Treatment of alcohols with mesitylenesulfonyl chloride yields the corresponding sulfonates. Mesitylenesulfonyl chloride is particularly useful for the selective sulfonation of polyhydroxylic systems such as carbohydrates (eq 4).[1,9] It is more selective than ***p-Toluenesulfonyl Chloride***, which has been frequently used but gives mixtures of products. Unfortunately, the mesitylenesulfonates are not as reactive as the corresponding tosylates. Numerous 1´-derivatives of sucrose have been synthesized via mesitylenesulfonyl derivatives.[10]

(4)

The selectivity of sulfonation has also been applied to other polyhydroxylic systems such as α- and β-cyclodextrins[11,12] and nucleotides.[13] Monosulfonated products have been reported from the treatment of diols with mesitylenesulfonyl chloride (eq 5).[14,15]

(5)

Mesitylenesulfonyl derivatives which have specific biological activities, such as 2,3-diaziridinyl-1,4-napthoquinone

sulfonates[16] and 1-arenesulfonyloxy-2-alkanones,[17] have also been prepared.

Nucleotide Synthesis.

Mesitylenesulfonyl chloride has been used as a condensing agent in the diester approach to nucleotide synthesis (eq 6).[2] However, it is not effective in the triester approach due to extensive sulfonation of the 5´-hydroxy group.[18] Other condensing agents include ***1,3-Dicyclohexylcarbodiimide*** (DCC), benzenesulfonyltriazole (BST), (1-mesitylyl-2-sulfonyl)-3-nitro-1,2,4-triazole (MSNT), ***Mesitylsulfonyl-1H-1,2,4-triazole*** (MST), *p*-nitrobenzenesulfonyltriazole (*p*-NBST), *p*-toluenesulfonyltriazole (TST), and triisopropylbenzenesulfonyl chloride (TPS).

(6)

Condensation Reactions.

Mesitylenesulfonyl chloride has also been employed as a condensing agent for the preparation of esters in the synthesis of nonactin (eq 7),[19] *N*-methylmaysenine,[20] and maysine.[21]

Sulfinate Ester Synthesis.

Sulfinate esters of menthol can be prepared via reaction of mesitylenesulfonyl chloride (as well as other sulfonyl chlorides) with menthol using ***Trimethyl Phosphite*** (eq 8).[22] Sulfinate esters of menthol are used for the preparation of optically active sulfoxides. See also ***10-Camphorsulfonyl Chloride*** and ***p-Toluenesulfonyl Chloride***.

(8)

Sulfonylalkyne Synthesis.

Sulfonylalkynes have been synthesized (eq 9) and subsequently reacted with *N*-(1-alkynyl)anilines to give 2-anilino-5-sulfinylfurans.[23]

Mesitylenesulfonylhydrazide

[16182-15-3] · $C_9H_{14}N_2O_2S$ · Mesitylenesulfonylhydrazide · (MW 214.32)

(used to form diazene;[1] condenses with ketones and aldehydes to form hydrazones that can be used as a source of reactive intermediates such as diazoalkanes, carbenes, carbenium ions, and alkyllithiums;[7,8] a good reagent for the Eschenmoser fragmentation[4])

Alternate Names: MSH; 2,4,6-trimethylbenzenesulfonylhydrazide.

Physical Data: mp 105 °C (dec).

Solubility: sol ether, THF, benzene, dichloromethane, chloroform, ethanol; insol water, hydrocarbons.

Form Supplied in: solid; widely available.

Analysis of Reagent Purity: IR, NMR.

Handling, Storage, and Precautions: is stable for many months below 0 °C and should be stored in a freezer. It is a toxic, potentially flammable solid which should be handled with gloves in a fume hood under an inert atmosphere.

Alkene Reduction/Allylic Diazene Rearrangement.

Mesitylenesulfonylhydrazide in refluxing methanol is a convenient source of diazene (diimide). It has intermediate reactivity, decomposing 16 times faster than ***p-Toluenesulfonylhydrazide*** (tosylhydrazide) and 24 times slower than ***2,4,6-Triisopropylbenzenesulfonylhydrazide*** (trisylhydrazide) under base-catalyzed conditions.[1] An analogous use of MSH is in allylic diazene rearrangements.[2] Eq 1 illustrates a recent example whereby an allylic alcohol is ionized with a Lewis acid and the resulting allyl cation trapped with MSH to give the diazene, which stereospecifically yields the rearranged product.[3]

Eschenmoser Fragmentation.

MSH condenses with ketones to form hydrazones, which participate in the Eschenmoser fragmentation. Eq 2 shows the mild fragmentation of two epoxy ketones to form 1-cyclononyn-4-one and 1-cyclodecyn-4-one in 1:1 CH_2Cl_2-AcOH at rt; compounds not accessible using the less reactive *p*-toluenesulfonylhydrazide.[4]

(2)

$n = 1$, 43%; $n = 2$, 69%

Miscellaneous.

MSH is oxidized by ***Benzeneseleninic Acid*** to give selenosulfonates in excellent yield and which themselves have diverse synthetic utility.[5,6] The few examples that employ mesitylenesulfonylhydrazones in the aprotic Bamford-Stevens reaction show that triisopropylbenzenesulfonylhydrazones are superior.[7,8] Hydrazones of esters (hydrazimidates) have been prepared using MSH but their properties have not been investigated.[9]

Related Reagents.

2,4-Dinitrobenzenesulfonylhydrazide; ***p-Toluenesulfonylhydrazide***; ***2,4,6-Triisopropylbenzenesulfonylhydrazide***.

Mesitylsulfonylimidazole

[54230-59-0] · $C_{12}H_{14}N_2O_2S$ · Mesitylsulfonylimidazole · (MW 250.35)

(condensing agent for oligonucleotide synthesis[1])

Alternate Name: MSI.

Physical Data: mp 97-99 °C.

Form Supplied in: solid; widely available from commercial sources.

Preparative Method: readily prepared by the reaction of equimolar ratios of ***Mesitylenesulfonyl Chloride***, ***Imidazole***, and ***Triethylamine*** in a chloroform solution (eq 1).

Oligonucleotide Synthesis.

MSI[1] was reported as a condensing agent for oligonucleotide synthesis by activation of phosphomonoester groups of nucleotides (eq 2).[2] Very few reports of the use of this reagent have appeared in literature. Reactions with MSI are reported to be very slow, but acid-sensitive functional groups are unaffected by these reaction conditions.[3]

Mesitylsulfonyl-1*H*-1,2,4-triazole

[54230-59-0] · $C_{11}H_{13}N_3O_2S$ · Mesitylsulfonyl-1*H*-1,2,4-triazole · (MW 251.34)

(reagent for phosphate activation[1] and nucleotide condensation[2])

Alternate Name: MST.

Physical Data: mp 135 °C.

Form Supplied in: solid; widely available from commercial sources.

Preparative Method: readily prepared by the reaction of equimolar ratios of ***Mesitylenesulfonyl Chloride***, ***1,2,4-Triazole***, and ***Triethylamine*** in a chloroform solution (eq 1).[3]

Purification: recrystallization from benzene.

Phosphate Activator.

MST was shown to be an effective catalyst for the phosphorylation of a 5´-protected mononucleoside.[1] MST was stirred with *p*-chlorophenyl phosphorodichloridate and triethylamine and the resulting agent was used directly for the

phosphorylation of 5´-protected nucleosides in 70-85% yields.

Oligonucleotide Synthesis.

As originally reported, the triester approach to the formation of oligonucleotides involved using triisopropylbenzenesulfonyl chloride (TPS) as a condensing agent for a 5´-3´ internucleotide condensation. Since that time, many modifications of this procedure have been reported, including (i) using a stepwise phosphorylation then condensation procedure,[2] (ii) synthesizing the oligonucleotide in the 3´-5´ rather than the 5´-3´ direction,[2] (iii) varying the protecting groups used in these transformations, and (iv) changing the condensing agent. MST is one of the more recently reported condensing agents for the synthesis of oligonucleotides through the formation of 3´,5´-internucleotide bonds via the triester approach. The initial report of the use of MST was in the synthesis of a fully protected dinucleotide (eq 2).[3]

A follow-up full paper by the same authors extended this methodology to the synthesis of hexanucleotides by an iterative phosphorylation and condensation sequence.[1] This paper also kinetically compared this reagent to some of the previously used condensing agents. It was reported that although the reaction using MST was significantly slower than that using TPS, the reaction mixture was much cleaner and the yields were much higher. This was especially true for

synthesis of nucleotides that contained purine units, which were formed only in low yields when TPS was employed as the condensing agent, perhaps due to the liberation of HCl from the reagent. MST was also employed as the condensing reagent in the synthesis of 3´,5´-bisphosphorylated oligonucleotides.[4]

Oligoribonucleotide Synthesis.

Subsequent work showed that this reagent was useful in the synthesis of the less stable oligoribonucleotides as well as deoxyribonucleotides.[5] In the same iterative manner as described above for deoxyribonucleotide synthesis, the tetrameric ribonucleotide GpApGpC was formed (eq 3). Yields were reported to be significantly improved over previously described methods that employed TPS as the condensing agent, especially in the coupling of purine residues. Note again that MST can also be used in the phosphorylation step of the condensation sequence. MST was also used as a condensing agent for the synthesis of 2´(3´)-*O*-aminoacyl triribonucleoside diphosphates.[6]

[107742-59-6] · $C_{16}H_{22}LiO$ · Mesityllithium · (MW 237.32) (**13**; $R^1 = R^2$ = Ph, .2Et_2O)

[133777-60-3] · $C_{32}H_{37}LiO_2$ · Mesityllithium · (MW 460.63)

(used for the generation of other amine-free organolithium compounds; derivatives are also synthetic building

blocks for the preparation of compounds containing low-coordinate main Group element functional groups which are otherwise not stable, i.e. steric protection)

Alternate Name: 2,4,6-trimethylphenyllithium.

Preparative Methods: the corresponding bromobenzene derivative is treated with 2 equiv ***t-Butyllithium***[3] in THF solution,[4,5] a method which leads to a 1:1 mixture of the desired Li derivatives (**1**)-(**8**) and ***Lithium Bromide*** (no alkyl halide is present under these conditions; eq 1).

According to X-ray structure determinations and molecular weight measurements in solution, the highly hindered organolithium compounds in the series (**1**)-(**13**) are monomeric,[6,7] i.e. not aggregated as are most other Li derivatives.

Handling, Storage, and Precautions: solutions of (**1**)-(**8**) may be kept under Ar or N_2 in a refrigerator; normally they are used right away; with (**1**), (**2**), and (**4**), a transmetalation from the nuclear to a benzylic position would lead to thermodynamically more stable Li compounds (such rearrangements[8] are catalyzed by tertiary amines, for instance ***N,N,N´,N´-Tetramethylethylenediamine***).

Use of *o,o´*-Disubstituted Compounds as Bases.

Two examples are shown in eqs 2 and 3.[3,4] The 1:1 acylation of Li enolates shown in the first reaction gives best yields of diketones such as (**14**) at -75 °C when the enolate solutions are amine-free (see ***Methyl 4-Nitrobutanoate*** and ***Methyl 3-Nitropropanoate***). The enolate formation from benzyl methyl ketone produces the thermodynamically less stable isomer (**15**) preferentially over the more stable one (**16**).[4,9]

(14)

Preparation of Low-Coordinate Main Group Element Derivatives.

Due to the steric hindrance, especially in the 2,4,6-tri-*t*-butyl aryl compounds (**3**) and (**11**), called supermesityllithium, it is possible to prepare derivatives of types of compounds which are otherwise not stable because they would be too reactive to be isolated. Three examples are the selenoaldehyde (**17**),[10] the dibora-allene anion derivative (**18**),[11] and the diphosphene (**19**).[12] A literature search reveals that this technique of steric protection was used all over the Periodic Table, including transition metals (consider also the principle of sterically protected but electronically effective functional groups,[13] and compare also the stabilization of tetrahedrane by *t*-butyl substitution[14]).

Mesityloxytris(dimethylamino)phosphonium Azide

[73014-63-8] · $C_{15}H_{29}N_6OP$ · Mesityloxytris(dimethylamino)phosphonium Azide · (MW 340.47)

(organic soluble source of azide ion[1])

Physical Data: mp 110-112 °C.

Solubility: sol most organic solvents.

Form Supplied in: not commercially available from common sources.

Preparative Method: readily prepared in a 68% yield from 2,4,6-trimethylphenol by treatment with ***Hexamethylphosphorous Triamide*** then ***Sodium Azide*** (eq 1).[1]

Purification: precipitation from an acetone solution by the addition of diethyl ether.

Mesityloxytris(dimethylamino)phosphonium azide is an organic soluble form of azide that is reported to be a better source of azide than tetrabutylammonium azide. It has been used for the preparation of glycosyl azides (eq 2).[1] The anomeric alcohol is first activated through formation of the phosphonium chloride by treatment with carbon tetrachloride and $(NMe_2)_3P$. The phosphonium salt is then reacted with the phosphonium azide, forming the glycosyl azide and regenerating $(NMe_2)_3P$.

(2)

The intermediate phosphonium chlorides are formed with a *trans* configuration relative to the C-2 substituent and the substitution generally occurs with inversion of configuration to give a *cis*-azide. Reported yields are good, mostly in the 65-80% range. Most common carbohydrate protecting groups appear to be stable to these conditions, including acetals, trityl (eq 3), benzyl (eq 4), and *t*-butyldiphenylsilyl. The resulting glycosyl azides are used in the synthesis of triazole nucleosides,[2] and purine[3] or pyrimidine[4] nucleosides.

(3)

(4)

Several advantages of this method over previously reported methods are described. The major advantage is that the use of toxic silver azide is eliminated. The reagent can be prepared from readily available starting materials and is soluble in organic solvents. The phosphonium azide is crystalline and nonhygroscopic. The reaction is fast and performed at low temperatures and the resulting glycosyl azide is readily separated from the water-soluble byproducts. The major disadvantage of this method is that $(NMe_2)_3P$ must be used. A later reported method which employs ***Azidotrimethylsilane*** and a Lewis acid catalyst has been reported to be a better method to carry out this transformation.[5]

O-(Mesitylsulfonyl)hydroxylamine[1]

[36016-40-7] · $C_9H_{13}NO_3S$ · *O*-(Mesitylsulfonyl)hydroxylamine · (MW 215.2)

(reagent for electrophilic aminations, NH_2 transfer to nucleophiles)

Physical Data: mp 93-94 °C.[1]

Solubility: very sol diethyl ether, chloroform, dichloromethane, benzene, ethanol, THF; insol water and petroleum ether.

Analysis of Reagent Purity: IR (KCl) ν(cm^{-1}) 3340, 3250, 1600, 1350, 1190, 1180.[1]

Preparative Methods: to a solution of 89 g (330 mmol) *O*-(mesitylsulfonyl)acetohydroxamate (**1**) in dioxane is added with stirring 30 mL perchloric acid (70%) at 0 °C within 10 min, and then stirred for another 10 min. After about 20 mL of the acid has been added, the reaction mixture becomes pasty. The crude reaction mixture is poured into ice-water to give a white solid of *O*-(mesitylsulfonyl)hydroxylamine (**2**) (eq 1) which is collected, washed with cold water (500 mL), then with cold petroleum ether (300 mL), and dried by maintaining suction for about 1 h; yield 55-65 g (77-92%).[1]

The product should be stored in a refrigerator below 0 °C. Iodometric titration indicates that (**2**) thus prepared contains 20-30% water. It can be used for most applications. A further purification can be achieved by dissolution of a small amount in diethyl ether at room temperature and precipitation with petroleum ether.

Handling, Storage, and Precautions: **caution**: *O*-(mesitylsulfonyl)hydroxylamine (**2**) must be handled with care. A first report about a rapid decomposition when standing at room temperature appeared in 1977.[2] After an

explosion of (**2**) during storage below 0 °C,[3] as suggested above,[1] it is strongly recommended that (**2**) be prepared immediately prior to use, and that it not be stored.[3]

Reactions with Heteroaromatic Amines.

N-Amine salts of heteroaromatic amines have received wide attention as synthetic intermediates for heterocyclic compounds.[4] The use of (**2**) in place of, e.g. ***Hydroxylamine-O-sulfonic Acid***, has many advantages. The amination procedure is outlined in (eq 2) and the results for some representative heteroaromatic systems are summarized in Table 1.

(2)

Table 1 *N*-Amine Salts[a] Formed from Heteroaromatic Amines and (**2**) According to Eq 2

Compound		Yield (%)
	**(3)**	80[5]
	**(4)**	42[6]
	**(5)**	53[7]

	(6)	54[8]
	(7)	81[9]
	(8)	65[10]

[a] X^- = mesitylsulfonate.

Typical Procedure for *N*-Amination.

To an ice-cold solution of the amine (e.g. 1.00 mmol ***Pyridine***) in dichloromethane (2 mL) is added dropwise a solution of (**2**) (1.00 mmol) in dichloromethane (2 mL). The reaction mixture is allowed to stand at 20 °C for 10 min. After addition of diethyl ether, the precipitated crystals are collected and recrystallized from methanol/ethyl acetate to give the *N*-aminopyridinium mesitylsulfonate (**3**); 235 mg yield (80%), mp 125-126 °C.[1]

Reactions with Tertiary Amines.

Reagent (**2**) aminates a variety of tertiary amines, including alkaloids, under very mild conditions to give the corresponding 1,1,1-trisubstituted hydrazonium salts in high yields.[11] Some typical examples are listed in Table 2.

Table 2 Reactions of **(2)** with Tertiary Amines[11]

	Compound	Yield (%)
$Bu_3\overset{+}{N}-NH_2$ X^-	**(9)**	87
$Ph-\overset{+}{N}(Me)_2-NH_2$ X^-	**(10)**	89
	**(11)**	77
	**(12)**	54

Reactions with Secondary Amines.

The formation of 1,1-disubstituted hydrazines with (**2**) occurs in lower yield than with hydroxylamine-*O*-sulfonic acid or ***Chloramine***; another useful reagent is ***O-Mesitoylhydroxylamine*** (**13**),[1,12] which gives (**14**) in 58% yield.

(13)

$(PhCH_2)_2N\text{-}NH_2$

(14)

More interesting is the reaction between (**2**) and compounds of the type (**15**), which leads (probably via **16-18**) to benzodiazepine derivatives such as (**19**) (eq 3).[13]

Reactions with the Anionic Nitrogen of Amides, Imides, and Pyrroles.

Reagent (**2**) is not a successful aminating reagent for these anionic species, with *O*-mesitoylhydroxylamine (**13**) being the more effective. Two examples, derived from their sodium salt, are (**20**) and (**21**).[14,15]

(20) 37%

(21) 43%

Reactions with Sulfides.

The reactions of sulfides with (**2**) provide the easiest and most efficient access to *S*-amine mesitylsulfonates (**22**) (eq 4). A few examples from a long list are collected in Table 3.[16]

(4)

(22)

Table 3 Reactions of (2) with Sulfides

(22)	Yield (%)
	66
	90
	84

With allyl sulfides, consecutive reactions of the *S*-amine mesitylsulfonates (**23**) lead, probably via the intermediate sulfilimines (**24**), to allylamines (**25**) (eq 5).[1]

(5)

Reactions with Sulfoxides.

The synthetically very important sulfoximines (**28**) are easily prepared from sulfoxides (**26**) and (**2**) via the *S*-aminosulfoxonium mesitylsulfonates (**27**) (eq 6). Some pertinent examples for the formation of (**27**) are given in Table 4.

(6)

Table 4 Reactions of **(2)** with Sulfoxides

Compound		Yield (%)
	**(29)**	72[17]
	**(30)**	65[17]
	**(31)**	80[18]
	**(32)**	60[18]

Reactions with *S,S*-Acetals.

S,S-Acetals are readily dethioacetalized by (**2**). This is thus a method to cleave *S,S*-acetals from α,β-unsaturated ketones, ketones, and aldehydes (eq 7 and Table 5).[19]

(7)

Table 5 Reactions of *S,S*-Acetals with (**2**) (eq 7)

R^1	R^2	*n*	Carbonyl compound (%)
Ph	H	3	74
PhCH=CH	H	3	72
Ph	Ph	2	85

The oxidation at sulfur with (**2**) is also achieved in the case of disulfides, thioketones, and thiols.[1]

Reactions with Phosphines.

Not surprisingly, (**2**) also aminates phosphines to give *P*-aminophosphonium salts such as (**33**) in very good yields (eq 8).[1] Other electrophilic H_2N transfer reagents aminate phosphines in a similar fashion.[1]

(8)

Reactions with Carbanions.

The amination of carbanions with (**2**) has also been investigated (eq 9).[20] The α-amino diethyl phosphonoacetate (**34**) was formed in moderate yields. Most probably, the basic anion deprotonated (**2**) at least in part, which should lead to fast decomposition of the resulting nitrenoid. In a similar fashion, aminomalonitrile tosylate (**35**) has been formed via a simple

procedure (eq 10).[3]

(9)

(10)

Amination of the enolate precursor to give 2-*exo*-amino-6-*endo*-(methylthio)-bicyclo[2.2.1]heptane-2-*endo*-carboxylic acid (**36**) in 38% yield has been described.[21]

(36)

Since early observations of electrophilic aminations of organoboranes with hydroxylamine-*O*-sulfonic acid or chloramine,[22] it is not surprising that the reaction of R_3B with (**2**) similarly gives primary amines, albeit under milder conditions. Some amines formed via di- or trialkylboranes are (**37**)-(**39**), shown with the corresponding alkenes (Scheme 1).[23]

Scheme 1

There exists a variety of aminating reagents for carbanions which are much better than (**2**). An excellent review on this topic has been written[20c] (see also ***O-(Diphenylphosphinyl)hydroxylamine***).

Reactions with Electrophiles.

Reagent (**2**) also reacts with electrophiles, although this chemistry is of minor importance. Thus reaction of (**2**) with ketones (**40**) leads to the corresponding oximes (**41**), which are intermediates for the Beckmann and Neber rearrangements (eq 11).[24,25]

(11)

With Schiff bases derived from aliphatic aldehydes (**42**) (aldimines), (**2**) forms diaziridines (**43**) (eq 12).[1,26]

(12)

$R^1 = C_6H_{13}$; $R^2 = Cy$

If R^1 is a phenyl group as in (**44**), phenylhydrazones are formed instead (eq 13).[27]

(13)

(44)

$R^1 = Ph$; $R^2 = t\text{-}Bu$

Finally, it has been reported that (**2**) also reacts with strongly electrophilic alkenes like (**45**) to give (**46**), which after treatment with base affords 1*H*-aziridines such as (**47**) (eq 14).[28]

Methacrolein

[78-85-3] · C_4H_6O · Methacrolein · (MW 70.10)

(used in cycloaddition reactions, aldol reactions; undergoes both 1,2- and 1,4-additions)

Alternate Name: 2-methylpropenal.

Physical Data: mp -81 °C; bp 69 °C; vapor pressure 121 mmHg at 20 °C; *d* 0.837 g cm^{-3}.

Solubility: miscible with water, alcohol, ether.

Form Supplied in: colorless liquid; widely available. *Drying:* fractional distillation (freshly distilled methacrolein turns cloudy within 1 or 2 h at rt; this can be prevented by the addition of 1% hydroquinone).[1]

Handling, Storage, and Precautions: methacrolein is extremely flammable, and a severe irritant and lachrymator. Use in a fume hood.

Diels-Alder Reactions.

Methacrolein (**1**) has been widely used in Diels-Alder reactions, where it most commonly functions as the dienophile[2] (eq 1); X = Me, CO_2Me, OMe;[2a] O_2CNMe_2;[2b] CH_2CO_2Me[2c]).

Methacrolein also undergoes a Diels-Alder reaction with itself to produce a dimer (eq 2).[1]

(2)

When treated with electron-rich alkenes, generally in the presence of a Lewis acid, methacrolein undergoes a hetero-Diels-Alder reaction (eq 3).[3]

(3)

There are numerous examples in which chiral Lewis acid catalysts have been used to obtain enantioselective [4 + 2] cycloadditions.[4] A few of these are listed in Table 1 as applied to the reaction of methacrolein with cyclopentadiene (eq 4).[5]

(4)

Table 1 Examples of Chiral Lewis Acid Catalysts (eq 4)

Catalyst[a]	*exo*:*endo*	ee (%)	Yield (*exo* + *endo*) (%)
A[5a]	49:1	98	100
B[5b]	99:1	97	84
C[5c]	8:1	96	85
D[5d]	37:1	90	85

[a] Prepared from (A) 3,3¢bis(2-phenyl)-4-phenanthrol and Et_2AlCl, (B) 1-methyl-2-(*S*)-(diphenylhydroxylmethyl)pyrrolidine and BBr_3, (C) 2,6-dimethoxybenzoyltartaric acid and BH_3, (D) (*S*)-1,1¢bi-2-naphthol and $H_2BBr{\cdot}SMe_2$.

Nucleophilic 1,2-Additions.

The reactions of methacrolein with Grignard reagents (eq 5),[6a] organozincs (eq 6),[7] alkyllithiums,[8] and lithium,[9] tin,[10] and boron[11] enolates yield, selectively, the products from 1,2-addition. These allylic alcohols are useful intermediates for a number of transformations, including formation of allyl vinyl ethers which then undergo Claisen rearrangements (eq 5).[6,8a,12]

Reaction of methacrolein with lithium enolates of hindered aryl esters yields selectively the *threo* aldol products (eq 7).[9c]

The reaction of the boron enolate of a chiral imide with methacrolein allows for the selective synthesis of *syn* aldol products (eq 8), which can be elaborated into α-amino acids.[11f]

A useful extension of the Evans methodology allows the selective preparation of either the *anti* aldol or the *syn* aldol products from the same substrate by simply changing the reaction conditions (eq 9).[11c]

Other 1,2-additions to methacrolein lead to the formation of acetals (eq 10),[13] imines (eq 11),[14] cyano ethers (eq 12),[15a] cyano esters (eq 13),[15b] and acyl silanes (eq 14).[16]

(12)

(13)

(14)

Nucleophilic 1,4-Additions.

Nucleophilic 1,4-addition of amines,[17] thiols,[18] and phosphorus reagents[19] to methacrolein leads to a wide variety of products in high yield (eqs 15-19).

(15)

(16)

(17)

(18)

(19)

The 1,4-addition of alkaline ***Hydrogen Peroxide***, with careful control of the pH, occurs in good yield to give α-methylglycidaldehyde.[20] The 1,4-addition of alcohols to methacrolein is less successful (however, a synthetically useful example is shown in eq 20).[21]

(20)

Unlike α,β-unsaturated ketones, α,β-unsaturated aldehydes such as methacrolein give poor yields of 1,4-addition products with carbon nucleophiles due to the preference for 1,2-addition to the carbonyl. Two important exceptions are the reactions with trialkylboranes (eq 21),[22] and the copper-catalyzed addition of Grignard reagents (eq 22).[23] Significantly, the latter procedure has been greatly improved by the addition of ***Chlorotrimethylsilane*** and ***Hexamethylphosphoric Triamide***.[23]

α-Methacrolein *N*-*t*-Butylimine

(*s-cis*)

[81569-06-4] · $C_8H_{15}N$ · α-Methacrolein *N*-*t*-Butylimine · (MW 125.24) (structure unspecified)

[90554-32-8]

(α,β-unsaturated aldimine or 1-aza-1,3-diene; useful building block for heterocyclic synthesis as a heterodiene or a functionalized imine and alkene[1-4])

Physical Data: bp 28-30 °C/10 mmHg.

Solubility: sol most organic solvents such as ether, alcohol, carbon tetrachloride, chloroform, dichloromethane, benzene, hexane.

Form Supplied in: colorless liquid.[1]

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$): δ 1.22 (s, 9H, *t*-Bu), 1.93 (s, 3H, Me), 5.28 (m, 1H, =C*H*H), 5.50 (m, 1H, =CH*H*), 7.84 (s, 1H, N=CH).[1,6]

Preparative Methods: by dehydrohalogenation of α-haloaldimines, which are prepared by halogenation of the corresponding aldimine with *N*-halosuccinimide (eq 1).[5,6] Alternatively, prepared by condensation of *N*-*t*-butylmethanimine and 1-piperidino-1-propene (eq 2).[1,2] Preparation of this type of γ-unsubstituted azadiene by direct condensation of an α,β-unsaturated aldehyde with an amine usually suffers from low yields due to side reactions.[7,8]

Handling, Storage, and Precautions: hygroscopic and should be handled in a dry atmosphere. It neither hydrolyzes in the absence of acid nor polymerizes upon heating and can be stored in a refrigerator for many months. Use in a fume hood.

Introduction.

α-Methacrolein *N*-*t*-butylimine (**1**) is known to be a heterodiene with considerable stability and versatile utility in organic synthesis as an electron-deficient alkene and an alkenyl imine, as well as an azadiene which has no substituent on the terminal carbon and the *s*-*cis* structure favorable for 1,4-cycloaddition leading to nitrogen-containing heterocycles. Another feature of the compound is the *t*-butyl group that often eliminates upon thermal or acidic treatment.

Polymerization.

While polymerization of imine (**1**) is not reported, analogous *N*-alkylmethacroleinimines such as *N*-cyclohexyl-3-methyl-1-aza-1,3-butadiene are known to polymerize by anionic catalysts but not by cationic or radical initiators. The polymerization proceeds through double bond addition and reactivity of this type with aldimines is less than that of methyl methacrylate.[8]

Oxidation.

Although oxidation of imine (**1**) itself is not reported, conversion of its analogs to alkenyloxaziridines with ***m***-

Chloroperbenzoic Acid occurs readily (eq 3).[3] Reaction of (**1**) with singlet oxygen does not proceed, while γ-substituted analogs are oxidized to 1,2-dioxolanes (eq 4).[9,10]

(3)

(4)

Reduction.

Selective reduction of *N*-alkylazadienes including imine (**1**) is a facile method for synthesis of secondary allylic amines (eq 5).[5]

(5)

Cycloaddition Leading to Heterocycles.

Methacrolein imines and their analogs react with various 1,3-dipoles, enophiles, and dienophiles to give four-, five-, and six-membered heterocyclic compounds; some representative examples are given below.

1,2-Cycloaddition of 1-Aza-1,3-dienes.

β-Alkenyl-β-lactams are synthesized by addition of ketenes across the C=N bond (eq 6). Formation of five-membered heterocycles from analogs via nitrilium ylide dipolar cycloaddition to the C=N or C=C bond (eqs 7 and 8) is reported.[3]

(6)

(7)

(8)

1,4-Cycloaddition of 1-Aza-1,3-dienes.

Formation of 3,5-disubstituted pyridines via [4 + 2] cycloaddition/cycloelimination of enamines to 1-aza-1,3-butadiene intermediates including (**1**) is known (eq 9).[1,2] This process is an inverse electron demand Diels-Alder reaction and can be performed with the isolated 1-azadienes to give various unsymmetrical 3,5-disubstituted pyridines (eq 10).[1,2]

R^1 = Me, Et, *i*-Pr, Cy, Ph, SPh; $NR^2{}_2$ = piperidino, morpholino, etc.

R^1 = Et, *i*-Pr
R^2 = Me, Et, *i*-Pr, Ph, EtOCO, piperidino, PhO, PhS, $PhSO_2$
$NR^3{}_2$ = piperidino, morpholino, etc.

Dihydropyridones (δ-lactams) are also prepared by Michael addition of ester enolates and subsequent cyclization (eq 11).[4]

Methacrolein Dimethylhydrazone

[66064-57-1] · $C_6H_{12}N_2$ · Methacrolein Dimethylhydrazone · (MW 112.174)

(electron-rich 1-azadiene reacting with electron-poor alkenes to yield Diels-Alder adducts[1-5])

Physical Data: bp 40-42 °C/20 mmHg.

Solubility: sol most organic solvents.

Preparative Methods: conveniently prepared either by the direct treatment of ***N,N-Dimethylhydrazine*** with ***Methacrolein*** or by a Hoffmann cleavage of the pyrazolinium iodide also obtained from methacrolein (eq 1).[1-5] These methods have been successfully applied to the preparation of various α,β-unsaturated hydrazones (Table 1).

Table 1 Synthesis of a,b-Unsaturated Hydrazones

R^1	R^2	R^3	Yield (method A) (%)	Yield (method B) (%)
H	Me	H	96	50
H	H	H	20	
H	H	Me	98	
H	H	Ph	88	
H	Et	H	85	56
Me	H	H	10	71
Me	Me	H		21

Handling, Storage, and Precautions: the compound darkens when kept at rt; however, it can be kept for long periods in the refrigerator without decomposition.

Diels-Alder Reactions.

Methacrolein dimethylhydrazone reacts as an electron-rich diene in Diels-Alder reactions with alkenes bearing electron-withdrawing groups (eqs 2 and 3).[1,5]

(2)

(3)

R = H (68%), Me (33%)

The diene is moderately reactive and best results are obtained with more reactive dienophiles (eqs 4 and 5).[1,6,7]

(4)

(5)

Dimethyl maleate was isomerized to the more stable dimethyl fumarate under these conditions and, therefore, both dienophiles yielded the *trans* adducts. Reductive cleavage of the N-N bond was readily effected by ***Zinc-Acetic Acid*** to yield substituted piperidines.

Pyridines could not be obtained by reacting α,β-unsaturated hydrazones with alkynic dienophiles.[6] However, they were readily obtained by reaction of methacrolein dimethylhydrazone with alkenic dienophiles bearing a nucleofugal group (eq 6)[3] or with an allenic dienophile (eq 7).[5]

Methacrolein dimethylhydrazone and related 1-azadienes have been extensively used for the preparation of aza- and diazaanthraquinone derivatives.[1,8] The cycloaddition reaction is highly regioselective (eqs 8 and 9).

Only few examples of intramolecular cycloadditions involving α,β-unsaturated hydrazones have been described.[9]

Asymmetric Cycloadditions.

Only one example of a reaction of methacrolein dimethylhydrazone with a chiral dienophile has been reported (eq 10).[10]

(10)

Also it has been recently shown that the replacement of the dimethylamino group by a chiral pyrrolidine gives a 1-azadiene which cycloadds to cyclic dienophiles with high facial selectivities (eq 11).[11] However, this diene did not react with dimethyl fumarate or acrylic derivatives.

Methallyl Bromide

[1458-98-6] · C_4H_7Br · Methallyl Bromide · (MW 135.01)

(alkylating agent attacking C, N, O, and S nucleophiles, often with enantiomeric or diastereomeric selectivity; alkyl-metal reagents provide α-(methallyl) alcohols with various carbonyl systems; provides derivatives leading to polymers and to other reagents)

Alternate Name: 3-bromo-2-methylpropene.

Physical Data: bp 94-95 °C; *d* 1.313 g cm^{-3}.

Solubility: organic solvents; sparingly sol water.

Form Supplied in: yellow to brown liquid.

Purification: wash with water and aq. $NaHCO_3$ until washings are not acidic. Dry ($MgSO_4$) and fractionally distill.

Handling, Storage, and Precautions: toxic irritant liquid; protect from light in brown glass. Use in a fume hood.

Methallyl derivatives are prepared by halide ion exchange of ***Methallyl Chloride*** (eq 1);[1] LiN_3 gives the azide[2] and KCNO provides tris(methallyl) isocyanurate through cyclic trimerization of the ROCN product.[3] Methallyl chloride undergoes conventional alkylation reactions with amines, alkoxides, etc.[4] (see ***Allyl Bromide***).

(1)

Barbier-type reactions occur (eq 2); octanal gives $RCH(OH)CH_2C(Me)=CH_2$ (R = heptyl) in the presence of Sb, and α,β-unsaturated aldehydes give only 1,2-addition.[5] Indium behaves similarly.[6] Mn in EtOAc or THF with ***Zinc Chloride*** (catalytic amount) gives homoallylic alcohols with both R^1CHO and R^1COR^2,[7] and the analogous Zn-

induced reaction in DMF is also successful.[8] The reaction with either R^1CHO or R^1COR^2 may be performed electrochemically, using a Cd-modified anode and reversing the polarity of the cell regularly.[9]

(2)

An interesting extension of the reductive alkylation reaction involves the use of the complex between ***Tin(II) Chloride*** and the disodio derivative of (+)-diethyl tartarate, which, when treated sequentially with methallyl bromide and then with R^1CHO, gives $CH_2{=}C(Me)CH_2CH(OH)R^1$ in good yield and with substantial ee (16-65%).[10] ***Samarium(II) Iodide*** promotes the alkylation of octanoyl chloride in THF. No ketones can be isolated from the reaction, which yields only the tertiary alcohol $R_2C(C_7H_{15})OH$ (R = methallyl).[11]

Lithiated species have been generally used as nucleophiles towards methallyl bromide. ***Lithium Diisopropylamide*** in THF-PhH at 0 °C deprotonates isobutyronitrile, which then methallylates in good yield.[12] The corresponding reactions of the phenylsulfonylbutenolide (**1**) (eq 3)[13] and of imidothioesters[14] proceed regioselectively.

(1)

(3)

2-Cyclohexenone reacts with methallyl bromide (RBr) and $LiC(SPh)_3$ in THF-NMP to give 2-methallyl-3-[tris(phenylthio)methyl]cyclohexanone (**2**) regiospecifically (eq 4). Treatment of (**2**) with ***Silver(I) Trifluoromethanesulfonate*** in THF provides 5-phenylthio-7-methyl-1-tetralone (**3**).[15] The diastereoselective allylation of a camphor imine by methallyl bromide has also been reported.[16]

(2)

(3)

(4)

Addition reactions also occur, and are exemplified by the reaction with $CHBr_3$ and NaOH in the presence of a phase-

transfer catalyst. Either addition of CBr_3^- or of **:**CBr_2 can be achieved specifically;[17] the similar addition of **:**CCl_2 has also been reported.[18] Pd-catalyzed ethoxycarbonylation of methallyl bromide (NaOEt-Na_2PdCl_4-$[(Ph_2P)_2CH_2]_2$ at rt) is also readily achieved.[19]

Methallyl Chloride

[563-47-3] · C_4H_7Cl · Methallyl Chloride · (MW 90.56)

(four-carbon alkylating agent and isobutyl halide equivalent;[1] acetone carbenium ion equivalent and annulating agent;[2] a nucleophile after conversion to an organometallic[3])

Alternate Name: 3-chloro-2-methylpropene.

Physical Data: bp 71.5-72.5 °C; *d* 0.9165 g cm^{-3}.

Form Supplied in: colorless liquid of 97-98% purity; 90% technical grade is also available (*d* 0.93 g mL^{-1}).

Purification: may be distilled from P_2O_5 prior to use.

Handling, Storage, and Precautions: lachrymator; irritating to mucous membranes and a CANCER SUSPECT AGENT. Use in a fume hood.

Electrophilic Alkylation.

As an electrophile, methallyl chloride undergoes nucleophilic displacement by a variety of substrates including Grignard reagents,[6] carbanions,[7] enolates,[8] carbonyl compounds,[9] alkynes,[10] alcohols,[11] phenols,[12] amines,[13,14] amides,[15] organoboranes,[16] and cyanide[17] to give the four-carbon alkylated product. The individual reagents, methallyl chloride, bromide, and iodide, should be considered as having unique reactivity profiles. For example, ***Methallyl Bromide*** is best suited for low temperature reactions (i.e. <-40 °C) with enolates.[18] Under these conditions the chloride is too unreactive, whereas ***Methallyl Iodide*** leads to mixtures of non- and dialkylated products.

When alkylation is followed by hydrogenation, the net result is addition of an isobutyl group, analogous to alkylation with an isobutyl halide.[1] Under standard catalytic hydrogenation conditions, isomerization to the more highly substituted alkene can also occur (eq 1).[19] Hydrogenation over Wilkinson's catalyst (***Chlorotris(triphenylphosphine)rhodium(I)***) avoids isomerization and affords the saturated product.

Under acid-catalyzed conditions, methallyl chloride can be used for the Friedel-Crafts alkylation of benzene to give 1´-chloro-*t*-butylbenzene.[20]

Annulation Reactions.

When the alkylation with methallyl iodide is coupled with an ozonolysis, the net effect is an alkylation with acetone.[21] More often, alkylation is followed by ozonolysis and a base-catalyzed annulation process to generate a cyclopentenone (eq 2).[2,22]

While ***2-Methoxyallyl Bromide*** offers an alternative to methallyl halides for both the acetonylation of anions and cyclopentenyl annulations, the instability of the reagent requires preparation prior to use. Methallyl chloride and bromide have the distinct advantage of being stable, commercially available compounds. Similarly, ***Isopropenyl Acetate*** is a comparable three carbon-annulating agent, but modest overall yields typically follow its use (see also ***Propargyl Chloride***).

With a dicarboxylic acid ester, methallylation and cyclization may be carried out in such a way so as to generate a cyclohexenone system (eq 3).[23]

Methallyl chloride, after conversion to the Grignard reagent, has also been used for the benzoannulation of 2-hydroxymethylene ketones (eq 4).[24]

(4)

Sigmatropic Rearrangements.

Because of the allylic functionality, alkylation with methallyl halides often provides intermediates which are ideally constructed to undergo intramolecular rearrangement. Phenols may be efficiently alkylated with methallyl chloride in DMF to give the corresponding isopropenyl ether.[12] Under thermal conditions, Claisen rearrangement of the ether provides the *o*-methallylphenol in high yield. When the reaction of an enolate with methallyl chloride gives mixtures of both *C*- and *O*-alkylated products, the Claisen rearrangement has been employed to afford solely the *C*-alkylated product.[22a] Similarly, the thio-Claisen rearrangement has been used to effect α-methallylation of a dithioester.[25] This method has been further extended to include asymmetric induction in the thio-Claisen rearrangement of both dithioesters[26] and thioamides.[27] Alkylation on the oxygen of a chiral allylic alcohol allows for a [2,3]-sigmatropic Wittig rearrangement with this asymmetric induction (eq 5).[11a]

(5)

In the case of a chiral oxathianone, effective alkylation on sulfur requires use of the highly reactive methallyl triflate.[5] Through the intermediacy of the ylide, [2,3]-sigmatropic rearrangement affords a diastereomeric mixture of substituted oxathianones (eq 6). By contrast, direct *C*-alkylation could be expected to be essentially nonselective, giving rise to a nearly equal mixture of diastereomers.

(6)

The methallyl group has also seen utility in a diastereoselective intramolecular ene cyclization, whereby Lewis acid catalysis provides a moderate yield of the indolizidine (eq 7).[14]

(7)

Nucleophilic Reactions.

As a halide, methallyl chloride can be converted to a wide variety of organometallic species for subsequent use as a nucleophile. This includes the methallyl organometallics of magnesium,[3,28] cerium,[29] lithium,[30] manganese,[31] mercury,[32] tin,[33] and zinc.[34] The π-(2-methallyl)nickel bromide complex has found utility in the reaction with various electrophiles.[35] Because of the nonbasic nature of the reagent, this is the preferred method of preparation for compounds such as methallylbenzene (eq 8),[4] where the nonconjugated product is desired. An alternate approach, the reaction of a methallyl halide with phenylmagnesium bromide, is complicated by both double bond isomerization and rearrangement.

(8)

Finally, the α-halomethallyllithium species can be generated in situ via the ***Lithium Diisopropylamide*** deprotonation of methallyl chloride.[36] The resulting allyl carbanion undergoes exclusive α-alkylation with primary bromides (secondary bromides give unacceptable yields) to give alkylated products which retain both the chloride and the double bond functionality (eq 9).

The above lithiated intermediate also reacts with ***Diethylaluminum Chloride*** to give a γ-chloromethallylaluminum species.[37] This in turn reacts stereoselectively with aldehydes to provide *cis*-substituted epoxides, via an intermediate *syn*-chlorohydrin.

Methallyl Iodide

[3756-30-7] · C_4H_7I · Methallyl Iodide · (MW 182.01)

(unstable but reactive alkylating agent attacking C, N, and S nucleophiles; the products are susceptible to addition reactions, especially electrophilically, across C=C systems)

Physical Data: golden-yellow liquid; bp 116-118 °C (dec), 37-40 °C/29 mmHg, 25-30 °C/3-5 mmHg.

Solubility: misc most organic solvents; sparingly misc aqueous media.

Preparative Methods: prepared from ***Methallyl Chloride*** by reaction with ***Sodium Iodide*** in acetone, MEK, or DMF.

Purification: wash with aq. $Na_2S_2O_3$; dry, and distill under reduced pressure.[1a]

Handling, Storage, and Precautions: sensitive to light and heat; prepare as required; decomposes appreciably after a few hours. Use in a fume hood.

The major reported use of methallyl iodide is as an allylating agent when its reactivity outweighs its sensitivity to light and heat.[1] The expected chemical reactions are those of the other methylallyl halides and, by extension, those of allyl halides. *N*-Alkylation occurs with iodo lactams[2] and with indoles.[3] *N*,*O*-Diacetylhydroxylamine is also *N*-methallylated when ***Potassium Carbonate*** is added to a solution of it and methallyl iodide in DMF; the methallyl iodide is preformed from the chloride and NaI in DMF (rt, 3 h; 91% conversion to the iodide).[4] Li derivatives of silylated acrylate esters (deprotonated by ***Methyllithium***) are specifically attacked on C by substituted allyl iodides.[5] 2-Cyclohexenone derivatives[6,7] give 6-(methallyl) derivatives via the corresponding carbanion (eq 1).

(1)

The crystalline Na enolate salts of 2,4-pentanedione derivatives similarly undergo specific (meth)allylation at C-3

using aprotic solvents such as DMSO.[8] The carbanion derived (LDA-THF-HMPA, -75 °C) from methyl crotonate apparently undergoes α-attack with an allylic shift (eq 2).[9]

Stereoselective attack occurs with chiral half-esters of methylmalonic acid, using ***Lithium Diisopropylamide*** (2 mole) and RI (R = allyl, methallyl).[10] Similarly, the glycine enolate synthon (**1**) has been used to provide α-(methallyl)glycine in a remarkably stereoselective process.[11]

(1) R = CO_2-*t*-Bu, CO_2Bn

Friedel-Crafts alkylation of benzene and other simple arenes may be brought about with Lewis acids (e.g. ***Aluminum Chloride***, ***Boron Trifluoride***) but (meth)allyl iodide with Cl_3CCO_2Ag (20 °C; 2 h) attacks benzofuran at both the 2- and 3-positions, though benzothiophene is allylated only at C-2.[12]

Related Reagents.

Allyl Bromide; ***Allyl Chloride***; ***Allyl Iodide***; ***Methallyl Bromide***; ***Methallyl Chloride***.

Methallyllithium

[61777-16-0] · C_4H_7Li · Methallyllithium · (MW 62.05)

(methallylating agent in substitutions and additions; used to attach methallyl groups to other metals and nonmetals)

Alternate Name: 3-lithio-2-methylpropene.

Physical Data: colorless crystals;[1] ^1H, ^{13}C, and ^6Li NMR spectra have been reported on solutions.[2]

Solubility: sol ethers; sparingly sol hydrocarbons.[1]

Preparative Methods: TMEDA complex by metalating ***Isobutene*** with ***n-Butyllithium/N,N,N´,N´-Tetramethylethylenediamine***;[3] by metalating isobutene with butyllithium/***Potassium t-Butoxide***, and then reacting the methallylpotassium with ***Lithium Bromide*** in ether;[4] from methallyltin compounds by exchange with ***Phenyllithium*** or butyllithium.[1]

Form Supplied in: prepared in situ and used directly.

Handling, Storage, and Precautions: must be prepared and transferred under inert gas to exclude oxygen and moisture.

Reactions.

Resonance-stabilized Li reagents such as methallyllithium are stronger nucleophiles but weaker bases than alkyllithium reagents, permitting displacement of halides from alkyl halides in Wurtz-type couplings (eq 1).[3] Additions to aldehydes and ketones,[3a] epoxides, and ***Carbon Dioxide*** also go well.[4] Methallyllithium has been used as a source of methallyl groups attached to boron[5] (useful in the synthesis of chiral homoallylic alcohols as shown in eq 2) and transition metals.[6] On heating, methallyllithium disproportionates, giving off isobutene and providing a source of dilithiotrimethylmethane (eq 3).[7]

Methallylmagnesium Chloride[1]

(X = Cl)

[5674-01-1] · C_4H_7ClMg · Methallylmagnesium Chloride · (MW 114.87) (X = Br)

[33324-92-4] · C_4H_7BrMg · Methallylmagnesium Bromide · (MW 159.32)

(structural unit in organic synthesis; reagent for aromatic annulation and for propenyl ketone synthesis; acetone enolate equivalent)

Alternate Name: 2-methyl-2-propenylmagnesium chloride.

Solubility: sol ether, THF.

Analysis of Reagent Purity: contains 2,5-dimethyl-1,5-hexadiene, the symmetrical dimer. The amount of dimer present depends upon the method of preparation.

Handling, Storage, and Precautions: air- and moisture-sensitive and is best stored at -20 °C under argon.

Grignard Synthesis.

The preparation of allylic and benzylic organomagnesium halides often takes place irreproducibly or in poor yield due to competing dimerization of the reactive halide. The most common solution to the general problem is to use excess magnesium.[1a] Alternatively, a more reactive form of the metal can be utilized. ***Magnesium*** turnings can be activated by treatment with ***Iodine*** or ***1,2-Dibromoethane***.[1b] A highly reactive form of magnesium can be prepared by reducing anhydrous magnesium chloride with ***Lithium*** in THF, using naphthalene as an electron carrier.[2] The metallic powder which results (Rieke magnesium) can be converted to Grignard reagents in high yield by addition of an alkyl halide. Metallic magnesium can also be evaporated and co-condensed with THF at low temperature in a metal-atom reactor.[3] This leads to the formation of a reactive magnesium slurry which is also very effective for the Grignard synthesis.[4] When magnesium powder is irradiated in an ultrasonic bath in the presence of anthracene in THF, a magnesium complex of anthracene is formed which is in equilibrium with free anthracene and a reactive form of magnesium metal. Slow addition of halides at -65 °C led to the Grignard reagents.[5] A disadvantage of this method is the requirement that the reaction product(s) be separated from anthracene.

Preactivation of magnesium turnings by mechanical stirring in the absence of solvent for 2 d under dry nitrogen in a Schlenk tube constitutes a simple method for the clean synthesis of diverse allylic and benzylic Grignard reagents.[6] Fragmentation of the metal surface to form microcrystalline particles effectively increases the surface area of the metal. Yields of (**1**)-(**5**) were high in all cases. The simplicity of this method, the absence of alkali metal salts or anthracene in the final product, and especially the high yields recommend its use.

(5) 95%

Propenyl Ketone Synthesis.[7]

Addition of excess methallylmagnesium chloride to an ester leads to the tertiary alcohol (eq 1). Exposure of the alcohol to ***Potassium Hydride*** in HMPA at 40 °C results in cleavage of one allylic C-C bond with loss of methallyl anion, and irreversible proton transfer to form the ketone enolate. Workup with aq NH_4Cl produces the unsaturated ketone as a mixture of α,β- and β,γ-isomers. This is an unconventional but effective method for converting esters to ketones.

Aromatic Annulation.

Nucleophilic addition of methallylmagnesium chloride to the α-oxoketene dithioacetal derived from menthone (eq 2) forms a tertiary allylic alcohol.[8] Exposure of this material to ***Boron Trifluoride Etherate*** in nitromethane initiates a series of reactions which results in the annulation of an aromatic ring. Similar chemistry has been reported for vinylogous silyl esters.[9] An advantage of this approach to aromatic ring synthesis is the control over the alkyl substitution pattern. A methyl, or other cation-stabilizing group, in the Grignard reagent is essential for high yields of annulated products.[10]

Acetone Enolate Equivalent.

Methallylmagnesium chloride serves as a convenient masked form of acetone enolate. Oxidative cleavage of the methylene group unmasks the carbonyl group.[11]

Related Reagents.

Allylic barium halides offer certain advantages over the corresponding Grignard reagents. For example (eq 3), reduction of BaI_2 with lithium biphenylide in THF, followed by addition at -78 °C of a slight deficiency of 1-chloro-2-methyl-2-butene, produces an organobarium chloride which was treated with cyclohexanone.[12] Workup leads to the tertiary alcohol in 92% yield with excellent selectivity.

Methaneselenol[1]

MeSeH

[6486-05-1] · CH_4Se · Methaneselenol · (MW 95.01)

(powerful nucleophilic species able to produce methaneselenolates and methyl selenides including functionalized ones; methaneselenol and methaneselenolates are valuable reducing agents)

Physical Data: bp 25.5 °C.[1a]

Solubility: sol most organic solvents.

Form Supplied in: sealed ampoule.

Analysis of Reagent Purity: as stable, benzene-soluble MeSe-DNP selenides using Sanger's reagent (1-fluoro-2,4-dinitrobenzene, FDNB) in DMF.[2,3] The molecular ion of MeSe-DNP is prominent in the spectra (*m/e* 262, with selenium fragments at 247 (-Me) and 169 (-$2NO_2$); a peak corresponding to the loss of MeSe is not observed).[3] TLC plate (including its visualization)[2,3] and HPLC[2] of MeSe-DNP are described.

Handling, Storage, and Precautions: volatile, bad smelling compound; use only in a fume hood. Store in cold room. Destroy by slow addition to a cold aqueous solution of NaOCl in the presence of an organic solvent. Clean the vessel with aqueous solution of NaOCl.

General Considerations.

Methaneselenol is a volatile, bad smelling liquid usually prepared by reduction of dimethyl diselenide (prepared from elemental selenium, aqueous KOH and potassium bisulfite) with ***Hypophosphorous Acid*** (H_3PO_2) or by acid hydrolysis of methaneselenolates (eq 1).[4,5] Methaneselenolates are prepared from ***Methyllithium*** or methylmagnesium iodide and elemental ***Selenium***[6] or from methaneselenol and bases (such as K_2CO_3,[7] NEt_3, pyridine,[4] KOH, or NaH) or more conveniently by reduction of dimethyl diselenide with ***Sodium Borohydride***[8,9] or with metal hydrides (eqs 1 and 2).[10] The synthesis of a series of methylseleno derivatives of Group 14 has been achieved[6] from methaneselenol with Group 14 amines or halides or on reaction of the latter compounds with methylselenolithium, methylselenomagnesium iodide, lithium tetra(methylseleno)aluminate, or methylseleno(trimethyl)silane.

Methaneselenol and the corresponding metal selenolates are powerful nucleophiles and in some cases act as reducing agents. Although methaneselenol is easily oxidized by oxygen present in air to dimethyl diselenide, the reaction is best achieved using ***Hydrogen Peroxide*** (stoichiometric),[11] methaneseleninic acid,[11] or ***Sodium Perborate***, (eq 3).[12] Use of an excess of hydrogen peroxide leads to methaneseleninic acid or methaneperseleninic acid, depending upon the amount of reagent used.[11,13]

Reactions of Methaneselenol.

Methaneselenol reacts with alcohols in the presence of an acid catalyst to form methyl selenides (eq 4).[14,15] The reaction, which is best achieved in the presence of ***Zinc Chloride***, only occurs with those alcohols which can form an intermediate carbenium ion, such as tertiary alcohols,[16] *s*-allyl and *t*-allyl alcohols,[15-18] and benzyl alcohols.[14,16] This reaction is used to form *t*-alkyl methyl selenides which cannot be prepared efficiently from methaneselenolates and alkyl halides. Methaneselenol reacts with ethylene oxide to produce 2-methylselenoethanol.[19]

Methaneselenol (1 equiv) and ***Hydrobromic Acid*** or ***Hydrochloric Acid*** also react with aldehydes to form α-haloalkyl

selenides (45-54% yields) and small amounts (20%) of selenoacetals.[20] The synthesis of the latter, which proved to be particularly valuable starting materials for the synthesis of α-selenoalkyllithiums,[21-23] is achieved by reaction of methaneselenol (2 equiv) with aldehydes or ketones in the presence of an acid catalyst (eq 5).[24] Best results are usually obtained using zinc chloride (0.5 equiv), although ***Titanium(IV) Chloride*** (0.3 equiv) is best used for aromatic or hindered carbonyl compounds (eq 5).[24] Reduction leading to methyl selenides occurs from aromatic ketones and with ketones when the reaction is carried out with an excess of zinc chloride for a long time (eq 5).[24,25] The reaction has been successfully used for the synthesis of a large variety of selenoacetals,[16,21,23,24,26-35] including those derived from (a) cyclanones (4-7 membered), β-chloropropanal (HCl, 20 °C, 65% yield), which proved to be a valuable precursor of 1,1-bis(methylseleno)cyclopropane,[31] and (b) unsaturated carbonyl compounds which afford, besides the expected unsaturated selenoacetals, products resulting from 1,4-addition.[36] Straight-chain enals and enones mainly lead to selenoacetals,[36] whereas cyclic enones produce 1,3-bis(methylseleno)propenes.[36] Modification of this method allows the direct synthesis of 2-methylseleno-2-phenylthiopropane from propanal, methaneselenol, benzenethiol (1 equiv each), and zinc chloride and of 1-methoxy-1-methylselenodecane from decanal, methaneselenol (1 equiv each), methanol, and ***Boron Trifluoride Etherate*** in THF.[37]

R = C_9H_{17}	0.5 equiv $ZnCl_2$, 20 °C, 3 h	91%	0%
	5 equiv $ZnCl_2$, 20 °C, 16 h	0%	91%
R = Ph	0.5 equiv $ZnCl_2$, 20 °C, 3 h	68%	26%
	1 equiv $TiCl_4$-NEt_3*, 20 °C, 3 h	72%	0%

Acetals also produce selenoacetals under closely related conditions. Best results are obtained with $BF_3.OEt_2$ as catalyst on straight-chain derivatives (eq 6)[37] and with $ZnCl_2$ on 1-ethoxy-1-trimethylsilyloxycyclopropane (eq 7 60% yield).[38] Extension of this reaction to orthoesters leads to selenoorthoesters (eq 8).[39]

Reactions of Methaneselenolates.

Methaneselenolates are excellent nucleophiles which react with a large variety of organic halides and usually provide the corresponding methyl selenides (eq 9).[1a,1b,10,40,41] However, primary benzyl halides, especially iodides bearing a nitro group on the aromatic ring, suffer significant reduction to the corresponding arylalkane.[42] Potassium or sodium methaneselenolates react with (a) α,α-dihalomethanes which leads to 1,1-bis(methylseleno)methane (MeSeK, CH_2I_2 or CH_2Br_2, EtOH, 20 °C, 76%[30] or CH_2Cl_2, phase-transfer catalysis, MeSeNa, $Et_4N^+Cl^-$, DMF, 93%),[43] (b) aromatic halides bearing an electron-withdrawing group on the aromatic ring such as 4,6-dibromoisophthalaldehyde (DMF, 20 °C, 12 h, 74%)[7] and ethyl 2-chloronicotinate (EtOH, reflux, 1 h, 88%)[44] to furnish 4,6-dimethylselenoisophthalaldehyde and ethyl 2-methylselenonicotinate, respectively (eq 10). β-Halo- and β-selenoalkyl halides do not produce the corresponding selenides but instead lead to alkenes (eq 11).[45] This reduction reaction is stereospecific with *vic*-dibromides and occurs by a formal antiperiplanar elimination reaction.

(9)

(10)

(11)

Methaneselenolates react with epoxides[8,9] and diethyl cyclopropane-1,1-dicarboxylate[46] to produce β-hydroxyalkyl methyl selenides and γ-methylselenobutyrates, respectively (eq 12). In HMPA or DMF they deprotect[47,48] aryl methyl ethers, sulfides, and selenides, producing the corresponding phenolates, arylthiolates, and arylselenolates (eq 13).

(12)

(13)

Methaneselenol, in the presence of pyridine, selectively adds to α,β-unsaturated aldehydes and ketones[49] and reacts with acid chlorides to produce the corresponding methylselenoesters.[4] If the reaction is performed in the presence of ***Chlorotrimethylsilane***, the intermediate enolates are trapped and γ-methylseleno-1-silyloxyalkenes are isolated.[50]

Methaneselenol or its sodium salt react with imidates or chloroimidates, respectively, and produce selenoimidates in poor (15%) to moderate (40-50%) yields.[51] Finally, Beckmann rearrangement of oxime *O*-sulfonates with simultaneous nucleophilic trapping of the imino carbocation intermediate by aluminum selenolate provides a new and highly efficient route to imino selenoethers (eq 14).[52]

(14)

Related Reagents.

Benzeneselenol; ***Methanethiol***; ***Phenyl Trimethylsilyl Selenide***.

Methanesulfenyl Chloride[1]

MeSCl

[5813-48-9] · CH_3ClS · Methanesulfenyl Chloride · (MW 82.56)

(reacts as a pseudohalogen;[1] reacts with carbanions and enolates to add the thiomethyl group α to the carbonyl;[2,3] adds across the double bonds of alkenes and allenes;[4,5] adds across triple bond of alkynes[6,7])

Physical Data: bp 27-28 °C/53-60 mmHg.

Solubility: sol ether, THF, dichloromethane, chloroform, carbon tetrachloride, dimethoxyethane.

Preparative Methods: by treatment of ***Dimethyl Disulfide*** at -15 °C with ***Sulfuryl Chloride***, or by treatment of ***Methanethiol*** with ***Chlorine*** gas in CCl_4 at -15 °C.[1] The latter procedure may be considered a variation of the former since it involves the intermediate formation of the disulfide. The reagent is not commercially available.

Purification: can be used crude from the above preparations. If purification is necessary it must be distilled at low temperature, under vacuum, due to its instability.

Handling, Storage, and Precautions: undergoes decomposition within 1-2 d even when kept in a refrigerator; lasts less than 1 month when stored at -78 °C.

Reaction with Nucleophilic Heteroatoms.

Methanesulfenyl chloride reacts with most N nucleophiles in a manner which can be considered as a direct substitution. Reaction with amines has recently found a use in the preparation of 7-methoxycephalosporins (eq 1).[8]

Methanesulfenyl chloride reacts similarly with thiols and other sulfur nucleophiles to give disulfides.[9] The reaction with alcohols gives complex mixtures of products and is not generally useful.[10] Alkoxides, however, react with methanesulfenyl chloride to give methanesulfenate esters when 1 equiv or less of methanesulfenyl chloride is employed (eq 2); methylsulfinate esters are formed when a 0.5 M excess of methanesulfenyl chloride is used (eq 3).[10]

$$\mathrm{MeSCl} + \mathrm{LiOC_5H_{11}} \xrightarrow[\text{-20 to -60 °C, 35-74\%}]{\text{THF or } Et_2O} \mathrm{MeSOC_5H_{11}} + \mathrm{LiCl} \quad (2)$$

$$3\ \mathrm{MeSCl} + 2\ \mathrm{LiOR} \xrightarrow[\text{-20 to -60 °C, 35-84\%}]{\text{THF or } Et_2O} \mathrm{Me(O)S(OR)} + \mathrm{MeSSMe} + \mathrm{RCl} + 2\ \mathrm{LiCl} \quad (3)$$

Reaction with Carbanions.

Methanesulfenyl chloride has also been used to thiomethylate carbanions, forming thiomethyl ethers (eq 4).[2]

(4)

Reaction with Alkenes, Allenes, and Alkynes.

Methanesulfenyl chloride adds to alkenes to give *anti* adducts with high stereoselectivity and proceeds through a thiiranium ion intermediate.[1,4] For additions to unsymmetrically substituted alkenes the ratio of regioisomers is governed by the steric requirements of the alkene substituents, and to an extent the nature of the solvent used, but gives predominantly anti-Markovnikov addition with alkyl substituted alkenes (Table 1).[4,6] In general, methanesulfenyl chloride tends to give a higher ratio of anti-Markovnikov adducts than do arenesulfenyl chlorides.[11]

Table 1 Effect of Sulfenyl Chloride Used and Alkene Substituent upon Product Ratio in the Addition of Sulfenyl Chlorides to Alkenes

System	Markovnikov (%)	anti-Markovnikov (%)
MeSCl + $MeCH{=}CH_2$	18	82
PhSCl + $MeCH{=}CH_2$	32	68
MeSCl + $Me_2CHCH{=}CH_2$	6	94
PhSCl + $Me_2CHCH{=}CH_2$	13	87
MeSCl + $Me_2C{=}CH_2$	20	80
MeC(O)SCl + $Me_2C{=}CH_2$	68	32

Reaction with allenes is similar with addition generally occuring at the least substituted double bond.[5]

The reaction of methanesulfenyl chloride with alkynes is similar to that with alkenes.[1] The addition is stereospecifically *anti* and goes through a thiirenium ion intermediate to give predominantly anti-Markovnikov products.[6,7]

The high regio- and stereoselectivity characteristic of the addition of methanesulfenyl chloride, and sulfenyl halides in general, to alkenes, allenes, alkynes, and other π-nucleophiles make this reaction very useful. This is especially so when the substrate contains an internal nucleophilic center capable of competing with chloride ion for attack of the thiiranium or thiirenium ion intermediate, such as in sulfenolactonization (eq 5),[12] or when there is additional functionality present which

may participate (eq 6).[13] In eq 6 the methanesulfenyl chloride initially adds to the allene to give a thiiranium ion which is then attacked by the isolated double bond.

Reaction with Enols and Enolates.

Methanesulfenyl chloride reacts with enols and enolates to give α-sulfenylated carbonyls (eq 7).[3,14,15]

Methanesulfonic Acid

$MeSO_3H$

[75-75-2] · CH_4O_3S · Methanesulfonic Acid · (MW 96.12)

(cyclocondensation reagent; precursor for methanesulfonyl chloride and anhydride; catalyst for polymerization, alkylation, and esterification reactions)

Alternate Name: MsOH.

Physical Data: mp 20 °C; bp 167 °C/10 mmHg, 122 °C/1 mmHg; *d* 1.481 g cm^{-3}; *n*D20 1.3210.

Solubility: sol water, ethanol, ether; insol hexane; very sparingly sol benzene, toluene.

Form Supplied in: technical quality is 95% pure containing 2% water.

Analysis of Reagent Purity: ^{17}O NMR.[1]

Preparative Method: by oxidation of ***Dimethyl Sulfide*** with ***Dimethyl Sulfoxide*** in the presence of water and a catalytic amount of ***Hydrogen Bromide***.[17]

Purification: stir with P_2O_5 (20 g for 500 mL of the acid) at 100 °C for 0.5 h and then distill under vacuum.

Handling, Storage, and Precautions: irritant and highly corrosive liquid; should be stored in glass containers. Use in a fume hood.

Cyclization Reactions.

MsOH is a weaker acid than ***Trifluoromethanesulfonic Acid*** and hence only few reports exist on the use of pure MsOH in cyclocondensation reactions.[2] MsOH in dichloromethane effects a symmetry allowed cyclization of the precursor diene to afford 1,2,3,4-tetramethyl-5-(trifluoromethyl)cyclopentadiene, which is used as a ligand in organometallic chemistry (eq 1).[3]

(1)

A 1:10 solution by weight of ***Phosphorus(V) Oxide*** in MsOH[4] is a convenient alternative to ***Polyphosphoric Acid*** for cyclization reactions. For example, the classical preparation of cyclopentenones via intramolecular acylation of alkenoic acids or their lactones (eq 2) and Beckmann rearrangement using polyphosphoric acid (eq 3) give comparable yields when performed with MsOH/P_2O_5.[4]

(2)

(3)

MsOH in conjunction with P_2O_5 has been used in the rearrangement of 2-vinylcyclobutanones to spiro and fused cyclopentenones (eqs 4 and 5).[5]

(4)

(5)

3-Unsubstituted indoles are formed regioselectively by treatment of precursor hydrazones with MsOH/P_2O_5.[6] In the example given in eq 6,[6] only 2-3% of the undesired 3-isomer is formed. Because decomposition sometimes occurs, it is advisable to dilute the reagent with a suitable polar, nonbasic solvent like sulfolane or dichloromethane.

(6)

MsOH itself is a better cyclizing agent than an admixture with P_2O_5 for the cyclization of 3-arylpropanoic and 4-arylbutanoic acids to 1-indanones (eq 7) and 1-tetralones (eq 8).[7]

(7)

(8)

Cyclization with neat MsOH is also observed in the formation of cyclopentenones from 2-vinylcyclobutanones (eq 9).[5]

(9)

MsOH has also been employed successfully in cyclocondensation reactions in the field of heterocycles (eq 10).[8,18] Thus the hexahydroimidazo[1,2-*a*]pyrimidine-5,7-dione shown in eq 10 gives the corresponding cyclized product in 81% yield.[8]

(10)

Other Applications.

MsOH is superior to ***Sulfuric Acid*** as the solvent and catalyst for the conversion of benzoic acid to ***Perbenzoic Acid*** (eq 11).[9]

(11)

MsOH in the presence of methionine is the reagent of choice and an excellent substitute for ***Boron Tribromide*** for *O*-demethylation of opioid derivatives (eq 12).[10] Among the other reagents tested, only TfOH is as effective as MsOH/methionine.

(12)

Schmidt rearrangement of optically active cyclic β-keto esters with retention of configuration is effectively carried out with MsOH in the presence of ***Sodium Azide*** (eq 13).[11]

(13)

Attempted acid-induced cyclization with MsOH of an intermediate diazo ketone involved in the synthesis of tricyclo[5.2.1.0^{4,10}]decane-2,5,8-trione affords the corresponding methylsulfonyloxy derivative via the protonated

diazonium salt (eq 14).[12]

(14)

MsOH is a useful reagent for the condensation of 2-(hydroxymethylene)cyclohexanone with sulfonamides in the presence of molecular sieves to afford products in the *cis-u* diastereoisomeric forms and with >90% stereoselectivity (eq 15).[13]

(15)

The reaction of trimethylphosphine-borane with MsOH in dichloromethane gives the methanesulfonate derivative of the borane (eq 16).[14] This compound can be condensed with diphenylphosphine-borane in the presence of ***Sodium Hydride*** to give the corresponding dimer. By repeating the sequences of mesylation and condensation, a tetramer containing a linear P-B bond has been synthesized.[14]

(16)

MsOH has also been used to deblock the benzyl protecting group[15] and to carry out the acidic hydrolysis of esters.[16]

Related Reagents.

Phosphorus(V) Oxide-Methanesulfonic Acid; ***Polyphosphoric Acid***; ***Trifluoroacetic Acid***; ***Trifluoromethanesulfonic Acid***.

Methanesulfonic Anhydride

$(MeSO_2)_2O$

[7143-01-3] · $C_2H_6O_5S_2$ · Methanesulfonic Anhydride · (MW 174.22)

(preparation of sulfonates[1-3])

Physical Data: mp 69-70 °C; bp 125 °C/4 mmHg.

Solubility: sol organic solvents.

Form Supplied in: off-white powder; widely available.

Purification: can be recrystallized from diethyl ether.

Handling, Storage, and Precautions: corrosive; moisture sensitive. Store in a cool, dry place.

Sulfonate Formation.

The preparation of an alkyl methanesulfonate from an alcohol can be achieved by treatment of an alcohol with methanesulfonic anhydride in the presence of ***Pyridine*** or ***2,4,6-Collidine*** (eq 1).[1] The use of methanesulfonic anhydride rather than ***Methanesulfonyl Chloride*** eliminates the formation of small amounts of alkyl chlorides which occurs when methanesulfonyl chloride is used. Methanesulfonic anhydride, however, does not work very well for the formation of mesylates of unsaturated alcohols. Glycosyl mesylates (eq 2)[2,3] and 11-*O*-methylsulfonylerythromycins[4] have been synthesized using methanesulfonic anhydride.

(1)

(2)

Glycosyl mesylates can be converted to glycosides by treatment with alcohols, and have also been used as intermediates in the synthesis of oxyglycals. Preparation of methyl ethers by solvolysis of mesylates in methanol has been reported.[5] Treatment of glycidols with methanesulfonic anhydride yields the epoxy mesylate which can then be treated with ***Tellurium*** to produce the allyl alcohol (eq 3).[6]

(3)

Sulfonamide Formation.

Treatment of amines with methanesulfonic anhydride in acetonitrile yields the methanesulfonamide (eq 4).[7] Sulfonamides are versatile protecting groups for the amino group, displaying good stability to both acidic and basic conditions. The sulfonamide group can be cleaved by ***Lithium Aluminum Hydride*** or dissolving metal reductions. Methanesulfonamides are also present in some biologically active molecules.

(4)

Sulfone Formation.

Friedel-Crafts methylsulfonation of benzene or substituted benzenes can be achieved via treatment with methanesulfonic anhydride in the presence of a Lewis acid catalyst (eqs 5 and 6).[8,9] Unlike methanesulfonyl chloride, which sulfonates only activated benzenes, treatment of deactivated benzenes with methanesulfonic anhydride produces the desired sulfones in good yields.[8,10] Diaryl sulfones can be formed using methanesulfonic anhydride and ***Sulfuric***

Acid (eq 7).[11]

(5)

2:1

(6)

(7)

R = H, Et, Me, OEt, OMe

Oxidation of Alcohols.

Primary and secondary alcohols can be oxidized to aldehydes and ketones in good yields via treatment with methanesulfonic anhydride and ***Dimethyl Sulfoxide*** in HMPA (eqs 8 and 9). Dichloromethane can be substituted as the solvent, but the use of HMPA leads to cleaner products. Methanesulfonic anhydride works especially well for the conversion of primary alcohols to aldehydes.[12] Benzylic aldehydes can also be formed using this method.

(8)

Related Reagents.

Acetic Anhydride; ***Benzoyl Chloride***; ***Dimethyl Sulfoxide-Methanesulfonic Anhydride***; ***Methanesulfonyl Chloride***; ***p-Toluenesulfonyl Chloride***; ***Trifluoroacetic Anhydride***.

Methanesulfonyl Azide

$MeSO_2N_3$

[1516-70-7] · $CH_3N_3O_2S$ · Methanesulfonyl Azide · (MW 121.14)

(diazo transfer reagent for activated methylene,[1] methine,[1,2] and methyl[3] groups; functionalization of double and triple bonds)

Alternate Name: mesyl azide.

Physical Data: mp 18-20 °C; bp 44-45 °C/1 mmHg; *n*20D 1.4675; *d*204 1.4361 g cm^{-3}.

Solubility: sol Et_2O, MeOH, MeCN; sparingly sol 95% EtOH, cold H_2O.

Form Supplied in: low-melting white solid or clear, colorless oil.

Analysis of Reagent Purity: IR, NMR, refractive index.

Preparative Methods: reaction of ***Methanesulfonyl Chloride*** with ***Sodium Azide*** in MeOH(EtOH)/H_2O[1,3] or acetone[2] (55-61 or 96% yields, respectively). By substituting acetone for methanol, the formation of $MeSO_2OMe$ is avoided and the reagent is obtained in >95% purity.[2]

Purification: crystallization from ether in dry-ice/acetone or from 95% EtOH at -75 °C; distillation in vacuo.

Handling, Storage, and Precautions: should be stored in the cold and the dark. Explosive when heated above 130 °C. No experimentalists have reported any difficulty handling MsN_3, but proper caution should be used, as with all azide reagents. Use in a fume hood.

Diazo Transfer Reagent.

Methanesulfonyl azide (MsN_3) is claimed to be a superior reagent[1,2] for diazo transfer reactions.[4] It is useful for both of the main strategies for accomplishing this process: (a) direct transfer of the diazo function to activated methylene groups; and (b) transfer to the methine position of α-acyl carbonyl substrates with a subsequent cleavage of the acyl group.

Direct transfer with MsN_3 has been reported for alkyl-,[1a] aryl-,[5a] and alkynyl-substituted (eq 1)[6] 3-keto esters, *N*,*N*-

disubstituted acetoacetamides,[5b] derivatives of malonic acid,[7] and 2,4-pyrrolidinediones,[8] and for alkynyl-substituted phenylsulfonyl acetates,[6] to give corresponding diazo dicarbonyl or diazo carbonylsulfonyl compounds in high yields. The process is usually realized with ***Triethylamine*** as the base,[4] or in the presence of sodium acetate.[5a]

(1)

R = H, Me, Ph, TMS, etc.

A very rare diazo transfer onto a methyl group is shown in eq 2.[3] Reaction of oxime ethers with 1 equiv of ***n-Butyllithium*** followed by addition of MsN_3 to the enolate affords pure 2-diazo oxime ethers.

(2)

R' = Me, Ar

The deformylation and deacetylation strategy using MsN_3 is an efficient route to numerous saturated,[1,5] alkynyl-substituted,[6] and chiral 2-diazo esters[5,9] and 2-diazo ketones.[2,6] Substituting trifluoroacetylation of lithium enolates for the usual Claisen formylation step[4] can be used to prepare unsaturated cyclic and acyclic 2-diazo ketones via α-trifluoroacetyl ketones (eq 3).[2]

(3)

Significant regioselectivity can be achieved in this process when ***Lithium Diisopropylamide*** or ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LTMP) is employed for generation of the enolate from 2-octanone (eq 4).[2]

(4)

1,3-Dipole.

Cycloaddition reactions of MsN_3 with activated triple bonds of alkoxyalkynes[10] and alkynylamines[11] give rise to substituted 1,2,3-triazoles (>85%)[11c] or their open-chain diazo isomers (54-96%). The particularly nucleophilic double bonds of 5-alkylidenedihydrotetrazoles react with mesyl azide to produce stable zwitterions or iminotetrazines, after elimination of N_2 and a 1,2-shift of a nitrogen atom in a postulated intermediate triazoline (eq 5).[12]

Regioselective formation of α-piperidone imines,[13] α-imino ethers,[14] and aziridines[15] occurs almost quantitatively in MsN_3 cycloadditions with the nucleophilic double bonds of tetrahydro- and dihydropyridines, vinyl ethers, and diazanorbornadiene. A tendency towards α-imino ether formation decreases in the order N_3SO_2Me > N_3CO_2Me > N_3Ph.[14] Isolation of tetracyclic azetidines from cycloaddition reactions of MsN_3 with 7-substituted norbornadienes has also been reported.[16]

Imination Agent and Nitrene Radical Precursor.

The imination of ***Triphenylphosphine***[17] and other trivalent phosphorus compounds[18] (Staudinger reaction[19]) with MsN_3 gives iminophosphoranes in good yields (eq 6).[18a] A related triphenylarsine imine, $Ph_3As{=}NSO_2Me$, is formed by Cu-catalyzed decomposition of MsN_3 at 110 °C in the presence of ***Triphenylarsine*** (74% yield).[20]

Efficient reduction of mesyl azide to the sulfonamide by hydrogen abstraction from the surrounding medium occurs on

photolysis in isopropyl alcohol[21] and a few other solvents.[22] However, methanesulfonylnitrene and the species generated by the photolysis or thermolysis of MsN_3 in hydrocarbons, aromatic, and other substrates are usually relatively unselective reagents.[23]

Methanesulfonyl Chloride

$MeSO_2Cl$

[124-63-0] · CH_3ClO_2S · Methanesulfonyl Chloride · (MW 114.56)

(synthesis of methanesulfonates;[1] generation of sulfene)

Alternate Name: mesyl chloride.

Physical Data: bp 60 °C/21 mmHg; *d* 1.480 g cm^{-3}.

Solubility: insol water; sol alcohol, ether.

Form Supplied in: liquid of 98% or 99+% purity.

Handling, Storage, and Precautions: highly toxic; corrosive; lachrymator; moisture sensitive; store in a cool dry place.

Methanesulfonates.

The most common use of methanesulfonyl chloride is for the synthesis of sulfonate esters from alcohols. This can be readily accomplished by treatment of an alcohol with mesyl chloride in the presence of a base (usually ***Triethylamine*** or ***Pyridine***).[1] The methanesulfonates formed are functional equivalents of halides. As such they are frequently employed as intermediates for reactions such as displacements, eliminations, reductions,[2] and rearrangements.[3] Selective mesylation of a vicinal diol is a common method of preparation of epoxides.[4] Alkynyl mesylates can be used for the synthesis of trimethylsilyl allenes.[5] Oxime mesylates undergo a Beckmann rearrangement upon treatment with a Lewis acid.[6] Aromatic mesylates have been used as substrates for nucleophilic aromatic substitution.[7] Mesylates are more reactive than tosylates toward nucleophilic substitution, but less reactive toward solvolysis.

Protection of Alcohols.

In addition to being used as a halide equivalent, methanesulfonates have also been used as protecting groups for alcohols and phenols. The use of methanesulfonate as a protecting group for alcohols is mainly limited to carbohydrate synthesis due to the lability of the methanesulfonate group toward nucleophilic attack. The sulfonate ester is stable to acidic conditions and can be cleaved by ***Sodium Amalgam***.[8]

Protection of Amines.

Amines also react with mesyl chloride to form the corresponding sulfonamide. The sulfonamide group is one of the most stable nitrogen-protecting groups, with good stability to both acidic and basic conditions. The sulfonamide can be cleaved back to the amine by ***Lithium Aluminum Hydride*** or dissolving metal reductions.[9] In addition to treatment of amines with mesyl chloride, other reports for the preparation of sulfonamides include a Reissert-type reaction of mesyl chloride with phthalazine[10] and addition of mesyl chloride to lactim ethers (eq 1).[11]

(1)

Chlorination.

Methanesulfonyl chloride can effect the direct chlorination of various substrates. The most notable of these reactions is the selective chlorination of the C-6 primary hydroxy group of carbohydrates (eq 2).[12] Under these conditions, 2-furyl alcohol (eq 3)[13] and guanine *N*-oxide (eq 4)[14] can also be chlorinated directly.

(2)

(3)

(4)

Meyers developed a procedure for the direct conversion of allylic alcohols to allylic chlorides that is general for a variety of terpenes (eq 5).[15] Primary alcohols give yields in the 85% range. A single example of a secondary alcohol produced the chloride in 50% yield. Certain allylic alcohols also undergo stereospecific chlorination under the conditions normally employed for mesylate formation (eq 6).[16]

(5)

(6)

Under Lewis acid catalysis, mesyl chloride reacts with unactivated benzenes to produce the aromatic chloride and only trace amounts of the corresponding sulfone (eq 7).[17] Mesylates have also been used as intermediates for the transformation of alcohols into halides.

(7)

Interconversion of Carboxylic Acid Derivatives.

Methanesulfonyl chloride is employed in the activation of carboxylic acids for the preparation of anhydrides (eq 8),[18] nitriles (eq 9),[19] amides (eq 10), and esters (eq 11).[20]

(8)

(9)

(10)

(11)

Eliminations.

Alkene formation by elimination can also be achieved with mesyl chloride. This is general for a variety of substrates. Peterson reported the elimination of β-hydroxy silanes to give predominantly *trans*-alkenes upon treatment with mesyl chloride (eq 12).[21] In a similar manner, β-hydroxy phenylselenates can also be eliminated (eq 13).[22]

(12)

(13)

Corey reported a mild elimination of iodohydrins by activation with mesyl chloride (eq 14).[23] The major advantage of this method over traditional methods is that the use of a strong reducing agent (***Zinc*** or ***Tin(II) Chloride***) is avoided.

(14)

The direct elimination of tertiary alcohols by treatment with mesyl chloride has also been reported.[24] A variety of acid sensitive functional groups including silyl ethers and acetals are stable to these reaction conditions (eq 15). Mixtures of *cis* and *trans* and internal and terminal alkenes are formed in all cases where possible (eq 16).

(15)

(16)

The synthesis of α-methylene lactones[25] and ketones[26] via the elimination of a mesylate has also been reported (eqs 17 and 18). In these cases, the pyridine or triethylamine is sufficiently basic to induce elimination under standard mesylate forming conditions.

(17)

(18)

Heterocycles.

Sulfene, generated by the treatment of methanesulfonyl chloride with base, undergoes [2 + 2], [3 + 2], and [4 + 2] cycloadditions to produce four-, five-, and six-membered heterocycles, respectively. Alkynyl amines[27] and enamines[28] both undergo [2 + 2] cycloadditions with sulfene to produce four-membered cyclic sulfones (eqs 19 and 20).

(19)

(20)

Five-membered sultones can be formed by reaction of α-hydroxy ketones with sulfene (eq 21).[29] Sulfene adds in a [4 + 2] manner across azadienes (eq 22)[30] and enones (eq 23).[31]

(21)

(22)

(23)

Addition Across Alkenes and Alkynes.

In the presence of a catalyst (usually ***Copper*** or ruthenium), methanesulfonyl chloride adds across alkenes and alkynes to produce β-chloro sulfones.[32] The stereochemistry of the product of addition across phenylacetylene depends on the reaction conditions used. In the absence of an added hydrochloride salt, the *cis* addition product predominates (eq 24), whereas the *trans* product is favored when the salt is added (eq 25).

(24)

(25)

TMS-substituted alkenes and alkynes are especially useful in these reactions (eqs 26 and 27).[33] Using this methodology, allylic sulfones can be prepared (eq 28). Kamigata reported only minor success in inducing chirality into this reaction by the use of optically active ruthenium catalysts (eq 29).[34]

(26)

(27)

(28)

(29)

Synthesis of Vinyl and Allyl Sulfones.

In addition to the methods presented above, vinyl and allyl sulfones have been prepared by the palladium-catalyzed cross coupling of vinyl- and allylstannanes with sulfonyl chlorides (eq 30).[35]

(30)

Acyliminium Cyclizations.

Formation of acyliminium ions by treatment of α-hydroxy amides with methanesulfonyl chloride is a mild way of effecting acyliminium ion cyclizations. Under these conditions, allylstannanes (eq 31)[36] and cyclic vinyl sulfides (eq 32)[37] undergo addition to the iminium ion generated. The allylstannane cyclizes with a high degree of *endo* selectivity.

(31)

(32)

Lactone Inversion.

Lansbury demonstrated the use of mesyl chloride for lactone inversion in his synthesis of aromatin (eq 33).[38] This method is superior to the classical methods since the problems of racemization and relactonization are overcome.

(33)

Rearrangement of Thioacetals to Aldehydes.

Sato et al. reported the rearrangement of α-hydroxy thioacetals to α-sulfenyl aldehydes (eq 34).[39] The thioacetals are prepared by the addition of the anion of methoxy(phenylthio)methane to aldehydes and ketones. This reaction is general for alkyl, allyl, and aromatic carbonyl compounds.

(34)

Methanesulfonyl Chloride-Dimethylaminopyridine

(MsCl)

[124-63-0] · CH_3ClO_2S · Methanesulfonyl Chloride-Dimethylaminopyridine · (MW 114.56) (DMAP)

[1122-58-3] · $C_7H_{10}N_2$ · Methanesulfonyl Chloride-Dimethylaminopyridine · (MW 122.19)

(conversion of alcohols to alkenes[1])

Alternate Name: Furukawa's reagent.

Physical Data: see ***Methanesulfonyl Chloride*** and ***4-Dimethylaminopyridine***.

Preparative Method: MsCl (2.5 equiv), DMAP (1.25 equiv), H_2O (1 equiv), and CH_2Cl_2 are stirred at rt for 2-3 d.

Handling, Storage, and Precautions: effective even after 6 months; for handling the components, see ***Methanesulfonyl Chloride*** and ***4-Dimethylaminopyridine***.

Conversion of Alcohols to Alkenes.

Furukawa and co-workers found that treatment of alcohols with MsCl/DMAP/H_2O/CH_2Cl_2 (Furukawa's reagent) produces the dehydrated products in good yields (eq 1).[1] In the absence of water, the dehydrated products can still be formed, but in very poor yield. Some examples of secondary alcohols undergoing this elimination have also been reported (eq 2).[2]

Yodav and co-workers reported that treatment of a variety of tertiary alcohols with methanesulfonyl chloride in the presence of DMAP and ***Triethylamine*** produces the dehydrated products (eq 3).[3] Acid-sensitive functionalities are not affected by the reaction conditions.

Mixtures of internal and terminal and *cis*- and *trans*-alkenes are formed in all cases. The reaction can be run at rt or below. For compounds with acid-sensitive groups, this method offers advantages over the use of other reagents used to effect this transformation.

Mesylate Formation.

Treatment of a secondary alcohol with methanesulfonyl chloride in the presence of DMAP yields the corresponding mesylate in good yield (eq 4).[4]

Methanethiol

MeSH

[74-93-1] · CH_4S · Methanethiol · (MW 48.12)

(conjugate base is utilized in nucleophilic aliphatic[1] and aromatic substitution;[2] addition to alkenes,[3] alkynes,[3] and as a Michael donor;[3c] formation of *S,S*-acetals for carbonyl protection,[4] umpolung reagent formation,[5] and thionium ion generation;[6] formation of *O,S*-acetals by protecting group interconversion;[7] formation of glycosylation substrates,[8] thioesters,[9] and thiocarbamates[10])

Physical Data: mp -123 °C; bp 6 °C; *d* 0.8665 g cm^{-3} (4 °C).

Solubility: sol water at 20 °C (23.30 g L^{-1}); very sol ethyl alcohol, ether.

Form Supplied in: gas; lecture bottle; widely available.

Handling, Storage, and Precautions: flammable, corrosive gas with a pungent odor. It is imperative that methanethiol be used in a well-ventilated hood. Exposure can be minimized by slow distillation from the storage container into the reaction vessel[11] and/or trapping the boil-off in a solution containing a strong oxidizing agent (e.g. $KMnO_4$[12]).

Nucleophilic Substitutions.

Reaction of methanethiolate (MeS^-), prepared from the reaction of MeSH with base, with primary and secondary alkyl halides or sulfonates provides methyl alkyl sulfides in good to excellent yields. As with alkoxide nucleophiles, primary substrates are most useful, secondary substrates provide lower yield, and elimination predominates with tertiary substrates. Displacement of appropriate primary chlorides provides sulfinyl sulfides (eq 1),[13] secondary tosylates can afford methylthio derivatives of proline (eq 2),[14] and S_N2' addition to substituted cyclopentenes results in stereospecific *anti* addition (eq 3).[15]

(3)

$X = OSO_2Me$	$Y = CO_2Me$	76%
$X = NMe_3BF_4$	$Y = CO_2Me$	91%
$X = OSO_2Me$	$Y = SO_2Ph$	73%
$X = NMe_3BF_4$	$Y = SO_2Ph$	52%

Epoxides undergo nucleophilic cleavage to provide β-hydroxy sulfides. Epichlorohydrin reacts with methanethiolate to provide an important intermediate for the generation of 1,3-bis(methylthio)allyllithium (eq 4),[11] α,β-epoxy ketones yield α-thiomethyl enones,[16] and 4-methyloxetanone provides β-(methylthio)butyric acid (eq 5).[17] Nucleophilic aromatic substitution of activated aryl halides is well documented[2] and even unactivated aryl halides react with methanethiolate in HMPA to give substituted arenes (eq 6),[18] with other alkanethiolates demonstrating this reactivity in various aprotic solvents (DMA,[19] DMF,[20] and polyglymes[21]).

(4)

(5)

(6)

Additions to Carbon-Carbon Multiple Bonds.

Electrophilic and radical addition of methanethiol and nucleophilic addition of methanethiolate to carbon-carbon multiple bonds is well documented.[3] Recent examples include the radical addition to α-allylglycine derivatives to provide trifunctional amino acids,[22] the stereospecific nucleophilic addition of potassium methanethiolate to alkyl alkynyl sulfides (eq 7),[23] under phase-transfer catalysis, and addition to propargyl sulfone.[24] Methanethiolate undergoes Michael addition to alkenes conjugated to electron-withdrawing substituents.[3c] When Michael addition is followed by protonation at low temperatures, high diastereoselectivity is obtained with nitro alkenes (eq 8).[25]

Formation of *S,S*- and *O,S*-Acetals.

Thioacetals are generally regarded as robust protecting groups for carbonyl compounds. Reactions of aldehydes, ketones, or acetals with MeSH and catalytic Brønsted or Lewis acid provides dimethyl dithioacetals, generally in good to excellent yield.[4] For labile substrates, ***Titanium(IV) Chloride*** at low temperature has proven successful (eq 9).[12a] Acetal exchange occurs readily with MeSH in the presence of ***Bromodimethylborane*** to give *O,S*-acetals, allowing conversion of MEM and MOM ethers into (methylthio)methyl (MTM) ethers (eq 10).[7] Formation of methyl thioglycosides (eq 11)[8] with the methanethiol analog methyl trimethylsilyl sulfide ($MeSSiMe_3$) provides the 1,2-*trans*-

thioglycoside stereospecifically.

(9)

(10)

R = MOM 91%
R = MEM 89%

(11)

MeSH, $BF_3 \cdot Et_2O$, CH_2Cl_2, 0-15 °C	7:1	86%
MeSTMS, $BF_3 \cdot Et_2O$, CH_2Cl_2, 25 °C, 36 h	100:0	66%

The utility of these thioacetals includes desulfurization with ***Raney Nickel*** to give methylene or methyl compounds[26] and the well documented[5] use as acyl anion equivalents or umpolung reagents upon deprotonation. Dimethyl dithioacetals provide intermediate thionium ions upon treatment with ***Dimethyl(methylthio)sulfonium Tetrafluoroborate*** (DMTSF); these undergo inter- and intramolecular additions with allylstannanes,[27] silyl enol

ethers,[6,28] vinylsilanes,[6] and indoles (eq 12).[29] Methyl *S*-glycosides undergo stereospecific glycosylation under the influence of nitrosyl tetrafluoroborate.[8]

(12)

Other Applications.

Methanethiol reacts with derivatized carboxylic acids and isocyanates to provide thioesters[9] and thiocarbamates,[10] respectively. Lithium methanethiolate cleaves hindered methyl esters to the corresponding acids[30] and, under forcing conditions, methyl phenyl ethers to phenols. Pyrrolizidinediones have been reduced with ***Sodium Borohydride*** in EtOH to give the corresponding ethoxy lactams. Exchange with MeSH under acidic conditions then provides the lactam thioether (eq 13).[31] Reduction of analogous pyrrolizidinediones in the presence of MeSH provides the corresponding lactam thioethers directly (eq 14).[32]

Methanesulfonamide

$MeSO_2NH_2$

[3144-09-0] · CH_5NO_2S · Methanesulfonamide · (MW 95.14)

(methanesulfonamide-derived reagents are used in the synthesis of porphyrins[1] and in Mitsunobu reactions;[2] methanesulfonamide itself is useful in the synthesis of nitriles,[4] *N*-sulfonyloxaziridines,[5] macrocycles,[6] site-directed antagonists,[7,8] and as a catalyst turnover reagent in osmium-catalyzed asymmetric dihydroxylations[9,10])

Physical Data: mp 91-92 °C.

Form Supplied in: white crystalline solid; widely available.

Handling, Storage, and Precautions: should be stored in a cool dry place. It is an irritant and should be handled carefully. Use in a fume hood.

Methanesulfonamide-Derived Reagents.

N-(2-Methylthio-1-*p*-toluenesufonyl)methanesulfonamide, derived from methanesulfonamide, methylthioacetaldehyde dimethyl acetal and *p*-toluenesulfenic acid, has been used as a key intermediate in the synthesis of symmetrically substituted porphyrins (eq 1).[1]

t-Butyl ((2-(trimethylsilyl)ethyl)sulfonyl)carbamate (**3**), a reagent for use in the Mitsunobu reaction, has been prepared from methanesulfonamide (eq 2).[2] Treatment of methanesulfonamide with ***n-Butyllithium*** in THF, followed by acylation with ***t-Butyl Azidoformate*** in the presence of ***Sodium Hydride*** and ***N,N,N´,N´-Tetramethylethylenediamine***, gave sulfonamide (**1**). Treatment of (**1**) with 2 equiv of ***Lithium Diisopropylamide*** gave the dianion (**2**). Addition of ***(Iodomethyl)trimethylsilane*** to (**2**) gave (**3**). An alternate route to (**3**) involves deprotonation of the known sulfonamide (**4**)[3] with ***Methyllithium***, followed by acylation with *t*-butyl azidoformate in the presence of sodium hydride (eq 3). The

use of this reagent in Mitsunobu reactions has been well demonstrated.[2]

Use in Synthetic Transformations.

The classical procedure for conversion of carboxylic acids to the corresponding nitriles through amides is simplified by the use of methanesulfonamide as the nitrogen source.[4] A variety of chlorobenzonitrile isomers and homologs, which are otherwise difficult to prepare, are made accessible through this route (eq 4).

N-Sulfonyloxaziridines are gaining importance as potential neutral chiral oxidants. *N*-Methanesulfonylimines, the precursors for the synthesis of *N*-sulfonyloxaziridines, are conveniently prepared by the reaction of methanesulfonamide with aromatic aldehydes (eq 5).[5]

(5)

Methanesulfonamide has been used as a locking fragment in the template synthesis of the azacyclam family of macrocycles. Methanesulfonamide in the presence of ***Formaldehyde***, ***Triethylamine***, and Cu^{II} effectively closes the open-chain tetramine 1,9-diamino-3,7-diazanonane to give (3-methanesulfonyl-1,3,5,8,12-pentaazacyclotetradecane)dinitratocopper(II) as a crystalline solid (eq 6).[6]

(6)

Methanesulfonamide reacts with 6,7-dichloro-3,4-dihydro-3-oxo-2-quinoxalinecarboxylic acid to give the corresponding *N*-methylsulfonyl derivative, which is a well-characterized antagonist at the glycine site of the NMDA receptor and AMPA receptor (eq 7).[7]

(7)

A highly potent histamine H_2 receptor antagonist has been prepared by reaction of methanesulfonamide with the corresponding imidate (eq 8).[8]

(8)

Use as a Catalyst Turnover Reagent.

In the case of osmium-catalyzed asymmetric dihydroxylation of nonterminal trisubstituted alkenes, 1,2-disubstituted alkenes,[9] and α,β- and β,γ-unsaturated amides,[10] where the hydrolysis of the osmate ester is turnover limiting, the presence of methanesulfonamide leads to shorter reaction times (eq 9).

Methoxyacetonitrile

$MeOCH_2CN$

[1738-36-9] · C_3H_5NO · Methoxyacetonitrile · (MW 71.09)

(a protected formaldehyde equivalent that undergoes metalation and addition to various electrophiles and that intercepts various nucleophiles at the cyano group)

Physical Data: bp 49 °C/60 mmHg,[1] 111 °C/624 mmHg,[2] 120-121 °C/759 mmHg;[3] *d* 0.956 g cm^{-3}.

Solubility: sol ethyl ether, chloroform, acetone, most common organic solvents.

Form Supplied in: liquid. *Drying:* distillation from phosphorus pentoxide.

Preparative Method: from ***Formaldehyde***, ***Sodium Cyanide***, and ***Dimethyl Sulfate***.[4]

Handling, Storage, and Precautions: an organic cyanide; should be handled with due care in a fume hood.

Metalation.

The deprotonation of methoxyacetonitrile with various bases (e.g. ***n-Butyllithium***, ***Lithium Diisopropylamide***, ***Sodium Hydride***) produces the corresponding nitrile-stabilized anion. Self-condensation of lithiomethoxyacetonitrile *[69521-26-2]* occurs in some cases.[5]

Additions to Carbonyl Electrophiles.

The addition of the nitrile-stabilized anion of methoxyacetonitrile to aldehydes and ketones gives β-hydroxy-α-methoxy nitriles (eq 1)[6] or α-methoxyacrylonitriles (eq 2)[6,7] depending on the reaction conditions. In the latter case the α-methoxyacrylonitriles are protected acyl cyanides, and demethylation using benzyl thiol in the presence of an amine provides acetamides (eq 2).[6] Bromination[5,8] of methoxyacetonitrile and an Arbuzov reaction provides 2-(diethoxyphosphono)-2-methoxyacetonitrile,[5] a useful reagent for the conversion of carbonyl compounds to α-methoxyacrylonitriles (Horner-Emmons-Wittig reaction) that complements the direct condensation of methoxyacetonitrile with carbonyl compounds (eq 2). The addition of methoxyacetonitrile to a putative iminium salt, derived from isopropoxy- or *t*-butoxybis(dimethylamino)methane, provides an avenue to β-dimethylamino-α-methoxyacrylonitriles.[9,10]

(1)

(2)

Additions to the Cyano Group.

The nucleophilic addition of Grignard[11-16] or organolithium reagents[17] as well as the acid-catalyzed addition (Hoesch reaction) of activated arenes[18] to the cyano group of methoxyacetonitrile leads to α-methoxy ketones. These products are useful intermediates for the synthesis of heterocycles (e.g. coumarins,[18] flavanones,[18-22] quinolinones,[14] pyrazoles[12]) or the synthesis of carbocycles.[15] Nucleophilic additions to methoxyacetonitrile followed by an intramolecular *N*-alkylation provides a one-step construction of 3,4-dihydroquinolines, albeit in modest yield.[23] The sequential addition of a Grignard reagent and an organolithium reagent to methoxyacetonitrile permits the addition of two alkyl groups to afford β-methoxy primary amines $MeOCH_2CR_2NH_2$, having an adjoining quaternary carbon.[24]

Other Reactions.

The acid-catalyzed addition of alcohols with methoxyacetonitrile (Pinner reaction) produces α-methoxy orthoesters[25,26] and the cyano group of methoxyacetonitrile intercepts carbocations (Ritter reaction) leading to decalins[27] or heterocycles.[28,29] A cobalt-catalyzed cycloaddition of methoxyacetonitrile to α,o-diynes leads to tetrahydroisoquinolines[30] and a [3 + 2] cycloaddition of the anion of ***p-Tolylthiomethyl Isocyanide*** to methoxyacetonitrile provides a substituted imidazole.[31]

Methoxyacetyl Chloride

[38870-89-2] · $C_3H_5ClO_2$ · Methoxyacetyl Chloride · (MW 108.53)

(acylating reagent;[1] precursor to methoxyketene;[4] in combination with Lewis acids is a reagent for aromatic chloromethylation[12])

Physical Data: bp 112-113 °C; *n*D20 1.4190; *d* 1.87 g cm^{-3}.

Solubility: miscible with most nonprotic organic solvents.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: reacts readily with water, alcohols, and other protic solvents. Stable to storage at rt for long periods if kept moisture-free in closed bottles.

Acylation: Generation of Methoxyketene.

Methoxyacetyl chloride has been used for the preparation of esters and amides by reaction with alcohols and amines.[1,2] Schotten-Baumann conditions or tertiary amine catalysis (eq 1)[3] gives excellent yields. Use of ***Triethylamine***, most commonly at rt, results in smooth generation of methoxyketene, [2 + 2] cycloaddition of which with both cyclic and acyclic imines (eq 2)[4] gives stereopure β-lactams in good to excellent yield.[5-8]

(1)

Aromatic Chloromethylation.

Although commercially available in bulk quantities, methoxyacetyl chloride can also be readily prepared in excellent yield by simple reaction of methoxyacetic acid with ***Thionyl Chloride***.[9] It is important, however, that the reagent be prepared and distilled fairly rapidly, and that it not be exposed for prolonged periods to acids as, like other alkoxyacetic acids, it undergoes decarbonylative decomposition to produce chloromethyl methyl ether. Both protic and Lewis acids catalyze the decarbonylation, and the procedure has been recommended as a convenient means of generating ***Chloromethyl Methyl Ether*** free of ***Bis(chloromethyl) Ether*** (eq 3).[9-11]

Aluminum Chloride-catalyzed decarbonylation is relatively slow at 0-5 °C in nitromethane, and it has been suggested that $MeO^{+}{=}CH_2\ AlCl_4^{-}$ is formed under these conditions. When the reaction is carried out in the presence of certain types of aromatic substrates, smooth chloromethylation is observed (eq 4).[12,13] The procedure is especially useful for anisoles which contain a powerful electron-withdrawing substituent in the *ortho* or *para* position (eqs 5 and 6). With aromatic substrates highly activated to electrophilic substitution, use of the same conditions leads either to formation of diarylmethanes (eq 7) or to polymerization.

1-Methoxyallenyllithium[1]

[61186-66-1] · C_4H_5LiO · 1-Methoxyallenyllithium · (MW 76.03)

(acryloyl carbanion equivalent; reagent for the synthesis of α,β-unsaturated carbonyl compounds, methoxybutadienes, acylsilanes, methoxycyclopropanes; reagent for annulation of 2-furanones, methoxyfurans, methylenecyclopentanones, and hydroxyquinones)

Alternate Name: (1-methoxy-1,2-propadienyl)lithium.

Physical Data: parent allene: bp 51.5-52.5 °C/760 mmHg;[2] n_D^{20} 1.4264;[2] ^{1}H NMR ($CDCl_3$) δ 6.77 (t, *J* = 5.9 Hz, 1 H), 5.48 (d, *J* = 5.9 Hz, 2 H), 3.42 (s, 3 H).[3]

Preparative Methods: methoxyallene[2,4] is easily prepared from ***Propargyl Alcohol*** by conversion to the methyl ether with aqueous ***Sodium Hydroxide*** and ***Dimethyl Sulfate*** followed by treatment with finely powdered ***Potassium t-Butoxide*** for 2-3 h at 70 °C. The overall yield of methoxyallene, following vacuum distillation, is 82% (eq 1).[5] Use of a heating mantle should be avoided; uneven heating during the isomerization or the distillation leads to polymerization of the sensitive allene. The allene can be stored over K_2CO_3 at -20 °C for several weeks without appreciable decomposition. Abstraction of the α-hydrogen atom from methoxyallene takes place rapidly on treatment with ***n-Butyllithium*** in ether at -30 °C.[6]

Handling, Storage, and Precautions: the parent allene is best stored at -20 °C, or below, over anhydrous K_2CO_3. Hydrolysis or polymerization take place in the presence of acid.

Introduction.

1-Methoxyallenyllithium (**1**) is a reactive nucleophile which functions as an acryloyl anion equivalent in its reactions with electrophiles.

Carbonyl Addition Reactions.[3]

Addition of (**1**) to cyclohexanone and hydrolysis of the methyl enol ether gives the hydroxy enone in 92% yield (eq 2).[6] The addition of (**1**) to chiral aldehydes shows good *anti* selectivity (eq 3).[7] The stereochemical preference for addition has been rationalized according to the Felkin-Anh model. Exposure of the major adduct to catalytic potassium *t*-butoxide leads to the 2,5-dihydrofuran derivative, which can be hydrolyzed to the furanone. Considerable attention has been focused on this unusual transformation.[8] The cyclohexenone adduct of (**1**) undergoes base-catalyzed conversion to the methoxydihydrofuran in what is formally a rare 5-*endo*-digonal cyclization (eq 4). It is noteworthy that no [1,3]- or [3,3]-sigmatropic rearrangements take place, even though these are not obviously precluded by geometrical constraints.[8]

(2)

(3)

(4)

Chelation controlled addition of (**1**) to carbonyl compounds is also known. Cleavage of the amine protecting group in the proline-derived ketone (**2**) results in a labile amino ketone (eq 5).[9] Addition of (**1**) to this ketone leads to a single product which is converted to the bicyclic methyl enol ether (**3**) by exposure to slightly less than 1 equiv of dry ***p-Toluenesulfonic Acid*** in acetonitrile at 23 °C.

(2)

(5)

(3)
35-40% overall

Addition of (**1**) to 3-chloro-2-butanone (eq 6), followed by brief exposure of the product to ***Potassium Hydroxide***, leads to an epoxy allene.[10] Rearrangement to 3-methoxy-2,4,5-trimethylfuran is accomplished by treatment with base. The mechanism is postulated to proceed by initial abstraction of a vinyl hydrogen with epoxide ring opening, leading to an intermediate enynol which undergoes base-catalyzed cyclization to the furan.

(6)

Additions to Alkyl Halides.

A convergent synthesis of α,β-unsaturated ketones makes use of (**1**) (eq 7).[11] Alkylation of (**1**) with a primary alkyl halide at C-1 is followed by deprotonation of the allene product at C-3 with *n*-butyllithium.[2] Quenching of the 1-methoxy-3-lithioallene with a second alkyl halide and hydrolysis of the product forms enones in excellent overall yield. The 1-methoxy-3-lithioallene can be intercepted by a variety of electrophiles (eq 8).[12] This work demonstrates the utility of (**1**) both as an α- and as a γ-acyl anion equivalent. The kinetic preference for the exclusive formation of the (*Z*)-keto ester (eq 8) is noteworthy, and is the result of stereoelectronic control during the protonation step.

(7)

R^1	R^2	Yield (%)
Bu	Et	91
Bu	Me	86
Et	C_5H_{11}	66
Me	Bu	89

(8)

E^+	E	Yield (%)	(*Z*):(*E*)
Me_2S_2	SMe	60	19:81
TMSCl	TMS	60	63:37
CO_2; MeI	CO_2Me	65	100:0

The products of alkylation of (**1**) with alkyl halides can be rearranged to methoxy dienes (eq 9). Exposure of the adducts to ***Pyridinium p-Toluenesulfonate*** at rt produces 1-substituted 2-methoxybutadienes in moderate yield with good selectivity for the (*E*) isomer.[13]

(9)

R	Yield (%)	(*E*):(*Z*)
Pr	47	5:1
$PhCH_2$	39	100:1
Ph	49	16:1
$BrCH_2CH_2$	41	6:1

More highly substituted methoxybutadienes are also accessible through (**1**). The adducts of (**1**) with carbonyl compounds (eq 10) are converted to the methanesulfinate ester derivatives.[14] Copper-catalyzed Grignard addition takes place selectively at the sp-hybridized carbon of the allene with displacement of methanesulfinate to produce 2-alkyl- or 2-aryl-3-methoxy-1,3-dienes in 70-95% overall yield (eq 10). Enol ether hydrolysis gives enones. Homocuprates are unsatisfactory in this instance because they attack the sulfur atom preferentially.

70-95% (10)

The alkylation products of (**1**) are useful for the synthesis of dioxaspiro compounds. For example, the allene (**4**), which is available in quantitative yield from (**1**), can be deprotonated with ***t-Butyllithium***, and the γ-anion trapped with ***Ethylene Oxide*** in 88% yield (eq 11).[15] Silyl protecting group cleavage, followed by mild, acid-catalyzed intramolecular acetalization, leads to a mixture of diastereoisomeric dioxaspiro compounds. Where additional control elements are present in the rings, the reaction can be biased toward a single product.[16]

(4)

(11)

The trapping of (**1**) by heteroatomic electrophiles to give (**5**) has been described.[6,17-19]

(5)

X =			
	TMS	(TMSCl)	50%

	I	(I_2)	95%

Reaction with Trialkylboranes.

An unusual synthesis of methoxycyclopropanes which proceeds from (**1**) has been disclosed (eq 12).[20] Exposure of the 9-BBN (see ***9-Borabicyclo[3.3.1]nonane***) adduct of 1-methylcyclohexene to a small excess of (**1**), followed by acidification and oxidative workup, leads to the methoxycyclopropane in high yield. The mechanism presumably involves acid-catalyzed rearrangement of a lithium borate salt, accompanied by allylic migration of boron. This is supported by the observation that use of deuterioacetic acid results in the formation of a methoxycyclopropane product in which one methylene group of the three-membered ring is fully deuterated.

(12)

Related 1-Alkoxyallenyllithiums and Reactions.

1-(1-Ethoxyethoxy)allenyllithium (**6**)[2] has been used to convert an aldehyde into an α,β-alkynic ketone (eq 13).[21] Aldehyde addition and quenching of the alkoxide with ***Chlorotrimethylsilane***, followed by treatment with *n*-butyllithium, leads to trimethylsilyl oxide elimination and generation of the ketone enol ether. The allenyllithium (**6**) has also been used for the preparation of acylsilanes.[22] Trapping with ***t-Butyldimethylchlorosilane*** leads to the allenylsilane which upon hydrolysis gives the silyl enone, and upon treatment with peroxy acid gives 1-*t*-butyldimethylsilyl-1,2-propanedione, presumably through an allene oxide intermediate (eq 14).

(6)

(13)

(14)

1-(Methoxymethoxy)allenyllithium (**7**) has been used in a cationic cyclopentannulation reaction.[23] Addition of (**7**) to 3-methyl-2-buten-1-one produces a tertiary alcohol which cyclizes to a five-membered ring upon treatment with ***Trifluoroacetic Anhydride*** and 2,6-***2,6-Lutidine*** (eq 15) in a process reminiscent of the Nazarov reaction. The success of the cyclization reaction requires that the oxygen substituent on the allene be capable of departing as a stable cation.[24]

(7)

(15)

Addition of (**7**) to the vinylogous silyl ester (**8**), followed by treatment of the product with fluoride, produces a tertiary allenic alcohol (eq 16). Epoxidation with buffered peroxy acid produces an epoxy keto aldehyde, presumably from intramolecular trapping of an oxyallyl zwitterion. Methanolic KOH leads to a hydroxy quinone which is *O*-methylated with ***Diazomethane***.[25] Treatment of the adduct of (**7**) and (**8**) with ***Boron Trifluoride Etherate*** in dichloromethane leads to the cyclopentannulation product (eq 17).[26]

(16)

(17)

Related Anions.

Trialkylsilyloxyallenes can be prepared from 2,2-dimethyl-4-methylene-1,3-dioxolane (eq 18).[27] Deprotonation with 2 equiv ***s-Butyllithium*** leads to the allylic carbanion which fragments to the lithium alkoxide of 1,2-propadien-1-ol. Quenching with ***t-Butyldiphenylchlorosilane*** leads to the siloxyallene in high overall yield. Allene deprotonation takes place under the same conditions as for (**1**).

(18)

The allenyllithium (**10**) is prepared selectively in 80% yield, along with 5-6% of (**9**), by γ-deprotonation of *t*-butoxyallene with sterically encumbered lithium dicyclohexylamide.[11] Deprotonation of 1-phenylthioprop-1-yne with *n*-butyllithium/TMEDA at -78 °C leads to thiophenoxyallenyllithium (**11**).[28] Anion (**12**) bears asymmetry on the ether sidechain. Modest levels of asymmetric induction are found in the addition reactions of (**12**) with ketones.[29] 1-Methoxy-1,2,3-butatrienyllithium (**13**) is prepared by treating 1,4-dimethoxy-2-butyne with 2 equiv *n*-butyllithium at -78 °C and warming to -45 °C.[30] This reagent has been used for a synthesis of enynes. The related lithioallenes (**14**)-(**16**)[24] and the copper derivative (**17**)[31] have also been described.

2-Methoxyallyl Bromide

(R = Me)

[26562-24-3] · C_4H_7BrO · 2-Methoxyallyl Bromide · (MW 151.01) (R = Et)

[26562-26-5] · C_5H_9BrO · 2-Ethoxyallyl Bromide · (MW 165.04)

(three-carbon electrophile in alkylations;[1] three-carbon component in arene cycloadditions;[2] bromoacetone equivalent;[1] cyclopentenone annulation reagent;[3] acetone equivalent in nucleophilic additions[4])

Alternate Names: 3-bromo-2-methoxy-1-propene; 1-(bromomethyl)vinyl methyl ether.

Physical Data: a mixture of 2-methoxyallyl bromide, 1-bromo-2-methoxypropene, and 1-bromo-2,2-dimethoxypropane in a ratio of 65:21:14 has bp 134-137 °C; *d* 1.16 g cm^{-3}.[4] A mixture of 2-ethoxyallyl bromide and 1-bromo-2-ethoxypropene in a ratio of approx 3:1 has bp 53-55 °C/26 mmHg.[5]

Solubility: sol common organic solvents (i.e. diethyl ether, THF).

Analysis of Reagent Purity: gas chromatography using Carbowax 20M (or comparable) stationary phase.[1,6]

Preparative Methods: Greenwood and Hoffman reported that treatment of ***2-Methoxypropene*** with ***N-Bromosuccinimide*** in CCl_4 at 55-65 °C provides a CCl_4 solution of 2-methoxyallyl bromide and 1-bromo-2-methoxypropene in an approx 3:1 ratio.[6] Alternatively, Jacobson's modification of existing pyrolytic procedures, pyrolysis of 1-bromo-2,2-dimethoxypropane in the presence of diisopropylethylammonium tosylate, results in a 65:21:14 ratio of 2-methoxyallyl bromide, 1-bromo-2-methoxypropene, and 1-bromo-2,2-dimethoxypropane with high mass recovery (85-90%).[1] In both cases the product mixtures are utilized in subsequent reactions. Polymerization limits the latter procedure to a scale of 30 g or less. 2-Ethoxyallyl bromide has been synthesized by pyrolysis of 1-bromo-2,2-diethoxypropane.[5] The mixture, a 3:1 ratio of 2-ethoxyallyl bromide and 1-bromo-2-ethoxypropene, is obtained in approx. 50% overall yield.

Purification: purification is performed by distillation. Synthetic procedures provide the reagent as a mixture containing 60-70% of 2-methoxyallyl bromide.[4-6] The remainder consists of 1-bromo-2-methoxypropene and/or 1-bromo-2,2-dimethoxypropane, depending on the method of synthesis.

Handling, Storage, and Precautions: neat 2-methoxyallyl bromide is unstable at rt and sensitive to moisture.[6] Mixtures obtained from the thermal cracking of 1-bromo-2,2-dimethoxypropane have been stored for extended periods at -20 °C.[1] Alternatively, a 50% solution in CCl_4 may be stored over Na_2CO_3 at rt in the dark.[6] *Caution*: this is an alkylation reagent; proper protective equipment should be worn and its use restricted to a fume hood.

Alkylations.

2-Methoxyallyl bromide (**1**) has been utilized as a three-carbon electrophile (bromoacetone equivalent) with carbanions derived from enamines,[1,7] esters,[1] nitriles,[1,8] ketones,[1,3] sulfones,[10,11] β-keto esters,[1] and substituted malonates (eq 1).[1] Dianions of carboxylic acids have been alkylated at the α-position[1] and, in the case of α,β-unsaturated acids, at the γ-position in the presence of $CuBr.SMe_2$ (see ***Copper(I) Bromide***).[12] Additional nucleophiles have included Grignard reagents,[13] copper enolates derived from conjugate additions,[14,15] alcohols (eq 2),[16] and lithiated aromatics (2-aryl-5-methyl-1,3,4-oxadiazoles and 4,5-diphenyl-2-methyl-1,3 oxazole) (eq 3).[17,18] The enol is more easily hydrolyzed to the ketone than other electrophilic acetone synthons (see ***2,3-Dichloropropene*** and ***Propargyl Chloride***).[1] Alternatively, the enol functionality has been retained in the synthesis of 1,3-dienes.[11,16]

(1)

(2)

(3)

Cyclopentenone Annulation.

Alkylation of ketones with (**1**), followed by hydrolysis, results in 1,4-diketones which provide a cyclopentenone upon base-induced cyclization. This methodology has been utilized for the de novo synthesis of substituted cyclopentenones and the annulation of cyclopentenones on to existing cyclic systems (eq 4).[1,3,9]

(4)

[4 + 3] Cycloaddition.

In the presence of ***Silver(I) Trifluoroacetate*** and ***Sodium Carbonate***, furan and (**1**) undergo a [4 + 3] cycloaddition, presumably via a 2-methoxyallyl cation, to give 8-oxabicyclo[3.2.1]oct-6-en-3-one after an acidic workup (eq 5).[2,19] Other dienes also react in this manner, albeit in low yields.[20,21]

(5)

Nucleophilic Addition.

π-(2-Methoxyallyl)nickel bromide, prepared from (**1**) and ***Tetracarbonylnickel***, reacts with aryl, alkyl, and vinyl halides, aldehydes, and ketones to give acetone addition products after mild acid hydrolysis (eq 6).[4]

(6)

Related Reagents.

Bromoacetone; ***3-Chloro-2-trimethylsilyloxy-1-propene***; ***2,3-Dichloropropene***; ***Methallyl Bromide***; ***Propargyl Chloride***.

1-Methoxyallyllithium

[53356-78-8] · C_4H_7LiO · 1-Methoxyallyllithium · (MW 78.05)

(reagent used for three-carbon homologation as a homoenolate anion equivalent)

Preparative Methods: the lithio anions of alkyl allyl ethers can generally be prepared by deprotonation with ***s-Butyllithium*** in THF at -65 °C or in ether or pentane with added ***N,N,N´,N´-Tetramethylethylenediamine*** in less than 30 min. ***n-Butyllithium*** can also be used as the base in THF with added TMEDA at -78 °C for 7 h.[1]

Handling, Storage, and Precautions: this and similar 1-alkoxyallyllithium reagents are stable for at least 1 day at -75 °C. At -50 °C there is at least 40% conversion to Wittig rearrangement products after 4 h and >81% conversion after 24 h. After 2 h at -25 °C, there is >89% rearrangement.[2]

General Considerations.

The impetus in the development of the title compound (**1**) was the desire for a convenient homoenolate anion equivalent. The first studies of the generation and reactivity of (**1**) brought out the major problem associated with its use: ambiguity in the site of its reactivity with electrophiles. Studies began almost immediately to find alternative reagents which exhibited predictable, controlled α vs. γ reactivity with electrophiles. This section will be concerned not only with (**1**), but with allied nucleophilic 3-alkoxy-1-propenyl reagents. Reagents of this genre have been covered in small sections of several larger reviews.[3]

1-Alkoxyallyllithiums.

The parent substance (**1**) was reported in 1974[4] along with brief studies of the reactivity of other alkyl allyl ethers. Mixtures of α and γ adducts were obtained in all reactions of the lithio anion regardless of the identity of R^1 (eq 1). The only reasonable (and often repeated) generalities arising from this study are that reaction with alkyl halides takes place predominantly at the γ-position while reaction with aldehydes and ketones occurs at the α-position. Even so, there are many exceptions, and perhaps the most accurate statement one may make regarding the reactivity of 1-alkoxyallyllithiums is that the site of reaction is dependent in a complex way on the identities of the cation, electrophile, solvent system, temperature, and the presence of additives.[5] In the case of reaction at the γ-site, *cis* isomers (**4**γ and **5**γ) are formed exclusively. This observation has prompted many workers to assume the structure of (**1**) to be the internally chelated species (**6**), whether or not a σ-bonded structure is called for in this and related cases. Attempts at rationalizing the observed selectivities have been few and are inadvisable in any case when dealing with mixtures where either the

transition state energy differences in a kinetic process or the product energy differences in a thermodynamic process are, for the most part, less than 1 kcal mol^{-1}. Regioselectivity control with the lithio anions and simple alkyl groups for R^1 appears to be problematic at this point. It was found by Evans in the original study that treatment of the anion (**3**) (R^1 = Me) with 1 equiv of ***Zinc Chloride*** or ***Cadmium Chloride***[6] favors α-alkylation (**5**α) with carbonyl compounds. Yamamoto also realized good regiochemical control in the reaction of 1-isopropoxyallyllithium and 1-(methoxymethoxy)allyllithium with carbonyl compounds by forming aluminum ate complexes with ***Triethylaluminum*** prior to addition of the electrophile resulting in exclusively α-adducts (**5**α).[7] A noteworthy aspect of the reactivity of these reagents is the aldehyde vs. ketone selectivity shown in eq 2.

A report by Still[8] describes the generation and reactivity of the silyloxy anions (**9**), which also show the trend of predominant, but not exclusive, reaction at the γ-position with alkyl halides (**4**γ). A subsequent report by Still describes the trend of predominant, but not exclusive, reaction at the α-position with carbonyl compounds (**5**α).[9] However, when R^1 = trimethylsilyl and 5% ***Hexamethylphosphoric Triamide*** is included in the reaction mixture, exclusive α-addition to aldehydes and ketones is observed (eq 3).

(3)

Generation of 1-Silyloxyallyllithiums via Brook Rearrangement.

1-Silyloxyallyllithiums as a class can also be formed in situ via Brook rearrangement (eq 4). The intermediate lithioalkoxide (**11**) is generated either by addition of vinyllithiums (see ***Vinyllithium***) to silyl ketones (**10**)[10] or by deprotonation of silyl carbinols (**13**) by *n*-BuLi.[11] Carbon to oxygen silyl group migration allows entry to the 1-silyloxyallyllithium reagents which can be trapped in situ with alkyl halides, resulting in the γ-alkylation products (**14**) in good yield. However, this technology has not been applied to the parent allyl systems (**10** or **13**) (R = H).

(4)

Lithiated Allyloxybenzimidazoles.

These derivatives have been found by Mukaiyama to be easily deprotonated and to undergo reaction with alkyl halides and aldehydes to give products of predominantly α-alkylation (**15** -> **16** or **17**) (eq 5).[12] Because the 2-benzimidazolyl

group can act as a good leaving group, this process can be exploited as a method to produce *cis*- and *trans*-vinyloxiranes (eqs 6 and 7).[13] When the addition is mediated by Et_3Al, the *syn*-products (**21**) are predominant and these lead to the *cis*-isomers (**22**).[14]

(5)

(6)

Lithiated Allylic Carbamates.

A significant advance in developing regiocontrolled γ-reactivity of 1-alkoxyallylcarbanions has been made by Hoppe.[15] The lithio derivatives of (**23**) and (**24**) undergo predominantly γ-alkylation when treated with alkyl halides[16] or aldehydes,[17] respectively, realizing a long sought goal of developing a homoenolate equivalent in the 1-alkoxyallyllithium system. Hydrolysis of the aldol adducts (**25**) leads to δ-hydroxy carbonyl compounds as lactols (**26**) or lactol ethers (eq 8). More importantly, deprotonation of substituted derivatives of (**23**) and (**24**) also proceeds well, opening up a family of homoenolate equivalents. Using this methodology, a synthesis of protected 4-oxoalkanoates has been developed (**27** -> **29**) which proceeds in moderate yield and with excellent γ-selectivity (eq 9).[18]

Diastereoselectivity in Additions to Aldehydes with γ-Alkoxyallylboronates.

1-Methoxyallyllithium may be converted to an intermediate γ-alkoxyallylboronate (**30**) by treatment with $(RO)_2B$-X (eq 10). This species undergoes highly regio- and diastereoselective additions to aldehydes to generate *syn*- and *anti*-1,2-diols.[19] A family of reagents (**31** and **32**) were prepared[20] and examined for their diastereoselectivity in reactions with aldehydes. The *cis*-isomers (**31**) give rise to predominantly the *syn*-products (**33**) (eq 11) while the *trans*-isomers (**32**) produce predominantly *anti*-products (**34**) (eq 12). A related study agrees with these results in the case of *cis*-γ-alkoxyallylboronates[21] and these reagents have seen use in target molecule synthesis.[22]

(10)

(11)

$R^1 = Me, CH_2OMe, CH_2CH_2TMS, CMe_2OMe$
$R^2 = Me, Et, i\text{-}Pr, Ph$

(12)

$R^1 = Me, CH_2CH_2TMS$
$R^2 = Me, Et, i\text{-}Pr, Ph$

Brown later extended this methodology, developing an enantioselective method for constructing *syn*-1,2-diols.[23] The boranes (**36**) and (**39**) are prepared from 1-methoxyallyllithium as exemplified in (**1**) -> (**36**) (eq 13). These enantiocomplementary reagents regio- and enantioselectively transfer a three-carbon unit to aldehydes, giving the enantiomeric diol precursors (**38**) (eq 13) and (**40**) (eq 14) in good yield with excellent enantioselectivity.

(13)

(14)

The stannane (**41**), also prepared from (**1**) shows diastereoselectivity similar to (**31**) in its Lewis acid-promoted reactions with aldehydes (eq 15).[24] Transformations analogous to the (**1**) to (**38**) conversion can be performed on systems having considerable complexity (**42**).[25]

(15)

(42)

Arene Ring Annulation.

The zinc ate complex of 1-methoxyallyllithium has been used in a method for the annulation of catechol rings onto cyclic ketones.[26] Reaction of the α-hydroxymethylene ketone (**43**) with the zinc reagent gives the enal (**44**). Without purification, this is oxidized to the methyl ketone (**45**) which is cyclized and aromatized with base to the catechol monomethyl ether (**46**) in good overall yield (eq 16).

γ-Keto Aldehyde Synthesis.

Trialkylsilyloxyallyllithiums can be generated and treated with trialkylchlorosilanes to trap the Brook rearrangement product (**49**) as the bis-silanes (**50**) in good yield. These substances can be treated with acyl chlorides in the presence of ***Titanium(IV) Chloride*** to provide γ-keto aldehydes (**51**) after a hydrolytic workup (eq 17).[27]

Related Reagents.

Allyllithium; ***t-Butoxymethyllithium***; ***(E)-1-(N,N-Diisopropylcarbamoyloxy)crotyllithium***.

p-Methoxybenzaldehyde

[123-11-5] · $C_8H_8O_2$ · *p*-Methoxybenzaldehyde · (MW 136.16)

(protection of diols as the versatile *p*-methoxybenzylidene acetal; protection of dithiols,[1] amines, hydroxy amines,[2] and diamines[3])

Alternate Name: *p*-anisaldehyde.

Physical Data: bp 248 °C; *d* 1.119 g cm^{-3}.

Form Supplied in: clear liquid; widely available.

Protection of Diols.

p-Methoxybenzylidene acetals are easily prepared from diols by reaction of the aldehyde in the presence of an acid catalyst such as ***Hydrogen Chloride***[4,5] or ***Zinc Chloride***.[6] They can also be prepared from the diol and *p*-$MeOC_6H_4CH_2OMe$ by oxidation with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** (CH_2Cl_2, rt, 30 min, 49-82% yield)[7] or by acid-catalyzed acetal exchange with *p*-$MeOC_6H_4CH(OMe)_2$.[8] The *p*-methoxybenzylidene acetal can be prepared by DDQ oxidation of a *p*-methoxybenzyl group that has a neighboring hydroxy function.[9] This methodology has been used to advantage in a number of syntheses.[10-12] Reaction of an epoxide with *p*-methoxybenzaldehyde in the presence of ***Tin(IV) Chloride*** results in the formation of the acetal without prior conversion to the diol (eq 1).[13]

The advantages of the *p*-methoxybenzylidene acetal are that acid-catalyzed hydrolysis (80% AcOH, 25 °C, 10 h, 100% yield) is 10 times faster than that of the benzylidene group;[5] it is cleaved oxidatively with ***Cerium(IV) Ammonium Nitrate*** (MeCN, H_2O)[14] and it is relatively stable to Na/NH_3.[15]

As with the benzylidene group, a variety of methods have been developed to effect cleavage of one of the two C-O bonds in this acetal. Cleavage with ***Diisobutylaluminum Hydride***[10,16,17] has proven to be quite selective and is controlled by both electronic and steric factors. Oxidative cleavage with DDQ[7] results in the formation of a mixture of the two possible monobenzoates. In the carbohydrate field, selective cleavage to give either the more- or less-substituted derivative is possible with the proper choice of reagents (eq 2).[4,14,18,19] Use of $LiAlH_4/AlCl_3$,[12] $BH_3.NMe_3/AlCl_3$,[4] BH_3.THF, heat,[20] or $NaBH_3CN$/TMSCl/MeCN[11] results in cleavage at the less-hindered side of the acetal, whereas $NaBH_3CN$/HCl,[4] or $NaBH_3CN$/TFA/DMF[11] result in formation of an MPM ether at the less-hindered alcohol.

Protection of Amines.

p-Methoxybenzaldehyde has been used to protect an amine as the MPM derivative by reductive amination with ***Sodium Borohydride***.[21] It is also used to prepare imine derivatives of glucosamines which are used in glycoside couplings.[22]

p-Methoxybenzyl Chloride[1]

(X = Cl)

[824-98-6] · C_8H_9ClO · *p*-Methoxybenzyl Chloride · (MW 156.62) (X = Br)

[2746-25-0] · C_8H_9BrO · *p*-Methoxybenzyl Bromide · (MW 201.07)

(protection of alcohols,[3] thiols,[42] phenols,[29] amides,[55] amines,[50] and carboxylic acids[31])

Alternate Name: MPMCl.

Physical Data: X = Cl: bp 117-118 °C/14 mmHg; *d* 1.155 g cm^{-3}.

Solubility: sol all organic solvents.

Form Supplied in: the chloride is commercially available. The bromide is not commercially available and is prepared immediately before use because of its instability.[2]

Preparative Methods: to prepare the bromide, an ether solution of the alcohol is stirred with concd HBr, the phases are separated, and the organic phase is washed with saturated aq. NaBr, dried over K_2CO_3, and concentrated.

Handling, Storage, and Precautions: the chloride is stored over K_2CO_3 to stabilize it; the bromide is stored in the freezer to prevent polymerization, which occurs within a few days at rt.[2]

Protection of Alcohols.

The inherent stability of the MPM ether, coupled with a large repertoire of methods for its removal under mild conditions that do not normally effect other functional groups, makes it a particularly effective derivative for the protection of alcohols. The most common method for its introduction is by the Williamson ether synthesis. A number of bases can be used to generate the alkoxide, but ***Sodium Hydride***[3] in DMF (eq 1) or THF[4] (eq 2) is the most common. Other bases such as ***n-Butyllithium***,[5] ***Potassium Methylsulfinylmethylide*** (dimsylpotassium)[6] (eq 3), and

Sodium Hydroxide under phase-transfer conditions[7] are also used. From these results, it is clear that protection can be achieved without interference from Payne rearrangement, and considerable selectivity can be obtained. In the ribose case, selectivity is probably achieved because of the increased acidity of the 2´-hydroxy group. The additive ***Tetra-n-butylammonium Iodide***[8] is used for in situ preparation of the highly reactive *p*-methoxybenzyl iodide, thus improving the protection of very hindered alcohols. Selective monoprotection of diols is readily occasioned with *O*-stannylene acetals.[9]

(1)

(2)

(3)

Cleavage of the MPM group is usually achieved oxidatively with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone***.[10-12] When DDQ is used, overoxidation of the alcohol occasionally occurs,[13,14] but for the most part this is not a problem. In general, selective cleavage of the MPM group is achieved in molecules containing benzyl groups, but more forcing conditions will result in benzyl cleavage.[15] ***Cerium(IV) Ammonium Nitrate***,[16] trityl tetrafluoroborate,[17] photolysis,[18]

electrolytic oxidation,[19] dimethylboron bromide,[20] ***Boron Trichloride***,[21] ***Iodotrimethylsilane***,[22] ***Tin(II) Chloride***/***Chlorotrimethylsilane***/anisole,[23] hydrogenolysis,[24] and ozonolysis[25] have also been used to cleave this derivative. Selectivity for the *O*-MPM is achieved over an amide MPM derivative with DDQ.[26]

In the presence of neighboring hydroxyl groups, the DDQ oxidation of MPM ethers leads to cyclic acetals, thus affording a level of selectivity which may not be possible to achieve otherwise.[27] In a synthesis of erythronolide (eq 4), the critical oxidative cyclization had to be performed with freshly recrystallized DDQ supported on molecular sieves in order to prevent acid-catalyzed isomerization of the acetal from its initial kinetic disposition to the more thermodynamically favorable orientation.[28]

(4)

Protection of Phenols.

Protection of phenols is achieved using *p*-methoxybenzyl chloride ($Bu_4N^+I^-$, K_2CO_3) in acetone,[29] or the benzyl bromide (*i*-Pr_2NEt) in CH_2Cl_2.[30] Deprotection is occasioned with ***Trifluoroacetic Acid***[29] or ***10-Camphorsulfonic Acid***/$Me_2C(OMe)_2$.[30]

Protection of Carboxylic Acids.

p-Methoxybenzyl esters have been prepared from the Ag^I salt of amino acids and the benzyl halide (Et_3N, $CHCl_3$, 25 °C, 24 h, 60% yield),[31] and from cephalosporin precursors and the benzyl alcohol [$Me_2NCH(OCH_2$-*t*-$Bu)_2$, CH_2Cl_2, 90% yield],[32] and from the benzyl halide ($NaHCO_3$, DMF).[33] They are also prepared by activation of the acid with

isopropenyl oxychloroformate ($MeOC_6H_4CH_2OH$, DMAP, 0 °C, CH_2Cl_2, 91%).[34] They are cleaved by acidic hydrolysis (CF_3CO_2H/PhOMe, 25 °C, 3 min, 98% yield;[35] HCO_2H, 22 °C, 1 h, 81% yield),[31] by heating with phenol,[36] by treatment with $AlCl_3$ (anisole, CH_2Cl_2 or $MeNO_2$, -50 °C; $NaHCO_3$, -50 °C, 73-95% yield),[37,38] or by $CF_3CO_2H/B(OTf)_3$.[39]

Protection of Thiols.

The protection of thiols as *S*-*p*-methoxybenzyl thioethers is occasioned with MPMCl and a base such as NH_3,[40] KOH (MeOH),[41] and NaH (THF, 60 °C, 1 h).[42] The reduction of disulfides with ***Lithium Aluminum Hydride*** affords an intermediate thiolate that can be trapped with MPMCl to give the thioether.[43] The cleavage of *S*-*p*-methoxybenzyl thioethers is effected with $Hg(OAc)_2/CF_3CO_2H$ (0 °C, 10-30 min), $Hg(OCOCF_3)_2$/aq AcOH (20 °C, 2-3 h, followed by H_2S or $HSCH_2CH_2OH$, 100% yield),[44,45] $Hg(OCOCF_3)_2/CF_3CO_2H$/anisole,[46] CF_3CO_2H/reflux,[40] anhydrous HF/anisole (25 °C, 1 h, quant),[47] $(4\text{-}BrC_6H_4)_3NH^+ SbCl_6^-$ (75%),[48] HCO_2H (5 °C, 30 min, 45%).[42] During the synthesis of peptides which contain 4-methoxybenzyl-protected cysteine residues, sulfoxide formation may occur (eq 5). These sulfoxides, when treated with HF/anisole, form thiophenyl ethers that cannot be deprotected; therefore the peptides should be subjected to a reduction step prior to deprotection.[49]

(5)

Protection of Amines.

The use of the MPM group to protect amines has not seen many applications, but a few examples are available in the literature. The MPM group can be introduced on an aromatic amine with MPMBr (DMF, KI, K_2CO_3, 92%),[50] or by reductive amination (anisaldehyde, PhH, H_2O; $NaBH_4$, MeOH, 92%),[51] but for the most part the MPM group acts as a carrier for the nitrogen to be introduced into a molecule. MPM amines can be cleaved by hydrogenolysis,[52] oxidation to the imine followed by hydrolysis,[53] or acylation with MeCHClOCOCl (CH_2Cl_2, -7 °C, 5 min; MeOH, reflux, 89%).[54]

Protection of the Amide Nitrogen.

Of the few methods for protection of the amide NH, the MPM group has found success where other methods have not been entirely successful.[55] The group can be introduced using methods similar to those used for alcohols: MPMCl/NaH/DMF,[56] MPMBr/NaH,[55] MPMCl (DBU, MeCN, 60 °C, 5 h, 92%),[57] MPMCl/Ag_2O.[58]

The most common method for removal of the amide MPM group is by oxidation with DDQ[59] or CAN.[60] With CAN, the benzoyl imide is sometimes a byproduct of the reaction (eq 6), but this is easily cleaved by hydrolysis.[61] The amide MPM group is also cleaved by solvolysis in TFA[51] or $AlCl_3$/anisole.[62] Metalation with ***t-Butyllithium*** followed by reaction with oxygen (62%) has been used successfully (eq 7).[63]

Protection of Phosphates.

There is one example where the MPM group is used for phosphate protection. It is cleaved with 48% aq HF/MeCN/H_2O (eq 8).[64]

(*p*-Methoxybenzyloxy)methyl Chloride[1]

[88023-78-3] · $C_9H_{11}ClO_2$ · (*p*-Methoxybenzyloxy)methyl Chloride · (MW 186.65)

(protection of alcohols;[1] one-carbon synthon[4])

Alternate Name: PMBM-Cl; 4-methoxybenzyl chloromethyl ether.

Physical Data: bp 66-67 °C/0.01 mmHg.

Preparative Method: easily prepared from the MTM ether of *p*-methoxybenzyl alcohol by treatment with ***Sulfuryl Chloride*** in CH_2Cl_2 at -78 °C followed by solvent evaporation and distillation.

Handling, Storage, and Precautions: decomposes upon storage[1] but can be stored in the freezer for at least 3 days.[2]

Alcohol Protection.

The PMBM group was developed as an alcohol protecting group for protection of the allylic alcohol in the indole (**1**) when other groups were found not to be suitable. The PMBM group is readily introduced (PMBM-Cl, ***Diisopropylethylamine***, CH_2Cl_2, rt, 5-30 h) on to a variety of structural types, as illustrated in Table 1. PMBM-Cl has also been used to trap alkoxides directly (eq 1).[3]

Table 1 Protection of Alcohols

	(1) Protection 100% Deprotection 65%[a]	Protection 84% Deprotection 89%
	Protection 78% Deprotection 88%	Protection 95% Deprotection 63% + 21% geranial

[a] Only the rearranged tertiary alcohol was isolated.

(1)

Deprotection is accomplished oxidatively with ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone***, but conditions used for the deprotection of the *p*-methoxybenzyl group may also be suitable. It may also be cleaved by a simple hydrolysis with 3:1 THF/6 M HCl at 50 °C.

One-Carbon Synthon.

The preparation of 4-methoxybenzyloxymethyllithium from PMBM-Cl proceeds smoothly and is used in a reaction with crotonaldehyde to form a differentially protected diol derivative (eq 2).[4]

(2)

Related Reagents.

p-Methoxybenzyl Chloride; ***4-Methoxybenzyl 2,2,2-Trichloroacetimidate***.

4-Methoxybenzyl 2,2,2-Trichloroacetimidate[1]

[89238-99-3] · $C_{10}H_{10}Cl_3NO_2$ · 4-Methoxybenzyl 2,2,2-Trichloroacetimidate · (MW 282.56)

(reagent for the protection of alcohols under mildly acid conditions)

Physical Data: bp 135-137 °C; *d* 1.361 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: clear liquid.

4-Methoxybenzyl 2,2,2-trichloroacetimidate is used to protect alcohols as the *p*-methoxybenzyl ether. It was first used in oligoribonucleotide synthesis[2] and the utility and generality of the method was extended by Yonemitsu.[3] The main advantage of using this reagent is that it provides an alternative to the Williamson ether synthesis, which is commonly used to introduce this protective group under basic conditions. Since this reagent is used to install the group under acidic conditions, it provides a method to protect base-sensitive alcohols. Protic acids such as ***Trifluoromethanesulfonic Acid***, ***10-Camphorsulfonic Acid***,[5] and ***p-Toluenesulfonic Acid***[6] generally give excellent yields of product. ***Boron Trifluoride Etherate***[7] and ***Triphenylmethyl Perchlorate*** are also effective catalysts. The preferred solvents are ether and CH_2Cl_2, but hydrocarbon cosolvents have been used.[2,7,8] Tertiary, secondary, and primary alcohols are protected with equal efficiency, but the question of selectivity has not been addressed. The reagent can be used to install the *p*-methoxybenzyl ether group in the presence of a variety of other protective groups, the most notable of which is the the *t*-butyl group considering the strong acids used as catalysts.[4] Table 1 shows some of the structural types that have been protected with this reagent. Many of these examples serve to illustrate cases where basic conditions could not be used to achieve protection. For a discussion of the deprotection of the MPM group, see ***p-Methoxybenzyl Chloride***.

1-Methoxy-1,3-bis(trimethylsilyloxy)-1,3-butadiene[1]

[67609-52-3] · $C_{11}H_{24}O_3Si_2$ · 1-Methoxy-1,3-bis(trimethylsilyloxy)-1,3-butadiene · (MW 260.53) (*E*)

[74590-73-1] (*Z*)

[81114-98-9]

(reactive diene for the Diels-Alder reaction;[1,2] acetoacetic ester dianion equivalent that reacts with various electrophiles[3])

Physical Data: bp 56-58 °C/2.0 mmHg.[2]

Solubility: insol H_2O; sol most organic solvents.

Preparative Methods: from methyl acetoacetate according to the scheme shown in eq 1.[2,3] A detailed experimental procedure is described by Chan et al.[3c] It is critical that the reaction temperature for the metalation step be less than -23 °C. Under these conditions, essentially pure diene is obtained, but at rt the reaction gives a 3:1 mixture of the diene and *C*-silylated products derived by rearrangement. The stereochemistry of the diene was first proposed to be (*E*),[3a] but later was shown to be (*Z*) by precise NMR studies.[4]

Handling, Storage, and Precautions: although this diene is purified safely by distillation below 80 °C,[2,5] *O*- to *C*-migration of a silyloxy group is observed at elevated temperatures (see eq 2).[3,5] Crude diene may be used directly without further purification and it can be kept in a stoppered container in a freezer for several weeks without appreciable decomposition. It is slowly hydrolyzed when exposed to air and moisture.[3c]

Thermal Rearrangement.

On being heated at 120 °C for 1 h, the diene (**1**) and related analogs rearrange to give *C*-silyl-(*E*)-α,β-unsaturated esters (eq 2).[5] Flash vacuum pyrolysis of the diene at 680 °C gives an allene ester via concomitant elimination of methyl trimethylsilyl ether (eq 3).[6]

Diels-Alder Reactions.

The diene reacts with ***Dimethyl Acetylenedicarboxylate*** in toluene at reflux to give aromatic products (eq 4). Elimination of methanol predominates over loss of trimethylsilanol.[2] Reaction with allenedicarboxylate gives similar products (eq 5).[7]

(4)

(5)

The most widely used dienophiles with (**1**) are quinones, such as benzoquinones,[4,8] naphthoquinones,[9-11] and anthraquinones,[12] with or without halogen-substituents at the α-position. In general, the reaction proceeds very smoothly at rt or below to give adducts in moderate yields (50-70%). With monohalogenated quinones the reaction is rapid and the initial Diels-Alder adducts usually lose HCl to give quinone derivatives directly (eq 6).[9] In the particular case of 2,6-dichlorobenzoquinone, the initial double Diels-Alder adduct was isolated as a crystalline product. X-ray crystallographic analysis of this intermediate established that the stereochemical course of the cycloaddition is via the *cis-endo* mode (eq 7).[4] In reactions with *vic*-dihalogenated quinones, however, only substitution of halide by an acetoacetate residue occurs and no cycloadducts are obtained.[13]

(6)

(7)

These methodologies have been applied to the syntheses of quinoid substances with fused aromatic systems, such as (±)-averufin (eq 7),[8] (±)-2-hydroxyaklavinone (eq 8),[10] and naphthopyran antibiotics.[13] Reaction with a sulfonamide dienophile gives adducts which are converted to potential anti-inflammatory drugs, oxicams (eq 9).[14]

(8)

(9)

Reactions with Electrophiles.

The diene reacts as a masked acetoacetate dianion with various electrophiles such as halogens,[3] carbonyls,[3,15-17] acetals,[18-20] acyl halides,[3] and imines.[21] These reactions give 4-substituted acetoacetates and their derivatives exclusively, and are promoted by Lewis acids such as ***Titanium(IV) Chloride***, ***Trimethylsilyl Trifluoromethanesulfonate***, ***Tin(II) Chloride***, etc. (eq 10).

(10)

These reactions have been applied to the synthesis of sclerin,[3] (±)-Δ^1-tetrahydrocannabinol (eq 11),[18] (-)-pestalotin (eq 12),[15] sperabilins,[17] (+)-dihydrocompactin,[16] and (+)-mevinolin analogs.[20] In the case of pestalotin synthesis, highly diastereoselective condensation is executed by the addition of the diene to a solution of $TiCl_4$ and 2-benzyloxyhexanal (*syn*:*anti* = 99:1). Addition of $TiCl_4$ to a mixture of the diene and the aldehyde, however, gives a mixture of diastereomers (*syn*:*anti* = 54:46).

(11)

1-Methoxy-1,3-bis(trimethylsilyloxy)-1,3-butadiene

(12)

A synthesis of substituted dihydrofurans involves treatment of (**1**) with ***Tetra-n-butylammonium Fluoride*** to give the ester enolate, which reacts with a cyclohexadiene-Co complex (eq 13).[22]

(13)

Other Annulation Reactions.

Reactions with 1,2-,[23] 1,3- (eq 14),[24] 1,4-, and 1,5-dicarbonyl compounds or their derivatives (eq 15)[25] give annulation

products with five- to eight-membered rings via double aldol-type cyclocondensations.

2-Methoxy-1,3-butadiene

[3588-30-5] · C_5H_8O · 2-Methoxy-1,3-butadiene · (MW 84.13)

(2π or 4π partner in cycloaddition reactions;[1] regioselective cyclopropanation substrate;[16] dihydrofuran precursor;[18] δ-hydroxy ketone synthon)

Physical Data: bp 75 °C; *d* 0.827 g cm^{-3}.

Solubility: sol alcohol, ether, benzene, acetone.

Form Supplied in: colorless liquid; not commercially available, but its precursor, 1,3,3-trimethoxybutane, can be purchased.

Preparative Method: by slow addition of the acetal precursor to a preheated mixture (150 °C) of acetal and $KHSO_4$ (1:1 w/w), and collection of the diene-containing distillate in a flask cooled to -78 °C. The distillate is poured into water, the organic and aqueous layers are separated, and the organic layer is dried with 4 Å molecular sieves. The resulting mixture is fractionally distilled in the presence of hydroquinone to afford the diene in modest yield.[5]

Handling, Storage, and Precautions: classified as a flammable liquid; reported to be toxic.

Reactivity.

2-Methoxy-1,3-butadiene (**1**) is a multifaceted diene that has seen application both as a masked cyclohexanone precursor in Diels-Alder cycloadditions and as an allylic vinylic ether. Polarization of the diene by the methoxy group dictates the regioselectivity of the reactions of (**1**);[1] the dipole moment has been calculated using the Halverstadt-Kumler method.[2] The regioselectivity observed is consistent with predictions obtained from frontier molecular orbital (FMO) theory using terminal and secondary orbital calculations,[3] and by Hehre's reactive surface mapping technique.[1,4]

Cycloaddition Reactions.

2-Methoxy-1,3-butadiene (**1**) is commonly used as a 4π component in $[_{\pi}4_s + _{\pi}2_s]$ cycloadditions to prepare masked

cyclohexanone (cyclohexanone methyl enol ether) systems. (**1**) reacts readily with a variety of dienophiles to afford predominately the *para*-isomer (eq 1). The *para*/*meta* ratio of isomers is highly dependent upon the dienophile. Glyoxylate esters (eq 2),[6] nitroso compounds (eq 3),[7] and bicyclic dienophiles[8] often afford regioisomeric mixtures, while quinones,[9] acrylic acid derivatives,[10] and cycloalkenes[11] afford exclusively the *para*-isomer. The observed predominance for the *para*-isomer has allowed this reagent to be used in key steps for the synthesis of several natural products,[12] most notably the anthracyclinone antibiotics (eq 4).[13]

(1)

(2)

(3)

(4)

In cycloaddition reactions with Fischer-type carbenes (eq 5) and other dienophiles, 2-methoxy-1,3-butadiene can be

exposed to extreme temperatures (219 °C, sealed tube) without significant decomposition.[12] However, (**1**) rapidly decomposes when exposed to Lewis acids (eq 6).[14] Depending upon the dienophile and temperature, (**1**) also can act the 2π component in [4 + 2] cycloadditions. Cycloaddition of (**1**) with electron-deficient 5-methoxycarbonyl-2-pyranones (eq 7) at 25 °C affords the expected tetrahydrocoumarin, resulting from participation of (**1**) as the 4π reaction partner; warming the reaction mixture to 114 °C provides the 2-oxabicyclo[2.2.2]oct-5-en-3-one system, where the vinyl ether double bond reacts as the 2π component in this inverse electron-demand Diels-Alder reaction.[15]

(5)

Decomposition (6)

(7)

(**1**) is also highly chemoselective with respect to the dienophile. In the synthesis of daunomycinone analogs, cycloaddition between (**1**) and an anthracene bisquinone affords the cycloadduct where the diene adds across the more electron-deficient tetrasubstituted double bond, rather than the more accessible, but less reactive, disubstituted double bond (eq 8).

(8)

Miscellaneous Reactions.

Predictable regioselectivity in the reactions of 2-methoxy-1,3-butadiene makes it an ideal cyclopropanation substrate. Reaction of (**1**) with the metallocarbenoid generated from ***Ethyl Diazoacetate*** occurs exclusively at the electron-rich 1,2-double bond to afford a 0.8 *trans*/*cis* isomeric mixture regardless of the cyclopropanation catalyst (eq 9).[16] The best cyclopropanation catalyst is ***Dirhodium(II) Tetraacetate***.

(9)

Transition metal-mediated transformation of these vinylcyclopropanes has been reported. Conversion of vinylcyclopropanes to dihydrofuran systems occurs with ***Copper Bronze*** (eq 10), whereas treatment with Pd^{II} and/or Rh^{I} or Rh^{II} affords ethyl 4-methoxy-2,4-hexadienoate (eq 11).[17] The same vinylcyclopropane has been transformed to a dihydrofuran via an oxepin intermediate under acidic conditions in the presence of rhodium tetraacetate (eq 12).[18]

(10)

(11)

δ-Hydroxy ketone systems have been prepared using (**1**). Alkylation of 2-methoxy-1,3-butadiene at the 4-position with an α-alkoxy iron carbene affords 6-ethoxy-6-phenylhex-3-en-2-one after acidic hydrolysis (eq 13).[19] Electroreductive coupling of (**1**) with acetone followed by acid hydrolysis of the enol ether affords 6-hydroxy-6-methyl-2-heptanone in 78% yield (eq 14).[20]

The vinyl ether portion of (**1**) permits the rapid formation of unsymmetrical allylic acetals that can be converted via Claisen rearrangement to chroman systems in a one-pot reaction sequence (eq 15).[21]

(15)

Related Reagents.

1-Acetoxy-1,3-butadiene.

1-Methoxy-3-buten-2-one

[43042-58-6] · $C_5H_8O_2$ · 1-Methoxy-3-buten-2-one · (MW 100.13)

(methyl vinyl ketone equivalent used in Robinson annulation,[1] and Diels-Alder,[2] [2 + 2],[3] and Michael addition[4] reactions)

Alternate Name: methoxymethyl vinyl ketone.

Physical Data: bp 52 °C/30 mmHg.

Solubility: sol dichloromethane, methanol, ethanol, diethyl ether.

Form Supplied in: generated in situ from 1,4-dimethoxy-2-butanone,[5] which is in turn synthesized from 2-butyne-1,4-diol (widely available).

Analysis of Reagent Purity: ^{1}H NMR[1a] [($CDCl_3$, δ 3.43 (s, 3H, Me); 4.25 (s, 2H, CH_2); 5.83 (dd, 1H, *J* = 1.7, 10 Hz, 4-H); 6.32 (dd, 1H, *J* = 1.7, 18 Hz, 4-H); 6.49 (dd, 1H, *J* = 10, 18 Hz, 3-H)] and GC.

Preparative Methods: the precursor, 1,4-dimethoxy-2-butanone, is prepared[5] by dimethylation of 2-butyne-1,4-diol, followed by oxidation with red ***Mercury(II) Oxide***. In situ generation is possible either by acid-induced elimination using ***p-Toluenesulfonic Acid***,[1a] base-induced elimination using ethanolic ***Potassium Hydroxide***,[1b] or pyrolysis in the presence of sodium benzoate.[6]

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: the colorless liquid is best used immediately upon generation. This toxic reagent should be handled in a fume hood.

Robinson Annulation.

This reagent was introduced by Wenkert[1b] in 1967 as a Robinson annulation component (***Methyl Vinyl Ketone*** equivalent) which produces cyclohexenones bearing an oxygen substituent at the 4-position of the newly constructed

six-membered ring. The α-oxygenation provides flexibility in the elaboration of cyclic frameworks, as seen in the synthesis of the decalone derivative (-)-valeranone (eq 1),[1b] as well as in the synthesis of the spirocyclic (-)-acorenone via an alkylative 1,2-carbonyl transposition (eq 2).[1c,d]

(1)

(2)

Diels-Alder Chemistry.

The use of (**1**) as a dienophile in Diels-Alder reactions provides a route for the construction of useful synthetic building

blocks such as isopiperitenone derivatives (eq 3)[2a] and, after ozonolysis and treatment with *N*-aminophthalimide, 2-methoxypyrrole derivatives (eq 4).[2b]

(3)

(4)

[2 + 2] Cycloadditions.

Another facet of this reagent's utility involves Lewis acid-catalyzed [2 + 2] cycloaddition,[3] allowing for the construction of functionalized cyclobutane rings (eq 5).

(5)

Michael Additions.

In addition to annulations, this reagent functions as a Michael acceptor for nucleophiles. Somei et al.[4] have shown that

a tricyclic heterocycle can be generated via Heck coupling of (**1**) to the iodoindole (**2**) followed by a Michael addition involving the nitronate anion (eq 6).

4-Methoxy-3-buten-2-one[1]

[51731-17-0] · $C_5H_8O_2$ · 4-Methoxy-3-buten-2-one · (MW 100.13)

(versatile four-carbon synthon; precursor to the Danishefsky diene;[2] Diels-Alder dienophile;[3] dipolarophile;[4] electrophilic four-carbon synthon subject to conjugate addition at C-4 followed by elimination of the methoxide anion;[5] its enolate is a nucleophilic four-carbon building block[6])

Physical Data: bp 200 °C/760 mmHg, bp 61-63 °C/12 mmHg; d_4^{20} 0.997 g cm^{-3}; n_D^{20} 1.469.

Solubility: sol THF, ether, acetonitrile, benzene

Form Supplied in: liquid, over 97% (GC) pure; commercially available in 10 or 50 mL units.

Analysis of Reagent Purity: GC analysis appears best; also IR;[7a] UV (cyclohexane) λ_{max} 237 nm (ε 13450);[7b] ^{1}H NMR ($CDCl_3$): δ 2.20 (s, 3H), 3.70 (s, 3H), 5.55 (d, 1H, *J* = 13.0 Hz), and 7.53 (d, 1H, *J* = 13.0 Hz);[6a,7c,d] ^{13}C NMR ($CDCl_3$) δ 27.5, 57.6, 107.0. 163.6, 196.6.[7e,f]

Handling, Storage, and Precautions: may be harmful by inhalation, ingestion, or skin absorption; may cause skin and eye irritation; in addition to standard safety practice, mechanical exhaust is required.[8] Do not breathe vapor. Store in refrigerator under nitrogen or argon.

Introduction.

4-Methoxy-3-buten-2-one may be regarded as a vinylogous homolog of methyl acetate and has three functional groups and one acidic site. Each of these shows characteristic reactivity.

Danishefsky Diene and Analogs.

4-Methoxy-3-buten-2-one is a valuable starting compound for the preparation of 1-methoxy-3-trimethylsilyloxy-1,3-butadiene, the Danishefsky diene (eq 1), and its equivalent.[2] These dienes undergo Diels-Alder cycloaddition or cyclocondensation reactions with a variety of dienophiles (see ***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene***).[2,9] A couple of slightly modified procedures for the preparation of the Danishefsky diene have also been reported.[10]

(1)

Diels-Alder Dienophile and Dipolarophile.

Only a handful of examples of cycloaddition reactions involving the C=C bond of this reagent have been reported. While no reaction can be observed in the absence of a catalyst, this C=C bond undergoes a Diels-Alder reaction with cyclopentadiene in the presence of the Lewis acid ***Tin(IV) Chloride***, providing the adduct with an *endo*/*exo* ratio of 15:1 (eq 2).[3] In general, the cycloadducts are unstable due to their propensity for the elimination of methanol.

(2)

The [2 + 3] cycloaddition reaction involving the C=C bond is also reported. Thus treatment of this reagent with 2-[(trimethylsilyl)methyl]-3-(trimethylsilyl)-2-propenyl carboxylates in the presence of a catalytic amount of ***Tetrakis(triphenylphosphine)palladium(0)*** provides the cyclopentane product in a highly regioselective manner (eq 3).[11] This captodative enone also undergoes an efficient, highly regioselective [2 + 3] dipolar cycloaddition reaction with acetonitrile oxide to give (after the elimination of methanol) 4-acetyl-3-methylisoxazole (eq 4).[4] Interestingly, a reversal in regioselectivity is observed for the corresponding reaction with 3-buten-1-one whereby the major product upon subsequent oxidation is 5-acetyl-3-methylisoxazole.[4] The 1-diazo derivative of 4-methoxy-3-buten-2-one is a versatile four-carbon building unit used for the efficient annulation of highly substituted aromatic rings (eq 5).[12] The diazo ketone first undergoes photochemical Wolff rearrangement to the vinylketene, which subsequently reacts with alkoxy alkynes in a [2 + 2] cycloaddition mode; the resulting cyclobutenones proceed through a sequence of electrocyclic ring cleavage and closure, and finally aromatization through tautomerization. The product shown in eq 5 has been converted to the host defense stimulant maesanin in 67% yield by oxidation with O_2 and ***Tetra-n-butylammonium Fluoride***.[12]

(5)

Synthesis of β-Substituted Enones through a Conjugate Addition/Elimination Sequence.

A number of nucleophiles have been added to C-4 of 4-methoxy-3-buten-2-one; the resulting adducts rapidly eliminate methanol in the reaction medium, providing a variety of β-substituted enones as shown in eq 6.[5b] A recent example includes the use of lithiated diethyl prop-2-enylphosphonate as a nucleophile.[13]

(6)

Addition Reactions of the Enolate Derivative.

The addition of the lithium enolate of 4-methoxy-3-buten-2-one to acid chlorides followed by acid treatment of the resulting enol provides γ-pyrones in good to excellent yields (eq 7).[6a] A similar, yet direct formation of γ-pyrones has been reported which uses 2.2 equiv of the potassium enolate of 4-methoxy-3-buten-2-one for the reaction with acid chlorides followed by aqueous workup (eq 8).[6b] In a similar vein, the lithium enolate of this reagent adds to a Boc-protected α-amino aldehyde (eq 9). The formation of the major stereoisomer (indicated in eq 9) of the 88:12 mixture (53% combined yield) is consistent with the prediction on the basis of the Felkin-Anh transition state conformation of the aldehyde.[14]

(*Z*)-1-Methoxy-1-buten-3-yne[1]

[3685-19-0] · C_5H_6O · (*Z*)-1-Methoxy-1-buten-3-yne · (MW 82.11)

(convenient building block for synthesis of spiroacetals, dialkynes, enones, and dienes)

Physical Data: bp 52 °C/28 mmHg.

Solubility: slightly sol H_2O; sol standard organic solvents.

Form Supplied in: 50 wt % solution in methanol-water.

Purification: can be obtained anhydrous by saturation of the solution of 1-methoxy-1-buten-3-yne in methanol-water with solid NaCl followed by extraction with ether and distillation under reduced pressure (52 °C/28 mmHg).

Handling, Storage, and Precautions: store under nitrogen.

(*Z*)-1-Methoxy-1-buten-3-yne is readily deprotonated by ***n-Butyllithium*** in THF. The resulting anion reacts with alkyl halides, carbonyl compounds, and trialkylchlorosilanes. The anion of 1-methoxy-1-buten-3-yne has been used in a direct synthesis of spiroacetals (eq 1).[2] When (*Z*)-1-methoxy-1-buten-3-yne is treated with 2 equiv of *n*-butyllithium, the monoanion of 1,3-butadiyne is formed (eq 2).[3] If 3 equiv of *n*-butyllithium are used, the dianion of 1,3-butadiyne is generated. (*Z*)-1-Methoxy-1-buten-3-yne also serves as a convenient precursor to α,β;γ,δ-unsaturated aldehydes by a sequence involving addition of its anion to an aldehyde followed by reduction of the resulting acetylenic alcohol using ***Lithium Aluminum Hydride*** and acid-mediated hydrolysis (eq 3).[4]

(1)

(2)

(3)

1-Methoxy-1-buten-3-yne can be alkylated and treated with dialkylboranes to form vinylboranes (eq 4).[5] The regiochemistry of the hydroboration reaction appears to be directed by the methoxy group. The vinylborane can be oxidized to provide a β-methoxy enone. The hydrozirconation of 1-methoxy-1-buten-3-yne proceeds regioselectively to form a diene which reacts with *N*-(phenylselenyl)phthalimide to afford 1-phenylselenyl-4-methoxy-1,3-butadiene in good yield.[6] 1-Methoxy-1-buten-3-yne also reacts with cyclopropyl carbene chromium complexes to form cyclopentenones.[7] (*Z*)-1-Methoxy-1-buten-3-yne can also be converted into a copper salt which reacts with aryl iodides, acid chlorides, and alkyl halides.[8]

(Z)-1-Methoxy-1-buten-3-yne

R^2 = cyclohexyl, 1,2-dimethylpropyl

2-Methoxycarbonylbenzoyl Chloride[1]

[4397-55-1] · $C_9H_7ClO_3$ · 2-Methoxycarbonylbenzoyl Chloride · (MW 198.61)

(*N*-phthaloylation of α-amino acids; preparation of isocoumarins)

Physical Data: mp 48-52 °C; bp 107-110 °C/0.1 mmHg; fp >110 °C.

Solubility: sol most organic solvents.

Form Supplied in: pale yellow oil.[1]

Preparative Method: heat *o*-methoxycarbonylbenzoic acid (methyl hydrogen phthalate) with ***Thionyl Chloride*** for 1 h on a steam bath (eq 1).[1]

Handling, Storage, and Precautions: corrosive and moisture sensitive; reacts with protic solvents; use in a fume hood; do not breathe vapors and avoid contact with skin, eyes, and clothing; causes burns and irritation of the respiratory system; lachrymator; use immediately after preparation.

Phthaloyl Amino Acids.

2-Methoxycarbonylbenzoyl chloride is used in the *N*-phthaloylation of α-amino acids.[2] *N*-Phthaloyl-α-amino acids may be obtained by heating mixtures of phthalic anhydride[3] and the appropriate α-amino acids. In a number of cases, racemization occurs and the experimental conditions are too drastic for the preparation of *N*-phthaloyl-α-amino acids containing additional functional groups. In addition, when α-amino acid esters are used, 2,5-diketopiperazines may result as the major product. On the other hand, the reagent reacts with α-amino acid esters at 0 °C (2 h) in THF or 1,4-dioxane in the presence of Et_3N to give *N*-phthaloyl-α-amino acid esters[2] in high yields (90-85%) and without racemization (eq 2). Under these

mild conditions the formation of 2,5-diketopiperazines and anhydrides is also suppressed. The reagent forms an intermediate *N*-(*o*-methoxycarbonylbenzoyl)amino acid ester with the amino acid ester (eq 2), which eliminates MeOH to gave the *N*-phthaloyl-α-amino acid ester. The corresponding *N*-phthaloyl-α-amino acids are obtained by selective removal of the ester group (i.e. Me, Et, Bn, *t*-Bu). The preferred ester is benzyl, since this group is easily removed by hydrogenolysis without racemization; the yields for (**1**) are consistently high (Tables 1 and 2).[4,5]

Methoxycarbonylmethanesulfonyl Chloride

[56146-83-9] · $C_3H_5ClO_4S$ · Methoxycarbonylmethanesulfonyl Chloride · (MW 172.60)

(synthesis of sultam analogs of β-lactams;[3] synthesis of biologically active sulfonamides[4-6])

Physical Data: bp 98 °C/8 mm Hg; *d* 1.505 g cm^{-3}; fp >110 °C.

Solubility: sol C_6H_6, CH_2Cl_2, Et_2O.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: reagent purity may be determined by standard analytical techniques.

Preparative Methods: from chlorosulfonylacetyl chloride by reaction with 1 equiv of methanol;[1] may also be prepared by chlorination of sodium methoxycarbonylmethanesulfonate with ***Phosphorus(V) Chloride***[2] or by direct chlorination of methyl thioglycolate.[3]

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: moisture sensitive; causes burns.

Synthesis of β-Sultams.[3]

Formation of the β-sultam (eq 1) proceeds via addition of methoxycarbonylmethanesulfonyl chloride to a solution of the desired imine (1 equiv) and a tertiary amine base (1.5 equiv) at -78 °C. Best results are obtained using THF as the solvent and ***Pyridine*** as the base. Yields are moderate to high. In general, the yields are higher when the R^1 substituent is aryl rather than alkyl.

Synthesis of Sulfonamides.[4-6]

Sulfonamides are formed in moderate to good yields by the reaction of methoxycarbonylmethanesulfonyl chloride with the desired amine in the presence of ***Triethylamine*** (eq 2). This reaction is usually carried out using arylamines, but can be extended to peptidic amines.[6]

(Methoxycarbonylmethylene)triphenylphosphorane[1]

$Ph_3P{=}CHCO_2Me$

[2605-67-6] · $C_{21}H_{19}O_2P$ · (Methoxycarbonylmethylene)triphenylphosphorane · (MW 334.37)

(stabilized phosphorane reagent useful for Wittig alkenation reactions to give methyl acrylate esters on reactions with carbonyl compounds[1] and ozonides;[2] formation of heterocyclic rings[3])

Alternate Name: methyl (triphenylphosphoranylidene)acetate.

Physical Data: mp 169-171 °C.

Solubility: sol $CHCl_3$ (26 g 100 mL^{-1}); slightly sol EtOH (2.7 g 100 mL^{-1}), THF (3.8 g 100 mL^{-1}); insol water (<0.5 g 100 mL^{-1}).

Form Supplied in: white crystalline powder; commercially available.

Preparative Methods: readily prepared by mild base treatment of (methoxycarbonylmethyl)triphenylphosphonium bromide (pK_a 8.8) (eq 1).[4,5]

Handling, Storage, and Precautions: storage at 5 °C in a tightly sealed bottle is recommended for prolonged periods. The compound decomposes to triphenylphosphine oxide in MeOH-water 1:1 ($t_{1/2}$ ca. 1.5 h) and in weakly basic aqueous solution (0.5 mM NaOH in MeOH-water 1:1) ($t_{1/2}$ ca. 1 h).

Weakly Basic Phosphorus Ylide.

(Methoxycarbonylmethylene)triphenylphosphorane is slightly less stable than the corresponding ethyl ester, but is widely used in a similar manner for Wittig alkenations and other reactions (see ***(Ethoxycarbonylmethylene)triphenylphosphorane***). As with the ethyl ester, this reagent exists in solution as a 3:1 mixture of *cis*/*trans* ylide/enolates (eq 2).[4,6] X-ray structure determination shows the *cis* form to have a short P-C bond and considerable C-C double bond character.[7] There is increasing exchange of the two forms at higher temperatures, and also in the presence of trace amounts of a proton source such as water.[6] Wittig reactions with the reagent work best as the exchange rate increases, due to the presence of greater amounts of the reactive ylide tautomer, so that it can be counterproductive to be overly scrupulous in drying these reactions.[6]

(Methoxycarbonylmethylene)triphenylphosphorane

(2)

Wittig Alkenation Reactions.

Among the many examples of the use of this reagent in synthesis,[1] only a few will be highlighted here. Typical reactions with aldehydes produce primarily the (*E*)-alkene, as in the condensation with PhCHO to give methyl cinnamates (eq 3).[8] Although Wittig reaction intermediates have not been observed by spectroscopic means,[9] it is expected that such reactions proceed through a four-membered oxaphosphetane prior to formation of products. The stereocontrol can be altered by the choice of solvent, temperature, and other factors.[1]

(3)

Treatment of $MeC(O)CF_3$ with $Ph_3P{=}CHCO_2Me$ results in formation of largely the (*E*) product (*E*:*Z* = 95:5), whereas condensation with the related Horner-Wadsworth-Emmons (HWE) reagent $(MeO)_2P(O)CHCO_2Me^-Na^+$ is not particularly stereoselective.[10] Larger amounts of the (*Z*)-isomer are often observed in reactions with aldehydes bearing adjacent hydroxy or alkoxy groups, such as those derived from carbohydrates.[1a] For example, reaction of a galactose-derived aldehyde with the phosphorane gives mainly the (*Z*)-alkene (eq 4); many other related systems have been examined.[11] The reactions of α-hydroxy carbonyl compounds are faster than those in which the hydroxy groups are protected.[12]

(4)

In cases where reactions are sluggish, such as those involving hindered carbonyls, the use of $Bu_3P{=}CHCO_2Me$ can prove advantageous.[1,12] In addition, this reagent often reacts with higher levels of (*E*) stereocontrol.[1,13]

Wittig/Michael reactions on the anomeric hemiacetals of sugars can lead directly to a *C*-glycoside structure. For example, an arabinose derivative was condensed with the phosphorane to give an anomeric mixture of *C*-glycosides (eq 5).[14] When this reaction is carried out using $Ph_3P{=}CHCO_2$-*t*-Bu, a 2:3 mixture of (*E*):(*Z*) noncyclized alkene isomers is observed.[15]

Imides react with the phosphorane to produce *N*-vinyl amides.[16] Thioimides react in a thio-Wittig reaction, albeit in low yields (eq 6).[17] The (*Z*)-isomer converts to the (*E*)-isomer upon a silica gel chromatography.

The phosphorane reacts with anhydrides to give enol lactones.[16] With highly substituted anhydrides the condensation occurs at the least hindered carbonyl; however, other factors come into play with only moderate steric hindrance. For example, 2-methyl- and 2-phenylsuccinic anhydrides suffer considerable attack at the 1-carbonyl.[16,18] This effect is particularly pronounced in the case of 2-methoxysuccinic anhydride, in which case complexation of the oxygen is thought to direct the phosphorane to the 1-carbonyl (eq 7).[18]

Alkenations of Ozonides.

Ozonides react directly with the phosphorane in the preparation of *trans*-acrylate esters (eq 8).[2] The sequence can be applied to a one-pot homologation of alkenes to (*E*)-acrylate esters.[2] Trapping experiments have shown that it is the ozonide itself, and not opened species such as a carbonyl ylide, which is the reactive partner.[2b]

Heterocyclic Ring Formation.

Several different ring systems can be prepared using stabilized phosphoranes, as they have both ylide and ester reactive sites (see ***(Ethoxycarbonylmethylene)triphenylphosphorane***). One example specifically involving (methoxycarbonylmethyl)triphenylphosphorane is the preparation of 2-chromenes from *o*-acyloxybenzyl bromide (eq 9).[3] In this condensation the ylide is first benzylated with the benzyl halide functionality, followed by intramolecular Wittig reaction with the *o*-acetoxy group.

(Methoxycarbonylmethylene)triphenylphosphorane

(9)

Condensation with benzoquinones involves initial Wittig reaction, followed by Michael addition of a second phosphorane. Elimination of triphenylphosphine and cyclization of the ester affords coumarin derivatives (eqs 10 and 11).[19]

(10)

(11)

Alkylation.

The reagent is sufficiently nucleophilic to be alkylated with reactive electrophiles to produce phosphorus reagents often suitable for further reactions.[1] Hydrolysis of the triphenylphosphorus and ester moieties after alkylation affords the corresponding carboxylic acids (eq 12).[19]

(12)

Alternatively, alkylation of the phosphorane with an α-halo ketone is followed immediately by elimination of triphenylphosphine to give an α,β-unsaturated γ-keto ester.[20] This reaction has been used in the synthesis of isocardenolides (eq 13).[21]

(13)

(Methoxycarbonylmethylene)triphenylphosphorane

The ylide can be halogenated[22] or sulfenylated[23] to prepare more complex ylides, which can then undergo Wittig reactions to yield vinyl halides or vinyl sulfides, respectively. Treatment of the phosphorane with a strong base in the absence of an added electrophile, followed by addition of ***Chlorotrimethylstannane***, leads to $Ph_3P{=}C{=}C{=}O$,[24] which is a useful reagent for the construction of certain heterocyclic rings.[25]

p-Methoxycarbonylperbenzoic Acid

[28276-78-0] · $C_9H_8O_5$ · *p*-Methoxycarbonylperbenzoic Acid · (MW 196.17)

(electrophilic reagent which delivers oxygen to alkenes[1])

Alternate Name: PMCPBA.

Physical Data: white crystalline solid; dec. 125 °C.

Solubility: sol ether, dioxane, CH_2Cl_2, $CHCl_3$; slightly sol benzene; insol cyclohexane, CCl_4.

Analysis of Reagent Purity: iodometric titration.

Preparative Methods: a mixture of aldehyde (**1**) (98% pure, 2 g) and CCl_4 (50 mL) is stirred under oxygen in a glass reactor at 25 °C and irradiated with a 2 kW high-pressure mercury lamp until about 95% of the theoretical amount of oxygen is absorbed (0.5 h) (eq 1). The product, which separates as a white crystalline powder, is collected and dried (yield 2.0 g, 84%; peroxy acid content 90%); this material can be used for general oxidation reactions.[1]

Purification: recrystallization from methanol.

Handling, Storage, and Precautions: the peroxy acid (**2**) is as stable as ***m-Chloroperbenzoic Acid*** and

shows less than 5% decomposition after storage at 10 °C for 1 year. (**2**) irritates nasal membranes and causes sneezing. Since the reagent is a peroxide and potentially explosive, care is required in carrying out reactions with it. During workup, check for peroxides before solvent removal. This reagent should be handled in a fume hood.

Epoxidation of Alkenes.

A number of alkenes have been epoxidized using the peroxy acid (**2**); the yields of epoxides obtained are comparable to the yields obtained using ***Perbenzoic Acid***. The following is a representative procedure. To a stirred mixture of peroxy acid (**2**) (6.112 g, 0.03 mol) and 200 mL of $CHCl_3$ maintained below 20 °C, is added dropwise a solution of cyclohexene (**3**) (2.544 g, 0.03 mol) in 20 mL of $CHCl_3$. The reaction mixture is stirred at 20 °C for 12 h. The precipitate of *p*-methoxycarbonylbenzoic acid (4.650 g) is removed by filtration. The filtrate is washed with aq Na_2CO_3 solution, aq $NaHSO_3$, and brine and then dried. The residue obtained after solvent removal is distilled under reduced pressure to furnish the epoxide (**4**) (yield 90%) (eq 2).[1]

(2)

The epoxidation of the triene (**5**) with the peroxy acid (**2**) is regio- and stereoselective, furnishing almost exclusively the epoxide (**6**) (eq 3).[2] Epoxidation of the triene (**5**) with MoO_5.2HMPA furnishes a 5:1 mixture of epoxides (**6**) and (**7**); epoxidation of (**5**) with ***Hydrogen Peroxide-Peracetic Acid*** furnishes a 2:1 mixture of epoxides (**6**) and (**7**).

(3)

(7)

Epoxidation of cholesteryl acetate (**8**) in CH_2Cl_2 furnishes a mixture of α- and β-epoxides in 65:35 ratio. The influence of solvents on the stereochemistry of epoxidation of (**8**) has been examined. The highest amount of β-epoxide (58%) is obtained when CCl_4 (in which the reagent is insoluble) is used as solvent; the highest amount of α-epoxide (76%) is obtained when *t*-butanol is used as solvent.[3]

(8)

Baeyer-Villiger Reaction.

Ketones undergo oxygen insertion reaction when reacted with the peroxy acid (**2**) (eq 4).[1] The yields obtained are comparable with perbenzoic acid oxidations.

(4)

(9) **(10)**

Oxidation of N-Heterocycles.

The oxidation of N-heterocycles to *N*-oxides proceeds smoothly when they are treated with a suspension of (**2**) in $CHCl_3$. The oxidation of pyridine, 3,4-dimethylpyridine, and 2-methylquinoline has been carried out employing both *m*-CPBA and acid (**2**); reagent (**2**) is as effective as *m*-CPBA.[4]

In the epoxidation of alkenes which are moderately or highly reactive, the yields obtained with (**2**) are comparable with the yields obtained using *m*-CPBA or $MeCO_3H$. However, *m*-CPBA and $MeCO_3H$ are available commercially; (**2**) is not available commercially but can be prepared easily in a short time and has a long shelf life.

Methoxycarbonylsulfamoyl Chloride[1]

[36914-92-8] · $C_2H_4ClNO_4S$ · Methoxycarbonylsulfamoyl Chloride · (MW 173.59)

(precursor for the Burgess reagent;[1] regent for heterocyclic cycloaddition[6])

Physical Data: mp 70-74 °C.

Solubility: sol benzene, cyclohexane, THF, MeCN.

Form Supplied in: white crystalline solid.

Preparative Method: readily prepared in high yield from the reaction of ***Chlorosulfonyl Isocyanate*** and anhydrous methanol.[1]

Handling, Storage, and Precautions: is moisture sensitive and should be stored in a dark bottle, protected from light. Violent decomposition has been observed when the product is stored in a clear-glass container or when advertently exposed to sunlight.

Formation of the Inner Salt of the Burgess Reagent.

The reaction of anhydrous ***Triethylamine*** with methoxycarbonylsulfamoyl chloride (**1**) in benzene produces the inner salt of ***(Methoxycarbonylsulfamoyl)triethylammonium Hydroxide*** (the Burgess reagent) (eq 1).[1] The Burgess reagent has been used in the formation of urethanes from primary alcohols; the urethanes are converted to primary amines upon hydrolysis.[1,2] The Burgess reagent has commonly been used in stereospecific *cis* elimination of secondary and tertiary alcohols to provide alkenes,[2,3] and in the synthesis of vinyltributyltin compounds.[4]

Cycloaddition Reactions.

Deprotonation of reagent (**1**) with ***Sodium Hydride*** provides the salt form of reagent (**1**), which undergoes cycloaddition with various alkenes. Decomposition of the salt form at 30 °C in THF yields the solvent complex of methyl *N*-sulfonylurethane, whereas reaction of the salt with acetonitrile, or other nitrile compounds, provides substituted 1,3,4,5-oxathiazines (eq 2). Both species are prone to cycloaddition reactions with alkenes (eq 2); however, the advantage of the latter species is the possibility of using higher reaction temperatures, thus enabling the formation of cycloadducts from otherwise unreactive alkenes.[5,6] The stereospecificity of the cycloaddition reaction has been investigated with a model substrate, *trans*-styrene-β-*d*, in both THF and acetonitrile. In both cases, cycloadducts (**4**) and (**5**) are formed in a ratio of 1:3 in 72% overall yield;[5] therefore, both [2 + 2] and [2 + 4] cycloadducts are formed with complete stereospecificity.

(2)

Intermediates (**2**) and (**3**) react with ynamines to form heterocycles (eq 3).[7] As with the cycloaddition reactions with alkenes, the nature of the product is dependent on whether species (**2**) or (**3**) is allowed to react with the ynamine.

(3)

Metal-assisted cycloadditions with intermediate (**2**) have been reported (eq 4).[8] These reactions are dominated by the metal functioning as an electron-donor center.

(Methoxycarbonylsulfamoyl)triethylammonium Hydroxide[1]

[29684-56-8] · $C_8H_{18}N_2O_4S$ · (Methoxycarbonylsulfamoyl)triethylammonium Hydroxide · (MW 238.35)

(dehydration agent[1])

Alternate Name: Burgess reagent.

Physical Data: mp 76-79 °C.

Solubility: sol benzene, toluene, THF, triglyme, acetonitrile.

Form Supplied in: colorless solid.

Preparative Method: although the Burgess reagent is commercially available, it can be easily synthesized in two steps:[1a] the reaction of anhydrous methanol with ***Chlorosulfonyl Isocyanate*** followed by the addition of ***Triethylamine*** affords the reagent in good yield.

Handling, Storage, and Precautions: moisture sensitive; the use of anhydrous solvent and atmosphere in reactions with this reagent is recommended.

Formation of Carbamates.

The reaction of primary alcohols with the Burgess reagent (**1**) produces alkyl *N*-methoxycarbonylsulfamate salts, which decompose on thermolysis via an S_N2 (or S_Ni) mechanism to give methyl urethanes (eqs 1 and 2).[1a,b] The products are isolated in good yields. Hydrolysis of the carbamate produces primary amines. Transformations of alcohols to amines are often multistep syntheses; therefore this reaction provides a distinct advantage over the existing methodology for such substitution reactions.

(1)

(2)

It was noted that when this reaction was applied to allylic alcohols, either elimination (see below) or an S_Ni' rearrangement ensued.[1c] The fate of this reaction can be determined by the experimental conditions employed. Whereas the reaction in triglyme gave good yields of dienes (eq 3), thermal decomposition of the *N*-methoxycarbonylsulfamate intermediate at 80 °C as a solid provided >90% of the allylurethane product (eq 4).

(3)

(4)

Formation of Alkenes.

The products of the reaction of the Burgess reagent with secondary and tertiary alcohols decompose smoothly at temperatures between 30 and 80 °C in a variety of solvents to give alkenes.[1] The stereochemical course of the reaction was established to be stereospecific *cis* elimination. This reaction minimizes the type of rearrangement products that are typical for carbonium ion-mediated elimination reactions. For example, the reaction of the Burgess reagent with 3,3-methyl-2-butanol gave three products in the ratios given in eq 5.[1a] The last two alkenes were generated as a consequence of the Wagner-Meerwein rearrangement, whereas the first product formed by direct β-proton removal. The choice of solvent did not affect the product ratios significantly. Usually, competition between the Wagner-Meerwein rearrangement and β-proton abstraction lies entirely in the direction of the former, which is not seen when the Burgess reagent is used.

(5)

1:3:1.5

The reaction of the Burgess reagent with 2-*endo*-methylbicyclo[2.2.1]heptan-2-ol afforded a mixture of the two cycloalkenes shown in eq 6.[1a] The ratio of the products was unexpectedly 1:1, an observation which was attributed to the

steric effects of the *endo* C-5 hydrogen, whereby the rate of proton abstraction at C-3 would be attenuated. No rearrangement products were reported. The reaction in eq 7 proceeded to give the sole product shown; no evidence for the formation of 2-cyclopropylidenepropane was found on grounds that the β-cyclopropyl hydrogen is sterically encumbered and unavailable for elimination.[1a] The reaction in eq 8 afforded a product mixture favoring the (*Z*)-isomer.[2] The selectivity is somewhat less in the case of acid-catalyzed dehydration of the same compound. It is noteworthy that similar CS_2-mediated dehydrations in the presence of base require pyrolysis at temperatures exceeding 200 °C.[2] Some related applications for the Burgess reagent are shown in eqs 9 and 10.[3,4] Dehydration of eq 9 with ***Acetic Anhydride*** in the presence of ***Pyridine*** at 70 °C gave only 56% of the desired product.

(6)

(7)

(8)

(9)

(10)

The requirement for a *cis* elimination chemistry was discussed earlier; however, there are a few exceptional reaction outcomes reported in steroid chemistry.[5] The results depicted in eqs 11 and 12 were unanticipated since the 11α-hydroxyl and 9β-hydrogen (eq 11) are *trans*-diaxial, as are the 3α-hydroxyl and 4β-hydrogen in eq 12. These results are rationalized by an intramolecular 1,2-hydrogen transfer. For example, it was suggested for eq 11 that a C-11 cation is formed first, which subsequently undergoes an intramolecular hydrogen transfer from C-9 to C-11. The resultant C-9 carbocation was postulated to be quenched by the loss of a hydrogen from C-11 and the formation of the Δ^9-double bond.[5]

(11)

Formation of Dienones and Furanones.

Furanones are formed typically by treatment of α-hydroxy enones with acid; the reaction is presumed to proceed via an acid-labile dienone, although no direct evidence for the existence of such an intermediate has been demonstrated. It has been shown that α-hydroxy enones undergo dehydration in the presence of the Burgess reagent to give isolable dienones, which are cyclized to give the corresponding furanones in a separate acid-catalyzed step (eq 13).[6]

Formation of Vinyltributyltin Compounds and Tributyltin Isocyanate.

The use of the Burgess reagent in the facile formation of vinyltributyltin compounds has been reported.[7] This type of molecule is otherwise typically synthesized under drastic flash pyrolytic conditions. Reaction of the butyltin Grignard reagent with ketones results in tertiary alcohols, which in the presence of the Burgess reagent furnish the vinytributyltin products (eq 14).

(14)

It was discovered that a side reaction during the vinyltributyltin formation, was the production of tributyltin isocyanate.[8] The formation of tributyltin isocyanate could account for the major portion of the product mixture when cyclic ketones are used, an observation which was attributed to the thermal instability of the intermediary organotin alcohols. These reagents decompose at elevated temperatures to the corresponding ketone and tributyltin hydride, which react with (**1**) to give rise to the isocyanate (eq 15). Correspondingly, it has been shown that tin hydride reduction of (**1**) gives tributyltin isocyanate in quantitative yield (eq 16).

(15)

(16)

Formation of Nitriles.

Dehydration of the primary amide function by the Burgess reagent takes place under mild conditions (eqs 17 and 18), and there is often no need for protection of many functionalities in more complex molecules; the reagent has been shown to tolerate alcohols, esters epoxides, ketones, carbamates, and secondary amides.[9] Excellent chemoselectivity is observed in this reaction, which takes place at room temperature.

(17)

(18)

Electrophilic Addition.

The ethyl analog of (**1**), (ethoxycarbonylsulfamoyl)triethylammonium hydroxide (**2**), has also been reported.[10] Compound (**2**) has been shown to undergo electrophilic addition to alkenes in average to good yields (eqs 19 and 20).

4-Methoxycarbonylthiolan-3-one

[2689-68-1] · $C_6H_8O_3S$ · 4-Methoxycarbonylthiolan-3-one · (MW 160.21)

(building block for polynuclear heterocyclic compounds;[1,9] precursor of substituted thiophenes;[10-12] synthetic equivalent of α-acrylate anion[13,14])

Alternate Name: methyl 4-oxothiolane-3-carboxylate.

Physical Data: mp 37-38 °C;[15-17] bp 128.5 °C/20 mmHg,[15] 116-117 °C/9 mmHg,[18] 109 °C/4 mmHg;[15] IR (KBr[16] or CCl_4[17]), ^{1}H NMR,[16,17] MS,[17] and a study of the keto-enol equilibrium[18] have been reported.

Preparative Methods: prepared by Dieckmann reaction of the Michael adduct of methyl thioglycolate and ***Methyl Acrylate***. Careful choice of the reaction conditions (MeONa, toluene, 80-120 °C) and a suitable workup procedure are recommended in order to control the direction of the cyclization which, in principle, can produce both 3-oxo-2-carboxylate and 4-oxo-3-carboxylate isomers.[15-17,19] A more sophisticated method to accomplish a direction-controlled Dieckmann cyclization leading to exclusive formation of the target compound as the ethyl ester *[78647-31-1]* requires the less common ethoxycarbonylethyl thioethoxycarbonylmethyl sulfide as the starting material.[20]

α-Acrylate Anion Equivalent.

Alkylation of 4-methoxycarbonylthiolan-3-one (**1**) with a variety of alkyl halides in the presence of ***Potassium Carbonate*** provides *C*-alkylated products in excellent yields. Their treatment with aqueous ***Sodium Hydroxide*** affords α-substituted acrylate esters through tandem Dieckmann-Michael retrograde reactions (eq 1).[13] This strategy has been successfully applied to the formal synthesis of integerrinecic acid.[14]

(1)

Building Block for Polynuclear Heterocyclic Compounds.

Aniline can chemoselectively react with both the ester and ketone carbonyl groups of (**1**) affording an enamine or an amide, respectively, depending on the experimental conditions used (eq 2).[21]

One of the most common synthetic approaches to the construction of heterocyclic compounds involves the reaction of β-keto esters with bifunctional nucleophiles. Thus a variety of reactions of (**1**) with different bifunctional heteronucleophiles, including hydrazine,[1] substituted aminotriazoles,[2] 2-aminopyridines,[3] *o*-phenylenediamines,[5-7] and *o*-aminothiophenol,[8] lead to polynuclear condensed thieno compounds (e.g. **2**-**8**) of potential medicinal interest featuring the pyrazolone, pyrimidinone, benzodiazepine, and benzothiazepine nuclei. Cannabinoid analogs can be prepared through cyclization of the condensation products of (**1**) with bifunctional oxygenated nucleophiles such as substituted resorcinols.[9]

(2)

(3)

(4)

(5)

(6)

(7)

(8)

Methyl (2*R*,3*S*)-2-Methyl-3-hydroxybutanoate.[22]

This useful chiral building block, which is not easy to obtain with high optical purity by reduction of the corresponding open chain β-keto ester, can be conveniently prepared by diastereo- and enantioselective ***Baker's Yeast*** reduction of (**1**), followed by ***Raney Nickel*** promoted desulfurization (eq 3).

(3)

Ring Expansion.

The *C*-alkylated products of (**1**) with diiodomethane[23] and chloromethyl phenyl selenide[24] undergo radical-promoted ring expansion on treatment with ***Tri-n-butylstannane*** to give the expanded γ-keto ester in 64% yield (eq 4).

(4)

Related Reagents.

4-Cyanothiolan-3-one; ***Ethyl Acetoacetate***; ***Ethyl Acrylate***; ***Methyl 3-(Dimethylamino)propionate***; ***Methyl 3-Hydroxypropionate***.

B-Methoxydiisopinocampheylborane[1]

(+)

[85134-98-1] · $C_{21}H_{37}BO$ · *B*-Methoxydiisopinocampheylborane · (MW 316.39) (-)

[99438-28-5]

(intermediate for the synthesis of *B*-allyl- and *B*-crotyldiisopinocampheylboranes;[2] reacts with potassium hydride to form an asymmetric reducing agent[3])

Physical Data: mp >110 °C.

Form Supplied in: white solid; commercially available; typical impurities include the disproportionation products $IpcB(OMe)_2$ and $B(OMe)_3$.

Analysis of Reagent Purity: ^{11}B NMR (δ +52).

Preparative Methods: prepared in two steps from either (+)- or (-)-α-pinene (eq 1).

Preparation of *B*-Allyldiisopinocampheylborane and Related Reagents.

Addition of allylic Grignard or potassium reagents to *B*-methoxydiisopinocampheylborane (Ipc_2BOMe) provides the

corresponding allylic boranes (eqs 2 and 3).[2] Note that (-)-Ipc_2BOMe, derived from (+)-α-pinene, produces (+)-Ipc_2BAll and Ipc_2BCrt reagents, and (+)-Ipc_2BOMe gives the corresponding (-)-allylic boranes. These allyl and crotyl boranes condense with aldehydes to provide secondary homoallylic alcohols with high levels of enantioselection (see also ***B-Allyldiisopinocampheylborane*** and ***B-Crotyldiisopinocampheylborane***).

(2)

(3)

Acetylide Coupling.

B-Methoxydiisopinocampheylborane reacts with ***Lithium (Trimethylsilyl)acetylide*** to provide, after iodine-promoted rearrangement and desilylation, α-chiral monosubstituted alkynes in excellent yield (eq 4).[4]

(4)

B-Methoxydiisopinocampheylborohydrides.

Treatment of Ipc_2BOMe with an excess of ***Potassium Hydride*** produces the corresponding potassium *B*-methoxydiisopinocampheylborohydride.[3] The reduction of ketones with this reagent proceeds in high yield but with modest enantioselection (eq 5).

(Methoxydimethylsilyl)(trimethylsilyl)methane

[5180-98-8] · $C_7H_{20}OSi_2$ · (Methoxydimethylsilyl)(trimethylsilyl)methane · (MW 176.45)

(Peterson alkenation reagent; synthesis of vinyl silanes from aldehydes and ketones[1])

Physical Data: bp 150-152 °C,[2] 54-58 °C/20 mmHg.[3]

Solubility: sol common organic solvents (THF, Et_2O, CH_2Cl_2, pentane, etc.)

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 3.38 (s, 3 H), 0.10 (s, 6 H), 0.02 (s, 9 H), -0.14 (s, 2 H); ^{13}C NMR ($CDCl_3$) δ 49.94, 4.14, 1.13, 0.03.[3]

Preparative Methods: prepared in 75% yield by treatment of $MeOSiMe_3$ with ***t-Butyllithium*** in pentane at -78 °C to ambient temperature followed by addition of ***Chlorotrimethylsilane*** at 0 °C.[2] Alternatively, the reagent is prepared in 34% yield by treatment of ***Trimethylsilylmethylmagnesium Chloride*** with ***Dichlorodimethylsilane*** followed by LiOMe in THF.[3]

Handling, Storage, and Precautions: use in a well-ventilated fume hood. Contact with the eyes and skin should be avoided.

Peterson Alkenation Reactions.[4]

The synthesis of vinylsilanes via alkenation reactions of [bis(trimethylsilyl)methyl]lithium is restricted to nonenolizable aldehydes and ketones.[5] However, [(methoxydimethylsilyl)(trimethylsilyl)methyl]lithium (**1**), generated from the title reagent by treatment with ***t-Butyllithium*** in pentane at rt, undergoes Peterson alkenation with aldehydes and ketones to give vinylsilanes in good yield (eq 1). Interestingly, the methoxydimethylsilyl unit is preferentially eliminated from the β-hydroxydisilane intermediate. Alkenation reactions of (**1**) with aldehydes and unsymmetrical ketones are only moderately stereoselective (eqs 2 and 3).

(2)

(*E*):(*Z*) = 2:1

(3)

(*E*):(*Z*) = 3:1

Avery and co-workers have applied this methodology to the synthesis of vinylsilane intermediates utilized in syntheses of artemisinin analogs (eqs 4 and 5).[6] The low efficiency of these Peterson alkenation reactions (31-50%) suggests that the relatively hindered carbonyl groups undergo competitive deprotonation by the anion (**1**).

2-Methoxy-1,3-dioxolane

[19693-75-5] · $C_4H_8O_3$ · 2-Methoxy-1,3-dioxolane · (MW 104.12)

(mild acetalization agent;[1] protected formyl group synthon[5])

Physical Data: bp 129 °C; *d* 1.092 g cm^{-3}.

Solubility: sol alcohol, acetone, THF, CH_2Cl_2.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: GC, NMR spectroscopy.

Handling, Storage, and Precautions: moisture sensitive, flammable liquid. Incompatible with oxidizing agents and strong acids.

Mild Acetalization Agent.

A principal advantage of 2-methoxy-1,3-dioxolane for carbonyl protection is the mild reaction conditions (25 °C to reflux, 2-24 h, usually in CH_2Cl_2, or neat, with catalytic ***p-Toluenesulfonic Acid***) used. Efficient trans-acetalization occurs with aldehydes or ketones, especially with acid-labile substrates or when other methods fail (eqs 1-4).[1-4]

(1)

(2)

(3)

(4)

Protected Formyl Group Synthetic Equivalent.

The reagent can be used for the introduction of a base-stable protected formyl substituent on carbonyl compounds. With silyl enol ethers (eq 5),[5] morpholino enamines,[6] or titanium enolates (eq 6),[7] 2-methoxy-1,3-dioxolane gives regiospecifically protected dicarbonyl compounds.

(5)

(6)

This reagent can also be used as a protected formyl synthetic equivalent when reacted with aryl Grignard reagents (eq 7)[8] and allylsilanes (eq 8)[9] to afford acetals.

2-Methoxyethoxymethyl Chloride[1]

[3970-21-6] · $C_4H_9ClO_2$ · 2-Methoxyethoxymethyl Chloride · (MW 124.58)

(protection of alcohols,[2] phenols,[15] and carboxylic acids;[20] functionalized one-carbon synthon[23])

Alternate Name: MEMCl.

Physical Data: bp 50-52 °C/13 mmHg; *d* 1.094 g cm^{-3}.

Handling, Storage, and Precautions: moisture sensitive; a lachrymator and possible carcinogen.

Protection of Alcohols.

The 2-methoxyethylmethyl (MEM) group was developed as a protective group that can be introduced with the ease of the methoxymethyl (MOM) group but can be cleaved under milder conditions, thus affording another level of selectivity in deprotection.[2] The most common method for its introduction is occasioned with MEMCl and ***Diisopropylethylamine*** (CH_2Cl_2, 25 °C, 3 h, quant.). Introduction of the MEM group is also faster than the formation of the related MOM derivative, which may be the result of anchimeric assistance. Alternatively the salt, $MEMNEt_3^+ Cl^-$ (MeCN, reflux, 30 min, >90% yield) may be used for its introduction, but this procedure has not seen extensive use. An alkoxide prepared from ***Sodium Hydride*** or ***Potassium Hydride***, when treated with MEMCl (THF or DME, 0 °C, 10-60 min, >95% yield), affords the MEM ether. The reaction of tributyltin ethers in the presence of ***Cesium Fluoride***, DMF, and MEMCl has also been used to prepare MEM ethers, but this method is primarily used as part of a scheme for the interconversion of protective groups.[3] For example, the reaction of THP ethers with $Bu_3SnSMe/BF_3.Et_2O$ gives the corresponding tin ethers. Since the MEM group is of low steric demand, little selectivity is expected when protecting two similar alcohols, but electronic effects can be used to advantage to achieve modest selectivity (eq 1).[4]

The original method devised to effect deprotection is to treat the MEM derivative with ***Zinc Bromide*** (CH_2Cl_2, 25 °C, 2-10 h, 90% yield)[1] or ***Titanium(IV) Chloride*** (CH_2Cl_2, 0 °C, 20 min, 95% yield)[1] to form a chelate, which upon further reaction reconstitutes the alcohol. Since then a number of other cleavage methods have been developed which rely on the fact that the MEM group can be viewed as an acetal or ether. Reagents such as ***Bromodimethylborane*** (CH_2Cl_2, -78 °C, $NaHCO_3$, H_2O, 87-95% yield),[5] Ph_2BBr (CH_2Cl_2, -78 °C, 71% yield),[6] (-SCH_2CH_2S-)BBr,[7] (*i*-$PrS)_2BBr$ (DMAP, K_2CO_3, H_2O),[8] and 2-bromo-1,3,2-benzodioxaborole[9] cleave ethers like BBr_3. Me_2BBr cleaves MTM and MOM ethers and acetals, but (*i*-$PrS)_2BBr$ converts the MEM group to the *i*-$PrSCH_2$- ether which can be cleaved using the same conditions used to cleave the MTM ether. The cyclic thio derivative appears to be sterically sensitive (eq 2). It does not cleave benzyl, allyl, methyl, THP, TBDMS, and TBDPS ethers, whereas the related oxygen analog (2-bromo-1,3,2-benzodioxaborole) is a much more powerful reagent and cleaves the following groups in the order: MOMOR &AApprox; MEMOR > *t*-Boc > Cbz > *t*-BuOR > BnOR > allylOR > *t*-BuO_2CR &AApprox; secondary alkylOR > BnO_2CR > primary alkylOR >> alkylO_2CR. The *t*-butyldimethylsilyl group is stable to this reagent.

(2)

Protic acids such as ***Pyridinium p-Toluenesulfonate*** (*t*-BuOH, or 2-butanone, heat, 80-99% yield)[10] and ***Tetrafluoroboric Acid*** (CH_2Cl_2, 0 °C, 3 h, 50-60% yield)[11] can also be used to cleave the MEM ethers. The former also cleaves the MOM ether and has the advantage that it cleanly cleaves allylic ethers which can not be cleaved by Corey's original procedure. The MEM group is reasonably stable to CF_3CO_2H/CH_2Cl_2 (1:1), which is used to cleave Boc groups, and to 0.2 N HCl, but it is not stable to 2.0 N HCl or HBr-AcOH.[12] ***Iodotrimethylsilane*** has long been known as a powerful reagent for the cleavage of ethers, esters, carbamates, etc., and thus it is no surprise that it will cleave the MEM ether as well. It does tend to form iodides when cleaving allylic and benzylic ethers, but this is somewhat suppressed when the reagent is prepared in situ (Me_3SiCl, NaI, MeCN, -20 °C, 79%).[13] In a synthesis of tirandamycin, deprotection of a MEM ether was unsuccessful using conventional methods and an entirely new method was developed which oxidizes the methylene (*n*-BuLi, THF; then $Hg(OAc)_2$, H_2O, THF, 81% yield) (eq 3).[14]

(3)

Protection of Phenols.

Methoxyethoxymethyl chloride can also be used to protect phenols. The conditions for its introduction are similar to those used for alcohols (NaH, THF, 0 °C; $MeOCH_2CH_2OCH_2Cl$, 0 °C -> 25 °C, 2 h, 75% yield).[15,16] In contrast to the alcohol derivatives, phenolic MEM ethers can be cleaved with ***Trifluoroacetic Acid*** (CH_2Cl_2, 23 °C, 1 h, 74% yield).[17] 1 M HCl (THF, 5 h, 60 °C)[18] and HBr/EtOH[19] will also effect cleavage. In general, the cleavage conditions used for alcohols are also effective with the phenolic derivatives. During an examination of the asymmetric reduction of an acetophenone derivative with ***(+)-B-Chlorodiisopinocampheylborane***, it was found that a phenolic MEM ether was slowly cleaved (eq 4).[16]

(4)

Protection of Acids.

Carboxylic acids are converted to MEM esters using conditions similar to those used for alcohol protection (MEMCl, *i*-Pr_2EtN, CH_2Cl_2, 0 °C, 2 h).[20] Deprotection of this ester is effected with 3 M HCl (THF, 40 °C, 12 h) or with $ZnBr_2$[21] or $MgBr_2$.[22]

Miscellaneous Uses.

Outside of the protective group arena, MEMCl has been used to alkylate enolates[23] and aryllithium reagents in the presence of Ph_2TlBr.[24] MEM ethers have also proven to be a good one-carbon source for the preparation of isochromans (eq 5)[25] and other oxygen heterocycles (eq 6).[26]

(5)

Guaiacolmethyl chloride (GUMCl) (**1**) is a reagent similar to MEMCl, but it produces derivatives that are somewhat more acid sensitive. In fact the GUM group can be removed in the presence of a MEM group. It is a more sterically demanding reagent, and thus it is possible to introduce this group selectively onto a primary alcohol in the presence of a secondary alcohol. Because of its similarity to a *p*-methoxyphenyl group, it should be possible to remove it oxidatively. Cleavage is effected with $ZnBr_2$ in CH_2Cl_2 just as with the MEM group.[27]

3-Methoxyisoprene[1]

(R = Me)

[25408-63-3] · $C_6H_{10}O$ · 3-Methoxyisoprene · (MW 98.16) (R = Et)

[17466-15-8] · $C_7H_{12}O$ · 3-Ethoxyisoprene · (MW 112.19)

(used as an equivalent of isopropenyl methyl ketone in iterative Claisen rearrangements and as a diene in the Diels-Alder reaction)

Alternate Name: 2-methoxy-3-methyl-1,3-butadiene.

Physical Data: R = Me: bp 93-95 °C. R = Et: bp 113-114 °C.

Preparative Method: R = Me: from 2-methyl-3-butyn-2-ol by successive dehydration, addition of methanol, and elimination of methanol.[1]

Iterative Claisen Rearrangements.

The methoxy group of 3-methoxyisoprene exchanges with secondary allylic alcohols under acid catalysis and the resultant intermediate undergoes Claisen rearrangement.[2] This technique has been applied in an iterative synthesis of squalene (**1**) (eq 1).[1a,3] The rearrangement provides cleanly an (*E*)-alkene and a terminal isopropenyl ketone which, upon reduction, affords an allylic alcohol that is ready for a second rearrangement. Each 3-methoxyisoprene is translated into an isoprene unit in the final product. A similar, alternative, approach to squalene employs isopropenyl methyl ketone dimethyl acetal (2,2-dimethoxy-3-methyl-3-butene) (**2**), which is readily available from isopropenyl methyl ketone.[4]

(1)

Reagent (**2**), followed by methyl vinyl ketone diethyl acetal (3,3-diethoxy-1-butene) (**3**), and, again, reagent (**2**) have been applied successively in an iterative extension of methallyl alcohol in refluxing toluene with 2,4-dinitrophenol as a catalyst (eq 2).[4] Two iterations of methyl 2-hydroxy-3-butenoate with 2-methoxy-3-ethyl-1,3-butadiene[1] or 3,3-dimethoxy-2-ethyl-1-butene[4] play a critical role in the synthesis of the C_{18} *Cecropia* juvenile hormone.

Enolic β-diketones react with 2-methoxy-1,3-butadiene (eq 3)[5] and methacrolein diethyl acetal (3,3-diethoxy-2-methyl-1-propene) (eq 4)[6] to give products that are believed to arise from exchange of the enol form of the diketone with the alkoxy residue of the reagent followed by sigmatropic rearrangement (see also ***2-Methoxy-1,3-butadiene*** and ***3,3-Diethoxy-1-propene***). An alternative mechanism holds that the enol adds in an S_N2' fashion to the oxonium ion. Hydrolysis of the enol ethers gives carbonyl compounds. The overall process is the equivalent of a neutral Michael addition of the diketone to the unsaturated aldehydes from which the reagents were derived.

Diels-Alder Reaction.

3-Methoxyisoprene reacts regioselectively with methyl coumalate in a thermal Diels-Alder reaction. Hydrolysis of the enol ether affords an α-methylcyclohexanone (eq 5).[7]

N-Methoxy-*N*-methylacetamide[1]

[78191-00-1] · $C_4H_9NO_2$ · *N*-Methoxy-*N*-methylacetamide · (MW 103.14)

(acetylation of carbon nucleophiles; formation and transient protection of ketones; C-nucleophile in enolate anion condensations; preparation of aldehydes)

Physical Data: bp 40-44 °C/20 mmHg.[2]

Solubility: sol ether and other organic solvents.

Analysis of Reagent Purity: ^{1}H NMR δ 2.12, 3.18, 3.70; ^{13}C NMR δ 19.58, 31.98, 60.86, 171.59; IR (neat) 2950, 1670, 1410, 1380 cm^{-1}.[2]

Preparative Method: reaction of ***Acetyl Chloride*** with commercially available ***N,O-Dimethylhydroxylamine*** hydrochloride in pyridine, followed by distillation at reduced pressure (65%).[2]

Handling, Storage, and Precautions: the compound is stable but should be protected from moisture; use in a fume hood.

General Considerations.

The title compound (**1**) and its analogs are versatile reagents for the acetylation of organolithium and magnesium reagents to form methyl ketones.[3] Lithium reagents have been reported to be superior to magnesium.[4] The reactions are carried out in ethereal solvents at 0 or -78 °C. Coordination stabilizes the resulting tetrahedral adduct. Thus further reaction to form tertiary carbinols is generally not observed.[5] The methyl ketone is generated by workup under mild acidic conditions (eq 1). Many examples have been reported. Higher homologs of the title compound have frequently been employed in acylation reactions and generally give favorable results. *N*-Methoxy-*N*-methylamides are sufficiently more reactive than the corresponding methyl esters that attack on difunctional starting materials occurs exclusively at the amide (eq 2).[6,7]

The tetrahedral complex has been used to mask the resulting ketone during subsequent transformations.[8] The complex has also been used to facilitate an intramolecular Diels-Alder condensation by providing conformational constraints.[9]

Compound (**1**) is an excellent reagent for acetylation of strongly nucleophilic enolate anions (eq 3).[2] It is less prone to enolate formation than ethyl acetate and uses a stoichiometric quantity of the nucleophile rather than 2 equiv commonly required in Claisen-type condensations. With less nucleophilic enolate anions, good results have been claimed in some cases[10] and poor results in others.[2,11] Tandem reaction of a bis(*N*-methoxy-*N*-methylamide) has been used in a biomimetic synthesis of pretetramide.[12]

The lithium salt (**2**) of the enolate anion of (**1**) can be prepared by treatment of (**1**) with ***Lithium Diisopropylamide***. The corresponding zinc reagent (**3**) can be prepared from the bromoacetamide and powdered zinc.[13] These reagents will condense with carbonyl compounds and the adducts can subsequently be used as acylating agents.

(2)

(3)

N-Methoxy-*N*-methylamides undergo reduction to aldehydes with ***Lithium Aluminum Hydride***, ***Diisobutylaluminum Hydride***, and other hydride reagents.[3] *i*-Bu_2AlH is more selective than $LiAlH_4$ for stopping at the aldehyde.

Related Reagents.

Acetic Anhydride; ***Acetyl Chloride***; ***Acetyl Cyanide***; ***Acetyl Methanesulfonate***; ***Acetyl p-Toluenesulfonate***; ***N,O-Dimethylhydroxylamine***; ***Imidazole***.

(Methoxymethyl)bis(trimethylsilyl)amine

[88211-44-3] · $C_8H_{23}NOSi_2$ · (Methoxymethyl)bis(trimethylsilyl)amine · (MW 205.50)

(electrophilic *N*,*N*-bis(trimethylsilyl)aminomethylating agent for a variety of molecules; after desilylation, the overall transformation achieves primary aminomethylation[1,2])

Physical Data: bp 94-95 °C/83 mmHg; *d* 0.873 g cm^{-3}; *n*20D 1.431-1.434.

Solubility: sol organic solvents such as hexane, dichloromethane, ether, alcohol; stable in neutral or basic solvents; unstable in protic solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: ^{1}H NMR δ ($CDCl_3$): 0.14 (18H, s, 2 × $(CH_3)_3Si$), 3.17 (3H, s CH_3O), 4.82 (2H, s, CH_2); ^{13}C NMR δ ($CDCl_3$): 1.90 (q), 53.4 (q), 80.9 (t).

Handling, Storage, and Precautions: fairly stable at rt; for long storage, keep at 0-10 °C in the absence of moisture.

General Considerations.

This reagent, conveniently prepared[3,4b] by the reaction of ***Lithium Hexamethyldisilazide*** or ***Sodium Hexamethyldisilazide*** with ***Chloromethyl Methyl Ether*** in THF, is utilized for introduction of a primary aminomethyl unit into a variety of molecules by a two-step procedure involving *N*,*N*-bis(trimethylsilyl)aminomethylation followed by solvolytic removal of the trimethylsilyl groups. The reagent can be regarded as a synthetic equivalent for $^+CH_2NH_2$, and it functions as a reagent for achieving Mannich-type transformations[5] which are rarely possible to afford primary amines. The reagent reacts successfully with Grignard and organolithium compounds,[3] ketene silyl (or bissilyl) acetals,[4] silyl sulfides, and silyl phosphites.[6] While the *N*,*N*-bis(trimethylsilyl)aminomethylated products themselves are useful as *N*-protected primary amines,[7] they are easily desilylated to the corresponding primary aminomethyl compounds in protic media.

Primary Aminomethylation of Organometallic

Compounds.[3]

Grignard compounds react with the reagent in equimolar proportions to produce aminomethylated products in the *N*-silyl-protected form. Alkyl, allyl, and aryl Grignard reagents react smoothly in Et_2O at rt usually in high yield, whereas alkynyl Grignard reagents react under reflux in THF. Alkyllithium compounds and aryllithium compounds (prepared in situ by lithiation of arenes with *n*-BuLi) do not react with the reagent unless an equimolar amount of anhydrous ***Magnesium Bromide*** (best prepared from 1,2-dibromoethane and Mg in Et_2O) or $MgCl_2$ is present. Organoaluminum compounds derived from allyl and propargyl bromides have also been shown to undergo *N*,*N*-bis(trimethylsilyl)aminomethylation with this reagent (eqs 1-6).[8]

(1)

(2)

(3)

(4)

(5)

(6)

Solvolytic removal of the *N*-trimethylsilyl groups in the products leads to the corresponding primary amines and is easily accomplished in refluxing MeOH or EtOH in the presence of a catalytic amount of acid such as TsOH or HCl. Silica gel is also capable of catalyzing the solvolysis.

Primary Aminomethylation of Carboxylic Acids and Esters.[4]

The reaction of ketene silyl acetals with the reagent followed by desilylation provides a general method for α-aminomethylation of carboxylic acids and esters. Ketene silyl acetals and bissilyl acetals, prepared from carboxylic esters and acids, respectively, by treatment with ***Lithium Diisopropylamide*** (LDA) and ***Chlorotrimethylsilane***, react smoothly with the reagent in CH_2Cl_2 at rt in the presence of a catalytic amount (0.01 mol equiv) of ***Trimethylsilyl Trifluoromethanesulfonate*** to afford *N*,*N*-bis(trimethylsilyl)-β-aminocarboxylic esters, generally in high yields. The triflate-catalyzed reaction involves electrophilic attack of $[(Me_3Si)_2N{=}CH_2]^+TfO^-$ with release of Me_3SiOMe (eqs 7-9).

(7)

$R^1, R^2 = H$ or alkyl, $R^3 = $ alkyl or H, $R^4 = $ alkyl or TMS

(8)

The alkyl and trimethylsilyl esters of *N*,*N*-bis(trimethylsilyl)-β-aminocarboxylic acids are desilylated to the corresponding β-amino acids by treatment with catalytic amounts of acid in aqueous solvents. Selective removal of the *N*-trimethylsilyl groups of the alkyl esters can be performed with AcOH-aq. THF to give the corresponding β-amino acid esters.

N,N-Bis(trimethylsilyl)aminomethylation of Heteroatoms.[6]

Electrophilic introduction of a *N*,*N*-bis(trimethylsilyl)aminomethyl group with this reagent is possible at sulfur and phosphorus atoms by using silyl sulfides and silyl phosphites. The reaction of the reagent with phenyl- or alkylthiotrimethylsilanes and trimethylsilyl dithiocarbamates smoothly proceeds on heating at 60 °C in the presence of ***Zinc Bromide*** (0.05 mol equiv) to give *N*,*N*-bis(trimethylsilyl)aminomethylated sulfur compounds. $PhSCH_2N(SiMe_3)_2$ behaves similarly to the title reagent and is especially effective for *N*,*N*-bis(trimethylsilyl)aminomethylation of cuprate complexes.[2]

The reaction of the reagent with trimethylsilyl phosphite proceeds well at 60 °C in the presence of ***Tin(II) Chloride*** (0.05 mol equiv) to give *N*,*N*-bis(trimethylsilyl)aminomethylphosphonates in good yields (eqs 10-12).

N,*N*-Bis(trimethylsilyl)aminomethylphosphonates are desilylated to give aminomethylphosphonates, whereas *N*,*N*-bis(trimethylsilyl)aminomethylated sulfur compounds are not convertible to primary aminomethyl sulfides because of their instability.

(3-Methoxy-3-methyl-1-butynyl)copper(I)[1]

[66769-63-9] · C_6H_9CuO · (3-Methoxy-3-methyl-1-butynyl)copper(I) · (MW 160.70)

(nontransferable ligand used in cuprate preparation for selective ligand transfer to electrophiles[2])

Physical Data: red solid.

Solubility: sol THF; moderately sol ether (0.1 M at 0 °C); insol hexane, H_2O.

Preparative Methods: lithiation of 3-methoxy-3-methyl-1-butyne followed by addition of ***Copper(I) Iodide***. Usually prepared and used in situ. Copper(I) acetylides can be stored under water, then dried in the air.

Handling, Storage, and Precautions: copper(I) acetylides are reported to be explosive when dry. Prepared reagent should be used within a few days for best results. Use in a fume hood.

Mixed Organocuprates.

Since their introduction by Corey in 1972,[3] mixed organocuprates of composition [RC&tbond;CCuR^t]Li have received widespread use for their ability (when R^t is sp^2- or sp^3-bound to Cu) to effect selective transfer of R^t to suitable electrophiles.[2] Of the range of organocuprates which have been investigated for use as nontransferable[4] or dummy ligands, cuprates derived from 3-methoxy-3-methyl-1-butynylcopper are among the most attractive (see also ***3,3-Dimethyl-1-butynylcopper(I)***, ***1-Hexynylcopper(I)***, and ***1-Pentynylcopper(I)-Hexamethylphosphorous Triamide***). This stems from a combination of their high solubility in traditional solvents for coupling reactions (ether, THF), and the economy of using an inexpensive alkynic precursor.[2] Treatment of the alkyne with the requisite organolithium species yields synthetically useful lithium organocuprate derivatives (eq 1).

Mixed Alkyl Cuprates.

Mixed alkyl cuprates will selectively alkylate alkyl halides in moderate yield (eq 2).[2] Higher yields have been reported for alkyl transfer by converting the cuprate into a lithium dialkylcuprate, which transfers one alkyl group.[5] Alkyl delivery to cycloalkenones (eq 3)[2] and epoxides[6] is efficient, and near-quantitative yields are obtained using a variety of alkyl donors.

(2)

(3)

R = Bu, 100%; R = *i*-Pr, 95%
R = *t*-Bu, 95%

Mixed Alkenyl and Aryl Cuprates.

Delivery of alkenyl and aryl groups is probably the most versatile and celebrated application of mixed cuprates containing this dummy ligand. A variety of excellent examples demonstrate the high degree of efficiency of the process;[7-11] the heavily substituted nature of many of the combining species is a testimony to the tolerance of such mixed cuprates. The 3-methoxy-3-methyl-1-butynyl ligand was found to be clearly superior to a phenylthio dummy ligand in a variety of vinylcopper species.[10] S_N2' addition sequences are also possible, giving highly functionalized products (eq 4).[12] Asymmetric induction (up to 92% ee) has been reported for the conjugate addition of the mixed lithiocuprate derived from the anion of methyl norephedrine acetone imine to cycloalkenones.[13,14]

Trimethylstannylcopper Reagents.

Treatment of ***Trimethylstannyllithium*** with 3-methoxy-3-methyl-1-butynylcopper results in formation of the corresponding trimethylstannylcopper species (eq 5).[15] Such reagents are, as predicted, able to chemoselectively transfer the nondummy ligand to an electrophile. Thus, addition of a stannylcopper species to alkynes results in formation of (*E*)-alkenes (eq 5) with very high selectivity.

Related Reagents.

For lithium dialkylcuprates, see ***Lithium Dimethylcuprate***; for phenylthio mixed cuprates, see e.g. ***Lithium Methyl(phenylthio)cuprate*** and ***Phenylthiocopper(I)***. Also see ***Lithium (1-Hexynyl)(2-tri-n-butylstannylvinyl)cuprate***, ***Lithium (1-Pentynyl)(2-tri-n-butylstannylvinyl)cuprate***, ***Lithium Phenylthio(trimethylstannyl)cuprate***, ***Tri-n-butylstannylcopper***, and ***Trimethylstannylcopper-Dimethyl Sulfide***.

5-(Methoxymethyl)-1,3-cyclopentadiene

[39872-54-3] · $C_7H_{10}O$ · 5-(Methoxymethyl)-1,3-cyclopentadiene · (MW 110.17)

(Diels-Alder cycloaddition diene, particularly useful in prostaglandin synthesis)

Solubility: sol most organic solvents.

Preparative Methods: prepared via the alkylation of freshly sublimed ***Thallium(I) Cyclopentadienide*** with ***Chloromethyl Methyl Ether*** in ether (-20 °C) according to the method of Corey and co-workers.[1,2] Thallium(I) cyclopentadienide is prepared via the reaction of cyclopentadiene with thallium(I) sulfate and aqueous potassium hydroxide (eq 1).[2-4] **Caution**: thallium and its salts are known to be highly toxic.[5] Other 5-alkyl-substituted 1,3-cyclopentadienes (e.g. 5-(benzyloxymethyl)-1,3-cyclopentadiene[2,6]) are prepared similarly.

Handling, Storage, and Precautions: 5-alkyl-substituted 1,3-cyclopentadienes undergo facile double bond migration;[7,8] as such, 5-(methoxymethyl)-1,3-cyclopentadiene is typically prepared fresh and used without isolation.

General Considerations.

The reactions of 5-(methoxymethyl)-1,3-cyclopentadiene with Diels-Alder cycloaddition ketene equivalents[9] have been widely studied due to their pivotal role in the classic Corey approach to the synthesis of prostaglandins. The cycloadducts are converted to the norbornenone which undergoes Baeyer-Villiger oxidation and subsequent rearrangement to the key lactone precursor to prostaglandins (eq 2).[10]

The reaction of 5-(methoxymethyl)-1,3-cyclopentadiene with ***2-Chloroacrylonitrile*** catalyzed by dry ***Copper(II) Tetrafluoroborate*** (0.3 equiv, 0 °C, 18 h) is reported to yield cycloadduct in 80-90% yield.[1] Aqueous $Cu(BF_4)_2$ apparently leads to facile isomerization of 5-(methoxymethyl)-1,3-cyclopentadiene and the use of aq $Cu(BF_4)_2$ catalysis leads to formation of the cycloadduct derived from 1-(methoxymethyl)-1,3-cyclopentadiene.[11] The reaction of 5-(methoxymethyl)-1,3-cyclopentadiene with 2-chloroacryloyl chloride in ether (0 °C, 18 h), without added Lewis acid catalyst, affords a mixture of diastereomeric cycloadducts.[12] Treatment of the cycloadduct with ***Sodium Azide*** (dimethoxyethane, 25 °C (1.5 h), then reflux (2 h)), followed by hydrolysis in 35% aq HOAc (55-60 °C) affords the 7-*syn*-methoxymethyl-2-norbornen-5-one (eq 3). The yield of norbornenone is 82% based on the amounts of thallium(I) cyclopentadienide and chloromethyl methyl ether used.

(3)

Treatment of 5-(methoxymethyl)-1,3-cyclopentadiene with ***Nitroethylene*** at -15 °C (or lower) affords a 9:1 mixture of cycloadducts in good yield (eq 4).[13,14] The minor cycloadduct arises from apparent isomerization to 1-(methoxymethyl)-1,3-cyclopentadiene. Acrylic acid has also been used as a dienophile in the reaction with 5-(methoxymethyl)-1,3-cyclopentadiene.[15]

(4)

Kanematsu and co-workers[16] reported the formation of a novel class of photoresponsive crown ethers via the [4 + 2] cycloaddition of 5-(methoxymethyl)-1,3-cyclopentadiene with a crowned *p*-benzoquinone followed by photochemical [2 + 2] cycloaddition. 5-(Methoxymethyl)-1,3-cyclopentadiene undergoes regio- and stereoselective cycloaddition with the benzoquinone under Lewis acid catalysis (***Boron Trifluoride Etherate***, -20 °C, CH_2Cl_2, 93%). The resulting cage compound undergoes quantitative thermal ring opening (110 °C, 3 h) and clean photochemical reclosure (eq 5).

(5)

5-Alkyl-substituted 1,3-cyclopentadienes undergo facile double bond migration.[7] For example, thermolysis of 5-(methoxymethyl)-1,3-cyclopentadiene via flash vacuum pyrolysis (FVP; 220 °C) affords a 1:1.5 equilibrium mixture of the 1- and 2-(methoxymethyl)-1,3-cyclopentadienes (eq 6).[8]

(6)

Related Reagents.

5-Bromo-1,3-cyclopentadiene; ***Cyclopentadiene***; ***5,5-Dimethoxy-1,2,3,4-tetrachlorocyclopentadiene***.

Methoxymethyl(diphenyl)phosphine Oxide[1]

[4455-77-0] · $C_{14}H_{15}O_2P$ · Methoxymethyl(diphenyl)phosphine Oxide · (MW 246.26)

(Horner-Wittig reagent for the preparation of methoxyvinyl ethers and hence homologous aldehydes;[2] the anion has greater stability and nucleophilicity than the analogous phosphonium ylide)

Physical Data: mp 114-116 °C; bp 138-139 °C/0.1 mmHg.

Solubility: sol THF, DME, CH_2Cl_2; insol H_2O.

Form Supplied in: white solid; commercially available.

Handling, Storage, and Precautions: commercial material (97-98%) is satisfactory as received. The toxicological properties of the reagent are unknown.

General Considerations.

Methoxymethyl(diphenyl)phosphine oxide has been widely[3] used in the Horner-Wittig reaction converting both aldehydes and ketones, including enolizable ones, into methoxyvinyl ethers (and hence to higher aldehydes) (eq 1). The reagent is available commercially or by routes A (90%),[2] B (89%),[4] or C (25%).[5] Its anion, generated from ***Lithium Diisopropylamide*** in THF, is more stable than the corresponding phosphonium ylide (Ph_3+P--CHOMe) and readily adds to the carbonyl substrate giving good yields of isolable β-hydroxyphosphine oxides. Alkene formation does not usually occur spontaneously (for exceptions, see eqs 4 and 6) because the lithium counterion binds strongly to the oxygen of the initial adduct, preventing attack by oxygen on phosphorus. In the case where R^1 &neq; R^2 the diastereoisomeric alcohols can often be separated by fractional crystallization or chromatographically. Completion of the Horner-Wittig reaction is achieved by treating the adducts with ***Sodium Hydride*** (or ***Potassium Hydride***) at ambient temperature. This elimination is stereospecifically *syn*, with each diastereomer giving a single geometric isomer. The methoxyvinyl ether(s) are readily separated from the phosphinate byproduct. Mild acid hydrolysis furnishes the homologous aldehyde.

The more nucleophilic and sterically less demanding nature of the $Ph_2P(O)CH_2OMe$ anion is illustrated by the examples in eqs 2-4.[6,7] In each case the ketone was inert towards the analogous phosphonium ylide. Diastereoselective attack of the anion on the 2-acylindole (**1**)[8] leads to single vinyl ether (**2**) (eq 4).

(4)

With enones, the anion undergoes 1,2-addition to afford 1-methoxy-1,3-dienes (eqs 5-7).[9,10] The phosphonium ylide, in contrast (eq 7), underwent 1,4-addition with the bicyclic ketone (**3**) to furnish the fused methoxycyclopropane (**4**).[11]

(6)

Isolation of a single β-hydroxyphosphine oxide is exemplified in eq 8.[12] The (*RS*,*SR*) adduct (**5**), which crystallized preferentially, was required to prepare (*E*,*E*)-1-methoxy-4-trimethylsilyl-1,3-butadiene, a Diels-Alder substrate.

Lactones[13] also react with the phosphonate anion, thus providing an alternative stratagem to obtain vinyl ether (**6**) (eq 9).

3-(Methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene[1]

[90330-49-7] · $C_{13}H_{26}O_3Si_2$ · 3-(Methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene · (MW 286.57)

(a reagent for reiterative Diels-Alder reactions[1])

Physical Data: colorless liquid; bp 72 °C/1.8 mmHg;[3a] IR, ^{1}H NMR, ^{13}C NMR, and MS spectra.[3a]

Solubility: very sol most organic solvents; decomposition occurs in protic solvents.

Preparative Method: by the bissilylation of 3-(methoxymethylene)-2,4-pentanedione[2] using ***Chlorotrimethylsilane***, dry ***Zinc Chloride***, and ***Triethylamine***.[3]

Purification: vacuum distillation.

Handling, Storage, and Precautions: stored safely for a few weeks in a refrigerator under nitrogen atmosphere; hydrolytic conditions should be avoided for reactions and handling.

General Considerations.

3-(Methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene (**1**) is a reactive cross-conjugated triene and can be effectively utilized in sequential Diels-Alder reactions, which are called diene-transmissive Diels-Alder reactions,[1] producing a variety of hydrobenzene and -naphthalene ring systems bearing many functional groups.

Phenol Synthesis.

3-(Methoxymethylene)-2,4-bis(trimethylsilyloxy)-1,4-pentadiene (**1**) smoothly reacts, at rt, with alkynes activated by

electron-withdrawing substituents. The 1:1 cycloadducts with unsymmetrical dienophiles are formed with high regioselectivity, and they undergo spontaneous elimination of methyl trimethylsilyl ether to give *o*-hydroxyacetophenone derivatives in moderate yields (eq 1).[3a]

Cyclohexenone Synthesis.

On the other hand, the reactions of (**1**) with electron-deficient alkenes require heating under reflux in benzene to produce either 3-cyclohexen-1-ones (the 1:1 cycloadducts) or tetrahydronaphthalen-1-ones (the 1:2 cycloadducts), depending upon the molar amounts of the dienophiles used or the reaction temperatures applied (eq 2).[3] When unsymmetrically substituted alkenes are employed (2 equiv), both the initial and second stages of the ring-forming processes are exclusively regioselective.[4]

Fused Phenol Synthesis.

Diels-Alder reactions of (**1**) with alkene dienophiles at rt form 1:1 cycloadducts selectively. A second ring-forming reaction can then be performed by using a variety of dienophiles. Especially, the cross reactions with alkynic dienophiles are useful, providing a convenient entry to highly functionalized tetrahydronaphthalen-1-ol derivatives (eq 3).[5]

Derivatives and Synthetic Equivalents.

Cross-conjugated trienes (**2**) bearing various substituents at the central double bond are accessible by applications of the synthetic procedures mentioned above.[6]

(2)

R = alkyl, alkenyl, aryl, hetaryl

Ring formation using two different dienophiles can also be performed with synthetic equivalents of cross-conjugated trienes.[7-10] The Grignard reagent of 2-chloro-1,3-butadiene (see ***1,3-Butadienyl-1-magnesium Chloride***) reacts with ketones to produce diene alcohols which serve as a versatile synthetic equivalent of cross-conjugated trienes.[7,8] A typical sequence of reactions involves initial Diels-Alder reaction of 1-(1-methylene-2-propenyl)-1-cyclopentanol with ***Dimethyl Acetylenedicarboxylate*** (DMAD), dehydration of the resulting 1,4-hexadiene with molecular sieves 5A, and a second Diels-Alder reaction with DMAD to give dihydrobenz[*e*]indenetetracarboxylate after dehydrogenative aromatization with ***Chloranil*** (eq 4).[8]

Related Reagents.

1-Methoxy-3-methyl-1-trimethylsilyloxy-1,3-butadiene; ***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene***; ***2-Trimethylsilyloxy-1,3-butadiene***.

Methoxymethylenetriphenylphosphorane

[20763-19-3] · $C_{20}H_{19}OP$ · Methoxymethylenetriphenylphosphorane · (MW 306.36)

(Wittig reagent for carbonyl homologation; vinyl ether synthesis[1-8])

Physical Data: deep red in solution; unstable at 25 °C.[1-3]

Solubility: sol organic solvents; decomposes in protic solvents, aldehydes, and ketones.[1]

Analysis of Reagent Purity: unstable at 25 °C, decomposing completely in <24 h producing PPh_3 (70%; ^{31}P NMR δ -5.1 ppm) and other unidentified species.[2] The ylide gives a ^{31}P NMR signal at δ 7.9 ppm (-90 °C) which is shifted upfield to 5.8 ppm ($^2J_{P\text{-}H}$ = 48 Hz; $^3J_{P\text{-}H}$ = 12 Hz) at ambient temperatures.

Preparative Methods: by the deprotonation of methoxymethyl(triphenyl)phosphonium chloride (from ***Triphenylphosphine*/*Chloromethyl Methyl Ether***)[4a,b] with a number of bases (alkyllithiums, alkoxides, dimsylsodium, amides).[4-8]

Handling, Storage, and Precautions: should be generated in situ at low temperature (e.g. -90 °C) under a nitrogen atmosphere and used immediately.

Vinyl Ether Homologs from Carbonyl Compounds.

The Wittig alkenation of carbonyl compounds has evolved to occupy a preeminent position in the hierarchy of carbon-carbon bond-forming reactions.[1] With α-alkoxy substitution, Wittig reagents convert carbonyl derivatives into their vinyl ether homologs, and methoxymethyltriphenylphosphorane (**1**) has enjoyed widespread use in this regard since its generation in 1958 by Levine (eq 1).[4a] In a more extensive study of α-substituted Wittig reagents (e.g. Ph_3PCHX, X = OH, Cl, OMe, SMe, and OAr), it was determined that ***Phenyllithium*** is superior to ***n-Butyllithium*** for the

deprotonation of the phosphonium salt and that X = OC_6H_4Me-*p* gives better yields of vinyl ether products than (**1**) in several cases.[4b,c] Moreover, the thermal instability of (**1**) has resulted in the reagent being commonly used in stoichiometric excess (2-4 equiv).[2-8]

While butylidene products have been observed on numerous occasions when *n*-BuLi has been used to generate (**1**),[4b,o,s] this base continues to be used for its preparation. Recently, it was discovered that *n*-BuLi, but not ***t-Butyllithium***, displaces PhLi from $(Ph_3PCH_2OMe)Cl$, ultimately producing $Ph_2(MeOCH_2)PCHPr$, which accounts for the observed butylidene products when employing this base.[2] Therefore, either PhLi[4a,b] or *t*-BuLi[4s] is superior to *n*-BuLi for the generation of (**1**). Alternatively, amide bases (e.g. ***Lithium Diisopropylamide***),[6] alkoxides (e.g. ***Potassium t-Butoxide***)[7] and ***Sodium Methylsulfinylmethylide***[8] are effective bases for the preparation of (**1**). As an example, (**1**) prepared from the *t*-BuKO method has been used for the effective conversion of conjugated enones to 1,3-dienyl ethers which function as useful Diels-Alder substrates (eq 2).[7d]

Insufficient comparative data exist for a definitive judgement on the best method to generate (**1**). However, the fact

that (**1**) decomposes at 25 °C suggests that its generation and reaction with carbonyl substrates should be conducted at low temperatures (i.e. -70 to -90 °C). A survey of representative procedures suggests that *t*-BuLi, which can be used to generate (**1**) at -90 °C, may eliminate the need for using a large excess of (**1**) because this method avoids its exposure to higher temperatures which result in its partial decomposition.[2] Moreover, even relatively hindered ketones are converted to the corresponding oxaphosphetanes at this temperature. Aliphatic carbonyl derivatives are likely to form these intermediates irreversibly, whereas their conjugated counterparts may well undergo complete or partial equilibration, ultimately giving rise to (*E*)-alkenes as the major vinyl ether products.[1a] With slow warming to 25 °C, the decomposition of the intermediate oxaphosphetane produces the corresponding vinyl ether very cleanly, at least in the systems examined (eq 3).[2] The excellent yields which have been achieved for many substrates add support to this generality.

Both aldehydes and ketones undergo reaction with (**1**), leading to vinyl ethers. While the product stereochemistry is not always reported, sufficient data are currently available for representative systems to indicate that unsymmetrical carbonyl compounds normally lead to (*Z*/*E*) product mixtures under Li^+-catalyzed conditions. A recent study employing the Levine-Wittig-Schlosser method (PhLi, Et_2O) provides useful stereochemical information for aromatic aldehydes which give roughly equal amounts of both *cis* and *trans* vinyl ethers under these conditions (e.g. PhCHO, 40:60; *p*-$MeOC_6H_4CHO$, 54:46; *o*-$CF_3C_6H_4CHO$, 45:55).[5g] With aliphatic derivatives, as mentioned above, kinetic control is operative and the process is more (*Z*) selective, as can be observed below for octanal[5g] and pentanoyltrimethylsilane[2] where the silyl group reverses the stereochemical relationship of the alkyl group with respect to the methoxy group in the vinyl ether products (**2**) and (**3**).

(2)
R = C_7H_{15} (54:46)

(3)
R = Bu (79:21)

Numerous synthetic applications have been found for (**1**) and several representative examples are shown in (**4**)-(**7**), which include the base and solvent employed for the generation of (**1**) as well as the yield and isomeric (*Z*/*E*) distribution of the vinyl ether products derived from their carbonyl precursors.[4d,4s,7c,7e]

(4)
$KOCMe_2Et$, PhMe
100% (1:4)

(5)
BuLi, THF
80% (1:3)

(6)
t-BuOK, THF
87% (1:2)

(7)
t-BuLi, THF
88% (2:3)

It can be noted from the above that the (*E*) isomer is isolated as the major product in each case, a result which may be attributable to oxaphosphetane equilibration either through its formation (i.e. highly conjugated systems) or through the participation of proximate functionality (e.g. alkoxy).[1a] In certain cases, these substrate features can result in a highly (*E*)-selective process, e.g. (**8**) and (**9**).[6g]

(8)

(9)

Homologation of Carbonyl Compounds.

The vast majority of the synthetic applications of (**1**) involve the homologation of carbonyl compounds. Often the intermediate vinyl ether is converted directly to the aldehyde (or acetal) which itself is a required intermediate for the total synthesis of a target molecule which can be a natural product (e.g. (+)-pleuromutilin (eq 4))[6e] or compounds of theoretical interest, such as 2a,8a,8b,8c-tetrahydropentaleno[6,1,2-*aji*]azulene (eq 5).[4p] The intermediate vinyl ethers can also be oxidized to provide α,β-unsaturated aldehydes as an important extension of the methodology (eq 6).[5i]

(4)

(5)

(6)

The hydrolysis of the vinyl ethers normally occurs smoothly with dilute aqueous acid at 25 °C, mild conditions which make these derivatives especially attractive precursors to the desired aldehydes, particularly in systems where the aldehyde must be generated selectively in the presence of other protected carbonyl functionalities (eq 7).[5f] For certain applications, other alkoxymethylene ylides (Ph_3PCHOR, R = $(CH_2)_2SiMe_3$,[7d] THP,[5j] or $Ph_2P(O)CHLi(OMe)$,[5k] or $Ph_2PCHLi(OMe)$)[9] provide alternative or superior choices to (**1**) for the alkenation process or other subsequent conversions. However, (**1**) is a proven reagent for the effective homologation of aldehydes, both saturated and unsaturated, as well as their ketone counterparts.

(4*S*,5*S*)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline[1]

(**1**; R = Me)

[52075-14-6] · $C_{12}H_{15}NO_2$ · (4*S*,5*S*)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline · (MW 205.28) (**2**; R = Et)

[51594-37-7] · $C_{13}H_{17}NO_2$ · (4*S*,5*S*)-4-Methoxymethyl-2-ethyl-5-phenyl-2-oxazoline · (MW 219.31) (**3**; R = $ClCH_2$)

[54623-66-4] · $C_{12}H_{14}ClNO_2$ · (4*S*,5*S*)-4-Methoxymethyl-2-chloromethyl-5-phenyl-2-oxazoline · (MW 239.72)

(enantiopure carboxylic ester derivatives for synthesis of enantiomerically pure or enriched 2- and 3-substituted alkanoic acids, γ-butyrolactones, valerolactones, and benzovalerolactones by α-lithiation and asymmetric alkylations)

Physical Data: (**1**): bp 85-87 °C/0.20 mmHg; [α]$CHCl_3$D -118°. (**2**): bp 91-93 °C/0.25 mmHg; [α]$CHCl_3$D -84.2°. (**3**): [α]$CHCl_3$D -84.1°.

Preparative Methods: (**1**) and (**2**): cyclocondensation of commercially available (1*S*,2*S*)-2-amino-1-phenyl-1,3-propanediol with the appropriate orthoester, followed by methylation of the free hydroxy group (eq 1).[2a]

(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline

Handling, Storage, and Precautions: no special precautions.

Asymmetric Alkylations.

The asymmetric synthesis of 2-alkanoic acids can be accomplished be treatment of the lithio salt of the 2-ethyl-2-oxazoline with alkyl halides followed by acidic hydrolysis of the oxazoline (eq 2).[2]

Alkylation of the 2-methyl-2-oxazoline (base/electrophile) results in homologated 2-oxazolines. A second alkylation sequence proceeds with asymmetric induction and results in the formation of highly substituted chiral 2-alkyl alkanoic

(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline

acids. Use of ethylene oxide as the electrophile in this process allows for the formation of chiral α-substituted γ-butyrolactones and α-substituted γ-valerolactones with good stereoselectivity (60-80% ee; eq 3).[3]

Conjugate Additions to 2-Vinyloxazolines.

The 2-methyl-2-oxazoline can be converted into a phosphonate for Horner-Emmons alkenations. A variety of (*E*)-alkenes containing the chiral oxazoline auxiliary (α,β-unsaturated oxazolines) can be synthesized in high yields (80-93%) as the sole geometric isomer (eq 4).[4] Conjugate addition of alkyllithium reagents to these Michael acceptors affords, after oxazoline hydrolysis, the 3-substituted alkanoic acids (or corresponding alcohol) with a high level of stereoselectivity (91-99% ee; eq 4).[4]

(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline

Use of appropriately substituted chiral α,β-unsaturated oxazolines allows access to 3-substituted δ-valerolactones and 4-substituted 2-chromanones with high stereoselectivity (95-98%; eq 5).[4a-c]

(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline

(5)

Asymmetric Aldol Additions.

2-Ethyl-2-oxazoline takes part in aldol condensations as its boron azaenolate. The *erythro* selectivity for this protocol is excellent (95:5 to 98:2) but the enantioselectivity is only moderate (29-71% ee; eq 6).[5]

(6)

Enantioenriched α-Chloro Carboxylic Acids.

(4S,5S)-4-Methoxymethyl-2-methyl-5-phenyl-2-oxazoline

Reaction of (1*S*,2*S*)-1-phenyl-2-amino-1,3-propanediol with the ethyl imidate of chloroacetonitrile gives (-)-2-chloromethyl-4-methoxymethyl-5-phenyl-2-oxazoline (eq 7).[6]

Alkylation of this oxazoline is accomplished by metalation with ***Lithium Diisopropylamide*** followed by adding a premixed solution of the electrophile and 2 equiv of HMPA (eq 8). Hydrolysis of the oxazoline moiety affords the enantioenriched 2-chloroalkanoic acids, albeit with low optical purity.[6]

Related Reagents.

(R)-(+)-t-Butyl 2-(p-Tolylsulfinyl)propionate; ***Chloro(cyclopentadienyl)bis[3-O-(1,2:5,6-di-O-isopropylidene-α-D-glucofuranosyl)]titanium***; ***10-Dicyclohexylsulfonamidoisoborneol***; ***Diisopinocampheylboron Trifluoromethanesulfonate***; ***(R,R)-2,5-Dimethylborolane***; ***2-(o-Methoxyphenyl)-4,4-dimethyl-2-oxazoline***; ***(S)-4-Benzyl-2-oxazolidinone***; ***3-Propionylthiazolidine-2-thione***; ***2,4,4-Trimethyl-2-oxazoline***.

2-Methoxy-6-methyl-1,4,3,5-oxathiadiazine 4,4-Dioxide

[40028-33-9] · $C_4H_6N_2O_4S$ · 2-Methoxy-6-methyl-1,4,3,5-oxathiadiazine 4,4-Dioxide · (MW 178.19)

(reagent for in situ generation of methyl *N*-sulfonylurethane; provides lower concentrations and higher reaction temperatures than direct formation)

Physical Data: mp 102-103 °C.

Preparative Method: reaction of ***Methoxycarbonylsulfamoyl Chloride*** with ***Sodium Hydride*** in acetonitrile[1] leads to the title reagent (**1**).

General Considerations.

Methyl *N*-sulfonylurethane (**2**) has demonstrated a high degree of electrophilic reactivity in cycloadditions with a variety of alkenes to provide 2-methoxycarbonyl-1,2-thiazetidines (**3**) and 2,3-dihydro-6-methoxy-1,4,5-oxathiazines (**4**) (eq 1).[2] Additions to alkynes proceed to give exclusively the 1,4,3-oxathiazine (**5**) (eq 2).

This unstable reagent has been prepared by two methods. First, by direct dehalogenation of methoxycarbonylsulfamoyl chloride using sodium hydride.[2] The second involves the in situ fragmentation of the title reagent (**1**).[3] This reagent apparently undergoes a thermal [2 + 4] cycloreversion above 30 °C. Reaction of (**1**) with a variety of alkenes provides identical products to those reported with (**2**). This second method has the advantage that longer reaction times and higher temperatures are possible. Cycloadducts were obtained from otherwise unreactive alkenes such as *cis*-stilbene and cyclooctatetraene, employing this method.

The two methods give differing results, however, in the addition to ynamines (**6**).[4] In this case the low-temperature generation provided the expected product (**7**), while the cycloreversion method led to the new product (**8**) (eqs 3 and 4).

(*S*)-2-Methoxymethylpyrrolidine[1]

[63126-47-6] · $C_6H_{13}NO$ · (*S*)-2-Methoxymethylpyrrolidine · (MW 115.20)

(chiral auxiliary; asymmetric syntheses with SMP enamines[2] and SMP amides;[3] asymmetric Birch reductions;[4] asymmetric Diels-Alder reactions[5])

Alternate Name: SMP.

Physical Data: bp 75 °C/40 mmHg; *d* 0.930 g cm^{-3}; n_D^{20} 1.4467; α_D^{20} -3 to -4° (neat).

Solubility: sol H_2O, ether, dichloromethane.

Form Supplied in: colorless liquid.

Handling, Storage, and Precautions: store at 0-4 °C under an argon atmosphere.

General Considerations.

Since the pioneering times of the mid-1970s, (*S*)-2-methoxymethylpyrrolidine has been one of the most generally useful chiral auxiliaries in asymmetric synthesis, with a very broad range of applications. As a proline derivative, it generally shows high stereoselectivities due to the rigidity of the five-membered ring and the ability to coordinate metal fragments[6,7] (see also ***(S)-1-Amino-2-methoxymethylpyrrolidine***, SAMP).

Lithiated SMP formamides and thioformamides have been used as acylanion equivalents (d^1 synthons) in the synthesis of enantiomerically pure α-hydroxy ketones and vicinal diols.[7] Metalated SMP aminonitriles have been used in nucleophilic acylation reactions to give α-hydroxy ketones.[8]

SMP enamines have a very broad range of applications as d^2 synthons. Cyclohexanone SMP enamine can be used for efficient Michael additions to nitroalkenes, Knoevenagel acceptors,[2a,b] and to a nitroallylic ester in a [3 + 3] carbocyclization[2c] with excellent stereoselectivities (eq 1). The synthesis of γ-oxo-α-amino acids using SMP enamines has been developed (eq 2).[2d]

(1)

(2)

≥ 98% de/ee

SMP amide enolates have been employed by several research groups. Alkylation of SMP amide enolates gives α-substituted acids (eq 3).[3a,b] Excellent yields and stereoselectivities are observed in the Birch reduction of aromatic SMP amides with subsequent alkylation (eq 4).[4]

R^1 = alkyl; R^2 = alkyl, allyl, benzyl

(3)

52-94% ee

(4)

SMP amides have been used in vanadium(II)-promoted pinacol cross-coupling[3c,d] and in asymmetric oxidations with chiral oxaziridines.[3e] The diastereoselective addition of thiocarboxylic acids to 1-(2-methylacryloyl) SMP amides[3f] and the stereocontrolled addition of various organometallics to α-keto SMP amides[3g] have been studied.

Metalated SMP allylamines or enamines have been used as the first chiral homoenolate equivalents (d^3 synthons; eq 5).[9]

(5)

SMP is a useful chiral auxiliary in various cycloaddition reactions. Chiral 2-amino-1,3-dienes have been used in the Diels-Alder reaction with 2-aryl-1-nitroethylenes,[5a,b] and 5-aryl-2-methyl-substituted 4-nitrocyclohexanones were

obtained in excellent enantiomeric purities (ee = 95-99%) and diastereoselectivities (ds = 75-95%; eq 6). The photo-Diels-Alder reaction of SMP acrylonitrile with 1-acetylnaphthalene has been carried out.[5b] After hydrolysis of the adduct, the 1,4-diketone was obtained in excellent enantiomeric purity (ee &egt; 97%; eq 7).

Stereoselective Diels-Alder reactions have been performed variously, using chirally modified sulfines as

dienophiles,[5c] chiral ynamines,[5d] SMP enamines,[5e] SMP acrylamides,[5f] and the in situ preparation of SMP *N*-acylnitroso dienophiles.[9g,h,i] The [2 + 2] cycloaddition reactions of chiral keteniminium salts obtained from SMP amides with alkenes have been studied.[10]

Various metalated chiral organosilicon compounds bearing the SMP moiety have been alkylated to synthesize chiral alcohols.[11] Excellent regio- and stereoselectivities have been observed in the alkylation of chiral silylpropargyl anions (eq 8).[11f]

(8)

The elegant application of SMP as a chiral leaving group has been studied,[13] using chiral nitroalkenes in the reaction with zinc enolates.[12] The coupling products were obtained in very good yields and enantiomeric purities (eq 9). SMP methyl-2-cycloalken-1-ones undergo conjugate addition with lithium diorganocuprates followed by elimination of the chiral auxiliary to form optically active cycloalkanones (eq 10).

(9)

Various other applications are conjugate addition,[14] the ultrasound-promoted perfluoralkylation of SMP enamines,[15] the enantioselective fluorodehydroxylation of SMP 1-yl-sulfur trifluoride,[16] asymmetric telomerization of butadiene,[17] the chiral modification of ruthenium clusters,[18] and the application of SMP amide bases.[19]

Related Reagents.

(S)-1-Amino-2-methoxymethylpyrrolidine.

(Methoxymethyl)trimethylsilane[1]

[147-14-4] · $C_5H_{14}OSi$ · (Methoxymethyl)trimethylsilane · (MW 118.28)

(Peterson alkenation reagent;[1] synthesis of enol ethers;[2] one-carbon homologation of ketones to aldehydes;[2] synthetic equivalent of lithiomethyl methyl ether[2])

Physical Data: bp 83 °C/760 mmHg;[2b] *d* 0.758 g cm^{-3}.[3]

Solubility: sol common solvents (THF, Et_2O, CH_2Cl_2, etc.).

Form Supplied in: colorless liquid, 98% purity.

Analysis of Reagent Purity: ^1H NMR: (CCl_4) δ 3.4 (s, 3 H), 3.1 (s, 2 H), 0.2 (s, 9 H).[2b]

Preparative Methods: prepared in 75% yield by the reaction of ***(Chloromethyl)trimethylsilane*** and ***Sodium Methoxide*** in dry methanol at reflux.[3]

Handling, Storage, and Precautions: the reagent is flammable and an irritant. It should be used in a well ventilated fume hood. Contact with the eyes and skin should be avoided.

Carbonyl Addition Reactions.[2]

Treatment of the title reagent with ***s-Butyllithium*** (1.4 M in cyclohexane) in THF at -78 °C to -25 °C provides a solution of methoxy(trimethylsilyl)methyllithium (**1**) that reacts with aldehydes and ketones to give the carbonyl adducts that are isolated in 55-89% yield (eq 1). Elimination of lithium trimethylsilanolate (Me_3SiOLi) does not occur under these conditions.

Peterson Alkenation.[2]

Treatment of the (β-hydroxy-α-methoxyalkyl)trimethylsilane adducts with ***Potassium Hydride*** in THF at 60 °C results in elimination of potassium trimethylsilanolate to give enol ethers in 70-87% yield (eq 2). Alternatively, when the 1:1 carbonyl adducts are treated with 90% ***Formic Acid*** at ambient temperature, they undergo elimination and hydrolysis to give the one-carbon homologated aldehydes (eq 3). This procedure fails with acid-sensitive aldehydes, such as 1-prenylacetaldehyde.[2b]

Kende utilized this methodology for the conversion of (**2**) to (**3**) during the total synthesis of (±)-warburganal and (±)-isotadeonal (eq 4).[4] The ketone function of (**2**) is quite hindered and failed to give satisfactory results in reactions with methylenetriphenylphosphorane, α-methoxymethylphosphonate, and tosylmethyl isocyanide.

Other Conversions.

Treatment of the carbonyl adducts of (**1**) with dry ***Cesium Fluoride*** in DMSO at 80 °C results in protodesilylation without elimination of the β-hydroxy group (eq 5). Alternatively, oxidation of the carbonyl adducts with ***Pyridinium Chlorochromate*** provides α-methoxy-α-trimethylsilyl ketones, which desilylate when chromatographed on silica gel to give α-methoxy ketones (eq 6). Carbanion (**1**) thus functions as a synthetic equivalent of $MeOCH_2Li$ for carbonyl addition reactions.

1-Methoxy-3-methyl-1-trimethylsilyloxy-1,3-butadiene

[73311-51-0] · $C_9H_{18}O_2Si$ · 1-Methoxy-3-methyl-1-trimethylsilyloxy-1,3-butadiene · (MW 186.36) (*E*)

[76927-59-8] (*Z*)

[76915-33-8]

(diene in Diels-Alder reactions; nucleophile; alkene substrate)

Physical Data: bp 40 °C/0.3 mmHg.

Analysis of Reagent Purity: for the thermodynamically favored isomer of the diene: ^{1}H NMR (C_6D_6, 270 MHz) δ 4.90 (br, d, *J* = 2.7 Hz, 1 H), 4.65 (m, *J* = 1.4, 2.7 Hz, 1 H), 4.23 (s, 1 H), 3.15 (s, 3 H), 2.00 (dd, *J* = 0.7, 1.4 Hz, 3 H), 0.14 (s, 9 H); ^{13}C NMR (15 MHz, C_6D_6, off-resonance decoupled) δ 159.4 (s), 141.9 (s), 110.2 (t), 83.7 (d), 56.5 (q), 25.6 (q), 2.2 (q); IR (hexane) 1660 cm^{-1}. The only difference between the ^{1}H NMR (C_6D_6) spectra of the two diene isomers are the CH_3O resonances, which appear at δ 3.15 and 3.12.

Preparative Method: silyl enolization of methyl 3-methyl-2-butenoate gives a 1:1 mixture of (*Z*) and (*E*) isomers.[1]

Purification: distillation at 65 °C/1 mm Hg or heating the mixture to 115 °C for 40 min causes isomerization to the thermodynamically favored isomer.

Handling, Storage, and Precautions: silyl migration occurs at 117 °C.[1a,2] Use in a fume hood.

Diels-Alder Reactions.

This diene has been used extensively in carbo-Diels-Alder reactions with a wide variety of quinones,[3] a trisubstituted alkene,[4] a β-phenylsulfinylnitroalkene,[5] and a tetrachlorocyclopropane (to prepare a troponoid).[6] Dienophiles that

have been used with the diene in hetero-Diels-Alder reactions include an orthoquinone (eq 1),[3g] thioaldehydes (eq 2),[7] and imine-$TiCl_4$ complexes.[8]

(1)

(2)

Alkylations.

With one exception,[9] the 3-methyl substituent of this diene appears to encourage predominantly γ- over α-attack in reactions with electrophiles such as 1,3-dithienium tetrafluoroborate (eq 3),[10] PCl_3 or $AsCl_3$,[11] the PhSCl adduct of dihydropyran,[12] and PhSCl (eq 4).[1d] The use of *i*-Pr or *t*-Bu ester analogs of this diene and/or bulky electrophiles further enhances γ selectivity.[13]

Chrysanthemic acid derivatives undergo ***Titanium(IV) Chloride***-catalyzed reactions with the diene (eq 5).[14] Homo coupling of the diene to give unsaturated esters has also been reported under $TiCl_4$-catalyzed conditions (eq 6).[15]

(6)

Amination.

Addition of 3-acetoxyaminoquinazolinone to the diene occurs at both double bonds to give a mixture of intermediate aziridines which then ring open (eq 7).[16]

(*E,Z*)-1-Methoxy-2-methyl-3-(trimethylsilyloxy)-1,3-pentadiene

[72486-93-2] · $C_{10}H_{20}O_2Si$ · 1-Methoxy-2-methyl-3-(trimethylsilyloxy)-1,3-pentadiene · (MW 200.39)

(highly functionalized diene used for a variety of [4 + 2] reactions including Diels-Alder and hetero-Diels-Alder reactions)

Physical Data: bp 83-85 °C/22 mmHg.

Preparative Method: prepared in multigram quantities as a colorless or slightly yellow liquid from 3-pentanone and ethyl formate via a three-step procedure (ca. 40% overall yield).[1]

Handling, Storage, and Precautions: easily hydrolyzed but may be stored indefinitely under anhydrous conditions at 0 °C.

General Considerations.

(*E,Z*)-1-Methoxy-2-methyl-3-(trimethylsilyloxy)-1,3-pentadiene (**1**) and its parent compound, Danishefsky's diene (***1-Methoxy-3-trimethylsilyloxy-1,3-butadiene***), have been used extensively for the synthesis of both carbocycles and heterocycles via formal [4 + 2] reactions. A wide variety of dienophiles show reactivity with (**1**).[2]

Early investigations into the reactivity of (**1**) in the Diels-Alder reaction showed that both alkenes and alkynes functioned well as dienophiles.[3] These observations facilitated the synthesis of a variety of highly substituted carbocycles. For example, the thermal cycloaddition of (**1**) with either ***Methacrolein*** or ***Dimethyl Acetylenedicarboxylate*** in refluxing benzene afforded the expected cycloadducts (eqs 1 and 2). The silyl enol ethers were hydrolyzed with subsequent loss of methanol to furnish 2,4,4,6-tetrasubstituted cyclohexeneone (**2**) and pentasubstituted benzene derivative (**3**).[3]

(1)

(1) (2)

(2)

(1) (3)

The highly electron-rich nature of diene (**1**) enables it to participate in cyclocondensation reactions with dienophiles of relatively low reactivity, such as aldimines and aldehydes. The condensation of (**1**) with imines has seen only limited application in synthesis.[4] In contrast, diene (**1**) has been used extensively in the Lewis acid-catalyzed diene aldehyde cyclocondensation (LADAC) reaction for the synthesis of 5,6-dihydro-4-pyrones (eq 3).[5] This reaction can be regarded as occurring either through a [4 + 2] cycloaddition or via a Mukaiyama aldol process. It is often the case that both types of products (e.g. **4** and **6**) are observed in a single experiment. Acid-promoted elimination or cyclization affords the pyrones (**8**) and (**9**). Levels of simple diastereoselection for the cyclocondensation are often as great as 10:1 and are highly dependent on choice of Lewis acid and solvent, polar solvents (e.g. CH_2Cl_2, MeCN) affording *trans*-substituted pyrones and nonpolar solvents (e.g. toluene) leading to the *cis* isomers.[6]

Cyclocondensation of (**1**) with aldehydes possessing chirality often shows excellent diastereofacial selectivity.[5a] Aldehydes bearing alkyl substitution at the α-position typically manifest diastereofacial selection consistent with the rules advanced by Cram and Felkin.[7] Chelation control (cyclic Cram model) can also be achieved using aldehydes having α- or β-alkoxy or -thioalkyl substitution. For example, the ***Magnesium Bromide***-catalyzed condensation of (**1**) with (*S*)-2-benzyloxypropanal (**10**) provides a single diastereomer having a *cis* relationship between the pyrone substituents and diastereofacial selectivity corresponding to chelation controlled addition to the aldehyde (eq 4).[8]

(4)

Recently, under the aegis of chiral catalysts, (**1**) has been shown to participate in the diene-aldehyde cyclocondensation reaction with several aldehydes to afford cycloadducts of very high enantiomeric excess. Several Lewis acid catalysts have been employed, including $Eu(hfc)_3$,[9] (*R*)-(+)-3,3´-bis(triphenylsilyl)binaphthol/$AlMe_3$,[10] and bis(3-acylcamphorato)oxovanadium(IV).[11] The enantiomeric excesses observed in these reactions are somewhat variable, ranging from 40 to >98% ee. However, many examples show high efficiency and enantioselectivity. Yamamoto has recently demonstrated that tartrate-based chiral catalysts (**12**) promote the efficient (84% yield) cyclocondensation of (**1**) with furfural to afford pyrone (**13**) with excellent diastereo- and enantioselectivity (eq 5).[12] Use of the enantiomeric catalyst leads to the enantiomer of (**13**) with comparable selectivity.

(5)

The capacity for (**1**) to participate in diastereo- and enantioselective reactions has resulted in its being used in several syntheses of important natural products, including zincophorin,[13] rifamycin,[14] the Prelog-Djerassi lactone,[5a] and

rapamycin.[15]

1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene[1]

[31469-15-5] · $C_8H_{18}O_2Si$ · 1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene · (MW 174.35)

(functional equivalent of enolate of methyl isobutyrate; ester enolate surrogate in electrophilic reactions including alkylation,[2] aldol reaction,[3-5] Michael reaction,[5a,6-8] initiator for group transfer polymerization of acrylates,[9] nitroarylation,[10] oxidation,[11] dimerization,[12] and cycloadditions[13-15])

Alternate Name: dimethylketene methyl trimethylsilyl acetal.

Physical Data: bp 35 °C/15 mmHg; *d* 0.858 g cm^{-3}.

Solubility: freely sol organic solvents.

Form Supplied in: clear colorless liquid; 95% pure.

Analysis of Reagent Purity: GC and NMR; likely impurities are methyl isobutyrate and hexamethyldisiloxane.

Handling, Storage, and Precautions: irritant; flammable; moisture sensitive; use in a fume hood.

General Considerations.

Ketene alkyl silyl acetals are functional equivalents of enolates of esters that can be readily prepared and stored. The title compound is a prototypical ketene silyl acetal (KSA) that can been prepared by either of the two most commonly employed methods: (a) deprotonation of the α-hydrogen of an ester followed by silylation (eq 1),[16] and (b) metal-catalyzed hydrosilylation of α,β-unsaturated esters (eq 2).[17]

Most of the reactions of KSAs are characterized by the highly nucleophilic nature of this class of compounds. Under many reaction conditions they also serve as silylating agents, often facilitating product formation via the trapping of an unstable intermediate.[10]

Electrophilic Reactions.

Alkylation.

Ketene silyl acetals readily undergo Lewis acid-mediated alkylation (eq 3) with alkylating agents that form stable carbenium ions (tertiary, benzylic, allylic, those carrying an α-oxygen, sulfur, or nitrogen).[2] The reaction can be extended to primary

alkylation by use of α-chloroalkyl phenyl sulfides which are valuable intermediates for not only alkylation but also alkylidenation.[18] Examples of electrophiles (see Table 1) include alkyl glycosides,[19] *N*-alkylhexahydro-1,3,5-triazine,[20] α-acetoxy[21] or α-sulfonyl amides,[22] cationic η^5-dienyliron complexes,[23] electron-deficient pyridines,[24] and elemental fluorine.[25] Addition to dimethyl acetals[5] give products which are protected aldol (eq 4) derivatives. Dibutyltin ditriflate can be used to activate acetals selectively in these type of reactions.[26]

(Y = cation-stabilizing group)

(4)

Aldol Reactions: Addition to Aldehydes and Imines.

Since its discovery, the Mukaiyama aldol reaction[27] has attracted considerable attention and several improvements in reaction conditions have been reported. Most useful catalysts for this reaction appear to be recently reported lanthanide triflates (eq 5),[3] ***Bis(cyclopentadienyl)titanium Bis(trifluoromethanesulfonate)***, or $Cp_2Zr(OTf)_2$.THF,[28] The metallocene salt also catalyzes additions to ketones (eq 6). This reaction can also be carried out under essentially neutral conditions by warming (70 °C) a stoichiometric mixture of the aldehyde and the KSA in acetonitrile (eq 7).[8,29] When an optically active aldehyde is used, a slightly better stereochemical control is noticed under catalysis of ***Zinc Iodide***.[29]

(5)

(6)

1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene

In the presence of an amino acid-derived boronate (e.g. **2**)[30] or a diamine-tin(II), complex,[31] as Lewis acids, optically active aldol products are obtained in good yields (eq 8). In the addition of KSAs to iminies, a diphosphonium ditriflate[32] (eq 9) or an acidic montmorillonite clay[33] has been claimed to give better results than the originally reported Lewis acids (***Titanium(IV) Chloride***[34] and ***Trimethylsilyl Trifluoromethanesulfonate***[35]). The products of this reaction are valuable intermediates for the synthesis of β-lactams.[36] Two excellent reviews covering this area have recently appeared.[4,37]

(2)

90% ee

Mukaiyama-Michael Reactions.

1,4-Addition of ketene alkyl silyl acetals to α,β-unsaturated carbonyl compounds (eq 10) is promoted by a variety of Lewis acids[38] (for example, $TiCl_4$, $Ti(OR)_4$, $SnCl_4$, trityl perchlorate, lanthanide salts, Al-montmorillonite clay), or Lewis bases such as fluoride ion (eq 11),[7] or quaternary ammonium carboxylates.[39] Lanthanide salts are particularly effective catalysts,[40] and in the case of ***Ytterbium(III) Trifluoromethanesulfonate***, the catalyst can be recovered (eq 10).[38]

1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene

This reaction can also be carried out thermally,[7,8] under neutral conditions. The thermal reaction is the most convenient when the conjugate adduct is to be trapped as the regiochemically pure silyl enolate. In the case of the disubstituted KSAs such as the title compound, this addition reaction is sluggish, and may require electrophilic catalysis (eq 11) (TMSCl,[7] 5.0 M $LiClO_4/Et_2O$[41]) or high pressure.[42] Sequential Michael additions to α,β-unsaturated esters lead to polymers (group transfer polymerization) whose molecular weight and end group functionality can be controlled (eq 12).[9] Mechanistic studies indicate an associative intramolecular silicon transfer process via (**2**), with concomitant C-C bond formation during the polymer growth. Other Michael-type reactions include additions to acetylenecarboxylic esters (eq 13),[15,43] and nitroalkenes (eq 14).[44] Stereochemical[45] and mechanistic (electron transfer?)[46] studies on the Mukaiyama-Michael reaction have been reported and ways of improving the diastereoselectivity have been prescribed.[6]

Nitroarylation.

In the presence of stoichiometric amounts of ***Tris(dimethylamino)sulfonium Difluorotrimethylsilicate***, (**1**) undergoes addition to aromatic nitro compounds to give dihydroaromatic nitro intermediates (eq 15), which are easily oxidized to α-nitroaryl carbonyl compounds by ***2,3-Dichloro-5,6-dicyano-1,4-benzoquinone*** or ***Bromine***.[10] These compounds are potentially useful for the synthesis of oxindoles and aryl acetic acids.

1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene

Oxidation of Ketene Silyl Acetals.

Singlet oxygen oxidizes KSAs resulting in a cleavage of C-C bonds (eq 16),[47] the reaction presumably proceeding through a silyl peroxide intermediate. ***Lead(IV) Acetate***[11] and ***m-Chloroperbenzoic Acid***[48] oxidize KSAs to α-acetoxy (or hydroxy) carboxylic acid derivatives. Oxidative dimerization of ketene silyl acetals by $TiCl_4$ (eq 17)[12] can be understood in terms of single-electron transfer to the Lewis acids.[49]

Cycloaddition Reactions of Ketene Silyl Acetals.

In the presence of ***Zirconium(IV) Chloride***, KSA adds to ethyl propiolate in a [2 + 2] fashion (eq 18).[15] Other cycloaddition reactions include cycloaddition to imines (eq 19),[13] addition of ***Ethyl Azidoformate***,[14] chlorovinylcarbene,[50] and (ethoxycarbonyl)nitrene.[51] Synthesis of β-lactams from KSAs and imines have attracted considerable attention and the subject has been reviewed recently.[4,37] Cyclopropanation of KSAs with Et_2Zn/CH_2I_2 to provide cyclopropanone acetals is also known (eq 20).[52]

1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene

2-(*o*-Methoxyphenyl)-4,4-dimethyl-2-oxazoline[1,2]

[57598-33-1] · $C_{12}H_{15}NO_2$ · 2-(*o*-Methoxyphenyl)-4,4-dimethyl-2-oxazoline · (MW 205.28)

(electrophilic arylation of Grignard reagents, lithium reagents, and lithium amides by methoxy displacement; synthesis of *o*-substituted benzoic acids, *o*,*o*´-biphenyls, and *o*-aminobenzoates[3,4])

Alternate Name: 2-(2´-methoxyphenyl)-4,4-dimethyl-4,5-dihydrooxazole.

Preparative Method: prepared from *o*-anisic acid and 2-amino-2-methyl-1-propanol in two steps.[3,4]

Handling, Storage, and Precautions: no special precautions are warranted.

General Considerations.

The title reagent, upon treatment with Grignard and organolithium reagents, undergoes displacement of the methoxy group (2-oxazolines are quite resistant to nucleophilic attack; Table 1).[4,5]

Table 1 Nucleophilic Displacement of the Title Reagent

Nucleophile	Product	Yield (%)
BuMgBr		85
PhMgBr		95

Many nucleophiles have been used for this methoxy displacement reaction, and a wide array of substitution on the aryl group of the oxazoline is also tolerated. Thus, this method allows facile preparation of unsymmetrical biphenyls as their *ortho* carboxylic acids and esters, after hydrolysis of the oxazoline (eqs 1-3).[6-8]

(2)

Moreover, the oxazoline can be directly converted to a variety of other functional groups, including ketones, alcohols, aldehydes, and nitriles.[1,2] Similar arylations occur by nucleophilic aromatic substitution of 2-(*o*-fluoroaryl)[9-11] and 2-(*o*-aminonaphthyl)oxazolines with Grignard and organolithium reagents. An extension of this methodology incorporates the lithio salts of primary and secondary amines as nucleophiles[12,13] (eq 4).

2-(*o*-Methoxyaryl)oxazolines derived from amino alcohols other than 2-amino-2-methyl-1-propanol can also participate in the above described methodology. For example, *o*-anisic acid and ethanolamine combine to form the corresponding oxazoline (75%), and on treatment with a Grignard reagent, the *o*-alkylated aryl oxazoline is obtained (eq 5).[14]

2-(o-Methoxyphenyl)-4,4-dimethyl-2-oxazoline

(5)

Optically active biphenyls and binaphthyls can be prepared by using the appropriately substituted chiral oxazoline precursors (eqs 6 and 7).[15-18]

(6)

The same process is applicable to methoxy displacement from enantiomerically pure 2-(*o*-methoxyaryl)oxazolines. Optically active biphenyls can be rapidly accessed in this manner.[19] For example, an enantiomerically pure (*S*)-valinol-derived oxazoline reacts with Grignard reagents to form C_2-symmetric biaryls after further elaboration (eq 7).[20]

A similar transformation of *o*-methoxybenzaldehydes to *o*-substituted benzaldehydes has been accomplished by conversion of the benzaldehyde to *N*-(2,4-dimethyl-3-pentyl)imine, which is resistant to nucleophilic attack at the C=N bond.[21] Similar methodology has been utilized to prepare enantiomerically enriched binaphthyls.[22] Likewise, bulky esters *ortho* to a methoxy group can be substituted for the oxazoline group in the above mentioned protocol, thus affording biaryls[23] and binaphthyls.[24] In addition, *ortho*-substituted fluoroaryl oxazoles undergo nucleophilic aromatic substitution reactions.[25]

7-Methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone

[65131-09-1] · $C_{15}H_{12}O_5S$ · 7-Methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone · (MW 304.34)

(regioselective synthesis of 1,4-dihydroxy-2,3-disubstituted naphthalenes)

Physical Data: colorless solid; mp 176-177 °C.

Solubility: partially sol THF; sol acetone.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 3.93 (s, 3H), 6.10 (s, 1H), 7.04 (d, *J* = 8 Hz, 1H), 7.40-7.92 (m, 7H).

Preparative Methods: ethyl 2-methoxy-6-methylbenzoate is oxidized via the dibromide to the corresponding 3-hydroxyisobenzofuranone, which is subsequently treated with thiophenol and catalytic acid. Oxidation to the sulfone is accomplished with either ***m-Chloroperbenzoic Acid*** or ***Hydrogen Peroxide***.[1a] An alternative one-step method utilizing the requisite phthaldehydic acid has also been described.[2]

Handling, Storage, and Precautions: apparently stable at rt and requires no special handling or precautions.

Aromatic Annulation.

7-Methoxy-3-(phenylsulfonyl)-1(3*H*)-isobenzofuranone (**1**) can be deprotonated at -78 °C with either ***Lithium Diisopropylamide*** or ***Lithium t-Butoxide*** to form a soluble yellow anion which can be utilized as an effective nucleophile in the Michael reaction. The initial anionic adduct cyclizes with concomitant elimination of benzenesulfinic acid to yield a 1,4-dihydroxynaphthalene which is unambiguously disubstituted at the 2- and 3-positions (eq 1).[1b]

The 1,4-dihydroxynaphthalene products are susceptible to air oxidation and are frequently protected as the 1,4-dimethoxy derivatives. Alternatively, they may be intentionally oxidized to the naphthoquinones. A variety of acyclic and cyclic Michael acceptors participate in this reaction and yields are generally good. A few representative examples are seen in Table 1.[1b,3]

Table 1 Examples of Michael Acceptors which React with **(1)**

84

74

85

In fact, (**1**) represents a group of reagents (**2**)-(**6**) all having the 3-(phenylsulfonyl)isobenzofuranone moiety and all capable of the aromatic annulation reaction previously discussed.[1b,4-6]

(2)

(3)

(4)

(5) (6)

Under conditions similar to those described above, these compounds have been frequently utilized as building blocks for the synthesis of a wide range of molecules in the anthracyclinone family.

Alternative Reagents.

3-Cyanoisobenzofuranones have also been synthesized and shown to be useful in identical aromatic annulation reactions (eq 2).[7] Moreover, in several direct comparisons of 3-cyano vs. 3-phenylsulfonyl, the cyano version generally provides higher yields of the desired product.[8] Nevertheless, on a large scale the liability of cyanide waste streams could be an important negative factor.

(2)

Related Reagents.

Similar aromatic annulations have been reported with a number of conceptually related reagents,[1b,9] the common thread of these methods being regioselective installation of substituents in the 2- and 3-positions of the newly formed naphthalene.

2-Methoxy-3-phenylthio-1,3-butadiene

[60603-16-9] · $C_{11}H_{12}OS$ · 2-Methoxy-3-phenylthio-1,3-butadiene · (MW 192.30)

(Diels-Alder diene)

Solubility: sol most organic solvents.

Preparative Methods: the cyclobutene precursors (e.g. **1**) to the reagent and related dienes are available from cyclobutanone in three steps (eq 1).[1] The ring opening of the cyclobutenes to form the title reagent (**2**) and related dienes may be accomplished by flash vacuum pyrolysis (eq 2), or is often carried out in situ in the presence of a dieneophile. Due to the instability of the dienes, they should be formed as needed from the precursor cyclobutenes.

Handling, Storage, and Precautions: the dienes should be both formed and used in the presence of a radical inhibitor such as BHT.

General Considerations.

2-Alkoxy(acyloxy)-3-arylthiobuta-1,3-dienes such as (**2**) are highly reactive and versatile in Diels-Alder reactions.[2] The Diels-Alder regiochemistry is usually controlled by the sulfur (eq 3), but the competition between dominance by the sulfur or oxygen depends on the substitution on the heteroatoms, the presence of Lewis acids, and the choice of dienophile. For example, the 2-acetoxy-3-*p*-anisylthiobutadiene (**3**) displays an increased tendency for sulfur dominance, especially in the presence of Lewis acids (eq 4). With an electron-withdrawing 2´-pyrimidyl group on the sulfur, the oxygen becomes dominant (eq 5).

When the sulfur dominates the regiochemistry, these dienes provide entries into 1,3-disubstituted cyclohexanes after

hydrolysis and desulfurization, reversing the normal orientation of Diels-Alder reactions. The more readily available and stable 1-phenylthio derivatives should be considered as alternatives for this purpose (see ***2-Methoxy-1-phenylthio-1,3-butadiene***). The phenylthio group is also useful for directing alkylations of the ketone obtained on hydrolysis of the Diels-Alder adducts (eq 6).

2-Methoxy-1-phenylthio-1,3-butadiene

[65415-13-6] · $C_{11}H_{12}OS$ · 2-Methoxy-1-phenylthio-1,3-butadiene · (MW 192.30) (*E*)

[67315-81-5] (*Z*)

[60466-66-2]

(Diels-Alder diene[3])

Physical Data: bp 85-95 °C/0.005 mmHg.[1]

Solubility: sol most organic solvents.

Preparative Methods: the pure (*Z*) reagent is available in two steps from ***Bis(phenylthio)methane*** and ***Acrolein*** by an *Organic Syntheses* procedure (eq 1).[1] Related dienes may be prepared either similarly or by *O*-methylation of enolates derived from sulfenylated enones.[2]

Handling, Storage, and Precautions: the (*Z*) reagent should be stored in a freezer in the presence of a radical inhibitor to avoid isomerization.[1]

General Discussion.

2-Alkoxy-1-phenylthio-substituted dienes are highly useful in Diels-Alder reactions due to their ready availability,[1,2] good reactivity, high selectivity,[3] and the many useful transformations of the product cyclohexenyl sulfides.[3,4] As shown in eq 2, the phenylthio group generally controls the regiochemistry. The Lewis acid-catalyzed reactions with enones seem particularly effective.[3] Hetero Diels-Alder reactions with diacylimines (eq 3) are also highly regioselective.[5] A nice example of the possible product transformations is the conversion in eq 4 with utilization of the Diels-Alder stereochemistry via a 2,3-sigmatropic rearrangement.[3]

(2)

(3)

(4)

The Diels-Alder reactions of 2-methoxy-1-phenylthiobutadiene with ***Acrylonitrile*** (eq 5) served as a key example in arguments supporting a large influence of secondary orbital interactions on the regiochemistry of Diels-Alder reactions, because the regioselectivity is significantly higher for the *endo* products.[6] This argument has been compromised in recent years by a continuing lack of ab initio support for the Woodward-Hoffmann-type secondary orbital interaction.[7]

Methoxy(phenylthio)methane[1]

(R = H)

[13865-50-4] · $C_8H_{10}OS$ · Methoxy(phenylthio)methane · (MW 154.25) (R = Li)

[95540-81-1] · C_8H_9LiOS · Methoxy(phenylthio)methyllithium · (MW 160.18)

(carbonyl anion equivalent useful for homologation and ring expansion)

Physical Data: bp 113-114 °C/18 mmHg; *d* 1.047 g cm^{-3}.

Form Supplied in: neat liquid; commercially available.

Preparative Methods: via the base-catalyzed condensation of ***Thiophenol*** and ***Chloromethyl Methyl Ether***[2] or via the ***Boron Trifluoride Etherate***-catalyzed condensation of thiophenol and ***Dimethoxymethane***.[3]

Handling, Storage, and Precautions: store under inert gas to avoid air oxidation of the sulfide. Hydrolysis of the reagent releases thiophenol (stench!) which is known to be toxic. Use in a fume hood.

One-Carbon Homologations.

Methoxy(phenylthio)methane is a convenient one-carbon homologation reagent (also see ***1,3-Dithiane*** and ***Methoxy(phenylthio)trimethylsilylmethane***) with distinct differences from similar reagents derived from dithioacetals. Since the reagent possesses two different functional groups (methoxy and phenylthio), chemoselective manipulation of either functional group can be performed, resulting in an extremely versatile reagent. Methoxy(phenylthio)methane undergoes a facile deprotonation at the central carbon upon treatment with ***Lithium Diisopropylamide*** or ***n-Butyllithium*** at -78 °C in THF. The resultant anion reacts with a variety of electrophiles such as alkyl halides, aldehydes, ketones, and epoxides (eq 1).[4] The thioacetal products thus formed can be chemically manipulated to afford a variety of homologated products.

(1)

For example, treatment with ***p-Toluenesulfonic Acid*** in methanol affords dimethoxyacetals which can be further hydrolyzed to aldehydes (eq 2).[4] Aldehydes are also available in one step by oxidation of the sulfide to the sulfoxide with ***m-Chloroperbenzoic Acid*** and hydrolytic workup (eq 2).[4] Vinyl ethers are produced via a thermal elimination of benzenesulfenic acid (eq 3).[4] Alternately, the anion formed from the addition of methoxy(phenylthio)methyllithium to aldehydes can be treated with ***Carbon Disulfide*** and ***Iodomethane*** to form a xanthate which when treated with ***Tri-n-butylstannane*** effects a radical reductive elimination to form (*Z*)- and (*E*)-enol ethers (eq 4).[5]

(2)

(3)

In addition, carboxylic acids are accessible from the homologated thioacetals via Jones oxidation (eq 5).[4] Conjugate addition of methoxy(phenylthio)methyllithium to a vinyl sulfone, followed by Jones oxidation and elimination of benzenesulfenic acid, afforded a dienoic acid (eq 6).[6] A novel approach to α-phenylthioaldehydes, which involves a phenylthio migration, results from treating the adducts of methoxy(phenylthio)methyllithium and ketones with ***Thionyl Chloride*** in ***Pyridine*** (eq 7)[7] or by treating the corresponding aldehyde adducts with ***Methanesulfonyl Chloride*** and ***Triethylamine***.[8] α-Phenylthioaldehydes thus obtained can be homologated further or converted to benzo[*b*]thiophenes.[9]

Alkylboronic esters available via the hydroboration of alkenes with dihaloboranes followed by alcoholysis can be homologated by reacting them with methoxy(phenylthio)methyllithium and treating the resulting ate complex with ***Mercury(II) Chloride*** followed by ***Hydrogen Peroxide*** (eq 8).[10] The use of an optically pure boronic ester affords optically pure aldehydes.[11]

Homologation via Operations on Thioacetals.

Four-carbon 1,3- and 1,4-dicarbonyl homologated compounds are accessible via subsequent manipulation of the adducts resulting from the condensation of methoxy(phenylthio)methyllithium with aldehydes. For example, reaction of the acylated adducts with enol silyl ethers under Lewis acid catalysis results in carbon-carbon bond formation and 1,2-migration of the phenylthio moiety. Such α-methoxy-γ-phenylthio ketones were converted into 1,3-dicarbonyl or 1,4-dicarbonyl compounds (Scheme 1).[12] Alternately, the α-phenylthioaldehydes can be converted into 1,4-dicarbonyl compounds (Scheme 1).

Scheme 1

The use of the thioacetal products as electrophiles in Lewis acid-promoted reactions of allyl- and propargylstannanes allows access to three-carbon homologated methyl ethers or phenyl sulfides (eq 9). Employment of ***Boron Trifluoride Etherate*** as the Lewis acid results in the selective cleavage of the phenylthio group to provide ether products. Similarly, the use of ***Titanium(IV) Chloride*** results in cleavage of the methoxy group and formation of phenyl thiosulfide products. These reactions partially compensate for the inability of monoalkylated *O,S*-acetals to undergo dialkylation. Apparently, substitution of one of the alkylthio groups for methoxy sufficiently decreases the stability of an α-carbanion such that it cannot be formed, thus precluding its alkylation (in contrast, dithioacetals can be dialkylated).

Ring Expansions.

Trost first demonstrated the advantages of methoxy(phenylthio)methane over ***Bis(phenylthio)methane*** as an acyl anion equivalent in a synthesis of α-methylene-δ-lactones via the ring expansion of γ-butyrolactones (eq 10).[2a] Use of the *O*,*S*-acetal reagent avoided problems encountered with enolization. Methoxy(phenylthio)methane has also been utilized for the ring expansion of nonenolizable 2-*n*-butylthiomethylene cyclohexanones to 3-formyl-2-cyclohepten-1-ones (eq 11).[13]

Methoxy(phenylthio)trimethylsilylmethane

[88738-21-0] · $C_{11}H_{18}OSSi$ · Methoxy(phenylthio)trimethylsilylmethane · (MW 226.45)

(convenient homologation reagent for carbonyl compounds and alkyl halides; acyl anion equivalent)

Physical Data: bp 120-122 °C/10 mmHg.

Solubility: sol ether, THF, dioxane, methanol, ethanol, benzene, hexane.

Form Supplied in: colorless liquid.

Preparative Method: from methoxy(phenylthio)methyllithium (see ***Methoxy(phenylthio)methane***) with ***Chlorotrimethylsilane***.[1]

Homologation of Carbonyl Compounds.

Methoxy(phenylthio)trimethylsilylmethyllithium (**1**), an acyl anion equivalent, is generated by treating methoxy(phenylthio)trimethylsilylmethane with ***n-Butyllithium*** at -80 °C in THF. This anion adds to carbonyl compounds in 1,2-fashion, providing ketene *O,S*-acetals via Peterson alkenation (eq 1).[1a] The ketene *O,S*-acetals thus obtained are converted to methyl esters by methanolysis in the presence of ***Hydrogen Chloride*** and ***Mercury(II) Chloride***. This procedure was applied to the synthesis of (±)-β-eudesmol (eq 2).[1a]

(1)

(2)

(±)-β-eudesmol

Cleavage of the ketene *O*,*S*-acetals under neutral or mildly basic conditions can be executed by using ***Iodotrimethylsilane*** to give the phenyl thioester or the ketene *O*-silyl,*S*-acetal (eqs 3 and 4).[2] In addition, amides can be prepared by sequential treatment of ketene *O*,*S*-acetals with lithium thiomethoxide in HMPA followed by addition of an amine (eq 5).[2]

(3)

(4)

(5)

The reaction of anion (**1**) with cyclic α,β-unsaturated ketones provides 1,4-addition products in the presence of HMPA (eqs 6 and 7).[3] The resulting enolate can be trapped with various alkyl halides to give α- and β-disubstituted cyclic ketones with the *trans* configuration. This protocol was successfully applied to syntheses of sarkomycin and prostaglandin.[4]

(6)

(7)

Homologation of Alkyl Halides.

Carbanion (**1**) serves as an acylsilane anion equivalent in reactions with alkyl halides. The alkylation proceeds smoothly at -40 °C in the presence of HMPA to provide *O,S*-acetals which are easily transformed into acylsilanes via oxidation with ***Sodium Periodate*** in wet dioxane (eq 8).[5] Acetalization of acylsilanes gives α-trimethylsilyl acetals, which are orthoester synthetic equivalents (eq 9).[6] The synthesis of isocarbacyclin was achieved by using this procedure.

In another synthetic application, the alkylation products of (**1**) undergo facile thermal elimination of methanol to afford (*Z*)-1-phenylthio-1-trimethylsilylalkenes in good yields with high stereoselectivity (eq 10).[7] The elimination is facilitated by oxygen and is further accelerated by the addition of ***Triethylborane***, which implies the involvement of a radical pathway. The resulting (*Z*)-1-phenylthio-1-trimethylsilylalkenes are transformed into (*E*)-vinylsilanes by reductive cleavage of the thiophenyl group with ***Lithium Naphthalenide*** (eq 11).[7]

Homologation of Arenes and Alk-1-enes.

Methoxy(phenylthio)trimethylsilylmethane undergoes Friedel-Crafts reaction with arenes in the presence of Lewis acids such as ***Titanium(IV) Chloride*** and ***Tin(IV) Chloride*** to afford (aryl(phenylthio)methyl)trimethylsilanes (eq 12).[8] This reagent also reacts with terminal alkenes in the presence of $SnCl_4$ to give ene products (eq 13).[8]

1-Methoxy-1,2-propadiene

[13169-00-1] · C_4H_6O · 1-Methoxy-1,2-propadiene · (MW 70.10)

(undergoes lithiation and reaction with electrophiles at C-1,[1] hetero-Diels-Alder[2] and dipolar[3] cycloadditions, and transition metal-catalyzed,[4,5] radical,[6] and electrophilic[7] addition reactions)

Alternate Name: methoxyallene.

Physical Data: bp 51-52 °C.

Solubility: sol THF, ether, pentane, hexane, CH_2Cl_2, $CHCl_3$, DMSO.

Analysis of Reagent Purity: ^{1}H NMR ($CDCl_3$) δ 6.77 (1H, t, *J* = 5.9 Hz), 5.48 (2H, d, *J* = 5.9 Hz), 3.42 (3H, s).

Preparative Methods: not commercially available, but can be prepared[1] on a tens-of-grams scale by the base-catalyzed isomerization of 1-methoxy-2-propyne (methyl propargyl ether) (eq 1). Related 1-alkoxy-1,2-propadiene ethers can be prepared similarly. A convenient version of this preparation has been reported.[8]

Purification: by distillation.

Metalation.

Many applications of 1-methoxy-1,2-propadiene require that it be converted to lithiated,[1,9-11] magnesiated,[12] zincated,[13] or cuprated[14] derivatives. Some of the conditions reported for effecting metalations at C-1 are summarized

in eq 2.

Owing to the steric requirement of the *t*-Bu substituent, lithiation can be directed with considerable selectivity to C-3 in 1-*t*-butoxy-1,2-propadiene (eq 3).[15,16] A minor amount of lithiation at C-1 occurs in this procedure. Related metalated intermediates of some significance in synthesis include (**3**)[16-20] and (**4**).[19]

Reaction of Electrophiles with Metalated Derivatives.

Through the intervention of metalated derivatives of the type described in the previous section, 1-methoxy-1,2-

propadiene and related allene ethers function as synthesis equivalents for the conventionally unavailable acryloyl acyl (**5**) and β-acryloyl (**6**) anions, and acryloyl dianion (**7**). These equivalencies depend on the electrophilic modification of derivatives like (**1**), (**2**),[15,16] and (**3**)[16-20] (eqs 4-6).

Examples of the capture of (**1**) (Met = Li) by relatively simple electrophiles[16,21-23] include those in eqs 7-10.[9,17,18,20,24-30] These invariably involve electrophilic attack at C-1 rather than C-3 in this potentially ambident nucleophile. (**1**) also engages in transition metal-mediated processes that elaborate the C-1 position (eqs 11 and 12).[11,31,32]

Hetero-Diels-Alder Cycloadditions.

The literature contains several examples of hetero-Diels-Alder reactions involving 1-methoxy-1,2-propadiene wherein inversion of the conventional electronic roles of the 4π and 2π components occurs. Reactions of this reagent with vinyl nitroso compounds,[33,34] unsaturated aldehydes and ketones,[35-37] and unsaturated sulfonimines[2,38] (eq 13) have been reported. The *endo* selectivity witnessed in the sulfonimine reactions is to be contrasted with an example of *exo* selectivity involving a vinyl nitroso coreactant.[33] The oxygenated double bond of the reagent is invariably attacked, and is intermediate in its reactivity relative to ethyl vinyl ether (more reactive) and trimethylsilyl vinyl ether (less reactive).[39]

Dipolar Cycloadditions.

This reagent likewise is reactive toward appropriate 4π components in dipolar cycloadditions. Examples involving nitrile imines,[40] nitrile oxides,[41] and diazo compounds[3] (eq 14) have been reported. The characteristic regioselectivity in this cycloaddition class differs from that described above.

Copper-Mediated Additions of Organometallic Reagents.

A mixture of this reagent and a catalytic amount of a copper(I) halide effects the propargylation of Grignard reagents, a process that involves a formal S_N2' displacement of the methoxy group (eq 15).[4,42,43] However, when the stoichiometric ratio of the copper(I) halide to the Grignard reagent (RMgX) is increased, simple addition products of the type $RCH_2CH{=}CHOMe$ are delivered after aqueous workup.[44] In the latter cases, larger R groups lead to increased proportions of the (*E*)-enol ether products.

(15)

An unusual copper-mediated addition process has been devised whereby two methylene groups derived from ***Iodomethylzinc Iodide*** are added across the 1,2-double bond of 1-methoxy-1,2-propadiene to give an organometallic intermediate that can be trapped by aldehydes and ketones (eq 16).[14]

(16)

Other Transition Metal-Mediated Additions.

Palladium and molybdenum catalyze the addition of tin, silicon, and germanium reagents of the type $R^1{}_6Sn_2$,[45,46] $R^1{}_3SiSnR^2{}_3$,[45,47] $R^1{}_3GeSnR^2{}_3$,[48] and $R^1{}_3SnH$[47,49] to 1-methoxy-1,2-propadiene. The addition reagent, the metal, and the size of the R^1 and R^2 groups all play roles in determining the regio- and stereoselectivity of these reactions (eqs 17 and 18).[45,47] For example, the regioselectivity shown in eq 17 for attack at the nonoxygenated double bond is reversed in an example involving *n*-$Bu_3SnGeMe_3$.[48] The stereo- and regioselectivity in eq 18 are much superior to those of the radical addition that produces the same materials (see below).

Transition metal-mediated transformations that involve 1-methoxy-1,2-propadiene in the creation of new carbon-carbon bonds, but which are difficult to classify, have been reported.[50,51] However, a few examples that occur by way of palladium (eq 19)[5] and iron catalysis[52,53] appear to be related.

(19)

Radical Additions.

Tri-n-butylstannane adds nonselectively in radical fashion to 1-methoxy-1,2-propadiene to give, among other products, a low yield of the enol ethers that arise from attachment of the tin to C-3.[47] In contrast, both ***Diphenylphosphine***[54] and ***Thiophenol*** (eq 20; product ratio reflects equilibrium mixture of geometrical isomers)[6] add selectively to the central C-2 carbon, a reflection of the intermediacy of allylic radicals.

(20)

Electrophilic Additions.

The π-electron-rich character of this reagent conferred by its alkoxy group makes it highly reactive in processes initiated by the addition of an electrophile. Interesting examples include eqs 21 and 22,[7,55] wherein it can be seen that the nucleophilic reaction partner can attach itself either to C-1 or to C-3. A number of additional applications of this reaction type require 1-methoxy-1,2-propadiene to provide a mixed acetal when exposed to an appropriate nucleophile in the presence of an electrophilic initiator.[56]

2-Methoxypropene[1]

[116-11-0] · C_4H_8O · 2-Methoxypropene · (MW 72.12)

(electron-rich alkene used in the monoprotection of aliphatic,[2] allylic,[3] and propargylic[4] alcohols, often followed by Claisen[3b -e] or other[2a,4c] rearrangements; protection of peroxides,[5] cyanohydrins,[6] α-hydroxy ketones,[2b] and phenols;[7] condensation with amines;[8] protection of 1,2-[9,10] and 1,3-diols,[10,11] sometimes followed by Prins[9f,g] rearrangements; protection of 1,2-dithiols[10a] and α-hydroxy carbamates;[12] participant in pericyclic reactions;[13] formation of 2-methoxyallyl halides[14] and substituted furans[4b])

Alternate Names: 2-MP; isopropenyl methyl ether.

Physical Data: bp 34-36 °C; *n*20D 1.3820; *d* 0.753 g cm^{-3}; flash point -29 °C.

Form Supplied in: colorless liquid; commercially available.

Preparative Method: prepared in high yield from ***Succinic Anhydride***, ***2,2-Dimethoxypropane***, benzoic acid, and ***Pyridine***.[15]

Handling, Storage, and Precautions: flammable liquid; light-sensitive; should be refrigerated.

Monoprotection of Alcohols.

2-Methoxypropene is used as a protective group for aliphatic,[2,11d] allylic,[3] and propargylic[4] alcohols, masking them as their mixed acetals (eq 1). Deprotection can be accomplished by stirring in MeOH over ion exchange resin,[4a] by reaction in methanol with catalytic ***Acetyl Chloride***,[11d] by ***Potassium Carbonate*** in methanol,[2c] or by 20% ***Acetic Acid***.[3a] A general advantage of this acetal, which undergoes hydrolysis at approximately 10^3 times the rate of THP,[2d,3a] is that it does not confer an additional diastereomeric center to the protected substrate. Access to allyl vinyl ethers for subsequent Claisen rearrangements[3b-e] is illustrated in eq 2.

(1)

(2)

A useful entry into β-keto allenes is provided by the reaction of 2-MP with tertiary propargylic alcohols.[4c] Base-catalyzed rearrangement of the allenes affords conjugated dienones (eq 3).

(3)

Stable allylic peroxyacetals have been prepared by reacting 2-MP with hydroperoxides (eq 4).[5] Organomercury functionality is tolerated in this reaction.[5b] Cyanohydrins,[6] α-hydroxy ketones,[2b] and phenols[7] are similarly protected.

(4)

Condensation with Amines.

Imine formation with loss of methanol occurs under acidic conditions, as illustrated in eq 5.[8]

(5)

Protection of 1,2- and 1,3-Diols and 1,3-Dithiols.

When another hydroxy group is in close proximity to the initially protected alcohol functionality, acetonide formation occurs.[9-11] The kinetic product is preferentially formed.[10b,c,11c] As anomeric hydroxy groups do not usually[11] participate, this reagent provides complementary selectivity to the more traditional acid/acetone acetonation protocol. Control of the amount of 2-MP can result in varying degrees of protection (eq 6).[10b]

(6)

Acetonide formation using ***n-Butyltrichlorostannane*** with 2-MP[10a] is quite general for 1,2- and 1,3-diols, as well as for 1,3-dithiols. Monoacetonide formation occurs with 1,2,3- and 1,2,4-triols. Yields of the acetonides (e.g. **1**-**5**) show improvement over conventional procedures.[10a]

(1) 83% **(2)** 94% **(3)** 77% **(4)** 82% **(5)** 98%

Protection of α-Hydroxy Carbamates.

Aminal formation from α-hydroxy carbamates also occurs using 2-MP, as illustrated in eq 7.[12]

(7)

Participation in Pericyclic Reactions.

2-MP is an active participant in pericyclic reactions. A few examples include a substitution-dependent ene reaction with an alkynyl Fischer carbene complex (eq 8),[13c] a [2 + 3] reaction with 2-amino-1,4-naphthoquinone (eq 9),[13f] a solvent-dependent photochemical cycloaddition with *o*-naphthoquinones,[13j] and reaction with 2-nitro-1,3-dienes to provide α,β-unsaturated 1,4-diones (eq 10).[13g]

(8)

M = W, Cr	R = TMS	30%	<2%
	R = Me	<2%	63%

Reaction with *N*-Halosuccinimides.

2-Methoxyallyl and -vinyl halides are formed by reaction of 2-MP with *N*-halosuccinimides.[14] Also, treatment of propargylic alcohols with 2-MP and ***N-Bromosuccinimide*** results in the formation of bromo acetals, which are subsequently cyclized to furans in good yield (eq 11).[4b]

Related Reagents.

2,2-Dimethoxypropane.

(*S*)-(-)-α-Methoxy-α-(trifluoromethyl)phenylacetic Acid

[17257-71-5] · $C_{10}H_9F_3O_3$ · (*S*)-(-)-α-Methoxy-α-(trifluoromethyl)phenylacetic Acid · (MW 234.19)

(determination of enantiomeric purity and absolute configuration of alcohols and amines[1])

Alternate Name: MTPA.

Physical Data: bp 115-117 °C/1.5 mmHg; $[\alpha]_D$ -71.8° (*c* 3.28, MeOH); *d* 1.344 g cm^{-3}.

Solubility: readily sol hexane, ether, THF, CH_2Cl_2, benzene.

Form Supplied in: both enantiomers are commercially available and generally possess similar applications.

Preparative Methods: both enantiomers are available by resolution of the racemic acid with α-phenylethylamine.[1] Other procedures have been described.[2]

Analysis of Reagent Purity: the enantiomeric purity of the reagent can be evaluated by capillary GC analysis of its methyl ester on a chiral stationary phase,[3] HPLC analysis of the corresponding 1-(α-naphthyl)ethylamide,[2] or by $LiAlH_4$ reduction to the corresponding alcohol, which is analyzed by chiral GC.[4]

Handling, Storage, and Precautions: very stable; commercial samples remain useful after extended periods of time.

Determination of the Enantiomeric Purity of Alcohols, Amines, and Other Compounds by Derivatization.

The enantiomeric purity of a variety of chiral amines and alcohols can be assayed by reaction with chiral MTPA, followed by determination of the diastereomeric purity of the resulting amide or ester.[1] This is usually done by chromatographic (HPLC, GC, TLC, etc.) or spectroscopic methods (^1H NMR, ^{19}F NMR, etc.). Either type of

experiment may provide the desired information and in fact they are often used in combination. MTPA is frequently converted to the corresponding acid chloride (MTPA-Cl) by refluxing in ***Thionyl Chloride***. After distillation, MTPA-Cl is treated with the desired amine or alcohol.[1] An improved procedure for the microscale preparation of MTPA-Cl with ***Oxalyl Chloride***, which does not require distillation of the MTPA-Cl prior to reaction with the alcohol/amine, has been described.[5] Alternatively, MTPA reacts directly with amines and alcohols in the presence of condensing agents such as ***1,3-Dicyclohexylcarbodiimide***[6] or 2-chloro-1-methylpyridinium chloride.[7] Inherent in the successful use of these procedures is the need to ensure complete derivatization of the alcohol/amine, so that the diastereomeric purity of the derivative is truly reflective of the enantiomeric purity of the alcohol/amine under scrutiny.[8]

Alcohols.

When using the ^{1}H NMR spectra of MTPA esters to determine the enantiomeric purity of alcohols, the MTPA methoxy peaks tend to be most useful. This technique can be sensitive enough to detect as little as 1% of the minor alcohol enantiomer. The enantiomeric purity of chiral alcohols (**1**)[9] and (**2**)[10] has been determined this way. The enantiomeric purity of primary alcohols (**3**)[11] and (**4**),[12,13] in which the asymmetric center is not the carbinol carbon, has also been determined by ^{1}H NMR analysis of their MTPA esters. A slight variation of this methodology is the use of shift reagents like $Eu(fod)_3$ to increase the chemical shift separation between diastereotopic MeO peaks; this procedure has been used in the analysis of alcohols (**5**)[14] and (**6**).[15]

(1)

(2)

(3)

(4)

(5)

(6)

^{19}F NMR is also extremely useful in the analysis of MTPA esters, and is often used in combination with ^{1}H NMR.[1] The CF_3 peak(s) is easy to observe, being unencumbered by unrelated peaks. Enantiomeric analysis of primary alcohols, e.g. (**7**),[16,17] as well as secondary alcohols (**8**)[18] and (**9**)[19] has been performed utilizing this method. ^{19}F NMR analysis of MTPA esters in the presence of shift reagents has also been utilized to increase the separation between diastereomeric ^{19}F peaks.[15]

(7)

(8)

(9)

^{13}C NMR analysis of MTPA esters has not received much attention, but some examples have been described, e.g. the MTPA ester of (**10**).[20]

(10)

Almost every available chromatographic technique has been utilized in the analysis of MTPA esters. For example, capillary GLC was used to evaluate the diastereomeric composition of the MTPA esters of chiral alcohols (**5**),[14] (**11**),[21] and (**12**).[22] HPLC is routinely used, for analytical as well as preparative purposes (see below).

(11)

(12)

Amines.

In a manner similar to alcohols, the enantiomeric purity of primary and secondary amines can be assayed by ^{1}H NMR analysis of their MTPA amides.[1] The technique has been particularly useful for amino acid derivatives,[23] e.g. (**13**),[24] (**14**),[25] and (**15**).[26]

(13)

(14)

(15)

^{19}F NMR spectroscopy is extremely sensitive in the stereochemical evaluation of MTPA amides of a wide range of amino acids (as low as 0.05% of the minor isomer detectable).[27,28] HPLC analysis of diastereomeric MTPA amides may provide valuable analytical information on the enantiomeric composition of chiral primary and secondary amines.[29]

Other Compounds.

In theory, any chiral compound with a reactive functional group can be derivatized with (*S*)- or (*R*)-MTPA in order to assess its enantiomeric purity. An example is the derivatization of cyclic carbamates, followed by ^{1}H NMR analysis (eq 1).[30] Similarly, axially chiral biaryls bearing amine or alcohol substituents, e.g. (**16**) and (**17**), have been analyzed via the corresponding MPTA derivatives.[31]

(1)

(16)

(17)

Noncovalent MTPA Derivatives.

The enantiomeric purity of some chiral amines can be determined by ^{1}H NMR with (*S*)- or (*R*)-MTPA as a chiral solvating agent.[32,33] The method is particularly useful for chiral tertiary amines that are not amenable to conversion into MTPA amides, e.g. (**18**) and (**19**),[34] although it has been utilized for primary and secondary amines as well, e.g. (**20**).[35]

(18)

(19)

(20)

Determination of Absolute Configuration in Alcohols and Amines.

The configuration of chiral alcohols and amines (where the heteroatom is attached to the stereocenter) has been correlated with the ^{19}F chemical shifts of their MTPA derivatives.[36] The model is not fully predictive, although the exceptions can often be rationalized. However, ^{1}H NMR spectroscopy of MTPA esters and amides has been more widely used in the assignment of configuration to chiral alcohols and amines.[37] Analysis of the chemical shifts of the MTPA methoxy peaks, in the presence of shift reagents, allows the correct stereochemical analysis of a series of bicyclic alcohols, such as (**6**).[15] The ^{1}H NMR shifts of the hydrogens directly attached to the carbinol carbons in MTPA esters have also been used to establish the configuration of chiral acyclic secondary alcohols.[38] Other peaks in

the MTPA derivatives have been used in the stereochemical elucidation of a series of alcohol natural products.[39] Although less commonly used, ^{13}C NMR spectroscopy of MTPA derivatives has been used in the stereochemical study of a large group of chiral alcohols.[40] The stereochemistry of amino acids has also been amenable to study by ^{1}H NMR spectroscopy of their MTPA derivatives.[23,41]

Preparative Uses of MTPA Derivatives.

Resolution of racemic compounds on a preparative scale is always a challenging endeavor. Conversion of the enantiomeric mixture into a mixture of diastereomers, each with unique physical properties, makes it possible to separate the components by a variety of physical methods, such as fractional recrystallization, distillation, or chromatography. One of the earliest uses of MTPA was the resolution of racemic alcohols via the separation of diastereomeric MTPA esters by preparative gas-liquid chromatography, followed by alcohol regeneration with ***Lithium Aluminum Hydride*** (eq 2).[1] More frequently, diastereomeric MTPA esters have been separated by high performance liquid chromatography (HPLC), followed by alcohol regeneration either by ester hydrolysis (eq 3)[42] or reduction (eq 4).[43]

(S)-(-)-alpha-Methoxy-alpha-(trifluoromethyl)phenylacetic Acid

This procedure is useful even when the carbinol carbon is not the asymmetric center of the molecule (eq 5).[44]

Far fewer examples of diastereomeric ester separations by fractional recrystallization have been described. However, this procedure is extremely practical for the resolution of a series of bromohydrins (eq 6).[45]

Juan C. Jaen

1-Methoxy-3-trimethylsilyloxy-1,3-butadiene[1]

[59414-23-2] · $C_8H_{16}O_2Si$ · 1-Methoxy-3-trimethylsilyloxy-1,3-butadiene · (MW 172.33) (*E*)

[54125-02-9]

(highly reactive diene for Diels-Alder reactions[1a,b] and hetero-Diels-Alder reactions[1c])

Alternate Name: Danishefsky's diene.

Physical Data: bp 68-69 °C/14 mmHg; *n*20D 1.4540; *d* 0.885 g cm^{-3}.

Solubility: insol H_2O; sol most organic solvents.

Form Supplied in: colorless neat liquid; may contain 3-5% of 4-methoxy-3-buten-2-one. This level of purity is sufficient for most preparative purposes.

Analysis of Reagent Purity: checked easily by its ^1H NMR spectrum.[2,4]

Preparative Methods: the diene was originally prepared from ***4-Methoxy-3-buten-2-one*** with ***Chlorotrimethylsilane-Triethylamine-Zinc Chloride*** in benzene as shown below (68% yield, eq 1).[2a] A detailed experimental procedure for preparative scale work is described by Danishevsky et al. (45-50%).[3] TMSCl-***Sodium Iodide*** in acetonitrile is also a mild procedure for the preparation of this reagent (60%).[4] At the present time, the most efficient method is to use TMSCl-***Lithium Bromide***-Et_3N in THF (91%).[5]

Handling, Storage, and Precautions: this diene can be kept in a stoppered container without appreciable decomposition, but it is extremely moisture sensitive.

Diels-Alder Reactions.

General Aspects.

1-Methoxy-3-trimethylsilyloxy-1,3-butadiene (**1**) is one of the most reactive species for use in the Diels-Alder reaction and was the first example of a multioxygenated polar 1,3-diene for preparative use. More recently, analogous siloxy dienes with two or more oxygen functions have been prepared and their reactivities have been studied widely.[1a,b] The extremely high reactivity of this diene is illustrated by its reaction with ***Maleic Anhydride***, in which instantaneous exothermic reaction leads to the formation of the adduct via *cis-endo* addition. The stereochemical course of the reaction is unambiguously determined by the isolation of the initial adduct before acidic workup (eq 2).[2,3]

The utility of this diene for the preparation of functionalized aromatic systems is demonstrated by the facile conversion of ***Dimethyl Acetylenedicarboxylate*** to a hydroxyphthalate (eq 3) and ***1,4-Benzoquinone*** to an oxygenated naphthalene (eq 4).[2]

(3)

(4)

The second pathway leads to alicyclic compounds. In most cases, α,β-unsaturated cyclohexenones are produced. For example, treatment with a reactive dienophile such as ***Methacrolein*** or ***Methyl Acrylate*** gives the desired system (eqs 5 and 6).[2,6] The important feature is that only one regioisomer is obtained by high orientational specificity of electron-donating substituents at the 1,3-positions of the diene.

(5)

(6)

The remarkable reactivity of this siloxy diene is exemplified by successful reaction with poor dienophiles such as methyl 1-cyclohexenecarboxylate, which does not give Diels-Alder adducts with ordinary dienes like butadiene. It requires more severe conditions, but the reaction gives a Δ^1-*cis*-3-octalone system in good yield (eq 7); this is not very easy to access via other methods. Several other examples show the generality of this process.[6]

(7)

The excellent reactivity and regio- and stereoselectivity of this diene have been demonstrated, and there have been enormous numbers of publications on applications to the synthesis of various types of carbocyclic systems.

Condensed Aromatic Compounds.

Completely opposite regioselectivity is seen when juglone (eq 8) and its methyl ether (eq 9) are reacted with this diene. Directing effects, with or without chelation by the hydroxy or methoxy group, clearly explain the selectivity.[7] The more polar carbonyl group, marked with an asterisk, controls the regiochemistry.

(8)

(9)

Similar regioselectivity is observed with 2,3-dichloro-5-hydroxy-1,4-naphthoquinone (eq 10),[8] 6,8-dimethoxy-1,4-naphthoquinone,[9] and anthraquinone derivatives.[10,11] These methodologies have been widely applied to the synthesis of alizarin analogs,[8] daumnomycinone,[12] and related anthracyclinones and their derivatives.[10,11,13]

(10)

Alkyl or alkoxy quinones[14] also give single isomers regioselectively (eq 11), while a chloroquinone[15] gives the opposite type of adduct as the sole product (eq 12).

(11)

(12)

Stereospecific cycloaddition from the less hindered side of an epoxyanthraquinone derivative gives a single adduct, which has been converted to a daunomycinone analog (eq 13).[16]

(13)

Reaction with an unsymmetrically substituted spiro-ene-dione dienophile also gives primarily the adduct from attack at the less hindered face (eq 14); the product is convertible to the fredericamycin A skeleton.[17]

+ β-isomer (14)

6:1

Cyclohexenones and Analogs.

1-Methoxy-3-trimethylsilyloxy-1,3-butadiene

As described earlier, α,β-unsaturated aldehydes and ketones are good dienophiles and the resulting polyfunctional cyclohexenones have been used for the synthesis of ajugarin I (eq 15)[18] and damscones.[19] The diene can even react with (trifluoromethyl)ethylenes to give the adducts regioselectively.[20]

(15)

Ajugarin I

Doubly activated dienophiles such as methylenemalonates,[21] alkylidenemalononitriles[22] and 2-trifluoromethylacrylates[23] easily react with the diene to give enones and dienones (eq 16), from which the cannabinoid skeleton[22] and trifluororetinal have been synthesized.[23]

(16)

Dienones are directly obtained using dienophiles with additional functionality such as sulfoxide (eq 17)[24-26] or acetate.[27] The process has been applied to the synthesis of prephenate,[24,27] pretyrosines,[25] and tazettine.[26]

(17)

Vinyl sulfones are useful dienophiles for the preparation of monocyclic cyclohexenones[28,29] or phenols.[30] Reactions with nitro alkenes give precursors for cyclic nitro alkenes[31] and amino alcohols.[32]

Fused Alicyclic Ring Systems.

As discussed earlier, even cyclohexenones or cyclohexene esters are useful dienophiles and various types of adducts with fused ring systems have been synthesized from these reaction partners. For example, methyl 1,4-cyclohexadienecarboxylate gives the *cis*-hexalin system, which is employed for the synthesis of vernolepin (eq 18).[33]

(18)

This general procedure for the construction of *cis*-fused decalin or extended systems has been applied to the synthesis of pentalenolactone,[34] both racemic and natural quassinoids, picrasin B, quassin (eq 19),[35] the compactin skeleton,[36] and (±)-halipanicine.[37]

(19)

Reactions with cyclopentene dienophiles give *cis*-fused hydrindenones.[38,39] In the case of 3-alkoxycarbonylcyclopentadienone, the alkoxycarbonyl group is the principal substituent for controlling the orientation of the cycloaddition (eq 20).[40] With the ene-dione of fused cyclopentanes, single regioisomers are produced because the carbonyl group (asterisk) is oriented out of the plane of the other conjugated enone (eq 21).[41] Using an activated dioxopyrroline as the dienophile, the spirocyclic system of the Erythrina alkaloid skeleton is constructed and the synthesis of Erythrina alkaloids has been achieved (eq 22).[42]

(20)

(21)

(22)

Cycloaddition with 1-acetylcyclobutene gives a bicyclic adduct, which is transformed to a cyclooctadienone (eq 23).[43] Exceptional stereoselectivity is also observed with bridged enones and a strained enone is a very reactive dienophile, giving the *exo* adduct exclusively in excellent yield (eq 24).[44]

(23)

(24)

Lactones are poor dienophiles under normal conditions, but, using high pressure, they smoothly afford the corresponding *endo* adducts (eq 25).[45]

(25)

On the other hand, γ-lactams (eq 26) and δ-lactams (eq 27) are much better dienophiles and give hydroisoindolines[46] and hydroisoquinoline-type manzamine skeletons.[47] Even 2,4-bis(methoxycarbonyl)furan reacts with this diene to give fused heterocycles (eq 28).[48]

(26)

(27)

(28)

Miscellaneous.

Danishefsky's diene reacts with strong electrophiles such as 2-methylene-1,3-cyclopentanedione to give Michael-type adducts at low temperature, but, on heating, it gives the usual cycloadduct (eq 29).[49]

(29)

The electron-rich enol ether moiety of the diene reacts with carbenes preferentially to give cyclopropane analogs, which afford hydroguaiazulene derivatives via Cope rearrangement (eq 30).[50]

(30)

Strained alkenes are useful dienophiles and tetrachlorocyclopropene reacts with the diene at ambient temperature to give substituted tropones and tropolones via bicycloheptenes (eq 31).[51] Polyhalocyclobutenes give benzocyclobutenones in good yield on a preparative scale (eq 32).[52]

(31)

(32)

Hetero-Diels-Alder Reactions.

General Aspects.

Activated hetero-alkenes such as carbonyls and imines with electron-withdrawing substituents react with the diene under pyrolytic conditions to give dihydropyrones (eq 33)[53-55] and dihydropyridones, respectively (eq 34).[54,56,57] In these cases, however, reactions are limited only to special hetero-alkenes.

(33)

(34)

A major generalization of this heterocycle synthesis has been achieved by the reaction of hetero-alkenes with the diene in the presence of Lewis acid catalysts. In these cases, even hetero-alkenes without activating groups can react under mild conditions to give the corresponding heterocycles (eqs 35 and 36).[58,59]

(35)

R	Yield (%)
$PhCH_2OCH_2$	87
Ph	65
Et	48
$CbzNHCH_2$	80

(36)

The most common catalyst is ***Zinc Chloride***, but $ZnBr_2$, $MgCl_2$, $MgBr_2$, BF_3 etherate, $TiCl_4$, and alkylaluminum chlorides are also useful. In some cases, even the lanthanide reagent $Eu(fod)_3$ can catalyze the cycloaddition to give

cyclic acetals,[60] and partial asymmetric induction is observed using $Eu(hfc)_3$ as a catalyst (eq 37).[61]

(37)

A mechanistic survey has revealed that this hetero-Diels-Alder reaction proceeds mainly via a pericyclic pathway with *endo* addition, but an aldol-type stepwise process is also followed and the ratio varies with the Lewis acid used.[62]

Oxygen Heterocycles.

Hetero-Diels-Alder reactions of chiral aldehydes give substituted dihydropyrones with high diastereoselectivity and Cram products are formed exclusively or predominantly. In the case of α-alkoxy or α-amino aldehydes, excellent selectivities are achieved (eqs 38-40).[63,64] The diastereoselectivity of the reaction with a protected serine-aldehyde is influenced by the amount of Lewis acid employed (eq 41).[65] Because of this high stereoselectivity and since the resulting multifunctionalized pyrone derivatives can be converted to various oxygen heterocycles, a number of natural products, especially carbohydrates and analogs, have been synthesized by this method. The following are representative examples: spiroacetals (*Mus musculus* pheromone[64a] and avermectins[66]); hexoses (fucose and daunosamine[67]); unusual sugars (tunicaminyluracil,[68] octosyl acid A,[69] and galantinic acid[70]); *C*-glycosides (papulacandins[71]).

(38)

(39)

(40)

(41)

Amount of catalyst	Ratio (β:α)	Yield (%)
2 mol %	1:1.3	94
7	18:1	89
70	60:1	57
5 (in THF)		0

Even remote chiral centers afford rather high diastereoselectivity, giving the desired isomers as major products; these are convertible to mevinolin and pravastatin (eq 42).[72]

(42)

Nitrogen and Sulfur Heterocycles.

As mentioned earlier, dihydropyridones and arylquinolizinones are readily prepared (eq 43).[73] Reaction with triazolediones without a catalyst gives pyridazine derivatives.[74] The diene reacts with in situ formed thioaldehydes without a catalyst to give thiopyranones (eq 44).[75]

(43)

(44)

R = $PhCH_2CH_2$	84%
R = $PhSeCH_2CH_2$	73%
R = Ph	74%

Miscellaneous.

Extremely polar hetero-alkenes react smoothly with the diene to give heterocycles. For example, reaction with

nitrosobenzene at 0 °C gives substituted oxazinones (eq 45).[76] Phosphabenzenes are prepared by the reaction with chlorophosphorus ylides formed in situ (eq 46).[77] Arsabenzene is formed using the arsine ylide.[78] Reaction with singlet oxygen yields cyclic peroxides.[79]

(45)

(46)

Asymmetric Synthesis.

Asymmetric Diels-Alder reactions with dienophiles containing a chiral auxiliary usually give adducts with high diastereoselectivity. For example, reaction with a nitro alkene having a chiral sulfoxide gives the hydrindenone with 95% ee after elimination of the sulfoxide.[80] In the case of 5-(-)-menthyloxy-5*H*-furanone, the reaction gives two diastereomers via both *endo* and *exo* attack, but diastereofacial selectivity is exclusive (eq 47).[81] Reaction with *O*-β-D-glucosyljuglone gives a single adduct (eq 48); this is a versatile precursor for optically active anthracyclinones.[82]

(47)

1-Methoxy-3-trimethylsilyloxy-1,3-butadiene

(48)

In the hetero-Diels-Alder reaction, the imine derived from D-galactosylamine gives the (*S*)-adduct preferentially, from which (*S*)-anabasin is obtained.[83] Imines of optically active amino acids give substituted pyridones with high diastereoselectivity (eq 49).[84]

(49)

R^1	LA, Sol	Temp (°C)	Ratio	Yield
Pr	$ZnCl_2$, THF	0	15:85	11%
i-Pr	Et_2AlCl, CH_2Cl_2	-78 to -20	97: 3	45%
i-Pr	$MeAlCl_2$, CH_2Cl_2	-78 to -20	93: 7	50%
$EtOCO(CH_2)_2$	Et_2AlCl, CH_2Cl_2	-78 to -20	93: 7	50%

Catalytic asymmetric hetero-Diels-Alder reactions using chiral acyloxyboranes[85] or oxazaborolidines[86] give substituted hydropyranones and hydropyridones with ca. 70-95% ee (eqs 50 and 51).

R	ee	Yield
o-$MeOC_6H_4$	79%	80%
1,3,5-$Me_3C_6H_2$	95%	47%

Related Reagents.

[72658-03-8] (**2**; R^1 = *t*-Bu, R^2 = Et)

[83165-77-9] · $C_{11}H_{24}O_2Si$ · 1-Ethoxy-1-(*t*-butyldimethylsilyloxy)propene · (MW 216.44) (*E*)-(**2**)

[89043-55-0] (*Z*)-(**2**)

[73967-98-3]

(reactive nucleophile in Mukaiyama-type aldol reactions[2,3] with aldehydes,[15-29] imines,[30] acetals,[36] dialkoxycarbenium ions,[40] and orthoesters;[41] Michael-type additions to α,β-unsaturated carbonyl compounds;[42-46] substitution reactions with allylic alcohols and esters;[56] acylations;[53] aminations;[54] hydroxylations;[55] and pericyclic reactions;[59] silylating agent[67])

Alternate Name: methylketene methyl trimethylsilyl acetal.

Physical Data: (*Z*)-(**1**): bp 57 °C/18 mmHg; ^{1}H NMR data have been reported.[11] (*Z*)- and (*E*)-(**2**): ^{1}H and ^{13}C NMR data have been reported.[8b]

Solubility: highly sol organic solvents.

Preparative Methods: since the first preparation of a ketene trialkylsilyl acetal by Petrov in 1959 by the reaction of triethylsilane and methyl acrylate,[4] several alternative pathways have been explored.[5] Ainsworth and co-workers prepared 1-methoxy-1-(trimethylsilyloxy)propene in 90% yield by deprotonation of methyl propionate with ***Lithium Diisopropylamide*** at -78 °C followed by addition of ***Chlorotrimethylsilane***.[6] Reaction of the lithium enolate of methyl acetate with TMS-Cl provides 65% *O*-silylated and 35% *C*-silylated products (eq 1).[7] Substitution on the alcohol portion of the ester favors *C*-silylation while substitution on the α-carbon favors *O*-silylation. An increase in the steric bulk of the silylating agent (e.g. use of ***t-Butyldimethylchlorosilane***) results in significantly more *O*-silylation.

Silyl ketene acetal geometry is controlled by the selective formation of the (*E*)- and (*Z*)-ester enolate. Deprotonation of methyl propionate with LDA in THF at -78 °C gives, upon silylation, a 6:94 ratio of the thermodynamic (*Z*) and kinetic (*E*) silyl ketene acetals (eq 2).[8] As noted by Ireland and co-workers, a change in the reaction solvent results in a reversal in selectivity. In a THF-23% HMPA mixture, the silyl ketene acetals are isolated in a 84:16 ratio. In THF-45% DMPU ratios of up to 98:2 are obtained. With bulkier amide bases and in the absence of dipolar additives, a (*Z*):(*E*) ratio of 5:95 is observed.[9,10]

THF	(*Z*):(*E*) = 6:94
THF, 23% HMPA	(*Z*):(*E*) = 84:16
THF, 45% DMPU	(*Z*):(*E*) = >95: 5

Treatment of alkyl carboxylates with trialkylsilyl triflates in the presence of ***Triethylamine*** yields the thermodynamically more stable (*Z*)-ketene acetals at rt; however, a mixture of *O*- and *C*-silylated products is generally obtained.[11] The (*Z*)-isomers are also prepared by the reaction of triethylsilyl perchlorates with aliphatic esters.[12] The action of zinc powder on α-bromo esters in the presence of TMS-Cl and TMEDA-Et_3N leads mainly to (*E*)-ketene acetals, while the reaction of trialkylsilanes on alkyl acrylates catalyzed by Wilkinson's reagent (***Chlorotris(triphenylphosphine)rhodium(I)***) gives the corresponding (*Z*)-isomers (*Z*:*E* >98:2).[13]

Handling, Storage, and Precautions: easily hydrolyzed and oxidized by exposure to air. Storage is possible in sealed tubes at rt. Use in a fume hood.

Alkylation.

The α-*t*-alkylation of silyl ketene acetals was reported by Reetz and Schwellnus.[14]

Additions to Aldehydes, Imines, and Oximes.

Silyl ketene acetals add to aldehydes[2,3,19] in the presence of a Lewis acid ($TiCl_4$, BF_3, $SnCl_4$, $TrClO_4$, cationic iron complexes,[15] HgI_2,[16] lanthanides,[17] and clay montmorillonite).[18] High diastereofacial selectivity in Lewis acid-mediated additions of methylketene acetals to aldehydes was reported by Heathcock and Flippin.[20 -24] The scope of this reaction was further extended by the introduction of camphor and *N*-methylephedrine derived chiral silyl ketene acetals.[25-28] The asymmetric variant of the Mukaiyama reaction also provides an efficient *anti*-selective chiral propionate equivalent (eqs 3 and 4). Reetz and Fox used a catalytic amount of ***Lithium Perchlorate*** suspended in CH_2Cl_2 for Mukaiyama aldol reactions of aldehydes with a silyl ketene acetal.[29]

High diastereoselectivities have been achieved in the Lewis acid-mediated addition of silyl ketene acetals to imines (eq 5).[30,31] In related applications, additions of *O*-silylated ketene acetals to β-lactams were used in the synthesis of carbapenem antibiotics.[32-34] Sekiya and co-workers have demonstrated that silyl ketene acetals add to *O*-benzyl oxime ethers in the presence of catalytic amounts of ***Trimethylsilyl Trifluoromethanesulfonate*** to afford β-benzyloxy amino esters.[35]

Additions to Acetals, Dialkoxycarbenium Ions, and Orthoesters.

Much attention has focused on the use of methylketene derivatives for the opening of chiral acetals.[36] Trimethylsilyl triflate-catalyzed addition of (*E*)-methylketene methyl trimethylsilyl acetal to benzaldehyde dimethyl acetal gives *syn*- and *anti*-esters in a 50:50 ratio, whereas the (*Z*)-silyl ketene acetal results in a 55:45 ratio (eq 6).[37]

syn:*anti* = 50:50

syn:*anti* = 55:45

A chain-extended trimethylsilyl ketene acetal was used by Johnson et al. in combination with ***Titanium(IV) Chloride*** for a stereoselective acetal opening in the preparation of enantiomerically pure mevinolin analogs (eq 7).[38,39]

1,3-Dioxolan-2-ylium cations react with silyl ketene acetals to give β-keto esters, selectively monoprotected at the ketone carbonyl (eq 8).[40]

1-Methoxy-1-(trimethylsilyloxy)propene

The reaction of an enolic orthoester with silyl ketene acetals results in the regiospecific formation of diketo ester monoacetals.[41]

Additions to α,β-Unsaturated Carbonyl Compounds.

The $TiCl_4$-catalyzed addition of silyl ketene acetals to α,β-unsaturated enones is often superior to enolate addition protocols, especially for the preparation of β-quarternary centers.[42,43] Danishefsky and co-workers reported an interesting tandem Michael-aldol sequence (eq 9).[44] Acetonitrile or high pressure are often sufficient to promote additions in the absence of a Lewis acid.[45,46] In a related process, aromatic heterocycles can be prepared by addition of silyl ketene acetals to nitrobenzenes.[47]

Alkylations with Allylic Alcohols and Esters.

Pearson and Schkeryantz[48] used a lithium perchlorate-promoted substitution of a tertiary alcohol with ketene silyl acetals for the preparation of a key intermediate in the synthesis of (±)-γ-lycorane.[49,50] Grieco and co-workers have also used cyclopropyl alcohols in substitution reactions of this type.[51] Pd^0-catalyzed coupling of allyl acetates and ketene silyl acetals leads to cyclopropane derivatives via alkylation of the central carbon (C-2) of the allyl group.[52]

Acylation, Amination, and Hydroxylation.

Acylation of silyl ketene acetals with acid chlorides occurs regioselectively and results in β-keto esters after acid hydrolysis.[53] α-Amino acid esters are prepared by amination of silyl ketene acetals with 3-acetoxyaminoquinazolin-4(3*H*)-ones followed by N-N bond cleavage.[54] Silyl ketene acetals may be epoxidized by peroxyacids and subsequently cleaved with fluoride ion to reveal the α-hydroxy esters.[55] Related sequences involve $^1O_2$,[56] and ***Lead(IV) Acetate***,[57] as well as camphor-derived auxiliaries.[58]

Claisen Rearrangements.

Silyl ketene acetals of allyl esters undergo rapid Claisen rearrangements,[8b,59] at or above rt to give γ,δ-unsaturated carboxylic acid derivatives (eq 10).[60]

(10)

Reactions with Sulfur-Containing Electrophiles.

Paterson has developed an alkylation of geminal phenylthio chlorides with silyl enol ethers as a general method to prepare 1,5 dicarbonyl compounds (eq 11).[61] Alkylation of the silyl enol ether gives a homoallylic sulfide. Ozonolysis of the alkene with concomitant sulfur oxidation produces an unstable sulfoxide which is thermally extruded to give a mixture of alkene isomers.

The ketene acetal has also been reported to react with dithianyl cations. Treatment of 1,3-dithian-2-ylium tetrafluoroborate with the silyl enol ether results in a β-dithio ester which can subsequently be hydrolyzed to a β-keto ester (eq 12).[62]

Cycloadditions and Photochemistry.

Silyl ketene acetals undergo inverse electron demand hetero-Diels-Alder reactions with enones.[63] Photochemically induced Diels-Alder and [2 + 2] cycloadditions of silyl ketene acetals with dienes have been reported by Schuster and co-workers.[64] Cyclopropanes with vicinal donor and acceptor ligands will heterolytically cleave to form zwitterionic intermediates. In the presence of the ketene silyl acetal, a [3 + 2] cycloaddition reaction can occur with the zwitterionic intermediate to form highly substituted cyclopentenones (eq 13).[65]

Reactions with Nitrenes.

N-Protected α-amino esters are produced by the reaction of (ethoxycarbonyl)nitrene with methylketene ethyl trimethylsilyl acetal.[66]

Use as a Silylating Agent.

1-Methoxy-1-(trimethylsilyloxy)propene has been used as a mild silylating agent for phenols, alcohols, carboxylic acids, thiols, and amides.[67]

Related Reagents.

Ketene Bis(trimethylsilyl) Acetal; ***Ketene t-Butyldimethylsilyl Methyl Acetal***; ***Ketene Diethyl Acetal***; ***1-Methoxy-3-methyl-1-trimethylsilyloxy-1,3-butadiene***; ***1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene***; ***Methylketene Bis(trimethylsilyl) Acetal***; ***Methylketene Dimethyl Acetal***; ***Tris(trimethylsilyloxy)ethylene***.

1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene[1]

(**1**; R = Me)

[32583-40-7] · $C_9H_{22}O_2Si_2$ · 1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene · (MW 218.49) (*E*)-(**1**)

[35003-73-7] (*Z*)-(**1**)

[35003-74-8] (**2**; R = Et)

[65946-56-7] · $C_{10}H_{24}O_2Si_2$ · 1-Ethoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene · (MW 232.52)

(two-carbon nucleophile toward aldehydes[2] and α,β-unsaturated ketones[3] with the assistance of Lewis acids; in combination with $TiCl_4$, a reagent for (*Z*)-selective alkenation of aldehydes[2])

Alternate Name: *O*-methyl-*C*,*O*-bis(trimethylsilyl)ketene acetal.

Physical Data: (**1**) bp 40-41 °C/0.5 mmHg; *d* 0.852 g cm^{-3}. (*E*)-(**1**) bp 86-87 °C/45 mmHg. (*Z*)-(**1**) bp 80-81 °C/25 mmHg. (**2**) bp 55-60 °C/0.3 mmHg.

Solubility: sol most aprotic solvents; reacts readily with H_2O and protic solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: measurement of the ^1H NMR spectrum is the most reliable way to evaluate the purity and isomer ratio; ^1H NMR, δ (CCl_4, 60 MHz), (*E*): 0.00 ($CSiMe_3$), 0.27 ($OSiMe_3$), 3.00 (CH), 3.54 (OMe); (*Z*): 0.00 ($CSiMe_3$), 0.18 ($OSiMe_3$), 2.87 (CH), 3.55 (OMe). ^{13}C NMR, δ ($CDCl_3$, 25 MHz), (*E*): -0.30 (=$CSiMe_3$), 0.04 ($OSiMe_3$), 53.79 (OMe), 72.61 (=CH), 161.45 (=C); (*Z*): 0.04 (=$CSiMe_3$), 0.38 ($OSiMe_3$), 54.96 (OMe), 63.78 (=CH), 164.57 (=C).

Preparative Methods: to a THF solution (260 mL) of ***Lithium Diisopropylamide*** (LDA), generated from ***n-Butyllithium*** (0.218 mol) and ***Diisopropylamine*** (22.4 g, 0.222 mol), is added methyl (trimethylsilyl)acetate (23.0 g, 0.517 mol) at -78 °C. After being stirred for 3.5 h at -78 °C, the reaction mixture is quenched with an excess of ***Chlorotrimethylsilane*** (28.3 g, 0.260 mol) at the same temperature. The mixture is stirred for 1.5 h at rt and concentrated under reduced pressure. Distillation of the residual liquid yields 27.8 g (81%

E:*Z* &AApprox; 3:1) of the title reagent as a colorless liquid. The pure (*E*)-form is prepared by distillation of the mixture obtained immediately after quenching of the ester enolate anion formed by the use of ***Lithium Hexamethyldisilazide*** instead of LDA.[4] The pure (*Z*)-form is prepared by isomerization of the (*E*)-form in a CH_2Cl_2 solution containing an equimolar amount of ***Bromotrimethylsilane*** and a catalytic amount of $HgBr_2$.[5]

Handling, Storage, and Precautions: the pure liquid and solutions must be stored in the absence of moisture. The sample sealed in an ampule under Ar can be stored for more than a year without decomposition; however, gradual isomerization from the (*E*)-form to the (*Z*)-form is observed on the storage.

Two-Carbon Homologation.

This reagent, like most *O*-silyl-ketene acetals,[6-8] becomes a powerful nucleophile in the presence of ***Titanium(IV) Chloride***[2,3] or other types of accelerators. The trimethylsilyl group on the α-carbon atom plays an important role as a control factor in stereodifferentiation in aldol reactions. Essentially, *syn* selectivity is observed in the reaction with aldehydes (eq 1) despite small variations in the geometry of the starting ketene acetal. The nucelophilic species generated by the addition of $TiCl_4$ is also highly reactive as a Michael donor toward α,β-unsaturated ketones. The *C*-trimethylsilyl group remaining in the products is readily replaced by H after protodesilylation under mild conditions.[3,9] As a consequence, this reagent has remarkable advantages as an equivalent of the methyl trimethylsilylacetate anion or the dimethyl malonate anion in the reactions with aldehydes, ketones, and α,β-unsaturated ketones. It has been utilized for introducing the β-side chain in the synthesis of (±)-methyl jasmonate[3,10] (eq 2) and (±)-methyl dihydrojasmonate.[3]

(1)

(2)

The resulting *C*-trimethylsilyl group in the Michael-type adducts is capable of participating in the Peterson-type alkenation.[11] For example, the *O*-ethyl analog of the title reagent has been used for the synthesis of α-methylene δ-lactones from α,β-unsaturated ketones (eq 3).[12] Intermolecular coupling has also been accomplished by the reaction of silyl ketene acetals with 1-adamantyl bromide,[13] $GeCl_4$,[14] PCl_3,[15] or $AsCl_3$.[16]

(3)

Carbonyl Alkenations.

The title ketene acetal is an efficient C_2 condensation unit toward aldehydes and gives methyl 2-alkenoates in a one-pot operation with the assistance of Lewis acids.[2] The high (*Z*) selectivity of the $TiCl_4$-induced reactions contrasts with the results of analogous condensations using the ethyl trimethylsilylacetate anion[11] or Wittig-Horner-type reagents.[17] That this transformation is the overall result of two steps, aldol-type addition and Peterson-type β-elimination, has been confirmed

by the isolation of aldol adducts under kinetic conditions. Reaction of the isolated *syn* isomer with $TiCl_4$ or $BF_3.Et_2O$ leads specifically to (*Z*)-methyl 2-alkenoates (eq 4). On the other hand, the *anti*-isomers give (*E*)-alkenes (eq 5). The predominant formation of (*Z*)-methyl 2-alkenoate is attained by the *syn*-selective aldol-type coupling under acidic conditions. High (*Z*) selectivity has been realized by use of (*Z*)-ketene acetals or modified Lewis acids (eq 6 and Table 1).[2,18]

Table 1 Effect of the Geometry of Ketene Acetal and Lewis Acid in the Alkenation of Nonanal

Geometry of ketene acetal	Lewis acid	Product

1-Methoxyvinyllithium[1]

[42722-80-5] · C_3H_5LiO · 1-Methoxyvinyllithium · (MW 64.02)

(acetyl anion equivalent; umpoled synthon; precursor to vinyl ethers)

Alternate Name: MVL.

Physical Data: white powder.

Solubility: sol THF, diethyl ether; insol alkanes; decomposes violently in protic solvents.

Analysis of Reagent Purity: the reagent reacts rapidly and quantitatively with chlorosilanes such as ***Chlorotrimethylsilane*** (TMSCl). To an aliquot of MVL solution at -78 °C, TMSCl (&egt;1 equiv) and *n*-decane standards are added. The yield of MVL is determined by GC analysis.

Preparative Methods: an ~1 M solution is prepared by the dropwise addition of ***t-Butyllithium*** (2 M) in pentane to a solution of methyl vinyl ether (2 M) in THF at ca. -78 °C, followed by slow warming (3 h) to 0 °C.[2] The pure solid is prepared from the reaction of ***n-Butyllithium*** in hexanes (ca. 2 M) with tetrakis(α-methoxyvinyl)tin (ca. 0.5 M) in pentane at 0 °C.[3] The precipitated lithium reagent is washed several times under an inert atmosphere with dry pentane to remove the tin impurities. The reagent can be isolated (>95%) or dissolved in ethereal solvents for subsequent reactions.

Handling, Storage, and Precautions: solid MVL is extremely dangerous, reacting explosively with atmospheric oxygen. Solutions of MVL can be pyrophoric and contact with atmosphere and moisture must be avoided. Individuals should thoroughly familiarize themselves with the special handling techniques required for such reagents prior to use.[4]

Nucleophilic Acylation and α-Alkoxyvinyllithium Reagents.

α-Methoxyvinyllithium is a very useful acetyl anion equivalent[1] because it readily adds to a variety of electrophiles, and the resulting vinyl ether adducts are readily hydrolyzed to the acetyl derivatives under dilute acid conditions,

normally in <1 h at 25 °C. In addition to methyl vinyl ether (MVE) and ***Ethyl Vinyl Ether*** (EVE), other vinyl ethers such as 1-propenyl, 1,3-dienyl, allenyl, and β-styryl ethers, but not β,β-disubstituted vinyl ethers, can also be α-lithiated.[1,5] However, even under optimal conditions the deprotonations of MVE and EVE also produce minor amounts of dilithioacetylene (1-2%). Fortunately, tetrakis(α-methoxyvinyl)tin is formed free of alkynic impurities with a nominal excess of MVL because lithium acetylides are efficiently displaced from tin.[3] Now available commercially, this tin reagent provides unsolvated MVL as a pure solid reagent from its reaction with *n*-butyllithium in hexanes through a simple transmetalation procedure. For research applications, MVL generated by this Sn/Li exchange method is superior to the reagent generated by the deprotonation of MVE both with respect to efficiency and product isolation (eq 1). The corresponding process for the preparation of ***1-Ethoxyvinyllithium*** (EVL) is less efficient because of its greater solubility in pentane compared to MVL.[6]

(1)

Addition to Carbon Electrophiles.

MVL readily adds to aldehydes and ketones to give excellent yields of the corresponding α-methoxyvinyl carbinols.[5a,7] Even ketones prone to enolization (e.g. phenylacetone, cyclopentanone) undergo smooth addition with high diastereofacial selectivity (e.g. eq 2).[7k] Moreover, 1,2-addition is observed with α,β-unsaturated aldehydes and ketones. The reagent undergoes double addition to esters to produce 3-hydroxy-2,4-pentanediones, which serve as highly useful precursors to 2-pyrazolin-4-ones (eq 3).[8]

(2)

(3)

Benzonitrile undergoes mainly monoaddition leading to α-diketones. MVL also adds to the carbonyl carbon of ***Phenacyl Bromide***, producing an α-methoxyvinyl epoxide which is hydrolyzed to an acetylated vicinal diol (eq 4). In some cases (e.g. γ,γ-dimethylallyl bromide and 1-iodooctane), alkylation can be achieved, but ***Benzyl Bromide*** gives only 1,2-diphenylethane.[5a]

(4)

Organocuprates from MVL.

The preparation of the α-methoxyvinylcuprate reagent $LiCu[C(OMe)=CH_2]_2$ was first accomplished through the deprotonation of MVE followed by treatment with purified ***Copper(I) Iodide*** and added ***Dimethyl Sulfide*** as a complexing agent (see ***Lithium Bis(1-methoxyvinyl)cuprate***).[9] The analogous α-ethoxyvinylcuprate is prepared similarly (see ***Lithium Bis(1-ethoxyvinyl)cuprate***). Both reagents undergo conjugate addition to α,β-unsaturated ketones, the process being less effective with β,β-disubstituted substrates (eq 5).[10] The corresponding unsaturated aldehydes undergo 1,2-addition. Moreover, these reagents efficiently vinylate allylic and benzylic halides, but neither primary nor secondary bromides nor epoxycyclohexane produce satisfactory results. From the transmetalation procedure the higher order organocuprate $Li_2Cu(CN)[C(OMe)=CH_2]_2$ is easily prepared from MVL and ***Copper(I) Cyanide*** in THF and this also undergoes allylation, providing 2-methoxy-1,4-pentadiene (eq 6), a useful intermediate for the preparation of either *exo*-brevicomin or frontalin in optically active form.[11]

(5)

(6)

α-Methoxyvinyl Derivatives of Group 14 Metalloids.

With the correct stoichiometry, the preparation of α-methoxyvinylsilanes, -germanes, and -stannanes from MVL and the metalloidal halide is a particularly efficient process (eq 7).[12] From one to four α-methoxyvinyl groups can be introduced, with no limitations being encountered over a wide range of metalloidal substituents. However, an excess of the halometalloid with respect to MVL can result in the hydrolysis of the α-methoxyvinyl moiety. Moreover, with ***Chlorotrimethylstannane***, an excess of MVL can also displace methyl groups from tin. While the deprotonation methodology gives excellent results under the proper conditions, the Sn/Li exchange route is superior for small scale reactions. The tin derivatives provide a simple access to MVL and also undergo smooth Stille coupling to produce α-methoxy enones.[12] Mechanistic studies have demonstrated that the protonation of the vinyl ether moiety is rate-limiting with the rate increasing in the order: H < Si < Ge < Sn < C for a series of α-substituted α-methoxyvinyl compounds.[13] Acetyl (e.g. **1**) and even polyacetyl derivatives (e.g. **2**) can also be prepared, but in the case of silanes, bulky substituents (e.g. *i*-Pr) are required to prevent product decomposition.[14]

M = Ge, 71%; Sn, 47%

(1)

90%

(2)

Markovnikov Vinylboranes.

Early studies on the reaction of MVL (generated by deprotonation) implicated the intermediacy of internal (Markovnikov) vinylboranes.[15] More recently, trialkylboranes have been found to undergo the clean addition of MVL (from Sn/Li exchange) to produce the organoborate complex which reacts efficiently with Me_3SiCl to give the corresponding Markovnikov vinylboranes which are isolable in high yields (70-90%) (eq 8).[16] Suzuki-Miyaura coupling of these boranes to alkenyl bromides occurs with complete retention of configuration, resulting in the efficient construction of stereodefined 1,3-dienes.[17] Styrenes and enynes are similarly prepared.

N,*N*-Diethyl vinylcarbamate can also be smoothly α-metalated,[18] but the organoborates derived from these reagents undergo rearrangment through a thermal rather than TMSCl-induced process.[19]

Related Reagents.

1,2-Dimethoxyvinyllithium; ***1-Ethoxyvinyllithium***.

Methyl Acrylate

(**1**; R = Me)

[96-33-3] · $C_4H_6O_2$ · Methyl Acrylate · (MW 86.10) (**2**; R = Et)

[140-88-5] · $C_5H_8O_2$ · Ethyl Acrylate · (MW 100.13) (**3**; R = *n*-Bu)

[141-32-2] · $C_7H_{12}O_2$ · Butyl Acrylate · (MW 128.19) (**4**; R = *t*-Bu)

[1663-39-4] · $C_7H_{12}O_2$ · *t*-Butyl Acrylate · (MW 128.19)

(electrophile in conjugate addition reactions; dienophile or dipolarophile in cycloaddition reactions; acceptor in radical addition reactions; used in ene reactions)

Alternate Name: methyl propenoate.

Physical Data: (**1**) mp -75 °C; bp 80 °C. (**2**) mp -71 °C; bp 99 °C. (**3**) bp 145 °C. (**4**) bp 61-63 °C/60 mmHg.

Solubility: sol most organic solvents; slightly sol water.

Purification: wash repeatedly with aqueous NaOH to remove inhibitors, wash with H_2O, dry over $CaCl_2$, and distill under reduced pressure.

Handling, Storage, and Precautions: store at 0 °C in the dark (material will polymerize if exposed to light). Inhibited with up to 200 ppm hydroquinone monomethyl ether. Lachrymator and potential vesicant. Use in a fume hood. The ethyl ester (**2**) is a cancer suspect agent.

Conjugate Additions.

Acrylic acid esters have been used as Michael acceptors for a variety of nucleophiles. A typical example using an

amino alcohol is shown in eq 1.[1] This example illustrates chemoselectivity (amine over alcohol) and demonstrates that primary amines can undergo multiple additions.[2] This reaction has been performed with anilines,[3] imines,[4] guanidines,[5] hydrazones,[6] xanthines,[7] and pyrrolopyrimidines.[8] Other heteroatomic nucleophiles have also been used, including alcohols,[9] thiols,[10] halides,[11] and phosphorus reagents.[12]

(1)

A variety of carbon nucleophiles have also been used with acrylates in conjugate additions. An example using an enamine is shown in eq 2.[13,14] This reaction has been extended to the synthesis of optically active esters through the use of chiral amines (eq 3).[15,16]

(2)

(3)

94% ee

Stabilized azaallyl anions have also been used in asymmetric conjugate additions with methyl acrylate, as shown in eq 4.[17,18] Other stabilized anions used in this reaction include hydrazones,[19] malonates,[20] α-cyano anions,[21] ester enolates,[22] α-nitro anions,[23] α-sulfonyl anions,[24] phosphorus ylides,[25] and organozinc reagents.[26]

(4)

98% de

Enolates formed upon Michael addition of nucleophiles to acrylates have been trapped with a variety of electrophiles. An example of an intermolecular trapping with an aldehyde is shown in eq 5.[27,28] Other traps have included ketones,[29] *N*-tosyl imines,[30] and Michael acceptors.[31]

(5)

Intramolecular variants of these reactions are also well known. For example, eq 6 shows an intramolecular trapping with an enone to produce a bicyclic ring system.[32] Both chiral enolates[33] and chiral acrylates[34] have been used in this reaction. Other intramolecular traps have included esters[35] and ketones.[36]

(6)

Cycloaddition Reactions.

Acrylates are commonly used as dienophiles in Diels-Alder reactions. *Endo* products predominate when stereochemistry is involved. A simple example is shown in eq 7.[32b,37]

(7)

A wide variety of attempts at asymmetric induction have been reported for this reaction. Chiral acrylate esters have been used in the cycloaddition process (eq 8),[38,39] as well as chiral catalysts.[40]

(8)

Acrylates have further utility as dipolarophiles and have been used to trap nitrile oxides (eq 9),[41] nitrones,[42] azomethine ylides,[43] and azomethine imines.[44] They have also been used in hetero Diels-Alder reactions[45] and [2 + 2] cycloadditions.[46]

(9)

Radical Trap.

Acrylates have been used as traps for alkyl radicals in radical chain processes.[47] A variety of radical precursors may be used and intramolecular cyclization often precedes intermolecular trapping. Frequently, it is necessary to use a large excess of the acrylate to enhance trapping. The example in eq 10 shows the reaction of cyclohexyl iodide with methyl acrylate in the presence of ***Tris(trimethylsilyl)silane***.[48]

(10)

Curran has developed atom transfer cycloaddition as a means of forming new rings and maintaining high levels of functionality in the final products (eq 11).[49] Acyl radicals have also been trapped by acrylates to produce 1,4-dicarbonyl compounds.[50] Ketones reduced with ***Samarium(II) Iodide*** have been trapped with ethyl acrylate to give the corresponding lactones (eq 12).[51]

Arylations and Vinylations.

Aryl and vinyl halides and triflates have been coupled to acrylates in the presence of palladium catalysts to produce the corresponding unsaturated esters. This method is very versatile and stereospecific when substituted vinyl halides are used. Coupling reactions with an aryl bromide,[52] a vinyl triflate,[53] and a vinyl halide[54] are shown in eqs 13-15.

(13)

(14)

(15)

Acrylates have also been oxidatively coupled to indoles and furans using palladium salts (eq 16). These reactions appear to proceed via π-complexation to the heterocyclic double bond, conversion to the σ-complex, addition to the acrylate, and subsequent reductive elimination of the palladium species.[55,56]

(16)

An interesting extension of this palladium chemistry, shown in eq 17, involves the vinylation of an imino iodide.[57] Under the same conditions, the corresponding imino chlorides are recovered unchanged.

(17)

Ene Reactions.

Acrylates have been used in Lewis acid catalyzed ene reactions. Methyl acrylate reacts with (-)-β-pinene (eq 18) at rt with catalysis by ***Aluminum Chloride***.[58] This reaction can be stereoselective and may proceed better if a salt mixture is present.[59]

(18)

Transesterifications.

The transesterification of acrylates is best carried out using ***p-Toluenesulfonic Acid*** in the presence of hydroquinone as an inhibitor of polymerization. A representative example is shown in eq 19.[60]

(19)

Related Reagents.

Ethyl Acrylate.

(designer Lewis acid for Claisen rearrangements;[1-4] epoxide rearrangements;[5-7] intramolecular ene reactions;[8-10] α-primary alkylation of ketones;[11] oxetanone synthesis[12])

Alternate Name: MABR.

Solubility: sol toluene, CH_2Cl_2.

Form Supplied in: prepared from commercially available reagents and used in situ.

Preparative Method: prepared by reaction of a 1-2 M hexane solution of ***Trimethylaluminum*** with 4-bromo-2,6-di-*t*-butylphenol (2 equiv) in CH_2Cl_2 or toluene at 25 °C for 1 h.[1]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Claisen Rearrangement.

The modified organoaluminum reagent methylaluminum bis(4-bromo-2,6-di-*t*-butylphenoxide) was developed as a bulky Lewis acid for effecting the stereoselective Claisen rearrangement of allylic vinyl ethers.[1] Thus reaction of 1-isobutyl-2-propenyl vinyl ether with MABR in CH_2Cl_2 at -78 °C affords (*Z*)-7-methyl-4-octenal with high stereoselectivity (*E*/*Z* = 7:93). This selectivity is opposite to that observed in ordinary thermal and Lewis acid-induced rearrangements (eq 1). The Claisen rearrangement of the optically active substrate with MABR reveals a chairlike transition-state conformation with the isobutyl substituent axial in order to relieve a severe 1,2-steric interaction between the isobutyl and very bulky MABR ligands.[2]

Such unusual behavior is also observed in the MABR-promoted Claisen rearrangement of bisallylic vinyl ethers and allylic phenyl ethers (eq 2).[3,4]

Epoxide Rearrangements.

A new, stereocontrolled rearrangement of epoxy silyl ethers to β-siloxy aldehydes has been effected using MABR as a catalyst under mild conditions. Used in combination with the Sharpless asymmetric epoxidation of allylic alcohols, this rearrangement represents a new approach to the synthesis of various optically active β-hydroxy aldehydes, useful intermediates in natural product synthesis (eq 3).[5] MABR has also been used to transform a variety of simple epoxides to carbonyl compounds with high efficiency and selectivity.

This approach enables the practical asymmetric synthesis of both *erythro* and *threo* aldols based on the MABR-promoted selective rearrangement of optically active *threo* and *erythro* epoxy silyl ethers (eq 4).[6] The migratory aptitude of alkyl substituents in the Lewis acid-promoted epoxide rearrangement has been investigated with the MABR reagent.[7]

(4)

Intramolecular Ene Reactions.

The intramolecular ene reaction of α-substituted δ,ε-unsaturated aldehydes has been executed with high *trans* selectivity, not observed with ordinary Lewis acids (eq 5).[8] This method has been used for the asymmetric synthesis of the cyclohexyl fragment of FK-506.[9] Since MABR is also the reagent of choice for epoxide rearrangements, this approach has been directly applied to the cyclization of alkenic epoxides (eq 6).[10]

(5)

Me_2AlCl	65%	9: 1
$BF_3 \cdot OEt_2$	58%	19: 1
MABR	85%	1:32

(6)

α-Primary Alkylation of Ketones.

α-Primary alkylation of carbonyl compounds via the corresponding enol silyl ethers with primary alkyl triflates has been realized in the presence of MABR under mild conditions (eq 7).[11] Here, only monoalkylation products are obtained.

Oxetanone Synthesis.

Reaction of ***Trimethylsilylketene*** and aldehydes with MABR affords *cis*-2-oxetanones with high selectivity (eq 8).[12] In the case of aromatic and α,β-unsaturated aldehydes, (*Z*)-2-alkenoic acids are directly obtained via the ring opening of the intermediary *cis*-2-oxetanones (eq 9).

Methylaluminum Bis(2,6-di-*t*-butyl-4-methylphenoxide)

[65260-44-8] · $C_{31}H_{49}AlO_2$ · Methylaluminum Bis(2,6-di-*t*-butyl-4-methylphenoxide) · (MW 480.78)

(designer Lewis acid for amphiphilic alkylation,[1,4,5] amphiphilic reduction,[6] conjugate addition,[7-10] discrimination of two different substrates (ethers and ketones),[12-14] strereocontrolled cycloadditions,[15-17] and polymerization[18])

Alternate Name: MAD.

Physical Data: a crystal structure of a MAD-benzophenone complex has been reported.[3]

Solubility: sol CH_2Cl_2, toluene, hexane.

Form Supplied in: prepared from commercially available reagents and used in situ.

Preparative Method: prepared by reaction of a 1-2 M hexane solution of ***Trimethylaluminum*** with 2 equiv of 2,6-di-*t*-butyl-4-methylphenol in toluene or CH_2Cl_2 at rt for 1 h.[1,2]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Amphiphilic Alkylation.

The exceptionally bulky, oxygenophilic organoaluminum reagent methylaluminum bis(2,6-di-*t*-butyl-4-methylphenoxide) has been developed for the stereoselective activation of carbonyl groups. Combination of MAD with Grignard reagents or organolithium reagents generates the amphiphilic alkylation systems, where substituted cyclohexanones and cyclopentanones afford equatorial alcohols with high stereoselectivity (eqs 1-3).[1] The X-ray

crystallographic determination of a benzophenone-MAD complex shows that the ketone coordinates such that the aluminum is in the nodal plane of the C=O π-bond.[3]

This methodology has been used in the final step of the stereocontrolled synthesis of a defense substance of the termite *Nastitermes princeps*, a secotrinervitane diterpene. Whereas ***Methyllithium*** adds exclusively to the β-face of the ketone to furnish the α-alcohol as the sole isolable product, attack of methyllithium occurs preferably at the α-face of the carbonyl in the amphiphilic alkylation system using MAD/MeLi to give the desired substance as a major

product (eq 4).[4]

(4)

MeLi	91%	0:100
MAD, MeLi	30%	75:25

Alkylation of α-substituted aldehydes with the MAD/RMgX system provides *anti*-alcohols preferentially (eq 5).[1] This amphiphilic system allows the chemoselective carbonyl alkylation and reduction of aldehydes in the presence of ketones (eq 6).[5]

(5)

25:75

(6)

Amphiphilic Reduction.

In contrast to the facile MAD-mediated alkylation of cyclic ketones with primary organolithiums or Grignard reagents, both alkylation and reduction take place with *s*-alkylmagnesium halides. When a bulky nucleophile such as *t*-BuMgCl is employed for the amphiphilic reaction system, substituted cyclohexanones afford equatorial alcohols exclusively as reduction products with high selectivity (eq 7).[6]

(7)

Conjugate Addition.

The MAD/RLi system can also be used for conjugate alkylation and reduction of α,β-unsaturated ketones with organolithiums and ***Lithium n-Butyl(diisobutyl)aluminum Hydride***, respectively (eqs 8 and 9).[7,8] This method is particularly effective for the conjugate alkylation and reduction of quinone monoacetals and their derivatives (eqs 10 and 11).[9,10]

(9)

(10)

(11)

Discrimination of Two Different Oxygen-Containing Substrates.

MAD can be used as a Lewis acidic receptor for the discrimination of two different oxygen-containing substrates based on selective Lewis acid-base complex formation.[11] Indeed, in an equimolar mixture of methyl and ethyl ether

substrates, MAD coordinates to the methyl ether exclusively (eq 12). This chemistry has been applied to a new type of coordination chromatography using polymeric, bulky organoaluminum compounds as a stationary phase that allows a surprisingly clean separation of structurally similar methyl ethers from ethyl ethers.[12,13]

Selective reduction of sterically more hindered ketones has been effected with the MAD/***Diisobutylaluminum Hydride*** system by selective complexation of the less hindered ketones with MAD and subsequent attack of *i*-Bu_2AlH at the free, more hindered ketones (eq 13).[14]

The selective binding behavior of Lewis acidic MAD for two different ester groups allows the regio- and stereocontrolled Diels-Alder reaction of unsymmetrical fumarates (eq 14).[15]

(14)

Cycloadditions.

The steric effects of MAD on stereoselectivity in the Diels-Alder reactions of cyclic dienes and α,β-unsaturated aldehydes has been studied (eq 15).[16] MAD promotes very mild and highly stereocontrolled [2 + 4] cycloaddition between a pyrone sulfone and an enantiomerically pure vinyl ether. After 12 h at -45 °C in 4:1 toluene/CH_2Cl_2 with 0.5 equiv of MAD and 2.5 equiv of the vinyl ether, cycloadducts are isolated in 93% yield as a 98:2 ratio of the *endo* diastereomers (eq 16).[17]

(15)

heat		1:5
Me_3Al	64%	1:15
MAD	76%	1:48

Polymerization.

A novel, Lewis acid-induced Michael addition of an enolate complex to an α,β-unsaturated ester has been developed, where the unfavorable reaction between the nucleophile and Lewis acid is sterically suppressed.[18] For example, the addition polymerization of methyl methacrylate (MMA) via an enolate complex of aluminum tetraphenylporphyrin (**1**) as the nucleophilic growing species has been effected in the presence of MAD, producing polymer molecules cleanly with a narrow molecular weight distribution (eq 17).

Methylaluminum Bis(2,6-di-*t*-butylphenoxide)

[128353-30-0] · $C_{29}H_{45}AlO_2$ · Methylaluminum Bis(2,6-di-*t*-butylphenoxide) · (MW 452.72)

(designer Lewis acid for amphiphilic alkylation and conjugate addition)

Solubility: sol CH_2Cl_2, toluene, hexane.

Form Supplied in: prepared from commercially available reagents and used in situ.

Preparative Method: prepared by reaction of a 1-2 M hexane solution of ***Trimethylaluminum*** with 2 equiv of 2,6-di-*t*-butylphenol in toluene or CH_2Cl_2 at rt for 1 h in a similar manner to that described in the preparation of MAD or MAT.[1]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Amphiphilic Alkylation.

The exceptionally bulky, oxygenophilic organoaluminum reagent methylaluminum bis(2,6-di-*t*-butylphenoxide), like ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD) and ***Methylaluminum Bis(2,4,6-tri-t-butylphenoxide)*** (MAT), has been used for stereoselective activation of carbonyl groups. Combination of this modified organoaluminum compound, as a bulky Lewis acid, with Grignard reagents or organolithium reagents generates the amphiphilic alkylation system, in which substituted cyclohexanones afford equatorial alcohols with high selectivity (eq 1).[2] This approach is quite useful in the stereoselective alkylation of steroidal ketones. Thus reaction of cholestan-3-one with ***Methyllithium*** gives predominantly 3β-methylcholestan-3α-ol (axial alcohol), whereas the amphiphilic methylation of the ketone gives 3α-methylcholestan-3β-ol (equatorial alcohol) exclusively (eq 2).[1,2]

Methylaluminum Bis(2,6-diphenylphenoxide)

[118496-00-7] · $C_{37}H_{29}AlO_2$ · Methylaluminum Bis(2,6-diphenylphenoxide) · (MW 532.64)

(designer Lewis acid for Claisen rearrangements,[1,3] aza-Cope rearrangements,[4] cycloadditions,[5] epoxide rearrangement,[6] stabilization of reactive aldehydes,[7] and aldehyde recognition[8,9])

Alternate Name: MAPH.

Solubility: sol toluene, CH_2Cl_2.

Form Supplied in: prepared from commercially available reagents and used in situ.

Preparative Method: treatment of 2,6-diphenylphenol (2 equiv) in dry CH_2Cl_2 with a 1 M hexane solution of ***Trimethylaluminum*** at 25 °C for 1 h.[1]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Claisen Rearrangement.

The modified organoaluminum reagent MAPH was developed for effecting the stereoselective Claisen rearrangement of allylic vinyl ethers.[1] Thus reaction of 1-isobutyl-2-propenyl vinyl ether with MAPH in toluene at -20 °C affords, after reduction of the Claisen products with ***Sodium Borohydride***, (*E*)-7-methyl-4-octen-1-ol with high stereoselectivity (eq 1), superior to that observed in the thermal rearrangement (*E*/*Z* ratio = 92:8). The Claisen rearrangement of the optically active substrate with MAPH reveals a chairlike transition-state, with the isobutyl substituent equatorial.[2]

The organoaluminum-promoted Claisen rearrangement of bisallylic vinyl ethers exhibits unprecedented regiochemical control not observed in the thermal Claisen rearrangement (eq 2).[3]

Aza-Cope Rearrangement.

The advantage of MAPH over other Lewis acids is exemplified by the Lewis-acid promoted 3-aza-Cope rearrangement of *N*-alkyl-*N*-allyl enamine substrates.[4] Here, MAPH shows highest diastereoselectivity in the C-C bond forming process (eq 3).

$TiCl_4$	72%	55:45
Me_3Al	94%	67:33
MAPH	73%	77:23

Tandem [4 + 2]/[3 + 2] Cycloaddition.

The [4 + 2] cycloaddition of a nitro alkene with a chiral (+)-camphor vinyl ether, promoted by MAPH, followed in tandem by a [3 + 2] cycloaddition of the intermediate nitronate with an intramolecularly tethered electron-deficient alkene, allows for the construction of five stereogenic centers with excellent stereoselectivity. The stereochemistry is opposite to that formed with a titanium reagent (eq 4).[5]

Catalytic Rearrangement of Epoxides.

MAPH mixed with silanized silica gel can be utilized as a stationary phase for immobilized organoaluminum columns. These can be used as a workup-free reactor for the catalytic rearrangement of various epoxides to carbonyl compounds.[6]

Stabilization of Reactive Aldehydes.

Reactive aldehydes such as formaldehyde and α-chloro aldehydes can be successfully generated by treatment of readily available trioxane and α-chloroacetaldehyde trimers, respectively, with MAPH and stabilized as their 1:1 coordination complexes with MAPH. The resulting CH_2=O.MAPH complex reacts with a variety of alkenes to furnish ene reaction products with excellent regio- and stereoselectivities (eq 5).[7] In addition, these complexes can be used as stable sources of formaldehyde and α-chloroacetaldehyde, respectively, for use in nucleophilic addition reactions with various carbanions (organometallics, enolates, etc.) (eq 6).[8]

(5)

(6)

Chemoselective Functionalization.

The high recognition and stabilization ability of MAPH enables the chemoselective alkylation of sterically more hindered aldehydes using alkyllithiums as the nucleophile (eq 7).[9]

MAPH (1 equiv), BuLi (1 equiv)	76%	1: 6.5
MAPH (2 equiv), BuLi (1 equiv)	45%	1:14

Methylaluminum Bis(2,4,6-tri-*t*-butylphenoxide)

[65260-46-0] · $C_{37}H_{61}AlO_2$ · Methylaluminum Bis(2,4,6-tri-*t*-butylphenoxide) · (MW 564.96)

(designer Lewis acid for amphiphilic alkylation,[1] conjugate addition,[2,3] and polymerization[4])

Alternate Name: MAT.

Solubility: sol CH_2Cl_2, toluene.

Form Supplied in: prepared from commercially available reagents.

Preparative Method: prepared by reaction of a 1-2 M hexane solution of ***Trimethylaluminum*** with 2 equiv of 2,4,6-tri-*t*-butylphenol in CH_2Cl_2 at rt for 1 h.[1]

Handling, Storage, and Precautions: the dry solid and solutions are highly flammable and must be handled in the absence of oxygen and moisture. The solution should be used as prepared for best results. Use in a fume hood.

Amphiphilic Alkylation.

The exceptionally bulky, oxygenophilic organoaluminum reagent MAT, like ***Methylaluminum Bis(2,6-di-t-butyl-4-methylphenoxide)*** (MAD), has been used for stereoselective activation of carbonyl groups. In combination with Grignard reagents or organolithium reagents, amphiphilic alkylation of substituted cyclohexanones affords equatorial alcohols almost exclusively. The equatorial selectivity is generally superior to that observed with MAD/RMgX or MAD/RLi systems (eqs 1 and 2).[1]

MAD, MeLi	84%	1 :99
MAT, MeLi	92%	0.5:99.5

MAD, MeLi	69%	9:91
MAT, MeLi	95%	3:97

This approach is useful in the stereoselective alkylation of steroidal ketones. Thus the amphiphilic alkylation of cholestan-3-one with MAT/MeLi gives 3α-methylcholestan-3β-ol (equatorial alcohol) almost exclusively with only trace amounts of 3β-methylcholestan-3α-ol (axial alcohol) (eq 3).[1]

MAD, MeLi	98%	2:98
MAT, MeLi	99%	1:99

A similar trend is observed in the amphiphilic alkylation of α-substituted aldehydes with MAT/RMgX, giving *anti*-alcohols preferentially (eq 4).

MAD, EtMgBr	90%	25:75
MAT, EtMgBr	90%	13:87

Conjugate Addition.

The MAT/RLi system can also be used for conjugate addition of organolithiums to α,β-unsaturated ketones. MAT gives comparable results to MAD in 1,4-selectivity (eq 5).[2] However, the conjugate reduction of α,β-unsaturated

ketones with MAT/***Lithium n-Butyl(diisobutyl)aluminum Hydride*** gives generally less satisfactory results (eq 6).[3]

MAD, MeLi	65%	16%
MAT, MeLi	63%	31%

MAD, LiBu(i-Bu)$_2$AlH	60%	28%
MAT, LiBu(i-Bu)$_2$AlH	37%	61%

Polymerization.

The addition polymerization of methyl methacrylate (MMA) via an enolate complex of aluminum tetraphenylporphyrin as the nucleophilic growing species has been effected in the presence of MAT and the related Lewis acid MAD.[4]

Methylaluminum Dichloride[1]

$MeAlCl_2$

[917-65-7] · CH_3AlCl_2 · Methylaluminum Dichloride · (MW 112.92)

(strong Lewis acid that can also act as a proton scavenger; reacts with HX to give methane and $AlCl_2X$)

Alternate Name: dichloro(methyl)aluminum.

Physical Data: mp 72.7 °C; bp 94-95 °C/100 mmHg.

Solubility: sol most organic solvents; stable in alkanes or arenes.

Form Supplied in: commercially available as solutions in hexane or toluene.

Analysis of Reagent Purity: solutions are reasonably stable but may be titrated before use by one of the standard methods.[1b]

Handling, Storage, and Precautions: must be transferred under inert gas (Ar or N_2) to exclude oxygen and water. Use in a fume hood.

Introduction.

The general properties of alkylaluminum halides as Lewis acids are discussed in the entry for ***Ethylaluminum Dichloride***. $MeAlCl_2$ is used less frequently than $EtAlCl_2$, since $EtAlCl_2$ is much cheaper and comparable results are usually obtained. In some cases, use of $MeAlCl_2$ is preferable, since the methyl group of $MeAlCl_2$ is less nucleophilic than the ethyl group of $EtAlCl_2$ and $EtAlCl_2$ can transfer a hydride.

Catalysis of Diels-Alder Reactions.

$MeAlCl_2$ has been used as a catalyst for Diels-Alder[2-4] and retro-Diels-Alder reactions.[5] $MeAlCl_2$ is the catalyst of choice for intramolecular Diels-Alder reactions of furans (eq 1) due to the ease of handling and reaction workup.[2]

(1)

Catalysis of Ene Reactions.

$MeAlCl_2$ has been used as a catalyst for ene reactions of trifluoroacetaldehyde[6] and for intramolecular ene reactions of trifluoromethyl ketones (eq 2).[7] Use of $EtAlCl_2$ leads to the ene adduct in lower yield accompanied by 25% of the saturated analog resulting from hydride delivery to the zwitterion.

(2)

Generation of Electrophilic Cations.

1:2 Aldehyde- or ketone-$MeAlCl_2$ complexes add intramolecularly to alkenes to give zwitterions that undergo 1,2-hydride and alkyl shifts to regenerate a ketone (eqs 3 and 4).[8-11] $EtAlCl_2$ can transfer a hydride to the zwitterion to give the reduced product (eq 3).[8]

(3)

(4)

$MeAlCl_2$ has been used as the catalyst for epoxide-initiated cation-alkene cyclizations.[12] A tertiary alcohol has been converted to a hydrazide by reaction with $MeAlCl_2$ in the presence of ***Mesitylenesulfonylhydrazide***.[13] α-Trimethylsilyl enones can be prepared by isomerization of 1-(trimethylsilyl)-2-propynyl trimethylsilyl ethers with $MeAlCl_2$.[14]

Nucleophilic Additions.

$MeAlCl_2$ has occasionally been used to introduce a methyl group. γ-Lactones react with $MeAlCl_2$ to give carboxylic acids with a methyl group at the γ-position.[15] The reagent prepared from $MeAlCl_2$ and ***Dichlorobis(cyclopentadienyl)titanium*** adds to trimethylsilylalkynes in a *syn* fashion.[16] Optimal stereoselectivity is obtained using $MeAlCl_2$ to transfer a methyl group to a formyl amide (eq 5).[17]

2-(Methylamino)thiophenol

[21749-63-3] · C_7H_9NS · 2-(Methylamino)thiophenol · (MW 139.24)

(template for assisting ring closure of cyclic ketones;[1] protecting group for ketones and aldehydes[2])

Physical Data: mp 65 °C; bp 126 °C/18 mmHg.

Solubility: sol ethanol, chloroform.

Form Supplied in: solid; commercially available.

Preparative Methods: reduction of ***2-Methylbenzothiazole*** with ***Lithium Aluminum Hydride***,[3] hydrolysis of *N*-methylbenzothiazolone,[4] or reduction of the disulfide with ***Sodium Borohydride***.[1]

Purification: vacuum distillation.

Handling, Storage, and Precautions: store away from air to avoid dimerization.

Template for Ketone Synthesis.

2-(Methylamino)thiophenol (**1**) has been used to assist in the formation of bonds to carbonyl carbons, leading to cyclic[1,5-7] and acyclic ketones,[5] as well as to β,γ-unsaturated esters and ketones.[7] Amido sulfides can be formed by treatment of (**1**) with an alkyl bromide followed by an acid chloride. Deprotonation with ***Lithium Diisopropylamide*** leads to acyl transfer (eq 1). Reductive desulfurization then liberates the new ketone. Enolizable amides will undergo acyl transfer only after oxidation of the thioether to a sulfoxide or sulfone.[1]

2-(Methylamino)thiophenol

Benzothiazine and Benzothiazoline Synthesis.

A variety of heterocycles have been prepared starting from (**1**). Treatment of (**1**) with bromo esters leads to the formation of 2-substituted 2*H*-1,4-benzothiazin-3-ones (eq 2).[8] Alkylation of (**1**) with dibromopyridazine-3,6-dione provides access to 10-methyl-2,3-dihydropyridazino[4,5-*b*][1,4]benzothiazine-1,4-diones.[9]

Condensation of (**1**) with aldehydes or ketones results in benzothiazolines, which can be used as protecting groups for aldehyde and ketone carbonyl groups.[2] The benzothiazoline moiety is highly resistant to attack by acids, bases, and reducing agents. The reaction is selective for aldehydes over ketones (eq 3), conjugated ketones over nonconjugated ketones, and ketones over acids and esters. The selectivity for conjugated over nonconjugated ketones is superior to that of acetalization or thioacetalization. Hydrolysis to regenerate the aldehyde proceeds in good yield with mild oxidants ($AgNO_3$, NCS, $HgCl_2$, others) or with FSO_3Me.

N-Methylanilinium Trifluoroacetate

$Ph{+}NH_2Me\ CF_3CO_2^-$

[29885-95-8] · $C_9H_{10}F_3NO_2$ · *N*-Methylanilinium Trifluoroacetate · (MW 221.20)

(α-methylenating agent for ketones;[1] activates internucleotide coupling[2])

Alternate Name: N-MATA.

Physical Data: mp 66.5 °C.

Solubility: insol pentane; sol THF; very sol MeCN.

Form Supplied in: crystalline white salt.

Analysis of Reagent Purity: elemental analysis.

Preparative Method: prepared from commercial grade ***Trifluoroacetic Acid*** and *N*-methylaniline (1:1) in dry Et_2O under a nitrogen atmosphere with cooling in an ice-bath.[1c]

Purification: by sublimation and drying in a desiccator under vacuum at rt.

Handling, Storage, and Precautions: nonhygroscopic; not deliquescent; can be weighed in the air and stored for months under an inert atmosphere.

Methylene Transfer Reagent.

Ketones of various types form α-methylene ketones by direct methylene transfer from formaldehyde in the presence of N-MATA (eq 1).[1,3,4]

(1)

Both paraformaldehyde and trioxane can be used as the source of formaldehyde, but, with the latter, low yields of methylene ketones are sometimes obtained.[3] With cyclohexanone, cyclopentanone, or aldehydes, preformation of the iminium intermediate [CH_2=+NMePh] is recommended from paraformaldehyde and N-MATA prior to addition of the carbonyl compound.[1c] Saturated[1] and unsaturated,[1b] cyclic,[1a,c,3] and acyclic,[1b,4] as well as methyl ketones,[1b,4] can be successfully used in the process (eqs 2 and 3).[1a,4]

(2)

(3)

Linear methyl ketones react at both the α- and α´-positions to give a mixture of regioisomeric methylene ketones (eq 4),[1b] as well as some divinyl ketone as a side product.

(4)

The reaction is not applicable to γ- or δ-lactones, or strained cyclic ketones such as norcamphor or cyclobutanone.[1a,c]

Activating Agent in Internucleotide Coupling.

Deoxynucleoside methyl- and phenylphosphoramidites[2] and also phosphorothioamidites[5] are effectively activated by N-MATA for condensation with other suitably protected nucleosides to give deoxydinucleoside phosphates (eq 5).[2] Phosphorodithioates[5] or oligonucleotides (over 95%) have also been prepared in this manner using a polymer silica gel support.[2]

(5)

DMT = di-*p*-anisylphenylmethyl, T = 1-thiminyl

In the synthesis of deoxydinucleoside phosphorodithiolates, however, N-MATA causes excessive detritylation and the most satisfactory activator in this process is pyridinium tetrafluoroborate.[5]

Analysis of Reagent Purity: (**1**) NMR,[5a] IR,[5b] UV.[5b] (**2**) NMR,[5a] IR,[5c] UV.[5d]

Handling, Storage, and Precautions: these compounds are reported to produce extreme and prolonged burning sensations on contact with the skin.

Preparation of Sulfinyl Compounds.

Methyl arenesulfinates react with compounds containing activated methylene groups, such as ketones[6] and sulfones,[7] in the presence of ***Sodium Hydride*** in DME or Et_2O to form α-arylsulfinyl compounds; arylsulfinyl chlorides react similarly (see ***Benzenesulfinyl Chloride***). These sulfinyl-activated compounds are useful synthetic intermediates since they can undergo further reaction;[8] the sulfinyl group can then be removed by reductive cleavage with agents such as ***Aluminum Amalgam***, Li(Hg), or ***Raney Nickel***.[9] Alternatively, the sulfoxide group may be removed via β-hydrogen elimination either by thermolysis (ca. 80 °C) (eq 1),[10,11] or by treatment with base (e.g. RO^-, CO_3^{2-}) with concomitant formation of a double bond.[11] Because of the mildness of the procedure, this is one of the better methods for the conversion of ketones, aldehydes, and esters into their α,β-unsaturated derivatives.[12]

(1)

Sulfinylation of a series of lactams by methyl benzenesulfinate is superior to sulfenylation with diphenyl disulfide followed by oxidation; substantial bissulfenylation occurs using the latter procedure.[13]

Methyl benzenesulfinate has been used to prepare unsaturated sulfoxides via reaction with functionalized unsaturated Grignard reagents,[14] and by reaction with phosphonates to form α-phosphoryl sulfoxides that, in turn, form vinyl sulfoxides by Horner-Emmons reactions with aldehydes and ketones.[15] These unsaturated sulfinyl compounds undergo a variety of synthetically useful reactions such as cycloadditions,[16] Michael additions,[17] and various rearrangements.[18,19]

p-Tolylsulfinylmethyl phenyl sulfone, available from methyl *p*-toluenesulfinate and ***Methyl Phenyl Sulfone***, reacts with aldehydes and some ketones to form vinyl sulfoxides; these sulfoxides afford γ-hydroxy-α,β-unsaturated sulfones after alkene isomerization and rearrangement (eq 2).[7]

Asymmetric Synthesis.

Although chiral sulfoxides have been prepared in high yield and enantiomeric purity via reaction of optically active *p*-$MeC_6H_4S(O)OMe$ with silyl enol ethers,[20] a more common procedure has been through reaction of a Grignard reagent or metalated substrate with menthyl *p*-toluenesulfinate (MenTs).[3] Methyl *p*-toluenesulfinate has been used to prepare menthyl *p*-toluenesulfinates,[21] which are very useful chiral sulfinyl-transfer reagents; the resulting chiral sulfoxides have been used widely in asymmetric synthesis[22] (see ***Benzenesulfinyl Chloride*** and ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate***). For example, MenTs has been used to generate β-hydroxy carboxylic esters in high optical yields (eq 3).[23]

2-Methylbenzothiazole[1]

[120-75-2] · C_8H_7NS · 2-Methylbenzothiazole · (MW 149.23)

(the α-lithio derivative represents a masked enolate;[2] the α-trimethylsilyl derivative is used for Peterson alkenations[3])

Physical Data: mp 14 °C; bp 238 °C/765 mmHg; bp 151 °C/15 mmHg; *d* 1.1763 g cm^{-3}; n_D 1.6092.

Solubility: insol H_2O; sol ethanol; very sol diethyl ether, THF.

Form Supplied in: liquid; widely available.

Analysis of Reagent Purity: ^1H and ^{13}C NMR spectra.

Purification: distillation under reduced pressure.

Handling, Storage, and Precautions: should be freshly distilled before use for best results. Toxic by inhalation, in contact with skin, and if swallowed. Use in a fume hood.

Introduction.

2-Methylbenzothiazole (**1**) has been used[4] in base- and acid-mediated condensations with aldehydes to give products which normally undergo dehydration in situ to give alkenes (**2**) (eq 1).

α-Lithio-2-methylbenzothiazole.[1]

This reagent is readily available by lithiation of 2-methylbenzothiazole (**1**) with ***n-Butyllithium*** at -78 °C (eq 2),[1,3] which gives rise to a yellow precipitate (indicating the formation of the organometallic compound) when diethyl ether is used as a solvent or to a clear light-brown solution in THF or 1,2-dimethoxyethane.

α-Lithio-2-methylbenzothiazole (**3**) reacts with various electrophiles such as aldehydes and ketones[2] to afford 2-(2-hydroxyalkyl)benzothiazoles in high yields (eq 3).

Chikashita et al.[2] have demonstrated the synthetic equivalence of (**3**) to a masked enolate anion through the liberation of the aldehyde by cleavage of the ***Benzothiazole*** ring (eq 4).

More recently, Lochon et al.[5] have reported the reaction of (**3**) with other electrophiles such as esters (eq 5) and nitriles (eq 6). When the same reaction is carried out with acyl chlorides, bisacylated compounds are obtained (eq 7).

2-(Trimethylsilylmethyl)benzothiazole.

α-Lithio-2-methylbenzothiazole (**3**) is quantitatively silylated with ***Chlorotrimethylsilane*** to give reagent (**4**), which can be further metalated and condensed with carbonyl compounds to give the corresponding alkenes (eq 8).[3] This two-carbon homologation sequence corresponds to a Peterson alkenation, i.e. it is an alternative to the Wittig and Horner-Emmons reactions.[6] Endocyclic analogs such as 2-(1-cyclohexenyl)- and 2-(1-cyclopentenyl)benzothiazoles are accessible via addition of 2-lithiobenzothiazole (see ***Benzothiazole***) to corresponding cyclic ketones and subsequent dehydration.[3]

The vinylbenzothiazole (**5**), derived from cyclohexanone through (**4**), undergoes efficient conjugate addition reactions with a variety of alkyllithium reagents (alkyl, vinyl, phenyl, and allyl) as well as with acetone and acetaldehyde *N*,*N*-dimethylhydrazone anions.[7a] The resulting adduct carbanions may be protonated (MeOH) or alkylated in situ with methyl, allyl, and propargyl halides. The double bond of (**5**) can be hydrogenated (H_2, Pd/C, EtOH) smoothly without catalyst poisoning. Conversion of the benzothiazole moiety to the formyl group is accomplished by *N*-methylation ($MeOSO_2F$, CH_2Cl_2), reduction ($NaBH_4$, EtOH), and hydrolysis ($AgNO_3$, aq. MeCN, pH 7). Aldol cyclization of the liberated aldehyde onto the α- or β-acetonyl substituents provide effective methods for fused and spiro annulation of cyclohexenone or cyclopentenone rings (e.g. eq 9).[7b]

Other 2-Alkylbenzothiazoles.

Florio et al.[8] have reported the metalation of 2-alkylbenzothiazoles (2-ethyl, 2-propyl, and 2-phenyl) to give the corresponding α-lithioalkylbenzothiazoles which undergo aldol condensations with carbonyl compounds (eq 10).

(10)

More recently,[9] the Darzens reaction between the lithio derivative of 2-chloromethylbenzothiazole (**6**) and carbonyl compounds to furnish epoxides has been described (eq 11).

Alessandro Dondoni

(*S*)-α-Methylbenzylamine

[2627-86-3] · $C_8H_{11}N$ · (*S*)-α-Methylbenzylamine · (MW 121.20)

(resolving agent for carboxylic acids;[7-11] determination of enantiomeric purity of carboxylic acids;[16,17] stereospecific reactions of carbonyl compounds;[18] reductive amination of carbonyl compounds[29,30])

Physical Data: bp 187 °C; *d* 0.940 g cm^{-3}; $[\alpha]_D$ -39° (neat).

Solubility: readily sol all organic solvents.

Form Supplied in: both enantiomers are commercially available.

Analysis of Reagent Purity: the enantiomeric purity of the reagent can be assessed by NMR analysis of the corresponding Mosher's amide.[4] Chiral complexing reagents (such as 1,1´-binaphthyl-2,2´-diylphosphoric acid) have also been used in the direct NMR analysis of the reagent.[5,6]

Preparative Methods: racemic α-methylbenzylamine has been resolved utilizing chiral acids such as tartaric acid[1] and (*S*)-(-)-carbamalactic acid,[2] among others. Several stereospecific syntheses have been reported.[3]

Handling, Storage, and Precautions: stable at rt for extended periods of time when stored under nitrogen.

Resolving Reagent for Carboxylic Acids and Other Types of Compounds.

A large number of carboxylic acids have been resolved via their diastereomeric salts with (*S*)- or (*R*)-α-methylbenzylamine (**1**). The ready availability of both enantiomers of (**1**) guarantees access to both enantiomers of the desired acid. Compounds (**2**)-(**6**) are representative examples of acids obtained in high enantiomeric purity.[7-11] Alternatively, racemic carboxylic acids have been resolved by covalent derivatization with (**1**) and separation of the

resulting diastereomeric amides by physical means such as chromatography (eq 1)[12] or fractional crystallization (eq 2).[13]

(2)

(3)

(4)

(5)

(6)

(2)

Racemic compounds other than carboxylic acids have also been resolved by reaction with enantiomerically pure (**1**) and separation of the corresponding diastereomeric mixtures by physical methods. For example, reaction of a racemic β-substituted γ-butyrolactone with (**1**) yields a mixture of hydroxy amides, which can be separated by fractional recrystallization and chromatography (eq 3).[14] Amide hydrolysis regenerates the chiral hydroxy acids, which spontaneously cyclize to produce the chiral lactones.

(3)

The displacement of a variety of leaving groups by (**1**) produces diastereomeric mixtures of amines, which can be separated into diastereomerically pure secondary amines and, following reductive removal of the α-methylbenzyl

group, serve as a source of chiral primary amines (eq 4).[15]

Reagent for the Determination of Enantiomeric Purity of Carboxylic Acids.

Amine (**1**) is frequently used as a derivatizing reagent for determining the enantiomeric purity of carboxylic acids by HPLC, with limits of detection often as low as 1%. Most commonly used coupling methods include use of dehydrating agents such as ***1,3-Dicyclohexylcarbodiimide*** (eq 5)[16] and the mixed anhydride method (eq 6).[17]

Stereospecific Reactions of Carbonyl Compounds.

One of the most frequent uses of both enantiomers of reagent (**1**) is in promoting the stereospecific reaction of

carbonyl compounds via the corresponding chiral imines. The transfer of chirality from (**1**) to the newly formed bonds is generally most effective in cyclization reactions. Some examples are the Lewis acid-catalyzed cyclization of o-unsaturated aldehyde imines to produce amines of high enantiomeric purity (eq 7),[18] the enantioselective synthesis of γ,δ-unsaturated aldehydes via the aza-Claisen rearrangement of derivatives of (**1**) (eq 8),[19] and the asymmetric Lewis acid-catalyzed aza-Diels-Alder reaction of aldehyde imines with electron-rich dienes (eq 9).[20]

Enantiomerically pure disubstituted β-lactams are also available by cyclization of acyclic intermediates containing (**1**) as a chiral appendage, which is later removed by catalytic hydrogenation (eq 10).[21]

Examples of highly stereoselective acyclic reactions include the Zr-mediated coupling of aldehydes with imines of (**1**) to produce chiral amino alcohol derivatives (eq 11),[22] and the addition of cyanide to aldimines of (**1**) to yield intermediates that can be elaborated into enantiomerically pure α-amino acids (eq 12).[23]

Another frequent use of (**1**) and its enantiomer is the stereospecific conjugate addition of carbonyl compounds to α,β-unsaturated systems. Most published examples contain chiral imine derivatives of cyclic ketones, which add to α,β-unsaturated esters and ketones in a highly stereoselective manner (eqs 13 and 14).[24,25] When the ketone is not symmetrically substituted, reaction usually occurs at the most substituted α-position, including those cases where the ketone is α-substituted by oxygen (eq 15).[26] High stereoselectivity can also be achieved when the Michael acceptor is other than an unsaturated ketone or ester, such as a vinyl sulfone (eq 16).[27] Intramolecular variations of this transformation have also been described (eq 17).[28]

(17)

Stereospecific Reductive Amination of Carbonyl Compounds.

Catalytic or chemical reduction of chiral imines derived from (**1**) often proceeds with high diastereoselectivity. Reductive removal of the α-methylbenzyl group yields chiral primary amines (eqs 18 and 19).[29,30]

(19)

Removable Chiral Appendage.

Even in reactions that proceed with moderate stereoselectivity, incorporation of a chiral moiety such as (**1**) frequently provides an opportunity to easily separate diastereomeric products. For example, the introduction of (**1**) into an imidazolone structure allows the easy separation of diastereomers by chromatography. Reductive removal of the chiral appendage and imidazolone hydrolysis provides a synthesis of optically pure α-amino acids (eq 20).[31] In another example, even though the conjugate addition of (**1**) to methyl crotonate proceeds with low stereoselectivity, the diastereomeric conjugates are easily separated by chromatography and elaborated to provide optically active β-amino esters (eq 21).[32] Similarly, cycloaddition of the aldimine of (**1**) with a substituted ketene produces a mixture of β-lactams, which can be separated by chromatography as a source of optically active β-lactams (eq 22).[33]

Miscellaneous Uses.

Substituted derivatives of (**1**), e.g. (**7**), react with α,β-unsaturated carbonyl systems in a highly stereoselective manner to produce chiral β-aminocarbonyl compounds.[34] The lithium amides of a different type of substituted derivatives, e.g. (**8**), have been used to deprotonate symmetrical ketones, usually cyclic, in a highly stereoselective manner.[35]

(metalation generates azadienolate anions which undergo α-alkylation and cycloaddition with electron-deficient alkenes and alkynes; alkylation and hydrolysis gives α-alkyl-α-methyl amino acids; cycloaddition affords 3-pyrroline- and pyrrolidine-2-carboxylates; ketenes and 2-(ethoxycarbonyl)allylzinc bromide add to the imine to form β-lactams and α-methylene-γ-lactams, respectively)

Physical Data: L-(**1**) bp 84 °C/0.04 mmHg. L-(**2**) bp 100 °C/0.3 mmHg.

Preparative Methods: prepared by condensation of benzaldehyde with the alkyl alaninate ester hydrochloride[1,2] in the presence or absence of dehydrating agents (molecular sieves or Na_2SO_4).[36,41] For example, a solution of triethylamine (30.3 g, 0.3 mol) in CH_2Cl_2 is added slowly to a suspension of alanine methyl ester hydrochloride (41.8 g, 0.3 mol) and freshly distilled benzaldehyde (31.8 g, 0.3 mol) in CH_2Cl_2 cooled to 0 °C. The reaction mixture is stirred overnight at rt. The product is isolated and distilled under reduced pressure to give 46 g (80%) of the imine.

Handling, Storage, and Precautions: although stable at rt, the compound is normally stored under argon at 0 °C.

α-Alkylation: Synthesis of α-Methyl α-Amino Acids.

Benzaldimine esters of alanine are versatile alanine anion synthons. The protected alaninates can be deprotonated with a variety of bases (typically ***Lithium Diisopropylamide***, ***Lithium Hexamethyldisilazide***, or ***Potassium t-Butoxide*** in THF at -

78 °C, or ***Potassium Carbonate*** or ***Potassium Hydroxide*** at rt in the presence of PTC) (eq 1). The anion reacts regiospecifically with alkyl halides (low enantiometric excess of ~16-50% is obtained with asymmetric PTC),[16] carbonyl derivatives, or Michael acceptors to yield, after deprotection, α-methyl α-amino acid analogs. Numerous examples of this methodology have been reported (Table 1). The adducts can be either purified by distillation in vacuo or directly hydrolyzed in acidic medium to the corresponding free amino acid analogs.

γ-Alkylation.

An abnormal alkylation in the γ-position is observed with hindered α-bromo esters (eq 2).

Preparation of 3-Pyrrolines and Pyrrolidines.

N-Benzylidenealaninate anions react with alkenes and alkynes bearing electron-withdrawing groups to give [2 + 3] adducts. The reaction proceeds in good yield through a Michael addition of the α-anion followed by cyclization on the imine to give the 3-pyrroline and pyrrolidine derivatives (eq 3).

Generally, the addition is carried out in refluxing toluene or xylene[2-5,18-22,31] and the 5-*endo-trig* cyclization adducts[26] are formed; the *endo* product is usually the major isomer. The *endo*:*exo* ratio varies from 2.3:1 to 6.9:1 for the monocyclic products. Only the *endo* isomer is observed for the bicyclic pyrrolidines.[22] The use of more polar solvents (acetonitrile, THF, CH_2Cl_2)[24,25,29] with nitrogen bases (***Triethylamine***, ***1,8-Diazabicyclo[5.4.0]undec-7-ene***)[25] and metal ions (Ag, Li, Zn, Mg)[16,23-25,29,33] increases the rate of the reaction and also the amount of *endo* adduct, which in some cases is the sole isomer formed.[24,29,33] The use of stronger bases (***Sodium Hydride***,[30] benzyltrimethylammonium methoxide[26]) yields mixtures of *endo* and *exo* adducts. Phenyl vinyl sulfone in DMSO containing NEt_3-LiOAc[28] gives a 3:10 mixture of *endo* and *exo* adducts. The Ti^{IV} salts (***Chlorotitanium Triisopropoxide***, ***Dichlorotitanium Diisopropoxide***)[27,32] of methyl *N*-benzylidenealaninate anions give a γ-cycloaddition adduct with methyl acrylate (eq 4).

(4)

Preparation of 3-Substituted 4-Phenyl-2-azetidinones (β-Lactams).

N-Benzylidenealaninates react with ketenes (generated in situ by treatment of the corresponding acid chloride with triethylamine) to give diastereoisomeric mixtures of *cis*-β-lactams (eq 5).[34-37]

(5)

Preparation of γ-Lactams.[38]

Addition of an excess of organozinc reagents derived from 2-(bromomethyl)acrylates to racemic *N*-benzylidenealaninate gives the corresponding α-methylene-γ-lactams as racemic mixtures. If the pure (*R*) or (*S*) isomer of the imine is used, only one enantiomer (*RR*) or (*SS*) of the α-methylene-γ-lactam is obtained with ee >95% (eq 6).

(6)

N-Oxidation: Synthesis of Oxaziridines and Nitrones.[39]

N-Oxidation of the imine by ***Monoperoxyphthalic Acid*** affords oxaziridines, which rearrange to nitrones by acid catalysis (eq 7).

(7)

Methylbis(methylthio)sulfonium Hexachloroantimonate[1]

[56648-69-2] · $C_3H_9Cl_6S_3Sb$ · Methylbis(methylthio)sulfonium Hexachloroantimonate · (MW 475.78)

(methylthiolating agent for several functional groups;[1] can induce cyclization of functionalized alkenes and alkynes[1])

Physical Data: mp 123-125 °C (dec).

Solubility: sol CH_2Cl_2, SO_2; reacts with H_2O, protic solvents, acetone, and other enolizable carbonyl derivatives.

Analysis of Reagent Purity: ^{1}H NMR spectrum at -50 °C in CD_2Cl_2 of the pure compound shows two signals at δ 3.6 and 3.0 with an intensity ratio 1:2.[2] At higher temperature in this solvent, as well as in other solvents (SO_2,[3] CD_3CN[4]), a single coalescence line is observed. This behavior is due to trace amounts of dimethyl disulfide impurities.[3]

Preparative Methods: to an ice cooled solution of ***Antimony(V) Chloride*** (7.85 mmol) in anhydrous CH_2Cl_2 (5 mL), a solution of ***Methanesulfenyl Chloride*** (7.85 mmol) and ***Dimethyl Disulfide*** (7.85 mmol) in CH_2Cl_2 (10 mL) is added dropwise. The product partially precipitates from the solution. Addition of *n*-pentane causes complete precipitation of the hexachloroantimonate salt. The product (95% yield) is isolated by filtration in a dry box and can be used without any further purification.[3] Alternatively, to a well-stirred solution of dimethyl disulfide (0.1 mol) in dry CH_2Cl_2 (50 mL) is dropped at 0 °C a solution of $SbCl_5$ (0.1 mol) in dry CH_2Cl_2 (50 mL). After completion of the addition the salt starts crystallizing as yellowish needles. Addition of dry Et_2O completes the precipitation of the product (92% yield).[4]

Purification: crystallization by solution in dry CH_2Cl_2 and addition of dry *n*-pentane or Et_2O.

Handling, Storage, and Precautions: stable for some months if stored in the refrigerator; sensitive to moisture, protic solvents, and enolizable carbonyl compounds.

Functional Group Methylthiolation.

The main feature of methylbis(methylthio)sulfonium hexachloroantimonate ($Me_3S_3SbCl_6$) is the easy transfer of a methylsulfenylium ion to a variety of functional groups more nucleophilic than the sulfur of dimethyl disulfide. The low nucleophilicity of the disulfide and of the hexachloroantimonate ion allows the isolation, or the characterization, of positively charged reaction products.

The methylthiolation of dialkyl or cyclic sulfides with $Me_3S_3SbCl_6$ proceeds smoothly at 0 °C in CH_2Cl_2 and gives methylthiosulfonium salts in good yields (60-80%).[5] Methylthiosulfonium salts can also be prepared by methylation of disulfides with trimethyloxonium salts.[6] However, the latter method cannot be applied to the synthesis of methylthiosulfonium salts derived from cyclic sulfides (eq 1). The reaction of $Me_3S_3SbCl_6$ with diphenyl sulfide gives an almost equimolar mixture of 4-methylthiodiphenyl sulfide and 4,4´-bis(methylthio)diphenyl sulfide (eq 2).[2] Other examples of methylthiolation of aromatic substrates have been reported.[7]

(1)

(2)

The reaction of $Me_3S_3SbCl_6$ with alkenes[8-12] and alkynes[13-16] gives thiiranium and thiirenium ions respectively. Depending on the structure of the unsaturated derivatives and reaction conditions, the three-membered ring sulfonium ions can be spectroscopically characterized or isolated as stable hexachloroantimonate salts. Some examples are shown in eqs 3-6. It is important to note the formation of only *trans,trans*-1-methylthiiranium salts from (*Z*)-alkenes[8,10,11] (eq 3) and the rearrangement of *cis,trans*-1-methyl-2,3-di-*t*-butylthiiranium ion to a thietanium ion (eq 4).[10,11] Dialkylacetylenes give thiirenium ions which are stable at low temperature in SO_2 solution. The presence of bulky alkyl residues makes these ions stable enough to be isolated at rt as hexachloroantimonate salts (eq 5).[14,16] Arylalkylacetylenes undergo addition of the Me_3S_3 residue to the triple bond (eq 6).[17] The characteristic reactivity of

thiiranium and thiirenium ions implies attack at ring carbons by nucleophiles with ring opening.[1] Nucleophiles also attack the sulfonium sulfur;[1] however, this reaction is masked sometimes by its reversibility.

Cyclofunctionalization of Alkenes and Alkynes.

The nucleophilic ring opening of thiiranium and thiirenium ions has been exploited for the synthesis of functionalized heterocycles using $Me_3S_3SbCl_6$ and suitably substituted alkenes and alkynes (eqs 7-13).[7,18-23]

Methyl Bis(2,2,2-trifluoroethoxy)phosphinylacetate

[88738-78-7] · $C_7H_9F_6O_5P$ · Methyl Bis(2,2,2-trifluoroethoxy)phosphinylacetate · (MW 318.13)

(Horner-Emmons reagent for the production of α,β-unsaturated esters with (*Z*) selectivity)

Alternate Name: bis(2,2,2-trifluoroethyl) (methyoxycarbonylmethyl)phosphonate

Physical Data: d 1.504 g cm^{-3}.

Solubility: sol THF, DME, CH_2Cl_2.

Form Supplied in: oil; widely available.

Preparative Methods: prepared by reaction of methyl dichlorophosphonoacetate with trifluoroethanol in benzene.

Purification: silica gel chromatography.

Handling, Storage, and Precautions: irritant.

Modified Wittig Reagent.

The Horner-Emmons reaction carried out by reacting methyl bis(trifluoroethoxy)phosphinylacetate with an aldehyde in the presence of a strongly dissociated base system yields α,β-unsaturated esters with a strong preference for the (*Z*) geometry. The reaction is not overly sensitive to the type of aldehyde used. Examples are shown in eqs 1-3.[1,2]

(1)

(2)

(3)

The strongly dissociated base system is necessary to maximize the (*Z*) selectivity of the alkenation reaction (see eq 4).[1,3]

(4)

In general, the reagent is slow to react with ketones, especially aryl ketones, providing little or no reaction (eq 5).[4] The majority of references to this reagent involve aldehydes as the coupling partner.[5]

Other Uses.

The anion of methyl bis(trifluoroethoxy)phosphinylacetate can undergo an S_N2 reaction with suitable electrophiles to make a more complex trisubstituted modified Wittig reagent, which can undergo alkenation reactions.[6]

N-Methyl-*N,O*-bis(trimethylsilyl)hydroxylamine

[22737-33-3] · $C_7H_{21}NOSi_2$ · *N*-Methyl-*N,O*-bis(trimethylsilyl)hydroxylamine · (MW 191.47)

(bis-trimethylsilylated *N*-methylhydroxylamine;[1-3] can convert aldehydes and ketones to *N*-methyl nitrones with regio- and chemoselectivity;[3] source of methylnitrene by pyrolysis;[4,5] source of the trimethylsilyl(methyl)aminyl radical by photolysis[6])

Physical Data: bp 40-41 °C/10 mmHg;[2,7,8] *n*20D 1.4146.[2]

Solubility: sol benzene, toluene, CH_2Cl_2, $CHCl_3$.[2]

Form Supplied in: colorless liquid;[2,8,9] commercially available.

Preparative Method: obtained in 52% yield by reaction of ***N-Methylhydroxylamine*** with ***Chlorotrimethylsilane*** (2.0 equiv) and ***Triethylamine*** (3.3 equiv) in ether at 25 °C.[1,2]

Handling, Storage, and Precautions: hydrolyzes readily upon exposure to moisture; stored without decomposition for several months in a sealed bottle at -10 to -15 °C;[2] relatively thermally stable, having $t_{1/2}$ of 46.5 h at 140 °C;[4] dec at 180-190 °C.[10]

N-Methyl Nitrone Formation.

Aldehydes or ketones react with a stoichiometric amount of $Me_3SiN(Me)OSiMe_3$ (**1**) in benzene at 50 °C for 24 h to give *N*-methyl nitrones in good to excellent yields (eq 1).[1] For deactivated carbonyl compounds, such as *p*-nitrobenzaldehyde, *p*-(dimethylamino)benzaldehyde, and 2-furaldehyde, addition of ***Trimethylsilyl Trifluoromethanesulfonate*** (0.03-0.04 equiv) as a catalyst is necessary for the formation of *N*-methyl nitrones; otherwise accumulation of hemiaminal intermediates (**2**) occurs. Sequential intra- and intermolecular [3 + 2] cycloadditions can be carried out in situ for substrates containing a C=C or a C=N double bond (eqs 2 and 3).

(2)

(3)

Regio- and Chemoselective Nitrone Formation.

The trimethylsilyl cationic (Me_3Si^+) moiety in $Me_3SiN(Me)OSiMe_3$ serves as a bulky proton,[11] which enables this reagent to react selectively with carbonyl groups having different steric environments. For example, regioselective nitrone formation occurs exclusively at the C-3, instead of the sterically more crowded C-20, carbonyl group in 5α-pregnane-3,20-dione in benzene at reflux (eq 4). Also, $Me_3SiN(Me)OSiMe_3$ preferentially reacts with trimethylacetaldehyde in the presence of acetone to afford the corresponding nitrone. The selectivity offered by $Me_3SiN(Me)OSiMe_3$ is higher than that offered by MeNHOH.HCl (14:1 versus 6:1). $Me_3SiN(Me)OSiMe_3$ reacts preferentially with aldehyde functionality in the presence of chlorides. This is evidenced by the reaction of $Me_3SiN(Me)OSiMe_3$ with 5-chloropentanal (1.0 equiv) in CH_2Cl_2 at reflux to give a nitrone in 79% yield without any substitution product being formed.

Protection of the Carbonyl Group.

For carbonyl compounds containing a second reducible functionality, selective reduction of the latter can be accomplished by protection of the carbonyl group in its hemiaminal form by use of $Me_3SiN(Me)OSiMe_3$. An example is shown in eq 5, in which 4-cyanobenzaldehyde is first treated with 1.3 equiv of $Me_3SiN(Me)OSiMe_3$ to give a hemiaminal intermediate. In situ, 1.2 equiv of a reducing agent are added to afford terephthalaldehyde in 80-93% yields after acidic workup. The applicable reducing agents include $NaBH_4$, Super-Hydride, L-Selectride, K-Selectride, LS-Selectride, BH_3.THF, 9-BBN, DIBAL, Red-Al, and Bu_3SnH.[2] This method provides a way to carry out protection-reduction-deprotection in one flask.

Methylnitrene Formation.

Pyrolysis of $Me_3SiN(Me)OSiMe_3$ at 150 °C gives methylnitrene (Me&NNuml;**:**) through α-deoxysilylation.[4,5] The nitrene intermediate can be trapped by $(MeO)_2MeSiH$ to give the insertion product $(MeO)_2MeSiNHMe$.

Silylalkylaminyl Radical Formation.

Irradiation of $Me_3SiN(Me)OSiMe_3$ with 260-340 nm UV light gives the trimethylsilyl(methyl)aminyl radical (Me(Me_3Si)N&bdot;).[6] This radical is more reactive than the Me_2N&bdot; radical and can be trapped by use of trialkyl phosphites to afford phosphoranyl radicals, such as &bdot;$P(OEt)_3N(Me)SiMe_3$.

10-Methyl-10-bora-9-oxabicyclo[3.3.2]decane

[99966-26-4] · $C_9H_{17}BO$ · 10-Methyl-10-bora-9-oxabicyclo[3.3.2]decane · (MW 152.07)

(air-stable methylating agent via Suzuki-Miyaura coupling[1])

Physical Data: bp 50 °C/3 mmHg.[1,2]

Solubility: sol organic solvents; insol water.[2]

Analysis of Reagent Purity: can be isolated in pure form and analyzed efficiently by GC or standard spectroscopic techniques (e.g. ^{11}B NMR ($CDCl_3$) δ 54.7 ppm).[2]

Preparative Methods: a one-pot sequence (57%) from *B*-MeO-9-BBN by reaction with MeLi in Et_2O at -78 °C, followed by ***Trimethylamine N-Oxide*** (TMANO) (1 equiv) in CH_2Cl_2 at 0 °C.[1] Alternatively, the intermediate *B*-Me-9-BBN can be isolated and oxidized with TMANO in $CHCl_3$ at 0 °C to afford the reagent (81%).[2]

Handling, Storage, and Precautions: indefinitely stable at 25 °C when stored under a nitrogen atmosphere; it can also be handled in the open atmosphere for brief periods of time without significant decomposition. Its preparation involves the handling of dangerously pyrophoric or flammable reagents (i.e. *B*-Me-9-BBN, *B*-MeO-9-BBN, MeLi). Individuals should thoroughly familiarize themselves with the special handling techniques required for such reagents prior to their use.[3]

Methylation via Suzuki-Miyaura Coupling.

The highly efficient oxidation of *B*-alkyl-9-BBN derivatives with TMANO leads to the exclusive formation of 10-alkyl-10-bora-9-oxabicyclo[3.3.2]decanes which are remarkably resistant to further oxidation compared to other borinate esters (eq 1).[2] This feature provides alkylboranes which are particularly convenient to handle while still undergoing useful carbon-carbon bond-forming reactions such as Pd-catalyzed cross coupling with alkenyl, alkynyl, and aryl bromides under basic conditions. The process occurs with retention of configuration in the case of the vinyl bromides, and *gem*-dibromides are efficiently dimethylated (eq 2).[1]

Methyl Bromoacetate

(**1**; R = Me)

[96-32-2] · $C_3H_5BrO_2$ · Methyl Bromoacetate · (MW 152.98) (**2**; R = Et)

[105-36-2] · $C_4H_7BrO_2$ · Ethyl Bromoacetate · (MW 167.01)

(forms a variety of enolates; the bromine atom is readily substituted by nucleophiles; undergoes carbonyl substitution reactions)

Physical Data: (**1**) bp 51-52 °C/15 mmHg; *d* 1.616 g cm^{-3}; *n*20D 1.4580. (**2**) bp 58-59 °C/15 mmHg; *d* 1.506 g cm^{-3}; *n*20D 1.4489.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; widely available.

Purification: vacuum distillation; decomposes upon distillation at atmospheric pressure.

Handling, Storage, and Precautions: corrosive lachrymator, irritating to eyes and respiratory system; should be used only in a chemical fume hood.

Formation of Enolates.

The reagent reacts with zinc metal to produce a zinc enolate (**3**) (eq 1) which is usually trapped in situ by aldehydes or ketones to produce β-hydroxy esters (the Reformatsky reaction).[1] Similar redox reactions to form enolates occur with a variety of metals.[1a]

(1)

(3)

Proton removal with alkoxide bases forms α-bromo ester enolates (**4**) (eq 2), which are trapped in situ by aldehydes or ketones to produce glycidic esters (the Darzens condensation).[2] The use of ***Lithium Dicyclohexylamide*** gives excellent yields.[3] Enolates analogous to (**4**) (M = Li) are produced with ***Lithium Hexamethyldisilazide***.[4]

(2)

(4)

Nucleophilic Substitution.

The bromine in methyl bromoacetate is readily substituted by nucleophiles. Substitution with ***Triphenylphosphine***[5] or with trialkyl phosphites[6] produces reagents used for Wittig alkenation reactions. Similar alkenation reagents are obtained with ***Tri-n-butylstibine*** (eq 3),[7] ***Dibutyl Telluride*** (eq 4),[8] and tributylarsine.[9] A wide variety of carbon nucleophiles are alkylated by methyl bromoacetate including ketone[10] and ester enolates,[11] metallo imines,[12] hydrazones,[13] oximes,[14] and metal π-allyls.[15]

(3)

79% (*E*)

(4)

Carbonyl Substitution.

Reaction of methyl bromoacetate with lithium perfluoroalkyls gives good yields of ketones (eq 5), presumably as a result of the stability of the intermediate hemiacetal anion (**5**).[16] Transesterification of methyl bromoacetate can be achieved efficiently with a distannoxane catalyst (eq 6).[17]

(5)

(5)

Methyl 2-Bromo-*N*-(*t*-butoxycarbonyl)glycinate

[135924-45-7] · $C_8H_{14}BrNO_4$ · Methyl 2-Bromo-*N*-(*t*-butoxycarbonyl)glycinate · (MW 268.13)

(reagent for amino acid synthesis)

Solubility: sol THF, CH_2Cl_2.

Form Supplied in: oil.[1]

Preparative Method: ***N-Bromosuccinimide*** bromination of methyl *N*-Boc-glycinate.[2]

Handling, Storage, and Precautions: can be stored at -20 °C for several months. It has to be protected from moisture to avoid hydrolysis. Use in a fume hood.

Reactions under Basic and Neutral Conditions.

Methyl 2-bromo-*N*-(*t*-butoxycarbonyl)glycinate (**1**), is a building block for α-amino acid synthesis.[3] A variety of analogs with different *N*-acyl and ester groups have been obtained in the same manner. The replacement of the bromine with nucleophiles allows the incorporation of side chains at the α-carbon of glycine. Thus with phosphites, α-phosphonyl esters[2,4,5] are accessible, which are converted to (*Z*)-dehydroamino acid derivatives by means of the Horner-Wadsworth-Emmons reaction (eq 1).[6]

(1)

(*E*):(*Z*) = 5:95

When reagent (**1**) is treated with tertiary amines an *N*-acylimino acetate intermediate is formed which smoothly adds organometallic reagents,[7,8] β-dicarbonyl compounds,[7] silyl enol ethers,[7] and other *C*-nucleophiles[9] to the C=N group. In the case of cyclic enamines[10] the addition can be achieved with remarkably high stereoselectivity (eq 2).

>98% de

As illustrated in eq 3, the use of an 8-phenylmenthyl ester enables the diastereoselective addition of Grignard reagents.[11] The difficulties in hydrolyzing the sterically hindered ester can be circumvented by the use of Oppolzer's auxiliary (eq 4).[12] In this case the free amino acid is easily accessible by treatment of the product with ***Boron Tribromide***.

(3)

(4)

Alternatively, enantiopure amino acids can be obtained by enzymatic resolution of the racemic products.[7,13] Thus treatment of 2-acetylamino-4-oxo-4-phenylbutyric acid with hog renal acylase provides the pure L-amino acid in high overall yield (eq 5).[7]

(5)

Reactions under Acidic Conditions.

2-Methoxy- and 2-haloglycinate esters with acid-stable urethane protecting groups can be used for acid-catalyzed amidoalkylations[14] of arenes,[15] vinylsilanes,[16] allylsilanes,[8b,17] and silyl enol ethers.[18] The glycine reagents can be obtained from glyoxylic acid hydrate by condensation with an *O*-alkylcarbamate followed by appropriate transformation of the resulting α-hydroxyglycine derivative. Electrochemical oxidation offers an alternative approach to these compounds.[19] Upon treatment of the α-methoxyglycine reagents with Lewis acids, highly electrophilic *N*-acyliminium intermediates are formed.[20] The scope of this method is illustrated by the stereoselective amidoalkylation of anisole (eq 6)[21] and the Sakurai-type addition of allylsilanes (eq 7).[17]

Radical Reactions.

Treatment of the α-bromo compounds with stannanes in the presence of ***Azobisisobutyronitrile*** induces radical

reactions which lead to the formation of 2-deuteroglycine,[22] 2-allylglycine, and 2-propargylglycine derivatives.[22b,23] Again the reaction with an 8-phenylmenthyl ester proceeds with excellent diastereoselectivity (eq 8).[24]

(8)

The reactions of 2-bromoglycinates with nucleophiles and radicals have recently been extended to peptide derivatives[1,25] and the synthesis of α,α-disubstituted α-amino acids.[17b,26]

Related Reagents.

10-Dicyclohexylsulfonamidoisoborneol; ***Ethyl N-Benzylideneglycinate***; ***Ethyl N-(Diphenylmethylene)-2-acetoxyglycinate***; ***Ethyl N-Benzylideneglycinate***; ***Glyoxylic Acid***; ***Methyl Glyoxylate***; ***(-)-8-Phenylmenthol***.

Methyl 4-Bromocrotonate

(**1**; R = Me)

[1117-71-1] · $C_5H_7BrO_2$ · Methyl 4-Bromocrotonate · (MW 179.02) (*E*)-(**1**)

[6000-00-6] (*Z*)-(**1**)

[56699-18-4] (**2**; R = Et)

[6065-32-3] · $C_6H_9BrO_2$ · Ethyl 4-Bromocrotonate · (MW 193.05) (*E*)-(**2**)

[37746-78-4] (*Z*)-(**2**)

[119011-89-1]

(precursor for Reformatsky reagents;[1-9] alkylating agent;[22-41] 1,4-addition electrophile[42-45])

Alternate Names: methyl 4-bromo-2-butenoate; methyl γ-bromocrotonate.

Physical Data: (**1**) bp 83-85 °C/13 mmHg; *d* 1.4900 g cm^{-3} (19 °C); *n*20D 1.50210. (**2**) bp 99.0-99.5 °C/17 mmHg; *d* 1.3990 g cm^{-3} (23 °C); *n*23D 1.49050.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid as a mixture of (*E*) and (*Z*) isomers. The methyl ester is available commercially.

Analysis of Reagent Purity: NMR, GC.

Preparative Methods: ethyl or methyl crotonate is treated with ***N-Bromosuccinimide***/CCl_4 and ***Dibenzoyl Peroxide***.[18b]

Handling, Storage, and Precautions: handle under nitrogen and in a fume hood. Store refrigerated and tightly closed. **Caution**: harmful material: allergenic, corrosive, lachrymator, and irritant.

Reformatsky and Other Anionic Reactions.

Methyl and ethyl 4-bromocrotonate have been used extensively as Reformatsky reagents. The reaction has been investigated with regard to the issue of alkylative regioselectivity of the allylic organometallic species toward simple aldehydes and ketones (eq 1).[2-8] In general, it is observed that by using ZnCu(HOAc) in ethyl ether, only α-addition occurs, and when Zn (dry) in THF or cyclohexane is used, γ-addition is favored.[3,6,8,9] Yields range between 90-95%.[6] Additional investigations lead to the development of conditions which furnish either the α-1,2 (**3**) (ZnCu(HOAc), Et_2O, 3 min) or the γ-1,4 (**6**) (Zn, THF, 4 h) adducts of α,β-enones.[8] The structure of the electrophile may affect the stereochemical outcome of the reaction as well.[10,11]

(3) α-1,2

(4) γ-1,2

(5) α-1,4

(6) γ-1,4

Other variations in the formation of the organo-Zn compound include the addition of ***Diethylaluminum Chloride***,[12] ***Silver***,[13] ***Boron Trifluoride Etherate***,[14] and ***Dichlorobis(cyclopentadienyl)titanium***.[15] In all cases, the α- or γ-regioselectivity of addition can be controlled, and yields range between 44-99%.

Zn has been replaced by other metallic reagents in the formation of the allylic carbanion. These include ***Cerium/Mercury(II) Chloride***[16] and $Bu_3SnAlEt_2$.[17] The reagents derived from these sources produce α-adducts in 51 and 74% yields, respectively, when treated with methyl 4-bromocrotonate and benzaldehyde, but the conjugated product is isolated from the cerium-mediated reaction. Electrolysis of methyl 4-bromocrotonate and treatment with α,β-unsaturated esters afford exclusively the α-adduct (in a Michael type addition) in 39% yield.[18] When mixtures of an imonium salt and methyl 4-bromocrotonate are subjected to electroreduction, Reformatsky-type products are obtained, in which only the γ-adducts form (93% yield).[19] The same results are obtained when the Reformatsky reaction is performed with Zn and imonium salts in acetonitrile (90% yield).[20]

When treated with the hindered base potassium 2,6-di-*t*-butylphenoxide, ethyl 4-bromocrotonate yields the α-bromo anion, which, in the presence of trialkylboranes, results in alkyl transfer and (upon workup) deconjugation of the alkene in 72-89% yields.[21]

Bromide Replacement.

Many examples of the direct replacement of the bromide from ethyl or methyl 4-bromocrotonate have been reported. Thus the 4-bromocrotonate esters undergo substitution at C-4 with aryltributylstannanes (catalyzed by palladium, 71-91% yield),[22] arenetricarbonylchromium anions (58% yield),[23] organomanganese derivatives of 3-sulfolenes (82% yield),[24] diphenylamine or *N*-methylaniline (catalyzed by copper(II) perchlorate and copper metal, 76-94% yield),[25] thiols under basic conditions (71% yield),[26a] and a variety of alcohols with ***Potassium Carbonate*** (83-87% yield).[26b]

Displacement of the bromide in methyl 4-bromocrotonate with allylic inversion (i.e. at C-2) can be achieved with organocopper reagents in 49-61% yields.[27] Mixtures of direct and allylic displacements (27:73, 91% yield) were obtained when alkylzirconium derivatives were used in the presence of ***Copper(I) Cyanide*** as catalyst.[28]

Triethyl phosphite reacts with methyl 4-bromocrotonate via C-4 alkylation. The resulting phosphonate, after deprotonation, serves as a typical Wadsworth-Emmons reagent (with aldehydes), furnishing the extended dienes in 84% yield (initial γ-addition).[29a] Triphenylarsine reacted with ethyl 4-bromocrotonate to yield, under basic conditions, an ylide which displayed Wittig-like reactivity toward ketones and aldehydes (45-95% yields).[29b]

The presence of the α,β-unsaturated ester moiety in ethyl and methyl 4-bromocrotonates makes them attractive as bifunctional electrophiles. In these cases, a cyclization follows the direct alkylation. Thus carbocyclic compounds have been obtained by palladium-catalyzed cyclizations[30] or [4 + 2] cycloadditions.[31] Indoles, isoquinolines, and other nitrogen heterocycles can be formed by palladium-catalyzed cyclizations,[32] oxidative electrocyclizations,[33] [4 + 2] cycloadditions,[34] or Michael additions.[35] Oxygen heterocycles are formed by radical cyclizations,[36] intramolecular 1,4-condensations,[37] palladium-catalyzed cyclizations,[38] [4 + 2] cycloadditions,[34] or Claisen rearrangements.[39] Sulfur heterocycles were formed through a variety of intramolecular cyclizations, all following initial sulfur alkylation at C-4.[40] Morpholines were prepared by intramolecular 1,4-cycloadditions.[41]

1,4-Additions and Subsequent Cyclopropane Formation.

When nucleophiles such as lithium alkylthiolates,[42] lithium ester enolates,[43] sulfur-containing carbanions,[44] or cross-conjugated lithium enolates[45] react with ethyl or methyl 4-bromocrotonate in a conjugate fashion, a ring closure by attack of the resulting enolate on C-4 follows to form the corresponding cyclopropanes. In some cases the direct substitution of the bromide is a competitive reaction.[42,43a]

(vinyl cyclopropanation/oxiranation reagent;[1,2] bisannulating agent[3a])

Alternate Names: methyl 2-bromo-2-butenoate; methyl α-bromocrotonate.

Physical Data: (**1**) bp 61 °C/9 mmHg; *d* 1.5064 g cm^{-3} (17 °C); *n*17D 1.48700. (**2**) bp 69-70 °C/12 mmHg; *d* 1.3952 g cm^{-3} (18.4 °C); *n*18D 1.47660.

Solubility: sol most organic solvents.

Form Supplied in: light yellow liquid as a mixture of (*E*) and (*Z*) isomers. The methyl ester is available commercially.

Analysis of Reagent Purity: NMR, GC.

Preparative Methods: ethyl or methyl crotonate is treated with Br_2/CCl_4 or Br_2/AcOH followed by dehydrobromination with quinoline[2] or DBU.[1]

Handling, Storage, and Precautions: handle under nitrogen in a fume hood; these reagents are moisture sensitive. Store refrigerated and in brown bottles to avoid polymerization. Caution: lachrymator and irritant; may be harmful.

Vinylcyclopropanation/Oxiranation Reagents.

The lithium dienolate of ethyl 2-bromocrotonate, formed upon low temperature addition to ***Lithium Diisopropylamide***, was reacted with enones to yield vinylcyclopropanes as *endo* and *exo* isomer mixtures (eq 1).[1,4] The *endo*/*exo* ratio was variable, and independent of the (*E*/*Z*) ratio of the starting ethyl bromocrotonate.

Yields of isolated products varied from 30 to 90%, depending on the enone. Thermal rearrangement of these vinylcyclopropanes afforded cyclopentene annulated systems (eq 2).[1,4,5]

This method was successfully applied to the synthesis of a number of natural products, including pentalenene (**3**)[6] (nonlinear sesquiterpene) and retigeranic acid (**4**)[1,7] (sesterterpene).

(3) Pentalenene

(4) Retigeranic acid

Reaction of the lithium dienolate of ethyl 2-bromocrotonate, with aldehydes as the electrophiles, furnished vinyloxiranes[2] in yields ranging from 47 to 70%. Only one stereoisomer (*anti*) was formed (eq 3). Aldehydes were, in general, more reactive than ketones. The vinyloxiranes were subjected to pyrolysis to afford the corresponding dihydrofurans in 7-95% yield (eq 3).[2] This method was applied to the synthesis of the natural product ipomeamarone (**5**).[8]

(5) Ipomeamarone

Bisannulation Reactions.[9]

Addition of a cross-conjugated dienolate to methyl 2-bromocrotonate resulted in double Michael addition, followed by alkylation. In the case of 2-cyclohexenone, the formation of the tricyclic system shown in eq 4 was accomplished in a one-step synthesis.[3] Yields ranged between 25 and 55%.

(4)

Natural products ishwarane (**6**)[10] and helminthosporal (**7**)[11] were prepared using this methodology.

(6) Ishwarane

(7) Helminthosporal

Use of acetylcyclohexenes as the enone component furnished the tricycle shown in eq 5.[12] Yields varied between 20 and 61%.

(5)

Substitution of Bromine.

Methyl 2-bromocrotonate is a substrate for halogen-metal exchange with ***Lithium Dimethylcuprate***; organocopper reagent (**8**) is the product.[13]

(8)

Reaction of methyl 2-bromocrotonate with ethanethiol produces the 2-ethylthiocrotonate (**9**).[14] When (**9**) is subjected to the bisannulation protocol of eq 4, the reaction stops at the point of the double Michael addition (eq 6).[15] The sulfide product lends itself to further modification (oxidation/elimination).

Methyl (*Z*)-(2)-(Bromomethyl)-2-butenoate

[60941-07-3] · $C_6H_9BrO_2$ · Methyl (*Z*)-(2)-(Bromomethyl)-2-butenoate · (MW 193.05)

(synthon for α-methylene-γ-butyrolactones[1,2] and allylic and vinylic substitution products[3])

Alternate Name: methyl β´-bromotiglate.

Physical Data: bp 68 °C/3 mmHg.[2]

Preparative Methods: allylic bromination of methyl 3-hydroxy-2-methylenebutanoate[4] with ***N-Bromosuccinimide/Dimethyl Sulfoxide***[5] or ***Hydrogen Bromide/Sulfuric Acid***.[2]

Synthesis of α-Methylene-γ-Butyrolactones.

Dreiding was the first to demonstrate that treatment of the title reagent (**1**) and cyclohexanone with zinc in THF gave a 78% yield of the spirocyclohexane α-methylene-γ-butyrolactone (eq 1).[1] When Reformatsky conditions were applied to (**1**) and 2-methylpropanal, a diastereomeric mixture of the *exo*-methylene lactones was obtained (eq 2).[6] In contrast, allylic chromium complexes of the reagent react with aliphatic and aromatic aldehydes to give α-methylene-γ-butyrolactones diastereoselectively in good yields (eq 3).[2] The title reagent (**1**) and an aluminum/tin reagent gave a 54% yield of the uncyclized product which could be cyclized to the lactone in a separate step (eq 4).[2]

(1)

Nucleophilic Displacements.

Both allylic and vinylic products are obtained from the nucleophilic displacement of bromide from the reagent (eq 5).[3] The product distribution is dependent on the nature of the base and nucleophile and in most cases both substitution routes are observed. Attack at the allylic carbon of the reagent (to give **2**) is favored by increasing the steric bulk of the nucleophile and using ***Sodium Ethoxide*** in ethanol as base. For example, when R is hydrogen (eq 5) a 4:1 ratio of normal (**2**) to rearranged (**3**) product is obtained using sodium ethoxide in ethanol. This is reversed to give a 1:4 ratio of (**2**) to (**3**) when ***Sodium Hydride*** in THF is the base-solvent system. When R is benzyl, only allylic product (**2**) is obtained with NaOEt/EtOH and the product distribution of (**2**) to (**3**) is 4:1 with sodium hydride as base.

Natural Product Synthesis.

Zinc-mediated coupling of methyl β´-bromotiglate has been used in the synthesis of necic acid and related compounds.[7] Thus addition of (**1**) to zinc in DMSO gave an 85% yield of the dimer (**4**) (eq 6). In contrast, treatment of (**1**) with ***Magnesium*** in THF gave a mixture of (**4**), (**5**), and (**6**) in a ratio of 11:7:1 (eq 6). Mikanecic acid-type structures can be obtained by treating the reagent with ***Potassium t-Butoxide*** (eq 7).[5] Recently, the reagent has been used as a synthon in the synthesis of kijanolide.[8]

Methyl 2,3-Butadienoate[1]

[18913-35-4] · $C_5H_6O_2$ · Methyl 2,3-Butadienoate · (MW 98.11)

(reactive electrophilic reagents for nucleophilic addition,[2] Michael addition,[3,4] [2 + 2],[5,6] [2 + 3],[7,8] and [2 + 4][9,10] cycloadditions, and hetero-Cope rearrangements[4])

Physical Data: bp 40 °C/14 mmHg.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: IR (film): 1965/1940, 1725 cm^{-1}; ^1H NMR (CCl_4): 5.65-5.35 (H-C(2)), 5.25-5.00 (2H-C(4)), 3.68 ppm (OMe).

Preparative Methods: most conveniently obtained via a Wittig reaction of $[E(R)CHPPh_3]^+X^-$ or $E(R)C{=}PPh_3$ and RR´CHCOCl (R, R´ = H, alkyl) in the presence of ***Triethylamine*** in CH_2Cl_2.[1] Alternatively, the Wittig reaction can be performed with the corresponding ketenes.[11]

Purification: rapid distillation under reduced pressure in a short-path distillation apparatus or column chromatography on Alox N with hexane/Et_2O (9:1). Hydroquinone may be added for distillation.

Handling, Storage, and Precautions: can undergo polymerization and so should be stored in the presence of hydroquinone. For best results, it should be freshly distilled. Use in a fume hood.

Preparation of Substituted 2,3-Butadienoates.

The method described above also works with α,β-unsaturated acid chlorides to yield 4-vinyl substituted 2,3-butadienoates[12] and may likewise be applied as a ring closure procedure for the synthesis of endocyclic allenelactones.[10] Alternative methods for the synthesis of 2,3-butadienoates and analogs include the Pd^0-catalyzed carbonylation of propargylic carbonates[13] and halides.[14] In the presence of acrylates instead of CO, vinyl analogs of allenic esters are obtained.[15] 2-Substituted 2,3-butadienoates are available from the Wittig reaction of corresponding

phosphoranes or phosphonates with ketenes[11,16,17] or by the oxidative degradation of 3,4-substituted pyrazol-3(2*H*)-ones with Tl^{III} salts[9,18] or ***(Diacetoxyiodo)benzene***.[19] 2-Phenyl-substituted 2,3-butadienoates have been prepared by a combined photolysis of trimethoxy-(1-methoxycarbonylbenzylidene)phosphorane and cyclohexanones in benzene.[20] Dimethyl 2,3-pentadienedioate can be prepared in three steps from diethyl acetone-1,3-dicarboxylate.[21]

Addition of Nucleophiles.

Nucleophiles add to 2,3-butadienoates and their analogs at the C-3 position.[22-24] The addition of primary or secondary amines leads to the formation of β-amino acrylates,[2a,3,25,26] which, on hydrolysis, yield β-keto esters (eq 1).[3] In a similar manner, β-azido crotonates can be synthesized which are photolytically transformed into 2*H*-azirine-3-carboxylates.[27] ***Triphenylphosphine*** adds to 2,3-butadienoates under acid catalysis to yield the corresponding phosphonium salts which, on treatment with MeONa/MeOH, form (*E*)-4-methoxy-2-butenoates (eq 2).[28,29] The methylation of ethyl 2,3-butadienoate at C-3 with ***Lithium Dimethylcuprate*** at -90 °C was utilized in the synthesis of lavandulol.[30]

Grignard reagents add in the same way to allenecarboxylic acids.[31] Blechert showed that ethyl 2,3-butadienoate reacts with the Li salt of *N*-acetyl-*N*-phenylhydroxylamines to yield, via a hetero-Cope rearrangement, ethyl 4-(2-

acetamidophenyl)-3-oxo-butanoates which undergo indolization upon treatment with ***Formic Acid*** (eq 3).[4]

Cycloadditions.

[2 + 2] Cycloadditions of 2,3-butadienoates with simple alkenes, promoted by ***Ethylaluminum Dichloride***[5] or ***Aluminum Chloride***,[6] take place at the C(3)=C(4) double bond without loss of the stereochemical integrity of the alkenes and lead to the formation of the corresponding cyclobutylideneacetates (eq 4). Conjugated imines seem to add to ethyl 2,3-hexadienoate in a similar manner when heated to reflux in benzene.[32] The azetidines which are formed primarily rearrange to yield 2-cyclohexenones after hydrolysis.

(4)

[2 + 3] Cycloadditions of 2,3-butadienoates and analogs have been investigated with nitrilium betaines (nitrile ylides,[7,33] nitrile imines,[34] nitrile oxides[34]), diazonium betaines (diazoalkanes,[35] azides[34]), and nitrones.[8,36] All 1,3-dipolar cycloadditions occur at the C(2)=C(3) double bond, but often regioisomers are formed. The cycloadducts may isomerize (spontaneously or with base catalysis) to yield the corresponding heteroaromatics (eq 5). Nitrones react smoothly with methyl 2,3-butadienoate and its 2-methyl derivative to yield regioselectively 5-methyleneisoxazolidines which, on heating, may undergo a 1,3-H shift or a skeletal rearrangement to the corresponding 3-pyrrolidones (eq 6).[8,37]

(5)

(6)

[4 + 2] Cycloadditions with allenecarboxylates as dienophiles have also been studied.[9,22,23] Thermal reaction with cyclopentadiene leads to the formation of *endo*- and *exo*-3-methylenebicyclo[2.2.1]hept-5-ene-2-carboxylates in a ratio of ca. 2:1.[9] The addition of $AlCl_3$[9] or $M(fod)_3$ (M = Eu, Pr)[38,39] allows the cycloaddition to be carried out at lower temperatures and with higher *endo*/*exo* ratios. The cycloaddition with furan as diene can also be catalyzed by $M(fod)_3$ and leads also to a predominance of the *endo* product.[40] Synthetically valuable [4 + 2] cycloadditions of 2,3-butadienoates and analogs with ***1,1-Dimethoxy-3-trimethylsilyloxy-1,3-butadiene*** have been performed by Gerlach and co-workers[10] and applied to the synthesis of (+)-(*R*)-lasiodiplodin (eq 7).

3-Methyl-3-buten-1-ynylcopper(I)[1]

[56964-06-8] · C_5H_5Cu · 3-Methyl-3-buten-1-ynylcopper(I) · (MW 128.65)

(coupling agent for introduction of the isopropenyl group;[2] nucleophilic species which effects decarbonylative ring contraction of bicyclic lactones[3])

Alternate Name: copper(I) isoprenylacetylide.

Physical Data: bright yellow solid; mp 120-200 °C (dec);[2] IR (KBr) 3095, 3003, 2970, 2921, 1932, 1603, 1440, 1428, 1380, 1363, 1255, 895, 878, 709, 552, 525 cm^{-1}.[4]

Solubility: sol pyridine, DMF, ethanol; insol water.

Preparative Method: ***Hydroxylamine*** hydrochloride reduction of ***Copper(II) Sulfate*** in aq ammonium hydroxide followed by addition of isopropenylacetylene in ethanol.[2] *Drying:* solid dried under P_2O_5 in vacuo.

Handling, Storage, and Precautions: all solid copper(I) acetylides are potentially explosive. Use in a fume hood.

Coupling Reactions.

Organocuprates such as isopropenylcopper alkynes couple to a variety of electrophiles (see also ***1-Hexynylcopper(I)***, ***1-Pentynylcopper(I)***, ***Phenylethynylcopper(I)***). The couplings, typically performed on aryl and vinyl iodides and bromides, give rise to substituted alkynes, which in one report included products of the dienyne class (eq 1).[5]

(1)

Coupling onto aryl iodides is one of the more studied reactions, due to its importance in the synthesis of natural product systems. A representative example is seen in the synthesis of frustulosin, a tetrasubstituted aromatic natural product (eq 2).[6]

(2)

Isolation of the disubstituted alkynic product is often not possible where an *o*-hydroxy group is present. Instead, concomitant cyclization to yield benzofuran-type structures usually ensues under the reaction conditions.[7] Numerous examples have been documented.[2,8-10] Often, heavily functionalized molecules do not pose any problem to the sequence, yielding complex heterocycles (eq 3).[11]

(3)

The requirement for an *o*-hydroxy group is not strict, as phenolic derivatives such as acetates[12,13] and even methyl ethers[14] have been shown to yield the corresponding cyclized benzofurans under the harsh reaction conditions, which typically involve thermolysis either in refluxing pyridine or quinoline.[12-14] Thus thermolysis of an *o*-iodo diacetate in pyridine yields a benzofuran (eq 4), an intermediate which was used in the synthesis of the dibenzofuranoid *Cannabis* constituents cannabifuran and dehydrocannabifuran.[15]

(4)

Nucleophilic Displacements.

Copper isopropenylacetylide can behave as a simple nucleophile under certain circumstances, effecting decarbonylative ring contractions (eq 5).[3]

(5)

The benzofuran product would presumably not be accessible via the traditional tolane cyclization route due to competing reactions at the bromo site.[9]

[63847-45-0] · C_5H_9BrMg · 3-Methyl-2-butenylmagnesium Bromide · (MW 173.35)

(terpene synthesis)

Alternate Names: chloro(3-methyl-2-butenyl)magnesium; prenylmagnesium chloride.

Physical Data: ^{13}C NMR solution data have been reported.[2]

Solubility: sol ether, THF.

Purification: solutions should be titrated before use by one of the standard methods.

Preparative Methods: prepared in situ under an inert atmosphere from prenyl chloride and an excess of magnesium in ether[3] or in THF.[4]

Handling, Storage, and Precautions: is air- and moisture-sensitive and is best stored at -20 °C under argon.

Grignard Synthesis.

The reagent is prepared by slow addition at 5 °C of 1.0 equiv of prenyl chloride in THF to 1.2 equiv of ***Magnesium*** turnings in the same solvent (350 ml per mol of the chloride). The reaction is initiated at 25 °C. The yield is estimated to be 90%.[4] The reagent appears to be a σ-bonded structure with the metal attached to the primary carbon. The internal isomer (metal bonded to the tertiary carbon) is present in low concentration. Structural changes to the reagent immediately prior to the reaction cannot be ruled out.[2]

Prenylation of Allylic Functional Groups.[5-7]

The copper(I)-catalyzed addition of prenylmagnesium chloride (**1**) to allylic chlorides leads in good yield and in high selectivity to the product of γ-attack (eq 1).[5]

(1)

Similar reactivity is observed for the copper(I)-catalyzed displacement of allylic phosphonates by (**1**) (eq 2).[6]

(2)

In the absence of copper(I), S_N2 displacement of allylic phosphonates by (**1**) takes place at the tertiary carbon of the nucleophile (eq 3). Bidentate complexation of two of the phosphate oxygen atoms with the metal is postulated to take place.[7]

Addition Reactions.

Addition of (**1**) to aldehydes[8] and ketones[9] also takes place at the tertiary carbon with excellent selectivity. The trend is reversed in acylsilanes, particularly those with bulky isopropyl groups on silicon.[8,10] This tendency is reinforced by substituting (**1**) for prenylzinc bromide. In general, the copper(I)-catalyzed addition reactions of (**1**) occur at the primary carbon. For example, the copper(I)-catalyzed ring opening of ***Epichlorohydrin*** by (**1**) takes place at the primary carbon of the nucleophile.[11]

The addition of (**1**) to 3,3-dimethylcyclopropene, followed by trapping of the intermediate cyclopropyl organometal by ***Carbon Dioxide***, constitutes an effective approach to chrysanthemic acid analogs.[12] The ***Dichlorobis(cyclopentadienyl)titanium***-catalyzed addition of (**1**) to ***Isoprene*** also takes place at the tertiary carbon, and is regioselective with respect to both nucleophile and isoprene. Trapping of the intermediate organometal with carbon dioxide produces carboxylic acid (**2**) in excellent yield (eq 4).[13]

Related Reagents.

Allylmagnesium Bromide; ***Crotylmagnesium Bromide***; ***Methallylmagnesium Chloride***.

2-(3-Methylbutoxy)-1,3-benzodithiolane[1]

(**1**; R = $CH_2CH_2CHMe_2$)

[55315-56-5] · $C_{12}H_{16}OS_2$ · 2-(Methoxyethoxyethoxy)-1,3-benzodithiolane · (MW 240.42) (**2**; R = *n*-C_3H_7)

[55315-54-3] · $C_{10}H_{12}OS_2$ · 2-Propoxy-1,3-benzodithiolane · (MW 212.36) (**3**; R = *n*-C_4H_9)

[55315-55-4] · $C_{11}H_{14}OS_2$ · 2-Butoxy-1,3-benzodithiolane · (MW 226.39) (**4**; R = $CH_2CH_2OCH_2CH_2OMe$)

[131549-15-0] · $C_{12}H_{16}O_3S_2$ · 2-(3-Methylbutoxy)-1,3-benzodithiolane · (MW 272.42)

(reagent for synthesis of 2-substituted 1,3-benzodithiolanes by substitution of the 2-alkoxy group by various carbon and hetero nucleophiles; 2-lithio-1,3-benzodithiolanes are useful for nucleophilic acylation)

Physical Data: (**1**) pale yellow oil; bp 120-125 °C/0.1 mmHg. (**2**) bp 104-106 °C/0.1 mmHg. (**3**) bp 116-118 °C/0.1 mmHg. (**4**) bp 152-156 °C/0.5 mmHg.

Preparative Methods: prepared[1] by adding dropwise 0.1 L of a solution of ***Anthranilic Acid*** (3 M in dioxane) to a gently refluxing solution of ***Isopentyl Nitrite*** (0.36 M), 3-methylbutanol (0.60 M) and ***Carbon Disulfide*** (0.15 L) in 1,2-dichloroethane (0.8 L). Diazotization of anthranilic acid with isopentyl nitrite generates, beside 1 equiv of 3-methylbutanol, reactive benzyne, which reacts with excess S=C=S to give 1,3-benzodithiole-2-carbene. Reaction of this carbene with 3-methylbutanol, as described by Nakayama,[1] gives 2-(3-methylbutoxy)-1,3-benzodithiolane (**1**) in about 50% yield. This method has been extended to prepare 2-(propoxy)-1,3-benzodithiolanes (**2**) and 2-(butoxy)-1,3-benzodithiolanes (**3**), but the yields are poor. Similarly, when a mixture of freshly prepared diazonium-2-carboxylate (from anthranilic acid, 25.7 g),[3] 2-(2-methoxyethoxy)ethanol (32 mL), CS_2 (63 mL), and CH_2Cl_2 (1.125 L) is allowed to reflux (1.5 h), about 25% yield of 2-[(2-methoxyethoxy)ethoxy]-1,3-benzothiole (**4**) can be obtained readily.[2]

Handling, Storage, and Precautions: dithiolane (**1**) is a stable and easy to handle material at ambient temperature. Thermally, it is unstable, undergoing substantial decomposition during distillation to give mainly 2,2´-bi(1,3-benzodithiolylidene).[4a] Use in a fume hood.

Introduction.

2-(3-Methylbutoxy)-1,3-benzodithiolane (**1**) and other related dithio orthoesters, upon treatment with acetic acid at rt, undergo smooth ionization to generate in situ the resonance-stabilized carbocation intermediate 1,3-benzodithiolium ion (**5**).[4b] Indeed, the propensity to form this 10π-electron aromatic system (i.e. **5**) is so great that treatment of (**1**) with either 42% ***Tetrafluoroboric Acid***[5] or trityl fluoroborate,[6] can be employed to obtain 1,3-benzodithiolium fluoroborate in yields in excess of 95%. Thus (**1**) has become a convenient precursor for the 1,3-benzodithiolium ion (**5**) (eq 1).

Reactions with Nucleophilic Reagents.

Dithiolane (**1**) reacts with nucleophiles, such as *N*,*N*-dialkylarylamines,[4b] polymethoxybenzene,[4b] aliphatic and aromatic thiols,[7a] activated methylene compounds,[7b] indole and pyrrole,[7c] and Grignard reagents, (64-89%)[7d-f] in a predictable manner to give a variety of 2-substituted 1,3-benzodithioles. While (**1**) is unreactive towards phenylethynylmagnesium bromide, the dithio orthoester (**4**) having a chelating group gave the 2-phenylethynyl-1,3-benzodithiole in 55% yield.[2]

1,3-Benzodithiolane Anions as Nucleophilic Acylation Reagents.[7f,8]

The 2-alkyl-1,3-benzodithiolanes are readily lithiated with ***n-Butyllithium*** in THF at -30 °C and the resulting anions may be alkylated with alkyl halides to give 2,2-dialkyl-1,3-benzodithiolanes.[8] This procedure for nucleophilic acylation is completed by hydrolysis to liberate the dialkyl ketones.

Alternatively, the intermediate anion may be efficiently coupled to branched organoboranes, producing hindered ketones or tertiary alcohols by one or two boron-carbon alkyl migrations, as shown in eq 2.[7f]

Reaction with Aqueous Chlorine.

Treatment of (**1**) with aqueous chlorine at or around 0-5 °C gives a highly useful compound, 1,2-benzenedisulfonyl dichloride,[9] in 90-95% yield.

Related Reagents.

1,3-Benzodithiol-1-ium Tetrafluoroborate; ***1,3-Dithiane***; ***2-Lithio-1,3-dithiane***; ***1,1,3,3-Tetramethylbutyl Isocyanide***.

(*R*)-Methyl 2-*t*-Butyl-3(2*H*)-oxazolecarboxylate

[104173-34-4] · $C_9H_{15}NO_3$ · (*R*)-Methyl 2-*t*-Butyl-3(2*H*)-oxazolecarboxylate · (MW 185.25)

(chiral oxazoline with highly reactive double bond;[1-3] chiral derivative of α-hydroxy- or α-aminoacetaldehyde; reactions with acylating reagents,[1a,2] with carbenes,[1a,3] and with electron-poor alkenes;[1a,3] cycloadditions;[1a,3] building block for the synthesis of amino alcohols and aminohydroxy carboxylic acid derivatives[1-3])

Physical Data: bp 70 °C/0.02 mmHg; [α]rtD = +434° (*c* 1, $CHCl_3$).

Solubility: sol all common nonprotic organic solvents.

Preparative Method: the acetal from serine methyl ester and pivaladehyde is *N*-methoxycarbonylated and saponified to give the *cis*-half ester (**2**) (61% yield). Oxidative decarboxylation by electrolysis in AcOH (1:3 by weight) in the presence of 5% Et_3N affords (**3**) (87%), which upon heating with NH_4Br in toluene yields the title oxazoline (**1**) (75% after distillation in vacuo) (eq 1).[4]

Handling, Storage, and Precautions: stable over many months in a freezer under inert atmosphere (N_2 or Ar). Use in a fume hood.

Reactions with Electrophiles at C-4.

(R)-Methyl 2-t-Butyl-3(2H)-oxazolecarboxylate

The oxazoline (**1**) can be metalated on the double bond carbon atom next to the ester group, and the resulting Li derivative coupled with electrophiles (eq 2).[2]

Direct Reactions with Electrophiles at C-5.

Vilsmeier and Friedel-Crafts reactions lead to 5-acyl derivatives (eq 3),[2] which can be further elaborated[3] as indicated in eq 4; a single enantiopure diastereoisomer of the anhydride (**4**) is formed. Seebach and co-workers[3] erroneously assigned (**4**) as arising from an *exo* rather than the *endo* addition.

Cycloadditions.[3]

[2 + 1], [2 + 2], and [4 + 2] cycloadditions with electrophilic reactants such as carbenes (eq 5), tetracyanoethylene (eq 6), and α-keto-β,γ-unsaturated nitriles[5] (eq 7) lead to interesting products which are all enantiopure; see, for instance, the 5-amino-6-hydroxy-2-keto acid (**5**).

Other 2,3-Dihydrooxazoles and -thiazoles from α-Amino Acids.

Table 1 shows oxazolines and thiazolines also prepared from amino acids (serine, threonine, or cysteine), with or without decarboxylation; common to all of them is the conversion of the original stereogenic center to a trigonal center, and chirality due to a *t*-butyl-substituted acetal carbon in the ring (see Table 1).[1-4,6,7] The structure and reactivity of such acetals has been discussed.[8,9]

(6)

Table 1 2,3-Dihydrooxazoles and -thiazoles (**6**) from a-Amino Acids

X	R^1	R^2	R^3	Amino acid
O	H	H	OMe	Serine[1 4]
O	Me	H	OMe	Threonine[1 4]
O	H	CO_2Me	OMe	Serine[1a,2]
O	Me	CO_2Me	OMe	Threonine[1a,2]

2-Methylbut-3-yn-2-ol[1]

[115-19-5] · C_5H_8O · 2-Methylbut-3-yn-2-ol · (MW 84.13)

(monoprotected alkyne;[1] undergoes Claisen rearrangements to conjugated dienoates and dienones)

Physical Data: mp 2.6 °C; bp 104 °C; *d* 0.868 g cm^{-3}.

Solubility: miscible with H_2O, alcohols, benzene, EtOAc, petroleum ethers.

Form Supplied in: colorless liquid; widely available. *Drying:* removal of residual water by azeotropic distillation (bp 90.7 °C, 28.4% H_2O).[1b]

Monoprotected Alkyne.

2-Methylbut-3-yn-2-ol (MB) has been used extensively as an alkyne equivalent in the preparation of arylalkynes and unsymmetrical diarylalkynes; acetylene itself leads to mixtures. These products are used mainly in the polymer or liquid crystal field. MB is a cheap alternative to ***Trimethylsilylacetylene***,[2] in the presence of which it may be selectively cleaved.[3] After palladium-catalyzed coupling of MB with an aromatic halide, the terminal alkyne function can be unmasked by heating in the presence of base; removal of acetone by distillation drives the reaction to completion (eq 1). One-pot procedures have been developed.[4] The methodology has been used on a wide range of aromatic[5] and heteroaromatic[6] halides (reactivity I > Br > Cl) as well as vinyl halides[7] and triflates.[8] Yields are good (normally 60-80% for the two steps) and most functionalities are compatible (aldehydes must be protected)[5] with the reaction conditions. When the coupling takes place *ortho* to a hydroxy or an amino group, benzofurans[9] and indoles[10] can result.

Oxidative Coupling with Alkynes.

Treatment of MB with ***Copper(I) Chloride*** in the presence of oxygen followed by heating the product with NaOH in xylene gives 1,3-butadiyne (diacetylene) in 80% yield.[11] Nonsymmetrical 1,3-diynes are produced from the coupling of MB with haloalkynes in the presence of Cu^{I} salts (Cadiot-Chodkiewicz coupling). Acetone can of course be removed as mentioned to allow further manipulation (eq 2).[12]

Claisen Rearrangements and Isomerizations.

Reaction of 2-methylbut-3-yn-2-ol with orthoesters gives, after Claisen rearrangement and isomerization of the allenes thus formed, 5-methyl hexa-2,4-dienoates,[13] useful in the preparation of alkyl chrysanthemates.[14] Similarily, reaction with enol ethers gives 6-methyl-3,5-dien-2-ones with *trans* selectivity (eq 3).[15] Isomerization (Meyer-Schuster rearrangement) of 2-methylbut-3-yn-2-ol in the presence of a titanium/copper-based catalyst gives 3-methyl-2-butenal in good yield (83%) (eq 4).[16] Partial hydrogenation gives 2-methylbut-3-en-2-ol.[17] Both of these compounds are of use in the synthesis of vitamin K-type products.[18]

(3)

cis:*trans* = 14:86

(4)

Chromene Preparation.

3-Chloro-3-methyl-1-butyne[19] (prepared with MB/HCl/$CuCl_2$, yield 69%) is the reagent of choice for the preparation of the chromene system in potassium-channel blockers such as cromakalim (eq 5).[20]

(5)

Methyl Chloroacetate

(**1**; R = Me)

[96-34-4] · $C_3H_5ClO_2$ · Methyl Chloroacetate · (MW 108.53) (**2**; R = Et)

[105-39-5] · $C_4H_7ClO_2$ · Ethyl Chloroacetate · (MW 122.56)

(alkylating agent;[1] undergoes Michael[2,3] and Darzens[4] condensations; effects two-carbon homologation of alkenes;[5] widely used in heterocyclic synthesis)

Physical Data: (**1**) mp -33 °C; bp 130-132 °C; *d* 1.238 g cm^{-3}.[6] (**2**) mp -26 °C; bp 144-146 °C; *d* 1.1498 g cm^{-3}.[6]

Solubility: insol water; sol alcohol, ether.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: store in a cool dry place. Toxic, corrosive lachrymator. Avoid contact and inhalation. Use in a fume hood.

Alkylation.

Methyl chloroacetate has been widely used as an alkylating agent for sulfur,[1,7-9] nitrogen,[1,10,11] and oxygen[1,12,13] nucleophiles under standard conditions. Reaction with phosphide anions affords o-phosphinocarboxylic acids.[14] Malonates are alkylated to form the 1,1,1-trialkoxycarbonyl derivatives,[15] which are easily monodecarboxylated and may function as masked 1,1-diesters in a synthetic sequence. *C*-Alkylation of ketones is accomplished by their reaction with Grignard reagents in HMPA to form magnesium enolates which are readily and selectively *C*-alkylated with methyl chloroacetate.[16]

Michael Reaction.

Reaction of α-halo esters, such as methyl chloroacetate, with α,β-unsaturated esters in the presence of base furnishes

cyclopropane derivatives (eq 1).

The effects of leaving group, base catalyst, and solvent polarity and solvating ability on the ratio of *cis*:*trans* isomer formation have been investigated.[2,3]

Darzens Condensation.

Methyl chloroacetate reacts with aldehydes and ketones in the presence of base to afford glycidic esters (eq 2).[4]

Subsequent hydrolysis to the corresponding glycidic acids and decomposition furnishes aldehydes or ketones, efficiently accomplishing one-carbon homologation. Mechanistic studies have investigated the effects of various esters (R^2)[17] and reaction temperature[18] on *cis*:*trans* isomer ratios obtained. In homologation sequences, dianions of α-halocarboxylic acids have often been employed to circumvent premature epoxide cleavage during ester hydrolysis.[19] A procedure involving reaction of ethyl chloroacetate with benzalaniline broadens the scope of the Darzens synthesis to include preparation of aziridine esters (eq 3).[20] The *trans*-aziridine is formed preferentially.

Two-Carbon Alkene Homologation.

Methyl chloroacetate adds to alkenes and dienes under redox catalysis by ***Copper(I) Chloride*** in the presence of 2,2´-bipyridyl or 1,10-phenanthroline, affording α-chloro esters or unsaturated esters.[21] Alkenes which have been converted to the corresponding trialkylboranes react with ethyl chloroacetate to effect two-carbon homologation of the alkene and furnish the corresponding esters (eq 4).[5] The reaction is widely applicable and yields are generally high. Reactions with ethyl bromoacetate proceed at a slightly faster rate, with somewhat higher yields.

Heterocycles.

A wide variety of heterocycles has been synthesized employing ethyl or methyl chloroacetate. Among the precursor nucleophiles, thiourea, salicylonitriles, mercaptobenzaldehydes, and cyanopyridinethiones furnish triazines,[22] benzofurans,[23] benzothiophenes,[24] and thienopyridines,[25] respectively.

Related Reagents.

Chloroacetonitrile; ***Iodoacetonitrile***; ***Methyl Bromoacetate***; ***Methyl Dichloroacetate***.

Methyl Chloroformate

[79-22-1] · $C_2H_3ClO_2$ · Methyl Chloroformate · (MW 94.50)

(protecting agent for many functional groups;[1-16] activates N-heteroaromatic rings and carboxylic acids toward nucleophilic attack;[17-26] methoxycarbonylating agent for organometallic reagents and enolates[27-39])

Alternate Name: MCF.

Physical Data: bp 70-72 °C; *d* (20 °C) 1.223 g cm^{-3}; *n*20D 1.3870.

Solubility: slightly sol water with slow decomposition; miscible with alcohols, benzene, chloroform, ether, etc.

Form Supplied in: colorless liquid; widely available.

Handling, Storage, and Precautions: flammable liquid; vesicant; its vapors are highly toxic, lachrymatory, and strongly irritating to the eyes. It should be handled with caution in a fume hood using protective gloves.

Functional Group Protection.

The protection of alcohols[1] and phenols[2] as their methyl carbonates can be achieved using methyl chloroformate under basic conditions (eq 1). Primary and secondary alkylamines are readily protected as their methyl carbamates using MCF, typically in the presence of Et_3N,[3,4] Na_2CO_3,[5] K_2CO_3,[6] or $NaHCO_3$.[7] Selective *N*-protection of amino alcohols can be achieved under these conditions (eq 2).[5]

Methyl carbonates are more resistant to basic hydrolysis than simple esters; however, both alcohol-[1c] and phenol-derived[2] methyl carbonates can be selectively hydrolyzed under mildly basic conditions in the presence of a methyl carbamate derivative, allowing for the overall selective *N*-protection of amino alcohols and amino phenols (eq 3).

MCF is also useful for the *N*-protection of α-amino acids (Schotten-Baumann conditions),[8] primary arylamines (using pyridine as base),[1b,9] amides (using ***Triethylamine/4-Dimethylaminopyridine*** as base),[10] and pyrrole and indole ring nitrogens (using NaH or KH as base).[11] *N*-Silylpyrroles can be converted to the corresponding methyl carbamates under milder conditions than are required for the direct *N*-protection of pyrroles.[12] *ortho*-Phenylenediamines are

readily converted to the corresponding benzimidazole-2-carbamates using MCF in the presence of $MeSCH(NH_2)=NH$.[13] The forcing conditions that are often required for removal of a methyl carbamate protecting group (e.g. ***Hydrazine***, KOH,[14] or aq $Ba(OH)_2$)[15] have limited the utility of this *N*-protecting group when compared with other carbamates; although milder *N*-deprotection conditions have been reported (***Iodotrimethylsilane***, $CHCl_3$, 50 °C; then MeOH),[16] this chemistry has not seen widespread use. ***Lithium Aluminum Hydride*** reduction of methyl carbamates affords the corresponding *N*-methylamines,[3,4] providing an attractive method for the overall *N*-methylation of primary and secondary amines (eq 4).

(4)

Activation of N-Heteroaromatic Rings Toward Nucleophilic Attack.

Pyridine, quinoline, and isoquinoline rings are activated by MCF toward in situ nucleophilic attack, leading to the formation of 1,2- and/or 1,4-dihydropyridines, -quinolines, or -isoquinolines. The addition of alkyl Grignard reagents proceeds with variable and often poor regioselectivity.[17] However, alkenyl- and alkynyl-Grignard reagents (eq 5),[17b] unhindered allylic[18] and allenylic[19] stannanes, cyanide ion,[20] and ***Sodium Borohydride*** (in MeOH at -70 °C[21]) all add with high 1,2-selectivity. Highly 1,4-selective addition reactions are observed using alkylcopper reagents (eq 6),[17a,22] dialkylcuprates,[17b,23] silyl enol ethers,[22] and benzylic stannanes.[24] The 1,4-addition of aryllithium reagents,[25] and methyllithium and methylmagnesium bromide,[26] to chiral 3-oxazolinylpyridines proceeds with high regio- and diastereofacial selectivity (eq 7). Removal of the chiral auxiliary affords chiral 4-substituted dihydropyridines in high ee.

(5)

(6)

(7)

89:11 diastereoselectivity

Methoxycarbonylation of Organometallic Reagents and Enolates.

Deprotonation of terminal alkynes (typically using *n*-BuLi,[27] LDA,[28] or EtMgBr[29]), followed by trapping the resulting alkynyllithium or -Grignard reagent with MCF, offers an excellent route to methyl alkynoates (eq 8) (see ***2,2,2-Trichloroethyl Chloroformate*** if subsequent cleavage to the carboxylic acid is desired). A related approach to methyl alkynoates proceeds via homologation of an aldehyde to the corresponding α,α-dibromoalkene. Dehydrobromination and halogen-metal exchange followed by trapping the resultant alkynyllithium with MCF provides the methyl alkynoate in high overall yield (eq 9).[30] Aryllithium[31] and alkenylaluminium[32] species are also effectively methoxycarbonylated by MCF, but the trapping of simple primary alkyllithiums with MCF appears to be of little synthetic utility.[33] The in situ trapping of a simple phosphonium ylide with MCF followed by deprotonation provides a convenient synthetic approach to α-methoxycarbonylphosphonium ylides (eq 10).[34]

(8)

(9)

(10)

The *C*-methoxycarbonylation of lithium ester[35] and amide[36] enolates can be effectively accomplished using MCF. Addition of *n*-BuLi to a chiral 1-oxazolinylnaphthalene followed by trapping the resulting azaenolate with MCF affords the *C*-acylation product with high diastereoselectivity (eq 11).[37] In contrast, reaction of copper[38] and potassium[39] ketone enolates with MCF typically results in *O*-acylation to afford the corresponding enol carbonates (eq 12). The weak nucleophilicity of enol carbonates (they are stable to peroxy acids and ***Ozone***)[38a] makes them useful masked enolate equivalents.

(11)

97:3 diastereoselectivity

(12)

Activation of Carboxylic Acids as Mixed Anhydrides.

Activation of *N*-(alkoxycarbonyl)-α-amino acids as mixed anhydrides using MCF/*N*-methylpiperidine in CH_2Cl_2 minimizes urethane byproduct formation and racemization during peptide bond formation.[40] Reaction of these mixed anhydrides with ***N,O-Dimethylhydroxylamine*** followed by $LiAlH_4$ reduction provides an attractive route to the corresponding *N*-(alkoxycarbonyl)-α-amino aldehydes (eq 13).[41] Attempts to generate mixed anhydrides from *N*-acyl-α-amino acids using MCF result in cyclization to the corresponding 5(4*H*)-oxazolones.[42,43]

(13)

α-Diazo ketones may be conveniently prepared by reaction of a mixed anhydride with ***Diazomethane***; the mixed anhydrides are typically prepared either by treatment of the parent carboxylic acid with MCF/***Triethylamine***[44] or by treatment of the corresponding methyl ester with potassium silyloxide and then MCF.[45] Attack by amines[46] or *N*-silylamines[47] on such mixed anhydrides provides a useful approach to amide synthesis (eq 14), while acyl azides are prepared in excellent yield by reaction of the mixed anhydride with ***Sodium Azide***.[48]

(14)

While the mixed anhydrides derived from the reaction of carboxylic acids with methyl chloroformate using Et_3N as base are relatively stable, the addition of catalytic amounts of ***4-Dimethylaminopyridine*** or *N*-methylmorpholine results in facile conversion to the corresponding methyl esters under very mild reaction conditions that are compatible with sensitive functionality.[49]

Related Reagents.

Benzyl Chloroformate; ***2,2,2-Trichloroethyl Chloroformate***.

Methyl Chlorooxalate

[5781-53-3] · $C_3H_3ClO_3$ · Methyl Chlorooxalate · (MW 122.51)

(acylating agent;[1] heterocycle synthesis;[2] deoxygenation intermediate;[3] chiral α-hydroxy ketones[4])

Alternate Names: MCO; methyl oxalyl chloride.

Physical Data: bp 118-120 °C; *d* 1.332 g cm^{-3}.

Form Supplied in: liquid; commercially available.

Preparative Methods: originally prepared from methyl oxalate and phosphorus pentachloride,[5] a simpler procedure involves treatment of crystalline potassium methyl oxalate with thionyl chloride and isolation of the product by distillation.[6]

Handling, Storage, and Precautions: corrosive liquid; lachrymator. Use in a fume hood.

Oxalyl Transfer.

Much of the chemistry of methyl chlorooxalate (MCO) is simply that of an acylating agent and parallels that of standard acid chlorides. Thus, in addition to acylating a variety of alcohols, this reagent has also been reported to acylate naphthols,[1] indoles,[7] and oxazoles.[8] An interesting acylation of a 1-deoxy-1-diazo fructose derivative (**1**) with MCO provided the product (**2**) in 65% yield (eq 1).[9] Attempts to use simpler acid chlorides (acetyl or benzoyl) for this chain elongation were not successful.

Heterocycle Synthesis.

Methyl chlorooxalate can be used to prepare a number of carboxy-substituted ring systems. For example, treatment of (**3**) with MCO in pyridine gave the isoflavone (**4**) in 66% yield (eq 2).[2] Another interesting use of this reagent in an intramolecular cyclization is the reported construction of penems and carbapenems.[10] Treatment of either (**5a**) or (**5b**) with ***Triethyl Phosphite*** provides the cyclized products (**6a**) and (**6b**) in 83% and 92% yields, respectively (eq 3). This reaction is thought to proceed by generation of a carbene intermediate. MCO has also been used for the construction of indole systems.[11]

(3)

(5a) X = CH_2
(5b) X = S

(6a) 83%
(6b) 92%

Deoxygenation of Alcohols.

Methyl chlorooxalate has found use in the deoxygenation of tertiary and secondary alcohols.[3] A number of gibberellic acid derivatives were acylated with this reagent under mild conditions without the use of base. The resulting methyl oxalyl esters were treated with ***Tri-n-butylstannane*** and 2,2´-azo-2-methylpropionitrile in refluxing toluene to provide the deoxygenated products in good yield (eq 4).

(4)

Finally, an interesting application of this reagent for the preparation of chiral α-hydroxy ketones has recently been reported.[4]

Methyl α-Chloro-α-phenylthioacetate

[85920-99-6] · $C_9H_9ClO_2S$ · Methyl α-Chloro-α-phenylthioacetate · (MW 216.70)

(an a^2 carbon electrophile for the introduction of methoxycarbonylmethyl and methoxycarbonylmethylidene groups by Lewis acid-catalyzed reaction with silyl enol ethers followed by a reductive or oxidative step)

Physical Data: bp 105-107 °C/18 mmHg.[1]

Solubility: freely sol CH_2Cl_2.

Analysis of Reagent Purity: δ ($CDCl_3$) 7.47 (5H, m), 5.57 (1H, s), and 3.77 (3H, s).

Preparative Methods: by chlorination of methyl phenylthioacetate using ***Sulfuryl Chloride***[2] or ***N-Chlorosuccinimide*** (NCS):[3,4] methyl phenylthioacetate (16.8 g) is stirred with powdered NCS (13.3 g) in CCl_4 at rt for 10 h, the mixture filtered, the filtrate evaporated, and the residue distilled using a short Vigreux column.[1]

Handling, Storage, and Precautions: generally prepared shortly before use. It is stable in the absence of water, and should be kept in a stoppered flask or sealed ampule if it is not used immediately. It is an alkylating agent, and should therefore be kept in a well-ventilated hood, with skin and eyes protected while handling it.

Methyl α-chloro-α-phenylthioacetate (**2**) reacts with silyl enol ethers (**1**) in the presence of Lewis acids, typically ***Zinc Bromide*** in catalytic quantities[3,4] or ***Titanium(IV) Chloride*** in stoichiometric quantities,[4] to give the 1,4-dicarbonyl products (**3**) (eq 1). The reaction is regiospecific (eqs 2 and 3),[4] and γ-selective with the silyl dienol ether (**4**) (eq 4).[3]

(1)

(3)

(2)

(3)

(4)

(4)

The $ZnBr_2$ reactions typically take 0.5-2 h at rt in CH_2Cl_2, and are carried out by adding the anhydrous salt to a 1:1

mixture of silyl enol ether and the chloride (**1**). The $TiCl_4$ reactions are carried out similarly, and typically take 2 h at -23 °C.

The products (**3**) can be desulfurized with ***Raney Nickel*** to give overall the products (**5**) of methoxycarbonylmethylation (eq 5).[3,4] They can also be oxidized using ***Sodium Periodate*** to give the corresponding sulfoxides, which undergo rapid cycloelimination when there is an appropriately placed hydrogen atom to give overall the products (**6**) of methoxycarbonylmethylidenation (eq 6).[3,4]

(5)

(3) (5)

(6)

(3) (6)

The homolog methyl 2-chloro-2-phenylthiopropanoate (**7**) can be used in similar reactions (eqs 7-9), but the oxidative desulfurization takes place towards the methyl group, giving the α-methylene ester (**8**) when R^2 is not hydrogen (eq 9).[4]

(7)

(7)

(8)

(9)

(8)

The corresponding Lewis acid-catalyzed reaction of silyl enol ethers with α-chloro-α-phenylthioketones gives furans.[5]

Related Reagents.

Chloromethyl Phenyl Sulfide.

Methylcopper[1]

MeCu

[1184-53-8] · CH_3Cu · Methylcopper · (MW 78.59)

(nucleophilic reagent for substitution reactions;[1b] selective for conjugate additions;[1c,d,2] adds to triple bonds[3])

Physical Data: oligomeric yellow solid;[4] stable at -10 °C, mp 20 °C (dec to ethane), explodes at 30-35 °C.[30]

Solubility: slightly sol ether, THF; sol dimethyl sulfide (DMS), tributylphosphine.

Preparative Methods: methylcopper and other alkylcopper species are most commonly prepared from equimolar amounts of alkyllithium or Grignard reagent and purified copper(I) halide in ether or THF.[3a,c,5-10] The byproduct halide salts, which can influence reagent activity, are easily removed by washing the precipitated alkylcopper with fresh solvent.[7,10] Alkylcoppers can be prepared from alkyl halides and highly active zero-valent copper.[11]

Handling, Storage, and Precautions: alkylcoppers are generally not long lived at temperatures above 0 °C. They are more thermally stable and more reactive when used in dimethyl sulfide.[12] Methylcopper may decompose explosively when dry.[30] Use in a fume hood.

Nucleophilic Substitutions.

Acyl chlorides are converted to the corresponding methyl ketones on treatment with methylcopper.[12,13] Ring opening of heterocycles, involving S_N2 processes, occurs with epoxides,[11,12,14] β-lactones,[15] and cyclic acetals.[16] In the latter case, mandelic acid-derived 1,3-dioxolan-4-ones react with Grignard-derived alkylcoppers to deliver protected chiral secondary alcohols in good yield and 54-94% diastereomeric excess (eq 1).

(1)

Primary alkylcoppers surpass many organometallic reagents in their selectivity for S_N2' substitution. Allyl halides,[17] allyl ethers,[9] propargyl sulfonates,[18] and propargyl halides[8] (eqs 2 and 3) all suffer predominately S_N2' attack.

(2)

(3)

Conjugate Additions.

As with cuprate reagents, alkylcoppers undergo conjugate addition to electron-poor alkenes and alkynes. Substrates include nitroalkenes,[7] alkenylsulfones,[19] alkynoates,[20] cyanoalkynes,[21] and alkynic sulfoxides[5,22] and sulfones.[22a,23] With the alkynes, the reaction gives exclusively the product of *cis* addition across the triple bond.

The addition of alkylcopper to alkenones, alkenals, and alkenoates is accelerated by ***Chlorotrimethylsilane*** or ***Iodotrimethylsilane***, the adducts being isolable as the silyl enol ethers.[10,24,25] Chemoselectivity (1,4- vs. 1,2-addition) is also enhanced by these silanes. The enhanced rates enable the use of both alkyl groups of dialkylcuprate reagents (eq 4).[24] Enhanced rate and chemoselectivity are likewise fostered by the use of stoichiometric or greater quantities of DMS[12] or trialkylphosphines.[20a,26]

(4)

The diastereoselectivities of conjugate additions of alkylcoppers to γ-alkoxyalkenoates[27] and optically active alkenylsulfoximines[28] have also been investigated. The sulfoximine adducts can be converted to optically active 3-alkylcarboxylic acids.

Additions to Alkynes.

Alkylcopper species add to terminal alkynes stereospecifically (*syn*) and with good regioselectivity to generate alkenylcopper species; subsequent addition of an electrophile provides the di- or trisubstituted alkene. The copper atom usually attaches to the 1-position in the addition step (eqs 5 and 6),[9,29] but this can be influenced by directing groups and choice of solvent.[3a]

Methylcopper-Boron Trifluoride Etherate[1]

$MeCu/BF_3.OEt_2$

(MeCu)

[1184-53-8] · CH_3Cu · Methylcopper-Boron Trifluoride Etherate · (MW 78.59) ($BF_3.OEt_2$)

[109-63-7] · $C_4H_{10}BF_3O$ · Methylcopper-Boron Trifluoride Etherate · (MW 141.95)

(selective nucleophilic reagent for conjugate additions[2] and substitution reactions[1])

Preparative Method: prepared by the addition of ***Boron Trifluoride Etherate*** to a suspension of ***Methylcopper*** in Et_2O or THF at -75 °C.[2]

Handling, Storage, and Precautions: see entries for ***Boron Trifluoride Etherate*** and ***Methylcopper***. Use in a fume hood.

Conjugate Additions.

The combination of an alkylcopper with boron trifluoride produces a nucleophilic reagent which is more reactive than the alkylcopper alone and which can exhibit regioselectivity on a par with organocuprate reagents. For example, in each of two syntheses of the sesquiterpene modhephene, RCu/BF_3 was used to establish a quaternary center by conjugate addition to a 3-alkyl-2-cyclopentenone moiety (eq 1).[3,4] Alkenoates and alkenoic acids are also suitable substrates.[2,5] In the development of methodology for asymmetric synthesis, the alkylcopper/BF_3 combination was found to be effective in preparing β-substituted carboxylic acids.[6] High enantiomeric excesses (94-98%) were obtained by the use of a camphorsulfonamide auxiliary (eq 2).[6a]

(1)

(2)

Enhancements of rate and regioselectivity in conjugate additions have also been observed with the combinations of alkylcopper/halosilane[7] and alkylcopper/***Aluminum Chloride***.[8]

Nucleophilic Substitutions.

Acetals are converted to the corresponding monosubstitution products on treatment with alkylcopper/BF_3.[9,10] Similarly, orthoformates give acetals in high yield.[9] Chiral cyclic acetals undergo this monosubstitution reaction stereoselectively (eq 3), although cuprates with BF_3 were found to give better results.[10]

(3)

Allylic halides, ethers, esters, and alcohols suffer regioselective γ-attack by alkylcopper/BF_3.[11] Propargyl chloride and acetate afford 1,2-heptadiene. The stereoselectivity of these substitutions has been less rigorously examined, but appears to be less dramatic than the regioselectivity. The regioselectivity of attack on γ-acetoxy-α,β-enoates by alkylcopper/$AlCl_3$ has also been documented.[12]

Related Reagents.

Methallyllithium; ***Phenylcopper-Boron Trifluoride Etherate***.

Methylcopper-Tributylphosphine[1]

$MeCu.PBu_3$

[24743-95-1] · $C_{13}H_{30}CuP$ · Methylcopper-Tributylphosphine · (MW 280.95)

(reagent for 1,4-addition of methyl group;[2] methylation of aryl iodides;[3] ring opening of β-propiolactones[4])

Alternate Name: methyl(tributylphosphine)copper.

Physical Data: mp 57-60 °C; dec above 90 °C.

Preparative Methods: prepared from ***Methyllithium*** or methylmagnesium halides and ***Copper(I) Iodide-Tributylphosphine*** complex.

Handling, Storage, and Precautions: sensitive to air and moisture. Hydrolysis produces methane, which can be an explosion hazard. Handle in a fume hood.

Introduction.

House and co-workers first described the reactions of methylcopper stabilized by tributylphosphine in the 1960s.[5] Yamamoto and co-workers[6] carried out a comprehensive study of the formation and stability of phosphine complexes of alkylcopper species. MeCu-tributylphosphine was prepared from copper(II) acetoacetate and dimethylethoxyaluminum. The complex was isolated (mp 57-60 °C) and shown to be light- and air-sensitive. Thermal decomposition[6b] occurred between 90 and 130 °C with the evolution of methane (61%) and ethane (39%); ethane was presumed to arise by hydrogen abstraction from the phosphine ligands. Since ethylene was not observed, the possibility of α-elimination was excluded.

Enone Additions.

1,4-Addition of MeCu-tributylphosphine to pent-3-en-2-one in the presence of ***Lithium Iodide*** provided 4-methylpentan-2-one in 99% yield. Subsequent studies[2] compared the reactivity of ***Methylcopper***, MeCu-tributylphosphine, and MeCu-trimethyl phosphite in 1,4-additions to 5-methylcyclohex-2-enone.

Methylcopper alone was unreactive, providing less than 1% of the 1,4-addition product. MeCu-tributylphosphine gave a 34% yield, while the MeCu-trimethyl phosphite reagent resulted in a 90% yield of *trans*-3,5-dimethylcyclohexanone (eq 1). Both of the phosphine complexes were generated in situ and required that lithium iodide be present in the reaction mixture for 1,4-addition to occur. Noyori and co-workers[7] reinvestigated the 1,4-addition of tributylphosphine-stabilized organocopper reagents and determined that the best results were obtained when 2 equiv of tributylphosphine were added to the organocopper reagent. MeCu-tributylphosphine proved to be the least reactive of the alkyl copper species investigated. For example, MeCu-tributylphosphine provided the 1,4-addition product from cyclopentenone in 73% yield, while reaction with the corresponding butyl copper reagent resulted in a 93% yield of 3-butylcyclopentane.

(1)

$MeCu \cdot PBu_3$	34%
$MeCu \cdot P(OMe)_3$	90%
MeCu	0%

The reactivity of MeCu-tributylphosphine has also been directly compared with that of ***Methylcopper-Boron Trifluoride Etherate***.[8] In reaction with acetylcyclohexene, MeCu-tributylphosphine provided the 1,4-addition product in 55% yield, while the MeCu-boron trifluoride complex gave the same product in 68% yield (eq 2). Only a trace of the 1,2-addition product was noted in each reaction. Interestingly, the addition of boron trifluoride to preformed MeCu-tributylphosphine did not result in improved yields of the 1,4-adduct.

(2)

$MeCu \cdot PBu_3$	55%	1%
$MeCu \cdot BF_3$	68%	2%
$MeCu \cdot PBu_3 \cdot BF_3$	39%	2%

These results are in contrast to the observations by Oppolzer and co-workers[9] in the asymmetric 1,4-addition

of MeCu-tributylphosphine to (-)-8-phenylmenthol crotonate esters (eq 3). In this study, MeCu-tributylphosphine resulted in much better yields of the 1,4-adduct and improved enantioselectivity when compared to MeCu-boron trifluoride. However, the combination of MeCu-tributylphosphine and boron trifluoride proved to be the reagent mixture of choice for asymmetric conjugate addition to a camphor-derived neopentyl ether chiral auxiliary. The asymmetric synthesis of (*S*)-citronellic acid was achieved using this method in 92% ee (eq 4).[9] Similar results were obtained with a dicyclohexylsulfonamide chiral auxiliary, providing the methyl addition product in >94% ee (eq 5).[10] This methodology can be applied to the synthesis of deoxypolypropionate derivatives in excellent optical purity.[11]

(3)

(4)

(5)

Displacement Reactions.

MeCu-tributylphosphine can also be used in coupling and displacement reactions. Reaction with 1-iodonaphthalene provided the methylated derivative in good yield.[3] Regioselective ring opening of β-propiolactones occurs cleanly with the tributylphosphine-stabilized copper reagent (eq 6).[4] MeCu-tributylphosphine also gave somewhat better results than ***Lithium Dimethylcuprate*** in the S_N2' displacement of optically active allenic bromides to form optically active alkynes (eq 7).[12]

(6)

(7)

Methyl Cyanodithioformate

[17008-22-9] · $C_3H_3NS_2$ · Methyl Cyanodithioformate · (MW 117.21)

(electron-deficient thiocarbonyl compound; readily undergoes Diels-Alder and ene reactions with dienes and alkenes, respectively; reacts readily with amines)

Physical Data: deep purple; bp 50-60 °C/1 mmHg.

Preparative Method: addition of ***Sodium Cyanide*** to ***Carbon Disulfide*** in DMF affords sodium cyanodithioformate, which is converted to the unsolvated tetraethylammonium cyanodithioformate by treatment with tetraethylammonium bromide in ethanol. Reaction of the tetraethylammonium salt with excess ***Iodomethane*** in acetonitrile for 1 min provides methyl cyanodithioformate in 65% yield.[1]

Handling, Storage, and Precautions: dimerizes on standing and in the presence of nucleophiles. It should be prepared immediately before use.

Methyl cyanodithioformate (**1**) is an electron-deficient thiocarbonyl compound[2] that reacts readily with dienes to give dihydrothiopyran Diels-Alder adducts.[3-5] The regiochemistry of these cycloadditions is opposite to that observed with electron-deficient carbonyl compounds. Reaction of 1-methoxy-1,3-butadiene with (**1**) at 0 °C for 1 h affords mainly dihydrothiopyran (**2**) in which the cyano group has added *endo*. Reaction of (**2**) with ***Osmium Tetroxide*** affords the carbohydrate analog (**3**) (eq 1).[3d]

(1)

Methyl cyanodithioformate undergoes ene reactions with excess alkene in toluene at 100-110 °C for 5-72 h, affording allylic sulfide ene adducts in 45-83% yield.[6] A carbon-sulfur, rather than carbon-carbon, bond is formed in the ene reaction, as shown for β-pinene in eq 2. Treatment of the adduct (**4**) with ***Lithium Diisopropylamide*** or ***n-Butyllithium*** in THF/HMPA generates an anion that undergoes a [2,3]-sigmatropic rearrangement to give (**5**) after trapping with MeI. Reduction of (**5**) with deactivated W-4 ***Raney Nickel*** affords nitrile (**6**). This sequence provides a procedure for the insertion of a functionalized carbon into an allylic carbon-hydrogen bond.

Methyl cyanodithioformate undergoes condensation reactions with amines[7] and dipolar cycloadditions followed by extensive rearrangements with triazolium imide 1,3-dipoles.[8]

Methyl Cyanoformate[1]

(**1**; R = Me)

[17640-15-2] · $C_3H_3NO_2$ · Methyl Cyanoformate · (MW 85.07) (**2**; R = Et)

[623-49-4] · $C_4H_5NO_2$ · Ethyl Cyanoformate · (MW 99.10) (**3**; R = $PhCH_2$)

[5532-86-5] · $C_9H_7NO_2$ · Benzyl Cyanoformate · (MW 161.17)

(agent for the regioselective methoxycarbonylation of carbanions;[1,2] reacts with organocadmium reagents to form α-keto esters;[3] may function as a dienophile,[4] dipolarophile,[5] or radical cyanating agent[6])

Physical Data: (**1**) mp 26 °C; bp 100-101 °C; *d* 1.072 g cm^{-3}. (**2**) bp 115-116 °C; *d* 1.003 g cm^{-3}. (**3**) bp 66-67 °C/0.6 mmHg; *d* 1.105 g cm^{-3}.

Solubility: sol all common organic solvents; dec by H_2O, alcohols, amines.

Form Supplied in: colorless liquid; methyl cyanoformate, as well as the ethyl and benzyl analogs, is available commercially.

Preparative Methods: small quantities of cyanoformate esters (up to 30 g) may be conveniently prepared from alkyl chloroformates by procedures employing phase-transfer catalysis with either ***18-Crown-6***[7] or ***Tetra-n-butylammonium Bromide***,[8] but several workers have found the products to be unsatisfactory when prepared on a larger scale.

Handling, Storage, and Precautions: store over 4Å molecular sieves; highly toxic; flammable; use in a fume hood.

Regioselective Methoxycarbonylation of Ketones.

Methyl cyanoformate gives generally excellent results in the regiocontrolled synthesis of β-keto esters by the *C*-acylation of preformed lithium enolates (eq 1)[1,2] and is normally superior to the more traditional acylating agents such as acyl halides, anhydrides,[9] and CO_2,[10] partly because these reagents afford variable amounts of *O*-acylated

products.[11] The enolates may be generated in a variety of ways, including direct enolization of ketones with suitable bases (eq 2),[2] liberation from silyl enol ethers and acetates (eq 3),[12] conjugate additions of cuprates to α,β-unsaturated ketones[13] (eq 4),[14] or by the reduction of enones by lithium in liquid ammonia (eq 5).[1,12]

(1)

(2)

(3)

(4)

(5)

Lithium enolates derived from sterically unencumbered cyclohexanones undergo preferential axial acylation (eq 6), whereas equatorial acylation is favored with $\Delta^{1(9)}$-2-octalones (eq 7),[12] even in the absence of an alkyl substituent at C-10.[15]

R = H	53%	14%
R = Me	78%	0%

For compounds in which the β-carbon of the enolate is sterically hindered, treatment with methyl cyanoformate may result in variable degrees of *O*-acylation, although this problem may be ameliorated by the use of diethyl ether as the solvent. In several cases a switch from predominantly *O*-acylation in THF to predominant *C*-acylation in diethyl ether has been observed (eqs 8-10).[12]

(8)

solvent: THF	87%	0%
solvent: Et_2O	6%	78%

(9)

MeLi, THF, -20 °C $NCCO_2Me$, -78 to 0 °C	78%	0%
BuLi, Et_2O, -10 °C $NCCO_2Me$, -78 to 0 °C	9%	68%

A comparative study of lithium, sodium, and potassium enolates indicated that the lithium derivatives reacted most satisfactorily.[2] There may be substrates for which the thermodynamic enolates are required, however, and the sodium and potassium enolates may therefore be selected. Good results have been reported with these intermediates (eqs 11 and 12), although the latter afford significant amounts of *O*-acylated products.[16,17] Quite apart from the issue of regioselectivity, the cyanoformate-based procedure is exceptionally reliable and makes it possible to prepare β-keto esters from ketones under especially mild conditions. It is not only the method of choice with sensitive substrates,[16] but it will often ensure superior results with more robust compounds as well.

(17)

Higher Alkyl Cyanoformates.

A range of other alkyl cyanoformates has been successfully utilized for the acylation of enolate anions, including ethyl,[23] allyl,[24] benzyl,[25] and *p*-methoxybenzyl,[26] but not *t*-butyl cyanoformate, which appears to be insufficiently reactive. Enantiomerically enriched cyanoformates derived from (+)-menthol, (-)-borneol, and the Oppolzer alcohol were reported to furnish good chemical yields, but the level of enantioselectivity was disappointingly low (eq 18).[27]

(18)

Additions to the Nitrile Group.

Ethyl cyanoformate reacts with organocadmium reagents to afford α-keto esters (eq 19),[3] and with malonate esters, β-keto esters, and other active methylene compounds to give α-aminoacrylates (eq 20).[28] Both processes require catalysis with Lewis acids, of which ***Zinc Chloride*** has proven to be the most effective.

(19)

R = Ph, *i*-Pr, *s*-Bu, cyclohexyl, cyclopentyl

(20)

Cycloadditions.

Methyl and ethyl cyanoformate have been reported to undergo [4 + 2] cycloadditions, e.g. with cyclopentadienones[4] and 2-alkyl-1-ethoxybuta-1,3-dienes to form pyridines (eq 21),[29] and with cyclobutadienes to form Dewar pyridines (eq 22).[30] Ethyl cyanoformate is also an effective dipolarophile, undergoing 1,3-dipolar addition to azides (eq 23)[31] and cyclic carbonyl ylides (eq 24).[5]

(21)

R = Me, Et, Pr, *i*-Pr, Bu, C_5H_{11}

(22)

(23)

(24)

Radical Cyanation.

The peroxide-initiated radical cyanation of cyclohexane and 2,3-dimethylbutane with methyl cyanoformate has been carried out in 72% and 77% yield, respectively.[6]

Related Reactions.

β-Keto ester formation from ketones may be achieved directly with dialkyl carbonates[32] and dialkyl dicarbonates,[33] or indirectly with dialkyl oxalates,[34] methyl magnesium carbonate,[35] and ethyl diethoxyphosphinyl formate.[36] Regiocontrol is problematical, however, and is more reliably effected by trapping enolates with carbon dioxide,[10] carbon disulfide,[37] or carbon oxysulfide[38] followed by methylation. In the latter cases, the dithio and thiol esters are converted into the parent carboxy esters by mercury(II)-catalyzed hydrolysis. The chemistry of acyl cyanides, but excluding cyanoformates, has been the subject of several reviews.[39]

Related Reagents.

Acetyl Cyanide; ***Carbon Dioxide***; ***Carbon Oxysulfide***; ***N,N´-Carbonyldiimidazole***; ***Diethyl Carbonate***; ***Methyl Chloroformate***; ***Methyl Magnesium Carbonate***.

(*R*)-4-Methylcyclohexylidenemethylcopper

[60164-96-7] · $C_8H_{13}Cu$ · (*R*)-4-Methylcyclohexylidenemethylcopper · (MW 172.76)

(optically active vinylcopper reagent;[1] useful in stereospecific synthesis of axially dissymmetric dienes and alkenes[1,2])

Solubility: dark black suspensions of the reagent (0.26 M) have been prepared in THF-pentane.[1,2]

Preparative Methods: (-)-(*R*)-(4-methylcyclohexylidene)methyl bromide[3,4] in THF is treated with ***s-Butyllithium*** in pentane at -75 °C to give a solution of (*R*)-4-methylcyclohexylidenemethyllithium. Addition of 1 equiv of ***Copper(I) Iodide*** to this mixture, followed by stirring at -35 °C for 30 min, gives a dark black suspension of (*R*)-4-methylcyclohexylidenemethylcopper (eq 1).[2] (*S*)-4-Methylcyclohexylidenemethylcopper may be prepared from (+)-(*S*)-(4-methylcyclohexylidene)methyl bromide[3,4] using a similar procedure.[1,2]

Handling, Storage, and Precautions: the reagent is prepared under inert gas atmosphere at temperatures of -35 °C or below. Upon heating to rt, or exposure to oxygen, the reagent decomposes with formation of bis(4-methylcyclohexylidene)ethane. Use in a fume hood.

Oxidative Coupling: Synthesis of Optically Active Dienes of Biaxial Dissymmetry.

Alkenylcopper reagents undergo thermal or oxidative coupling to give 1,3-dienes with retention of configuration at the

alkenic bond.[5] Passage of a stream of oxygen through a solution of (*R*)-4-methylcyclohexylidenemethyl-copper affords (*aR*,*aR*)-bis(4-methylcyclohexylidene)ethane in 30% yield (eq 2).[1,2] The dissymmetry of the latter compound results from the combination of two chiral alkenic axes which are oriented in a planar transoid conformation. The chiroptical properties of this and closely related planar acyclic 1,3-dienes have been reported.[2,6] Additional members of this novel class of optically active dienes could be synthesized by oxidative coupling of analogous chiral vinylcopper reagents.

(2)

Alkylation: Formation of Optically Active 4-Methylcyclohexylidenealkanes.

Alkenylcopper reagents can be alkylated by treatment with alkyl halides and other electrophiles.[7] Reaction of (*S*)-4-methylcyclohexylidenemethylcopper (enantiomer of the title reagent) with ***Iodomethane*** gives (+)-(*S*)-4-(methylcyclohexylidene)ethane with 98% retention of configuration (eq 3).[1,2] Alkylation of (*R*)-4-methylcyclohexylidenemethylcopper with methyl iodide and other alkyl halides is expected to show similar stereospecificity.

2-Methyl-1,3-cyclopentanedione[1]

[765-69-5] · $C_6H_8O_2$ · 2-Methyl-1,3-cyclopentanedione · (MW 112.14)

(building block for the total synthesis of 19-norsteroids[2] and many other naturally occurring cyclopentanoids;[1] precursor for 2,2-, 2,4-, and 2,5-dialkylated cyclopentanediones[1])

Alternate Name: MCPD.

Physical Data: mp 214-216 °C.

Solubility: sparingly sol cold H_2O, MeOH, EtOH; insol cold Et_2O, benzene, toluene; sol boiling H_2O.

Form Supplied in: colorless solid; commercially available.

Preparative Methods: $AlCl_3$-promoted acylation of succinic acid with propanoyl chloride in nitromethane[3] or cyclization of 4-oxohexanoic acid[4] or its esters.[5]

Handling, Storage, and Precautions: the pure reagent is a stable compound, which is reputed to be of low toxicity.

Introduction.

2-Methyl-1,3-cyclopentanedione (**1a**) is completely enolized and therefore has the structure of 3-hydroxy-2-methyl-2-cyclopenten-1-one (**1b**).[6]

Reactions with Nucleophiles at the Carbonyl Group.

With alcohols in the presence of acidic catalysts (**1**) forms 3-alkoxy-2-methyl-2-cyclopenten-1-ones (enol ethers).[7] With primary or secondary amines the corresponding 3-amino-2-methyl-2-cyclopenten-1-ones (enamino ketones) are obtained.[8] These derivatives of (**1**) afford 2,3-dialkylated 2-cyclopenten-1-ones in reactions with organolithium or Grignard reagents (eq 1).[1]

(1)

Reactions with Electrophiles at C-2.

Diketone (**1**) reacts with the tertiary allyl alcohol (**2**) to give the secosteroid (**3**), which represents a key intermediate in the estrone synthesis of Torgov (eq 2).[9]

(2)

(2) **(3)**

Diketone (**1**) adds in a Michael reaction to α,β-unsaturated carbonyl compounds, acrylonitrile, nitroalkenes, and Mannich bases, forming 2,2-disubstituted 1,3-cyclopentanediones.[1,10] The thus available triketone (**4**) affords the (*S*)-diketone (**5**) in a highly enantioselective aldol condensation catalyzed by (*S*)-proline (eq 3).[11,12]

(3)

(4) **(5)**

The palladium(0)-catalyzed reaction of allyl acetate with (**1**) affords exclusively the 2-allylated compound (eq 4),[13] whereas allyl, propargyl, and benzyl halides, as well as alkyl bromoacetates, react with the potassium or sodium salt of (**1**) to form mixtures of *C*- and *O*-alkylated products. In water as solvent the *C*-alkylation is favored; in DMF or DMSO the *O*-alkylation predominates.[14] 2,2-Disubstituted 1,3-cyclopentanediones are easily cleaved by aqueous sodium hydroxide in a retro aldol reaction to 5-substituted 4-oxoalkanoic acids (eq 4).[15]

(4)

Reactions with Electrophiles at the Enolic Hydroxy Group.

The enolic hydroxy group of (**1**) is substituted by chloro, sulfonyloxy, diethoxyphosphinyloxy, or trimethylsilyloxy groups by reaction with ***Oxalyl Chloride***, sulfonyl chlorides, ***Diethyl Phosphorochloridate***, and ***Hexamethyldisilazane***, respectively.[1] The β-substituted enones obtained serve as intermediates for many further reactions (eq 5).[1]

(5)

Reactions with Electrophiles at C-4 and C-5.

Enol ethers and enamines of (**1**) are versatile intermediates for further functionalization. ***Lithium Diisopropylamide*** deprotonates these compounds at C-5,[16,17] whereas ***Lithium Hexamethyldisilazide*** removes a proton at C-4.[17-19] The monoanions thus obtained can be selectively alkylated in the corresponding positions (eq 6). By repeating the deprotonation and subsequent alkylation, 2,4,5-trialkylated 1,3-cyclopentanedione derivatives are available.[18]

The reactions reported here for (**1**) are typical also for its higher alkyl homologs.

Related Reagents.

1,3-Cyclohexanedione; ***1,3-Cyclopentanedione***.

Physical Data: bp 39-43 °C/10 mmHg.

Solubility: sol diethyl ether, dichloromethane, chloroform, benzene.

Preparative Method: from methyl glycinate hydrochloride and sodium nitrite upon treatment with a 5% solution of sulfuric acid.[11]

Handling, Storage, and Precautions: extreme caution should be exercised in handling methyl diazoacetate since it is thermally unstable and has been found to detonate if heated rapidly or overheated (do not expose to temperatures >50 °C), emitting toxic fumes of NO_x. Diazo esters are also toxic and should be handled in a well-ventilated fume hood.

Cyclopropanation.

Under catalytic conditions, methyl diazoacetate readily forms an ester carbenoid which adds to a variety of alkenes, yielding cyclopropyl esters. ***Dirhodium(II) Tetraacetate*** effectively catalyzes the addition of methyl diazoacetate to *cis*-2-octene.[2] Substituted conjugated dienes can be selectively cyclopropanated with methyl diazoacetate.[12] The observed regio- and stereoselectivity is determined by the choice of catalyst and the electronic characteristics of the diene. The enantioselective cyclopropanation of an alkene with methyl diazoacetate can be achieved with the use of a chiral catalyst.[13] Methyl diazoacetate reacts under copper catalysis with the trimethylsilyl enol ether of cyclopentanone to give a silyloxycyclopropane. Treatment with a fluoride source yields a 1,4-keto ester (eq 1).[14,15]

2-(Trimethylsilyloxy)buta-1,3-diene can be cyclopropanated in a regioselective manner with methyl diazoacetate and ***Copper(II) Acetylacetonate***. Subsequent nucleophilic addition of methanol yields methyl 6-methoxy-4-oxohexanoate in excellent yield (eq 2).[16]

A number of 6- or 7-functionalized 4-oxoalkanoates can be prepared utilizing this protocol with a variety of Michael adducts. Methyl diazoacetate addition to ***Allyltrimethylsilane*** followed by treatment with ***Tetra-n-butylammonium Fluoride*** yields methyl 4-pentenoate (eq 3).[17] Cyclopropyl boronates[18] and cyclopropyl amines[19] can also be prepared from methyl diazoacetate under catalytic conditions.

The addition of the methyl diazoacetate-derived carbene to benzene gives rise to methyl cyclohepta-2,4,6-triene-1-carboxylate with a high degree of selectivity (eq 4).[5] The rhodium-catalyzed addition to substituted phenyls yields an isomeric mixture of products. In addition to substituted phenyls, methyl diazoacetate can add to various aromatic hetrocycles.[6]

(4)

Cyclopropenation.

Cyclopropenyl esters are formed by the addition of methyl diazoacetate to various alkynes using $Rh(OAc)_2$ as the catalyst.[20] This cyclopropenation protocol is incompatible with alkynic alcohols (eq 5).[4] The catalyzed insertion of methyl diazoacetate into the O-H bond successfully competes with cyclopropene formation. High enantioselectivity can be achieved in a cyclopropenation with the use of a chiral dirhodium(II) carboxylate.[21]

37% 36%

(5)

Insertion.

The insertion of methyl diazoacetate into the X-H bond (where X = S or O) is catalyzed efficiently with rhodium carboxylates.[7,22] The catalyzed insertion into allyl alcohol yields an α-alkoxy ester (eq 6).[23] Mild selectivity can be achieved over a competitive cyclopropanation with an appropriate catalyst.

Condensation.

Lewis acid-catalyzed addition of methyl diazoacetate to an aldehyde provides a convenient method for the preparation of a 1,3-dicarbonyl. Treatment of 2,3-*O*-isopropylidene-D-glyceraldehyde with methyl diazoacetate yielded methyl (4*R*)-4,5-*O*-isopropylidene-3-keto-4,5-dihydroxypentanoate in good yield (eq 7).[24]

1,3-Dipolar Cycloaddition.

The uncatalyzed 1,3-dipolar cycloaddition of methyl diazoacetate with a suitable dipolarophile yields a substituted pyrazoline or pyrazole.[9,10,25] *N*-(1-Cyclohexenyl)pyrrolidine reacts with methyl diazoacetate, yielding a pyrazoline which eliminates pyrrolidine to give a pyrazole in excellent yield (eq 8).

(8)

Related Reagents.

Diazoacetaldehyde; ***Diazoacetone***; ***Dimethyl Diazomalonate***; ***Ethyl Diazoacetate***.

O-Methyldibenzofuranium Tetrafluoroborate[1]

[36883-49-5] · $C_{13}H_{11}BF_4O$ · *O*-Methyldibenzofuranium Tetrafluoroborate · (MW 270.05)

(methylating agent, more powerful than trimethyloxonium salts[1,2])

Solubility: sol dichloromethane; insol benzene.

Preparative Methods: obtained as an unstable off-white solid by heating dry 2-methoxybiphenyl-2´-yldiazonium tetrafluoroborate in anhydrous benzene.[2,3] The diazonium precursor is conveniently prepared.[3] For synthetic applications the reagent is generated in situ by refluxing a solution (or suspension) of the dry diazonium tetrafluoroborate in anhydrous CH_2Cl_2 in the presence of a suitable substrate.[2,3]

Handling, Storage, and Precautions: the anhydrous diazonium precursor is unstable; it should be stored in vacuo over phosphoric anhydride at rt for a maximum of 2-3 days. Although information on hazardous properties is lacking, skin and eye contact with solutions of the methylating reagent or with the diazonium precursor should strictly be avoided (see also ***Triethyloxonium Tetrafluoroborate***). Use in a fume hood.

Introduction.

O-Methyldibenzofuranium tetrafluoroborate (**1**) has not yet been established as a widely employed reagent, although its methylating power has been reported to exceed that of trimethyloxonium salts or methyl fluorosulfonate.[2,3] The rare use of (**1**) may be due to two disadvantages of its use: the multistep synthesis of its precursor and the fact that methyl transfer from (**1**) to suitable substrates is coupled with the formation of dibenzofuran, which has to be separated from the methylation product. Alkylations with the readily available trimethyloxonium salts do not require extra separation, since only volatile dimethyl ether is formed as a byproduct.

Functional Group Alkylations.

The advantage of the in situ preparation of (**1**) is clearly demonstrated by the methylation of pyridine: when (**1**) is generated from its diazonium precursor (eq 1) in the presence of pyridine, *N*-methylpyridinium tetrafluoroborate is formed in essentially quantitative yield (eq 2).[3] Addition of pyridine to the preformed tetrafluoroborate (**1**) or to the analogous 2,4,6-trinitrobenzenesulfonate (**2**) gives lower yields (28% or 44%, respectively) of the pyridinium salt.[3] The reagent (**1**) is also capable of methylating halogenated pyridine derivatives (eqs 2 and 3).[2,3] When using trialkyloxonium salts the corresponding alkylations occur only to a small extent (<15%).[3] In the following sequences the reagent is indicated as $MeDIB^+BF_4^-$ (**1**), although methylations are performed via the in situ procedure using the diazonium precursor; in all reactions, dibenzofuran is the common byproduct.

Reaction of (**1**) with *N*,*N*-dimethyl-1-naphthylamine results in the formation of the quaternary ammonium salt.[2,3] Similar to methylation with trimethyloxonium tetrafluoroborate, benzonitrile reacts with (**1**) to yield *N*-methylbenzonitrilium tetrafluoroborate, which may be hydrolyzed to *N*-methylbenzamide (eq 4).[3]

O-Methylations via (**1**) have been reported to occur with tetrahydrofuran, α-pyridone, or dimethyl sulfoxide (eq 5) to give high yields of *O*-methyltetrahydrofuranium salt,[2] 2-methoxypyridine,[2,3] and methoxydimethylsulfonium tetrafluoroborate,[2,3] respectively. Methylation of benzo[*b*]thiophene via (**1**) results in the formation of *S*-methylbenzo[*b*]thiophenium tetrafluoroborate (eq 6).[3]

O-Methylation of anisole has not been achieved using either trimethyloxonium tetrafluoroborate or methyl fluorosulfonate.[2,3] However, methyl transfer to anisole oxygen has been shown to proceed when *O*-trideuteriomethyldibenzofuranium tetrafluoroborate is generated in situ from its appropriate diazonium precursor in the presence of anisole. After aqueous workup a mixture of trideuteriomethoxybenzene, unlabeled anisole, and benzofuran is obtained.[3]

Hydride Acceptor Agent.

Hydride transfer to the methyl group of (**1**) formed in situ has been reported to occur in the reaction with cycloheptratriene, to give tropylium tetrafluoroborate (eq 7),[3] or with triphenylmethane, to yield triphenylcarbenium tetrafluoroborate (21%).[3]

Related Reagents.

Dimethoxycarbenium Tetrafluoroborate; ***Dimethyliodonium Hexafluoroantimonate***; ***Methyl Fluoride-Antimony(V) Fluoride***; ***Methyl Trifluoromethanesulfonate***; ***Triethyloxonium Tetrafluoroborate***.

N-Methyl-*N,N´*-di-*t*-butylcarbodiimidium Tetrafluoroborate

[39509-34-7] · $C_{10}H_{21}BF_4N_2$ · *N*-Methyl-*N,N´*-di-*t*-butylcarbodiimidium Tetrafluoroborate · (MW 256.14)

(dehydrative coupling)

Physical Data: mp 85-86 °C.

Form Supplied in: colorless hygroscopic crystals.

Preparative Method: N,N-di-*t*-butylcarbodiimide (1 equiv) is added dropwise to 1 equiv of ***Trimethyloxonium Tetrafluoroborate*** at 0 °C and stirred for 6 h before warming to rt and stirring for an additional 18 h. Isolation under fairly anhydrous conditions gives the diimidium salt in 62% yield.[1]

Dehydrative Coupling.

The reagent has been used in dehydrative coupling processes.[2] For example, diols (**1**) may be dehydratively cyclized to ethers by 1.0 equiv of the diimidium salt (**2**) and slightly more than 1 equiv of ***Triethylamine*** (eq 1) to give the corresponding cyclic ether and the urea (**3**). Yields vary and examples of ring sizes larger than seven members formed in the process have not been reported.

Appropriately protected amino acids have been coupled to dipeptides (eq 2). There is no apparent reason to favor this reagent over others in this process.

(synthesis of α-chloroglycidic esters[1] and/or 3-chloro 2-keto ester isomers[1,2] (Darzens reaction); 2,2-dichloro esters (alkylation);[3] 1,2-dialkoxycarbonylchlorocyclopropanes (Michael reaction);[4] precursor[5] for Reformatsky reagents; precursor for 1,1-dithioalkyl (or aryl) acetates[6])

Physical Data: (**1**) bp 143 °C; *d* 1.3774 g cm^{-3}. (**2**) bp 157 °C; *d* 1.2827 g cm^{-3}. (**3**) bp 164-165 °C; *d* 1.2053 g cm^{-3}.

Solubility: sol ether, acetone, alcohol, THF, chloroform.

Handling, Storage, and Precautions: lacrymatory; handle in a well-ventilated fume hood. The reagents are quite stable at rt under neutral conditions.

Introduction.

Dichloracetic esters have a very acidic α-proton which allows, after deprotonation with the appropriate bases, Darzens reaction with carbonyl compounds and imines, alkylation, and Michael reactions followed by cyclization with acrylic esters.

Synthesis of α-Chloroglycidic Esters, β-Chloro α-Keto Esters, and 2,2-Dichloro Esters.

One of the most important applications of dichloro acetates has been found in the synthesis of α-chloroglycidic esters[1] and their β-chloro α-keto ester isomers via the Darzens reaction in the presence of potassium or sodium alcoholates in alcohols.[7] When applied to aromatic aldehydes in aprotic media this reaction gives α-chloropyruvates.[2] The reaction also applies to various carbonyl compounds, such as carbohydrates[8] and steroids.[9] The same reaction was developed from the corresponding 2-dichloromethyl-4,4-dimethyl-2-oxazolidine (eq 1).[10]

In the presence of imines this reaction gave analogous 1-chloro-1-alkoxycarbonylaziridines (eq 2).[11]

Tandem Darzens-hydrolysis reactions have been used for the synthesis of natural 3-hydroxy 2-keto esters,[12] while tandem Darzens-isomerization-dehalogenation gave rise to α-keto esters (eq 3).[8]

Lithium dichloroenolates have been prepared by deprotonation of dichloracetates with ***Lithium Diethylamide***,[3] ***Lithium Diisopropylamide***,[13] ***Lithium Dicyclohexylamide***,[14] or ***n-Butyllithium***.[15] Coupling of these anions with carbonyl compounds afforded 3-hydroxy-2,2-dichloroesters[3,15] or α-chloroglycidic esters[15] at rt, while 2,2-dichloroalkanoates have been prepared by alkylation of bromoalkanes in the presence of HMPA (eq 4).[3,13,16]

However, vicarious substitution of nitroarenes by dichloroacetate potassium enolates (***Potassium t-Butoxide*** in DMF) only gave the corresponding α-chlorobenzyl esters via addition of enolates and subsequent hydrochloric acid elimination (eq 5).[17]

(5)

Preparation of 1,2-Dialkoxycarbonyl-1-chlorocyclopropanes.

Dichloroenolates from dichloroacetates have been involved in a tandem Michael-cyclization reaction with acrylic esters in the presence of lithium hydride,[18] electrogenerated bases,[19] or under mildly basic phase-transfer conditions[20] (eq 6).

(6)

Chlorine abstraction by metals (Zn/Ag)[21] or under electrocatalysis[22] with a zinc sacrificial anode in the presence of a nickel complex led to the formation of the intermediate Reformatsky reagents MCHCl-CO_2R and allowed preparations of 3-hydroxy-2-chloroalkanoates or glycidic esters on coupling with carbonyl compounds (eq 7).

(7)

The corresponding copper carbenoids, obtained intermediately by reaction of copper in DMSO, gave mixtures of fumarates and maleates.[23]

Selective Synthesis of 2,4-Dichloroalkanoates and 2,2-

Dichloroalkanoates.

Addition of dichloroacetates to 1-alkenes by a radical pathway can lead to the formation of both 2,4-dichloroalkanoates and 2,2-dichloroalkanoates, depending on reaction conditions.[24] When performed in the presence of 0.7 mol % dichlorotris(triphenylphosphine)ruthenium(II)[25] or copper(I) chloride-1,10 phenanthroline complexes,[26] 2,4-dichloroalkanoates are formed exclusively, while 2,2-dichloroalkanoates are formed preferentially in the presence of peroxides (eq 8).[27] The mechanism of this reaction has been fully investigated.[25,28] Butadiene can also be used as a substrate.[29]

(8)

Miscellaneous.

Dialkyl-[6] and diarylthioacetates[6,30] can be easily prepared by substitution of dichloroacetates by thiolates. Reaction with ***Phosphorus(III) Chloride*** occurs in the presence of ***Triethylamine*** and leads to the formation of the corresponding dichlorophosphines.[31]

Related Reagents.

Dichloroacetonitrile; ***Methyl Chloroacetate***.

Methyl Dichlorofluoroacetate

[431-44-77] · $C_3H_3Cl_2FO_2$ · Methyl Dichlorofluoroacetate · (MW 160.96)

(Reformatsky-type reactions with aldehydes to give 2-fluoroenoates)

Physical Data: bp 82-85 °C/0.5 mmHg.

Solubility: usually used in polar solvents (acetone)

Analysis of Reagent Purity: satisfactory microanalytical data reported.[1]

Preparative Method: prepared in 65% yield by reaction of methyl trichloroacetate and ***Antimony(III) Chloride*** in the presence of ***Bromine***.[1,2]

The methyl ester of dichlorofluoroacetic acid is a useful reagent in Reformatsky-type reaction with aldehydes (eq 1).[2] This procedure allows preparation of 2-fluoroenoates (**1**) in synthetically useful yields; (*Z*)-isomers are formed in high preponderance (&egt;93% (*Z*)-isomer obtained). In the absence of molecular sieves the reaction does not occur.

(1)

The use of anhydride sources as an alternative to the simple acetyl anhydride employed in eq 1 has been reported as an improvement to this method (Table 1 and eq 2).[3] The same report describes several reactions in which the previously claimed high selectivity for the (*Z*)-isomer in the alkenation reaction is not observed; up to 40% (*E*)-alkene is obtained.

(2)

N-Methyl-*N,N´*-dicyclohexylcarbodiimidium Iodide

[36049-77-1] · $C_{14}H_{25}IN_2$ · *N*-Methyl-*N,N´*-dicyclohexylcarbodiimidium Iodide · (MW 348.31)

(conversion of alcohols to iodides)

Physical Data: colorless hygroscopic crystals; mp 111-113 °C.

Preparative Method: ***1,3-Dicyclohexylcarbodiimide*** (42 g, 0.204 mol) was dissolved in a large excess of ***Iodomethane*** (90 mL, 1.45 mol) and stirred at 70 °C for 3 days under a nitrogen atmosphere. The excess MeI was removed by distillation under reduced pressure and the residue was dissolved in dry toluene (150 mL) at 40 °C. The resulting crystalline mass was filtered off under an inert atmosphere and the crystals were washed with cold, dry toluene until colorless. The product was dried under vacuum (0.1 mmHg) at rt to provide 35 g (75%) of colorless crystals.

Handling, Storage, and Precautions: the compound should be stored under an inert atmosphere at refrigerator temperatures, where it is reputed to be stable for several months.

Conversion of Alcohols to Iodides.

First reported in 1972, the sole reported use of *N*-methyl-*N,N´*-dicyclohexylcarbodiimidium idodide (**1**) is in the conversion of alcohols to iodides. The original article[1] contains the first description of the preparation in bulk of a carbodiimidium salt and describes its use in the preparation of some primary and secondary iodides. In three of the examples, inversion of configuration was exclusive, (**2**) -> (**4**), hinting at a mechanism such as that shown in eq 1. The reagent was said to be good for the preparation of very hindered secondary iodides, but the yields are generally low (eqs 2 and 3). The reagent is, however, quite successful in preparing iodides from alcohols in multifunctional compounds (**6**),[2] (**7**),[3] and (**8**).[4]

Methyl Diethylamidosulfite[1]

[21954-69-8] · $C_5H_{13}NO_2S$ · Methyl Diethylamidosulfite · (MW 151.26)

(conversion of carboxylic acids to *N*,*N*-diethylamides[2])

Physical Data: bp 73-74 °C/10 mmHg.

Solubility: sol diethyl ether.

Form Supplied in: clear oil.

Analysis of Reagent Purity: titration with iodine.

Preparative Method: reaction of diethylamine and chlorosulfurous acid in diethyl ether.[1,2]

Purification: vacuum distillation.[2]

Handling, Storage, and Precautions: prolonged heating at atmospheric pressure causes decomposition with evolution of sulfur dioxide.

This reagent reacts with primary and secondary carboxylic acids in the presence of pyridine to give *N*,*N*-diethylamides (eq 1). The reaction is typically run at rt and requires a long reaction time (several days). In general, tertiary acids and α-amino carboxylic acids do not react.[2,3]

Methyl Diformylacetate

(dione)

[50427-65-1] · $C_5H_6O_4$ · Methyl Diformylacetate · (MW 130.11) (enol)

[39947-70-1]

([2 + 2] cycloaddition[1] (de Mayo reaction);[2] [4 + 2]cycloaddition (hetero-Diels-Alder reaction with inverse electron demand);[3] transformation to enamino aldehydes and their photochemical and thermal cycloadditions;[4] Wittig reaction[5])

Physical Data: bp 54-55 °C/3.5 mmHg.

Solubility: slightly sol water; sol aqueous alkali and diethyl ether.

Form Supplied in: colorless liquid.

Preparative Methods: by Panizzi's formylation procedure[6] of commercially available methyl 3,3-dimethoxypropanoate[7] with methyl formate,[1i] by diformylation of potassium monomethyl malonate with dimethyl formamide and phosphorus oxychloride followed by decarboxylation, and by ozonolysis of dimethyl 2,5-cyclohexadiene-1,4-dicarboxylate.[8]

Purification: fractional vacuum distillation.

Handling, Storage, and Precautions: stable for at least 6 months if stored at -20 °C; it is a highly acidic compound. Use in a fume hood.

Methyl diformylacetate (**1**) undergoes photochemical [2 + 2] cycloadditions ([2 + 2] photoannulation) with alkenes. Thus irradiation of (**1**) and the alkene (**2**) leads primarily to the *cis*-fused cyclobutane derivative (**3**), which by retro-aldol cleavage to a 1,5-dialdehyde and cyclization gives the hemiacetal (**4**). Treatment of (**4**) with methanol in the presence of IR-120 cation exchange resin yields the methyl acetal (**5**) (eq 1), which was converted into the iridoid-

glucoside loganin.[1i,j] In a similar way, methyl diformylacetate has been used for the synthesis of hydroxyloganin, secologanin derivatives, and sarracenin.[1a-g]

In the photoaddition of methyl diformylacetate with ***Isobutene*** the two possible regioisomeric dihydropyrans (**6**) and (**7**) were formed in the ratio 2.5:1 (eq 2).[1c]

Methyl diformylacetate can also be employed as heterodiene in [4 + 2] cycloaddition with reactive dienophiles like enol ethers to give dihydropyrans. Thus the hetero-Diels-Alder reaction with inverse electron demand of (**1**) and 1-methoxycyclopentene at 20 °C for 200 h leads to the diastereomers (**8**) and (**9**) in the ratio 3:1 with 82% yields (eq 3).[3a] Methyl *O*-acyldiformylacetates are more reactive in the cycloadditions and the diastereomeric ratio is almost inverted. The use of chiral *O*-acyl derivatives allows an asymmetric induction.[3a] Triformylmethane may be used in a similar way.[3b]

Enamino aldehydes (**8**) were prepared by condensation of methyl diformylacetate with amines in the presence of a drying agent such as flame-dried Na_2SO_4 (eq 4).[4a] The [2 + 2] photoannulation of (**8**) with alkenes gives 2-hydroxytetrahydropyridines, which easily undergo elimination of water on treatment with an acid to afford 1,4-dihydropyridines. The reaction is highly selective; thus with electron-donating alkenes only 3-substituted 2-hydroxytetrahydropyridines are obtained (eq 5), and with electron-accepting alkenes only 4-substituted 2-hydroxytetrahydropyridines are obtained (eq 6).[4]

(6)

In a sequential transformation,[9] which consists of a [2 + 2] photoannulation of an enamino aldehyde, obtained from (**1**), and an intramolecular C-C bond formation of the intermediate iminium salt, benzo[*a*]quinolizidines, quinolizidines, and pyrido[1,2-*a*]azepines can be synthesized.[4a,f]

N-Acyl-enamino aldehydes from (**1**) react with enol ethers in a hetero-Diels-Alder reaction with inverse electron demand to give 4-aminodihydropyrans with the skeleton of branched amino sugars of the garosamine type.[4c]

Methyl diformylacetate[5b] and its acetylated form[5a] were also used as carbonyl compounds for a Wittig reaction, with moderate yields.

Related Reagents.

3-Ethoxyacrolein; ***Ethyl 3,3-Diethoxypropanoate***; ***Ethyl 3-Ethoxyacrylate***; ***Ethyl Hydroxymethyleneacetate, Sodium Salt***; ***Malondialdehyde***.

Methyl Dilithioacetoacetate

[30568-00-4] ($M^1 = M^2 = Li^+$)

[53437-05-1] · $C_5H_6Li_2O_3$ · Methyl Dilithioacetoacetate · (MW 127.99) ($M^1 = Li^+$, $M^2 = Na^+$)

[64670-05-9] · $C_5H_6LiNaO_3$ · Methyl Lithiosodioacetoacetate · (MW 144.04)

(four-carbon chain, all four carbons of which can be reacted regioselectively; versatile starting material in synthesis of complex molecules; undergoes γ-alkylation and γ-acylation)

Solubility: sol THF, ether, dimethoxyethane, and HMPA; slightly sol hydrocarbon solvents.

Form Supplied in: generated in situ.

Analysis of Reagent Purity: NMR spectroscopy or mass spectrometry of D_2O quench.[1]

Preparative Methods: dianion (**1**) is prepared in a dry solvent, usually THF or diethyl ether, by adding the β-keto ester to 1.1 equiv of ***Sodium Hydride***, which has been washed free of mineral oil, and then adding 1.05 equiv of ***n-Butyllithium*** at 0 °C (eq 1).[1] It may also be prepared by treating the β-keto ester with 2.0 equiv of ***Lithium Diisopropylamide*** or ***Lithium 2,2,6,6-Tetramethylpiperidide*** at 0 °C.[1] These methods may be used to generated the dianions of a wide range of β-keto esters. The dianion (**1**) may be quenched with D_2O and the degree of dianion formation determined by integration of the ^1H NMR methyl peak at δ 2.2 relative to the ester signal or by mass spectrometry.[1] Occasionally it is necessary to add HMPA to dissolve the dianions of more substituted β-keto esters.

Handling, Storage, and Precautions: generated in solution; stable for hours at 0 °C; reacts with moisture and oxygen.

Introduction.

Acetoacetate esters provide a four-carbon chain to homologate simpler molecules. The utility of this homologation is that all four carbons subsequently can be reacted regioselectively. Thus the acetoacetate unit is one of the most versatile starting materials available in the synthesis of complex natural and unnatural products.

Alkylation of Methyl Acetoacetate Dianion.

The dianion (**1**) reacts with primary and secondary halides and sulfonates to give the γ-alkylated products (**2**) in good yield (eq 2 and Table 1). Halides are the most common alkylating agents. However, sulfonates will also react. The triflate is effective in the case of hindered alkylating agents.[7] Primary halides react without difficulty. Secondary halides are less reactive and some do not react under these conditions. Tertiary halides do not undergo alkylation. The reaction is compatible with a number of other functional groups and protecting groups. It is not necessary to protect alcohol groups, provided excess dianion is used. Following monoalkylation of (**1**), addition of a second equiv of base will regenerate a dianion which can be alkylated a second time (eq 3).[57] Highest yields in this one-pot bisalkylation required the addition of ***N,N´-Dimethylpropyleneurea***.[57] Other esters of acetoacetate, such as ethyl, *t*-butyl, and 2-trimethylsilylethyl, have also been used in these reactions.

Benzylic halides	40-85	1, 18, 50-52
	30-50	55
Epoxides	50-90	16, 59-61

A recent example which exemplifies the complex carbon skeletons which can be assembled from acetoacetate dianions is taken from the synthesis of latrunculin A (eq 4).[58] The dianion of the β-keto ester (**3**) reacts with the phosphonium salt (**4**) which is generated in situ. The resulting phosphorane is treated with an aldehyde to give the diene β-keto ester (**5**), all in one pot. The next higher vinylog of (**4**) yields (*E*,*E*,*Z*)-trienes in the same reaction.[58c]

Epoxides react with (**1**) to give alcohols (Table 1). In the case of simple epoxides the initially formed alcohols often could not be isolated, because they underwent cyclization to tetrahydrofuranylidene-2-acetates (**6**) (eq 5).[16] In the case of more complex epoxides the alcohols usually could be isolated in good yield and in most cases the opening of the epoxide ring was regioselective.[68-70]

The dianion of methyl acetoacetate reacts with other simple electrophiles including benzenesulfenyl halides,[62] alkyl nitrates,[63] chlorophosphates,[64] and carbon dioxide.[65] Often the reaction is very clean, leading to the γ-substituted product.

The dianion (**1**) undergoes aldol condensations with a variety of aldehydes (Table 2). The resulting δ-hydroxy-β-keto esters (**7**) can be cyclized to the β-keto-δ-lactones, oxidized or dehydrated (eq 6). The stereoselectivity in the addition to chiral aldehydes is low, although it can be improved with the addition of Lewis acids.[77] In the case of α,β-unsaturated aldehydes and ketones, only 1,2-addition is observed.

Table 2 Aldol Condensations of Acetoacetate Dianions with Aldehydes and Ketones (eq 6)

R^1COR^2	Yield (%)	Ref.

Aliphatic ketones	25-70	67, 68, 86, 87
Conjugated ketones[a]	60-85	67, 88, 89
Aromatic ketones	60-95	67, 90
	17	91

[a] Yield of 1,2-addition product.

Dianion (**1**) can be acylated. A limited amount of work has been carried out using nitriles as the acylating agent and the product was found to be the enamino β-keto ester (**8**) (eq 7).[92]

(7)

(1) **(8)** R = Me, Ph

A much larger range of ester derivatives have been condensed with dianion (**1**) (Table 3). Because the monoanion of the initial product (**9**) is more acidic than the monoanion (**10**) of acetoacetate, the starting dianion (**1**) is quenched as the reaction proceeds. Initially this problem was overcome by adding an extra equiv of base during the reaction.[92] However, the problem does limit the yield of (**9**) (eq 8). Now an excess of dianion (**1**) is usually used to optimize the yield of acylated product (**9**). It was also found that addition of ***Boron Trifluoride Etherate*** improves the yield of (**9**).[93] Addition of TMEDA also leads to increased yields in these acylations.[94]

(8)

(1) **(9)**

Table 3 Acylation Reactions of Acetoacetate Dianions (eqs 8-10)

Acylating reagent	Yield (%)	Ref.
Aliphatic esters	45-80	92, 93, 96c
Aromatic esters	40-85	92-94
Lactones	40	95-96d
Diesters	30-95	100-102
Amides	60-85	93
Bisamides	45-70	93
	40-90	96b, 103

The acylated products have been used in the synthesis of many polyketide aromatic natural products.[96] For example, condensation of (**1**) with the monoanion (**10**) of methyl acetoacetate yields the triketo ester (**11**), which can be cyclized to the orsellinate (**12**) (eq 9).[92,97] The conversion of (**1**) to (**12**) can be carried out in one pot by refluxing the solution of the

dianion (**1**) and the monoanion (**10**) (eq 9).[98,99] These condensations could be applied to dicarboxylic acid derivatives to yield polyketo diesters which readily cyclized (eq 10).[96,101] Acylations with amides in the presence of $BF_3.Et_2O$ led to improved yields of the triketo esters (**11**).[93] This was further refined with the use of *N*-methoxy-*N*-methylamides as acylating agents.[96b,103]

(9)

(10)

Dianion (**1**) undergoes 1,4-addition to certain Michael acceptors such as α,β-unsaturated thioamides,[104] α,β-unsaturated sulfoxides,[105] and α,β-unsaturated sulfones.[106]

Dianion (**1**) has proven to be so useful that several synthetic equivalents to it have been developed and these are listed in Table 4. Most of these reagents are generated under the strongly basic conditions that (**1**) is formed under. However, the

bistrimethylsilyl ether (**13**) reacts with alkylating and acylating reagents in the presence of Lewis acids and provides a very useful complement to (**1**).

Methyl 3-(Dimethylamino)propionate[1]

[3853-06-3] · $C_6H_{13}NO_2$ · Methyl 3-(Dimethylamino)propionate · (MW 131.20)

(masked acrylate synthetic equivalent; for preparation of α-methylene esters, acids, and lactones[2])

Physical Data: bp 56 °C/15 mmHg.

Solubility: sol all common solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: ^{1}H and ^{13}C NMR; GC.

Preparative Method: reaction of ***Methyl Acrylate*** with dimethylamine in ether at 0-25 °C.[3]

Purification: distillation at reduced pressure.

Handling, Storage, and Precautions: routine laboratory techniques; exhibits typical tendency of amines to undergo slow oxidation in the air. Use in a fume hood.

Preparation of 2-Substituted Acrylate Derivatives.

Methyl 3-(dimethylamino)propionate undergoes straightforward enolate formation upon treatment with ***Lithium Diisopropylamide***. The resulting enolate undergoes high yield reactions with a number of alkylating agents. A representative reaction sequence is shown using a cyclic allylic halide (eq 1). The alkylation product is converted to the quaternary ammonium salt using ***Iodomethane*** followed by ***1,5-Diazabicyclo[4.3.0]non-5-ene***-induced elimination to give the 2-substituted acrylate derivative. Among the possible further reactions are iodo lactonization of the free acid and then either ***1,8-Diazabicyclo[5.4.0]undec-7-ene***-induced dehydroiodination or ***Tri-n-butylstannane***-promoted reductive deiodination.

Alternative Reagents.

The primary motivation for the development of this reagent and a large number of related methods was the common natural occurrence of α-methylene lactones. Literally thousands of these compounds are known, and several of them

possess antitumor activity.[1] The other methods are too numerous to describe here,[1] but a recent modification of the present method employs imines in place of alkyl halides in the reaction of the enolate; the ultimate products are α-alkylidene-β-lactam derivatives.[4]

Related Reagents.

Ethyl Acrylate; ***Formaldehyde***; ***Methyl 3-Hydroxypropionate***.

Methyl (4*R*,5*R*)-(*E*)-3-(1,3-Dimethyl-4,5-diphenyl-2-imidazolidinyl)propenoate

[135212-29-2] · $C_{21}H_{24}N_2O_2$ · Methyl (4*R*,5*R*)-(*E*)-3-(1,3-Dimethyl-4,5-diphenyl-2-imidazolidinyl)propenoate · (MW 336.47)

(a chiral synthetic equivalent of methyl (*E*)-4-oxo-2-butenoate)

Physical Data: colorless needles (MeOH); mp 109-110 °C; [α]23D +45.0° (*c* 0.6, $CHCl_3$);[1] IR, ^{1}H NMR, ^{13}C NMR, MS spectral data, and X-ray structural data are also available.[1]

Solubility: very sol dichloromethane, chloroform, ethyl acetate, acetone; sol methanol, ethanol; hardly sol hexane.

Analysis of Reagent Purity: chiral HPLC.[1]

Preparative Methods: both the (4*R*,5*R*) and (4*S*,5*S*) compounds are readily available by condensation of optically active 1,2-bis(methylamino)-1,2-diphenylethanes[2] with methyl (*E*)-4-oxo-2-butenoate.[3]

Pyrrolidine Synthesis.

The lithium (*Z*)-enolate of methyl *N*-benzylideneglycinate undergoes a cycloaddition rapidly at -78 °C with methyl (4*R*,5*R*)-(*E*)-3-(1,3-dimethyl-4,5-diphenyl-2-imidazolidinyl)propenoate (**1**) to give pyrrolidine-2,4-dicarboxylate in quantitative yield and as a single stereoisomer (eq 1).[1] Removal of the chiral auxiliary from the cycloadduct can be readily performed by treatment with conc ***Sulfuric Acid*** in MeOH at rt to produce the optically pure pyrrolidine-2,4-dicarboxylate bearing an acetal substituent at the 3-position.

(1)

(1)

Asymmetric Nitrile Oxide Cycloadditions.

Although the dipolar cycloadditions of nitrile oxides with (**1**) are poor both in reactivity and regioselectivity, regioisomeric isoxazolines are obtained as single diastereomers (eq 2).[4] Removal of the chiral auxiliary can again be performed by an acetal exchange reaction under reflux in MeOH in the presence of H_2SO_4.

34% 16%

(2)

Related α,β-Unsaturated Esters.

Similar α,β-unsaturated esters bearing a heterocyclic chiral auxiliary of α-amino acid origin at the β-position are known and have been utilized in asymmetric synthesis. Effective asymmetric conjugate additions of cuprates to (**2**),[5] (**3**),[6] and (**5**),[7] epoxidations of (**3**),[8] and dipolar cycloadditions of (**2**)[9] have been reported. Although oxazolidine (**4**)[10] is only obtained as an 86:14 equilibrating mixture of stereoisomers, reactions with the lithium (*Z*)-enolate of methyl *N*-benzylideneglycinate (see ***Ethyl N-Benzylideneglycinate***) are exclusively diastereoselective.

Methyldiphenylchlorosilane

$MePh_2SiCl$

[144-79-6] · $C_{13}H_{13}ClSi$ · Methyldiphenylchlorosilane · (MW 232.80)

(protecting group for alcohols; reacts with carboxylic acids and sulfoximes; C-silylates lithium ester enolates)

Physical Data: bp 295 °C/760 mmHg; *d* 1.128 g cm^{-3}; *n*20D 1.5742.

Form Supplied in: clear or transparent, pale yellow liquid.

Analysis of Reagent Purity: gas chromatography on a nonpolar column such as SE-30.

Solubility: sol most organic solvents; reacts with protic solvents such as alcohols, acids, amines, water.

Purification: vacuum distillation is preferred method.

Handling, Storage, and Precautions: chlorosilanes react with water and even moisture in the air to generate HCl and siloxanes, care should be taken to minimize contact with air. Use in a fume hood.

Protecting Group for Alcohols.

The reaction of methyldiphenylchlorosilane with alcohols in the presence of imidazole provides the methyldiphenylsilyl-protected alcohol. The protection of primary, secondary, and tertiary alcohols proceeds with high yields. The methyldiphenylsilyl-protected alcohols are intermediate in stability between those of the trimethylsilyl- and *t*-butyldimethylsilyl-protected ones.[1] It has been shown that, in general, the phenyl-substituted silyl groups are more readily removed by base, where electronic factors are more important, than the trialkylsilyl protecting groups. On the other hand, with acid hydrolysis steric factors play a more significant role and the phenyl-substituted silyl groups are more stable than the trimethylsilyl group, but less stable than the more sterically hindered triethylsilyl and other trialkylsilyl groups.[2] The methyldiphenylsilyl ethers can be oxidized by the chromium reagents ***Dipyridine Chromium(VI) Oxide***, ***Pyridinium Chlorochromate***, and ***Pyridinium Dichromate*** (eq 1). [1]

(1)

A primary alcohol was readily methyldiphenylsilylated by the reaction of methyldiphenylchlorosilane in the presence of an amine. In eq 2 the amine is also the reagent being silylated.[3]

$$MePh_2SiCl + 2\,HOCH_2CH_2NR_2 \longrightarrow MePh_2SiOCH_2CH_2NR_2 + HOCH_2CH_2NR_2 \cdot HCl \quad (2)$$

$$R = Me\ (99\%),\ Et\ (95\%)$$

The methyldiphenylsilyl esters of carboxylic acids can be prepared by the reaction of the chlorosilane with the acid in the presence of ***Triethylamine*** or with the potassium salt of the acid (eqs 3 and 4).[4]

$$MePh_2SiCl + RCO_2H \xrightarrow{Et_3N} RCO_2SiPh_2Me + Et_3N \cdot HCl \quad (3)$$

(4)

Sulfoximes can be silylated with methyldiphenylchlorosilane. The resulting methyldiphenylsilylated sulfoximes can be deprotonated at the methyl group and the anion condensed with aldehydes. The diastereospecificity is greater with the methyldiphenylsilyl group than with the *t*-butyldimethylsilyl group (eqs 5 and 6).[5]

(5)

(6)

C-Silylation of Lithium Ester Enolates.

A very useful asset of methyldiphenylchlorosilane is its ability to directly provide α-(methyldiphenylsilyl) esters (eq 7).[6] These α-(methyldiphenylsilyl) esters have themselves proved to be precursors to alkenes, ketones, α-(methyldiphenylsilyl) ketones, and enol silyl ethers and have been used in the synthesis of some natural products.[6b] An elegant use of the methyldiphenylsilyl group in synthesis (eq 8) is that reported by Villanueva and Prieto,[7] who methyldiphenylsilylated the protected ethyl 4-oxolevulinate to give the α-silyl ester (**1**). This was then treated with 3-phenylpropylmagnesium bromide to give ketone (**2**), a reaction made possible by the presence of the bulky methyldiphenylsilyl group. This ketone was then regioselectively deprotonated on the side opposite to the methyldiphenylsilyl group and the resulting enolate trimethylsilylated to give enol silyl ether (**3**), which was subjected to an intramol ecular Mukaiyama reaction to give cyclopentanone (**4**). Deprotonation and reaction with ***Formaldehyde*** produces a methylenomycin B derivative, (**5**).

(7)

(8)

Other Methyldiphenylsilylations.

Methyldiphenylchlorosilane was used to form 6-silyluracils and uridines.[8] The yields were better than those obtained with ***Chlorotrimethylsilane*** (eq 9). The methyldiphenylsilylation of the lithium anion of 3-triethylsilyloxy-1,4-pentadiene occurs to place the methyldiphenylsilyl group on the 1-position, providing, after deprotection, the β-

methyldiphenylsilyl ketone (**6**) (eq 10).[9]

(10)

(6)

Related Reagents.

t-Butyldimethylchlorosilane; ***t-Butyldiphenylchlorosilane***; ***Ethyl 2-(Methyldiphenylsilyl)propanoate***.

2,2´-Methylenebis(1,3,2-dioxaborinane), Lithium Complex[1]

(**1**; *n* = 2)

[63035-39-2] · $C_7H_{13}B_2LiO_4$ · 2,2´-Methylenebis(1,3,2-dioxaborinane), Lithium Complex · (MW 189.76)
(**2**; *n* = 1)

[57404-82-7] · $C_5H_9B_2LiO_4$ · 2,2´-Methylenebis(1,3,2-dioxaborolane), Lithium Complex · (MW 161.70)

(converts aldehydes to (*E*)-alkenylboronic esters,[1,2] which can be converted to the homologous aldehyde[3] or coupled with alkenyl halides;[4] converts primary alkyl halides to 1,1-alkylidenebis(boronic esters)[2])

Physical Data: air-sensitive solid; precipitates from THF at 0 °C. The immediate precursor, 2,2´-methylenebis(1,3,2-dioxaborinane), crystallizes from 4:1 Et_2O/pentane, mp 42-43 °C, ^1H NMR δ 0.13 (s, BCH_2B).

Preparative Methods: methylenebis(boronic acid) tetramethyl ester is prepared by addition of a mixture of $(MeO)_2BCl$ and CH_2Cl_2 to Li dispersion in THF vigorously stirred at -40 to -30 °C,[1a,5] then transesterified with 1,3-propanediol.[2] The lithium complex is formed by treatment with ***Lithium 2,2,6,6-Tetramethylpiperidide*** (LiTMP) and TMEDA in THF.[2]

Handling, Storage, and Precautions: 2,2´-methylenebis(1,3,2-dioxaborinane) can be transferred and weighed in air, but should be stored under an inert atmosphere. The lithium complex is generated as needed and must be protected from moisture and oxygen.

Reagent Preparation.

Dimethoxyboron chloride is prepared by mixing ***Trimethyl Borate*** with ***Boron Trichloride*** below 0 °C, then mixed with dichloromethane and added to a vigorously stirred suspension of lithium metal dispersion in THF kept at an internal temperature between -40 and -30 °C by manipulating the rate of addition and the position of the -78 °C cooling bath.[1a,5] It is essential that the stirring be very vigorous, that there be some excess of $(MeO)_2BCl$ and CH_2Cl_2 over the

amount of Li, and that large amounts of unreacted $(MeO)_2BCl/CH_2Cl_2$ not be allowed to accumulate before the exothermic reaction sets in. The lithium salts are filtered with the aid of celite in a large Büchner funnel under a blanket of argon (*CAUTION*: some pyrophoric lithium metal may remain). The filtrate is given an initial rapid distillation, and the distillate is redistilled to separate the $CH_2[B(OMe)_2]_2$ (**3**), bp 48-52 °C 15 mmHg (35%). Treatment of (**3**) with 1,3-propanediol and crystallization from 4:1 Et_2O/pentane yields 2,2´-methylenebis(1,3,2-dioxaborinane) (**4**), mp 42-43 °C (78%). The lithium complex of 2,2´-methylenebis(1,3,2-dioxaborinane) (**1**) precipitates on treatment of (**4**) with LiTMP and TMEDA in THF (eq 1).[2] For some purposes, (**1**) can be used as a slurry, but for reaction with aldehydes the yields are much improved if (**1**) is filtered in a Schlenk apparatus first.[2]

Substitution of $CHCl_3$ for CH_2Cl_2 in the above procedure provides $HC[B(OMe)_2]_3$,[1a,5] which with ethylene glycol yields 2,2´,2´´-methanetris(1,3,2-dioxaborolane) (**5**), which with BuLi forms the lithium complex of 2,2´-methylenebis(1,3,2-dioxaborolane) (**2**) (eq 2).[6] Yields of $HC[B(OMe)_2]_3$ varied more than those of (**3**),[2] and the deprotonation of (**4**) is generally more practical even though the lithiation of (**2**) is cleaner, and use of (**2**) does not require the Schlenk filtration.

Alkenylboronic Esters.

A key step in the palytoxin synthesis was reaction of (**1**) with a structurally complicated aldehyde to form the corresponding (*E*)-1-alkenylboronic ester (eq 3), (*E*):(*Z*) ratio 8:1.[4] The usual route to (*E*)-1-alkenylboronic esters, hydroboration of an alkyne with catecholborane,[7] could not be used in this case because of interference by a remote urethane substituent.

The model reactions for the foregoing chemistry were previous work done with (**2**), which yielded a series of (*E*)-1-alkenylboronic esters in ~10:1 (*E*):(*Z*) ratio.[6]

Carbonyl Homologation.

Reaction of (**2**) with aldehydes followed by in situ oxidation with ***Hydrogen Peroxide*** buffered with $NaHCO_3$ or, preferably, ***Sodium Perborate*** yields the homologous aldehydes (eq 4).[3]

$R = Me(CH_2)_n$, $n = 3, 4, 7$; $R = Ph$; $R = H_2C{=}CH(CH_2)_3$

Ketones $R_2C{=}O$ were similarly converted to $R_2CH\text{-}CHO$ (65-81%). The use of (**1**) for this purpose has been shown to

give equivalent results in the one example tested, heptanal to octanal, but only if the (**1**) is collected by filtration in a Schlenk apparatus before reaction with the aldehyde.[3]

Alkylation and Acylation of (1).

Primary alkyl bromides or iodides alkylate (**1**), and the resulting 1,1-diboronic esters (**6**) can be deprotonated and alkylated a second time (eq 5).[2] In general, a better route to (**6**) is provided by dihydroboration of an alkyne with $HBCl_2$,[8] provided there is no interfering functionality or chain branching in R^1.

Reaction of (**1**) or the anion from (**6**) with carboxylic esters yields ketones (eq 6).[2] The recent ready availability of $RCH_2CH(BCl_2)_2$ and hence (**6**) via hydroboration[8] makes this route potentially useful.

Related Reagents.

Other boronic esters that can be deprotonated and undergo reactions analogous to those of (**1**) include $Me_3SiCH_2BO_2C_2Me_4$[9] and $PhSCH_2BO_2C_2Me_4$.[10]

Methylenecyclobutane

[1120-56-5] · C_5H_8 · Methylenecyclobutane · (MW 68.13)

(synthesis of 1-methylcyclobutene, cyclobutanone, and cyclopentanone)

Physical Data: bp 42 °C; *n*20D 1.4210.

Form Supplied in: usually available in ampules because of volatility.

Preparative Methods: may be prepared in 70% yield by ***Zinc*** reduction of pentaerythritol tetrabromide.[1] Typical impurities in samples prepared by this method are 2-methyl-1-butene and spirocyclopropane. An alternative synthesis is available via methylenation of ***Cyclobutanone***.[2]

Purification: NMR spectroscopy is the best method for determination of purity unless a GC equipped for determination of quite volatile materials is readily available.

Handling, Storage, and Precautions: use in a fume hood.

Methylenecyclobutane is used to prepare 1-methylcyclobutene by base-catalyzed double bond isomerization.[3] A useful allyllithium reagent may be prepared from methylenecyclobutane via ***n-Butyllithium/N,N,N´,N´-Tetramethylethylenediamine*** mediated metalation (eq 1).[4,5] Reaction of the cyclobutenylmethyllithium anion with electrophiles gives mixtures of regioisomeric products. In some cases the major cyclobutene products may be thermolyzed to give 2-substituted 1,3-butadienes.[4,5]

Methylenecyclobutane has also been used to prepare cyclobutanone[2] by ozonolysis (eq 2) and cyclopentanone[6] by ring expansion (eq 3).

(2)

(3)

Related Reagents.

Cyclobutanone; ***Methylenecyclopropane***; ***Squaric Acid***; ***Tricarbonyl(cyclobutadiene)iron***.

Methylenecyclopropane[1]

[6142-73-0] · C_4H_6 · Methylenecyclopropane · (MW 54.10)

(four-carbon building block useful for thermal, photochemical, and transition metal-mediated cycloadditions;[1] epoxidation and rearrangement yields cyclobutanone;[2] can be metalated[3] or transformed to 2,4-dilithio-1-butene[4])

Physical Data: bp 11 °C; *d* 0.85 g cm^{-3}.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid.

Preparative Method: readily prepared by treatment of 3-chloro-2-methyl-1-propene with sodium *t*-butoxide (eq 1).[2]

Cycloaddition.

Methylenecyclopropane (**1**) reacts as a dienophile in the Diels-Alder reaction (eq 2)[5] and undergoes photochemical [2 + 2] cycloadditions with both electron-rich and electron-poor alkenes (eq 3).[6] Neat thermolysis of (**1**) yields a mixture of [2 + 2] dimers (eq 4).[7]

(2)

(3)

(4)

Dipolar cycloadditions proceed smoothly and regioselectively between (**1**) and ***Diazomethane***,[8] ***Phenyl Azide***,[8] and nitrones (eq 5).[9] The major nitrone cycloadducts such as (**2**) thermally rearrange to give 4-oxopiperidines (eq 6).[9]

(5)

(6)

Transition metal-mediated chemistry of (**1**) can involve several intermediate forms (**5**)-(**7**) (eq 7). Reactions involving

Mo, Fe, Co, Rh, Ni, Pd, and Pt have been reported.[1]

Palladium-catalyzed dimerization of methylenecyclopropane gives a high yield of (**8**) (eq 8)[11a] (compare with eq 4).

Cycloadditions with 1-trimethylsilyl-1-alkynes[10] and with α,β-unsaturated aldehydes, ketones, esters, nitriles, and sulfones have been extensively studied[11] and representative results are shown in eq 9. Metal-catalyzed [2 + 2] reactions of (**1**) have also been reported.[12]

(9)

Conditions	(8)	(9):(10):(11)	Yield
$Pd(acac)_2$ *i*-Pr_3P	19%	2:3:-	67%
$Ni(cod)_2$ $(ArO)_3P$	-	1:3:-	42%
$Ni(C_2H_3CN)_2$	-	3:2:45	20%

Other Chemistry.

Under carefully optimized conditions, (**1**) can be condensed with ***Carbon Dioxide*** to give butenolide (**12**) in good yield (eq 10).[13]

(10)

Epoxidation of (**1**) yields the isolable oxaspiropentane, which exothermically rearranges to cyclobutanone (**13**) with catalytic ***Lithium Iodide*** (64% overall) (eq 11).[2]

(11)

Deprotonation of (**1**) occurs at C-2, yielding an allylic anion.[3] This ambident nucleophile reacts exclusively at the ring position to yield 2-substituted methylenecyclopropanes (eq 12).

(12)

Treatment of (**1**) with ***Lithium*** in ether yields a stable solution of dilithiobutene (**14**) (70-75%) (eq 13).[4]

Methylenetriphenylphosphorane[1]

$Ph_3P{=}CH_2$

[3487-44-3] · $C_{19}H_{17}P$ · Methylenetriphenylphosphorane · (MW 276.33)

(methylenating agent for aldehydes and ketones;[1] can convert lactols into hydroxy alkenes;[2] can form a lithio derivative;[3] can be transformed into a β-ketophosphorus ylide[4-6])

Physical Data: mp 96 °C; yellow crystals turning white in air.

Solubility: sol ether, THF, DME, benzene, toluene, DMSO; water and protic solvents destroy the reagent completely.

Form Supplied in: not available commercially; prepared as a solution immediately prior to use.

Analysis of Reagent Purity: ylide concentration can be calibrated by color end-point titration of an aliquot with PhCHO in ether or $PhCO_2H$ in THF at -20 °C under N_2.

Preparative Methods: usually prepared by treatment of a suspension of ***Methyltriphenylphosphonium Bromide*** (or iodide) in an appropriate solvent with a strong base. Butyllithium, dimsylsodium, *t*-BuOK, and sodamide are commonly used. Typically, a suspension of dry methyltriphenylphosphonium bromide in dry ether or THF is treated with ***n-Butyllithium*** at 0 °C under N_2 and the resulting solution is stirred at rt for 1 h. A yellow to deep orange color indicates the ylide formation. The dimsylsodium (***Sodium Methylsulfinylmethylide***) procedure[7] requires heating a suspension of NaH in dry DMSO at 75-80 °C for 1 h followed by ice-cooling prior to the addition of phosphonium bromide. A salt-free ylide is usually prepared using ***Sodium Amide*** in liquid ammonia[8] or in refluxing THF.[9]

Handling, Storage, and Precautions: should always be handled under N_2 or Ar. The ylide should be used as prepared for best results.

Methylenation of Aldehydes and Ketones.

The most versatile utility of $Ph_3P{=}CH_2$ is Wittig methylenation[10] of aldehydes and ketones.[1,10] Under salt-free conditions, 1,2-oxaphosphetanes have been observed as the only intermediate in the methylenation of aldehydes and ketones.[8] Even in cases where a lithium base is used, the classically favored betaine intermediate could not be observed. Decomposition of 1,2-oxaphosphetanes upon warming then provides terminal alkenes from aldehydes and 1,1-disubstituted alkenes from ketones. Hydroxy aldehydes[11a] and ketones[11b] can be directly converted to hydroxy

alkenes when excess reagent is employed (eqs 1 and 2). Often one-carbon homologation of an alcohol can be achieved through a sequence of oxidation, Wittig methylenation, and hydroboration (eq 3).[12]

(1)

(2)

(3)

Vinyl cyclopropanes[13a] and cyclobutanes[13b] are conveniently prepared from corresponding cyclopropyl and cyclobutyl carbonyl compounds. Likewise, vinyl epoxides[14] and aziridines[15] can be prepared (eqs 4 and 5). α,β-Unsaturated aldehydes and ketones are readily converted to 1,3-dienes (eqs 6 and 7).[16]

(4)

(5)

(6)

(7)

Substituted 1,3-dienes can be prepared by the treatment of corresponding enals and enones with $Ph_3P{=}CH_2$. Some examples include dienyl iodide,[17a] silyldiene,[17b] and dienyltin[17c] (eqs 8-10). Under carefully controlled reaction conditions, dienol ethers and sulfides are obtained from vinylogous formates and thioesters, respectively (eqs 11 and 12).[18] The 1,3-dienes prepared this way are often used as Diels-Alder dienes.

(8)

(9)

(10)

(11)

(12)

α-Thioalkoxy aldehydes give rise to allylic sulfides in reaction with $Ph_3P{=}CH_2$.[19] Wittig methylenation can also be effected even in the presence of unusual functional groups such as a phosphonate ester,[20] *O*-silyl oxime,[21] peracetal,[22] and ketene dithioacetal[23] (eqs 13-16).

(13)

(14)

(15)

(16)

However, sterically hindered and enolizable ketones are not readily methylenated with $Ph_3P{=}CH_2$.[24] Methylenation of a sterically hindered ketone generally requires a substantial excess of the reagent at elevated temperature and a minimum amount of solvent, as demonstrated in a modhephene synthesis (eq 17).[24a] In this particular example, it was necessary to add the ketone to a preheated (92 °C) solution of a sevenfold excess of $Ph_3P{=}CH_2$ in toluene. One practical modification used to increase the yield of methylenation of enolizable ketones is the repeated additions of stoichiometric amounts of water and the reagent.[24b] Cyclooctanone was therefore methylenated in ether in 89% yield (44%, otherwise) after five cycles of additions (eq 18).

(17)

(18)

Other problems commonly observed in Wittig methylenation are β-elimination,[25a,b] retro-aldol,[25c,d] and α-ketol rearrangement,[25e] all of which are caused by the basic nature of $Ph_3P{=}CH_2$ (eqs 19-21).

(19)

(20)

(21)

Methylenation of Lactols and Carbinollactams.

Lactols readily undergo methylenation with excess $Ph_3P{=}CH_2$ to give hydroxy terminal alkenes (eqs 22 and 23).[2] γ-Lactones,[26] as well as δ-lactones,[27] can be converted to acyclic alkenic products via reductive methylenation (eq 24). α-Substituted lactols are sometimes disposed to a rapid equilibration with the more stable conformers through their acyclic tautomers, giving rise to the epimerized product (eq 25).[26e] o-Carbinollactams also undergo methylenation to give corresponding alkenic amides (eq 26).[28]

(22)

(23)

(24)

(25)

(26)

Reaction with Esters and Carbonyl Equivalents.

$Ph_3P{=}CH_2$ can react with esters to give either acetylated or isopropenyl compounds, depending on the nature of the

ester and the reaction conditions.[29] Aromatic esters usually give rise to isopropenyl compounds, while aliphatic esters result in a mixture of both (eqs 27 and 28).[29a] Polar aprotic solvents and salt-free conditions favor the formation of isopropenyl compounds.[29b] This method has been used recently in the synthesis of the unnatural enantiomer of rothrockene (eq 29).[30]

(27)

(28)

(29)

Carbonyl equivalents such as mixed acetals[31] and β-acyloxy enol esters[32] also react with $Ph_3P{=}CH_2$ to provide corresponding alkenic products (eqs 30 and 31).

(30)

(31)

Formation of Allylic and Homoallylic Alcohols via Oxido Ylides.

$Ph_3P{=}CH_2$ can be activated by lithiation with ***t-Butyllithium*** (or ***s-Butyllithium***) in ether.[3] α-Lithiomethylenetriphenylphosphorane ($Ph_3P{=}CHLi$) thus formed reacts with a hindered ketone, which is unaffected by $Ph_3P{=}CH_2$, to give a methylenated compound. Reaction of $Ph_3P{=}CHLi$ with 2 equiv of aldehyde results in formation of a *trans*-allylic alcohol via a β-oxido ylide (eq 32). $Ph_3P{=}CHLi$ also reacts with an epoxide to give a γ-oxido ylide which in turn couples with an aldehyde to provide a *trans*-homoallylic alcohol (eq 33). β-Oxido ylides are also formed in a SCOOPY reaction[33a] in which a mixture of *cis*- and *trans*-allylic alcohols is usually obtained (eq 34).[33b]

(32)

(33)

(34)

Formation of Extended Phosphorus Ylides.

Various phosphorus ylides can be produced by reaction of $Ph_3P{=}CH_2$ with electrophiles. β-Ketophosphorus ylides are prepared by acylation of $Ph_3P{=}CH_2$ with an ester,[4] thioester,[5] acid chloride,[6] acylimidazole,[34] or even with a 5(4*H*)-oxazolone[35] (eqs 35-39). β-Thiocarbonylphosphorus ylides can be prepared in a similar manner.[36]

(35)

$R^1 = H, OMe$
$R^2 = H, Me, Pr, allyl$

(36)

(37)

(38)

$R = CyCH_2CH_2$, C_7H_{15}, $MeOCH_2CH_2CH_2$

(39)

$R^1 = R^2 = Ph$
$R^1 = Me$, $R^2 = Ph$

On the other hand, alkylation of $Ph_3P{=}CH_2$ with alkyl halides provides novel phosphonium salts which in turn can yield ylides upon treatment with a base (eq 40).[37] Likewise, four- through seven-membered cyclic phosphorus ylides can be prepared by alkylation of corresponding alkyl dihalides with $Ph_3P{=}CH_2$ followed by deprotonation (eq 41).[38] Alkylation can also be effected with 1-alkylbenzotriazole,[39a] epoxide,[39b,c] or lactone.[39d] In the latter case, lactones may undergo either alkylation or acylation depending upon the reaction conditions used.[39d,e]

(40)

(41)

Other electrophiles which can be reacted with $Ph_3P{=}CH_2$ include a disulfide,[40] sulfonyl halide,[41] halosilane,[42] selenenyl halide,[43] and cyanate[44] to yield various ylides after treatment with a base. Transylidation[45] of phosphonium salts with $Ph_3P{=}CH_2$ provides yet another entry to extended ylides (eq 42).[46] Phosphacumulene ylides have been prepared via double transylidation with $Ph_3P{=}CH_2$ (eq 43).[47] Allylidenephosphoranes are also formed from the reaction of $Ph_3P{=}CH_2$ with dialkylaluminum alkylidenamides (eq 44).[48]

(42)

(43)

$X = CR^1R^2$, NR, S; Hal = Cl, Br

(44)

R^1, R^2 = H or alkyl; R^3 = alkyl

(chiral ligand for the enantioselective reduction of ketones with lithium aluminum hydride; chiral auxiliary for the diastereoselective aldol condensation; chiral catalyst for the enantioselective Darzens reaction; chiral catalyst for the enantioselective alkylation of aldehydes with dialkylzincs; chiral catalyst for the enantioselective conjugate addition of dialkylzincs to enones; chiral catalyst for the enantioselective alkylation of imines with dialkylzincs; chiral catalyst for the enantioselective Michael addition of nitromethane to α,β-unsaturated ketones)

Alternate Name: [*R*-(*R**,*S**)]-α-[1-(dimethylamino)ethyl]benzenemethanol.

Physical Data: (**1**) mp 86-88 °C; [α]21D -29.2° (*c* 5, MeOH). (**2**) bp 170 °C/2 mmHg; [α]25D + 24.4° (c 2, hexane).

Solubility: sol many organic solvents.

Form Supplied in: (**1**) colorless crystals; (**2**) colorless oil; (**1**) and (**2**) are commercially available.

Enantioselective Reduction of Ketones with Lithium Aluminum Hydride-*N*-Methylephedrine.

Aryl alkyl ketones and α-alkynic ketones are reduced enantioselectively by a chiral complex of ***Lithium Aluminum***

Hydride, *N*-methylephedrine (**1**), and 3,5-dimethylphenol (molar ratio, 1:1:2) to afford optically active alcohols with 75-90% ee (eq 1).[2]

(1)

The optically active alkynyl alcohols are converted into the corresponding optically active 4-alkyl-γ-butyrolactones[3] and 4-alkylbutenolides.[4]

A chiral complex of (**1**), $LiAlH_4$, and *N*-ethylaniline (molar ratio, 1:1:2) reduces aryl alkyl ketones to optically active alcohols in high ee.[5] α,β-Unsaturated ketones are reduced enantioselectively to afford optically active (*S*)-allylic alcohols with 80-98% ee. An intermediate in an anthracyclinone synthesis is prepared in 92% ee by the enantioselective reduction of a cyclic α,β-unsaturated ketone (eq 2).[6]

(2)

A chiral complex of (**1**), $LiAlH_4$, and 2-ethylaminopyridine (molar ratio, 1:1:2), prepared in refluxing ether for 3 h, reduces cyclic ketones to (*R*)-alcohols in 75-96% ee.[7] Advantages of the enantioselective reduction of ketones with $LiAlH_4$ modified with (**1**) and additives are the ready availability of (**1**) in either enantiomeric form and easy removal of (**1**) from the reaction mixture by washing with dilute acid.

anti-Selective Aldol Condensation and Related Reactions.

Silyl ketene acetals react with aldehydes in the presence of ***Titanium(IV) Chloride*** to give β-hydroxy esters.[8] The silyl ketene acetal derived from (1*R*,2*S*)-(**1**)-*O*-propionate reacts with benzaldehyde in the presence of $TiCl_4$ and ***Triphenylphosphine*** to afford the *anti*-α-methyl-β-hydroxy ester in 94% de (eq 3).[9]

(1R,2S)-N-Methylephedrine

(3)

When the same silyl ketene acetal is reacted with benzylideneaniline in the presence of $TiCl_4$, the *anti*-β-amino ester is obtained (*anti*/*syn* > 10/1). Cyclization of the β-amino ester affords the *trans*-β-lactam in 95% ee (eq 4).[10]

(4)

The reaction of this silyl ketene acetal with ***Di-t-butyl Azodicarboxylate*** in the presence of $TiCl_4$ affords the adduct in 45-70% yield with ca. 90% de. The subsequent treatment of the adduct with ***Trifluoroacetic Acid*** and ***Lithium Hydroxide*** affords (*R*)-α-hydrazo acids (eq 5).[11]

(5)

Enantioselective Butylation of Carbonyl Compounds with Lithium Tetra-*n*-butylaluminate Modified with (1).

The reaction between lithium tetra-*n*-butylaluminate and (**1**) forms the chiral lithium alkoxytri-*n*-butylaluminate. This chiral ate complex reduces carbonyl compounds to form secondary and tertiary alcohols in 8-31% ee (eq 6).[12]

(6)

Enantioselective Darzens Reaction.

An enantioselective Darzens reaction between ethyl methyl ketone and chloromethyl *p*-tolyl sulfone in the presence of a chiral ammonium salt derived from (**1**) and chloromethylpolystyrene affords an optically active α,β-epoxy sulfone in 23% ee.[13]

Catalytic Enantioselective Alkylation of Aldehydes with Dialkylzincs.[1]

The chiral *N*,*N*-dialkylnorephedrines, analogs of (**1**), are highly efficient catalysts for the enantioselective addition of dialkylzincs to aliphatic and aromatic aldehydes.[14,15] Optically active aliphatic and aromatic secondary alcohols with high ee are obtained using *N*,*N*-dialkylnorephedrines (4-6 mol%) as chiral catalyst precursors. When (1*S*,2*R*)-*N*,*N*-dialkylnorephedrine is used as a chiral catalyst precursor, prochiral aldehydes are attacked at the *si* face to afford (*S*)-alcohols (when the priority order is $R^1 > R^2$) (eq 7).

(7)

N-Alkyl substituents on the (1*S*,2*R*)-*N*,*N*-di-*n*-alkylnorephedrines have a significant effect on the enantioselectivity of the addition of diethylzinc to aldehydes (3-methylbutanal). As shown in Table 1, the optical purity of the product [(*S*)-5-methylhexane-3-ol] increases as the chain length of the *N*-*n*-alkyl substituent increases and reaches a peak of 93% ee at a chain length of four carbons (Table 1, entry 4). Thus, among *N*,*N*-di-*n*-alkylnorephedrines examined, (1*S*,2*R*)-*N*,*N*-di-*n*-butylnorephedrine (DBNE) (**2**) is the best chiral catalyst precursor.[14,15]

Table 1 Effect of *N*-Alkyl Substituents of (1*S*,2*R*)-*N*,*N*-Dialkylnorephedrine as Chiral Ligand for the Addition of Diethylzinc to 3-Methylbutanal to Yield (*S*)-5-Methylhexan-3-ol

Entry	*N*-Alkyl substituent	Yield (%)	ee (%)
1	Me (**1**)	53	53
2	Et	95	83
3	*n*-Pr	90	87
4	*n*-Bu (DBNE) (**2**)	92	93
5	*n*-C_5H_{11}	91	85
6	*n*-C_6H_{13}	85	83
7	*n*-C_7H_{15}	80	79
8	*n*-C_8H_{17}	53	76
9	$(CH_2)_5$ (**5**)	81	70

As shown in Table 2 (eq 7), the advantages of *N*,*N*-di-*n*-alkylnorephedrines (most typically DBNE) over other chiral catalysts for the enantioselective addition of dialkylzincs to aldehydes are as follows:

- 1)DBNE is highly enantioselective for the alkylation of *aliphatic* aldehydes (Table 2, entries 5-11) as well as for the alkylation of *aromatic* aldehydes (Table 2, entries 1-4). Most of other types of chiral catalysts are effective only for the alkylation of *aromatic* aldehydes. Thus, various types of optically active *aliphatic* alcohols are first synthesized using DBNE (Table 2, entries 5-11). (It should be noted that the structures of aliphatic alcohols synthesized by asymmetric reduction of ketones or by asymmetric hydroboration of alkenes have been somewhat limited.)
- 2)The structures of dialkylzincs catalyzed by *N*,*N*-di-*n*-alkylnorephedrines (most typically DBNE) are not limited to *primary* ones. Diisopropylzinc (with a *secondary* alkyl substituent) adds to benzaldehyde in the presence of a catalytic amount of DBNE to afford the corresponding alcohol with high ee (entry 4).[15] The reaction of diisopropylzinc in the presence of other types of catalysts may result in the reduction of aldehydes.
- 3)*N*,*N*-Di-*n*-alkylnorephedrines are readily synthesized in a one-pot reaction between norephedrine and alkyl iodide in the presence of potassium carbonate.[14,15] (DBNE is commercially available.)
- 4)Either enantiomer of the *N*,*N*-di-*n*-alkylnorephedrines are available. Therefore by using the appropriate enantiomer of *N*,*N*-di-*n*-alkylnorephedrine as a chiral catalyst precursor, the optically active alcohol of the desired configuration with the same ee can be synthesized (entries 8 and 9).

Optically active fluorine-containing alcohols (91-93% ee) (entries 12 and 13)[16] and deuterio alcohols (84-94% ee) (entries 14 and 15)[17] are synthesized, respectively, by the enantioselective alkylation of fluorine-containing aldehyde and deuterio aldehyde using DBNE.

(1*S*,2*R*)-1-phenyl-2-(1-pyrrolidinyl)propan-1-ol (**6**) (entry 10) and (1*S*,2*R*)-*N*,*N*-diallylnorephedrine (**3**) (entry 11) are also highly enantioselective catalyst precursors.[15]

Enantioselective Addition of Various Organozinc Reagents to Aldehydes.

(1R,2S)-N-Methylephedrine

Catalytic enantioselective addition of dialkynylzinc reagents to aldehydes using (1*S*,2*R*)-DBNE (20 mol %) affords optically active (*R*)-alkynyl alcohols with 43% ee in 99% yield.[18] When an alkylalkynylzinc is used with (1*S*,2*R*)-DBNE (5 mol %), an alkynyl alcohol with 40% ee is obtained.[18] When 2-phenylzinc bromide is reacted with an aldehyde in the presence of 1 equiv of the lithium salt of (1*R*,2*S*)-(**1**), the corresponding alkynyl alcohol is obtained in 88% ee (eq 8).[19]

(8)

Alkenylzinc bromides add to aldehydes to afford optically active allyl alcohols with 88% ee in 80% yield using a stoichiometric amount of the lithium salt of (1*S*,2*R*)-(**1**) (eq 9).[20]

(9)

A mixture of phenyl Grignard and zinc halide adds to aldehydes in the presence of a stoichiometric amount of (1*R*,2*S*)-DBNE to afford optically active phenyl alcohols with 82% ee in 90% yield (eq 10).[21]

(10)

(1R,2S)-N-Methylephedrine

Difurylzinc adds to aldehydes in the presence of a stoichiometric amount of the lithium salt of (1*S*,2*R*)-*N*,*N*-bis(4-phenylbutyl)norephedrine (**4**) to afford optically active furylalcohols with 73% ee in 58% yield (eq 11).[22a]

Enantioselective addition of a Reformatsky reagent to aldehydes[22b] and ketones[22c] in the presence of DBNE or *N*,*N*-diallylnorephedrine (**3**) affords the corresponding β-hydroxy esters in up to 75% ee (eq 12).

Enantioselective Addition of Dialkylzincs to Aldehydes with Functional Groups.

Enantioselective and chemoselective addition of dialkylzincs to formyl esters using (1*S*,2*R*)-DBNE as a catalyst affords optically active hydroxy esters. The subsequent hydrolysis of the esters afford the corresponding optically active alkyl substituted lactones with up to 95% ee (eq 13).[23]

(1R,2S)-N-Methylephedrine

(13)

Enantio- and chemoselective addition of diethylzinc to keto aldehydes using DBNE as a chiral ligand affords optically active hydroxy ketones with 91% ee in 84% yield (eq 14).[24] This reaction cannot be realized by Grignard reagents or alkyllithium reagents because of the strong reactivity towards both aldehydes and ketones.

(14)

Enantioselective addition of dialkylzinc to furyl aldehydes using DBNE as a chiral catalyst affords optically active furyl alcohols in up to 94% ee (eqs 15 and 16).[25]

(15)

(16)

Enantioselective additions of dialkylzincs to 4-(diethoxymethyl)benzaldehyde,[26] 3-pyridinecarbaldehyde,[27] terephthalyl aldehyde,[28] and 2-bromobenzaldehyde[29] using DBNE as a chiral catalyst afford, after appropriate treatment, optically active hydroxy aldehydes,[26] pyridyl alcohols (eq 17),[27] diols (eq 18),[28] and 3-alkylphthalides (eq 19),[29] respectively, with high ee.

(17)

(18)

100% ee

(1R,2S)-N-Methylephedrine

A highly functionalized chiral aldehyde when treated with Et_2Zn using (1*R*,2*S*)-DBNE as a chiral catalyst affords the optically active alcohol with 82% de in 98% yield (eq 20).[30] The alcohol has been further elaborated into (+)-lepicidin.

Stereoselective Addition of Dialkylzincs to Chiral Aldehydes.

Stereoselective addition of dibutylzinc to racemic 2-phenylpropanal using (1*S*,2*R*)-DBNE as a chiral catalyst affords

optically active alcohols (84% ee, 92% ee) as a result of the *si* face attack of the aldehyde regardless of its configuration (eq 21).[31]

By changing the configuration of the chiral catalyst precursor (DBNE), stereoselective synthesis of optically active *syn* (78% de) and *anti* (91% de) 1,3-diols has been reported in the addition of diethylzinc to optically active β-alkoxyaldehyde (eq 22).[32] The method has an advantage over the R_2Zn-$TiCl_4$ method,[33] which is only *anti* selective.

Catalytic Enantioselective Conjugate Addition of Dialkylzincs to Enones.

A chiral nickel complex modified with DBNE and an achiral ligand such as 2,2´-bipyridyl in acetonitrile/toluene is an highly enantioselective catalyst for the addition of dialkylzincs to enones.[34] β-Substituted ketones with up to 90% ee are obtained (eq 23).[34c] The method is the first highly enantioselective catalytic conjugate addition of an organometallic reagent to an enone.

In addition, a chiral amino alcohol [1-phenyl-2-(1-piperidinyl)propan-1-ol] mediates the reaction without using any nickel

(1R,2S)-N-Methylephedrine

compound to afford the adduct in 94% ee (eq 24).[34d]

Enantioselective Addition of Dialkylzincs to Imines.

Enantioselective addition of dialkylzincs to *N*-diphenylphosphinoylimines in the presence of DBNE or its analog affords optically active phosphoramides. Subsequent hydrolysis affords optically active amines in up to 91% ee (eq 25).[35] When the amount of DBNE is catalytic (10 mol %), the enantioselectivity is 75% ee. One of the advantages of this method over the alkyllithium method[36] is the use of a lesser amount of chiral ligand.

Diethylzinc also adds to *N*-(amidobenzyl)benzotriazoles (masked *N*-acylimines) in the presence of DBNE to afford an optically active amide with 76% ee (eq 26).[37]

Asymmetric Michael Addition of Nitromethane to Enone.

N-Methylephedrinium fluoride catalyzes the Michael addition of nitromethane to chalcone to afford the adduct with 23% ee in 50% yield (eq 27).[38]

Methyl Fluoride-Antimony(V) Fluoride[1]

MeF/SbF_5

(MeF)

[593-53-3] · CH_3F · Methyl Fluoride-Antimony(V) Fluoride · (MW 34.04) (SbF_5)

[7783-70-2] · F_5Sb · Methyl Fluoride-Antimony(V) Fluoride · (MW 216.75)

(reactive methylating agent;[1] Friedel-Crafts type electrophilic methylations; preparation of onium salts)

Physical Data: MeF: bp -78.2 °C; SbF_5: bp 149.5 °C.

Form Supplied in: MeF: gas; SbF_5: viscous liquid. Both are commercially available.

Preparative Methods: prepared by mixing equimolar amounts of freshly distilled MeF and ***Antimony(V) Fluoride*** in SO_2F_2 solution at low temperature.[2] The reagent can also be prepared in situ in the reaction flask.

Handling, Storage, and Precautions: corrosive, moisture sensitive, and potentially carcinogenic. Thus, caution should be exercised accordingly. Use in a fume hood.

Introduction.

Methyl fluoride/antimony(V) fluoride is the most reactive methylating agent reported.[1] It methylates almost all organic bases, including hydrocarbons. The structure of MeF/SbF_5 has been extensively studied.[2-4] MeF and SbF_5 form a strong donor-acceptor complex in SO_2F_2 solution, but not a free methyl cation, which is too reactive to exist in the condensed state. When more nucleophilic solvents such as SO_2 and SO_2ClF are used, *O*-methylation products, Me+O=SO and Me+O=SOClF are, respectively, formed. These systems in their own right are highly effective methylating agents.

Friedel-Crafts Methylation and Related Reactions.

Aromatic compounds are readily alkylated with MeF/SbF_5 in high yields (eq 1).[2d] In the case of toluene, a mixture of isomers was obtained with *ortho*:*meta*:*para* ratio of 54:18:28. Even highly deactivated perfluoronaphthalene is reported to react with MeF/SbF_5 to form 1- and 2-methylheptafluoronaphthalene (2:1) in 40-50% yields (eq 2).[5]

(1)

(2)

Methyl fluoride/antimony(V) fluoride can add the methyl group to double bonds of alkenes to form carbenium ions (eq 3).[2c] The reagent also reacts with CO to form the acetylium ion. Hydrolysis of the ion yields acetic acid.[2c] In the presence of excess MeF, self-condensation to the *t*-butyl cation takes place via initial formation of ethyl fluoride through σ-C-H bond insertion (eq 4).[2c]

(3)

(4)

Methylation of Heteroatoms.

Methyl fluoride/antimony(V) fluoride has been widely used for methylation of heteroatoms. Various nitrogen-

containing compounds have been studied, including cyanogen halides,[6a] nitriles (eq 5),[6a,6b] sulfur difluoride imides,[6c] sulfur trifluoride imides and derivatives,[6d] and fluorinated imines (eq 6).[6e] In most cases, stable methylation salts are isolated. For example, the sulfur(VI) dication $[(Me_2N)_2SF_2]^{2+}$ is prepared upon treating NSF_2NMe_2 with MeF/SbF_5 in SO_2 solution (eq 7).[6f]

(5)

(6)

(7)

As mentioned, MeF/SbF_5 is able to *O*-methylate SO_2. Similarly, methylated oxonium ions are obtained from ethers (eq 8), sulfoxides, nitrates, and ketones.[2a,2c,7] It is reported that even weak nucleophiles, such as sulfones, were successfully alkylated with MeF/SbF_5 (eq 9).[7] At higher temperature, MeF/SbF_5 reacts with ***Copper(I) Oxide*** to form dimethyl ether (eq 10);[8a] in the presence of CO the reaction produces methyl acetate.[8b]

(8)

(9)

(10)

Sulfur-containing compounds are similarly alkylated with MeF/SbF_5. Sulfonium salts were prepared from starting

materials such as sulfides (eq 11)[2d,9a,9b] and thiophosphoryl halides (eq 12).[9c,9d]

$$(CF_3)_2S \xrightarrow[SO_2]{MeF/SbF_5} (CF_3)_2\overset{+}{S}Me \qquad (11)$$

$$X^1{}_2X^2PS \xrightarrow[SO_2]{MeF/SbF_5} X^1{}_2X^2P\overset{+}{S}Me \qquad (12)$$

$$X^1 = Br, Cl;\ X^2 = Br, Cl, F$$

Treatment of alkyl halides (with the exception of fluorides) with MeF/SbF_5 leads to formation of alkyl(methyl)halonium ions.[2c] A series of cyclopropyl- as well as vinylhalonium ions have also been prepared (eq 13).[10] The preparation of the methyl(trifluoromethyl)iodonium ion is interesting since CF_3 is a strongly electron-withdrawing group (eq 14).[11] Reaction between Br_2 and MeF/SbF_5 generates the dimethylbromonium ion. In contrast, the polycationic species $(MeI_2)_n{}^{n+}(SbF_6{}^-)_6$ are obtained upon the treatment of MeF/SbF_5 with I_2 (eq 15).[12]

(13)

$$X = Cl, Br, I$$

$$CF_3I \xrightarrow[SO_2]{MeF/SbF_5} CF_3\overset{+}{I}Me \qquad (14)$$

$$I_2 \xrightarrow[SO_2]{MeF/SbF_5} (MeI_2)_n{}^{n+} \qquad (15)$$

Related Reagents.

Dimethyliodonium Hexafluoroantimonate; ***O-Methyldibenzofuranium Tetrafluoroborate***; ***Methyl Trifluoromethanesulfonate***; ***Trimethyloxonium Tetrafluoroborate***.

N-Methylformanilide

[93-61-8] · C_8H_9NO · *N*-Methylformanilide · (MW 135.18)

(formylating reagent for certain organometallics;[1] used in combination with $POCl_3$ for Vilsmeier-Haack reactions[2] and heterocycle syntheses[3,4])

Alternate Name: *N*-methyl-*N*-phenylformamide.

Physical Data: mp 8-13 °C; bp 243-244 °C; *d* 1.095 g cm^{-3}.

Form Supplied in: colorless liquid; widely available.

Analysis of Reagent Purity: IR, NMR.

Handling, Storage, and Precautions: irritant, toxic.

General Discussion.

N-Methylformanilide (**1**) has been used for formylating organolithium and Grignard reagents (eq 1).[1]

Alternatively, formylation can be achieved under Vilsmeier-Haack reaction conditions.[2] In this manner, aromatic compounds such as (**2**) can be formylated by treatment with the chloromethylene ammonium salt generated from reagent (**1**) (eq 2).

1,3-Cyclohexanediones and vinyl acetates undergo some interesting transformations on reaction with (**1**) in the presence of ***Phosphorus Oxychloride*** (eqs 3 and 4).[3] A wide variety of vinyl compounds other than vinyl acetate have been successfully utilized in this reaction (eq 4).[3b]

(4)

1,3,5-Triazines (**3**) can be obtained by condensing cyanoamidines with (**1**) and phosphorus oxychloride (eq 5).[4] Enaminals can be afforded by the reaction of (**1**) with a vinyl ether and ***Oxalyl Chloride***.[5]

(5)

(3)

A convenient synthesis of both symmetrical and unsymmetrical 1,5-diketones (**4**) has been achieved (eq 6).[6]

(6)

(4)

N-Acylamino-2-azaallene salts are the products of reaction of (**1**) with nitrilium salts.[7] Enamines can be easily made by reacting metal carbene complexes with (**1**).[8] Reduction of (**1**) to *N*,*N*-dimethylaniline can be effected using bis(2-bromoethylselenium dibromide) and sodium borohydride.[9]

(formylating agent for carbonyl compounds;[1-3] electrophile for organometallic agents[4])

Physical Data: (**1**) bp 34 °C; *d* 0.974 g cm^{-3}. (**2**) bp 52-54; *d* 0.917 g cm^{-3}. (**3**) bp 80-81 °C; *d* 0.904 g cm^{-3}. (**4**) bp 106-107 °C; *d* 0.892 g cm^{-3}. (**5**) bp 82-83 °C; *d* 0.872 g cm^{-3}. (**6**) bp 32.1 °C; *d* 0.990 g cm^{-3}.

Solubility: partially sol water; miscible with alcohol, ether.

Form Supplied in: liquid; widely available in 97-99% purity.

Handling, Storage, and Precautions: most formates are colorless, flammable, irritant, and moisture-sensitive liquids. Inhalation of methyl formate vapor produces nasal and conjunctional irritation, retching, narcosis, death from pulmonary effects. Ethyl formate is irritating to skin, mucous membranes, and, in high concentrations, narcotic. Use in a fume hood.

Among all the formates listed, methyl and ethyl formate are the most widely used agents in organic synthesis. These formates are mainly used as a formylating agent for carbonyl compounds. As shown in eq 1, cyclohexanone (**7**) is converted into the enolate (**8**) in the presence of either ***Sodium Ethoxide*** or ***Sodium Hydride*** and condensed with ethyl formate to give 2-hydroxymethylene cyclohexanone (**9**) or its tautomer, 2-formylcyclohexanone (**10**).[1i]

To generate enolate (**8**) from the carbonyl compounds, sodium alkoxide[1] or sodium hydride (or ***Potassium Hydride***)[2] is generally used. Examples for using ***Potassium t-Butoxide*** are also reported.[3] The solvent can be either benzene, toluene, ether, dimethoxyethane, or THF. **Caution**: gas evolution has been cited in the formylation of cyclopentanone with ethyl formate in a solution of potassium *t*-butoxide in THF.[3] Among the carbonyl compounds, ketones are the most commonly used substrates for the formylation. A few examples for formylating lactones[5] and esters[6] are also reported.

A classic example of the synthetic utility is illustrated (eq 2) in the formylation of a cyclic ketone to block one α-position (**11** to **12** to **13a-c**) and alkylating the α´-position (**13a-c** to **14a-c**). The blocking group is then removed (**14a-c** to **15** to **16**).[1b,1c,1g]

Organometallic agents are combined with the formates to give alcohols or aldehydes.[4] For example, treatment of an ethereal solution of 5-pentenylmagnesium bromide with methyl formate at 0 °C gives undeca-1,10-dien-6-ol in 86% yield (eq 3).[4c]

(3)

The carbanion generated from the deprotonation of *O,S*-acetal (**17**) reacts with ethyl formate at -80 °C to give the aldehyde (**18**) in 89% yield (eq 4).[4d]

(4)

(17) **(18)**

The formates are also reported to react in the following unusual transformations. Nitrobenzene is reacted with the formates, catalyzed by $PdCl_2(PPh_3)_2$, together with Bu_3PO/KBr under carbon monoxide atmosphere, to give *N*-phenylcarbamates in 29-63% yield (eq 5).[7]

(5)

Benzylic, aryl, and alkyl halides react with the formates under carbon monoxide atmosphere, in the presence of $(RhLCl)_2$ (L = 1,5-hexadiene), KI, and, optionally, $Pd(PPh_3)_4$, to give the corresponding carboxylate esters in 20-94% yield (eq 6).[8]

$$R^1X \xrightarrow[\text{(L = 1,5-hexadiene)}\ \text{20-94\%}]{CO,\ HCO_2R,\ KI,\ (RhLCl)_2} R^1CO_2R^2 \qquad (6)$$

The formates add regioselectively to alkenes or alkynes, such as *p*-methylstyrene, catalyzed by ***Tetrakis(triphenylphosphine)palladium(0)*** and ***1,4-Bis(diphenylphosphino)butane*** under carbon monoxide atmosphere, to give the linear isomer and the branched isomer (6.5:1 ratio) in 67% yield (eq 7).[9]

$$p\text{-}MeC_6H_4CH{=}CH_2 \xrightarrow[(Ph_2P)_2(CH_2)_4,\ \text{toluene, 150 °C},\ \text{67\%}]{CO,\ HCO_2Bu,\ Pd(PPh_3)_4}$$

$$p\text{-}MeC_6H_4(CH_2)_2CO_2Bu + p\text{-}MeC_6H_4CH(CO_2Bu)Me \qquad (7)$$

[129444-92-4] · $C_{18}H_{24}O_3$ · 8-Phenylmenthyl Glyoxylate · (MW 288.42)

(two-carbon synthon utilized in electrocyclic processes (Diels-Alder reaction[1], ene reactions[2]), various condensations (Mannich,[3] aldol,[4] Wittig,[5] Prins,[6] acyloin[7]), carbinolamine formation,[8] and Friedel-Crafts reactions[9])

Alternate Name: methyl oxoacetate.

Physical Data: (**1**) bp 45-50 °C/29 mmHg. (**2**) bp 49 °C/35 mmHg. (**3**) mp 46-48 °C; bp 55 °C/14 mmHg. (**4**) bp 130-132 °C/25 mmHg. (**5**) bp 34-36 °C/18 mmHg. (**6**) bp 135-140 °C/0.3 mmHg.

Solubility: sol most organic solvents, e.g. ether, CH_2Cl_2, THF, acetone, etc. (**1**) sol H_2O (as monohydrate).

Form Supplied in: prepare fresh before use for optimum results. *Drying:* distill from P_2O_5.[10b]

Preparative Methods: efficient methods include oxidative cleavage of tartrate diesters, ozonolysis of maleate/fumarate derivatives, exchange reaction between appropriate dialkoxyacetate and glyoxylic acid, and NaOAc-catalyzed elimination of nitrite ion from nitrate esters.[10]

Purification: distillation of methyl glyoxylate monohydrate through a 10-cm Vigreux column.

Handling, Storage, and Precautions: store under N_2 in a refrigerator due to their tendency to form a monohydrate and/or polymerize.

Ene Reactions.

Thermal ene reactions of glyoxylate esters with alkenes (cyclohexene, 1-alkenes, β-pinene and isobutene) occur at 150 °C, whereas the Lewis acid ($AlCl_3$, $SnCl_4$, $FeCl_3$) catalyzed ene reactions proceed at a lower temperature (25-45 °C).[11] The *endo*/*exo* selectivity of the thermal and ***Iron(III) Chloride***-catalyzed ene reactions of methyl glyoxylate with *cis*- and *trans*-2-butene, cyclohexene, 2-methyl-2-butene and 1-methylcyclohexene has been well studied. With *cis*-2-butene at 200 °C, a 7.4:1 mixture of *endo*/*exo* adducts is obtained. Similar reaction with *trans*-2-butene produced a 1:0.57 mixture of *endo*/*exo* adducts (eq 1). With cyclohexene and $FeCl_3$ catalyst, a 4.4:1 mixture of *endo*/*exo* adduct is obtained.[12] Extensive *cis*-*trans* isomerization of the double bond in the substrate under the reaction conditions, as well as contamination of halogen adducts in the products, point to a stepwise cationic mechanism for the Lewis acid-catalyzed glyoxylate-ene reactions.[13]

(1)

The reaction course of vinylsilane with glyoxylate, on the other hand, depends on the geometry of the vinylsilane and the Lewis acid employed.[14] ***Tin(IV) Chloride***-catalyzed reaction of *trans*-vinylsilane produces the ene adduct; that of the *cis*-vinylsilane produces both the ene adduct and a silicon substitution product. When ***Titanium(IV) Chloride*** was substituted for $SnCl_4$, the *cis* isomer underwent substitution to the exclusion of ene reaction (eq 2).

When the alkene bears a silyl substituent, the glyoxylate-ene reaction produces only a single regioisomer, the vinylsilane (eq 3).[15] Allylic ethers with a wide range of protecting groups also produce single regioisomers via glyoxylate-ene reactions (eq 4).[16] Excellent stereo- and regiocontrol are obtained with a 1,2-unsymmetrically disubstituted allylic component, producing exclusively the *anti* ester, which serves as a synthetic precursor for oxetanocin A (eq 5).[17]

By appropriate choice of the Lewis acid, the glyoxylate-ene reactions have been shown to proceed with a high level of

either *syn* or *anti* diastereoselection, irrespective of the ene geometry (eq 6).[18b] The regio- and stereoselective glyoxylate-ene reactions have been exploited in the syntheses of brassinosteroids,[18b] avenaciolide,[18] tetrahydrofuranyl units of polyether antibiotics (eq 7),[19] and highly functionalized unsaturated amino acids (eq 8).[20]

(6)

(7)

(8)

A high level of asymmetric induction (>99%) can be obtained in the glyoxylate-ene reaction with chiral glyoxylate esters derived from cyclohexyl-based chiral auxiliaries (eq 9).[21]

(9)

R* = 8-phenylmenthyl,
trans-2-phenylcyclohexyl

>99% de

A chiral titanium complex prepared in situ from $(i\text{-PrO})_2TiX_2$ (X = Cl or Br) and (*R*)- or (*S*)-binaphthol in the presence of molecular sieves (MS 4Å) has been shown to be a catalyst for an efficient asymmetric glyoxylate-ene reaction (eq 10).[22] The catalytic glyoxylate-ene reaction has been extended to vinyl sulfides, providing a high level of enantioface selection (>99% ee) along with high *anti* diastereoselectivity (eq 11).[23]

(10)

X = Cl (10 mol%) 95% ee, 72% yield (8 h)
(1 mol%) 93% ee, 78% yield (8 h)
X = Br (10 mol%) 94% ee, 87% yield (3 h)

(11)

anti, >99% ee

The catalytic ene technology has been utilized in the asymmetric synthesis of functionalized carbocyclic building blocks,[24] a 1α,25-$(OH)_2$-vitamin D_3 synthon,[25] as well as in asymmetric desymmetrization of prochiral bis-allylic silyl ethers (eq 12).[26]

(12)

In asymmetric ene reactions of racemic allylic as well as homoallylic ethers, the chiral BINOL-titanium catalyst discriminates between the two enantiomeric substrates sufficiently to provide efficient kinetic resolution.[16a,2c] Also, the chiral titanium complex derived from partially resolved BINOL is found to exhibit a remarkable level of asymmetric amplification, wherein the enantiomeric excess of the product significantly exceeds that of the chiral mediator employed.[27]

Cycloaddition Reactions.

[4 + 2] Cycloadditions of various alkoxy-1,3-butadiene derivatives with alkyl glyoxylates, under thermal as well as Lewis acid-catalyzed conditions, afford the corresponding dihydropyran derivatives, which are important intermediates in the total synthesis of monosaccharides and δ-lactones (eq 13).[28] These cycloadditions are facilitated by high pressure and microwave radiation.[29]

(13)

The chiral BINOL-titanium complex (eq 10) is also an effective catalyst for the hetero Diels-Alder reaction between methyl glyoxylate and 1-methoxy-1,3-butadiene, providing the *cis* adduct in 96% ee (eq 14). Similar cycloaddition of methyl glyoxylate and 1-methoxy-1,3-pentadiene simultaneously produces three stereogenic centers with high selectivity (eq 15).[30]

(14)

(15)

Organometallic Addition.

The reaction of 2-butenylstannanes with glyoxylate esters is *syn* selective, whereas the *anti* isomer is preferentially produced via the corresponding 9-BBN derivative. The selectivity increases with increasing steric bulk of the ester group (eq 16).[31]

(16)

M = $SnBu_3$	R = Me	25:75
	R = *i*-Pr	10:90
M = 9-BBN	R = Me	25:75
	R = *i*-Pr	10:90

Asymmetric addition of various organometallic reagents (M = Mg, Zn, Sn) to chiral 8-phenylmenthyl glyoxylate produces the corresponding α-hydroxy esters in high (>99%) enantiomeric excesses.[32]

Aromatic Substitution.

Ortho-hydroxyalkylation of phenols (via complexes of metal phenolates) with chiral glyoxylates produces the corresponding *ortho*-hydroxymandelic ester in high diastereomeric purity (eq 17).[33]

Glyoxylate as Nucleophile.

The two-carbon acyl anion equivalent derived from a glyoxylate ester acetal has been utilized for the preparation of novel heterocyclic α-oxoacetic acid esters (eq 18).[34]

Cross Coupling.

Reductive cross-coupling reactions of glyoxylate esters with carbonyl compounds in the presence of low-valent titanium compounds produce the corresponding α,β-dihydroxy carboxylates (eq 19).[35]

(19)

The glyoxylate esters have been utilized as valuable synthetic intermediates in the syntheses of actinolbin,[36] oxacyclic carbocyclic esters,[37] tetrahydro-4*H*-furoazepines,[38] and (±)-naphthyridinomycin.[39] A chiral synthesis of Pravastatin®, an important HMG-CoA reductase inhibitor, utilizes desymmetrization of 1-methyl-4-methylenecyclohexane by a catalytic asymmetric ene reaction, which provides the initial asymmetric framework (eq 20).[26b]

(20)

α-Imino esters derived from glyoxylate esters are valuable synthetic intermediates and act as enophiles[40] and/or dienophiles[41] to produce nonproteinogenic α-amino acids,[42] β-lactams,[43] an anti-Bredt lactam,[44] β,γ-alkynylglycine derivatives,[45] and proline analogs.[46]

Related Reagents.

Methyl Hydrazinocarboxylate

(**1**; R = Me)

[6294-89-9] · $C_2H_6N_2O_2$ · Methyl Hydrazinocarboxylate · (MW 90.10) (**2**; R = Et)

[4114-31-2] · $C_3H_8N_2O_2$ · Ethyl Hydrazinocarboxylate · (MW 104.13) (**3**; R = *t*-Bu)

[870-46-2] · $C_5H_{12}N_2O_2$ · *t*-Butyl Hydrazinocarboxylate · (MW 132.19)

(used for conversion of ketones to nitriles, dehydrohalogenation of α-bromo ketones, and formation of azidoformates)

Alternate Name: methyl carbazate.

Physical Data: (**1**) mp 70-73 °C; bp 108 °C/12 mmHg. (**2**) mp 44-47 °C; bp 110 °C/22 mmHg. (**3**) mp 39-42 °C; bp 65 °C/0.03 mmHg.

Ketones to Nitriles.

Methyl and ethyl carbazate are used as derivatizing reagents for aldehydes and ketones.[1] The methyl derivative is employed in the conversion of ketones to nitriles through the base-catalyzed decomposition of the intermediate diazene (eq 1).[2] The procedure also works well for α-substituted ketones. If the diazene decomposition is conducted in aprotic medium (DME) in the presence of stoichiometric base (LiOMe), the resultant nitrile anion can be alkylated.

Dehydrohalogenation.

Ethyl carbazate is employed in the Kendall-Mattox dehydrohalogenation of α-bromo ketones (eq 2).[3]

t-Butyl Azidoformate.

Nitrosation converts *t*-butyl carbazate into ***t-Butyl Azidoformate***, a reagent for the protection of amines as their Boc derivatives.[4]

Related Reagents.

2,4-Dinitrophenylhydrazine; ***Hydrazine***; ***Semicarbazide***; ***p-Toluenesulfonylhydrazide***; ***p-Tolylsulfonylmethyl***

Isocyanide; ***2,4,6-Triisopropylbenzenesulfonylhydrazide***; ***Trimethylaminoacetohydrazide Chloride***.

N-Methylhydroxylamine

MeNHOH

[593-77-1] · CH_5NO · *N*-Methylhydroxylamine · (MW 47.07) (.HCl)

[4229-44-1] · CH_6ClNO · *N*-Methylhydroxylamine Hydrochloride · (MW 83.53)

(ambident nucleophile; reagent for the preparation of *N*-methyl nitrones from aldehydes and ketones, of *N*-methylhydroxamic acids from carboxylic acids and related functional groups, and of heterocyclic compounds)

Physical Data: mp 38.5 °C; bp 115 °C, 60-63 °C/20 mmHg;*n*20D 1.4164. HCl salt: mp 88-90 °C.

Solubility: very sol H_2O, methanol, ethanol; sparingly sol diethyl ether. HCl salt: sol H_2O, ethanol.

Form Supplied in: widely available as the HCl salt, a clear-to-white solid (hygroscopic).

Preparative Methods: usually prepared in solution form by treatment of the HCl salt with a suitable base; used directly upon preparation as it gradually decomposes upon standing.

Handling, Storage, and Precautions: the HCl salt is a possible irritant; avoid skin and eye contact, avoid inhaling particles. The salt is hygroscopic and must be protected from moisture during storage.

Formation and Reactions of Nitrones.

The condensation of *N*-methylhydroxylamine with aldehydes and ketones leads readily to the formation of *N*-methyl nitrones. In some cases, such as *N*-methyl-*C*-phenyl nitrone, the condensation product can be isolated and characterized prior to subsequent reactions; the more usual practice, however, is the in situ generation of nitrones as a prelude to subsequent cycloaddition reactions,[1] the most common of the

reactions of nitrones. *N*-Methyl nitrones have been shown to undergo cycloadditions with mono-, di-, and trisubstituted alkenes as well as mono- and disubstituted alkynes. Consistent with FMO theory, *N*-methyl-*C*-phenyl nitrone gives 5-substituted isoxazolidines with monosubstituted alkenes such as 1-hexene and styrene; however, strongly electron-withdrawing substituents alter the cycloaddition regiochemistry.[2] Methyl acrylate and phenyl vinyl sulfone give mixtures of cycloadducts, while nitroethylene gives only the 4-substituted isoxazolidine.

Intramolecular cycloadditions of *N*-methyl nitrones (eq 1) have been extensively studied since the 1960s.[3] The influence of a number of factors (e.g. length of chain connecting alkene and nitrone, type of atoms in the connecting chain, presence of chiral centers, alkene geometry) on the regiochemistry and stereochemistry have been reported.[1] Fused polycyclic ring systems are often obtained, while in selected cases bridged cycloadducts are found. In one case a reverse Cope elimination reaction has been observed in competion with *N*-methyl nitrone formation and cycloaddition.[4] There are a number of examples of natural product total synthesis, including (+)-chanoclavine I,[5] (-)-bisabolol,[6] and hirsutene,[7] in which intramolecular *N*-methyl nitrone cycloadditions have been utilized.

(1)

In addition to [3 + 2] cycloaddition reactions, *N*-methyl nitrones can also be used as precursors to vinylnitrosonium cations for [4 + 2] cycloadditions.[8]

Additional reagents derived from *N*-methylhydroxylamine are described in the literature for the preparation of nitrones. These include *N*-methylhydroxylamine-*O*-sulfonic acid,[9] which has been shown to react with imines to afford nitrones, and *N*-methyl-*N*,*O*-bis(trimethylsilyl)hydroxylamine,[10] which allows formation and cycloaddition of nitrones under nonbasic, aprotic conditions.

Other Reactions.

Carboxylic acids and related functional groups are readily converted to *N*-methylhydroxamic acids through *N*-acylation (eq 2).[11]

(2)

If *N*-methylhydroxylammonium chloride is acylated under nonbasic conditions, however, *O*-alkanoylhydroxylamines are obtained as the *O*-acylation product.[12] α,β-Unsaturated compounds readily undergo conjugate addition, giving β-amino-*N*-hydroxy-*N*-methylcarboxylate esters which cyclize in the presence of base to isoxazolidin-5-ones (eq 3).[13] Unsaturated sugar lactones also give isoxazolidin-5-ones,[14] while sugar enolones give the simple conjugate addition product.[15] Interestingly, when *N*-methylhydroxylamine is slowly generated in the presence of both aqueous formaldehyde and an unsaturated carbonyl compound, the preferred reaction is formation of *N*-methyl nitrone followed by cycloaddition to the unsaturated carbonyl compound (eq 4).[16] Isoxazolidin-5-ones are also readily prepared by the Reformatsky reaction of purified nitrones, such as *N*-methyl-*C*-phenyl nitrone, with α-bromo esters in the presence of zinc.[17]

O-Methylhydroxylamine

$MeONH_2$

[67-62-9] · CH_5NO · *O*-Methylhydroxylamine · (MW 47.07)

(for electrophilic amination;[1] for conversion of aldehydes and ketones to methoxyimines)

Alternate Name: methoxyamine.

Physical Data: mp -86.4 °C; bp 48.1 °C; pK_b 9.40.

Solubility: miscible with water, alcohol, ether, hexane.

Form Supplied in: white HCl salt (mp 149 °C).

Analysis of Reagent Purity: IR[2] and ^{1}H NMR.[3]

Preparative Methods: from methylation of adduct of sodium nitrite and sodium metabisulfite,[4] or fractional distillation from the HCl salt in sodium hexyloxide/hexanol.[5]

Handling, Storage, and Precautions: a highly mobile and poisonous clear colorless liquid and should be refrigerated. Methoxyamine is a severe irritant. Use in a fume hood.

Introduction of the Methoxyimino Function.

The methoxyimino (*O*-methyl oxime ether) group is easily introduced by treating ketones or aldehydes with the HCl salt of methoxyamine. The methoxyimino function is a convenient and often most effective way of protecting ketones or aldehydes during alkaline transformations.[6] For example, the ring of the dioxabicyclooctane (**1**) was opened with methoxyamine.HCl to afford the 6-methoxyiminooxepane (**2**) (eq 1).[7] Attempts to trap the intermediate ketones as the dithioacetal led to intractable product mixtures. After acetylating the 3-hydroxy group, the desired oxepan-6-one was recovered in 73% yield by treating the methoxyimine in acetone with 2 N HCl at rt for 3 h.

α,β-Unsaturated methoxyimines are readily prepared by treating the corresponding ketones or aldehydes with methoxyamine.HCl.[8] Except in cases of α,β-unsaturated aldehydes or highly reactive α,β-unsaturated ketones, the free base of methoxyamine undergoes 1,4-addition regioselectively (see below).

As a NH_2^+ Synthon.

Lithium salts of strongly basic carbanions can be stoichiometrically converted to the corresponding primary amines by treating with 2 equiv of methyllithium-methoxyamine (eq 2).[9]

To prepare the methyllithium-methoxyamine adduct (**3**), a hexane solution of methoxyamine is added dropwise to an ether solution of ***Methyllithium*** at -78 °C. Then, to obtain the primary amine, an organolithium is added, the reaction mixture is allowed to warm to -15 °C for 2 h, and then quenched with water. Examples of primary amines prepared via eq 2 are provided in Table 1.

[a] Based on moles RLi. [b] Isolated as amide. [c] Required 1 h reflux. [d] Based on moles RLi precursor. [e] Isolated as amine.

Lithium α-lithiophenylacetate, 2-lithiocyclohexanone, 2-lithiothiophene, 2-lithiofuran, or 3-lithiopyridine could not be aminated via eq 2.

The best yields of primary amines from (**3**) are obtained with organolithium compounds.[10] While organozinc, magnesium, and copper compounds are aminated with (**3**), the yields are generally low.

As a $^{-}NH^{+}$ Synthon.

Since the nitrogen of methoxyamine functions both as a nucleophilic and electrophilic center, methoxyamine can be used to prepare secondary amines and nitrogen heterocycles. The methoxyamine (**4**) was prepared by converting acetophenone to the methoxyimine with methoxyamine.HCl in methanol/pyridine at reflux overnight, followed by reduction with ***Borane-Pyridine*** complex and HCl in methanol at -10 °C to 10 °C for 10 min (eq 3).[11]

(3)

It was found that treating (**4**) with methyllithium followed by ***n-Butyllithium*** afforded the secondary amine (**5**) (eq 4).

(4)

The electrophilic aminations of carbanions with *N*-monosubstituted methoxyamines are executed as with methoxyamine (see above). However, only 1 equiv of the methyllithium adduct is required. Furthermore, because the amination reaction occurs by a S_N2 displacement,[5] it must be conducted at higher temperatures when the nitrogen of the *N*-monosubstituted methoxyamine is sterically hindered.[10] Other examples of secondary amines prepared by the above approach have been published.[10,11]

Intramolecular electrophilic amination of the *N*-substituted methoxyamines (**6**) provides the corresponding nitrogen heterocycles (**7**) (eq 5).[10,11]

(5)

The methoxyamines (**6**) were prepared by reductive amination of the corresponding aldehydes with methoxyamine and pyridine-borane complex (see above). Then they were treated with methyllithium in the presence of ***t-Butyllithium***, to effect halogen-metal exchange,[12] and, after warming to -15 °C for 3 h, the nitrogen heterocycles (**7**) were isolated as the *N*-acetyl derivatives. The yields of (**7**), based on the starting aldehyde, when n = 1, or its progenitor, when n = 2, 3, and 4, were 16, 15, 25, and 9%, respectively.

Treating α,β-unsaturated ketones with the free base of methoxyamine at rt results in 1,4-addition.[8] Treating the resulting β-methoxyamino ketones (**8**) with 2 equiv of ***Sodium Methoxide*** yields the *trans*-ketoaziridines (**9**) stereoselectively (eq 6).[8,13,14]

(6)

Alternatively, the *trans*-ketoaziridines are obtained directly by treating the α,β-unsaturated ketones with methoxyamine in the presence of alkoxide. The yields of (**9**), when R^1 = phenyl and R^2 = 4-methoxyphenyl or 4-methylphenyl, were 46 and 61%, respectively.

The keto ester (**10**) and methoxyamine.HCl react to afford the methoxyimine (**11**).[15] Radical cyclization of (**11**) with ***Tri-n-butylstannane*** and ***Azobisisobutyronitrile*** (AIBN) affords the indan (**12**) (eq 7).

(10) **(11)**

(12) (7)

It was found that (**12**) could be rearranged to the quinoline (**13**) with ***Lithium Aluminum Hydride*** (LAH) (eq 8).[16]

(12) **(13)** (8)

Kostyanovsky and co-workers treated the *N*-tosylate (**14**) with methoxyamine and obtained the diaziridine (**15**) (eq 9).[17]

(14) **(15)** (9)

As a $^{-}NH^{-}$ Synthon.

The N-O linkage can be reductively cleaved under mild conditions.[18] Consequently, the *N*-methoxy group should function as an activating/protecting group when preparing disubstituted nitrogen compounds with methoxyamine. This strategy was elegantly demonstrated in the synthesis of β-lactam precursors of monobactam antibiotics.[19] L-Serine (**16**) was treated sequentially with ***Di-t-butyl Dicarbonate*** (Boc_2O) and methoxyamine.HCl, in one pot, to afford the Boc-protected hydroxamate (**17**) (eq 10).

(10)

(16) **(17)**

The condensation to (**17**), which occurred in 30 min at rt, was mediated by ***1-Ethyl-3-(3´-dimethylaminopropyl)carbodiimide Hydrochloride*** (EDCI). The mesylate (**18**), prepared by treating (**17**) with ***Methanesulfonyl Chloride***, was easily cyclized to the 1-methoxyazetidinone (**19**) (eq 11).

(11)

(18) **(19)**

Reductive cleavage of the *N*-methoxy group of (**19**) afforded the β-lactam (**20**) (eq 12).

(12)

(20)

L-Threonine and L-allo-threonine were also converted to the respective β-lactams in comparable yields using the above sequence. The conversion of amino acid to β-lactam proceeded stereospecifically in all cases.

Anti-Bredt β-lactams are also prepared using the above strategy.[20] However, the hydroxamate was cyclized under Mitsunobu conditions.[21] Thus treatment of the hydroxamate (**21**) with ***Triphenylphosphine*** and ***Diethyl Azodicarboxylate***

(DEAD) generated the 1-methoxyazetidinone (**22**) (eq 13).

The primary amide versions do not cyclize to the β-lactams by either of the above methods. This is due to competing proton transfers. An alkoxy or acyloxy substituent on the amide nitrogen lowers the pK_a of the amide enough that cyclization becomes competitive.[22] The methoxy substituent appears to be particularly advantageous due to the ease with which it is reductively cleaved.[19]

Methyl 3-Hydroxypropionate

[6149-41-3] · $C_4H_8O_3$ · Methyl 3-Hydroxypropionate · (MW 104.12)

(preparation of α-substituted acrylate and hydracrylate derivatives;[1] photochemical conjugate additions;[2] protection of the carboxy group[3])

Alternate Names: methyl 3-hydroxypropanoate; methyl hydracrylate.

Physical Data: bp 71-73 °C/9 mmHg.[4]

Analysis of Reagent Purity: ^{1}H NMR and MS.[5]

Preparative Methods: two methods have been published: reaction of β-***Propiolactone*** with ***Sodium Methoxide*** in MeOH (17-36%),[5,6] or treatment of 3-hydroxypropionitrile with HCl in aqueous MeOH (68%).[4] The latter method appears to be more desirable based upon yield of product and the high cost and toxicity of β-propiolactone.

Preparation of α-Substituted Acrylate and Hydracrylate Derivatives.

Methyl 3-hydroxypropionate (**1**) is a useful reagent for the preparation of α-substituted acrylate and hydracrylate derivatives. Reaction of the dianion arising from (**1**) with a variety of electrophiles is shown in eq 1.[1] The alkylated products can be dehydrated under acidic (***Phosphoric Acid***) or basic (***p-Toluenesulfonyl Chloride***, ***Pyridine***) conditions (eq 2).[7] An interesting example of this method is shown in eq 3.[8] Treatment of the dianion of (**1**) with an aldehyde gives an intermediate diol. The less hindered hydroxy group is then eliminated in two steps by reaction with TsCl, followed by treatment with ***1,8-Diazabicyclo[5.4.0]undec-7-ene***.

(1)

RX	R	Yield (%)
MeI	Me	94
i-PrI	*i*-Pr	89
MOMCl	$MeOCH_2$	95
$(MeS)_2$	MeS	88

(2)

(3)

Photochemical Conjugate Addition.

A photochemically induced conjugate addition reaction has been observed between (**1**) and a conjugated enone in the presence of benzophenone (eq 4).[2] If the hydroxy group in the product is protected as a THP acetal (***3,4-Dihydro-2H-pyran***, ***p-Toluenesulfonic Acid***) prior to isolation, the yield increases to 71%.

(4)

Protection for the Carboxy Group.

The 2-methoxycarbonylethyl esters derived from (**1**) have been used as protecting groups for the carboxy functionality.[3] Beginning with the carboxylic acid, mixed anhydride formation followed by esterification with (**1**) in the presence of ***4-Dimethylaminopyridine*** gives the protected ester (eq 5). Deprotection occurs upon treatment with DBU in acetonitrile (eq 6).

(5)

Ar = 2,4,6-trichlorophenyl

(6)

Related Reagents.

Ethyl Acrylate; ***Ethyl 3-Hydroxybutanoate***; ***Methyl 3-(Dimethylamino)propionate***; β-***Propiolactone***.

Methyl Hypofluorite

MeOF

[36336-08-0] · CH_3FO · Methyl Hypofluorite · (MW 50.04)

(used for adding the elements of MeO and F across double bonds,[1] for electrophilic methoxylation α to carbonyls,[2] and as a tool for introducing the short lived ^{11}C isotope for positron emission tomography (PET)[3])

Physical Data: mp -142 °C; bp -33 °C (by extrapolation); ^{19}F NMR +120 ppm ($^3J_{HF}$ = 45 Hz); ^1H NMR 4.51 ppm ($^3J_{HF}$ = 45 Hz).

Handling, Storage, and Precautions: MeOF is an unstable substance and for all practical purposes has to be prepared in situ in solution and used soon after its formation. **Neat solid and liquid MeOF can be unpredictably explosive at temperatures above** -78 °C. The concentration of the reagent is determined iodometrically (MeOF + 2KI + H_2O -> I_2 + KF + MeOH + KOH). As with all hypofluorites, it may be toxic and should be treated accordingly. Use in a fume hood.

Addition to Alkenes.

Although MeOF has been a subject for several theoretical studies,[4] it was synthesized only recently by passing relatively concentrated fluorine through methanol in the presence of acetonitrile.[1] Unlike other hypofluorites such as ***Trifluoromethyl Hypofluorite*** or ***Acetyl Hypofluorite*** the fluorine in MeOF is nucleophilic, leaving the rest of the molecule (MeO) to act as a strong electrophile. This formally constitutes the previously unknown methoxylium ion. This is evident from the addition of MeOF to unsymmetrical alkenes such as styrene, which produces exclusively 1-fluoro-1-phenyl-2-methoxyethane (eq 1).[1]

(1)

Methoxylation of Ketones.

This unique electrophilic system was used to methoxylate ketones in their α-position in a fast and direct mode. It was found that the methoxylation is best when performed on methyl enol ethers.[2] Since this reaction takes only a few seconds, and since it is relatively easy to make $^{11}CH_3OH$ (half life of the positron emitting ^{11}C isotope is about 20 min), this method adds a new route (to the very few existing ones) for incorporating this isotope into organic molecules for PET studies (eq 2).[3]

(2)

It should be noted that addition of the elements of MeO and F can also be achieved when electrophilic fluorination reagents such as CF_3OF,[5] $FClO_3$,[6] or $CsSO_4F$[7] are reacted with alkenes in the presence of MeOH (eq 3). The same is true when XeF_2/MeOH is employed, although in this case the intermediate MeOXeF was suggested (eq 4).[8] In some of these reactions the fluorine acts as an electrophile, but in others most of the regioselectivity is lost.

(3)

(4)

X = OMe, Y = F; X = F, Y = OMe

Related Reagents.

Hypofluorous Acid.

N-Methylimidazole

[616-47-7] · $C_4H_6N_2$ · *N*-Methylimidazole · (MW 82.12)

(phosphorylation; acylation)

Physical Data: bp 195-197 °C; *d* 1.031 g cm^{-3}.

Solubility: usually used in THF, Et_2O.

Form Supplied in: redistilled liquid (99+%); packed under nitrogen.

Analysis of Reagent Purity: the reagent may be analyzed using standard techniques.

Purification: dried with sodium metal and then distilled.

Handling, Storage, and Precautions: store at 0 °C under dry argon. The compound is harmful in contact with skin and if swallowed, and causes burns.

Introduction.

N-Methylimidazole is used for phosphorylation and acylation. It can be lithiated at the 2-position by treating with ***n-Butyllithium*** at -78 °C in THF or diethyl ether. The Grignard reagent can also be prepared by exchange with ***Ethylmagnesium Bromide*** at the 2-position.[1]

Phosphorylation.

Alcohols may be phosphorylated in good yield by the reaction of phosphorous acid, mercury(II) chloride and *N*-methylimidazole (eq 1). An intermediate salt (**1**) is formed. This method has been used to prepare nucleoside 5´-phosphates in yields of 60-70%.[2] Similarly, amines may be phosphorylated by reaction with ***Phosphorus Oxychloride*** and *N*-methylimidazole (eq 2).[3]

(1)

(1)

(2)

Acylation.

N-Methylimidazole reacts with acid chlorides and chloroformates to give *N*-acylimidazolium salts. These can then be used as effective acylating agents, for example of amines, in aqueous solution (eq 3).[4]

(3)

N-Methylimidazole has been used as an effective catalyst of acylation by ***Acetic Anhydride***. It has a catalytic activity about 4×10^2 greater than pyridine (eq 4).[5]

(4)

Reactions of 2-Lithio-1-methylimidazole.

2-Lithio-1-methylimidazole reacts with ketones at -78 °C in 65-96% yield to give 2-(1-hydroxyalkyl)-1-methylimidazoles. These can be dehydrated with hot acetic anhydride to give 2-vinyl-1-methylimidazoles in 73-85% yield (eq 5).[6]

(5)

2-Lithio-1-methylimidazole reacts with alkyl or aryl nitriles to give 2-acyl-1-methylimidazoles (acid anhydrides, acid chlorides and amides give poor, nonreproducible yields of the ketones). These then yield 1-methylimidazolethylenes via a Wittig reaction. Vinylimidazoles are reported to be potentially useful as monomers in the synthesis of heterocyclic polymers (eq 6).[7]

2-Imidazolylsilanes may be synthesized by reacting ***Chlorotrimethylsilane*** with 2-lithio-1-methylimidazole and subsequent transsilylation (eq 7).[8]

Methyl Isocyanate[1]

MeN=C=O

[624-83-9] · C_2H_3NO · Methyl Isocyanate · (MW 57.06)

(carbamoylates NH, OH, SH, and active CH compounds; converts epoxides to 1,2-amino alcohols via 2-oxazolidinones; undergoes [2 + *x*] cycloadditions to give rise to heterocycles; transforms aldoximes to nitriles[2] and nitroalkanes to nitrile oxides[3])

Alternate Name: MIC.

Physical Data: mp -17 °C; bp 39 °C; *d* 0.96 g cm^{-3}.

Solubility: sol chlorinated, aromatic, ethereal solvents; reacts violently with H_2O, basic, and protic solvents.

Form Supplied in: colorless liquid; no longer widely available. Usually prepared industrially in situ as needed.

Handling, Storage, and Precautions: **Warning: Highly toxic! Lachrymator! Irritant! Extremely flammable!** Use only in a fume hood. Wear protective gloves and preferably a NIOSH-approved respirator. All transfers and reactions should be carried out under anhydrous conditions. Store in a cool dry place, taking care to avoid contamination with protic, basic, or organometallic materials, as these may induce (exothermic) polymerization. Toxicity data for methyl isocyanate are available.[1]

N-Methylcarbamoylation.

The *N*-methylcarbamate (urethane) and *N*-methylurea moieties are common targets in organic synthesis, due to their function as pharmacophores in a stunning variety of compounds of pharmaceutical and agricultural interest. A typical method for their introduction makes use of the propensity of methyl isocyanate to add active hydrogen-bearing atoms (in either neutral or ionized form) to the central carbon atom.[4] Reaction with alkyl-[5] and arylamines,[6,7] sulfonamides,[8] and guanidines[9] proceeds to give the ureas, often with high regioselectivity.[6,7,10] Ring nitrogen atoms of heterocycles that bear a hydrogen (e.g. pyrazoles[10]) may also be carbamoylated under conditions mild enough even to avoid rupture of aziridines.[11] Both alcohols[12-14] and aryl hydroxys[15] react readily with MIC, yielding the carbamates. Reaction of secondary alcohols is typically slow and incomplete, unless catalysts (usually basic) are used.[16] A novel rearrangement of carbamate derivatives of hydroxamic acids affords *N*-methyl amino acids (eq 1).[17]

(1)

Thiols and thiocarbonyls that may be enolized react similarly;[18] a protocol for the protection of peptidic SH groups as *N*-methylthiocarbamates has recently been developed.[19] Malonates,[20] cyanoacetates,[20] and dithianes[21] may be cleanly mono-*N*-methylcarbamoylated upon treatment with MIC.

Conversion of Oxiranes to 2-Oxazolidinones and 1,2-Amino Alcohols.

This transformation is very similar to that of simple epoxides to 2-oxazolidinones induced by ***p-Toluenesulfonyl Isocyanate***. However, due to the lower reactivity of MIC, it is most often carried out in two or more steps via the epoxycarbamate derived from α-hydroxy epoxides (eq 2)[12,22] or α-hydroxy esters.[13] Hydrolysis of the 2-oxazolidinone yields the 1,2-amino alcohol.

(2)

Heterocycle Synthesis via Tandem Electrophilic-Nucleophilic Ring Closure.

The electrophilicity of the central carbon atom and latent nucleophilicity of the nitrogen atom endow MIC with the potential to form adducts with any other atomic array that exhibits a similar donor-acceptor character. Thus, a huge variety of heterocyclic products may be prepared with MIC (eq 3), and this list is not exhaustive.

(3)

Nu = NH, NR, OH; E = CN, C=O, C=N, Michael acceptor

Reaction with ynamines gives [2 + 2] adducts of single regiochemistry.[23] Azomethine ylides derived from aziridines afford 4-imidazolinones by [2 + 3] cycloaddition highly regioselectively.[24] Other [2 + 3] adducts are 1,2,4-triazol-5-ones (from hydrazides),[25] imidazolin-5-imin-2-one-4-thiones (from cyanothioamides),[26] 1,2,4-triazolin-5-ones (from hydrazones),[27] and 2-oxazolones (from ketols).[28] Some examples of [2 + 4] adducts are 1,3-benzoxazines (from hydroxychalcones),[29] 1,2,4-oxathiazine *S*,*S*-dioxides (from alkynylsulfonamides),[30] pteridineimines (from aminocyanodiazines),[31] pyrazolopyrimidinones (from aminocyanopyrazoles),[32] 1,2,4-thiadiazin-3-one *S*,*S*-dioxides (from β-ketosulfonamides),[33] triazinones (from 1,3-diazadienes),[34] and 1,3-oxazine-2,4-diones (from 1,3-dioxan-4-ones).[35] While most of these annulations are triggered or completed by base catalysis, a thermal reaction has also appeared in the literature (eq 4).[35]

(4)

$Y = Me_2, (CH_2)_5$; $R^1 = CO_2R$, alkyl, H; R^2 = alkyl, H

Azaphosphoranes (from azides and phosphines) are easily converted to carbodiimides with MIC,[36] and these also show a propensity for condensation with a variety of nucleophiles. An interesting strategy for [5 + 1] annulation utilizes intramolecular addition of the nucleophile (eq 5).[37] Note that the NH group reacts with MIC before the azaphosphorane does.[38]

(5)

A number of unsaturated hydrocarbons react with MIC via the intermediacy of nickelacycles. Allenes give, after hydrolysis, 1:1 adducts with MIC (α-methyleneamides),[39] as does styrene (*N*-methyldihydrocinnamide).[40] Alkynes afford 2:1 adducts (2-pyridones) with MIC and this reaction is catalytic in nickel complex,[41] unlike the styrene and allene reactions, which are stoichiometric in nickel.

Functional Group Interchanges.

Aldoximes are converted to nitriles in high yield upon treatment with MIC.[2] In a very closely related reaction, alkyl nitro compounds yield nitrile oxides when subjected to reaction with MIC.[3] These dipolar species are easily trapped intramolecularly, and this protocol provides an alternative to harsher reagents. Both functional group interchanges are dehydrations that exploit the high reactivity of MIC with H_2O.

Related Reagents.

Phenyl Isocyanate; ***p-Toluenesulfonyl Isocyanate***.

Methyl Isocyanide

R-+N&tbond;C-

(**1**; R = Me)

[593-75-9] · C_2H_3N · Methyl Isocyanide · (MW 41.06) (**2**; R = *n*-Bu)

[2769-64-4] · C_5H_9N · Butyl Isocyanide · (MW 83.15) (**3**; R = Cy)

[931-53-3] · $C_7H_{11}N$ · Cyclohexyl Isocyanide · (MW 109.19)

(reactive amphiphilic reagents for 1,1-additions to form heterocyclic *N*-*t*-butylimines, iminoyl halides, α-hydroxy amides, α,β-enals, α-acylamino amides via Passerini reactions, and polymethylene imines; oxidative additions to isocyanates and isothiocyanates[1,2])

Physical Data: (**1**) bp 60 °C; *d* 0.75 g cm^{-3}. (**2**) bp 123-124 °C; *d* 0.79 g cm^{-3}. (**3**) bp 173-176 °C, 56-58 °C/11 mmHg; *d* 0.88 g cm^{-3}.

Solubility: sol most organic solvents, e.g. methanol, ethanol, ether, toluene, dichloromethane.

Form Supplied in: pure liquids; methyl isocyanide is not commercially available; *n*-butyl and cyclohexyl isocyanides are commercially available.

Analysis of Reagent Purity: by GC.

Preparative Methods: the preparation of methyl isocyanide is well established.[3]

Handling, Storage, and Precautions: should be freshly distilled before use; foul smelling liquid; should be stored and used in a fume hood. Contaminated equipment should be washed with 5% methanolic sulfuric acid.

Heterocyclic Imines.[2]

[4 + 1] Cycloadditions of dimethyl tetrathiooxalate with alkyl isocyanides afford 2-imino-1,3-dithiolines under simple reaction conditions in good yields (eq 1).[4] Iminodioxolidine derivatives are available in good yields from cyanoketimines (eq 2).[5]

(1)

R = Me (81%), Bu (90%), Cy (83%)

(2)

R = Bu (70%), *t*-Bu (97%), Cy (82%)

Iminoyl Halides via 1,1-Additions.

Chlorination of cyclohexyl isocyanide (**3**) in THF containing $HgCl_2$ incorporates the solvent in a ring-opening reaction (eq 3).[6] Pivaloyl chloride reacts with methyl isocyanide (**1**) to give an α-keto iminoyl chloride (eq 4).[7] *N*-Alkyl perfluoroalkylimidoyl iodides are easily accessible by copper-catalyzed condensation of iodo perfluoroalkanes and alkyl isocyanides in excellent yields. The products can be reduced by ***Sodium Borohydride*** to the corresponding secondary amines (eq 5).[8]

The Ugi four-component reaction between aldehydes, methyl isocyanide, and ammonium trifluoroacetate affords α-amino *N*-methylamides (eq 6).[9] Nocardicine, a monocyclic β-lactam antibiotic, is synthesized in one step together with the β-lactam by an Ugi reaction (eq 7).[10]

(6)

(7)

68% diastereomers

Other Applications.

α,β-Unsaturated aldehydes are available in a one-pot reaction, zirconium catalyzed, with *n*-butyl isocyanide (**2**) and alkynes (eq 8).[11]

(8)

The reaction of methyl isocyanide with ***Titanium(IV) Chloride*** in CH_2Cl_2 affords an iminoyltitanium reagent which undergoes 1,2-addition to aldehydes and ketones. Hydrolysis of the adduct gives the homologous α-hydroxy-*N*-methylamide (eq 9).[12]

(9)

Isocyanides undergo formal [1 + 4] cycloaddition to cisoid α,β-enones in the presence of ***Diethylaluminum Chloride*** or ***Ethylaluminum Dichloride*** to give *N*-alkyl imines of β,γ-butenolides (eq 10).[13] The imines can be solvolyzed to γ-keto esters or hydrogenated and hydrolyzed to γ-butyrolactones.

(10)

Oxidative addition of oxygen, sulfur, and selenium to alkyl isocyanides affords isocyanates,[14] isothiocyanates (eq 11),[15] and, isoselenocyanates,[16] respectively.

Polymerization of isocyanides with Ni^{II} catalysis leads to helical polymethyleneimine (*M* > 30 000 for *n*-butyl isocyanide, 75%).[17]

Related Reagents.

t-Butyl Isocyanide; ***Cyclohexyl Isocyanide***; ***Ethyl Isocyanoacetate***; ***Phenyl Isocyanide***; ***1,1,3,3-Tetramethylbutyl Isocyanide***; ***p-Tolylsulfonylmethyl Isocyanide***.

Methyl Isothiocyanate[1]

MeN=C=S

[556-61-6] · C_2H_3NS · Methyl Isothiocyanate · (MW 73.13)

(thiocarbamoylates NH, OH, SH, and organometallic compounds; used for preparation of a variety of heterocycles; derivatizes amino acids and peptides)

Alternate Name: MITC.

Physical Data: mp 31 °C; bp 117 °C; *d* 1.07 g cm^{-3}.

Solubility: sol chlorinated, aromatic, hydrocarbon, ethereal solvents; reacts violently with H_2O, basic and protic solvents.

Form Supplied in: white to pale orange solid; commercially available.

Handling, Storage, and Precautions: **Warning: Toxic! Lachrymator! Irritant! Extremely flammable!** Use only in a fume hood. Wear protective gloves and preferably a NIOSH-approved respirator. All transfers and reactions should be carried out under anhydrous conditions. Store in a cool dry place, taking care to avoid contamination with protic, basic, or organometallic materials, as these may induce (exothermic) polymerization.

N-Methylthiocarbamoylation.

Methyl isothiocyanate often differs from ***Methyl Isocyanate*** in reactivity, due to its lower overall electrophilicity and the high nucleophilicity of the S atom.[2] Thus, while reaction of oxiranes with methyl isocyanate has often been reported, the same is not true for MITC, and requires a catalyst.[3] Alkyl, aryl, primary, and secondary amines require no catalyst for serviceable reaction rates, and yield *N*,*N*´-disubstituted thioureas, which often display useful biological activity.[4] Alcohols react slowly with MITC (days);[5] the use of alkanolate salts increases the rate markedly.[6] The nucleophilicity of the S atom in alkenylthiocarbamates may be attenuated to allow the preparation of 1,2-amino alcohols (from the oxazolidinones, see eq 1).[6]

(1)

Thiols react sluggishly (days, weeks), but often completely with MITC.[7] Use of catalytic silylated thiol greatly increases the rate.[8] Organometallic compounds[9] and enolates[10] react with MITC to provide *C*-thiocarbamoylated products, usually with high yields. Electron-rich aromatics will undergo extremely *para*-selective Friedel-Crafts acylation with MITC in high yield.[11]

Heterocycle Synthesis.

Although not used as widely for heterocycle preparation as is methyl isocyanate, MITC provides access to a considerable variety of products. Hydrazino ketones, amino ketones, and aminoimidazoles afford (triazolo)imidazole derivatives.[12] Amidines give triazines,[13] amidrazones yield thiadiazoles,[14] and diazomethane derivatives afford thiotriazoles.[15] Hydroxychalcones provide 1,3-benzoxazine-2-thiones[16] and arylpropynamides yield thiazolidin-4-ones[17] upon treatment with MITC. Finally, cyanothioamides and enolizable ketones give 1,3-thiazoles[18] and pyrimidinedithiones,[19] respectively (see eq 2).

(2)

Phenyl isothiocyanate is generally interchangeable with MITC in the above reactions, but it seems uniquely able to undergo a Diels-Alder type reaction with 2-azadienes (see eq 3).[20]

(3)

Amino Acid and Peptide Derivatization.

MITC converts nearly all amino acids into 2-thioxo-4-oxoimidazolidines. These derivatives are readily differentiated by TLC, GC, and circular dichroism analyses, which is of use for protein analysis.[21] Peptides may be modified for enhancement of activity and/or augmentation of bioavailability by reaction of side chain NH, OH, or SH groups with MITC.[22]

Related Reagents.

Methyl Isocyanate; ***Phenyl Isocyanate***.

S-Methylisothiosemicarbazide[1]

[44387-06-6] · $C_2H_7N_3S$ · *S*-Methylisothiosemicarbazide · (MW 105.19)

(synthesis of substituted 1,2,4-triazines,[1] tetrazoles,[2] and guanylhydrazones[3])

Alternate Names: methyl hydrazinecarboximido thioate; *S*-methylisothiocarbohydrazide; *S*-methylisothiosemicarbazone.

Physical Data: mp 140 °C (HI salt);[2] mp 144-146 °C (TsOH salt).[4]

Preparative Methods: HI salt:[2] prepared by refluxing thiosemicarbazide and methyl iodide in absolute ethanol for 45 min. Crystallized upon cooling the reaction mixture to give 90% yield. Recrystallized from absolute ethanol. TsOH salt:[4] prepared by refluxing a mixture of 0.5 mol of thiosemicarbazide and 0.5 mol of methyl *p*-toluenesulfonate in 500 mL of methanol for 18 h. After reducing the volume to 250 mL in vacuo, the mixture was treated with 500 mL of ether to give 135 g of *S*-methylisothiosemicarbazide tosylate.

Handling, Storage, and Precautions: use in a fume hood.

S-Methylisothiosemicarbazide readily reacts with α-dicarbonyl compounds to afford the 3-methylthio derivatives of 1,2,4-triazines.[1] α-Keto aldehydes exclusively gave the expected 5-substituted 3-methylthio-1,2,4-triazines (eq 1).[1] Diethyl oxomalonate produces two isomers, depending on reaction conditions.[4] In acetic acid at reflux, the reaction product was 3-methylthio-5-oxo-6-ethoxycarbonyl-4,5-dihydro-1,2,4-triazine. When the free *S*-methylisothiosemicarbazide was used in aqueous solution, in addition to the above product, a less polar isomer was formed in 3:2 ratio (eq 2).[5] The condensation with an indole anhydride was reported to give only one product (eq 3).[6] 3-Amino-1,2,4-triazine 4-oxide was formed in modest yield when the HBr salt of *S*-methylisothiosemicarbazide was heated with an α-diketone monooxime under mild acidic conditions (eq 4).[7]

(1)

R^1	R^2	Yield (%)
H	Me	64
Me	Me	86
H	Ph	81
Ph	Ph	88

(2)

Formation of methylthiotetrazole was achieved by using the HCl salt of *S*-methylisothiosemicarbazide and potassium nitrite (eq 5).[2] Isothiocyanates also react with *S*-methylisothiosemicarbazide to give an intermediate which upon heating yielded substituted triazoles (eq 6),[8] but when the intermediate was heated in the presence of hydrochloric acid it afforded substituted thiadiazoles (eq 7).[8] Substituted guanylhydrazones can be easily prepared by condensation with aldehydes followed by aminolysis (eq 8).[3]

S-Methylisothiourea

[2986-19-8] · $C_2H_6N_2S$ · *S*-Methylisothiourea · (MW 90.17)

(synthesis of heterocycles;[1] guanylation reagent;[2] source of methanethiol[3])

Physical Data: free base not isolated; sulfate salt mp 240-241 °C.

Solubility: salts sol water, methanol, ethanol.

Form Supplied in: commercially available as 2-methyl-2-thiopseudourea sulfate *[867-44-7]* (MW 278.37).

Preparative Methods: both *S*-methylisothiourea sulfate[4] and *S*-ethylisothiourea hydrobromide[5] can be readily synthesized.

Handling, Storage, and Precautions: salts are toxic; when heated to decomposition, salts emit toxic fumes of SO_x and NO_x. *S*-Ethylisothiourea hydrogen sulfate reacts with Cl_2 to produce nitrogen trichloride (***Trichloramine***), a dangerous explosive.[6] Use in a fume hood.

Heterocycle Synthesis.

One of the most widely used syntheses of pyrimidines involves condensation of *S*-methylisothiourea with various 1,3-bis electrophilic compounds including β-dialdehydes, β-keto aldehydes, β-diketones, β-aldehydo esters, β-keto esters, malonic esters, β-alkoxy-α,β-unsaturated malonates, cyanoacetates, and malonitriles.[1b,7] The ease of formation of six-membered rings is evidenced in the reaction of ethyl 4-bromoacetoacetate with *S*-methylisothiourea which led only to the pyrimidine, albeit in low yield,[8a] whereas base-catalyzed condensation of phenacyl bromide with *S*-benzylisothiourea afforded only the expected 2-benzylthio-4-phenylimidazole (eq 1).[8b]

(1)

Synthesis of 2-substituted 5-acylpyrimidines is achieved using *S*-methylisothiourea hydroiodide and ethoxymethylene-β-diketones, with unsymmetrical 1,3-diketones yielding regioisomeric pyrimidines (eq 2).[9] Triformylmethane reacts with *S*-methylisothiourea to give 2-methylmercapto-5-formylpyrimidine in 33% yield,[10] whereas use of a 2-iminovinamidinium salt yields this compound quantitatively.[11] With equimolar amounts of triacetylmethane and *S*-methylisothiourea, the expected pyrimidine was not formed.[12] Instead, a triazine was isolated which was postulated to arise from condensation of 2 equiv of the isothiourea with the triketone via a biguanidine intermediate (eq 3).

(2)

Triarylpyrylium salts react with *S*-methylisothiourea to yield 2-methylmercapto-4,6-diarylpyrimidines.[13] A convenient synthesis of *trans*-5,6-diphenyl-5,6-dihydrouracils involves condensation of *S*-methylisothiourea with diphenylcyclopropenone followed by hydrolysis. Although both *cis* and *trans* isomers were detected in the crude reaction mixture, prolonged reaction times in the basic medium afforded only the thermodynamic product.[14]

A new synthesis of 1,3,5-triazines involves ring opening of 2-aroylimino-1,3-thiazetidines with *S*-methylisothiourea, cyclodehydration, and subsequent loss of thioformaldehyde (eq 4).[15]

A series of 5,6-dihydro-3-methylthio-4*H*-1,2,4-thiadiazine 1,1-dioxides have been prepared from *S*-methylisothiourea and 2-chloroethanesulfonyl chloride derivatives.[16] Reaction of an alkyl chloroformate with *S*-methylisothiourea gives either the mono- or di-*N*-alkoxycarbonyl derivative,[17] while reaction with chloromethanesulfonyl chloride affords the corresponding sulfonamide,[18] all useful intermediates for synthesis of a variety of heterocycles.

Guanylation Reagent.

The Rathke synthesis of guanidines using *S*-methylisothiourea is one of the oldest and most common methods available.[2] Selective reactions of primary vs. secondary amines with this reagent are possible,[19] while selectivity between primary amines and anilines has also been described.[20] Nitration of *S*-methylisothiourea gives the mono-*N*-nitro derivative in high yield, a useful reagent for direct preparation of *N*-nitro-protected guanidines, as well as in solid-phase peptide synthesis (SPPS).[21] N^G-Methyl-L-arginine has been prepared using *S*-methylisothiourea.[22] A series of *N*,*N*,*N*′-trialkylguanidines have been prepared from *N*-monoalkyl-*S*-methylisothioureas and secondary amines.[23] 1*H*-Pyrazole-1-carboxamidine hydrochloride has been reported as an alternative guanylating agent to *O*-methylisourea, *S*-methylisothiourea, or commercially available 1-guanyl-3,5-dimethylpyrazole nitrate for use in SPPS.[24] None of these reagents was sufficiently reactive for generalized use in SPPS, although 1-guanyl-3,5-dimethylpyrazole is superior to *S*-methylisothiourea for synthesis of some guanidines.[25]

Direct introduction of di-Boc-protected guanidine moieties during the total synthesis of racemic 15-deoxyspergualin[26] and caracasanamide[27] was achieved with *N*,*N*´-bis(*t*-butoxycarbonyl)-*S*-methylisothiourea, itself readily prepared from *S*-methylisothiourea and ***Di-t-butyl Dicarbonate***. Analogously, *N*,*N*´-bis(benzyloxycarbonyl)-*S*-methylisothiourea, available from *S*-methylisothiourea and ***Benzyl Chloroformate***, has been used in the synthesis of both L- and D-*C*-α-methylarginine.[28] Guanylation of the tridentate copper complexes of *erythro*- and *threo*-2-hydroxy-L-ornithine with *S*-methylisothiourea gave the (3*S*)- and (3*R*)-L-arginines in good yield. *O*-Methylisourea tosylate was not as efficient in this conversion.[29]

Source of Methanethiol.

A mild method for generating methanethiol involves warming an aqueous solution of *S*-methylisothiourea sulfate with 5N NaOH and trapping the liberated thiol as the sodium salt with sodium ethoxide.[3]

Related Reagents.

Acetoxime O-(2,4,6-trimethylphenyl)sulfonate; ***Cyanogen Bromide***; ***Diphenyl Cyanocarbonimidate***; ***Formamidine Acetate***; ***Guanidine***; ***O-Methylisourea***; ***1H-Pyrazole-1-carboxamidine Hydrochloride***.

O-Methylisourea[1]

[2440-60-0] · $C_2H_6N_2O$ · *O*-Methylisourea · (MW 74.10)

(synthesis of heterocycles;[2] guanylation reagent;[3] selective alkylating agent[4])

Physical Data: mp 44-45 °C; bp 82 °C/9 mmHg; pK_a 9.9 (25 °C).

Solubility: free base readily sol most organic solvents. Salts sol water, methanol, ethanol.

Form Supplied in: commercially available as *O*-methylisourea hydrogen sulfate *[29427-58-5]* (MW 172.16) or *O*-methylisourea sulfate *[52328-05-9]* (MW 246.24).

Preparative Methods: O-methylisourea hydrochloride is prepared in 69-80% yield by adding 1.15 equiv HCl(g) with ice cooling to cyanamide dissolved in excess anhydrous methanol. The free base is obtained from the salt using powdered KOH in a water-ether mixture or with sodium methoxide in methanol.[5] The monoacetate salt can be prepared from the free base with 1 equiv of HOAc.[6] *Drying:* vacuum desiccator over P_2O_5.

Handling, Storage, and Precautions: salts are hygroscopic and should be stored in a desiccator even for brief periods. Heating *O*-methylisourea to decomposition can liberate toxic fumes of NO_x. Use in a fume hood.

Heterocycle Synthesis.

O-Methylisourea has been used to prepare a variety of substituted pyrimidines by condensation with β-diketones.[7] Interestingly, if the condensation is conducted at rt with 30% aqueous K_2CO_3, the 2-methoxy analogs are isolated in good yield (eq 1), whereas reactions performed in refluxing ethanol afforded the 2-hydroxy derivatives directly (eq 2). An attractive synthesis of uracils, which obviates problems encountered using thiourea or an alkylisothiourea, involves condensation of *O*-methylisourea with a β-keto ester in aqueous ethanol. The resulting 2-methoxy-6-alkyl- or 2-methoxy-5,6-dialkyl-4(3*H*)-pyrimidinone is smoothly hydrolyzed to the corresponding uracil with dilute acid.[8]

Conjugate addition of *O*-methylisourea hydrogen sulfate to a preformed α-alkylidene-β-keto ester, subsequent cyclization, and acid hydrolysis affords 1,2,3,4-tetrahydro-6-methyl-2-oxo-5-pyrimidinecarboxylic acid esters, thus providing an attractive alternative to the Biginelli condensation (eq 3).[9a] Mixtures of both 1,4- and 1,2-dihydropyrimidines are obtained. Substitution of an alkylisothiourea affords the 2-thioxo derivatives after hydrolysis.[9b] Selective functionalization of the pyrimidine N-3 nitrogen with a variety of electrophiles, an otherwise difficult transformation, is possible using the 1,4-dihydropyrimidine.[9c]

(3)

A general synthesis of 2-substituted 5-formylpyrimidines from 2-iminovinamidinium salts and a variety of amidines including *O*-methylisourea has been described.[10] Cyclization of an unsaturated β-keto ester with *O*-methylisourea afforded a 1,4-dihydropyrimidine ester which was smoothly converted to the acyl portion of the bicyclic guanidine alkaloids crambine A and crambine B. Attempts to incorporate the guanidine moiety directly using guanidine itself were uniformly unsuccessful.[11] Oxidation of *O*-methylisourea *p*-toluenesulfonate[12] in a Graham reaction[13] generated bromomethoxydiazirine, a precursor to fluoromethoxycarbene.[14] Reaction of *O*-ethylisourea with ***Methyl Chloroformate*** followed by *o*-phenylenediamine produced 2-aminobenzimidazoles protected as the methylurethane.[15]

Guanylation Reagent.

Guanylation of primary and secondary aliphatic amines has been accomplished in good to excellent yields using *O*-methylisourea sulfate.[16] Diamines yield the analogous bis-guanidines, while amino alcohols produce hydroxy guanidines. Reaction of ornithine[17] and lysine[18] containing peptides with *O*-methylisourea sulfate at pH 10-11 smoothly generates the arginine and homoarginine analogs without guanylation of the *N*-terminus.[19] Incorporation of C-13 labels into homoarginine-containing derivatives of cytochrome *c* was accomplished using ^{13}C-labeled *O*-

methylisourea.[20]

Alkylating Agent.

Methylation of the SH group of mercaptoethanol can be achieved using *O*-methylisourea at pH 8.5. Functionalized side chains of simple amino acids such as arginine, aspartic acid, histidine, methionine, glutamine, and serine do not react under these conditions, although some guanylation of the N-terminal amino group was observed.[4] Selective methylation of the cysteine residues, with subsequent inactivation of papain, has been reported based on these observations.[21] When *O*-methylisourea was heated with 2 equiv KI, methyl iodide was obtained in excellent yield.[22]

Related Reagents.

Aminoiminomethanesulfonic Acid; ***Cyanogen Bromide***; ***Diphenyl Cyanocarbonimidate***; ***Formamidine Acetate***; ***Guanidine***; ***S-Methylisothiourea***; ***1H-Pyrazole-1-carboxamidine Hydrochloride***.

Methylketene Bis(trimethylsilyl) Acetal

[31469-22-4] · $C_9H_{22}O_2Si_2$ · Methylketene Bis(trimethylsilyl) Acetal · (MW 218.44)

(reactive nucleophile in Mukaiyama-type aldol reactions;[1,2] additions to imines[7] and enones;[8] alkylations with α-halo sulfides;[9] α-hydroxylations[10])

Alternate Name: 1,1-bis(trimethylsilyloxy)propene.

Physical Data: bp 63-68 °C/12 mmHg.

Solubility: highly sol organic solvents.

Preparative Methods: ketene bis(trialkylsilyl) acetals are prepared by silylation of lithium trialkylsilyl carboxylates or treatment of the dianions of carboxylic acids with ***Chlorotrimethylsilane*** at -78 °C (eq 1).[3] Alternatively, silyl carboxylates are silylated by trialkylsilyl triflates in the presence of ***Triethylamine***.[4]

Handling, Storage, and Precautions: easily hydrolyzed and oxidized by exposure to air. Storage possible in sealed tubes at rt.

Additions to Aldehydes.

Dubois and co-workers examined the stereochemistry of the Lewis acid-catalyzed Mukaiyama aldol condensation of ketene bis(trimethylsilyl) acetals.[5] Mainly the *anti*-hydroxy acid is obtained from methylketene bis(trimethylsilyl) acetal, benzaldehyde, and ***Titanium(IV) Chloride*** (eq 2). With increasing size of the alkyl substituent on the ketene, the *syn* isomer predominates. Fluoride anion also serves as a catalyst, providing predominantly *syn* product (eq 2).[6]

Additions to Imines.

A diastereoselective synthesis of β-amino esters by $TiCl_4$-mediated reaction of *N*-tosylaldimines with ketene bis(trimethylsilyl) acetals was realized (eq 3).[7]

Alkylation by α-Halo Sulfides.

The ***Zinc Bromide***-catalyzed phenylthioalkylation of methylketene bis(trimethylsilyl) acetal with α-chloro sulfides provides phenylthiolactones which can be converted to α,β-unsaturated γ- and δ-lactones (eq 4).[9]

Additions to α,β-Unsaturated Carbonyl Compounds.

The regio- and stereoselectivity of $TiCl_4$-catalyzed 1,2- and 1,4-additions of ketene bis(trimethylsilyl) acetals to α,β-unsaturated enones and enals were investigated by Bellassoued and Mladenova.[8]

Hydroxylations.

Treatment with peroxy acids in hexane followed by acidic workup allows isolation of α-hydroxy acids in good yields.[10] Bissilyl ketene acetals devoid of β-protons undergo a clean sigmatropic ene reaction with $^1O_2$ to generate the α-silylperoxy silyl ester quantitatively (eq 5).[11]

Related Reagents.

1,2-Diethoxy-1,2-bis(trimethylsilyloxy)ethylene; ***Ketene Bis(trimethylsilyl) Acetal***; ***Ketene Diethyl Acetal***; ***1-Methoxy-2-methyl-1-(trimethylsilyloxy)propene***; ***1-Methoxy-1-(trimethylsilyloxy)propene***; ***1-Methoxy-2-trimethylsilyl-1-(trimethylsilyloxy)ethylene***; ***Methylketene Dimethyl Acetal***; ***Tetramethoxyethylene***; ***Tris(trimethylsilyloxy)ethylene***.

Methylketene Dimethyl Acetal[1]

[5434-53-6] · $C_5H_{10}O_2$ · Methylketene Dimethyl Acetal · (MW 102.15)

(electron-rich alkene which can act as propionyl carbocation equivalent in reactions with electrophiles; undergoes [2 + 2] cycloadditions with electron-deficient alkenes, aldehydes, and imines; also participates in inverse Diels-Alder reactions and 1,3-dipolar cycloadditions)

Alternate Name: 1,1-dimethoxypropene.

Physical Data: bp 99 °C.

Preparative Methods: best method is from acrolein dimethyl acetal by isomerization of the double bond with potassium amide.[2] The method is also applicable for other dialkoxy analogs.

Handling, Storage, and Precautions: sensitive to moisture, especially in the presence of traces of acids. It can be stored for longer time in dry base-rinsed vessels under nitrogen.

General Reactivity.

Dimethoxypropene belongs to the class of the ketene acetals. These compounds react as strong electron-rich alkenes due to the electron-donating ability of the two alkoxy groups.

Over the years, the chemistry of the ketene acetals has been reviewed several times.[1a,c,d] Electronically symmetrical ketene acetals sometimes show different chemistry than the electronically asymmetrical ketene acetals like the 1,1-dialkoxyethylenes. In cycloadditions, the former give mostly stable cycloadducts, whereas the latter give unstable cycloadducts or products derived from dipolar intermediates. In this respect, dimethoxypropene shows an intermediate behavior.[3] Since the mid-1970s, much attention has also been paid to the alkyl trialkylsilylketene acetals. In reactions with electron-poor double bonds these compounds often yield acyclic products, whereas the dialkylketene acetals yield cycloadducts.[1c] 1,1-Dimethoxypropene has been more extensively studied since the mid-1980s due to its easy availability and because it can act as propionyl carbocation equivalent.

Acids, alcohols, and thiols react rapidly with ketene acetals, but these reactions have not been explored for synthetic purposes. The main application of 1,1-dimethoxypropene lies in the field of cycloaddition reactions.

Carbenes.

Ethyl Diazoacetate reacts with 1,1-dimethoxypropene in the presence of ***Copper(II) Acetylacetonate*** to give ethyl 2,2-dimethoxy-3-methylcyclopropane-1-carboxylate, which can be methanolized in situ to ethyl 4,4,4-trimethoxy-3-methylbutanoate (eq 1).[4]

The analogous reaction with diazo ketones which was investigated for 1,1-diethoxypropene yields 2,2-diethoxy-3-methyldihydrofurans (eq 2).[5]

Cyclobutanes.

Electron-deficient alkenes undergo polar [2 + 2] cycloadditions with 1,1-dimethoxypropene (eq 3).[6]

(3)

R = H, alkyl, phenyl

X^1 and/or X^2 = electron withdrawing substituent

The resulting cyclobutanes can be further hydrolyzed into cyclobutanones[7] or γ-funtionalized esters.

Oxetanes.

Carbonyl compounds having electron-withdrawing substituents add to 1,1-dimethoxypropene to give 2,2-dimethoxy-3-methyloxetanes. In the presence of Lewis acids the cycloaddition can be performed with normal aldehydes.[2]

This cycloaddition can also be achieved under high pressure without Lewis acids. The combination of Lewis acids and high pressure extends the scope of the reaction to include ketones.[8] The reaction has very high regioselectivity. Furthermore the *cis*/*trans* stereoselectivity is controlled by the reaction conditions.[9] Interestingly, the photochemical cycloaddition gives mainly the products with the reverse regiochemistry.[10,11] As reactive orthoesters, the oxetanes are easily hydrolyzed to β-hydroxy esters or methanolyzed to β-hydroxy orthoesters (eq 4).[12]

(4)

Oxetanes obtained in this way from α- or β-oxy-functionalized aldehydes or ketones are interesting precursors for the synthesis of 3-methyl-4-hydroxy-γ- or δ-lactones (eq 5).[13,14]

(5)

The oxetanes from α,β-epoxy aldehydes have been further converted into 4-hydroxy-5-hydroxymethyl-3-methyltetrahydrofuran-2-ones (eq 6).[15]

(6)

Cycloaddition reactions of α-diketones with 1,1-dimethoxypropene afford mono- and bis-oxetanes which can be further converted to bis-γ-lactones (eq 7).[16]

(7)

α,β-Unsaturated aldehydes undergo cycloadditions to the kinetically favored oxetanes at low temperatures in the presence of Lewis acids, whereas above rt the thermodynamically more stable 2,2-dimethoxydihydropyrans are formed (eq 8). Cyclobutanes are the main products under high pressure without Lewis acid catalyst.[17]

(8)

Azetidines.

Electron-deficient imines undergo [2 + 2] cycloaddition with 1,1-dimethoxypropene to give 2,2-dimethoxy-3-methylazetidines. The scope of the reaction can be extended to weakly activated imines by application of high pressure (eq 9).[18]

(9)

p-Chlorophenyl isocyanate affords the β-lactam 1-*p*-chlorophenyl-4,4-dimethoxy-3-methylazetidin-2-one.[19]

Benzonitrile adds photochemically to 1,1-dimethoxypropene. The cycloadduct is not stable and it reacts further by ring opening to 1,1-dimethoxy-2-aza-3-phenylpenta-1,3-diene (eq 10).[20]

(10)

Diels-Alder Reactions.

Apart from cycloadditions with α,β-unsaturated carbonyl compounds, inverse electron-demand Diels-Alder reactions of 1,1-dimethoxypropene with electron-poor alkenes have been infrequently investigated. Only 1,1-dicyanobutadienes having a preferred cisoid conformation give Diels-Alder adducts. Transoid 1,1-dicyanobutadienes yield [2 + 2] cycloadducts. Interestingly, 5-nitropyrimidine reacts with 1,1-dimethoxypropene via an unstable Diels-Alder adduct to give 2-hydroxy-3-methyl-5-nitropyridine (eq 11).[21]

(11)

1,3-Dipolar Cycloadditions.

Most of the 1,3-dipolar cycloadditions have been studied with 1,1-dialkoxyethylenes. ***Ethyl Azidoformate*** and 1,1-dimethoxypropene form a triazoline cycloadduct at -15 °C, whereas at 35 °C ethyl *N*-(1,2-dimethoxypropylidene)carbamate is obtained.[1b,d] Three-membered ring compounds which can open up to 1,3-dipolar intermediates react with 1,1-dimethoxypropene to form five-membered cycloadducts, e.g. 2,2-dimethoxy-3-methyltetrahydrofurans from epoxides (eq 12) and 1,1-dimethoxy-2,2-dicyano-5-methylcyclopentanes from 1,1-dicyanocyclopropanes.[1c]

(12)

Methyl Lithiodithioacetate[1]

[82452-67-3] · $C_3H_5LiS_2$ · Methyl Lithiodithioacetate · (MW 112.16)

(enolate equivalent, capable of reacting as a carbon or sulfur nucleophile)

Preparative Methods: colorless solutions of the reagent are prepared by addition of ***Lithium Diisopropylamide*** to an ether or THF solution of methyl dithioacetate at -78 °C; reaction is complete in minutes.

Handling, Storage, and Precautions: solutions in THF are stable for at least 24 h at 20 °C.[2] Solutions of the closely related ethyl lithiodithioacetate are reported to decompose rapidly above 0 °C.[3]

Reaction as a Carbon Nucleophile.

Methyl lithiodithioacetate gives aldol products with simple aldehydes.[4] Selective conjugate addition is observed with enones (eq 1).[5] The unexpected *syn* selectivity in the reaction arises from internal proton transfer to produce (**1**). Similar reactions conducted in the presence of ***Chlorotitanium Triisopropoxide*** (4 equiv) give exclusively the 1,2-addition product (eq 2).[6] A variety of transformations possible for the products obtained from reactions with carbonyl compounds is described in a review article.[1]

Reaction as a Sulfur Nucleophile.

Methyl lithiodithioacetate reacts exclusively as a sulfur nucleophile with a variety of alkyl halides,[7] epoxides,[8] and with ***Chlorotrimethylsilane***.[9] Presumably, *C*-allylation products can be obtained by the thio-Claisen rearrangement, examined in detail with aldol products derived from methyl lithiodithioacetate.[4]

Related Reagents.

t-Butyl α-Lithioisobutyrate; ***Dilithioacetate***; ***Ethyl Bromozincacetate***; ***Ethyl Lithioacetate***.

Methyllithium

MeLi

[917-54-4] · CH_3Li · Methyllithium · (MW 21.98)

(methylating agent for several functional groups; cleaves protecting groups; synthesis of other methyl organometallics, i.e. of Cu, Ga, Ti, Mg, Si, Ir, B; can function as a base; reduces transition metals)

Physical Data: unsolvated solid is pyrophoric; densities listed below.

Solubility: insol hydrocarbon solvents; moderately sol ethereal solvents; reacts exothermically with water and protic solvents to generate methane.

Form Supplied in: commonly available as >1.4 M in diethyl ether, *d* >0.732 g mL^{-1}; >1.5 M in diethyl ether (with ~1.0 equiv of LiBr), *d* >0.852 g mL^{-1}. New formulations are >1 M in THF/cumene with 0.08 M Me_2Mg,[1] *d* 0.86 g mL^{-1}; 70 wt % solid[2] complexed with 22 wt % diethyl ether, 6% LiCl, and ~1% LiOH.

Analysis of Reagent Purity: titration of 0.5 N *s*-butanol in toluene (10 mL) with methyllithium via tared syringe at 15 °C using 2,2´-biquinoline as an indicator.

Handling, Storage, and Precautions: methyllithium in diethyl ether is pyrophoric in absence of LiBr, according to US Dept of Transportation regulations (49 CFR 173, Appendix E), while all other available formulations (solution and solid) are nonpyrophoric. Store in a cool, dry place in a tightly sealed container under an inert atmosphere.

Introduction.

Most preparations involve use of diethyl ether[3] or THF[1] from which solvated solids[4,5] may be isolated. Unsolvated methyllithium[1,6] preparations would allow systematic investigation of solvent[7] and halide[8] effects. Aggregation and crystal studies have been reported.[9]

Addition Reactions.

Methyllithium can have different stereoselectivity compared to methyl Grignards in 1,2-additions to cyclic carbohydrates,[10] heterocycles,[11] and acyclic[12] substrates. The origin of the high diastereoselectivity in nucleophilic addition to ketones (eq 1) is based on chelation control.[13a] Stereoselectivity can also be affected by prior complexation of the carbonyl compound with aluminum and other Lewis acids.[13b]

Conversion of organolithiums to organometallics of titanium,[14] cerium,[15] and zinc[16] has lead to improved chemo- and stereoselectivity. For instance, conversion of MeLi to a chiral titanate prior to 1,2-addition to benzaldehyde resulted in 91% ee (eq 2).[14a]

Methyl ketones can be prepared from acids[17] and esters, usually with greater success by subsequent treatment with ***Chlorotrimethylsilane***.[18,19] Methyllithium is a convenient deacylating agent for alkoxycarboxyl- and benzoyl-protected secondary hydrazides.[20] Addition of methyllithium with ***Lithium Bromide*** to silyl ketone (**1**) gave silyl enol ethers (**2**) with high stereochemical purity when warmed to 0 °C (eq 3).[21]

Similarly, almost quantitative yields of 2,2-difluoroenol silyl ethers were obtained from a perfluoroacylsilane.[22] Enolates, free of amine, can be prepared by cleavage of silyl enol ethers[23] and enol trifluoromethanesulfinates with methyllithium.[24]

Of 1,2-additions to carbon-nitrogen multiple bonds, nitriles, imines, and oxazolidine are the most useful substrates. For

instance, addition of methyllithium in cumene/THF to protected cyanohydrins gave excellent yield of methyl steroidal ketones after hydrolysis.[25] Addition of aryl heterocycles, such as tetrazines[26] and pyrazines,[27] are problematic.

Conjugate addition is routinely achieved by prior transformation to the corresponding cuprate[28,29] or even aluminate.[30] In absence of any co-metals, methyllithium will undergo 1,4-addition to naphthalimines[31] in the presence of ***Hexamethylphosphoric Triamide*** (eq 4). Without HMPA, methyllithium undergoes 1,2-additions to naphthalimines[31] and oxazolidines.[32]

(4)

Secondary allylic alcohols, 3-substituted with SO_2Ph and $SiMe_3$, will undergo conjugate addition to give only the *syn*-adduct.[33] Asymmetric addition to sulfines in the presence of chiral ligands had only modest stereoselectivity.[34]

Miscellaneous Reactions.

Methyllithium was the base of choice for the metalation of *o*-allylbenzamide, which cyclizes to a naphthol derivative (eq 5).[35]

(5)

Rearrangement of *gem*-dibromides of cyclopropyl derivatives with methyllithium leads to mixtures of allenes[36a] and monobromide derivatives.[36] Substituted epoxides,[37] silacyclopentane,[38] and cyclotriphosphazene[39] can be ring opened. The transmetalation of trimethylstannyl compounds to form vinyl-, allenyl-, and propargyllithium reagents is usually best done with methyllithium.[40] Zero-valence Pd for coupling alkenyl halides and organolithiums can be prepared from

Palladium(II) Chloride and methyllithium.[41] Even preparation and utility of transition metal-activated organic compounds of molybdenum[42a] and tungsten[42b] are reported.

Related Reagents.

Dilithium Trimethylcuprate; ***Dichlorodimethyltitanium***; ***Lithium Cyano(methyl)cuprate***; ***Lithium Dimethylcuprate***; ***Methylcopper***; ***Methylmagnesium Bromide***; ***Methyltitanium Triisopropoxide***; ***Lithium Trimethylzincate***.

Methylmagnesium Bromide[1]

MeMgX

(X = Br)

[75-16-1] · CH_3BrMg · Methylmagnesium Bromide · (MW 119.25) (X = Cl)

[676-58-4] · CH_3ClMg · Methylmagnesium Chloride · (MW 74.80) (X = I)

[917-64-6] · CH_3IMg · Methylmagnesium Iodide · (MW 166.25)

(adds to many unsaturated functional groups; methyl can displace halide and like groups; can function as a strong base and a Lewis acid)[1b-f]

Physical Data: NMR, IR, kinetic, and calorimetric observations indicate that MeMgBr in Et_2O and THF, and MeMgCl in Et_2O, actually are mixtures of MeMgX, Me_2Mg, and MgX_2.[2] MeMgBr is essentially monomeric in THF, but it and MeMgI are associated significantly in Et_2O except at low concentrations.[3] Solids isolated include $MeMgBr(THF)_3$,[4] shown by X-ray diffraction to have five-coordinate Mg, and (low-melting) $MeMgX(Et_2O)_2$ (X = Br or I).[5] Complete removal of Et_2O leaves a mixture of Me_2Mg and MgX_2 (X = Cl or Br).[6]

Solubility: MeMgBr and MeMgI sol Et_2O; MeMgCl and MeMgBr sol THF. MgI_2 precipitates when MeMgI is prepared in THF, leaving mainly Me_2Mg in solution; some $MgCl_2$ generally precipitates when MeMgCl is prepared in Et_2O, particularly if the solution stands for several days. All are insoluble in hydrocarbons.

Form Supplied in: solutions of MeMgCl in THF, MeMgBr and MeMgI in Et_2O and Bu_2O, and MeMgBr in toluene/THF are commercially available.

Analysis of Reagent Purity: a small excess is used ordinarily to ensure that sufficient reagent is present, but concentration should be determined when exact stoichiometry is important.[7] R-Mg is conveniently determined by hydrolysis of an aliquot followed by addition of excess acid and back-titration with base.[8] Since this procedure does not distinguish R-Mg from HO-Mg and RO-Mg formed from reaction of the Grignard reagent with water and oxygen, respectively, a direct titration[9] more specific for R-Mg or a double titration procedure[10] should be used when such exposure is suspected. A qualitative color test is convenient for detecting the presence of Grignard reagent.[11]

Preparative Methods: [1c,e,12,13] in spite of their commercial availability, solutions of MeMgCl,[14,15] MeMgBr,[14,16] and MeMgI[17] are often prepared from reaction of a methyl halide and Mg, usually in Et_2O or THF.

Handling, Storage, and Precautions: Grignard reagents react readily with oxygen, water, and carbon dioxide. Reactants and apparatus used in their preparations and reactions should be dry throughout preparation, storage, and use; Grignard reagent solutions should be maintained under nitrogen or argon, though the vapor of a volatile solvent (especially Et_2O) provides some protection for short periods of time. Methyl Grignard reagents do not significantly attack Et_2O or THF at normal reaction temperatures.

Structure.[1a,c]

The structure of a Grignard reagent, an important influence on reactions, is more elaborate than implied by the formula RMgX. In solution, a Grignard reagent is a mixture (Schlenk equilibrium) of RMgX, R_2Mg, and MgX_2, the composition varying with solvent and X. Mg is most commonly four-coordinate in solids but may have even higher coordination;[18] all evidence indicates similar coordination in solutions. The additional bonds to Mg result from some combination of association by bridging of the X atom (or R group) between two Mg atoms and coordination by donor molecules (usually solvent). Coordination by donor groups of substrates can play an important role in reactions.

Workup Procedures.[13]

Workup of a Grignard reaction requires adding a proton source and removing magnesium salts. This is done conveniently by adding an aqueous HCl or H_2SO_4 solution and separating the organic and aqueous layers. When products cannot tolerate acids, however, a saturated aqueous ammonium chloride solution is generally used, either a large volume[19] sufficient to dissolve all magnesium salts or, alternatively, just enough[15] to completely precipitate the magnesium salts, leaving a nearly anhydrous solution of the product.

Representative Applications.[1b-f]

A Grignard reagent is used in an extraordinary variety of reactions, the majority leading to attachment of its organic group to an electrophilic carbon atom of the substrate. Most common are additions to carbonyl groups (eq 1),[20] nitriles, and imines (eq 2),[21] and displacements of halide and like leaving groups. Although generally less reactive than organolithium compounds, Grignard reagents are often used for convenience, because of a different reactivity pattern, or to minimize competing reactions. MeMgX and MeLi, for example, sometimes exhibit quite different regioselectivities (eq 1) and stereoselectivities (eq 2). The key step in the synthesis of chiral $O{=}CHCH(Me)NH_2$ (eq 2) also illustrates the common practice in Grignard reagent additions of using a disposable group whose coordination or steric effects impart stereoselectivity.

(1)

MeMgBr, THF, -78 °C	60%	-
MeLi, TMEDA, THF, -107 °C	9%	87%

(2)

MeMgBr, Et_2O, reflux, 24 h	80:20
MeMgBr, toluene, 20 °C, 1 h	94:6
MeLi, Et_2O, -78 °C to rt	2:98

Grignard reagents are strong bases and Lewis acids, a problem in many reactions but of use in others. MeMgX, for example, extracts a proton from most N-H and O-H bonds and from particularly acidic C-H bonds. Volumetric measurement of the methane evolved from reaction with a compound of MeMgI was once a significant procedure (Zerewitinoff determination) for quantitative determination of its active hydrogens.[22] MeMgX still is used as a base, for example in forming magnesium amides (eq 3)[23] and enolates. Cleavage of aryl-alkyl ethers (eq 4)[24] is a displacement that must require the Lewis acid properties of the Grignard reagent. Me_2Mg is sometimes used in place of MeMgX to minimize reactions, such as isomerization of oxiranes to aldehydes or ketones,[25] that involve Lewis acidity but not displacement.

(3)

(4)

Strongly coordinating solvents tend to reduce reactivity in additions to unsaturated functions but to increase reactivity in reactions with alkyl halides and as bases. The greater rate and stereoselectivity of an addition (eq 2) in toluene than in Et_2O illustrate the importance of solvent.

Transition metal impurities, often introduced in the Mg used to prepare a Grignard reagent, can lead to unwanted products,[26] and where this is a problem particularly pure Mg should be used. Catalytic or stoichiometric amounts of transition metal compounds, of course, often are added deliberately to Grignard reagents.[27] Examples are copper compounds[28] to promote 1,4-additions to α,β-unsaturated carbonyl compounds (one variant of organocuprate chemistry) and nickel compounds[29] to promote substitution of aryl and vinyl halides.

Methyl Magnesium Carbonate[1]

[4861-79-4] · $C_3H_6MgO_4$ · Methyl Magnesium Carbonate · (MW 130.40)

(agent for the α-carboxylation of nitroalkanes, ketones, lactones, hydantoins, and phenols[1])

Alternate Name: MMC.

Preparative Methods: prepared in situ by saturating a solution (2 M) of ***Magnesium Methoxide*** in DMF with ***Carbon Dioxide***.[3] It is assumed to have the formula $MeOMgOCO_2Me.(CO_2)_n$ where *n* varies with temperature and solvent.[2]

Carboxylation of Nitroalkanes and Ketones.

Stiles and Finkbeiner discovered that methyl magnesium carbonate readily carboxylated nitroalkanes at the α-position (eq 1).[2] They concluded that the reaction proceeds to give a magnesium chelate which confers stability on the products (eq 2).[4] The procedure has recently been used to prepare isotopically labelled α-oxoglutaric acid from [^{13}C]nitromethane.[5]

(1)

R = H, Me, Et, Pr, Bu, *i*-Pr, pentyl, Bn

(2)

MMC has also been used to carboxylate ketones (eqs 3 and 4), although quite vigorous conditions (100-130 °C) are required.[6] The process is considered to be reversible and results in the carboxy group occupying the less hindered location. It is thus highly selective for carboxylation at the terminal methyl group of 2-alkanones.[7] Carboxylation at a methine site has not been observed. β-Tetralones, which might have been expected to undergo carboxylation at the more acidic C-1 position, afford the C-3 isomers (eq 5) since the *peri* interaction between the aromatic ring and a carboxy group at C-1 would be destabilizing.[8]

(3)

(4)

(5)

The carboxylation of hydrindenones with MMC (eq 6) was observed to take a very different course[9,10] from that experienced with the equivalent octalone (eq 7)[9] and with cholest-4-en-3-one (eq 8).[11] The difference was attributed to a preference for heteroannular dienolate formation in the hydrindene substrate, relative to the decalin systems. Carboxylation of a ketone, used as an intermediate in the synthesis of quassins, failed when a neighboring acetoxy group underwent hydrolysis. When the interfering hydroxy was protected as a TBDMS or THP ether, however, an excellent yield of the desired product was obtained (eq 9).[12]

(9)

Carboxylation and α-Methylenation of Lactones.

Lactones are readily carboxylated with MMC and the higher stability of the products, relative to those from ketones, ensures generally excellent yields (eq 10).[13] The carboxylic acid products may be used in a particularly efficaceous preparation of α-methylene lactones with formaldehyde (eq 11)[14] or Eschenmoser's salt (eq 12).[15]

(10)

(11)

(12)

During the synthesis of protolichesterinic acid, the carboxylation failed on a lactone substrate bearing a methoxycarbonyl substituent, but the reaction proceeded satisfactorily with the parent acid (eq 13).[16]

(13)

Miscellaneous Carboxylations.

Hydantoins are readily carboxylated with MMC (eq 14) and the products may be alkylated in situ (eq 15).[17] The carboxylation of resorcinols has been reported, including a phenolic intermediate in the synthesis of cannabinoids (eq 16).[18]

(14)

(15)

(16)

Related Reactions.

Modest yields have been obtained from the carboxylation of ketones with a 2:1 complex of potassium phenoxide and CO_2,[19] and with the complexes (**1**),[20] (**2**),[21] (**3**),[22] and (**4**).[23] However, the ureide complexes (**5**)[24] afforded significantly improved yields, as does a mixture of ***Triethylamine*** with ***Magnesium Iodide*** (prepared in situ from $MgCl_2$ and NaI) in acetonitrile.[25] This last magnesium carbamate differs from the others in allowing carboxylation at methine positions, as in dimethylcyclohexanone (65% yield) and isobutyrophenone (90% yield).

Methylmagnesium *N*-Cyclohexylisopropylamide[1]

[102276-92-6] · $C_{10}H_{21}MgN$ · Methylmagnesium *N*-Cyclohexylisopropylamide · (MW 179.63)

(isomerization of epoxides to allylic alcohols[1])

Alternate Name: MMA.

Solubility: sol toluene.

Form Supplied in: prepared and used in situ.

Preparative Methods: prepared by adding ***n-Butyllithium*** (1 equiv) to a 0 °C solution of *N*-cyclohexylisopropylamine in anhydrous toluene (0.85 M). After 15 min, ***Methylmagnesium Bromide*** (1 equiv, 3 M in Et_2O) is introduced dropwise. Stirring is continued for another 30-45 min, during which time a white precipitate develops.[1a]

Handling, Storage, and Precautions: moisture sensitive; prepared and used in situ.

Isomerization of Epoxides to Allylic Alcohols.[1]

The isomerization of epoxides to allylic alcohols (eq 1) is a common and preparatively useful functional group interchange.[2] Methylmagnesium *N*-cyclohexylisopropylamide is an efficient reagent for the isomerization of epoxides to allylic alcohols. Although the nature of the reagent and its state of aggregation are unknown, the formation of allylic alcohols from epoxides is assumed to proceed by a β-elimination pathway by analogy with related systems.[2]

(1)

The epoxide in toluene is added to a 3-4 fold excess of MMA (final MMA concentration 0.55 M) at 0 °C and the mixture is

maintained under the conditions summarized in Table 1. Proton abstraction from a methyl group is greatly preferred over that from a methylene in acyclic[3] (entry 1) and cyclic (entry 2) systems. However, in some cases such as a 1,1-disubstituted epoxide (entry 3) and a simple cyclic epoxide (entry 5), nucleophilic addition of methyl from MMA is the major result. In contrast, the more sterically biased pyranoside[4] in entry 4 isomerizes exclusively to the allylic alcohol. It is noteworthy that, unlike lithium amides,[5] MMA converts 5,6-epoxycyclooctene (entry 6) to 2,5-cyclooctadien-1-ol without significant ketone or conjugate diene formation. Exposure of 14,15-epoxyicosatrienoic acid (**1**) (entry 7) to MMA affords 15-hydroxyicosatetraenoic acid (15-HETE; **2**). The yield of 15-HETE decreases dramatically if THF or toluene/HMPA (2:1) is the solvent.[6,7] Abstraction of an allylic proton in a related bis-epoxide (**3**) (entry 8) also leads to a conjugated (*E*,*Z*)-dienol (**4**).

Table 1 Reaction of Epoxides with MMA

			(7)	45

(1)

(2)

(3)

(4)

The epoxide (**5**) of oleic acid displays intermediate reactivity with respect to isomerization or nucleophilic addition. Treatment with MMA furnishes approximately equal amounts of allylic alcohols (**6**) and methyl addition product (**7**) (entry 9). The ethylmagnesium and isopropylmagnesium analogs of MMA behave similarly. On the other hand, phenylmagnesium *N*-cyclohexylisopropylamide gives rise to only allylic alcohol (**6**), albeit in low yield (~20%).

Methylmagnesium Iodide-Copper(I) Chloride[1]

MeMgI-CuCl

(MeMgI)

[917-64-6] · CH_3IMg · Methylmagnesium Iodide-Copper(I) Chloride · (MW 166.25) (CuCl)

[7758-89-6] · ClCu · Methylmagnesium Iodide-Copper(I) Chloride · (MW 99.00)

(methyl group transfer in 1,4- and 1,6-conjugate additions to unsaturated carbonyl compounds; coupling with acid chlorides gives methyl ketones)

Physical Data: see entries for ***Methylmagnesium Bromide*** and ***Copper(I) Chloride***.

Preparative Methods: generated in situ by using varying, often catalytic, amounts of purified and dried CuCl.

Handling, Storage, and Precautions: air- and moisture-sensitive. Use in a fume hood.

Conjugate Additions.

While the reaction of methylmagnesium iodide with α,β-unsaturated carbonyl compounds usually produces a mixture of 1,2- and 1,4-adducts, a selective 1,4-addition is observed in the presence of copper(I) chloride in most cases. Many successful conjugate additions to acyclic[2] or cyclic[3-5] enones (including steroidal ketones[6]) as well as to enoate esters[7] have been reported (eqs 1-3). A similar transformation of phenylpropiolic acid gives 3-phenyl-2-butenoic acid.[8]

(2)

(3)

A conjugate 1,6-addition is possible (eq 4).[9]

(4)

Addition to cyclic enones usually proceeds stereoselectively (eqs 1 and 2). Being irreversible, the reaction is governed by kinetic control. The stereochemical outcome can be predicted in most cases on the basis of transfer of the methyl group from the reagent perpendicular to the alkenic bond and from the least hindered side of the substrate.[3c,6e]

Steric hindrance may result in low yield of the addition product. Reduction of the alkenic bond[7c] or 1,2-addition to the

carbonyl group[6a] have been observed as major reaction pathways for sterically hindered substrates.

Synthesis of Methyl Ketones.

Treatment of acid chlorides, including highly sterically hindered derivatives, with MeMgI in the presence of CuCl gives methyl ketones in excellent yields.[10]

Related Reagents.

Ethylmagnesium Bromide-Copper(I) Iodide; ***1-(Trimethylsilyl)vinylmagnesium Bromide-Copper(I) Iodide***; ***Vinylmagnesium Bromide-Copper(I) Iodide***.

Methyl Methanethiosulfonate[1]

[2949-92-0] · $C_2H_6O_2S_2$ · Methyl Methanethiosulfonate · (MW 126.22)

(methylsulfenylating agent with many applications;[2] reagent for the rapid and selective modification of the essential SH groups of enzymes. The MeS-protecting group is easily removed under mild conditions[3])

Alternate Name: S-methyl thiomethanesulfonate.

Physical Data: bp 69-71 °C/0.4 mmHg; *d* 1.227 g cm^{-3}; *n* 1.5130.

Form Supplied in: colorless oil; widely available.

Handling, Storage, and Precautions: stench; irritant. Use in a fume hood.

Introduction.

Methyl methanethiosulfonate is a versatile reagent mainly used to form sulfenylated intermediates used en route to the synthesis of various interesting compounds. It is a much more reactive and effective sulfenylating agent than ***Dimethyl Disulfide*** or MeSCl.[4] $MeSSO_2Me$ (and its reaction products) has little odor, which makes it considerably more agreeable to work with than MeSSMe. The MeS group transferred via deprotonation of the substrate's acidic proton with a base, followed by electrophilic substitution, can serve as a protecting group,[5] an activating group for carbanion formation, or as a masked ketone or aldehyde. It can serve as a handle for subsequent transformation to various functionalities (e.g. alkene, ketone, and alkyl group) via oxidation or reduction.

Preparation of 2-(Methylthio)alkanoic Acids and Esters and 3-Methylthio-2-alkanones.

2-(Methylthio)alkanoic acids and esters are synthesized by successive treatment of substituted malonic esters with ***Sodium Ethoxide*** and $MeSSO_2Me$, followed by alkaline hydrolysis which causes concurrent decarboxylation (eq 1).[6]

More conveniently, 2-(methylthio)alkanoic esters are prepared from 2-acetylalkanoates (eq 2).[7] MeSSMe cannot replace $MeSSO_2Me$ as the sulfenylating agent in this transformation. Advantages of these methods over others such as sulfenylation of an alkanoic acid and its ester or alkylation of (methylthio)acetic acid are (1) simplicity of the procedure; (2) efficiency and convenience of using inexpensive base (EtONa) and EtOH as solvent with high product yields; and (3) no bissulfenylation. Moreover, the latter method allows direct α-sulfenylation of 2-acetylalkanoates which also contain an additional keto group, without its protection (eq 2).

This contrasts to thiomethylation of methyl 9-oxodecanoate with MeSSMe and lithium cyclohexyl(isopropyl)amide, as reported by Trost.[8] In spite of various reaction conditions employed, Trost's procedure gives less than 30% yield of 2-methylthio-9-oxodecanoate, accompanied by bissulfenylation when the 9-oxo group is not protected. Moreover, toxic HMPA is required to obtain 86% of the sulfenylated ester even when the 9-oxo group is protected. The transformation

described in eqs 1 and 2 works with $PhSSO_2Ph$ as well.

Similarly, 3-methylthio-2-alkanones are prepared by the reaction of a 3-alkyl-2,4-pentanedione with 1 mol equiv (important) of $MeSSO_2Me$ in the presence of EtONa in EtOH at rt or ***Potassium Carbonate*** in acetone at reflux followed by addition of MeOH and reflux. An advantage of using weaker base K_2CO_3 in this reaction is that no bissulfenylation takes place even when excess sulfenylating agent is used. The method was applied to an efficient synthesis of pseudoionone (eq 3).[9]

Diethyl 1-Methylthio-1(*Z*),3-butadienephosphonate.

An efficient synthesis of diethyl 1-methylthio-1(*Z*),3-butadienephosphonate from ***Diethyl Methylthiomethylphosphonate*** is carried out in four steps without contamination with the (*E*) geometric isomer (eq 4).[10] The methylthiobutadienephosphonate reacts smoothly with enamines. It also undergoes 1,4-addition with dialkylcuprates to yield exclusively (*E*)-alkenes. The resultant allylic phosphonates from these additions can be employed for the synthesis of 2-methylthio-substituted butadienes.

One-Pot Procedure for α-Methylthio β-Keto and Enamine Phosphonates.

α-Methylthio β-keto and enamine phosphonates are prepared from diethyl methylphosphonate by a one-pot procedure using a nitrile as an acyl cation equivalent, followed by treatment with $MeSSO_2Me$ as an electrophile (eq 5).[11]

MeSSMe does not undergo this transformation due to the low reactivity of the anion toward the electrophilic sulfur moiety; however, the reaction proceeds smoothly with PhSSPh, PhSCl, and PhSeBr. Interestingly, $PhSO_2Cl$ affords α-chloro substituted phosphonates but no α-sulfonylated products.

γ-Oxocrotonate Derivatives through Bis(methylsulfenylation).

An efficient sequence of reactions to transform an alkoxycarbonylmethyl group to γ-oxocrotonate via bis(methylsulfenylation) is described in a synthesis of brefeldin-A (eq 6).[12]

(6)

It is important that the methoxycarbonylmethyl group is treated twice with 1 equiv of ***Lithium Diisopropylamide*** and $MeSSO_2Me$ each to effect a one-pot bis(methylsulfenylation). Two equiv of both LDA and $MeSSO_2Me$ cannot be present at the outset of the reaction since destruction of the reagent(s) occurs faster than the introduction of the second

MeS group.[13] It is also noteworthy that a direct, one-step hydrolysis of the thioacetal group in the homologated ester to give ultimately the required γ-oxocrotonate is possible only with the dimethyl thioacetal but not with the diphenyl equivalent.[8]

Dithioacetal Formation.

Dithioacetals are prepared from activated methylene compounds with $MeSSO_2Me$ absorbed on ***Potassium Fluoride-Alumina*** (eq 7). Microwave irradiation without solvent provides a powerful activation for this preparation. MeSCl gives only poor yields and MeSSMe does not react under these conditions.[14]

(7)

$R^1 = CO_2Et$; $R^2 = CO_2Et$, CN, Ph, MeCO (70-94%)
$R^1 = CO_2Et$; $R^2 = PO(OEt)_2$ (21%)
$R^1 = PO(OEt)_2$; $R^2 = PO(OEt)_2$ (95%)

Stereoselective Methylsulfenylation of Enones and Alkenes.

An α-oxoketene dithioacetal containing two different alkylthio substituents was prepared stereoselectively from a β-alkylthio-α,β-enone via treatment with LDA and $MeSSO_2Me$ in THF-HMPA (eq 8).[15] Use of MeSCl in this reaction yields a 1:1 mixture of the stereoisomers, possibly due to isomerization of the double bond geometry by the chloride ion formed in the reaction (eq 9). The reaction of the α-oxoketene dithioacetal with organocuprate reagents proceeds stereospecifically (eq 10), in that the alkylthio substituent *syn* to the ketone carbonyl is replaced by the cuprate ligand in all cases studied.

(8)

(9)

(10)

1-(Methylthio)-substituted cyclopropenes are easily prepared by electrophilic substitution of the protected monolithiated 3,3-dimethylcyclopropenes. Upon heating or under photolysis, the substituted cyclopropenes rearrange to allenes via possible mechanisms described in eq 11. Both the substituted cyclopropenes and rearranged products provide an interesting combination of functionalities, which make them potentially useful building blocks in organic synthesis.[16]

Unsymmetrical Disulfides.

Unsymmetrical aryl and alkyl disulfides are prepared from silyl sulfides and $MeSSO_2Me$ in $CHCl_3$ at 60 °C.[17] Methyl 2- and 4-pyridyl disulfide are prepared conveniently from 2- and 4-thiopyridone and $MeSSO_2Me$ in the presence of NaOH in H_2O in excellent yields.[18]

Related Reagents.

Dimethyl Disulfide; ***Methylsulfenyl Trifluoromethanesulfonate***; ***Methyl p-Toluenethiosulfonate***.

Methyl 5-Methoxy-3-oxopentanoate

[62462-05-9] · $C_7H_{12}O_4$ · Methyl 5-Methoxy-3-oxopentanoate · (MW 160.19)

(precursor to the annulating agent, Nazarov's reagent;[1] can function as an annulating agent under acidic reaction conditions[2])

Physical Data: bp 75-76 °C/0.5 mmHg.

Analysis of Reagent Purity: IR, NMR.[3]

Preparative Methods: see below.

General Discussion.

Methyl 5-methoxy-3-oxopentanoate was first synthesized by Nazarov[1] and co-workers in 1953 utilizing the Hunsdiecker cleavage. Several modern methods have been reported for preparation of this compound. Heathcock[2] and co-workers based their synthesis of the ethyl 5-ethoxy analog on a reaction developed by Ireland.[4] The magnesium enolate of ethyl hydrogen malonate is reacted with β-ethoxypropionyl chloride followed by decarboxylation (eq 1). The title compound was also prepared in this manner.[5]

(1)

Trost[6] prepared methyl 5-phenylthio-3-oxopentanoate by alkylation of the dianion of methyl acetoacetate (eq 2). In this case, iodomethyl phenyl sulfide must be prepared from thioanisole and sulfuryl chloride. The resulting ***Chloromethyl Phenyl Sulfide*** is then treated with ***Sodium Iodide*** in acetone.

(2)

Methyl 5-methoxy-3-oxopentanoate has also been prepared using ***Chloromethyl Methyl Ether*** (R^2 = H) as the alkylating agent (eq 3).[7] Compounds with R^1 = R^2 = alkyl groups were reported also.

(3)

An alternative preparation of methyl 5-methoxy-3-oxopentanoate involves a Friedel-Crafts reaction,[3] as shown in eqs 4 and 5.

(4)

(5)

A novel Wittig-type reaction[8] has also been used to prepare 5-alkoxy-3-oxopentanoate esters (eq 6). The advantage here is the flexibility of the alkoxy and ester groups.

Methyl 5-methoxy-3-oxopentanoate has been used in two principal areas. The first is to prepare and isolate ***Methyl 3-Oxo-4-pentenoate*** (Nazarov's reagent),[2] a now well-known annulating agent. Methanol is eliminated under acidic conditions to give the Michael acceptor (eq 7). The methanol elimination is sometimes difficult and isolation of Nazarov's reagent can be problematic due to rapid polymerization.

In the 5-thiophenoxy compound (eq 2), elimination and isolation are reported to be facile processes (eq 8).[6]

Heathcock[2] circumvented the isolation difficulties of Nazarov's reagent by reaction of ethyl 5-ethoxy-3-oxopentanoate under acid catalysis in the presence of the nucleophile. Nazarov's reagent is generated in situ and the annulation occurs smoothly (eq 9). Several groups have utilized this method in synthesis.[5]

Related Reagents.

Methyl(methylene)oxonium Hexafluoroantimonate

$MeOCH_2^+SbF_6^-$

[41581-97-9] · $C_2H_5F_6OSb$ · Methyl(methylene)oxonium Hexafluoroantimonate · (MW 280.82)

(methoxymethylating agent; methylating agent; cationic polymerization initiator)

Preparative Methods: can be prepared either by treating ***Methoxyacetyl Chloride*** with anhydrous hexafluoroantimonic acid (see ***Hydrogen Fluoride-Antimony(V) Fluoride***) in SO_2, or by combining ***Chloromethyl Methyl Ether*** with the acid in methylene chloride.[1] In both cases, the pure $MeOCH_2^+SbF_6^-$ was obtained by washing the crude products with dry Freon 113.

Handling, Storage, and Precautions: is corrosive and moisture sensitive. It should be stored in a Teflon or Nalgene bottle under anhydrous conditions.

General Discussion.

The methyl(methylene)oxonium ion ($MeOCH_2^+$) is one of the few stable primary carbenium ions and has been a subject of many experimental and theoretical studies.[5-7] The experimental investigation of the carbenium ion has been carried out both in liquid[5] and gas phases.[6] The hexafluoroantimonate salt is a stable crystalline compound and is capable of electrophilic addition to carbon-carbon double bonds.[8] When methyl geranylate was combined with $MeOCH_2^+SbF_6^-$, cyclization occurred. Both epimers of the cyclization product were obtained in almost equal molar ratio (eq 1). However, when the substrate was changed to geranylacetone, one of the epimers was produced as a predominant product (eq 2). The low stereoselectivity in the case of methyl geranylate at the epimeric site is due to the decreased electron density of the α,β-unsaturated methyl carboxylic ester double bond in the molecule.

(1)

(2)

Due to the ambident nature of methyl(methylene)oxonium ion, $MeOCH_2^+SbF_6^-$ is also capable of methylation of nucleophiles through displacement of formaldehyde. This was shown in the reaction of $MeOCH_2^+SbF_6^-$ with benzene (eq 3).[1] Toluene was obtained in high yield in the reaction.

(3)

It was reported that $MeOCH_2^+SbF_6^-$ can also initiate cationic polymerization.[9]

Methoxycarbenium salts with other counterions such as ClO_4^-,[2] BF_4^-,[3] and $SbCl_6^-$ [4] are also known and have been used in organic synthesis.

Related Reagents.

Chloromethyl Methyl Ether.

Methyl *O*-Methyllactate[1]

[17639-76-8] · $C_5H_{10}O_3$ · Methyl *O*-Methyllactate · (MW 118.15)

(lithium enolate used in the stereoselective synthesis of 2-methoxy-3-hydroxypropionate derivatives[3])

Physical Data: bp 130-131 °C.

Preparative Methods: by esterification of the known *O*-methyllactic acid.[2,3a]

The (*Z*)-lithium enolate (**2**), derived from reaction of methyl *O*-methyllactate (**1**) with ***Lithium Diisopropylamide***, reacts with aldehydes to form (**3**) (*l* isomer) in preference to (**4**) (*u* isomer) (eq 1).[3] The stereoselectivity is approximately 3:1 in reactions with straight-chain and aromatic aldehydes. Stereospecificity is achieved in reactions with aldehydes with branching at the α-carbon. Other ethers (e.g. benzyl or MEM) derived from methyl lactate exhibit the same trend in stereoselectivity, although the magnitude is lower.[3] Stereoselectivity in favor of compounds of *u* relative stereochemistry, illustrated in (**4**), is obtained in reactions using the benzyl ether derivative of a hindered ester (e.g. **5**).[3] The stereoselectivity in aldol reactions of (**2**) has been used to set the relative stereochemistry at C-3 and C-4 in a synthesis of L-cladinose (**6**).[4]

Methyl 2-Methylthioacrylate

[43228-10-0] · $C_5H_8O_2S$ · Methyl 2-Methylthioacrylate · (MW 132.20)

(versatile and reactive Michael acceptor[2-5])

Physical Data: bp 78 °C/12 mmHg.

Solubility: sol Et_2O, THF, EtOH, and most organic solvents.

Analysis of Reagent Purity: IR, NMR, GLC.

Preparative Methods: prepared either by the reaction of methyl 2-chloroacrylate[1a] or methyl 2-bromoacrylate[1b] with ***Methanethiol*** in the presence of ***Triethylamine*** and ***N,N-Dimethylformamide***. It is also obtained[1c] quantitatively by chlorination of methyl 2-alkylthiopropionates (alkyl = Me/Et) with ***Sulfuryl Chloride*** at 0 °C followed by dehydrochlorination using refluxing chloroform. For preparation of alkyl 2-alkylsulfonylacrylates and its uses, see Gipstein.[8]

Handling, Storage, and Precautions: since the reagent is an acrylate, it should be stored under N_2 in the refrigerator and should be inhibited with ionol or 100 ppm of hydroquinone monomethyl ether. Use in a fume hood.

1,4-Dicarbonyl Compounds.

Lithium enolates derived from esters,[2a] lactones,[2a] and thioacetal monosulfoxide[2b] undergo smooth Michael addition in high yield. These adducts on hydrolysis give the corresponding carbonyl analogs (eqs 1-3). Enamines[2a] give high yields of Michael adducts (eq 4).

Synthesis of (±)-Vincamine.[3]

The lithium enolate of a lactam undergoes Michael addition to methyl 2-methylthioacrylate at -78 °C, furnishing 98%

yield of the adduct (eq 5) which was later converted to (±)-vincamine alkaloid. A similar Michael addition was used in the synthesis of α-kainic acid (eq 6).[4]

Diels-Alder Substrate.

The reagent undergoes a facile, ***Aluminum Chloride***-catalyzed Diels-Alder[5a] reaction with ***Isoprene***, ***Cyclopentadiene***, and cyclohexadiene and gives [4 + 2] addition products (eqs 7 and 8). If the reaction is carried out under thermal

conditions, mixtures of *endo* and *exo* adducts are formed. These adducts are converted to ketones using ***N-Chlorosuccinimide***/*t*-butanol.

(7)

(8)

This further demonstrates that methyl 2-methylthioacrylate can be regarded as a ketene[5b] equivalent. With electron-poor dienes such as 3-aryl-1,2,4,5-tetrazine,[6] it gives regioselectively only one of two possible [4 + 2] cycloadducts (eq 9).

(9)

Use of this reagent in the acid-catalyzed ene reaction[7] does not give any ene product; instead, it rearranges to *trans*-β-(methylthio)acrylate (eq 10).

(10)

Related Reagents.

Methyl 2-Trimethylsilylacrylate; ***Trimethyl 2-Phosphonoacrylate***.

N-Methylmorpholine *N*-Oxide[1]

[7529-22-8] · $C_5H_{11}NO_2$ · *N*-Methylmorpholine *N*-Oxide · (MW 117.17)

(used as a co-oxidant with OsO_4[2] and ruthenates;[3] acts a mild oxidizing agent[4])

Alternate Name: NMO.

Physical Data: mp 75-76 °C (as monohydrate)

Solubility: sol water, acetone, alcohol, ether.

Form Supplied in: colorless deliquescent crystals; available commercially.

Purification: crystallize from ethanol.

Handling, Storage, and Precautions: refrigerate; hygroscopic; irritant; handle in a fume hood using gloves; avoid skin contact and inhalation; in case of contact, rinse immediately with water.

Co-oxidation Reagent.

N-Methylmorpholine *N*-oxide is commonly used as a mild co-oxidant. The stoichiometric use of ***Osmium Tetroxide*** to *cis*-dihydroxylate alkenes is avoided by using NMO as a reoxidant (eq 1).[1,2,5] This reagent is preferred over other *cis*-dihydroxylation reagents such as ***Potassium Permanganate***, ***Iodine-Silver Acetate***, or ***Osmium Tetroxide*** in the presence of barium perchlorate or ***Hydrogen Peroxide***, since these reagents give poor yields, require cumbersome workups, or are prohibitively expensive for large-scale glycolization reactions.[2,5] See also ***Osmium Tetroxide-N-Methylmorpholine N-Oxide***.

(1)

Oxidation of allylic alcohols using NMO/OsO_4 occurs with high stereoselectivity. The relative stereochemistry of the incoming hydroxy group is *erythro* to the hydroxy, alkoxy, or methyl group in the allylic position of the product (eq 2).[6] Similar results are obtained using this procedure to oxidize higher-carbon sugars containing allylic alcohols.[7]

(2)

Asymmetric dihydroxylation is accomplished by using NMO in the presence of OsO_4 and dihydroquinidine *p*-chlorobenzoate (eq 3).[8] This procedure works well for a variety of alkenes but gives the best results for those alkenes with aromatic directing groups. The method is insensitive to scale, moisture, and can be run with very low concentrations of OsO_4.

A kinetic study using ***Trimethylamine N-Oxide*** in place of NMO as a reoxidant has been reported.[9] Crystallographic analysis of an isolated intermediate using NMO (eq 4) has provided mechanistic evidence for osmate ester intermediates in tertiary amine *N*-oxide oxidation systems.[1,10]

(4)

Intermediate *cis*-diols generated by NMO/OsO_4 oxidation can be cleaved to give the corresponding dialdehydes by periodate oxidation (eq 5).[11]

(5)

α-Hydroxyaldehydes and their tautomeric hydroxymethyl ketones can be conveniently prepared using NMO/OsO_4 or $KMnO_4$ to *cis*-hydroxylate enol phosphonates (eq 6).[12] The oxidation step is accomplished in high yields and the

overall synthesis requires only three steps from a ketone.

The NMO/OsO_4 oxidation system efficiently oxidizes terminal alkenes. However, this reagent may be replaced in some cases by ***Potassium Ferricyanide***/OsO_4 to give comparable yields of the corresponding 1,2-diol (eq 7).[13]

Besides OsO_4, other oxidants can be used catalytically in the presence of NMO. For example, epoxides are left intact when oxidizing a primary alcohol with NMO in the presence of catalytic ***Tetra-n-propylammonium Perruthenate*** (TPAP) (eq 8) and when oxidizing a secondary alcohol using catalytic tetra-*n*-butylammonium perruthenate (TBAP) (eq 9).[3] This reagent will also oxidize 1,4- and 1,5-primary/secondary diols to lactones.[14]

(9)

NMO along with a catalytic amount of $RuCl_2(PPh_3)_3$ will oxidize alcohols to aldehydes and ketones; $RuCl_2(PPh_3)_3$/NMO efficiently oxidizes (+)-carveol to (+)-carvone in 94% yield at rt after 2 h.[15] This reagent system will also oxidize sulfides and phosphines to their respective oxides.[16]

Mild Oxidant.

Activated halides can efficiently be converted to aldehydes or ketones under mild conditions using NMO. For example, cinnamyl bromide is converted to cinnamaldehyde by stirring the activated halide with NMO in acetonitrile.[4] This reagent will oxidize a halide in the presence of a double bond (eq 10).

(10)

NMO can also be used as a reoxidant in the Pauson-Khand reaction for the synthesis of cyclopentenones.[17] This reaction typically is run at elevated temperatures (60-110 °C) or with ultrasound at 45 °C. Milder conditions are used with NMO, thus allowing for higher stereoselectivity in cycloadditions involving dicobalt hexacarbonyl complexes of alkynes (eq 11).

Conditions	Yield (%)	Stereoselectivity
NMO, CH_2Cl_2, rt	68	11:1
MeCN, 82 °C	75	4:1
MeCN,))))), 45 °C	45	3:1

Peptide synthesis can be performed using NMO as a mild oxidizing agent in the presence of the peptide hydrochloride, ***Diphenyl Diselenide*** and ***Tri-n-butylphosphine*** at 60 °C.[18] The phosphine and selenide act as a reductant and oxidant respectively. NMO inhibits the formation of byproducts by oxidizing selenophenol produced in the reaction mixture (eq 12) (see also ***Trimethylamine N-Oxide***).

Methyl 3-Nitroacrylate

[4749-37-5] · $C_4H_5NO_4$ · Methyl 3-Nitroacrylate · (MW 131.10) (*E*)

[52745-92-3] (*E*)-ethyl ester

[5941-50-4] · $C_5H_7NO_4$ · Ethyl 3-Nitroacrylate · (MW 145.13)

(Diels-Alder dienophile;[4] Michael acceptor[13])

Physical Data: bp 73 °C/10 mmHg; mp 38 °C.[1]

Preparative Methods: by reaction of ***Methyl Acrylate*** with either nitryl chloride[1] or N_2O_4/iodine (see ***Nitrogen Dioxide*** and ***Iodine***),[2] followed by elimination with sodium acetate (eq 1). An *Organic Synthesis* preparation of the corresponding ethyl ester using N_2O_4/iodine has been reported.[3]

Purification: can be crystallized from methanol-water or vacuum distilled.[1] However, significant losses were reported on vacuum distillation of the ethyl ester, which was best crystallized from pentane at -15 to 0 °C.[3]

Handling, Storage, and Precautions: lachrymatory solid; best stored in a refrigerator.

Diels-Alder Reactions.

Methyl 3-nitroacrylate is a very electron-deficient and highly reactive dienophile with electron-rich or unactivated dienes in Diels-Alder reactions (e.g. eq 2).[4-7] The nitro group is readily eliminated from the adducts, making the reagent a useful ***Methyl Propiolate*** equivalent for Diels-Alder reactions (eq 3).[4]

(2)

2:1 mixture of isomers

(3)

A most useful aspect of these reactions is that the nitro group controls the regioselectivity. Thus the regioselectivity after elimination is reversed from that preferred in reactions of methyl propiolate, affording *meta* disubstituted final products instead of the usual *ortho*/*para* (eq 4).[5] This regioselectivity has been used to advantage in the Diels-Alder-based synthesis of isogabaculine.[8]

(4)

The Diels-Alder adducts can also be reduced to the amine, as in an approach to the synthesis of gelsemine (eq 5).[9] The adduct with furan (eq 2) has seen particular use in synthesis of various *C*-nucleosides[4,10] and (+)-compactin.[11]

(5)

43% + 39% *exo*

Very low *endo* stereoselectivity has generally been observed in the reactions of methyl 3-nitroacrylate. The high regioselectivity of the Diels-Alder reactions does not also necessarily apply to 1,3-dipolar cycloadditions; reactions with nitrones afforded all four possible adducts with very low selectivity.[12]

Michael Additions.

Methyl nitroacrylate is also a powerful Michael acceptor. The nitro group dictates the regiochemistry of the addition of nucleophiles. This allows the equivalent of Michael additions α in methyl propiolate. McMurry takes advantage of this in his α-methylenelactone synthesis (eq 6).[13]

Methyl 4-Nitrobutanoate[1]

(**1**; X = OMe)

[13013-02-0] · $C_5H_9NO_4$ · Methyl 4-Nitrobutanoate · (MW 147.15) (**2**; X = OH)

[16488-43-0] · $C_4H_7NO_4$ · 4-Nitrobutanoic Acid · (MW 133.12) (**3**; X = OEt)

[2832-16-8] · $C_6H_{11}NO_4$ · Ethyl 4-Nitrobutanoate · (MW 161.18) (**4**; X = Cl)

[75938-95-3] · $C_4H_6ClNO_3$ · 4-Nitrobutanoyl Chloride · (MW 151.56)

(bifunctional C_4 synthetic building blocks with d^4 reactivity; preparation of functionalized carbo-[2,3] and heterocyclic[4] compounds; undergoes nitroaldol,[5] Michael addition, and ketone acylation reactions[6]; the α-NO_2 position has also been acylated;[7] the mononitrile oxide can be trapped by alkene and alkyne groups to give isoxazoline and isoxazole derivatives[8,9])

Physical Data: (**1**) bp 106-110 °C/9 mmHg. (**2**) bp 120 °C/0.04 mmHg. (**3**) bp 97-98 °C/1 mmHg. (**4**) bp 70 °C/0.03 mmHg.

Solubility: sol most common organic solvents.

Form Supplied in: the methyl ester (**1**) is commercially available.

Preparative Methods: the esters (**1**) and (**3**) are prepared by Michael addition of ***Nitromethane*** to the corresponding acrylates[10] (higher primary and secondary nitroalkanes can be added likewise); (**2**) is obtained by acid-catalyzed hydrolysis of the ester; the acid chloride (**4**) is prepared from the acid (**2**) and ***Thionyl Chloride***.[6]

Handling, Storage, and Precautions: as for the 3-nitropropanoic acid derivatives (see ***Methyl 3-Nitropropanoate***).

Ring Forming Reactions of 4-Nitrobutanoic Acid Derivatives.

The nucleophilic reactivity of the α-NO_2 position in the esters (**1**) and (**3**) or the electrophilicity of the acid chloride carbonyl group in (**4**) may be used to form the first bond of a new ring. In the second step, an intramolecular acylation or Henry reaction leads to ring formation.

Thus a Mannich-type variation of the nitroaldol addition of (**3**) to aromatic aldehydes produces a *trans*-substituted aryl-nitro-valerolactam, the nitro group of which can be reduced to give the lactam (**5**), a 4,5-diamino acid derivative (eq 1).[4]

(1)

Michael addition of the ethyl ester (**3**) to enones to afford (**6**) and Dieckmann condensation produces nitro diketones (**7**) with a bicyclo[4.3.0]nonane, -[4.4.0]decane, or -[5.4.0]undecane skeleton in ca. 20% overall yield (eq 2).[3]

(2)

Ketone lithium enolate acylation with the acid chloride (**4**) under conditions as specified in the article ***Methyl 3-Nitropropanoate*** furnishes 6-nitro 1,3-diketones (**8**), as demonstrated with numerous examples (yields 40-85%).[6,11] Those products of type (**8**) containing no ring or a six- or a twelve-membered ring, but not the cyclopentanone, -heptanone, and -octanone derivatives, undergo cyclization ($NaHCO_3$)/THF/H_2O) to give hydroxy-nitro ketones such as (**9**) and (**10**).[2] The 8-methyl-substituted decalin (**9**), isolated as a single diastereoisomer in 50% yield, reacts with ***Methyltitanium Triisopropoxide*** to give the nitrodiol (**11**) containing five stereogenic

centers also as a single diastereoisomer.[12,13] Acetalization and ***Raney Nickel*** catalyzed hydrogenation of the nitro group of (**9**) (R = H) lead to the amino alcohol (**12**) (77% overall), the oxalate salt of which undergoes Tieffeneau-Demjanov rearrangement upon treatment with $NaNO_2/H_2O$; after acetal cleavage, the *trans*-fused bicyclic diketone (**13**) is isolated in 80% yield.

(8)

(9)

(10)

(11)

(12)

(13)

The 1,2-, 1,4-, and 1,6-distances between functional groups in the products (**5**)-(**13**) show that 4-nitrobutanoic acid is a reagent with reactivity umpolung (d^1),[14] which is itself prepared by a reaction involving reactivity umpolung (d^1 reactivity when nitromethane is added to acrylate).

1-Methyl-3-nitro-1-nitrosoguanidine

[70-25-7] · $C_2H_5N_5O_3$ · 1-Methyl-3-nitro-1-nitrosoguanidine · (MW 147.12)

(precursor to diazomethane[1])

Alternate Names: MNNG; *N*-methyl-*N´*-nitro-*N*-nitrosoguanidine.

Physical Data: mp 118 °C (dec).

Solubility: sol alcohol, chloroform, acetone.

Form Supplied in: orange-yellow powder; commercially available.

Handling, Storage, and Precautions: shelf life of several years (somewhat longer than that of ***N-Methyl-N-nitroso-p-toluenesulfonamide***); store in brown bottle, refrigerated; severe irritant, carcinogen, potent mutagen;[2] contact may lead to sensitization, so contact by all routes must be avoided; handle in a fume hood.

General Discussion.

This reagent reacts to generate ***Diazomethane*** upon treatment with aqueous sodium hydroxide at rt. For the generation of small quantities of diazomethane (e.g. less than 1 mmol), this compound is probably the reagent of choice. A convenient apparatus (Figure 1) has been reported by Fales et al;[3,4] the following procedure is representative.

1 mmol (133 mg) of the reagent is placed in the inside tube through its screw-cap opening along with 0.5 mL of water to dissipate any heat generated. 3 mL of ether is placed in the outside tube and the two parts

are assembled with a butyl O-ring and held with a pinch-type clamp. The lower part is immersed in an ice bath and about 0.6 mL of 5 N sodium hydroxide is injected through the silicone rubber septum via a syringe with a narrow-gauge (No. 22) needle to prevent leakage around the shank.[1,3] Diazomethane is collected in ether.

The alkali injection must be dropwise and very slow to control the volume of gas produced. At least 45 min are required for acceptable yields (over 50%). Solvents other than ether can be used for the collection of diazomethane. It is generally desirable to dissolve the substrate for reaction with diazomethane in the solvent in the outer tube prior to the generation, so that the reagent is consumed as it is produced.

Methyl 3-Nitropropanoate[1]

(**1**; X = OMe)

[20497-95-4] · $C_4H_7NO_4$ · Methyl 3-Nitropropanoate · (MW 133.12) (**2**; X = OH)

[504-88-1] · $C_3H_5NO_4$ · 3-Nitropropanoic Acid · (MW 119.09) (**3**; X = OEt)

[3590-37-2] · $C_5H_9NO_4$ · Ethyl 3-Nitropropanoate · (MW 147.15) (**4**; X = Cl)

[51834-15-2] · $C_3H_4ClNO_3$ · 3-Nitropropanoyl Chloride · (MW 137.53)

(nitroaldol additions,[2,3] condensation[4] reactions, and Michael additions[5] involving the NO_2-substituted carbon; the α-carbonyl carbon in dilithionitronate enolates of the esters undergoes alkylations,[6-9] double alkylations,[6,8] and aldol[6,8] and Michael additions;[6,8] elimination of HNO_2 from the products gives α,β-unsaturated esters with substituents in either the β-[2,3a,5b] or the α-position,[8,9] thus making the reagent a synthetic equivalent of acrylate anions with d^3 or d^2 reactivity;[8,10] precursor to nitrile oxide for [3 + 2] cycloadditions;[11] 3-nitropropanoyl chloride can be used for enolate acylation[12-15] and five-membered ring annulation[14])

Physical Data: (**1**) bp 63 °C/0.5 mmHg. (**2**) mp 65-68 °C. (**3**) bp 146 °C/760 mmHg. (**4**) bp 123 °C/10 mmHg.

Solubility: sol most organic solvents.

Preparative Methods: the acid (**2**) and its esters (**1**) and (**3**) are prepared from the corresponding 3-halopropanoic acid derivatives with nitrite. (**2**) is a commercial product and can be esterified[8] and converted to the acid chloride (**4**)[15,18] and anhydride[15] by conventional methods.

Handling, Storage, and Precautions: the acid (**2**) is a natural, toxic metabolite of aspartic acid in plants[16] and in fungi.[17] The nitropropanoic acid derivatives should be handled with caution, as should all nitro compounds of low molecular weight. They are stable when stored in dark bottles in a refrigerator. Acid chloride (**4**) should be stored with exclusion of air and moisture.

Reactions of the Esters (1) and (3) at C-3.

Although the 3-nitropropanoate esters readily undergo HNO_2 elimination to acrylates, it is possible to carry out typical nitronate transformations such as the Henry reaction and the Michael addition to enones. The resulting chain-elongated β-nitro esters (**5**) can then be subjected to β-elimination, so that the carbon skeleton of the compound introduced as an electrophile has been elongated by a β-acrylate unit (eq 1).

Alternatively, the original adducts can be converted without loss of the nitrogen functionality; for example, reduction of NO_2 to NH_2 leads to β-amino acid derivatives. Thus, nitropropanoate esters (**1**) and (**3**) have been used for the synthesis of amino sugars, e.g. (**6**),[3b,3c] of macrolides such as brefeldin,[2b] of macrodiolides such as pyrenophorin via the intermediate (**7**),[2a] and of bicyclo[3.3.0]octane-2,8-dione (**9**) (by Michael addition of (**3**) with cyclopentenone, HNO_2 elimination to (**8**), hydrogenation, and Dieckmann condensation) (eq 2).[5b]

Reactions of the Esters (1) and (3) at C-2.

Double deprotonation of 3-nitropropanoate esters to nitronate enolates (**10**) enables alkylation (by alkyl halides and enones) and hydroxyalkylation (by aldehydes and ketones) at the 2-position, to give α-substituted acrylates (**11**) (eq 3).[8,9]

The reaction with alkyl iodides and bromides to give monoalkylated products (**12**) is so efficient that an in situ double alkylation is possible; for instance, a 71% yield of (**13**) (R^1 = Me, R^2 = Bn) is obtained.[8] Addition to aldehydes to give (**14**) (R^2 = H) gives better yields (50-85%) than addition to ketones (<30%). The products (**15**) and (**16**) of HNO_2 elimination are formed in high yields when Eiter bases[19] are employed. The overall yield for the preparation of (**15**) (R = $CH_2CH{=}CH_2$) from methyl 3-nitropropanoate (**1**) and allyl bromide is 64%, and that for the preparation of the hydroxy methylene ester (**16**) (R = C_5H_{11}) from (**1**) and hexanal is 71%.

(12)

(13)

(14)

(15)

(16)

Lithium Enolate Acylation and Five-Membered Ring Annulation.

Direct 1:1 acylation of amine-free solutions of ketone lithium enolates by addition to a 3-nitropropanoyl chloride (**4**) solution in THF (both cooled to temperatures between -78 and -100 °C) gives 5-nitro 1,3-diketones (**17**) in yields of 40-

80% (eq 4). The enolates may be derived from open-chain ketones such as diethyl ketone, or from cyclic ketones with, for instance, six-, seven-, eight-, and twelve-membered rings.[12-15]

(4)

Meerwein acylation of ketones with the anhydride of 3-nitropropanoic acid/BF_3 is also feasible.[15,20] The products of type (**17**) undergo nitroaldol cyclization with formation of a hydroxynitrocyclopentanone ring which, depending upon the particular structure and upon the conditions used, may lose HNO_2 to give a hydroxycyclopentenone derivative. Examples are the annulation products (**18**) (mp 155-156 °C) and (**19**) (mp 68-70 °C) of cyclododecanone and cycloheptanone. The hydroxy enone with a tertiary hydroxy group may rearrange to the isomer with a secondary hydroxy group, e.g. (**20**) obtained from cyclohexanone. Pure products (as single diastereoisomers, where applicable) can be isolated in yields of 15-90%.[14]

(alkylating agent;[2] source of diazomethane;[3] useful as activated acylating agent;[4] precursor to esters and alkenes[1a,5,6])

Physical Data: (**1**) bp 115-116 °C/760 mmHg. (**2**) bp 59-60 °C/14 mmHg. (**3**) bp 35-37 °C/0.1 mmHg. (**4**) bp 63-65 °C/6 mmHg.

Solubility: sol benzene, Et_2O, $CHCl_3$, acetone.

Preparative Methods: nitrosation of *N*-alkyl amides with ***Sodium Nitrite***/acid mixtures, ***Nitrosyl Chloride***, or ***Nitrogen Dioxide***.[10] *N*-Deprotonation of the amide with ***n-Butyllithium*** or ***Sodium Hydride***, followed by treatment with nitrosonium salts[11] or ***Nitrogen Dioxide***,[12] is a second approach that is particularly useful in the preparation of thermally labile nitrosoamides.

Handling, Storage, and Precautions: the stability of *N*-nitrosoamides is dependent largely on steric factors.[1a,7] For *N*-nitrosoacetamides, RN(NO)COMe, compounds with a primary *N*-alkyl group are stable for weeks at 25 °C if kept dry; decomposition occurs at approx 75 °C. Compounds with secondary *N*-alkyl groups decompose at 25 °C ($t_{1/2}$ about 0.5 h). Compounds with tertiary alkyl groups must be synthesized and utilized at low temperatures. Alkyl substitution on the acyl group leads to increases in decomposition rates similar to those for the alkyl group. *N*-Nitrosoamides are decomposed by acids and bases. Nitrosoamides bearing small alkyl groups possess potent mutagenic[8] and carcinogenic[9] (local and systemic) activity. Use in a fume hood and take reasonable precautions.

Alkylation Reactions.

N-Alkyl-*N*-nitrosoamides (**1**) are thermolabile compounds which undergo first-order decay[7] to yield, via diazotate esters (**5**), diazonium carboxylate ion pairs (**6**) as reaction intermediates (eq 1).[13] If the alkyl group is allylic, secondary, or tertiary, highly active nitrogen-separated ion pairs (**7**) are formed;[13a] the carbocations can subsequently undergo the usual types of reactions: nucleophilic capture by solvent or counterion, proton elimination, and skeletal rearrangement (eq 2).

Analogs of the nitrosoamides are known, and the counterions can be derived from a range of acids (carboxylic,

carbonic, carbamic, sulfonic, etc.). In nonreactive solvents, ion pair combination to give the corresponding ester can be the major reaction (eq 2); the esters are usually formed with retention of configuration. Further, a nitrosoamide labeled in the carbonyl group with ^{18}O decomposes to yield ester with a preponderance of ^{18}O in the carbonyl group.[13a] If the solvent (and the carbocation) are sufficiently reactive, solvent capture becomes the major reaction.[2b,13a] For example, the decomposition of *N*-benzyl-*N*-nitrosotrifluoromethanesulfonamide (**8**) in benzene ($t_{1/2}$ &AApprox; 10-20 min) at 30 °C yields ~60% diphenylmethane,[2b] and decomposition in acetonitrile yields the nitrilium salt.[2b] The nitrosoamide decomposition, thus, can produce a series of alkylating agents of differing activity: carbocations, nitrilium salts (and related products from relatively unreactive solvents), and alkyl sulfonate esters. The nitrosoamide decomposition is a method for the production of highly reactive alkylating agents under mild conditions in nonpolar solvents and in the absence of electrophilic agents;[2b] it lends itself especially to transformations of isotopically labeled amines and chiral amines.

(8)

Acylation Reactions.

N-Nitrosation of amides markedly activates the amide group to cleavage by nucleophiles. For example, thiolate ions react at rt with nitrosoamides to afford *S*-alkyl and *S*-aryl thioesters in good yields (eq 3);[3a] byproducts arising from *N*- to *S*-*trans*-nitrosations are rarely formed.[3a]

(3)

Amides of general formula R^1CONHR^1 can be nitrosated and the resulting nitrosoamides converted into R^1CONH_2, R^1CONHR^2, or $R^1CONR^2R^3$ by reaction with ammonia or an amine.[14] The overall two-step reaction is almost quantitative.[14] By this approach, *N*-alkyl amides are formed without the competitive *O*- and *C*-alkylations that may occur in the direct alkylation of amides. Analogous reactions with aromatic amines are less successful.[14] In another application, racemic carboxylic acids have been converted into diastereomeric amides; separation of the diastereomers by chromatography and subsequent deamination via the nitrosoamide route, followed by ester hydrolysis, affords essentially the pure chiral carboxylic acids.[15]

N-Nitrosoamides react with alkoxide-alcohol mixtures to yield diazoalkanes corresponding to the amine moiety of the amide (eq 4).[24] This approach is widely used to synthesize this very useful class of alkylating agents (see ***Diazomethane***).

(4)

Acylation and Alkylation Reactions.

The generation of highly reactive carbocations from *N*-nitrosoamides lends itself to the active-site mapping and inhibition of enzymes.[4b,c] In these studies, R^1 and R^2 are recognized by the binding site of the enzyme, and the carbocation formed alkylates nucleophilic centers in the active site such as amide linkages and amino acid side chains.[4b]

Miscellaneous Reactions.

The acyl groups of nitrosoamides are readily reduced to primary alcohols (50-82% yields) by ***Sodium Borohydride*** at 25 °C.[16] Reduction to the corresponding hydrazide is achieved with ***Zinc-Acetic Acid*** (~80%)[17] and ***Titanium(IV) Chloride/Magnesium*** (~60%).[16] In nonpolar solvents at 80-100 °C, nitrosoamides decompose in the presence of rhodium(II) carboxylates (see ***Dirhodium(II) Tetraacetate***) to yield, ultimately, the corresponding alkene (eq 5).[6]

(5)

Photolysis of nitrosoamides results in initial scission of the N-N bond followed by hydrogen abstraction from the solvent by the amido radical. In the final step the nitric oxide generated in the first step reacts with the new carbon radical to yield ketones from alcohols,[18] and oximes, nitrosoalkane dimers, and nitrite esters from hydrocarbons.[19]

Related Alkylating Agents.

A number of alkylating agents utilizing deaminatively formed carbocations are available. Compounds with replaceable protons are alkylated by *syn*- and *anti*-alkanediazotate salts,[20] and by *N*-alkyl-*N*-nitrososulfamates.[21] Conditions can be found for alkylation by *N*-alkyl-*N*-nitro-*O*-acylhydroxylamines[22] and the corresponding *N*-nitroso analogs.[13a,23] These methods are mechanistically related to alkylations with diazoalkanes (see ***Diazomethane***) or with 3-alkyl-1-*p*-tolyltriazenes (see ***3-Methyl-1-p-tolyltriazene***).

The thermal decomposition of *N-nitro*amides in nonreactive solvents yields the same ester/alkene products as are formed from the corresponding *N-nitroso*amides via analogous intermediates. The nitroamides are, like their nitroso analogs, good acylating agents of nucleophiles.[14]

N-[*N´*-Methyl-*N´*-nitroso(aminomethyl)]benzamide

[59665-02-0] · $C_9H_{11}N_3O_2$ · *N*-[*N´*-Methyl-*N´*-nitroso(aminomethyl)]benzamide · (MW 193.23)

(precursor of diazomethane[1])

Alternate Name: N-[(methylnitrosoamino)methyl]benzamide.

Physical Data: mp 128-131 °C.

Solubility: sol acetone, ethanol, dioxane, chloroform; slightly sol ether; insol water, petroleum ether.

Form Supplied in: crystalline solid; commercially available.

Preparative Method: by nitrosation of *N*-[(methylamino)methyl]benzamide hydrochloride, which is itself obtained from methylamine hydrochloride, formaldehyde, and benzamide.[2]

Handling, Storage, and Precautions: stable at rt for many years. Storage in a brown bottle is recommended. Although the mutagenicity of this reagent has not been reported, like all nitroso compounds it should be treated as a highly toxic substance. All handling should be conducted in an efficient fume hood.

General Discussion.

This reagent was introduced[1] in 1976 as a new type of ***Diazomethane*** precursor which may be regarded as a modified Mannich base. It liberates diazomethane in the presence of alkali hydroxide, presumably through β-elimination to form *N,N´*-methylenebisbenzamide and formaldehyde (eq 1).

(1)

The generation of diazomethane with this reagent proceeds similarly to that of ***N-Methyl-N-nitroso-p-toluenesulfonamide***, and the procedure can be performed by the use of the same apparatus. The following improved procedure is recommended over that originally described. In a flask are placed a solution of 3 g of potassium hydroxide in 4 mL of water, 5 mL of 2-(2-methoxyethoxy)ethanol, and 10 mL of ether, and a condenser is connected to two receiving flasks in series, both cooled in ice-salt baths. The second receiver contains 10 mL of ether and an inlet tube which dips below the surface of the solvent. The mixture is heated in a water bath at about 70 °C with magnetic stirring, and a solution of 5.8 g (0.03 mol) of *N*-[(methylnitrosoamino)methyl]benzamide in 40 mL of 2-(2-methoxyethoxy)ethanol diluted with 40 ml of ether is added from a dropping funnel over about 20 min. The dropping funnel is rinsed with 30-50 mL of additional ether. The distillation is continued until the distilling ether is colorless. The combined distillate contains 0.77-0.82 g (61-65%) of diazomethane.

A drawback of this reagent is that its poor solubility in ether requires the use of a mixed solvent system of 2-(2-methoxyethoxy)ethanol and ether as described above. In place of 2-(2-methoxyethoxy)ethanol, 2-methoxyethanol (bp 125 °C) (in which the reagent is somewhat more soluble) can be also used. An analog possessing high solubility in ether has been reported: isopropyl *N*-[(methylnitrosoamino)methyl]carbamate,[4] *i*-PrOCONHCH$_2$N(NO)Me. However, this reagent has been reported to exhibit significant mutagenicity.[3]

N-Methyl-*N*-nitroso-*p*-toluenesulfonamide

[80-11-5] · $C_8H_{10}N_2O_3S$ · *N*-Methyl-*N*-nitroso-*p*-toluenesulfonamide · (MW 214.27)

(precursor of diazomethane[1a])

Alternate Names: Diazald; *p*-tolylsulfonylmethylnitrosamide.

Physical Data: mp 61-62 °C.

Solubility: sol petroleum ether, ether, benzene, alcohol, $CHCl_3$, CCl_4; insol H_2O.

Form Supplied in: pale yellow powder; commercially available.

Preparative Methods: prepared by the reaction of ***p-Toluenesulfonyl Chloride*** with methylamine, followed by nitrosation with ***Sodium Nitrite*** in glacial acetic acid.[1c]

Purification: recrystallization is best achieved by dissolving the reagent in hot ether (1 mL g^{-1}), adding an equal volume of petroleum ether (or pentane), and cooling in a refrigerator overnight.[1c]

Handling, Storage, and Precautions: store in a brown bottle. Has a shelf-life of at least 1 year at rt. For longer periods of storage, it is recommended that the reagent be purified by recrystallization[1c] and refrigerated. Toxic; severe skin irritant; handle only in a fume hood.

General Discussion.

Diazomethane is a yellow gas (bp -23 °C, mp -145 °C) with the dipole structure $CH_2=N^+=N^-$ ⇂ $^+CH_2-N=N^-$ ⇂ $^-CH_2-N=N^+$. This versatile compound behaves as a methylene precursor with release of nitrogen and also functions as a 1,3-dipole in a variety of reactions, as documented in several reviews.[2] Diazomethane itself is both highly toxic and unpredictably explosive, and has been suggested to be a carcinogen.[3] Great care must be taken in handling this substance. However, these risks are minimal when diazomethane is prepared and handled as a dilute solution in an inert solvent such as ether using the proper equipment as discussed below (for further discussion, see

Diazomethane). A large number of compounds which previously served as diazomethane precursors can be represented by the formula RN(NO)Me, where R can be sulfonyl, carbonyl, imidoyl, or similar electron-withdrawing groups. Among these the reagent, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide, introduced by de Boer and Backer in 1954,[1a] is the most common reagent used for the preparation of diazomethane. However, in some cases ***N-[N´-Methyl-N´-nitroso(aminomethyl)]benzamide*** and ***1-Methyl-3-nitro-1-nitrosoguanidine*** have advantages as diazomethane precursors. In addition, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide does suffer from some drawbacks, including its relatively short shelf life (1-2 years) and its mutagenic activity.[4]

Diazomethane is prepared as a dilute solution in ether by the decomposition (eq 1) of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide catalyzed by alkali hydroxide.

This preparation and all reactions involving diazomethane should be carried out in an efficient fume hood and behind a sturdy safety shield. Rough surfaces and strong sunlight are known to initiate detonation. Carefully fire-polished glassware for diazomethane preparation is commercially available.[5] A typical experimental procedure is as follows.[1b] A 125 mL, 3-neck flask is charged with a solution of 6 g of potassium hydroxide in 10 mL of water, 35 mL of 2-(2-ethoxyethoxy)ethanol (carbitol), and 10 mL of ether, and is then fitted with an efficient condenser set downward for distillation. The condenser is connected to two receiving flasks in series, both cooled in an ice-salt bath. The second receiver contains 25 mL of ether and the inlet tube should dip below the surface of the solvent. The generating flask is heated in a water bath at about 70 °C, stirring is started (Teflon-coated magnetic stirring bar), and a solution of 21.4 g (0.1 mol) of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide in 125 mL of ether is added from the dropping funnel over about 20 min. The rate of addition should about equal the rate of distillation. When the dropping funnel is empty, 50-100 mL of additional ether is added slowly. The distillation is continued until the distilling ether is colorless. The combined ethereal distillate contains 2.7-2.9 g (64-69%) of diazomethane. The content of diazomethane in the codistilled ethereal solution can be determined by titration; excess benzoic acid is added to the solution (to react with diazomethane) and the excess acid is titrated with a standard solution of NaOH. If moisture must be removed from the ethereal diazomethane solution, the drying agent of choice is KOH pellets. It is recommended that diazomethane solutions be used immediately and not stored, even at low temperature.

An alternative popular procedure for the generation of small quantities (1-50 mmol) of diazomethane from Diazald employs a commercial mini-Diazald apparatus with a dry-ice/acetone cold finger in place of the water-jacketed condenser.[5] The generation of diazomethane is carried out by treatment of the Diazald with KOH in aqueous ethanol.[2g]

Methyl 6-Oxo-1-cyclohexenecarboxylate

(**1**; R = Me)

[52784-37-9] · $C_8H_{10}O_3$ · Methyl 6-Oxo-1-cyclohexenecarboxylate · (MW 154.18) (**2**; R = Et)

[57205-09-1] · $C_9H_{12}O_3$ · Ethyl 6-Oxo-1-cyclohexenecarboxylate · (MW 168.21)

(dienophile for Diels-Alder reactions[5] and other cycloadditions;[7] Michael acceptor in conjugate additions)

Alternate Name: 2-methoxycarbonyl-2-cyclohexen-1-one.

Physical Data: (**2**) bp 59 °C/0.1 mmHg.

Preparative Methods: the ethyl ester has been prepared by phenylselenylation of the sodium enolate of ethyl 6-oxo-1-cyclohexanecarboxylate with ***Benzeneselenenyl Chloride*** using ***Sodium Hydride*** as the base in THF, followed by oxidation with ***Hydrogen Peroxide*** in a water-dichloromethane system. *Syn* elimination of benzeneselenic acid occurs at rt under essentially neutral condition, allowing the isolation of the compound with an enol content of less than 2%.[1,2] Kügelrohr distillation increases the enol content, which can vary from 5 to 50%. Normally, the crude product is sufficiently pure to be used. The methyl ester has been prepared in a similar way using pyridine as the base in dichloromethane, thus avoiding the use of strong base in anhydrous solvent; isolation of the phenylseleno intermediate is unnecessary.[3] Mention should be made of an efficient synthesis of the methyl ester, which avoids the use of toxic selenium reagents, through Birch reduction of methyl 2-methoxybenzoate followed by acidic hydrolysis.[4]

Handling, Storage, and Precautions: these compounds with doubly activated double bonds are unstable and should be used as soon as possible, although they can be stored for several weeks in solution at -20 °C. Use in a fume hood.

Diels-Alder Reactions.

These reagents are very good dienophiles for different types of cycloaddition. With ***Tin(IV) Chloride*** as catalyst, methyl 6-oxo-1-cyclohexenecarboxylate undergoes Diels-Alder reaction with a variety of dienes to give directly the *cis*-

decalin system with methoxycarbonyl group at the angular position (eq 1).[5] Secondary orbital overlap of the diene with the ester carbonyl rather than the ketone carbonyl is responsible for the stereochemistry of the major isomer. On the other hand, reaction of this dienophile in refluxing benzene with a silyloxydiene derived from 1-acetylcyclopentene gives the *endo* adduct as the major isomer (eq 2).[4] A [2 + 3] cycloaddition of the trimethylenemethane-palladium complex to methyl 6-oxo-1-cyclohexenecarboxylate readily gives the methylenecyclopentane adduct.[6]

Base-Catalyzed Cycloaddition.

A very closely related transformation by base-catalyzed cycloaddition (or double Michael addition) of methyl 6-oxo-1-

cyclohexenecarboxylate with ***t-Butyl (E)-3-Oxo-4-hexenoate*** gives the corresponding *cis*-decalin, the *t*-butyl ester being selectively cleaved by acid with concomitant decarboxylation (eq 3).[7] High stereoselectivity in favor of the *exo* adduct is achieved using a nonpolar solvent. Several substituted 6-oxo-1-cyclohexenecarboxylates react similarly. Reversal of the methyl group stereochemistry is surprisingly achieved by using the corresponding γ,δ-unsaturated β-keto sulfoxide as the diene (eq 4).[7] Very good selectivity is obtained irrespective of the solvent polarity, in contrast to the reaction with the *t*-butyl ester. This methodology has been applied to the synthesis of 14-α-hydroxy-13α-methyl steroids[8] and optically active 14β-hydroxy steroids.[9]

Michael Addition.

Conjugate addition of *O*-silylated ketene acetals to methyl 6-oxo-1-cyclohexenecarboxylate is readily achieved by using high pressure (eq 5).[10] It has been shown that, in other substrates, this procedure overcomes steric and conformational requirements while maintaining conditions compatible with acid-sensitive functionalities. Conjugate addition of allyl,[11] vinyl,[12] tributylstannyl,[13] and dimethylphenylsilyl[14] groups have been reported.

Related Reagents.

t-Butyl (E)-3-Oxo-4-hexenoate; ***Diethyl Ethylidenemalonate***; ***Ethyl Ethoxymethyleneacetoacetate***; ***Ethyl 2-Methyl-4-oxo-2-cyclohexene-1-carboxylate***; ***Methyl 5-Methoxy-3-oxopentanoate***; ***Methyl 3-Oxo-4-pentenoate***.

Methyl 3-Oxo-4-pentenoate[1]

(**1**; R = Me)

[37734-05-7] · $C_6H_8O_3$ · Methyl 3-Oxo-4-pentenoate · (MW 128.14) (**2**; R = Et)

[22418-80-0] · $C_7H_{10}O_3$ · Ethyl 3-Oxo-4-pentenoate · (MW 142.17)

(Michael acceptor in the Robinson annulation[2])

Alternate Names: Nazarov's reagent; methyl acryloylacetate; vinyl β-methoxycarbonylmethyl ketone.

Physical Data: (**1**) bp 65 °C/19 mmHg. (**2**) bp 76-78 °C/18 mmHg.

Solubility: sol common organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: exists as a mixture of keto and enol forms; IR (film) cm^{-1} 2984, 1741, 1659, 1588, 1423, 1242, 1150, 1038, and 812; ^1H NMR ($CDCl_3$) δ 1.2-1.3 (overlapping t, 3 H), 3.6 (s, ketonic H at C-2), 4.1-4.3 (m, 2 H), 5.05 (s, enolic H at C-2), 5.50 (appt, 1 H), 5.91-6.43 (m, 2 H), 11.8 (s, enol OH); ^{13}C NMR ($CDCl_3$) δ 14.0, 14.2, 46.4, 60.2, 61.4, 91.8, 122.5, 130.2, 131.2, 135.7, 167.1, 168.6, 172.7, and 192.6.

Preparative Methods: first prepared by Nazarov[3] in 1953 by the reaction shown in eq 1. (**2**) is known as Nazarov's reagent, although (**1**) is often referred to as Nazarov's reagent also.

The original preparation of (**2**) suffers several problems. It has been termed tedious[4] and has a low overall yield. Several new syntheses of esters of 3-oxo-4-pentenoic acid have been reported since 1953.[2,4-10]

The most facile preparation of Nazarov's reagent and ester analogs was reported by Zibuck and Streiber in 1989. A variety of ester enolates react with ***Acrolein*** to provide good yields of β-hydroxy esters that can be oxidized to β-keto esters such as Nazarov's reagent and analogs (eqs 2 and 3).[1] The reaction sequence can be safely and successfully carried out on a 1 mol scale. Also, the β-hydroxy ester may be oxidized without purification. Interestingly, (-)-bornyl acetate leads to an annulating agent that contains a chiral auxiliary. ***Methacrolein*** and ***Crotonaldehyde*** give 4- and 5-methyl substituted reagents. C-4 and C-5 substituted analogs of Nazarov's reagent have been prepared by many other research groups, using reactions similar to those presented above.[11-16]

(2)

(3)

Purification: by Kugelrohr distillation at 0.6 mmHg (oven temperature 45 °C) with a receiving bulb cooled at -78 °C.

Handling, Storage, and Precautions: polymerizes rapidly at rt; stable to storage at -20 °C under nitrogen for up to 6 months; toxic; handle in a fume hood.

Robinson Annulations and Other Ring-Forming Processes.

Methyl and ethyl 3-oxo-4-pentenoate (**1**) and (**2**) are often used as Michael acceptors in strategies such as the Robinson annulation. Typical examples are shown in eqs 4 and 5.[17]

(4)

(5)

Other cyclizations involving this reagent include Mannich and Mannich-like reactions (eqs 6-8).[18-20] Thioimidates react as nucleophiles with methyl 3-oxo-4-pentenoate as shown in eq 9.[21]

(6)

(7)

(8)

(9)

Methyl 3-oxo-4-pentenoate has also been used in the well-known carbon zip reaction. Cycloheptyl, -octyl, and -dodecyl nitro ketones yield ring-enlarged adducts in 90-93% yield (eq 10).[22] Finally, esters of 3-oxo-4-pentenoate have often been used as Michael acceptors in many other synthetic sequences.[23-27]

(*E*)-Methyl 2,4-Pentadienoate

[1515-75-9] · $C_6H_8O_2$ · (*E*)-Methyl 2,4-Pentadienoate · (MW 112.14)

(electron-poor diene capable of cycloaddition reactions with activated dienophiles to form carbocyclic[1] and heterocyclic[2] compounds; metal-promoted [6 + 4] cycloadditions[3] and metal-promoted chain extensions[4])

Physical Data: bp 55-57 °C/14 mmHg.

Solubility: sol most organic solvents.

Form Supplied in: colorless liquid.

Analysis of Reagent Purity: NMR.

Preparative Methods: Wittig alkenation of ***Acrolein*** with ***(Methoxycarbonylmethylene)triphenylphosphorane***;[5] reaction of ***Malonic Acid*** with acrolein, followed by esterification.[6]

Purification: distillation.

Handling, Storage, and Precautions: polymerizes easily.

Diels-Alder Reactions.

As an electron-poor diene, the cycloaddition reactions of (*E*)-methyl 2,4-pentadienoate are optimal when combined with electron-rich dienophiles such as enamines (eq 1).[1] When electron-deficient dienophiles such as benzyljuglone,[7] or relatively nonpolarized dienophiles are employed (eq 2),[8] more forcing conditions are needed.

(E)-Methyl 2,4-Pentadienoate

(1)

(2)

Heterocycle Synthesis.

Nitroso compounds can react with the dienoate to afford 3,6-dihydro-1,2-oxazines (eq 3).[2] The 3,4-double bond can act as a 2π component in reactions with diphenylnitrilimine (eq 4).[9]

(3)

(E)-Methyl 2,4-Pentadienoate

Metal-Promoted Reactions.

The diene is a useful acceptor in the Heck reaction (eq 5).[4] It should be noted that the metal acts in a catalytic fashion in this reaction. When other reactants are not included in the reaction mixture, dimerization and further oligomerization is observed.[10-12] Other metal-promoted reactions can induce cycloaddition processes. In a noncatalytic process, complexation of thiepin dioxide with chromium tricarbonyl brings about [6 + 4] cycloaddition (eq 6).[3]

(Methylphenylamino)triphenylphosphonium Iodide

[34257-63-1] · $C_{25}H_{23}INP$ · (Methylphenylamino)triphenylphosphonium Iodide · (MW 495.36)

(synthesis of amines from alcohols; synthesis of unsymmetrical sulfides; synthesis of alkenes from allyl alcohols; synthesis of 1,3-dienes)

Alternate Name: Murahashi's reagent.

Physical Data: mp 237-242 °C (dec); commercial material quotes a higher melting point than material made in the reference.[1]

Solubility: sol DMF, EtOAc. Behaves as a Wittig-type reagent in terms of solubility.

Form Supplied in: solid.

Preparative Method: phenyliminotriphenylphosphorane is reacted with excess ***Iodomethane*** at reflux for 2 h. Removal of MeI followed by recrystallization gives a quantitative yield.[1]

Purification: may be recrystallized from chloroform-ethyl acetate (1:2).

Handling, Storage, and Precautions: store in sealed bottle on bench. Do not breathe dust, fumes, or vapor. Avoid contact with skin and eyes. Use in a fume hood.

Synthesis of Amines from Alcohols.

The reagent is similar to the Mitsunobu reagent in that it converts alcohols to alkylating agents. Hence, the reaction of an alkoxide ion with Murahashi's reagent in the presence of a primary or secondary amine leads to *N*-alkylation in high yield.[2] The reaction is mild and high yielding (eq 1), although replacing benzene for DMF as a solvent for secondary amines is recommended. Analogously, the preparation of azides can be accomplished by using ***Sodium Azide*** as the nucleophile.

(1)

Synthesis of Unsymmetrical Sufides.

Unsymmetrical sulfides may also be prepared by the reaction of alkoxides and thiols utilizing aminophosphoranes (eq 2). This method has been applied to the synthesis of various thiols, e.g. alkyl, benzyl, phenyl, *t*-butyl, and vinyl thiols.[3] Both *cis*- and *trans*-cinnamyl alcohols have been used, as well as geraniol, yielding the corresponding sulfides with retention of configuration.

(2)

Synthesis of Alkenes from Allyl Alcohols.

Allylic alcohols may be alkylated by an excess of alkyllithium in the presence of ***Methyllithium***, ***Copper(I) Iodide***, and Murahashi's reagent (eq 3).[4] The detailed structure of the lithium alkoxyallylcuprate and alkylcuprate having the stoichiometry $R^1OCuR^2{}_3Li_3$ is not known.

$$R^1\text{-}R^2 + Ph_3PO + R^2{}_2CuN(Me)PhLi_2 \quad (3)$$

γ-Alkylation of allylic alcohols with organolithium reagents using (methylphenylamino)tributylphosphonium iodide proceeds as shown in eq 4.[5] The latter reagent is easily prepared by addition of ***Phenyl Azide*** to ***Tri-n-butylphosphine*** in refluxing ether, followed by treatment with ***Iodomethane*** at reflux (90% yield; mp 120-120.5 °C, recrystallized from ethyl acetate.

(4)

Thus the reaction provides an efficient single-step process for the regio- and stereoselective synthesis of alkenes. Excellent yields are obtained from primary, secondary, and tertiary alcohols. Importantly, 1-substituted 2-propen-1-ols, which are readily available, can be converted into *trans*-1,2-disubstituted alkenes in a regio- and stereospecific manner. Alkylation of tertiary alcohols occurs with predominant allylic rearrangement, giving trisubstituted alkenes. The *cis*/*trans* ratios of the alkenes are not dependent upon the substitution of the tertiary allylic alcohol nor upon the organolithium compound; constant values of 32-36/68-64 are obtained. A reinvestigation of the regio- and stereochemistry was carried out by Goering.[6] In the initial study, triphenylphosphorane derivatives were used and there was no indication of any regiospecificity. More recently, tributylphosphorane salts have been used and S_N2' regiospecificity is observed (eq 5).

(5)

It is reported that the differences in regiochemistry do not result from using different phosphoranes, but instead result from a change in the experimental procedure. In fact, under the same conditions, the regio- and stereochemistry are the same with both reagents: this would be expected if the mechanistic pathway proposed by Murahashi[5] (eq 6) is followed.

(6)

In a further study of the alkylation of acylic systems by the same group,[7] it was found that *syn* γ-alkylation predominates in acyclic systems, but *anti* γ-alkylation predominates in cyclic systems. The results show that the reaction is highly regioselective.

Synthesis of 1,3-Dienes.

Alkylation of α-allenic alcohols by organolithiums using Murahashi's reagent leads to formation of 1,3-dienes (eq 7).[8] This allows direct nucleophilic substitution of labile or hindered α-allenic alcohols by organolithium reagents; the yields are in the range 35-55%.

(7)

This procedure invoves the in situ transformation of the hydroxy group of an unsaturated alcohol into an alkoxyphosphonium salt and the reaction of this with a nucleophile. The stereoselectivity seems to be dependent on the nucleophile and the nature of the substituent on the α-allenic carbon atom. The main interest of the reaction lies in the possibility of using various carbonucleophiles.

A review has appeared in the literature concerning the utility of the reagent in preparation and nucleophilic substitution of the hydroxy group of alcohols in organic synthesis.[8]

(*Z*)-*N*-Methyl-*N*-phenylbenzohydrazonyl Bromide

[59259-48-2] · $C_{14}H_{13}BrN_2$ · (*Z*)-*N*-Methyl-*N*-phenylbenzohydrazonyl Bromide · (MW 289.19)

(coupling mediator in peptide synthesis)

Physical Data: bp 82-85 °C/0.5 mmHg.

Solubility: usually used in polar solvents (acetone).

Analysis of Reagent Purity: satisfactory microanalytical data reported.[1]

Preparative Method: from the corresponding hydrazide using either ***Phosphorus(V) Chloride*** in dry benzene or ***Triphenylphosphine-Carbon Tetrabromide*** in acetonitrile for 2 h.[1] The solid material resulting is extracted four times with ether and the resulting organic layer is concentrated to yield the crude product. Distillation provides the pure compound as exclusively the (*Z*)-isomer.

General Discussion.

Imidoyl halide reagents such as (**1**) have been utilized as coupling mediators in peptide synthesis.[2] This reactivity is based on the instability of (**1**) in polar media, in which rapid unimolecular ionization occurs to give nitrilium ions (**2**) (eq 1).[3] These ions exhibit unusual reactivity, being more reactive with carboxylate ions than with simple amines; thus in the presence of equal amounts of acetic acid and morpholine, the major product is the *O*-acyl isoamide (**3**) rather than the amidine (eq 2). This situation is enhanced by pH control so that, when trapping of the nitrilium ion is carried out at pH 6 (i.e. >2 pH units below the pK_a of the amine), the isoamide (**3**) is the exclusive product. Furthermore, (**2**) will discriminate between carboxylate and water as nucleophile and thus the reaction can be carried out in aqueous media. Addition of an amine to (**3**) results in formation of amides in good yields. Use of *N*-protected α-amino acids in reaction with (**1**) gives isoamides (**4**) (eq 3), whose reaction with α-amino esters allows efficient preparation of peptides (eq 4). No racemization occurs during the reaction (as shown by the Anderson[4] method). Base hydrolysis of the crude reaction mixture gives *N*-

protected peptides in 80% overall yield. No acyl migration occurs in the reaction.

(1)

(1) **(2)**

(2)

(3)

(3)

(4)

(4)

The unusual reactivity and concomitant pronounced selectivity of (**1**) allows peptides to be synthesized with a minimum number of protecting groups. Indeed, completely unprotected amino acids may be coupled using the above protocol, but best results are obtained when there is a protection of the nitrogen of the first amino acid to be coupled (Table 1). This facilitates separation of the product and subsequent manipulation is simplified.

Table 1 Preparation of Dipeptides using *N*-Methyl-*N*-phenylbenzohydrazonyl Bromide

Acid	Amine	*N*-Protected dipeptide	Yield (%)
Z-Gly-OH	H-Gly-OEt	Z-Gly-Gly-OH	80[a]
Z-Gly-OH	H-Gly-OH	Z-Gly-Gly-OH	78
Z-Gly-OH	H-Trp-OH	Z-Gly-Trp-OH	82
Z-Trp-OH	H-Trp-OH	Z-Trp-Trp-OH	76
Z-Trp-OH	H-Ser-OH	Z-Trp-Ser-OH	80

N-Methyl-*N*-phenylcarbamoyl Chloride[1]

[4285-42-1] · C_8H_8ClNO · *N*-Methyl-*N*-phenylcarbamoyl Chloride · (MW 169.62)

(reagent for formylation of arenes[2])

Physical Data: mp 87-90 °C; bp 280 °C.

Form Supplied in: solid; commercially available.

Purification: recrystallize from dry ether.[3]

Handling, Storage, and Precautions: a corrosive lachrymator. Store under dry nitrogen. Use in a fume hood.

Formylation Reagent.

N-Methyl-*N*-phenylcarbamoyl chloride saw early use for the formation of aromatic aldehydes, through the two-step procedure of a Friedel-Crafts acylation of an arene, followed by reduction of the resultant *N*-methylbenzanilide with ***Lithium Aluminum Hydride***.[2] Yields in both steps are generally only moderate (eq 1).[2] The mechanism of the reduction has been studied.[3] Other reagents for arene formylation have been developed that have greater utility[1] (see ***Bis(1,3-diphenyl-2-imidazolidinylidene)*** and ***N-Ethoxymethyleneaniline***).

Vinyl and Aryl Amides.

The reagent undergoes reasonably efficient palladium-catalyzed cross coupling with a variety of vinyl- and arylstannanes to give the corresponding amides (eq 2).[4]

N-Methyl-*N*-phenyl(chloromethylene)ammonium Phosphorochloridate

[80984-92-5] · $C_8H_9Cl_3NO_2P$ · *N*-Methyl-*N*-phenyl(chloromethylene)ammonium Phosphorochloridate · (MW 288.50)

(formylation of activated aromatic systems[1,2] and alkenes[2])

Alternate Name: N-methylformanilide-phosphorus oxychloride complex.

Physical Data: see ***N-Methylformanilide*** (MFA) and ***Phosphorus Oxychloride***.

Form Supplied in: prepared in situ.

Preparative Method: $POCl_3$ is slowly added to a small excess of MFA.[3] A solvent may be added,[4] typically 1,2-dichloroethane or 1,2-dichlorobenzene; MFA may also be used as the solvent in the reaction.

Handling, Storage, and Precautions: phosphorus oxychloride is corrosive and lachrymatory. *N*-Methylformanilide is toxic and harmful by absorption. The iminium salt reacts vigorously with water. Use in a fume hood.

Formylation of Arenes.

Simple unactivated aromatic systems do not react with most Vilsmeier reagents (the adduct from ***N,N-Dimethylformamide-Trifluoroacetic Anhydride*** has been reported to formylate unactivated systems;[5]) electron-rich aromatic systems undergo monoformylation with MFA-$POCl_3$ in moderate to good yields.[1] Thus anthracene gives 9-anthracenecarbaldehyde (eq 1);[6] pyrene gives 3-pyrenecarbaldehyde (53%);[7] and azulene gives 1-azulenecarbaldehyde (eq 2).[8] Recent reports suggest that the adduct of ***Pyrophosphoryl Chloride*** ($P_2O_3Cl_4$) and MFA is a more effective formylating agent. For example, formylation of anisole with MFA-$P_2O_3Cl_4$ gives *p*-methoxybenzaldehyde in 72% yield, compared to only 34% with MFA-$POCl_3$.[9]

Heterocyclic systems have been formylated in moderate to good yields using MFA-$POCl_3$, e.g. thiophene (eq 3)[3,10] and indole (eq 4).[4] It is notable that poor yields of 3-indolecarbaldehyde (highest yield 37%) are obtained in the absence of a solvent.[4]

Formylation of Alkenes.

Styrene and several of its derivatives have been converted into the corresponding α,β-unsaturated aldehydes (eq 5).[11] A series of 1,1-diarylethylenes have been similarly converted into α,β-unsaturated aldehydes (eq 6).[12]

(6)

Reaction with Ketones.

9-Anthraquinone is converted into 10-chloro-9-anthracenecarbaldehyde (eq 7).[13] However, few examples of the synthesis of β-chlorovinyl aldehydes[14] using MFA-$POCl_3$ have been reported.[15]

(7)

Cyclizations under Vilsmeier Conditions.

Numerous cyclizations have been reported when DMF-$POCl_3$ is used as the reagent, but few have been reported using MFA-$POCl_3$.[16] Hippuric acid is converted into a substituted isoxazole by the action of MFA-$POCl_3$ (eq 8).[17] An allylbenzene has been reported to give a dihydronaphthaldehyde (eq 9).[18]

(8)

(9)

Although the use of MFA-$POCl_3$ in Vilsmeier reactions has been largely replaced by adducts formed from DMF-$POCl_3$ (see ***Dimethylchloromethyleneammonium Chloride***), MFA-$POCl_3$ often gives aldehydes in higher yield and at lower temperatures than required for reactions with DMF-$POCl_3$.[1a,19] MFA-$POCl_3$ is considered to be more reactive,[19] but extensive decomposition occurs at high reaction temperatures. The cost and low molecular weight favors the use of DMF-$POCl_3$.[1a,19]

Methyl α-Phenylglycinate

[6591-61-3] · $C_9H_{11}NO_2$ · Methyl α-Phenylglycinate · (MW 165.21) (.HCl)

[15028-40-7] · $C_9H_{12}ClNO_2$ · Methyl α-Phenylglycinate Hydrochloride · (MW 201.67)

(synthesis of β,γ-unsaturated ketones from carboxylic acids and substituted allylic alcohols)

Physical Data: hydrochloride (*RS*)-form: mp 224 °C.[1]

Solubility: hydrochloride: insol ether; sol H_2O, alcohol, benzene.

Form Supplied in: hydrochloride: colorless crystals.

Preparative Method: from α-phenylglycine and methanol.[1,2]

General Discussion.

Methyl α-phenylglycinate is used as a reagent for the conversion of carboxylic acids into β,γ-unsaturated ketones.[3,4] For this purpose, the acid is linked to the amino group of the α-amino acid ester and the resulting methyl *N*-acyl derivative is transesterified with an appropriate allylic alcohol, e.g. geraniol (eq 1). On treatment with ***Triphenylphosphine***/***Hexachloroethane***/***Triethylamine***[5] the geranyl *N*-acyl-α-phenylglycinate is cyclized to a 5-(geranyloxy)oxazole intermediate which immediately rearranges to the 5(2*H*)-oxazolone via a Claisen-aza-Cope sequence.[6] Subsequent reductive cleavage of the oxazolone ring by ***Chromium(II) Acetate***/H_3PO_2 in DMF[7] yields the β,γ-unsaturated ketone. This three-step procedure offers a novel effective means to accomplish nucleophilic acylation with carboxylic acids. Alternatively, the geranyl *N*-acyl-α-phenylglycinate can be synthesized from the preformed amino acid geranyl ester, which can be stored in the form of its hydrochloride.[4]

(1)

Whereas the scope of this reaction is nearly unlimited with respect to the carboxylic acid, the choice of the allylic alcohol requires attention. Thus with prenyl alcohols,[4] cinnamyl derivatives,[8] and 2,4-dienols,[4] the sequence proceeds smoothly and in high yields. In the case of crotyl[9] and 3-phenylpropargyl derivatives,[10] the formation of the 5(2*H*)-oxazolone requires elevated temperatures and longer reaction times. Simple allyl esters cannot be used for the chain elongation because the cyclization step in this case leads to stable 4-allyl-5(4*H*)-oxazolones.[3]

The α-phenylglycine technique constitutes an efficient alternative to the use of organometallic reagents for the conversion of carboxylic acid derivatives into β,γ-unsaturated ketones.[11] The mild reaction conditions and absence of strong bases allow even the use of sensitive carboxylic acids, as is illustrated by the conversion of *O*-acetyl protected D-gluconic acid into *C*-farnesyl α-D-glucopyranoside (eq 2).[4] Isomerization of the β,γ-unsaturated ketone to the conjugated enone, a notorious problem with other procedures,[12] is not observed, and stereogenic centers in the α-position to the carboxyl group maintain their stereochemical integrity.[4,13] During the chain elongation, the configuration at the trisubstituted double bond is conserved.[14] This is of importance for the attachment of terpenoid chains to carboxylic acids,[4] e.g. in the synthesis of 12-oxosqualene from farnesoic acid and farnesol (eq 3).[7] Interestingly, both diastereomers of cinnamyl alcohol afford the (*E*)-β,γ-unsaturated ketone (eq 4).[9] In the case of secondary cinnamyl

alcohols, the reaction proceeds with complete transfer of chirality (eq 5).[10]

(2)

(3)

(4)

(5)

The chain elongation via allyl *N*-acyl-α-phenylglycinates can be used for the conversion of carboxylic acids into β-keto aldehydes, 1,3-diketones, and β-keto esters, and heterocycles derived therefrom.[8,13] The general procedure is outlined in eq 6 for the synthesis of a *C*-nucleoside.[8]

Related Reagents.

Ethyl N-Benzylideneglycinate; ***Methyl N-Benzylidenealaninate***.

3-Methyl-2-phenyl-1,3,2-oxazaphospholidine

[1885-79-6] · $C_9H_{12}NOP$ · 3-Methyl-2-phenyl-1,3,2-oxazaphospholidine · (MW 181.19)

(formation of thiophosphoramides[1])

Physical Data: bp 75-78 °C/0.05 mmHg.

Solubility: sol chloroform.

Form Supplied in: clear liquid; becomes viscous on standing.

Analysis of Reagent Purity: bp and ^{31}P NMR (143.1 ppm).

Preparative Method: prepared by heating a mixture of phenylphosphorus dichloride and *N*-methylethanolamine at 130 °C (81%).[2]

Purification: distillation in vacuo immediately before use.

Handling, Storage, and Precautions: hygroscopic. Dimerizes and polymerizes on standing.

General Discussion.

The title compound (**1**) undergoes dimerization (eq 1) at rt to form a ten-membered macrocycle. This compound has been isolated as a mixture of two isomers.[3]

Treatment of (**1**) with ***Diphenyl Disulfide*** results in production of (**2**), presumably by alkylation on phosphorus followed by ring opening by the phenylthiolate anion (eq 2).[1]

Methyl 2-(Phenylsulfinyl)acetate

[14090-83-6] · $C_9H_{10}O_3S$ · Methyl 2-(Phenylsulfinyl)acetate · (MW 198.26)

(synthetic equivalent of a vinyl organometallic species; undergoes addition/elimination to aldehydes to give conjugated dienoates or 4-hydroxy (2*E*)-enoates)

Physical Data: mp 53-55 °C; bp 130-131 °C/0.5 mmHg.

Form Supplied in: solid; widely available.

Handling, Storage, and Precautions: fp >100 °C.

Knoevenagel Condensation with Aldehydes.

The sodium and lithium enolates of methyl 2-(phenylsulfinyl)acetate are very stable and tend not to react with aldehydes under normal conditions; however, the Knovenagel amine-catalyzed condensation[1,2] occurs under mild conditions to give 3-aryl-2-(phenylsulfinyl)(2*E*)-propenoate methyl esters stereoselectively (eq 1) in a 98:2 (*E*:*Z*) ratio as determined by Tf_2O/dimethyl sulfide reduction followed by GLC analysis. These compounds are useful because they are powerful dienophiles in a variety of Diels-Alder reactions.

(1)

Preparation of 3-Hydroxy Enoates.

Under similar Knovenagel conditions, methyl 2-(phenylsulfinyl)acetate can undergo addition to afford the sulfinyl condensation product; base-catalyzed deconjugation, a [2,3]-sigmatropic shift, and hydrolysis of the sulfenate ester intermediate then affords 4-hydroxy (2*E*)-enoates[3-5] in one pot (eqs 2 and 3).

(2)

(3)

Preparation of 1,3-Dienoates from Alkenes.

Trost et al.[5] have demonstrated that the palladium-catalyzed addition of methyl 2-(phenylsulfinyl)acetate to palladium π-allyl complexes gives intermediate allylsulfinates, which undergo a standard thermal elimination of the sulfoxide group to afford 2,4-dienoates efficiently from alkenes (eqs 4 and 5).

(4)

(5)

Alkylation Followed by Elimination to Give Enones.

Despite the low reactivity of the enolates, methyl 2-(phenylsulfinyl)acetate can be induced to undergo nucleophilic attack. Methyl cyclobutenecarboxylate[6] can be prepared by deprotonation of the reagent with a solution of 2 equiv of ***Sodium Hydride*** and ***1,3-Diiodopropane*** in DMF to give the cyclic product; pyrolysis at 160 °C affords the cyclobutene product in a low (39%) overall yield (eq 6).

Benzylic bromides also undergo an efficient one-pot alkylation/elimination using ***Potassium Carbonate*** in the presence of a phase-transfer catalyst such as aliquat-336 in DMF to afford *trans*-unsaturated esters in good yields (eq 7).[7]

Synthesis of 1,4-Dicarbonyl Compounds via Pummerer Reaction.

Treatment of methyl 2-(phenylsulfinyl)acetate with ***Tin(II) Trifluoromethanesulfonate*** effects conversion of the sulfoxide group to the Pummerer intermediate. This reacts with silyl enol ethers in the presence of ***N-(Trimethylsilyl)imidazole*** to afford 1,4-dicarbonyl compounds[8] containing a phenylthio group, which can be oxidized and thermally eliminated to give unsaturated dicarbonyl compounds or reductively removed to give the saturated analogs (eq 8).

Michael Addition Reactions of Methyl 2-(Phenylsulfinyl)acetate.

The potassium salt of methyl 2-(phenylsulfinyl)acetate can be induced to undergo a Michael addition in the presence of ***18-Crown-6***. Subsequent thermal elimination of the sulfoxide group in refluxing xylenes affords the α,β-unsaturated

enone, via equilibration of the double bond into conjugation with the ketone. This reaction constitutes the synthetic equivalent of an acetate anion addition to an α,β-unsaturated system with retention of unsaturation (eq 9).[9]

(9)

A tandem Michael addition/enolate acylation reaction with α,β-unsaturated methyl ketones is possible in the presence of ***Magnesium Methoxide***, giving rise to a 1,3-diketocyclohexane system; on heating, this eliminates the sulfoxide group to give an aromatic resorcinol system (eq 10).[10]

Dinos Santafianos

Methyl Phenyl Sulfone

[3112-85-4] · $C_7H_8O_2S$ · Methyl Phenyl Sulfone · (MW 156.22)

(generally used as the lithiated form, which reacts with a variety of electrophiles[1])

Physical Data: mp 86-88 °C.

Solubility: sol ethanol, benzene.

Form Supplied in: white solid; widely available. [^{13}C]Methyl phenyl sulfone is also available.

Preparative Methods: by the reaction of ***Sodium Benzenesulfinate*** with ***Dimethyl Sulfate***; by oxidation of methyl phenyl sulfide with 30% ***Hydrogen Peroxide*** in acetic acid; or by the reaction of polymer-supported benzenesulfinate anion with ***Iodomethane*** in refluxing benzene.[2]

Purification: recrystallized from carbon tetrachloride and 1:3 ethanol-water. On a small scale, water is convenient for recrystallization.[3]

General Discussion.

The lithium salt of methyl phenyl sulfone reacts with electrophiles by alkylation to give homologs which possess acidic methylene protons for further synthetic transformations. Alkylation of [(phenylsulfonyl)methyl]lithium ($PhSO_2CH_2Li$) with primary iodides proceeds smoothly in THF in the presence of HMPA to furnish homologs (eq 1).[4] The factors that control mono- vs. dialkylation of methyl phenyl sulfone have been studied. Alkylation of methyl phenyl sulfone using a lithium base can lead to significant polyalkylation. Use of a potassium base such as ***Potassium Hydride*** enhances formation of monosubstituted product, presumably by decreasing ion pairing.[5]

Double coupling reactions of sulfonylmethyl anions with epoxides and then with aldehydes have been developed for the synthesis of homoallyl alcohols (eq 2).[6] The difficulties experienced in the coupling reaction with hindered epoxides may often be overcome by the use of solvent additives (especially ***Hexamethylphosphoric Triamide***) and/or Lewis acids such as ***Boron Trifluoride Etherate***. Indeed, reaction of [(phenylsulfonyl)methyl]lithium (2 equiv $PhSO_2CH_2Li$; HMPA/THF/-78 °C) with the hindered epoxide shown proceeds smoothly in the presence of $BF_3.OEt_2$ (2 equiv) (eq 3).[7]

Treatment of methyl phenyl sulfone with 2 equiv of ***n-Butyllithium*** in THF at 0 °C produces [(phenylsulfonyl)methylene]dilithium ($PhSO_2CHLi_2$), which has been used as a powerful nucleophile. Geminal dialkylation of this α,α-dianion with 2 equiv of epoxides has been applied to a synthesis of *trans*-2,6-disubstituted piperidines (eq 4).[8]

Alkylation followed by intramolecular alkylation with $PhSO_2CHLi_2$ serves as a method for the construction of carbocyclic frameworks. $PhSO_2CHLi_2$ reacts with dihalo alkanes (eq 5), as well as with halo epoxides to furnish cyclic products. In the case of halo epoxides, initial attack occurs on the epoxide terminus to give the larger of the two possible cyclic products (eqs 6 and 7).[9]

(6)

(7)

In acylation reactions, the use of excess base or sulfonyl carbanions is necessary, because the acidic β-keto sulfone product consumes up to half of the starting sulfonyl carbanion by proton transfer. This problem is often overcome by employing $PhSO_2CHLi_2$, which provides directly the anion of the β-keto sulfone product. Condensation of either acid chlorides[10] or esters with $PhSO_2CHLi_2$ gives keto sulfones (eq 8).[11]

(8)

The reaction of $PhSO_2CHLi_2$ with ethyl 4-bromobutyrate gives the enolate of the β-keto sulfone, which is further converted to vinyl ethers as a mixture of (*E*)- and (*Z*)-isomers (34:44) through intramolecular *O*-alkylation. The cyclopropyl ketone is also observed as a minor product, which presumably arises by equilibration of the enolates (eq 9).[12]

(9)

The counter cations of phenylsulfonylmethide influence the outcome of stereochemistry when added to the chiral aldehyde pentodialdo-1,4-furanose. When the counter cation is magnesium, the *anti*-product is highly favored over the *syn*-product. When $PhSO_2CH_2Li$ is treated with ***Zinc Chloride*** and HMPA, the selectivity reverses to mainly the *syn*-product (eq 10).[13]

(10)

$PhSO_2CH_2M$	*anti*:*syn*	Yield (%)
$PhSO_2CH_2MgBr$	95:5	85
$PhSO_2CH_2Li$	73:27	92
$PhSO_2CH_2Li$, $ZnCl_2$, HMPA	23:77	92

The homologation of α-diketones using $PhSO_2CHLi_2$ is considered to involve attack on both electrophilic sites followed by ring opening of the cyclopropanediolate involving the expulsion of sulfinate anion. Electron transfer competes in this reaction, judging from the fact that benzoin is isolated in as much as 30% yield (eq 11). In the case of 2-chlorocyclohexanone, the ring-expansion product results (eq 12).[9]

(*E*)-Vinyl sulfones are stereoselectively prepared in one pot through phosphorylation of $PhSO_2CHLi_2$ followed by Horner-Emmons reaction of the resulting phosphonate with aldehydes (eq 13).[14]

Methyl Phenylsulfonylacetate

[34097-60-4] · $C_9H_{10}O_4S$ · Methyl Phenylsulfonylacetate · (MW 214.26)

(soft nucleophile which undergoes palladium(0)-catalyzed additions to allylic acetates, pivalates, tosylates, and epoxides; desulfonation affords aliphatic (4*E*)-enoates)

Alternate Name: (methoxycarbonyl)methyl phenyl sulfone.

Physical Data: bp 165 °C/0.05 mmHg; *d* 1.282 g cm^{-3}.

Form Supplied in: liquid/oil; widely available.

Palladium(0)-Catalyzed Addition to Allylic Systems.

Methyl phenylsulfonylacetate has been used as a soft nucleophile in a variety of palladium(0)-catalyzed additions to allylic acetates, allylic pivalates, and allylic epoxides to afford alkyl 2-phenylsulfonyl (4*E*)-enoates. Addition to allylic acetates[1,2] followed by desulfonation[3] leads to the construction of *trans*-4-enoates (eq 1). Addition to allylic tosyl systems can be achieved, giving vinylcyclopropanes (eq 2).[4]

(1)

(2)

Cyclopentadiene monoepoxide can undergo palladium-catalyzed ring opening to give a palladium π-allyl complex which reacts with methyl phenylsulfonylacetate to afford *cis*-4-substituted 2-cyclopenten-1-ols[5,6] after desulfonation using ***Sodium Amalgam*** (eq 3).[7] The cyclopentenols can also be prepared in an optically active form starting from *cis*-4-acetoxy-1-hydroxy-2-cyclopentene.[8]

(3)

Methyl phenylsulfonylacetate can be alkylated using π-allyl complexes to afford alk-4-ene functionalities which can be treated with a palladium catalyst to form vinylcyclopropane ring systems. The phenylsulfonyl group can be removed by Na(Hg) reduction and the ester converted to aldehyde by reduction followed by oxidation to give a 60:40 mixture of *cis*- and *trans*-cyclopropanecarbaldehydes (eq 4).[9]

(4)

Alkylation with 5-bromo-1-pentene or 5-bromo-1-pentyne gives the alkenyl and alkynyl derivatives which can undergo palladium-catalyzed cyclization followed by a Heck reaction to give cyclopentanes or vinylidenecyclopentanes (eqs 5 and 6).[10,11]

The palladium cyclization reaction using the soft nucleophilic properties of the phenylsulfonylacetate system has been extended to the construction of macrocyclic ring systems.[12,13] Methyl phenylsulfonylacetate can be deprotonated with ***Potassium t-Butoxide*** in *t*-butanol/DMSO and added, via Michael addition, to the unsaturated ketone. Macrocyclization is effected with ***Tetrakis(triphenylphosphine)palladium(0)*** and ***N,O-Bis(trimethylsilyl)acetamide*** in THF at reflux (eq 7).

(7)

Methyl phenylsulfonylacetate also undergoes a reductive addition to dienes in the presence of palladium(0) catalysts[14] under basic conditions to give functionalized alkenes (eq 8).

Methyl 3-Phenylsulfonyl-2-propenoate

(*E*)

[1865-13-0] · $C_{10}H_{10}O_4S$ · Methyl 3-Phenylsulfonyl-2-propenoate · (MW 226.27) (*Z*)

[91077-67-7]

(used in Michael addition reactions;[1] [2 + 2],[2] [3 + 2],[3] and [4 + 2][4,5] cycloadditions)

Physical Data: (*E*)-isomer mp 100 °C; (*Z*)-isomer mp 50.5-51.5 °C.

Solubility: (*E*)-isomer sol ethanol, methanol; (*Z*)-isomer sol chloroform, toluene; insol pentane.

Form Supplied in: both white crystalline solids.

Preparative Methods: methyl (*E*)-3-phenylsulfonyl-2-propenoate (**1**) is prepared in 70% yield by the reaction of ***Methyl Acrylate*** with benzenesulfonyl iodide followed by treatment with ***Triethylamine***.[3] Methyl (*Z*)-3-phenylsulfonyl-2-propenoate (**2**) is prepared in 88% yield by the ***Boric Acid*** mediated addition of ***Sodium Benzenesulfinate*** to ***Methyl Propiolate***.[5,6]

Handling, Storage, and Precautions: potential alkylating and vesicant. Use in a fume hood.

Midhael Addition Reaction.

Methyl (*E*)-3-phenylsulfonyl-2-propenoate (**1**) has been reported to undergo Michael addition reactions with ***Pyrrolidine*** (eq 1), ***Sodium Methoxide*** (eq 2), and the morpholino enamine of cyclopentanone (eq 3) to produce, initially, β-substituted acrylates.[1] In each case, attack of the nucleophile at the carbon α to the phenylsulfonyl group was followed by irreversible elimination of benzenesulfinic acid to give rise to the observed products.

Cycloaddition.

Methyl (*E*)-3-phenylsulfonyl-2-propenoate (**1**) undergoes [2 + 2] cycloaddition with ***N,N-Diethyl-1-propynylamine*** (eq 4) to provide regioselectively the corresponding tetrasubstituted cyclobutene in quantitative yield at 25 °C.[2]

[3 + 2] Cycloaddition.

It has been communicated that methyl (*E*)-3-phenylsulfonyl-2-propenoate (**1**) reacts with the nitrile imine generated in situ from phenylhydrazonyl chloride and triethylamine to afford a single regioisomeric 4,5-dihydropyrazole (eq 5) in

65% yield.[3] The regioselectivity of this process was rationalized in terms of frontier orbital theory.

(5)

[4 + 2] Cycloaddition.

Heating methyl (*Z*)-3-phenylsulfonyl-2-propenoate (**2**) with a tricylic triene at 55-60 °C overnight results in the formation of the [4 + 2] cycloadduct in quantitative yield (eq 6).[4] The latter cycloadduct was transformed into a quadricyclane derivative upon photolysis. Methyl (*Z*)-3-phenylsulfonyl-2-propenoate (**2**) also reacts with (*E*)-4-methylhexa-3,5-dien-1-ol in refluxing toluene to give the *endo* Diels-Alder adduct in 81% yield (eq 7).[5] Interestingly, the ethyl ester analogous to methyl (*E*)-3-phenylsulfonyl-2-propenoate (**1**) reacts with this diene to give a quantitative yield of products derived from *endo* addition (eq 8), which have the opposite phenylsulfonyl regiochemistry to that observed with (**2**).

4-(4´-Methyl-1´-piperazinyl)-3-butyn-2-one

[67543-08-2] · $C_9H_{14}N_2O$ · 4-(4´-Methyl-1´-piperazinyl)-3-butyn-2-one · (MW 166.25)

(peptide coupling)

Physical Data: colorless crystals; mp 18-19 °C.

Preparative Method: can be made in multigram quantities in three steps from commercially available ***4-Methoxy-3-buten-2-one*** in 54% overall yield (eq 1).[1] The intermediates (**2**) and (**3**) are purified by recrystallization or distillation. No chromatography is involved. The final product can be purified by distillation under reduced pressure.

Handling, Storage, and Precautions: stable for a period of hours at rt. It should be stored at refrigerator/freezer

temperatures to prolong its shelf life.

Peptide Coupling.

This push-pull alkyne reagent has found use in the production of amides from carboxylic acids and amines (eq 2).[2] Typically, the carboxylic acid is added to a solution of the ynone in THF at 0 °C and stirred for 30 min. The amine is added at -20 °C and the reaction is allowed to warm to rt. It has been confirmed by isolation that enol esters such as (**7**) are intermediates in the process, which is thought to proceed as shown in (**5**) -> (**8**). A variety of saturated and unsaturated carboxylic acids can be combined with primary and secondary amines to give amides in 73-95% yields.

Because of the near-neutral conditions of the coupling process, the reagent is excellent in the formation of peptides (eq 3).[3] Because (**4**) reacts quickly with carboxylic acids to form (**5**), peptide fragments containing unprotected and potentially nucleophilic groups can be used in the coupling process. For example, unprotected serine, methionine, hydroxyproline, tyrosine, and histidine react only at the primary amino group (eq 3). Yields are excellent and little or no racemization is observed.

2-Methyl-1-propenyl Trifluoromethanesulfonate

[53282-30-7] · $C_5H_7F_3O_3S$ · 2-Methyl-1-propenyl Trifluoromethanesulfonate · (MW 204.19)

(precursor to dimethylvinylidene carbene,[1] 2-methyl-1-propenyl ethers,[1] isopropylidenecyclopropanes,[2] isopropylidenecyclopropenes,[2] 3-isopropylindazoles,[3] and 2-methyl-1-propenyltriphenylphosphonium triflates[4])

Physical Data: bp 65-66 °C/70 mmHg.

Solubility: sol most organic solvents.

Preparative Method: prepared in a single step from 2-methylpropionaldehyde, ***Trifluoromethanesulfonic Anhydride***, and a hindered pyridine in 1,2-dichloroethane at reflux (eq 1). Distillation gives the product in 45% yield.[5]

General Discussion.

This reagent is quantitatively converted to the electrophilic carbene (**2**) (eq 2) on treatment with ***Potassium t-Butoxide***.[1] This carbene readily inserts into an oxygen-hydrogen bond, and thus reacts with *t*-butanol to give ether (**3**) (eq 3).[1]

(2)

(3)

Carbene (**2**) reacts normally with a variety of substrates. When an alkene is used as solvent (eqs 4 and 5), the corresponding isopropylidenecyclopropanes are generated in good to excellent yield.[1] The silicon-hydrogen bond is an efficient trap (eq 6); the reaction proceeds with retention of configuration at silicon.[6]

(4)

(5)

(6)

Alkynes react with (**2**) to yield isopropylidenecyclopropenes (**4**) (eq 7).[2] These products cannot be isolated, but will undergo a facile Diels-Alder reaction. Alternatively, protonation of the product gives isopropylcyclopropenium

ions.

(7)

Reaction of (**1**) in the presence of azoarenes yields the unusual 3-isopropylindazoles (eq 8), presumably via an isopropylidenediaziridine.[3] In the presence of ***Triphenylphosphine***, a palladium catalyst converts (**1**) into the corresponding phosphonium salt in good yield (eq 9).[4]

Methyl Propiolate

(**1**; R = Me)

[922-67-8] · $C_4H_4O_2$ · Methyl Propiolate · (MW 84.08) (**2**; R = Et)

[623-47-2] · $C_5H_6O_2$ · Ethyl Propiolate · (MW 98.11)

(α,β-unsaturated ester capable of undergoing Diels-Alder[1] and other cycloaddition reactions,[2] Michael additions,[3] acetylide formation,[4] halogen addition,[5] and a variety of cyclization reactions to generate heterocycles[6] and aromatics[7])

Alternate Name: methyl propynoate.

Physical Data: (**1**) bp 104 °C; *d* 0.945 g cm^{-3}. (**2**) bp 120 °C; *d* 0.968 g cm^{-3}.

Form Supplied in: colorless oil; widely available.

Handling, Storage, and Precautions: methyl and ethyl propiolate are lachrymatory liquids; handle in a well-ventilated fume hood.

Diels-Alder Reactions.

Methyl and ethyl propiolate are effective dienophiles and enter into the Diels-Alder reaction with electron-rich (eq 1)[8] and electron-neutral dienes (eq 2)[9] as well as with heterodienes (eq 3).[10] The regiochemical outcome of this transformation is in accord with standard HOMO-LUMO considerations.

(1)

(2)

(3)

Other Cycloaddition Reactions.

Methyl and ethyl propiolate are effective partners in [2 + 2] cycloadditions to afford cyclobutenes (eq 4).[11] They also represent good dipolarophiles, undergoing [3 + 2] cycloadditions with a variety of 1,3-dipoles[12] to generate five-membered heterocycles (eq 5).

(4)

(5)

Halogenation.

Methyl and ethyl propiolate are readily halogenated to afford versatile intermediates such as 3-bromopropiolate esters (eq 6),[13] (*Z*)-haloacrylates (bromo,[14] chloro,[15] and iodo[16]) (eq 7), and 2,3-dihaloacrylates.[17] In the latter case, the stereoselectivity depends on the reaction conditions; both (*E*)-[18] and (*Z*)-[19] dibromides can be prepared specifically (eq 8).

(6)

(7)

(8)

Conjugate Additions.

Conjugate additions to methyl and ethyl propiolate are well documented, particularly for heterocycle formation. Good Michael donors include thiols,[20] salts of sulfinic acids (which generate potent dienophiles) (eq 9),[21] enolate anions (eq 10),[22] carbon nucleophiles (eq 11),[23] and phenols.[24] In general, heteronucleophiles afford (*Z*)-products and carbon nucleophiles give (*E*)-isomers.

(9)

(10)

(11)

Heterocycle Formation.

Amidines undergo intermolecular Michael addition followed by cyclization to generate pyrimidones (eq 12).[25] Similar reactions with suitably substituted pyridinium salts afford indazoles (eq 13)[26] and with hydrazines give pyrazolones.[27] Dihydropyridines are prepared using the Michael addition of the elements of ammonia to methyl propiolate with concomitant condensation of the adduct with a simple aldehyde (eq 14).[28] [3 + 2] Cyclizations generate pyrazoles,[29] thiazoles,[30] and oxazoles,[31] among others. Benzofurans are prepared by either the palladium-[32] or copper-catalyzed[33] cyclization of an *o*-halophenol with ethyl propiolate (eq 15).

(12)

(13)

(14)

(15)

Acetylide Formation.

Acetylide anions, readily formed with either butyllithium or LDA, undergo nucleophilic addition to a variety of functional groups. These include epoxides,[34] ketones,[35] aldehydes,[36] and carbon dioxide.[37]

Related Reagents.

2-Butynoic Acid; ***3-Butyn-2-one***; ***(E)-(Carboxyvinyl)trimethylammonium Betaine***; ***3,3-Diethoxy-1-propyne***; ***Dimethyl Acetylenedicarboxylate***; ***Propargyl Alcohol***; ***Propargyl Aldehyde***.

β-Methyl-β-propiolactone[1]

(±)

[3068-88-0] · $C_4H_6O_2$ · β-Methyl-β-propiolactone · (MW 86.10) (*R*)

[32082-74-9] (*S*)

[65058-82-4]

(three-carbon homologating reagent for synthesis of chiral β-methyl carboxylic acids[1])

Physical Data: mp -43.5 °C; bp 71-73 °C/29 mmHg; *d* 1.056 g cm^{-3}. (*R*)-isomer: [α]20D -27.8° (*c* 4.14, $CHCl_3$); (*S*)-isomer: [α]22D +28.8° (*c* 4.30, $CHCl_3$).

Solubility: misc alcohol, acetone, ether, chloroform.

Form Supplied in: colorless oil; the racemic form is widely available.

Preparative Methods: by ring-closure of 3-bromobutyric acid with ***Sodium Carbonate***,[2a] or by hydrogenation of ***Diketene***.[2b] The optically active forms are obtained in the same manner starting from (*R*)- or (*S*)-3-bromobutyric acid, which may be resolved with the (*S*) form of ***1-(1-Naphthyl)ethylamine***.[3] Asymmetric aldol condensation using an enantiopure iron acetyl complex followed by cyclization,[3c] or asymmetric hydrogenation of diketene catalyzed by a chiral ruthenium complex,[3d] also gives the optically active β-lactone.

Handling, Storage, and Precautions: can be stored in the refrigerator for several months without noticeable changes; cancer suspect reagent; should be handled with due care.

General Discussion.

β-Methyl-β-propiolactone is particularly useful as a reactive four-carbon building block. Like β-***Propiolactone***, β-methyl-β-propiolactone undergoes a variety of ring-opening reactions in which the regiochemistry is dependent on the

nature of the nucleophile (eq 1). Addition to the carbonyl carbon predominates in reactions with organolithium[4] or Grignard reagents,[5] giving α,β-unsaturated ketones (**2**) or 1,3-diols (**3**). Organocadmium reagents[4] effect C-O bond fission to give β-methyl carboxylic acids (**4**).

Selective β-attack is best accomplished by the use of organocopper reagents (eq 2).[6] Organocuprates prepared from 2 equiv of Grignard reagents and 1 equiv of ***Copper(I) Iodide*** give β-methyl carboxylic acids (**4**) in better yields than when the corresponding organolithium reagents are used. In the presence of a catalytic amount of a copper(I) salt, Grignard reagents also attack at the β-carbon to give the same products in good yields.[7]

A: R_2CuMgX, THF · Me_2S
B: RMgX, cat CuX, THF
C: RCu · PBu_3, Et_2O

The ***Potassium*** complex of ***18-Crown-6*** or ***Potassium Naphthalenide*** effects ring-opening to give acetates or their alkylated derivatives in good yield (eq 3). Treatment of the reaction mixture obtained from β-methyl-β-propiolactone and potassium-18-crown-6 with hydrochloric acid or alkyl halides gives the acetate (**5**) or its alkylated derivative (**6**), respectively.[8] The α,β-unsaturated carboxylic acid (**7**) or its ester (**8**) is formed by the action of the potassium naphthalenide-18-crown-6 complex.[9]

(3)

β-Methyl-β-propiolactone is useful as a four-carbon building block for terpenoid synthesis (eq 4). Citronellic acid (**9**) is prepared by reaction with the homoprenyl Grignard reagent; pulegone (**10**), citronellol (**11**), geraniol, and nerol (**12**) can be obtained by further functional group manipulations.[10]

(4)

Optically active (*R*)- and (*S*)-β-methyl-β-propiolactone serve as versatile reagents for the synthesis of 3-sulfinylbutyric acid[11] and for various natural products in optically active form. (*S*)-*ar*-Turmerone (**13**) is obtained by reaction of the (*R*)-enantiomer with a di-*p*-tolylcopper reagent followed by functional group manipulation (eq 5).[3a] (*R*,*R*)-Phytol (**15**) is prepared by ring-opening with the Grignard reagent (**14**) followed by the chain-elongation reaction (eq 6).[12] (*R*,*Z*)-Trogodermal (**18**), an insect pheromone of *Trogoderma inclusum*, is synthesized by using the *cis*-alkenylcopper reagent (**17**) (eq 7).[13] The enantiomeric purity of the final natural products is 83-84% ee. Comparison of this value with that of the starting (*S*)-(+)-3-bromobutyric acid (90% ee) indicates that these magnesiocuprate coupling reactions occur with &egt;92% inversion of configuration at the β-position of the (*R*)-(+)-β-methyl-β-propiolactone.[3a]

(5)

(6)

(7)

1,3-Dimethyl-2,9-dioxabicyclo[3.3.1]nonane (**19**), an insect pheromone, has been synthesized starting from (*R*)-(**1**) via ring-opening at the acyl carbon followed by conjugate addition to the resulting α,β-unsaturated ketone (eq 8).[14]

Related Reagents.

1-Methyl-2(1*H*)-pyridinethione

[2044-27-1] · C_6H_7NS · 1-Methyl-2(1*H*)-pyridinethione · (MW 125.21)

(sulfur transfer; carbonyl activation)

Physical Data: pale yellow leaflets; mp 89-90 °C.

Preparative Method: prepared in 80-90% yield from commercially available 1-methyl-2(1*H*)-pyridone by treatment with ***Phosphorus(III) Iodide*** at 130 °C for 4-5 h.

Purification: crystallization from water.[1,2]

Introduction.

The reactivity of 1-alkyl-2(1*H*)-pyridone (and -pyridinethione) derivatives has been studied extensively by Tomisawa.[3]

Carbonyl Activation.

The title reagent (**1**) reacts with acyl chlorides to produce 2-acylthio-1-methylpyridinium salts (**2**) as stable hygroscopic solids (eq 1). These may then be treated with a variety of oxygen and nitrogen nucleophiles in the presence of base to effect transfer of the acyl group to the nucleophilic species to produce (**3**) and regenerate (**1**).[4]

(1)

R = Ph, Me, *i*-Pr, OEt; Nu = primary amines, phenols, carboxylic acids

Sulfur Transfer.

The reagent has been used as a method of producing thiols from halides by alkylation on sulfur followed by hydrolysis.[5] The initial alkylation proceeds best with activated halides such as benzylic halides or α-halo carbonyl compounds, although the conversion of bromocyclohexane to the corresponding thiol occurs in 70% yield. An example (eq 2) shows the compatibility and mildness of the reagent.[6] No β-elimination product was reported.

N-Methyl-*N*-(2-pyridyl)formamide

[67242-59-5] · $C_7H_8N_2O$ · *N*-Methyl-*N*-(2-pyridyl)formamide · (MW 136.17)

(formylating reagent for Grignard reagents[1] and certain organolithiums;[6] sequential addition of two Grignard reagents can provide unsymmetrical secondary alcohols[3])

Alternate Name: 2-(*N*-formyl-*N*-methyl)aminopyridine.

Physical Data: bp 71-72 °C/0.05 mmHg; *d* 1.137 g cm^{-3}.

Form Supplied in: colorless liquid; commercially available.

Analysis of Reagent Purity: IR, NMR.

Handling, Storage, and Precautions: moisture sensitive; irritant; should be kept under argon or nitrogen.

General Discussion.

N-Methyl-*N*-(2-pyridyl)formamide (**1**) is a good formylating reagent for certain organometallics. Dropwise addition of Grignard reagents to (**1**) provides good yields of aldehydes (eq 1).[1]

$$\mathrm{RM} \xrightarrow{(1)} \mathrm{RCHO} \qquad (1)$$

$$\mathrm{R = alkyl\ or\ aryl;\ M = MgBr}$$

Various Grignard reagents have been studied and yields are good to excellent. The formylation is effective and facile because of a six-membered chelate complex formed in situ; this inhibits further reaction at low temperature (eq 2).[1,2] On workup with aqueous acid the complex is protonated and dissociates to give the aldehyde and amine salt. The aldehyde is isolated by ether extraction, and the byproduct, 2-(methylamino)pyridine, can be recovered by

neutralization of the aqueous layer with sodium hydroxide and extraction with CH_2Cl_2. The amine can be economically recycled to (**1**) in 90% yield by formylation with a formic acid-acetic anhydride mixture.[3]

R = alkyl or aryl; M = MgBr

Using a modification of this methodology, unsymmetrical secondary alcohols can be synthesized via a one-pot reaction using two different Grignard reagents (eq 3).[3] Similarly, the vinyl Grignard reagent (**2**) has been formylated using the reagent (**1**) (eq 4).[4]

(3)

R^1 = alkyl or aryl; R^2 = alkyl or aryl

(4)

Using a one-pot reaction, a dithioester has been converted to a protected α-keto carbaldehyde using the reagent (**1**) (eq 5).[5] Heterocycles can be converted to their formyl derivatives by lithiation and reaction with (**1**) (eq 6).[6] The importance of the reagent (**1**) has been demonstrated by its application in natural product synthesis.[7]

1-Methyl-2-pyrrolidinone[1]

[872-50-4] · C_5H_9NO · 1-Methyl-2-pyrrolidinone · (MW 99.15)

(special solvent;[1] source of enolates[2])

Alternate Names: NMP; *N*-methylpyrrolidone.

Physical Data: mp -24.4 °C; bp 202 °C; *d* 1.030 g cm^{-3}.

Solubility: completely misc H_2O and virtually all organic solvents.

Form Supplied in: colorless liquid. *Drying:* dry over anhydrous K_2CO_3 and anhydrous cerium(IV) sulfate and purify by vacuum distillation through a 50 cm Vigreux column; or distill from CaH_2 and store over 4Å molecular sieves.

Handling, Storage, and Precautions: can be handled safely since it has a high flash point (95 °C), low vapor hazard, high boiling and low freezing points, and good chemical and thermal stability; hydrolyzed by 4% NaOH to the extent of 50-70% in 8 h. The lactam ring is cleaved when exposed to conc HCl for an extended period of time.

Solvent.

NMP is an effective solvent for both inorganic and organic compounds. H-bond basicity in tertiary amides is decreased more by bulky substituents on carbon than by bulky substituents on nitrogen.[3] Thus, the pK_{HB} values for DMF, NMP, and *N*-methyl-2-piperidinone are 2.10, 2.38, and 2.57, respectively. Some measure of the nucleophilicity of NMP is provided by the equilibrium constant for salt formation with trimethylsilyl triflate.[4] The K_{rel} of salt formation decreases in the order: 4-dimethylaminopyridine (32 800) > *N*-methyl-2-pyridone (182) > NMP (1.0) > DMF (0.81) > pyridine (0.10). NMP has advantages over both ***Dimethyl Sulfoxide*** and ***N,N-Dimethylformamide*** for nucleophilic displacement reactions because of its greater stability, and over ***Hexamethylphosphoric Triamide*** because of the lack of adverse physiological properties. NMP has superior properties for several nucleophilic disp lacement reactions:[5] 2- and 4-halo-1,8-naphthalic anhydrides and imides undergo very smooth aromatic substitution with *n*-butylamine, ***Copper(I) Cyanide***, and ***Sodium Methoxide***. The alkylation of lithioalkynes also works exceptionally well in NMP.[5]

Other nucleophilic substitutions have been explored: hydrolysis of halodaunomycinones to adriamycinones,[6] hydrolysis of primary alkyl iodides and bromides to alcohols,[7] and substitution of alkyl iodides and bromides with inorganic Li salts.[1b]

Alkylation of the carbanion from ethyl 6-methylsalicylate *O*-methyl ether[8] has been performed in NMP. The intramolecular nucleophilic displacement of halogen by the carbonyl oxygen of an acylsilane and subsequent cyclization to 2-silyldihydropyrans (eq 1) is accelerated in NMP.[9]

(1)

A simple, safe, and inexpensive synthesis of ***Cyanotrimethylsilane*** has been achieved from ***Chlorotrimethylsilane*** and metal cyanides in NMP (DMF and DMSO are not inert).[10] Some earlier experiments with TMSCN in situ failed. With NMP the product is distilled directly from the pot. The use of NMP raises the yield of the alkynic oxy-Cope rearrangement.[11] The catalytic conversion of ***Methyl Formate*** to ***Acetic Acid*** (eq 2) works best in NMP as solvent, with ***Palladium(II) Acetate*** as catalyst (<1%), and ***Lithium Iodide*** as promoter.[12]

(2)

NMP is also an effective solvent for the decarbonylation of aldehydes. At 110-130 °C in the presence of ***Chlorotris(triphenylphosphine)rhodium(I)***, simple aldoses are converted to the lower alditols. The decarbonylation of sugars has only recently been accomplished, probably for the lack of a compatible solvent.[13] The carbonylation of alkenes (1-decene) to aldehydes by a copper-based catalyst system gives the best yields with $CuCl/PPh_3$/NMP.[14] There are several advantages to using NMP as cosolvent for Cu^{II} catalyzed alkylation of organomanganese chloride reagents. The reactions are easier to perform, no excess of organometallics is required, and higher yields and better selectivity are observed (eq 3).[15]

(3)

The reducing power of telluride anion is enhanced in hot NMP.[16] Benzaldehydes and ketones are reduced to the corresponding alcohols (halogens in the molecule are displaced with telluride). Few byproducts are formed, since

Cannizzaro-type disproportionation does not occur. Aromatic nitriles are usually inert to Na_2Te, but in NMP they form 7-deaza-9*H*-purines (eq 4). ***Sodium Telluride*** in NMP is formed at 100-110 °C as a deep purple solution, whereas in DMF it forms a yellow suspension at 140 °C.

(4)

NMP as a Reagent.

Amidines formed from NMP exist as amidine-enediamine tautomers.[17] *C*-Michael addition leads to functionalized pyrrolidines (eq 5). The stereochemistry of Michael additions of amide or thioamide enolates to α,β-unsaturated ketones has been studied.[2] NMP is a model for an (*E*) lithium enolate (eq 6). Preferential 1,4-addition is observed. Oxo lactams give higher proportions of the *anti*-diastereomers, whereas thiolactams (softer enolates)[18] give mainly the *syn*-diastereomers.[2b] The preference for *syn*-isomers is better seen with K and Na enolates than with the Li analogs.

(5)

Enamine formation from NMP (unactivated lactam) with various Li reagents has been achieved.[19] The enolate of NMP reacts with many electrophiles to introduce functions into the 3-position of NMP. Thus nitroalkenyl,[20a] bromo,[20b] chloro,[20c] alkyl, allyl,[20a,d] nitro,[20c] and phosphonic acid[20f] derivatives can be formed.

Related Reagents.

3-Methyl-2-selenoxobenzothiazole

[2786-43-8] · C_8H_7NSSe · 3-Methyl-2-selenoxobenzothiazole · (MW 228.19)

(stereospecifically converts epoxides and episulfides into alkenes[1])

Physical Data: mp 114-116 °C.

Solubility: sol acetone, CH_2Cl_2, THF; slightly sol ether, ethanol; insol H_2O.

Form Supplied in: red solid; commercially available.

Handling, Storage, and Precautions: toxic; light sensitive; store in a dark glass bottle.

General Discussion.

The title reagent (**1**) reacts with epoxides in CH_2Cl_2 in the presence of stoichiometric quantities of ***Trifluoroacetic Acid*** at 0 °C to give the corresponding alkenes almost quantitatively. The method is rapid and stereospecific, proceeding in a fashion that preserves the stereochemistry of the starting epoxide (eq 1).[1] Episulfides react under the same conditions, though slowly, to afford alkenes stereospecifically (eq 2).[1] Another feature of these reactions is the quantitative recovery of selenium, which may be reused in the synthesis of the reagent.

(1)

(2)

The mildness of the reaction conditions allows the deoxygenation of epoxides bearing other functionalities, e.g. sugar epoxides (eq 3),[2] for which other reagents such as diphenylsilyllithium[3] or lithium diphenylphosphide[4] cannot be used. In some cases, the deoxygenation occurs with rearrangement (eq 4).[2]

(3)

(4)

The synthesis of valienamicin, a branched-chain amino cyclitol, requires a mild deoxygenation of epoxy cyclitol intermediates; this can be accomplished using (**1**) (eq 5).[5]

The reagent has also been used for deoxygenation of sterically crowded epoxides to give bicyclic trienes (eq 6).[6]

(5)

(6)

The related compound 3-methylbenzothiazole-2-thione (**2**) [*2254-94-6*] (mp 91-92 °C, also commercially available) converts epoxides to episulfides stereospecifically under the reaction conditions used for reagent (**1**) (eq 7).[7]

Methylsulfenyl Trifluoromethanesulfonate

[59259-48-2] · $C_2H_3F_3O_3S_2$ · Methylsulfenyl Trifluoromethanesulfonate · (MW 196.19)

(activator for formation of glycosidic linkages)

Solubility: prepared and used in 1,2-dichloroethane,[1] acetonitrile, or CH_2Cl_2.[1,2]

Form Supplied in: prepared and utilized in situ; no characterization is reported and the compound is not commercially available from the main chemical suppliers.

Preparative Methods: prepared by injecting methylsulfenyl bromide into a light-protected flask containing ***Silver(I) Trifluoromethanesulfonate*** dispersed in dry 1,2-dichloroethane. The resulting supernatant liquid is removed by syringe from the precipitated solids and utilized immediately. Alternatively, the reagent may be generated in situ by addition of methanesulfenyl bromide to a mixture of substrates and silver triflate in the presence of powdered 4Å molecular sieves.

Methylsulfenyl trifluoromethanesulfonate (**1**) is an activator in the thioglycoside-mediated formation of glycosidic linkages.[1-4] (**1**) mediates 1,2-*trans* glycosidation of thioglycosides (**2**) (eq 1) by providing a superior source of the sulfenyl cation; in the absence of silver triflate, sulfenyl bromides are not glycosidation mediators.[1]

Sialosides may be prepared efficiently using (**1**) (eq 2).[3,4] The high reactivity of (**1**) allows reaction at low temperature, which is essential to minimize side reactions. Trisaccharides may also be prepared in high yield by a similar method.[5] In these reactions, the use of a hindered amine base (such as ***Diisopropylamine***) prevents the formation of methylthioacetamides.

The same amine-modified activation process allows preparation of intermediates (**3**) crucial to the synthesis of highly complex ganglioside lactones such as GM_3 (eq 3).[6]

(+)-(*S*)-*N*-Methylsulfonylphenylalanyl Chloride

[63640-54-0] · $C_{10}H_{12}ClNO_3S$ · (+)-(*S*)-*N*-Methylsulfonylphenylalanyl Chloride · (MW 261.75)

(chiral reagent for the resolution of racemic alcohols via separation of the corresponding diastereomeric esters[1])

Physical Data: mp 84-85 °C; [α]20D +4.3° (*c* 1.6, THF).

Solubility: readily sol THF, benzene, ether.

Form Supplied in: pale yellow needles; not available commercially.

Preparative Method: prepared from (*S*)-phenylalanine by reaction with ***Methanesulfonyl Chloride***, followed by ***Phosphorus(V) Chloride***.[1b]

Purification: the crude compound can be recrystallized from hexane/ether.

Handling, Storage, and Precautions: best if prepared immediately prior to use. Can be stored at 0 °C under nitrogen for several days without appreciable decomposition.

Introduction.

Enantiomerically pure alcohols can frequently be obtained by physical separation of the diastereomeric esters prepared from the racemic alcohols and chiral acids.[2] Chiral acids that have been successfully employed for this purpose and are available in either enantiomeric form include o-camphanic acid[3] and the monomethyl ester of diacetyltartaric acid.[4] No reagent can be considered generally applicable to all alcohols, since the ease of separation of the diastereomeric esters frequently depends on their crystallinity and/or chromatographic properties. A successful resolution is frequently the result of multiple trials and errors with a variety of acids.

N-Sulfonylated α-Amino Acids.

N-Protected derivatives of the natural α-amino acids offer a wide range of potential derivatizing agents.[5] Particularly useful are *N*-arylsulfonyl-α-amino acids,[6] many of which are commercially available and produce crystalline ester mixtures from which pure diastereomers can often be isolated by recrystallization. *N*-Methylsulfonyl-α-amino acids or the corresponding acid chlorides are generally not commercially available, but in some cases have been shown to be superior to the corresponding *N*-tosyl derivatives (eq 1).[1b,7]

N-Methylsulfonylphenylalanyl chloride (**1**) is particularly useful in the derivatization of *meso*-diols. Mixtures of diastereomeric monoesters can be obtained, from which pure diastereomers are usually isolated by fractional recrystallization and/or chromatography. Chemical transformation of the free hydroxy group, followed by removal of the chiral auxiliary, allows the selective transformation of each prochiral hydroxy group. Isolation of the other diastereomeric ester from the mother liquors, followed by a series of protection-deprotection steps, provides the flexibility of converting 100% of the *meso*-material into one single enantiomer of the product. Alternatively, by rearranging the order of the chemical transformations, both enantiomers of the product can be obtained (eqs 2 and 3).[1,8]

2-Methyl-2-thiazoline

[2346-00-1] · C_4H_7NS · 2-Methyl-2-thiazoline · (MW 101.19)

(lithiation produces an acetaldehyde enolate equivalent for synthesis of mono-, di-, and trisubstituted acetaldehydes,[1,2] β-hydroxy aldehydes,[3] homoallylic alcohols,[3] and α,α-disubstituted β-ethylenic methyl ketones[4])

Alternate Name: 4,5-dihydro-2-methylthiazole.

Physical Data: bp 144.5-145 °C; *d* 1.067 g cm^{-3}.

Form Supplied in: commercially available.

Handling, Storage, and Precautions: no special precautions are warranted. Use in a fume hood.

General Discussion.

2-Methyl-2-thiazoline functions as a latent acetaldehyde equivalent. Lithiation with ***n-Butyllithium*** occurs at -78 °C to produce the thiazoline anion, which can be alkylated with a variety of electrophiles. Reductive hydrolysis of the thiazoline ring then releases the free monoalkylated acetaldehyde (eq 1).[2] Some examples of this methodology are given in Table 1.[2,5] Neutral conditions are employed (***Aluminum Amalgam***/***Mercury(II) Chloride***) for the release of the substituted acetaldehyde. ***Sodium Cyanoborohydride*** in MeOH/TsOH has been utilized instead of Al(Hg) for the reduction of the thiazoline ring to the thiazolidine ring.[6] A variety of methods have been used to convert the thiazolidines to aldehydes (e.g. I_2, MeOH).[7]

(1)

Table 1 Monosubstituted Acetaldehyde Formation

RX	Product	Yield (%)
		56
		53
		37
		77
		50

If the initially alkylated thiazoline is again metalated and alkylated, dialkylated acetaldehydes are formed (eqs 2-4).[2] Repeating this process (with ***Lithium Diisopropylamide*** as the base) results in trialkylated acetaldehydes (eq 5).[2]

(2)

(3)

(4)

(5)

Deuterated aldehydes are formed when the aluminum amalgam reduction is conducted in the presence of D_2O (eq 6).[2]

(6)

Treatment of 2-aminoethanethiol with alkyl cyanides results in cyclization to the corresponding thiazolines, which can take part in the above outlined protocol. For example, enantiomerically pure (+)-(*S*)-3-methylpentanenitrile can be converted to the thiazoline in 60% yield (eq 7).[8] Metalation and reaction with 2-iodomethyl-1,3-dioxolane affords the alkylated product in 68% yield. This differentially protected dialdehyde can be selectively deprotected.

(7)

Addition of the lithio salt of the title reagent to nitriles forms the corresponding enamino thiazoline which can, in principle, be hydrolyzed to β-keto aldehydes (eq 8).[9]

The lithio anion of 2-methyl-2-thiazoline undergoes 1,2-carbonyl addition to aldehydes and ketones.[3] Aldehyde liberation from the thiazoline then results in the corresponding β-hydroxy aldehydes (eq 9).

Due to the instability of β-hydroxy aldehydes, in situ methoxymethylation with ***Chloromethyl Methyl Ether*** (MOMCl) is necessary immediately after nucleophilic addition to the carbonyl carbon (eq 10).[3] The MOM group is resistant to the thiazoline cleavage conditions (i.e. Al(Hg) and $HgCl_2$).

These protected β-hydroxy aldehydes can be conveniently transformed into homoallylic alcohols by treatment with a Wittig reagent and then subsequent alcohol deprotection.[3] 2-Methyl-2-thiazoline has also successfully formed adducts with electrophilic species such as α-oxo ketene dithioacetals,[10] isotopically labeled alkyl halides,[11] and hydroxamates.[12]

1,2-Addition of allylic Grignard reagents to the imine double bond of 2-methyl-2-thiazoline (and derivatives) occurs with transposition of the allylic double bond in good yields (eq 11).[4] Thiazoline hydrolysis affords the two-carbon extended α,α-disubstituted β-ethylenic methyl ketones.

In addition to the title reagent, similar two-carbon extension synthons, such as ***2-Methylbenzothiazole*** (**1**)[13] and 4,5-dihydroimidazoles (e.g. **2**),[14,15] have been utilized in homologation procedures.

Methylthioacetylene

[10152-75-7] · C_3H_4S · Methylthioacetylene · (MW 72.14)

(synthesis of methylthioalkynes;[1] synthesis of methylthiocyclobutenes;[2] synthesis of heterocyclic compounds;[3] synthesis of vinyl sulfides[4] and carbonyl compounds)

Physical Data: bp 70 °C/760 mmHg; *n*20D ~1.485.

Solubility: sol organic solvents.

Form Supplied in: pale yellow to dark brown liquid.

Preparative Methods: by double elimination of HBr from the dibromide (obtained by bromination of methyl vinyl sulfide) (eqs 1 and 2).[5] The preparation of methyl vinyl sulfide from commercially available methylthioethanol has been described.[6] Methylthioacetylene has also been prepared by the reaction of sodium acetylide with sulfur followed by quenching of the resulting sulfide ion with methyl iodide.[7a]

Purification: distillation under nitrogen at atmospheric pressure.

Handling, Storage, and Precautions: should be used freshly distilled for best results (pale yellow). Since methylthioacetylene has limited thermal stability, distillation at normal pressure

should be carried out (under N_2) with relatively small amounts of material.

Reactions of Methylthioacetylene.

Functionalized methylthio-substituted alkynes can be prepared by deprotonation of methylthioacetylene and reaction of the resulting acetylide ion with an appropriate electrophile (eq 3).[1] An interesting thio-Claisen substrate can be constructed in this fashion (eq 4).[7b]

(3)

(4)

Methylthioacetylene participates in an asymmetric [2 + 2] cycloaddition with a fumarate amide derivative catalyzed by a chiral Ti^{IV} alkoxide to furnish a methylthiocyclobutene (eq 5).[2] Condensation of methylthioacetylene as the nucleophilic component with thiobenzoyl isocyanate provides a sulfur-containing heterocyclic structure (eq 6).[3] Finally, addition of a [(trimethylsilyl)methyl]copper(I) reagent to methylthioacetylene produces a bifunctional allylic silane (eq 7)[8] and condensation of methylthioacetylene as the electrophilic component with 2-(dialkylamino)arylacetonitriles gives rise to enamino allylic sulfides (eq 8).[9]

Vinyl Sulfides.

Regio- and stereoselective syntheses of functionalized methyl vinyl sulfides is accomplished by Pd^0-catalyzed hydrostannation (eq 9)[4a,b] and carbocupration (eq 10)[4c] of 1-methylthio-1-alkynes. In turn, vinyl sulfides are very useful intermediates in organic synthesis, not only as carbonyl-masking moieties[10] but also in a variety of other transformations[11] including the Ni^0-catalyzed cross-coupling reaction with Grignard reagents.[12] 1-Methylthio-1-alkynes can in principle be prepared by deprotonation of methylthioacetylene and subsequent reaction with an appropriate electrophile (e.g. eq 3).[13] However, the 1-methylthio-1-alkynes shown in eq 9 and eq 10 were prepared by the reaction of a metal acetylide derivative with either *S*-methyl methylthiosulfonate or dimethyl disulfide.[4b,14]

Methylthiomaleic Anhydride

[64810-01-1] · $C_5H_4O_3S$ · Methylthiomaleic Anhydride · (MW 144.16)

(2π partner in [4 + 2] cycloaddition reactions;[1] synthon for methoxycarbonylketene or methyleneketene[5])

Alternate Name: 3-(methylthio)-2,5-furandione.

Physical Data: mp 36-37 °C (ether); bp 123-125 °C/0.5 mmHg.

Analysis of Reagent Purity: IR 1845, 1745, 1566 cm^{-1}; ^1H NMR ($CDCl_3$) δ 6.28, 2.56; ^{13}C NMR ($CDCl_3$) δ 162.4, 162.1, 155.5, 118.5, 15.2.

Preparative Method: prepared by the addition of ***Methyl Isothiocyanate*** to acetylenedicarboxylic acid (ethanol, 25 °C) to afford a 6:1 mixture of 2-(methylthio)fumaric and -maleic acids, which are dehydrated by dissolution in ***Thionyl Chloride*** for 1 h at 25 °C, then 7 h at 60 °C. Excess $SOCl_2$ is removed at 120 °C at aspirator pressure, followed by distillation of the residue to afford the crystalline anhydride in 68-77% yield.[1]

Reactivity.

Methylthiomaleic anhydride (**1**) has been reported to react as a regioselective, *endo*-selective, electron-deficient 2π partner in [$_\pi4_s$ + $_\pi2_s$] cycloaddition reactions.[1]

Cycloaddition Reactions.[1]

Cycloadditions were carried out by mixing the neat dieneophile (**1**) with the appropriate diene at 0-80 °C in the presence of 2,6-di-*t*-butyl-4-methylphenol (BHT) or hydroquinone as a stabilizer. Exclusive *endo* selectivity was observed in the cycloaddition of cyclopentadiene with dienophile (**1**) to afford the bicyclo[2.2.1]heptene adduct (eq

1). Reaction of (**1**) with ***Isoprene*** afforded the cyclohexene adduct as a single regioisomer (eq 2). Similarly, a single regioisomeric cycloadduct was observed with (**1**) and 1-vinyl-6-methoxy-3,4-dihydronaphthalene (eq 3). The thiomethyl group[2] was postulated to be responsible for the excellent regiocontrol observed in cycloadditions of (**1**), since comparable cycloadditions with methylmaleic anhydride exhibited poor regioselectivity.[3]

(1)

(2)

(3)

Oxidative decarboxylation[4] of cycloadducts of (**1**) affords access to β-keto ester functionality. Treatment of the isoprene-(**1**) cycloadduct with methanol followed by ***N-Chlorosuccinimide*** afforded the corresponding dimethyl acetal, which could be hydrolyzed to afford the β-keto ester (eq 4).[1]

In bicyclic adducts (eq 1), thiol enol ethers are the direct products of oxidative decarboxylation; reduction of the ester and subsequent hydrolysis of the thiol enol ethers affords α-methylene ketones (eq 5).[5] Thus eqs (4) and (5) demonstrate the utility of (**1**) as a methoxycarbonylketene (**2**) or methyleneketene (**3**) synthon in [4 + 2] cycloaddition reactions.

N-(Methylthiomethyl)piperidine[1]

[7257-48-9] · $C_7H_{15}NS$ · *N*-(Methylthiomethyl)piperidine · (MW 145.30) (.HCl)

[7960-22-8] · $C_7H_{16}ClNS$ · *N*-(Methylthiomethyl)piperidine Hydrochloride · (MW 181.76)

(methylthiomethylating agent for 1,3-dicarbonyl compounds[1] and β-keto phosphonates[2])

Physical Data: bp 82 °C/12 mmHg;[3] *n*23D 1.5065;[2] .HCl mp 144-149 °C.[1]

Solubility: insol ether, hexane, benzene; sol CH_2Cl_2, $CHCl_3$, ethanol, methanol; slightly sol hot THF, hot dioxane.

Preparative Methods: ***Methanethiol*** gas (generated by adding conc. ***Sulfuric Acid*** (50 mL) to 15% aqueous sodium methanethiolate (150 mL)) is introduced to a soln of ***Piperidine*** (16 g) and 37% aqueous ***Formaldehyde*** (20 g) at 0 °C. As the reaction progresses an oil separates. The organic layer is extracted with ether, dried, and concentrated. The residual oil (19.5 g) is distilled to give *N*-(methylthiomethyl)piperidine; yield: 16.6 g (61%). An ethereal soln of this amine is added to ether saturated with hydrogen chloride to afford *N*-(methylthiomethyl)piperidine hydrochloride; yield 20 g (58% from piperidine). For alternative preparations, see Mikolajczyk and Balaczewski[2] and Böhme and Hafner.[3]

Handling, Storage, and Precautions: the hydrochloride is very hygroscopic and must be stored in the absence of moisture. The reagent is stable for a few years as long as it is kept in a tightly sealed vessel.

Methylthiomethylation.

Active methylene compounds are heated with the reagent hydrochloride in dioxane to give methylthiomethylated products. β-Diketones,[1,4] β-keto esters,[1] β-keto amides,[1] and β-keto phosphonates[2]

are α-methylthiomethylated in good yields. The closely related reagent *N*-(phenylthiomethyl)piperidine hydrochloride[5] may be used similarly to prepare α-phenylthiomethyl β-diketones (eqs 1 and 2).[4]

(1)

$R^1 = R, Ar; R^2 = R, Ar, OR, NR_2$

(2)

The α-methylthiomethyl β-diketones are useful intermediates for preparing unstable α-methylene β-diketones[1,4] via oxidation to the sulfoxide and thermal elimination,[6] as illustrated in eq 3.[1] The elimination reactions are conducted in refluxing toluene containing catalytic amounts of ***Calcium Carbonate***[1,4a,4b] or ***Acetic Acid***.[4c] These procedures were instrumental in the synthesis of α-methylene derivatives of acetal-protected aryl 1,3,5-triketones as intermediates in biogentic-type cyclizations producing fulvic acid and the 4*H*,5*H*-pyrano[3,2-*c*][1]benzopyran-4-one nucleus of citromycetin.[4a,4b]

Methylthiomethyl *p*-Tolyl Sulfone[1]

[59662-68-9] · $C_9H_{12}O_2S_2$ · Methylthiomethyl *p*-Tolyl Sulfone · (MW 216.35)

(synthetic reagent for acyclic ketones, cyclic ketones, and conjugated unsaturated ketones)

Alternate Names: MT-sulfone; formaldehyde methyl *p*-tolyl dithioacetal *S,S*-dioxide; methyl *p*-toluenesulfonylmethyl sulfide; methylthio(*p*-toluenesulfonyl)methane.

Physical Data: mp 82-83 °C; bp 164 °C/3 mmHg.

Solubility: sol DMF (87 g/100 mL), acetone (76 g/mL), $CHCl_3$ (57 g/mL), acetic acid (13 g/mL); slightly sol MeOH (5.8 g/mL), ethanol (3.3 g/mL), ethyl ether (3.0 g/mL), CCl_4 (2.2 g/mL); practically insol H_2O, hexane.

Form Supplied in: colorless crystals; commercially available. *Drying:* over P_2O_5 in a desiccator.

Preparative Method: conveniently synthesized from ***Dimethyl Sulfoxide*** in a one-pot reaction, i.e. Pummerer reaction of DMSO with ***Acetic Anhydride*** followed by treatment with ***RS111-***.[2]

Handling, Storage, and Precautions: very stable under alkaline, acidic, and neutral conditions. Handle in a fume hood.

Synthesis of Esters and Aldehydes.

Monoalkylation of methylthiomethyl *p*-tolyl sulfone (MT-sulfone) with an alkyl halide is achieved by the action of a phase-transfer catalyst (PTC) in toluene-50% aq NaOH.[3] ***Sodium Hydride***[3] and ***n-Butyllithium***[4] also generate a carbanion of MT-sulfone. Arylmethyl derivatives of MT-sulfone are prepared by ***Sodium Borohydride*** reduction of the Knoevenagel condensation products with aromatic aldehydes.[5] The monoalkylated products are converted into the corresponding methyl esters (eq 1).[3,6] This functionalization can be utilized for synthesizing α-alkoxy carboxylic esters (eq 2)[3] and α-amino acids (eq 3).[7]

(2)

Irradiation (254 nm) of the monoalkylated product in dioxane-H_2O hydrolyzes the dithioacetal *S*,*S*-dioxide to produce an aldehyde. This method is suitably applied to the preparation of aldehydes which are susceptible to acidic conditions (eq 4).[8]

The carbanion of MT-sulfone is stable enough to add to α,β-unsaturated carbonyl compounds in a [1,4] fashion. The (methylthio)(*p*-tolylsulfonyl)methyl group introduced is easily converted into a (methylthio)carbonyl group or a formyl group.[4]

Ketone Synthesis.

The monoalkylated MT-sulfone undergoes further alkylation by action of alkyl halide and NaH or *n*-BuLi to give a dialkylated product. Since the dialkylated product can be hydrolyzed easily, MT-sulfone has proven to be very useful for

synthesizing ketones (eq 5).[5,8,9] Symmetrical ketones are prepared by direct dialkylation with NaH and alkyl halide in DMF and hydrolysis (eq 6).[8] Cyclic ketones are also synthesized from α,o-dihaloalkanes.[3,10] An efficient synthesis of α-hydroxy ketones is also achieved by the addition of the monoalkyl derivative to an aldehyde to give an adduct and subsequent hydrolysis (eq 7).[11]

(5)

(6)

Acylation of MT-sulfone.

MT-sulfone was acylated by treatment with an ester and excess NaH in THF.[3,12,13] The acylated MT-sulfone was oxidized with ***Hydrogen Peroxide*** in ***Acetic Acid***, by slowly warming the reaction to give an *S*-methyl α-keto carbothioate (eq 8).[3]

An alkoxyacetyl derivative of MT-sulfone exhibits intriguing behavior on treatment with a weak base to form an acetal of 3-methylthio-2-oxopropanal (eq 9).[14]

(9)

Synthesis of α,β-Unsaturated Ketones.

Alkylidene derivatives of MT-sulfone are useful synthetic precursors for α,β-unsaturated ketones (eq 10).[15] This method can be extended to provide an efficient synthesis of α,β,γ,δ-unsaturated aldehydes and ketones (eq 11).[16,17]

(10)

Electrophilic (Methylthio)methylation.

Lewis acids such as ***Aluminum Chloride*** or ***Ethylaluminum Dichloride*** assist the heterolytic cleavage of the C-SO_2 bond of the dithioacetal *S,S*-dioxide to produce a MeS-stabilized carbocation, which reacts with allylsilanes[18] and benzene rings[19] (eq 12).

Reactivity of a 1-(Methylthio)-1-(*p*-tolylsulfonyl)-1-alkene.

1-(Methylthio)-1-(*p*-tolylsulfonyl)-1-alkenes show extremely high reactivity towards carbon radicals to provide a synthetic route leading to new types of 1-methylthio-1-(*p*-tolylsulfonyl)alkanes.[20,21] They also undergo nucleophilic epoxidation with ***Lithium t-Butoxide*** to give an α,β-epoxy-α-methylthio sulfone, a precursor for an α-bromo thiol ester (eq 13).[22]

(13)

Methyl Methylthiomethyl Sulfone.

Methyl methylthiomethyl sulfone is the *S*-methyl analog of MT-sulfone and it is conveniently synthesized by oxidation of methyl methylthiomethyl sulfoxide (FAMSO) with ***Potassium Permanganate*** or H_2O_2-NaOH.[23] It is useful for synthetic methods similar to those using MT-sulfone: synthesis of carboxylic esters,[24] ketones,[25] and α-alkoxy-α-arylacetates.[26] In the reaction of this reagent with allylic bromides, α-methylthio-γ,δ-unsaturated sulfones are obtained by stirring the bromide with ***Potassium Carbonate*** and ***Potassium Iodide*** in ***Hexamethylphosphoric Triamide*** (eq 14), which does not occur with MT-sulfone.[24]

N-Methylthionomaleimide

[141707-79-1] · C_5H_5NOS · *N*-Methylthionomaleimide · (MW 127.18)

(dienophile which reacts at the ring double bond;[1] some regioselectivity with unsymmetrical dienes[1])

Physical Data: mp 44-44.5 °C.

Solubility: sol most organic solvents.

Form Supplied in: volatile purple crystals; not commercially available.

Preparative Method: reaction of *N*-methylmaleimide with Lawesson's reagent (***2,4-Bis(4-methoxyphenyl)-1,3,2,4-dithiadiphosphetane 2,4-Disulfide***) under carefully controlled conditions.[1]

Handling, Storage, and Precautions: stable for several months in the freezer; decomposes to yellow crystals at ambient temperature in the presence of light and air.

Introduction.

This is the first thiocarbonyl analog of maleimide with no substituents on the ring carbons. Its use as a dienophile in [4 + 2] reactions has been studied.

Chemoselectivity.

Previously reported thiocarbonyl analogs of maleimide undergo [4 + 2] reactions with a variety of dienes to give reaction at the thiocarbonyl function.[2] *N*-Methylthionomaleimide (**1**) reacts predominantly at the ring unsaturation. Reaction with 2,3-dimethylbutadiene in various solvents leads almost exclusively to the adduct (**2**) (Table 1). Only when reacted in 5 M ethereal ***Lithium Perchlorate***[3] was a significant amount of the adduct (**3**) produced (eq 1).

Table 1 Cycloaddition of (**1**) with 2,3-Dimethylbutadiene (eq 1)

Solvent	Temp. (°C)	Reaction time	Product ratio (**2**):(**3**)	Total yield (%)
Toluene	70	5 h	100:0	87
Toluene	rt	3 week	100:0	85
CH_2Cl_2	rt	32 h	90:10	85
$CHCl_3$	rt	32 h	93:7	81
$MeNO_2$	rt	32 h	95:5	88
$LiClO_4$/ether	rt	10 min	44:56	62

Regioselectivity.

Some degree of regioselectivity can be expected in using (**1**) as a dienophile. Reaction of (**1**) with 1-methoxy-1,3-cyclohexadiene (**4**) in toluene at 70 °C gave a 2:1 mixture of the *endo* adducts (**5**) and (**6**) (eq 2). Using ethereal $LiClO_4$ as solvent improved the ratio to 85:15. Reaction with Danishefsky's diene (**7**) gave adduct (**8**) as the only isolated product in

56% yield (eq 3).

(*E*)-3-Methylthio-2-propenyl *p*-Tolyl Sulfone[1]

[92610-41-8] · $C_{11}H_{14}O_2S_2$ · (*E*)-3-Methylthio-2-propenyl *p*-Tolyl Sulfone · (MW 242.39)

(a synthetic reagent for preparation of α,β-unsaturated aldehydes and ketones)

Alternate Names: MTPTS; (*E*)-1-methylthio-3-(*p*-toluenesulfonyl)-1-propene.

Physical Data: colorless crystals; mp 79-80 °C (from EtOH).

Solubility: sol DMF, $CHCl_3$; slightly sol MeOH, EtOH, diethyl ether, CCl_4; practically insol H_2O, hexane.

Preparative Methods: either by the reaction of sodium methanethiolate or dimethyl sulfide with 3-chloro-1-propenyl *p*-tolyl sulfone[2] or by α-selenylation of 3-(methylthio)propyl *p*-tolyl sulfone and subsequent oxidative dehydroselenylation.[3]

Handling, Storage, and Precautions: very stable at ambient temperature. Use in a fume hood.

Synthesis of α,β-Unsaturated Aldehydes.

Monoalkylation of MTPTS can be achieved by treatment with an alkyl halide in the presence of ***Potassium Hydroxide***-TOMAC (a phase-transfer catalyst) or ***Sodium Hydride*** in DMF.[4] The reaction of the monoalkylation product with ***Titanium(IV) Chloride*** and ***Copper(II) Chloride*** in acetic acid-water followed by treatment with ***Potassium Carbonate*** in DME affords α,β-unsaturated aldehydes (eq 1).

(E)-3-Methylthio-2-propenyl p-Tolyl Sulfone

The second alkylation of MTPTS also occurs regiospecifically at the carbon α to the sulfonyl group. Since the dialkylated product is sensitive to silica gel, the reaction mixture is subjected without purification to hydrolysis with $TiCl_4$ and $CuCl_2$ in acetic acid-water to yield directly the corresponding β,β-disubstituted α,β-unsaturated aldehyde (eq 2).

Synthesis of α,β-Unsaturated Ketones.

The dialkylated MTPTS undergoes a facile 1,3-rearrangement of its sulfonyl group on silica gel and a thermodynamically stable 2-alkenal dithioacetal *S,S*-dioxide is produced.[5] Since it has an active proton, the rearrangement product can be further alkylated. Subsequent hydrolysis of the alkylated product with $CuCl_2$ in methanol-water produces α,β-unsaturated ketones (eq 3). The synthetic method using MTPTS is characterized by its wide applicability to make various α,β-unsaturated ketones, three substituents of which are optionally and regiospecifically selected.

2-(Methylthio)tetrahydrofuran

[98194-87-7] · $C_5H_{10}OS$ · 2-(Methylthio)tetrahydrofuran · (MW 118.22)

(methanethiol carbanion, $HSCH_2^-$, equivalent[1])

Physical Data: bp 66-67 °C/21 mmHg; *n*20D 1.4868.[2]

Preparative Methods: conveniently prepared in two steps in 46% yield from THF by light-initiated α-chlorination with ***Sulfuryl Chloride*** at -30 °C followed by reaction with ***Methanethiol***/***Triethylamine*** at -78 °C.[2] Deprotonation with ***n-Butyllithium*** gives 2-tetrahydrofuranyl(thiomethyl)lithium *[98194-88-8]*.[1]

Thiol and Disulfide Synthesis.

Reaction of 2-tetrahydrofuranyl(thiomethyl)lithium with ***t-Butyldimethylchlorosilane***, followed by *n*-BuLi and a second equivalent of *t*-butyldimethylchlorosilane followed by hydrolysis of the adduct with ***Silver(I) Nitrate*** or ***Mercury(II) Chloride*** followed by ***Hydrogen Sulfide*** or ***Hydrogen Chloride*** gives bis(*t*-butyldimethylsilyl)methanethiol ($(t\text{-}BuMe_2Si)_2CHSH$; 91%) (eq 1).[1]

Related Reagents.

2-(Methylthio)tetrahydropyran.

2-(Methylthio)tetrahydropyran

[31053-11-9] · $C_6H_{12}OS$ · 2-(Methylthio)tetrahydropyran · (MW 132.25)

(methanethiol carbanion, $HSCH_2^-$, equivalent[1])

Physical Data: bp 47-48 °C/5 mmHg;[2] *n*20D 1.4910;[3] colorless oil with minty aroma.

Preparative Methods: prepared in 84% yield by ***Pyridinium p-Toluenesulfonate***-catalyzed addition of ***Methanethiol*** to 2,3-dihydropyran;[1] this method is superior to an earlier procedure using HCl as catalyst.[2] Deprotonation with ***t-Butyllithium*** gives 2-tetrahydropyranyl(thiomethyl)lithium *[98194-89-9]*.[1]

Handling, Storage, and Precautions: stable to alkali; decomposed by dilute acid to methanethiol and 5-hydroxypentanal.[2]

Thiol and Disulfide Synthesis.

Reaction of 2-tetrahydropyranyl(thiomethyl)lithium with benzaldehyde, *n*-heptyl iodide, 1,6-dibromohexane, ***Benzyl Bromide***, ***t-Butyldimethylchlorosilane***, or ***Dichlorodimethylsilane***, followed by hydrolysis of the adduct with ***Silver(I) Nitrate*** or ***Mercury(II) Chloride*** followed by ***Hydrogen Sulfide*** or ***Hydrogen Chloride*** gives, respectively, $PhCH(OH)CH_2SH$ (100%), *n*-$C_8H_{17}SH$ (60%), $HS(CH_2)_8SH$ (76%), $PhCH_2CH_2SH$ (93%), *t*-$BuMe_2SiCH_2SH$ (77%), and $Me_2Si(CH_2SH)_2$ (22%). If the adduct is treated instead with iodine, disulfides instead of thiols result.[1] Repetitive treatment of the initial adduct with base and electrophile has been used to prepare $(Me_3Si)_3CSH$.[1] Application of these procedures to the synthesis of *cis*- and *trans*-3-mercaptocyclobutanol has been reported (eq 1).[4] Related work has been reported for the tetrahydropyran derivative of diphenylmethanethiol.[5]

(Methylthio)trimethylsilane

[3908-52-2] · $C_4H_{12}SSi$ · (Methylthio)trimethylsilane · (MW 120.32)

(thioacetalization under neutral conditions;[1,2] cleavage of ethers[3,4])

Physical Data: bp 110-114 °C; *d* 0.848 g cm^{-3}.

Solubility: sol organic solvents (CH_2Cl_2, benzene, acetonitrile, ether).

Form Supplied in: colorless liquid; commercially available.

Preparative Method: prepared as described by Evans et al.[14]

Handling, Storage, and Precautions: the reagent is sensitive to moisture and incompatible with strong oxidizing agents. Should be used in a well-ventilated fume hood.

Carbonyl Protection.

The Lewis acid-catalyzed reaction of aldehydes and ketones with (methylthio)trimethylsilane gives rise to the corresponding thioacetals (eq 1).[1,2] Selective thioacetalization can be achieved with this reagent (eq 2).[1] The reaction with α,β-unsaturated aldehydes and ketones leads to the formation of the 1,4-addition product.

(1)

Cleavage of Acyclic and Cyclic Ethers.

Acyclic ethers are readily cleaved by (methylthio)trimethylsilane (eq 3).[3] In contrast to ***Iodotrimethylsilane***, esters are unaffected under the reaction conditions. The reagent is also compatible with acetals and amides.[4] The zinc chloride-catalyzed reaction of oxetanes with (methylthio)trimethylsilane leads to the formation of ring-opened products (eq 4).[5] No reaction takes place in the absence of ***Zinc Chloride***.

Vinyl Sulfides.

A general route to vinyl sulfides has been achieved through the reaction of thiosilanes with silyl enol ethers in the presence of ***Boron Trifluoride Etherate*** (eq 5).[6]

(5)

Miscellaneous Transformations.

The reaction of Me_3SiSMe with glycopyranoses leads to the stereoselective formation of 1-thioglycosides (eq 6).[7,8] When primary nitro compounds are treated sequentially with ***n-Butyllithium*** followed by Me_3SiSMe, the corresponding thiohydroximates are produced in good yields (eq 7).[9] 4-Sulfinylazetidin-2-ones undergo a novel substitution reaction with silylated heteronucleophiles in the presence of a catalytic amount of ***Zinc Iodide*** (eq 8).[10,11] When propenoyltrimethylsilane is treated with Me_3SiSMe, the synthetically useful silyl enol ethers of acylsilanes are formed (eq 9).[12] Orthothioesters are formed when esters are treated with Me_3SSiMe and ***Aluminum Chloride***.[13]

Methyltitanium Trichloride[1]

$MeTiCl_3$

[2747-38-8] · CH_3Cl_3Ti · Methyltitanium Trichloride · (MW 169.27)

(nonbasic nucleophilic reagent with high Lewis acidity;[1,2] adds to aldehydes, ketones, and acetals with high chemo- and stereoselectivity;[1,2] reagent for the S_N1 substitution of tertiary halides[3] and the geminal dimethylation of carbonyl compounds[4,5])

Alternate Names: trichloromethyltitanium; methyltitanium(IV) trichloride.

Physical Data: mp 29 °C; bp 37 °C/1 mmHg.

Solubility: sol most commonly used aprotic solvents, including pentane, Et_2O, THF, CH_2Cl_2. Forms octahedral complexes with bidentate ligands such as glycol ethers, ethylenediamines, and diphosphines as well as with solvents such as Et_2O and THF.

Form Supplied in: purple crystals; not available commercially.

Analysis of Reagent Purity: ^1H NMR: 2.9 ppm (s).

Preparative Methods: $MeTiCl_3$:[6] ether-free reagent, suitable for chelation-controlled carbonyl additions and S_N1 substitutions, can be prepared from a 2:1 mixture of ***Titanium(IV) Chloride*** and Me_2Zn[5] in CH_2Cl_2 at -78 °C. The resulting solution can be used as is or distilled under vacuum. A 1:1 mixture of $TiCl_4$ and Me_2Zn produces ***Dichlorodimethyltitanium***, which is more effective for S_N1 substitutions.[5] MeLi-$TiCl_4$-Et_2O:[2] solutions of $MeTiCl_3$ in Et_2O can be more conveniently prepared from ***Methyllithium*** and $TiCl_4$. Other organometallics, such as ***Methylmagnesium Bromide***, can also be used. In the workup, simple quenching with ice water is preferred. The use of ***Sodium Carbonate*** may lead to cumbersome emulsions of TiO_2, which can be avoided with NH_4F or ***Potassium Fluoride***.

Handling, Storage, and Precautions: moisture sensitive; stable at low temperature in the dark. At rt, it decomposes over several hours. Me_2Zn is very pyrophoric in a pure form.

Organotitanium Reagents.

While many titanium compounds are used widely as key components of Ziegler-Natta polymerization catalysts,[1a,1c] a variety of organotitanium derivatives have found great utility in organic synthesis as well. Compounds of the general type R^1TiX_3 (X = Cl, OR^2, or NR^3_2), studied extensively by Reetz and others,[1] often add to carbonyl groups with a high degree of chemo-, regio-, diastereo-, and enantioselectivity as compared with organomagnesium (RMgX, Grignard) or organolithium reagents (RLi). The synthetic advantages of these organotitanium reagents arise from the modulation of their nucleophilicity and Lewis acidity and basicity, as well as their improved solubility in organic solvents, and their increased steric and electronic requirements. Among the various commonly used derivatives, $MeTiCl_3$ is the most Lewis acidic, while ***Methyltitanium Triisopropoxide*** is the least acidic. Other homologs of type $RTiCl_3$ are more difficult to prepare and have found only limited synthetic use. The similar reagent Me_2TiCl_2 is more nucleophilic than $MeTiCl_3$ and is more effective for S_N1 substitutions.[5]

Chemoselective Addition to Aldehydes and Ketones.

$MeTiCl_3$ reacts quickly with aldehydes at low temperatures, while similar reactions with ketones require higher temperatures. Among other related organometallics, $MeTiCl_3$ exhibits one of the highest levels of aldehyde selectivities (eq 1).[2] In the presence of phosphines, however, an in situ blocking of the aldehyde group allows the reagent to react selectively with ketones in the presence of aldehydes.[7]

(1)

$MeTiCl_3$	99: 1
$MeTi(O\text{-}i\text{-}Pr)_3$	85:15
$MeZrCl_3$	74:26
MeLi	70:30

In general, $MeTiCl_3$ shows higher reactivity towards ketones than $MeTi(O\text{-}i\text{-}Pr)_3$. Discrimination between different ketones is also most effective with this reagent (eq 2).[2]

$MeTiCl_3$	99: 1
$MeTi(O\text{-}i\text{-}Pr)_3$	97: 3
MeLi	39:61

A wide variety of functional groups are tolerated under the reaction conditions, including ester, cyano, or nitro groups (eq 3).[2]

$MeTiCl_3$	76%
$MeTi(O\text{-}i\text{-}Pr)_3$	15%

Being the least basic, $MeTiCl_3$ is the reagent of choice for the addition of methyl groups to highly enolizable ketones (eq 4).[2]

$MeTiCl_3$	90%
MeLi	60%

Stereoselective Additions to Aldehydes and Ketones.

The reagent, formed in situ from the combination of MeLi and $TiCl_4$ in Et_2O, adds to chiral aldehydes according to Cram's rule with higher stereoselectivity than ether-free preformed $MeTiCl_3$ or even $MeTi(O\text{-}i\text{-}Pr)_3$ (eq 5).[2,8]

(5)

$MeTi(OPh)_3$	93: 7
$MeZr(O\text{-}i\text{-}Pr)_3$	90:10
$MeLi\text{-}TiCl_4\text{-}Et_2O$	90:10
$MeTi(O\text{-}i\text{-}Pr)_3$	88:12
$MeTiCl_3$	81:19
MeMgBr	66:34
MeLi	65:35

The addition of ether-free $MeTiCl_3$ to α-alkoxy aldehydes proceeds with chelation control[9] and high diastereofacial selectivity, while $MeTi(O\text{-}i\text{-}Pr)_3$ exhibits the opposite selectivity (eq 6).[10,11] The postulated titanium chelates have been observed directly by ^{13}C NMR spectroscopy.[11]

(6)

$MeTiCl_3$	92: 8
$MeTi(O\text{-}i\text{-}Pr)_3$	8:92

Similar chelation control with 1,3-asymmetric induction takes place with β-alkoxy aldehydes (eq 7).[12]

(7)

90:10

Although preformed $MeTiCl_3$ and the combination of Me_2Zn-$TiCl_4$ often behave similarly, in some cases they exhibit significantly different diastereofacial selectivities (eq 8).[13]

(8)

$MeTiCl_3$	140: 1
Me_2CuLi	80:20
Me_2Zn-$TiCl_4$	68:32
$MeTi(O\text{-}i\text{-}Pr)_3$	58:42
MeLi	58:42
MeMgCl	37:63
MeMgCl-$ZnBr_2$	22:78
Me_2CuLi-Et_3B	15:85

Chelation of $MeTiCl_3$ with neighboring sulfur groups is also possible (eq 9).

(9)

$MeTiCl_3$ adds efficiently and stereoselectively to the carbonyl group of β-keto sulfoxides, despite the facile enolization of these compounds. Presumably this process involves chelation with the sulfoxide oxygen (eq 10).[14]

(10)

$MeTiCl_3$, Et_2O	96%	97: 3
Me_2Al, PhMe	71%	13:87

Additions to Acetals.

$MeTiCl_3$ reacts readily with acetals at low temperature even in the presence of ketones. With chiral acetals, the reaction is highly stereoselective (eq 11).[15]

(11)

S_N1 Methylation of Tertiary Alkyl Halides.

The high Lewis acidity of $MeTiCl_3$ and the related derivative Me_2TiCl_2, obtained from $MeTiCl_3$ or Me_2Zn and 1 equiv of $TiCl_4$, makes them suitable for the S_N1 substitution of tertiary chlorides (eq 12)[3] or bromides (eq 13).

Primary or secondary halides do not undergo this reaction, which presumably proceeds via a carbocation.

(12)

(13)

Geminal Dimethylation of Carbonyl Compounds.

Reaction of ketones with $MeTiCl_3$, or more effectively with Me_2TiCl_2[16,17] or Me_2Zn-$TiCl_4$,[5] gives the corresponding geminal dimethyl derivatives directly[4] (eq 14).[16] This process presumably involves an initial addition to the carbonyl followed by ionization and S_N1 substitution by a second methyl group.

(14)

When a combination of Me_2Zn and $TiCl_4$ is used in this reaction, the geminal dimethylation products are maximized when at least 2 equiv of each is utilized.[5] Otherwise, the corresponding tertiary alcohol or tertiary chloride are obtained as major products (eq 15).[5]

(15)

$TiCl_4$ (equiv)	Me_2Zn (equiv)	X
1	1	OH
3	1	Cl
2	2	Me

The reaction works well with a variety of aliphatic and aromatic ketones, with the exception of α,β-unsaturated derivatives, which give a mixture of products. It is even possible to generate adjacent quaternary carbons in this manner (eq 16).[5]

(16)

Although aliphatic aldehydes give alcohols under these reaction conditions, aromatic aldehydes undergo geminal dimethylation to form isopropyl derivatives (eq 17).[17]

(17)

Similarly, acid chlorides undergo a direct geminal trimethylation (eq 18).[5]

Methyltitanium Triisopropoxide[1]

$MeTi(O\text{-}i\text{-}Pr)_3$

[18006-13-8] · $C_{10}H_{24}O_3Ti$ · Methyltitanium Triisopropoxide · (MW 240.22)

(nonbasic nucleophilic reagent;[1] adds to aldehydes and ketones with very high chemo-[1,2] and stereoselectivity;[1,3] adds to lactols stereoselectively[4,5])

Alternate Names: methyltriisopropoxytitanium; methyltitanium tris(isopropoxide); methyltris(2-propanolato)titanium; triisopropoxymethyltitanium.

Physical Data: bp 50 °C/0.01 mmHg; mp 10 °C.

Solubility: miscible with most nonprotic organic solvents, e.g. Et_2O, THF, CH_2Cl_2, toluene. In dilute solutions it is mainly monomeric, while in more concentrated solutions some degree of aggregation occurs.

Form Supplied in: bright yellow liquid; not available commercially.

Analysis of Reagent Purity: ^1H NMR in C_6D_6: 4.61 (m, 3H); 1.26 (d, 18H); 0.98 (s, 3H).

Preparative Methods: pure reagent can be prepared by the addition of a solution of ***Methyllithium*** in Et_2O to an equimolar amount of ***Chlorotitanium Triisopropoxide*** or ***Titanium Tetraisopropoxide*** in Et_2O at -40 °C followed by warming to rt.[2] It can be isolated in excellent yields by removal of the solvent in vacuo and distillation. For carbonyl additions[6] the reagent can be prepared in situ from MeLi and $ClTi(O\text{-}i\text{-}Pr)_3$ (which can be prepared in situ from a 3:1 mixture of $Ti(O\text{-}i\text{-}Pr)_4$ and ***Titanium(IV) Chloride***). The yields from these in situ methods are essentially the same as when purified reagent is employed.

Handling, Storage, and Precautions: moisture and air sensitive. Under N_2 it can be kept in the refrigerator for weeks; at rt it decomposes into a deep blue-green liquid over 12 h.

Organotitanium Reagents.

The nucleophilic addition of alkyl groups to aldehydes and ketones to give alcohols is traditionally performed with organomagnesium (RMgX, Grignard) or organolithium reagents (RLi). The conversion of these carbanion equivalents to derivatives of the general type R^1TiX_3 (X = Cl, OR^2, or NR^3_2) often results in significant improvements in the chemo-, regio-, diastereo-, and enantioselectivity of these processes.[1] Consequently, these organotitanium compounds

have found widespread synthetic utility, beyond their traditional use as components of Ziegler-Natta polymerization catalysts.[1a,1b] The synthetic advantages of these reagents are derived not only from the modulation of their nucleophilicity and Lewis basicity, but also through their improved solubility in organic solvents and their increased steric and electronic requirements. In the case of MeTi(O-*i*-Pr)$_3$, the three bulky alkoxy substituents on the titanium prevent oligomerization and dramatically reduce its Lewis acidity, which decreases in the following order: ***Methyltitanium Trichloride*** > MeTiCl$_2$(O-*i*-Pr) > MeTiCl(O-*i*-Pr)$_2$ > MeTi(O-*i*-Pr)$_3$. Similarly to other organotitanium reagents, MeTi(O-*i*-Pr)$_3$ exhibits much higher chemo- and stereoselectivity than MeLi or ***Methylmagnesium Bromide***.

Chemoselective Additions to Aldehydes and Ketones.[2,7]

MeTi(O-*i*-Pr)$_3$ adds readily to aldehydes in a 1,2-fashion, under mild conditions (-50 °C to 22 °C, over 2-3 h), forming methyl addition products in high yields. It also has low basicity and tolerates a wide variety of functional groups. While the reagent does not add to the carbonyl group of esters, it can promote transesterification to the isopropyl esters. Surprisingly, a similar reaction takes place with acyl chlorides, which are also converted to isopropyl esters. Other functional groups, such as epoxides, alkyl halides, amides, cyano or nitro substituents, do not interfere with the carbonyl addition process (eq 1).[6] The use of MeLi or MeMgBr in these cases gives complex mixtures and low yields of the alcohols.

(1)

The reagent reacts with aldehydes at much faster rates than with ketones (up to 10^5:1) and it can be used for the selective addition to aldehydes in the presence of ketones[7] (eq 2).[2]

(2)

The reagent is highly regioselective and is sensitive to both steric and electronic effects. Among two aldehydes or two ketones, it adds to the least hindered one with a high degree of preference.[2] The order of relative reactivity for selected carbonyls is shown in eq 3.[8]

Other reagents of the general type RTi(O-*i*-Pr)$_3$, exhibit analogous selectivities, adding preferentially to the least hindered carbonyls.[9] The reverse selectivity can be achieved via the in situ protection of the least hindered group with a bulky organoaluminum reagent (eq 4).[10]

Stereoselective Additions to Aldehydes and Ketones.

The addition of MeTi(O-*i*-Pr)$_3$ to carbonyl groups proceeds according to Cram's rule (Felkin-Anh model), but with enhanced stereoselectivities. Although other reagents can be slightly more selective, overall MeTi(O-*i*-Pr)$_3$ is often the reagent of choice (eq 5).[1c,1f,3]

MeTi(OPh)$_3$	93:7
MeZr(O-*i*-Pr)$_3$	90:10
MeLi-TiCl$_4$-Et$_2$O	90:10
MeTi(O-*i*-Pr)$_3$	88:12
MeTiCl$_3$	81:19
MeMgBr	66:34
MeLi	65:35

Although the addition of several organometallics (particularly MeTiCl$_3$) to chiral α- or β-alkoxy aldehydes often proceeds via chelation control,[1h,11] the reactions of MeTi(O-*i*-Pr)$_3$ tend to take place without chelation[8] and with high diastereoselectivity in the opposite sense (eq 6).[12]

MeTi(O-*i*-Pr)$_3$	7:93
MeLi · LiBr	45:55
MeMgBr	45:55
Me$_2$CuLi	47:53
MeCu · MgBr$_2$	96:4

Despite its low Lewis acidity, however, the additions of MeTi(O-*i*-Pr)$_3$ to ketones with neighboring chelating substituents proceed with rate-accelerating chelation,[1h,8,11] giving tertiary alcohols with a high degree of stereocontrol

(eq 7),[13] including remote asymmetric induction.[14]

Additions to cyclohexanones take place preferentially from the equatorial direction, even with conformationally labile substrates (eq 8).[3]

Stereoselective Additions to Lactols.

MeTi(O-*i*-Pr)$_3$ is the reagent of choice for the stereoselective addition to lactol derivatives (eqs 9 and 10).[4,5] These reactions presumably involve chelated alkoxytitanium intermediates.[4,5,15,16]

(9)

$MeTi(O\text{-}i\text{-}Pr)_3$	12:1
$MeTiCl_3$	8.4:1
MeLi	1.7:1
MeMgBr	1.3:1
Me_3Al	1.1:1

(10)

Copper-Catalyzed S_N2' Alkylations.

Although the $RTi(O\text{-}i\text{-}Pr)_3$ reagents generally behave as poor nucleophiles, in the presence of catalytic amounts of copper salts they react with allyl halides or phosphonates exclusively in an S_N2' manner (eq 11).[17]

Methyltitanium Tris(diethylamide)[1]

$MeTi(NEt_2)_3$

[25483-56-1] · $C_{13}H_{33}N_3Ti$ · Methyltitanium Tris(diethylamide) · (MW 279.37)

(thermally stable reagent useful for alkylative amination of carbonyl compounds[2])

Physical Data: mp 5 °C.

Solubility: sol Et_2O.

Form Supplied in: not available commercially.

Analysis of Reagent Purity: ^1H NMR in C_6D_6: 3.71 (q, 12H); 1.25 (t, 18H); 0.43 (s, 3H).

Preparative Methods: a solution of ***Methyllithium*** (or ***Methylmagnesium Bromide***) in Et_2O is added slowly to a stirred equimolar solution of ***Chlorotris(diethylamino)titanium***[3] or $BrTi(NEt_2)_3$ in Et_2O at -30 °C. After 0.5 h at -30 °C and 1 h at rt, the yellow solution can be used as is[2,4] or can be isolated[5] by sublimation at 60-70 °C/0.001 mmHg.

Handling, Storage, and Precautions: moisture sensitive; thermally stable.

Organotitanium Reagents.

The use of titanium compounds as components of Ziegler-Natta polymerization catalysts[1b,1c] has led to the preparation of numerous organotitanium derivatives that have found other synthetic applications as well.[1d] Among the various titanium ligands the dialkylamido groups produce the least acidic and most thermally stable organotitanium species, presumably due to stronger electron donation and larger steric hindrance. Thus, while ***Methyltitanium Trichloride*** and ***Methyltitanium Triisopropoxide*** decompose at rt over several hours, $MeTi(NEt_2)_3$ is thermally stable at rt and decomposes at temperatures above 120 °C.[6]

Alkylative Amination.

Nonenolizable aldehydes react with $MeTi(NEt_2)_3$ to give tertiary amines through the addition of both the methyl group and one of the NEt_2 ligands. The reaction works in moderate yields with aliphatic (eq 1),[2] aromatic, and α,β-unsaturated aldehydes (eq 2).[2] The reaction proceeds via the initial addition of the amino group to the carbonyl, followed by the formation of an iminium intermediate which undergoes nucleophilic attack by the methyl group. The yields are lowered by a competitive formation of diamine or enamine products (with enolizable aldehydes). Both of these hydrolyze back to the starting material during the acidic aqueous workup.

(1)

(2)

This reaction also works with the corresponding perfluoroalkyl derivatives (eq 3).[7]

(3)

Additions to Aldehydes.

Unlike $MeTiCl_3$ and $MeTi(O\text{-}i\text{-}Pr)_3$, which carry out Grignard-type additions to aldehydes and ketones, $MeTi(NEt_2)_3$ is not suitable for this type of reaction since the diethylamide group adds to the carbonyl faster than the methyl group. However, with $RTi(NEt_2)_3$ derivatives of more reactive carbon nucleophiles, such as $CH_2{=}CHCH_2Ti(NEt_2)_3$, the carbonyl additions can be efficient (eq 4).[4]

[137694-00-9]

(chiral auxiliary: *N*-enoyl derivatives undergo highly stereoselective Diels-Alder reactions with cyclopentadiene[2] and 1,3-dipolar cycloadditions with nitrile oxides;[3] enolates of *N*-acyl derivatives participate in highly stereoselective alkylations, acylations, and aldolizations[4])

Physical Data: (**1a**) mp 92 °C. (1´*S*)-(**1a**) [α]20D -30.0° (*c* 1.21, $CHCl_3$). (1´*R*)-(**1a**) [α]20D +31.0° (*c* 0.6, EtOH). (**1b**) mp 129-130 °C. (1´*S*)-(**1b**) [α]20D -53.9° (*c* 1.00, $CHCl_3$). (**1b**) has been incorrectly assigned.[3]

Preparative Methods: both enantiomers of the α-methyl sultam may be prepared on a multigram scale in optically pure form by asymmetric hydrogenation of imine (**2a**) followed by simple crystallization (eq 1).[5] The (*R*)-enantiomer of the α-*t*-butyl sultam may also be prepared in enantiomerically pure form by asymmetric reduction of imine (**2b**) followed by fractional crystallization.[3] However, multigram quantities of either enantiomer of the α-*t*-butyl sultam may be prepared by derivatization of the racemic auxiliary (obtained in 98% yield from reaction of (**2b**) with ***Sodium Borohydride*** in MeOH) with ***10-Camphorsulfonyl Chloride***, separation of the resulting diastereomers by fractional crystallization, and acidolysis.[3] Prochiral imines (**2a**) and (**2b**) are readily prepared from inexpensive Saccharine by treatment with ***Methyllithium*** (73%) and ***t-Butyllithium*** (66%), respectively.

Handling, Storage, and Precautions: these auxiliaries are white crystalline solids which are stable indefinitely at ambient temperature in sealed containers.

Introduction.

alpha-Methyltoluene-2,alpha-sultam

The toluene-2,α-sultams are recently introduced relatives of the well established ***10,2-Camphorsultam*** chiral auxiliary and have been designed to provide similar high levels of face discrimination in reactions of pendent prochiral functionality. Features that distinguish them include high crystallinity and facile NMR and HPLC analysis of derivatives, favorable acylation and aldolization characteristics of derived *N*-acyl enolates, and improved cleavage characteristics.

Preparation of Derivatives.

N-Enoyl[2,3] and *N*-acyl[4] sultam derivatives are readily prepared using either ***Sodium Hydride***-acid chloride or ***Triethylamine***-acid chloride single-step protocols. Various alternative derivatization procedures that work for the 10,2-camphorsultam auxiliary would also be expected to be effective.

Reactions of *N*-Enoyl and *N*-Acyl Derivatives.

[2 + 4] Diels-Alder Cycloadditions (Alkene -> Six-Membered Cycloadduct).[2]

N-Acryloyl-α-methyltoluene-2,α-sultam (**3a**) participates in highly *endo* and C(α)-*re* π-face selective Lewis acid promoted Diels-Alder reactions with ***Cyclopentadiene***, ***1,3-Butadiene*** and ***Isoprene*** (eq 2 and Table 1). These levels of induction compare favorably with most alternative auxiliaries, including the 10,2-camphorsultam. However, *N*-crotonyl-α-methyltoluene-2,α-sultam (*ent*-**3b**) reacts with cyclopentadiene with only moderate π-face selectivity (cf. 93% de with 10,2-camphorsultam). Unusually high *endo* selectivity is observed for the non-Lewis acid-catalyzed reaction of sultam (**3a**) with cyclopentadiene but again the π-face selectivity is only moderate. The corresponding reactions of both α-*t*-butyl- and α-benzyltoluene-2,α-sultams are less selective.

Table 1 Intermolecular Diels Alder Reactions of *N*-Enoyl Sultams (**3a**) or (**3b**) ® (**4**) and (**3a**) ® (**5**) (eq 2)

Dienophile	Diene	Lewis acid[a]	Temp (°C)	Time (h)	Adduct	Yield crude (cryst.) (%)	de crude (cryst.) (%)

1,3-Dipolar Cycloadditions with Nitrile Oxides (Alkene -> Isoxazoline).[3]

1,3-Dipolar cycloaddition reactions of *N*-acryloyl-α-*t*-butyltoluene-2,α-sultam (**6**) with various nitrile oxides give isoxazolines with extremely high C(α)-*re* π-facial control (eq 3). The levels of selectivity exceed those obtainable with the 10,2-camphorsultam auxiliary and are comparable to the highest levels reported for such cycloadditions.[6] The corresponding reactions of α-methyltoluene-2,α-sultams are less selective.

*using *ent*-(**6**) → *ent*-(**7**)

Acylation, Alkylation, and Aldolization (Acyl Species -> α-, β-, or α/β-Functionalized Acyl Product).[3]

Alkylation reactions of sodium enolates of various *N*-acyl-α-methyltoluene-2,α-sultams with selected (both "activated" and "nonactivated") alkyl iodides and bromides proceed with good C(α)-*re* stereocontrol (90-99% de). Analogous acylations with various acid chlorides can also be performed, giving β-keto products (97-99% de). Selective reduction of these latter products with ***Zinc Borohydride*** (chelate controlled, 82.6-98.2% de) or N-Selectride (nonchelate controlled, 95.8-99.6% de) can provide *syn*- and *anti*-aldol derivatives, respectively.[3]

Syn-aldol derivatives may also be obtained directly from boryl enolates of the same *N*-acyl-α-methyltoluene-2,α-sultams by condensation with aliphatic and aromatic aldehydes (eq 4).[3,7] The high C(α)-*si* topicity of these reactions parallels but exceeds that when using the 10,2-camphorsultam auxiliary and is the result of an analogous transition state.[3] It is noteworthy, however, that aldolizations of α-methyltoluene-2,α-sultam derivatives generally proceed to completion with just a small excess of aldehyde (1-1.2 equiv, cf. 2-3 equiv when 10,2-camphorsultam mediated). This may be ascribed to the lack of acidic protons α to the SO_2 group in the Saccharine derived auxiliary.

R = Me, *i*-Pr, *i*-Bu, Ph
71-84% (cryst); [R = *i*-Pr, 95% (FC)]
(>99% of crude)

Nondestructive Auxiliary Cleavage.

The toluene-2,α-sultam auxiliaries are even more readily cleaved from derivatives than the 10,2-camphorsultam auxiliary. Following *N*-acyl bond cleavage, simple extraction and crystallization usually effect almost quantitative recovery of enantiomerically pure auxiliary which may be re-used if desired.

Enantiomerically pure carboxylic acids are routinely obtained from *N*-acylsultams by ***Hydrogen Peroxide*** assisted saponification with ***Lithium Hydroxide*** in aqueous THF.[2,4] Alternatively, transesterification can be effected under neutral conditions in allyl alcohol containing ***Titanium Tetraisopropoxide***, giving the corresponding allyl esters which can be isomerized/hydrolyzed with Wilkinson's catalyst (***Chlorotris(triphenylphosphine)rhodium(I)***) in EtOH-H_2O. This provides a convenient route to carboxylic acids containing base-sensitive functionality.[8] Primary alcohols are obtained by treatment with L-Selectride (***Lithium Tri-s-butylborohydride***) in THF at ambient temperature.[3]

The α-methyltoluene-2,α-sultam auxiliary is also displaced by a variety of dilithiated alkyl phenyl sulfones.[7,9] This unique procedure provides direct access to synthetically useful β-oxo sulfones which may be further functionalized or simply subjected to

reductive desulfonation to give alkyl ketones. A particularly striking use of this method is the preparation of β-oxo sulfone (**8**), a key intermediate in a concise synthesis of (-)-semicorole (eq 5).[7] Remarkably, the $MeCLi_2SO_2Ph$ reagent attacks selectively the C(4)-imide C=O group in preference to the C(6)-ester C=O group and no epimerization occurs at C(3) or C(1´).

Related Reagents.

Methyl *p*-Toluenethiosulfonate[1]

[4973-66-4] · $C_8H_{10}O_2S_2$ · Methyl *p*-Toluenethiosulfonate · (MW 202.32)

(methylsulfenylating agent for formation of useful intermediates which have many applications)

Alternate Name: methyl thiotosylate.

Physical Data: mp 58 °C.

Form Supplied in: white solid.

Preparative Method: prepared by methylation of sodium *p*-toluenethiosulfonate with ***Dimethyl Sulfate*** (65%).[2]

Optically Active Methyl Sulfoxide Derived from Camphor.

(+)-Camphor is converted by methylsulfenylation of the lithium enolate with methyl *p*-toluenethiosulfonate (MeSTs) into *exo*-3-(methylthio)camphor, which upon reduction with ***Diisobutylaluminum Hydride*** gives the corresponding *exo*-(methylthio)isoborneol. Oxidation of the sulfide with ***m-Chloroperbenzoic Acid*** gives optically pure *exo*-3-(methylsulfinyl)isoborneol (eq 1).[3]

Interestingly, use of excess ***Lithium Diisopropylamide*** and ***Hexamethylphosphoric Triamide*** allows exclusively thermodynamic *endo*-3-(methylthio)camphor formation. The alternative methylsulfenylating agent ***Dimethyl Disulfide*** is not suitable for this highly stereoselective transformation since it gives a mixture of *exo*/*endo* sulfides in low yield. The method is elaborated for use of allyl *p*-toluenethiosulfonates which furnish optically pure *exo*-3-(allylsulfinyl)isoborneols. The derived dianions of these isoborneols undergo diastereoselective conjugate addition reactions with cyclopentenones.[4]

Beckmann Fragmentation of α-Methylsulfenyl Oximes.

It is known that a second-order Beckmann fragmentation is favored by introduction of a methylsulfenyl group α to the oxime group.[5] The termini of the bond that is cleaved are obtained in different oxidation states which can be manipulated for further functionalization. MeSTs is used to prepare an α-methylthio ketone, a precursor to the oxime for the fragmentation. An application of this fragmentation is exemplified by a conversion of a cyclohexanone into a δ-valerolactone (eq 2).[6]

α-Keto Aldehyde from α-(Methylsulfenyl)methyl Ketone.

A two-step conversion of a methyl ketone to an α-keto dimethyl acetal via methylsulfenylation with MeSTs, followed by oxidation with ***N-Chlorosuccinimide*** has been described (eq 3).[7]

Efficient Synthesis of Cardenolides.

A general and efficient method has been described for the synthesis of cardenolides, consisting of (1) α-methylsulfenylation of pregnen-20-one, (2) Reformatsky reaction, and (3) butenolide formation by alumina chromatography of the epoxy ester obtained from the *S*-methylated Reformatsky product (eq 4).[8]

Related Reagents.

Dimethyl Disulfide; ***Methyl Methanethiosulfonate***.

(*R*)-(+)-Methyl *p*-Tolyl Sulfoxide

[1519-39-7] · $C_8H_{10}OS$ · (*R*)-(+)-Methyl *p*-Tolyl Sulfoxide · (MW 154.25)

(agent used in the synthesis of chiral β-keto sulfoxides[1b,10])

Physical Data: $[\alpha]_D$ +146° (acetone, *c* = 2), +192° ($CHCl_3$, *c* = 1.2).

Preparative Methods: the most popular means of preparing this reagent is the nucleophilic displacement of ***(-)-(1R,2S,5R)-Menthyl (S)-p-Toluenesulfinate*** with methyl Grignard with complete inversion of configuration at sulfur (eq 1).[1]

This reagent is also prepared by the reaction of ***Methylmagnesium Bromide*** with optically active (*S*)-*N*-sulfinyloxazolidinone, which is obtained by asymmetric synthesis[2] from the oxazolidinone derived from (4*R*,5*S*)-norephedrine with a low diastereoselectivity (70:30) (eq 2).

Both enantiomers of methyl *p*-tolyl sulfoxide are also prepared from diacetyl D-glucose giving, with mesyl chloride, and according to the base used, the (*S*)-methyl sulfinate with diisopropylethylamine or the (*R*)-methyl

sulfinate with pyridine, which are then transformed with *p*-tolylmagnesium bromide into the corresponding (*S*)- or (*R*)-methyl *p*-tolyl sulfoxide (eq 3).[3]

(*R*)-(+)-methyl *p*-tolyl sulfoxide is obtained by asymmetric oxidation of the corresponding sulfide with ***t-Butyl Hydroperoxide*** in the presence of a stoichiometric amount of a modified Sharpless reagent (***Titanium Tetraisopropoxide***)-(+)-(*R*,*R*)-diethyl tartrate-H_2O in a ratio of 1:2:1) in 96% ee.[4]

(-)-α,α-Dichlorocamphorsulfonyloxaziridine (**1**) was shown to be a highly efficient reagent for the asymmetric oxidation of methyl *p*-tolyl sulfide, giving the corresponding (+)-(*R*)-sulfoxide in 95% ee.[5]

It was shown recently that chloroperoxidase-catalyzed oxidation of methyl *p*-tolyl sulfide, using ***Hydrogen Peroxide*** or *t*-BuOOH as the stoichiometric oxidant, afforded the corresponding (+)-(*R*)-sulfoxide in 99% ee.[6]

Synthesis of β-Keto Sulfoxides.

Optically active β-keto sulfoxides are very useful building blocks (eq 4) because they can be stereoselectively reduced to afford either diastereomer of the corresponding β-hydroxy sulfoxide under appropriate conditions (***Diisobutylaluminum Hydride*** or ***Zinc Chloride***/DIBAL)[8] and thus give access to a wide variety of compounds: chiral carbinols[7] by desulfurization with ***Raney Nickel*** or ***Lithium***/ethylamine in the case of allylic alcohols;[8b] epoxides[8a] via cyclization of the derived sulfonium salt; butenolides[7b] by alkylation of the hydroxy sulfoxide; 1,2-diols via a Pummerer rearrangement followed by reduction of the intermediate.[9]

(4)

a) oxidation to sulfone; b) alkylation with sodium iodoacetate;
c) lactonization; d) sulfone elimination;
e) sulfoxide reduction to sulfide with $LiAlH_4$;
f) sulfur methylation with Me_3OBF_4; g) cyclization with a base;
h) OH protection; i) Pummerer rearrangement in Ac_2O;
j) reduction of the Pummerer intermediate.

Numerous applications to total synthesis of natural products have been reported. In the case of the macrolide (*R*)-lasiodiplodin, the achiral ester (eq 5) was reacted with the (+)-(*R*)-methyl *p*-tolyl sulfoxide derived anion to give the corresponding β-keto sulfoxide, which was then reduced with DIBAL to give, after desulfurization, the seco-ester of (*R*)-lasiodiplodin (eq 5).[10] This is an example showing that the chirality can be introduced at the end of the synthesis in the desired configuration.

In the synthesis of (*S*)-zearalenone[11] and of a chiral spiroacetal, (2*S*,6*R*)-2-methyl-1,7-dioxaspiro[5.6]dodecane,[12] the starting product was a functionalized β-keto sulfoxide resulting from the reaction of glutaric anhydride with lithiated (+)-(*R*)-methyl *p*-tolyl sulfoxide (eq 6).

It was also shown in the enantioselective synthesis of the macrolide patulolide A[13] that the anion of methyl *p*-tolyl sulfoxide was more reactive towards the imidazolide, prepared from the hemi ethyl sebacate, than the ester group (eq 7).

In a similar way,[9] lithiated (+)-(*R*)-methyl *p*-tolyl sulfoxide was able to react only with the methyl ester group in presence of a *t*-butyl ester, as shown in the case of *t*-butyl methyl octadioate (eq 8).

The enantioselective syntheses of yashabushiketol[14] and gingerols[15] showed the synthetic utility of chiral epoxides obtained

from (*R*)-methyl *p*-tolyl sulfoxide (eq 9).

(9)

Methyl chloroacetate reacts with the anion of (*R*)-methyl *p*-tolyl sulfoxide to give the corresponding δ-chloro-β-keto sulfoxide (eq 10), which can be easily transformed into the corresponding β-hydroxy sulfoxide which gives, in presence of a base, the optically active α-sulfinyl epoxides.[16] As illustrated here, α-sulfinyl epoxides can be opened by cuprates, leading

to chiral homoallylic alcohols.[17]

(10)

(*R*)-Methyl *p*-tolyl sulfoxide anion also reacts with β-keto esters to give the corresponding β,δ-diketo sulfoxides,[18] which are useful in the preparation of optically active 1,3-diols (eq 11).[19]

(11)

Difluoroalkyl sulfinylmethyl ketones have been prepared in enantiomerically pure form from (+)-(*R*)-methyl *p*-tolyl sulfoxide in high yield (eq 12).[20] The ketone function was then reduced with complete diastereoselectivity.

(12)

The absolute configuration at C-32 in recently isolated triterpenoids was assigned by reduction of a β-keto sulfoxide (eq 13).[21]

Miscellaneous.

A vinylic sulfoxide was prepared from (*R*)-methyl *p*-tolyl sulfoxide and benzophenone. Cyclopropanation of the double bond with ***Dimethylsulfoxonium Methylide*** gave a good diastereoselectivity (eq 14).[22]

3-Sulfinylpropionic acid was made from lithium 2-bromoacetate and (*R*)-methyl *p*-tolyl sulfoxide (eq 15).[23]

Sulfinyl dienes were made from α,β-unsaturated esters and methyl *p*-tolyl sulfoxide followed by enolization of the ketone group (eq 16).[24]

Although the carbanion of (*R*)-methyl *p*-tolyl sulfoxide reacted with aldehydes and ketones with a poor diastereoselectivity,[25] it reacts with imines with a much higher stereoselectivity[25] as long as the imine substituent is an aromatic ring.[26] (*R*)-(+)-Tetrahydropalmatine was synthesized by addition of (*R*)-methyl *p*-tolyl sulfoxide carbanion to 3,4-

dihydro-6,7-dimethoxyisoquinoline (eq 17).[27]

[85013-27-0] · $C_{13}H_{12}BrN_3$ · 3-Benzyl-1-*p*-bromophenyltriazene · (MW 290.18)

(methylating agent for carboxylic acids,[2] other acids, alcohols, phenols, and thiols[3])

Physical Data: mp: (**1**) 79-81 °C; (**2**) 112-114 °C; (**3**) 36-38 °C; (**4**) 28-30 °C; (**5**) 29-30 °C; (**6**) 87-88 °C.

Alternate Name: MTT.

Solubility: in general, slightly sol hexane; sol Et_2O, chloroform, acetone, DMSO. May undergo degradation in protic media.

Form Supplied in: (**1**) colorless solid; commercially available in 98% purity.

Preparative Methods: disubstituted triazenes can be prepared by the reaction of Grignard[4] or organolithium reagents[5] with azides, or by the reaction of aryl diazonium salts with primary amines.[6] Chief impurities present in the latter case are the pentazadienes (2:1 condensation products) and diaryltriazenes.

Handling, Storage, and Precautions: can be safely stored for reasonable periods. Alkyltriazenes are potent biological alkylating agents and should be treated as toxic and potentially carcinogenic. Efficient

fumehoods and use of reasonable precautions are recommended when handling these compounds.

Alkylation by Triazenes.

N-Methyltriazenes can achieve low temperature methylation of acidic substances including benzoic acids,[2b,6] fatty acids,[7] enols,[8] polymeric carboxylic acids,[2a,2c] and presumably any compound that can be methylated by ***Diazomethane***. Succinimide and phenols are also methylated directly by 3-methyl-1-*p*-tolyltriazene, but methylation of alcohols and thiols requires aluminum alcoholate catalysis.[3]

In nonpolar solvents the alkylations probably involve displacement reactions on the methyldiazonium ion (eq 1); yields are essentially quantitative. The reaction intermediate is probably identical or very similar to the corresponding intermediate generated from diazomethane. The triazene approach is of special advantage in the case of higher homologs (alkyltriazenes) since most alkyl-substituted diazomethanes are quite unstable; in contrast, primary and secondary alkyltriazenes can be readily prepared.[4,9] 1-Bicyclo[2.2.1]heptyltriazenes are quite stable,[10] but tertiary alkyltriazenes that would lead to relatively stable carbocations, e.g. R^2 = *t*-butyl, are generally not isolable under normal circumstances.

The triazenes have several advantages over diazoalkanes. They are crystalline; they are more stable and need not be freshly prepared; they are far less volatile and thus less toxic via the pulmonary route; they are less prone to explosion; and they do not normally lead to the cycloaddition reactions observed for diazomethane.[11] Finally, chiral triazenes can form chiral esters with retention of configuration[12] (the reactive center of diazoalkanes is achiral) (see eq 3).

Reactions of Higher Triazene Homologs.

Triazenes with alkyl groups bearing β-hydrogens may give elimination products, which can account for ~20-60% (values estimated for reactions of free carbocations) of the alkyl groups (eq 2) (the diazoalkane approach would yield similar amounts of elimination).

As the electron-donating capacity of the alkyl group increases and as the solvent becomes more polar, the mechanism shifts from S_N2 to S_N1, leading to carbenium ion pair intermediates (eq 3),[12,13] which form the esters with net retention of configuration. In these cases, alkylation of the arylamine also occurs (as well as the elimination reaction), and alkylation of the solvent may become a major reaction,[14] especially when a removable β-hydrogen is not available. This fact can be turned to advantage since, in this way, weakly acidic or nonacidic compounds can be alkylated.[14]

Other Reactions of Triazenes.

The common acylating agents react with mono- and disubstituted triazenes to give the corresponding acyl derivatives; ***Phenyl Isocyanate*** (eq 4) and ***Acetic Anhydride*** have been particularly widely used.[15] These acyl derivatives obtained from dialkyltriazenes still have alkylating capabilities.[16]

Salts of disubstituted triazenes can be alkylated, and with unsymmetrical triazenes alkylation can occur at either or

both terminal nitrogens.[17] Triazenes are readily reduced to a mixture of amines and hydrazines (the reaction cannot be stopped at the triazane stage).[18] Oxidation of disubstituted triazenes with permanganate produces hexazadienes.[19] Triazenes form complexes with transition metals in the capacity of mono- and bidentate ligands and as bridging agents.[20]

The Triazene Moiety as an Amino Blocking Group.

The isomeric bromoanilines have been converted into the corresponding triazenes, which were subjected to lithium-halogen exchange to yield triazenylaryllithiums.[21] These react with a variety of electrophiles; subsequent deblocking of the products by hydrolysis regenerates the arylamino function.[21]

Biological Alkylation.

Alkyltriazenes are cytotoxic compounds which have carcinogenic,[22] mutagenic,[23] teratogenic,[24] antifungal,[25] bactericidal,[25] and antitumor[26] properties. This broad spectrum of biological activity is commonly attributed to their capacity to alkylate biomolecules, in particular DNA.[27] 5-(3-Methyl-1-triazeno)imidazole-4-carboxamide (MTIC) (**7**), for example, possesses antitumor activity,[26,27] methylating DNA primarily at N-7 and O-6 of the guanine residues.[27]

(7)

Related Methylating Agents.

A number of mechanistically related alkylating agents are available, but they are not generally competitive with the triazenes or diazomethane except under specific conditions. For example, acidic compounds are methylated by *syn* and *anti* methanediazoate salts[28] and by *N*-methyl-*N*-nitrososulfamates.[29] Conditions can be found for alkylation by *N*-methyl-*N*-nitro-*O*-acylhydroxylamines[30] and by the corresponding *N*-nitroso analogs.[31] Finally, an elegant approach suitable for isotopically labeled compounds and other valuable compounds involves the prior incorporation of the incipient methylating group and the acidic group (carboxylic acids, carbonic and carbamic acids, sulfonic acids, etc.) into a single molecule, followed by first-order decomposition[32] (see ***N-Methyl-N-nitrosoacetamide***).

Related Reagents.

Methyl *N*-(*p*-Tolylsulfonylmethyl)thiobenzimidate

(*E*)

[80224-81-3] · $C_{16}H_{17}NO_2S_2$ · Methyl *N*-(*p*-Tolylsulfonylmethyl)thiobenzimidate · (MW 319.48) (*Z*)

[80224-48-2]

(reagent for the synthesis of 2,3,4-trisubstituted pyrroles[1] from Michael acceptors, and of 2,5-disubstituted oxazoles[2] from aldehydes)

Physical Data: mp 98.5-100.5 °C (*E*,*Z*-mixture).

Form Supplied in: colorless crystalline, shelf-stable material.

Analysis of Reagent Purity: IR (Nujol) 1600 (C=N), 1320 and 1135 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$; *E*/*Z* mixture) δ 2.0 (s), 2.3 (s), 2.4 (s), and 2.5 (s) (2 × Me), 4.7 (s) and 5.0 (s) (CH_2); ^{13}C NMR ($CDCl_3$) δ 74.1 and 74.6 (CH_2).

Preparative Methods: prepared by *S*-methylation of *N*-(*p*-tolylsulfonylmethyl)thiobenzamide in 74% yield using methyl fluorosulfonate,[1a] and in 91% yield using ***Iodomethane***.[1b]

Introduction.

Methyl *N*-(*p*-tolylsulfonylmethyl)thiobenzimidate (**1**) has been designed as a derivative of ***p-Tolylsulfonylmethyl Isocyanide*** (TosMIC). TosMIC is a multipurpose synthesis reagent. One of the major applications of TosMIC is the base-induced cycloaddition of the C-N-C unit of TosMIC across the C=C double bond of Michael acceptors to form 3,4-disubstituted pyrroles, which inherently do not carry substituents at the ring positions 1, 2, and 5. Modified reagents such as (**1**) bearing two substituents on the isocyano carbon of TosMIC may react with Michael acceptors to give 2,3,4-trisubstituted pyrroles, in much the same way as TosMIC does. Thus reagent (**1**) would provide the product

pyrroles with a phenyl substituent at position 2 (next to the ring carbon carrying the electron-withdrawing group of the former Michael acceptor molecule) (eq 1).[1] The second substituent at the isocyano carbon of TosMIC (MeS in **1**) needs to be a leaving group.

Synthesis of Pyrroles.

Reaction of (**1**) with Michael acceptors produces 2,3,4-trisubstituted pyrroles in one operation (eq 1),[1] with a phenyl substituent at C-2. Substituents in (**1**) other than Ph and MeS have also been used.[1]

(1)

Synthesis of Oxazoles and Imidazoles.

The reaction of (**1**) with aromatic aldehydes provides 2,5-disubstituted oxazoles (eq 2).[2] 2-Methoxyoxazoles have been prepared by a similar process using dimethyl *N*-(*p*-tolylsulfonylmethyl)iminocarbonate (**2**), instead of (**1**) (eq 3).[2] 1,2,5-Trisubstituted imidazoles are formed accordingly by reaction of (**1**) with imino compounds.[3]

N-Methyl-*N*-tosylpyrrolidinium Perchlorate

[39830-53-0] · $C_{12}H_{18}ClNOS$ · *N*-Methyl-*N*-tosylpyrrolidinium Perchlorate · (MW 339.84)

(selective tosylating reagent for amines)

Physical Data: mp 148-150 °C.

Solubility: usually used in CH_2Cl_2.

Form Supplied in: not commercially available.

Analysis of Reagent Purity: sharp mp and satisfactory elemental analysis are reported.[1]

Preparative Method: N-methylpyrrolidine is reacted with ***p-Toluenesulfonyl Chloride*** in CH_2Cl_2, in the dark, in the presence of ***Silver(I) Perchlorate***, to yield the required production in 67.7 % yield.[1-3]

Handling, Storage, and Precautions: N-methyl-*N*-tosylpyrrolidinium perchlorate can be stored for six months without significant decomposition. It is reasonably stable in water, with approximately 50% remaining unchanged after 60 min.

Introduction.

N-Methyl-*N*-tosylpyrrolidinium perchlorate is used as a selective tosylating reagent for amines in the presence of alcohols.[1] The use of ClO_4^- as counterion avoids a possible side reaction that occurs when $SbCl_6^-$ is used as counterion, namely attack of Cl^- liberated from $SbCl_6^-$ on the S atom of the sulfonamide. This yields TsCl.

Protection of Primary and Secondary Amines.

The protection of amines is easily achieved by reacting the amine and tosylating agent in CH_2Cl_2 at 0 °C. The hindered amine ***1,3-Dicyclohexylcarbodiimide*** is tosylated in better yield than by previous methods[4] which have used TsCl. However, when the weakly basic diphenylamine is used, slow and forcing conditions are required and tosylation is only achieved in moderate yield (Table 1).

Table 1 Tosylating Conditions and Yields for Amines

Amine	Conditions	Yield (%)
p-Toluidine	0 °C, 1.5 h	97.8
Indoline	0 °C, 2 h	96.7
DCC	0 °C, 1.5 h	65.8
Diphenylamine	40 °C, 2 h	49

Alcohols are not tosylated by *N*-methyl-*N*-tosylpyrrolidinium perchlorate, as exemplified by stirring cholesterol in CH_2Cl_2 with the tosylating reagent, at room temperature for 7 h. No reaction occurs.

Selective Tosylation of Amines in the Presence of Alcohols.

The attempted *N*-tosylation of amino alcohol (**1**), an intermediate in the synthesis of β,β-disubstituted indoline alkaloids, using 10% NaOH and TsCl resulted in 20-40% of the required product, plus a significant amount of the N-Ts/O-Ts compound.[4] However, using *N*-methyl-*N*-tosylpyrrolidinium perchlorate, yields of the required N-Ts compound are improved to 75% (eq 1).

(1)

Similarly, amino alcohol (**2**) is *N*-tosylated in 80% yield with only 5% of the *N*-tosyl-*O*-tosyl compound being formed (eq 2).

N-Methyl-*N*-tosylpyrrolidinium perchlorate is stable in water (approximately 50% remaining unchanged after 60 min). The authors[1] therefore suggest that it may be applicable to protein modification. However, no reports on this application have been forthcoming.

4-Methyl-1,2,3-triazine[1]

[77202-08-5] · $C_4H_5N_3$ · 4-Methyl-1,2,3-triazine · (MW 95.12)

(an electron-deficient heteroaromatic azadiene capable of participation in inverse electron demand Diels-Alder reactions with electron-rich dienophiles employed for preparation of substituted pyridines[1])

Physical Data: mp 31 °C.

Solubility: sol $CHCl_3$, CH_2Cl_2, EtOH.

Form Supplied in: plates (*i*-Pr_2O).

Preparative Method: an ice-cold solution of 0.01 mol of *N*-amino-5-methylpyrazole in 30 mL of CH_2Cl_2 and 10 mL of H_2O is treated with 0.02 mol of solid ***Sodium Periodate*** or potassium periodate with stirring. The resulting mixture is allowed to stir at 0-5 °C overnight and then extracted repeatedly with $CHCl_3$. The $CHCl_3$ phase is dried over Na_2SO_4, concentrated, and purified by recrystallization or column chromatography on silica gel.[2]

Handling, Storage, and Precautions: stable at room temperature and is probably hygroscopic.

Cycloaddition Reactions.

4-Methyl-1,2,3-triazine (**1**) is an electron-deficient heteroaromatic azadiene that has been shown to participate in inverse electron demand Diels-Alder reactions. It is capable of reacting with electron-rich dienophiles including pyrrolidine enamines and ynamines in a regioselective fashion to give, after a retro Diels-Alder reaction with loss of N_2 and in situ elimination of pyrrolidine, 2,3,6-trisubstituted pyridines (eqs 1 and 2).[3,4] Cycloaddition occurs across N-3/C-6 of the 1,2,3-triazine nucleus and the nucleophilic carbon of the dienophile attaches to C-6 of the 1,2,3-triazine. The utility of this reagent has been demonstrated in the total syntheses of fabianine (eq 3)[5] and guaipyridine (eq 4).[6] A change in the mode of cycloaddition and/or loss of regioselectivity have been observed in reactions conducted under more vigorous conditions (eqs 5 and 6).[7,8]

Methyl Tributylstannyl Sulfide

Bu_3SnSMe

[17314-32-8] · $C_{13}H_{30}SSn$ · Methyl Tributylstannyl Sulfide · (MW 337.15)

(methanethiol equivalent in thioglycoside synthesis)

Physical Data: bp 104 °C/0.2 mmHg; *n*22D 1.5110.

Solubility: insol H_2O; sol hexane, acetone, ether.

Analysis of Reagent Purity: reacts readily with iodine and can be titrated against a solution of iodine in carbon tetrachloride.

Preparative Methods: prepared simply by mixing ***Bis(tri-n-butyltin) Oxide*** and ***Methanethiol*** followed by distillation under vacuum.[1] Preparation from ***Tri-n-butylchlorostannane*** and NaSMe is also possible.[2]

Handling, Storage, and Precautions: due to the low volatility, this reagent is much easier to handle than the parent thiol (MeSH; bp 6 °C). However, in addition to the strong odor, it is highly toxic (as is the case with all organotin compounds) and should be handled and stored accordingly.

Thioglycoside Synthesis.

Methyl tributylstannyl sulfide is widely applicable to the preparation of a variety of thioglycosides which are useful synthetic blocks in oligosaccharide synthesis. For instance, glycopyranosyl bromide or acetate gives the corresponding methylthioglycoside in high yield by the action of Bu_3SnSMe in combination with ***Tin(IV) Chloride***.[3] In general, glycosyl bromide gives the product as a mixture of anomers, because of the partial anomerization of the initially formed β-thioglycoside catalyzed by some Lewis acidic species generated in situ. Although the transformation from glycosyl bromide can be achieved without $SnCl_4$, the reaction requires higher temperature and results in incomplete conversion. On the other hand, the reaction of glycopyranosyl acetate gives the 1,2-*trans* product selectively (eq 1). In addition to such stereoselectivity, the ease of preparation and stability makes the use of a glycosyl acetate preferable over the glycosyl bromide as a starting material. A similar reaction using ribofuranosyl acetate gives a mixture of β- and α-anomers (eq 2).

(1)

(2)

Since it is known that the reaction of such sugar derivatives with free thiols and ***Zinc Chloride*** sometimes gives a dithioacetal instead of desired thioglycoside,[4] the substitution of hydrogen by a tributylstannyl group seems to attenuate the nucleophilicity of the alkylthio group.

The preparation of complex oligosaccharide-derived thioglycosides is also possible. For this purpose, trichloroacetimidate is the substrate of choice, since it is much more reactive than the corresponding glycosyl acetate (eq 3).[5]

$R^1 = p\text{-}MeC_6H_4CO$

$R^2 = MeCO(CH_2)_2CO$

(3)

The use of alkoxystannane (Bu_3SnOR) in place of tributylstannyl sulfide gives *O*-glycosides under similar conditions.[6]

Thioglycosides in Oligosaccharide Synthesis.

Thioglycoside linkages are stable under acidic and basic conditions, which are usually encountered in carbohydrate manipulations such as protection-deprotection of hydroxy groups. In spite of such stability, thioglycosides are powerful glycosyl donors under certain conditions and are widely used in oligosaccharide synthesis (examples[7]). Numerous methods are now available to activate alkylthioglycosides. Some examples of promotors are as follows: $MeOSO_2CF_3$,[8] $PhHgOSO_2CF_3$,[9] $Me_2SSMe^+CF_3SO_2^-$,[10] $CuBr_2$-Bu_4NBr,[11] PhSeCl-$AgOSO_2CF_3$,[12] MeSBr-$AgOSO_2CF_3$,[13] NIS-CF_3SO_3H,[14] $AgOSO_2CF_3$-Br_2.[15]

Methyltrichlorosilane[1]

[75-79-6] · CH_3Cl_3Si · Methyltrichlorosilane · (MW 149.48)

(precursor to organosilicon compounds;[1] silylating agent;[1] Lewis acid[2])

Physical Data: bp 66 °C; *d* 1.273 g cm^{-3}.

Solubility: sol methylene chloride.

Form Supplied in: liquid; commercially available.

Purification: can be purified by distillation.

Handling, Storage, and Precautions: is corrosive and moisture sensitive. It should be handled in an anhydrous atmosphere in a fume hood.

Organosilicon Compounds.

$MeSiCl_3$ is an important precursor to organosilicon compounds.[1] It reacts with carbanions to form corresponding alkyl(aryl) methylsilanes.[3] Grignard and organolithium reagents are the most frequently used carbanion sources in this transformation. Generally, the organolithiums are preferred over Grignard reagents, especially in the preparation of tetraorganosilanes. However, it was reported that the reaction using Grignard reagents was facilitated by a catalytic amount of cyanide or thiocyanate ions.[4] Stepwise substitution on $MeSiCl_3$ can be accomplished by introducing carbanions sequentially, yielding dichloro-, monochloro-, and tetraorganosilanes, respectively (eq 1). This makes it possible to design a silane with a specific steric bulkiness, a feature often required for the monochlorosilanes to serve as protecting groups.[5]

$MeSiCl_3$ has been used as a coupling agent in the preparation of the multidentate ligand (*RRR*)-siliphos {(*RRR*)-$MeSi[CH_2P(t\text{-}Bu)Ph]_3$} (eq 2).[6] The preparation of this optically pure tristertiary phosphine was achieved by deprotonation of optically pure (*R*)-$P(BH_3)Me(t\text{-}Bu)Ph$, followed by silylation of the resulting carbanion with $MeSiCl_3$, and the subsequent removal of the BH_3 protecting group with ***Morpholine***. The function of $MeSiCl_3$ as a coupling agent has also been widely used for the synthesis of star-branched polymers.[7] Cyclic silanes are obtained by treating $MeSiCl_3$ with dicarbanions and tricarbanions, albeit in lower yields (eqs 3 and 4).[8] Treatment of $CFCl_3/(Et_2N)_3P$ with $MeSiCl_3$ led to the formation of $CFCl_2SiCl_2Me$.[9]

(4)

Substitutions of $MeSiCl_3$ can also be performed under radical conditions or with transition metal catalysis.[1,10] The radical reactions can be initiated either by higher temperature or photolysis. However, the selectivity of the reaction is generally poor.[1] Better results were obtained with transition metal-catalyzed reactions. It was reported that $MeSiCl_3$ reacted with terminal alkynes in the presence of a catalytic amount of ***Copper(I) Chloride*** to form alkynyldichlorosilanes (eq 5).[11]

(5)

Besides *C*-silylation, $MeSiCl_3$ is also capable of silylating heteroatoms such as, O, N, and S.[1] It reacts with alcohols, oximes, alkoxysilanes, and esters to form corresponding silylated products.[12] In fact, certain poly- or oligoorganosiloxanes were prepared from $MeSiCl_3$ and hydroxy-containing compounds.[13] When aldehydes and ketones are used, tris(alkenyloxy)silanes are obtained in good yields (eq 6).[14] In the case of 1,3-diketones, organosilicon(IV) β-diketonate complexes are formed (eq 7).[15] Amines are silylated in a similar fashion.[16]

(6)

(7)

Reactions as a Lewis Acid.

$MeSiCl_3$ is an effective Lewis acid in the condensation of carboxylic acids with alcohols and amines.[17] Good yields of esters and amides are obtained. $MeSiCl_3$ reacts with epoxides to form β-chloroalkoxysilanes in good yields.[18] It also promotes the addition of allylstannanes to aldehydes (eq 8).[19] Compared to the traditional Lewis acids, $MeSiCl_3$ is relatively mild and less moisture sensitive. The reaction is very selective. When both allylstannanes and allylsilanes are present in the reaction, aldehydes react only with allylstannanes. It was reported that acetylacetone was condensed to pyrylium chloride by using $MeSiCl_3$.[20]

(8)

$MeSiCl_3$ cleaves the ether linkage of *gem*-amino ethers to form dialkyl(methylene)ammonium chloride (Mannich-type salts) in excellent yields (eq 9).[21a] This procedure is much more convenient, efficient, economical, and less dangerous compared to earlier methods. The Mannich salts were also prepared in situ for electrophilic substitution of nucleophilic aromatic compounds (eq 10).[21b,c]

(9)

(10)

In conjunction with CuCl, $MeSiCl_3$ promotes conjugate addition of both organomagnesium and manganese(II) reagents to α,β-ethylenic esters (eq 11).[22] These are much higher yield reactions compared to conjugate addition of copper or cuprate reagents to the substrates. The exact role of $MeSiCl_3$ in the reactions is not clear.

(11)

$M = Mg, Mn^{II}$

$MeSiCl_3$ has been found useful as a deprotecting agent in peptide chemistry.[23] It also promotes, in conjunction with diphenyl sulfoxide, formation of disulfide bonds in peptides (eq 12).[24]

(12)

$MeSiCl_3$/***Sodium Iodide***[2] is an equivalent of ***Iodotrimethylsilane***,[25] a widely used silicon Lewis acid, which has been used for various organic transformations. Compared to Me_3SiI, $MeSiCl_3$/NaI is milder, and thus it is more regioselective when used in ether cleavage (eq 13). Methyl ethers (ROMe) are cleaved affording alcohols as sole products, provided that the alkyl groups are either primary or secondary. Benzyl, trityl, and tetrahydropyranyl ethers are also cleaved regioselectively at ambient temperature to give quantitative yields of alcohols. If a tertiary alkyl group is present in the ethers, an alkyl iodide is then obtained. Esters and lactones are similarly cleaved to carboxylic acids. Acetals are converted to carbonyl compounds by $MeSiCl_3$/NaI (eq 14).

(13)

R^1 = primary and secondary alkyl group;

R = Me, benzyl, trityl, tetrahydropyranyl

(14)

$MeSiCl_3$/NaI is a good iodinating agent, which converts alcohols to corresponding iodides (eq 15). Primary alcohols react very slowly even under reflux conditions, giving low yields. However, moderate and excellent yields of alkyl iodides can be obtained with secondary, tertiary, and benzylic alcohols.

(15)

$MeSiCl_3$/NaI was found to dehalogenate α-halo ketones reductively (eq 16). The conversion of 5-cyano-7-oxabicyclo[2.2.1]hept-2-ene to 2-furanpropanenitrile was also reported (eq 17).[26]

N-Methyltrifluoromethanesulfonamide

[34310-29-7] · $C_2H_4F_3NO_2S$ · *N*-Methyltrifluoromethanesulfonamide · (MW 163.14)

(methylamine derivative found to react with alcohols under Mitsunobu conditions to give derivatized secondary amines)

Physical Data: bp 90-94 °C/20 mmHg.[1]

Solubility: sol THF, chloroform, methylene chloride.

Form Supplied in: clear liquid.

Preparative Method: prepared from methylamine and ***Trifluoromethanesulfonic Anhydride*** as follows. Methylamine (25.5 g, 0.5 mol) is added to chilled (-70 °C) dichloromethane (250 mL). A solution of triflic anhydride (28.2 g, 0.1 mol) in dichloromethane (20 mL) is added dropwise and the mixture is stirred at -70 °C for 3 h. The mixture is washed with 1N HCl (2 × 250 mL) and the organic layer is separated and dried ($MgSO_4$). The solvent is removed at atmospheric pressure by slow distillation through a column (500 cm × 20 cm) packed with glass helices (product codistills with solvent and evaporation on a rotary evaporator gives very low yields). The residue is distilled to give 9.3 g (57%) of a clear liquid, bp 95-98 °C/30 mmHg.

Secondary Amines.

Alcohols react with this compound in THF under Mitsunobu conditions to give derivatized secondary amines.[2] The reaction proceeds with inversion of configuration (eq 1).[2]

Methyl Trifluoromethanesulfonate

(R = CF_3)

[333-27-7] · $C_2H_3F_3O_3S$ · Methyl Trifluoromethanesulfonate · (MW 164.12) (R = F)

[421-20-5] · CH_3FO_3S · Methyl Fluorosulfonate · (MW 114.11)

(powerful methylating agents[1,2])

Alternate Name: R = CF_3, methyl triflate; R = F, Magic Methyl.

Physical Data: methyl triflate: bp 99 °C, mp -64 °C, *d* 1.50 g cm^{-3}. Methyl fluorosulfonate: bp 92 °C, mp -92.5 °C, *d* 1.45 g cm^{-3}.

Solubility: both reagents are miscible with all organic solvents, but react with many. They are only sl sol water, but hydrolyze rapidly as they dissolve. Useful inert solvents are CH_2Cl_2, SO_2, sulfolane, nitromethane, Me_2SO_4, and Me_3PO_4.

Form Supplied in: methyl triflate (MeOTf) is available as a colorless liquid. Methyl fluorosulfonate ($MeOSO_2F$) was formerly available as Magic Methyl™ but has been withdrawn (see below).

Analysis of Reagent Purity: MeOTf gives a singlet in ^1H NMR at δ 4.18, with ^{13}C absorption at δ 61.60 and 119.32 (q), and a ^{19}F shift of 75.4 ppm. $MeOSO_2F$ absorbs at δ 4.19 in ^1H NMR (J_{HF} &AApprox; 0.4 Hz or less), with ^{13}C absorption at δ 62.45, and a ^{19}F shift of -31.2 ppm. ^{33}S and ^{17}O NMR data have been reported for both compounds.[9]

Preparative Methods: both reagents are prepared[3,4] by distilling an equimolar mixture of the corresponding acid with ***Dimethyl Sulfate*** in an all-glass apparatus with a short Vigreux column. They may be dried by standing over fused K_2CO_3 and redistillation. ***Trifluoromethanesulfonic Acid*** and ***Fluorosulfuric Acid*** are both available, and are comparably priced.

Handling, Storage, and Precautions: both reagents are **extremely hazardous**. All possible precautions should be taken to avoid inhalation or absorption through the skin. A fatality has occurred with $MeOSO_2F$ through inhalation of the vapors leading to pulmonary edema.[5] Dexamethasone isonicotinate (Auxiloson® spray) has been recommended as a first aid in the treatment of such pulmonary irritation.[5] The oral LD_{50} of $MeOSO_2F$ is 112 mg/kg in mice, and an LC_{50} for 1 h exposure for rats between 5 and 6 ppm has been reported; severe eye irritation was noted.[6] It is very unlikely[7] that MeOTf is less dangerous, but no data on toxicity have been reported. Both materials are extremely destructive to the tissue of the mucous membranes and upper respiratory tract, eyes, and skin. Inhalation may be fatal as a result of spasm, inflammation, and edema of the larynx and bronchi, chemical pneumonitis, and pulmonary edema. Use in a fume hood.

The reagents are stable in glass when dry, but storage of $MeOSO_2F$ in bottles with ground glass joints should be avoided as these slowly become fused. It is reported[8] that $MeOSO_2F$ after storage over CaH_2 for two weeks contained 17% Me_2SO_4.

General Reactivity.

MeOTf and $MeOSO_2F$ are two of the most powerful reagents for methylation and are more reactive by a factor of ~10^4 than ***Iodomethane*** and Me_2SO_4.[1,2] The only reagents which are substantially more powerful are ***Methyl Fluoride-Antimony(V) Fluoride*** and related reagents[10] and the dimethylhalonium ions; these reagents pose more severe handling problems. The reactivity of MeOTf and $MeOSO_2F$ is not effectively enhanced by addition of Lewis acids. Thus addition of ***Antimony(V) Chloride*** to $MeOSO_2F$ and ***Dimethyl Sulfone*** led to complexation of the sulfone rather than methylation;[11] it is also reported that addition of $SbCl_5$ leads to formation of MeCl.[12]

The qualitative reactivity of some methylating agents toward a range of functional groups is shown in tabular form (Table 1).[1] Few quantitative data are available, but MeOTf and $MeOSO_2F$ are only a little less reactive than the trimethyloxonium ion, with the dimethoxycarbenium ion probably somewhat more reactive again. Substitution rates with various nucleophiles are reported to be in the order: Me_3O^+ > MeOTf > $MeOSO_2F$ > $MeOClO_3$, with rate ratios of 109:23:8:6:1.0 for reaction with acetonitrile at 0 °C.[13,14] Methyl perchlorate, an explosion hazard, therefore never offers a practical advantage. Our experience is that the relative rates for MeOTf and $MeOSO_2F$ rarely differ by more than a factor of 2-5.

Table 1 Reactivity[a] of Methylating Agents towards Functional Groups

	Approx. pK_a[18]	MeI	Me_2SO_4	$MeOSO_2F$ (MeOTf)	Me_3O^+	$HC(OMe)_2^+$	Me_2Cl^+
Me_3N	9	+	+	++	++	++	++
Pyridine	5	+	+	++	++	++	++
Me_2S	1	+	+	++	++	++	++
Me_2SO	0	+	+	+	+	+	++
$HCONMe_2$	0	-	+	+	+	+	++
MeCN	- 10	-	-	+	+	+	+
Me_2O	- 5	-	-	+	(+)	+	+
PhCHO	- 6	-	-	+	-	+	+
R_2CO	- 6	-	-	±	-	±	+
Lactone	- 7	-	-	+	-	+	+
Ester	- 7	-	-	(+)	-	+	+
MeI	?	-	-	(+)	-	(+)	+
$MeNO_2$	- 10	-	-	-	-	-	+
Me_2SO_2	- 10	-	-	-	-	-	+

[a] Key: ++ methylation occurs and may be strongly exothermic; + methylation occurs; - little reaction; (+) equilibrium transfer reaction; ± reaction is complex.

It is noteworthy that neither MeOTf nor $MeOSO_2F$ shows any reactivity on their own in Friedel-Crafts methylation reactions even with highly reactive substrates (Me_3O^+ ion is similar). Reaction has been observed in the presence of protic or Lewis acids.[15] Olah has recently suggested that this reactivity is associated with generation of superelectrophiles by further protonation.[16] $MeOSO_2F$ has been reported to react as a methylsulfonylating agent towards phenol and anisole,[17] but this alternative reactivity is usually not significant.

The alkylation reactions of MeOTf and $MeOSO_2F$ are discussed according to the atom alkylated. To avoid unnecessary repetition, reactions can be assumed to use MeOTf unless $MeOSO_2F$ is specified. Historically, $MeOSO_2F$ was mainly used up until about 1980, but MeOTf has since become the reagent of choice. In the great majority of cases these reagents can probably be used interchangeably.

Alkylation at Nitrogen.

Most amines react violently with MeOTf or $MeOSO_2F$, and only those with severe steric hindrance or conjugated with strong electron-withdrawing groups really require the use of these reagents. Of derivatives with sp^3 nitrogen, ***Diisopropylamine***, *N*,2,2,6,6-pentamethylpiperidine, and ***1,8-Bis(dimethylamino)naphthalene*** (Proton Sponge™) can all be quaternized by $MeOSO_2F$, and *N*,*N*,2,6-tetramethylaniline reacts on heating.[1] However, it has been reported that *i*-Pr_3N does not react with $MeOSO_2F$.[19] ***2,6-Lutidine*** reacts exothermically with $MeOSO_2F$ at room temperature, and 2,6-dimethoxycarbonylpyridine can be quantitatively quaternized.[1] A range of [*n*](2,6)-pyridinophanes have been methylated with $MeOSO_2F$, with *n* as small as 6 (eq 1).[20]

(1)

2,6-Di-t-butylpyridine does not react at normal pressure, and this or 2,6-di-*t*-butyl-4-methylpyridine (synthesis[21]), are often used in applications which require base (see below). Note that 2,6-di-*t*-butylpyridine can be alkylated under high pressure with $MeOSO_2F$ to give >90% of the methylation product when water is carefully excluded.[22]

Simple imines, such as benzylideneaniline, react readily. The *N*-methylation of imine and amidine derivatives of amino acid esters, followed by hydrolysis, has been used as a method for the preparation of *N*-alkylated amino acids with minimal racemization.[23] A convenient synthesis of *N*-methyl nitrones has been developed by alkylation of OTMS oximes with MeOTf, followed by treatment with fluoride ion.[24]

Besides the pyridine derivatives already mentioned, most heterocyclic nitrogens can be alkylated. Aspects of the quaternization of heteroaromatics have been recently reviewed.[25] With respect to the limits of reactivity, it is interesting that dimethylation of 2-phenyl-4,6-dimethylpyrimidine could only be achieved with ***Trimethyloxonium Tetrafluoroborate***; $MeOSO_2F$ only gave monoalkylation.[26] 2-Benzoylbenzothiazole can be *N*-alkylated with $MeOSO_2F$ (but not with MeI) and then acts as an active acylating agent.[27] Formation of an *N*-methylindole from an *N*-ethoxycarbonylindole has been achieved with $MeOSO_2F$.[28]

A number of alkylation products from MeOTf and heterocycles have been advocated as useful intermediates. Thus treatment of 2-substituted thiazoles with MeOTf in acetonitrile, followed by reduction of the salt formed with ***Sodium Borohydride***/CuO in CH_2Cl_2, leads to aldehydes.[29] 1-(Benzenesulfonyl)-3-methylimidazolium and 1-(*p*-toluenesulfonyl)-3-methylimidazolium triflates have been proposed as efficient reagents for the preparation of aryl sulfonamides and aryl sulfonates.[30] MeOTf alkylates 2,5-oxazoles to give salts which can be reduced by $PhSiH_3$/CsF to give 4-oxazolines, and these provide a route to stabilized azomethine ylides.[31]

A novel synthesis of 2-aryl-4-piperidones by Mannich cyclization of imino acetals, initiated by methylation of the imine, has been described.[32] MeOTf has been used in the generation of a munchnone for cycloaddition.[33] Finally, methylation of 1-lithio-2-*n*-butyl-1,2-dihydropyridine with MeOTf gives 2-butyl-5-methylpyridine in 42% yield.[34]

Nitriles, with sp hybridized nitrogen, are unreactive to MeI or Me_2SO_4, but are readily methylated by $MeOSO_2F$,[1] MeOTf,[35] or oxonium ions. Nitrilium salts have been shown to have a number of useful applications. The reduction of nitrilium salts by $NaBH_4$ in alcohols leads first to iminoethers and subsequently to amines.[36] Reduction of *N*-alkylnitrilium ions by organosilicon hydrides gives *n*-alkylaldimines, and thus provides a route to aldehydes from nitriles.[37] Nitrilium triflate salts have been shown to be useful reagents for the synthesis of ketones and ketenimines by electrophilic substitution of reactive aromatics, and also provide good routes to amidinium, imidate, and thioimidate salts.[35] Reaction with 2-amino alcohols gives oxazolidines.[38] Synthesis of either 5-substituted 1-methyl-1*H*-tetrazoles or 3,5-disubstituted 1,4-dimethyltriazolium salts from *N*-methylnitrilium triflate salts can be controlled in reactions with $(Me_2N)_2C{=}NH_2^+N_3^-$.[39] Reaction of nitrilium ions with alkyl azides gives 1,2,3-trisubstituted tetrazolium salts.[40] These can be deprotonated to highly reactive 2-methylenetetrazoles.[41]

Amides are alkylated largely on oxygen, as expected (see below), although some *N*-alkylation can be seen by NMR.[1] *N*-Alkylation is more apparent with carbamates (see the section on ambident nucleophiles). *N*,*N*-Dimethylmethanesulfonamides can be *N*-alkylated ($MeOSO_2F$) to provide salts which are effective reagents for mesylation.[42] *N*,*N*-Dimethylsulfamate esters react with $MeOSO_2F$ to give trimethylammoniumsulfate esters, which rapidly give methyl esters unless the O-group is aryl, showing that $Me_3N^+SO_3^-$ is a very powerful leaving group.[43] $Me_3N^+SO_2OPh$ reacts with nucleophiles at either the sulfur or a methyl carbon atom.[44]

Azo compounds, which do not react with methyl iodide, can be *N*-methylated by $MeOSO_2F$.[45]

A steroidal oxaziridine was converted ($MeOSO_2F$) to an oxaziridinium salt which showed oxidizing properties.[46]

Alkylation at Oxygen.

Most neutral functionalities with lone pairs on oxygen are not alkylated by MeI or Me_2SO_4 but do react with MeOTf or $MeOSO_2F$, although not all such reactions are preparatively useful.[1,2] Ethers react reversibly, and the ultimate product depends on the conditions. Thus good yields of the oxonium ion can be obtained from reaction of THF with stoichiometric amounts of MeOTf, but the use of catalytic amounts leads to polymerization. Cationic ring opening polymerization, initiated by MeOTf and $MeOSO_2F$ among other reagents, has been extensively investigated and recently reviewed.[47]

Reaction of $MeOSO_2F$ with 2-methoxyethyl carboxylates gives 2-alkyl-1,3-dioxolanium ions.[1] The reaction of these ions with trialkylalkynylborate anions provides versatile and direct routes to (*Z*)-α,β-unsaturated ketones (eq 2). Specifically protected 1,3-diketones and other ketonic species can also be prepared from the intermediates.[48]

(2)

Almost all carbonyl functions can be methylated. Enolizable aldehydes and ketones usually lead to complex mixtures, probably because of deprotonation to enol ethers, followed by reaction of these with the electrophilic species in the reaction mixture. Nonenolizable aldehydes and ketones give methoxycarbenium ions cleanly, and the relative thermodynamic stabilities of these have been assessed via pairwise equilibrations.[49] Most esters only generate low equilibrium concentrations of dialkoxycarbenium ions, but lactones are readily alkylated.[1]

Amides, carbamates, and ureas are rapidly alkylated, usually on carbonyl oxygen (see the section on ambident nucleophiles). Alkylation of amides with MeOT5f in CH_2Cl_2 followed by reduction of the salts provides a route for the selective reduction of amides; esters, nitriles, acetals, and double bonds are left unaffected by this procedure.[50] Alkylation of isoindolin-1-ones and subsequent deprotonation can provide routes to methoxyisoindoles.[51]

Alcohols can be converted to methyl ethers by the use of MeOTf + 2,6-di-*t*-butylpyridine or 2,6-di-*t*-butyl-4-methylpyridine. This procedure was initially developed in the carbohydrate field.[52] Me_3PO_4 provides a good polar solvent for this process.[53] A recent application, in the synthesis directed at lonomycin, was to methylation of the complex alcohol (**1**) without causing retro-aldol cleaveage.[54]

(1)

MeOTf has been reported to effect complete methylation of inositol polyphosphates, P-OMe groups being formed as well.[55] MeOTf will effect *O*-alkylation at the anomeric center, but the stereochemistry is affected by the presence of a crown ether.[56] Reaction of Meisenheimer complexes with $MeOSO_2F$ can lead to capture of the anion as a nitronate ester.[57]

Alkylation at Sulfur and Selenium.

Dialkyl and most arylalkyl sulfides are readily converted into sulfonium salts.[1] Cyclic sulfides, especially dithiolanes, react somewhat faster.[58] Reaction of disulfides with MeOTf gives Me_2SSMe^+ OTf^-; this salt, with ***Triphenylphosphine***, reacts with alkenes in a stereo- and regioselective fashion and the products can be converted into vinylphosphonium salts.[59] Thione groups are also alkylated even when electronegative groups are present. Thus 4,5-bis(trifluoromethyl)-1,3-dithiolane-2-thione was converted into a methylated salt.[60] Sulfoxides are *O*-alkylated,[1] and formation of various oxa- and azasulfonium ions has been reported, up to and including triazasulfonium salts.[61] Alkylation of R_2SO with $MeOSO_2F$, followed by reduction with ***Sodium Cyanoborohydride***, leads to sulfides.[62]

Reaction of MeOTf with the product from P_2S_5/Na_2CO_3 ($Na_2P_4S_{10}O$) gave a useful electrophilic thionation reagent.[63] $MeOSO_2F$ has been used in the conversion of thiols to reactive sulfenating agents (eq 3).[64]

Methylation of dithioacetals by $MeOSO_2F$, followed by reaction with various nucleophiles, has been used for the removal of this protecting group or its conversion into other protecting groups, e.g. acetals (eq 4).[65-68]

The reaction of the sulfonium intermediate with alcohols leads to their protection as hemithioacetals.[69] Treatment of thioglycosides with MeOTf gives an efficient glycosylating agent,[70] and pyruvic acetal formation from a pyruvyl thioacetal has been achieved in a reaction catalyzed by MeOTf (amongst other electrophiles).[71]

Alkenes can be prepared by methylation of selenides by $MeOSO_2F$ and treatment of the selenonium ions formed with ***Potassium t-Butoxide***.[72]

Alkylation at Phosphorus.

Phosphines and phosphites undergo easy quaternization. Thus methylation of tris(2,6-dimethylphenoxy)phosphine with MeOTf, followed by treatment of the product with sodium 2,6-dimethylphenoxide, gave methyltetrakis(2,6-dimethylphenoxy)phosphane.[73] Methoxyphosphonium triflates are relatively stable intermediates in Arbuzov reactions.[74] Phosphine oxides and sulfides are alkylated. *S*-Methylation of chiral phosphine sulfides, followed by treatment with ***Hexamethylphosphorous Triamide***, has been advocated as a general synthesis of optically active phosphines.[75]

Ambident Nucleophiles.

Amides and related functional groups can be alkylated on oxygen or nitrogen and, as has been noted already, alkylation on carbonyl oxygen normally predominates. In the case of carbamates, *O*-alkylation by $MeOSO_2F$ can be faster, but *N*-alkylation predominates at equilibrium.[76] It has been noted that methylation of secondary amides and thioamides occurs at the protonless heteroatom in the major tautomer.[77] The ionic products of these reactions can be deprotonated to give synthetically useful products, e.g. imidates,[78] but excess $MeOSO_2F$ should be removed before treatment with base.[77]

Reaction of most enolates with MeOTf or $MeOSO_2F$ is always likely to be kinetically controlled. There does not appear to have been a definitive study, but *O*-alkylation is the normal outcome. *O*-Alkylation of a bicyclodecatrienone by $MeOSO_2F$ is enhanced by the use of polar solvents like HMPA.[79] *O*-Alkylation of enolates of appropriate cyclohexadienones by MeOTf has been used to generate various 3a*H*-indenes.[80] A ketene acetal is formed by exclusive *O*-alkylation of the sodium enolate of isopropyl bis(pentachlorophenyl)acetate by MeOTf.[81]

Alkylations at Carbon.

In an important recent development, primary α-alkylation of carbonyl compounds under nonbasic conditions has been achieved (eq 5) by alkylation of silyl enol ethers with MeOTf and other primary alkyl triflates, catalyzed by ***Methylaluminum Bis(4-bromo-2,6-di-t-butylphenoxide)*** (MABR).[82]

(5)

Related Reagents.

Dimethoxycarbenium Tetrafluoroborate; ***Dimethyliodonium Hexafluoroantimonate***; ***O-Methyldibenzofuranium Tetrafluoroborate***; ***Triethyloxonium Tetrafluoroborate***.

Methyl(trifluoromethyl)dioxirane[1]

[115464-59-0] · $C_3H_3F_3O_2$ · Methyl(trifluoromethyl)dioxirane · (MW 128.06)

(selective, reactive oxidizing agent capable of epoxidation of unreactive alkenes[5] and arenes,[7] oxyfunctionalization of alkanes,[3] oxidation of alcohols[16] and ethers[19])

Alternate Name: TFDO.

Physical Data: known only as a dilute solution.

Solubility: sol acetone and CH_2Cl_2; sol most other organic solvents, but reacts slowly with many of these.

Form Supplied in: dilute solutions of the reagent in 1,1,1-trifluoro-2-propanone are prepared from Oxone (***Potassium Monoperoxysulfate***) and this ketone as described below. *Drying:* initial drying of reagent solutions is accomplished with reagent grade anhyd $MgSO_4$ in the cold. After filtration, solutions are typically stored over molecular sieves.

Analysis of Reagent Purity: concentrations of the reagent can be determined by classical iodometric titration or by reaction with an excess of an organosulfide and determination of the amount of sulfoxide formed by NMR or gas chromatography.

Preparative Methods: TFDO solutions are prepared by mixing 1,1,1-trifluoro-2-propanone (TFP) and aqueous buffered Oxone in the cold and collecting the volatile TFDO-TFP mixture by transfer into a cold trap in a stream of inert gas under reduced pressure (eq 1).[3]

Handling, Storage, and Precautions: solutions of the reagent can be kept in the freezer of a refrigerator at -20 °C for as long as a week. The concentration of the reagent decreases relatively slowly (ca. 6-8% in 48 h), provided solutions are properly stored. It is particularly important that solutions be kept from light and traces of heavy metals, since the reagent is particularly susceptible to their influence. These dilute solutions are not known to decompose explosively, but the usual precautions for handling peroxides should be applied, including the use of a shield. All reactions should be performed in a hood to avoid exposure to the

powerful, volatile oxidant.

Introduction.

Methyl(trifluoromethyl)dioxirane is a fluorinated derivative of the extremely useful oxidant ***Dimethyldioxirane*** (DDO), over which it has several advantages as a reagent. However, it is more expensive and difficult to prepare, since it is obtained from the volatile (bp 22 °C) ketone TFP.[2] Nonetheless, the much greater reactivity of TFDO can be of major advantage for less reactive substrates. Furthermore, the concentration of TFDO (ca. 0.8 M) normally obtained is several times greater than that of DDO. Solutions of TFDO in halocarbon solvents free of starting ketone can be obtained by extraction of the TFP into water, owing to the water solubility of the ketone hydrate.[4] Oxidations with TFDO are performed by adding the reagent to the reactant, often in CH_2Cl_2 solution, and then simply removing the volatile solvents when reaction is complete (usually minutes).

Alkenes and Arenes.

Like DDO, TFDO performs rapid epoxidations of alkenes with retention of alkene stereochemistry.[1,2] Since DDO is adequately reactive towards most double bonds, there is ordinarily no reason to employ TFDO in reactions of this type. One important exception is the epoxidation of trifluoromethyl-substituted alkenes, which are resistant to classic epoxidizing reagents and which require a large excess of DDO during two weeks to complete epoxidation.[5] TFDO rapidly converts such alkenes to epoxides (eq 2). Another example of the beneficial effect of TFDO is in the preparation of the sensitive epoxides of enol ethers, where the short reaction times and facile product isolation are crucial.[6]

(2)

Polycyclic aromatic hydrocarbons like phenanthrene are converted to epoxides by TFDO.[7] This reactive reagent even permits the epoxidation of naphthalene, which undergoes fast sequential diepoxidation as shown in eq 3. Interestingly, the second epoxidation shows high *anti* stereoselectivity. Catechol is oxidatively cleaved by TFDO into (*Z*,*Z*)-muconic acid in good yield (eq 4).[8] This reagent also oxidizes 2,6-di-*t*-butylphenol to the corresponding quinone and a hydroxyquinone derivative (eq 5).[8]

(3)

(4)

(5)

Alkynes are oxidized by TFDO to give a variety of different products, depending on the nature of the alkynic substituents.[9] Reaction is thought to proceed via an oxirene intermediate. This highly unstable, anti-aromatic heterocycle quickly rearranges to the isomeric α-ketocarbene, which then leads to the observed products by typical carbenoid transformations. For example, cyclodecyne gives bicyclic ketones by transannular insertion processes common to this medium-ring system (eq 6).

Alkanes.

The most impressive applications of TFDO to date have involved the hydroxylation of unactivated C-H bonds.[1,3] While dimethyldioxirane performs similar reactions, the much greater reactivity of TFDO permits higher conversions of alkanes with less oxidant and in minutes rather than hours. Despite its more reactive nature, TFDO displays selectivity for attack at tertiary > secondary > primary C-H bonds almost as advantageous as that for DDO.[3] Examples include the exclusive formation of the tertiary alcohol from 2,3-dimethylbutane (eq 7) and the stereospecific oxidation of *cis*-1,2-dimethylcyclohexane (eq 8). Cyclohexane is oxidized to cyclohexanone by TFDO in a slower process that involves a fast second oxidation of the initially formed cyclohexanol. Heptane generates a 41:41:18 mixture of 2-, 3-, and 4-heptanone.

The stereospecificity of these C-H oxidations is illustrated in eq 9 by the benzylic oxidation of optically active (*S*)-(-)-2-phenylbutane, which gives only the tertiary alcohol with total retention of configuration.[10] Interestingly, ketone-free TFDO in CH_2Cl_2 is three times more reactive than TFDO-TFP.

(9)

Adamantane is an informative substrate for oxidation by TFDO; it not only shows very high bridgehead selectivity, but can be converted to mono-, di-, tri-, and even tetrahydroxylated adamantane (eq 10) in good yields by varying the ratio of oxidant to hydrocarbon.[11]

(10)

Several impressive oxyfunctionalization reactions on steroid substrates illustrate the enormous potential of this process. Not only is there a preference for tertiary C-H oxidation, but there is also significant site selectivity, presumably governed by steric features. For example, the cholestane derivative in eq 11 gives rapid, selective C-25 side-chain oxidation without appreciable reaction at other tertiary carbons.[12] Coprostane[13] and estrone[14] derivatives undergo C-5 and C-10 hydroxylation, respectively.

(11)

The stability of TFDO to strong acid adds a further dimension to its chemistry, as illustrated by the reactions of amines in the form of their fluoroborate salts with ketone-free solutions of TFDO.[15] The amino group is deactivated under these conditions and remote C-H hydroxylation takes place (eq 12).

(12)

Alcohols.

Secondary alcohols are smoothly oxidized to the corresponding ketones by TFDO, whereas primary alcohols are converted to acids in a slower process.[16] In view of the many methods for alcohol oxidations, this reagent will be advantageous for such conversions only in special situations. However, TFDO does perform sensitive oxidations under favorable experimental conditions that may be useful with problem cases. Cyclobutanol is oxidized by TFDO without the ring cleavage that is often problematic (eq 13). Other reactive functions can be accommodated as shown for the epoxy alcohol in eq 14.

(13)

(14)

Vicinal diols are oxidized to α-hydroxy ketones by TFDO without cleavage between the two functional groups. Thus, tertiary-secondary *vic*-diols are usefully oxidized by TFDO (eq 15).[17] Optically active secondary-secondary diols have been converted to α-hydroxy ketones without racemization.[18]

(15)

Ethers and Acetals.

TFDO selectively oxidizes adjacent to an oxygen atom in compounds of these types.[19] The initially generated hemiacetals decompose to carbonyl compounds and alcohols, which may be subject to further oxidation. Ethylene glycol acetals are attacked at the dioxolane ring, leading to an interesting deprotection of the carbonyl unit under nonacid conditions (eq 16). Cyclic ethers like tetrahydropyran yield lactones by subsequent oxidation of a stable cyclic hemiacetal intermediate (eq 17). Even methyl *t*-butyl ether is oxidatively liberated to *t*-butanol upon reaction with TFDO.

Methyl 2-Trimethylsilylacrylate

[18269-31-3] · $C_7H_{14}O_2Si$ · Methyl 2-Trimethylsilylacrylate · (MW 158.30)

(reactive, α-silyl Michael acceptor for conjugate addition of carbanions, enolate anions, organolithium reagents, and Grignard reagents; affords 3-cyclopentenecarboxylates and cyclohexanecarboxylates by [3 + 2] and [4 + 2] annulation methods; provides α-silyl esters and vinylsilanes by organolithium conjugate additions[1,3,5])

Physical Data: bp 75 °C/50 mmHg, 152 °C/690 mmHg.

Solubility: sol Et_2O, THF, EtOH, and most organic solvents.

Analysis of Reagent Purity: IR, NMR, GC.

Preparative Methods: prepared[2a,b] by the reaction of ***(E)-2-(Trimethylsilyl)vinyllithium*** with ***Methyl Chloroformate*** or by carbonation of the corresponding Grignard reagent prepared from ***(1-Bromovinyl)trimethylsilane***,[2c] giving 2-trimethylsilylacrylic acid. The methyl ester is prepared from the acid by direct esterification with absolute methanol in the presence of mineral acid, by reaction with ***Diazomethane*** at low temperature, or by treatment with BF_3.MeOH complex. For preparation of various trialkylsilylacrylic acid esters[2d] and *t*-butyl 2-trimethylsilylcrotonate,[8] see the cited references.

Handling, Storage, and Precautions: should be stored in a refrigerator and addition of a few crystals of ionol is recommended in order to prevent polymerization. Use in a fume hood.

Cyclopentenes by [3 + 2] Annulation.

Conjugate addition of allylithium reagents bearing stabilizing groups in the α- and β-positions to methyl 2-trimethylsilylacrylate leads to an anionic [3 + 2] cyclization,[3a,b] generating the trimethylsilyl-substituted 3-cyclopentenecarboxylate in 57% yield (eq 1). α-Unsubstituted Michael acceptors do not give good yields of the cyclopentene product.

Cyclohexanecarboxylates by [4 + 2] Annulations.

The kinetic enolate of 1-acetylcyclohexene on reaction with methyl 2-trimethylsilylacrylate undergoes a two-fold Michael addition, giving rise to 5-substituted 1-decalones (eq 2), one of which was converted to (±)-khusitone[4a] and (±)-khusilal.[4b]

In another annulation sequence,[5] a functionalized aryllithium generated chemoselectively from (2-bromo-4,5-dimethoxyphenyl)ethyl bromide at -100 °C undergoes conjugate addition with methyl 2-trimethylsilylacrylate, and the adduct cyclizes by intramolecular alkylation to give the tetrahydronaphthalenecarboxylate in 80% yield (eq 3).

α-Silyl Esters.

Conjugate addition of organometallic reagents (magnesium or lithium) to methyl 2-trimethylsilylacrylate gives either 1:1 or 1:2 adduct[6c] anions (eq 4), depending upon the reaction conditions and reactivity of donor molecules. These anions undergo either alkylation[6b] with a suitable alkylation agent or add to another electrophile[6a] such as ketones, aldehydes, or α,β-unsaturated aldehydes.

(4)

Synthesis of Pyrrolidones.

2-Azaallyl anions[7] derived from aryl-substituted imines undergo highly diasteroselective Michael addition to methyl 2-trimethylsilylcrotonate. The Michael adducts are converted to pyrrolidones through hydrolytic cyclization (eq 5).

Related Reagents.

Ethyl Acrylate; ***1-(Trimethylsilyl)vinyllithium***; ***Methyl 2-Methylthioacrylate***; ***Trimethyl 2-Phosphonoacrylate***; ***3-Trimethylsilyl-3-buten-2-one***; ***Vinyltrimethylsilane***.

[74542-82-8] · $C_7H_{14}Si$ · 3-Methyl-1-(trimethylsilyl)allene · (MW 126.30)

(propargylic anion equivalents;[2,3] three-carbon synthons for [3 + 2] annulations leading to five-membered compounds including cyclopentenes,[4] dihydrofurans,[5] pyrrolines,[5] isoxazoles,[6] furans,[7] and azulenes[8])

Physical Data: (**1a**) bp 111 °C; bp 54-56 °C/90 mmHg; (**1b**) bp 62-65 °C/30 mmHg; (**1d**) bp 107-110 °C.

Solubility: sol CH_2Cl_2, benzene, THF, Et_2O, and most organic solvents.

Form Supplied in: colorless liquid; not commercially available.

Analysis of Reagent Purity: (**1a**) IR (neat) 2955, 2910, 2900, 2860, 1935, 1440, 1400, 1250, 935, 880, 830, 805, 750, and 685 cm^{-1}; ^1H NMR (250 MHz, $CDCl_3$) δ 0.08 (s, 9H), 1.67 (t, 3H, *J* = 3.3), and 4.25 (q, 2H, *J* = 3.3); ^{13}C NMR (67.9 MHz, $CDCl_3$) δ -2.1, 15.1, 67.3, 89.1, and 209.1.[4b,9]

Preparative Methods: 1-methyl-1-(trialkylsilyl)allenes can be conveniently prepared by the method of Vermeer.[9,10] Silyl-substituted propargyl mesylates thus undergo S_N2' displacement by the organocopper reagent generated from methylmagnesium chloride, ***Copper(I) Bromide***, and ***Lithium Bromide***. 1-Methyl-1-(trimethylsilyl)allene is produced in 52% yield from commercially available (trimethylsilyl)propargyl alcohol in this fashion (eq 1).[4b,9] The *t*-butyldimethylsilyl and triisopropylsilyl analogs are synthesized by the same method in 90% and 58% yield, respectively.[7] Propargyl alcohols bearing these and other trialkylsilyl groups can be prepared by treatment of ***Propargyl Alcohol*** with ***n-Butyllithium*** and the appropriate trialkylsilyl chloride.[7] Allenylsilanes bearing other C-1 substituents can be prepared in an analogous manner by using the appropriate

Grignard reagents.

1-Methyl-1-(trialkylsilyl)allenes can be alkylated at C-3 with a variety of alkyl halides by treatment of the allenylsilane with *n*-butyllithium and the desired alkyl halide (e.g. eq 2).[7] In addition to ethyl bromide, alkylating agents such as *n*-heptyl bromide,[6] 1,2-dibromobutane,[7] and 5-bromo-1-pentene[8] have been employed in this reaction.

3-Methyl-1-(trimethylsilyl)allene (**1d**) is prepared by the direct silylation of the lithium derivative of 1,2-butadiene.[4b] Sequential treatment of a THF solution of 1,2-butadiene with 1.0 equiv of ***Lithium 2,2,6,6-Tetramethylpiperidide*** (-78 °C, 3 h) and 1.05 equiv of ***Chlorotrimethylsilane*** (-78 °C to 25 °C, 12 h) affords (**1d**) in 41% yield after distillation (eq 3).

Purification: allenes (**1a**), (**1b**), and (**1c**) are purified by distillation at reduced pressure or by column chromatography. Allene (**1d**) is distilled at atmospheric pressure. The allenylsilanes obtained by the Vermeer method typically contain up to 7-8% of the trialkylsilyl-1-butyne isomer produced by S_N2 reaction. This mixture can be used directly in most subsequent reactions without further purification. If desired, however, the alkynyl contaminant can be selectively removed by treatment of the mixture with ***Silver(I) Nitrate*** in (10:1) methanol-water at room temperature for one hour.[9] 1-Methyl-1-(trimethylsilyl)allene is obtained in 79% yield after pentane extraction and distillation.

Handling, Storage, and Precautions: 1-methyl-1-(trimethylsilyl)allene is stable indefinitely when stored under nitrogen in the refrigerator.

Propargylic Anion Equivalents.

Due to the silicon β-effect, allenylsilanes react with electrophiles at the 3-position in a fashion analogous to the behavior of allyl- and propargylsilanes.[11] Allenylsilanes can thus function as propargylic anion equivalents. Particularly important is the reaction of (trimethylsilyl)allenes with aldehydes and ketones to provide a regiocontrolled route to homopropargylic alcohols of a variety of substitution types. Allenylsilanes substituted at the 1-position undergo the addition to carbonyl compounds in the presence of ***Titanium(IV) Chloride*** to afford homopropargylic alcohols directly (eq 4).[2]

In contrast, allenylsilanes lacking a substituent at C-1 react with carbonyl compounds to produce a mixture of the desired homopropargylic alcohols and (trimethylsilyl)vinyl chlorides. This initial product can be converted to the desired alkyne using the method of Cunico and Dexheimer:[12] exposure of the crude mixture of allenylsilane adducts to 2.5 equiv of ***Potassium Fluoride*** in DMSO furnishes the homopropargylic alcohols in good yield (eq 5).[2]

A number of methods have been reported for the preparation of homopropargylic alcohols.[13] Alcohols having the substitution pattern represented in structure (**3**), for example, can be prepared using 3-alkyl-substituted allenyltitanium,[14] -alanate,[15] and -zinc compounds.[16] Unfortunately, these methods are not applicable to the synthesis of type (**4**) products. Zweifel has shown that allenyldialkylboranes (generated via the reaction of lithium chloropropargylide with trialkylboranes) combine with aldehydes (but not ketones) to produce type (**4**) homopropargylic alcohols.[17] The preparation of type (**2**) homopropargylic alcohols is discussed in the article on ***(Trimethylsilyl)allene***.

1-Methyl-1-(trimethylsilyl)allene

Santelli has demonstrated that allenylsilanes without a C-1 substituent undergo conjugate addition to α,β-unsaturated acyl cyanides to give δ,ε-alkynic acyl cyanides.[3]

Three-Carbon Synthon for [3 + 2] Annulations.

Danheiser and co-workers have exploited allenylsilanes as the three-carbon components in a [3 + 2] annulation strategy for the synthesis of a variety of five-membered carbocycles and heterocycles. The pathway by which a typical annulation proceeds is shown in eq 6. Reaction of the 2-carbon component (the allenophile) at C-3 of the allenylsilane is followed by rapid rearrangement of the silicon-stabilized vinyl cation. Ring closure then affords the five-membered product.

(6)

Synthesis of Five-Membered Carbocycles.

1-Substituted allenylsilanes react with α,β-unsaturated carbonyl compounds in the presence of titanium tetrachloride to produce cyclopentenes.[4] For example, carvone and 1-methyl-1-(trimethylsilyl)allene react smoothly to give a *cis*-fused bicyclic system (eq 7).[4d]

As illustrated above, the reaction proceeds with a strong preference for suprafacial addition of the allene to the allenophile, thus permitting the stereocontrolled synthesis of a variety of mono- and polycyclic systems. Both cyclic and acyclic enones participate in the reaction. Spiro-fused products are obtained from α-alkylidene ketone substrates (eq 8).[4b]

When α,β-unsaturated acyl silanes are employed, the type of product formed varies depending on the trialkylsilyl substituent of the acyl silane: five-membered carbocycles are produced from reaction with *t*-butyldimethylsilyl derivatives, whereas six-membered carbocycles are obtained from trimethylsilyl compounds (eq 9).[4c]

Allenylsilanes lacking a C-1 alkyl substituent do not function efficiently as three-carbon synthons in the [3 + 2] annulation. This phenomenon is attributable to the relative instability of the terminal vinyl cation intermediate required according to the proposed mechanism for the annulations (eq 6). Fully substituted five-membered rings result from annulations employing allenylsilanes substituted at both C-1 and C-3.[4]

Synthesis of 1,3-Dihydrofurans.

(*t*-Butyldimethylsilyl)allenes combine with aldehydes to produce dihydrofurans (eq 10).[5] In a typical reaction, the aldehyde and 1.1 equiv of titanium tetrachloride are premixed at -78 °C in methylene chloride for 10 min. The allenylsilane (1.2 equiv) is then added, and the reaction mixture is stirred in the cold for 15-45 min.

(10)

In reactions of a C-3 substituted allenylsilane with achiral aldehydes, *cis*-substituted dihydrofurans are the predominant products (eq 11).[5]

(11)

(Trimethylsilyl)allenes are unsuitable for this [3 + 2] annulation, as the intermediate carbocations undergo chloride-initiated desilylation to produce alkynic byproducts. This unwelcome reaction pathway is suppressed when the bulkier (*t*-butyldimethylsilyl)allenes are employed.

Synthesis of Pyrrolizinones.

Cyclic *N*-acyl imine derivatives combine with (*t*-butyldimethylsilyl)allenes to afford nitrogen heterocycles (eq 12).[5] The *N*-acyliminium ions are generated from ethoxypyrrolidinones in the presence of titanium tetrachloride.

(12)

Synthesis of Furans and Isoxazoles.

Electrophilic species of the general form Y&tbond;X^+ serve as heteroallenophiles, combining with allenylsilanes in a regiocontrolled [3 + 2] annulation method. As illustrated in the mechanism shown in eq 13, addition of the heteroallenophile at C-3 of the allenylsilane produces a vinyl cation stabilized by hyperconjugative interaction with the adjacent carbon-silicon σ-bond. A 1,2-trialkylsilyl shift then occurs to generate an isomeric vinyl cation, which is intercepted by nucleophilic X. Elimination of H^+ furnishes the aromatic heterocycle.

(13)

Isoxazoles are synthesized when the heteroallenophile is nitrosonium ion. Thus, reaction of commercially available ***Nitrosonium Tetrafluoroborate*** with allenylsilanes in acetonitrile at -30 °C affords silyl-substituted isoxazoles in good yield (eq 14).[6]

(14)

In a variation of the above procedure, (trimethylsilyl)allenes are employed in a one-pot procedure that produces 5-substituted and 3,5-disubstituted isoxazoles lacking the 4-silyl substituent (eq 15). Desilylation is encouraged by addition of water and warming the reaction mixture to 65-70 °C after the initial annulation.[6] Alternatively, addition of electrophilic reagents to the reaction mixture leads to isoxazoles with C-4 substituents such as Br, COMe, etc.

(15)

1-Methyl-1-(trimethylsilyl)allene

The heteroaromatic strategy is extended to the synthesis of furans when acylium ions are employed as the heteroallenophile (eq 16).[7] Acylium ions are generated in situ via the reaction of acyl chlorides and ***Aluminum Chloride***. Typically, the allenylsilane is added to a solution of 1.0 equiv each of $AlCl_3$ and the acyl chloride in methylene chloride at -20 °C. The reaction is complete in 1 h at -20 °C.

(16)

Intramolecular [3 + 2] annulation affords bicyclic furans (eq 17).[7]

(17)

(*t*-Butyldimethylsilyl)- and (triisopropylsilyl)allenes are superior to their trimethylsilyl counterparts for this annulation, presumably due to the ability of the larger trialkylsilyl groups to suppress undesirable desilylation reactions. In annulations involving allenylsilanes which lack C-3 substituents, the bulkier triisopropylsilyl derivatives are superior to *t*-butyldimethylsilyl analogs.

Synthesis of Azulenes.

Reaction of tropylium cations with allenylsilanes produces substituted azulenes.[8] Typically, commercially available ***Tropylium Tetrafluoroborate*** (2 equiv) is employed. The second equivalent dehydrogenates the dihydroazulene intermediate to produce the aromatic product. ***Poly(4-vinylpyridine)*** (poly (4-VP)) or methyltrimethoxysilane is used to scavenge the HBF_4 produced in the reaction.

(18)

The azulene synthesis proceeds best with 1,3-dialkyl (*t*-butyldimethylsilyl)allenes. (Trimethylsilyl)allenes desilylate to generate propargyl-substituted cycloheptatrienes as significant byproducts. As observed in the other [3 + 2] annulations discussed already, allenylsilanes lacking C-1 alkyl substituents do not participate in the reaction.

Synthesis of Silylalkynes via Ene Reactions.

(Trimethylsilyl)allenes undergo ene reactions with ***4-Phenyl-1,2,4-triazoline-3,5-dione*** and other reactive enophiles to give silylalkenes.[18]

2-Methyl-2-(trimethylsilyloxy)-3-pentanone[1]

[72507-50-7] · $C_9H_{20}O_2Si$ · 2-Methyl-2-(trimethylsilyloxy)-3-pentanone · (MW 188.38)

(lithium enolate used in the synthesis of *syn*-β-hydroxy acids, aldehydes, and ketones)

Physical Data: bp 71-75 °C/15 mmHg.

Preparative Methods: prepared in four steps from propionaldehyde in 14-33% overall yield;[2] in three steps from ***Acetone Cyanohydrin*** in 40% overall yield;[3] and in two steps from 3-hydroxy-3-methyl-2-butanone in 55% overall yield.[4]

Handling, Storage, and Precautions: use in a fume hood.

Stereoselection in Reactions of Lithium Enolates.

The (*Z*)-lithium enolate (**2**), obtained from the reaction of 2-methyl-2-trimethylsilyloxypentan-3-one (**1**) with ***Lithium Diisopropylamide***, reacts with aldehydes to afford *syn*-β-hydroxy ketones (**3**) exclusively (eq 1).[2,3,5] The synthetic utility of (**3**) is demonstrated by conversion to β-hydroxy acids (**4**), β-hydroxy aldehydes (**5**), and other β-hydroxy ketones by straightforward procedures (eqs 2, 3, and 4).[2,3,5,6] Table 1 illustrates examples of condensations of (**2**) with simple aldehydes and subsequent conversions to (**4**), (**5**), and (**6**).

[a] Isolated as an acetate ester. [b] Isolated as a methyl ester after esterification with diazomethane. [c] Yield of this conversion was not reported.

The reaction of (**2**) with aldehydes containing additional functional groups and stereocenters has been reported (eq 5, Table 2).[2,3,9,10] In all instances the stereoselection is high in favor of aldol product of *syn* relative stereochemistry at the α- and β-positions (**7** and **8**), but the degree of stereoselection at the β- and γ-positions is highly variable. Only 2,4-dimethylpent-3-enal exhibits a high level of diastereoselection in formation of the product predicted by Cram's rule (**7**); this product has been used to prepare the C-1 to C-7 fragment of erythronolide A.[10] Additional examples of aldol condensations of (**2**) with complex aldehydes are given in (eq 6).[9] When R and R´ are H, the ratio of (**9**):(**10**) is 5.7:1. When R is Et and R´ is Me, the ratio of (**9**):(**10**) is 3:1. It is noteworthy that significantly higher levels of diastereocontrol are achieved in the synthesis of compounds with the same relative stereochemistry as (**7**) (R = Ph, X = Me; 98:2) and (**9**) (R = Et, R´ = Me; >98:2) using propionate equivalents (**11**)[8a] and (**12**),[8b] respectively.

2-Methyl-2-(trimethylsilyloxy)-3-pentanone

Aldol reactions of lithium enolates of higher homologs of propionate equivalent (**1**) have been studied in the context of natural product syntheses and yield similar levels of stereoselection.[9] The amino sugars (±)-ristosamine and (±)-megalosamine and the nucleus of crassin acetate were prepared using this methodology.[9] Aldol reactions of (**2**) generated from chiral bases or in the presence of chiral solvents yield products of low to moderate levels of optical purity.[10] Asymmetric aldol reactions are best accomplished using other methods.[1] Michael additions of (**2**) have been shown to be highly stereoselective in some instances.[11]

Stereoselection in Reactions of Other Enolates and Enol

Derivatives.

A few examples of reactions of boron, magnesium, and tin enolates of (**1**) and Lewis acid-catalyzed reactions of enol silanes derived from (**1**) have been reported.[12-15] The boron enolate formed by reaction of (**1**) with ***Di-n-butylboryl Trifluoromethanesulfonate*** and ***Diisopropylethylamine*** yields *syn* aldol products.[12] The magnesium enolate formed from (**2**) by exchange with ***Magnesium Bromide*** yields a higher ratio (5:1) of chelation to nonchelation controlled product than (**2**) in reaction with (*R*)-3-benzyloxymethoxy-2-methylpropionaldehyde (see Table 2).[13] Excess tin enolate of (**1**) reacts with β-lactam (**13**) to give (**14**) and its 1α-epimer in a 95:5 ratio.[14] In contrast to the enolates, enol silane (**15**) reacts with benzaldehyde to afford primarily *anti* aldol product (**16**) with ***Boron Trifluoride Etherate*** (**16**:**3** (R = Ph) = 5:1) or ***Titanium(IV) Chloride*** (**16**:**3** (R = Ph) = 9:1) as a catalyst.[15a] Reaction of (**15**) with (*S*)-2-benzyloxypropionaldehyde catalyzed by ***Tin(IV) Chloride*** gave a single isomer (**17**) that possessed the same relative stereochemistry as the minor isomer in the reaction with (**2**) (see Table 2).[15b]

Methyltrioctylammonium Chloride-Alkali

$$[Me(CH_2)_7]_3\overset{+}{N}Me\ \ Cl^-$$

[5137-55-3] · $C_{25}H_{54}ClN$ · Methyltrioctylammonium Chloride · (MW 404.25)

(quaternary ammonium salt; phase transfer catalyst[1])

Alternate Names: Aliquat® 336; tricaprylylmethylammonium chloride.

Physical Data: d 0.884 g cm^{-3}.

Solubility: sol most organic solvents (alcohols, hydrocarbons, aromatics, halogenated solvents), and water.

Form Supplied in: neat liquid; amines are typical impurities.

Purification: toluene solutions (30% by weight) can be washed either twice with equal volumes of 1.5 M HBr solution[2] or three times with equal volumes 4 N NaOH followed by three washes with 1.5 M HCl.[3]

Handling, Storage, and Precautions: hygroscopic; highly toxic; may decompose on prolonged heating (see below).

Introduction.

Methyltrioctylammonium chloride (**1**) has found widespread use in organic synthesis. Typical of phase transfer reagents, (**1**) has been used in dehydrohalogenation, alkylation, saponification, conjugate addition, and carbene reactions. As a caution on catalyst stability and performance, it should be noted that (**1**) has a half-life of 34 h at 110 °C in chlorobenzene, decomposing to a 2:3 mixture of $(Oct)_2NMe$ and $(Oct)_3N$ via Hofmann elimination or dealkylation. Under strongly basic conditions (50% ***Sodium Hydroxide***, PhCl, 60 °C), decomposition is more rapid ($t_{1/2}$ = 9 h), with a greater percentage of Hofmann product formed (95:5).[4]

Carbonyl Transformations.

Saponification of esters can be carried out either in solution[5] or under solvent-free conditions.[6] In the latter case, isolated yields of acids from hindered esters were comparable or better than other methods (eq 1). Similarly, ester formation may be carried out without solvent, but ***Potassium Carbonate*** is preferable to ***Potassium Hydroxide*** as saponification does not occur.

(1)

Alkylations.

At Heteroatoms.

Methyltrioctylammonium chloride (**1**) has been used to effect phase transfer alkylation of phenols,[7] alcohols,[8] and thiols.[9] Care must be taken in solvent choice, as the use of dichloromethane can give rise, under basic conditions, to the formation of acetals (eq 2)[10] or thioacetals[7] in excellent yields (90 +%).

(2)

The reaction may be carried out intramolecularly for the preparation of oxetanes[1a] or β-lactams.[11]

At Carbon.

Substrates bearing acidic protons may be alkylated under phase transfer catalysis (PTC) conditions. For example, cyclopropane-1,1-dicarboxylates have been prepared in 75-91% yields using 1,2-dichloroethane (eq 3).[12] Although catalytic water is necessary for the reaction to proceed, large amounts reduce yields. Reactions carried out under solid/liquid phase transfer conditions suffer less from side reactions such as product saponification than those using aqueous solutions of base. For similar reasons, K_2CO_3 is preferred over KOH in the reaction. Alternatively, if cyclopropanecarboxylic acid products are desired, saponification may be carried out in situ.[13]

(3)

Alkynes can be deprotonated under PTC conditions (eq 4), and the resulting anions can be trapped.[14] Simple ketones may be alkylated by the combination of (**1**) and potassium hydroxide (eq 5),[15] and α-protons can be exchanged for deuterium in the presence of NaOD/D_2O.[16] Preparation of hydroxycyclopentenones was carried out by the reaction of (**1**) with a keto aldehyde in the presence of ***Lithium Hydroxide*** (eq 6).[17]

(4)

(5)

(6)

Carbene Chemistry.

Preparation of dichlorocarbene under phase transfer conditions is well known;[1c] (**1**) is an effective catalyst for the formation of this reactive species,[15] as exemplified in eq 7.[18]

(7)

Miscellaneous.

The Ramberg-Bäcklund reaction of α-halo sulfones has been catalyzed by (**1**) and 10% NaOH solution in excellent yields. A single-pot reaction sequence in which a sulfone is halogenated and rearranged was also described (eq 8).[19]

(8)

An improved method of α-diazocarbonyl preparation was reported using (**1**).[20] The method typically produces diazo compounds of high purity, free from starting material and in excellent yield (eq 9).

(9)

Related Reagents.

See the entries for benzyltriethylammonium, benzyltrimethylammonium, tetrabutylammonium, tetraethylammonium, and tetramethylammonium salts.

Methyltriphenoxyphosphonium Iodide[1]

$(PhO)_3$+PMe I^-

[17579-99-6] · $C_{19}H_{18}IO_3P$ · Methyltriphenoxyphosphonium Iodide · (MW 452.24)

(reagent for selective conversion of alcohols to alkyl iodides;[4c,13c] effects dehydration of alcohols[14a] and dehydrohalogenation of alkyl halides[15a] to alkenes; deoxygenates epoxides to alkenes[17])

Alternate Names: MTPI; triphenyl phosphite methiodide; triphenoxy(methyl)phosphonium iodide.

Physical Data: mp 146 °C.

Solubility: sol CH_2Cl_2, DMF, MeCN, THF, HMPA, DMI (1,3-dimethyl-2-imidazolidinone); sl sol PhH.

Form Supplied in: amber to white crystals; commercially available; purity >95%; typical impurity: $MeP(O)(OPh)_2$ (see analytic data below).

Analysis of Reagent Purity: IR (film): 1600, 1500 (Ph), 1160, 980 (P-O-C), 770, 690 (Ph); ^{1}H NMR ($CDCl_3$): 3.1 (d, 3H, $J_{P,H\alpha}$ = 16.5 Hz, Me), 7.45 (m, 15H, OPh). ^{31}P NMR ($CHCl_3$): +41 ± 1 (q). $MeP(O)(OPh)_3$: ^{1}H NMR ($CDCl_3$): 1.8 (d, $J_{P,H\alpha}$ = 18 Hz, Me), 7.2 (m, OPh); ^{31}P NMR ($CHCl_3$): +24 ± 1 (q).

Preparative Methods: further improvements[13c] have been introduced to the original preparation.[4c]

Purification: commercial or synthesized material can, if necessary, be purified by washing with EtOAc or by repetitive (×3) precipitation of the reagent from a CH_2Cl_2 or MeCN solution with ether; the almost colorless solid so obtained is filtered and dried in vacuo.

Handling, Storage, and Precautions: harmful material which may cause irritation; should be handled under N_2 in a dry box; keep container closed; light and moisture sensitive; store in the dark, under N_2 in a cool dry place; avoid breathing dust and contact with eyes, skin, and clothing; incompatibility: strong oxidizing agent.

Introduction.

First described at the beginning of the century[2] the adduct of ***Triphenyl Phosphite*** and ***Iodomethane*** was further developed for use in synthesis 50 years later[4] and has been widely used since that time. Stable in the absence of

moisture, the oxyphosphonium salt MTPI behaves unlike the alkyloxyphosphonium halide analogs; these latter reagents undergo nucleophilic displacement with their own counterions, unless very bulky substituents are involved,[3b] via the Michaelis-Arbuzov reaction. The stability of MTPI arises from the inability of the phenyl group to suffer nucleophilic substitution. ^{31}P NMR data[3] clearly suggest the ionic tetracovalent nature of phosphorus in MTPI.

Preparation of Alkyl Iodides.

In 1951 it was reported[4a] that the Michaelis' salt MTPI reacts with alcohols to form alkyl iodides with release of PhOH and $MeP(O)(OPh)_2$. The reaction appears to involve initial displacement of a phenoxy group by the hydroxyl group of the alcohol, followed by nucleophilic S_N2 substitution to give the iodide (eq 1).

The MTPI reagent has been used to convert alcoholic hydroxyl groups into iodides in saturated and unsaturated aliphatic compounds (eq 2),[4-9] carbohydrates,[10,11] and nucleosides.[13]

A one-pot procedure involving in situ generation of MTPI from $(PhO)_3P$ and MeI through prolonged heating is generally convenient for reactions of saturated primary and sterically hindered alcohols.[5,6] A two-step procedure[6] using isolated MTPI and milder conditions is preferred for sensitive alcohols and in cases where elimination is expected, such as with all tertiary and many secondary alcohols. Both of these original procedures were conducted without solvent. Subsequent improvements include the use of polar solvents like DMF, which appear to promote the iodination reaction and allows it to proceed at rt in most cases.[13c]

Some carbon skeletal rearrangement is observed with highly hindered alcohols: *t*-pentyl iodide (6%) is formed in the conversion of neopentyl alcohol to neopentyl iodide;[5] steroidal neopentyl alcohols undergo rearrangement followed by an elimination reaction.[8]

MTPI has been used for the synthesis[9] of iodoallenes and iodoalkynes via S_N2' and S_N2 reactions; thus the primary alkynic alcohol prop-2-ynol gives either mainly iodoallene in DMF or mainly the iodoalkyne in CH_2Cl_2 (eq 3).[9a]

In the carbohydrate field, MTPI provides iodides from primary[10] and secondary alcohols.[10a,b,11] The latter alcohols generally give iodides with inverted configuration by S_N2 reaction, but sometimes isomeric mixtures (resulting from isomerization by iodide ion) are obtained.[11c,d] Some structural rearrangements involving the participation of hydroxyl protecting groups are reported to occur in the preparation of iodides[11a-d] from hindered secondary alcohols; however, this work was later partly questioned in light of subsequent results.[12]

In the sugar moiety of nucleosides the primary 5´-hydroxyl group is converted into iodide[13a-f] in high yield with MTPI, and the reaction can exhibit primary/secondary selectivity (eq 4).[13c] In some cases, with more polar solvents or in presence of an external base, cyclic *N* or *O*,5´-anhydro derivatives, resulting from the attack of the base moiety on the 5´-oxyphosphonium or 5´-iodide intermediate, are obtained.[13c-e,g].

Such cyclic anhydro intermediates, isolated under other reaction conditions, explains the retention of configuration by double inversion observed in the substitution reactions of secondary 2´- or 3´-hydroxyl groups (eq 5).[13c,h]

(5)

Reaction of MTPI with *cis*-vicinal glycols, such as nucleosides with secondary 2´- and 3´-hydroxy groups, provides phosphorane intermediates that yield a mixture of 2´- and 3´-phosphonates[13c,h] on hydrolysis. Linear γ-diols can be cyclized by dehydration with MTPI to give *C*-glycoside precursors.[13i]

Alternative agents which convert various kinds of alcohols into iodides with good results include the ***Triphenylphosphine***-additive reagent systems: I_2,[13f] CI_4,[18] triiodoimidazole,[12] NIS, etc.

Alcohol Dehydration and Alkyl Halide Dehydrohalogenation.

MTPI in HMPA at 75 °C selectively dehydrates secondary alcohols under mild conditions,[14a-d] leading predominantly to the more stable Saytzeff alkene with various (*E*/*Z*) stereoselectivity.[14a,c] Tertiary alcohols are unaffected under these conditions.

In eq 6, virtually stereospecific dehydration to the (*E*)-alkene is accompanied by transformation of the pyranyl ether group to the iodide, in high yield.[14c]

(6)

Conjugated polyenes are formed, either by dehydration of unsaturated alcohols or by dehydrohalogenation of the corresponding bromides, with MTPI in aprotic solvents such as HMPA[15a,b] and DMI.[15c] The suggested mechanism for this transformation involves initial conversion of the alcohol into the iodide with inversion, followed by dehydrohalogenation by either iodide ion or HMPA.

In a special case, leading to the formation of conjugated exocyclic double bond, primary alcohols undergo dehydration with MTPI in DMF under unusually mild conditions. This reaction provides a good method for α-methylenation of γ-butyrolactones.[16]

Deoxygenation of Epoxides to Alkenes.

In combination with ***Boron Trifluoride Etherate***, MTPI converts epoxides into alkenes in 75-99% yields,[17] via *syn* elimination and with retention of stereochemistry. The reaction is conducted at rt in MeCN-C_6H_6 mixtures as solvent. An excess of both MTPI (10 molar equiv) and BF_3 etherate (1-3 molar equiv) are generally required for satisfactory yields. This method compares favorably with another procedure using a ***Potassium Iodide***-crown ether reagent system.

A modification of the MTPI reagent involves the use of ***Methyl Trifluoromethanesulfonate*** (methyl triflate) in place of MeI, thus providing the nonnucleophilic anion $CF_3SO_3^-$ instead of iodide.[19] Treatment of aliphatic alcohols with $MeP(OPh)_3^+$ TfO^- leads to symmetrical dialkyl ethers, whereas alkyl phenyl ethers are formed with sodium alcoholates.[19b]

Methyltriphenylphosphonium Bromide[1]

Ph_3+PMe Br^-

[1779-49-3] · $C_{19}H_{18}BrP$ · Methyltriphenylphosphonium Bromide · (MW 357.24)

(forms methylenetriphenylphosphorane upon treatment with butyllithium,[2] sodamide,[3] dimsylsodium,[4] or potassium *t*-butoxide;[5] also used as a phase-transfer catalyst[6])

Physical Data: mp 234-235 °C.

Solubility: sol alcohols, DMSO; insol Et_2O, THF, benzene, toluene, hexane.

Form Supplied in: white solid; widely available. *Drying:* when used to prepare methylenetriphenylphosphorane, methyltriphenylphosphonium bromide must be strictly dried immediately prior to use for best results. Drying can be achieved effectively by heating the flask containing the phosphonium salt at 110 °C/0.2 mmHg for several hours, or by repetitive (three times or more) azeotropic removal of water with benzene or toluene.

Preparation of Methylenetriphenylphosphorane.

Methyltriphenylphosphonium bromide can be readily deprotonated with a strong base to give the corresponding methylide (eq 1),[2-5,7,8] the most versatile reagent for Wittig methylenation (see also ***Methylenetriphenylphosphorane***). ***n-Butyllithium*** is the most widely preferred base because of its ready availability. The solvents chosen in this case are invariably Et_2O,[2a,b] THF,[2c,d] or DME.[2e] A typical procedure involves suspension of the dry phosphonium salt in THF and subsequent addition of 1 equiv of 1.6 M solution of butyllithium in hexane at rt followed by stirring at rt for 3 h.[2c] Other lithium bases, although less frequently used, include ***Phenyllithium***, ***Methyllithium***, and ***Lithium Diisopropylamide***.[7]

$$Ph_3\overset{+}{P}-Me\ Br^- \xrightarrow[\text{solvent}]{\text{base}} Ph_3P{=}CH_2 \qquad (1)$$

Sodium Amide[3] is generally used to produce a salt-free ylide. The ylide is generated by stirring a mixture of methyltriphenylphosphonium bromide and $NaNH_2$ in anhydrous liquid ammonia.[2d,3a] Upon completion, ammonia is allowed to evaporate, a dry solvent (Et_2O, THF, or toluene) is added, and the resultant ylide solution is now ready to use. $NaNH_2$ in refluxing THF also can be used instead of liquid ammonia.[3b,c] Dimsylsodium (***Sodium***

Methylsulfinylmethylide) is also widely used to provide the ylide.[4] The required dimsylsodium solution is prepared by stirring a mixture of NaH in dry DMSO at 75-80 °C for ca. 45 min. The resultant solution is cooled to rt followed by addition of methyltriphenylphosphonium bromide in DMSO. In some applications the base used is ***Potassium t-Butoxide***.[5] The reaction is usually run in THF or benzene at rt. Potassium *t*-pentylate is also used occasionally.[8]

Phase-Transfer Catalysis.

Due to the higher thermal stability of phosphonium salts as compared to that of ammonium salts, methyltriphenylphosphonium bromide has been used as a phase-transfer catalyst in a number of reactions.[6] 4,4´-Biphenyldicarboxylic acid has been efficiently converted to the corresponding diacid dichloride with ***Thionyl Chloride*** in the presence of a catalytic amount of methyltriphenylphosphonium bromide (eq 2).[6a] Likewise, the yields of thiocyanatoalkyl methacrylic esters have been increased under phase-transfer conditions (eq 3).[6b] In most cases, however, ammonium salts exhibit far better phase-transfer catalytic activities than phosphonium salts.[6c]

Methyltriphenylphosphonium Permanganate

Ph_3+PMe MnO_4^-

[73335-41-8] · $C_{19}H_{18}MnO_4P$ · Methyltriphenylphosphonium Permanganate · (MW 396.28)

(oxidant, useful for the conversion of alkenes into *cis*-diols[1])

Physical Data: purple solid; decomposes at 102 °C.[2]

Solubility: 1.17 × 10^{-3} M in H_2O; 1.15 M in CH_2Cl_2; 0.941 M in $CHCl_3$; insol toluene, carbon tetrachloride.[2]

Analysis of Reagent Purity: ε = 2530 ± 30 L mol^{-1} cm^{-1} at 526 nm.[2] IR (KBr) 3420, 3050, 2980, 2890, 1585, 1485, 1435, 1120, 905, 750, 725, and 695 cm^{-1};[3] ^1H NMR (CD_2Cl_2) δ 7.80 and 2.80 ppm.[2]

Preparative Method: ***Potassium Permanganate*** (3.07 g, dissolved in a minimum of H_2O) is added dropwise to ***Methyltriphenylphosphonium Bromide*** (4.63 g in 100 mL of H_2O) with stirring. The purple precipitate is collected, washed with water, dried over P_2O_5, and recrystallized from a solution of CH_2Cl_2 and toluene (2:1, v/v). The yield is 70-75%.[3]

Handling, Storage, and Precautions: oxidant; small quantities may be stored in glass vessels at or below rt. Similar compounds have been known to undergo violent thermal decompositions.[4] Always work behind a protective shield.

cis-Dihydroxylation of Alkenes.

Methyltriphenylphosphonium permanganate has been used to dihydroxylate alkenes using CH_2Cl_2 as the solvent.[1] The reaction is easy to carry out and good yields are observed. Several examples are shown in

eqs 1-3.

(1)

(2)

(3)

The reactions of methyltriphenylphosphonium permanganate are very similar to those of quaternary ammonium permanganates such as ***Tetra-n-butylammonium Permanganate*** and ***Benzyltriethylammonium Permanganate***. Similar reactions may also be carried out more simply by use of phase transfer processes that are described under ***Potassium Permanganate***.

Methyl Vinyl Ketone[1]

[78-94-4] · C_4H_6O · Methyl Vinyl Ketone · (MW 70.10) (enol)

[59120-04-6]

(reagent for attachment of 3-oxobutyl side chains, i.e. Michael additions;[2] reagent for the annulation of cyclohexenones[3])

Alternate Names: MVK; 3-buten-2-one.

Physical Data: fp -6 °C; bp 81.4 °C, 36.5-36.8 °C/145 mmHg, 33-34 °C/130 mmHg, 32-34 °C/60 mmHg; *d* (20 °C) 0.8636 g cm^{-3}, (25 °C) 0.8407 g cm^{-3}; *n*20D 1.4086; liquid with pungent odor.

Solubility: sol water, methanol, ethanol, ether, acetone, glacial acetic acid; slightly sol hydrocarbons; forms binary azeotrope with water, bp 75 °C (12% water).

Form Supplied in: clear liquid stabilized with 0.1% acetic acid and 0.05% or 1% hydroquinone.

Handling, Storage, and Precautions: should be kept cold. Polymerizes upon standing in the pure form. Readily absorbed through skin; lachrymator; highly toxic and flammable. For best results, dry over K_2CO_3 and freshly distill at reduced pressure. Use in a fume hood.

Introduction.

As a synthetic reagent, methyl vinyl ketone is commonly viewed as a 3-oxobutyl synthon which undergoes predominantly 1,4 conjugate addition (Michael addition) resulting in the attachment of a 3-ketoalkyl side chain. The resulting products are often poised for a subsequent cyclization step, thus resulting in a cyclohexenone derivative; this tandem is the well-known Robinson annulation.[4] In most cases, MVK is the electrophilic partner, but there are a few important nucleophilic (umpolung) derivatives of MVK which also are useful for accomplishing ring construction (see below). MVK itself is particularly susceptible to anionic polymerization, which limited its early use under basic conditions; however, it should be noted that MVK will polymerize under certain acidic and radical conditions as well.[5] The many efforts to improve the Robinson ring synthesis have led to monumental synthetic advances with respect to both nucleophilic reactants and MVK synthetic equivalents (3-oxobutyl synthons).

Aside from inducing the anionic polymerization of MVK, enolates as nucleophilic partners in alkylations are limited by *O*- vs. *C*-alkylation, mono- vs. polyalkylation, rapid proton transfer, and by the ability to control the regioselectivity of their generation. These problems have found solutions through the development of trimethylsilyl enol ethers,[6] in the utilization of enamine chemistry,[7] and by employing metalloenamines (imine anions).[8] With each of these developments in the nucleophilic partner, improvements in MVK alkylation have resulted in a greatly expanded use of the reagent. Nevertheless, a number of MVK synthetic equivalents have been successfully developed and are briefly reviewed in Table 1. Note that in this context, MVK equivalent is defined as any reagent which contains all four carbon atoms; also the 3´-oxo functionality is in place or is one transformation away.

Methyl Vinyl Ketone versus its Synthetic Equivalents (as Alkylating Agents).

Primarily to circumvent the polymerization problem, numerous MVK synthetic equivalents have been developed, and these reagents should also be explored as possible sources of the 3-oxobutyl synthon. However, each reagent is handicapped by the fact that there are additional synthetic steps involved in its preparation, and the newly alkylated adduct often must be transformed into the 3-oxobutyl side chain. It should be noted that the manipulation of the side chain to arrive at the keto side chain may require harsh conditions not compatible with the other functional groups present in the molecule.

One of the first reagents developed as an MVK equivalent was ***1,3-Dichloro-2-butene*** (**1**) (the Wichterle reagent).[9] Relative to MVK, it is generally regarded as a superior alkylating agent, but the stringent hydrolytic conditions for conversion of the vinyl chloride to its corresponding ketone limits its application. An excellent alternative reagent of the same type (i.e. allylic halides) is the iodovinylsilane (**2**).[10] The use of this reagent leads to high yields of alkylated adducts, and the subsequent conversion of the alkylated vinylsilanes to their corresponding ketones is achieved by oxidative rearrangement with ***m-Chloroperbenzoic Acid***. These vinylsilanes can be used with enolates and enamines alike.

Robinson himself recognized that MVK polymerization was compromising the efficiency of the annulation protocol and developed the first in a series of compounds which serve as precursors to MVK. The synthetic equivalents (**3**),[11] (**4**),[12] and (**5**)[13] are characterized by β-elimination to generate MVK in situ, but often the results are still not satisfactory (albeit improved) over the use of MVK itself. The principal problems involve poor yields and polyalkylated adducts and, if the synthetic sequence is extended further, unusual cyclization products.

The strategy of carbonyl protection in MVK in order to retard base-catalyzed polymerization fostered interest in a group of β-halo acetals, mixed acetals, and thioacetals of the type (**6**). After alkylation with such reagents, the 3-oxo functionality can be easily regenerated under mildly acidic conditions. The haloacetals (**6**; X = Br, I)[14,15] are prepared in two steps by the conjugate addition of the halo acid to MVK followed by acetalization of the β-halo ketone. The corresponding tosylate (**6**; X = OTs)[16] has also been prepared by a similar, albeit longer, route. At first glance, these reagents would seem ideal for appending the 3-oxobutyl side chain, by alkylation followed by mild acidic deprotection of the carbonyl. Unfortunately, in most cases these reagents are poor alkylating agents. A notable exception is the general annulation procedure (eq 1) which employs imine anions (metalloenamines) as the nucleophilic partner and the bromo acetal (**6**; X = Br) as the MVK equivalent. The sequence commences with the Wadsworth-Emmons alkenation of ketones to afford 2-azadienes, which can be isolated at this point but are usually treated with ***n-Butyllithium*** to generate the highly reactive metalloenamine. The imine anions thus generated can be trapped with the bromoacetal (**6**; X = Br). Hydrolytic workup followed by aldol cyclization-dehydration completes the preparation of 4,4-disubstituted cyclohexenones in yields of 55-65% from the ketones.[17]

(1)

Another pair of MVK equivalents are the α-trialkylsilyl derivatives of MVK itself (**7**; R = Me, Et).[18,19] The trialkylsilyl group stabilizes the incipient negative charge after Michael addition and provides some steric bulk to impede polymerization. The silyl group can then be removed under basic conditions, usually those employed for a cyclization step. These MVK equivalents are especially important in that they allow effective Michael additions to vinyl ketones under aprotic conditions. The major disadvantage of these reagents is the multistep linear synthesis required for their preparation.

Methyl Vinyl Ketone versus its Synthetic Equivalents (Umpolung Reagents).

In those instances in which the 3-oxobutyl side chain is to be connected to pre-existing carbonyl (or other electrophilic) centers, several umpolung-type MVK equivalents have been developed. Although somewhat capricious in its stability, the Grignard reagent (**8**)[20] derived from the bromo acetal (**6**; X = Br) has been successfully employed in a number of synthetic applications. Particularly useful is the fact that the acetal moiety may be unmasked in the usual hydrolytic workup or carried on as an acetal for removal at a later stage in the synthesis.[21] Special mention should be made of the Grignard reagent's use in the presence of catalytic copper salts (**9**).[22] This technique allows for the conjugate addition of the acetal moiety to α,β-unsaturated ketones as well as the direct attachment of the side chain to less complex systems. The related homologous Wittig reagent (**10**)[23] was developed in the late 1960s and the Horner-Emmons variant (**11**) appeared shortly thereafter.[24] Both compounds have been employed as reacting partners with lactones, ultimately leading to cyclohexanone products via an intramolecular Wittig alkenation process.

1,4-Conjugate Additions (Michael Addition Reactions, Achiral).

There are numerous examples of the use of MVK in conjugate 1,4-addition reactions, i.e. the Michael reaction. Although most of these applications are framed in the context of an annulation procedure (e.g. the Robinson annulation), many of these reactions are worthy of discussion in their own right. The prototypical Michael addition of an enolate with MVK is, in fact, the first step of the Robinson annulation (eq 2).

(2)

Under basic conditions (e.g. alkylation reactions employing enolates), MVK suffers a high degree of polymerization, leading to the development of the aforementioned MVK equivalents. However, there are derivatives of ketones which are particularly suitable for Michael addition reactions, most notably the silyl enol ethers.[25] The development of silyl enol ethers addressed the most serious problems encountered in the alkylations of enolates. Firstly, the reactions are conducted in aprotic media under

anhydrous conditions, thus avoiding proton transfer side reactions. Secondly, by judicious choice of the base used to generate the intermediate enolate, the regiochemistry of the alkylation can be controlled. However, the strongly basic conditions required for the regeneration of the enolates themselves preclude successful additions to MVK, resulting in the formation of polymer. Only recently have trimethylsilyl enol ethers been efficiently added to MVK with the assistance of Lewis acid catalysis (eqs 3 and 4).[26,27] The acidic conditions not only serve to activate MVK towards Michael addition, but assist in unmasking the enolate as well. These procedures are usually conducted under relatively mild aprotic conditions which also retard MVK polymerization.

β-Keto esters, α-nitro ketones, and α-keto sulfones are but a few of the stabilized enolate derivatives which have been used successfully in efficient Michael additions to MVK. One of the most troublesome examples involving β-keto esters was the condensation of cyclohexanone methyl carboxylate with MVK under equilibrating conditions,[28] but this reaction has been developed into a viable synthetic procedure with the use of high pressure techniques under otherwise mild conditions (eq 5).[29]

(5)

Another stabilized enolate family includes the α-nitro ketones; although the nitro group activates the formation of the enolate, it is usually necessary to remove it in a subsequent procedure (eq 6).[30] Nevertheless, the overall yields of the products are good.

(6)

Simple nitro alkanes have recently been used in an exceptionally mild procedure for the attachment of the 3-oxobutyl side chain using MVK (eq 7). This protocol highlights the use of ***Alumina*** at room temperature for the conditions of the Michael addition, and the yields are good to moderate.[31]

(7)

The Michael addition of α-cyanoamines to MVK (eq 8) has also been used for the preparation of 1,4-dione systems,[32] which are historically difficult to prepare.[33] The reaction occurs under mild conditions; however, the use of ***Hexamethylphosphoric Triamide*** as the solvent limits the scale and the widespread use of this procedure. In this sequence, acidic hydrolysis of the alkylated α-cyanoamine leads to the dione system.

(8)

β-Methylthio allylic systems have also served as the nucleophilic partner in reactions with MVK (eq 9).[34] The procedure employs the hyperbasic media of the ***Lithium Diisopropylamide***/HMPA complex[35] and generates a quaternary carbon center in the product.

(9)

Recently, dithioenamines have emerged as useful synthetic intermediates in general alkylation methods.[36] In their Michael additions with MVK in the presence of Lewis acid catalysts, an intermediate iminium dithiane is generated which is somewhat sluggishly hydrolyzed; however, the overall yields of alkylated adducts are impressive (eq 10).[37]

1,4-Conjugate Additions (Michael Addition Reactions, Chiral).

In recent years, perhaps the most significant development in synthetic organic chemistry has been the explosion in the field of asymmetric induction. As the reactive intermediates of the enolate, enamine, and imine anions were developed into their chiral counterparts, not only were standard alkylation reactions studied but also Michael additions to α,β-unsaturated systems. It is not surprising that the prototypical model studies involved MVK as the Michael acceptor. While most of these methods are used in asymmetric ring synthesis (see below), some examples terminate at the alkylation step with MVK. All of these methods feature the chiral auxiliary in the nucleophilic reagent. One of the earliest examples of asymmetric induction using MVK was developed by Yamada and utilizes chiral pyrrolidino enamines (eq 11).[38] Although the yields of the Michael additions are moderate and the asymmetric induction itself is not particularly impressive by today's standards, this methodology laid the groundwork for many improvements which were to follow. A notable advancement in chiral imine alkylations with MVK is found in the method of d'Angelo, in which the conjugate addition is catalyzed by ***Titanium(IV) Chloride*** (eq 12).[39] A particularly attractive feature of this method is that the chiral auxiliary, ***(S)-α-Methylbenzylamine***, is readily available, and the chemical yields are good with high asymmetric induction.

(11)

(12)

Another chiral enamine system which has been used with MVK takes advantage of the high nucleophilicity of imine anions (i.e. metalated enamines). In this method the intermediate enolate from the Michael addition is trapped as its TMS enol ether, which is subsequently hydrolyzed in the workup (eq 13).[40] The yields are fair and the asymmetric induction is effective.
