ***Ethoxymethylenemalonitrile***.[41] Malononitrile reacts with 2,3-bis(phenylsulfonyl)-1,3-butadiene via a novel 4*H*-annulation to yield 1-sulfonyl-4,4-dicyanocyclopentene.[42] Cholest-1-en-3β-yl esters undergo allylic alkylation with malononitrile in the presence of a palladium catalyst.[43] Malononitrile may be used to prepare adenine,[44,45] aminopyrroles,[46] aminocyanopyrroles,[47] diaminopyrimidines,[48] and many other heterocycles.[1] Malononitrile is converted to aminomalononitrile (aminopropanedinitrile) which is useful in the synthesis of heterocycles including pyrazines,[49,50] *C*-nucleosides,[51,52] dicyanoazomethine ylides,[53] substituted 2-aza-1,3-butadienes,[54] piperazines,[55] and thiazoles.[56] Malononitrile is also an important precursor for dicyanocarbene[57] and for dibromodicyanomethane, which is useful in the synthesis of tetracyanocyclopropanes.[58-61]

Malonyl Chloride

[1663-67-8] · $C_3H_2Cl_2O_2$ · Malonyl Chloride · (MW 140.95)

(reactive acyl chloride/C_3O_2 equivalent;[1] self condensation;[2] reacts with various functional groups to give heterocyclic compounds[3])

Physical Data: colorless liquid, bp 58 °C/26 mmHg; *d* 1.4486 g cm^{-3}.

Solubility: sol most organic solvents; *reacts violently with H_2O and protic solvents*.

Form Supplied in: colorless or red liquid; widely available in differing purity.

Preparative Methods: from ***Malonic Acid*** and ***Thionyl Chloride***.[4]

Handling, Storage, and Precautions: unstable at rt and should be used freshly distilled in vacuo or freshly prepared; however, it can be stored in the cold for several days; lachrymatory; use in a fume hood.

Acylation.

Malonyl chloride may be used as other acyl halides in Friedel-Crafts and related reactions.[5] Thus cyclic hydrocarbons may be prepared by a [3 + *n*] annulation from aromatic compounds (eq 1) and organometallics (eq 2). Similarly, malonyl chloride can be used like other α,ο-carboxylic acid derivatives for the synthesis of macrocycles.[6] In this respect, malonyl chloride behaves identically to C_3O_2 (see ***Carbon Suboxide***), although its reactivity is significantly lower.[1,7]

(1)

(2)

Preparation of Heterocycles.

Compounds possessing two nucleophilic centers yield heterocycles upon treatment with malonyl chloride. The reaction proceeds via initial HCl elimination from malonyl chloride[8] to give chlorocarbonyl ketenes (**1**) which are stable for the substituted counterparts (see ***(Chlorocarbonyl)ethylketene***). This elimination is even induced by weak bases such as acetone.[2,8] The ketene intermediate may then react with the respective nucleophile or it dimerizes in the case of malonyl chloride in a [4 + 2] fashion to yield 6-chloro-3-chlorocarbonyl-4-hydroxy-2-oxo-2*H*-pyran (**2**) (eq 3).[2]

(1) (2) (3)

With enolizable ketones and β-dicarbonyl compounds, pyrones are normally obtained via ketene (**1**). Unsymmetrically substituted diketones give, however, mixtures of isomers.[9] Furthermore, some of the pyrones formed can further add malonyl chloride or ketene (**1**) to give pyrano[4,3-*b*]pyran-2,5-diones (eq 4).[1,10]

Of the numerous examples reported so far for the condensation of malonyl chloride with 1,2- and 1,3-heteroatom-containing nucleophiles, most of the products are very similar to those obtained from the respective nucleophile and C_3O_2, chlorocarbonyl ketene, or active malonates.[1] Some newer examples for the use of malonyl chloride include the preparation of barbituric acid derivatives from silylated carbodiimides,[11] coumarins from salicylic aldehyde imines,[12] pyridones from ketene *S*,*N*-acetals,[13] diazepines from diamines,[14] and pyranopyrans from malonamides.[15] Amidines and similar nucleophiles condense with malonyl dichloride, chlorocarbonyl ketene, and C_3O_2 to give mesoionic heterocycles (betaines).[3,16] These are synthetically useful compounds since, for example, highly substituted pyridones can be prepared by a cycloaddition reaction (eq 5). Enol ethers that are derived from aldehydes react at low temperature with malonyl chloride via (**1**) to give, after workup with ethanol, 1,3,5-tricarbonyl compounds that can be further converted to otherwise difficult to obtain 6-unsubstituted pyrones (eq 6).[17]

From ketone-derived alkyl and trimethylsilyl enol ethers, mixtures of the corresponding phloroglucinols, cyclophanes, and substituted or methylene-bridged pyrones are produced upon condensation with malonyl chloride (eq 7).[18]

R = Me, Et,	TMS$R^1 = R^2 = H$	52%	43%
	$R^1 = H$, $R^2 = Et$	80%	11%
	$R^1 = R^2 = Me$	53%	30%
	$R^1, R^2 = -(CH_2)_n-$	(n = 2-9, hy)	

Less nucleophilic functional groups like nitriles react with malonyl chloride via the intermediate chlorocarbonyl pyrone (**2**) to give pyrano[3,4-*e*][1,3]oxazines.[19] However, the product distribution depends on the nitrile, the reaction conditions and, if present, on the substituent of the malonyl chloride. Thus oxazinones (eq 8),[20] pyridones (eq 9),[21] and pyrimidones (eq 10)[19] can be obtained as well.

(8)

(9)

(10)

The condensation of nitriles with malonyl chloride has been reviewed.[1b] Thiocyanates,[22] isothiocyanates,[23,24] and cyanates[24] condense with malonyl chloride in a similar fashion to nitriles via (**2**) to give 2-substituted 7-chloropyrano[3,4-*e*][1,3]oxazine-4,5-diones (eq 11). Similarly, cyanamides yield pyrano[4,3-*d*][1,3]oxazines and pyrano[4,3-*b*]azetidinones, depending on the reaction conditions (eq 12).

Mandelic Acid

(*S*)-(+)

[17199-29-0] · $C_8H_8O_3$ · Mandelic Acid · (MW 152.16) (*R*)-(-)

[611-71-2]

(useful reagent for the resolution of enantiomeric amines[1] and alcohols;[5] serves as a chiral nonracemic template for asymmetric reductions,[11-14] aldol condensations,[15-17] and Diels-Alder reactions;[18,19] chiral nonracemic starting material[22])

Alternate Names: phenylglycolic acid; α-hydroxyphenylacetic acid.

Physical Data: (*S*)-(+): mp 134-135 °C; [α]20D + 156.6° (H_2O, *c* = 2.9). (*R*)-(-): mp 133-135 °C; [α]20D - 158.0° (H_2O, *c* = 2.5). (±): mp 121-123 °C; *d* 1.341 g cm^{-3}; K_a 4.3 × 10^{-4} (25 °C).

Solubility: sol water (1 g/6.3 mL), ethanol (1 g/mL), acetic acid, chloroform; very sol ether.

Form Supplied in: white crystalline solid; widely available.

Handling, Storage, and Precautions: darkens and decomposes upon prolonged exposure to light.

Resolving Reagent.

Due to the ready availability of both enantiomers of this compound in high enantiomeric purity, mandelic acid is widely used as a reagent for enantiomeric resolutions.[1] It is used in resolving racemic mixtures of amines[1] or diamines[2] as the diastereomeric ammonium salts. Amino esters[3] or amino lactams[4] are resolved by formation of the amides or ammonium salts,[4b] and alcohols[5] are resolved by formation of the corresponding diastereomeric esters[5a,b] or ethers.[5c] Generally, the derivatives are crystalline solids easily purified by recrystallization. In a related application, enantiomeric purity determinations of chiral nonracemic amines by ^1H NMR are obtained using mandelic acid as a solvating agent.[6] As well, absolute configuration determinations of enantiomers can be undertaken using either isomer of mandelic acid in conjunction with CD-ORD,[7] X-ray,[8] and mass spectral analyses.[9] Mandelic acid can also be utilized in enantiomeric chromatography[10] as a chiral nonracemic mobile phase additive[10a] or as a solid support component.[10b]

Asymmetric Reductions.

Acyloxy-alkoxy borohydrides, produced from the reaction of mandelic acid enantiomers and ***Sodium Borohydride***,[11] and aluminum hydride reagents modified with ligands derived from mandelic acid,[12] will reduce ketones with poor stereoselectivity. Reactions of nitriles with a mixture of $NaBH_4$ and mandelic acid followed by alkylation of the intermediate *N*-boryl imine with organometallic reagents provide the corresponding primary amines in good yield but with low stereoselectivity (eq 1).[13] However, catalytic hydrogenations with chiral nonracemic phosphino ligands (**1**),[14b-d] easily derived from mandelic acid (eq 2), with rhodium have given the corresponding products (e.g. amino acids) with high enantiomeric purity (eq 3).[14]

(3)

Aldol Condensations.

Mandelic acid and a variety of easily prepared derivatives serve as excellent chiral nonracemic auxiliaries for aldol condensations, giving products in high diastereoselectivity. Lewis acid mediated condensation of silyl enol ethers or allylsilanes with 1,3-dioxolan-4-ones (**2**), produced from the reaction of mandelic acid with various aldehydes and ketones, gives the corresponding products in up to 86% de (eq 4).[15] The diastereomers are easily separated and the chiral nonracemic auxiliaries are readily removed with ***Lead(IV) Acetate*** without racemization, giving enantiomerically pure aldols or homoallylic alcohols.

(4)

Chiral nonracemic silyl ketene acetals produced from mandelic acid derived amino alcohols successfully undergo asymmetric Mukaiyama aldol condensations,[16] and the magnesium enolates of acetoxy-1,1,2-triphenylethanols (**3**) derived from mandelic acid (eq 5) condense with aldehydes with high stereoselectivity (eq 6).[17]

(5)

(6)

Diels-Alder Reactions.

Hydroxamic acids of the mandelic acid enantiomers serve as precursors to chiral nonracemic acylnitroso dienophiles (**4**) (eq 7).[18] In most examples the stereoselectivity of the cycloaddition is relatively low. However, in some cases (with double asymmetric induction),[19] significant diastereoselectivities can be achieved (eq 8).

(7)

Asymmetric Organometallic Reagents.

Amino derivatives (**5**) of mandelic acid serve as ligands for copper reagents, facilitating conjugate additions to enones with high enantioselectivity (eqs 9 and 10).[20] Lithio benzylmandelate enantioselectively cleaves tricyclic anhydrides to give enantiomers of bicyclic dicarboxylic acids.[21]

(10)

Chiral Nonracemic Starting Material.

Both (*S*)-(+)- and (*R*)-(-)-mandelic acid are used extensively for enantiomeric syntheses.[22] It is a convenient starting material for enantiomerically pure phenylethanediol and styrene oxide (eq 11).[23] These methodologies are useful in preparing enantiomerically enriched deuterated compounds.[24] Enantiomerically pure benzoins produced from mandelic acid serve as templates for preparing enantiomerically enriched [^{16}O, ^{17}O, ^{18}O] phosphate esters[25] and sulfate esters.[26] The alcohol, acid, or aromatic ring functional groups can be interconverted in a variety of ways, so mandelic acid serves as an excellent chiral nonracemic starting material for numerous categories of compounds, including such complex molecules as macrolide antibiotics.[27]

Manganese(III) Acetate[1]

$Mn(OAc)_3$

($Mn(OAc)_3$)

[993-02-2] · $C_6H_9MnO_6$ · Manganese(III) Acetate · (MW 232.09) ($Mn(OAc)_3.2H_2O$)

[19513-05-4] · $C_6H_{13}MnO_8$ · Manganese(III) Acetate · (MW 268.13)

(one-electron oxidant used to oxidize acetic acid and β-dicarbonyl compounds to the corresponding radical and for α´-acetoxylation of enones)

Physical Data: the commercially available dihydrate is cinnamon brown. The anhydrous form is dark brown. The crystal structure of the anhydrous form indicates an oxo-centered trimer with bridging acetates.[2]

Solubility: sol acetic acid, ethanol, and a variety of other organic solvents; disproportionates in water.

Preparative Methods: commercially available dihydrate is easily prepared by the reaction of manganese(II) acetate with potassium permanganate in acetic acid at reflux.[1] The anhydrous form is prepared in acetic acid and acetic anhydride.[1]

$Mn(OAc)_3$ has been extensively used for the oxidative addition of acetic acid to alkenes to give γ-butyrolactones.[3,4] The addition of acetic acid to alkenes in acetic acid at reflux is quite general.[1] ***Acetic Anhydride*** and sodium acetate are often used as additives that modify the rate of reaction and ratio of products. With simple carboxylic acids, this reaction is limited to acetic acid and other acids which can be used as solvent. Mechanistic studies[5a] have shown that the rate determining step is formation of a Mn^{III} enolate which rapidly transfers an electron to give the carboxymethyl radical and Mn^{II}. This radical adds to the alkene to give a γ-carboxyalkyl radical that is oxidized by a second equivalent of $Mn(OAc)_3$ to give mixtures of lactone, alkene, and γ-acetoxycarboxylic acid (eq 1), depending on the exact reaction conditions and structure of the alkene.[6]

(1)

The lactonization reaction is much more facile with cyanoacetic acid and malonic acid, which undergo the rate-determining enolization more rapidly in acetic acid at rt (eq 2).[1,5,7] Malonic acid gives only bis-lactone 2:1 adducts resulting from the addition to two molecules of alkene (eq 3).[8]

(2)

(3)

$Mn(OAc)_3$ oxidizes ketones and aldehydes to α-carbonyl radicals which add to alkenes to give γ-oxo radicals. If these radicals are secondary, they are not oxidized unless ***Copper(II) Acetate*** is used as a co-oxidant (eqs 4 and 5).[9,10] Instead they undergo chain-transfer reactions to give saturated carbonyl compounds. Tertiary radicals give mixtures of saturated and unsaturated carbonyl compounds.

(4)

(5)

These reactions proceed in good yield based on oxidant consumed but must be carried out with a large excess of ketone or aldehyde, which is sometimes used as the solvent, since the products are oxidized further to give radicals at about the same rate as the starting carbonyl compound is oxidized.

A wide variety of β-dicarbonyl compounds can be oxidized by $Mn(OAc)_3$ to radicals in the presence of alkenes.[11] Addition of the radical to styrene and other electron-rich alkenes affords dihydrofurans. Addition to enol ethers occurs readily to give 1-alkoxy-1,2-dihydrofurans, which can be hydrolyzed to yield 1,4-diketones or dehydrated to form furans.[12]

Intramolecular versions of these reactions provide an efficient route to cyclic ring systems. Oxidation of unsaturated β-keto acids affords cyclopentanones fused to γ-lactones (eq 6).[13]

(6)

Oxidation of unsaturated β-keto esters affords α-keto radicals which add to alkenes to give alkyl radicals which are oxidized to alkenes in the presence of $Cu(OAc)_2$ (see ***Manganese(III) Acetate-Copper(II) Acetate***). If the alkyl radical is a 4-phenylbutyl radical, cyclization onto the aromatic ring results in the formation of a tetralin. This reaction occurs stereospecifically, as shown in the synthesis of *O*-methylpodocarpic acid (eq 7).[14]

(7)

Haloalkenes are compatible with radical generation by oxidation of β-dicarbonyl compounds with $Mn(OAc)_3$ and can be used to control the regiochemistry of the cyclization (eq 8).[15] Loss of HCl from the intermediate affords the naphthol in 79% yield in one pot. This reaction is compatible with allylic oxygen functionality and has been used for the synthesis of okicenone (eq 9).[16]

(8)

(9)

Oxidation of allylic β-keto amides with $Mn(OAc)_3$ in EtOH affords γ-lactams. The primary radical formed in the cyclization abstracts a hydrogen from the solvent (eq 10).[17] Similarly, saturated γ-lactones can be prepared by oxidation of allylic malonates and acetoacetates.[18]

(10)

The radicals formed by oxidation of 1,3-dicarbonyl compounds will add to electron-rich naphthalenes (eq 11).[19] Tetralins and dihydronaphthalenes can be formed by oxidation of diethyl α-benzylmalonate in the presence of an alkene or alkyne (eq 12).[20-22]

(11)

(12)

α´-Acetoxylation of conjugated enones with $Mn(OAc)_3$ in acetic acid proceeds in modest yield.[23] The reaction proceeds in much better yield with well-dried oxidant in refluxing benzene (eq 13).[24] A wide variety of α-esters can be introduced by exchange of carboxylic acids with $Mn(OAc)_3$ in benzene at reflux prior to the addition of the enone.[25] This procedure is applicable to α- and β-alkoxy enones[26] and is suitable for α-acetoxylation of aryl alkyl ketones.[27]

Manganese(III) Acetate-Copper(II) Acetate[1]

$Mn(OAc)_3$-$Cu(OAc)_2$

($Mn(OAc)_3$)

[993-02-2] · $C_6H_9MnO_6$ · Manganese(III) Acetate-Copper(II) Acetate · (MW 232.09) ($Mn(OAc)_3.2H_2O$)

[19513-05-4] · $C_6H_{13}MnO_8$ · Manganese(III) Acetate-Copper(II) Acetate · (MW 268.13) ($Cu(OAc)_2$)

[142-71-2] · $C_4H_6CuO_4$ · Manganese(III) Acetate-Copper(II) Acetate · (MW 181.65) ($Cu(OAc)_2.H_2O$)

[6046-93-1] · $C_4H_8CuO_5$ · Manganese(III) Acetate-Copper(II) Acetate · (MW 199.67)

(Mn^{III} oxidizes mono- and β-dicarbonyl compounds to the corresponding radical which adds to alkenes to give an alkyl radical; Mn^{III} oxidizes tertiary radicals to cations but does not oxidize primary and secondary alkyl radicals; thermodynamically weaker oxidant Cu^{II} oxidizes primary and secondary radicals about 350 times faster than Mn^{III} does to give alkenes, rather than cations)

Solubility: oxidations are usually carried out in acetic acid or ethanol, although other organic solvents can be used.[2] $Mn(OAc)_3$ disproportionates in water.

Form Supplied in: $Cu(OAc)_2$ is readily available and can be used as either the hydrate or anhydrous form.

Intermolecular Reactions.

Reaction of 1-octene with ***Manganese(III) Acetate*** in acetic acid containing potassium acetate affords mainly γ-*n*-hexylbutyrolactone.[3] If the reaction is run in acetic acid/acetic anhydride with a catalytic amount of ***Copper(II) Acetate***, the secondary radical reacts more rapidly with Cu^{II} to give the Cu^{III} intermediate, which loses Cu(OAc) and HOAc to give mainly 4-decenoic acid and some 3-decenoic acid (eq 1);[4] 2 equiv of $Mn(OAc)_3$ are still required and $Cu(OAc)_2$ can be used in catalytic amounts since Cu^{I} is reoxidized to Cu^{II} by Mn^{III}.

Oxidation of acetone with $Mn(OAc)_3$ in the presence of 1-heptene affords 2-decanone.[5] If $Cu(OAc)_2$ is present, the secondary radical is oxidized to an alkene, affording a mixture of 4- and 5-decenone (eq 2).[5] Similar results are obtained by oxidizing aldehydes with $Mn(OAc)_3$ and $Cu(OAc)_2$ in the presence of alkenes.[6]

Oxidation of diethyl malonate with $Mn(OAc)_3$ in acetic acid at 90 °C in the presence of 1-heptene affords 50% of diethyl heptylmalonate since the secondary radical abstracts hydrogen faster than it is oxidized by Mn^{III}.[7] If the

reaction is run in the presence of $Cu(OAc)_2$, oxidation of the secondary radical is rapid so that diethyl 2-heptenylmalonate is the only product (eq 3).

The yields of all of the reactions discussed above are based on oxidant consumed. Since the products are also susceptible to further oxidation, the mono- or 1,3-dicarbonyl compound must be used in large excess. This is practical when the carbonyl compound is a low molecular weight compound such as acetone or acetic acid which can be used as solvent.

Annulations can be carried out by oxidation of diethyl allylmalonate with Mn^{III} and Cu^{II} in the presence of an alkene (eq 4). The radical formed by addition to the alkene cyclizes to the allyl double bond to give a primary radical that is oxidized by Cu^{II} to an alkene.[8]

Intramolecular Reactions.

Oxidative cyclizations can be carried out in high yield with substrates containing double bonds and 1,3-dicarbonyl compounds, which are much more easily oxidized than monocarbonyl compounds. Oxidation of (**1a**) with $Mn(OAc)_3$ and $Cu(OAc)_2$ affords 71% of (**2a**) (eq 5).[9,10] However, oxidation of 1,3-dicarbonyl compounds with two α-hydrogens usually proceeds in lower yield since the product can be oxidized further by Mn^{III}. The formation of

38% of (**2b**) and 10% of (**3**), formed by further oxidation of (**2b**), shows that this problem is more serious in the formation of five- than six-membered rings.[10]

Oxidative cyclization of 1,3-dicarbonyl compounds that contain only a single α-hydrogen typically proceed in good yield and can be used to form five-, six-, seven- and eight-membered rings (eqs 6-9).[10-13]

(8)

(9)

Oxidation of α-chloro-1,3-dicarbonyl compounds generally proceeds in good yield (eqs 9 and 10).[14] Reduction with zinc removes the chloride, affording the cyclized product with an α-hydrogen. This product usually cannot be obtained directly due to problems with further oxidation as discussed above.[13,15,16]

(10)

Oxidation of acetoacetates such as that shown in eq 11 with 4 equiv of Mn^{III} and a catalytic amount of Cu^{II} results in 6-*endo* cyclization and further oxidation to afford methyl salicylate.[17-19] This reaction can be used for the formation of more highly functionalized salicylate derivatives.[19]

(11)

Tandem,[9,20-26,28] triple,[22] and even quadruple[27] cyclizations can be carried out with multiply unsaturated 1,3-dicarbonyl compounds, as shown in eqs 12-14.[2a,22,24-27] High levels of asymmetric induction can be achieved with phenylmenthyl acetoacetate esters and dimethylpyrrolidine acetoacetamides.[29-31]

Manganese(II) Chloride

$MnCl_2$

($MnCl_2$)

[7773-01-5] · Cl_2Mn · Manganese(II) Chloride · (MW 125.84) ($MnCl_2.4H_2O$)

[13446-34-9] · $Cl_2H_8MnO_4$ · Manganese(II) Chloride · (MW 197.92)

(starting material for preparation of organomanganese chloride reagents;[1] in combination with RLi or RMgX catalyzes reduction of vinyl and aryl halides,[2] stereoselective coupling of vinyl iodides,[3] and alkylation of enol triflates;[4] also used for Mn-Cu-catalyzed conjugate addition of RMgX to enones[5] and for Mn-catalyzed acylation of RMgX by acyl chlorides;[6] in combination with $NaBH_4$ is diastereoselective reducing agent;[7] starting material for the preparation of Mn enolates regio- and stereoselectively[8])

Physical Data: anhydrous material: mp 650 °C; bp 1190 °C; *d* 2.98 g cm^{-3}; hygroscopic. Tetrahydrate: mp 58 °C, *d* 2.01 g cm^{-3}.

Solubility: sol H_2O and some polar organic solvents (DMF, NMP, DMPU, etc.); insol hydrocarbons, ether, THF. $MnCl_2$ can be dissolved in THF as its ate complex $MnCl_4Li_2$. The latter is easily obtained by mixing LiCl (2 equiv) and anhydrous $MnCl_2$ in THF at rt until dissolution (about 1 h). $MnCl_4Li_2$ is generally used in place of $MnCl_2$; it reacts similarly but more rapidly owing to its solubility.[1]

Form Supplied in: pink grayish powder; widely available. *Drying:* for organometallic uses, it is recommended that the commercial anhydrous $MnCl_2$ be dried since the industrial anhydrous material contains 0.1-1% H_2O. The following procedure is convenient: heating at 200 °C under vacuo (10^{-2} mmHg) for 2 h.

Handling, Storage, and Precautions: anhydrous $MnCl_2$ is a very hygroscopic material. It must be handled very quickly and stored in a tightly closed bottle.

Preparation of Organomanganese Reagents.[1]

RMnCl are easily prepared by adding RLi or RMgX to a solution of $MnCl_4Li_2$ (see above) in THF (eq 1):

$$\text{RLi (or RMgX)} + MnCl_2 \xrightarrow{THF} \text{RMnX} \qquad (1)$$

According to the ratio RLi:$MnCl_2$ or RMgX:$MnCl_2$, several other types of organomanganese reagents can be prepared: the symmetrical organomanganeses R_2Mn and the organomanganates R_3MnLi and R_4MnLi_2 or R_3MnMgX and $R_4Mn(MgX)_2$.

In most cases, the transmetalation reaction can be performed between 0 and 20 °C (-20 °C to -10 °C when R = *s*- or *t*-alkyl) and the Li-Mn or Mg-Mn exchange occurs quantitatively and almost instantaneously. RMnCl react with carboxylic acid chlorides to give ketones and with ketones or aldehydes to lead to the corresponding alcohols. In the presence of copper, they also add to conjugated unsaturated ketones, aldehydes, esters, and amides to afford the 1,4-addition products. All these reactions have a large scope and give high yields under mild conditions. It is important to note that RMnCl react chemoselectively and are especially useful in the preparation of multifunctionalized molecules (see ***n-Butylmanganese Chloride***).

Reduction of Vinyl and Aryl Halides.[2]

In the presence of $MnCl_2$, in THF, *i*-PrMgCl reduces vinyl and aryl halides in good yields (eqs 2 and 3). Some functional groups such as ethers or amines are tolerated.

(2)

(3)

Stereospecific Symmetrical Coupling of Vinyl Iodides.[3]

In ether, in the presence of $MnCl_2$, MeLi or *n*-BuLi react with vinyl iodides to give stereospecifically the corresponding conjugated dienes in excellent yields (eq 4).

(4)

Alkylation of Enol Triflates.[4]

Organomagnesium compounds react with enol triflates, in the presence of $MnCl_4Li_2$, to give the substituted alkenes (eq 5). However, good yields are obtained only with aryl, benzyl, or allyl Grignard reagents.

(5)

$MnCl_2$ as Precursor of Mn^0.

$MnCl_2$ is reduced by ***Lithium Aluminum Hydride*** in THF at 0 °C (eq 6) to give a very fine black suspension of Mn^0 (the exact nature of this precipitate has not been established). The subsequent addition of allyl bromide leads to an intermediate species which reacts with aldehydes or reactive ketones to give the corresponding homoallylic alcohols (eq 7).[9]

(6)

(7)

From a practical point of view, it is interesting to note that such a Mn-mediated Barbier reaction can be more efficiently performed by using commercial manganese metal,[10] a very cheap material. Thus, upon reaction of Mn^0 with allylic halides in EtOAc at 50 °C in the presence of aldehydes or ketones, the 1,2-addition product is obtained in high yields. With functionalized aldehydes or ketones, the chemoselectivity is excellent (eq 8).

(8)

In THF, the reaction takes place at 60 °C and only in the presence of ***Zinc Chloride***. Even allylic chlorides can be used (eq 9).

(9)

A Mn-mediated Reformatsky reaction can also be effected in EtOAc in the presence of $ZnCl_2$. The alcoholates resulting from the addition of the intermediate ester Mn-enolates to aldehydes or ketones can be trapped by Ac_2O to give good yields of β-acetoxy esters (eq 10).

(10)

Mn-Cu-Catalyzed Conjugate Addition of Organomagnesium Reagents to Enones.[5]

RMgX add to enones in the presence of both Mn and Cu chlorides to afford good yields of 1,4-addition products. This procedure is generally superior to the classical Cu-catalyzed conjugate addition of RMgX as well as to the reaction of

organocuprates (eq 11).

Mn-Catalyzed Acylation of Organomagnesium Reagents by Acyl Chlorides.[6]

In THF, in the presence of $MnCl_4Li_2$, RMgX react with acyl chlorides under mild conditions to give the corresponding ketones in high yield. This procedure is very interesting from both practical and economical points of view. The chemoselectivity is excellent (eq 12).[6]

Diastereoselective Reduction of Ketones.[7]

In the presence of $MnCl_2$, the reduction of α-methyl β-keto esters or amides by ***Sodium Borohydride*** leads to the corresponding β-hydroxy esters or amides with an excellent stereoselectivity (eq 13).

Regioselective and Stereoselective Preparation of Manganese Enolates: Applications in Organic Synthesis.[8]

Mn enolates are easily prepared from Na, Mg, or Li enolates by transmetalation with $MnCl_2$ (or $MnBr_2$). The stereo- and the regiochemistry of the starting enolate is maintained during the reaction.

It is important to note that Mn enolates can also be quantitatively obtained regio- and stereoselectively (>95% of the less hindered (*Z*) isomers) by enolization of ketones with Mn amides prepared from $MnCl_2$. This procedure very often gives better yields and the (*Z*) stereoselectivity is clearly superior.

Mn enolates are regioselectively alkylated in good yields; interestingly, the formation of polyalkylated products is never observed (eq 14). They react regio- and stereospecifically with Me_3SiCl or carboxylic acid anhydrides to give respectively silyl enol ethers and enol esters (95-99% *Z*) in high yields (eq 15). Finally, they add to α,β-ethylenic carbonyl compounds (Michael addition) as well as to aldehydes and reactive ketones (diastereoselective aldolization condensation). In all cases, the reactions give excellent yields and occur regioselectively.

(14)

regioisomeric purity = 93%

(15)

Z = 97%, regioisomeric purity = 98%

Manganese Dioxide[1]

MnO_2

[1313-13-9] · MnO_2 · Manganese Dioxide · (MW 86.94)

(useful selective oxidizing reagent for organic synthesis; oxidation of allylic alcohols to α,β-ethylenic aldehydes or ketones;[2] conversion of allylic alcohols to α,β-ethylenic esters or amides;[3] oxidation of propargylic alcohols,[4] benzylic or heterocyclic alcohols,[5] and saturated alcohols;[6] oxidative cleavage of 1,2-diols;[7] hydration of nitriles to amides;[8] dehydrogenation and aromatization reactions;[9] oxidation of amines to aldehydes, imines, amides, and diazo compounds[10])

Alternate Names: manganese oxide; manganese(IV) oxide.

Physical Data: mp 535 °C (dec); *d* 5.03 g cm^{-3}.

Solubility: insol H_2O and organic solvents.

Form Supplied in: dark brown powder, widely available. The commercial active MnO_2 used as oxidizing reagent for organic synthesis is a synthetic nonstoichiometric hydrated material. The main natural source of MnO_2 is the mineral pyrolusite, a poor oxidizing reagent.

Structure of Active Manganese Dioxide.[1,11,12]

The structure and the reactivity of active manganese dioxides used as oxidizing reagents in organic synthesis closely depends on their method of preparation (see below). Active manganese oxides are nonstoichiometric materials (generally MnO_x; $1.93 < x < 2$) and magnetic measurements reveal the presence of lower valency Mn species, probably Mn^{II} and Mn^{III} oxides and hydroxides. Thermogravimetric analysis experiments show the existence of bonded and nonbonded water molecules (hydrated MnO_2). On the basis of ESR studies and other experiments, a locked-water associated structure (**1**) has been proposed for the apomorphous precipitated MnO_2.[12]

(1)

In addition, variable amounts of alkaline and alkaline earth metal derivatives are detected by atomic adsorption analysis. X-ray studies have shown that the structures of active MnO_2 are quite complex; they are either amorphous or of moderate crystallinity (variable proportions of β- and γ-MnO_2).

Preparation of Active MnO_2, Oxidizing Power, and Reproducibility of the Results.[1,13]

Pyrolusite (natural MnO_2) and pure synthetic crystalline MnO_2 are poor oxidants.[1] The oxidation of organic compounds requires an active, specially prepared MnO_2 and several procedures have been reported.[1,13] According to the method of preparation, the structure, the composition, and therefore the reactivity of active MnO_2 are variable. On this account, the choice of a procedure is of considerable importance to obtain the desired oxidation power and the reaction conditions must be carefully controlled to obtain a consistent activity. The active manganese dioxides described in the literature are generally prepared either by mixing aqueous solutions of $KMnO_4$ and a Mn^{II} salt ($MnSO_4$, $MnCl_2$) between 0 and 70 °C under acid, neutral, or basic conditions[13a-e] or by pyrolysis of a Mn^{II} salt (carbonate, oxalate, nitrate) at 250-300 °C.[13d,f] In this case the activity of the resulting material can be increased by washing with dilute nitric acid.[13f] A similar treatment has also been used to activate pyrolusite (natural MnO_2).[13h] On the other hand, it has been reported that the efficiency of an active MnO_2 depends on the percentage of the γ-form present in the material.[13i] Indeed, active γ-MnO_2 is sometimes clearly superior to the classical active MnO_2 prepared according to Attenburrow.[13j]

It worthy of note that the percentage water content strongly influences both the oxidizing power and the selectivity (oxidation of multifunctional molecules) of active MnO_2. Thus it is well known that the wet material (40-60% H_2O) obtained after filtration must be activated by drying[1,13] (heating to 100-130 °C for 12-24 h[13a-d] or, better, at 125 °C for 52 h).[13e] Indeed, an excess of water decreases the oxidation power[1e,13k] since, according to the triphasic mechanism generally postulated,[12] it would prevent the adsorption of the substrate to the oxidatively active polar site on the surface of MnO_2.[1a,c,e] On the other hand, it is very important not to go past the point of complete activation since the presence of hydrated MnO_2 species is essential to obtain an active reagent. For this reason, the drying conditions must be carefully controlled.[1,13a,d,g,k] Alternatively, the wet material can be activated by azeotropic distillation since this mild procedure preserves the active hydrated species.[131] Thus azeotropic distillation has been used to remove the water produced during the oxidation reaction to follow the rate of MnO_2 oxidations.[13e] Finally, the active MnO_2 mentioned above contains various metallic salts as impurities. According to their nature, which depends on the method of preparation, they can also influence the oxidizing power of the reagent (for instance, permanganate).[13d] Finally, it should be noted that the preparation of active MnO_2 on carbon[13m] or on silica gel[13n] as well as the activation of nonactive MnO_2 (pure crystalline MnO_2) by ultrasonic irradiation[13o] has also been reported. Some typical procedures to prepare active MnO_2 are reported below.

Preparation of Active MnO_2 from $KMnO_4$ under Basic Conditions (Attenburrow).[13a]

A solution of $MnSO_4.4H_2O$ (110 g) in H_2O (1.5 L) and a solution of NaOH (40%; 1.17 L) were added simultaneously during 1 h to a hot stirred solution of $KMnO_4$ (960 g) in H_2O (6 L). MnO_2 precipitated soon after as a fine brown solid. Stirring was continued for an additional hour and the solid was then collected with a centrifuge and washed with water until the washings were colorless. The solid was dried in an oven at 100-120 °C and ground to a fine powder (960 g) before use.

Preparation of Active MnO_2 from $KMnO_4$ under Acidic Conditions.[13k]

Active MnO_2 was made by mixing hot solutions of $MnSO_4$ and $KMnO_4$, maintaining a slight excess of the latter for several hours, washing the product thoroughly with water and drying at 110-120 °C. Its activity was unchanged after storage for many months, but it was deactivated by H_2O, MeOH, thiols, or excessive heat (500 °C). MnO_2 was less active when prepared in the presence of alkali and ineffective when precipitated from hot solutions containing a large excess of $MnSO_4$.

Preparation of Highly Active MnO_2 from $KMnO_4$.[1a]

A solution of $MnCl_2.4H_2O$ (200 g) in H_2O (2 L) at 70 °C was gradually added during 10 min, with stirring, to a solution of $KMnO_4$ (160 g) in H_2O (2 L) at 60 °C in a hood. A vigorous reaction ensued with evolution of chlorine; the suspension was stirred for 2 h and kept overnight at rt. The precipitate was filtered off, washed thoroughly with H_2O (4 L) until pH 6.5-7 and the washing gave a negligible chloride test. The filter cake was then dried at 120-130 °C for 18 h; this gave a chocolate-brown, amorphous powder; yield 195-200 g. Alternatively, the wet cake was mixed with benzene (1.2 L) and H_2O was removed by azeotropic distillation giving a chocolate-brown, amorphous powder; yield 195 g. The last procedure gave a slightly less active material.

Preparation of Active MnO_2 by Pyrolysis of $MnCO_3$.[13f]

Powdered $MnCO_3$ was spread in a one-inch thick layer in a Pyrex glass and heated at 220-280 °C for about 18 h in an oven in which air circulated by convection. The initially tan powder turned darker at about 180 °C, and black when maintained at over 220 °C. No attempt was made to determine lower temperature or time limits, nor the upper limit of temperature. The MnO_2 prepared as above was stirred with about 1 L of a solution made up of 15% HNO_3 in H_2O. The slurry was filtered with suction, the solid was washed on the Buchner funnel with distilled water until the washes were about pH 5, and finally was dried at 220-250 °C. The caked, black solid was readily crushed to a powder which retained its oxidizing ability even after having been stored for several months in a loosely stoppered container.

Preparation of γ-MnO_2.[1a]

To a solution of $MnSO_4$ (151 g) in H_2O (2.87 L) at 60 °C was added, with stirring, a solution of $KMnO_4$ (105 g) in H_2O

(2 L), and the suspension was stirred at 60 °C for 1 h, filtered, and the precipitate washed with water until free of sulfate ions. The precipitate was dried to constant weight at 60 °C; yield 120 g (dark-brown, amorphous powder).

Preparation of Active MnO_2 on Silica Gel.[13n]

$KMnO_4$ (3.79 g) was dissolved in water (60 mL) at rt. Chromatographic grade silica gel (Merck, 70-230 mesh, 60 g) was added with stirring, and the flask connected to a rotary evaporator to strip off the water at 60 °C. The purple solid was ground to fine powder and then added with vigorous stirring to a solution of $MnSO_4.H_2O$ (9.3 g) in H_2O (100 mL). The resulting brown precipitate was filtered with water until no more Mn^{II} ion could be detected in the wash water by adding ammonia. After being dried at 100 °C for 2 h, each gram of this supported reagent contained 0.83 mmol of MnO_2.

As shown above, a wide range of products of various activities are called active MnO_2 and the results described in the literature are sometimes difficult to reproduce since the nature of the MnO_2 which was used is not always well defined. Now, the commercial materials give reproducible results but they are not always convenient to perform all the oxidation reactions described in the literature. In addition, their origin (method of preparation) is not often indicated and comparison with the active MnO_2 described in the literature is sometimes difficult. For all these reasons, the use of activated MnO_2 has been somewhat restricted in spite of the efficiency and selectivity of its reactions since only an empirical approach and a careful examination of the literature allow selection of the suitable activity of MnO_2 and the optimum reaction conditions for a defined substrate.

Oxidation of Organic Compounds with MnO_2: Reaction Conditions.[1,13]

Solvent.

Oxidation of organic compounds with MnO_2 has been performed in many solvents. The choice of the solvent is important; thus primary or secondary alcohols (or water) are unsatisfactory since they can compete with the substrate being adsorbed on the MnO_2 surface and they have a strong deactivating effect.[13k] A similar but less pronounced influence has also been observed with various polar solvents such as acetone, ethyl acetate, DMF, and DMSO. However, these polar solvents, including water,[13p] acetic acid, and pyridine, can be used successfully at higher temperatures. This deactivating influence due to the polarity of the solvent can be used to control the reactivity of active MnO_2 and sometimes to avoid side reactions or to improve the selectivity (for instance, allylic alcohol vs. saturated alcohol). Most of the reactions described in the literature were carried out in aliphatic or aromatic hydrocarbons, chlorinated hydrocarbons, diethyl ether, THF, ethyl acetate, acetone, and acetonitrile (caution: MeCN can react with highly active MnO_2 or with classically activated MnO_2 on prolonged treatment). In the case of the oxidation of benzylic[13f] and allylic[13d] alcohols, the best results have been obtained using diethyl ether (diethyl ether > petroleum ether > benzene). Caution: a spontaneous ignition has been observed when highly active MnO_2 was used in this solvent.[13f]

Temperature and Reaction Time.

At rt, the reaction time can vary from 10 min to several days according to the nature of the substrate and the activity of the MnO_2.[13a,d,e,f,l,p] The reaction times are shortened by heating[13d] but the selectivity is very often much lower.[13q]

Ratio MnO_2:Substrate.

The amount of active MnO_2 required to perform the oxidation of an organic substrate depends on the type of MnO_2, on the substrate, and on the particle size of the MnO_2.[13d,f,g] With a classical material (100-200 mesh), the ratio varies from 5:1 to 50:1 by weight.

Oxidation of Allylic Alcohols.[2]

MnO_2 was used as oxidizing reagent for the first time by Ball et al. to prepare retinal from vitamin A_1 (eq 1).[2a] Since that report, the use of MnO_2 for the conversion of allylic alcohols to α,β-ethylenic aldehydes has been extensively utilized. Interestingly, the configuration of the double bond is conserved during the reaction (eqs 2-4).[2b,c] In some cases a significant rate difference between axial and equatorial alcohols has been observed[2d] (eq 5).[2e]

MnO_2 has been frequently used for the preparation of very sensitive polyunsaturated aldehydes or ketones (eq 6).[2f]

(6)

Numerous functionalized α,β-ethylenic aldehydes are readily obtained by chemoselective oxidation of the corresponding allylic alcohols (eqs 7-11).[2g-k]

(7)

(8)

(9)

(10)

(11)

The α,β-ethylenic ketone obtained by treatment of an allylic alcohol with MnO_2 can undergo an in situ Michael addition (eqs 11 and 12).[21]

(12)

Conversion of Allylic Alcohols to α,β-Ethylenic Esters and Amides.[2b,3]

This procedure was first described by Corey.[2b,3] The key step is the sequential formation and oxidation of a cyanohydrin. In the presence of an alcohol or an amine the resulting acyl cyanide leads by alcoholysis or aminolysis to the corresponding α,β-ethylenic ester[2b] or amide[3] (eqs 13-15).

(13)

(14)

(15)

Oxidation of Propargylic Alcohols.[4]

Propargylic alcohols are easily oxidized by MnO_2 to alkynic aldehydes and ketones (eqs 16-18).[4a-c] In the example in eq 19 the unstable propargyl aldehyde is trapped as a Michael adduct.[4d]

(16)

(17)

(18)

(19)

Oxidation of Benzylic and Heterocyclic Alcohols.[2b,5]

Conjugated aromatic aldehydes or ketones can be efficiently prepared by treatment of benzylic alcohols with MnO_2 (eq 20).[5a] Numerous functional groups are tolerated (eqs 21-24).[5a-c]

(23)

(24)

Benzyl allyl and benzyl propargyl alcohols have been oxidized successfully to ketones (eqs 25 and 26).[5d,e]

(25)

(26)

The oxidation reaction can be extended to heterocyclic alcohols (eq 27)[5f] and the Corey procedure gives the expected esters (eq 28).[2b]

(27)

(28)

Oxidation of Saturated Alcohols.[6]

Cyclic and acyclic saturated alcohols react with MnO_2 to give the saturated aldehydes or ketones in good yields (eqs 29-32).[6a,b]

(29)

(30)

Oxidative Cleavage of 1,2-Diols.[7]

1,2-Diols are cleaved by MnO_2 to aldehydes or ketones. With cyclic 1,2-diols, the reaction leads to dialdehydes or diketones (eqs 33 and 34)[7] and the course of the reaction depends on the configuration of the starting material (eqs 34 and 35).[7]

cis-diol

(34)

trans-diol

(35)

Hydration of Nitriles to Amides.[8]

By treatment with MnO_2, nitriles are readily converted to amides. MnO_2 on silica gel is especially efficient to perform this reaction (eqs 36 and 37).[8a,b]

(36)

active MnO_2	30%
MnO_2, SiO_2	100%

(37)

Dehydrogenation and Aromatization Reactions.[9,13j,q]

MnO_2 has been widely used to carry out various dehydrogenation and aromatization reactions (eqs 38-41).[9a-c] In some

cases the dehydrogenation can occur as a side reaction during, for instance, the hydration of nitriles (eq 37)[8b] or the oxidation of allylic alcohols.[13q]

(38)

(39)

(40)

(41)

It is interesting to note that the use of γ-MnO_2 is essential to achieve the following dehydrogenation reactions (eqs 42 and 43).[13j]

(42)

(43)

Oxidation of Amines to Aldehydes, Imines, Amides, and Diazo Compounds.[10,13g,p]

The oxidation of amines by MnO_2 can lead to various products according to the structure of the starting material. Thus the formation of imines (eq 44),[10] formamides (eqs 45 and 46),[13g] and diazo compounds (eq 47)[13p] have all been described.

(44)

(45)

(46)

Miscellaneous Reactions.[13p,14]

MnO_2 has also been used to perform various oxidation reactions: the oxidative cleavage of α-hydroxy acids (eq 48),[13p] the oxidative dimerization of diarylmethanes (eq 49),[14a] or their conversion to diaryl ketones (eq 50),[14a] the oxidation of aldehydes to carboxylic acids,[13p] the preparation of disulfides from thiols,[14b] of phosphine oxides from phosphines,[13p] or of ketones from amines.[14c]

Manganese(III) Acetylacetonate

[14284-89-0] · $C_{15}H_{21}MnO_6$ · Manganese(III) Acetylacetonate · (MW 352.30)

(one-electron oxidant used to oxidize phenols, β-dicarbonyl compounds, and thiols to the corresponding radical)

Physical Data: lustrous brown crystalline solid; mp 172 °C.[1]

Solubility: slightly sol water; sol acetone, benzene, chloroform, ether, ethanol, ethyl acetate.[1]

Manganese(III) acetylacetonate, $Mn(acac)_3$, was reported to be the most useful manganese(III) reagent for oxidative coupling of phenols.[2,3] For instance, 2-naphthol is oxidized to 2,2´-binaphthol in 69% yield in acetonitrile or carbon disulfide (eq 1).[2] $Mn(acac)_3$ has been used for the intramolecular oxidative coupling of a series of α,o-bis(3,4-dimethoxyphenyl)alkanes.[4] Anodic oxidation gives somewhat higher yields than $Mn(acac)_3$. Intramolecular oxidative coupling with $Mn(acac)_3$ has been used as a key step in the synthesis of (+)- and (-)-galanthamine (eq 2).[5] $Mn(acac)_3$ induces the oxidative cyclization of a phenolic oxime to give the spiroisoxazoline in 50% yield (eq 3).[6] $Mn(acac)_3$ in carbon disulfide oxidizes aryl, alkyl, and benzyl thiols at rt in 1-2 h to disulfides in 85-99% yield.[7]

(1)

(2)

(3)

In the absence of a more readily oxidizable substrate, $Mn(acac)_3$ reacts with alkenes[8,9] and electron-rich arenes[10] to give radicals that are oxidized by $Mn(acac)_3$ to give the final product (eqs 4 and 5). The acetylacetone radical is probably not an intermediate in these reactions.[11]

(4)

(5)

Peroxy hemiacetals are prepared by oxidative addition of $Mn(acac)_3$ to alkenes in the presence of oxygen (eq 6).[12]

(-)-(1*R*,2*S*,5*R*)-Menthyl (*S*)-*p*-Toluenesulfinate

[1517-82-4] · $C_{17}H_{26}O_2S$ · (-)-(1*R*,2*S*,5*R*)-Menthyl (*S*)-*p*-Toluenesulfinate · (MW 294.50)

(agent used for the synthesis of chiral sulfoxides[1,3])

Physical Data: $[\alpha]_D$ = -202° (acetone, *c* = 2.0).

Preparative Method: obtained by reaction of (-)-menthol with *p*-toluenesulfinyl chloride. This esterification showed no particular stereoselectivity, giving an equal amount of the two sulfinate diastereomers.[1] In order to avoid a chromatographic separation, it is possible to epimerize these sulfinate esters in acidic medium and displace the resulting equilibrium towards the less soluble isomer, (-)-menthyl (*S*)-*p*-toluenesulfinate, in 80% yield (eq 1).[2] This procedure was later extended to large scale preparation.[3]

The absolute configuration of (-)-menthyl (*S*)-*p*-toluenesulfinate was established by correlation with (-)-menthyl *p*-iodobenzenesulfinate, known from X-ray diffraction analysis.[4]

Synthesis of Chiral Sulfoxides.

Alkyl Sulfoxides.

Any Grignard reagent reacts with (-)-menthyl (*S*)-*p*-toluenesulfinate and displaces the menthoxy group with complete inversion of configuration at sulfur (eq 2; R = Me,[3,5] Et,[5,6] *n*-C_6H_{13}[7]).

It was also reported that using methyllithium instead of the methyl Grignard could give some racemization of methyl *p*-tolyl sulfoxide as a result of methyl group exchange via a methylene sulfine intermediate.[8]

(*R*)-4-Substituted cyclohexylmethyl *p*-tolyl sulfoxide (**1**)[9] as well as (*R*)-4-hydroxybutyl *p*-tolyl sulfoxide (**2**)[10] and (*R*)-3-butenyl *p*-tolyl sulfoxide (**3**)[11] were also obtained by reaction of (-)-menthyl (*S*)-*p*-toluenesulfinate and the corresponding Grignard reagent.

(1)

R = Me, $MeOCH_2$, $ClCH_2$

(2)

(3)

Vinyl Sulfoxides.

A stereocontrolled preparation of (*E*)-1-alkenyl *p*-tolyl sulfoxide from (-)-menthyl-(*S*) *p*-toluenesulfinate was reported (eq 3).[12a]

(3)

One example was also reported showing the formation of an (*E*)-alkenyl sulfoxide in the reaction of a vinylic lithium compound on menthyl sulfinate (eq 4).[12b]

(4)

(+)-(*S*)-2-(*p*-Tolylsulfinyl)-2-cyclopentenone was also prepared by reaction of a vinyllithium derivative and menthyl

sulfinate (eq 5).[13]

The preparation of optically pure (*E*)- and (*Z*)-1-alkenyl *p*-tolyl sulfoxides was described via stereoselective reduction of 1-alkynyl *p*-tolyl sulfoxides (eq 6).[14]

Alkynic sulfoxides have been made from trimethylsilylethynylmagnesium bromide and the resulting alkyne disilylated on silica gel (eq 7).[15]

(7)

Chiral vinyl sulfoxides can also be prepared by a Horner-Emmons reaction of carbonyl compounds with α-phosphoryl sulfoxides which are obtained from lithiated dimethyl methylphosphonate and (-)-menthyl (*S*)-*p*-toluenesulfinate (eq 8).[16] However, this reaction applied to carbonyl compounds often gives a mixture of the (*E*) and (*Z*) isomers of the vinylic sulfoxide.

(8)

The reaction of α-phosphoryl sulfoxide with the dimethyl acetal of pyruvic aldehyde allowed the preparation of the corresponding vinylic sulfoxide as a 1:1 mixture of (*E*) and (*Z*) isomers which could be isomerized with ***Lithium Diisopropylamide*** to the lithiated (*E*) isomer, used for the asymmetric synthesis of α-tocopherol (eq 9).[17]

(9)

The Wittig reaction of an optically active sulfinylphosphonium ylide was reported to yield only the (*E*)-vinylic

sulfoxides (eq 10).[18]

Diaryl Sulfoxides.

Optically active diaryl sulfoxides are prepared by reaction of an aryl Grignard with (-)-menthyl (*S*)-*p*-toluenesulfinate: 2,5-dimethoxyphenyl *p*-tolyl sulfoxide (**4**), a precursor of sulfinyl quinones,[19] and 3-pyridyl *p*-tolyl sulfoxide (**5**), a precursor of sulfinyl dihydropyridines (studied as NADH model compounds)[20] are two typical examples.

(4) **(5)**

Sulfinyl Esters and Derivatives.

(*R*)-(+)-*t*-Butyl 2-(*p*-tolylsulfinyl)acetate is conveniently prepared by reaction of the magnesium enolate of *t*-butyl acetate (readily made with ***Bromomagnesium Diisopropylamide***) with (-)-menthyl (*S*)-*p*-toluenesulfinate (eq 11).[21]

(11)

Substituted sulfinyl esters (**6**) have also been prepared by this reaction using the same base[22a] or lithium cyclohexyl(isopropyl)amide,[22b] which gives higher yields.

(6) R = Me, Et, $C_{14}H_{29}$

The anion of acetonitrile also reacts with (-)-menthyl (*S*)-*p*-toluenesulfinate to give the corresponding β-sulfinylacetonitrile (eq 12).[23]

(12)

Similarly, *exo*-metalation with LDA of the racemic 3-methyl-4,5-dihydroisoxazole and reaction with (-)-menthyl (*S*)-*p*-toluenesulfinate afforded the sulfinyl-4,5-dihydroisoxazole as a diastereomeric mixture;[24] lithiated *N*,*N*-dimethylthioacetamide leads to the sulfinyl *N*,*N*-dimethylthioacetamide,[25] and lithiated ethyl *N*-methoxyacetimidate leads to *p*-tolylsulfinylethyl-*N*-methoxyacetimidate (eq 13).[26]

(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate

(13)

β-Keto Sulfoxides.

Cyclic β-keto sulfoxides are readily obtained from the magnesium enolate of the ketone and (-)-menthyl (*S*)-*p*-toluenesulfinate[27] as a mixture of diastereomers in which the major epimer has the sulfoxide group in the equatorial orientation (eq 14).

(14)

By condensation of the dianion of *t*-butyl acetoacetate and (-)-menthyl (*S*)-*p*-toluenesulfinate, the corresponding β-keto sulfoxide was obtained in high yield (eq 15) and shown to be an efficient precursor of both enantiomers of β-hydroxybutyric acid via selective reduction of the ketone carbonyl group.[28] β,δ-Diketo sulfoxides were prepared in a similar way from diketone dianions (eq 16).[29]

(15)

Imino Sulfoxides.

Metalated imines reacted with (-)-menthyl (*S*)-*p*-toluenesulfinate to yield the corresponding sulfinylimines as a diastereoisomeric mixture (eq 17).[30]

Similarly, *exo*-metalated cyclic imines afforded the sulfinylimines as an alkaloid precursor (eq 18).[31]

Miscellaneous.

(*S*,*S*)-Bis(*p*-tolylsulfinyl)methane (**7**) is readily prepared from (-)-menthyl (*S*)-*p*-toluenesulfinate and (*R*)-methyl *p*-tolyl sulfoxide.[32] (+) (*S*)-*p*-Tolylsulfinylmethyl *t*-butyl sulfone (**8**) was made from the *t*-butyl methyl sulfone anion and (-)-menthyl (*S*)-*p*-toluenesulfinate.[33]

Chiral *N*-benzylidene *p*-toluenesulfinamides were prepared by reaction of benzonitrile with an alkyllithium followed by

addition of (-)-menthyl (*S*)-*p*-toluenesulfinate and converted into optically active amines and amino acids (eq 19).[34]

2-Mercaptoethanol

[60-24-2] · C_2H_6OS · 2-Mercaptoethanol · (MW 78.15)

(synthesis of 1,3-oxathiolanes from ketones; reducing agent for fluorimetric assay of amino acids)

Physical Data: bp 157-158 °C; flash point 73 °C; *d* 1.114 g cm^{-3}; *n*20D 1.4996.

Solubility: sol alcohols, Et_2O, benzene; sparingly sol H_2O.

Form Supplied in: liquid; commercially available.

Analysis of Reagent Purity: mp of 2-(2,4-dinitrophenylthio)ethanol is 101-102 °C.[1]

Preparative Methods: by reaction of ethylene chlorohydrin with ***Sodium Hydrogen Sulfide*** or ***Potassium Hydrogen Sulfide***;[2] by treatment of bis(β-hydroxyethyl) disulfide with zinc dust in aqueous alcoholic sulfuric acid at 40 °C;[3] or by reaction of ***Ethylene Oxide*** (2 mol) and ***Hydrogen Sulfide*** (1 mol) in thiodiglycol at 45-60 °C.[4]

Purification: by distillation (bp 157-158 °C).

Handling, Storage, and Precautions: can be stored as colorless, odorous liquid in a refrigerator for several months without significant coloration developing. Toxic by inhalation, in contact with skin and if swallowed. Irritating to eyes, respiratory system, and skin. Stench; can be incinerated neat for disposal. Use in a fume hood.

Synthesis of 1,3-Oxathiolanes from Ketones.[5]

The synthesis of 1,3-oxathiolanes from ketones constitutes one of the principal synthetic applications of 2-mercaptoethanol (eq 1). It was found that using 1 equiv of ***Boron Trifluoride Etherate*** in the reaction gave highest yields of 1,3-oxathiolanes. Reducing the amount of solvent below 750 mL per mol of ketone reduced yields of oxathiolanes and increased yields of polymeric materials.

Conversion of Steroidal Ketones to Ethylenehemithioacetals (1,3-Oxathiolanes).

2-Mercaptoethanol was introduced by Djerassi[6] for the conversion of steroidal ketones to ethylenehemithioacetals (1,3-oxathiolanes) (eq 2). These are more readily reconverted to the ketone (using Raney nickel) than the similar ethylene thioacetals. The simplest procedure uses boron trifluoride etherate as catalyst.[7]

Fluorimetric Assay of Amino Acids.

o-Phthaldialdehyde reacts with amino acids in alkaline medium in the presence of 2-mercaptoethanol, as reducing agent, giving rise to fluorescent compounds.[8] This permits fluorimetric assay of amino acids down to the nanomolar range. The sensitivity is better than with ninhydrin procedures. The amino acids proline and hydroxyproline are not detected by the method.

Mercury(0)

Hg

[7439-97-6] · Hg · Mercury(0) · (MW 200.59)

(photosensitizer for C-H bond cleavage reactions;[1-6] solvent for metals to give amalgams which can act as selective reducing agents;[8-19] heterogeneous catalyst poison, especially for Group 10 metal catalysts;[22] electrode material in electrosynthesis[24])

Physical Data: mp -38.87 °C; bp 356.6 °C; *d* 13.6 g cm^{-3}.

Solubility: sparingly sol organic solvents and water.

Form Supplied in: silvery liquid; widely available; electronic grade (foreign metals <=1 ppm) and ACS grade (99.9995%) are available, normally making purification unnecessary.

Handling, Storage, and Precautions: as a volatile heavy metal, care must be taken to prevent long term inhalation of the vapor. Carrying out reactions in a fume hood, cleaning up spills, and assuring that the air handling system of the laboratory is operating normally is generally sufficient.

Mercury Photosensitization.

This allows the dehydrodimerization of a variety of volatile organic molecules on a 1 to 50 g scale without a solvent in a simple apparatus which can be put together from standard laboratory photochemical equipment.[1-5] A 254 nm low-pressure mercury lamp is used, together with quartz glassware. The reactive triplet excited state of mercury is usually designated Hg*. The reaction happens in the vapor phase at rt and pressure, but no special precautions have to be taken; the normal vapor pressure of the substrate is usually enough to replenish the vapor above the substrate when reaction has taken place. Mercury is supplied in the form of a small mercury drop in the substrate. Normal laboratory glassware can contain sufficient adsorbed mercury so that Hg photosensitized reactions can occur. To obtain a valid control experiment in the absence of mercury, it is sometimes necessary to anneal the glassware in a glassblower's oven. This implies that care needs to be taken in interpreting the results of what are ostensibly normal or nonmercury photosensitized reactions where special care to remove trace mercury may not have been taken.

The liquid phase is unreactive and this has important effects on the selectivity of the reaction. Dehydrodimerization or functionalization always leads to the condensation of the product, which protects it from further reaction and so the substrate only undergoes one homolysis even if there are several C-H bonds of similar strength. To take a simple example, cyclohexane dimerizes to bicyclohexyl with no further oligomerization. The origin of the nonreactivity of the liquid phase is probably that the very narrow atomic absorption line for vapor-phase mercury is broadened and shifted

when the mercury is dissolved. Perfect matching of the emitter and absorber in the vapor phase, where both are vapor-phase mercury atoms, leads to efficient energy transfer in the vapor; energy transfer is probably poor for dissolved Hg. The use of a high-pressure mercury lamp (or even allowing the temperature of the lamp to become abnormally high) causes the selectivity of the reaction to change sharply for the worse, presumably because absorption can now take place in the liquid phase and so condensation no longer protects the condensate from further reaction.

The absorption coefficient for mercury vapor is so large that all the light is absorbed within a few micrometers of the inside surface of the reactor and so the bulk of the vapor is protected from irradiation. This means that normal organic photochemistry is severely suppressed; essentially all the energy is absorbed by the mercury atoms, leaving none to excite the much more weakly absorbing organic species. Absorption of the 254 nm line is responsible for the chemistry described here, and so the excited state responsible is the $^3P_1$ state of mercury. The quartz glassware is transparent to the 254 nm line, allowing for efficient transmission to the reaction zone.

A useful modification for certain substrates is the use of a reactive atmosphere. In this case, the temperature is typically adjusted so that the vapor pressure of the substrate is 100 Torr. This is necessary so that the reactive gas has a substantial partial pressure (*P*) in the reaction zone; in the case where the substrate has a *P*(substrate) of 100 Torr, the *P*(reactive gas) would be 660 Torr. The two most useful reactive gases are H_2 (Hg*/H_2 conditions)[4] and NH_3 (Hg*/NH_3 conditions).[5] The reason for moving to these reactive gases is that the standard conditions, with reflux under N_2 (Hg* conditions), completely fail when the Hg* attacks a functional group in the substrate. This typically happens for substrates having multiple bonds or N lone pairs. Under Hg*/H_2 or Hg*/NH_3 conditions, H atoms take over from Hg* as the active species, and a much wider range of substrates are reactive. For example, NEt_3 fails to react at all under Hg* conditions, presumably because Hg* attacks the N lone pair, and energy transfer leads to thermal excitation of the substrate but not to productive chemistry. Under Hg*/H_2 conditions the compound undergoes dehydrodimerization at the C-H bond α to N. Arenes seem to work best under Hg* conditions, probably because H atom addition leads to undesired and unselective partial saturation of the aromatic ring. In practice there is little point in attempting to predict what will happen with a given substrate because it is easy to try Hg* conditions first and then move to Hg*/H_2 conditions if the results are unsatisfactory.

In each case, the crude product is collected by removing the volatile starting material by rotary evaporation after the reaction is over. The main limitation is that the substrate be volatile, but compounds with up to 16 nonhydrogen atoms have been successfully dimerized. The reaction proceeds under reduced pressure if this is useful to vaporize the substrate. Another useful modification is to use steam distillation to bring the substrate into the vapor phase; in this variant, water is added to the substrate and the mixture is refluxed. The weakest C-H (or X-H) bond in the molecule is homolyzed and the resulting C-centered (or, in general, X-centered) radicals recombine. That part of the radical pool which disproportionates instead of recombining does not in general lead to lower chemical yield because the H atoms present add to the alkene disproportionation product and re-form the initial radical. Quantum yields of 0.04-0.8 are usual and the majority of substrates have values in the range 0.2-0.6. Chemical yields are good to excellent (40-98%). Conversions depend on photolysis time.

The great advantage of the method is that it allows a number of difficult synthetic transformations to be carried out in one step. The synthesis of a few simple compounds that are otherwise very difficult to make is shown below. In the diamine synthesis, Hg*/NH_3 conditions gave the best results (eq 1).

(1)

A variant, hydrodimerization of alkenes, takes place under Hg^*/H_2 conditions (eq 2). The H atoms add to the terminal carbon of the alkene to give the intermediate radical shown.

(2)

Another useful feature is the facility with which two different substrates cross dimerize (eq 3).

(3)

In suitable cases, the volatility or polarity differences among the three allow easy separation by distillation or chromatography (eq 4).

(4)

The intermediate radicals can undergo rearrangement in special cases, as in the case of hexenyl radicals which cyclize. Trapping the intermediate radicals with CO, SO_2, and O_2 has proved possible, giving aldehydes, ketones, sulfonic acids, and hydroperoxides.[6]

Since methane has strong C-H bonds, it only reacts well under Hg^*/NH_3 conditions to give CH_2=NH as product.[5a] Arenes do not undergo cleavage of the strong aryl C-H bonds but benzylic C-H bonds of side chain alkyl groups can be cleaved under Hg* conditions; neither Hg^*/H_2 nor Hg^*/NH_3 conditions seem to be useful for arenes, however, probably because H atoms readily add to arene rings to give a complex mixture of products.

Reduction.

Ultrasonically dispersed mercury reduces α,α´-dibromo ketones to an intermediate that is believed to be a mercurated 2-oxyallyl species which gives a 4-methylene-1,3-dioxolane with acetone.[7]

Amalgams.

This is a traditional and well-established application of Hg^0. Metallic mercury readily forms amalgams with most metals but Na/Hg, Al/Hg, and Zn/Hg are the most useful in organic chemistry. The mercury serves both to keep the surface of the metal clean (because inorganic salts adhere poorly to the amalgam) and to dilute the active metal (and so moderate its thermodynamic reducing potential), which can improve the selectivity of the reduction.

Sodium Amalgam.

Sodium Amalgam is a liquid up to 1%, semisolid at 1.2%, and a pulverizable solid at higher concentrations, except in a narrow range around 40% Na, where the material is a low melting (<30 °C) solid. These materials can be made from elemental Na and Hg (*caution*: much heat is evolved) and analyzed by titration with acid.[8] Na/Hg is useful for the reduction of α,β-unsaturated carboxylic acids to the saturated forms, and for the Emde degradation of a quaternary amine (eq 5).[9] The reduction of aldonolactones to aldoses with Na/Hg is a key transformation in sugar chemistry.[10] Oximes are readily reduced to amines.[11]

(5)

Aluminum Amalgam.

Aluminum Amalgam, readily prepared[12] by treating base-etched elemental aluminum with aqueous mercury(II) salts, is a useful replacement for Na/Hg when the compound to be reduced is base sensitive. Diethyl oxaloacetate can be reduced to diethyl malate (70-80% yield) (eq 6) and aryl ketones can be reduced to the corresponding pinacols (30-60% yield) (eq 7) in this way.[12] Desulfurization of disulfides is also possible.[13]

(6)

(7)

Dienes undergo what is effectively a 1,4-addition of H_2 to give the monoenes, and cumulenes undergo a 1,2-reduction.[14] The C-S bond in α,β-unsaturated phenyl sulfones can be hydrogenolyzed stereospecifically to give the alkene in excellent yield.[15] Net hydrogenolysis of a P=C bond is involved in the sequence shown in eq 8, in which an acyl halide is converted to a keto ester.[16a]

In a recent synthesis of mannostatin A, King and Ganem have shown how the N-O bond of a cyclic acyl-nitroso compound can be hydrogenolyzed by Al/Hg (eq 9).[16b]

Zinc Amalgam.

The classic use of ***Zinc Amalgam*** is the Clemmensen reduction of ArCOR to $ArCH_2R$.[17] Variants of this method have proved successful for specific substrates.[18] The nitroalkene closure shown in eq 10 is a more recent application of Zn/Hg.[19]

Ultrasound[20] and Rieke[21] methods are increasingly being used as an alternative to Hg amalgamation for activating metals, a trend encouraged by disposal problems of mercury-contaminated wastes.

Catalyst Poison.

Mercury selectively poisons heterogeneous catalysts, particularly of the platinum group metals (PGM). This can be useful when a homogeneous PGM catalyst decomposes with time to give the free metal; in such a case, Hg^0 can suppress the heterogeneous component of the reaction.[22] This can improve selectivity or give mechanistic information about which products are attributable to which pathway.

Potential Route to Organomercury Compounds from Hg^0.

Organomercury compounds are synthetically accessible[23] from metallic mercury by a number of routes, including reaction of elemental mercury with alkenes in acid medium and with acyl and alkyl halides (under thermal or photochemical conditions). Organic synthetic applications of this chemistry seem to be very rare, however.

Electrolysis at Mercury Cathodes.

The high overvoltage of a mercury surface in several electrochemical processes is often used to advantage; for example, proton reduction to H_2 is kinetically disfavored relative to electron transfer to an organic substrate. An example of an organic electrochemical application is provided by reduction of a number of alkyl halides, RX, to the radical, R&bdot;, which dimerizes to R_2, disproportionates to RH and the corresponding alkene, and also leads to the formation of R_2Hg.[24]

Mercury(II) Acetate

$Hg(OAc)_2$

[1600-27-7] · $C_4H_6HgO_4$ · Mercury(II) Acetate · (MW 318.69)

(inter- and intramolecular oxy-,[1-3] amino-, and amidomercuration[1,40,43,47] of alkenes and alkynes; cleavage of cyclopropanes;[64,65] mercuration of aromatics;[75] *o*-mercuration of phenols;[76] mild oxidation[101,102])

Alternate Name: mercuric acetate.

Physical Data: mp 179-182 °C; bp dec; *d* 3.28 g cm^{-3}.

Solubility: sol CH_2Cl_2, AcOH; slightly sol alcohols; insol benzene, hexane, etc.; sol H_2O (slowly hydrolyzed to HgO).

Form Supplied in: white, hygroscopic crystals. *Drying:* recrystallization from AcOH followed by storage in a desiccator.

Handling, Storage, and Precautions: acute poison. $Hg(OAc)_2$ is easily absorbed through the skin and is corrosive. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Oxymercuration.[1,2]

Electrophilic Hg^{2+} is capable of attacking alkenic double bonds to effect Markovnikov addition,[3] typically with *anti* stereochemistry (eq 1).[4,5] However, *syn* attack can be enforced if the *anti*-face is severely hindered;[4] thus norbornene,[5] *trans*-cyclooctene,[6] and *trans*-cyclononene[6] give *syn* addition products.[6] Solvomercuration occurs in hydroxylic solvents (water or alcohols)[1,7,8] except when *t*-BuOH is utilized.[7] Using Hg^{II} salts with less nucleophilic anions (e.g. $CF_3CO_2^-$) improves the yields of the solvomercuration products.[7] In the presence of Cl_2 or Br_2, the HgX group in the original adduct is replaced by halogen.[7] Peroxymercuration of alkenes occurs in the presence of peroxides.[9] Methoxymercuration of alkynes[10] or allenes[11] in methanol gives mercurated vinyl ethers (eq 2),[10] whereas vinyl acetates are formed in AcOH.[12] Mercury(II) acetate also catalyzes the perborate or MoO_5.HMPA-mediated oxidation of terminal alkynes to α-acetoxy ketones (eq 3).[13]

(1)

(2)

(3)

Although mercuration exhibits features common to most electrophilic additions,[14] it differs in details. Thus the rate-limiting step for mercuration is the cleavage of the intermediate mercuronium ion by a nucleophile; in contrast, bromination proceeds by the rate-limiting formation of the bromonium ion.[15]

Mercuration is very sensitive to steric factors in which it parallels hydroboration.[16] The following reactivity of alkenes has been observed: terminal disubstituted > terminal monosubstituted > internal disubstituted >> trisubstituted > tetrasubstituted (eq 4);[17] *cis*-alkenes are more reactive than their *trans* counterparts[17] and enol ethers are much more reactive than any other alkene.[18] Attempted asymmetric mercuration in the presence of cyclodextrin or in chiral micelles has only been partly successful, giving 3-55% ee; in one case the ee was 96%.[19]

(4)

Neighboring group participation can be employed to construct cyclic structures such as tetrahydrofurans and tetrahydropyrans[3c,20-22] (eqs 5 and 6),[3c,20,21] spiroacetals (eq 7),[23] lactones,[24] and cyclic peroxides,[25] or to introduce a hydroxy group stereoselectively.[26] 4-Pentynoic acid reacts with $(AcO)_2Hg$ to produce α´-angelicalactone (eq 8).[27] A neighboring ether or hydroxy group can steer the approach of Hg^{2+} to the double bond by coordination and thus exercise a relatively high degree of stereocontrol (up to 93% de).[28]

(5)

(6)

(7)

(8)

The adducts can be demercurated by hydrides (e.g. ***Sodium Borohydride***)[1] or sulfur compounds (***1,3-Propanedithiol*** or ***Sodium Trithiocarbonate***)[29,30] so that the method can be used as a formal addition of ROH across a double bond. While the hydride reduction may result in inversion (4:1), predominant retention of configuration (20:1) has been reported for the latter method.[29,30] The hydride reduction proceeds via a C-centered radical which can be trapped in a number of ways, e.g. by addition across an electron-deficient double bond[31-34] (eqs 9 and 10),[31,32] or by oxygen.[35] The latter method (O_2/$NaBH_4$) replaces HgX with OH.[1,36] Transmetalation of organomercurials by palladium is another option.[1,36]

(9)

(10)

On treatment with bromine, NBS, NBA, or KBr_3, organomercurials are converted into the corresponding halides[37] (in a nonstereoselective fashion[38]). If applied to α,β-unsaturated acids,[37a,b] this reaction can be employed as a key step for the synthesis of serine or threonine (eq 11).[39]

(11)

Amino- and Amidomercuration.

Amino alkenes can similarly be cyclized by $(AcO)_2Hg$ to afford various nitrogen heterocycles[22b,d,e,40] via a 5- or 6-(N)^n-*exo-trig* pathway (eq 12).[41] This method has also been applied to the synthesis of indoles.[42] An interesting intra/intermolecular version has been developed for the stereoselective synthesis of piperidines (eq 13).[43,44]

(12)

(13)

Intramolecular amidomercuration is another variation on the same theme[32-34,35d,45] which works even with β-lactams (eq 14).[46] Intermolecular amidomercuration can be accomplished in acetonitrile through a Ritter-type reaction.[47]

(14)

Unsaturated oximes also undergo a ring-closure reaction on treatment with $(AcO)_2Hg$ to produce nitrones which can be trapped via a [3 + 2] cycloaddition (eq 15).[48]

(15)

3-Alken-1-ynes undergo catalytic aminomercuration in the presence of $(AcO)_2Hg$ or HgCl at elevated temperatures to produce enamines.[49] By contrast, propargylic alcohols (HC&tbond;CCH_2OH) undergo oxidative aminomercuration to afford bis-aminated aldehydes, e.g. (*Z*)-PhNHCH=C(NHPh)CH=O.[50] Catalytic aminomercuration of protected propargylic alcohols gives enamines, $CH_2=C(NR^1{}_2)CH_2OR^2$, as the result of a regioselective Markovnikov addition-demercuration.[51] Dipropargyl ethers produce aminofurans.[51]

Polyene Cyclization.

Treatment of dienes or trienes with $(AcO)_2Hg$ triggers cyclization analogous to the Johnson polyene cyclizations.[52,53] The HgX group in the resulting cyclic organomercurial can best be eliminated to afford the corresponding alkene by photochemically induced transmetalation with ***Diphenyl Diselenide*** followed by standard selenoxide elimination.[54] Allenes with another alkenic bond can also be employed in this cyclization.[55] By contrast, 1,4-cyclohexadiene gives a mixture of mono- and bis-methoxymercurated products with no transannular C-C bond formation.[56]

Addition of Alcohols to Vinyl Ethers.

Vinyl ethers such as CH_2=CHOEt undergo a formal exchange reaction with another alcohol in the presence of $(AcO)_2Hg$, which occurs via elimination of EtOH from the intermediate.[1,57] Acetals can also be isolated from this reaction.[18,58] Similar reactions occur with vinyl esters (e.g. vinyl acetate)[59] and vinyl thioethers.[60] Ketone trimethylsilyl enolates give α-mercurio ketones[61] which are capable of the ***Boron Trifluoride Etherate***-catalyzed aldol condensation with aldehydes;[62] the reaction exhibits a high degree of *syn* stereoselectivity, comparable with that obtained from the Zr or Ti enolates.[61]

Mercuration of Enamines.

Enamines react with $(AcO)_2Hg$ in DMF to give intermediate iminium salts ($R^1{}_2N^+$=CHC(HgOAc)R^2R^3), which are reduced with $NaBH_4$ to afford the corresponding tertiary amines $R^1{}_2NCH_2CHR^2R^3$ (50-90%).[63]

Ring Opening of Cyclopropanes.

The cleavage of cyclopropanes with Hg^{II} occurs[34,64] predominantly with inversion of configuration at the carbon attacked by Hg^{2+} (corner opening)[65,66] and nucleophiles such as AcO^- or MeOH are incorporated in the product (eq 16).[65] Peroxides can also be employed as nucleophiles to produce the corresponding organic peroxides.[67] Cyclopropenes are either opened on treatment with $(AcO)_2Hg$ to produce allylic acetates[68] or undergo addition across the C=C bond (if the cleavage is suppressed by an electron-withdrawing group).[69]

(16)

Allylic Oxidation.

At higher temperatures (typically 70-150 °C), alkenes are oxidized with $(AcO)_2Hg$ to give allylic acetates (eq 17; the Treibs reaction)[70,71] or dienes;[72] the yields vary in the range 20-70%.[73] Similarly, enolizable ketones and carboxylic

acids undergo α-acetoxylation, but the yield seldom surpasses other methods.[70] Certain alkenes are oxidized to α,β-unsaturated ketones.[74]

(17)

Mercuration of Aromatics.

Being an electrophile, $(AcO)_2Hg$ effects aromatic electrophilic substitution of reactive aromatics.[75] A strong *o*-directing effect of groups capable of coordination with Hg^{2+} has been observed. Thus, for instance, on treatment with $(AcO)_2Hg$ in boiling water followed by NaCl quenching, phenol affords exclusively *o*-chloromercuriophenol (eq 18).[76] Mercuration of the following aromatics and heteroaromatics[37c,d] has been described: acetanilide[77] and its derivatives,[78] aromatic Schiff bases,[79] 3,4,5-trimethoxybenzoic acid,[80] estradiol,[81] α-phenylpyridine,[82] furan,[83] furfuryl diacetate,[84] pyrrole,[83,85] thiophene,[86] 1,3-thiazole,[87] indole,[88] pyrimidines,[89] pyridazines,[90] diazines,[91] trithiadiazepine,[92] ferrocene,[93] tricarbonyl(η-cyclobutadiene)iron,[94] pentamethylruthenocene,[95] Ni^{II}, Pd^{II}, and Pt^{II} porphyrins,[96] and others.[1] Since organomercurials RHgX are readily converted to the corresponding bromide RBr on reaction with Br_2, Hg^{II} salts can serve as effective catalysts in aromatic bromination.[97] An indirect route to mercurioaromatics ArHgOAc is by transmetalation of the corresponding silyl[98] or stannyl[99] derivatives ($ArSiMe_3$ or $ArSnBu_3$) with $(AcO)_2Hg$.[98] The resulting organomercurials can be further transmetalated with borane.[98,99] Reversed transmetalation of organoboranes with $(AcO)_2Hg$ ($R^1BR^2_2$ -> R^1HgX) has also been described.[100]

(18)

Mercuriaromatics are coupled to give bisaryl derivatives on catalytic reaction with $PdCl_2$[101] or $[Rh(CO)_2Cl_2]_2LiCl$[102,103] in a process similar to Ullmann coupling.

Dehydrogenation of Tertiary Amines.

Tertiary amines react with Hg^{II} to generate iminium salts (eq 19), which on treatment with base are converted into enamines.[104] Alternatively, the iminium intermediate can be trapped by an internal nucleophile (eq 19).[105] The reaction is improved by adding ethylenediaminetetraacetic acid (EDTA).[106]

(19)

Miscellaneous Reactions.

$(AcO)_2Hg$ has been found to oxidize α-amino ketones to α-dicarbonyl compounds (50-95%),[107] to effect *cis* -> *trans* isomerization of alkene,[108] to induce hydrolysis of vinyl chlorides to the corresponding ketones (a modification of the Wichterle reaction),[109] to mediate Koenigs-Knorr-type reactions (in analogy to Ag^+),[110] to oxidize β-aminocyclohexenones to *m*-aminophenols,[111] to hydrate nitriles (to give primary amides),[112] to effect oxidative degradation of penicillins,[113] and to mediate Claisen rearrangement.[114] Trialkylboranes R_3B, obtained by hydroboration of alkenes, react with $(AcO)_2Hg$ and I_2 to afford terminal acetates ROAc; this is an alternative to the usual H_2O_2/OH^- oxidation.[115] This B -> Hg -> OAc transformation has also been accomplished with vinylic substrates.[100b] On treatment with $(AcO)_2Hg$ in MeOH followed by demercuration with KSCN, cinnamyl esters $PhCH{=}CHCH_2OCOR$ undergo cleavage to furnish $PhCH(OMe)CH{=}CH_2$ (eq 20). The reaction is catalyzed by HNO_3 (apparently, mercury(II) nitrate is the reactive species) and can be used for protection-deprotection of carboxylic acids.[116]

Related Reagents.

Mercury(II) Acetate-Ethylenediaminetetraacetic Acid; ***Mercury(II) Acetate-Sodium Trimethoxyborohydride***; ***Mercury(II) Nitrate***; ***Mercury(II) Perchlorate***; ***Mercury(II) Trifluoroacetate***; ***Thallium(III) Acetate***; ***Thallium(III) Trifluoroacetate***.

Mercury(II) Acetate-Ethylenediaminetetraacetic Acid

($Hg(OAc)_2$)

[1600-27-7] · $C_4H_6HgO_4$ · Mercury(II) Acetate-Ethylenediaminetetraacetic Acid · (MW 318.69) (EDTA)

[60-00-4] · $C_{10}H_{16}N_2O_8$ · Mercury(II) Acetate-Ethylenediaminetetraacetic Acid · (MW 292.28)

(dehydrogenation of tertiary amines,[2] oxidation of tertiary amines to amides[3])

Physical Data: $Hg(OAc)_2$: mp 179-182 °C. EDTA: mp 250 °C (dec).

Solubility: sol CH_2Cl_2, AcOH; slightly sol alcohols; insol benzene, hexane, etc.

Preparative Method: by simply mixing the two commercially available reagents in an appropriate solvent.

Handling, Storage, and Precautions: acute poison. $Hg(OAc)_2$ is easily absorbed through the skin and is corrosive. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

The addition of EDTA to Hg^{II} salts has a beneficial effect on the selectivity of dehydrogenation of tertiary amines (see also ***Mercury(II) Acetate***).[1] Thus papaverin has been reported to produce a mixture of two dehydrogenated products (eq 1) when treated with equal amounts of $(AcO)_2Hg$ and EDTA. By contrast, in the absence of EDTA, papaverin is cleaved at the methylene bridge.[2] Amine oxidation has also been employed in the construction of ajmalicine (eq 2)[3] and yohimbine.[4] In this case, only 2 equiv of Hg^{II} are required as opposed to 5 equiv if $(AcO)_2Hg$ is used alone.[4]

(1)

(2)

The mixture of $(AcO)_2Hg$ and EDTA can also convert oxidizable tertiary amines into lactams (eq 3).[5]

(3)

Related Reagents.

Mercury(II) Acetate; ***Mercury(II) Trifluoroacetate***.

Mercury(II) Acetate-Sodium Trimethoxyborohydride[1]

$Hg(OAc)_2$-$NaBH(OMe)_3$

($Hg(OAc)_2$)

[1600-27-7] · $C_4H_6HgO_4$ · Mercury(II) Acetate-Sodium Trimethoxyborohydride · (MW 318.69)
($NaBH(OMe)_3$)

[16940-17-3] · $C_3H_{10}BNa$ · Mercury(II) Acetate-Sodium Trimethoxyborohydride · (MW 170.83)

(organomercury acetates are powerful reagents for radical carbon-carbon bond formation in combination with borohydrides[1])

Physical Data: mp 178-180 °C (overheating results in decomposition); *d* 3.27 g cm^{-3}.

Solubility: sol ethanol, methanol, acetic acid, ethylene glycol, hot water; slightly sol acetone, ethyl acetate, water.

Form Supplied in: white solid; widely available.

Purification: recrystallization from a mixture of hot ethanol, water, and acetic acid (10:10:1).

Handling, Storage, and Precautions: mercury(II) acetate has a slight acetic odor; forms white light-sensitive crystals. Keep well closed and protected from light. Inhalation of mercury(II) acetate dust should be avoided: wearing of protecting gloves for handling this compound is recommended. Extremely toxic. Use in a fume hood.

Reduction of Organomercury Acetates.

Reaction of ***Mercury(II) Acetate*** with alkenes, cyclopropanes, ketones, organoboron and metalloorganic compounds leads to organomercury acetates.[2] On reduction with ***Sodium Borohydride*** or ***Sodium Trimethoxyborohydride*** they give organomercury hydrides,[3] which are potential precursors for carbon radicals. In the presence of alkenes, crossed-coupled products are formed in a radical chain process. To achieve high yields, electron-poor alkenes like acrylonitrile, vinyl ketones, acrylates, fumarodinitrile, or maleic anhydrides should be used.[4] Compared with the tin method, the mercury method has the advantages of mild reaction conditions (20 °C), short reaction times (30-60 min), and easy workup procedures (after filtration of the precipitated mercury, distillation of the residual product).

Alkenes.

Alkenes with an electron-rich terminal double bond can be coupled with electron-poor alkenes in a one pot reaction.[5] The reaction proceeds via hydroboration of the alkene, transformation of the boron-carbon into a mercury-carbon bond, and reaction with $NaBH_4$ and alkene. The reaction conditions tolerate substituents like Br, Cl, OH, OAc, OTs, OR, and CO_2R. Alkenes with two different substituted double bonds react regioselectively (eq 1).[5] An example of the high stereoselectivity of this method is demonstrated in the reaction of β-pinene (eq 2).[5]

The reaction of mercury salts with electron-rich alkenes yields different β-substituted organomercury acetates via addition of the electrophilic mercury ion to the double bond and subsequent trapping by nucleophilic solvent (water, alcohol, acids).[6] The addition reaction follows the Markovnikov rules (eq 3).[7]

Alkenes with nucleophilic neighboring groups such as alcohols (eq 4), carboxylates (eq 5), amides, amines, and

alkenes, lead to cyclic products in the mercuration/reductive coupling sequence.[8] The nucleophiles act as intramolecular traps for the mercurated alkenes.

(4)

(5)

Cyclopropanes.

The ring opening of cyclopropanes proceeds by attack of mercury acetate at the least substituted ring position and ring opening towards the most substituted position. Different functional groups are introduced into the products by varying solvents (see above).[9] The acyclic organomercury salt can be coupled with an alkene (eq 6).[10]

(6)

Carbonyl compounds can act as precursors for cyclopropanes. An aldehyde or ketone is converted to its trimethylsilyl enol ether which is then subjected to the Simmons-Smith cyclopropanation reaction (eq 7).[11]

Ketones.

Ketones can be coupled with electron-poor alkenes via hydrazones.[12,13] A large variety of ketones can be used; the bulky *t*-butyl group is tolerated (eq 8).[14] With sterically hindered starting materials or less reactive alkenes, as a side reaction the reduction products are formed.

The reactions of norcamphor derivatives illustrate how an electrophilic carbon of a carbonyl group can be coupled with electron-poor alkenes (umpolung) (eq 9).[15]

Mercury(II) Chloride[1]

$HgCl_2$

[7487-94-7] · Cl_2Hg · Mercury(II) Chloride · (MW 271.49)

(electrophilic mercuration of multiple bonds;[1] cleavage of vinyl sulfides and thioacetals;[17] transmetalation;[1] preparation of amalgams[30-33])

Alternate Name: mercuric chloride.

Physical Data: mp 277 °C; bp 302 °C; *d* 5.440 g cm^{-3}.

Solubility: sol H_2O, alcohol, ether, glycerol, acetic acid, acetone, ethyl acetate; slightly sol benzene, pyridine, CS_2.

Form Supplied in: white rhombic crystals.

Handling, Storage, and Precautions: violent poison; may be fatal if swallowed in 0.2-0.4 g doses. Exposure to any mercury reagent is to be avoided. Teratogen; mutagen; irritant. Reacts violently with K, Na. Releases toxic Hg vapor when heated to decomposition. Handle in a fume hood.

Electrophilic Attack on Multiple Bonds.

Although less electrophilic than other Hg^{II} reagents, $HgCl_2$ has been successfully employed in electrophilic cyclization of various dienes[1,2] (see also ***Mercury(II) Acetate***) (eq 1);[3] an allylic hydroxyl controls the diastereoselectivity of the latter reaction.[3] Aromatization of certain conjugated systems has also been observed on treatment with $HgCl_2$.[4] Similar to Tl^{I} salts,[5] $HgCl_2$ promotes iodocyclization of alkenic alcohols.[6] In the presence of a halogen (Cl_2 or Br_2), $HgCl_2$ facilitates halogenation of a C=C bond.[2]

Intramolecular aminomercuration of δ,ε-unsaturated amines has also been accomplished with $HgCl_2$[7,8] (eq 2).[8] The stereochemistry of the reaction is solvent dependent[8] and may be reversible.[9]

Terminal alkynes (RC&tbond;CH) add MeOH in the presence of ***Triethylamine*** and a catalytic amount of $HgCl_2$ to give enol ethers of the corresponding ketones ($RC(OMe)=CH_2$).[10] This reaction parallels the well-known $HgSO_4$-catalyzed hydration of alkynes, producing ketones. 3-Alken-1-ynes undergo catalytic aminomercuration in the presence of $HgCl_2$ at 70 °C over 3-6 h to produce enamines.[11] By contrast, propargylic alcohols (HC&tbond;CCH_2OH) undergo oxidative aminomercuration to afford bis-aminated aldehydes, e.g. (*Z*)-PhNHCH=C(NHPh)CH=O.[12] Propargyl amines (HC&tbond;C-CH_2NR_2) add $HgCl_2$ in aqueous HCl to give ClCH=C(HgCl)-CH_2NR_2.[13]

Treatment of silyl enol ethers of ε-alkynic ketones or aldehydes with $HgCl_2$ (1.1 equiv) and ***Hexamethyldisilazane*** (0.2 equiv; acid scavenger) induces cyclization (eq 3).[14]

Enol ethers derived from carbohydrates can be readily converted into carbocycles via a $HgCl_2$-mediated reaction which involves an electrophilic attack at the C=C bond to generate the corresponding ketoaldehyde, which cyclizes

spontaneously via an intramolecular aldol condensation (eq 4).[15]

Aldehydes $RCH_2CH{=}O$ (R = Me, Et) afford α,α-bischloromercurated products on treatment with excess $HgCl_2$.[16]

Hydrolysis of Vinyl Sulfides and Thioacetals to Carbonyl Compounds.[17]

Whereas the hydrolysis of vinyl sulfides to ketones works well with a mixture of $HgCl_2$ and an additive (HgO, $CaCO_3$, or $CdCO_3$), the reaction leading to aldehydes often gives unsatisfactory results. In this case, yields can be dramatically improved if HCl is first added across the double bond of the vinyl sulfide (RCH=CHSPh) to generate R-$CH_2CH(Cl)SPh$. The latter intermediate is then quantitatively hydrolyzed by $HgCl_2$ and water to the aldehyde $RCH_2CH{=}O$.[18]

Thioacetals[19,20] and *O*,*S*-acetals[21] are hydrolyzed by means of $HgCl_2$ to the corresponding carbonyl compounds; addition of ***Calcium Carbonate*** usually improves the yields (see also ***Mercury(II) Chloride-Cadmium Carbonate***). This method, involving spontaneous spirocyclization of the resulting keto group, has been employed in the synthesis of talaromycin B (eq 5).[20]

Methylthiomethyl (MTM) ethers can be converted into 2-methoxyethoxy (MEM), methoxymethyl (MOM), or ethoxymethyl (EOM) ethers on reaction with $HgCl_2$ and $MeOCH_2CH_2OH$, MeOH, or EtOH, respectively, in 70-80% yields.[22]

Addition of $HgCl_2$ to boronate ate complexes derived from *O*,*S*-acetals induces B -> C migration. This sequence has been used to obtain optically pure aldehydes (eq 6).[23] Selenoacetals are similarly hydrolyzed by $HgCl_2/CaCO_3$ in acetonitrile.[24]

Preparation of Organomercurials by Exchange Reactions.

Among the methods developed for the synthesis of organomercurials is the transmetalation of other organometallics with $HgCl_2$ (e.g. ArLi -> ArHgCl or RMgCl -> RHgCl),[1,25] and reactions of aromatic diazonium salts with $HgCl_2$ and copper (ArN_2^+ Cl^- -> ArHgCl).[26] The yields in the latter methods do not exceed 50%.[25] Sodium *p*-toluenesulfinate is also converted into the corresponding organomercurial (MeC_6H_4HgCl) on reaction with $HgCl_2$.[27] Vinylmercury chlorides (RCH=CH-HgCl) can be prepared by transmetalation of the corresponding vinylalanes, which, in turn, are available from terminal alkynes; the transmetalation occurs with >98% retention of configuration.[28] A stable metalated cubane derivative has been obtained by lithiation of the diisopropylamide of cubanecarboxylic acid with ***Lithium 2,2,6,6-Tetramethylpiperidide*** followed by transmetalation with $HgCl_2$.[29] Reversed transmetalation (cubane-HgCl -> cubane-Li) has also been described.[29]

Amalgams.

Mercury(II) chloride has been extensively utilized for the preparation of a variety of amalgams (e.g. Zn,[30] Mg,[31] and Al)[32,33] to be employed in reductive processes such as Clemmensen reduction (with Zn)[30] or pinacol coupling (Mg),[31] and to prepare, for example, aluminum ethoxide[32] and *t*-butoxide.[33]

Miscellaneous.

Penam derivatives result from the $HgCl_2$-promoted ring closure of azetidin-2-one.[34] Mercury(II) chloride seems to be a reagent of choice for isolation of histidine from a mixture of amino acids in the form of an insoluble complex.[35] In combination with iodine, $HgCl_2$ facilitates α-iodination of enolizable ketones and aldehydes.[36]

Related Reagents.

Mercury(II) Chloride-Cadmium Carbonate

$HgCl_2$-$CdCO_3$

($HgCl_2$)

[7487-94-7] · Cl_2Hg · Mercury(II) Chloride-Cadmium Carbonate · (MW 271.49) ($CdCO_3$)

[513-78-0] · $CCdO_3$ · Mercury(II) Chloride-Cadmium Carbonate · (MW 172.42)

(hydrolysis of thioacetals;[1-5] glycosylation[10])

Preparative Method: from the components in situ.

Handling, Storage, and Precautions: acute poison. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

The mixture of ***Mercury(II) Chloride*** and ***Cadmium Carbonate*** serves as a mild reagent for the hydrolysis of thioacetals[1-3] and 1,3-dithianes (eqs 1-3).[4-7] This method is particularly suited to the synthesis of chiral ketones from chiral aldehydes (using the umpolung methodology) because only a little racemization occurs at the α-carbon.[4,5]

(1)

(2)

(3)

Thioacetals derived from aldehydes often give lower yields than those made from ketones; in these cases the ***Mercury(II) Oxide/Boron Trifluoride Etherate*** mixture in THF/H_2O is recommended.[8]

Thioglycosides react with alcohols such as cardenolides in the presence of $HgCl_2$ and $CdCO_3$ to give the corresponding glycosides.[9] This reaction is generally nonstereoselective (e.g. both α- and β-glycosides are formed). However, neighboring group participation can ensure that only one anomer is produced in a kinetically controlled reaction (eq 4).[10]

Mercury(II) Chloride-Silver(I) Nitrite

$HgCl_2$-$AgNO_2$

($HgCl_2$)

[7487-94-7] · Cl_2Hg · Mercury(II) Chloride-Silver(I) Nitrite · (MW 271.49) ($AgNO_2$)

[7783-99-5] · $AgNO_2$ · Mercury(II) Chloride-Silver(I) Nitrite · (MW 153.88)

(nitromercuration[1-4] and synthesis of nitroalkenes from alkenes[4,5])

Form Supplied in: white, odorless needles or powder (both reagents).

Handling, Storage, and Precautions: acute poison. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Mixing ***Mercury(II) Chloride*** and ***Silver(I) Nitrite*** generates $Hg(NO_2)_2$ in situ, which reacts with alkenes to give nitromercuration products with high regio- and stereoselectivity (eq 1).[1-3] The reaction with norbornene occurs without rearrangement, indicating that carbocationic character in the transition state is little developed. On treatment with a base (NaOH or R_3N), the primary adducts undergo an elimination reaction to afford nitroalkenes (eq 1).[4] This two-step transformation represents a general route to nitroalkenes[4] and has been employed in the synthesis of 3-nitrocycloalkenones[5] and (*E*)-2-nitrovinyltrimethylsilane.[6] However, better yields are usually obtained if $AgNO_2/I_2$ is used instead.[7]

Mercury(II) Cyanide

$Hg(CN)_2$

[592-04-1] · C_2HgN_2 · Mercury(II) Cyanide · (MW 252.63)

(glycosidation reagent[1])

Alternate Name: mercuric cyanide.

Physical Data: mp 320 °C dec; *d* 3.996 g cm^{-3}.

Solubility: insol benzene; sol H_2O, alcohol, NH_3; slightly sol ether.

Form Supplied in: colorless, odorless, tetragonal crystals or white powder.

Handling, Storage, and Precautions: acute poison. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Mercury(II) cyanide is sometimes superior to Ag_2CO_3 in the formation of glycosides from bromo sugars with isolated yields up to 90%; $MeNO_2$ or CH_2Cl_2 seem to be the best solvents.[1] Evomonoside, a steroidal cardioactive glycoside, has been prepared from digitoxigenin in 44% yield;[2] attempted synthesis with Ag_2CO_3 failed because of an extensive elimination of the 14β-OH of the aglycon.[2] Nucleosides can be obtained from pyrimidine bases and protected halo sugars by heating with $Hg(CN)_2$ in an inert solvent (toluene, MeCN, or $MeNO_2$).[3]

Mercury(II) Fluoride[1]

HgF_2

[7783-39-3] · F_2Hg · Mercury(II) Fluoride · (MW 238.59)

(fluorinating reagent)

Alternate Name: mercuric fluoride.

Physical Data: mp 645 °C, bp >650 °C, *d* 8.95 g cm^{-3}.

Solubility: hydrolyzes in water; slightly sol MeCN, DMSO.

Form Supplied in: white powder.

Handling, Storage, and Precautions: turns yellow on exposure to moist air; highly toxic.

Metathesis Reactions.

Mercury(II) fluoride has been used to replace chlorine,[2] bromine,[3] and iodine[4] at sp^3 carbon with fluorine, as shown in eqs 1-3. In cases where a typical S_N2 reaction occurs, ***Potassium Fluoride*** in the presence of ***18-Crown-6*** is a better reagent. However, for highly halogenated compounds,[5] HgF_2 is the reagent of choice.

(1)

$$1\text{-}C_8H_{17}Br \longrightarrow \underset{23\%}{1\text{-}C_8H_{17}F} + \underset{27\%}{2\text{-}C_8H_{17}F} \qquad (2)$$

(3)

Addition Reactions.

Alkenes treated with an electrophile in the presence of mercury(II) fluoride add the electrophile and fluoride to give the *trans* product stereoselectively, as shown in eqs 4 and 5.[6,7]

(4)

(5)

α-Fluoro Sulfides.

Thioacetals, on treatment with mercury(II) fluoride in acetonitrile, give rise to α-fluoro sulfides, as shown in eq 6.[8] Treatment of sulfoxides with ***N,N-Diethylaminosulfur Trifluoride*** also results in the formation of α-fluoro sulfides.[9]

(6)

Selective Photochemical Fluorination.

Triphenylacetic acid, triphenylethylene, and triethyl phosphite have been selectively fluorinated in DMSO/HgF_2 solutions under UV-visible illumination (eqs 7-9).[10]

(7)

(8)

(9)

Fluorodecarboxylations have also been accomplished with ***Xenon(II) Fluoride***.[11] Phosphites can also be oxidatively fluorinated with carbonyl fluoride[12] or ***2H-Hexafluoropropyl Azide***.[13]

Mercury(I) Nitrate[1]

$Hg_2(NO_3)_2.2H_2O$

[7782-86-7] · $Hg_2N_2O_6$ · Mercury(I) Nitrate · (MW 561.24)

(synthesis of alkyl nitrates from alkyl halides[3])

Alternate Name: mercurous nitrate.

Physical Data: mp about 70 °C (dec); bp explodes; *d* 4.785 g cm^{-3}

Solubility: insol alcohol, ether; sol H_2O containing 1% HNO_3 (with H_2O alone, basic salt is formed).

Form Supplied in: dihydrate (usual form); colorless monoclinic crystals, usually with slight odor of HNO_3. *Drying:* dehydration in vacuum; however, heating above 100 °C causes decomposition.[2]

Handling, Storage, and Precautions: acute poison. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

While nitrates are frequently prepared from alkyl halides on reaction with ***Silver(I) Nitrate*** in MeCN, mercury(I) nitrate offers a cheaper alternative (eq 1). Yields are high for primary, allylic, and benzylic bromides and satisfactory for secondary bromides. Tertiary bromides react slowly, whereas α-bromo carbonyl compounds are virtually inert.[3]

$$RBr \xrightarrow[-\,HgBr]{HgNO_3} RONO_2 \qquad (1)$$

Benzyl nitrates ($ArCH_2ONO_2$) synthesized in this way give the corresponding aldehydes (ArCH=O) upon reflux with NaOH in aq MeOH.[4]

Mercury(II) Nitrate[1]

$Hg(NO_3)_2.H_2O$

[7783-34-8] · $H_2HgN_2O_7$ · Mercury(II) Nitrate · (MW 342.63)

(oxymercuration;[4-9] amidomercuration;[12,15] cyclopropane cleavage;[17,19] glycosylation[23])

Alternate Name: mercuric nitrate.

Physical Data: mp 79 °C; bp (dec); *d* 4.3 g cm^{-3}.

Solubility: insol alcohol; very sol H_2O (in dilute solutions forms an insol basic salt); sol acetone, THF, DME, dioxane, NH_3, HNO_3, and other dilute acids.

Form Supplied in: transparent, hygroscopic crystals with slight odor of HNO_3. *Drying:* heating of the monohydrate to 55-60 °C/10^{-2} mmHg.[2,3]

Handling, Storage, and Precautions: acute poison. Exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Oxymercuration.

The reactivity of $Hg(NO_3)_2$ is similar to that of other Hg^{II} salts (acetate and trifluoroacetate)[1] so that this reagent can be employed to achieve similar goals such as electrophilic additions. The nitrate is often superior to its relatives (due to its higher electrophilicity) and may exhibit some variations in reactivity.[4] Thus, for instance, conjugated dienes afford products of both 1,4- and 1,2-addition (eq 1).[5,6] By contrast, with $Hg(OAc)_2$, only the 1,2-adduct is formed.[5] In the absence of stronger nucleophiles (in a nonnucleophilic solvent), nitratomercuration has been observed.[7] In the presence of Cl_2 or Br_2, the HgX group in the original adduct is replaced by halogen.[7]

In the presence of ***Hydrogen Peroxide***, alkenes are peroxymercurated[8] on reaction with $Hg(NO_3)_2$ as a result of H_2O_2 being a stronger nucleophile than NO_3^-.

Like other Hg^{II} salts, mercury(II) nitrate effects intramolecular alkoxymercuration of unsaturated alcohols to produce oxygen heterocycles (eq 2).[9] Similar to other electrophilic additions, oxymercuration is a priori a reversible reaction. It has been shown that selecting the method of quenching is crucial to minimize the reversion. Thus, oxymercuration products with rigid, antiperiplanar arrangement of the C-HgX and C-O bonds (eq 2) immediately revert back to the starting material upon treatment with sources of hard halogen anion (NaCl, KBr, $CuCl_2$, etc.). By contrast, quenching with soft reagents (e.g. CuCl) reliably affords the stable chloromercurio compound. Excess of strong acids should be avoided as H^+ catalyzes reversion.[9,10]

In a close analogy to alkenic alcohols, unsaturated hydroperoxides react with $Hg(NO_3)_2$ to give cyclic peroxides which can be further elaborated.[8,11]

Amidomercuration.[12]

The mercuration of terminal or cyclic alkenes with $Hg(NO_3)_2$ in MeCN[2,13,14] affords amides via the Ritter reaction (eq 3).[13] In contrast to the original, strong acid-mediated reaction, this modification is less prone to rearrangements as it proceeds via a mercuronium ion.[13,14] The reaction works with mono- and disubstituted double bonds but fails with trisubstituted alkenes.[14] Other Hg^{II} salts, namely $(AcO)_2Hg$ and $(CF_3CO_2)_2Hg$, are not satisfactory,[13] apparently owing to their lower electrophilicity.

(3)

Primary amides and $TsNH_2$ similarly add across alkenic double bonds to give the corresponding tosylamides.[15] Asymmetric, intramolecular amidomercuration employing chiral carbamates has also been described (eq 4).[16]

(4)

Cyclopropane Ring Opening.[17-19]

Mercury(II) nitrate appears to be the reagent of choice to accomplish stereospecific corner opening[19] of cyclopropyl derivatives (eqs 5 and 6);[19,20] other Hg^{II} salts are less reactive.[19,21] The reaction is also regioselective: the cleavage occurs between the most and the least substituted carbon.[19] The resulting organomercurials can be transmetalated by transition metals (Pd, Mo, Cu) to accomplish a variety of interesting transformations.[19]

(5)

(6)

Glycosylation.

Thioglycosides can be utilized as glycosylating agents in conjunction with anhydrous $Hg(NO_3)_2$ (or $AgNO_3$).[22] Although the reaction normally affords mixtures of α- and β-glycosides,[22] neighboring group participation can render it stereoselective (for discussion and examples, see ***Mercury(II) Chloride-Cadmium Carbonate***).[23]

Miscellaneous.

β-Pinene undergoes a Ritter-type transformation on reaction with $Hg(NO_3)_2$/MeCN[24] to give the starting material for the synthesis of aristoteline[25] and other indole alkaloids (eq 7);[25] the reaction is not enantioselective and gives racemic products.[24,25] Mercuration of enolizable ketones has little synthetic value: thus, for instance, acetone has been found to produce a mixture of nine compounds.[26]

(7)

Related Reagents.

Mercury(II) Acetate; ***Mercury(II) Trifluoroacetate***; ***Mercury(II) Perchlorate***.

Mercury(II) Oxide[1]

HgO

[21908-53-2] · HgO · Mercury(II) Oxide · (MW 216.59)

(promotion of thio-Claisen rearrangement;[2] deprotection of dithianes, dithiolanes,[3] thioorthoesters;[4] synthesis of tetrahydrofurans;[5] oxidizing agent[6-18])

Alternate Name: mercuric oxide.

Physical Data: mp 500 °C (dec); *d* 11.14 g cm^{-3}.

Solubility: sol dilute HCl, HNO_3; insol water, ethanol.

Form Supplied in: commercially available in both yellow and red crystalline forms.

Handling, Storage, and Precautions: highly toxic; oxidizer; protect from light.

Conversion of Ketones into Unsaturated Aldehydes.

Mercury(II) oxide promotes the Wittig-thio-Claisen rearrangement sequence which converts ketones into unsaturated aldehydes (eq 1).[2] The reaction proceeds via formation of an allyl vinyl sulfide followed by rearrangement to form the α-allyl aldehyde.

(1)

Preparation of Aldehydes and Ketones by Hydrolysis of Sulfur-Containing Compounds.

A mixture of mercury(II) oxide/35% aqueous ***Tetrafluoroboric Acid***/THF can be used for the hydrolysis of 1,3-benzodithioles (eq 2), 1,3-benzoxathioles (eq 3), 1,3-oxathiolanes (eq 4), 1,3-dithiolanes (eq 5), and 1,3-dithianes (eq 6).[3] These reaction conditions offer an alternative to those reported by Vedejs and Fuchs[19] which use a mixture of mercury(II) oxide/***Boron Trifluoride Etherate***/THF.

(2)

(3)

(4)

(5)

(6)

Synthesis of Esters by Solvolysis of α-Hydroxy Thioorthoesters.

The use of mercury(II) oxide/50% aqueous tetrafluoroboric acid/THF and an alcohol is a fast and mild procedure for the hydrolysis of α-hydroxy thioorthoesters to the corresponding ester (eq 7).[4]

(7)

Cyclization of Primary and Secondary Alcohols to Yield Tetrahydrofurans.

Primary and secondary unbranched aliphatic alcohols are readily converted into the corresponding tetrahydrofuran derivatives using mercury(II) oxide and ***Iodine*** in carbon tetrachloride (eqs 8 and 9).[5]

(8)

(9)

Synthesis of β-Substituted Polynitroalkyl Vinyl Ethers.

The inherent instability of β-substituted polynitroaliphatic alcohols in acidic and basic media precludes the use of traditional vinyl ether synthesis. The use of mercury(II) oxide/***Trifluoroacetic Acid*** in refluxing dichloromethane permits a one-step, high-yielding synthesis of β-substituted polynitroalkyl ethers (eq 10).[6] The use of mercury(II) oxide alone produces the product in 20-30% yield, whereas the addition of TFA as cocatalyst substantially increases the yield of the desired product.

(10)

Synthesis of *trans*-Cinnamyl Ethers.

Oxidation of allylbenzene using mercury(II) oxide/tetrafluoroboric acid and alcohols in THF forms exclusively *trans*-cinnamyl ethers (eq 11).[7]

(11)

Diamination of Alkenes.

The mercuration of alkenes using mercury(II) oxide and tetrafluoroboric acid in the presence of excess amine leads to the formation of 1,2-diamines (eq 12).[8] Presumably, the reaction takes place via formation of a β-aminomercury(II) tetrafluoroborate which undergoes nucleophilic attack of an amine.

(12)

Hydroxy(alkoxy)phenylamination of Alkenes.

A one-pot procedure for hydroxy(alkoxy)phenylamination of alkenes has been developed using mercury(II) oxide and tetrafluoroboric acid (eq 13).[9] The reaction proceeds through the formation of the aminomercurial from the alkene

followed by reaction with water or alcohol. The ratio of products depends on the substitution pattern on the alkene. For terminal alkenes, the rearranged isomer predominates and cyclic alkenes afford *trans* products (eq 14).[9]

(13)

(14)

Cyclization of Alkynecarboxylic Acids.

A variety of γ-methylenebutyrolactones have been successfully synthesized by cyclization of the appropriate alkynecarboxylic acid with mercury(II) oxide as catalyst (eqs 15 and 16).[10] In some instances the reaction must be run neat; in other cases, solvents such as chloroform, acetone, benzene, dioxane and even refluxing DMF are necessary.

(15)

(16)

In a similar approach, mercury(II) oxide has also been used to catalyze the cyclization of γ-allenic acids into γ-ethylenic δ-lactones (eq 17).[11]

(17)

Preparation of Alkyl Halides.

Alkanes react with a mixture of ***Bromine*** and mercury(II) oxide to afford the corresponding alkyl bromide in good yield (eqs 18 and 19).[12] This combination of reagents is more reactive than bromine or ***N-Bromosuccinimide***. The mechanism has been postulated to proceed through the formation of bromine monoxide in situ as the brominating agent.[12] Primary and secondary alkyl bromides are readily formed, but tertiary bromides and benzylic bromides are rather problematic.

(18)

$$CH_2Cl_2 \xrightarrow[\substack{Br_2 \\ 80\%}]{HgO} CHBrCl_2 \qquad (19)$$

Alkyl and aryl halides can also be synthesized using the Cristol-Firth modification of the Hunsdiecker reaction (eqs 20 and 21).[13,14] Even bridgehead carboxylic acids can be transformed into the corresponding bromide using mercury(II) oxide and bromine. Aromatic acids form insoluble mercury(II) salts which normally lead to lower yields, but it has been found that irradiation of the reaction with a 100 W bulb affords excellent yields.[14] Interestingly, irradiation of reactions of aliphatic acids does not improve the yield and, in some cases, even produces lower yields.

(20)

(21)

Decarboxylation of bridgehead carboxylic acids has been accomplished in two steps. The bromide is formed first followed by reduction with ***Tri-n-butylstannane***. The deuterated analog can be made using tributyltin deuteride (eq 22).[15]

(22)

Oxidation of Phenols and Hydroquinones.

In most cases, mercury(II) oxide can be used instead of ***Mercury(II) Trifluoroacetate*** to oxidize phenols and hydroquinones (eqs 23 and 24).[16] These conditions are attractive in that they do not require the use of an acid scavenger to neutralize the trifluoroacetic acid that is formed during the course of the reaction.

(23)

(24)

Oxidation of Hydrazones.

Aliphatic and aromatic hydrazones are oxidized with mercury(II) oxide to afford the corresponding diazo compound (eqs 25-27).[17] Reaction of the monohydrazones derived from α-diketones give α-diazo ketones, which, upon heating, form ketenes (eq 28).[17] Treatment of the bis-hydrazones of α-diketones with mercury(II) oxide at higher temperatures affords alkynes (eq 29).[17] Seven- and eight-membered cycloalkynes as well as even larger cycloalkynes have been synthesized using this methodology (eq 30).[17]

(25)

(26)

(27)

(28)

(29)

(30)

Hydration of Alkynes.

A mixture of mercury(II) oxide and ***Sulfuric Acid*** effects hydration of alkynes to form the corresponding methyl ketone. This protocol was utilized in the synthesis of some daunomycinone analogs (eq 31).[18]

(31)

Related Reagents.

Mercury(II) Oxide-Bromine; ***Mercury(II) Oxide-Iodine***; ***Mercury(II) Oxide-Tetrafluoroboric Acid***.

Mercury(II) Oxide-Bromine[1]

$HgO\text{-}Br_2$

(HgO)

[21908-53-2] · HgO · Mercury(II) Oxide-Bromine · (MW 216.59) (Br_2)

[7726-95-6] · Br_2 · Mercury(II) Oxide-Bromine · (MW 159.80)

(reagent for the generation of isolable Br_2O,[2] which reacts with alcohols and carboxylic acids to give the corresponding alkyl hypobromites, ROBr,[3] and acyl hypobromites, RCO_2Br,[2c] respectively)

Physical Data: Br_2: mp -7.25 °C; bp 59.5 °C; *d* 3.187 g cm^{-3} (0 °C), 7.59 g dm^{-3} (gas).

Solubility: Br_2: sol water ethanol, ether, chloroform, CS_2.

Handling, Storage, and Precautions: since releasing the used reagent into the environment could be hazardous, one must follow the appropriate regulations. Use in a fume hood.

Reagent for Preparation of Alkyl Hypobromites.[3]

Alkyl hypobromites can be prepared by the reaction of alcohols with this reagent in a manner parallel to the preparation of hypoiodites by the reaction of alcohols with ***Mercury(II) Oxide-Iodine*** (eqs 1 and 2).

$$HgO + 2\,Br_2 \longrightarrow Br_2O + HgBr_2 \qquad (1)$$

$$Br_2O + 2\,ROH \longrightarrow 2\,ROBr + H_2O \qquad (2)$$

The reactive species generated from the combination of ***Mercury(II) Oxide*** and ***Bromine*** is Br_2O, and, in contrast to I_2O from HgO and I_2, it can be isolated.[2] These alkyl hypobromite intermediates dissociate to alkoxyl and bromine radicals upon heating or irradiation with Pyrex-filtered light, as in the case of hypoiodites, and thus can be used for remote functionalization as well as β-scission in a manner similar to that of the hypoiodites. Thus treatment of cedrol with mercury(II) oxide-bromine, followed by irradiation, gives the corresponding cyclic ether (eq 3).[3a] The mechanism is parallel to that for the formation of cyclic ethers from alkyl hypoiodites (see ***Mercury(II) Oxide-Iodine***). An example of the β-scission of an alkoxyl radical generated from alkyl hypobromite is illustrated in eq 4.[3b]

(4)

Reagent for the Modified Hunsdiecker Reaction.[1]

When the silver salt of a carboxylic acid is treated with bromine, the carboxy group is lost as CO_2 and alkyl or aryl bromides are produced. This reaction has been known as the Hunsdiecker reaction.[4] Cristol found that treatment of excess red mercury(II) oxide in a refluxing solution of an aliphatic carboxylic acid in CCl_4 with approximately 1 equiv of Br_2 in the dark gave good yields of the corresponding alkyl bromide (eq 5)[1] (see also ***Mercury(II) Oxide-Iodine***). Subsequently, a number of investigators have reported that the Cristol method is simpler than the original Hunsdiecker method in that it does not require the preparation of the dry silver salt.[5]

$$Me(CH_2)_{16}CO_2H \xrightarrow[\text{2. } \Delta,\ 93\%]{\text{1. HgO, } Br_2\text{, } CCl_4} Me(CH_2)_{16}Br \qquad (5)$$

The reaction involves the formation of RCO_2Br intermediates, followed by the removal of CO_2 via a radical intermediate. Thus cyclopropanecarboxylic acid is converted to bromocyclopropane in 41-46% yield by the treatment of red HgO and bromine in 1,1,2,2-tetrachloroethane (eq 6).[6] 6-Bromo-4-*t*-butylhexanoic acid is converted to 1,5-dibromo-3-*t*-butylpentane (eq 7).[7]

(6)

(7)

Bromination of Alkanes.

The combination of bromine and mercury(II) oxide is a reagent for the radical bromination of alkanes. The reagent, which involves Br_2O as the brominating species, is significantly more reactive than ***Bromine*** or ***N-Bromosuccinimide*** and is applicable to a substitution of the primary and secondary C-H bonds (eq 8).[8]

$$2\,RH + 2\,Br_2 + HgO \longrightarrow 2\,RBr + HgBr_2 + H_2O \qquad (8)$$

Mercury(II) Oxide-Iodine

$HgO-I_2$

(HgO)

[21908-53-2] · HgO · Mercury(II) Oxide-Iodine · (MW 216.59) (I_2)

[7553-56-2] · I_2 · Mercury(II) Oxide-Iodine · (MW 253.80)

(hypoiodite formation; generation of alkoxyl radicals)

Physical Data: see ***Mercury(II) Oxide*** and ***Iodine***.

Solubility: I_2: sol organic solvents (g I_2/100 g solvent, 25 °C): benzene (14.09), CS_2 (16.47), EtOH (21.43), Et_2O (25.20), cyclohexane (2.72), CCl_4 (2.60, 35 °C); sol $CHCl_3$, AcOH, glycerol.

Form Supplied in: both reagents are widely available. HgO: bright red or orange-red solid; yellow when finely powdered. I_2: violet crystals.

Handling, Storage, and Precautions: protect from light. Avoid contact with skin and eyes.

Introduction.

The $HgO-I_2$ combination is widely used for the conversion of an alcohol to a hypoiodite.[1] A nonpolar solvent is generally used for the reaction. Due to the weak RO-I bond (~56 kcal mol^{-1}), hypohalites are generally not isolable but are generated and used in situ. Their subsequent decomposition under thermal or photochemical conditions yields alkoxyl radicals, which are highly reactive and undergo a variety of reactions including H&bdot; abstraction, cleavage of the adjacent C-C bond (β-fragmentation), and addition to unsaturated compounds.

Hydrogen Abstraction.

Intramolecular hydrogen abstraction by an alkoxyl radical is most favored through a six-membered ring transition state (1,5-abstraction) and enables the functionalization of remote unactivated carbons.[2] Interception of the intermediate radical by iodine is then followed by cyclization to give tetrahydrofurans (eq 1).[2a] This Barton-type reaction has been applied extensively in steroid chemistry.[1] Other oxidants, such as ***Lead(IV) Acetate-Iodine*** can also be used, although the $HgO-I_2$ combination has been reported to give a cleaner and higher yielding reaction.[2] An analogous reaction with *N*-nitro amines gives, by way of hydrogen abstraction by a nitrogen-centered radical, *N*-nitropyrrolidines.[3] Although

1,5-hydrogen abstraction is preferred, 1,6-abstraction is possible, particularly in cases where the former is not feasible (eq 2)[2c] or when it leads to stabilized radicals (eq 3).[4] The title reagents have also been used for functionalization at more remote positions,[5] in analogy with the work of Breslow.[6]

β-Fragmentation.

An important reaction of alkoxyl radicals is the homolytic cleavage of the adjacent C-C bond to yield a carbonyl and (generally) the more stable of the two possible carbon-centered radicals. In an early example, Barton found that irradiation of a mixture of cyclopentanol, HgO, and I_2 gives δ-iodovaleraldehyde.[2a] These fragmentation conditions are quite mild, as evidenced by the degradation of a highly functionalized steroidal alcohol to an aldehyde, presumably through an iodo intermediate (eq 4).[7] The β-fragmentation is particularly advantageous when the hydroxy group is located on a ring junction, since medium or large ring ketones can be formed, sometimes with elimination of the expected iodide (eq 5).[8] The factors that determine whether the central or the side-ring bond is broken are not well understood, although the stability of the resulting radical and relief of ring strain appear to be important (eq 6).[9]

An analogous fragmentation process, involving the reaction of lactol-derived hypoiodites, provides a general route to medium and large ring lactones (eq 7).[10] The HgO-I_2 mediated fragmentation of hydroxy groups on nonbridging carbons gives iodoformates, via oxidative fragmentation of a lactol intermediate. Treatment of adamantan-2-ol under these conditions gives oxaadamantane directly, presumably by way of the lactol (eq 8).[11] Related fragmentations have

been studied extensively and offer a general route to cyclic ethers (eq 9).[12] Vicinal diols have been cleaved to the corresponding aldehydes using this reagent system.[2b]

(7)

(8)

(9)

Additions to Unsaturated Compounds.

The title reagent system effects the addition of alkoxy-iodide to an alkene in an inter- or intramolecular sense (eq 10).[13]

Interestingly, the intramolecular addition is possible even for allylic alcohols and yields α-iodo epoxides (eq 11),[14] which are synthetically useful intermediates.[15] The yield of the iodo epoxide is significantly higher in the presence of a small amount of pyridine.

Miscellaneous Reactions.

Advantage has been taken of HgO-I_2 as a source of electrophilic iodide. Thianaphthene can be iodinated using this reagent system (eq 12).[16] Similarly, anisole is iodinated at the *para* position in high yield. The ethylene acetal of *p*-benzoquinone can be made through a two-step sequence in which both steps utilize HgO-I_2, first for electrophilic aromatic iodination and then for the formation of an alkoxyl radical from a hypoiodite intermediate (eq 13).[17]

Mercury(II) Oxide-Tetrafluoroboric Acid

$HgO\text{-}HBF_4$

(HgO)

[21908-53-2] · HgO · Mercury(II) Oxide-Tetrafluoroboric Acid · (MW 216.59) (HBF_4)

[16872-11-0] · BF_4H · Mercury(II) Oxide-Tetrafluoroboric Acid · (MW 87.82)

(capable of diamination[1] and hydroxyamination[2] of alkenes, cycloamination of dienes,[7,8] and of hydrolysis of alkyl bromides;[11] facilitates *m*-iodination of deactivated arenes[9])

Solubility: HBF_4: sol ethereal solvents.

Form Supplied in: HgO: red or yellow precipitate; the yellow form is more finely divided and more reactive than the red form. HBF_4: available as liquid Et_2O or Me_2O complexes.

Preparative Methods: reaction of ***Mercury(II) Oxide*** (red) with ***Tetrafluoroboric Acid*** (Et_2O solution) generates $Hg(BF_4)_2$ in situ.

Handling, Storage, and Precautions: acute poison; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light. Tetrafluoroboric acid is extremely corrosive.

Electrophilic Additions.

Mercury(II) tetrafluoroborate, generated in situ from HgO and HBF_4, appears to be the reagent of choice to promote diamination of alkenes with primary and secondary amines. The reaction occurs in THF at reflux and gives good to excellent yields (eq 1).[1] In the presence of alcohols, hydroxyamination is observed.[2] The structure of the products is consistent with an overall *anti* mechanism, involving aminomercuration followed by replacement of $HgBF_4^-$. The latter step occurs with overall retention,[3] apparently due to the participation of the neighboring nitrogen.[4]

Allylic alcohols are converted into allylic amines with an overall 1,3-rearrangement (eq 2).[5]

The reagent differentiates between di- and trisubstituted double bonds. Thus, for example, only the methylene group of limonene reacts (eq 3). Due to the nonnucleophilic anion, a variety of nucleophiles can be introduced in this way: H_2O (84% yield), MeOH (87%), AcOH (85%), NaN_3 (80%), and MeCN (80%, Ritter reaction).[6]

Conjugated dienes react with primary amines in the presence of HgO/HBF_4 to give products of 1,4-addition as reactive intermediates, which are converted to the corresponding pyrrolidine derivatives via an intramolecular S_N2 reaction (eq 4).[7] Nonconjugated dienes react with 2 equiv of $Hg(BF_4)_2$ to afford the corresponding adduct whose -$HgBF_4$ groups can be replaced by heteroatom nucleophiles such as water in a stereospecific manner (eq 5).[8]

(4)

(5)

Allylic Oxidation.

Allylbenzene ($PhCH_2CH{=}CH_2$) is oxidized with HgO/HBF_4 in the presence of alcohols to afford exclusively *trans*-cinnamyl ethers, e.g. $PhCH{=}CHCH_2OMe$.[2a,9]

Aromatic Electrophilic Substitution.

Aromatic compounds can be iodinated by I_2 in the presence of the HgO/HBF_4 reagent. The orientation obeys the rules for aromatic electrophilic substitution: *ortho* attack is favored over *para* substitution with activated arenes. The method appears to be particularly useful for *meta* iodination of deactivated arenes (up to 99% selectivity).[10]

Hydrolysis of Dithioacetals.

The same reagent, generated in situ from HgO and 35% aq HBF_4 in THF, can hydrolyze dithioacetals and hemithioacetals more effectively than $HgO/BF_3.Et_2O$.[11]

Substitution Reactions.

Alkyl bromides are hydrolyzed by HgO/HBF_4 in THF, dioxane, or CH_2Cl_2 to the corresponding alcohols.[12] Similarly, ethers are obtained if stoichiometric amounts of alcohols are used. The yields range from 55 to 95% (eq 6).[12]

$$R^1Br \xrightarrow[HgO,\ HBF_4]{R^2OH} R^1OR^2 \qquad (6)$$

Mercury(II) Perchlorate[1]

$Hg(ClO_4)_2.3H_2O$

[73491-34-6] · Cl_2HgO_8 · Mercury(II) Perchlorate · (MW 453.55)

(can hydrolyze vinyl halogenides[4] and thioacetals;[5] promotes formation of dialkyl ethers by nucleophilic substitution of alkyl bromides with alcohols;[7] cleaves cyclopropanes[8])

Alternate Name: mercuric perchlorate.

Physical Data: d ca. 4 g cm^{-3}.

Solubility: sol CH_2Cl_2, THF, DME; slightly sol alcohols; insol benzene, hexane, etc.

Form Supplied in: colorless lumps; widely available as the trihydrate.

Preparative Methods: can be prepared in situ by heating ***Mercury(II) Oxide*** and 60% aq $HClO_4$ at 40-60 °C for 1-5 min, or at rt by mixing ***Mercury(II) Acetate*** and $HClO_4$ in DME or THF.

Handling, Storage, and Precautions: acute poison; oxidizer; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg and Cl_2 fumes when heated to decomposition. Protect from light.

Like other Hg^{II} salts, the perchlorate facilitates electrophilic additions across alkenic double bonds.[1,2] Whereas oxymercuration normally occurs with *anti* stereoselectivity, products of *syn* addition have been observed for norbornene.[3]

Mercury(II) perchlorate and other Hg^{II} salts (namely sulfate, nitrate, and tetrafluoroborate) promote hydrolysis of vinyl halogenides to ketones (50-90%). The reaction is not catalytic and is believed to involve oxymercuration/dehalogenation (eq 1; X = Cl, Br).[4] Other Hg^{II} salts, such as $HgSO_4$, $Hg(NO_3)_2$, and $Hg(BF_4)_2$, react similarly.[4]

(1)

Monothioacetals of α-diketones can be converted into α-diketones upon oxidation with $Hg(ClO_4)_2$ (eq 2).[5] Analogous reaction with ***Thallium(III) Nitrate*** in MeOH results in the formation of the corresponding dimethyl monoacetal.[6]

(2)

In the presence of $Hg(ClO_4)_2$, ethers (R^1OR^2) are formed from alkyl bromides (R^1Br) and aliphatic alcohols (R^2OH) via a nucleophilic substitution (R^1, R^2 = Me, Et, $PhCH_2$).[7]

In addition to other Hg^{II} salts, $Hg(ClO_4)_2$ is also very effective in the cleavage of cyclopropanes (eq 3).[8,9]

(3)

Related Reagents.

Mercury(II) Acetate; ***Mercury(II) Nitrate***; ***Mercury(II) Trifluoroacetate***.

Mercury(II) Pivalate

$(t\text{-BuCO}_2)_2Hg$

[32276-77-0] · $C_{10}H_{18}HgO_4$ · Mercury(II) Pivalate · (MW 402.87)

(oxymercuration[2])

Alternate Name: mercuric pivalate.

Solubility: sol THF, DME; insol benzene, hexane, etc.

Preparative Methods: see White et al.[2]

Handling, Storage, and Precautions: acute poison; mercury carboxylates are generally easily absorbed through the skin and are corrosive; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Mercury(II) pivalate has similar synthetic applications as the acetate and other Hg^{II} electrophiles.[1,2] In contrast to, e.g. ***Mercury(II) Acetate***, the pivalate has better solubility in THF and exhibits higher regio- and stereoselectivity in oxymercuration reactions.[3] The pivalate has been employed to conduct the intramolecular oxymercuration which afforded isolineatin in 42% yield after hydride reduction of the intermediate organomercurial (eq 1).[2]

(1)

Related Reagents.

Mercury(II) Acetate; ***Mercury(II) Trifluoroacetate***.

Mercury(II) Sulfate

$HgSO_4$

[7783-35-9] · HgO_4S · Mercury(II) Sulfate · (MW 296.66)

(converts alkynes and vinyl halides into ketones;[1-5,9] facilitates conversion of glucals into furan derivatives[7])

Alternate Name: mercuric sulfate.

Physical Data: mp dec; *d* 6.470 or 7.56 g cm^{-3}.

Solubility: insol H_2O (dec into a yellow, basic sulfate); sol HCl, hot dil H_2SO_4, HNO_3, and conc solution of NaCl.

Form Supplied in: white, odorless, monoclinic crystals, granules, or powder.

Handling, Storage, and Precautions: acute poison; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

In combination with strong acids[1-4] or Dowex 50,[4,5] $HgSO_4$ is often employed as a catalyst for effecting hydration of alkynes, which results in the formation of the corresponding ketones (eq 1). This strategy has been used in the synthesis of 19-norprogesterone[6] and histamine.[3b]

(1)

D-Glucal has been found to produce (2*R*)-(1,2-dihydroxyethyl)furan when treated with $HgSO_4/H_2SO_4$ (eq 2).[7] Other glycals undergo hydration or elimination.[8]

(2)

Similarly to other mercury(II) salts, $HgSO_4$ effects hydrolysis of vinyl halides to ketones[9] and allylic oxidation (Deigès reaction).[10]

Related Reagents.

Mercury(II) Acetate.

Mercury(II) Thiocyanate

$Hg(SCN)_2$

[592-85-8] · $C_2HgN_2S_2$ · Mercury(II) Thiocyanate · (MW 316.77)

(catalyst for addition of HSCN to alkynes[1,2])

Alternate Name: mercuric thiocyanate.

Physical Data: mp ca. 165 °C (dec).

Solubility: slightly sol H_2O, alcohols; sol NH_3 and NH_4 salts.

Form Supplied in: white, odorless needles or powder.

Handling, Storage, and Precautions: acute poison; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light.

Mercury(II) salts, e.g. $Hg(SCN)_2$, catalyze addition of thiocyanic acid (HSCN) across the triple bond of a variety of alkynes (eq 1);[1,2] HSCN is formed in situ from $Bu_4N^+SCN^-$ and a strong acid (H_2SO_4, HCl, or HBF_4).[2] $Hg(SCN)_2$ appears to be the catalyst of choice as it suppresses the formation of the corresponding methyl ketones.[2] In the presence of ***Bromine***, $Hg(SCN)_2$ has been reported to effect a formal addition of Br-SCN across a C=C bond (due to the replacement of HgX in the primary adduct by halogen).[3]

Mercury(II) Trifluoroacetate[1]

$(CF_3CO_2)_2Hg$

[13257-51-7] · $C_4F_6HgO_4$ · Mercury(II) Trifluoroacetate · (MW 426.63)

(oxymercuration[3] and aminomercuration[17] of alkenes; polyene cyclization;[21] allylic oxidation;[32] macrolide synthesis[37])

Alternate Name: mercuric trifluoroacetate.

Physical Data: mp 171-173 °C.

Solubility: sol THF, DME, dioxane; insol hexane.

Preparative Methods: can be prepared from ***Mercury(II) Oxide*** in ***Trifluoroacetic Acid***[2-4] or generated in situ from ***Mercury(II) Acetate*** and CF_3CO_2H.[8b]

Form Supplied in: white, hygroscopic crystals.

Handling, Storage, and Precautions: acute poison; is easily absorbed through the skin and is corrosive; exposure to all mercury compounds is to be strictly avoided. Releases toxic Hg fumes when heated to decomposition. Protect from light. Use in a fume hood.

Oxymercuration.[3-5]

The reactivity of mercury(II) trifluoroacetate is similar to that of ***Mercury(II) Acetate*** but exhibits higher electrophilicity.[3] Thus, for instance, while cholesterol and other alkenes with a trisubstituted double bond are normally reluctant to react with $(AcO)_2Hg$ (unless neighboring group participation boosts the reaction), $(CF_3CO_2)_2Hg$ reacts readily with cholesteryl acetate (eq 1).[6] Even α,β-unsaturated esters react with $(CF_3CO_2)_2Hg$; the corresponding adducts are readily transformed into α-bromo derivatives (eq 2).[7] Generally, in the presence of Cl_2 or Br_2, the HgX group in the original adduct is replaced by halogen.[1,5]

(1)

(2)

Increased selectivity in oxymercuration has been observed when $(CF_3CO_2)_2Hg$ and other Hg^{II} salts were generated in situ from HgO and RCO_2H in an inert solvent (CH_2Cl_2, hexane, or aq THF) on sonication.[4]

Whereas oxymercuration normally occurs with *anti* stereoselectivity,[3,4] products of *syn* addition have been observed for norbornene derivatives.[8]

Intramolecular oxymercuration[9] has been extensively utilized for the construction of various oxygen heterocycles, usually with high stereoselectivity (eq 3).[10] Both isolated[9,10] and conjugated[11] double bonds react, and 5-*exo-trig*, 5-*endo-trig*, and 6-*exo-trig* reactions have all been observed.[9-11] Similarly, cyclic peroxides are formed from the unsaturated peroxides.[12]

(3)

The relatively stable trichloroacetals derived from allylic alcohols can be utilized as intermediates to accomplish stereo- and regiocontrolled mercuration which gives *cis*-1,2-diols (eq 4).[13] However, this method has the following limitations: (1) the original hydroxy group must be equatorial, (2) the double bond cannot be trisubstituted, (3) the reaction is not regioselective for acyclic allylic alcohols, and (4) the reaction is unsuccessful with homoallylic alcohols.[13]

Hydroxy allenes seem to be particularly suitable substrates as the sp^2-bonded mercury can be transmetalated with palladium salts, which expands the versatility of this methodology (eq 5).[14] Alkynic alcohols also produce vinylmercurials (with some preference for (*Z*) isomers)[15] which can be further elaborated, e.g. by conversion into vinyl halides on reaction with sources of electrophilic halogen (***N-Iodosuccinimide***).[16]

Aminomercuration.

Intramolecular aminomercuration followed by demercuration is a useful method of construction of a variety of nitrogen heterocycles such as aza sugars.[17] Intramolecular amidomercuration, employing $(CF_3CO_2)_2Hg$, has also been reported.[18] It has been shown that the steric course of mercuration can be controlled by a neighboring nitrogen group (eq 6).[19]

Azidomercuration of an alkenic double bond can be accomplished in quantitative yield (in the case of a

monosubstituted double bond) by the reaction carried out with $(CF_3CO_2)_2Hg$ and ***Sodium Azide*** (3:1) in THF-H_2O (1:1) at 60 °C for 48 h.[20] This method has been utilized for syntheses of amino sugars. By contrast, $(AcO)_2Hg$ gives only 20% in the same case.[20]

Polyene Cyclization.

Acyclic isoprenoids are stereospecifically cyclized on reaction with $(CF_3CO_2)_2Hg$ to afford polycyclic structures (eq 7).[21] An aromatic ring can be used in place of the nucleophilic double bond in a similar type of cyclization.[22]

(7)

Cyclopropane Ring Opening.

Mercury(II) trifluoroacetate readily opens up cyclopropane rings.[23] The reaction is usually faster than that with $(AcO)_2Hg$ and slower than for ***Mercury(II) Nitrate***.

Mercuration of Aromatics.

Being a good electrophile, $(CF_3CO_2)_2Hg$ and other Hg^{II} salts also attack aromatic rings.[24,25] Combined with the subsequent reaction with iodine, this method has long served to accomplish iodination in cases where the arene is inert to direct iodination. Polyhaloaromatics can also be synthesized in this way.[26]

[3,3]-Sigmatropic Rearrangements.

Oxy-Cope rearrangement can be initiated at rt by $(CF_3CO_2)_2Hg$ (1 equiv); the intermediate α-mercurio ketone is then demercurated with ***Sodium Borohydride***.[27] The reaction can be carried out with a catalytic amount of Hg^{II} and an excess of lithium triflate or trifluoroacetate.[28] The Claisen rearrangement of allylic carbamates can be best achieved via a suprafacial [3,3]-migration mediated by $(CF_3CO_2)_2Hg$ (eq 8); the reaction is thermodynamically controlled.[29] Using a carbamate derived from an optically active amine, formation one of the diastereoisomers may be preferred; however, this method seems to have a limited value due to the low de.[30]

(8)

Allylic Oxidation (Treibs Reaction[31]).[32]

More effective than the acetate, $(CF_3CO_2)_2Hg$ facilitates allylic oxidation[33,34] of alkenes which are generally reluctant to be oxymercurated (namely those with trisubstituted double bonds). Thus, cholesterol and its esters are converted, after hydrolysis, to the 3β,6β-dihydroxy-4-ene at 0 °C in 40-70% yields.[33]

Hydrolysis of Vinyl Chlorides.

The original Wichterle reaction[35] relied on the hydrolysis of vinyl chlorides with H_2SO_4. The improved version utilizing $(CF_3CO_2)_2Hg$ allows the control of regioselectivity by the solvent.[36] Thus, hydrolysis in $MeNO_2$, CH_2Cl_2, or AcOH gives only 1,5-diketone (to be cyclized) in up to 97% yield, whereas hydrolysis in MeOH gives mainly the 1,4-diketone (eq 9).[36]

Synthesis of Macrolides.

t-Butyl thioesters are converted to esters on reaction with $(CF_3CO_2)_2Hg$ or $(MeSO_3)_2Hg$. This method is general for synthesis of macrolides (eq 10) but cannot be used for substrates containing electron-rich centers such as double bonds (which undergo oxymercuration); other less electrophilic cations can be employed in those instances (Cu^+, Cu^{2+}, or Ag^+).[37]

Miscellaneous.

Like HgO or Tl^{III}, mercury(II) trifluoroacetate oxidizes phenols and hydroquinones to quinones in the presence of an acid scavenger.[38] Monohydrazones of α-diketones are oxidized with $(CF_3CO_2)_2Hg$ to give α-diazo ketones.[2] Enol esters, obtained by the reaction of 4-dimethylamino-3-butyn-2-one with o-hydroxy carboxylic acids, react with $(CF_3CO_2)_2Hg$ or ***10-Camphorsulfonic Acid*** to give macrocyclic lactones.[39] 1,3-Dioxolanium salts are converted to α-mercurio derivatives of carboxylic acids on reaction with $(CF_3CO_2)_2Hg$ or $(AcO)_2Hg$.[40] TMS derivatives of tertiary vinyl alcohols undergo Wagner-Meerwein migration on treatment with $(CF_3CO_2)_2Hg$; this can be used as a ring-expansion methodology in cyclic systems.[41]

Related Reagents.

t-Butyldimethylsilyl Hydroperoxide-Mercury(II) Trifluoroacetate; ***Mercury(II) Acetate***.

O-Mesitoylhydroxylamine

[37477-17-1] · $C_{10}H_{13}NO_2$ · *O*-Mesitoylhydroxylamine · (MW 179.24)

(reagent for electrophilic aminations, H_2N transfers to nucleophiles)

Physical Data: oil; mp of *N*-acetyl-*O*-mesitoylhydroxylamine 128-129 °C.[1]

Preparative Method: a solution of 10.0 g (35.8 mmol) *t*-butyl *N*-mesitoyloxycarbamate in 150 mL of nitromethane was treated with a stream of anhydrous hydrogen chloride for 5-7 min. After standing for 15 min the precipitated solid (**1**) (mp 125-127 °C, dec) was filtered, washed with nitromethane, dried in air and then suspended in 100 mL of water and treated with 1 M sodium bicarbonate solution until gas evolution stopped. The resulting oil was extracted with three 15 mL portions of CH_2Cl_2, the extracts dried over magnesium sulfate, and the solvent removed from a water bath at room temperature under reduced pressure (ca. 12-20 mmHg). *O*-mesitoylhydroxylamine (**2**) remained as a clear, colorless oil; 5.5 g (86%) (eq 1).[2]

(1)

Handling, Storage, and Precautions: explosions which have been reported for compounds similar to (**2**), e.g. ***O-(Mesitylsulfonyl)hydroxylamine*** or *O*-(*p*-tolylsulfonyl)hydroxylamine,[2] have not been described for (**2**).

Reactions with Amines.

While *O*-(mesitylsulfonyl)hydroxylamine is the reagent of choice for the *N*-amination of heteroaromatic and tertiary amines,[1] it is (**2**) which should be used for the preparation of 1,1-disubstituted hydrazines from secondary amines (Table 1).[1,2a,3] Compound (**2**) is also a good reagent for the amination of anionic nitrogen atoms of amides, pyrroles, and related compounds, as shown in Table 2.[4,5]

Table 1 1,1-Disubstituted Hydrazines from **(2)** and Secondary Amines

(3) 58%

(4) 39%

Table 2 *N*-Amination of 'Anionic' Nitrogen Atoms of Organometallic Compounds RM with **(2)**

(5) 43% (RNa)

(6) 57% (RNa)

(4) 87% (RNa)

(7) 37% (RNa)

One should mention here that *O*-(2,4-dinitrophenyl)hydroxylamine (**8**) also aminates substrates of this type quite well.[1,6,7] In contrast, *O*-(mesitylsulfonyl)hydroxylamine[1] is not a good reagent for such reactions.

(8)

Miscellaneous Reactions.

O-Mesitoylhydroxylamine (**2**) was used (among others) for the α-amination of dilithiated carboxylic acids, $RCHLiCO_2Li$;[8] however, success was very poor. Other aminating reagents for these and other carbanions turned out to be much better, as excellently described in a recent review.[9]

Makhova et al. used (**2**) for the preparation of diaziridines,[10] a reaction which is also performed with *O*-(mesitylsulfonyl)hydroxylamine.

Finally, (**2**) has been identified as an oxidative inhibitor of cysteine proteinases.[11]

Related Reagents.

O-(Diphenylphosphinyl)hydroxylamine; ***O-(Mesitylsulfonyl)hydroxylamine***.

Mesitylcopper(I)

[75732-01-3] · $C_9H_{11}Cu$ · Mesitylcopper(I) · (MW 182.75)

(thermally stable and soluble metalation agent for active hydrogen compounds;[1] nontransferable group of mixed organocuprates;[1] catalyst for conjugate reduction of α,β-unsaturated carbonyl compounds by lithium aluminum hydride[1])

Alternate Name: 2,4,6-trimethylphenylcopper(I).

Physical Data: thermally stable up to ca. 100 °C; exists as a pentamer.

Solubility: sol benzene, ether, THF; partly sol hexane.

Preparative Method: prepared by the metathesis reaction between ***Copper(I) Chloride*** and mesitylmagnesium bromide in THF and can be isolated by precipitating magnesium salts with addition of dioxane.[1]

Handling, Storage, and Precautions: extremely oxygen- and moisture-sensitive. Preparation and reaction should be conducted under rigorously oxygen-free and anhydrous conditions.

Metalation.

Copper(I) t-Butoxide has been known to be a useful metalation agent for a variety of active hydrogen compounds under mild conditions with concomitant quantitative liberation of *t*-butyl alcohol to generate corresponding organic Cu^I compounds. Mesitylcopper(I) is a unique organocopper(I) compound with high thermal stability and solubility, and acts as a more powerful metalation agent than copper(I) *t*-butoxide with concomitant liberation of inert mesitylene and without accompanying salts. For example, mesitylcopper(I) effects the metalation of primary and secondary amines (eq 1),[1,2] which copper(I) *t*-butoxide cannot perform. Metalation of functionalized benzoic acids[3] such as 2-bromobenzoic acid (eq 2) occurs readily, where mesitylcopper(I) is more efficient than 2-tolylcopper(I). Copper(I) 2-bromobenzoate is an intermediate of the Hurtley reaction and cannot be prepared by the conventional ***Copper(I) Oxide*** method. Metalation of perfluoro-*t*-butyl alcohol affords copper(I) perfluoro-*t*-butoxide (eq 3),[4] which is one of the

most volatile copper alkoxides and may be useful for sol-gel and chemical vapor deposition processes. Organic reactions utilizing the excellent thermal stability of mesitylcopper(I) have been reported: formaldehyde insertion into its Cu-C bond[5] and its palladium(0)-catalyzed cross-coupling[6] with aryl iodides in the presence of Bu_4NX (X = Br, I).

(2)

(3)

Nontransferable Group of Mixed Organocuprates.

Nontransferable groups of mixed organocuprates have been developed for stabilizing organocuprate reagents and for saving one organic group of diorganocuprates. Mesitylcopper(I) can be used for a nontransferable group of mixed organocuprates having primary and secondary alkyl groups (eq 4).[1]

R = Bu	90%	0%
R = *s*-Bu	85%	trace
R = *t*-Bu	26%	19%

Catalyst for Conjugate Reduction of α,β-Unsaturated Carbonyl Compounds by Lithium Aluminum Hydride.

Mesitylcopper(I) catalyzes conjugate reduction of α,β-unsaturated aldehydes and ketones by ***Lithium Aluminum Hydride*** (LAH) in the presence of ***Hexamethylphosphoric Triamide*** (HMPA) (eq 5).[1] Mesitylcopper(I)/LAH/HMPA has been the basis of the development of the related reagents CuI/LAH/HMPA[7] and $MeCu^{I}$/DIBAL/HMPA,[8] which similarly effect conjugate reduction of α,β-unsaturated carbonyl compounds (see ***Lithium Aluminum Hydride-Copper(I) Iodide***, ***Methylcopper***, and ***Diisobutylaluminum Hydride***).

Mesitylenesulfonyl Chloride

[773-64-8] · $C_9H_{11}ClO_2S$ · Mesitylenesulfonyl Chloride · (MW 218.72)

(preparation of sulfonates;[1] condensing agent in nucleotide synthesis[2])

Alternate Name: 2,4,6-trimethylbenzenesulfonyl chloride.

Physical Data: mp 55-57 °C.

Solubility: sol organic solvents.

Form Supplied in: white crystalline solid; widely available.

Purification: can be recrystallized from hexane or pentane.

Handling, Storage, and Precautions: corrosive; moisture sensitive; handle and store under nitrogen.

Sulfonamide Formation.

Reaction of mesitylenesulfonyl chloride with amines in the presence of ***Pyridine*** or ***Triethylamine*** yields the corresponding sulfonamides (eq 1),[3] which have been used as intermediates in synthesis.

The mesityl group has been used as a protecting group for various amines including amino acids (eq 2)[4] and peptides.[5-7]

The mesitylsulfonyl-protected amino acids can be deblocked by treatment with ***Hydrogen Bromide*** and ***Acetic Acid***. The stability of the sulfonamide towards both acidic and basic conditions makes it a useful protecting group for peptide synthesis. The mesitylenesulfonyl group has been used to protect the indole group of tryptophan[6] and the guanidine group of arginine.[7] These mesityl derivatives can be cleaved with ***Trifluoromethanesulfonic Acid*** or ***Methanesulfonic Acid***. Partial cleavage of the guanidinomesityl group occurs when treated with HBr/HOAc. The mesitylenesulfonyl group has also been used as a blocking group for other indoles. Boteju et al. reported the formation of the indole sulfonamide by treatment with ***n-Butyllithium*** and mesitylenesulfonyl chloride, but the sulfonamide group was not subsequently removed (eq 3).[8]
